A method known as capillary depletion has been developed to separate the vascular component from the parenchymal component. Since the BBB is surrounded by a robust basement membrane, it is possible to separate the microvasculature from brain using mechanical homogenization and density centrifugation techniques. In this way, antibody that remains associated with the vasculature can be distinguished from that which has transcytosed fully into the parenchymal fraction. However, homogenization techniques can lead to a large fraction of negative control antibodies appearing to accumulate in the parenchymal fraction. To help circumvent this issue, parenchymal uptake time course measurements can be performed (Pardridge et al., 1991).

Immunocytochemical techniques have been used to qualitatively demonstrate parenchymal uptake of biologics into brain at microscopic resolution. However, when a biologic leaves the concentrated trafficking vesicles in endothelial cells and enters brain, it undergoes a roughly 1000-fold dilution. Thus, unless the biologic also subsequently targets a receptor on brain cells that allows it to reconcentrate, it often escapes detection. Autoradiographic techniques can be more sensitive and allow for semiquantitative uptake analyses, but at much lower resolution, such that distinguishing between vascular and parenchymal contributions can be difficult. The final strategy for measuring the quantity of biologic that transcytoses and enters brain is to monitor its accumulation in the CSF (Haqqani et al., 2013). While sampling of CSF has long been used as a surrogate measure of brain uptake, one has to distinguish the BBB and choroid plexus routes of entry into the CSF to avoid overestimating the amount of biologic crossing the BBB and leading to brain exposure.

Researchers have also developed pharmacodynamic approaches to quantify brain uptake of biologics that rely on the functional output of the biologic. For example, putative transcytosing antibodies have been connected to drug cargo that allows for straightforward phenotypic readouts in animal models. A widely used model involves the conjugation of a BBB-crossing antibody with an antiamyloid therapeutic; a decrease in the amyloid burden in a transgenic mouse is used as a surrogate measure of full BBB crossing of the therapeutic at pharmacologically relevant concentrations. Another strategy is based on delivery of the neuropeptide neurotensin. Neurotensin causes transient hypothermia, changes in locomotion, and changes in pain response if directly administered into the CNS, whereas blood-borne neurotensin cannot cross the BBB to elicit these effects. However, if neurotensin is conjugated to a BBB-crossing domain, it can accumulate in the CNS, causing pharmacodynamic responses, again demonstrating full transcytosis of the biologic at pharmacologically relevant doses (Demeule et al., 2014).

Adsorptive-Mediated Strategies

One approach for delivery of biologics is to modify the molecules themselves such that they can access the adsorptive-mediated transport network of brain endothelial cells. Cationization of a biologic can allow for its interaction with negatively charged moieties on the endothelial surface such as sialylated proteins and heparan sulfate proteoglycans. Such engagement can lead to membrane invagination and entry into the endosomal trafficking system of brain endothelial cells. In this way, biologics can transport into and across brain endothelial cells, leading to increased brain uptake. Cationization is often achieved by modifying carboxyl residues on the protein surface, such as through the conjugation of putrescine or spermine (Poduslo and Curran, 1996). To rate the efficiency of various BBB-crossing approaches for biologics, the resulting PS product can be compared. For instance, cationized antibodies had 4- to 100-fold higher PS products compared with control antibodies (see Table 17–1). While cationization can increase brain uptake, cationization will also increase interactions with vascular beds and cells throughout the body, leading to off-target drug accumulation. In addition, broad organ uptake can also reduce the AUC of circulating biologics, thereby limiting brain uptake (%ID/g) despite improved PS attributes.

Receptor-Mediated Strategies

Since adsorptive strategies are inherently nonspecific, alternative strategies have been developed that target specific receptor-mediated transcytosis (RMT) receptors at the BBB. Brain endothelial cells express a host of RMT receptors that bring large-molecule cargo into the brain. These include the transferrin receptor, insulin receptor, and low-density lipoprotein family receptors. Conceptually, RMT systems can be co-opted for brain drug delivery by using a natural or artificial targeting ligand conjugated to the drug of interest. The drug-ligand conjugate can bind to RMT receptors on the blood side of the brain endothelial cells and trigger endocytosis and trafficking, and a subset of the trafficked material can undergo full transcytosis. In this way, conjugated drug cargo can be shuttled across the BBB and into brain (see Figure 17–8). The transport properties of the targeting ligands can be further optimized through the modulation of targeting ligand binding affinity and the number of binding sites per ligand (valency). Several RMT-based strategies have recently moved to the clinic but are not yet at the point of FDA approval, as will be described below.

Transferrin Receptor

The transferrin receptor (TfR) was the first RMT system explored for delivery of biologics across the BBB (Pardridge et al., 1991), and it is still the most commonly used system. The TfR is highly abundant in the brain vasculature. TfR is responsible for transporting iron into the brain by mediating the trafficking of the iron-binding protein transferrin (Tf). The TfR has been targeted by conjugating therapeutic cargo to Tf itself. For example, Tf has been conjugated to monoclonal antibodies and various forms of nanoparticulate cargo, including pegylated albumin nanoparticles and pegylated liposomes, with the potential to increase brain uptake severalfold. Alternative strategies have employed iron-mimicking peptides that bind to Tf and ferry across the BBB with conjugated drug cargo. Targeting RMT receptors with the natural ligand-drug conjugate has a substantial drawback because to achieve transport of the desired drug conjugate, it needs to compete successfully with the endogenous natural ligands. For example, endogenous Tf is present at high concentrations in the bloodstream; hence, any Tf-drug conjugates will need to compete with this Tf pool for RMT binding and transport, necessitating high doses. Thus, research teams have instead been developing antibodies capable of targeting RMT receptors using epitopes that do not overlap with the natural ligand. In this way, the antibodies will not compete with endogenous ligand, which can help with delivery efficiency and potentially reduce side effects by not interfering with normal nutrient transport. Such antibodies raised against the TfR have elevated PS products by 20- to 30-fold that meet or exceed those of the natural ligand, leading to %ID in the 0.5% to 2% range (see Table 17–1). Targeted antibody strategies yield PS products that can exceed those of cationized antibodies by severalfold. Brain exposure of anti-TfR antibodies can reach actual brain concentrations as high as 50 nM with antibody optimization and elevated doses of 20 to 50 mg/kg (Yu et al., 2011). As such, TfR antibodies have been used to deliver a wide range of therapeutic cargo to animal models (e.g., delivery of antiamyloid antibodies in mouse and primate models of Alzheimer's disease). Anti-TfR–based biologics have already moved into clinical development. For example, conjugates of anti-TfR

antibodies with lysosomal enzymes are being tested in patients with lysosomal storage diseases like Hunter syndrome with early evidence of efficacy (Okuyama et al., 2019) (JCR Pharmaceuticals NCT04573023 and Denali NCT04251026).

Insulin Receptor

The insulin receptor (IR) has also been targeted for biologics delivery to brain. The IR at the BBB mediates brain import of insulin by an RMT mechanism. Targeting this transport system using the endogenous insulin ligand has not been pursued owing to the very short serum half-life of insulin and concerns that insulin-linked drugs could cause hypoglycemia. Thus, monoclonal antibodies against IR have been tested for their potential as RMT-targeting agents. The most widely used anti-IR antibody is a mouse antibody known as 83-14 that targets the human IR (Pardridge et al., 1995). This antibody has a PS product that is 4-fold higher than the native insulin ligand, suggesting it is an efficient BBB-targeting moiety. Uptake in primate brain can reach nearly 4%ID. For clinical translation, the 83-14 antibody has been humanized to help prevent unwanted immunogenicity as a result of the murine antibody framework. As with the TfR, conjugation of therapeutic cargo with the 83-14 antibody can lead to increased brain uptake. For example, in primates, pegylated liposomes carrying transgene-encoding DNA could lead to selective expression of transgene within targeted neuronal populations. Also, 83-14 conjugation with neurotrophic cargo led to 10-fold increases in brain levels. Moreover, when the lysosomal enzyme that is deficient in patients with mucopolysaccharidosis type I is conjugated to 83-14, it could also enter primate brain. In a clinical trial, the humanized 83-14 antibody-enzyme construct stabilized cognitive function in patients with severe forms of mucopolysaccharidosis (Giugliani et al., 2018) (Armagen NCT03053089, NCT03071341).

The therapeutic drug cargo needs to be carefully mated to the antibody-RMT system for successful deployment. Given that the total concentrations of antibody uptake in brain remains in the 1 to 50 nM range even under high dosages, the conjugated therapeutic needs to be efficacious at these concentrations. For this reason, early clinical trials with anti-TfR and anti-IR antibodies have focused on delivery of enzymes that catalytically process many substrate molecules and, hence, operate within the modest concentration ranges afforded by targeted RMT systems.

Low-Density Lipoprotein Family Receptors

Low-density lipoprotein receptor family (LDLRf) receptors such as LRP1, LRP2, and LDLR are expressed at the BBB. These RMT receptors mediate the transport of lipoproteins and other ligands across the BBB. They may have significant potential for trans-BBB transport as the brain uptake rates of LDLRf ligands such as receptor-associated protein and melanotransferrin (P97) exceed that observed for Tf, suggesting a high-capacity RMT pathway (Demeule et al., 2002; Pan et al., 2004). Only ligand-based LDLRf approaches have been described thus far. Apolipoprotein (Apo) B and ApoE are protein constituents of lipoproteins that mediate interactions with LDLRf receptors. Fusion of therapeutic cargo to ApoB and ApoE receptor binding domains can lead to brain uptake and pharmacological effects in rodent models including the delivery of an Aβ-degrading enzyme and lysosomal enzymes. Similarly, a peptide based on a conserved binding motif of several LDLRf ligands known as the Kunitz protease inhibitor domain has been used for trans-BBB delivery. Known as Angiopep-2, this peptide enters the brain via LRP1 RMT receptor, and when conjugated to neurotensin, it can elicit pharmacodynamic responses. Subsequently Angiopep-2 has used to deliver genes, peptides, and small-molecule P-glycoprotein substrates to the brain. Angiopep-2 was tested in phase I and II clinical trials for the delivery of *paclitaxel* for primary and metastatic brain tumors (e.g., Angiochem, NCT00539383, NCT01967810). These trials have demonstrated brain uptake of the conjugate and have suggested therapeutic efficacy (Kurzrock et al., 2012).

Improving BBB Transport of RMT-Targeted Systems

Transferrin receptor, IR, and LDLRf RMT systems have significant drawbacks despite early success in clinical studies. They target RMT systems that are not exclusive in their BBB expression, but rather are expressed all throughout the body both at the vascular and tissue levels. For molecules targeting these RMT systems, this leads to a decreased plasma AUC because of peripheral organ uptake, which in turn can lead to a decrease in brain uptake. Moreover, side effects can be caused by conjugated drug cargo accumulation in nonbrain tissues. Identification of other RMT systems with more brain specificity would be desirable. In addition, the commonly used RMT systems may not have the optimal capacity for trans-BBB delivery either because of receptor abundance or differential trafficking dynamics. For instance, antibodies targeting the TfR can be sequestered and degraded within the brain endothelial cells, limiting full transcytosis across the BBB. As such, the PS products for all RMT systems are not necessarily the same. Therefore, to increase the brain uptake of RMT-targeted biologics, one needs to increase the AUC or PS products of the targeting molecules. Two strategies for improving these parameters are to search for more BBB-specific RMT systems, which could increase the AUC due to less uptake in the periphery, or to optimize the current antibody-RMT systems by increasing their BBB PS product. Hence, ongoing research is focused on finding better BBB RMT systems and optimization of existing antibody-RMT systems.

BBB Opening

The BBB can be disrupted by pathological conditions such as stroke and brain cancer, but the timing and extent of disruption are often not adequate for efficient therapeutic delivery. On the other hand, chemical and physical methods can enhance the BBB opening and have been employed for drug delivery to the brain.

Chemical Methods

Chemical methods include the use of intra-arterial infusion of hyperosmolar *mannitol* that can transiently and reversibly disrupt the BBB in one brain hemisphere by opening the tight junctions in brain endothelial cells. *Mannitol* disruption has been deployed in the clinic for the treatment of glioblastoma and used in combination with therapeutic antibodies and small molecules (e.g., *bevacizumab*, NCT00968240; *cetuximab*, NCT02861898; and *temozolomide*, NCT01180816) and may enhance chemotherapy delivery, although the efficacy needs to be further evaluated (Neuwelt et al., 1983). Unfortunately, the method is inherently nonspecific and causes blood vessel opening throughout the entire targeted brain hemisphere and not just in the diseased region. The mechanism of opening allows not only the therapeutic to enter, but also any other blood-borne substances, which can lead to significant side effects such as seizures and brain edema. The patient also needs to be anesthetized for the procedure.

To identify agents that could be more selective in their regional modulation of BBB permeability, several biochemical agents have been used. These include ATP-sensitive and calcium-activated potassium channel activators that appear to selectively increase tumor BBB permeability by increasing the number of transport vesicles at the tumor BBB. Another approach is to activate bradykinin type 2 receptors. Bradykinin receptor activation can selectively increase tumor BBB permeability without breakdown of the healthy BBB. The mechanisms driving BBB opening are complex and may include both tight junction disruption and increased nonspecific transcytosis. In clinical studies, bradykinin analogues increased chemotherapeutic uptake into glioma tissue (Emerich et al., 2001). Region-specific BBB modulation with chemical approaches usually relies on the selective expression of brain endothelial targets in the diseased region. Hence, treatment paradigms aimed at preferentially increasing BBB permeability in the diseased brain region tend to be disease specific and are not generalizable.

Physical Methods

Physical methods, unlike biochemical methods, can be targeted to specific brain regions regardless of pathology. The most advanced physical BBB opening approach is focused ultrasound (FUS) (Figure 17–9). Microbubbles administered systemically are excited by focused ultrasonic

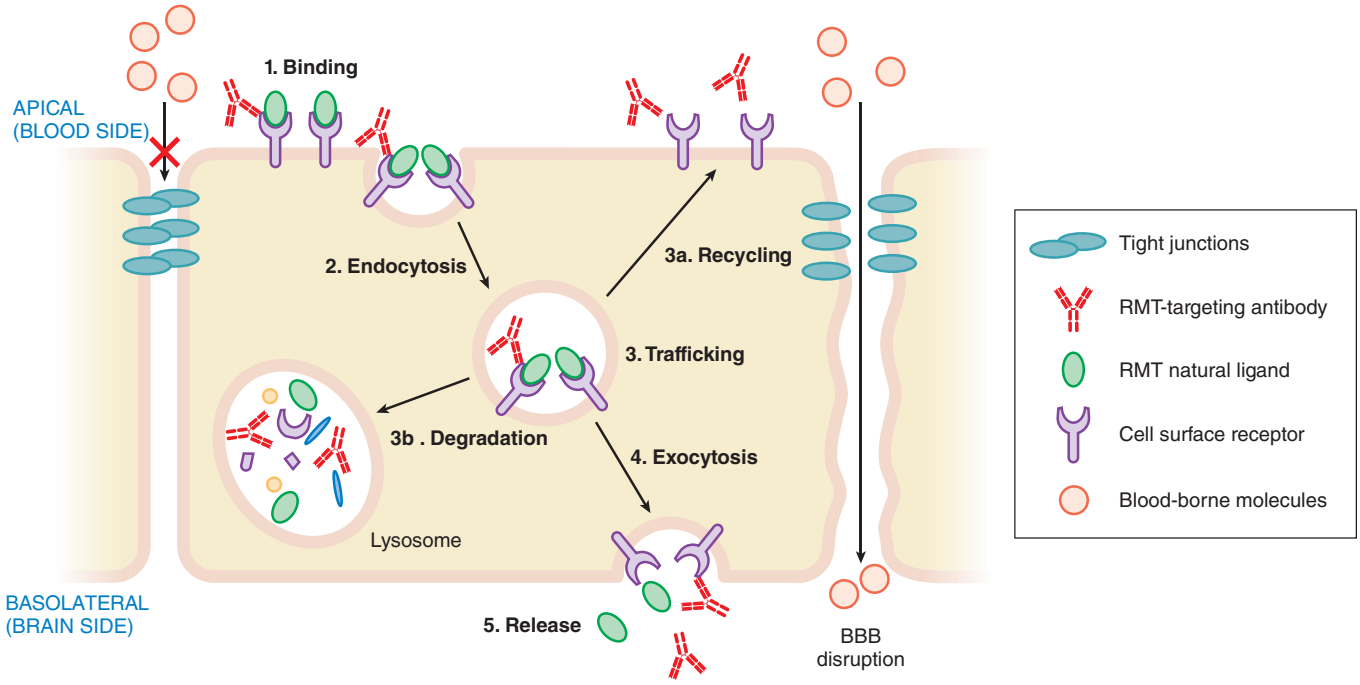

Figure 17–8 *Schematic representation of the BBB RMT mechanism.* A natural ligand or antibody targeting an RMT receptor traffics through the brain endothelial cell vesicle transport network. Transcytosis across the BBB and into brain would constitute a molecule passing through steps 1 to 5.

waves, which in turn transiently and reversibly disrupt the BBB in FUS-treated regions.

The FUS procedure generates mechanical shear, which is thought to downregulate tight junction proteins and upregulate transcellular transport machinery, thereby increasing BBB permeability. After FUS, uptake of small molecules and biologics is increased in targeted regions. As with chemical methods, FUS-mediated BBB opening is not selective, and blood-borne substances can enter brain tissue, causing unwanted side effects. The mechanical shear forces may also cause immune activation and hemorrhage. FUS is being evaluated in several clinical trials for patients with glioma, neuropathic pain, Parkinson's and Alzheimer's disease (glioma, NCT03322813; neuropathic pain, NCT03309813; Parkinson's disease, NCT02347254; and Alzheimer's disease, NCT03671889). BBB-opening methods are increasingly studied for enhancing therapeutic uptake in the CNS. Given potential side effects, they may be best suited for conditions that do not require chronic treatment and repeated opening of the BBB.

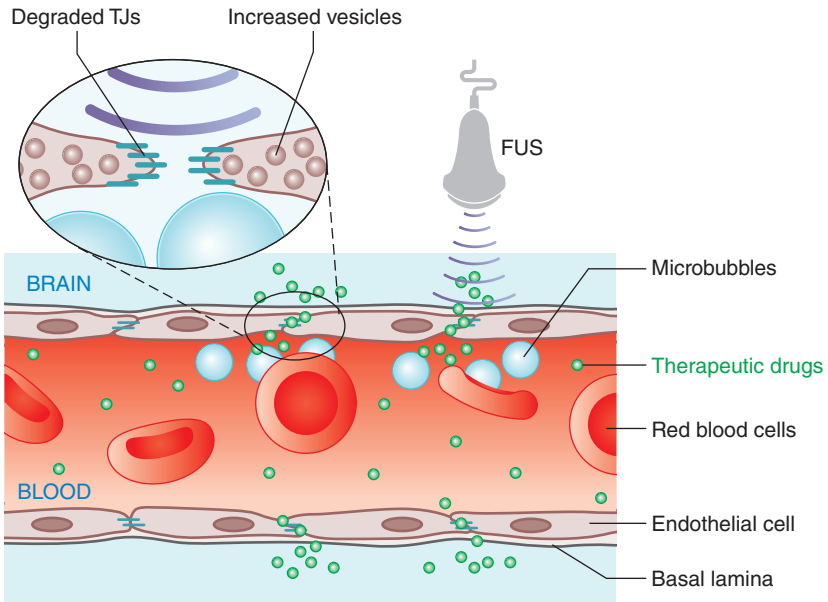

Figure 17–9 *Schematic representation of BBB disruption by focused ultrasound (FUS).* Upon FUS application, microbubbles apply mechanical forces on brain endothelial cells leading to increased transport vesicles and disrupted tight junctions (TJs).

Summary

The BBB poses specific hurdles for brain disease drug development. Different components of the neurovascular unit cooperate to maintain the BBB in brain endothelial cells. The BBB is necessary for healthy brain function but challenges drug delivery. Some small nonpolar molecular drugs easily cross the BBB, but many drugs do not, due to the presence of active efflux transporters at the BBB. On the other hand, efflux transporters can minimize CNS side effects, such as for antihistamine sedation. Some drugs co-opt the active uptake systems that are expressed at the BBB. The function of the BBB limits the entry of antibodies and other biologics even more severely. Strategies to circumvent the BBB using adsorptive-mediated or receptor-mediated transcytosis are currently in development, and chemical or mechanical BBB disruption are additional possibilities for enhancing brain drug uptake.

Chapter 18 Drug Therapy of Depression and Anxiety Disorders

James M. O'Donnell, Robert R. Bies, and Aislinn J. Williams

Depression and anxiety disorders are the most common mental illnesses, each affecting in excess of 15% of the population at some point in the life span. With the advent of more selective and safer drugs, the use of antidepressants and anxiolytics has moved from the exclusive domain of psychiatry to primary care and other medical specialties. *The relative safety of the majority of commonly used antidepressants and anxiolytics notwithstanding, their optimal use requires a clear understanding of their mechanisms of action, pharmacokinetics, adverse effects, potential drug interactions, and the differential diagnosis of psychiatric illnesses* (Thronson and Pagalilauan, 2014).

Both depression and anxiety can affect an individual patient simultaneously; some of the drugs discussed here are effective in treating both types of disorders, suggesting common underlying mechanisms of pathophysiology and responses to pharmacotherapy. In large measure, our current understanding of pathophysiological mechanisms underlying depression and anxiety has been inferred from the mechanisms of action of psychopharmacological compounds, notably their actions on neurotransmission involving serotonin (5HT, 5-hydroxytryptamine), norepinephrine (NE), and γ-aminobutyric acid (GABA) (see Chapter 16). While depression and anxiety disorders comprise a wide range of symptoms, including changes in mood, behavior, somatic function, and cognition, progress has been made in developing animal models that respond with some sensitivity and selectivity to antidepressant or anxiolytic drugs (Cryan and Holmes, 2005; Xu et al., 2012). The last half-century has seen notable advances in the discovery and development of drugs for treating depression and anxiety (Hillhouse and Porter, 2015).

Characterization of Depressive and Anxiety Disorders

Symptoms of Depression

Depression can occur in major depressive disorder (i.e., unipolar depression), persistent depressive disorder (dysthymia), or bipolar I and II disorders (i.e., manic-depressive illness). Bipolar depression and its treatment are discussed in Chapter 19. Lifetime risk of unipolar major depression is approximately 15%. Females are affected with major depression twice as frequently as males (Brody et al., 2018). There also is some evidence for sex-based, differential response to pharmacotherapy. Depressive episodes are characterized by sad mood, pessimistic worry, diminished interest in normal activities, mental slowing and poor concentration, insomnia or increased sleep, significant weight loss or gain due to altered eating and activity patterns, psychomotor agitation or retardation, feelings of guilt and worthlessness, decreased energy and libido, and suicidal ideation. In depressive episodes, these symptoms occur most days for a period of at least 2 weeks. In some cases, the primary complaint of patients with depression involves somatic pain or other physical symptoms, which can present a diagnostic challenge for primary care physicians. Depressive symptoms also can occur secondary to other illnesses, such as hypothyroidism, Parkinson's disease, and inflammatory conditions, among others. In addition, depression often complicates the management of other medical conditions (e.g., severe trauma, cancer, diabetes, and cardiovascular disease, especially myocardial infarction).

Depression is underdiagnosed and undertreated (Johansson et al., 2013). Given that approximately 10% to 15% of those with severe depression attempt suicide at some time, it is important that symptoms of depression be recognized and treated in a timely manner. Furthermore, the response to treatment must be assessed and decisions made regarding continued treatment with the initial drug, dose adjustment, adjunctive psychotherapy, or alternative medication.

Symptoms of Anxiety

Anxiety is a normal human emotion that serves an adaptive function from a psychobiological perspective. Symptoms of anxiety include feelings of worry, muscle tension, restlessness, poor concentration, and panic (shortness of breath, heart palpitations, sweating, fear of impending doom). Anxiety disorders occur when symptoms of anxiety interfere significantly with normal function and are classified as generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, acute stress disorder, posttraumatic stress disorder (PTSD), separation anxiety disorder, social phobia, and specific phobias (Atack, 2003). Although anxiety is not abnormal in itself, anxiety disorders are common and often require treatment. All of the anxiety disorders, with the exception of specific phobias, can be treated with antidepressant medications, particularly selective serotonin reuptake inhibitors (SSRIs). Drug treatment includes both acute drug administration to manage episodes of anxiety and chronic treatment to manage unrelieved and continuing anxiety disorders. Symptoms of anxiety also are often associated with depression and other medical conditions.

Pharmacotherapy for Depression and Anxiety

Most antidepressants enhance serotonergic or noradrenergic transmission, or both. Sites of interaction of antidepressant drugs with serotonergic and noradrenergic neurons are depicted in Figure 18–1. Table 18–1 summarizes the actions of the most widely used antidepressants. The most commonly used medications, often referred to as second-generation

Abbreviations

ADHD: attention-deficit/hyperactivity disorder
AMPA: α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, an exogenous ligand for the GluA subtype of glutamate receptors
BDNF: brain-derived neurotrophic factor
CREB: cyclic AMP response element binding protein
CYP: cytochrome P450
DA: dopamine
DAT: dopamine transporter
GABA: γ-aminobutyric acid
GI: gastrointestinal
MAO: monoamine oxidase
MAOI: monoamine oxidase inhibitor
NE: norepinephrine
NET: neuronal NE transporter
NMDA: *N*-methyl-D-aspartate
PTSD: posttraumatic stress disorder
SERT: neuronal serotonin/5HT transporter
SNRI: serotonin-norepinephrine reuptake inhibitor
SSRI: selective serotonin reuptake inhibitor
TCA: tricyclic antidepressant

antidepressants, are the SSRIs and the serotonin-norepinephrine reuptake inhibitors (SNRIs), which have less toxicity and improved safety compared to the first-generation drugs, which include monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs) (Millan, 2006; Rush et al., 2006).

In monoamine systems, termination of neurotransmitter action occurs via neuronal reuptake of the neurotransmitter from the synaptic cleft. This reuptake occurs via presynaptic high-affinity transporters; inhibition of these transporters enhances neurotransmission by slowing clearance of the transmitter and prolonging its dwell time in the synapse (Shelton and Lester, 2006). Reuptake inhibitors block the neuronal serotonin/5HT transporter (SERT), the neuronal NE transporter (NET), or both. Similarly, TCAs and MAOIs enhance monoaminergic neurotransmission—the TCAs by inhibiting 5HT or NE reuptake via SERT or NET and the MAOIs by inhibiting monoamine metabolism and thereby increasing the levels of neurotransmitter in storage granules available for later release.

Long-term effects of antidepressant drugs evoke regulatory mechanisms that might contribute to the effectiveness of therapy (Shelton, 2000). These responses include altered adrenergic or serotonergic receptor density or sensitivity, altered receptor–G protein coupling and cyclic nucleotide signaling, induction of neurotrophic factors, and increased neurogenesis in the hippocampus (Schmidt and Duman, 2007). Persistent antidepressant effects depend on the continued inhibition of SERT or NET or enhanced serotonergic or noradrenergic neurotransmission achieved by an alternative pharmacological mechanism (Delgado et al., 1991). Compelling evidence suggests that sustained signaling via NE or 5HT increases the expression of specific downstream gene products, particularly brain-derived neurotrophic factor (BDNF), which appears to influence dendritic spine formation, synaptogenesis, and neurogenesis (Duman and Duman, 2015).

Genome-wide association studies have suggested novel pathways that might be exploited for the discovery of antidepressants (Cannon and Keller, 2006; Lin and Lane, 2015). These include systems and pathways outside of monoaminergic neurotransmission, such as glutamatergic signaling (*ketamine, esketamine*), the endogenous opioid system (*naltrexone*), and GABAergic signaling (*brexanolone*) (Sanches et al., 2021). Other novel approaches involve enhancing neurogenesis (Pascual-Brazo et al., 2014) or cyclic nucleotide signaling (O'Donnell and Zhang, 2004), which may be impaired in depressed patients (Fujita et al., 2012). There also are emerging data suggesting a role for inhibition of somatosensory feedback loops with botulinum toxin for treatment of depression (Schulze et al., 2021).

Clinical Considerations With Antidepressant Drugs

The response to antidepressant drug treatment generally has a "therapeutic lag" lasting 3 to 4 weeks before a clinically relevant response is evident; however, symptoms respond differentially, with sleep disturbances improving sooner and mood and cognitive deficits later (Katz et al., 2004). Some of the lag is pharmacokinetic in nature, i.e., effective plasma concentrations are not achieved initially. However, it is likely that a component of the lag is related to delayed pre- and postsynaptic changes. After the successful initial treatment phase, a 6- to 12-month maintenance treatment phase is typical, after which the drug can be gradually withdrawn. If a patient is chronically depressed (i.e., has been depressed for >2 years), lifelong treatment with an antidepressant is advisable. Approximately two-thirds of patients show a marked decrease in depressive symptoms with an initial course of treatment, with one-third showing complete remission (Rush et al., 2006).

Antidepressants are not recommended as monotherapy for bipolar disorder. These drugs, notably TCAs, SNRIs, and, to a lesser extent, SSRIs, can induce a switch from a depressed episode to a manic or hypomanic episode in some patients (Gijsman et al., 2004; Williams et al., 2018).

A controversial issue regarding the use of all antidepressants is their relationship to suicide (Mann et al., 2006). Data establishing a clear link between antidepressant treatment and death by suicide are lacking. However, the U.S. Food and Drug Administration (FDA) has issued a "black-box" warning regarding the use of SSRIs and a number of other antidepressants in children and adolescents due to the possibility of an association between antidepressant treatment and suicidal ideation or behavior (Boaden et al., 2020; Isacsson and Rich, 2014). For seriously depressed patients, the risk of not being on an effective antidepressant drug outweighs the risk of being treated with one (Gibbons et al., 2007). However, it is important to monitor patients closely, particularly children and adolescents, especially during initial periods of treatment.

Classes of Antidepressant and Antianxiety Agents

Selective Serotonin Reuptake Inhibitors

The SSRIs are effective in treating major depression. SSRIs also are anxiolytics with demonstrated efficacy in the treatment of generalized anxiety, panic, social anxiety, and obsessive-compulsive disorders (Rush et al., 2006). *Sertraline* and *paroxetine* are approved for the treatment of PTSD. SSRIs also are used for treatment of premenstrual dysphoric syndrome and for preventing vasovagal symptoms in postmenopausal women, with *fluoxetine* specifically FDA-approved for treatment of bulimia nervosa.

As noted above, neuronal uptake by SERT is the primary process by which neurotransmission via 5HT is terminated (see Figure 18–1). SSRIs block reuptake and enhance and prolong serotonergic neurotransmission. SSRIs used clinically are relatively selective for inhibition of SERT over NET (Table 18–2).

Treatment with an SSRI causes stimulation of $5HT_{1A}$ and $5HT_{7}$ autoreceptors on cell bodies in the raphe nucleus and of $5HT_{1D}$ autoreceptors on serotonergic terminals; this initially reduces net synthesis and release of 5HT. With repeated treatment with SSRIs, there is a gradual downregulation and desensitization of these autoreceptor mechanisms, and with reuptake inhibited, net 5HT transmission is enhanced. In addition, downregulation of postsynaptic $5HT_{2A}$ receptors may contribute to antidepressant efficacy directly or by influencing the function of noradrenergic and other neurons via serotonergic heteroreceptors. Other postsynaptic 5HT receptors likely remain responsive to increased synaptic concentrations of 5HT and contribute to the therapeutic effects of the SSRIs.

Later-developing effects of SSRI treatment also may be important in mediating ultimate therapeutic responses. These include sustained increases in cyclic AMP signaling and phosphorylation of the cyclic AMP

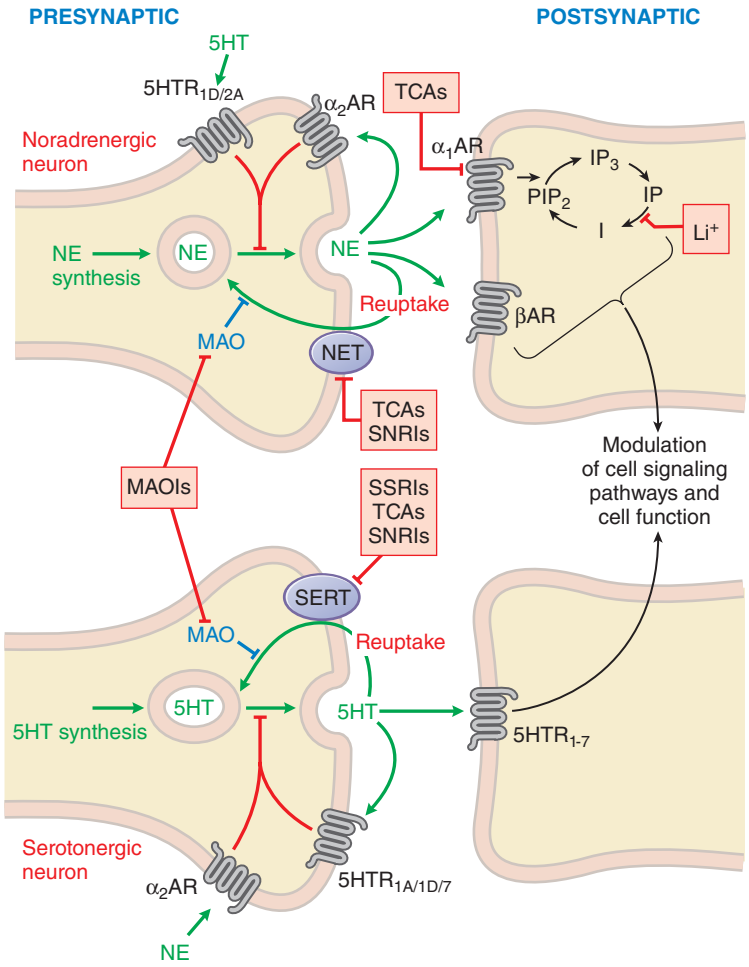

Figure 18–1 *Sites of action of antidepressants at noradrenergic (top) and serotonergic (bottom) nerve terminals.* SSRIs, SNRIs, and TCAs increase noradrenergic or serotonergic neurotransmission by blocking the NE or 5HT transporter (NET or SERT) at presynaptic terminals. MAOIs inhibit the catabolism of NE and 5HT. *Trazodone* and related drugs have direct effects on 5HT receptors (5HTRs) that contribute to their clinical effects. Chronic treatment with a number of antidepressants desensitizes presynaptic autoreceptors and heteroreceptors, producing long-lasting changes in monoaminergic neurotransmission. Postreceptor effects of antidepressant treatment, including modulation of G protein-coupled receptor (GPCR) signaling and activation of protein kinases and ion channels, are involved in the mediation of the long-term effects of antidepressant drugs. Li^+ inhibits IP breakdown and thereby enhances its accumulation and sequelae (Ca^{2+} mobilization, protein kinase C activation, depletion of cellular inositol). Li^+ may also alter release of neurotransmitters by a variety of putative mechanisms (see Chapter 19: Hypotheses for the Mechanism of Action of Lithium and Relationship to Anticonvulsants). Note that NE and 5HT may also affect each other's neurons by activating presynaptic receptors that couple to signaling pathways that reduce transmitter release. I, inositol; IP, inositol monophosphate; IP_3, inositol 1,4,5-trisphosphate; PIP2, phosphatidylinositol 4,5-bisphosphate.

response element binding protein (CREB), as well as increased expression of trophic factors such as BDNF and increased neurogenesis from progenitor cells in the hippocampus and subventricular zone (Licznerski and Duman, 2013; Santarelli et al., 2003). Repeated treatment with SSRIs reduces the expression of SERT, resulting in reduced clearance of released 5HT and increased serotonergic neurotransmission (Kittler et al., 2010; Matthaus et al., 2016).

Serotonin-Norepinephrine Reuptake Inhibitors

Five medications with a nontricyclic structure that inhibit the reuptake of both 5HT and NE have been approved for use in the U.S. and Europe for treatment of depression, anxiety disorders, pain, or other specific conditions: *venlafaxine* and its demethylated metabolite *desvenlafaxine*, *duloxetine*, *milnacipran*, and *levomilnacipran*.

The SNRIs inhibit both SERT and NET (see Table 18–2) and cause enhanced serotonergic and noradrenergic neurotransmission. Similar to the action of SSRIs, the initial inhibition of SERT induces activation of $5HT_{1A}$ and $5HT_{1D}$ autoreceptors, resulting in a decrease in serotonergic neurotransmission by a negative-feedback mechanism until these serotonergic autoreceptors are desensitized. Then, the enhanced 5HT concentration in the synapse can interact with postsynaptic 5HT receptors. The noradrenergic action of these drugs may contribute to downstream gene expression changes affecting BDNF, Trk-B, and other neurotrophic factors and their signaling pathways (Shelton, 2000). Repeated treatment with SNRIs reduces the expression of SERT or NET, resulting in reduced neurotransmitter clearance and increased serotonergic or noradrenergic neurotransmission (Zhao et al., 2009).

The SNRIs were developed with the rationale that they might improve overall treatment response compared to SSRIs (Entsuah et al., 2001). The remission rate for *venlafaxine* appears slightly better than for SSRIs in head-to-head trials (Cipriani et al., 2018). *Duloxetine*, in addition to being approved for use in the treatment of depression and anxiety, is used for treatment of fibromyalgia and neuropathic pain associated with peripheral neuropathy (Finnerup et al., 2015). Off-label uses include stress urinary incontinence (*duloxetine*), autism, binge-eating disorders, hot flashes, pain syndromes, premenstrual dysphoric disorders, and PTSD (*venlafaxine*).

Serotonin Receptor Antagonists

Antagonists of the $5HT_2$ family of receptors are effective antidepressants. These include two close structural analogues, *trazodone* and *nefazodone*, as well as *mirtazapine* and *mianserin* (not marketed in the U.S.)

TABLE 18–1 ■ PROFILES OF REPRESENTATIVE ANTIDEPRESSANTS

CLASS Agent	DOSE[a] mg/day	BIOGENIC AMINE	SIDE EFFECTS									REPRESENTATIVE DRUG
			AGITATION	SEIZURES	SEDATION	HYPOTENSION	ANTI-ACh EFFECTS	GI EFFECTS	WEIGHT GAIN	SEXUAL EFFECTS	CARDIAC EFFECTS	
NE reuptake inhibitors: 3° amine tricyclics												 Imipramine

0, negligible; 0/+, minimal; +, mild; 2+, moderate; 3+, moderately severe; 4+, severe. Other significant side effects for individual drugs are described in the text. Selegiline transdermal patch approved for depression.

[a]Higher and lower doses are sometimes used, depending on patient's needs and response to the drug; see the literature and FDA recommendations.

[b]Children, 0.5–1 mg/kg, up to 70 kg; see black-box warning.

TABLE 18–2 ■ SELECTIVITY OF ANTIDEPRESSANTS AT THE HUMAN BIOGENIC AMINE TRANSPORTERS

DRUG	SELECTIVITY	DRUG	SELECTIVITY
NE SELECTIVE	**NET vs. SERT**	**5HT SELECTIVE**	**SERT vs. NET**
Oxaprotiline	800	*S*-Citalopram	7127
Maprotiline	532	*R,S*-Citalopram	3643
Viloxazine	109	Sertraline	1390
Nomifensine	64	Fluvoxamine	591
Desipramine	22	Paroxetine	400
Protriptyline	14	Fluoxetine	305
Atomoxetine	12	Clomipramine	123
Reboxetine	8.3	Venlafaxine	116
Nortriptyline	4.2	Zimelidine	60
Amoxapine	3.6	Trazodone	52
Doxepin	2.3	Imipramine	26
		Amitriptyline	8.0
DA SELECTIVE	**DAT vs. NET**	Duloxetine	7.0
Bupropion	1000	Dothiepin	5.5
		Milnacipran	1.6

Selectivity is defined as the ratio of the relevant K_i values (SERT/NET, NET/SERT, NET/DAT). Bupropion is selective for the DAT relative to the NET and SERT. Data from Frazer, 1997; Owens et al., 1997; and Leonard and Richelson, 2000.

The efficacy of *trazodone* may be somewhat more limited than that of the SSRIs; however, low doses of *trazodone* (50–200 mg) have been used widely, both alone and concurrently with SSRIs or SNRIs, to treat insomnia. Both *mianserin* and *mirtazapine* are sedating and are treatments of choice for some depressed patients with insomnia. *Trazodone* blocks $5HT_2$ and α_1 adrenergic receptors. *Trazodone* also inhibits SERT but is markedly less potent for this action relative to its blockade of $5HT_{2A}$ receptors. Similarly, the most potent pharmacological action of *nefazodone* also is the blockade of the $5HT_2$ receptors. Both *mirtazapine* and *mianserin* potently block histamine H_1 receptors. They also have some affinity for α_2 adrenergic receptors. Their affinities for $5HT_{2A}$, $5HT_{2C}$, and $5HT_3$ receptors are high, although less than for histamine H_1 receptors. Both of these drugs increase the antidepressant response when combined with SSRIs compared to the action of the SSRIs alone. *Vortioxetine* is a potent SERT inhibitor and binds to a number of serotonergic receptors; the drug is a partial agonist at $5HT_{1A}$ and $5HT_{1B}$ receptors and an antagonist at $5HT_{1D}$, $5HT_3$, and $5HT_7$ receptors.

Bupropion

Bupropion has the chemical backbone of β-phenethylamine; it is discussed separately because it acts via multiple mechanisms that differ somewhat from the mechanisms of SSRIs and SNRIs (Foley et al., 2006; Gobbi et al., 2003). It enhances both noradrenergic and dopaminergic neurotransmission via inhibition of reuptake by the norepinephrine transporter (NET) and the dopamine transporter (DAT) (although its effects on DAT are not potent in animal studies) (see Table 18–2). *Bupropion*'s mechanism of action also may involve the presynaptic release of NE and DA and effects on the vesicular monoamine transporter (VMAT2; see Figure 10–8). The metabolite, hydroxybupropion, may contribute to the therapeutic effects of the parent compound: this metabolite has a similar pharmacology and is present at substantial levels. *Bupropion* is indicated for the treatment of depression, prevention of seasonal depressive disorder, and as a smoking cessation treatment (Carroll et al., 2014). *Bupropion* has effects on sleep electroencephalograms that are opposite those of most antidepressant drugs and has fewer sexual side effects and results in less weight gain than other antidepressants (Patel et al., 2016). *Bupropion* may improve symptoms of attention-deficit/hyperactivity disorder (ADHD) and has been used off-label for neuropathic pain and weight loss. Clinically, *bupropion* is widely used in combination with SSRIs with the intent of obtaining a greater antidepressant response; however, there are limited clinical data providing support for this practice.

Atypical Antipsychotics

In addition to their use in schizophrenia, bipolar depression, and major depression with psychotic features, atypical antipsychotics are used in the treatment of major depression without psychotic features, typically as an adjunct along with more conventional treatments (Jarema, 2007). The combination of *aripiprazole* or *quetiapine* with SSRIs and SNRIs and a combination of *olanzapine* and the SSRI *fluoxetine* have been FDA approved for treatment-resistant major depression (i.e., following an inadequate response to at least two different antidepressants). Additionally, *brexpiprazole* is FDA-approved as an adjunct medication for major depressive disorder in adults. *Quetiapine* may have either primary antidepressant actions on its own or adjunctive benefit for treatment-resistant depression. The mechanisms of action and adverse effects of the atypical antipsychotics are described in Chapter 19. The major risks of these agents are weight gain and metabolic syndrome, a greater problem for *quetiapine* and *olanzapine* than for *aripiprazole*. The mechanism by which atypical antipsychotics enhance the efficacy of antidepressant medications is not fully understood but may be due in part to $5HT_{2A}$ receptor blockade.

Tricyclic Antidepressants

While TCAs have long-established efficacy, they exhibit serious side effects and generally are not used as first-line drugs for the treatment of depression. TCAs and first-generation antipsychotics are synergistic for the treatment of psychotic depression. Tertiary amine TCAs (e.g., *doxepin, amitriptyline*) have been used for many years in relatively low doses for treating insomnia. In addition, because of the roles of NE and 5HT in nociception, these drugs are commonly used to treat a variety of pain conditions, typically at doses lower than those used psychiatric disorders (Finnerup et al., 2015).

The pharmacological action of TCAs is antagonism of SERT and NET (see Table 18–2). In addition to inhibiting NET somewhat selectively (*desipramine, nortriptyline, protriptyline, amoxapine*) or both SERT and NET (*imipramine, amitriptyline*), these drugs block other receptors (H_1 histamine, $5HT_2$, α_1 adrenergic, and muscarinic cholinergic receptors). Given the comparable activities of *clomipramine* and SSRIs (see Tables 18–2 and 18–4; see also Decloedt and Stein, 2010), it is possible that some combination of these additional pharmacological actions contributes to the therapeutic effects of TCAs and possibly SNRIs. One TCA, *amoxapine*, also is a DA receptor antagonist; its use, unlike that of other TCAs, poses some risk for the development of extrapyramidal side effects such as tardive dyskinesia.

Monoamine Oxidase Inhibitors

Monoamine oxidases A and B (MAO-A, MAO-B) are widely distributed mitochondrial enzymes. MAO activities in the gastrointestinal (GI) tract and liver, mainly MAO_A, protect the body from biogenic amines in the diet. In presynaptic nerve terminals, MAO metabolizes monoamine neurotransmitters via oxidative deamination. MAO_A preferentially metabolizes 5HT and NE and can metabolize DA; MAO_B is effective against 5HT and DA (see Chapters 10 and 15; see also Nestler et al., 2020). MAOIs have efficacy equivalent to that of the TCAs but are rarely used because of their toxicity and major interactions with some drugs (e.g., sympathomimetics and some opioids). The MAOIs first approved in the U.S. for treatment of depression—*tranylcypromine*, *phenelzine*, and *isocarboxazid*—irreversibly inhibit both MAO_A and MAO_B. These agents inhibit the body's capacity to metabolize not only endogenous monoamines such as NE and 5HT but also exogenous biogenic amines such as tyramine. This is problematic because some foods contain high amounts of tyramine. Global inhibition of MAOs will increase the bioavailability of dietary tyramine, and tyramine-induced NE release can cause marked increases in blood pressure (hypertensive crisis) (see Chapter 10).

This potential to exacerbate the effects of indirectly acting sympathomimetic amines seems to relate mainly to inhibition of MAO_A. *Selegiline* is an irreversible MAO inhibitor but with selectivity for MAO_B. Administration of *selegiline* at low doses spares MAO_A activity in the GI tract and elsewhere, reducing the risk of deleterious interactions with sympathomimetics (at higher doses, *selegiline* will also inhibit MAO_A). *Selegiline* is available as a transdermal patch for the treatment of depression; transdermal delivery may reduce the risk for diet-associated hypertensive reactions. Some MAOIs, such as *moclobemide* and *eprobemide*, are reversible, competitive inhibitors of MAO_A, and thus dietary substrates will still be metabolized to the extent that they compete with the inhibitor for binding to MAO_A (i.e., tyramine will still be metabolized and will compete better as a substrate for MAO_A as its concentration rises, dampening negative interactions). These reversible inhibitors of MAO_A are used elsewhere but are not approved for use in the U.S. (Finberg, 2014).

Mechanistically Distinctive Compounds: NMDA Receptor Antagonists and Neurosteroids

Antidepressant medications have traditionally focused their actions on the monoamine neurotransmitters NE, DA, and 5HT, and those medications generally require several weeks to produce clinical effects. In contrast, *ketamine*, acting on *N*-methyl-D-aspartate (NMDA) receptors to antagonize glutamate binding, and secondarily affecting AMPA receptors, produces rapid and lasting antidepressant effects. *Brexanolone* (*allopregnanolone*) acts at a peripheral site on the $GABA_A$ receptor to modulate Cl^- flux: It is approved for treatment of postpartum depression. These agents are the first mechanistically distinct antidepressants approved in decades and represent novel approaches to the pharmacotherapy of depression.

NMDA Receptor Antagonists. *Ketamine* is an NMDA receptor antagonist that is effective for depression as well as suicidality (Xiong et al., 2021; Xu et al., 2016). Its antidepressant effects are thought to be due to blockade of NMDA receptors on GABAergic interneurons, which leads to disinhibition of glutamatergic neurons and subsequent increases in glutamate release, ultimately affecting AMPA receptors and BDNF in the postsynaptic cell (Figure 18-2). *Ketamine* might also have a role in the treatment of bipolar disorder; more data are required to draw firm conclusions (Joseph et al., 2021). Although *ketamine* appears effective, its use in depression treatment is off-label; only *esketamine*, its *S*-enantiomer, is FDA-approved. It is available as a nasal spray, under a Risk Evaluation and Mitigation Strategy, for treatment-resistant depression. There is some debate as to whether the antidepressant effects of *ketamine* are due to the parent compound or its bioactive metabolites, such as (2R,6R)-hydroxynorketamine (HNK). A number of other glutamatergic modulators currently are under investigation (Sanches et al., 2021).

Neurosteroids. *Brexanolone* (*allopregnanolone*) is a neurosteroidal antidepressant with a novel mechanism of action: it is a positive allosteric modulator of the $GABA_A$ receptor (see Figure 16–11) (Sanches et al., 2021). Hypothetically, *brexanolone* may restore reduced levels of this neurosteroid found to be associated with depression, as well as altering $GABA_A$ receptor function. Currently, *brexanolone* is the only medication that is specifically FDA-approved for the treatment of postpartum depression. It is administered by continuous intravenous infusion over 2.5 days and subject to a Risk Evaluation and Mitigation Strategy; its use is somewhat limited due to the high cost of treatment. It is unknown whether neurosteroids, including *brexanolone*, are effective for depression treatment outside of postpartum depression.

ADME

These agents conveniently fit into groups with similarities of basic pharmacologic properties. Thus, information on the pharmacokinetics, clinical use, drug interactions, and adverse responses are presented sequentially, class by class.

Metabolism

The metabolism of most antidepressants is mediated by hepatic cytochromes P450 (CYPs); the half-lives and predominant CYPs responsible for metabolism are summarized in Table 18–3. Some antidepressants inhibit the clearance of other drugs by the CYP system and vice versa, and the possibility of drug interactions should be a significant factor in considering the choice of agents. Likewise, dose considerations have to include awareness of hepatic function (Mauri et al., 2014). CYPs 2D6 and 2C19 are highly polymorphic, and for antidepressants metabolized primarily by those CYPs, a range of metabolic rates can be expected. Patients at the extremes of CYP 2C19 and 2D6 activities, ultra-rapid and ultra-slow metabolizers, would seem most likely to exhibit adverse responses, from failure of therapy (ultra-rapid metabolism) to toxicity (ultra-slow metabolism). For example, in a fraction of patients, TCAs are metabolized slowly due to a variant CYP2D6 (poor metabolizers), and this necessitates a dose reduction (see Tricyclic Antidepressants, below). Probst-Schendzielorz et al. (2015) have reviewed the pertinent literature in the case of SSRIs and provide dosing recommendations for *fluvoxamine*, *paroxetine*, *citalopram*, *escitalopram*, and *sertraline* based on *CYP2D6* and/or *CYP2C19* genotype. Data on this subject are accumulating and recommendations may change; updated information on many compounds is available at the following site: http://www.pharmgkb.org.

Although genetic polymorphisms among CYPs can influence antidepressant metabolism, a number of other factors, such as disease processes, diet, environmental factors, and drug-drug interactions, influence CYP activities and drug disposition. Polymorphisms of target proteins (e.g., a specific 5HT receptor) may influence drug response (see Table 7–2). Dubovsky and Dubovsky (2015) have argued that CYP genotyping alone may be insufficient and also is not yet proven to have a practical influence on choice of drug treatment in clinical settings. In any event, there is no substitute for clinical judgement and careful monitoring.

Selective Serotonin Reuptake Inhibitors

All of the SSRIs are orally active and possess elimination half-lives consistent with once-daily dosing (Hiemke and Hartter, 2000). In the case of *fluoxetine*, the combined action of the parent and the demethylated metabolite norfluoxetine allows for a once-weekly formulation. CYP2D6 is involved in the metabolism of most SSRIs, and the SSRIs are at least moderately potent inhibitors of this isoenzyme. This creates a significant potential for drug interaction for postmenopausal women taking the breast cancer drug and estrogen antagonist *tamoxifen* (see Chapter 73). Because *venlafaxine* and *desvenlafaxine* are weak inhibitors of CYP2D6, these antidepressants are not contraindicated in this clinical situation. However, care should be used in combining SSRIs with drugs that are metabolized by CYPs. SSRIs such as *escitalopram* and *citalopram* should be dosed with care in elderly patients due to an age-dependent decrease in CYP2C19 metabolism. There is some evidence that the clearance of the *R*-enantiomer of *citalopram* is slower in women than in men (13 vs. 9 L/h, respectively), a difference that would result in higher exposures to the *R*-enantiomer in women (Akil et al., 2016).

Serotonin-Norepinephrine Reuptake Inhibitors

Both immediate-release and extended-release (tablet or capsule) preparations of *venlafaxine* result in steady-state levels of drug in plasma within 3 days. The elimination half-lives for the parent *venlafaxine* and its active and major metabolite *desmethylvenlafaxine* are 5 and 11 h, respectively. *Desmethylvenlafaxine* is eliminated by hepatic metabolism and by renal excretion. *Venlafaxine* dose reductions are suggested for patients with renal or hepatic impairment. *Duloxetine* has a $t_{1/2}$ of 12 h. *Duloxetine* is not recommended for those with end-stage renal disease or hepatic insufficiency.

Serotonin Receptor Antagonists

Mirtazapine has an elimination $t_{1/2}$ of 16 to 30 h. Thus, reaching a new steady-state blood level after a change in daily dose would take 90 to 150 h (five half-lives, 4–6+ days); dose changes are suggested no more often than 1 to 2 weeks. The recommended initial dosing of *mirtazapine* is 15 mg/day, with a maximal recommended dose of 45 mg/day. Clearance of *mirtazapine* is decreased in the elderly and in patients with moderate-to-severe renal or hepatic impairment. Pharmacokinetics and adverse effects of *mirtazapine* may have an enantiomer-selective

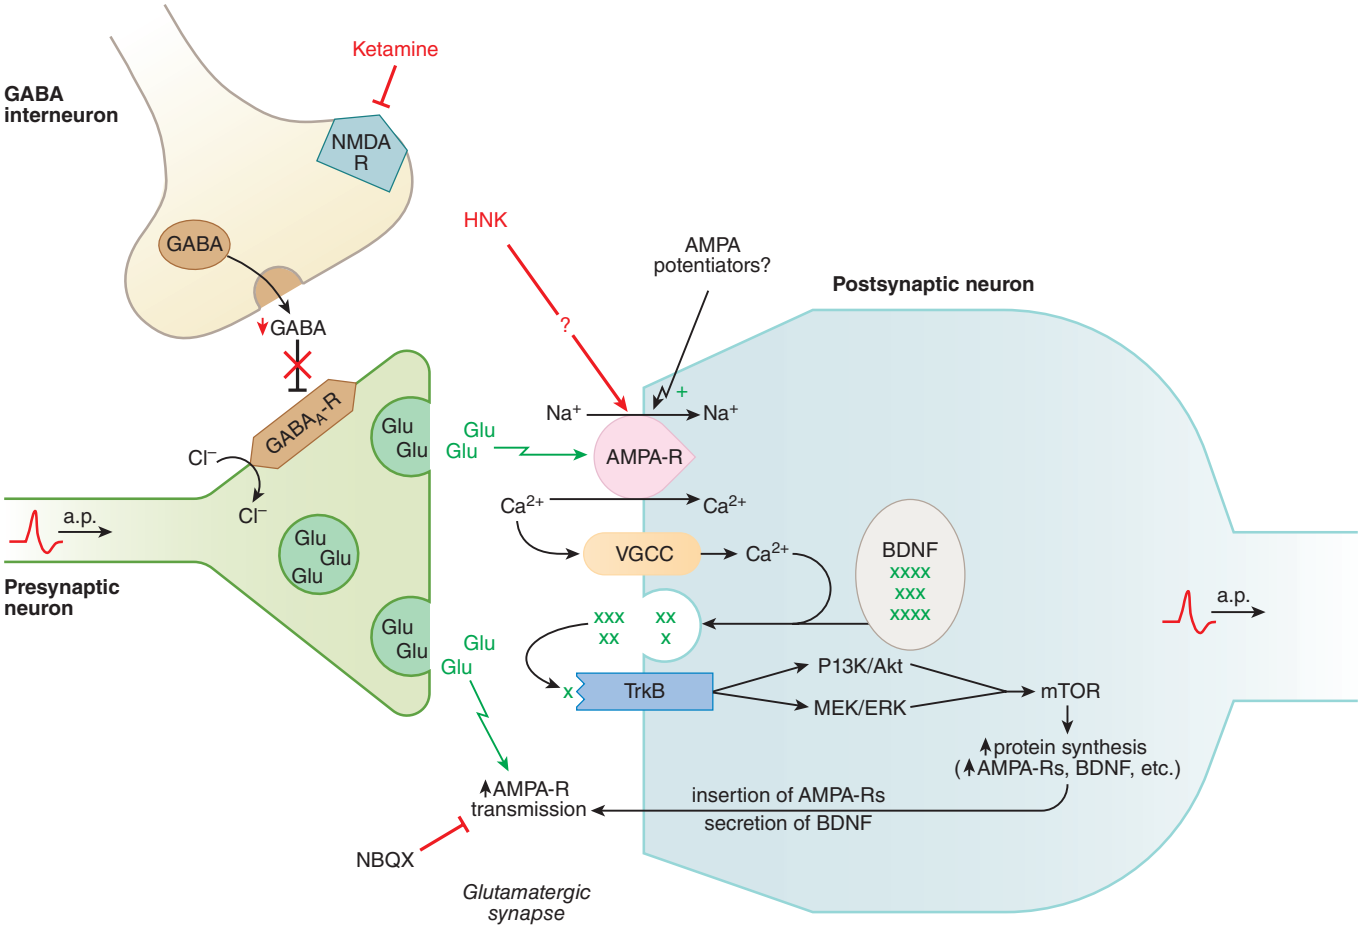

Figure 18–2 *Proposed mechanisms for the antidepressant effects of ketamine.* The figure depicts an interneuron interacting with the presynaptic fiber of a glutamatergic synapse, such as might occur in the prefrontal cortex. *Ketamine* interacts with and inhibits the function of NMDA receptors on the GABAergic interneuron, thereby inhibiting cation flux through the receptor channel and reducing excitability of the interneuron. The downstream effect is a reduction in GABA release onto the $GABA_A$ receptor of the presynaptic neuron, causing a disinhibition of that glutamatergic neuron (a reduction in the hyperpolarizing flow of chloride ions that stimulation of the $GABA_A$ receptor would normally cause), thereby promoting depolarization and glutamate release into the synaptic space. Released glutamate activates AMPA receptors (GluA1/GluA2 receptors) on the postsynaptic cell, resulting in depolarization of that cell and a number of sequelae, including Ca^{2+} entry (via voltage-gated calcium channels [VGCCs]) and release of brain-derived neurotrophic factor (BDNF). BDNF activates a membrane receptor tyrosine kinase, tropomyosin receptor kinase B (TrkB), initiating cellular responses that include stimulation of neuronal protein synthesis (including synthesis of BDNF and AMPA receptors), leading to further enhancement of glutamatergic neurotransmission (restoration of normal transmission). Hypothetically, these events account for the antidepressant activity of *ketamine*. Blockade of *ketamine*'s antidepressant effects by the AMPA receptor antagonist NBQX (see Table 16–2) is consistent with this scheme. The FDA-approved antidepressant is *esketamine*, the *S*-enantiomer of *ketamine*, but there is also interest in the therapeutic potential of other enantiomers and metabolites of ketamine. *R*-ketamine has antidepressant properties, and, as indicated in the figure, a ketamine metabolite, (2R,6R)-hydroxynorketamine (HNK), can also facilitate (enhance) neurotransmission mediated by the AMPA receptor, suggesting that this metabolite may play a role in the postsynaptic responses depicted above and raising the possibility of designing antidepressants that are direct potentiators of AMPA-mediated neurotransmission. For further details, see Sanacora and Schatzberg (2015), Zanos and Gould (2018), and Hashimoto (2020). a.p., action potential; mTOR, mechanistic target of rapamycin.

component (Brockmöller et al., 2007). Steady-state *trazodone* is observed within 3 days following initiation of a dosing regimen. *Trazodone* has a $t_{1/2}$ of 6 h; a metabolite, m-chlorophenylpiperazine, is a tryptaminergic agonist. *Trazadone* typically is started at 150 mg/day in divided doses, with 50-mg increments every 3 to 4 days. The maximally recommended dose is 400 mg/day for outpatients and 600 mg/day for inpatients. *Nefazodone* has a $t_{1/2}$ of only 2 to 4 h; its major metabolite hydroxynefazodone has a $t_{1/2}$ of 1.5 to 4 h.

Bupropion

Bupropion elimination has a $t_{1/2}$ of 21 h and involves both hepatic and renal routes. Patients with severe hepatic cirrhosis should receive a maximum dose of 150 mg every other day; consideration for a decreased dose should also be made in cases of renal impairment.

Tricyclic Antidepressants

The TCAs, or their active metabolites, have plasma half-lives of 8 to 80 h; this makes once-daily dosing possible for most of the compounds (Rudorfer and Potter, 1999). Steady-state concentrations occur within several days to several weeks of beginning treatment, as a function of the $t_{1/2}$. TCAs are largely eliminated by hepatic CYPs (see Table 18–3). Dosage adjustments of TCAs are typically made according to a patient's clinical response, not based on plasma levels. Nonetheless, monitoring the plasma exposure has an important relationship to treatment response; there is a relatively narrow therapeutic window. About 7% of patients metabolize TCAs slowly due to a variant CYP2D6 isoenzyme, causing a 30-fold difference in plasma concentrations among different patients given the same TCA dose. To avoid toxicity in "slow metabolizers," plasma levels should be monitored and doses adjusted downward.

Monoamine Oxidase Inhibitors

The MAOIs are metabolized by acetylation. A significant portion of the population (50% of the population of European descent and an even higher percentage among those of Asian ancestry) are "slow acetylators" (see Figure 65–4) and will exhibit elevated plasma levels. The nonselective

TABLE 18–3 ■ DISPOSITION OF ANTIDEPRESSANTS

DRUG	ELIMINATION $t_{1/2}$ (h) OF PARENT DRUG ($t_{1/2}$ of active metabolite)	TYPICAL C_p (ng/mL)	PREDOMINANT CYP INVOLVED IN METABOLISM
Tricyclic antidepressants			
Amitriptyline	16 *(30)*	100–250	2D6, 2C19, 3A3/4, 1A2
Amoxapine	8 *(30)*	200–500

Serotonin-norepinephrine reuptake inhibitors			
Duloxetine	11	47–110	2D6
Venlafaxine	5 *(11)*	2–3200	2D6, 3A4
Other antidepressants			
Atomoxetine	5–20; child, 3	—	2D6, 3A3/4
Brexanolone	9	1800–7500 (ng*h/mL with 60 µg/h to 90 µg/h infusion range; 10–140 breast milk concentrations)	AKRs, UGTs, SULTs
Bupropion	11	75–100	2B6
Esketamine	7–12 *(8)*	5–300	2B6, 3A4 (primary) 2C9, 2C19 (minor)
Mirtazapine	16	5–100	2D6
Nefazodone	2–4	80–2300	3A3/4
Reboxetine	12	25–203	3A4
Trazodone	6	800–1600	2D6

Values shown are elimination $t_{1/2}$ values for a number of clinically used antidepressant drugs; numbers in parentheses are $t_{1/2}$ values of active metabolites. Fluoxetine (2D6), fluvoxamine (1A2, 2C8, 3A3/4), paroxetine (2D6), and nefazodone (3A3/4) are potent inhibitors of CYPs; sertraline (2D6), citalopram (2C19), and venlafaxine are less-potent inhibitors. Plasma concentrations are those observed at typical clinical doses.
Information sources: FDA-approved package inserts and Appendix I of this book.

MAOIs used in the treatment of depression are irreversible inhibitors; thus, it takes up to 2 weeks for MAO activity to recover, even though the parent drug is excreted within 24 h (Livingston and Livingston, 1996). Recovery of normal enzyme function is dependent on synthesis and transport of new MAO to monoaminergic nerve terminals.

Esketamine

Esketamine, the *S*-enantiomer of the NMDA antagonist *ketamine*, is administered as a nasal spray. The absolute bioavailability after intranasal administration is approximately 50% for the 56- and 84-mg intranasal doses. Approximately 46% of the inhaled dose is swallowed; 19% of this swallowed dose reaches the systemic circulation. This NMDA antagonist is noncompetitive and has a very slow off rate from its allosteric binding site on the NMDA receptor (see Figure 16–9), resulting in a much longer dosage interval for effective control of depression than would be predicted from the terminal plasma $t_{1/2}$ of 7 to 12 h. The maximal plasma concentration (C_{max}) occurs 20 to 40 min after intranasal administration. Elderly individuals and those with mild hepatic impairment have slower clearance of the drug, which results in higher exposure to the drug, as evidenced by increased C_{max} (67% higher); noresketamine's apparent clearance is 19% lower in this subgroup. Interindividual variability in concentration exposure to *ketamine* has been reported to be as high as 66% (FDA, 2019; Perez-Ruixo, 2021).

Brexanolone

Brexanolone acts at $GABA_A$ receptors to enhance Cl^- current. After administration by IV infusion, the terminal plasma concentration $t_{1/2}$ of *brexanolone* is 9 h (Scott, 2019). The primary metabolic pathways are α-keto reduction, glucuronidation, and sulfation; the disposition of *brexanolone* is not affected by renal function. However, the solubilizing agent used in the IV formulation (betadex sulfobutyl ether sodium) can accumulate in individuals with severe renal impairment (<5 mL/min glomerular filtration rate). There are no known pharmacokinetic drug interactions. *Brexanolone* exhibits linear pharmacokinetics across the range of infusions from 30 µg/kg/h through 270 µg/kg/h with low intersubject variability in concentration exposure (<21%) (Leader et al., 2019).

Adverse Effects

Selective Serotonin Reuptake Inhibitors

The SSRIs have no major cardiovascular side effects, are generally free of antimuscarinic side effects (dry mouth, urinary retention, confusion), and do not block α adrenergic receptors. Most SSRIs, with the exception of *paroxetine*, do not block histamine receptors and usually are nonsedating (Table 18–4).

Adverse side effects of SSRIs from excessive stimulation of brain $5HT_2$ receptors may result in insomnia, increased anxiety, irritability, and decreased libido, effectively worsening prominent depressive symptoms. Excess activity at spinal $5HT_2$ receptors causes sexual side effects, including erectile dysfunction, anorgasmia, and ejaculatory delay (Clayton et al., 2014). These effects may be more prominent with *paroxetine*. Aspects of sexual dysfunction can be treated with the PDE5 inhibitor *sildenafil* (Nurnberg, 2001; Nurnberg et al., 2008; see also Figure 49–6 and Table 49–2). Stimulation of $5HT_3$ receptors in the central nervous system (CNS) and periphery contributes to GI effects, which are usually limited to nausea but may include diarrhea and emesis. Some patients experience an increase in anxiety, especially with the initial dosing of SSRIs. With continued treatment, some patients also report a dullness of intellectual abilities and concentration. In general, there is not a strong relationship between SSRI serum concentrations and therapeutic efficacy. Thus, dosage adjustments are based more on evaluation of clinical response and management of side effects.

Sudden withdrawal of antidepressants can precipitate a discontinuation syndrome (Harvey and Slabbert, 2014). For SSRIs and SNRIs, the symptoms of withdrawal may include dizziness, headache, nervousness, nausea, and insomnia. This withdrawal syndrome appears most intense for *paroxetine*, *venlafaxine*, and *desvenlafaxine*, due to their relatively

TABLE 18–4 ■ POTENCIES OF SELECTED ANTIDEPRESSANTS AT MUSCARINIC, HISTAMINE H_1, AND α_1 ADRENERGIC RECEPTORS

DRUG	RECEPTOR TYPE		
	MUSCARINIC CHOLINERGIC	HISTAMINE H_1	α_1 ADRENERGIC
Amitriptyline	18	1.1	27
Amoxapine	1000	25	50
Atomoxetine	≥1000	≥1000	≥1000
Bupropion	40,000	6700	4550
R,S-Citalopram	1800	380	1550
S-Citalopram	1240	1970	3870
Clomipramine	37	31.2	39
Desipramine	196	110	130
Doxepin	83.3	0.24	24
Duloxetine	3000	2300	8300
Fluoxetine	2000	6250	5900
Fluvoxamine	24,000	>100,000	7700
Imipramine	91	11.0	91
Maprotiline	560	2.0	91
Mirtazapine	670	0.1	500
Nefazodone	11,000	21	25.6
Nortriptyline	149	10	58.8
Paroxetine	108	22,000	>100,000
Protriptyline	25	25	130
Reboxetine	6700	312	11,900
Sertraline	625	24,000	370
Trazodone	>100,000	345	35.7
Trimipramine	59	0.3	23.8
Venlafaxine	>100,000	>100,000	>100,000

Values are experimentally determined potencies (K_i values, nM) for binding to receptors that contribute to common side effects of clinically used antidepressant drugs: muscarinic cholinergic receptors (e.g., dry mouth, urinary retention, confusion); histamine H_1 receptors (sedation); and α_1 adrenergic receptors (orthostatic hypotension, sedation). Data from Leonard and Richelson, 2000.

short half-lives and, in the case of *paroxetine*, lack of active metabolites. Conversely, the active metabolite of *fluoxetine*, norfluoxetine, has such a long $t_{1/2}$ (1–2 weeks) that few patients experience any withdrawal symptoms with discontinuation of *fluoxetine*.

Unlike the other SSRIs, *paroxetine* is associated with an increased risk of congenital cardiac malformations when administered in the first trimester of pregnancy (Gadot and Koren, 2015). There has been substantial debate regarding the potential for SSRI administration to pregnant women to cause persistent pulmonary hypertension in newborns. While the data support this association, the absolute increase in risk to newborns is small compared to the high likelihood of harm to women whose antidepressants are discontinued during pregnancy (Ng et al., 2019).

Serotonin-Norepinephrine Reuptake Inhibitors

The SNRIs have a side effect profile similar to that of the SSRIs, including nausea, constipation, insomnia, headaches, and sexual dysfunction. The immediate-release formulation of *venlafaxine* can induce sustained diastolic hypertension (diastolic blood pressure >90 mmHg at consecutive weekly visits) in 10% to 15% of patients at higher doses; this risk is reduced with the extended-release form. This effect of *venlafaxine* may not be associated simply with inhibition of NET because *duloxetine* does not share this side effect. *Venlafaxine* also is associated with an increased risk of perinatal complications.

Serotonin Receptor Antagonists

The main side effects of *mirtazapine*, seen in more than 10% of the patients, are somnolence, increased appetite, and weight gain. A rare side effect of *mirtazapine* is agranulocytosis. *Trazodone* use is associated with priapism in rare instances. *Nefazodone* was voluntarily withdrawn from the market in several countries after rare cases of liver failure were associated with its use. In the U.S., *nefazodone* is marketed with a black-box warning regarding hepatotoxicity.

Bupropion

Typical side effects associated with *bupropion* include anxiety, mild tachycardia and hypertension, irritability, and tremor. Other side effects include headache, nausea, dry mouth, constipation, appetite suppression, insomnia, and, rarely, aggression, impulsivity, and agitation. Seizures are dependent on dose and plasma concentration, with seizures occurring rarely within the recommended dose range. *Bupropion* should be avoided in patients with seizure disorders as well as those with bulimia, due to an increased risk of seizures (Horne et al., 1988; Noe et al., 2011). At doses higher than that recommended for depression (450 mg/day), the risk of seizures increases significantly. The use of extended-release formulations often blunts the maximum concentration observed after dosing and minimizes the chance of reaching drug levels associated with an increased risk of seizures.

Tricyclic Antidepressants

The TCAs are potent antagonists at histamine H_1 receptors, and this antagonism contributes to the sedative effects of TCAs (see Table 18–4). Antagonism of muscarinic acetylcholine receptors contributes to cognitive dulling as well as a range of adverse effects mediated by the parasympathetic nervous system (blurred vision, dry mouth, tachycardia, constipation, difficulty urinating). Some tolerance does occur for these anticholinergic effects. Antagonism of α_1 adrenergic receptors contributes to orthostatic hypotension and sedation. Weight gain is another side effect of this class of antidepressants.

The TCAs have quinidine-like effects on cardiac conduction that can be life threatening with overdose and that limit the use of TCAs in patients with heart disease. This is the primary reason that only a limited supply should be available to the patient at any given time. Like other antidepressant drugs, TCAs also lower the seizure threshold.

Monoamine Oxidase Inhibitors

Hypertensive crisis resulting from food or drug interactions is one of the life-threatening toxicities associated with the use of the MAOIs (Rapaport, 2007). Foods containing tyramine are a contributing factor. MAO_A within the intestinal wall and MAO_A and MAO_B in the liver normally degrade dietary tyramine. When MAO_A is inhibited, tyramine can enter the systemic circulation and be taken up into adrenergic nerve endings, where it causes release of catecholamines from storage vesicles resulting in stimulation of postsynaptic receptors and an increase in blood pressure to dangerous levels. The concurrent use of MAOIs and medications that contain sympathomimetic compounds also results in a potentially life-threatening elevation of blood pressure. In comparison to *tranylcypromine* and *isocarboxazid*, the *selegiline* transdermal patch (*selegiline* is selective for MAO_B) is better tolerated and safer, as are the reversible, competitive inhibitors *moclobemide* and *eprobemide*. Another serious, life-threatening issue with chronic administration of MAOIs is hepatotoxicity.

Esketamine

Esketamine increases blood pressure for several hours following administration. It is reported to be sedating and to disrupt sleep and to impair

memory and concentration. It has abuse potential; partly because of this, it is administered under a Risk Evaluation and Mitigation Strategy.

Brexanolone

Brexanolone is sedating and can cause dizziness. Because of its association with sudden loss of consciousness, it is administered under a Risk Evaluation and Mitigation Strategy. Additionally, *brexanolone* should not be used in patients with end-stage renal disease because of concern that the solubilizing agent, betadex sulfobutyl ether sodium, may accumulate in the kidney and liver and cause adverse effects.

Drug Interactions

Many antidepressant drugs are metabolized by hepatic CYPs, especially by CYP2D6. Thus, other agents that are substrates (e.g., *hydrocodone, diphenhydramine*) or inhibitors (e.g., *imatinib, fluoxetine, paroxetine, mirabegron, quinidine*) of CYP2D6 can increase plasma concentrations of the primary drug. The combination of other classes of antidepressant agents with MAOIs is inadvisable and can lead to *serotonin syndrome*, a serious triad of abnormalities consisting of cognitive, autonomic, and somatic effects due to excess serotonin. Symptoms of serotonin syndrome include hyperthermia, muscle rigidity, myoclonus, tremors, autonomic instability, confusion, irritability, and agitation; this can progress to coma and death.

Selective Serotonin Reuptake Inhibitors

Paroxetine and, to a lesser degree, *fluoxetine* are potent inhibitors of CYP2D6 (Hiemke and Hartter, 2000). The other SSRIs, outside of *fluvoxamine*, are at least moderate inhibitors of CYP2D6. This inhibition can result in disproportionate increases in plasma concentrations of drugs metabolized by CYP2D6 when doses of these drugs are increased. *Fluvoxamine* directly inhibits CYP1A2 and CYP2C19; *fluoxetine* and *fluvoxamine* also inhibit CYP3A4. A prominent interaction is the increase in TCA exposure that may be observed during coadministration of TCAs and SSRIs.

The MAOIs enhance the effects of SSRIs due to inhibition of 5HT metabolism. Administration of these drugs together can produce synergistic increases in extracellular brain 5HT, leading to serotonin syndrome (see previous discussion). Other drugs that may induce serotonin syndrome include substituted amphetamines such as *methylenedioxymethamphetamine* (MDMA; Ecstasy) and synthetic cathinones (i.e., "bath salts"), which directly release 5HT from nerve terminals.

The SSRIs should not be started until at least 14 days following discontinuation of treatment with an irreversible inhibitor of MAO; this time period allows for synthesis of new MAO. For all SSRIs but *fluoxetine*, at least 14 days should pass prior to beginning treatment with an MAOI following the end of treatment with an SSRI. Because the active metabolite norfluoxetine has a $t_{1/2}$ of 1 to 2 weeks, at least 5 weeks should pass between stopping *fluoxetine* and beginning an MAOI.

Serotonin-Norepinephrine Reuptake Inhibitors

While a 14-day period is recommended between ending MAOI therapy and starting *venlafaxine* treatment, an interval of 7 days is considered safe. *Duloxetine* has a similar interval for initiation following MAOI therapy; conversely, only a 5-day waiting period is needed before beginning MAOI treatment after ending *duloxetine*. Failure to observe these required waiting periods can result in serotonin syndrome.

Serotonin Receptor Antagonists

Trazodone dosing may need to be lowered when given together with drugs that inhibit CYP3A4. *Mirtazapine* is metabolized by CYPs 2D6, 1A2, and 3A4 and may interact with drugs that share these CYP pathways, requiring mutual dose reductions. *Trazodone* and *nefazodone* are weak inhibitors of 5HT uptake and should not be administered with MAOIs due to concerns about serotonin syndrome.

Bupropion

The major route of metabolism for *bupropion* is via CYP2B6. *Bupropion* and its metabolite hydroxybupropion can inhibit CYP2D6, the CYP responsible for metabolism of several SSRIs (see Table 18–3) as well *propranolol* and *haloperidol*, among others. Thus, the potential for interactions of *bupropion* with SSRIs and other drugs metabolized by CYP2D6 should be kept in mind until the safety of the combination is firmly established.

Tricyclic Antidepressants

Drugs that inhibit CYP2D6, such as *bupropion* and SSRIs, may increase plasma exposures of TCAs. TCAs can potentiate the actions of sympathomimetic amines and should not be used concurrently with MAOIs or within 14 days of stopping MAOIs. A *number of other drugs have similar side effect profiles as TCAs, and concurrent use risks enhanced side effects* (see previous discussion in Adverse Effects); this includes phenothiazine antipsychotic agents, type 1C antiarrhythmic agents, and other drugs with antimuscarinic, antihistaminic, and α adrenergic antagonistic effects.

Monoamine Oxidase Inhibitors

Serotonin syndrome is the most serious drug interaction for the MAOIs (see Adverse Effects). The most common cause of serotonin syndrome in patients taking MAOIs is the accidental coadministration of a 5HT reuptake-inhibiting antidepressant or *tryptophan*. Other serious drug interactions include those with *meperidine* and *tramadol*. MAOIs also interact with sympathomimetics such as *pseudoephedrine*, *phenylephrine*, *oxymetazoline*, *phenylpropanolamine*, and *amphetamine*; these are commonly found in cold and allergy medications and diet aids and should be avoided by patients taking MAOIs. Likewise, patients on MAOIs must avoid foods containing high levels of tyramine: soy products, dried meats and sausages, dried fruits, home-brewed and tap beers, red wine, pickled or fermented foods, and aged cheeses.

Esketamine

No clinically significant pharmacokinetic drug interactions have been reported for *esketamine*. Some reduction in plasma concentrations occurs with coadministration of *rifampin* (Perez Ruixo et al., 2021). *Esketamine* is primarily metabolized via CYPs 2B6 and 3A4 with minor contributions from CYPs 2C19 and 2C9 (FDA, 2019).

Brexanolone

No pharmacokinetic drug interactions have been reported to date for *brexanolone*. *Brexanolone* is primarily metabolized via aldo-keto reduction (AKR), glucuronidation, and sulfation (FDA, 2018).

Anxiolytic Drugs

Primary treatments for anxiety-related disorders include the SSRIs, SNRIs, benzodiazepines, *buspirone*, and β adrenergic antagonists (Atack, 2003). The SSRIs and the SNRI *venlafaxine* are well tolerated with a reasonable side effect profile; in addition to their documented antidepressant activity, they have anxiolytic activity with chronic treatment. The benzodiazepines are effective anxiolytics as both acute and chronic treatment. There is concern regarding their use because of their potential for dependence and abuse as well as negative effects on cognition and memory. *Buspirone*, like the SSRIs, is effective following chronic treatment. It acts, at least in part, via the serotonergic system, where it is a partial agonist at $5HT_{1A}$ receptors. *Buspirone* also has antagonistic effects at DA D_2 receptors, but the relationship between this effect and its clinical actions is uncertain. β Adrenergic antagonists, particularly those with higher lipophilicity (e.g., *propranolol* and *nadolol*), are occasionally used for performance anxiety such as fear of public speaking; their use is limited due to significant side effects, such as hypotension.

Antihistamines and sedative-hypnotic agents have been tried as anxiolytics but are generally not recommended because of their side effect profiles and the availability of superior drugs. *Hydroxyzine*, which produces short-term sedation, is used in patients who cannot use other types of anxiolytics (e.g., those with a history of drug or alcohol abuse where benzodiazepines would be avoided). *Chloral hydrate* has been used for situational anxiety, but there is a narrow dose range where anxiolytic effects

are observed in the absence of significant sedation; therefore, the use of *chloral hydrate* is not recommended.

Clinical Considerations With Anxiolytic Drugs

The choice of pharmacological treatment of anxiety is dictated by the specific anxiety-related disorders and the clinical need for acute anxiolytic effects (Millan, 2003). Among the commonly used anxiolytics, only the benzodiazepines and β adrenergic antagonists are effective acutely; the use of β adrenergic antagonists is generally limited to treatment of situational anxiety. While SSRIs, SNRIs, and *buspirone* are the first-line medications for anxiety, chronic treatment is required to produce and sustain anxiolytic effects; these agents are not effective acutely. When an immediate anxiolytic effect is clinically indicated, benzodiazepines are typically selected.

Benzodiazepines, such as *alprazolam*, *chlordiazepoxide*, *clonazepam*, *clorazepate*, *diazepam*, *lorazepam*, and *oxazepam*, are effective in the treatment of generalized anxiety disorder, panic disorder, and situational anxiety. In addition to their anxiolytic effects, benzodiazepines produce sedative, hypnotic, anesthetic, anticonvulsant, and muscle relaxant effects. The benzodiazepines also impair cognitive performance and memory, adversely affect motor control, and potentiate the effects of other sedatives, including alcohol and opioids. The anxiolytic effects of this class of drugs are mediated by allosteric interactions with the pentameric benzodiazepine-$GABA_A$ receptor complex, in particular $GABA_A$ receptors comprising α2, α3, and α5 subunits (see Chapters 16 and 22). The primary effect of the anxiolytic benzodiazepines is to enhance the inhibitory effects of the neurotransmitter GABA.

One area of concern regarding the use of benzodiazepines in the treatment of anxiety is the potential for habituation, dependence, and abuse. Patients with certain personality disorders or a history of drug or alcohol abuse are particularly susceptible. In the context of the opioid abuse crisis, the rates of accidental overdose and death secondary to combining benzodiazepines and opioids have increased substantially, even in patients not previously identified as being at high risk of drug abuse (Dowell et al., 2016; Sun et al., 2017). While benzodiazepines are effective in both short- and long-term treatment of patients with sustained or recurring bouts of anxiety, caution is advised in initiating benzodiazepine treatment, with a focus on minimizing dose and co-initiation of long-term treatment with first-line medications, such as SSRIs or SNRIs, and/or psychotherapy. Further, premature discontinuation of benzodiazepines, in the absence of other pharmacological treatment, results in a high rate of relapse. Withdrawal of benzodiazepines after chronic treatment, particularly with benzodiazepines with short durations of action, can cause increased anxiety and seizures. For this reason, it is important that discontinuation be carried out in a gradual manner.

Benzodiazepines cause many adverse effects, including sedation, mild memory impairments, decreased alertness, and slowed reaction time (which may lead to accidents). Memory problems can include visual-spatial deficits but will manifest clinically in a variety of ways, including difficulty in word finding. Occasionally, paradoxical reactions can occur with benzodiazepines, such as increases in anxiety, sometimes reaching panic attack proportions. Other pathological reactions can include irritability, aggression, or behavioral disinhibition. Amnesic reactions (i.e., loss of memory for particular periods) can also occur. Benzodiazepines should not be used in pregnant women; there have been rare reports of fetal craniofacial defects. In addition, benzodiazepines taken prior to delivery may result in sedated, underresponsive newborns and prolonged withdrawal reactions. In the elderly, benzodiazepines increase the risk for falls and must be used cautiously. These drugs are safer than classical sedative-hypnotics in overdosage and typically are fatal only if combined with other CNS depressants.

Benzodiazepines have abuse potential, although their capacity for abuse is considerably below that of other classical sedative-hypnotic agents such as barbiturates. When these agents are abused, it is generally in a multidrug abuse pattern, frequently connected with failed attempts to control anxiety. Tolerance to the anxiolytic effects develops with chronic administration, with the result that some patients escalate the dose of benzodiazepines over time, contributing to increased adverse effects and morbidity. Ideally, benzodiazepines should be used for short periods of time and in conjunction with other medications (e.g., SSRIs) or evidence-based psychotherapies (e.g., cognitive behavioral therapy for anxiety disorders).

The SSRIs and the SNRI *venlafaxine* are first-line treatments for most types of anxiety disorders, except when an acute drug effect is desired; *fluvoxamine* is approved only for obsessive-compulsive disorder. As for their antidepressant actions, the anxiolytic effects of these drugs become manifest following chronic treatment. Other drugs with actions on serotonergic neurotransmission, including *trazodone*, *nefazodone*, and *mirtazapine*, also are used in the treatment of anxiety disorders. Details regarding the pharmacology of these classes were presented previously in this chapter.

Both SSRIs and SNRIs are beneficial in specific anxiety conditions, such as generalized anxiety disorder, social phobias, obsessive-compulsive disorder, and panic disorder. These effects appear to be related to the capacity of serotonin to regulate the activity of brain structures such as the amygdala and locus coeruleus that are thought to be involved in the genesis of anxiety. Interestingly, the SSRIs and SNRIs often will produce some increases in anxiety in the short term; these dissipate with time. Therefore, the maxim "start low and go slow" is indicated with anxious patients; however, many patients with anxiety disorders ultimately will require doses that are about the same as those required for the treatment of depression, and sometimes higher, especially in the treatment of obsessive-compulsive disorder. Anxious patients appear to be particularly prone to severe discontinuation reactions with certain medications such as *venlafaxine* and *paroxetine*; therefore, slow off-tapering is required.

Buspirone is used in the treatment of generalized anxiety disorder (Goodman, 2004). Like the SSRIs, *buspirone* requires chronic treatment for effectiveness. Also, like the SSRIs, *buspirone* lacks many of the other pharmacological effects of the benzodiazepines: It is not an anticonvulsant, muscle relaxant, or sedative, and it does not impair psychomotor performance or result in dependence. *Buspirone* is primarily effective in the treatment of generalized anxiety disorder, but not for other anxiety disorders. In fact, patients with panic disorder often note an increase in anxiety acutely following initiation of *buspirone* treatment; this may be the result of the fact that *buspirone* causes increased firing rates of the locus coeruleus, which is thought to underlie part of the pathophysiology of panic disorder.

Drug Facts for Your Personal Formulary: *Depression and Anxiety Disorders*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Selective Serotonin Reuptake Inhibitors		
Citalopram Escitalopram Fluoxetine Fluvoxamine Paroxetine Sertraline Vilazodone	• Anxiety and depression disorders • Obsessive-compulsive disorder, PTSD • SERT selective; little effect on NET • Vilazodone also acts as $5HT_{1A}$ partial agonist	• Risks of bleeding, mania/hypomania, seizures • May increase risk of suicidal thoughts or behavior • Serotonin syndrome with MAOIs • Numerous drug-drug interactions mediated by CYPs • May cause sexual dysfunctions, weight gain (less with vilazodone) • GI disturbances
Serotonin-Norepinephrine Reuptake Inhibitors		
Venlafaxine Desvenlafaxine Duloxetine Milnacipran Levomilnacipran	• Anxiety and depression, ADHD, autism, fibromyalgia, PTSD, menopause symptoms • Inhibitors of SERT and NET	• Side effects include nausea and dizziness • May increase risk of suicidal thoughts or behavior • Risk of bleeding, hyponatremia, sexual dysfunction • Duloxetine and milnacipran contraindicated in uncontrolled narrow-angle or angle-closure glaucoma
Tricyclic Antidepressants		
Amitriptyline Clomipramine Doxepin Imipramine Trimipramine Nortriptyline Maprotiline Protriptyline Desipramine Amoxapine	• Block SERT, NET, α_1, H_1, and M_1 receptors • Major depression	• Generally replaced by newer antidepressants with fewer side effects • Numerous side effects: orthostatic hypertension, weight gain, GI disturbances, sexual dysfunction, seizures, irregular heart beats • Should not be used within 14 days of taking MAOIs, linezolid, or methylene blue • May increase suicidal thoughts or behavior
Atypical Antipsychotics		
Aripiprazole Brexpiprazole Lurasidone Olanzapine Quetiapine Risperidone	• Treatment-resistant major depression and depression with psychotic features • Schizophrenia • Bipolar depression	• See Chapter 19 for details • Metabolic syndrome and weight gain
Monoamine Oxidase Inhibitors		
Isocarboxazid Phenelzine Selegiline Tranylcypromine	• Inhibit MAO_A and MAO_B to prevent NE, DA, and 5HT breakdown • Major depression disorders resistant to other antidepressants	• Many side effects, including weight gain and sexual dysfunction; replaced by newer antidepressants • May increase suicidal thoughts or behavior • Slow elimination • May cause hypertensive crisis if taken with tyramine-containing foods/beverages • At lower doses, selective for MAO_B (serotonergic neurons) • A transdermal patch is approved for treatment of depression
Atypical Antidepressants		
Bupropion (DAT inhibitor) Trazodone ($5HT_2$ antagonist) Nefazodone ($5HT_2$ antagonist) Mirtazapine ($5HT_2$ antagonist) Mianserin (not marketed in the U.S.) Vortioxetine (SERT inhibitor, $5HT_{1A}$ agonist, and $5HT_3$ antagonist)	• Depression • Smoking cessation (bupropion) • Insomnia (low-dose trazodone)	• Risk of adverse cerebrovascular events in elderly with dementia • Bupropion, no weight gain effect • Mirtazapine, trazodone, and nefazodone may cause drowsiness; take at bedtime • Risk of hepatic failure with nefazodone • May increase suicidal thoughts or behavior • Do not use within 14 days of taking MAOI
Esketamine	• Treatment-resistant depression	• Administered as a nasal spray under a Risk Evaluation and Mitigation Strategy
Brexanolone	• Postpartum depression	• Administered as an intravenous infusion over 2.5 days under a Risk Evaluation and Mitigation Strategy • Avoid in patients with end-stage renal disease

Chapter 19

Pharmacotherapy of Psychosis and Mania

Jonathan M. Meyer

Treatment of Psychosis

Psychosis is a symptom of numerous psychiatric illnesses, characterized by a distorted or nonexistent sense of reality or by disorganized behavior or speech. Psychotic disorders have different etiologies, each of which demands a unique treatment approach. Common psychotic disorders include mood disorders (major depression or mania) with psychotic features, substance-induced psychosis, dementia with psychotic features, delirium with psychotic features, brief psychotic disorder, delusional disorder, schizoaffective disorders, and schizophrenia.

The worldwide schizophrenia point prevalence has remained relatively constant, with the global estimate of 0.28% remaining unchanged from 1990 to 2016; however, the number of individuals suffering from schizophrenia rose nearly 60% due to population increases (Charlson et al., 2018). Older sources cite schizophrenia prevalence rates of 1%, but a 2018 analysis of 101 studies noted that higher study quality was associated with a lower estimated prevalence of psychotic disorders ($P < .001$) (Moreno-Kustner et al., 2018). Schizophrenia is considered the prototypic disorder for understanding chronic psychosis, but patients with schizophrenia exhibit features not seen in other psychotic illnesses. The positive symptoms of psychosis include hallucinations, delusions, disorganized speech, and disorganized or agitated behavior. These positive psychotic symptoms are found individually, and occasionally together, in all psychotic disorders and are typically responsive to pharmacotherapy. Schizophrenia patients also suffer from negative symptoms (apathy, avolition, diminished expression, reduced social drive) and cognitive deficits.

Neurotransmitter Bases for Psychosis

Dysfunction in cholinergic, glutamatergic, serotonergic, GABA-ergic, and dopaminergic systems is implicated in psychosis (McCutcheon et al., 2019). That excessive dopamine (DA) neurotransmission is linked to positive psychosis symptoms has been known for over 60 years since Carlsson deduced that postsynaptic DA receptor antagonism was the common mechanism for *haloperidol* and *chlorpromazine*'s therapeutic effects and for their ability to induce parkinsonism. This insight informed the development of antipsychotics that act at D_2 receptors including first-generation antipsychotics (FGAs) and second-generation antipsychotics (SGAs) that possess D_2 antagonism and newer agents with D_2 partial agonism (McCutcheon et al., 2019). DA dysfunction is no longer considered a hypothesis but an established fact now that imaging can demonstrate a direct correlation between positive psychotic symptoms and excessive D_2-mediated DA activity in the associative striatum and adjacent sensorimotor striatum of schizophrenia patients, and the association between antipsychotic exposure, reduced postsynaptic DA activity in these regions, and improved positive psychosis symptoms (McCutcheon et al., 2019).

Involvement of other neurotransmitters is based on the psychotomimetic effects of *N*-methyl-D-aspartate (NMDA) glutamate receptor antagonists (e.g., *phencyclidine*, *ketamine*), serotonin $5HT_{2a}$ agonists (e.g., LSD [*lysergic acid diethylamide*]), and muscarinic anticholinergic agents. Combining the understanding of LSD's mechanism with the finding that Parkinson's disease psychosis (PDP) is associated with upregulation of cortical $5HT_{2A}$ receptors led to the approval of *pimavanserin*, a potent $5HT_{2a}$ inverse agonist with no DA binding, for treatment of PDP (Cummings et al., 2014). Recognition that muscarinic M_4 knockout mice exhibit the phenotype of psychosis spurred ongoing trials of the M_4 and M_1 agonist *xanomeline* for schizophrenia, with a positive phase II study published in 2021 (Brannan et al., 2021). Phase III trials of glutamate modulators (e.g., glycine reuptake inhibitors, metabotropic receptor agonists) have not been successful to date, but the importance of glutamatergic pathways means that these circuits will remain a focus of antipsychotic drug development (Figure 19–1).

Mechanisms of Action at D_2 Receptors

All DA receptors are G protein-coupled receptors (GPCRs), and D_2 receptors share common properties with D_3 and D_4 receptors in that each is linked to an inhibitory G protein G_i. D_2 receptor stimulation results in decreased cyclic AMP production and reduction in intracellular cyclic AMP (see Figure 19–1), whereas agonists at D_1 and D_5 receptors stimulate the G_s–adenylyl cyclase–cyclic AMP pathway. Antipsychotic actions at D_2 receptors are also mediated through a non-G protein pathway, particularly via modulation of glycogen synthase kinase-3β (GSK-3β) activity through the β-arrestin-2/PKB/PP2A signaling complex (see Chapter 3). SGAs antagonize D_2 receptor/β-arrestin-2 interactions more than GPCR-dependent signaling, but FGAs inhibit both pathways with similar efficacy (Urs et al., 2016). While antipsychotics reverse cognitive disruption induced by NMDA antagonists (e.g., MK-801), they are not effective at improving the cognitive dysfunction of schizophrenia thought to be associated with deficient D_1-mediated cortical signaling. However, experimental β-arrestin-2 biased D_2 partial agonists with limited GPCR effects exhibit a distinctly different profile as they are capable of the striatal D_2 antagonism needed for antipsychotic effects, but also possess cortical agonism as seen by enhanced firing of fast-spiking interneurons (Urs et al., 2016).

Abbreviations

ACEI: angiotensin-converting enzyme inhibitor
ARB: angiotensin receptor blocker
COX-2: cyclooxygenase 2
CV: cardiovascular
DA: dopamine
DRP: dementia-related psychosis
ECG: electrocardiogram
ECT: electroconvulsive therapy
eGFR: estimated glomerular filtration rate
ENaC: epithelial Na^+ channel
EPS: extrapyramidal symptom
FGA: first-generation antipsychotic
GFR: glomerular filtration rate
GI: gastrointestinal
GPCR: G protein-coupled receptor
GSK: glycogen synthase kinase
5HT: serotonin
I_{kr}: inwardly rectifying K^+ channels
LAI: long-acting injectable
Li^+: lithium
LSD: lysergic acid diethylamide
MCM: major congenital malformations
NDI: nephrogenic diabetes insipidus
NMDA: *N*-methyl-D-aspartate
NMS: neuroleptic malignant syndrome
ODT: oral dissolving tablet
PDP: Parkinson's disease psychosis
Pgp: P-glycoprotein
PI: phosphatidylinositol
PK_: protein kinase _, as in PKA, PKB, PKC
PP2A: protein phosphatase 2A
SCD: sudden cardiac death
SGA: second-generation antipsychotic
TAAR1: trace amine-associated receptor 1
TD: tardive dyskinesia
TSH: thyrotropin (thyroid-stimulating hormone)
VMAT2: vesicular monoamine transporter 2
VPA: valproic acid

Review of Relevant Pathophysiology

Not all psychosis is schizophrenia, and the pathophysiology relevant to effective schizophrenia treatment may not apply to other psychotic disorders as evidenced by the efficacy of *pimavanserin*, a $5HT_{2A}$ inverse agonist devoid of any DA receptor binding used to treat PDP. The effectiveness of DA D_2 modulators for the positive symptoms of psychosis suggests a common etiology related to excessive dopaminergic neurotransmission in striatal DA pathways. Prior studies ascribed the presence of positive psychotic symptoms to increased DA activity in mesolimbic pathways terminating in the ventral striatum, but this view has been revised. Improved imaging techniques indicate that the DA dysfunction associated with positive psychosis symptoms in schizophrenia patients is localized to the associative striatum and adjacent sensorimotor striatum (McCutcheon et al., 2019).

Delirium, Dementia, and Parkinson's Disease Psychosis

The psychoses related to delirium and dementia, particularly dementia of the Alzheimer type, may have cholinergic and noncholinergic etiologies: deficiency in muscarinic cholinergic neurotransmission due to medications, age- or disease-related neuronal loss (delirium and dementia), and excessive activity at cortical $5HT_{2a}$ receptors (dementia). Delirium can have numerous precipitants, including medication, infection, electrolyte imbalance, inflammation, or metabolic derangement, all of which require specific treatment in addition to removing offending anticholinergic and sedating medications. While PDP is related to Lewy body–associated loss of serotonin raphe neurons and subsequent upregulation of cortical postsynaptic $5HT_{2a}$ receptors, there is evidence for this process in other dementia syndromes. *Pimavanserin* is now approved for PDP and has one positive phase II study for dementia-related psychosis (DRP) in Alzheimer's disease patients (Ballard et al., 2018).

Schizophrenia

Schizophrenia is a neurodevelopmental disorder with complex genetics and incompletely understood pathophysiology. In addition to environmental exposures such as maternal infections (e.g., *Toxoplasma gondii*), fetal second-trimester infectious or nutritional insults, birth complications, and substance abuse in the late teen or early adult years, over 150 genes appear to contribute to schizophrenia risk. Implicated are genes that regulate neuronal migration, synaptogenesis, cellular adhesion, neurite outgrowth, synaptic DA availability, and glutamate, nicotinic, and DA neurotransmission. The impact of common single nucleotide polymorphisms can be quantified in a polygenic risk score that sums the genetic burden and its impact on schizophrenia risk and disease phenotype. Patients with schizophrenia also have increased rates of genome-wide DNA microduplications, termed *copy number variants* (Bergen et al., 2019) and *epigenetic changes*, including disruptions in DNA methylation patterns in various brain regions (Chen et al., 2020). This genetic variability is consistent with the heterogeneity of the clinical disease and suggests that multiple mechanisms account for disease risk and its manifestations.

Review of Psychosis Pathology and the General Goals of Pharmacotherapy

Common to all psychotic disorders are positive symptoms, which may include hallucinations, delusions, and behavioral dysfunction. All approved schizophrenia treatments to date have a direct impact on D_2-mediated DA neurotransmission, but research into muscarinic M_4 agonists (Brannan et al., 2021) and newly discovered trace amine-associated receptor 1 (TAAR1) agonists may drastically alter the established dogma that direct D_2 binding is necessary for an effective schizophrenia medication (Koblan et al., 2020) (see Figure 19–1).

Short-Term Antipsychotic Treatment

For some psychotic disorders the symptoms are transient, and antipsychotic drugs are only administered during and shortly after periods of symptom exacerbation. Patients with psychosis due to delirium, dementia, major depressive disorder, mania, substance-induced psychoses, and brief psychotic disorder will typically receive short-term antipsychotic treatment that is discontinued after resolution of psychotic symptoms, although the duration may vary considerably based on the etiology. Bipolar I disorder patients in particular may have antipsychotic treatment extended after resolution of mania and psychotic symptoms, as those on combined mood stabilizer and antipsychotic therapy have lower rates of manic relapse; moreover, several antipsychotics (*cariprazine, lumateperone, lurasidone, quetiapine*) are approved for bipolar I depression, and ongoing use may be dictated by treatment of that mood state (Wingård et al., 2019). Chronic psychotic symptoms in patients with dementia may also be amenable to longer term drug therapy, but potential benefits must be balanced by increased mortality risk associated with antipsychotics in this patient population (Maust et al., 2015).

Long-Term Antipsychotic Treatment

Delusional disorder, schizophrenia, and schizoaffective disorders are chronic diseases that require long-term antipsychotic treatment. For DRP and PDP, ongoing assessment of antipsychotic treatment appears reasonable given the paucity of long-term data, bearing in mind that the underlying disease processes are progressive and the prospect of remission remote. For schizophrenia and the schizoaffective disorders, the goal of antipsychotic treatment is to maximize functional recovery by decreasing the severity of positive symptoms and their behavioral influence and possibly improving negative symptoms and remediating cognitive

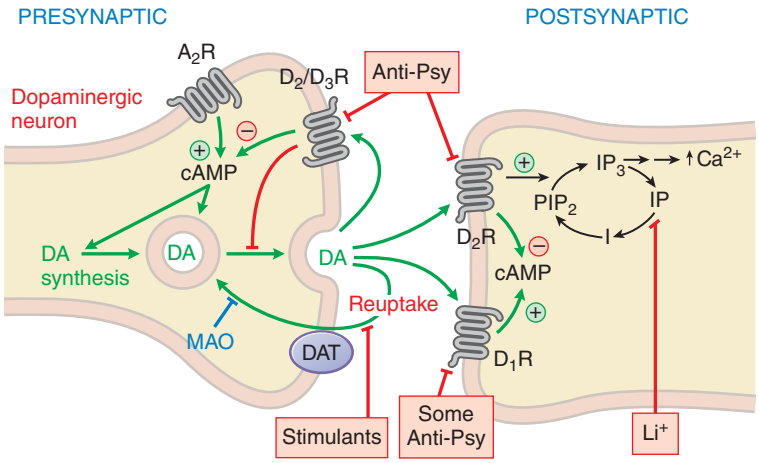

Figure 19–1 *Sites of action of antipsychotic agents and Li⁺.* Following exocytotic release, DA interacts with postsynaptic receptors (R) of D_1 and D_2 types and presynaptic D_2 and D_3 autoreceptors. Termination of DA action occurs primarily by active transport of DA into presynaptic terminals via the DA transporter (DAT), with secondary deamination by mitochondrial monoamine oxidase (MAO). Stimulation of postsynaptic D_1 receptors activates the G_s–adenylyl cyclase–cAMP pathway. D_2 receptors couple through G_i to inhibit adenylyl cyclase and through G_q to activate the PLC-IP_3-Ca^{2+} pathway. Activation of the G_i pathway can also activate K^+ channels, leading to hyperpolarization. Li^+ inhibits breakdown of inositol phosphates (IP) and thereby enhances IP accumulation and sequelae (Ca^{2+} mobilization, PKC activation, depletion of cellular I). Li^+ may also alter release of neurotransmitter by a variety of putative mechanisms (see text). D_2-like autoreceptors suppress synthesis of DA by diminishing phosphorylation of rate-limiting tyrosine hydroxylase (TH), and by limiting DA release. In contrast, presynaptic α_2 receptors activate the adenylyl cyclase–cAMP–PKA pathway and thence TH activity. All antipsychotic agents act at D_2 receptors and autoreceptors; some also block D_1 receptors (Table 19–2). Stimulant agents inhibit DA reuptake by DAT, thereby prolonging the dwell time of synaptic DA. Initially in antipsychotic treatment, DA neurons release more DA, but following repeated treatment, they enter a state of physiological depolarization inactivation, with diminished production and release of DA, in addition to continued receptor blockade. Symbols: ⊣, inhibition or blockade; ⊕, elevation of activity; ⊖, reduction of activity. Abbreviations: cAMP, cyclic AMP; IP_3, inositol 1,4,5-trisphosphate; PIP_2, phosphatidylinositol 4,5-bisphosphate.

dysfunction, although the impact on the last two symptom domains is modest at best with existing agents. Continuous antipsychotic treatment reduces 1-year relapse rates from 80% among unmedicated patients to 15%. Poor adherence to antipsychotic treatment increases relapse risk, and nonadherence is often related to adverse effects, cognitive dysfunction, substance use, and limited illness insight (Meyer and Stahl, 2021).

Regardless of the underlying pathology, the immediate goal of antipsychotic treatment is a decrease in acute symptoms that induce patient distress, particularly behavioral symptoms (e.g., hostility, agitation) that may present a danger to the patient or others. The dosing, route of administration, and choice of antipsychotic depend on the underlying disease state, clinical acuity, drug-drug interactions with concomitant medications, and patient sensitivity to short- or long-term adverse effects. With the exception of *pimavanserin* for PDP and *clozapine*'s superior efficacy for treatment-resistant schizophrenia or for schizophrenia patients with suicidality, psychogenic polydipsia, or persistent impulsive aggression (Meyer and Stahl, 2019), neither the clinical presentation nor biomarkers predict the likelihood of response to a specific antipsychotic class or agent. As a result, avoidance of adverse effects based on patient and drug characteristics and exploitation of certain medication properties (e.g., the availability of a long-acting injectable [LAI] preparation) are the principal determinants for choosing initial antipsychotic therapy.

Short-Term Antipsychotic Treatment

Delirium, Dementia, and Parkinson's Disease Psychosis

Psychotic symptoms of delirium or dementia are generally treated with low medication doses, although doses in delirium patients may have to be repeated at frequent intervals initially to achieve adequate behavioral control. Despite widespread clinical use, no antipsychotic has yet received approval for DRP. As of 2021, all antipsychotic drugs carry warnings on increased mortality in elderly dementia patients, although *pimavanserin* has a modified warning since the psychosis of PDP can exist with cognitive impairment. *Pimavanserin* for PDP has a $t_{1/2}$ of 57 h, and clinical effects are seen over 2 to 6 weeks. (See Use in Pediatric Populations and Use in Geriatric Populations, below.) Because central nervous system (CNS) anticholinergic effects may worsen delirium, high-potency FGAs (e.g., *haloperidol*) or SGAs with limited antimuscarinic properties (e.g., *risperidone*) are often the drugs of choice for agitated delirium (Meyer et al., 2016). There are no data to support antipsychotic use in hypoactive delirium. The only role for antipsychotics is short-term management of psychosis and related behavioral symptoms; antipsychotics do not address the underlying pathophysiology of delirium nor shorten recovery (Girard et al., 2018). DRP patients may require extended treatment, so avoidance of extrapyramidal symptoms (EPSs) is paramount due to the fall risk. For this reason, FGAs are avoided due to their potent D_2 receptor blockade in lieu of SGAs given in modest dosages, especially agents with limited anticholinergic properties. Antipsychotic doses for patients with dementia are one-fourth of adult schizophrenia doses (e.g., *risperidone* 0.5–1.5 mg/day), as EPSs, orthostasis, and sedation are particularly problematic in this patient population (see Chapter 21).

Mania

All SGA medications with the exception of *brexpiprazole*, *clozapine*, *iloperidone*, *lumateperone*, and *lurasidone* have indications for acute mania, and doses are titrated rapidly toward the maximum FDA-approved dose over the first 24 to 72 h of treatment. FGAs are also effective in acute mania but may be eschewed due to the risk for EPSs. Clinical response (decreased psychomotor agitation and irritability, increased sleep, and reduced or absent delusions and hallucinations) usually occurs within 7 days but may be apparent as early as day 2. Patients with mania may need to continue on antipsychotic treatment for many months after the resolution of psychotic and manic symptoms, typically in combination with a mood stabilizer such as *lithium* (Li^+) or *valproic acid* (VPA) preparations (e.g., *divalproex*) (Wingård et al., 2019). Oral *aripiprazole* and *olanzapine* have indications as monotherapy for bipolar disorder maintenance treatment, but the use of *olanzapine* has decreased dramatically due to concerns over adverse metabolic effects (e.g., weight gain, hyperlipidemia, hyperglycemia). LAI *risperidone* also has indications for maintenance monotherapy and adjunctively with Li^+ or VPA in patients with bipolar I disorder, but population-based cohort data indicate that patients on any antipsychotic monotherapy have higher relapse rates than those on Li^+ or VPA monotherapy or on antipsychotic/mood

stabilizer combinations (Wingård et al., 2019). While combining an antipsychotic with a mood stabilizer improves control of mood symptoms and reduces relapse risk, weight gain from the additive effects of both agents is a significant clinical problem. Antipsychotic agents with greater weight-gain liabilities (e.g., *quetiapine*, *olanzapine*, *clozapine*) should be avoided unless patients are unresponsive to preferred treatments.

The recommended duration of treatment after resolution of bipolar mania varies considerably, but as symptoms permit, a gradual drug taper should be attempted after 6 months of treatment to lessen weight gain when combined with a mood stabilizer. This must be balanced by the accruing data on the benefits of combination therapy and the need for antipsychotics that specifically treat the depressive pole of the illness (e.g., *cariprazine*, *lumateperone*, *lurasidone*, *quetiapine*).

Major Depression

Management of major depressive disorder with psychotic features requires lower-than-average doses of antipsychotics, and these must be given in combination with an antidepressant to treat the underlying mood disorder. Extended antipsychotic treatment is not usually required, but certain SGAs provide adjunctive antidepressant benefit. Most antipsychotics show limited antidepressant benefit when used as monotherapy with the exception of *amisulpride*, *cariprazine*, *lumateperone*, *lurasidone*, and *quetiapine*. Some SGAs are effective as adjunct therapy in unipolar major depression (e.g., *aripiprazole*, *brexpiprazole*, *quetiapine*) and might be preferentially used for unipolar depression with psychotic features. The postulated antidepressant mechanisms include $5HT_7$ antagonism (*amisulpride*, *lurasidone*), $5HT_{2c}$ antagonism (*olanzapine*, and *quetiapine*'s metabolite, *norquetiapine*), DA D_3 partial agonism (*aripiprazole*, *brexpiprazole*, *cariprazine*), or a combination of $5HT_{2A}$ antagonism and D_1 activation (*lumateperone*). Potent D_3 antagonists are hypothesized to block autoreceptors on the cell body of mesocortical DA neurons, resulting in increased prefrontal D_1-mediated activity at glutamatergic pathways.

Schizophrenia

The immediate goals of acute antipsychotic treatment are the reduction of agitated, disorganized, or hostile behavior; decreased impact of hallucinations; improvement in the organization of thought; and the reduction of social withdrawal. Doses used acutely may be higher than those required for maintenance treatment of stable patients, but not always. In acute psychosis, significant antipsychotic benefits are usually seen within 60 to 120 min after drug administration. Delirious or demented patients may be reluctant or unable to swallow tablets, but oral dissolving tablet (ODT) preparations or liquid concentrate forms are available. Intramuscular administration of *ziprasidone* or *olanzapine* represents an option for treating agitated and minimally cooperative patients and presents less risk for drug-induced dystonia than does *haloperidol*. An inhaled form of *loxapine* 10 mg is available in the U.S. with a median t_{max} of less than 2 min. Following rapid distribution, levels drop 75% over the next 10 min and then follow typical kinetics with a $t_{1/2}$ of 7.6 h. Inhaled *loxapine* was approved for agitation associated with schizophrenia or bipolar I disorder, so use outside of those conditions is off-label. It can also only be administered in healthcare facilities that can provide advanced airway management in the rare event of acute bronchospasm.

Aside from *clozapine*, which is uniquely efficacious in treatment resistant schizophrenia, SGAs are not more effective than FGAs, but they do offer a more favorable neurological side effect profile (Huhn et al., 2019). Excessive D_2 blockade, as is often the case with use of high-potency FGAs (e.g., *haloperidol*), not only increases risk for short-term neurological adverse effects (e.g., muscular rigidity, bradykinesia, tremor, dystonia, akathisia) but also slows mentation (bradyphrenia) and interferes with central reward pathways, resulting in patient complaints of anhedonia (loss of capacity to experience pleasure) or even dysphoria with symptomatic worsening (Meyer and Stahl, 2021). Low-potency FGAs such as *chlorpromazine* are not commonly used due to the high affinities for H_1, M_1, and α_1 adrenergic receptors that result in undesirable effects (sedation, anticholinergic properties, orthostasis). Concerns regarding QT_c prolongation further limit their clinical usefulness. In agitated acutely psychotic patients, sedation may be desirable, but the use of a sedating antipsychotic drug may interfere with cognitive function and assessment.

Because schizophrenia requires long-term treatment, antipsychotics with greater metabolic liabilities, especially weight gain (discussed further in this chapter), should be avoided as first-line therapies. High-potency FGAs (e.g., *haloperidol*, *fluphenazine*, *perphenazine*) have low risk for metabolic adverse effects, and this is one reason why these agents are still used (Huhn et al., 2019). Among the SGAs, *ziprasidone*, *aripiprazole*, *iloperidone*, *brexpiprazole*, *cariprazine*, *lumateperone*, and *lurasidone* are the most metabolically benign. Patients with schizophrenia have a 2-fold higher prevalence of metabolic syndrome and type 2 diabetes mellitus and have 2-fold greater cardiovascular (CV)-related mortality rates than the general population. Consensus guidelines therefore recommend baseline determination of serum glucose, lipids, weight, blood pressure, and personal and family histories of metabolic and CV disease (American Psychiatric Association, 2021).

With the lower EPS risk experienced during therapy with SGAs, or even when FGAs are used in modest dosages, prophylactic use of antiparkinsonian medications (e.g., *benztropine*, *trihexyphenidyl*) must be avoided, especially given the cognitive impairment that results. Nonetheless, drug-induced parkinsonism can occur at higher dosages or among elderly patients exposed to antipsychotics with higher D_2 affinity; recommended doses in older patients are often 50% of those used in younger patients with schizophrenia. (See also Use in Pediatric Populations and Use in Geriatric Populations further in the chapter.) If an antiparkinsonian medication must be used, *amantadine* is preferable to anticholinergics (Silver and Geraisy, 1995).

Long-Term Treatment

The need for long-term treatment is the foundation for chronic psychotic illnesses such as schizophrenia and schizoaffective disorder. However, long-term antipsychotic treatment is sometimes used for bipolar I disorder patients, for ongoing psychosis in patients with DRP, for PDP, and for adjunctive use in treatment-resistant depression. Safety concerns combined with limited long-term efficacy data have dampened enthusiasm for extended antipsychotic drug use in patients with dementia (Maust et al., 2015). Justification for ongoing use, based on documentation of patient response to tapering of antipsychotic medication, is often mandated in long-term care settings.

Antipsychotic Agents

The choice of antipsychotic for long-term schizophrenia treatment is based primarily on avoidance of adverse effects, prior history of patient response, and the need for a LAI formulation due to oral nonadherence. While concerns over EPSs and tardive dyskinesia (TD) decreased with the introduction of SGAs, the estimated risk for TD with chronic SGA use is still 7.2% among those with no prior FGA exposure (Carbon et al., 2017). Since the advent of SGAs, there has been increased concern over metabolic effects of treatment: weight gain, dyslipidemia (particularly hypertriglyceridemia), and an adverse impact on glucose-insulin homeostasis (Huhn et al., 2019). *Clozapine*, *olanzapine*, and higher dose *quetiapine* have the highest metabolic risk and are not considered first-line agents. For treatment-resistant schizophrenia, response rates for most antipsychotics are less than 5%, but for *olanzapine*, the rate is 7% to 9% (Meyer and Stahl, 2019). While the *clozapine* response rate for treatment-resistant schizophrenia is 40% to 60%, *olanzapine* is sometimes used prior to *clozapine* after failure of more metabolically benign agents, since response to *olanzapine* lessens the monitoring burden and risk for certain unusual adverse effects associated with *clozapine* use.

Acutely psychotic patients usually exhibit some response within hours after drug administration, and extensive analyses of symptom response in clinical trials indicate that the majority of response to any antipsychotic dose in acute schizophrenia is seen by week 2. Failure of response after 2 weeks should prompt clinical reassessment, including determination of medication adherence and, ideally, extent of drug exposure using plasma antipsychotic levels, before a decision is made to increase the dose or

consider switching to another agent (Meyer and Stahl, 2021). Patients with first-episode schizophrenia often respond to lower doses, and chronic patients may require doses that exceed recommended ranges, but the best proxy for CNS drug exposure is the peripheral plasma level. For many antipsychotics, there are sufficient data from fixed-dose trials and imaging studies to define plasma level response thresholds and an upper limit (the point of futility) beyond which response rates are less than 5% even if tolerated (Meyer and Stahl, 2021).

Usual dosages, plasma level response thresholds, and the point of futility are noted in Table 19–1. *While the dose in milligrams is what is ordered, issues with oral medication nonadherence, drug-drug interactions, and population variation in drug metabolism mean that plasma levels correlate significantly better with response than does the prescribed dose. Dosing should be adjusted based on clinically observable signs of antipsychotic benefit and adverse effects.* As noted above, less than minimal response after 2 weeks of a given dose portends a low likelihood of response at week 6. Obtaining a plasma level as a 12-h trough (for oral antipsychotics) or 1 to 72 h prior to the next LAI injection can be helpful in ruling out kinetic or adherence failures and determining whether the current level exceeds the response threshold (Meyer and Stahl, 2021). Having a level beyond the response threshold is no guarantee of response, as some patients may need higher levels, and certain patients may indeed be treatment resistant. Nonetheless, *antipsychotic titration in nonresponding schizophrenia patients should proceed until one of three hard endpoints is reached:*

1. The patient is markedly improved
2. The patient experiences dose-limiting adverse effects, or
3. The *point of futility* is reached

While intolerability is often a clinical endpoint signaling the end of an antipsychotic trial, a small proportion of patients may never exhibit dose-limiting adverse effects and will tolerate further antipsychotic titration, even with high-potency FGAs (see Table 19–1). Defining the upper limit of the response range as the *point of futility* encapsulates these important concepts: *intolerability may not limit the drug trial in some instances, but ongoing titration beyond a certain plasma level (the point of futility) is fruitless as less than 5% of patients will respond to these higher plasma levels* (Meyer and Stahl, 2021).

Certain antipsychotic adverse effects, including weight gain, sedation, orthostasis, and EPSs, can be predicted based on potencies at neurotransmitter receptors (Table 19–2). The detection of dyslipidemia or hyperglycemia is based on laboratory monitoring (see Table 19–1). Dose reduction often resolves EPSs, orthostasis, and sedation, but hyperprolactinemia and metabolic abnormalities may only improve with discontinuation of the offending agent and switching to a less offending medication. The decision to switch a medication for stable schizophrenia patients with either metabolic dysfunction or hyperprolactinemia must be individualized based on patient preferences, severity of the metabolic or endocrine disturbance, likelihood of improvement with antipsychotic switching, and history of response to prior agents. Patients with treatment-resistant schizophrenia on *clozapine* are not good candidates for switching because they are resistant to other medications (see the definition of treatment-resistant schizophrenia further in this section). Other strategies must be used to manage metabolic adverse effects as discussed below.

Psychotic Relapse

There are many reasons for psychotic relapse or inadequate response to antipsychotic treatment in patients with schizophrenia; these reasons include substance use, psychosocial stressors, and poor medication adherence. The common problem of medication nonadherence among patients with schizophrenia has led to the development of LAI antipsychotic medications, often referred to as depot antipsychotics (Meyer and Stahl, 2021). The kinetic properties and dosing of commonly used LAI formulations are summarized in Table 19–2. Patients receiving LAI antipsychotic medications show consistently lower relapse rates compared to patients receiving the identical oral forms and may have fewer adverse effects due to lower peak plasma levels (Kishimoto et al., 2021).

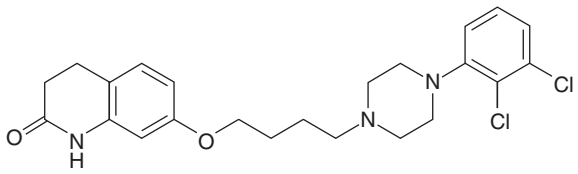
Treatment-Resistant Schizophrenia

Lack of response to adequate antipsychotic drug doses for adequate periods of time may indicate treatment-resistant illness. Use of antipsychotic plasma levels is critical to separate those who are nonadherent or are kinetic failures from those who are not responding to adequate medication exposure (Meyer and Stahl, 2021). In treatment-resistant schizophrenia, response rates are less than 5% for FGAs and less than 10% for *olanzapine*, but consistently 40% to 60% for *clozapine* (Meyer and Stahl, 2019). The therapeutic threshold for *clozapine* is 350 ng/mL, but patients may require levels as high as 1000 ng/mL for response (Meyer and Stahl, 2021). When ongoing titration finally achieves a therapeutic plasma concentration *for that patient*, response to *clozapine* occurs on average after 17 ± 14 days (Meyer and Stahl, 2019). *Clozapine* can have numerous adverse effects: risk of severe neutropenia (requires hematological monitoring), high metabolic burden, myocarditis, dose-dependent lowering of the seizure threshold, tachycardia, orthostasis, constipation and ileus, sedation, anticholinergic effects (especially constipation), and sialorrhea. Electroconvulsive therapy also has proven efficacy for treatment-resistant schizophrenia (Meyer and Stahl, 2019). Most clinicians recognize that treatment-resistant patients have virtually no viable option to *clozapine* and so become adept at monitoring for, and managing, these adverse effects.

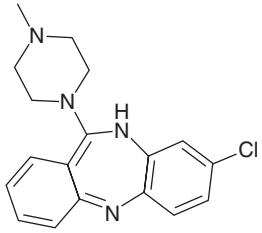
Pharmacology of Antipsychotic Agents

Chemistry

Antipsychotic agents include many different chemical structures with a range of activities at different neurotransmitter receptors. As a result, structure-function relationships that were relied on in the past have become less important, while receptor binding and functional assays are more clinically relevant. *Aripiprazole* represents a good example of how an examination of the structure provides little insight into the mechanism of partial agonism at D_2 DA receptors. Detailed knowledge of receptor affinities (see Table 19–2) and the functional effect at specific receptors (e.g., full, partial, or inverse agonism or antagonism) provides useful information about the therapeutic and adverse effects of antipsychotic agents. Nevertheless, there are limits. For example, it is not known which properties are responsible for *clozapine*'s unique effectiveness in resistant schizophrenia, although there are several hypotheses. Other notable antipsychotic properties not fully explained by receptor parameters include reduced seizure threshold, weight-independent effects on glucose and lipid metabolism, and increased risk for cerebrovascular events and mortality among dementia patients (see Adverse Effects and Drug Interactions, below).



ARIPIPRAZOLE



CLOZAPINE

Mechanism of Action

With the exception of *pimavanserin* for PDP, no antipsychotic approved through the end of 2021 is devoid of D_2-modulating activity

TABLE 19–1 ■ DRUGS FOR PSYCHOSIS AND SCHIZOPHRENIA: ORAL DOSING AND METABOLIC RISK PROFILE

	ORAL DOSAGE INFORMATION**		PLASMA LEVEL RANGE FOR SCHIZOPHRENIA (ng/mL)		METABOLIC SIDE EFFECTS

BID, twice a day; EM, extensive metabolizer; IM, acute intramuscular; IntM, intermediate metabolizer; O, tablet or capsule; ODT, orally dissolving tablet; PM, poor metabolizer; S, solution; SL, sublingual.

**Concentration dose relationship value, multiplied by the oral dose (mg), estimates the 12h trough level in ng/ml (e.g.: female nonsmoker on clozapine 300 mg qhs: 300 × 1.32 = 396 ng/ml).

[a]A small proportion of patients may never exhibit dose-limiting adverse effects even at supratherapeutic dosages; however, ongoing titration beyond the plasma level point of futility is fruitless as less than 5% of patients will respond at these higher plasma levels (Meyer, 2014; Meyer and Stahl, 2021).

[b]Not available in the U.S.

[c]Transdermal doses per 24 h are 3.8, 5.7, and 7.6 mg, equivalent to sublingual asenapine doses of 10, 15, and 20 mg/day, respectively.

[d]Due to orthostasis risk, dose titration of iloperidone is 1 mg twice daily on day 1, increasing to 2, 4, 6, 8, 10, and 12 mg twice daily on days 2 to 7 (as needed).

[e]Dose must be given with 350 kcal food to facilitate absorption. Administration with evening meal improves tolerability.

[f]Only one dose approved for schizophrenia (42 mg). A 21 mg dose and 10.5 mg dose are available for those on CYP 3A4 moderate or strong inhibitors, respectively.

[g]A combination tablet with olanzapine (doses of 5, 10, 15, or 20 mg) and 10 mg of samidorphan was approved in the U.S. in June 2021 for schizophrenia or bipolar I disorder with manic or mixed episodes as monotherapy, or for adjunctive use to lithium or valproate in bipolar I. Samidorphan is a μ-opioid receptor antagonist and modest κ-opioid receptor partial agonist that blunts the endorphin signal that reinforces eating behavior.

[h]Indicated for Parkinson's disease psychosis and dementia-related psychosis.

[i]Oral dose must be given with 500 kcal food to facilitate absorption.

TABLE 19–2 ■ MEAN HALF-LIFE AND KINETIC PROPERTIES OF COMMONLY USED LONG-ACTING INJECTABLE ANTIPSYCHOTICS

DRUG	VEHICLE	DOSAGE	t_{max}	$t_{1/2}$ MULTIPLE DOSING	ABLE TO BE LOADED
First-generation antipsychotics					
Fluphenazine decanoate	Sesame oil	12.5–75 mg/2 weeks **Max:** 75 mg/week	0.3–1.5 days	14 days	Yes
Haloperidol decanoate	Sesame oil	25–300 mg/4 weeks **Max:** 300 mg/2 weeks	3–9 days	21 days	Yes
Perphenazine decanoate[a]	Sesame oil	27–216 mg/3–4 weeks **Max:** 216 mg/3 weeks	7 days	27 days	Yes
Flupenthixol decanoate[a]	Coconut oil	20–40 mg/2–4 weeks **Max:** 100 mg/2 weeks	4–7 days	17 days	Yes
Zuclopenthixol decanoate[a]	Coconut oil	25–100 mg/2–4 weeks **Max:** 400 mg/2 weeks	3–7 days	19 days	Yes
Newer antipsychotics					
Risperidone subcutaneous (Perseris)	Water	90–120 mg/4 weeks **Max:** 120 mg/4 weeks	7–8 days	9–11 days	Not needed
Risperidone subcutaneous (Uzedy)	Water	50–125 mg/4 weeks 100–250 mg/8 weeks **Max:** 125 mg/4 weeks 250 mg/8 weeks	8–14 days	15–21 days	Not needed
Risperidone microspheres (Risperdal Consta)	Water	12.5–50 mg/2 weeks **Max:** 50 mg/2 weeks	21 days	See note[a]	**No** (21–28 days oral overlap)
Paliperidone palmitate (monthly) (Invega Sustenna)[b]	Water	39–234 mg/4 weeks (25–150 mg/4 weeks) **Max:** 234 mg/4 weeks (150 mg/4 weeks)	13 days	25–49 days	Yes
Paliperidone palmitate (3 month) (Invega Trinza)[c]	Water	273–819 mg/12 weeks (175–525 mg/12 weeks) **Max:** 819 mg/12 weeks (525 mg/12 weeks)	84–95 days (deltoid) 118–139 days (gluteal)	30–33 days	No
Paliperidone palmitate (6 month) (Invega Hafyera)[d]	Water	1092–1560 mg/26 weeks (700–1000 mg/26 weeks) **Max:** 1560 mg/26 weeks (1000 mg/26 weeks)	148–159 days (gluteal)	29–32 days	No
Olanzapine pamoate (Zyprexa Relprevv)	Water	150–300 mg/2 weeks 300–405 mg/4 weeks **Max:** 300 mg/2 weeks	7 days	30 days	Yes
Aripiprazole monohydrate (Abilify Maintena)	Water	300–400 mg/4 weeks **Max:** 400 mg/4 weeks	6.5–7.1 days	29.9–46.5 days	**No** (14 days oral overlap)
Aripiprazole lauroxil (Aristada)[e]	Water	441, 662, 882 mg/4 wks 882 mg/6 weeks 1064 mg/8 weeks **Max:** 882 mg/4 weeks	41 days (single dose) 24.4–35.2 days (repeated dosing)	53.9 – 57.2 days	No (start with AL_{NCD} 675 mg IM + 30 mg oral ***OR*** 21 days oral overlap)
Aripiprazole lauroxil nanocrystal (Aristada Initio)[f]	Water	675 mg once	27 days (range: 16–35 days)	15–18 days (single dose)	—

AL_{NCD}, nanocrystalline milled dispersion of aripiprazole lauroxil.
[a]Not available in the U.S.
[b]The dosages in parentheses reflect those used outside the U.S., expressed as paliperidone equivalent doses.
[c]Only for those on paliperidone palmitate monthly for 4 months. Cannot be converted from oral medication.
[d]Only for those on paliperidone palmitate monthly for 4 months or on paliperidone palmitate 3-month. Cannot be converted from oral medication.
[e]Requires 21 days of oral overlap unless starting with aripiprazole lauroxil nanocrystal plus a single 30-mg oral dose.
[f]AL_{NCD} is only used for initiation of treatment with aripiprazole lauroxil or for resumption of treatment. It is always administered together with the clinician-determined dose of aripiprazole lauroxil, although the latter can be given up to 10 days after the aripiprazole lauroxil nanocrystal injection.

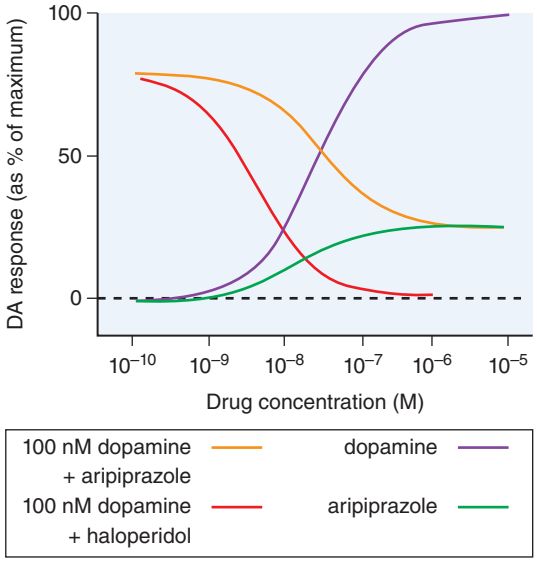

Figure 19–2 *Partial agonist activity of aripiprazole at D_2 receptors.* *Aripiprazole* is a partial D_2 agonist. In this stylized representation, *aripiprazole* inhibits the effects of DA and reduces stimulation at the D_2 receptor only to the extent of its own capacity as an agonist (orange tracing); in the absence of DA, its partial agonist effects are apparent (green line), becoming maximal at about 25% of the maximal effect of DA alone (purple line). *Haloperidol*, an antagonist without agonist activity, completely antagonizes D_2 receptor activation by 100 nM DA (red tracing). Here, receptor activation is measured as inhibition of forskolin-induced cAMP accumulation in cultured cells transfected with human D_{2l} DNA. (Data from Burris et al., 2002).

(Egerton et al., 2021). This direct reduction in dopaminergic neurotransmission is presently achieved through one of two mechanisms: D_2 antagonism or partial D_2 agonism (*aripiprazole*, *brexpiprazole*, and *cariprazine*). The mechanism of action for partial agonist antipsychotics relies on intrinsic activity at D_2 receptors that is a fraction of the efficacy of DA (i.e., 18%–25% of DA's activity), as depicted in Figure 19–2 for *aripiprazole*. (Recall that a partial agonist will also occupy the receptor and antagonize the binding of other antagonists and also full agonists; see Chapter 3.) Antipsychotics that primarily rely on D_2 antagonism need striatal D_2 occupancy (i.e., reduction in postsynaptic D_2 signal) of 60% to 80% for optimal efficacy. While higher levels of D_2 occupancy increase the risk for EPSs with DA antagonists, partial agonist antipsychotics require significantly higher D_2 occupancy levels (80%–100%). The presence of intrinsic DA agonism from the partial agonist generates a sufficient postsynaptic DA signal to remain below the EPS threshold, although reports of parkinsonism and dystonia do exist, primarily in antipsychotic-naïve, younger patients.

Clozapine was not suspected to possess antipsychotic activity until experimental human use in the mid-1960s revealed it to be an effective treatment of schizophrenia with virtually no EPS risk, particularly in patients who failed other antipsychotic medications. *Clozapine* possesses weaker D_2 antagonism than other antipsychotics, combined with potent $5HT_{2a}$ antagonism. *Clozapine* and its active metabolite *N*-desmethylclozapine also possess activity at numerous other receptors, including agonism at various muscarinic receptor subtypes, NMDA receptor activation via glycine site agonism (Meyer and Stahl, 2019), and activation of TAAR1 (Karmacharya et al., 2011).

Dopamine Receptor Occupancy and Behavioral Effects

Dopaminergic projections from the midbrain terminate on septal nuclei, the olfactory tubercle and basal forebrain, the amygdala, and other structures within the temporal and prefrontal cerebral lobes and the hippocampus. Excessive DA neurotransmission in the associative striatum and adjacent sensorimotor striatum is central to the positive symptoms of psychosis for schizophrenia patients (McCutcheon et al., 2019). The behavioral effects and the time course of antipsychotic response parallel the decrease in postsynaptic D_2 activity in this region. DA D_2 receptor occupancy predicts clinical efficacy, EPSs, and plasma level–clinical response relationships for the D_2 antagonist antipsychotics. Occupancy of greater than 78% of D_2 receptors in the basal ganglia is associated with greater risk of EPSs across all DA antagonist antipsychotic agents, while occupancies in the range of 60% to 75% are associated with antipsychotic efficacy and lower EPS risk (Figure 19–3). With the exception of the D_2 partial agonists, all SGAs at low doses have much greater occupancy of $5HT_{2a}$ receptors (e.g., 75%–99%) than FGAs (Table 19–3). Given the large variations in drug metabolism, plasma levels of antipsychotic agents (rather than doses) are the best predictors of D_2 occupancy (see Table 19–1).

The Role of Nondopamine Receptors for Atypical Antipsychotic Agents. The concept of atypicality was initially based on *clozapine*'s absence of EPSs combined with potent $5HT_2$ receptor antagonism. $5HT_{2a}$ antagonism exerts its greatest effect on prefrontal and basal ganglia DA release, thereby decreasing EPS risk in the context of nigrostriatal D_2 antagonism. That $5HT_{2A}$ antagonism conveys antipsychotic activity is exemplified by *pimavanserin* and *lumateperone*, antipsychotics that possess no or very low D_2 occupancy. As discussed with *clozapine*, muscarinic M_4 agonism is hypothesized to be an antipsychotic mechanism and is the basis for trials of the M_4 preferring agonist *xanomeline*. Most recently, there have been studies of TAAR1 agonists resulting from preclinical

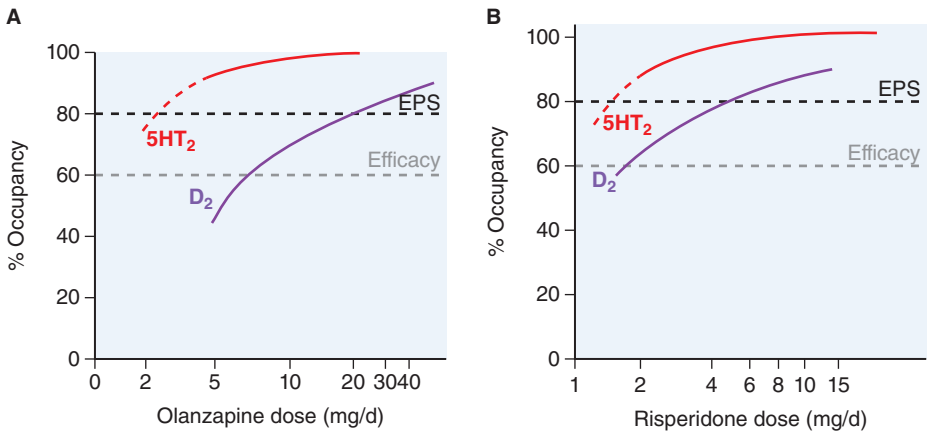

Figure 19–3 *Receptor occupancy and clinical response for D_2 receptor antagonist antipsychotics.* Antipsychotic effects are seen when D_2 receptor occupancy exceeds 60%, while occupancy greater than 80% increases risk of EPSs. Atypical agents combine weak D_2 receptor blockade with more potent $5HT_{2a}$ antagonism/inverse agonism. Inverse agonism at $5HT_2$ receptor subtypes may contribute to the reduced EPS risk of *olanzapine* (**A**) and *risperidone* (**B**) and efficacy at lower D_2 receptor occupancy (*olanzapine*, **A**). *Aripiprazole* is a partial D_2 agonist that can achieve only 75% functional blockade (see Figure 19–2).

TABLE 19–3 ■ POTENCIES OF ANTIPSYCHOTIC AGENTS AT NEUROTRANSMITTER RECEPTORS[a]

		DOPAMINE	SEROTONIN	MUSCARINIC	ADRENERGIC		HISTAMINE
		D_2	$5HT_{2A}$	M_1	α_{1A}	α_{1B}	H_1
First-generation agents (oral equivalent) (Leucht et al., 2020)

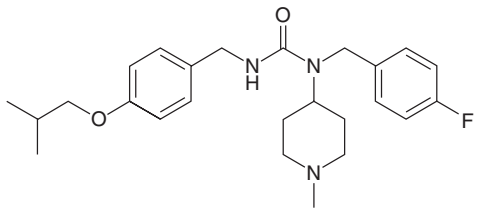
assays that predicted antipsychotic activity, with positive human data reported in 2020 in a phase II schizophrenia trial of *ulotaront* (Koblan et al., 2020).



PIMAVANSERIN

Tolerance and Physical Dependence

As defined in Chapter 28, antipsychotics are not addicting; however, tolerance to the α_1 adrenergic, antihistaminic, and anticholinergic effects usually develops over days or weeks. Loss of efficacy with prolonged treatment is not known to occur with antipsychotics; however, tolerance to antipsychotic drugs and cross-tolerance among agents are demonstrable in behavioral and biochemical experiments in animals. One correlate of tolerance in striatal dopaminergic systems is the pathological development of postsynaptic DA receptor supersensitivity due to the upregulation of supersensitive D_2 receptors, referred to as D_2^{High} receptors (Seeman et al., 2005). These changes in the nigrostriatal pathway underlie the pathophysiology of TD, while comparable changes in the associative striatum are associated with supersensitivity psychosis (Nakata et al., 2017).

ADME

Absorption for most antipsychotics following oral administration is quite high, with notable exceptions including *asenapine* (<2%), *fluphenazine* (3%), *lumateperone* (4%), and *lurasidone* (9%–19%). Most ODTs and liquid preparations provide similar pharmacokinetics because there is little mucosal absorption and absorption occurs in the gastrointestinal (GI) tract. *Asenapine* is the only exception: it was available initially only as an ODT preparation administered sublingually; absorption occurred via the oral mucosa with bioavailability of 35%. If *asenapine* is swallowed (i.e., the patient consumes water within 2 min after the ODT is placed in the mouth), the first-pass effect is greater than 98% and the drug is essentially not bioavailable. A transdermal form of *asenapine* is now available that avoids the kinetic issues of the ODT preparation.

Intramuscular forms for acute administration exist for many antipsychotics, and this route provides measurable concentrations in plasma within 15 to 30 min. There is also an inhaled form of *loxapine* that generates peak levels within 2 min.

The pharmacokinetic binding constants and metabolic pathways for many SGAs and FGAs are listed in Tables 19–3 and 19–4. Antipsychotics are highly lipophilic and accumulate in the brain, lung, and other tissues with a rich blood supply. Most antipsychotic agents are highly protein bound, primarily to α_1-glycoproteins, and do not significantly displace other medications bound to prealbumin or albumin. Antipsychotics also enter the fetal circulation and breast milk. Despite half-lives that may be short, the biological effects of single doses of most antipsychotic medications usually persist for at least 24 h, permitting once-daily dosing after the patient has adjusted to initial side effects. Due to accumulation in tissue stores, both parent compound and metabolites of LAI medications can be detected several months after discontinuation, a useful property for those who may miss injections (see Table 19–2).

Other Therapeutic Uses

Antipsychotics are also utilized in several nonpsychotic neurological disorders and as antiemetics.

Anxiety Disorders

Double-blind, placebo-controlled trials have shown the benefit of adjunctive treatment with several SGAs for obsessive-compulsive disorder, with a recent meta-analysis showing no significant efficacy differences between agents, although *quetiapine* and *paliperidone* were significantly less tolerable than placebo. Data from the largest double-blind, placebo-controlled study did not support routine use of adjunctive *risperidone* for posttraumatic stress disorder (Krystal et al., 2011). The use of SGAs for generalized anxiety disorder is not evidenced based. The last comprehensive meta-analysis was published in 2011 and concluded that SGAs are not superior to placebo as augmentation for refractory generalized anxiety disorder (LaLonde and Van Lieshout, 2011).

Tourette Disorder

The ability of antipsychotic drugs to suppress tics in patients with Tourette disorder relates to reduced D_2 neurotransmission at sites within the basal ganglia. *Aripiprazole* is the only antipsychotic FDA-approved for the treatment of Tourette disorder starting at doses of 2 mg/day and increasing (if needed) to a maximum of 10 mg/day for those weighing less than 50 kg or to 20 mg/day if weighing 50 kg or more (Yang et al., 2020). In prior decades, low-dose, high-potency FGAs (e.g., *haloperidol*) were treatments of choice, but nonpsychotic patients are extremely sensitive to the impact of DA blockade on cognitive processing speed and on reward centers. Moreover, safety concerns regarding *pimozide*'s QTc prolongation and increased risk for ventricular arrhythmias have largely ended its clinical use.

Huntington's Disease

Huntington's disease is another neuropsychiatric condition that, like tic disorders, is associated with basal ganglia pathology. DA blockade can suppress the severity of choreoathetotic movements but is not strongly endorsed due to the risks associated with excessive DA antagonism that outweigh the marginal benefit. Inhibition of the vesicular monoamine transporter 2 (VMAT2) with tetrabenazine compounds (e.g., *tetrabenazine*, *deutetrabenazine*) has replaced DA receptor blockade in the management of choreiform movements for these patients (see Chapter 21).

Autism

Autism is a disease whose neuropathology is incompletely understood but that can be associated with explosive behavioral outbursts and aggressive or self-injurious behaviors that may be stereotypical. *Risperidone* and *aripiprazole* are FDA-approved for irritability associated with autism in child and adolescent patients ages 5 to 16 and are used temporarily for disruptive behavior problems in autism and intellectual disability when behavioral programs are not effective. Long-term use is not supported by existing data, and children with intellectual disabilities may be very sensitive to weight gain and somnolence. Initial *risperidone* daily doses are 0.25 mg for patients weighing less than 20 kg and 0.5 mg for others, with a target dose of 0.5 mg/day in those weighing less than 20 kg and 1.0 mg/day for other patients, with a range of 0.5 to 3.0 mg/day. For *aripiprazole*, the starting dose is 2 mg/day, with a target range of 5 to 10 mg/day and maximum daily dose of 15 mg.

Antiemetic Use

The D_2 antagonist antipsychotics protect against the nausea- and emesis-inducing effects of DA agonists such as *apomorphine* that act at central DA receptors in the medullary chemoreceptor trigger zone (see Figure 54–6). Medications or other stimuli that cause emesis by an action on the nodose ganglion, or locally on the GI tract, are not antagonized by antipsychotics, but potent piperazines and butyrophenones are sometimes effective against nausea caused by vestibular stimulation. The commonly used antiemetic phenothiazines (e.g., *prochlorperazine*) and *metoclopramide* are weak DA antagonists without antipsychotic activity but can be associated with EPSs, akathisia, and TD if used chronically. Both *prochlorperazine* and *metoclopramide* have label warnings for TD. Emesis and antiemetic agents are discussed at length in Chapter 54.

Adverse Effects and Drug Interactions

Adverse Effects Predicted by Monoamine Receptor Affinities

Dopamine D_2 Receptors. With the exception of *pimavanserin* and the D_2 partial agonists (*aripiprazole*, *brexpiprazole*, *cariprazine*), all other antipsychotic agents possess D_2 antagonist properties, the strength of which determines the likelihood for short-term EPSs, akathisia, neuroleptic malignant syndrome (NMS), and hyperprolactinemia. As expected, FGAs also have 4-fold higher TD risk than SGAs (Carbon et al., 2017).

Extrapyramidal Symptoms. The manifestations of EPSs are described in Table 19–5, along with the usual treatment approach. Acute dystonic reactions occur in the early hours and days of treatment, with highest risk among younger patients (peak incidence ages 10–19), especially antipsychotic-naïve individuals, in response to abrupt decreases in nigrostriatal D_2 neurotransmission. Dystonia typically involves head and neck muscles and the tongue and, in its severest form, the oculogyric crisis, extraocular muscles, all of which are frightening to the patient.

Parkinsonism resembling its idiopathic form may occur; it will respond to dose reduction or switching to an antipsychotic with weaker D_2 antagonism. If this is neither possible nor desirable, antiparkinsonian medication may be employed but with the caveat that use of anticholinergic antiparkinsonian medication induces cognitive dysfunction. Elderly patients are at greatest risk for parkinsonism and are most sensitive to the cognitive and peripheral adverse effects of anticholinergic antiparkinsonian medications.

Muscarinic M_1 cholinergic receptors are present on nigrostriatal medium spiny neurons. Acetylcholine released from adjacent cholinergic interneurons stimulates these M_1 receptors and balances out the effects of DA agonism at D_2 receptors. When a D_2 antagonist causes disinhibition of medium spiny neurons, M_1 antagonists help mitigate this effect, resulting in reduced symptoms of parkinsonism and dystonia. Important issues in the use of anticholinergics include the negative impact on cognition and memory; peripheral antimuscarinic adverse effects (e.g., urinary retention, dry mouth, cycloplegia); exacerbation of TD; and risk of cholinergic rebound following abrupt anticholinergic withdrawal. For parenteral administration, intramuscular (IM) *diphenhydramine* (25–50 mg) and *benztropine* (1–2 mg IM) are most commonly used. *Diphenhydramine* possesses both antihistaminic and anticholinergic properties and is used preferentially in intramuscular combinations with *haloperidol* to provide dystonia prophylaxis and sedation. *Benztropine* combines a benzhydryl group with a tropane group to create a compound that is more anticholinergic than trihexyphenidyl but less antihistaminic than *diphenhydramine* and therefore less sedating in routine usage. The clinical effect of a single dose is sufficiently short that patients typically require two or three daily doses. *Benztropine* dosing usually starts at 0.5 to 1 mg twice daily,

TABLE 19–4 ■ DRUG DISPOSITION AND EFFECTS OF CYP INHIBITION AND INDUCTION ON ORAL ANTIPSYCHOTIC LEVELS

	t_{max}; ORAL BIOAVAILABILITY	METABOLISM	EFFECT OF CYP INHIBITION	EFFECT OF CYP INDUCTION
Commonly used atypical antipsychotics				
Aripiprazole	Bioavailability: 87% t_{max}: 3–5 h	CYPs 2D6 and 3A4 produce active metabolite, dehydroaripiprazole. $t_{1/2}$: aripiprazole, 75 h; dehydroaripiprazole, 94 h Metabolite = 40% of AUC at steady state	In 2D6 PM: ↑ AUC of aripiprazole up to 80%, 30% ↓ AUC of metabolite. $t_{1/2}$: 146 h in PMs. Strong CYP2D6 inhibitors (e.g., ketoconazole) can double AUC of parent drug. Ketoconazole (a strong 3A4 inhibitor) increased the AUCs of aripiprazole and its active metabolite by 63% and 77%, respectively.	3A4 induction ↓ max concentration and AUC of aripiprazole and metabolite by 70%.
Asenapine (transdermal)	Relative bioavailability: the 3.8 mg/24 h, 5.7 mg/24 h, and 7.6 mg/24 h doses are bioequivalent to the sublingual doses of 5 mg BID, 15 mg/day, and 10 mg BID, respectively t_{max}: 12–24 h	Primarily CYP1A2 and direct glucuronidation by the phase 2 enzyme UGT1A4. CYP3A4 and CYP2D6 are minor pathways. No active metabolites. $t_{1/2}$: 24 h	Fluvoxamine, (25 mg twice daily for 8 days) ↑ C_{max} by 13% and AUC 29%, but a greater effect from higher fluvoxamine doses is possible. The asenapine dose may need to be adjusted in those circumstances. There is no impact from the strong CYP2D6 inhibitor paroxetine or the UGT1A4 inhibitor valproate. Of note, asenapine increases paroxetine exposure 2-fold, so paroxetine doses should be decreased by 50%.	Smoking: no effect on clearance or other kinetic parameters. Carbamazepine, can ↓ C_{max} and AUC (16%).
Asenapine (sublingual)	Bioavailability: 32%–40% after 10 min of buccal residence time. If water is given before 10 min, absorption is decreased. Oral: <2% t_{max}: 1 h	Primarily CYP1A2 and direct glucuronidation by the phase 2 enzyme UG 1A4. CYP3A4 and CYP2D6 are minor pathways. No active metabolites. $t_{1/2}$: 30 h	Fluvoxamine (25 mg twice daily for 8 days) ↑ C_{max} by 13% and AUC 29%, but a greater effect from higher fluvoxamine doses is possible. The asenapine dose may need to be adjusted in those circumstances. There is no impact from the strong CYP2D6 inhibitor paroxetine or the UGT1A4 inhibitor valproate. Of note, asenapine increases paroxetine exposure 2-fold, so paroxetine doses should be decreased by 50%.	Smoking: no effect on clearance or other kinetic parameters. Carbamazepine, can ↓ C_{max} and AUC (16%).
Brexpiprazole	Bioavailability: 95% t_{max}: 4 h	CYPs 2D6 and 3A4 convert brexpiprazole to inactive metabolite (DM-3411). $t_{1/2}$: 91 h	Strong CYP2D6 or CYP3A4 inhibitors increase AUC_{0-24h} by 2-fold. Combined use of a strong CYP3A4 and CYP2D6 inhibitor (or with CYP2D6 PM) increased AUC_{0-24h} 4.8- to 5.1-fold. Reduce the dose by 50% with strong 2D6 or 3A4 inhibitors and by 75% with combined strong CYP2D6/CYP3A4 inhibitors.	Strong 3A4 inducers reduce exposure AUC_{0-24h} by ~70%. Double the dose with strong CYP3A4 inducers.

(*Continued*)

TABLE 19–4 ■ DRUG DISPOSITION AND EFFECTS OF CYP INHIBITION AND INDUCTION ON ORAL ANTIPSYCHOTIC LEVELS (*CONTINUED*)

	t_{max}; ORAL BIOAVAILABILITY	METABOLISM	EFFECT OF CYP INHIBITION	EFFECT OF CYP INDUCTION
Cariprazine	Bioavailability: 65% t_{max}: 3–6 h	CYP3A4 converts cariprazine to active metabolites DCAR and DDCAR. At steady state on 6 mg/day: cariprazine 28%, DCAR 9%, and DDCAR 63%. CYP2D6 is a minor pathway. Parent drug and DDCAR show good brain penetration; after oral cariprazine, brain-to-plasma ratios for both are ~9.8. $t_{1/2}$: 31.6–68.4 h; DCAR, 29.7–39.5 h; DDCAR, 314–446 h ≥50% of DDCAR present 1 week after discontinuation.	The strong CYP3A4 inhibitor ketoconazole at the dose of 400 mg/day increased cariprazine C_{max} and AUC_{0-24h} by 3.5- and 4.0-fold, respectively. Ketoconazole also increased DDCAR C_{max} and AUC_{0-24h} by 1.5-fold and decreased DCAR C_{max} and AUC_{0-24h} by about one-third. Reduce the dose by 50% with strong 3A4 inhibitors. There is no impact from 2D6 inhibitors.	Not studied. Impact unknown. Not recommended with 3A4 inducers.
Clozapine	Bioavailability: 60% t_{max}: 2.5 h	The mean contributions of CYPs 1A2, 2C19, 3A4, 2C9, and 2D6 are 30%, 24%, 22%, 12%, and 6%, respectively, but in some instances CYP1A2 is responsible for 40%–55% of clozapine biotransformation. CYP1A2 is the most important form at low concentrations, which is in agreement with clinical findings. Norclozapine is an active metabolite. In the largest data set available, the steady-state ratio of clozapine to norclozapine in nonsmokers is 1.32. Other studies report different values (e.g., 1.73). The important concept is that this is genetically determined and only modified by exposure to medications or other chemicals (e.g., cigarette smoke) that alter CYP activity or by erratic timing of the clozapine dose with respect to plasma level determinations. $t_{1/2}$: 12 h (4–66) with chronic dosing $t_{1/2}$: 22.5 h (norclozapine)	Fluvoxamine, a strong CYP1A2 inhibitor, increases plasma levels 5- to 10-fold. Strong CYP2D6 or CYP3A4 inhibitors increase trough plasma levels approximately 2-fold.	Carbamazepine, phenytoin, phenobarbital, rifampin, and omeprazole ↓ clozapine trough levels up to 50%. Smoking as few as 7–12 cigarettes/day is sufficient to fully induce CYP1A2, and ↑ its activity 1.66-fold. Upon smoking cessation, CYP1A2 activity declines with a half-life of 38.6 h (range, 27.4–54.4 h), and CYP1A2 activity will return to baseline after 5 half-lives, or 8 days on average. Loss of smoking-related 1A2 induction results in ≥50% increase in plasma levels.
Iloperidone	Bioavailability: well absorbed, but data limited t_{max}: 2–4 h	CYP2D6/3A4 produce active metabolites P88 and P95. Exposure to P88 and P95 can be significant. P88 $t_{1/2}$: EM, 26 h; PM, 37 h P95 $t_{1/2}$: EM, 23 h; PM, 31 h $t_{1/2}$: 18 h (CYP2D6 EMs), 33 h (CYP2D6 PMs)	Ketoconazole, fluoxetine, and paroxetine can ↑ AUC of iloperidone and metabolites by 50%–300%, with similar effects on C_{max} at steady state.	Impact of 3A4 inducers not documented.

Lumateperone	Bioavailability: 4.4% t_{max}: 1–2 h	CYP3A4 is the primary pathway. UGT1A4 is involved in phase 2 metabolism. Lumateperone is not a Pgp or BCRP substrate.	Itraconazole, a strong 3A4 inhibitor, increased the AUC 4-fold, while diltiazem, a moderate CYP3A4 inhibitor, increased AUC 2-fold. Due to the lack of multiple dosage forms, cannot be used with CYP3A4 inhibitors or UGT inhibitors (e.g., VPA).	Rifampin ↓ AUC by >95%. Cannot be taken with CYP3A4 inducers.
Lurasidone	Bioavailability: 9%–19% Mean C_{max} and AUC increased 3-fold and 2-fold, respectively, when administered with food. t_{max}: 1–3 h	CYP3A4 $t_{1/2}$: 18–36 h	The strong CYP3A4 inhibitor ketoconazole at a dose of 400 mg/day for 7 days in 10 healthy volunteers increased AUC 9.3-fold from baseline. Lurasidone cannot be used with strong CYP3A4 inhibitors. Exposure to the moderate CYP3A4 inhibitor diltiazem 240 mg/day for 7 days increased the single-dose AUC 2.2-fold for lurasidone and similarly for its metabolite ID-14283. The lurasidone dose should be decreased by 50% with moderate CYP3A4 inhibitors.	DO NOT USE with strong inducers of CYP3A4. Concurrent rifampin ↓ C_{max} to a seventh of prior levels and decreases AUC by 80%.
Olanzapine	Bioavailability: 60% t_{max}: 6 h	Direct glucuronidation via UGT1A4 or UGT2B10, or CYP1A2-mediated oxidation to *N*-desmethylolanzapine (inactive). $t_{1/2}$: 30 (21–54) h	The mean increases in olanzapine AUC following fluvoxamine exposure are 52% and 108%, respectively, in female nonsmokers and male smokers, respectively, but the effect is dependent on the fluvoxamine dose. Fluvoxamine 100 mg/day for 8 weeks resulted in an increase in trough olanzapine levels from 31 ± 15 ng/mL to 56 ± 31 ng/mL (81%), with a range of 12%–112%. A smaller fluvoxamine dose (25 mg/day) increased exposure only 26%.	Carbamazepine use ↑ clearance by 50%. The olanzapine concentration:dose ratio is at least 30% lower in smokers and may be 50% lower in some patients.
Paliperidone	Bioavailability: 28% t_{max}: 24 h	59% excreted unchanged, 32% appears as metabolites (primarily phase 2 via UGT1A4). 80% of elimination is renal, related to active excretion by the efflux transporter Pgp.	No significant impact of CYP inhibitors. At steady state (5 days), divalproex extended-release 1000 mg once daily increased the AUC of paliperidone 12 mg by 50%.	Carbamazepine use ↓ steady-state C_{max} and AUC by 37%.
Pimavanserin	Bioavailability: not determined t_{max}: 6 (4–24) h	Predominantly CYP3A4 to metabolite *N*-desmethylpimavanserin, which is active peripherally but has limited CNS penetration. $t_{1/2}$: 57 h $t_{1/2}$: 200 h (*N*-desmethylpimavanserin)	Ketoconazole increases pimavanserin AUC by 3-fold.	One week exposure to 600 mg rifampin ↓ pimavanserin AUC by 91%. A moderate CYP3A4 inducer (efavirenz) may ↓ AUC of pimavanserin by 70%.

(*Continued*)

TABLE 19–4 ■ DRUG DISPOSITION AND EFFECTS OF CYP INHIBITION AND INDUCTION ON ORAL ANTIPSYCHOTIC LEVELS (*CONTINUED*)

	t_{max}; ORAL BIOAVAILABILITY	METABOLISM	EFFECT OF CYP INHIBITION	EFFECT OF CYP INDUCTION
Quetiapine	Bioavailability: 9% t_{max}: 1–2 h t_{max}: 6 h (extended release)	CYP3A4 converts quetiapine to active metabolite norquetiapine. Steady-state mean AUC of norquetiapine is ~ half, of that for quetiapine. Unlikely to be a Pgp substrate at clinical concentrations. $t_{1/2}$: 6 h $t_{1/2}$: 9–12 h (norquetiapine)	Ketoconazole (200 mg once daily for 4 days) reduced oral clearance of quetiapine by 84%, resulting in a 335% increase in maximum plasma concentration.	Phenytoin increases clearance 5-fold.
Risperidone	Bioavailability: 70% t_{max}: 1 and 3 h for risperidone and 9-OH risperidone, respectively. In CYP2D6 PM, t_{max} for 9-OH risperidone is 17 h.	CYP2D6 converts risperidone to 9-OH risperidone (active). $t_{1/2}$: 3–4 h; 20–24 h (9-OH risperidone) In 2D6 PMs, half-lives are: risperidone, 20 h; 9-OH risperidone, 30 h.	Strong CYP2D6 inhibitors increase exposure to the active moiety (i.e., the AUC) by 1.5-fold (range, 1.3–1.8). Strong CYP3A4 inhibitors have no significant impact on active moiety levels.	Carbamazepine decreases exposure to the active moiety (i.e., the AUC) by 49%.
Ziprasidone	Bioavailability: 60% when given with food A 500-kcal meal (of any composition) ↑ AUC of a 20-mg, 40-mg, and 80-mg capsule by 48%, 87%, and 101%, respectively. t_{max}: 6–8 h	Aldehyde oxidase (66%), CYP3A4 (34%) $t_{1/2}$: 7.5 h	35%–40% increase in ziprasidone AUC by concomitantly administered ketoconazole.	35% decrease in ziprasidone AUC by carbamazepine.
Typical antipsychotics				
Haloperidol	Bioavailability: 60% t_{max}: 2–6 h	Multiple CYP pathways, particularly 2D6, 3A4. No active metabolites. $t_{1/2}$: 24 h (12–36 h)	Strong CYP2D6 inhibitors increase exposure 25%–50%. Individuals with only one functional CYP2D6 gene experience 2-fold greater trough serum levels. Those with no functioning alleles 3- to 4-fold higher. Strong CYP1A2 inhibitors increase exposure on average 62.5% (range, 48%–79%). Strong 3A4 inhibitors increase exposure 17%.	Carbamazepine, phenobarbital, or phenytoin ↓ C_p by 40%–72%. Rifampin ↓ C_p by 70%. Discontinuation of carbamazepine results in a 2- to 5-fold increase in C_p.
Chlorpromazine	Bioavailability is dose dependent: 25 mg: mean, 8.07%; max, 14.7% 100 mg: mean, 18.4%; max, 34.2% t_{max}: 1.4–2.0 h	CYP2D6 and to a lesser extent CYP1A2 convert chlorpromazine to an active metabolite, 7-OH chlorpromazine, which is present at levels ~34% of the parent compound. $t_{1/2}$: 11.05–15 h (range, 8–33 h with chronic dosing)	Strong CYP1A2 and CYP2D6 inhibitors will increase exposure as much as 38% and 70%, respectively.	Carbamazepine lowers C_p by 61% (range, 28%–84%). Phenobarbital lowers C_p by 36%–60%. Cigarette or cannabis smoking ↑ clearance 38%–50%.

AUC, area under the curve; BCRP, breast cancer resistance protein; BID, twice a day; EM, extensive metabolizer; PM, poor metabolizer.

TABLE 19–5 ■ NEUROLOGICAL SIDE EFFECTS OF ANTIPSYCHOTIC DRUGS

REACTION	FEATURES	TIME OF ONSET AND RISK INFO	PROPOSED MECHANISM	TREATMENT
Acute dystonia	Spasm of muscles of tongue, face, neck, back	Time: 1–5 days. Young, antipsychotic-naïve patients at highest risk	Acute DA antagonism	Antiparkinsonian agents are diagnostic and curative[a]
Akathisia	Subjective and objective restlessness; *not* anxiety or "agitation"	Time: 5–60 days	Unknown, but relates in part to DA antagonism. Can also be seen with DA partial agonists.	Reduce dose or change drug; low-dose mirtazapine (7.5–15 mg), clonazepam, and propranolol more effective than antiparkinsonians. Long-term use of benzodiazepines associated with higher mortality in schizophrenia patients, especially suicide mortality.[b]
Parkinsonism	Bradykinesia, rigidity, variable tremor, mask facies, shuffling gait	Time: 5–30 days. Elderly at greatest risk	DA antagonism	Dose reduction; change medication; antiparkinsonian agents. If possible, use amantadine and avoid anticholinergic medications due to adverse cognitive effects.[c]
Neuroleptic malignant syndrome	Extreme rigidity, fever, unstable blood pressure, myoglobinemia; can be fatal	Time: weeks–months. Can persist for days after stopping antipsychotic	DA antagonism	Stop antipsychotic immediately; supportive care; dantrolene and bromocriptine.[d]
Perioral tremor ("rabbit syndrome")	Perioral tremor (may be a late variant of parkinsonism)	Time: months or years of treatment	DA antagonism	Antiparkinsonian agents often help.[c] If possible, use amantadine and avoid anticholinergic medications due to adverse cognitive effects.
Tardive dyskinesia	Orofacial dyskinesia, choreiform movements, tic-like movements, stereotypy, and possibly dystonia. Approximately one-third do not have head/neck involvement.	Time: months or years of treatment. Elderly at 5-fold greater risk. Risk proportional to potency of D_2 blockade	Upregulation of supersensitive postsynaptic dopamine D_2 receptors	Typically irreversible but may be reversible with early recognition and drug discontinuation. VMAT2 inhibitors valbenazine and deutetrabenazine are FDA-approved for tardive dyskinesia and very effective with effect sizes as high as 0.90. Anticholinergics exacerbate tardive dyskinesia but may be used for residual tardive dystonia not responsive to VMAT2 inhibition.

[a]Treatment: diphenhydramine 25–50 mg IM or benztropine 1–2 mg IM. Due to long antipsychotic $t_{1/2}$, may need to repeat or follow with oral medication.
[b]Propranolol often effective in relatively low doses (20–80 mg/day in divided doses). β_1-Selective adrenergic receptor antagonists are less effective. Nonlipophilic β adrenergic antagonists (e.g., atenolol) have limited CNS penetration and are of no benefit.
[c]Use of amantadine avoids anticholinergic effects of benztropine or diphenhydramine.
[d]Despite the response to dantrolene, there is no evidence of abnormal Ca^{2+} transport in skeletal muscle; with persistent antipsychotic effects (e.g., long-acting injectable agents), prolonged bromocriptine may be necessary in large doses (10–40 mg/day). Antiparkinsonian agents are not effective.

with a daily maximum of 6 mg, although slightly higher doses are used in rare circumstances. The piperidine compound *trihexyphenidyl* was one of the first synthetic anticholinergics. It also inhibits the presynaptic DA reuptake transporter, and this property creates a higher risk of abuse than *diphenhydramine* or *benztropine*. *Trihexyphenidyl* has good GI absorption, achieving peak plasma levels in 1 to 2 h, with a serum $t_{1/2}$ of about 10 to 12 h generally necessitating multiple daily dosing to achieve satisfactory clinical results. The total daily dosage range is 5 to 15 mg, given two or three times a day as divided doses. *Biperiden* is another drug in this class.

Amantadine, originally marketed as an antiviral agent for influenza A, is an alternative medication for antipsychotic-induced parkinsonism and avoids the adverse CNS and peripheral effects of anticholinergic medications (Silver and Geraisy, 1995). Its mechanisms of action involve presynaptic DA reuptake blockade, facilitation of DA release, postsynaptic DA agonism, and/or DA receptor modulation. *Amantadine* is well absorbed after oral administration with peak levels achieved 1 to 4 h after ingestion; clearance is renal with more than 90% recovered unmetabolized in the urine. The plasma $t_{1/2}$ is 12 to 18 h in healthy young adults but is longer with renal impairment. For those with creatinine clearance of 30 to 50 mL/min, the recommended dose is 200 mg given once followed by 100 mg every 24 h. The starting dosage is 100 mg orally once daily in healthy adults, which should be increased to 100 mg twice daily. Maximal doses for management of antipsychotic-related parkinsonism are 300 to 400 mg/day. A dose of 100 mg twice daily yields peak plasma levels of 500 to 800 ng/mL and trough levels of 300 ng/mL. Toxicity is seen at serum levels between 1000 and 5000 ng/mL.

Tardive Dyskinesia. Tardive dyskinesia results from increased postsynaptic nigrostriatal dopaminergic activity due to upregulation of postsynaptic supersensitive D_2 receptors from chronic D_2 blockade (and possible direct toxic effects of high-potency DA antagonists). TD occurs five times more frequently in elderly patients, and the risk may be somewhat greater in patients with mood disorders than in those with schizophrenia. The prevalence of TD averages 25% in adults treated with FGAs for more than a year but is estimated at 7.2% in those exposed only to SGAs (Carbon et al., 2017).

Tardive dyskinesia is characterized by stereotyped, repetitive, involuntary, quick choreiform (tic-like) movements of the face, eyelids (blinks or spasm), mouth (grimaces), tongue, extremities, or trunk, with varying degrees of slower athetosis (twisting movements). As part of the syndrome, there may also be tardive dystonia, tardive akathisia, and, rarely, tardive pain. TD movements disappear during sleep, vary in intensity over time, and are dependent on the level of arousal or emotional distress, sometimes reappearing during acute psychiatric illnesses following

prolonged disappearance. TD movements can be suppressed partially by using a potent DA antagonist to block supersensitive postsynaptic D_2 receptors, but such interventions may worsen the severity over time as this was part of the initial pharmacological insult. Switching patients from potent D_2 antagonists to weaker antagonists is not effective and should not be employed to manage TD (Bhidayasiri et al., 2018). The sole exception is switching to *clozapine* for patients with moderate/severe TD, but this should be performed only in patients who have other indications for *clozapine* (e.g., treatment-resistant schizophrenia), since the newly approved VMAT2 inhibitors are well tolerated and effective when given with existing antipsychotic therapy (Mentzel et al., 2018). In patients who do not require continuous antipsychotic therapy (e.g., adjunctive use for mood disorders), drug discontinuation may be beneficial when TD is recognized early but is effective in only 12% of cases with more established symptoms (Bhidayasiri et al., 2018).

The VMAT2 inhibitors *valbenazine* and *deuterated-tetrabenazine* (*deutetrabenazine*) are FDA-approved for TD. Both are derivatives of *tetrabenazine* but with more favorable kinetics that also improve on the tolerability profile of *tetrabenazine* (Bhidayasiri et al., 2018). *Valbenazine* is a prodrug metabolized to a *tetrabenazine* metabolite (α-dihydrotetrabenazine) that is a potent VMAT2 inhibitor. *Valbenazine* is dosed once daily and is titrated after 1 week from 40 mg to 80 mg unless tolerability or kinetic issues limit use of the highest dosage. The clearance of *valbenazine* and its active metabolite involve CYPs 2D6 and 3A4. Thus, exposure to the parent drug and its active metabolite will be increased in CYP-2D6-poor metabolizers, in the presence of strong inhibitors of CYP2D6 (e.g., *paroxetine*) or CYP3A4 (e.g., *ketoconazole*), or in patients with moderate-to-severe hepatic impairment. Use of *valbenazine* in the presence of strong inducers of CYP3A4 (e.g., *rifampin*) is not recommended; concomitant use of monoamine oxidase inhibitors should be avoided. *Valbenazine* also inhibits the P-glycoprotein (Pgp) efflux transporter and will increase *digoxin* exposure. *Deutetrabenazine* is approved for TD and for managing the chorea of Huntington's disease. (See Chapter 21 for discussion of *deutetrabenazine* and *tetrabenazine* use for Huntington's chorea.) *Deutetrabenazine* is given twice daily and has a titration of 6 mg/week from the starting dose of 6 mg twice daily to the effective dosage range of 24 to 48 mg/day (Bhidayasiri et al., 2018). Both *valbenazine* and *deutetrabenazine* were well tolerated in clinical trials, with high completion rates (80%–90%) that were comparable to placebo. Efficacy is sustained during long-term use, but given the irreversible nature of TD in most patients, symptoms typically return to baseline when a VMAT2 inhibitor is discontinued.

Akathisia. Unlike antipsychotic-induced parkinsonism and acute dystonia, the phenomenology and treatment of akathisia suggest involvement of structures outside the nigrostriatal pathway. Despite the association with D_2 blockade, akathisia has minimal response to anticholinergic antiparkinsonian drugs, so other treatment strategies are employed acutely, including high-potency benzodiazepines (e.g., *clonazepam*), nonselective β adrenergic blockers with excellent CNS penetration (e.g., *propranolol*), and the $5HT_{2A}$ antagonist antidepressant *mirtazapine* at doses of 7.5 to 15 mg at bedtime (American Psychiatric Association, 2021). Over time, one should pursue dose reduction or switching to another antipsychotic. That *clonazepam* and *propranolol* have significant cortical activity and are ineffective for other forms of EPSs points to an extrastriatal origin for akathisia symptoms.

Neuroleptic Malignant Syndrome. NMS resembles a severe form of parkinsonism, but with additional symptoms including autonomic instability (hyperthermia and labile pulse, blood pressure, and respiration rate), stupor, elevation of serum creatine kinase, and resultant myoglobinuria with potential nephrotoxicity. At its most severe, this syndrome may persist for more than a week after the offending agent is discontinued and can be associated with mortality. NMS has been associated with myriad antipsychotic agents, but risk is greatest with relatively high doses of potent D_2 antagonists. Aside from cessation of antipsychotic treatment and provision of supportive care (e.g., aggressive cooling measures), specific pharmacological treatment with a DA agonist such as *bromocriptine* is helpful, with conflicting data on the value of *dantrolene*. Electroconvulsive therapy (ECT) can also be considered in patients with inadequate response to other measures. There are fewer reports of NMS with SGAs compared to those from FGA exposure, so this syndrome is less commonly seen in its full presentation (Gurrera et al., 2017). Consensus criteria to assist in NMS diagnosis were published in 2011, with a subsequent validation study released in 2017 using the proposed scoring scheme from the 2011 paper (Gurrera et al., 2017).

Hyperprolactinemia. Hyperprolactinemia results from blockade of tuberoinfundibular D_2 receptors. Dopaminergic neurons project from the arcuate nucleus of the hypothalamus to the median eminence where they deliver DA to the anterior pituitary via the hypophyseoportal vessels. D_2 receptors on lactotrophs in the anterior pituitary mediate the tonic prolactin-inhibiting action of DA. Correlations between the D_2 potency of antipsychotic drugs and prolactin elevations are excellent. With the exception of *amisulpride*, *risperidone*, and *paliperidone*, SGAs show limited effects (*asenapine*, *iloperidone*, *olanzapine*, *quetiapine*, *ziprasidone*) to almost no effects (*clozapine*, *aripiprazole*, *brexpiprazole*, *cariprazine*, *lumateperone*) on prolactin secretion. *Amisulpride*, *risperidone*, and *paliperidone* have the highest risk for prolactin elevation, even more so than high-potency FGAs, and this is related to their high affinity for the Pgp efflux transporter (Huhn et al., 2019). High Pgp affinity results in reflux at the blood-brain barrier, thereby exposing pituitary cells to locally high concentrations of the antipsychotic. The impact on prolactin secretion is thus disproportionate to the D_2 affinity.

Hyperprolactinemia can directly induce breast engorgement and galactorrhea and can cause amenorrhea in women and sexual dysfunction or infertility in women and men. Dose reduction can be tried to decrease serum prolactin levels, but caution must be exercised to keep treatment within the antipsychotic therapeutic range. Switching from offending antipsychotic agents (especially from *amisulpride*, *risperidone*, and *paliperidone*) is the preferred strategy, but when not feasible, *bromocriptine* can be employed. The hyperprolactinemia from antipsychotic drugs is rapidly reversed when the drugs are discontinued. Use of the partial agonist *aripiprazole* is generally not advisable as there are case reports of exacerbation due to the displacement of D_2 antagonist antipsychotics (e.g., *haloperidol*, *risperidone*, *paliperidone*) by *aripiprazole* (Takeuchi and Remington, 2013). Like all partial agonist antipsychotics, *aripiprazole* has extremely high D_2 affinity, even higher than that of FGAs.

Histamine H_1 Receptors. Antagonism of CNS of H_1 receptors is associated with two major adverse effects: sedation and weight gain via appetite stimulation. Certain antipsychotic agents cause these adverse effects by virtue of their high H_1 binding (see Table 19–3).

Sedation. Examples of sedating antipsychotic drugs include low-potency FGAs such as *chlorpromazine* and the SGAs *clozapine* and *quetiapine*. The sedating effect is predicted by their high H_1 receptor affinities (see Table 19–3). Some tolerance to the sedative properties will develop, a helpful fact to remember when considering switching a patient to a nonsedating agent. Rapid discontinuation of sedating antihistaminic antipsychotics is inevitably followed by significant complaints of rebound insomnia and sleep disturbance. If discontinuation of sedating antipsychotic treatment is deemed necessary, the sedating antipsychotic should be tapered slowly over 4 to 12 weeks, and the clinician should be prepared to utilize a sedative at the end of the taper. *Hydroxyzine* (an antihistamine) or *diphenhydramine* (an anticholinergic antihistamine) are reasonable options. Following emergency cessation of *clozapine* for severe neutropenia or myocarditis, high doses of anticholinergics must be used to prevent cholinergic rebound. Sedation may be useful during acute psychosis, but excessive sedation can interfere with patient evaluation, may prolong emergency room and psychiatric hospital stays unnecessarily, and is poorly tolerated among elderly patients with dementia and delirium; thus, the prescriber must exercise caution with the choice of agent and the dose.

Weight Gain. Weight gain is a significant problem during long-term use of antipsychotic drugs and represents a major barrier to medication adherence as well as a significant threat to the physical and emotional health

of the patient. Weight gain has effectively replaced concerns over EPS as the adverse effect causing the most consternation among patients and clinicians alike. Appetite stimulation is the primary mechanism involved, with little evidence to suggest that decreased activity (due to sedation) is a main contributor to antipsychotic-related weight gain. Laboratory studies indicated that medications with significant H_1 antagonism induce appetite stimulation through effects at hypothalamic sites. Antagonism at $5HT_{2c}$ receptors may play an additive role in promoting weight gain for medications that possess high H_1 affinities (e.g., *clozapine*, *olanzapine*) but appears to have no effect in the absence of significant H_1 blockade, as evidenced by *ziprasidone*, an antipsychotic with low weight gain risk, extremely high $5HT_{2c}$ affinity, and poor affinity for H_1 histamine receptors. *Chlorpromazine* and the SGAs *olanzapine*, *quetiapine*, and *clozapine* are the agents of highest risk, but some weight gain occurs with nearly all antipsychotic drugs (Huhn et al., 2019).

Younger and antipsychotic-naïve patients are more sensitive to the weight gain from all antipsychotics, including agents that appear more weight neutral in adults. Switching to more weight-neutral medications can achieve significant results; however, when changing medications is not feasible or unsuccessful, behavioral strategies must be employed and should be considered. *Metformin* is also used to moderate the antipsychotic-induced weight gain from *olanzapine* and *clozapine* and should be introduced when starting the antipsychotic. Glucagon-like peptide-1 agonists such as *exenatide* and *liraglutide* can also be helpful (Siskind et al., 2019). In June 2021, a combination tablet of *olanzapine* and *samidorphan* was approved in the U.S. for schizophrenia and bipolar I disorder. *Samidorphan* is a μ-opioid receptor antagonist and modest κ-opioid receptor partial agonist whose role is to limit *olanzapine*-related weight gain in patients newly started on *olanzapine* by blunting the endorphin signal that reinforces eating behavior.

Muscarinic M_1 Receptors. Muscarinic antagonism is responsible for the central and peripheral anticholinergic effects of medications. The clinically relevant anticholinergic burden of most SGAs are limited, whereas *clozapine* and low-potency phenothiazines have significant anticholinergic adverse effects (see Table 19–3). *Quetiapine* has modest muscarinic affinity; its active metabolite norquetiapine is likely responsible for the anticholinergic effects. *Clozapine* is particularly associated with significant constipation and ileus due to its anticholinergic properties and possibly effects at $5HT_3$ receptors. Routine use of multiple stool softeners and secretagogues is necessary to manage the problem. Psyllium should be avoided since the colonic transit time for *clozapine*-treated patients may exceed 100 h, thereby resulting in inspissation of psyllium into a gel that itself can cause intestinal obstruction (Meyer and Stahl, 2019). Anticholinergic medications should be avoided in elderly patients, especially those with dementia or delirium, due to the adverse effects on cognition, with *clozapine* being the notable exception due to lack of other options for treatment-resistant schizophrenia.

Adrenergic α_1 Receptors. α_1 Adrenergic antagonism is associated with orthostatic hypotension, and this can be particularly problematic for elderly patients who have poor vasomotor tone. The extent to which an antipsychotic causes this effect in clinical practice is dependent on the doses employed and the rapidity of titration. Compared to high-potency FGAs, low-potency FGAs pose greater risk for orthostasis. Among SGAs, *iloperidone* carries a warning regarding minimization of orthostasis risk through slower titration. *Clozapine* can be associated with significant orthostasis, even when titrated slowly. Because *clozapine*-treated patients have few other antipsychotic options, the potent mineralocorticoid *fludrocortisone* starting at 0.1 mg/day (maximum dose 0.5 mg/day) is used as a volume expander (Meyer and Stahl, 2019).

Adverse Effects Not Predicted by Monoamine Receptor Affinities

Adverse Metabolic Effects. Metabolic effects are an area of great concern during long-term antipsychotic treatment, paralleling the overall concern for the high prevalence of prediabetic conditions, type 2 diabetes, and 2-fold greater CV mortality among patients with schizophrenia. Aside from weight gain, the two predominant metabolic adverse effects seen with antipsychotic drugs are dyslipidemia, primarily elevated serum triglycerides, and impairments in glycemic control.

Low-potency phenothiazines elevate serum triglyceride levels, an effect not seen with high-potency phenothiazines. Among SGAs, significant increases in fasting triglyceride levels are noted during *clozapine*, *olanzapine*, and high-dose *quetiapine* (>400 mg/day) exposure. Effects on total cholesterol and cholesterol fractions are significantly less but show expected associations related to agents of highest risk: *clozapine*, *olanzapine*, and *quetiapine* (Huhn et al., 2019). Weight gain can induce deleterious lipid changes; however, evidence indicates that antipsychotic-induced hypertriglyceridemia is a weight-independent adverse event that occurs within weeks of starting an offending medication and improves within 6 weeks after medication discontinuation. In individuals not exposed to antipsychotics, elevated fasting triglycerides are a direct consequence of insulin resistance, as insulin-dependent lipases in fat cells are normally inhibited by insulin. As insulin resistance worsens, inappropriately high levels of lipolysis lead to the release of excess amounts of free fatty acids, which are transformed into triglyceride particles. Elevated fasting triglyceride levels thus become a sensitive marker of insulin resistance, leading to the hypothesis that the triglyceride increases seen during antipsychotic treatment are the result of derangements in glucose-insulin homeostasis.

The ability of antipsychotics to induce hyperglycemia was first noted during low-potency phenothiazine treatment; indeed, *chlorpromazine* was occasionally exploited for this specific property as adjunctive presurgical treatment of insulinoma. As SGAs gained widespread use, numerous papers documented the association of new-onset diabetes and diabetic ketoacidosis with SGA exposure, especially during *clozapine*, *olanzapine*, and *quetiapine* therapy. The mechanism by which antipsychotic drugs disrupt glucose-insulin homeostasis is not known, but *in vivo* animal experiments document immediate dose-dependent effects of *clozapine* and *olanzapine* on whole-body and hepatic insulin sensitivity.

There may also be inherent disease-related mechanisms that increase risk for metabolic disorders among schizophrenia patients, but medication choice is a primary modifiable risk factor, and all SGAs in the U.S. include a warning about hyperglycemia on the drug label. Use of metabolically more benign agents is recommended for the initial treatment of all patients for whom long-term treatment is expected. Clinicians should obtain baseline metabolic data, including a fasting glucose or hemoglobin A_{1c}, a fasting lipid panel, and weight, and then establish a plan for ongoing monitoring of metabolic parameters. As with weight gain, changes in fasting glucose and lipids should prompt reevaluation of ongoing treatment, institution of measures to improve metabolic health (diet, exercise, nutritional counseling), and consideration of switching antipsychotic agents.

Adverse Cardiac Effects. Multiple ion channels are involved in the depolarization and repolarization of cardiac ventricular cells (see Chapters 33 and 34). Some antipsychotics can interfere with the functioning of these channels, elevating the risk of ventricular arrhythmias and sudden cardiac death (SCD). While most FGAs (e.g., *thioridazine*) significantly inhibited inwardly rectifying K^+ channels (I_{kr}) in cardiac myocytes, this effect is much less pronounced for SGAs (Xiong et al., 2020). Antagonism of voltage-gated Na^+ channels causes QRS widening and an increase in the PR interval, with increased risk for ventricular arrhythmia. Myocyte repolarization is mediated in part by K^+ current through two channels: the rapid I_{kr} and the slow I_{ks} channels. The α subunit of the I_{kr} channel, $K_{v11.1}$, is encoded by *hERG*, the human-ether-à-go-go related gene. $K_{v11.1}$ is thus part of the K^+ channel that mediates the repolarizing I_{kr} current of the cardiac action potential. Polymorphisms of *hERG* are involved in the congenital long QT syndrome associated with syncope and SCD. Antagonism of I_{kr} channels is responsible for most cases of drug-induced QT prolongation and is the suspected mechanism for the majority of antipsychotic-induced SCDs (Xiong et al., 2020).

Aside from individual agents, for which anecdotal and pharmacosurveillance data indicate risk for torsades de pointes (e.g., *thioridazine*, *pimozide*), most of the commonly used newer antipsychotic agents

are not associated with a known increased risk for ventricular arrhythmias. Prior associations between *clozapine* use and QT prolongation are now recognized as spurious artifacts related to use of the outdated and inaccurate Bazett QT correction formula in a group of patients who are often tachycardic (Meyer and Stahl, 2019). One current exception is *sertindole*, an agent not available in the U.S. that was withdrawn in 1998 based on anecdotal reports of torsades de pointes, but reintroduced in Europe in 2006 with strict electrocardiogram (ECG) monitoring guidelines. Although *in vitro* data revealed *sertindole*'s affinity for I_{kr}, several epidemiological studies published over the past decade were unable to confirm an increased risk of sudden death due to *sertindole* exposure, thereby providing justification for its reintroduction.

Currently, no data suggest a benefit of routine ECG monitoring for prevention of SCD among patients using antipsychotic drugs (Xiong et al., 2020). Nonetheless, all antipsychotic medications marketed in the U.S. (with the exception of *lurasidone* and *cariprazine*) carry a class label warning regarding QTc prolongation. A specific black-box warning exists for *thioridazine*, *pimozide*, intramuscular *droperidol*, and *haloperidol* (intravenous formulation but not oral or intramuscular) concerning torsades de pointes and subsequent fatal ventricular arrhythmias (discussed next and in Chapter 34). Overdose with FGAs is of particular concern with certain agents (e.g., *chlorpromazine*, *thioridazine*, *pimozide*) due to the risk of torsades de pointes and, for the lower potency antipsychotics, a likelihood of sedation, anticholinergic effects, and orthostasis. Patients who overdose on high-potency FGAs (e.g., *haloperidol*) and the substituted benzamides are at greater risk for EPSs (due to the high D_2 affinity) and for ECG changes. Overdose experience with SGAs indicates a much lower risk for torsades de pointes and other ventricular arrhythmias compared to older antipsychotic medications; however, combinations of antipsychotic agents with other medications can lead to fatality, primarily through respiratory depression.

Effects of *clozapine* on the heart include tachycardia that occurs independently of orthostasis, myocarditis, and dilated cardiomyopathy. Myocarditis risk is 1% and occurs only during the first 6 weeks of treatment. It is suspected by clinical signs (e.g., chest pain, malaise, fever) with diagnosis confirmed by troponin I or T levels greater than or equal to 2 times the upper limit of normal or a C-reactive protein greater than or equal to 100 mg/L (Meyer and Stahl, 2019).

Other Adverse Effects. In the U.S., there is a class label warning for seizure risk (<1%) on all antipsychotics except *pimavanserin*. Among commonly used SGAs, only *clozapine* has a dose-dependent seizure risk, with a prevalence of 3% to 5%. The structurally related *olanzapine* had an incidence of 0.9% in premarketing studies. Patients with seizure disorder who commence antipsychotic treatment must receive adequate prophylaxis, with consideration given to avoiding *carbamazepine* and *phenytoin* due to their potent induction of CYPs and Pgp. *Carbamazepine* is also contraindicated during *clozapine* treatment due to its rare risk for bone marrow effects. VPA derivatives (e.g., *divalproex*) are used for *clozapine*-associated seizures as they best cover the spectrum of generalized and myoclonic or atonic seizures. *Divalproex* should not be used prophylactically for two reasons: seizure rates even at *clozapine* doses greater than 600 mg/day are less than 2%, and VPA itself is associated with neutropenia risk, which may complicate *clozapine* treatment (Meyer and Stahl, 2019).

Clozapine is associated with several adverse effects, the most concerning of which is severe neutropenia, with an incidence of slightly under 1%; the highest risk occurs during the initial 6 months of treatment, peaking at months 2 to 3 and diminishing rapidly thereafter (Meyer and Stahl, 2019). The mechanism is immune mediated, and patients who have severe neutropenia are usually not rechallenged, with rare exceptions (Meyer and Stahl, 2019). An extensive algorithm guiding clinical response to neutropenia is available from manufacturer websites and must be followed, along with mandated absolute neutrophil count monitoring. An important update to the U.S. prescribing guidelines lowered the starting neutropenia threshold for those with benign ethnic neutropenia to 1000/mm^3.

Other uncommon antipsychotic-related adverse effects include pigmentary retinopathy (*thioridazine* at daily doses ≥800 mg/day), photosensitivity, and elevations of alkaline phosphatase and, rarely, hepatic transaminases (low-potency phenothiazines).

Increased Mortality in Patients With Dementia. Perhaps the least-understood adverse effect is the increased risk for cerebrovascular events and all-cause mortality among elderly patients with dementia exposed to antipsychotics (~1.7-fold increased mortality risk for drug vs. placebo) (Maust et al., 2015). Mortality is due to heart failure, sudden death, or pneumonia. The underlying etiology for antipsychotic-related cerebrovascular and mortality risk is unknown, but the finding of virtually equivalent mortality risk for FGAs and SGAs (including *aripiprazole*) suggests an impact of reduced D_2 signaling regardless of individual antipsychotic mechanisms.

Drug-Drug Interactions

Antipsychotics are not significant inhibitors of CYPs, with a few notable exceptions: *chlorpromazine*, *perphenazine*, and *thioridazine* inhibit CYP2D6, and *asenapine* increases *paroxetine* levels 2-fold, presumably by CYP inhibition. The plasma half-lives of most antipsychotics are influenced by induction or inhibition of hepatic CYPs and by genetic polymorphisms that alter specific CYP activities (see Table 19–4). While antipsychotics are highly protein bound, the binding sites are to α_1-glycoproteins. There is no evidence of significant displacement of other protein-bound medications that bind to albumin or prealbumin, so dosage adjustment is not required for anticonvulsants, *warfarin*, or other agents with narrow therapeutic indices. Antipsychotics are not removed by renal dialysis (Meyer and Stahl, 2021).

It is also important to consider the kinetic effects of environmental exposures (smoking, nutraceuticals, grapefruit juice) on drug metabolism and the impact of changes in these behaviors. Aromatic hydrocarbons in tobacco smoke induce CYP1A2, so changes in smoking status can be especially problematic for *clozapine*-treated patients (Meyer and Stahl, 2019). Placing a smoker in a smoke-free environment will result in decreased CYP1A2 activity and an elevation of *clozapine* plasma levels, with potentially toxic results. Conversely, a patient discharged from a nonsmoking facility who resumes smoking will experience an increase in CYP1A2 activity and a 50% decrease in plasma *clozapine* levels. Monitoring of plasma *clozapine* concentrations, anticipation of changes in smoking habits, and dosage adjustment can minimize development of subtherapeutic or supratherapeutic levels. Serious bacterial or viral infections (e.g., COVID-19), and occasionally the COVID-19 vaccination itself, cause marked cytokine release, and this significantly downregulates CYP1A2 expression. This decreased CYP1A2 availability can induce *clozapine* toxicity (Meyer and Stahl, 2019; Tio et al., 2021).

Use in Pediatric Populations

Aripiprazole, *olanzapine*, *quetiapine*, *risperidone*, *lurasidone*, and *paliperidone* have indications for adolescent schizophrenia (ages 13–17). *Aripiprazole*, *quetiapine*, and *risperidone* are approved in child and adolescent acute mania (ages 10–17), and *lurasidone* is approved for bipolar I depression in this same age group; *risperidone* and *aripiprazole* are also FDA-approved for irritability associated with autism in child and adolescent patients (ages 5–16). As discussed in the sections on adverse effects, antipsychotic drug-naïve patients and younger patients are more susceptible than other patients to EPSs and weight gain (Correll et al., 2020). Use of the minimum effective dose can minimize EPS risk, and use of agents with lower weight gain liability is critical. The greater impact of *risperidone* and *paliperidone* on serum prolactin must be monitored. Delayed sexual maturation was not seen in adolescents in clinical trials with *risperidone*; nonetheless, the prescriber must be alert for such changes and for issues such as amenorrhea in girls and gynecomastia in boys and girls. There are compelling data for the use of *metformin* to mitigate the higher weight gain liability of SGAs in child/adolescent patients (Correll et al., 2020).

Use in Geriatric Populations

The increased sensitivity to EPSs, orthostasis, sedation, and anticholinergic effects are important for the geriatric population and often dictate the choice of antipsychotic medication. Avoidance of drug-drug interactions is also important, as older patients are on numerous concomitant medications. Dose adjustment can offset known drug-drug interactions, but clinicians must be attentive to changes in concurrent medications and the potential pharmacokinetic and pharmacodynamic consequences. Vigilance must also be maintained for the additive pharmacodynamic effects of α_1 adrenergic, antihistaminic, and anticholinergic properties of other agents.

Elderly patients have an increased risk for TD and parkinsonism, with TD rates about 5-fold higher than those seen with younger patients. With FGAs, the reported annual TD incidence among elderly patients is 20% to 25%, compared to 4% to 5% for younger patients. With SGAs, the annual TD rate in elderly patients is much lower (2%–3%). Increased risk for cerebrovascular events and all-cause mortality is also seen in elderly patients with dementia (see Increased Mortality in Patients With Dementia). Compared to younger patients, antipsychotic-induced weight gain is lower in elderly patients.

Use During Pregnancy and Lactation

Results from a recent large database study comprising 9991 women with first-trimester exposure did not show increased rates of major congenital malformations (MCMs) after first-trimester antipsychotic exposure (Huybrechts et al., 2016). While concerns over MCM risk have lessened, antipsychotic drugs are designed to cross the blood-brain barrier and also have high rates of placental passage. Placental passage ratios are estimated to be highest for *olanzapine* (72%), followed by *haloperidol* (42%), *risperidone* (49%), and *quetiapine* (24%). This has implications for neonatal care at time of delivery, including concerns over EPSs, sedation, or withdrawal syndromes in the newborn. Neonates exposed to *olanzapine*, the atypical agent with highest placental passage ratio, exhibit a trend toward greater neonatal intensive care unit admission, and exposure to sedating medications such as *clozapine* can be associated with decreased arousal and hypotonia ("floppy baby" syndrome). Schizophrenia spectrum patients should continue medication throughout pregnancy, but tapering antipsychotics used for other indications can be considered for 1 to 2 weeks prior to the expected delivery date to lessen neonatal exposure. Use in nursing mothers raises a separate set of concerns due to the reduced capacity of the newborn to metabolize xenobiotics, thus presenting a significant risk for antipsychotic toxicity. Available data do not provide adequate guidance on choice of agent, and only *clozapine* is absolutely contraindicated in breastfeeding mothers due to risk for neutropenia, sedation, and seizures in the infant (Meyer and Stahl, 2019).

Major Drugs Available in the Class

Atypical antipsychotics have largely replaced older agents, primarily due to their more favorable EPS profile. However, high-potency FGAs are widely used when a higher level of D_2 antagonism is required. Table 19–1 describes the acute and maintenance doses for adult schizophrenia treatment based on consensus recommendations. There are numerous LAI FGA formulations (see Table 19–2), but in the U.S., the only available LAI FGAs are *fluphenazine* and *haloperidol* (as decanoate esters). There are now multiple LAI SGAs approved, including a 2-month form of *aripiprazole* (*aripiprazole lauroxil*), and both 3- and 6-month forms of LAI *paliperidone*. *Pimavanserin* is the only medication indicated for PDP; it does not worsen motor symptoms due to the lack of DA antagonism (Cummings et al., 2014).

Treatment of Mania

Mania is a period of elevated, expansive, or irritable mood with coexisting symptoms of increased energy and goal-directed activity and decreased need for sleep. Mania represents one pole of bipolar I disorder. As with psychosis, mania may be induced by prescribed medications (e.g., DA agonists, antidepressants, stimulants) or substances of abuse, primarily cocaine and amphetamines, although periods of substance-induced mania should not be relied on solely to make a diagnosis of bipolar disorder. However, a full manic episode that emerges during antidepressant treatment (for example) *but persists at a fully syndromal level beyond the physiological effect of that treatment* is sufficient evidence for a manic episode and, therefore, a bipolar I diagnosis.

Mania is distinguished from its less-severe form, hypomania, by the fact that hypomania, by definition, does not result in functional impairment or hospitalization. Patients who experience periods of hypomania and major depression have bipolar II disorder; those with mania at any time, bipolar I; and those with hypomania but less-severe forms of depression, cyclothymia. The prevalence of bipolar I disorder is roughly 1% of the population, and the prevalence of all forms of bipolar disorder is 3% to 5%.

Genetic studies of bipolar disorder have yielded several loci of interest associated with disease risk and predictors of treatment response, but the data are not yet at the phase of clinical application. Unlike schizophrenia, for which the biological understanding of monoamine neurotransmission has permitted synthesis of numerous effective compounds, no medication has yet been designed to treat the full spectrum of bipolar disorder based on biological hypotheses of the illness. Lithium carbonate was introduced fortuitously in 1949 for the treatment of mania and approved for this purpose in the U.S. in 1970. While many classes of agents demonstrate efficacy in acute mania, including Li^+, antipsychotic drugs, and certain anticonvulsants, no medication has surpassed Li^+'s efficacy for prophylaxis of future manic and depressive phases of bipolar disorder, and no other medication has demonstrated Li^+'s reduction in suicidality among bipolar patients (Baldessarini et al., 2019). There is also compelling data supporting Li^+'s neuroprotective effects based on decreased dementia risk in older bipolar patients maintained on Li^+ (Velosa et al., 2020).

Pharmacological Properties of Agents for Mania

Antipsychotic Agents

The chemistry and pharmacology of antipsychotics are addressed earlier in this chapter. When used for acute mania, the dosages are often at the high end of approved maximum dosing, and the antimanic effect relates to D_2 blockade, not sedation from H_1 antagonism. *Clozapine* can be beneficial in patients with treatment-resistant mania as adjunctive therapy and as monotherapy (Meyer and Stahl, 2019). Certain antipsychotics have efficacy for adjunctive use (*olanzapine/fluoxetine* combination, *lumateperone*, *lurasidone*, *quetiapine*, *lumateperone*) or as monotherapy (*quetiapine*, *lurasidone*, *cariprazine*, *lumateperone*) for bipolar depression, typically at lower dosages than those used for schizophrenia or acute mania.

Anticonvulsants

The pharmacology and chemistry of the anticonvulsants used in treating acute mania (VPA compounds, *carbamazepine*) and for bipolar maintenance (*lamotrigine*) are covered extensively in Chapter 20. The therapeutic serum levels for the commonly used mood-stabilizing anticonvulsants and for Li^+ are listed in Table 19–6.

Lithium

Lithium is the lightest of the alkali metals (group Ia). Salts of Li^+ share some characteristics with those of Na^+ and K^+. Li^+ is readily assayed in biological fluids and can be detected in brain tissue by magnetic resonance spectroscopy. Traces of the ion occur normally in animal tissues, but it has no known physiological role. Li^+ carbonate and Li^+ citrate are used therapeutically in the U.S.

Therapeutic concentrations of Li^+ have almost no discernible psychotropic effects in individuals without psychiatric symptoms. There are numerous molecular and cellular actions of Li^+, some of which overlap with identified properties of other mood-stabilizing agents (particularly VPA) and are discussed next. An important characteristic of Li^+ is that, unlike Na^+ and K^+, Li^+ develops a relatively small gradient across

TABLE 19–6 ■ COMPARATIVE EFFICACY AND TARGET SERUM LEVELS FOR MOOD STABILIZERS

	ACUTE MANIA	PROPHYLAXIS	BIPOLAR DEPRESSION
Lithium	+++ 1.0–1.5 mEq/L[a]	+++ 0.6–1.0 mEq/L[b]	+ 0.6–1.0 mEq/L
Valproate	++++ 100–120 μg/mL[c]	+++ 60–100 μg/mL	—
Carbamazepine	+ 6–12 μg/mL	++ 6–12 μg/mL	+ 6–12 μg/mL
Lamotrigine	—	++	++ 2.5–20 μg/mL[d]

[a]Lithium can be loaded with three 10 mg/kg doses of an extended-release preparation administered at 4 PM, 6 PM, and 8 PM (Kook et al., 1985). Treatment should continue on day 2 with lithium carbonate given once nightly to minimize the risk of polyuria and renal insufficiency.
[b]Outpatient levels should never exceed 1.2 mEq/L, as this increases the risk of long-term renal insufficiency by 74% (Castro et al., 2016).
[c]Divalproex can be loaded at 30 mg/kg over 24 h, administered as a single dose or separated into two doses.
[d]These levels are based on anticonvulsant use and do not necessarily correlate with efficacy for mood disorders.

biological membranes. Although it can replace Na^+ in supporting a single action potential in a nerve cell, it is not a substrate for the Na^+ pump and therefore cannot maintain membrane potentials. It is uncertain whether therapeutic concentrations of Li^+ (0.5–1.0 mEq/L) affect the transport of other monovalent or divalent cations by nerve cells.

Hypotheses for the Mechanism of Action of Lithium and Relationship to Anticonvulsants

Plausible hypotheses for the mechanism of action focus on Li^+'s impact on monoamines implicated in the pathophysiology of mood disorders and on second-messenger and other intracellular molecular mechanisms involved in signal transduction, gene regulation, and cell survival. Li^+ has limited effects on catecholamine-sensitive adenylyl cyclase activity or on the binding of ligands to monoamine receptors in brain tissue, although it can influence response of 5HT autoreceptors to agonists. Presynaptic 5HT release is regulated by $5HT_{1a}$ autoreceptors located on the cell body and $5HT_{1b}$ receptors on the nerve terminal. *In vitro* electrophysiological studies suggest that Li^+ facilitates 5HT release. Li^+ augments effects of antidepressants, and in animal models of depression, Li^+'s activity appears to be mediated through desensitizing actions at $5HT_{1b}$ sites; Li^+ also antagonizes mouse behaviors induced by administration of selective $5HT_{1b}$ agonists.

Li^+ inhibits inositol monophosphatase and interferes with the cycling of the phosphatidylinositol (PI) pathway (see Figure 19–1). One result is an enhancement of IP_3 accumulation when the G_q-PLC-IP_3-Ca^{2+} pathway is activated. As a result, IP_3 signaling and consequent mobilization of Ca^{2+} from intracellular stores may also be enhanced acutely, along with the sequelae of those effects: Ca^{2+} mobilization and PKC activation; another result is a decrease in available inositol for resynthesis/reincorporation into membrane PI phosphates. The uncompetitive inhibition of inositol phosphatase by Li^+ occurs within the range of therapeutic Li^+ concentrations. A genome-wide association study implicated diacylglycerol kinase in the etiology of bipolar disorder, strengthening the association between Li^+ actions and PI metabolism. Further support for the role of inositol signaling in mania rests on the finding that VPA and its derivatives decrease intracellular inositol concentrations. Unlike Li^+, VPA decreases inositol through inhibition of myo-inositol-1-phosphate synthase. In cultured cell systems, *carbamazepine* also appears to act via inositol depletion and may contribute to VPA's and *carbamazepine*'s mood-stabilizing properties.

Treatment with Li^+ ultimately leads to decreased activity of several protein kinases in brain tissue, including PKC, particularly isoforms α and β (Valvassori et al., 2020). Among other proposed antimanic or mood-stabilizing agents, this effect is also shared with VPA (particularly for PKC) but not with *carbamazepine* (Einat et al., 2007). Long-term treatment of rats with Li^+ carbonate or VPA decreases cytoplasm-to-membrane translocation of PKC and reduces PKC stimulation–induced release of 5HT from cerebral cortical and hippocampal tissue. Excessive PKC activation can disrupt prefrontal cortical regulation of behavior, but pretreatment of monkeys and rats with Li^+ carbonate or VPA blocks the impairment in working memory induced by activation of PKC in a manner also seen with the PKC inhibitor *chelerythrine*. A major substrate for cerebral PKC is the MARCKS protein, which is implicated in synaptic and neuronal plasticity. The expression of MARCKS protein is reduced by treatment with both Li^+ and VPA but not by *carbamazepine*, antipsychotics, or antidepressants. This proposed mechanism of PKC inhibition has been the basis for therapeutic trials of *tamoxifen*, a selective estrogen receptor modulator that is also a potent centrally active PKC inhibitor. In acutely manic bipolar I patients, *tamoxifen* has shown evidence of efficacy as adjunctive treatment (Valvassori et al., 2020). The impact of Li^+ or VPA on PKC activity may secondarily alter the activity of tyrosine hydroxylase.

Both Li^+ and VPA treatment also inhibit the activity of GSK-3β. GSK-3 inhibition increases hippocampal levels of β-catenin, a function implicated in mood stabilization. In animal models, Li^+ induces molecular and behavioral effects comparable to those seen when one GSK-3β gene locus is inactivated (Alda, 2015). These Li^+-sensitive behaviors are related to the impact of Li^+ on the stability of the β-arrestin-2/PKB/PP2A signaling complex. Li^+ disrupts β-arrestin-2/PKB/PP2A complex formation and thus prevents PP2A from dephosphorylating (and thereby inactivating) the serine-threonine kinase Akt. While Akt remains active, it continues to phosphorylate the ser^9 residue on GSK-3β, directly inhibiting GSK-3β activity.

Another proposed common mechanism for the actions of Li^+ and VPA relates to reduction in arachidonic acid turnover in brain membrane phospholipids. Rats fed Li^+ in amounts that achieve therapeutic CNS drug levels have 83% reduced turnover of PI and 73% reduced turnover of phosphatidylcholine; chronic intraperitoneal VPA achieves reductions of 34% and 36%, respectively. Li^+ also decreases gene expression of phospholipase A_2 and levels of cyclooxygenase 2 (COX-2) and its products (Alda, 2015).

ADME

Li^+ is almost completely absorbed from the GI tract. Peak plasma concentrations occur 2 to 4 h after an oral dose, although peak CNS levels occur on average 3 hours later (Malhi and Tanious, 2011). As noted below, Li^+ is always dosed once daily at night for two reasons: once-daily dosing minimizes renal adverse effects, and nighttime dosing allows one to obtain 12-h trough levels in the morning (Castro et al., 2016). Slow-release preparations of Li^+ carbonate have lower maximal levels and a delayed peak, which may help mitigate GI adverse effects (Malhi and Tanious, 2011). Li^+ initially distributes to the extracellular fluid, does not bind appreciably to plasma proteins, and gradually accumulates in tissues, with a volume of distribution of 0.7 to 0.9 L/kg. The concentration gradient across plasma membranes is much smaller than those for Na^+ and K^+. Passage through

the blood-brain barrier is slow, and when a steady state is achieved, the concentration of Li^+ in the cerebrospinal fluid and in brain tissue is about 40% to 50% of the concentration in plasma. The kinetics of Li^+ can be monitored in human brain with magnetic resonance spectroscopy.

Approximately 95% of a single dose of Li^+ is eliminated in the urine, with a $t_{1/2}$ of about 24 h (varies with age and can be ~12 h in the young and ~36 h in the elderly [secondary to reduced glomerular filtration rate (GFR)]). That the CNS $t_{1/2}$ is approximately 28 h also supports once-daily dosing. As noted above, once-nightly dosing not only improves adherence but decreases long-term risk for renal insufficiency by at least 20% compared to multiple daily dosing (Castro et al., 2016). With repeated administration, Li^+ levels and excretion increase until a steady state is achieved (after 4–5 half-lives). When Li^+ is stopped, there is a rapid phase of renal excretion followed by a slow 10- to 14-day phase. Although the pharmacokinetics of Li^+ vary considerably among subjects, the volume of distribution and clearance are relatively stable in an individual patient.

Less than 1% of ingested Li^+ leaves the human body in the feces; 4% to 5% is secreted in sweat. Li^+ is secreted in saliva in concentrations about twice those in plasma, while its concentration in tears is about equal to that in plasma. Li^+ is secreted in human milk, but serum levels in breast-fed infants are only 20% that of maternal levels and are not associated with notable behavioral effects, although impact on thyroid function was noted in one case (Imaz et al., 2019).

Li^+ competes with Na^+ for proximal tubular reabsorption, and Li^+ retention can be increased by Na^+ loss related to diuretic use, diarrhea, and other GI illness. Heavy sweating leads to a preferential secretion of Li^+ over Na^+ in sweat and may lower Li^+ levels slightly; however, the repletion of excessive sweating using free water without electrolytes can cause hyponatremia and promote Li^+ retention.

Serum-Level Monitoring and Dose

Because of Li^+'s narrow therapeutic index, regular determination of serum concentrations is crucial. Concentrations considered to be effective and acceptably safe are between 0.6 and 1.5 mEq/L. The range of 1.0 to 1.5 mEq/L is favored *only* for treatment of acutely manic patients. Lower values (0.6–1.0 mEq/L) are safer for long-term prophylaxis, with long-term risk for renal insufficiency associated with any outpatient levels that exceed 1.2 mEq/L (Castro et al., 2016). Serum concentrations of Li^+ have been found to follow a dose-effect relationship between 0.4 and 1.0 mEq/L, but with a corresponding dose-dependent rise in polyuria and tremor as indices of adverse effects (Gitlin, 2016). Nonetheless, patients who maintain trough levels of 0.8 to 1.0 mEq/L experience decreased mania relapse risk compared to those maintained at lower serum concentrations. There are patients who may do well with serum levels of 0.5 to 0.8 mEq/L, but there are no current clinical or biological predictors to permit *a priori* identification of these individuals. Individualization of serum levels is often necessary to obtain a favorable risk-benefit relationship.

By convention, the serum Li^+ concentration is measured from samples obtained 10 to 12 h after the evening dose. Single daily doses at night generate relatively large oscillations of plasma Li^+ concentration but lower mean trough levels than with multiple daily dosing; moreover, single nightly dosing means that peak serum levels occur during sleep, so complaints of CNS adverse effects are minimized (Gitlin, 2016). While relatively uncommon, GI complaints are a compelling reason for using delayed-release Li^+ preparations, also given once daily at night.

Therapeutic Uses

Drug Treatment of Bipolar Disorder. Treatment with Li^+ ideally is initiated in patients with acceptable renal function, typically defined as estimated glomerular filtration rate (eGFR) greater than 70 mL/min. Occasionally, patients with severe systemic illnesses are treated with Li^+ provided that the indications are compelling, but the need for medications that pose potential kinetic problems often precludes Li^+ use in those with multiple medical problems. Treatment of acute mania and the prevention of recurrences of bipolar illness in adults or adolescents are uses approved by the FDA. Li^+ is the mood stabilizer with the most robust data on suicide reduction in bipolar patients (Baldessarini et al., 2019); Li^+ is also efficacious for augmentation in unipolar depressive patients who respond inadequately to antidepressant therapy and is also associated with a 5-fold reduction in suicidality in that population compared to nonlithium therapies.

Pharmacotherapy of Mania. The modern treatment of the manic, depressive, and mixed-mood phases of bipolar disorder was revolutionized by the introduction of Li^+ in 1949, initially for acute mania only and later for prevention of mania recurrence. While Li^+, VPA, and *carbamazepine* have efficacy in acute mania, in clinical practice, these are usually combined with atypical antipsychotic drugs, even in manic patients without psychotic features, due to their complementary modes of action. Li^+, *carbamazepine*, and VPA preparations are effective only with daily dosing that maintains adequate serum levels, and thus require monitoring of serum levels. Patients with mania are often irritable and poorly cooperative with medication administration and phlebotomy; thus, atypical antipsychotic drugs may be the sole initial therapy. While antipsychotics have proven efficacy as monotherapy for acute mania, population-based cohort studies indicate that relapse rates are high when used long term as monotherapy (Wingård et al., 2019). Acute intramuscular forms of *olanzapine* and *ziprasidone* can be used to achieve rapid control of psychosis and agitation. Benzodiazepines are often used adjunctively for agitation and sleep induction, but use outside of acute hospital settings is discouraged due to concerns about tolerance and dependence.

Li^+ is effective in acute mania and can be loaded in those with normal renal function using three individual 10-mg/kg doses of a sustained-release preparation administered at 2-h intervals in the evening (Kook et al., 1985). Since Li^+ has a 28-h $t_{1/2}$ in the CNS there is no plausible reason for split daily dosing or routine use of sustained-release preparations. The sustained-release form is only used to minimize GI adverse effects (e.g., nausea, diarrhea) due to the lower C_{max} and delayed peripheral t_{max}. Acutely manic patients may require higher dosages to achieve therapeutic serum levels, and downward adjustment may be necessary once the patient is euthymic. Efficacy following loading can be achieved within 5 days. When adherence with oral capsules or tablets is an issue, the liquid Li^+ citrate can be used. A 300-mg dose of Li^+ carbonate provides 56 mg of elemental Li^+, which is equivalent to 8 mEq. Li^+ citrate can be ordered in either milligram or milliequivalent doses, with most forms of the syrup containing 300 mg (or 8 mEq) per 5 mL.

The anticonvulsant VPA also provides antimanic effects, with therapeutic benefit seen within 3 to 5 days when loaded. The most common form of VPA is *divalproex* due to its lower incidence of GI and other adverse effects. *Divalproex* is initiated at 30 mg/kg given as single or divided doses in the first 24 h, and then titrated to effect based on the desired 12-h trough serum level. Trough serum concentrations of 90 to 120 μg/dL show the best response in clinical studies. With immediate-release forms of VPA and *divalproex*, 12-h troughs are used to guide treatment. With the extended-release *divalproex* preparation, the trough occurs 24 h after dosing. However, obtaining serum levels at night may be difficult in outpatient settings, so 12-h troughs are commonly used, bearing in mind that 12-h trough levels for sustained-release *divalproex* are 18% to 25% higher than the 24-h trough.

Divalproex lacks Li^+'s risk for renal and thyroid adverse effects, but there is concern about its use in women of reproductive age related to risks of polycystic ovary syndrome and also the known mutagenic potential, which demands routine use of contraception (Anmella et al., 2019). *Divalproex* is also associated with hyperammonemia due to effects on the carnitine shuttle and can induce thrombocytopenia and neutropenia. Given Li^+'s superior efficacy for depressive episodes and for reduction in suicidal behavior, Li^+ should be preferentially used for bipolar I prophylaxis unless there is a clear medical contraindication to initiation (e.g., baseline eGFR <60 mL/min). *Carbamazepine* is effective for acute mania, but *carbamazepine* cannot be loaded or rapidly titrated over 24 h due to the development of adverse effects such as dizziness or ataxia, even within the therapeutic range (6–12 μg/dL). An extended-release form of *carbamazepine* is effective as monotherapy with once-daily dosing.

Carbamazepine response rates are lower than those for VPA compounds or for Li^+, with mean rates of 45% to 60% (Post et al., 2007). Nevertheless, certain individuals respond to *carbamazepine* after failing Li^+ and VPA. Initial doses are 400 mg/day in two divided doses. Titration proceeds by 200-mg increments every 24 to 48 h based on clinical response and serum trough levels, not to exceed 1600 mg/day.

Serious and potentially fatal skin reactions (e.g., Stevens-Johnson syndrome and toxic epidermal necrolysis) may occur with administration of *carbamazepine* in patients positive for the HLA-B*1502 allele. The FDA recommends genetic screening in patients of Asian ancestry (among whom the prevalence of this allele is >15%) before initiation of *carbamazepine* therapy and recommends using alternative therapies in patients positive for the allele. See Chapter 20 for more information on *carbamazepine*.

Lamotrigine has no role in acute mania due to the slow, extended titration necessary to minimize risk of Stevens-Johnson syndrome. It is used for bipolar maintenance and for treatment of depressive phases, although the antidepressant effect is delayed considerably due to the slow titration to effective doses (200–400 mg/day).

Prophylactic Treatment of Bipolar Disorder. The medication choice for prophylaxis is determined by the need for continued antipsychotic drug use to mitigate manic or depressive relapse and for use of a mood-stabilizing agent. Both *aripiprazole* and *olanzapine* are effective as monotherapy for mania prophylaxis, but *olanzapine* use is eschewed out of concern for metabolic effects, and *aripiprazole* offers no benefit for prevention of depressive relapse. LAI *risperidone* is also approved for bipolar maintenance treatment as monotherapy or adjunctively with Li^+ or VPA. Despite these indications, population-based cohort data indicate that bipolar I patients on antipsychotic monotherapy after a manic episode fare poorly, with higher relapse rates than patients on Li^+ monotherapy (Wingård et al., 2019). Relapse rates are lowest for bipolar I patients maintained on combination therapy with a primary mood stabilizer (e.g., Li^+ or VPA) and an antipsychotic, although many patients do well on mood stabilizer monotherapy and thus avoid adverse effects. In patients exhibiting sustained remission following a manic episode, the optimal duration of antipsychotic treatment is unclear.

Overriding concerns during bipolar treatment are the high recurrence rate and the high risk of suicide. Individuals who experience mania have an 80% to 90% lifetime risk of subsequent manic episodes. As with schizophrenia, lack of insight, poor psychosocial support, and substance abuse all interfere with treatment adherence. While the anticonvulsants *lamotrigine*, *carbamazepine*, and *divalproex* have data supporting their use in bipolar prophylaxis, only Li^+ has consistently been shown to reduce the risk of suicide compared to other treatments. *Lamotrigine* is effective for bipolar patients whose most recent mood episode was manic or depressed, with greater effect on depressive relapse (Baldessarini et al., 2019). The ability to provide prophylaxis for future depressive episodes combined with data in acute bipolar depression have made *lamotrigine* a useful choice for bipolar treatment, given that patients with bipolar I and bipolar II disorders spend 32% and 50% of the time, respectively, in a depressive phase. While *lamotrigine* requires no serum level monitoring and lacks many of the adverse effects seen with Li^+ and VPA (e.g., weight gain, tremor), it causes class IB antiarrhythmic activity at therapeutically relevant concentrations. Based on this finding, the U.S. FDA issued a warning in March 2021 that *lamotrigine* could slow ventricular conduction and induce arrhythmias, including sudden death, in those with cardiac conduction disorders (second- or third-degree heart block), ventricular arrhythmias, myocardial ischemia, heart failure, structural heart disease, Brugada syndrome, or other Na^+ channelopathies. Concomitant use of other Na^+ channel blockers may increase the risk of arrhythmia.

Bipolar disorder is a lifetime illness with high recurrence rates. Individuals who experience an episode of mania should be educated about the probable need for ongoing treatment. Stopping mood stabilizer therapy can be considered in patients who have experienced only one lifetime manic episode, particularly when there may have been a pharmacological precipitant (e.g., substance or antidepressant use), and who have been euthymic for extended periods. For patients with bipolar II, the impact of hypomania is relatively limited, so the decision to recommend prolonged maintenance treatment with a mood stabilizer is based on clinical response and the risk:benefit ratio. Discontinuation of maintenance Li^+ treatment in patients with bipolar I carries a high risk of early recurrence and of suicidal behavior over a period of several months, even if the treatment had been successful for several years. Recurrence is much more rapid than is predicted by the natural history of untreated bipolar disorder, in which cycle lengths average about 1 year. This risk may be moderated by slow, gradual removal of Li^+; rapid discontinuation should be avoided unless dictated by medical emergencies.

Other Uses of Lithium. Li^+ is effective as adjunct therapy in treatment-resistant major depression. Meta-analyses indicated that Li^+'s benefit on suicide reduction extends to patients with unipolar mood disorder (Tondo et al., 2001). While maintenance Li^+ levels in the range of 0.6 to 1.0 mEq/L are used for bipolar prophylaxis, a lower range (0.4–0.6 mEq/L) is recommended for antidepressant augmentation.

When older patients maintain sufficient eGFR to continue Li^+ (e.g., ≥50 mL/min), it is well-tolerated without evidence of disproportionate safety concerns, especially when compared to *divalproex* (Fotso Soh et al., 2019). The most compelling reasons to continue Li^+ in older bipolar I individuals with acceptable eGFR are the neuroprotective properties. Long-term use of Li^+ is associated with a decreased dementia risk of 50% (Velosa et al., 2020), and this effect emerges with as little as 301 to 365 days of treatment. Based on animal and human data documenting neuroprotective properties, Li^+ treatment has been suggested for conditions associated with excitotoxic and apoptotic cell death, such as stroke and spinal cord injury, and in neurodegenerative disorders, including dementia of the Alzheimer type, Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis, progressive supranuclear palsy, and spinocerebellar ataxia type I (Morris and Berk, 2016).

Drug Interactions. Li^+ levels are increased with medical conditions and with use of medications that promote hyponatremia due to the decreased competition with Na^+ for proximal resorption. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) increase Li^+ levels, and this effect can be managed by obtaining an Li^+ level after 1 week of combination therapy and downward adjustment of the Li^+ dose to prevent toxicity (Meyer et al., 2005). The unique exception is the ACEI *lisinopril* due to the fact that *lisinopril* is 100% renally cleared. *Lisinopril* accumulates in those with subnormal renal function, and the steadily increasing *lisinopril* levels lead to higher Li^+ levels, decreased renal function, and even higher *lisinopril* levels in a positive feedback loop (Meyer et al., 2005). *Lisinopril should never be used with* Li^+; any other ACEI can be used with dosing adjustment based on levels. Distal collecting tubule diuretics cause Na^+ wasting and thereby increase reabsorption of Li^+ proximally. Among the commonly used agents in this class, the thiazides present the greatest risk and must be avoided. *Amiloride* causes less Na^+ wasting and can be used to manage Li^+-related polyuria as discussed below. Loop diuretics such as *furosemide* decrease Li^+ clearance only approximately 20% in healthy younger individuals and are the diuretics of choice for most patients on Li^+. However, older patients, particularly those with some degree of renal dysfunction, may become sufficiently volume contracted and Na^+ depleted during *furosemide* therapy that virtually all filtered Li^+ is reabsorbed in the proximal tubule leading to risk of toxicity (Juurlink et al., 2004). Through alteration of renal perfusion, some nonsteroidal anti-inflammatory agents can facilitate renal proximal tubular resorption of Li^+ and thereby increase serum concentrations. This interaction appears to be particularly prominent with *indomethacin*, but also may occur with *ibuprofen*, *naproxen*, *meloxicam*, *ketorolac*, and COX-2 inhibitors, and less so with *sulindac* and *aspirin*.

Adverse Effects of Lithium

CNS Effects. The most common effect of Li^+ in the therapeutic dose range is fine postural hand tremor, indistinguishable from essential tremor. Severity and risk for tremor are dose and serum level dependent, with incidence ranging from 15% to 70%. In addition to the avoidance

of caffeine and other agents that increase tremor amplitude, therapeutic options include dose reduction (bearing in mind the increased relapse risk with lower serum Li^+ levels) and the β-adrenergic antagonist *propranolol* (also effective for VPA-induced tremor). At peak serum (and CNS) levels of Li^+, patients may complain of incoordination, ataxia, or slurred speech, all of which can be avoided by dosing Li^+ at bedtime.

Seizures have been rarely reported in nonepileptic patients with therapeutic plasma concentrations of Li^+. Li^+ treatment has also been associated with increased risk of post-ECT confusion and is generally tapered off prior to a course of ECT. In some instances, addition of Li^+ to existing antipsychotics may increase the sensitivity to D_2 blockade resulting in EPSs.

Li^+ treatment results in weight gain, a problem magnified by concurrent use of antipsychotic drugs. There is one case report of *metformin* use to mitigate Li^+-related weight gain (Praharaj, 2016), and this should be considered especially in those on concurrent SGA therapy.

Renal Effects. The kidney's ability to concentrate urine decreases during Li^+ therapy, and about 60% of individuals exposed to Li^+ experience some form of polyuria and compensatory polydipsia. The mechanism of polyuria is related to the fact that Li^+ has 1.5- to 2.0-fold greater affinity than Na^+ for the epithelial Na^+ channel (ENaC) present on the apical (i.e., luminal) surfaces of distal tubular cells (Grünfeld and Rossier, 2009). Intracellular Li^+ is a poor substrate for the Na^+/K^+-ATPase present on the basal membrane, leading to accumulation of Li^+ in these distal tubular cells; high intracellular Li^+ concentrations inhibit GSK-3β, causing vasopressin insensitivity, downregulation of aquaporin-2 channels, and nephrogenic diabetes insipidus (NDI). Multiple daily dosing increases this risk at least 20%. Renal function should be monitored with semiannual serum blood urea nitrogen and creatinine levels for calculation of eGFR, and urine osmolality to monitor development of NDI (Morriss and Benjamin, 2008). Patient complaints of polyuria should be solicited throughout the course of Li^+ treatment so that the extent of the problem can be quantified using a spot urine osmolality. Li^+ discontinuation or a switch to single daily dosing may reverse the impact on renal concentrating ability in patients with less than 5 years of Li^+ exposure, but the preferred option is use of *amiloride,* which blocks entry of Li^+ into renal distal tubule ENaCs and has been used to safely manage NDI associated with Li^+ therapy (Bedford et al., 2008). This use of *amiloride* requires electrolyte monitoring to track Na^+ depletion that may necessitate Li^+ dosage adjustments (Bedford et al., 2008). Reassessment of Li^+ treatment should be considered when the eGFR is less than 60 mL/min on several periodic measurements, when daily urinary volume exceeds 4 L, or when serum creatinine continues to rise on three separate occasions; discontinuation is recommended when eGFR is less than 50 mL/min to prevent toxicity and further declines in renal function (Schoot et al., 2020). With modern monitoring principles, no patient should develop stage 3b chronic kidney disease (eGFR 30–44 mL/min), and patients should never have renal dysfunction to the extent of requiring renal dialysis.

Thyroid and Endocrine Effects. A small number of patients on Li^+ develop a benign, diffuse, nontender thyroid enlargement suggestive of compromised thyroid function; many of these patients will have normal thyroid function. Measurable effects include overt hypothyroidism (7%–10%) and subclinical thyroid disease (23%), with women at 3 to 9 times greater risk than men (Gitlin, 2016). Ongoing monitoring of thyrotropin (TSH) and free thyroxine is recommended throughout the course of Li^+ treatment. The development of hypothyroidism is easily treated through exogenous replacement and is not a reason to discontinue Li^+ therapy. Rare reports of hyperthyroidism during Li^+ treatment also exist. Hypercalcemia related to hyperparathyroidism has been reported in about 10% of Li^+-treated patients. Routine monitoring of serum Ca^{2+} should be included with measurements of electrolytes, thyroid indices, renal function, and serum Li^+ levels.

ECG Effects. Li^+ induces ECG changes related to dose-dependent inhibition of myocyte voltage-gated Na^+ channels and decreases in intracellular K^+ levels (Mehta and Vannozzi, 2017). T-wave depression is the most widely reported ECG change (incidence, 16%–33%). Those with more substantial T-wave changes may have U waves as seen with hypokalemia. T-wave changes depend on the duration of treatment rather than the Li^+ level and are usually reversible. Sinus node dysfunction and bradycardia are the second most common finding. Li^+ slows atrial conduction time, with complete right bundle branch block seen in 6.5% and incomplete intraventricular conduction delay in 6.5%. Li^+ may unmask rare asymptomatic Brugada syndrome patients (up to 0.5%). Li^+ can cause electrical instability in both the atria and ventricles; significant cardiac toxicity with symptomatic bradycardia, ST depression or elevation, and conduction problems is usually only seen with Li^+ levels greater than 1.5 mEq/L (Mehta and Vannozzi, 2017). Routine ECG monitoring may be considered in patients greater than 60 years old, those with a history of arrhythmia or coronary heart disease, and patients with a concerning family history of cardiac issues (e.g., sudden death, Brugada syndrome) (Mehta and Vannozzi, 2017).

Skin Effects. Allergic reactions such as dermatitis, folliculitis, and vasculitis can occur with Li^+ administration. Worsening of acne vulgaris, psoriasis, and other dermatological conditions is a common problem that is usually treatable by topical measures, but a small number of patients may improve only on discontinuation of Li^+ (Gitlin, 2016). Ten percent to 12% of patients on Li^+ (and VPA) may experience alopecia. Li^+ and VPA attenuate the dihydrotestosterone-induced downregulation of intracellular β-catenin levels by inhibiting GSK-3β. Daily multivitamins with at least 100 μg of selenium and 15 mg of zinc may help, but consider early use of topical 5% *minoxidil* as soon as the complaint surfaces.

Pregnancy and Lactation. The use of Li^+ in early pregnancy may be associated with Ebstein anomaly and related right ventricular outflow tract malformations; however, the risk of Ebstein anomaly (about 1 per 20,000 live births in controls) is now known to be only modestly increased with first-trimester Li^+ exposure (Patorno et al., 2017). In balancing the risk versus benefit of using Li^+ during the first trimester of pregnancy, it is important to evaluate the risk of inadequate prophylaxis for a bipolar I patient and subsequent risk that mania poses for the patient and fetus. If the history of decompensation upon stopping Li^+ or inadequate mood control on antipsychotic monotherapy presents a compelling need for Li^+, screening ultrasonography for CV anomalies is recommended. In patients who choose to forgo Li^+ exposure during the first trimester, potentially safer treatments for acute mania include antipsychotics or ECT.

In pregnancy, maternal polyuria may be exacerbated by Li^+. Concomitant use of Li^+ with medications that waste Na^+ or a low-Na^+ diet during pregnancy can contribute to maternal and neonatal Li^+ intoxication. Li^+ freely crosses the placenta, and fetal or neonatal Li^+ toxicity may develop when maternal blood levels are within the therapeutic range. Fetal Li^+ exposure is associated with neonatal goiter, CNS depression, hypotonia ("floppy baby" syndrome), and cardiac murmur. Most experts recommend withholding Li^+ therapy for 24 to 48 h before delivery if possible, and this is considered standard practice to avoid potentially toxic increases in maternal and fetal serum Li^+ levels associated with postpartum diuresis. The physical and CNS sequelae of late-term neonatal Li^+ exposure are reversible once Li^+ exposure has ceased and no long-term neurobehavioral consequences are observed (Diav-Citrin et al., 2014).

Other Effects. A benign, sustained increase in circulating polymorphonuclear leukocytes commonly occurs (at times up to 12,000–15,000 cells/mm^3), related to Li^+-induced increases in levels of granulocyte colony-stimulating factor and augmented production of granulocyte colony-stimulating factor by peripheral blood mononuclear cells (Focosi et al., 2009). Li^+ also directly stimulates the proliferation of pluripotent stem cells. Some patients may complain of a metallic taste, making food less palatable.

Acute Toxicity and Overdose. The occurrence of toxicity is related to the serum concentration of Li^+ and its rate of rise following administration. Acute intoxication is characterized by vomiting, profuse diarrhea, coarse tremor, ataxia, coma, and convulsions. Symptoms of milder toxicity are most likely to occur at the absorptive peak of Li^+ and include nausea, vomiting, abdominal pain, diarrhea, sedation, and fine tremor. The more serious effects involve the CNS and include mental confusion, hyperreflexia, gross tremor, dysarthria, seizures, and cranial nerve and

focal neurological signs, progressing to coma and death. Sometimes both cognitive and motor neurological damage may be irreversible, with persistent cerebellar tremor the most common (Kores and Lader, 1997). Other toxic effects are cardiac arrhythmias, hypotension, and albuminuria.

Treatment of Lithium Intoxication. There is no specific antidote for Li^+ intoxication, and treatment is supportive, including intubation if indicated and continuous cardiac monitoring. Levels greater than 1.5 mEq/L are considered toxic, but inpatient medical admission is usually not indicated (in the absence of symptoms) until levels exceed 2 mEq/L. Care must be taken to ensure that the patient is not Na^+ and water depleted. There are several issues involved in the assessment, including whether the ingestion occurred in an Li^+-naïve patient or one on chronic therapy, and whether the intoxication represents an acute event or a chronic problem (e.g., high level for an extended period of time). In acute ingestion, levels should be checked every 2 to 4 h until they peak, especially as the peak may be delayed with controlled-release Li^+. Importantly, serum levels do not always correlate well with clinical toxicity since the danger lies in the Li^+ level in the CNS, which reaches a maximal level more slowly than plasma. Dialysis is the most effective means of removing Li^+ from its intracellular and CNS locations and is indicated in the following situation: Li^+ levels greater than or equal to 5.2 mEq/L and/or serum creatinine greater than or equal to 2.26 mg/dL (Vodovar et al., 2020). Complete recovery occurs with an average maximal level of 2.5 mEq/L; permanent neurological symptoms result from mean levels of 3.2 mEq/L; death occurs with mean maximal levels of 4.2 mEq/L (Kores and Lader, 1997).

Use in Pediatric Populations. Li^+ is FDA-approved for child/adolescent bipolar disorder for ages 12 years or older (Duffy and Grof, 2018). *Aripiprazole*, *quetiapine*, and *risperidone* are FDA-approved for acute mania in children and adolescents aged 10 to 17 years. Children and adolescents have higher volumes of body water and higher eGFR than adults. The resulting shorter $t_{1/2}$ of Li^+ demands dosing increases on a milligram/kilogram basis, and multiple daily dosing may be required. In children ages 6 to 12 years, a dose of 30 mg/kg per day given in three divided doses will produce an Li^+ concentration of 0.6 to 1.2 mEq/L in 5 days, although dosing is always guided by serum levels and clinical response (Duffy and Grof, 2018). Use in children under 12 represents an off-label use for Li^+, and caregivers should be alert to signs of toxicity. As with adults, ongoing monitoring of renal and thyroid function is important, along with clinical inquiry into extent of polyuria.

A limited number of controlled studies suggested that VPA has efficacy comparable to that of Li^+ for mania in children or adolescents. As with Li^+, weight gain and tremor can be problematic; moreover, there are reports of hyperammonemia in children with urea cycle disorders. Ongoing monitoring of platelets and liver function tests, in addition to serum drug levels, is recommended.

Use in Geriatric Populations. The majority of older patients on Li^+ therapy are those maintained for years on the medication, but any person with adequate renal function (eGFR >70 mL/min) is a Li^+ candidate, *especially given its neuroprotective properties*. Elderly patients frequently take medications for other illnesses, and the potential for drug-drug interactions is substantial. An increased risk of Li^+ toxicity is seen within a month of initiating treatment with a loop diuretic or an ACEI, but not with thiazide diuretics or nonsteroidal anti-inflammatory drugs (Juurlink et al., 2004).

Age-related reductions in total body water and creatinine clearance reduce the safety margin for Li^+ treatment in older patients. Targeting lower maintenance serum levels (0.6–0.8 mEq/L) may reduce the risk of toxicity. As eGFR drops below 50 mL/min, strong consideration must be given to use of alternative agents, despite Li^+'s therapeutic advantages (Morriss and Benjamin, 2008).

Elderly patients who are drug naïve may be more sensitive to the CNS adverse effects of all types of medications used for acute mania, especially parkinsonism and TD from D_2 antagonism, confusion from antipsychotic medications with antimuscarinic properties, and ataxia or sedation from Li^+ or anticonvulsants.

Drug Facts for Your Personal Formulary: *Antipsychotic and Mood-Stabilizing Agents*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
First-Generation Antipsychotics • Low-potency D_2 antagonists		
Chlorpromazine	• Schizophrenia • Acute mania	• High M_1, H_1, and α_1 adrenergic affinities increase rates of anticholinergic side effects, sedation and weight gain, and hypotension, respectively; high risk of adverse metabolic events • Less QTc risk than thioridazine; photosensitivity
First-Generation Antipsychotics • Medium- and high-potency D_2 antagonists		
Haloperidol	• Schizophrenia • Acute mania	• Higher rates of EPSs, akathisia, hyperprolactinemia • Limited anticholinergic side effects, sedation, weight gain, and hypotension • Avoid IV use (QTc prolongation); chlorpromazine 75 mg po equivalence: 2 mg
Fluphenazine	• Schizophrenia • Acute mania	• Higher rates of EPSs, akathisia, hyperprolactinemia • Limited anticholinergic side effects, sedation, weight gain, and hypotension • Chlorpromazine 75 mg oral equivalence: 2 mg
Trifluoperazine	• Schizophrenia • Acute mania	• Higher rates of EPSs, akathisia, hyperprolactinemia • Limited anticholinergic side effects, sedation, weight gain, and hypotension • Chlorpromazine 75 mg oral equivalence: 5 mg
Thiothixene	• Schizophrenia • Acute mania	• Higher rates of EPSs, akathisia, hyperprolactinemia • Limited anticholinergic side effects, sedation, weight gain, and hypotension • Chlorpromazine 75 mg oral equivalence: 7.5 mg
Perphenazine	• Schizophrenia • Acute mania	• Modest rates of EPSs, akathisia • Limited anticholinergic side effects, sedation, weight gain, and hypotension • Chlorpromazine 75 mg oral equivalence: 7.5 mg
Loxapine	• Schizophrenia • Acute mania	• Modest rates of EPS, akathisia; chlorpromazine 75 mg oral equivalence: 25 mg • Limited anticholinergic side effects, sedation, weight gain, and hypotension

Drug Facts for Your Personal Formulary: *Antipsychotic and Mood-Stabilizing Agents (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Second-Generation Antipsychotics • $5HT_{2a}$ and D_2 antagonists		
Asenapine	• Schizophrenia • Acute mania	• Available in ODT formulation due to 98% first-pass effect if swallowed. The ODT tablet is administered sublingually: avoid water for 10 min to achieve maximum oral-buccal absorption (avoiding water for 2 min achieves 80% of maximum absorption) • Available in transdermal formulation: 3.8 mg/24 h = 10 mg/day ODT; 5.7 mg/24 h = 15 mg/day ODT; 7.6 mg/24 h = 20 mg/day ODT • Low risk of metabolic adverse effects • Limited drug-drug kinetic interactions
Clozapine	• Resistant schizophrenia • Schizophrenia with suicidality, polydipsia, or persistent impulsive aggression • Resistant mania	• Must register patient and prescriber due to mandatory hematological monitoring • High M_1, H_1, and α_1 adrenergic affinity increases rates of anticholinergic side effects, sedation and weight gain, and hypotension, respectively • High risk of metabolic adverse effects • Significant constipation; avoid other anticholinergic agents, iron, and psyllium. Manage aggressively with docusate, polyethylene glycol 3350, bisacodyl, and if needed, linaclotide. • Sialorrhea; manage with locally administered agents (sublingual atropine 1% drops or ipratropium 0.06% spray)
Iloperidone	• Schizophrenia	• High α_1 adrenergic affinity; titrate to minimize orthostasis • Low risk of metabolic adverse effects
Lumateperone	• Schizophrenia • Bipolar depression (monotherapy and adjunct)	• Very low risk for anticholinergic side effects, sedation and weight gain, and hypotension, respectively • Very low risk of EPSs and metabolic and endocrine adverse effects
Lurasidone	• Schizophrenia • Bipolar depression (monotherapy and adjunct)	• Low risk for anticholinergic side effects, sedation and weight gain, and hypotension, respectively • Low risk of metabolic adverse effects • Absorption increased 100% by administration with 350 kcal food
Olanzapine	• Schizophrenia • Acute mania • Bipolar depression (in combination with fluoxetine)	• High risk of metabolic adverse effects • Anticholinergic effects at high dosages
Paliperidone	• Schizophrenia	• Moderate risk of metabolic adverse effects • High rates of hyperprolactinemia
Quetiapine	• Schizophrenia • Acute mania • Bipolar depression (monotherapy) • Unipolar depression (adjunct)	• High risk of metabolic adverse effects at full therapeutic dosages for schizophrenia • High H_1 and α_1 adrenergic affinities increase rates of sedation and hypotension, respectively • Low rates of EPSs, akathisia, and hyperprolactinemia
Risperidone	• Schizophrenia • Acute mania	• Moderate risk of metabolic adverse effects • High rates of hyperprolactinemia
Sertindole	• Schizophrenia	• Not available in the U.S. • Restricted use in Europe, with extensive monitoring for QTc prolongation • Low risk of metabolic adverse effects
Ziprasidone	• Schizophrenia • Acute mania	• Low risk of metabolic adverse effects • Absorption increased 100% by administration with 500 kcal food • Improved tolerability at starting doses >80 mg/day with food
Second-Generation Antipsychotics • D_2 partial agonists		
Aripiprazole	• Schizophrenia • Acute mania • Unipolar depression (adjunct)	• Low risk of metabolic adverse effects • Lowers serum prolactin • Akathisia noted in depression trials—can be lessened with starting dose of 2.0–2.5 mg at bedtime
Brexpiprazole	• Schizophrenia • Unipolar depression (adjunct)	• Low risk of metabolic adverse effects • Lowers serum prolactin
Cariprazine	• Schizophrenia • Acute mania/bipolar mixed • Bipolar depression (monotherapy)	• Low risk of metabolic adverse effects • Lowers serum prolactin • Akathisia
Second-Generation Antipsychotics • D_2 and D_3 antagonists		
Amisulpride	• Schizophrenia • Unipolar depression (adjunct, at low dosages)	• Higher rates of EPSs • Higher rates of hyperprolactinemia • Low risk of metabolic adverse effects

Drug Facts for Your Personal Formulary: *Antipsychotic and Mood-Stabilizing Agents (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
5HT$_{2a}$ Inverse Agonist Without D$_2$ Binding		
Pimavanserin	• Parkinson's disease psychosis (PDP)	• Potent 5HT$_{2a}$ inverse agonist with no D$_2$ affinity • Monotherapy efficacy data for psychosis available only for PDP • Only one dose available: 34 mg once daily, with or without food • Decrease dose by 50% with concurrent strong 3A4 inhibitors; may lose efficacy with strong 3A4 inducers • Clinical effects may not be seen for 2–6 weeks
Mood Stabilizers • Acute mania and/or bipolar maintenance		
Lithium	• Acute mania • Bipolar maintenance • Unipolar depression (adjunct)	• Reduces suicidality more than other treatments • Evidence for neuroprotective properties in older bipolar patients • Renally cleared • Risk for weight gain • Monitor TSH, renal function tests, serum calcium, lithium levels • May cause tremor, hair loss • Therapeutic serum level: acute mania 1.0–1.5 mEq/L • Therapeutic serum level: maintenance 0.6–1.0 mEq/L
VPA (divalproex)	• Acute mania • Bipolar maintenance	• Can be loaded in acute mania: 30 mg/kg over 24 h • Highly protein bound • Risk for weight gain • Risk for polycystic ovary syndrome—avoid in women of childbearing age if possible • High risk for neural tube defects—women of childbearing age must be using contraception • May cause thrombocytopenia, neutropenia, hyperammonemia, tremor, hair loss • Monitor complete blood count, liver function tests, levels • Therapeutic serum level: acute mania 100–120 µg/dL • Therapeutic serum level: maintenance 60–100 µg/dL
Carbamazepine	• Acute mania • Bipolar maintenance	• Less effective than lithium and valproic acid • Highly protein bound • Human leukocyte antigen testing for those from East Asia to identify high risk of Stevens-Johnson syndrome • May cause hyponatremia, leukopenia • Strong inducer of CYP3A4 and Pgp • Cannot be loaded. Avoid rapid titration to minimize risk of sedation, ataxia • Therapeutic serum level 6–12 µg/dL
Lamotrigine	• Bipolar maintenance	• Prolonged titration to minimize risk of Stevens-Johnson syndrome • 50% dosage reduction required if patient on valproic acid or divalproex • Warning by U.S. FDA in March 2021 regarding arrhythmia risk in those with preexisting conditions. Should be avoided in those with cardiac conduction disorders (e.g., second- or third-degree heart block), ventricular arrhythmias, myocardial ischemia, heart failure, structural heart disease, Brugada syndrome, or other sodium channelopathies.

Chapter 20

Pharmacotherapy of the Epilepsies

Cameron S. Metcalf, Misty D. Smith, and Karen S. Wilcox

The epilepsies are common and frequently devastating disorders, affecting approximately 2.5 million people in the U.S. alone. More than 40 distinct forms of epilepsy have been identified. Epileptic seizures often cause transient impairment of awareness, leaving the individual at risk of bodily harm and often interfering with education and employment. Current therapy is symptomatic, as available antiseizure drugs (ASDs) inhibit seizures, but neither effective prophylaxis nor cure is available. Adherence to prescribed treatment regimens is a major problem because of the need for long-term therapy together with unwanted effects of many drugs.

The mechanisms of action of ASDs fall into the following major categories (Porter et al., 2012):

1. Modulation of sodium, potassium, or calcium ion channels. This can include prolongation of the inactivated state of voltage-gated Na^+ channels, positive modulation of K^+ channels, and inhibition of Ca^{2+} channels.
2. Enhancement of γ-aminobutyric acid (GABA) neurotransmission through actions on $GABA_A$ receptors, modulation of GABA metabolism, or inhibition of GABA reuptake into the synaptic terminal.
3. Modulation of synaptic release through actions on the synaptic vesicle protein SV2A or Ca^{2+} channels containing the α2δ subunit.
4. Diminishing synaptic excitation mediated by ionotropic glutamate receptors (e.g., α-amino-3-hydroxy 5-methyl-4-isoxazolepropionic acid [AMPA] receptors).

Despite these broad classifications, it is noteworthy that many ASDs act through mechanisms distinct from the primary known mode of action. Furthermore, ASDs with similar mechanistic categories may have disparate clinical uses.

Although many treatments are available, much effort is being devoted to elucidating the genetic causes and the cellular and molecular mechanisms by which a normal brain becomes epileptic, insights that promise to provide molecular targets for both symptomatic and preventive therapies.

Terminology and Epileptic Seizure Classification

The term *seizure* (from the Latin *sacire* meaning "to take possession of") refers to a transient alteration of behavior due to the disordered, synchronous, and rhythmic firing of populations of brain neurons. The term *epilepsy* refers to a disorder of brain function characterized by the risk of periodic and unpredictable occurrence of seizures. Seizures can be

Abbreviations

AMPA: α-amino-3-hydroxy 5-methyl-4-isoxazolepropionic acid
ASD: antiseizure drugs
CBD: cannabidiol
CSF: cerebrospinal fluid
CYP: cytochrome P450
EEG: electroencephalogram
ENT-1B: equilibrative nucleoside transporter 1
GABA: γ-aminobutyric acid
GI: gastrointestinal
MRI: magnetic resonance imaging
NMDA: *N*-methyl-D-aspartate receptor
PEMA: phenylethylmalonamide
SV2A: synaptic vesicle protein 2A
THC: tetrahydrocannabinol
UGT: uridine diphosphate-glucuronosyltransferase

"nonepileptic," when evoked in a normal brain by treatments such as electroshock or chemical convulsants, or "epileptic," when occurring without evident provocation. While agents in current clinical use inhibit seizures, whether any of these prevent the development of epilepsy (epileptogenesis) is uncertain.

Seizures are generally thought to arise from the cerebral cortex and not from other central nervous system (CNS) structures such as the thalamus, brainstem, or cerebellum. Recently, the classification for epileptic seizures has been revised, and this new nomenclature will be used in this chapter. Thus, those epileptic seizures previously classified as *partial* seizures will be referred to as *focal* seizures, whereas *generalized* seizures, those that involve both hemispheres widely from the outset, will still be referred to as generalized seizures (Commission on Classification and Terminology, 2016). In addition, the International League Against Epilepsy has added a classification for seizures with *unknown onset*, which include such seizure types as tonic-clonic, atonic, and epileptic spasms. The behavioral manifestations of a seizure are determined by the functions normally served by the cortical site at which the seizure arises. For example, a seizure involving motor cortex is associated with clonic jerking of the body in the area controlled by this region of cortex. This type of *focal* seizure is associated with preservation of awareness. *Focal* seizures may also be associated with impairments of awareness. The majority of such focal seizures originate from the temporal lobe. Generalized seizures are now distinguished by the involvement of the motor system or those that lack motor involvement (e.g., typical and atypical absence and eyelid myoclonic). The type of epileptic seizure is one determinant of the drug selected for therapy. Detailed information pertaining to seizure classifications is presented in Figure 20–1 (modified from Ayala et al., 1973). More detailed information is presented in Table 20–1.

Apart from this epileptic seizure classification, an additional classification specifies epileptic syndromes, which refer to a cluster of symptoms frequently occurring together and include seizure types, etiology, age of onset, and other factors (Commission on Classification and Terminology, 1989). More than 50 distinct epileptic syndromes have been identified and categorized into focal versus generalized epilepsies. The focal epilepsies may consist of any of the focal seizure types (see Table 20–1) and

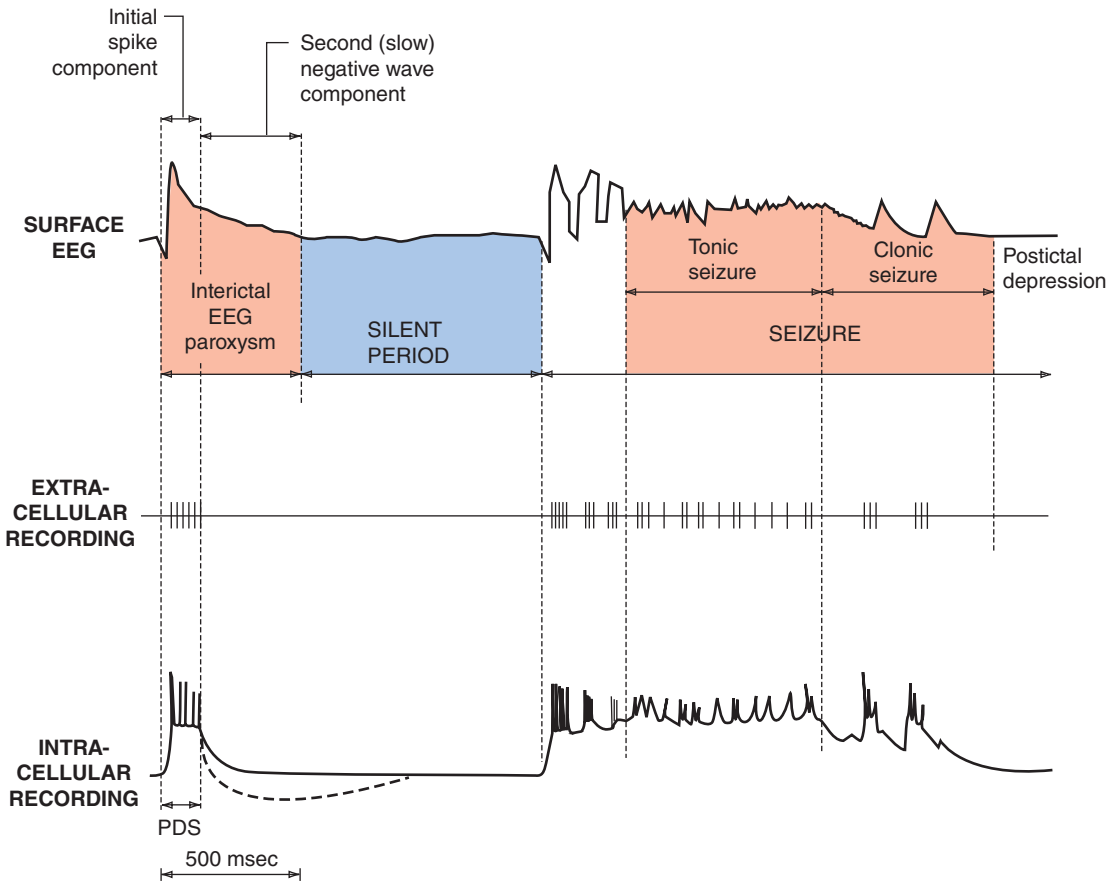

Figure 20–1 *Relationship of cortical EEG, extracellular, and intracellular recordings in a seizure focus induced by local application of a convulsant agent to mammalian cortex.* The extracellular recording was made through a high-pass filter. Note the high-frequency firing of the neuron evident in both the extracellular and intracellular recording during the paroxysmal depolarization shift (PDS). (Modified with permission from Ayala GF, et al. Genesis of epileptic interictal spikes. New knowledge of cortical feedback systems suggests a neurophysiological explanation of brief paroxysms. *Brain Res*, **1973**, *52*:1–17. Copyright © Elsevier.)

TABLE 20–1 ■ CLASSIFICATION OF EPILEPTIC SEIZURES

SEIZURE TYPE	FEATURES	CONVENTIONAL ANTISEIZURE DRUGS	RECENTLY DEVELOPED ANTISEIZURE DRUGS
Focal Seizures			
Focal Aware	Diverse manifestations determined by the region of cortex activated by the seizure (e.g., if motor cortex representing left thumb, clonic jerking of left thumb results; if somatosensory cortex representing left thumb, paresthesia of left thumb results), lasting approximately 20–60 sec. *Key feature is preservation of awareness.*	Carbamazepine, phenytoin, valproate	Brivaracetam, cenobamate, eslicarbazepine, ezogabine, gabapentin, lacosamide, lamotrigine, levetiracetam, perampanel, rufinamide, tiagabine, topiramate, zonisamide
Focal With Impaired Awareness	Impaired awareness lasting 30 sec to 2 min, often associated with purposeless movements such as lip smacking or hand wringing.		
Focal to Bilateral Tonic-Clonic	Simple or complex focal seizure evolves into a tonic-clonic seizure with loss of awareness and sustained contractions (tonic) of muscles throughout the body followed by periods of muscle contraction alternating with periods of relaxation (clonic), typically lasting 1–2 min.	Carbamazepine, phenobarbital, phenytoin, primidone, valproate	
Generalized Seizures			
Generalized Absence	Abrupt onset of impaired awareness associated with staring and cessation of ongoing activities typically lasting less than 30 sec.	Ethosuximide, valproate, clonazepam	Lamotrigine
Generalized Myoclonic	A brief (perhaps a second), shocklike contraction of muscles that may be restricted to part of one extremity or may be generalized.	Valproate, clonazepam	Levetiracetam
Generalized Tonic-Clonic	As described earlier in table for partial with secondarily generalized tonic-clonic seizures except that it is not preceded by a partial seizure.	Carbamazepine, phenobarbital, phenytoin, primidone, valproate	Lamotrigine, levetiracetam, topiramate
Syndrome-Specific Uses	Seizures arising from - Dravet syndrome - Lennox-Gastaut syndrome - Tuberous sclerosis complex		Cannabidiol, fenfluramine (Dravet syndrome)

account for roughly 60% of all epilepsies. The etiology commonly consists of a lesion in some part of the cortex, such as a tumor, developmental malformation, or damage due to trauma or stroke. Such lesions often are evident on brain magnetic resonance imaging (MRI). Alternatively, the etiology may be genetic. The generalized epilepsies are characterized most commonly by one or more of the generalized seizure types listed in Table 20–1 and account for approximately 40% of all epilepsies. The etiology is usually genetic. The most common generalized epilepsy is referred to as juvenile myoclonic epilepsy, accounting for approximately 10% of all epileptic syndromes. The age of onset is in the early teens, and the condition is characterized by myoclonic, tonic-clonic, and often absence seizures. Like most of the generalized-onset epilepsies, juvenile myoclonic epilepsy is a complex genetic disorder that is probably due to inheritance of multiple susceptibility genes; there is a familial clustering of cases, but the pattern of inheritance is not Mendelian. The classification of epileptic syndromes guides clinical assessment and management and, in some instances, selection of ASDs.

Nature and Mechanisms of Seizures and Antiseizure Drugs

Focal Epilepsies

More than a century ago, John Hughlings Jackson, the father of modern concepts of epilepsy, proposed that seizures were caused by "occasional, sudden, excessive, rapid and local discharges of gray matter," and that a generalized convulsion resulted when normal brain tissue was invaded by the seizure activity initiated in the abnormal focus. This insightful proposal provided a valuable framework for thinking about mechanisms of focal epilepsy. The advent of the electroencephalogram (EEG) in the 1930s permitted the recording of electrical activity from the scalp of humans with epilepsy and demonstrated that the epilepsies are disorders of neuronal excitability.

The pivotal role of synapses in mediating communication among neurons in the mammalian brain suggested that defective synaptic function might lead to a seizure. That is, a reduction of inhibitory synaptic activity or enhancement of excitatory synaptic activity might be expected to trigger a seizure; pharmacological studies of seizures support this notion. The neurotransmitters mediating the bulk of synaptic transmission in the mammalian brain are amino acids, with GABA and glutamate being the principal inhibitory and excitatory neurotransmitters, respectively. Pharmacological studies disclosed that *antagonists* of the $GABA_A$ receptor or *agonists* of different glutamate receptor subtypes (*N*-methyl-D-aspartate receptor [NMDA], AMPA, or kainic acid) (see Chapter 16) trigger seizures in experimental animals *in vivo*. Conversely, pharmacological agents that enhance GABA-mediated synaptic inhibition suppress seizures in diverse models. Glutamate receptor antagonists also inhibit seizures in diverse models, including seizures evoked by electroshock and chemical convulsants, such as *pentylenetetrazol*.

These findings suggest pharmacological regulation of synaptic function can regulate the propensity for seizures and provide a framework

for electrophysiological analyses aimed at elucidating the role of both synaptic and nonsynaptic mechanisms in seizures and epilepsy. Progress in techniques has fostered the progressive refinement of the analysis of seizure mechanisms from the EEG to populations of neurons (field potentials) to individual neurons to individual synapses and individual ion channels on individual neurons. Beginning in the mid-1960s, cellular electrophysiological studies of epilepsy focused on elucidating the mechanisms underlying the depolarization shift, the intracellular correlate of the "interictal spike" (see Figure 20–1). The interictal (or between-seizures) spike is a sharp waveform recorded in the EEG of patients with epilepsy; it is asymptomatic, as it is not accompanied by overt change in the patient's behavior. However, the location of the interictal spike helps localize the brain region from which seizure activity originates in a given patient. The depolarization shift consists of a large depolarization of the neuronal membrane associated with a burst of action potentials. In most cortical neurons, the depolarization shift is generated by a large excitatory synaptic current that can be enhanced by activation of voltage-gated intrinsic membrane currents. Although the mechanisms generating the depolarization shift and whether the interictal spike triggers a seizure, inhibits a seizure, or is an epiphenomenon remain unclear, the study of the mechanisms underlying depolarization shift generation set the stage for inquiry into the cellular mechanisms of a seizure.

During the 1980s, various *in vitro* models of seizures were developed in isolated brain slice preparations in which many synaptic connections are preserved. Electrographic events with features similar to those recorded during seizures *in vivo* have been produced in hippocampal slices by multiple methods, including altering ionic constituents of media bathing the brain slices (McNamara, 1994) such as low Ca^{2+}, zero Mg^{2+}, or elevated K^+. The accessibility and experimental control provided by these *in vitro* preparations have permitted mechanistic investigations into the induction of seizures. Analyses of multiple *in vitro* models confirmed the importance of synaptic function for initiating a seizure, demonstrating that subtle reductions (e.g., 20%) of inhibitory synaptic function could lead to epileptiform activity and that activation of excitatory synapses could be pivotal in seizure initiation. Other important factors were identified, including the volume of the extracellular space as well as intrinsic properties of a neuron, such as voltage-gated ion channels (e.g., K^+, Na^+, and Ca^{2+} channels) (Traynelis and Dingledine, 1988). Identification of these diverse synaptic and nonsynaptic factors controlling seizures *in vitro* provides potential pharmacological targets for regulating seizure susceptibility *in vivo*.

Additional studies have centered on understanding the mechanisms by which a normal brain is transformed into an epileptic brain. Some common forms of focal epilepsy arise months to years after cortical injury sustained as a consequence of stroke, trauma, infection, or other factors. Effective prophylaxis administered to patients at high risk would be highly desirable in the clinical setting. However, no effective antiepileptogenic agent has yet been identified. The drugs described in this chapter provide symptomatic therapy; that is, the drugs inhibit seizures in patients with epilepsy.

Understanding the mechanisms of epileptogenesis in cellular and molecular terms should provide a framework for development of novel therapeutic approaches. The availability of animal models provides an opportunity to investigate the underlying mechanisms and have also enabled the discovery of numerous ASDs that have proven safe and efficacious in humans.

One model, termed *kindling*, is induced by periodic administration of brief, low-intensity electrical stimulation of the amygdala or other limbic structures that evokes a brief electrical seizure recorded on the EEG without behavioral change. Repeated (e.g., 10–20) stimulations result in progressive intensification of seizures, culminating in tonic-clonic seizures that, once established, persist for the life of the animal. Additional models are produced by induction of continuous seizures that last for hours (*status epilepticus*). The inciting agent used in these models is typically either a chemoconvulsant, such as *kainic acid* or *pilocarpine*, or sustained electrical stimulation. The fleeting episode of status epilepticus is followed weeks later by the onset of spontaneous seizures, an intriguing parallel to the scenario of complicated febrile seizures in young children preceding the emergence of spontaneous seizures years later. In contrast to the limited or absent neuronal loss characteristic of the kindling model, overt destruction of hippocampal neurons occurs in the *status epilepticus* models, reflecting aspects of hippocampal sclerosis observed in humans with severe limbic seizures. Indeed, the discovery that complicated febrile seizures precede and presumably are the cause of hippocampal sclerosis in young children (VanLandingham et al., 1998) establishes yet another commonality between these preclinical models and the human condition.

Several questions arise with respect to these models. What transpires during the latent period between status epilepticus and emergence of spontaneous seizures that causes the epilepsy? Might an antiepileptogenic agent that was effective in one of these models demonstrate disease-modifying effects in other models?

Important insights into the mechanisms of action of drugs that are effective against focal seizures have emerged in the past two decades (Rogawski and Löscher, 2004). These insights largely have come from electrophysiological studies of relatively simple *in vitro* models, such as neurons isolated from the mammalian CNS and maintained in primary culture. The experimental control and accessibility provided by these models—together with careful attention to clinically relevant concentrations of the drugs—led to clarification of their mechanisms. Although it is difficult to prove unequivocally that a given drug effect observed *in vitro* is both necessary and sufficient to inhibit a seizure in an animal or humans *in vivo*, there is an excellent likelihood that the putative mechanisms identified do in fact underlie the clinically relevant antiseizure effects. Table 20–2 summarizes putative mechanisms of action of ASDs.

Electrophysiological analyses of individual neurons during a focal seizure demonstrate that the neurons undergo depolarization and fire action potentials at high frequencies (see Figure 20–1). This pattern of neuronal firing is characteristic of a seizure and is uncommon during physiological neuronal activity. Thus, selective inhibition of this pattern of firing would be expected to reduce seizures with minimal adverse effects. *Carbamazepine*, *lamotrigine*, *phenytoin*, *lacosamide*, and *valproic acid* inhibit high-frequency firing at concentrations known to be effective at limiting seizures in humans (Rogawski and Löscher, 2004). Inhibition of the high-frequency firing is thought to be mediated by reducing the ability of Na^+ channels to recover from inactivation (Figure 20–2). That is, depolarization-triggered opening of the Na^+ channels in the axonal membrane of a neuron is required for an action potential; after opening, the channels spontaneously close, a process termed *inactivation*. This inactivation is thought to cause the refractory period, a short time after an action potential during which it is not possible to evoke another action potential. Upon recovery from inactivation, the Na^+ channels are again poised to participate in another action potential. Because firing at a slow rate permits sufficient time for Na^+ channels to recover from inactivation, inactivation has little or no effect on low-frequency firing. However, reducing the rate of recovery of Na^+ channels from inactivation would limit the ability of a neuron to fire at high frequencies, an effect that likely underlies the effects of *carbamazepine*, *lamotrigine*, *lacosamide*, *phenytoin*, *topiramate*, *valproic acid*, and *zonisamide* against focal seizures.

Insights into mechanisms of seizures suggest that enhancing GABA-mediated synaptic inhibition would reduce neuronal excitability and raise the seizure threshold. Several drugs are thought to inhibit seizures by regulating GABA-mediated synaptic inhibition through an action at distinct sites of the synapse (Rogawski and Löscher, 2004). The principal postsynaptic receptor of synaptically released GABA is termed the $GABA_A$ receptor (see Chapter 16). Activation of the $GABA_A$ receptor inhibits the postsynaptic cell by increasing the inflow of Cl^- ions into the cell, which tends to hyperpolarize the neuron. Clinically relevant concentrations of both benzodiazepines and barbiturates enhance $GABA_A$ receptor–mediated inhibition through distinct actions on the $GABA_A$ receptor (Figure 20–3), and this enhanced inhibition probably underlies the effectiveness of these compounds against focal and tonic-clonic seizures in humans. At higher concentrations, such as might be used for status epilepticus, these drugs also can inhibit high-frequency firing of action potentials. A second mechanism of enhancing GABA-mediated

TABLE 20–2 ■ PROPOSED MECHANISMS OF ACTION OF ANTISEIZURE DRUGS

MOLECULAR TARGET AND ACTIVITY	DRUG	CONSEQUENCES OF ACTION
Na^+ channel modulators that:		
Enhance fast inactivation	PHT, CBZ, LTG, FBM, OxCBZ, TPM, VPA, ESL	• Block action potential propagation • Stabilize neuronal membranes • ↓ Neurotransmitter release, focal firing, and seizure spread
Enhance slow inactivation	LCM	• ↑ Spike frequency adaptation • ↓ AP bursts, focal firing, and seizure spread • Stabilize neuronal membrane
Ca^{2+} channel blockers	ESM, VPA, LTG	• ↓ Neurotransmitter release (N- and P-types) • ↓ Slow depolarization (T-type) and spike-wave discharges
α2δ ligands	GBP, PGB	• Modulate neurotransmitter release
$GABA_A$ receptor allosteric modulators	BZDs, PB, FBM, TPM, CBZ, OxCBZ, STP, CLB	• ↑ Membrane hyperpolarization and seizure threshold • ↓ Focal firing BZDs—attenuate spike-wave discharges PB, CBZ, OxCBZ—aggravate spike-wave discharges
GABA uptake inhibitors/GABA-transaminase inhibitors	TGB, VGB	• ↑ Extrasynaptic GABA levels and membrane hyperpolarization • ↓ Focal firing • Aggravate spike-wave discharges
NMDA receptor antagonists	FBM	• ↓ Slow excitatory neurotransmission • ↓ Excitatory amino acid neurotoxicity • Delay epileptogenesis
AMPA/kainate receptor antagonists	PB, TPM	• ↓ Fast excitatory neurotransmission and focal firing
Enhancers of HCN channel activity	LTG	• Buffers large hyperpolarizing and depolarizing inputs • Suppresses action potential initiation by dendritic inputs
Positive allosteric modulator of KCNQ2-5	EZG	• Suppresses bursts of action potentials • Hyperpolarizes membrane potentials
SV2A protein ligand	LEV, BRV	• Unknown; may decrease transmitter release
Inhibitors of brain carbonic anhydrase	ACZ, TPM, ZNS	• ↑ HCN-mediated currents • ↓ NMDA-mediated currents • ↑ GABA-mediated inhibition
Mixed/unknown	CNB	Mixed, not fully understood mechanism • Inhibit voltage-gated sodium channels (persistent current) • Positive modulation of $GABA_A$
Unknown	CBD	Unknown; potential mechanisms include • Activation of TRPV1 • Antagonism of GPR55 and GPR55-mediated elevations of presynaptic Ca^{2+} • Activation of $5HT_{1A}$ receptors • Inhibition of ENT-1 (modulation of adenosine tone)
Mixed	FEN	• Inhibition of serotonin transporter-mediated uptake • Activation of 5HT receptors: $5HT_{1D}$, $5HT_{2C}$ • Sigma-1–positive allosteric modulator

ACZ, acetazolamide; AP, action potential; BRV, brivaracetam; BZDs, benzodiazepines; CBD, cannabidiol; CBZ, carbamazepine; CLB, clobazam; CNB, cenobamate; ESL, eslicarbazepine; EZG, ezogabine; FEN, fenfluramine; FBM, felbamate; GBP, gabapentin; HCN, hyperpolarization-activated cyclic nucleotide–gated; 5HT, serotonin; LEV, levetiracetam; LCM, lacosamide; LTG, Lamotrigine; OxCBZ, oxcarbazepine; PER, perampanel; PB, phenobarbital; PGB, pregabalin; PHT, phenytoin; STP, stiripentol; TGB, tiagabine; TPM, topiramate; VGB, vigabatrin; VPA, valproic acid; ZNA, zonisamide.

synaptic inhibition is thought to underlie the antiseizure mechanism of *tiagabine*; *tiagabine* inhibits the GABA transporter, GAT-1, and reduces neuronal and glial uptake of GABA (Rogawski and Löscher, 2004). Finally, ASDs may either increase the production (i.e., *gabapentin*) or decrease the transaminase metabolism (i.e., *valproic acid*, *vigabatrin*) of GABA, resulting in increased GABA concentrations (Ben-Menachem, 2011; Cai et al., 2012; Larsson et al., 1986).

Generalized-Onset Epilepsies: Absence Seizures

In contrast to focal seizures, which arise from localized regions of the cerebral cortex, generalized-onset seizures arise from the reciprocal firing of the thalamus and cerebral cortex (Huguenard and McCormick, 2007). Among the diverse forms of generalized seizures, absence seizures have been studied most intensively. The striking synchrony in appearance of

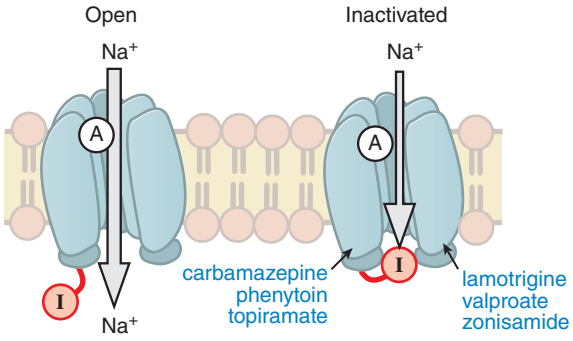

Figure 20–2 *ASD-enhanced Na⁺ channel inactivation.* Some ASDs (shown in blue text) prolong the inactivation of the Na^+ channels, thereby reducing the ability of neurons to fire at high frequencies. Note that the inactivated channel appears to remain open but is blocked by the inactivation gate **I**. A, activation gate.

generalized seizure discharges in widespread areas of neocortex led to the idea that a structure in the thalamus and/or brainstem (the "centrencephalon") synchronized these seizure discharges. Focus on the thalamus in particular emerged from the demonstration that low-frequency stimulation of midline thalamic structures triggered EEG rhythms in the cortex similar to spike-and-wave discharges characteristic of absence seizures. Intracerebral electrode recordings from humans subsequently demonstrated the presence of thalamic and neocortical involvement in the spike-and-wave discharge of absence seizures.

Many of the structural and functional properties of the thalamus and neocortex that lead to the generalized spike-and-wave discharges have been elucidated (Huguenard and McCormick, 2007).

The EEG hallmark of an absence seizure is generalized spike-and-wave discharges at a frequency of 3 per second (3 Hz). These bilaterally synchronous spike-and-wave discharges, recorded locally from electrodes

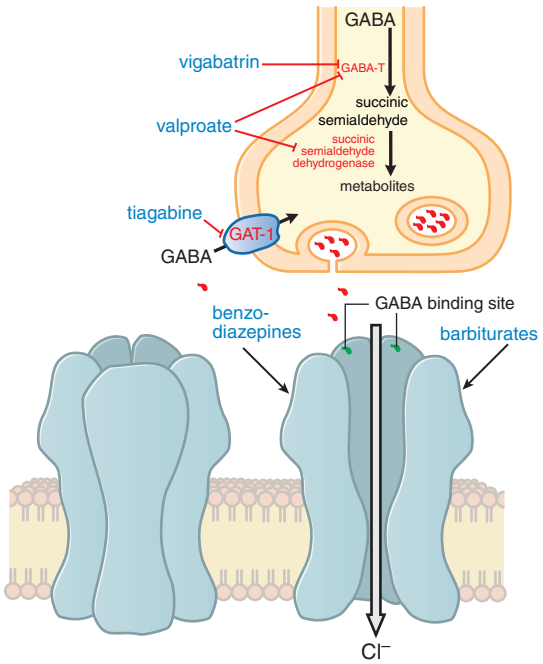

Figure 20–3 *Enhanced GABA synaptic transmission.* In the presence of GABA, the $GABA_A$ receptor (structure on left) is opened, allowing an influx of Cl^-, which in turn increases membrane polarization (see Figure 16–12). Some antiseizure drugs (shown in larger blue text) act by reducing the metabolism of GABA. Others act at the $GABA_A$ receptor, enhancing Cl^- influx in response to GABA. As outlined in the text, gabapentin acts presynaptically to promote GABA release; its molecular target is currently under investigation. (), GABA molecules; GABA-T, GABA transaminase; GAT-1, GABA transporter.

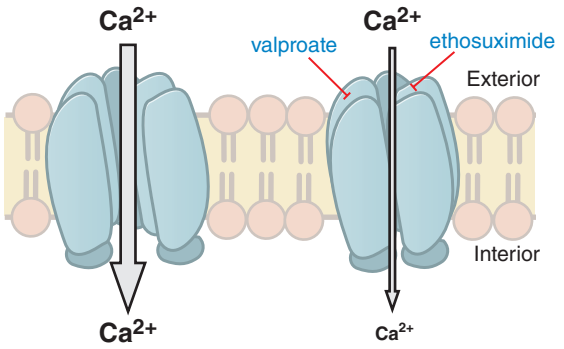

Figure 20–4 *ASD-induced reduction of current through T-type Ca^{2+} channels.* Some ASDs (shown in blue text) reduce the flow of Ca^{2+} through T-type Ca^{2+} channels thus reducing the pacemaker current that underlies the thalamic rhythm in spikes and waves seen in generalized absence seizures.

in both the thalamus and the neocortex, represent oscillations between the thalamus and neocortex. A comparison of EEG and intracellular recordings reveals that the EEG spikes are associated with the firing of action potentials and the following slow wave with prolonged inhibition. These reverberatory, low-frequency rhythms are made possible by a combination of factors, including reciprocal excitatory synaptic connections between the neocortex and thalamus as well as intrinsic properties of neurons in the thalamus (Huguenard and McCormick, 2007). One intrinsic property of thalamic neurons that is pivotally involved in the generation of the 3-Hz spike-and-wave discharges is a particular type of Ca^{2+} current, the low threshold ("T-type") current. T-type Ca^{2+} channels are activated at a much more negative membrane potential (hence, "low threshold") than most other voltage-gated Ca^{2+} channels expressed in the brain. T-type currents are much larger in many thalamic neurons compared to neurons outside the thalamus. Indeed, bursts of action potentials in thalamic neurons are mediated by activation of the T-type currents. T-type currents amplify thalamic membrane potential oscillations, with one oscillation being the 3-Hz spike-and-wave discharge of the absence seizure. Importantly, the principal mechanism by which anti–absence seizure drugs (*ethosuximide, valproic acid*) are thought to act is by inhibition of the T-type Ca^{2+} channels (Figure 20–4) (Rogawski and Löscher, 2004). Thus, inhibiting voltage-gated ion channels is a common mechanism of action among ASDs, with anti–focal seizure drugs inhibiting voltage-activated Na^+ channels and anti–absence seizure drugs inhibiting voltage-activated Ca^{2+} channels.

Genetic Approaches to the Epilepsies

Genetic causes contribute to a wide diversity of human epilepsies. Genetic causes are solely responsible for rare forms inherited in an autosomal dominant or autosomal recessive manner. Genetic causes also are mainly responsible for more common forms such as Dravet syndrome, juvenile myoclonic epilepsy, or childhood absence epilepsy, the majority of which are likely due to inheritance of two or more susceptibility genes. Genetic determinants also may contribute some degree of risk to epilepsies caused by injury of the cerebral cortex.

Enormous progress has been made in understanding the genetics of human epilepsy, with more than 70 genes whose mutations are now known to contribute to epilepsy. Gene mutations have been identified for a number of symptomatic epilepsies, in which the epilepsy is a manifestation of the underlying neurodegenerative disease. Because most patients with epilepsy are neurologically normal, elucidating the genes underlying familial epilepsy in otherwise normal individuals is of particular interest. Perhaps not surprisingly, many of the identified epilepsy-conferring mutations are in genes that encode voltage- or ligand-gated ion channels (Reid et al., 2009). However, mutations have also been identified in signaling pathways, transporters, and even synaptic vesicle proteins (EpiPM Consortium, 2015). Furthermore, many of the mutations arise *de novo*, thus complicating efforts in diagnoses. The genotype-phenotype correlations of these genetic syndromes are complex; the same mutation in

one channel can be associated with divergent clinical syndromes ranging from simple febrile seizures to intractable seizures with intellectual decline. Conversely, clinically indistinguishable epilepsy syndromes have been associated with mutation of distinct genes. The implication of genes encoding ion channels in familial epilepsy is particularly interesting because episodic disorders involving other organs also result from mutations of these genes. For example, episodic disorders of the heart (cardiac arrhythmias), skeletal muscle (periodic paralyses), cerebellum (episodic ataxia), vasculature (familial hemiplegic migraine), and other organs all have been linked to mutations in genes encoding components of voltage-gated ion channels (Ptacek and Fu, 2001).

The cellular electrophysiological consequences of these mutations can inform on the mechanisms of seizures, inform as to the actions of ASDs, and allow for the determination of precision therapies for patients with specific mutations. For example, generalized epilepsy with febrile seizures is caused, in some cases, by a point mutation in the β subunit of a voltage-gated Na^+ channel (*SCN1B*). As described previously, several ASDs act on Na^+ channels to promote their inactivation; the phenotype of the mutated Na^+ channel appears to involve defective inactivation (Wallace et al., 1998).

Spontaneous mutations in *SCN1A* (encoding the α subunit of the major voltage-gated Na^+ channel in neurons, Nav1.1) that result in truncations and presumed loss of Na^+ channel function have been identified in a subset of infants with a catastrophic severe myoclonic epilepsy of infancy or Dravet syndrome. The fact that these loss-of-function mutations in Na^+ channels result in seizures is somewhat surprising. However, seizures may arise as a consequence of the cell types that express these channels within neural circuits that underlie seizure initiation. Interestingly, patients with these mutations are generally found to be refractory to ASDs that block Na^+ channels.

Advances in the Genetics of Epilepsy

Some deletions or additions to segments of DNA, referred to as *copy number variants*, can contribute to the pathology of epilepsy. These variants have been identified by chromosome microarray studies and whole-genome sequencing (Hirabayashi et al., 2019; Monlong et al., 2018; Myers and Mefford, 2015). Genome-wide association studies have been used to identify risk factors and variants that contribute to epilepsy (International League Against Epilepsy Consortium on Complex Epilepsies, 2018; Myers and Mefford, 2015). Identification of critical genetic variants that contribute to risk may, in turn, lead to novel therapeutic approaches (e.g., antisense oligonucleotides, novel drug targets, and antibody-based therapies).

Antiseizure Drugs: General Considerations

History

The first antiepileptic drug was *bromide*, which was used in the late 19th century. *Phenobarbital* was the first synthetic organic agent recognized as having antiseizure activity. Its usefulness, however, was limited to generalized tonic-clonic seizures and, to a lesser degree, focal seizures. It had no effect on absence seizures. Merritt and Putnam developed the electroshock seizure test in experimental animals to screen chemical agents for antiseizure effectiveness; in the course of screening a variety of drugs, they discovered that *diphenylhydantoin* (later renamed *phenytoin*) suppressed seizures in the absence of sedative effects. The maximal electroshock seizure test is extremely valuable because drugs that are effective against the tonic hind limb extension induced by corneal electroshock generally have proven to be effective against focal and generalized tonic-clonic seizures in humans. In contrast, seizures induced by the chemoconvulsant *pentylenetetrazol* are most useful in the identification of ASDs that are effective against myoclonic seizures in humans. These screening tests are still used in addition to many other phenotypically and/or etiologically relevant acute and chronic animal models.

The chemical structures of most of the drugs introduced before 1965 were closely related to *phenobarbital*. These included the hydantoins and the succinimides. Between 1965 and 1990, the chemically distinct structures of the benzodiazepines, iminostilbene (*carbamazepine*), and a branched-chain carboxylic acid (*valproic acid*) were introduced, followed in the 1990s by a phenyltriazine (*lamotrigine*), a cyclic analogue of GABA (*gabapentin*), a sulfamate-substituted monosaccharide (*topiramate*), a nipecotic acid derivative (*tiagabine*), and a pyrrolidine derivative (*levetiracetam*). The Epilepsy Therapy Screening Project, formerly known as the Anticonvulsant Screening Project, was established by the National Institutes of Health with a contract to the University of Utah in the 1970s as a way to incentivize the continued development of ASDs, with academic scientists working in partnership with private industry and government. Using a wide array of animal models of seizures and epilepsy, the program has contributed to the preclinical identification and development of many of the clinically available ASDs.

Therapeutic Aspects

The ideal ASD would suppress all seizures without causing any unwanted effects. Unfortunately, drugs used currently not only fail to control seizure activity in approximately one-third of patients but also frequently cause unwanted adverse effects that range in severity from minimal impairment of the CNS to death from aplastic anemia or hepatic failure. In 2009, all manufacturers of ASDs were required by the FDA to update their product labeling to include a warning about an increased risk of suicidal thoughts or actions and to develop information targeted at helping patients understand this risk (FDA, 2008). The risk applies to all ASDs used for any indication. A recent meta-analysis of medications approved since 2008 (*eslicarbazepine*, *perampanel*, *brivaracetam*, *cannabidiol*, and *cenobamate*) suggests that there is no risk of suicidality associated with these newer agents (Klein et al., 2021).

The clinician who treats patients with epilepsy is faced with the task of selecting the appropriate drug or combination of drugs that best controls seizures in an individual patient at an acceptable level of untoward effects. As a general rule, complete control of seizures can be achieved in up to 50% of patients, while another 25% can be improved significantly. The degree of success varies as a function of seizure type, cause, and other factors.

To minimize adverse effects, treatment with a single drug is preferred. If seizures are not controlled with the initial agent at adequate plasma concentrations, substitution of a second drug is preferred to the concurrent administration of another agent. However, multiple-drug therapy may be required, especially when two or more types of seizure occur in the same patient.

Measurement of drug concentrations in plasma facilitates optimizing antiseizure medication, especially when therapy is initiated, after dosage adjustments, in the event of therapeutic failure, when toxic effects appear, or when multiple-drug therapy is instituted. However, clinical effects of some drugs do not correlate well with their concentrations in plasma, and recommended concentrations are only guidelines for therapy. The ultimate therapeutic regimen must be determined by clinical assessment of effect and toxicity.

The individual agents are introduced in the next sections, followed by a discussion of some general principles of the drug therapy of the epilepsies.

Hydantoins

Phenytoin

Phenytoin is effective against all types of focal and tonic-clonic seizures but not absence seizures. Properties of other hydantoins, such as *ethotoin*, are described in previous editions of this book.

Pharmacological Effects

Central Nervous System. Phenytoin exerts antiseizure activity without causing general depression of the CNS. In toxic doses, it may produce excitatory signs, and at lethal levels, it may produce a type of decerebrate rigidity.

Mechanism of Action

Phenytoin limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord neurons maintained *in vitro*

(McLean and Macdonald, 1986a). This effect is mediated by a slowing of the rate of recovery of voltage-activated Na^+ channels from inactivation, an action that is both voltage dependent (greater effect if membrane is depolarized) and use dependent. At therapeutic concentrations, the effects on Na^+ channels are selective, and no changes of spontaneous activity or responses to iontophoretically applied GABA or glutamate are detected. At concentrations 5- to 10-fold higher, multiple effects of *phenytoin* are evident, including reduction of spontaneous activity and enhancement of responses to GABA; these effects may underlie some of the unwanted toxicity associated with high levels of *phenytoin*.

Pharmacokinetic Properties

Phenytoin is available in two types of oral formulations that differ in their pharmacokinetics: rapid-release and extended-release forms. Once-daily dosing is possible only with the extended-release formulations, and due to differences in dissolution and other formulation-dependent factors, the plasma *phenytoin* level may change when converting from one formulation to another. Confusion also can arise because different formulations can include either *phenytoin* or *phenytoin sodium*. Therefore, comparable doses can be approximated by considering "*phenytoin* equivalents," but serum level monitoring is also necessary to assure therapeutic safety.

The pharmacokinetic characteristics of *phenytoin* are influenced markedly by its binding to serum proteins, by the nonlinearity of its elimination kinetics, and by its metabolism by hepatic cytochromes P450 (CYPs) (Table 20–3). *Phenytoin* is extensively bound (~90%) to serum proteins, mainly albumin. Small variations in the percentage of *phenytoin* that is bound dramatically affect the absolute amount of free (active) drug. Some agents can compete with *phenytoin* for binding sites on plasma proteins and increase free *phenytoin* at the time the new drug is added to the regimen. However, the effect on free *phenytoin* is only short-lived and usually does not cause clinical complications unless inhibition of *phenytoin* metabolism also occurs. For example, *valproate* competes for protein binding sites *and* inhibits *phenytoin* metabolism, resulting in marked and sustained increases in free *phenytoin*. Measurement of free rather than total *phenytoin* permits direct assessment of this potential problem in patient management.

Phenytoin is one of the few drugs for which the rate of elimination varies as a function of its concentration (i.e., the rate is nonlinear). The plasma $t_{1/2}$ of *phenytoin* ranges between 6 and 24 h at plasma concentrations below 10 μg/mL. At low blood levels, metabolism follows first-order kinetics. However, as blood levels rise, the maximal limit of the liver to metabolize *phenytoin* is approached; as a result, plasma drug concentration increases disproportionately as dosage is increased, even with small adjustments for levels near the therapeutic range.

The majority (95%) of *phenytoin* is metabolized in the hepatic endoplasmic reticulum by CYP2C9/10 and to a lesser extent CYP2C19 (see Table 20–3). The principal metabolite, a parahydroxyphenyl derivative, is inactive. Because its metabolism is saturable, other drugs that are metabolized by these CYPs can inhibit the metabolism of *phenytoin* and increase its plasma concentration. Conversely, the degradation rate of other drugs that serve as substrates for these enzymes can be inhibited by *phenytoin*; one such drug is *warfarin*, and addition of *phenytoin* to a patient receiving *warfarin* can lead to bleeding disorders (see Chapter 36). An alternative mechanism of drug interactions arises from *phenytoin*'s ability to induce various CYPs (see Chapter 5). Of particular note in this regard are oral contraceptives, which are metabolized by CYP3A4; treatment with *phenytoin* can enhance the metabolism of oral contraceptives and lead to unplanned pregnancy. The potential teratogenic effects of *phenytoin* underscore the importance of attention to this interaction. *Carbamazepine*, *oxcarbazepine*, *phenobarbital*, and *primidone* also induce CYP3A4 and likewise might increase degradation of oral contraceptives.

The low water solubility of *phenytoin* hindered its intravenous use and led to production of *fosphenytoin*, a water-soluble prodrug. *Fosphenytoin* is converted into *phenytoin* by phosphatases in liver and red blood cells with a $t_{1/2}$ of 8 to 15 min. *Fosphenytoin* is extensively bound (95%–99%) to human plasma proteins, primarily albumin. This binding is saturable, and *fosphenytoin* displaces *phenytoin* from protein-binding sites. *Fosphenytoin* is useful for adults with focal or generalized seizures when either the intravenous or intramuscular route of administration is indicated.

Toxicity

The toxic effects of *phenytoin* depend on the route of administration, the duration of exposure, and the dosage.

When *fosphenytoin*, the water-soluble prodrug, is administered intravenously at an excessive rate in the emergency treatment of status epilepticus, the most notable toxic signs are cardiac arrhythmias with or without hypotension and/or CNS depression. Although cardiac toxicity occurs more frequently in older patients and in those with known cardiac disease, it also can develop in young, healthy patients. These complications can be minimized by administering *fosphenytoin* at a rate of less than 150 mg of *phenytoin sodium* equivalents per minute. Acute oral overdose results primarily in cerebellar and vestibular symptoms; high doses have been associated with marked cerebellar atrophy. Toxic effects associated with chronic treatment also are primarily dose-related cerebellar-vestibular effects but also include other CNS effects, behavioral changes, increased frequency of seizures, gastrointestinal (GI) symptoms, gingival hyperplasia, osteomalacia, and megaloblastic anemia. Hirsutism is a particularly problematic untoward effect in females. Usually, these phenomena can be diminished by proper adjustment of dosage. Serious adverse effects, including those on the skin, bone marrow, and liver, probably are manifestations of drug allergy. Although rare, they necessitate withdrawal of the drug. Moderate transient elevation of the plasma concentrations of hepatic transaminases sometimes can also occur.

Gingival hyperplasia occurs in approximately 20% of all patients during chronic treatment and can be minimized by good oral hygiene. Related to this, *phenytoin* can also produce coarsening of facial features. Inhibition of release of antidiuretic hormone has been observed. Hyperglycemia and glycosuria appear to be due to inhibition of insulin secretion. Osteomalacia, with hypocalcemia and elevated alkaline phosphatase activity, has been attributed to both altered metabolism of vitamin D and he att(nd ınt inhibition of int .sti ıal abso ɔtion of Ca^{2+}. *Phen toin* also increases the metabolism of vitamin K and reduces the concentration of vitamin K–dependent proteins that are important for normal Ca^{2+} metabolism in bone. This may explain why the osteomalacia is not always ameliorated by the administration of vitamin D.

Hypersensitivity reactions include morbilliform rash in 2% to 5% of patients and occasionally more serious skin reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis. Drug-induced systemic lupus erythematosus, hepatic necrosis, hematological reactions including neutropenia and leukopenia, red cell aplasia, agranulocytosis, and mild thrombocytopenia also have been reported. Hypoprothrombinemia and hemorrhage have occurred in the newborns of mothers who received *phenytoin* during pregnancy; vitamin K is effective treatment or prophylaxis.

Plasma Drug Concentrations

A good correlation usually is observed between the total concentration of *phenytoin* in plasma and its clinical effect. Thus, control of seizures generally is obtained with total concentrations above 10 μg/mL, while toxic effects such as nystagmus develop at total concentrations around 20 μg/mL. Control of seizures generally is obtained with free *phenytoin* concentrations of 0.75 to 1.25 μg/mL.

Drug Interactions

Concurrent administration of any drug metabolized by CYP2C9 or CYP2C10 can increase the plasma concentration of *phenytoin* by decreasing its rate of metabolism (see Table 20–3). Conversely, the degradation rate of other drugs that are substrates for these enzymes can be inhibited by *phenytoin*. *Carbamazepine*, which may enhance the metabolism of *phenytoin*, causes a well-documented decrease in *phenytoin* concentration. *Phenytoin* can also induce expression of a number of different CYPs, leading to increased degradation of coadministered drugs such as oral contraceptives. Conversely, *phenytoin* reduces the concentration of *carbamazepine*.

Therapeutic Uses

Epilepsy. *Phenytoin* is one of the more widely used ASDs, and it is effective against focal and generalized tonic-clonic, focal to bilateral tonic-clonic, and tonic-clonic of unknown onset (tonic-clonic) seizures, but not generalized absence (absence) seizures. The use of *phenytoin* and other agents in the therapy of epilepsies is discussed further at the end of this chapter. *Phenytoin* preparations differ significantly in bioavailability and rate of absorption. In general, patients should consistently be treated with the same drug from a single manufacturer. However, if it becomes necessary to temporarily switch between products, care should be taken to select a therapeutically equivalent product and patients should be monitored for loss of seizure control or onset of new toxicities.

Other Uses. Trigeminal and related neuralgias occasionally respond to *phenytoin*, but *carbamazepine* may be preferable. The use of *phenytoin* in the treatment of cardiac arrhythmias is discussed in Chapter 34.

Benzodiazepines

The benzodiazepines are used primarily as sedative-antianxiety drugs; their pharmacology is described in Chapters 16 and 22. Discussion here is limited to their use in the therapy of the epilepsies. A large number of benzodiazepines have broad antiseizure properties, but only *clonazepam* and *clorazepate* have been approved in the U.S. for the long-term treatment of certain types of seizures. *Midazolam* was designated an orphan drug in 2006 for intermittent treatment of bouts of increased seizure activity in refractory patients with epilepsy who are on stable regimens of ASDs. *Diazepam* and *lorazepam* have well-defined roles in the management of status epilepticus. Figure 22–1 shows the basic structure of the benzodiazepines. Unlike other marketed 1,4-benzodiazepines, *clobazam* is a 1,5-benzodiazepine that is less lipophilic, less acidic, and may be better tolerated than traditional 1,4-benzodiazepines. *Clobazam* is used in a variety of seizure phenotypes and is approved in the U.S. for the treatment of Lennox-C .staut syndrome in patients aged 2 years or (lde)

Antiseizure Properties

In animal models, inhibition of *pentylenetetrazol*-induced seizures by the benzodiazepines is much more prominent than is their modification of the maximal electroshock seizure pattern. *Clonazepam* is unusually potent in antagonizing the effects of *pentylenetetrazol*, but it is almost without action on seizures induced by maximal electroshock. Benzodiazepines, including *clonazepam*, suppress the spread of kindled seizures and generalized convulsions produced by stimulation of the amygdala but do not abolish the abnormal discharge at the site of stimulation.

Mechanism of Action

The antiseizure actions of the benzodiazepines, as well as other effects that occur at nonsedating doses, result in large part from their ability to enhance GABA-mediated synaptic inhibition. Molecular cloning and study of recombinant receptors have demonstrated that the benzodiazepine receptor is an integral part of the $GABA_A$ receptor. At therapeutically relevant concentrations, benzodiazepines act at subsets of $GABA_A$ receptors and increase the frequency, but not duration, of openings at GABA-activated Cl^- channels (Twyman et al., 1989). At higher concentrations, *diazepam* and many other benzodiazepines can reduce sustained high-frequency firing of neurons, similar to the effects of *phenytoin*, *carbamazepine*, and *valproate*. Although these concentrations correspond to concentrations achieved in patients during treatment of status epilepticus with *diazepam*, they are considerably higher than those associated with antiseizure or anxiolytic effects in ambulatory patients. *Clobazam* potentiates GABA-mediated neurotransmission in the same fashion as other benzodiazepines at $GABA_A$ receptors.

Pharmacokinetic Properties

Benzodiazepines are well absorbed after oral administration, and concentrations in plasma are usually maximal within 1 to 4 h. After intravenous administration, they are redistributed in a manner typical of that for highly lipid-soluble agents. Central effects develop promptly but wane rapidly as the drugs move to other tissues. *Diazepam* is redistributed especially rapidly, with a $t_{1/2}$ of redistribution of approximately 1 h. The extent of binding of benzodiazepines to plasma proteins correlates with lipid solubility, ranging from approximately 99% for *diazepam* to approximately 85% for *clonazepam*.

The major metabolite of *diazepam*, *N*-desmethyl-diazepam, is somewhat less active than the parent drug and may behave as a partial agonist. This metabolite also is produced by the rapid decarboxylation of *clorazepate* following its ingestion. Both *diazepam* and *N*-desmethyldiazepam are slowly hydroxylated to other active metabolites, such as *oxazepam*. The $t_{1/2}$ of *diazepam* in plasma is between 1 and 2 days, while that of *N*-desmethyl-diazepam is approximately 60 h. *Clonazepam* is metabolized principally by reduction of the nitro group to produce inactive 7-amino derivatives. Less than 1% of the drug is recovered unchanged in the urine. The $t_{1/2}$ of *clonazepam* in plasma is approximately 23 h. *Lorazepam* is metabolized chiefly by conjugation with glucuronic acid; its $t_{1/2}$ in plasma is approximately 14 h. *Clobazam* has a $t_{1/2}$ of 18 h and is effective at doses between 0.5 and 1 mg/kg daily, with limited development of tolerance. The active metabolite of *clobazam* is norclobazam.

Toxicity

The principal side effects of long-term oral therapy with *clonazepam* are drowsiness and lethargy. These occur in approximately 50% of patients initially, but tolerance often develops with continued administration. Muscular incoordination and ataxia are less frequent. Although these symptoms usually can be kept to tolerable levels by reducing the dosage or the rate at which it is increased, they sometimes force drug discontinuation.

Other side effects include hypotonia, dysarthria, and dizziness. Behavioral disturbances, especially in children, can be very troublesome; these include aggression, hyperactivity, irritability, and difficulty in concentration. Both anorexia and hyperphagia have been reported. Increased salivary and bronchial secretions may cause difficulties in children. Seizures are sometimes exacerbated, and status epilepticus may be precipitated if the drug is discontinued abruptly. Other aspects of the toxicity of the benzodiazepines are discussed in Chapter 22. Cardiovascular and respiratory depression may occur after the intravenous administration of *diazepam*, *clonazepam*, or *lorazepam*, particularly if other ASDs or central depressants have been administered previously.

Plasma Drug Concentrations

Because tolerance affects the relationship between drug concentration and drug antiseizure effect, plasma concentrations of benzodiazepines are of limited value.

Therapeutic Uses

Clonazepam is useful in the therapy of absence seizures as well as myoclonic seizures in children. However, tolerance to its antiseizure effects usually develops after 1 to 6 months of administration, after which some patients will no longer respond to *clonazepam* at any dosage. The initial dose of *clonazepam* for adults should not exceed 1.5 mg/day and for children 0.01 to 0.03 mg/kg per day. The dose-dependent side effects are reduced if two or three divided doses are given each day. The dose may be increased every 3 days in amounts of 0.25 to 0.5 mg/day in children and 0.5 to 1 mg/day in adults. The maximal recommended dose is 20 mg/day for adults and 0.2 mg/kg per day for children. *Clonazepam* intranasal spray is designated as an orphan drug for recurrent acute repetitive seizures.

While *diazepam* is an effective agent for treatment of status epilepticus, its short duration of action is a disadvantage, leading to the more frequent use of *lorazepam*. Although *diazepam* is not useful as an oral agent for the treatment of seizure disorders, *clorazepate* is effective in combination with certain other drugs in the treatment of focal seizures. The maximal initial dose of *clorazepate* is 22.5 mg/day in three portions for adults and children older than age 12 years and 15 mg/day in two divided doses in children 9 to 12 years of age. *Clorazepate* is not recommended for children under the age of 9. *Clobazam* is used in a variety of seizure phenotypes and is approved in the U.S. for the treatment of Lennox-Gastaut syndrome in patients aged 2 years or older. In patients weighing greater than 30 kg, *clobazam* is initiated orally at 5 mg every 12 h and then titrated up to a maximum of 40 mg/day, if tolerated. Dose escalation must be done gradually, not exceeding more than once per week.

Antiseizure Barbiturates

The pharmacology of the barbiturates as a class is described in Chapter 22; discussion in this chapter is limited to *phenobarbital* and *primidone*.

Phenobarbital

Phenobarbital was the first effective organic antiseizure agent. It has relatively low toxicity, is inexpensive, and is still one of the more effective and widely used drugs for this purpose. While most barbiturates have antiseizure properties, only some barbiturates, such as *phenobarbital*, exert maximal antiseizure effects at doses below those that cause hypnosis. This therapeutic index determines a barbiturate's clinical utility as an antiseizure therapeutic drug.

Mechanism of Action

The mechanism by which phenobarbital inhibits seizures likely involves potentiation of synaptic inhibition through an action on the $GABA_A$ receptor (see Figure 20–3). Intracellular recordings of mouse cortical or spinal cord neurons demonstrated that *phenobarbital* enhances responses to iontophoretically applied GABA. These effects have been observed at therapeutically relevant concentrations of *phenobarbital*. Analyses of single channels in outside-out patches isolated from mouse spinal cord neurons demonstrated that *phenobarbital* increased the $GABA_A$ receptor–mediated current by increasing the duration of bursts of $GABA_A$ receptor–mediated currents without changing the frequency of bursts

(Twyman et al., 1989). At levels exceeding therapeutic concentrations, *phenobarbital* also limits sustained repetitive firing; this may underlie some of the antiseizure effects of higher concentrations of *phenobarbital* achieved during therapy of status epilepticus.

Pharmacokinetic Properties

Oral absorption of *phenobarbital* is complete but somewhat slow; peak concentrations in plasma occur several hours after a single dose. It is 40% to 60% bound to plasma proteins and bound to a similar extent in tissues, including brain. Up to 25% of a dose is eliminated by pH-dependent renal excretion of the unchanged drug; the remainder is inactivated by hepatic microsomal enzymes, principally CYP2C9, with minor metabolism by CYP2C19 and CYP2E1. *Phenobarbital* induces uridine diphosphate-glucuronosyltransferases (UGTs) as well as the CYP2C and CYP3A subfamilies. Drugs metabolized by these enzymes can be more rapidly degraded when coadministered with *phenobarbital*; importantly, oral contraceptives are metabolized by CYP3A4. The terminal $t_{1/2}$ of *phenobarbital* varies with age, with values ranging in adults from 5 to 140 h and in children less than 5 years of age from 40 to 70 h. *Phenobarbital*'s duration of effect usually exceeds 6 to 12 h in nontolerant patients.

Toxicity

Sedation, the most frequent undesired effect of *phenobarbital*, is apparent to some extent in all patients upon initiation of therapy, but tolerance develops during chronic medication. Nystagmus and ataxia occur at excessive dosage. *Phenobarbital* can produce irritability and hyperactivity in children and agitation and confusion in the elderly. Scarlatiniform or morbilliform rash, possibly with other manifestations of drug allergy, occurs in 1% to 2% of patients. Exfoliative dermatitis is rare. Hypoprothrombinemia with hemorrhage has been observed in the newborns of mothers who have received *phenobarbital* during pregnancy; vitamin K is effective for treatment or prophylaxis. As with *phenytoin*, megaloblastic anemia that responds to folate and osteomalacia that responds to high doses of vitamin D occur during chronic *phenobarbital* therapy of epilepsy. Other adverse effects of *phenobarbital* are discussed in Chapter 22.

Plasma Drug Concentrations

During long-term therapy in adults, the plasma concentration of *phenobarbital* averages 10 µg/mL per daily dose of 1 mg/kg; in children, the value is 5 to 7 µg/mL per 1 mg/kg. Although a precise relationship between therapeutic results and concentration of drug in plasma does not exist, plasma concentrations of 10 to 35 µg/mL are usually recommended for control of seizures.

The relationship between plasma concentration of *phenobarbital* and adverse effects varies with the development of tolerance. Sedation, nystagmus, and ataxia usually are absent at concentrations below 30 µg/mL during long-term therapy, but adverse effects may be apparent for several days at lower concentrations when therapy is initiated or whenever the dosage is increased. Concentrations greater than 60 µg/mL may be associated with marked intoxication in the nontolerant individual. Since significant behavioral toxicity may be present despite the absence of overt signs of toxicity, the tendency to maintain patients, particularly children, on excessively high doses of *phenobarbital* should be resisted. The plasma *phenobarbital* concentration should be increased above 30 to 40 µg/mL only if the increment is adequately tolerated and only if it contributes significantly to control of seizures.

Drug Interactions

Interactions between *phenobarbital* and other drugs usually involve induction of the hepatic CYPs by *phenobarbital* (see Table 20–3 and Chapters 5 and 22). The interaction between *phenytoin* and *phenobarbital* is variable. Concentrations of *phenobarbital* in plasma may be elevated by as much as 40% during concurrent administration of *valproic acid*.

Therapeutic Uses

Phenobarbital is an effective agent for generalized tonic-clonic, focal to bilateral tonic-clonic, tonic-clonic of unknown onset (generalized tonic-clonic), and focal seizures. Its efficacy, low toxicity, and low cost make it an important agent for these types of epilepsy. However, its sedative effects and its tendency to disturb behavior in children have reduced its use as a primary agent. It is not effective for absence seizures.

Primidone

Although primidone is indicated in the U.S. for patients with focal and/or generalized epilepsy, it has largely been replaced by *carbamazepine* and other newer ASDs that possess a lower incidence of sedation.

Mechanism of Action

Primidone, also known as 2-desoxyphenobarbitol, is metabolized to two active metabolites: *phenobarbital* and *phenylethylmalonamide* (PEMA). Each of these three compounds has antiseizure effects on focal and generalized tonic-clonic seizures. The exact mechanism of *primidone*'s antiseizure effect is not fully understood.

Pharmacokinetics

Primidone is completely absorbed and generally reaches peak plasma concentration within approximately 3 h of oral administration. *Primidone* is not highly protein bound in plasma (30%) and is rapidly metabolized to both *phenobarbital* and PEMA. Both *primidone* and *phenobarbital* undergo extensive conjugation prior to excretion. *Primidone*'s $t_{1/2}$ is approximately 6 to 8 h. In contrast, the terminal $t_{1/2}$ of *phenobarbital* varies with age, with values ranging in adults from 5 to 140 h and in children less than 5 years of age from 40 to 70 h. Because of its slow clearance, *phenobarbital* reaches therapeutic concentrations approximately two to three times higher than that of *primidone*. Care should be taken and *phenobarbital* plasma levels closely monitored during titration of *primidone* doses since *primidone* may reach steady-state levels rapidly (1–2 days), whereas the metabolites, *phenobarbital* and PEMA, each attain steady state more slowly (2–20 days and 3–4 days, respectively).

Toxicity

The dose-dependent adverse effects of *primidone* are similar to those of *phenobarbital*, except that pronounced drowsiness is observed early after *primidone* administration. Common adverse effects include ataxia and vertigo, both of which diminish and may disappear with continued therapy. *Primidone* is contraindicated in patients with either porphyria or with hypersensitivity to *phenobarbital*.

Therapeutic Uses

Doses of 10 to 20 mg/kg per day reach clinically relevant steady-state plasma concentrations (8–12 µg/mL), although interpatient variation is common. In addition to its early use in patients with focal-onset and/or generalized epilepsy, *primidone* is still considered to be a first-line therapy for essential tremor with the β adrenergic antagonist *propranolol*.

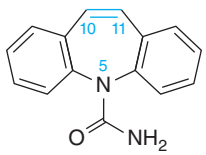
IMINOSTILBENES

Carbamazepine

Carbamazepine has been employed since the 1960s for the treatment of trigeminal neuralgia. It was initially approved in the U.S. for use as an antiseizure agent in 1974 and is now considered to be a primary drug for the treatment of generalized tonic-clonic, focal to bilateral tonic-clonic, tonic-clonic of unknown onset (generalized tonic-clonic), and focal seizures.

Chemistry

Carbamazepine is related chemically to the tricyclic antidepressants. It is a derivative of iminostilbene with a carbamyl group at the 5 position; this moiety is essential for potent antiseizure activity.



CARBAMAZEPINE

Mechanism of Action

Like *phenytoin*, *carbamazepine* limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord or cortical neurons maintained *in vitro* (McLean and Macdonald, 1986a). This appears to be mediated by a slowing of the rate of recovery of voltage-activated Na^+ channels from inactivation. These effects of *carbamazepine* are evident at concentrations in the range of therapeutic drug levels in cerebrospinal fluid (CSF) in humans. At those concentrations, the effects of *carbamazepine* are selective, in that there are no effects on spontaneous activity or on responses to iontophoretically applied GABA or glutamate. The *carbamazepine* metabolite, 10,11-epoxycarbamazepine, also limits sustained repetitive firing at therapeutically relevant concentrations, suggesting that this metabolite may contribute to the antiseizure efficacy of *carbamazepine*.

Pharmacokinetic Properties

The pharmacokinetics of *carbamazepine* are complex. They are influenced by its limited aqueous solubility and by the ability of many ASDs, including *carbamazepine* itself, to increase their conversion to active metabolites by hepatic oxidative enzymes (see Table 20–3). *Carbamazepine* is absorbed slowly and erratically after oral administration. Peak concentrations in plasma usually are observed 4 to 8 h after oral ingestion but may be delayed by as much as 24 h, especially following the administration of a large dose. The drug distributes rapidly into all tissues. Approximately 75% of *carbamazepine* binds to plasma proteins, and concentrations in the CSF appear to correspond to the concentration of free drug in plasma. The predominant metabolic pathway in humans involves conversion to the 10,11-epoxide, a metabolite as active as the parent compound in various animals; its concentrations in plasma and brain may reach 50% of those of *carbamazepine*, especially during the concurrent administration of *phenytoin* or *phenobarbital*. The 10,11-epoxide is metabolized further to inactive compounds, which are excreted in the urine, principally as glucuronides. *Carbamazepine* also is inactivated by conjugation and hydroxylation. Hepatic CYP3A4 is primarily responsible for biotransformation of *carbamazepine*. *Carbamazepine* induces CYP2C, CYP3A, and UGT, thus enhancing the metabolism of drugs degraded by these enzymes. Of particular importance in this regard are oral contraceptives, which are also metabolized by CYP3A4.

Toxicity

Acute intoxication with *carbamazepine* can result in stupor or coma, hyperirritability, convulsions, and respiratory depression. During long-term therapy, the more frequent untoward effects of the drug include drowsiness, vertigo, ataxia, diplopia, and blurred vision. The frequency of seizures may increase, especially with overdose. Other adverse effects include nausea, vomiting, serious hematological toxicity (aplastic anemia, agranulocytosis), and hypersensitivity reactions (dangerous skin reactions, eosinophilia, lymphadenopathy, splenomegaly). A late complication of therapy with *carbamazepine* is retention of water, with decreased osmolality and concentration of Na^+ in plasma, especially in elderly patients with cardiac disease.

Some tolerance develops to the neurotoxic effects of *carbamazepine*, and they can be minimized by gradual increase in dosage or adjustment of maintenance dosage. Various hepatic or pancreatic abnormalities have been reported during therapy with *carbamazepine*, most commonly a transient elevation of hepatic transaminases in plasma in 5% to 10% of patients. A transient, mild leukopenia occurs in approximately 10% of patients during initiation of therapy and usually resolves within the first 4 months of continued treatment; transient thrombocytopenia also has been noted. In approximately 2% of patients, a persistent leukopenia may develop that requires withdrawal of the drug. The initial concern that aplastic anemia might be a frequent complication of long-term therapy with *carbamazepine* has not materialized. In most cases, the administration of multiple drugs or the presence of another underlying disease has made it difficult to establish a causal relationship. The prevalence of aplastic anemia is approximately 1 in 200,000 patients who are treated with the drug. It is not clear whether monitoring of hematological function can avert the development of irreversible aplastic anemia. Although *carbamazepine* is carcinogenic in rats, it is not known to be a human carcinogen. Possible teratogenic effects are discussed later in the chapter.

Plasma Drug Concentrations

There is no simple relationship between the dose of *carbamazepine* and concentrations of the drug in plasma. Therapeutic concentrations are reported to be 6 to 12 μg/mL, but with considerable variation. Side effects referable to the CNS are frequent at concentrations above 9 μg/mL.

Drug Interactions

Phenobarbital, *phenytoin*, and *valproate* may increase the metabolism of *carbamazepine* by inducing CYP3A4; *carbamazepine* may enhance the biotransformation of *phenytoin*. Concurrent administration of *carbamazepine* may lower concentrations of *valproate*, *lamotrigine*, *tiagabine*, and *topiramate*. *Carbamazepine* reduces both the plasma concentration and therapeutic effect of *haloperidol*. The metabolism of *carbamazepine* may be inhibited by *propoxyphene*, *erythromycin*, *cimetidine*, *fluoxetine*, and *isoniazid*.

Therapeutic Uses

Carbamazepine is useful in patients with generalized tonic-clonic and both focal aware and focal with impaired awareness seizures (see Table 20–1). When it is used, renal and hepatic function and hematological parameters should be monitored. The therapeutic use of *carbamazepine* is discussed further at the end of this chapter.

Carbamazepine can produce therapeutic responses in patients with bipolar disorder, including some in whom *lithium carbonate* is ineffective. Further, *carbamazepine* has antidiuretic effects that are sometimes associated with increased concentrations of antidiuretic hormone in plasma via poorly understood mechanisms.

Carbamazepine is the primary agent for treatment of trigeminal and glossopharyngeal neuralgias. It is also effective for lightning-type ("tabetic") pain associated with bodily wasting. *Carbamazepine* is also used in the treatment of bipolar affective disorders, as discussed further in Chapter 19.

Oxcarbazepine

Oxcarbazepine (10,11-dihydro-10-oxocarbamazepine) is a keto analogue of *carbamazepine*. *Oxcarbazepine* has been approved for monotherapy or adjunct therapy for focal seizures in adults, as monotherapy for focal seizures in children ages 4 to 16, and as adjunctive therapy in children 2 years of age and older with epilepsy. *Oxcarbazepine* is a prodrug that is almost immediately converted to its metabolite, *eslicarbazepine*. *Eslicarbazepine* is then extensively converted to the active S(+) enantiomer, *S-licarbazepine*. *Oxcarbazepine* is inactivated by glucuronide conjugation, is eliminated by renal excretion, and has a $t_{1/2}$ of only 1 to 2 h.

Oxcarbazepine has a mechanism of action similar to that of *carbamazepine* but is a less potent enzyme inducer than *carbamazepine*. Substitution of *oxcarbazepine* for *carbamazepine* is associated with increased levels of *phenytoin* and *valproic acid*, presumably because of reduced induction of hepatic enzymes. *Oxcarbazepine* does not induce the hepatic enzymes involved in its own degradation. Although *oxcarbazepine* does not appear to reduce the anticoagulant effect of *warfarin*, it does induce CYP3A and thus reduces plasma levels of steroid oral contraceptives. Fewer hypersensitivity reactions have been associated with *oxcarbazepine*, and cross-reactivity with *carbamazepine* does not always occur. Although most adverse effects are similar to those with *carbamazepine*, hyponatremia may occur more commonly with *oxcarbazepine* than with *carbamazepine*.

Eslicarbazepine Acetate

Eslicarbazepine acetate is a prodrug approved in the U.S. as a monotherapy and adjunctive treatment of focal-onset seizures. As described previously, *eslicarbazepine* is converted to its active metabolite, *S-licarbazepine*, faster than its prodrug, *oxcarbazepine*; ultimately, *eslicarbazepine* has a similar mechanism of action as *oxcarbazepine*, since both serve as prodrugs of same active metabolite, *S-licarbazepine*. *Eslicarbazepine* competitively

inhibits fast voltage-gated sodium channels, stabilizing the inactivated state and the sodium-dependent release of neurotransmitters. *Eslicarbazepine* has a $t_{1/2}$ similar to that of *carbamazepine* (8–12 h); it is excreted as a glucuronide. *Eslicarbazepine acetate* in adults may be initiated at 400 to 1200 mg/day. Higher doses require careful titration based on patient response. Reduction in dosing is necessary in patients with renal impairment.

Succinimides

Ethosuximide

Ethosuximide is a primary agent for the treatment of absence seizures.

Structure-Activity Relationship

The structure-activity relationship of the succinimides is in accord with that for other antiseizure classes. *Ethosuximide*, with alkyl substituents, is the most active of the succinimides against seizures induced by pentylenetetrazol and is the most selective for absence seizures. A related compound, *methsuximide*, has phenyl substituents and is more active against maximal electroshock seizures. It is no longer in common use. Discussion of its properties can be found in previous editions of this book.

Pharmacological Effects

The most prominent characteristic of *ethosuximide* at nontoxic doses is protection against clonic motor seizures induced by *pentylenetetrazol*. By contrast, at nontoxic doses, *ethosuximide* does not inhibit tonic hind limb extension of electroshock seizures or kindled seizures. This profile correlates with efficacy against absence seizures in humans.

Mechanism of Action

Ethosuximide reduces low-threshold Ca^{2+} currents (T-type currents) in thalamic neurons (Coulter et al., 1989). The thalamus plays an important role in generation of 3-Hz spike-and-wave rhythms typical of absence seizures (Huguenard and McCormick, 2007). Neurons in the thalamus exhibit large-amplitude T-type currents that underlie bursts of action potentials and likely play an important role in thalamic oscillatory activity such as 3-Hz spike-and-wave activity. At clinically relevant concentrations, *ethosuximide* inhibits the T-type current, as is evident in voltage-clamp recordings of acutely isolated, ventrobasal thalamic neurons from rats and guinea pigs. *Ethosuximide* reduces this current without modifying the voltage dependence of steady-state inactivation or the time course of recovery from inactivation. By contrast, *succinimide* derivatives with convulsant properties do not inhibit this current. *Ethosuximide* does not inhibit sustained repetitive firing or enhance GABA responses at clinically relevant concentrations. Inhibition of T-type currents likely is the mechanism by which *ethosuximide* inhibits absence seizures.

Pharmacokinetic Properties

Absorption of *ethosuximide* appears to be complete, with peak concentrations in plasma within approximately 3 h after a single oral dose. *Ethosuximide* is not significantly bound to plasma proteins; during long-term therapy, its concentration in the CSF is similar to that in plasma. The apparent volume of distribution averages 0.7 L/kg.

Approximately 25% of the drug is excreted unchanged in the urine. The remainder is metabolized by hepatic microsomal enzymes, but whether CYPs are responsible is unknown. The major metabolite, the hydroxyethyl derivative, accounts for approximately 40% of *ethosuximide* metabolism, is inactive, and is excreted in the urine, as such and as the glucuronide. The plasma $t_{1/2}$ of *ethosuximide* averages between 40 and 50 h in adults and approximately 30 h in children.

Toxicity

The most common dose-related side effects are GI complaints (nausea, vomiting, and anorexia) and CNS effects (drowsiness, lethargy, euphoria, dizziness, headache, and hiccough). Some tolerance to these effects develops. Parkinson-like symptoms and photophobia also have been reported. Restlessness, agitation, anxiety, aggressiveness, inability to concentrate, and other behavioral effects have occurred primarily in patients with a prior history of psychiatric disturbance.

Urticaria and other skin reactions, including Stevens-Johnson syndrome, as well as systemic lupus erythematosus, eosinophilia, leukopenia, thrombocytopenia, pancytopenia, and aplastic anemia, also have been attributed to the drug. The leukopenia may be transient despite continuation of the drug, but several deaths have resulted from bone marrow depression. Renal and hepatic toxicity have not been reported.

Plasma Drug Concentrations

During long-term therapy, the plasma concentration of *ethosuximide* averages approximately 2 μg/mL per daily dose of 1 mg/kg. A plasma concentration of 40 to 100 μg/mL usually is required for satisfactory control of absence seizures.

Therapeutic Uses

Ethosuximide is effective against absence seizures but not tonic-clonic seizures. An initial daily dose of 250 mg in children (3–6 years old) and 500 mg in older children and adults is increased by 250-mg increments at weekly intervals until seizures are adequately controlled or toxicity intervenes. Divided dosage is required occasionally to prevent nausea or drowsiness associated with once-daily dosing. The usual maintenance dose is 20 mg/kg per day. Increased caution is required if the daily dose exceeds 1500 mg in adults or 750 to 1000 mg in children. The therapeutic use of *ethosuximide* is discussed further at the end of the chapter.

Other ASDs

Acetazolamide

Acetazolamide, the prototype for carbonic anhydrase inhibitors, is discussed in Chapter 29. Its antiseizure actions have been discussed in previous editions of this textbook. Although it is sometimes effective against absence seizures, its usefulness is limited by the rapid development of tolerance. Adverse effects are minimal when it is used in moderate dosage for limited periods.

Cannabidiol

Cannabidiol (CBD) is a nonintoxicating phytocannabinoid derived from *Cannabis sativa*. CBD has been demonstrated to have significant analgesic, anti-inflammatory, anticonvulsant, and anxiolytic activities without the psychoactive effect of tetrahydrocannabinol (THC) (Costa et al., 2007; Devinsky et al., 2014). CBD is supplied as a highly purified solution. This phytocannabinoid was approved by the U.S. FDA in 2018 and by the European Commission. Chapter 26 describes the biosynthesis and pharmacological effects of CBD and other cannabinoids.

Mechanism of Action

While the mechanism(s) of action contributing to CBD's reduction of seizures is unknown, CBD has demonstrated affinity for a diverse array of targets that functionally modulate neuronal excitability. CBD has little binding affinity for the endogenous cannabinoid receptors, CB_1 or CB_2 (Thomas et al., 2007). CBD acts as a noncompetitive negative allosteric modulator of CB_1 receptor when in the presence of agonists, such as THC (Laprairie et al., 2015), as an inverse agonist of the CB_2 receptor (Dos Santos et al., 2021), and as an inhibitor of the reuptake and hydrolysis of the endocannabinoid *anandamide* (Leweke et al., 2012).

CBD's antiseizure effects likely involve one or more of its actions on a diverse array of non–cannabinoid receptor–mediated targets. These targets include:

1. Activation of the vanilloid receptor, TRPV1 (Bisogno et al., 2001)
2. Antagonism of the orphan GPR55 and GPR55-mediated elevation of presynaptic Ca^{2+} (Sylantyev et al., 2013)
3. Activation of $5HT_{1A}$ receptors (Resstel et al., 2009)
4. Competitive inhibition of the equilibrative nucleoside transporter 1 (ENT-1) to regulate adenosine tone (Devinsky et al., 2014; Gray and Whalley, 2020)

Pharmacokinetics

CBD is a highly lipophilic phytocannabinoid with low water solubility and is administered orally (Rosenberg et al., 2015). According to Perucca and Bialer (2020), the oral bioavailability of CBD under fasting conditions is approximately 6% and increases 4-fold when the medication is coadministered with a high-fat meal. CBD is primarily protein bound in the blood and preferentially deposits in brain and adipose tissue (Rodriguez de Fonseca et al., 1994). The release of CBD from adipose tissue is responsible for its prolonged terminal elimination half-life of 18 to 32 h (Devinsky et al., 2014). CBD is metabolized in the liver and intestines by CYPs. Despite undergoing first-pass hepatic metabolism, a large proportion of the CBD dose is excreted unchanged in the feces (Wall et al., 1976).

Plasma Concentrations

Taylor et al. (2018) reported pharmacokinetic data obtained from the phase I, randomized, double-blind, placebo-controlled clinical trial of CBD conducted in healthy human subjects. After single oral dosing, CBD appeared rapidly in plasma with a time to maximum plasma concentration (t_{max}) of 4 to 5 h. The major circulating metabolites were 7-carboxy-CBD > parent CBD > 7-hydroxy-CBD (active metabolite) > 6-hydroxy-CBD (a relatively minor metabolite). The maximum plasma concentration (C_{Pmax}) and area under the plasma concentration-time curve from time zero to time t (AUC) increased in a less than dose-proportional manner. CBD reached steady state after approximately 2 days with moderate accumulation. CBD elimination was multiphasic. The terminal elimination $t_{1/2}$ was approximately 60 h following twice-daily dosing of either 750 or 1500 mg of CBD, and the half-life of effect was estimated to be 10 to 17 h. Similarly, after twice-daily dosing with 1500 mg of CBD, the C_{Pmax} was 541 ng/mL and AUCτ was 3236 ng·h/mL. Intake of a high-fat meal increased CBD plasma exposure by approximately 4.5-fold with no effect of food on either the t_{max} or the terminal half-life.

Drug Interactions

CBD is metabolized by hepatic CYPs. CBD inhibits CYP2C isozymes at low concentrations and CYP3A4 isozymes at higher concentrations (Bornheim et al., 1993; Jiang et al., 2011; Stout and Cimino, 2014). CBD also inhibits other CYPs, including 2D6 (Yamaori et al., 2011) and 1A1 (Yamaori et al., 2010). Since CYP2C and CYP3A4 are induced by ASDs, such as *carbamazepine*, *topiramate*, and *phenytoin*, and inhibited by other ASDs, such as *valproate*, there is a potential for bidirectional drug-drug interactions with CBD (Patsalos et al., 2020). For example, during open-label CBD clinical trials, patients treated with CBD and the benzodiazepine *clobazam* had elevated levels of the nordesmethyl metabolite of *clobazam*, which may contribute to both the sedation and the efficacy of CBD in these studies (Devinski et al., 2014; Friedman and Devinski, 2015; Pauli et al., 2020).

Toxicity

Human CBD studies have reported CBD-induced drug-drug interactions and dose-dependent hepatic abnormalities. The most common adverse events included diarrhea, fatigue, vomiting, and somnolence (Huestis et al., 2019).

Therapeutic Uses

In the U.S., CBD is indicated for the treatment of seizures associated with Lennox-Gastaut syndrome, Dravet syndrome, and tuberous sclerosis complex in patients who are 1 year of age and older. In the European Union, CBD has received orphan drug designation from the European Medicines Agency and is approved as adjunctive therapy with *clobazam* to treat seizures associated with Lennox-Gastaut syndrome and Dravet syndrome and for adjunctive use to treat seizures associated with tuberous sclerosis complex.

Cenobamate

Cenobamate is approved for use in partial-onset seizures in adults both as a monotherapy and as an add-on agent.

Pharmacological Effects and Mechanism of Action

Cenobamate reduces seizure burden, increases the responder rate, and increases the rate of seizure freedom in patients with partial-onset seizures (Buckley et al., 2021). The mechanism of action of *cenobamate* is not fully understood but may involve enhancement of slow and fast sodium channel inactivation as well as inhibition of the persistent sodium current (Buckley et al., 2021). It also acts as a positive allosteric modulator of the $GABA_A$ channel (Sharma et al., 2020).

Pharmacokinetics

Cenobamate is orally bioavailable and at therapeutic doses has a $t_{1/2}$ of 30 to 76 h (Buckley et al., 2021). Further, *cenobamate* may possess nonlinear pharmacokinetics, particularly at higher doses at which greater concentrations can prolong $t_{1/2}$. *Cenobamate* is metabolized primarily in the liver by CYPs (2E1, 2A6, and 2B6, and to a lesser extent 2C19 and 3A4) and UGT2B7; it is excreted mainly as a glucuronides in the urine and feces. *Cenobamate* is an inducer of CYP3A4, which may increase the potential for drug-drug interactions with concomitantly administered antiseizure drugs as well as a variety of other medications including oral contraceptives.

Therapeutic Use

Multicenter, double-blind, randomized, placebo-controlled trials have demonstrated that *cenobamate* reduces focal seizures. Adjunctive use of *cenobamate* reduced partial-onset seizures in patients with pharmacoresistant epilepsy in a dose-dependent manner (Krauss et al., 2020). *Cenobamate* is initiated slowly (initial doses 12.5–25 mg) and increased gradually over several weeks (escalating to 200–400 mg daily doses).

Toxicity

Common adverse effects include somnolence, dizziness, fatigue, diplopia, and headache. Major adverse effects include risk for allergic reactions and potential to shorten QT interval (contraindicated patients with history of shortened QT). Drug reaction with eosinophilia and systemic symptoms (DRESS; also known as multiorgan hypersensitivity) can occur in some patients, particularly when dose escalations are rapid.

Ezogabine

Pharmacological Effects and Mechanisms of Action

Ezogabine, known as *retigabine* in the European Union, is a first-in-class potassium channel opener. *Ezogabine* enhances transmembrane potassium currents mediated by the KCNQ family of ion channels (i.e., Kv7.2–Kv7.5). Through its activation of the KCNQ channels, *ezogabine* may stabilize the resting membrane potential and reduce brain excitability. *In vitro* studies suggest that *ezogabine* may also enhance GABA-mediated currents.

Therapeutic Use

Ezogabine was approved in the U.S. as adjunctive treatment of focal-onset seizures in patients aged 18 years and older who have inadequately responded to alternative ASDs and for whom the benefits outweigh the risk of retinal abnormalities and visual acuity deficits. Due to addition by the FDA of a black-box warning in 2017, the drug was removed from distribution.

Pharmacokinetics

Dosing in adults is typically initiated at 300 mg/day and gradually titrated to 600 to 1200 mg/day over several weeks. *Ezogabine* is rapidly absorbed after oral administration; absorption is unaffected by food. *Ezogabine* is approximately 80% protein bound in plasma. *Ezogabine* is metabolized by glucuronidation and acetylation, with a $t_{1/2}$ of 7 to 11 h. The parent drug and its metabolites are excreted in the urine. Thus, *ezogabine* generally requires three times daily dosing. Concomitant administration of *phenytoin* or *carbamazepine* may reduce plasma concentrations of *ezogabine*; thus, an increase in *ezogabine* dosage should be considered when adding *phenytoin* or *carbamazepine*.

Toxicity

The most common adverse effects associated with *ezogabine* include dizziness, somnolence, fatigue, confusion, and blurred vision. Vertigo, diplopia, memory impairment, gait disturbance, aphasia, dysarthria, and balance problems also may occur. Serious side effects, such as skin

discoloration, QT prolongation, and neuropsychiatric symptoms, including suicidal thoughts and behavior, psychosis, and hallucinations, have been reported. Due to the presence of Kv7.2–Kv7.5 in the bladder urothelium, *ezogabine* is also associated with urinary retention. Blue pigmentation of skin and lips occurs in as many as one-third of patients maintained on long-term *ezogabine* therapy. Chronic treatment with *ezogabine* may also cause retinal abnormalities, independent of changes in skin coloration. The FDA has changed the labeling of *ezogabine* to warn about the risks of serious adverse effects, all of which may be permanent. *Ezogabine* should thus be discontinued if clinical benefit is not achieved after careful titration. However, the discontinuation of *ezogabine* should be done gradually, while under the care of a physician.

Felbamate

Felbamate is not indicated as a first-line therapy for any type of seizure activity. Rather, *felbamate* was FDA-approved for focal seizures in patients who have inadequately responded to alternative ASDs and in patients for whom the severity of their epilepsy outweighs the substantial risk of aplastic anemia and hepatitis. The potential for such serious and life-threatening adverse effects has limited the clinical utility of *felbamate*.

Pharmacological Effects and Mechanisms of Action

Clinically relevant concentrations of *felbamate* inhibit NMDA-evoked responses and potentiate GABA-evoked responses in whole-cell, voltage-clamp recordings of cultured rat hippocampal neurons (Rho et al., 1994). This dual action on excitatory and inhibitory transmitter responses may contribute to the wide spectrum of action of the drug in seizure models.

Therapeutic Use

Despite the potential serious adverse effects, *felbamate* is used at doses ranging from 2 to 4 g/day. Randomized, double-blind, appropriately controlled clinical studies have demonstrated the efficacy of *felbamate* in patients with poorly controlled focal and secondarily generalized seizures (Sachdeo et al., 1992). *Felbamate* also reduced seizures in patients with Lennox-Gastaut syndrome (Felbamate Study Group in Lennox-Gastaut Syndrome, 1993). The clinical efficacy of this unique compound, which inhibits responses to NMDA while potentiating GABAergic neurotransmission, underscores the potential therapeutic value of identifying additional ASDs with novel mechanisms of action.

Fenfluramine

Fenfluramine was originally approved for treating obesity but was removed from the market by the FDA in 1997 due to the potential of serious adverse cardiac events due to finding of valvulopathies and primary pulmonary hypertension in significant numbers of patients. However, during this time, *fenfluramine* was also being examined for the potential use as an ASD when used at lower doses than those used for appetite suppression. Subsequently, it proved to successfully reduce seizures in children with Dravet syndrome, a severe epileptic encephalopathy often resulting from loss of function mutations in the SCN1A sodium channel subunit (Lagae et al., 2019; Nabbout et al., 2020). Low-dose *fenfluramine* was then approved by the FDA for the treatment of refractory seizures in Dravet syndrome in 2020.

Pharmacological Effects and Mechanism of Action

Fenfluramine, an amphetamine derivative, can increase extracellular levels of serotonin (5HT) by preventing uptake by the serotonin transporter SERT. In addition, fenfluramine exhibits agonist activity at the $5HT_2$, $5HT_{1D}$, and $5HT_{2C}$ receptors. *Fenfluramine* is also a positive modulator of the sigma-1 receptor (Martin et al., 2020). Such additional mechanisms may contribute to its superiority in seizure suppression compared to other 5HT uptake inhibitors.

Pharmacokinetics

Fenfluramine is orally bioavailable with a half-life of nearly 20 h. It is metabolized to norfenfluramine primarily by CYP1A2, CYP2B6, and CYP2D6. Additionally, CYP2C9, CYP2C19, and CYP3A4/5 are involved in *fenfluramine* metabolism, albeit to a lesser extent. Norfenfluramine is then deaminated and oxidized to form inactive metabolites that are excreted in the urine. *Fenfluramine* does not induce or inhibit CYPs. However, given the role of these enzymes in metabolizing *fenfluramine*, care should be taken when administering this drug with other drugs that either induce or inhibit these enzymes. This is of primary importance in Dravet syndrome, given that the standard of care can include the use of *stiripentol*, *clobazam*, and/or *valproic acid*, all drugs that increase risk for drug-drug interactions.

Therapeutic Use

Fenfluramine was approved for the use as an ASD in Dravet syndrome in patients 2 years of age and older in 2020. The initial starting and maintenance dosage is 0.1 mg/kg twice daily, although this can be increased weekly based on both efficacy and tolerability. The maximum daily maintenance dose of *fenfluramine* is 0.35 mg/kg twice daily. If patients are also taking *stiripentol* plus *clobazam*, then the maximum maintenance dosage is 0.2 mg/kg twice daily.

Toxicity

As noted above, the greatest risks for serious adverse events are for valvulopathies and primary pulmonary hypertension, risks that prompted a boxed warning from the FDA on the package insert. It is also suggested that cardiac assessments of patients be routinely performed. Of note, because the doses used for seizure control are less than those prescribed for weight loss, the risk of these adverse events appears to be reduced (Schoonjans et al., 2017). While *fenfluramine* is generally well tolerated, other adverse effects include decreased appetite, fatigue, pyrexia, diarrhea, nasopharyngitis, and decreased blood glucose (Lagae et al., 2019; Nabbout et al., 2020).

Gabapentin and Pregabalin

Gabapentin and *pregabalin* are ASDs that consist of a GABA molecule covalently bound to either a lipophilic cyclohexane ring or isobutane. *Gabapentin* was designed to be a centrally active GABA agonist, with its high lipid solubility aimed at facilitating its transfer across the blood-brain barrier.

Pharmacological Effects and Mechanisms of Action

Gabapentin inhibits tonic hind limb extension in the electroshock seizure model. Interestingly, *gabapentin* also inhibits clonic seizures induced by *pentylenetetrazol*. Its efficacy in both these tests parallels that of *valproic acid* and distinguishes it from *phenytoin* and *carbamazepine*. Despite their design as GABA agonists, neither *gabapentin* nor *pregabalin* mimics GABA when iontophoretically applied to neurons in primary culture. These compounds interact with multiple targets in neurons. They bind with high affinity to a protein in cortical membranes with an amino acid sequence identical to that of the α_2-δ1 subunit of Ca_V, the voltage-gated Ca^{2+} channel (Gee et al., 1996). *Gabapentin* also binds to the voltage-gated K^+ channels KCNQ2/3 (the molecular correlate of neuronal M-currents) and homomeric KCNQ3 and KCNQ5 (Manville and Abbott, 2018). The proposed responses to *gabapentin*'s binding at these sites are the reduction of neuronal Ca^{2+} currents (via interaction with Ca_V) and activation of KCNQ2/3 and homomeric KCNQ3 and KCNQ5 channels, leading to hyperpolarization of susceptible neurons, with concomitant reduction in excitability. Whether the anticonvulsant effects of *gabapentin* are mediated by these interactions is not yet clear. *Pregabalin* binding is reduced but not eliminated in mice carrying a mutation in the $\alpha_2\delta$-1 protein (Field et al., 2006), and analgesic efficacy of *pregabalin* is eliminated; whether the anticonvulsant effects of *pregabalin* are also eliminated was not reported.

Pharmacokinetics

Gabapentin and *pregabalin* are absorbed after oral administration and are not metabolized in humans. These compounds are not bound to plasma proteins and are excreted unchanged, mainly in the urine. Their half-lives, when used as monotherapy, approximate 6 h. These compounds have no known interactions with other ASDs.

Therapeutic Uses

Gabapentin and *pregabalin* are effective for focal seizures, with and without progression to bilateral tonic-clonic seizures, when used in addition to other ASDs

Double-blind placebo-controlled trials of adults with refractory focal seizures demonstrated that addition of *gabapentin* or *pregabalin* to other ASDs is superior to placebo (French et al., 2003; Sivenius et al., 1991). A double-blind study of *gabapentin* monotherapy (900 or 1800 mg/day) disclosed that *gabapentin* was equivalent to *carbamazepine* (600 mg/day) for newly diagnosed focal or generalized epilepsy (Chadwick et al., 1998). *Gabapentin* also is being used for the treatment of migraine, chronic pain, and bipolar disorder.

Gabapentin usually is effective in doses of 900 to 1800 mg daily in three doses, although 3600 mg may be required in some patients to achieve reasonable seizure control. Therapy usually is begun with a low dose (300 mg once on the first day), which is increased in daily increments of 300 mg until an effective dose is reached.

Toxicity

Overall, *gabapentin* is well tolerated with the most common adverse effects of somnolence, dizziness, ataxia, and fatigue. These effects usually are mild to moderate in severity but resolve within 2 weeks of onset during continued treatment. With respect to use during pregnancy, *gabapentin* and *pregabalin* can cause fetal adverse effects in animal studies, but there are no adequate human studies; potential benefits may warrant use despite potential risks.

Lacosamide

Lacosamide is a stereo-selective enantiomer of the amino acid, L-serine. This functionalized amino acid was approved by the FDA in 2008 as adjunctive therapy for focal-onset seizures in patients 17 years of age or older. The FDA assigned *lacosamide* a Controlled Substance Act Schedule V designation, meaning it has a low potential for abuse. However, abuse of *lacosamide* may lead to limited physical or psychological dependence compared to the substances designated as Controlled Substance Act Schedule IV.

Pharmacological Effects and Mechanism of Action

Lacosamide is the first ASD to enhance the slow inactivation of voltage-gated Na^+ channels and to limit sustained repetitive firing, the neuronal firing pattern characteristic of focal seizures. *Lacosamide* also binds collapsin response mediator protein 2 (crmp-2), a phosphoprotein involved in neuronal differentiation and axon outgrowth, but the contribution of crmp-2 to *lacosamide*'s antiseizure efficacy remains unclear. Rather, *lacosamide*'s antiseizure mechanism is likely mediated by its enhancement of slow inactivation of Na^+ channels. *Lacosamide* was extensively evaluated by the Epilepsy Therapy Screening Project and found to be highly effective in numerous preclinical animal models of seizures and epilepsy, including maximal electroshock, hippocampal kindling, and the Frings and 6-Hz models, giving *lacosamide* a unique preclinical profile compared to other Na^+ channel blockers.

Pharmacokinetics

An injectable formulation of *lacosamide* is available for short-term use when oral administration is not possible. *Lacosamide* neither induces nor inhibits CYPs and thus has a low potential to induce harmful drug-drug interactions. As a monotherapy for the treatment of focal seizures, the initial recommended dose is 50 to 100 mg twice daily and, depending on patient response, may be increased at weekly intervals by 50 mg twice daily to a recommended maintenance dose of 100 to 200 mg twice daily, or 200 to 400 mg/day. Peak *lacosamide* plasma concentrations occur approximately 1 to 4 h after oral administration, and food consumption does not affect the absorption. *Lacosamide* has a $t_{1//2}$ of approximately 12 to 16 h and is 95% excreted in urine, 40% as the parent drug. The major metabolite, *O*-desmethyl-lacosmide, is inactive.

Therapeutic Use

Lacosamide has been approved for both monotherapy and add-on therapy for focal-onset seizures in patients aged 17 years and older. The pharmacological profile is advantageous for hospitalized patients, since it is available in an intravenous formulation, has minimal hepatic metabolism, and has no adverse respiratory effects. In addition, double-blind, placebo-controlled studies of adults with refractory focal seizures suggest that addition of *lacosamide* to other ASDs is superior to the addition of placebo.

Toxicity

Lacosamide is generally well tolerated. Although it has been associated with a brief (6 msec) prolongation of the PR interval, recent studies in healthy patients find that *lacosamide* does not appear to prolong the QT interval. No major adverse effects have been reported, although minor adverse effects include headache, dizziness, double vision, nausea, vomiting, fatigue, tremor, loss of balance, and somnolence. In addition, like most currently available ASDs, *lacosamide* may contribute to suicidal ideations and suicide. As a consequence, the FDA has mandated a boxed warning for this concern.

Lamotrigine

Lamotrigine is a phenyltriazine derivative initially developed as an antifolate agent based on the incorrect idea that reducing folate would effectively combat seizures. Structure-activity studies have since indicated that its effectiveness as an ASD is unrelated to its antifolate properties (Macdonald and Greenfield, 1997).

Pharmacological Effects and Mechanisms of Action

Lamotrigine suppresses tonic hind limb extension in the maximal electroshock model and focal and secondarily generalized seizures in the kindling model but does not inhibit clonic motor seizures induced by *pentylenetetrazol*. *Lamotrigine* blocks sustained repetitive firing of mouse spinal cord neurons and delays the recovery from inactivation of recombinant Na^+ channels, mechanisms similar to those of *phenytoin* and *carbamazepine* (Xie et al., 1995). This may explain *lamotrigine*'s actions on focal and secondarily generalized seizures. However, as mentioned below (see Therapeutic Use section), *lamotrigine* is effective against a broader spectrum of seizures than *phenytoin* and *carbamazepine*, suggesting that *lamotrigine* may have actions in addition to regulating recovery from inactivation of Na^+ channels. The mechanisms underlying its broad spectrum of actions are incompletely understood. One possibility is suggested by *lamotrigine*'s inhibition of glutamate release in rat cortical slices treated with *veratridine*, a Na^+ channel activator, raising the possibility that *lamotrigine* inhibits synaptic release of glutamate by acting at Na^+ channels themselves.

Pharmacokinetics

Lamotrigine is completely absorbed from the GI tract and is metabolized primarily by glucuronidation. The plasma $t_{1/2}$ of a single dose is 24 to 30 h. Administration of *phenytoin*, *carbamazepine*, or *phenobarbital* reduces the $t_{1/2}$ and plasma concentrations of *lamotrigine*. Conversely, addition of *valproate* markedly increases plasma concentrations of *lamotrigine*, likely by inhibiting glucuronidation. Addition of *lamotrigine* to *valproic acid* produces a reduction of *valproate* concentrations by approximately 25% over a few weeks. Concurrent use of *lamotrigine* and *carbamazepine* is associated with increases of the 10,11-epoxide of *carbamazepine* and clinical toxicity in some patients.

Therapeutic Use

Lamotrigine is useful for monotherapy and add-on therapy of focal and secondarily generalized tonic-clonic seizures in adults and Lennox-Gastaut syndrome in both children and adults. Lennox-Gastaut syndrome is a disorder of childhood characterized by multiple seizure types, intellectual disability, and refractoriness to antiseizure medication.

Lamotrigine monotherapy in newly diagnosed focal or generalized tonic-clonic seizures is equivalent to monotherapy with *carbamazepine* or *phenytoin* (Brodie et al., 1995; Steiner et al., 1999). A double-blind, placebo-controlled trial of addition of *lamotrigine* to existing ASDs further demonstrated effectiveness of *lamotrigine* against tonic-clonic seizures and drop attacks in children with the Lennox-Gastaut syndrome (Motte et al., 1997). *Lamotrigine* was also superior to placebo in a double-blind study of children with newly diagnosed absence epilepsy (Frank et al., 1999).

Patients who are already taking a hepatic enzyme–inducing ASD (e.g., *carbamazepine*, *phenytoin*, *phenobarbital*, or *primidone*, but not *valproate*) should be given *lamotrigine* initially at 50 mg/day for 2 weeks. The dose is increased to 50 mg twice per day for 2 weeks and then increased in increments of 100 mg/day each week up to a maintenance dose of 300 to 500 mg/day divided into two doses. For patients taking *valproate* in addition to an enzyme-inducing ASD, the initial dose should be 25 mg every other day for 2 weeks, followed by an increase to 25 mg/day for 2 weeks; the dose then can be increased by 25 to 50 mg/day every 1 to 2 weeks up to a maintenance dose of 100 to 150 mg/day divided into two doses.

Toxicity

The most common adverse effects are dizziness, ataxia, blurred or double vision, nausea, vomiting, and rash when *lamotrigine* is added to another ASD. A few cases of Stevens-Johnson syndrome and disseminated intravascular coagulation have been reported. The incidence of serious rash in pediatric patients (~0.8%) is higher than in the adult population (0.3%).

Levetiracetam and Brivaracetam

Levetiracetam is a pyrrolidine, the racemically pure S-enantiomer of α-ethyl-2-oxo-1-pyrrolidineacetamide, and FDA-approved for adjunctive therapy for myoclonic, focal-onset, and primary generalized tonic-clonic seizures in adults and children as young as 4 years old. *Brivaracetam*, an analogue of *levetiracetam*, was FDA-approved in 2016 as an adjunctive therapy for focal-onset seizures in patients with epilepsy aged 16 years and older.

Pharmacological Effects and Mechanism of Action

Levetiracetam exhibits a novel pharmacological profile: It inhibits focal and secondarily generalized tonic-clonic seizures in the kindling model yet is ineffective against maximum electroshock- and *pentylenetetrazol*-induced seizures, findings consistent with clinical effectiveness against focal and secondarily generalized tonic-clonic seizures. The mechanism by which *levetiracetam* exerts these antiseizure effects is not fully understood. However, the correlation between binding affinity of *levetiracetam* and its analogues and their potency toward audiogenic seizures suggests that the synaptic vesicle protein, SV2A, mediates the anticonvulsant effects of *levetiracetam* (Rogawski and Bazil, 2008). Hypothetically, binding of *levetiracetam* to SV2A might affect cellular function or neuronal excitability by modifying the release of glutamate and GABA through an action on vesicular function. In addition, *levetiracetam* inhibits calcium fluxes from intracellular stores and via N-type calcium channels.

Brivaracetam is a novel, high-affinity (selective) ligand for SVA2 that also demonstrates inhibitory effects on neuronal voltage-gated sodium channels (Kenda et al., 2004; Zona et al., 2010). Preclinical studies suggest a broad spectrum of anticonvulsant protection.

Pharmacokinetics

Levetiracetam is rapidly and almost completely absorbed after oral administration and is not bound to plasma proteins. The plasma half-life is 6 to 8 h but may be longer in elderly patients. Ninety-five percent of the drug and its inactive metabolite are excreted in the urine, 65% of which is unchanged drug; 24% of the drug is metabolized by hydrolysis of the acetamide group. It neither induces nor is a high-affinity substrate for CYPs or glucuronidases and thus is devoid of known interactions with other ASDs, oral contraceptives, or anticoagulants. Oral, extended-release, and intravenous formulations are all available. In comparison, *brivaracetam* is rapidly absorbed and well tolerated with an elimination $t_{1/2}$ of approximately 7 to 8 h.

Therapeutic Use

Levetiracetam is marketed for the adjunctive treatment of focal seizures in adults and children, for primary generalized tonic-clonic seizures, and for myoclonic seizures of juvenile myoclonic epilepsy. It is available in tablet (10, 25, 50, 75, or 100 mg), oral solution (10 mg/mL), or injectable form (50 mg/5 mL). Adult dosing is initiated at 500 to 1000 mg/day and increased every 2 to 4 weeks by 1000 mg to a maximum dose of 3000 mg/day. The drug is administered twice daily. Double-blind, placebo-controlled trials of adults with either refractory focal seizures or uncontrolled generalized tonic-clonic seizures associated with idiopathic generalized epilepsy revealed that addition of *levetiracetam* to other antiseizure medications was superior to placebo. *Levetiracetam* also has efficacy as adjunctive therapy for refractory generalized myoclonic seizures (Andermann et al., 2005). There is insufficient evidence on its use as monotherapy for focal or generalized epilepsy. The recommended starting dose for *brivaracetam* is 50 mg twice daily, which based on patient response and tolerability may be adjusted to either 25 mg twice daily or 100 mg twice daily, as needed.

Toxicity

Both *levetiracetam* and *brivaracetam* are well tolerated. The most frequently reported adverse effects associated with *levetiracetam* are somnolence, asthenia, ataxia, and dizziness. Behavioral and mood changes are serious but less common. For *brivaracetam*, the most common adverse effects are similarly mild and include somnolence, sedation, dizziness, and GI upset. In patients with hepatic insufficiency, dose adjustment may be required with *brivaracetam* to 25 mg twice daily and a maximal dosage of 75 mg twice daily. Hypersensitivity reactions may occur.

Perampanel

Pharmacological Effects and Mechanisms of Action

Perampanel is a first-in-class selective, noncompetitive antagonist of the AMPA-type ionotropic glutamate receptor (see Table 16–2; Bialer and White, 2010; Stephen and Brodie, 2011). Unlike NMDA antagonists, which shorten the duration of repetitive discharges, AMPA receptor antagonists prevent repetitive neuronal firing. Preclinical studies show a broad spectrum of activity in both acute and chronic seizure models, indicating that *perampanel* reduces fast excitatory signaling critical to the seizure generation (Tortorella et al., 1997) and spread (Namba et al., 1994; Rogawski and Donevan, 1999). However, data suggest that *perampanel* contributes a greater inhibitory effect on seizure propagation than on their initiation, since afterdischarge firing persists despite complete inhibition of behavioral seizures (Hanada et al., 2011).

Therapeutic Use

Perampanel is FDA-approved as an adjunctive therapy for the treatment of focal-onset seizures in patients 12 years and older with or without secondarily generalized seizures. The recommended oral starting dose is 2 mg once daily, titrated to a maximal dose of 4 to 12 mg/day at bedtime.

Pharmacokinetics

Perampanel is absorbed well after oral administration, with a plasma $t_{1/2}$ of approximately 105 h, allowing it to be administered once daily. It is 95% bound to plasma protein, mainly albumin, and is metabolized by hepatic oxidation and glucuronidation. A linear relationship between *perampanel* dose and plasma concentration has been reported over the dose range of 2 to 12 mg/day.

Drug Interactions

Primary metabolism is mediated by hepatic CYP3A, so specific drug interactions and dose adjustments may need to be considered. For example, *perampanel* may decrease the effectiveness of progesterone-containing contraceptives, *carbamazepine*, *clobazam*, *lamotrigine*, and *valproic acid*, but it may increase exposure to *oxcarbazepine*. Furthermore, serum *perampanel* may be decreased when taken with *carbamazepine*, *oxcarbazepine*, and *topiramate*.

Toxicity

Common adverse effects include somnolence, anxiety, confusion, imbalance, double vision, dizziness, GI distress or nausea, imbalance, and weight gain. Rare but serious adverse behavioral reactions, including hostility, aggression, and suicidal thoughts and/or behaviors, independent of clinical history of psychiatric disorder, have also been reported.

Rufinamide

Rufinamide is novel triazole derivative that is structurally unrelated to other marketed ASDs. It is FDA-approved for adjunctive treatment of seizures related to Lennox-Gastaut syndrome in children aged 4 years and older and adults.

Pharmacological Effects and Mechanism of Action

Rufinamide enhances slow inactivation of voltage-gated Na^+ channels and limits sustained repetitive firing, the firing pattern characteristic of focal seizures. The complete mechanism of action of *rufinamide* remains unclear.

Pharmacokinetics

Rufinamide is well absorbed orally, minimally protein bound in plasma, and reaches peak plasma concentrations approximately 4 to 6 h after oral administration. The $t_{1/2}$ is approximately 6 to 10 h. *Rufinamide* is metabolized by carboxylesterases, and the products are excreted in the urine.

Therapeutic Use

Rufinamide is effective against all seizure phenotypes in Lennox-Gastaut syndrome. In adults, 400 to 800 mg/day *rufinamide* is initially administered in two equal doses. Doses are then adjusted every other day by 10 mg/kg to whichever is less between maximal doses of 45 mg/kg per day or 3200 mg/day. Children are initiated at 10 mg/kg per day divided into two equal daily doses that are increased to the lesser of 45 mg/kg per day or 3200 mg/day.

Toxicity

Common adverse effects include headache, dizziness, somnolence, fatigue, and nausea.

Stiripentol

Therapeutic Use

Stiripentol is an aromatic alcohol that is structurally unrelated to any other ASDs. Although *stiripentol* was granted orphan drug status for the treatment of Dravet syndrome in 2008, it did not receive FDA approval until 2018. *Stiripentol* is used clinically in conjunction with *clobazam* and *valproate* as an adjunctive therapy for refractory generalized tonic-clonic seizures in patients with severe myoclonic epilepsy in infancy (Dravet syndrome) whose seizures are not adequately controlled with *clobazam* and *valproate* (Aneja and Sharma, 2013; Plsker, 2012). A randomized, double-blind, placebo-controlled clinical trial demonstrated that adjunctive *stiripentol* in children with Dravet syndrome who failed to respond to *valproate* and *clobazam* produced a 71% response rate (Chiron et al., 2000; Nabbout and Chiron, 2012). *Stiripentol* will also reduce the frequency and severity of tonic-clonic seizures as well as status epilepticus in infants and children with a variety of epilepsy syndromes (Inoue et al., 2009; Perez et al., 1999; Rey et al., 1999).

Pharmacological Effects and Mechanisms of Action

Although the exact nature of its antiseizure mechanism is not clear, *stiripentol* may increase central levels of GABA, the major inhibitory neurotransmitter in mammalian brain, by inhibition of synaptosomal uptake of GABA and/or by inhibition of GABA transaminase. *Stiripentol* has also been shown to enhance $GABA_A$ receptor–mediated neurotransmission and increase the mean open duration of $GABA_A$ receptor chloride channels in a barbiturate-like fashion in immature rat hippocampus (Fisher, 2011; Quilichini et al., 2006).

Drug Interactions

Stiripentol has diverse pharmacokinetic and pharmacodynamic interactions with other concomitantly administered drugs. It is a potent inhibitor of CYPs 3A4, 1A2, and 2C19. Thus, adjunctively administered ASDs, such as *carbamazepine*, *sodium valproate*, *phenytoin*, *phenobarbital*, and other benzodiazepines, may require dose adjustments due to the potent inhibition of their hepatic metabolism (Tran et al., 1997). *Stiripentol* can increase *clobazam* and *valproate* concentrations by 2- to 3-fold when given concomitantly, and reduction of their doses may be necessary to avoid toxicity. The initiation of adjunctive therapy with *stiripentol* is complex and should be undertaken gradually with frequent plasma monitoring for both the parent ASDs as well as their active metabolites. Plasma monitoring is important to inform reductions in concomitant ASDs as needed, based on patient response.

Pharmacokinetics

Stiripentol is quickly absorbed, with a time to peak plasma concentration of approximately 1.5 h, and is highly protein bound in plasma. *Stiripentol*'s kinetics are nonlinear. Plasma clearance decreases markedly at high doses and after repeated administration, possibly due to inhibition of the CYPs responsible for phase 1 of its metabolism. The elimination $t_{1/2}$ ranges from 4 to 13 h, increasing in a dose-dependent manner. A large fraction of the drug (73%) is ultimately metabolized to glucuronides and eliminated in the urine; most of the remainder is excreted unchanged in the feces.

Toxicity

The most commonly reported adverse effects in patients on *stiripentol* include anorexia, weight loss, insomnia, drowsiness, ataxia, hypotonia, and dystonia.

Tiagabine

Tiagabine is a derivative of nipecotic acid and approved by the FDA as adjunct therapy for focal seizures in adults.

Pharmacological Effects and Mechanism of Action

Tiagabine inhibits the GABA transporter, GAT-1, and thereby reduces GABA uptake into neurons and glia. In CA1 neurons of the hippocampus, *tiagabine* increases the duration of inhibitory synaptic currents, findings consistent with prolonging the effect of GABA at inhibitory synapses through reducing its reuptake by GAT-1. *Tiagabine* inhibits maximum electroshock seizures and both limbic and secondarily generalized tonic-clonic seizures in the kindling model, results suggestive of clinical efficacy against focal and tonic-clonic seizures. Paradoxically, *tiagabine* has been associated with the occurrence of seizures in patients without epilepsy, and off-label use of the drug is discouraged.

Pharmacokinetics

Tiagabine is rapidly absorbed after oral administration, extensively bound to serum or plasma proteins, and metabolized mainly in the liver, predominantly by CYP3A. Its $t_{1/2}$ of approximately 8 h is shortened by 2 to 3 h when coadministered with hepatic enzyme–inducing drugs such as *phenobarbital*, *phenytoin*, or *carbamazepine*.

Therapeutic Use

Double-blind, placebo-controlled trials have established *tiagabine*'s efficacy as add-on therapy of refractory focal seizures with or without secondary generalization. Its efficacy as monotherapy for newly diagnosed or refractory focal and generalized epilepsy has not been established.

Toxicity

The principal adverse effects include dizziness, somnolence, and tremor; they seem mild to moderate in severity and appear shortly after initiation of therapy. *Tiagabine* and other drugs that enhance effects of synaptically released GABA can facilitate spike-and-wave discharges in animal models of absence seizures. Case reports suggest that *tiagabine* treatment of patients with a history of spike-and-wave discharges causes exacerbations of their EEG abnormalities. Thus, *tiagabine* may be contraindicated in patients with generalized absence epilepsy.

Topiramate

Topiramate is a sulfamate-substituted monosaccharide that is FDA-approved as initial monotherapy (in patients at least 10 years old) and as adjunctive therapy (for patients as young as 2 years of age) for focal-onset or primary generalized tonic-clonic seizures, for Lennox-Gastaut syndrome in patients 2 years of age and older, and for migraine headache prophylaxis in adults.

Pharmacological Effects and Mechanisms of Action

Topiramate reduces voltage-gated Na^+ currents in cerebellar granule cells and may act on the inactivated state of the channel similar to *phenytoin*.

In addition, *topiramate* activates a hyperpolarizing K^+ current, enhances postsynaptic $GABA_A$-receptor currents, and limits activation of the AMPA-kainate subtype(s) of glutamate receptor (GluA and GluK receptors; see Table 16–2). *Topiramate* is a weak carbonic anhydrase inhibitor. *Topiramate* inhibits maximal electroshock- and *pentylenetetrazol*-induced seizures as well as focal and secondarily generalized tonic-clonic seizures in the kindling model, findings predictive of a broad spectrum of antiseizure actions clinically.

Pharmacokinetics

Topiramate is rapidly absorbed after oral administration, exhibits little (10%–20%) binding to plasma proteins, and is mainly excreted unchanged in the urine. The remainder undergoes metabolism by hydroxylation, hydrolysis, and glucuronidation with no single metabolite accounting for greater than 5% of an oral dose. Its $t_{1/2}$ is approximately 1 day. Reduced estradiol plasma concentrations occur with concurrent *topiramate*, suggesting the need for higher doses of oral contraceptives when coadministered with *topiramate*.

Therapeutic Use

Topiramate is equivalent to *valproate* and *carbamazepine* in children and adults with newly diagnosed focal and primary generalized epilepsy (Privitera et al., 2003). *Topiramate* is also effective as monotherapy for refractory focal epilepsy (Sachdeo et al., 1997) and refractory generalized tonic-clonic seizures (Biton et al., 1999) and is significantly more effective than placebo against both drop attacks and tonic-clonic seizures in patients with Lennox-Gastaut syndrome (Sachdeo et al., 1999).

Toxicity

Topiramate is well tolerated. The most common adverse effects are somnolence, fatigue, weight loss, and nervousness. It may precipitate renal calculi (kidney stones), likely due to inhibition of carbonic anhydrase. *Topiramate* has been associated with cognitive impairment, and patients may complain about a change in the taste of carbonated beverages.

Valproic Acid

The antiseizure properties of *valproic acid* were discovered serendipitously when it was employed as a vehicle for other compounds that were being screened for antiseizure activity.

Chemistry

Valproic acid (*n*-dipropylacetic acid) is a simple branched-chain carboxylic acid. Certain other branched-chain carboxylic acids have potencies similar to that of *valproic acid* in antagonizing *pentylenetetrazol*-induced convulsions. However, increasing the number of carbon atoms to nine introduces marked sedative properties. Straight-chain carboxylic acids have little or no activity.

Pharmacological Effects

Valproic acid is strikingly different from *phenytoin* and *ethosuximide* in that it is effective in inhibiting seizures in a variety of models. Like *phenytoin* and *carbamazepine*, *valproate* inhibits tonic hind limb extension in maximal electroshock seizures and kindled seizures at nontoxic doses. Like *ethosuximide*, *valproic acid* at subtoxic doses inhibits clonic motor seizures induced by *pentylenetetrazol*. Its efficacy in diverse models parallels its efficacy against absence as well as focal and generalized tonic-clonic seizures in humans.

Mechanism of Action

Valproic acid produces effects on isolated neurons similar to those of *phenytoin* and *ethosuximide* (see Table 20–2). At therapeutically relevant concentrations, *valproate* inhibits sustained repetitive firing induced by depolarization of mouse cortical or spinal cord neurons (McLean and Macdonald, 1986b). The action is similar to that of both *phenytoin* and *carbamazepine* and appears to be mediated by a prolonged recovery of voltage-activated Na^+ channels from inactivation. *Valproic acid* does not modify neuronal responses to iontophoretically applied GABA. In neurons isolated from the nodose ganglion, *valproate* also produces small reductions of T-type Ca^{2+} currents (Kelly et al., 1990) at clinically relevant but slightly higher concentrations than those that limit sustained repetitive firing; this effect on T-type currents is similar to that of *ethosuximide* in thalamic neurons (Coulter et al., 1989). Together, these actions of limiting sustained repetitive firing and reducing T-type currents may contribute to the effectiveness of *valproic acid* against focal and tonic-clonic seizures and absence seizures, respectively.

Another potential mechanism that may contribute to *valproate*'s antiseizure actions involves metabolism of GABA. Although *valproate* has no effect on responses to GABA, it does increase the amount of GABA that can be recovered from the brain after the drug is administered to animals. *In vitro*, *valproate* can stimulate the activity of the GABA synthetic enzyme, glutamic acid decarboxylase, and inhibit GABA degradative enzymes, GABA transaminase, and succinic semialdehyde dehydrogenase. Thus far, it has been difficult to relate the increased GABA levels to the antiseizure activity of *valproate*.

Finally, it is known that *valproic acid* is a potent inhibitor of histone deacetylase. Thus, some of its antiseizure activity may be due to its ability to modulate gene expression through this mechanism.

Pharmacokinetic Properties

Valproic acid is absorbed rapidly and completely after oral administration. Peak plasma concentration occurs in 1 to 4 h, although this can be delayed for several hours if the drug is administered in enteric-coated tablets or is ingested with meals.

The apparent volume of distribution for *valproate* is approximately 0.2 L/kg. Its extent of binding to plasma proteins is usually approximately 90%, but the fraction bound is reduced as the total concentration of *valproate* is increased through the therapeutic range. Although concentrations of *valproate* in CSF suggest equilibration with free drug in the blood, there is evidence for carrier-mediated transport of *valproate* both into and out of the CSF.

The majority of *valproate* (95%) undergoes hepatic metabolism, with less than 5% excreted unchanged in urine. Its hepatic metabolism occurs mainly by UGT enzymes and β-oxidation. *Valproate* is a substrate for CYP2C9 and CYP2C19, but metabolism by these enzymes accounts for a relatively minor portion of its elimination. Some of the drug's metabolites, notably 2-propyl-2-pentenoic acid and 2-propyl-4-pentenoic acid, demonstrate near equipotent antiseizure activity as the parent compound; however, only the 2-en-valproate accumulates in plasma and brain to a potentially significant extent. The $t_{1/2}$ of *valproate* is approximately 15 h but is reduced in patients taking other antiepileptic drugs.

Toxicity

The most common side effects are transient GI symptoms, including anorexia, nausea, and vomiting (~16%). Effects on the CNS include sedation, ataxia, and tremor; these symptoms occur infrequently and usually respond to a decrease in dosage. Rash, alopecia, and stimulation of appetite have been observed occasionally, and weight gain has been seen with chronic *valproic acid* treatment in some patients. *Valproic acid* has several effects on hepatic function; elevation of hepatic transaminases in plasma is observed in up to 40% of patients and often occurs asymptomatically during the first several months of therapy.

A rare complication is a fulminant hepatitis that is frequently fatal (Dreifuss et al., 1989). Pathological examination reveals a microvesicular steatosis without evidence of inflammation or hypersensitivity reaction. Children below 2 years of age with other medical conditions who were given multiple ASDs were especially likely to suffer fatal hepatic injury. At the other extreme, there were no deaths reported for patients over the age of 10 years who received only *valproate*. Acute pancreatitis and hyperammonemia have been frequently associated with the use of *valproic acid*. *Valproic acid* can also produce teratogenic effects such as neural tube defects.

Plasma Drug Concentrations

Valproate plasma concentrations associated with therapeutic effects are approximately 30 to 100 μg/mL. However, there is a poor correlation between the plasma concentration and efficacy. There appears to be a threshold at approximately 30 to 50 μg/mL; this is the concentration at which binding sites on plasma albumin begin to become saturated.

Drug Interactions

Valproate inhibits the metabolism of drugs that are substrates for CYP2C9, including *phenytoin* and *phenobarbital*. *Valproate* also inhibits UGTs and thus inhibits the metabolism of *lamotrigine* and *lorazepam*. A high proportion of *valproate* is bound to albumin, and the high molar concentrations of *valproate* in the clinical setting result in *valproate* displacing *phenytoin* and other drugs from albumin. With respect to *phenytoin* in particular, *valproate*'s inhibition of the drug's metabolism is exacerbated by displacement of *phenytoin* from albumin. The concurrent administration of *valproate* and *clonazepam* has been associated with the development of absence status epilepticus; however, this complication appears to be rare.

Therapeutic Uses

Valproate is a broad-spectrum ASD that is effective in the treatment of absence, myoclonic, focal, and tonic-clonic seizures. The initial daily dose usually is 15 mg/kg, increased at weekly intervals by 5 to 10 mg/kg per day to a maximum daily dose of 60 mg/kg. Divided doses should be given when the total daily dose exceeds 250 mg. The therapeutic uses of *valproate* in epilepsy are discussed further at the end of this chapter.

Vigabatrin

Vigabatrin is FDA-approved as adjunctive therapy of refractory focal seizures with impaired awareness in adults. In addition, *vigabatrin* is designated as an orphan drug for treatment of infantile spasms (see below).

Pharmacological Effects and Mechanism of Action

Vigabatrin is a structural analogue of GABA that irreversibly inhibits the major degradative enzyme for GABA, GABA transaminase, thereby leading to increased concentrations of GABA in the brain. *Vigabatrin*'s mechanism of action is thought to involve effects of increased extracellular GABA concentrations in the brain and enhancement of GABA-mediated inhibition.

Pharmacokinetics

Although *vigabatrin* has a $t_{1/2}$ of only 6 to 8 h, the pharmacodynamics effects are prolonged and do not correlate well with plasma $t_{1/2}$. Adult dosing is generally initiated orally at 500 mg twice daily and then increased in 500-mg increments weekly to 1.5 g twice daily.

Therapeutic Use

A 2-week, randomized, single-masked clinical trial of *vigabatrin* for infantile spasms in children less than 2 years old revealed time- and dose-dependent increases in responders, evident as freedom from spasms for 7 consecutive days. The subset of children in whom infantile spasms were caused by tuberous sclerosis was particularly responsive to *vigabatrin*.

Toxicity

Due to progressive and permanent bilateral vision loss, *vigabatrin* must be reserved for patients who have failed several alternative therapies, and its availability is limited. The most common side effects (>10% patients) include weight gain, concentric visual field constriction, fatigue, somnolence, dizziness, hyperactivity, and seizures.

Zonisamide

Zonisamide has a small ringed structure related to sulfonamide antibiotics. It is FDA-approved as adjunctive therapy of focal seizures in children and adults aged 12 years or older.

Pharmacological Effects and Mechanism of Action

Zonisamide inhibits the sustained, repetitive firing of spinal cord neurons, presumably by prolonging the inactivated state of voltage-gated Na^+ channels in a manner similar to actions of *phenytoin* and *carbamazepine* and preventing neurotransmitter release. In addition, *zonisamide* also inhibits T-type Ca^{2+} currents and prevents influx of calcium. *Zonisamide* has been shown to scavenge free radicals, which may contribute to its neuroprotective effects.

Pharmacokinetics

Zonisamide is almost completely absorbed after oral administration, has a long $t_{1/2}$ (~60 h), is approximately 40% bound to plasma protein, and has linear kinetics at doses ranging from 100 to 400 mg. *Zonisamide* is metabolized by hepatic CYPs and glucuronidases. Approximately 85% of an oral dose is excreted in the urine, principally as unmetabolized *zonisamide* and a glucuronide of sulfamoylacetyl phenol, which is a product of metabolism by CYP3A4. As such, *phenobarbital*, *phenytoin*, and *carbamazepine* decrease the plasma concentration/dose ratio of *zonisamide*, whereas *lamotrigine* increases this ratio. Conversely, *zonisamide* has little effect on the plasma concentrations of other ASDs.

Therapeutic Use

Double-blind, placebo-controlled studies of patients with refractory focal seizures demonstrated that addition of *zonisamide* to other drugs was superior to placebo. There is insufficient evidence for its efficacy as monotherapy for newly diagnosed or refractory epilepsy.

Toxicity

Overall, *zonisamide* is well tolerated. The most common adverse effects include somnolence, dizziness, cognitive impairment, ataxia, anorexia, nervousness, and fatigue. Potentially serious skin rashes are rare but may occur. Approximately 1% of individuals develop renal calculi during treatment with *zonisamide*, which may relate to its ability to inhibit carbonic anhydrase. Patients with predisposing conditions (e.g., renal disease, severe respiratory disorders, diarrhea, surgery, ketogenic diet) may be at greater risk for metabolic acidosis while taking *zonisamide*. The risk of *zonisamide*-induced metabolic acidosis also appears to be more frequent and severe in younger patients. Measurement of serum bicarbonate prior to initiating therapy and periodically thereafter, even in the absence of symptoms, is recommended. Lastly, spontaneous abortions and congenital abnormalities have been reported in female patients of childbearing age receiving polytherapy including *zonisamide* at twice the rate (7%) of the healthy control population (2%–3%).

General Principles and Choice of Drugs for the Therapy of the Epilepsies

Early diagnosis and treatment of seizure disorders with a single appropriate agent offers the best prospect of achieving prolonged seizure-free periods with the lowest risk of toxicity. An attempt should be made to determine the cause of the epilepsy with the hope of discovering a correctable lesion, either structural or metabolic. The drugs commonly used for distinct seizure types are listed in Table 20–1. The cost/benefit ratio of the efficacy and the unwanted effects of a given drug are considered to determine which particular drug is optimal for a given patient.

The first decision to make is whether and when to initiate treatment (French and Pedley, 2008). For example, it may not be necessary to initiate therapy after an isolated tonic-clonic seizure in a healthy young adult who lacks a family history of epilepsy and who has a normal neurological exam, a normal EEG, and a normal brain MRI scan. The odds of seizure recurrence in the next year (15%) are similar to the risk of a drug reaction sufficiently severe to warrant discontinuation of medication (Bazil and Pedley, 1998). On the other hand, a similar seizure occurring in an individual with a positive family history of epilepsy, an abnormal neurological exam, an abnormal EEG, and an abnormal MRI carries a risk of recurrence approximating 60%, odds that favor initiation of therapy.

Unless extenuating circumstances such as status epilepticus exist, only monotherapy should be initiated. Initial dosing should target steady-state plasma drug concentrations within at least the lower portion of the range associated with clinical efficacy. At the same time, the initial dose should be as low as possible to minimize dose-related adverse effects. Dosage is increased at appropriate intervals as required for control of seizures or as limited by toxicity. Such adjustment should be assisted by monitoring of drug concentrations in plasma. Compliance with a properly selected, single drug in maximal tolerated dosage results in complete control of seizures in approximately 50% of patients. If a seizure occurs despite optimal drug levels, the physician should assess the presence of potential precipitating factors such as sleep deprivation, a concurrent febrile illness, or drugs (e.g., large amounts of caffeine or over-the-counter medications that can lower the seizure threshold).

If compliance has been confirmed yet seizures persist, another drug should be substituted. Unless serious adverse effects of the drug dictate otherwise, dosage always should be reduced gradually to minimize risk of seizure recurrence. In the case of focal seizures in adults, the diversity of available drugs permits selection of a second drug that acts by a different mechanism (see Table 20–2). Among previously untreated patients, 47% became seizure free with the first drug and an additional 14% became seizure free with a second or third drug (Kwan and Brodie, 2000).

If therapy with a second single drug also is inadequate, combination therapy is warranted. This decision should not be taken lightly, because most patients obtain optimal seizure control with the fewest unwanted effects when taking a single drug. Nonetheless, some patients will not be controlled adequately without the simultaneous use of two or more ASDs. No properly controlled studies have systematically compared one particular drug combination with another. The chances of complete control with this approach are not high; Kwan and Brodie (2000) found that epilepsy was controlled by treatment with two drugs in only 3% of patients. Moreover, a rational approach may be to select two drugs that act by distinct mechanisms (e.g., one that promotes Na^+ channel inactivation and another that enhances GABA-mediated synaptic inhibition). Side effects of each drug and the potential drug interactions also should be considered. As specified in Table 20–3, many of these drugs induce expression of CYPs and thereby impact the metabolism of themselves and/or other drugs (see Table 20–3).

Essential to optimal management of epilepsy is the filling out of a seizure chart by the patient or a relative. Frequent visits to the physician may be necessary early in the period of treatment, since hematological and other possible side effects may require a change in medication. Long-term follow-up with neurological examinations and possibly EEG and neuroimaging studies is appropriate. Most crucial for successful management is patient adherence to the drug regimen; noncompliance is the most frequent cause for failure of therapy with ASDs. Pharmacotherapy has also benefitted from recent advances in genetic testing. For example, Na^+ channel blockers can be detrimental to patients with mutations in SCN1A (Perucca and Perucca, 2019); therefore, these medications can be avoided in favor of more beneficial therapies (Cross et al., 2019).

Measurement of plasma drug concentration at appropriate intervals greatly facilitates the initial adjustment of dosage to minimize dose-related adverse effects without sacrificing seizure control. Periodic monitoring during maintenance therapy can also detect noncompliance. Knowledge of plasma drug concentrations can be especially helpful during multiple-drug therapy. If toxicity occurs, monitoring helps to identify the drug(s) responsible and can guide adjustment of dosage.

Finally, there have been several improvements in recent years that have added to the treatment of women with epilepsy. A greater understanding of sex-based differences in disease pathophysiology and therapy response (Reddy, 2017) contributes to better patient outcomes. Similarly, catamenial epilepsy (i.e., linked to the menstrual cycle) may contribute to cyclical changes both in epilepsy symptoms and drug metabolism (Navis and Harden, 2016; Reddy, 2016). Pregnancy and breastfeeding also present unique challenges to epilepsy therapy over concerns of exposure of the developing child to antiseizure medications. Ongoing research is aimed at the identification of safe and effective pharmacotherapy for women during and following pregnancy.

Duration of Therapy

Once initiated, ASDs are typically continued for at least 2 years. Tapering and discontinuing therapy should be considered if the patient is seizure free after 2 years.

Factors associated with high risk for recurrent seizures following discontinuation of therapy include EEG abnormalities, known structural lesions, abnormalities on neurological exam, and history of frequent seizures or medically refractory seizures prior to control. Conversely, factors associated with low risk for recurrent seizures include idiopathic epilepsy, normal EEG, onset in childhood, and seizures easily controlled with a single drug. The risk of recurrent seizures ranges from 12% to 66% (French and Pedley, 2008). Typically, 80% of recurrences will occur within 1 month of discontinuing therapy. The clinician and patient must weigh the risk of recurrent seizure and the associated potential deleterious consequences (e.g., loss of driving privileges) against the various implications of continuing medication including cost, unwanted effects, implications of diagnosis of epilepsy, and so on. Medications should be tapered slowly over a period of several months.

Focal and Focal to Bilateral Tonic-Clonic Seizures

The efficacy and toxicity of *carbamazepine*, *phenobarbital*, and *phenytoin* for treatment of focal and secondarily generalized tonic-clonic seizures in adults have been examined in a double-blind prospective study (Mattson et al., 1985). *Carbamazepine* and *phenytoin* were the most effective agents. The choice between *carbamazepine* and *phenytoin* required assessment of toxic effects of each drug. All three drugs decreased libido and increased impotence (*carbamazepine* 13%, *phenobarbital* 16%, and *phenytoin* 11%). In direct comparison with *valproate*, *carbamazepine* provided superior control of complex focal seizures (Mattson et al., 1992). With respect to adverse effects, *carbamazepine* was more commonly associated with skin rash, but *valproate* was more commonly associated with tremor and weight gain. Overall, the data demonstrated that *carbamazepine* and *phenytoin* are preferable for treatment of focal seizures, but *phenobarbital* and *valproic acid* are also efficacious.

Control of secondarily generalized tonic-clonic seizures did not differ significantly with *carbamazepine*, *phenobarbital*, or *phenytoin* (Mattson et al., 1985). *Valproate* was as effective as *carbamazepine* for control of secondarily generalized tonic-clonic seizures (Mattson et al., 1992). Since secondarily generalized tonic-clonic seizures usually coexist with focal seizures, these data indicate that among drugs introduced before 1990, *carbamazepine* and *phenytoin* are the first-line drugs for these conditions.

One key issue confronting the treating physician is choosing the optimal drug for initiating treatment in new-onset epilepsy. At first glance, this issue may appear unimportant because approximately 50% of newly diagnosed patients become seizure free with the first drug, whether old or new drugs are used (Kwan and Brodie, 2000). However, responsive patients typically receive the initial drug for several years, underscoring the importance of proper drug selection. Among the drugs available before 1990, *phenytoin*, *carbamazepine*, and *phenobarbital* induce hepatic CYPs, thereby complicating use of multiple ASDs as well as impacting metabolism of oral contraceptives, *warfarin*, and many other drugs. These drugs also enhance metabolism of endogenous compounds including gonadal steroids and vitamin D, potentially impacting reproductive function and bone density. Factors arguing against use of recently introduced drugs include higher costs and less clinical experience with the compounds.

Ideally, a prospective study would systematically compare newly introduced ASDs with drugs available before 1990 in a study design adjusting dose as needed and observing responses for extended periods of time (e.g., 2 years or more), in much the same manner as that used when comparing the older ASDs with one another, as described earlier (Mattson et al., 1985).

Unfortunately, such a study has not been performed. Many of the studies referenced in description of newer drugs compared a new ASD with an older ASD, but study design did not permit declaring a clearly superior drug; moreover, differences in study design and patient populations preclude comparing a new drug with multiple older drugs or with other new drugs. The use of recently introduced ASDs for newly diagnosed epilepsy was analyzed by subcommittees of the American Academy of Neurology and the American Epilepsy Society (French et al., 2004a, 2004b). The authors concluded that available evidence supported the use of *gabapentin*, *lamotrigine*, and *topiramate* for newly diagnosed focal or mixed seizure disorders. None of these drugs, however, has been FDA-approved for either of these indications. Insufficient evidence was available on the remaining newly introduced drugs to permit meaningful assessment of their effectiveness for this indication.

Generalized Absence Seizures

Ethosuximide and *valproate* are considered equally effective in the treatment of generalized absence seizures (Mikati and Browne, 1988).

Between 50% and 75% of newly diagnosed patients are free of seizures following therapy with either drug. If tonic-clonic seizures are present or emerge during therapy, *valproate* is the agent of first choice. Available evidence also indicates that *lamotrigine* is effective for newly diagnosed absence epilepsy despite the fact that *lamotrigine* is not approved for this indication by the FDA (Ben-Menachem, 2011).

Myoclonic Seizures

Valproic acid is the drug of choice for myoclonic seizures in the syndrome of juvenile myoclonic epilepsy, in which myoclonic seizures often coexist with tonic-clonic and absence seizures. *Levetiracetam* also has demonstrated efficacy as adjunctive therapy for refractory generalized myoclonic seizures.

Febrile Convulsions

Two to four percent of children experience a convulsion associated with a febrile illness. From 25% to 33% of these children will have another febrile convulsion. Only 2% to 3% become epileptic in later years, a 6-fold increase in risk compared with the general population. Several factors are associated with an increased risk of developing epilepsy: preexisting neurological disorder or developmental delay, a family history of epilepsy, or a complicated febrile seizure (i.e., the febrile seizure lasted >15 min, was one-sided, or was followed by a second seizure in the same day). If all of these risk factors are present, the risk of developing epilepsy is approximately 10%.

The increased risk of developing epilepsy or other neurological sequelae led many physicians to prescribe ASDs prophylactically after a febrile seizure. Uncertainties regarding the efficacy of prophylaxis for reducing epilepsy combined with substantial side effects of *phenobarbital* prophylaxis (Farwell et al., 1990) argue against the use of chronic therapy for prophylactic purposes (Freeman, 1992). For children at high risk of developing recurrent febrile seizures and epilepsy, rectally administered *diazepam* at the time of fever may prevent recurrent seizures and avoid side effects of chronic therapy.

Seizures in Infants and Young Children

Infantile spasms with *hypsarrhythmia* (abnormal interictal high-amplitude slow waves and multifocal asynchronous spikes on EEG) are refractory to the usual ASD. *Corticotropin* or the glucocorticoids are commonly used, and repository *corticotropin* was designated as an orphan drug for this purpose in 2003. A randomized study found *vigabatrin* (γ-vinyl GABA) to be efficacious in comparison to placebo (Appleton et al., 1999). Constriction of visual fields has been reported in a high percentage of patients treated with *vigabatrin* (Miller et al., 1999). The potential for progressive and permanent vision loss has resulted in *vigabatrin* being labeled with a black-box warning and marketed under a restrictive distribution program. The drug received orphan drug status for the treatment of infantile spasms in the U.S. in 2000 (and was FDA-approved in 2009 as adjunctive therapy for adults with refractory focal seizures with impaired awareness). *Ganaxolone* also has been designated as an orphan drug since 1994 for the treatment of infantile spasms and completed a phase II clinical trial for uncontrolled focal-onset seizures in adults in 2009. In 2020, the FDA granted Rare Pediatric Disease designation to *ganaxolone* for the treatment of patients with CDKL5 deficiency disorder, a rare refractory form of pediatric epilepsy.

Lennox-Gastaut syndrome is a severe form of epilepsy that usually begins in childhood and is characterized by cognitive impairments and multiple types of seizures including tonic-clonic, tonic, atonic, myoclonic, and atypical absence seizures. Addition of *lamotrigine* to other ASDs resulted in improved seizure control in comparison to placebo in a double-blind trial (Motte et al., 1997), demonstrating *lamotrigine* to be an effective and well-tolerated drug for this treatment-resistant form of epilepsy. *Felbamate* is also effective for seizures in this syndrome, but the occasional occurrence of aplastic anemia and hepatic failure limit its use (French et al., 1999). *Topiramate* is effective for Lennox-Gastaut syndrome (Sachdeo et al., 1999), and *clobazam* is approved for the adjunctive treatment in Lennox-Gastaut syndrome.

Dravet syndrome, previously referred to as severe myoclonic epilepsy of infancy, clinically presents in infancy (before 15 months of age) usually as focal or generalized convulsive seizures and a variety of behavioral, cognitive, and physiological comorbidities. A majority of individuals with this disorder have a mutation in the Na^+ channel gene *SCN1A* (Bender et al., 2012). Early-life seizures in Dravet syndrome can persist and develop into a variety of seizure types later in life. Patients with this disorder are also at an increased risk of sudden unexplained death in epilepsy (Shmuely et al., 2016). One or more medications are often required to achieve full control of seizures, and it is often the case that patients do not experience full seizure control (Cross et al., 2019). Initial treatment options may include *clobazam*, *stiripentol*, *valproic acid*, *topiramate*, and other medications (Cross et al., 2019). However, Na^+ channel blockers are contraindicated, as they may worsen seizures.

Status Epilepticus and Other Convulsive Emergencies

Status epilepticus is a neurological emergency. Mortality for adults approximates 20% (Lowenstein and Alldredge, 1998). The goal of treatment is rapid termination of behavioral and electrical seizure activity; the longer the episode of status epilepticus is untreated, the more difficult it is to control and the greater the risk of permanent brain damage. Critical to the management is a clear plan, prompt treatment with effective drugs in adequate doses, and attention to hypoventilation and hypotension. Since hypoventilation may result from high doses of drugs used for treatment, it may be necessary to assist respiration temporarily. To assess the optimal initial drug regimen, a double-blind, multicenter trial compared four intravenous treatments: *diazepam* followed by *phenytoin*; *lorazepam*; *phenobarbital*; and *phenytoin* alone (Treiman et al., 1998). The treatments had similar efficacies, with success rates ranging from 44% to 65%. *Lorazepam* alone was significantly better than *phenytoin* alone. No significant differences were found with respect to recurrences or adverse reactions. A more recent randomized, double-blind clinical trial (RAMPART) indicated that *midazolam* administered via the IM route was equally effective as *lorazepam* administered via the IV route and was not associated with either respiratory distress or seizure recurrence. Thus, emergency treatment with *midazolam* (IM) may prove to be the preferred treatment prior to arrival to the hospital.

Antiseizure Therapy and Pregnancy

Use of ASDs has diverse implications of great importance for the health of women. Issues include interactions with oral contraceptives, potential teratogenic effects, and effects on vitamin K metabolism in pregnant women (Pack, 2006). Guidelines for the care of women with epilepsy have been published by the American Academy of Neurology (Morrell, 1998). The FDA's Pregnancy and Lactation Labeling rule phased out the assignment of letter categories (A, B, C, D, and X) for prescription drug products. The FDA now requires labeling to include a summary of a prescription drug's known risk, a discussion of the data supporting that summary, and relevant information regarding its use during pregnancy and lactation (Epilepsy Foundation, 2013).

The effectiveness of oral contraceptives appears to be reduced by concomitant use of ASDs. The failure rate of oral contraceptives is 3.1/100 years in women receiving ASDs compared to a rate of 0.7/100 years in nonepileptic women. One attractive explanation of the increased failure rate is the increased rate of oral contraceptive metabolism caused by ASDs that induce hepatic enzymes (see Table 20–2), especially CYP3A4.

Teratogenicity

Epidemiological evidence suggests that ASDs have teratogenic effects (Pack, 2006). These teratogenic effects add to the deleterious consequences of oral contraceptive failure. Infants of epileptic mothers are at 2-fold greater risk of major congenital malformations than offspring of nonepileptic mothers (4%–8% compared to 2%–4%). These malformations include congenital heart defects, neural tube defects, cleft lip, cleft palate, and others. Inferring causality from the associations found in large epidemiological studies with many uncontrolled variables can be

hazardous, but a causal role for ASDs is suggested by association of congenital defects with higher concentrations of a drug or with polytherapy compared to monotherapy. *Phenytoin*, *carbamazepine*, *valproate*, *lamotrigine*, and *phenobarbital* all have been associated with teratogenic effects. Newer ASDs have teratogenic effects in animals, but whether such effects occur in humans is uncertain (Güveli et al., 2017). One consideration for a woman with epilepsy who wishes to become pregnant is a trial free of ASD; monotherapy with careful attention to drug levels is another alternative. Polytherapy with toxic levels should be avoided. Folate supplementation (0.4 mg/day) has been recommended by the U.S. Public Health Service for all women of childbearing age to reduce the likelihood of neural tube defects, and this is appropriate for epileptic women as well.

ASDs that induce CYPs have been associated with vitamin K deficiency in the newborn, which can result in a coagulopathy and intracerebral hemorrhage. Treatment with vitamin K_1 (phylloquinone), 10 mg/day during the last month of gestation, has been recommended for prophylaxis. Collard and turnip greens, raw spinach and kale, broccoli, and soybeans are vegetables rich in phylloquinone (National Institutes of Health, 2021).

Development of Novel Treatments for Epilepsy

Nearly one-third of all patients with epilepsy do not experience full control of seizures, and numerous antiseizure drugs have dose-limiting side effects. Furthermore, there are no known treatments that halt or stop disease progression in epilepsy. Therefore, there is an ongoing need for the development of novel treatments for epilepsy. Many therapies have emerged that target specific epilepsy subpopulations (e.g., cannabidiol for Dravet syndrome and Lennox-Gastaut syndrome). In addition to refinement and optimization of current drug targets, numerous additional targets have been identified that include various signaling, inflammatory, transcriptional, and metabolic pathways (see Raut and Bhatt, 2020, for review). For example, glial cells continue to emerge as critical regulators of epilepsy pathophysiology and represent a significant therapeutic target. Further, the widespread use of the ketogenic diet has furthered understanding of signaling pathways and therapeutic targets contributing to the antiseizure properties of ketone bodies. Researchers continue to elucidate additional therapeutic targets and to develop novel therapies. We can be hopeful.

Drug Facts for Your Personal Formulary: *Antiseizure Agents*

Drugs	Therapeutic Uses (Seizure Types)	Clinical Pharmacology and Tips
Sodium Channel Modulators • Enhance fast inactivation		
Phenytoin	*Focal* • Aware • With impaired awareness *Generalized* • Tonic-clonic	• Once-daily dosing only available with extended-release formulation • Intravenous use with fosphenytoin • Nonlinear pharmacokinetics • May interfere with drugs metabolized by CYP2C9/10/19 • Induces CYP enzymes (e.g., CYP3A4) • *Side effects*: gingival hyperplasia, facial coarsening; hypersensitivity (rare)
Carbamazepine	*Focal* • Aware • With impaired awareness • Focal to bilateral tonic-clonic *Generalized* • Tonic-clonic	• Induces CYPs (e.g., 2C, 3A4) and UGTs • Active metabolite, the 10,11-epoxide • *Side effects*: drowsiness, vertigo, ataxia, blurred vision, increased seizure frequency
Eslicarbazepine	*Focal* • Aware • With impaired awareness	
Lamotrigine	*Focal* • Aware • With impaired awareness *Generalized* • Absence • Tonic-clonic	• Reduced $t_{1/2}$ in presence of phenytoin, carbamazepine, or phenobarbital • ↑ concentration in presence of valproic acid • Also used in Lennox-Gastaut syndrome
Oxcarbazepine	*Focal* • Aware • With impaired awareness	• Prodrug, metabolized to eslicarbazepine • Short $t_{1/2}$ • ↓ enzyme induction vs. carbamazepine • *Side effects*: ↓ incidence of hypersensitivity reactions (vs. carbamazepine)
Rufinamide	*Focal* • Aware • With impaired awareness	• Can be used in Lennox-Gastaut syndrome
Sodium Channel Modulators • Enhance slow inactivation		
Lacosamide	*Focal* • Aware • With impaired awareness	
Calcium Channel Blockers • Block T-type calcium channels		
Ethosuximide	*Generalized* • Absence	• *Side effects*: GI complaints, drowsiness, lethargy, dizziness, headache, hypersensitivity/skin reactions • Titration can reduce side effect oc ıı.ence

Drug Facts for Your Personal Formulary: *Antiseizure Agents* (*continued*)

Drugs	Therapeutic Uses (Seizure Types)	Clinical Pharmacology and Tips
Zonisamide	*Focal* • Aware • With impaired awareness	• *Side effects*: somnolence, ataxia, anorexia, fatigue
Calcium Channel Modulators • $\alpha_2\delta$ ligands		
Gabapentin	*Focal* • Aware • With impaired awareness	• *Side effects*: somnolence, dizziness, ataxia, fatigue
Pregabalin	*Focal* • Aware • With impaired awareness	• *Side effects*: dizziness, somnolence • Linear pharmacokinetics • Low potential for drug-drug interactions
GABA-Enhancing Drugs • $GABA_A$ receptor allosteric modulators (benzodiazepines, barbiturates)		
Clonazepam	*Generalized* • Absence • Myoclonic	• *Side effects*: drowsiness, lethargy, behavioral disturbances • Abrupt withdrawal can facilitate seizures • Tolerance to antiseizure effects
Clobazam	*Lennox Gastaut syndrome* *Generalized* • Atonic • Tonic • Myoclonic	• *N*-desmethylclobazam, active metabolite, ↑ in patients with poor CYP2C19 metabolism • *Side effects*: somnolence, sedation • Tapered withdrawal recommended
Diazepam	*Status epilepticus*	• Short duration of action • *Side effects*: drowsiness, lethargy, behavioral disturbances • Abrupt withdrawal can facilitate seizures • Tolerance to antiseizure effects
Phenobarbital	*Focal* • Focal to bilateral tonic-clonic *Generalized* • Tonic-clonic	• Induces CYPs and UGTs • *Side effects*: sedation, nystagmus, ataxia; irritability and hyperactivity (children); agitation and confusion (elderly); allergy, hypersensitivity (rare)
Primidone	*Focal* • Focal to bilateral tonic-clonic *Generalized* • Tonic-clonic	• Induces CYPs • Not commonly used
GABA-Enhancing Drugs • GABA uptake/GABA transaminase inhibitors		
Tiagabine	*Focal* • Aware • With impaired awareness	• Metabolized by CYP3A • *Side effects*: dizziness, somnolence, tremor
Stiripentol	*Generalized* • Tonic-clonic (Dravet syndrome)	• Used in Dravet syndrome • Inhibits CYPs 3A4 and 2C19
Vigabatrin	*Focal* • With impaired awareness	• Used in infantile spasms, especially when caused by tuberous sclerosis • *Side effects*: can cause progressive and bilateral vision loss
Glutamate Receptor Antagonists • AMPA receptor antagonists		
Perampanel	*Focal* • Aware • With impaired awareness	• Metabolized by CYP3A • *Side effects*: anxiety, confusion, imbalance, visual disturbance, aggressive behavior, suicidal thoughts
Potassium Channel Modulators • KCNQ2-5–positive allosteric modulator		
Ezogabine	*Focal* • Aware • With impaired awareness	• *Side effects*: blue pigmentation of skin and lips, dizziness, somnolence, fatigue, vertigo, tremor, attention disruption, memory impairment, retinal abnormalities, QT prolongation (rare)
Synaptic Vesicle (SV2A) Modulators		
Levetiracetam	*Focal* • Aware • With impaired awareness *Generalized* • Myoclonic • Tonic-clonic	• *Side effects*: somnolence, asthenia, ataxia, dizziness, mood changes
Brivaracetam	*Focal* • Aware • With impaired awareness	

Drug Facts for Your Personal Formulary: *Antiseizure Agents (continued)*

Drugs	Therapeutic Uses (Seizure Types)	Clinical Pharmacology and Tips
Mixed or Unknown Mechanisms of Action		
Topiramate	*Focal* • Aware • With impaired awareness *Generalized* • Tonic-clonic	• Used in Lennox-Gastaut syndrome • *Side effects*: somnolence, fatigue, cognitive impairment
Valproic acid	*Focal* • Aware • With impaired awareness • Focal to bilateral tonic-clonic *Generalized* • Absence • Myoclonic • Tonic-clonic	• *Side effects*: transient GI symptoms, sedation, ataxia, tremor, hepatitis (rare) • Inhibits CYP2C9, UGT
Cenobamate	*Focal* • Aware • With impaired awareness	• *Side effects*: somnolence, dizziness, fatigue, diplopia, headache • DRESS* more likely with rapid dose escalations
Cannabidiol	*Generalized* • Lennox-Gastaut syndrome • Dravet syndrome • Tuberous sclerosis complex	• *Side effects*: dry mouth, low blood pressure, light headedness, drowsiness. Signs of liver injury (elevated liver enzymes) have also been reported in some patients using higher doses of Epidiolex**.
Fenfluramine	*Generalized* • Dravet syndrome	*Black-box warning*: valvulopathy and pulmonary hypertension risk

*DRESS, Drug reaction with eosinophilia and systemic symptoms.
**The FDA-approved prescription form of cannabidiol (CBD).

Chapter 21

Treatment of Central Nervous System Degenerative Disorders

Erik D. Roberson and Talene A. Yacoubian

Introduction to Neurodegenerative Disorders

Neurodegenerative disorders are characterized by progressive and irreversible loss of neurons from specific regions of the brain. Prototypical neurodegenerative disorders include PD and HD, where the loss of neurons from structures of the basal ganglia results in abnormalities in the control of movement; AD, where the loss of hippocampal and cortical neurons leads to impairment of memory and cognitive ability; and ALS, where degeneration of spinal, bulbar, and cortical motor neurons results in motor weakness. For the most part, currently available therapies for neurodegenerative disorders alleviate the disease symptoms without altering the underlying neurodegenerative process, but a new era of disease-modifying treatments targeting the molecules implicated in pathogenesis is beginning with the approval of the anti-Aβ antibody, *aducanumab*, for AD.

Common Features of Neurodegenerative Disorders

Proteinopathies

Each of the major neurodegenerative disorders is characterized by accumulation of particular proteins in cellular aggregates: *α-synuclein* in PD; *amyloid β* (Aβ) and the *microtubule-associated protein tau* in AD; *TDP-43* in most cases of ALS; and *huntingtin* in HD (Prusiner, 2013). The reason for accumulation of these proteins is unknown, and it is also unclear in most cases whether it is the large cellular aggregates or smaller soluble species of the proteins that most strongly drive pathogenesis.

Selective Vulnerability

A striking feature of neurodegenerative disorders is the selectivity of the disease processes for particular types of neurons in different brain regions. For example, in PD, there is extensive destruction of the dopaminergic neurons of the substantia nigra, whereas neurons in the cortex and many other areas of the brain are less affected. In contrast, neural injury in AD is most severe in the hippocampus and neocortex, and even within the cortex, the loss of neurons is not uniform but varies dramatically in different brain networks. In HD, the mutant gene responsible for the disorder is expressed throughout the brain and in many other organs, yet the pathological changes are most prominent in the neostriatum and cortex. In ALS, there is a loss of spinal motor neurons and the cortical neurons that provide their descending input. The diversity of these patterns of neural degeneration suggests that the process of neural injury results from the interaction of intrinsic properties of different neural circuits, genetics, and environmental influences. The intrinsic factors may include susceptibility to excitotoxic injury, regional variation in capacity for oxidative metabolism, and the production of toxic free radicals as by-products of cellular metabolism.

Genetics and Environment

Each of the major neurodegenerative disorders can be inherited due to genetic mutations, but how commonly this occurs varies widely among the diseases. *HD is exclusively genetic*; it is transmitted by autosomal dominant inheritance of an expanded repeat in the *huntingtin* gene. Nevertheless, environmental factors importantly influence the age of onset and rate of progression of HD symptoms. PD, AD, and ALS are usually sporadic, but for each, there are well-recognized genetic forms. For example, there are both dominant (*α-synuclein, LRRK2*) and recessive (*parkin, DJ-1, PINK1*) gene mutations that may give rise to PD (Kumar et al., 2012; Singleton et al., 2013). In AD, mutations in the genes coding for *APP* and the *presenilins* (involved in APP processing) lead to inherited forms of the disease. About 10% of ALS cases are familial, most commonly due to mutations in the *C9ORF72* gene (Renton et al., 2014).

There are also genetic risk factors that influence the probability of disease onset and modify the phenotype. For example, the *APOE* genotype constitutes an important risk factor for AD. Three common alleles of this gene encode different isoforms of apoE protein, and individuals with even one copy of the high-risk allele, ε4, have a several-fold higher risk of developing AD than those with the most common allele, ε3. In PD, risk factor genes include *α-synuclein, LRRK2, tau,* and *GBA*, among others.

Environmental factors, including infectious agents, environmental toxins, and acquired brain injury, have been proposed in the etiology of neurodegenerative disorders. Traumatic brain injury has been suggested

Abbreviations

AADC: aromatic L-amino acid decarboxylase
Aβ: amyloid β
ACh: acetylcholine
AChE: acetylcholinesterase
AD: Alzheimer's disease
ALDH: aldehyde dehydrogenase
ALS: amyotrophic lateral sclerosis
apoE: apolipoprotein E
APP: amyloid precursor protein
ARIA: amyloid-related imaging abnormality
ASO: antisense oligonucleotides
BPSD: behavioral and psychiatric symptoms in dementia
BuChE: butyrylcholinesterase
CNS: central nervous system
COMT: catechol-*O*-methyltransferase
CSF: cerebrospinal fluid
DA: dopamine
DAT: DA transporter
DβH: dopamine-β-hydroxylase
DOPAC: 3,4-dihydroxyphenylacetic acid
FALS: familial ALS
GABA: γ-aminobutyric acid
GBA: β-glucocerebrosidase
GI: gastrointestinal
Glu: glutamatergic
GPCR: G protein-coupled receptor
GPe: globus pallidus extern
GPi: globus pallidus interna
HD: Huntington's disease
5HT: serotonin
HTT: huntingtin
HVA: homovanillic acid
ICD: impulse control disorder
LRRK2: leucine-rich repeat kinase 2
MAO: monoamine oxidase
MCI: mild cognitive impairment
MPTP: *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MRI: magnetic resonance imaging
3MT: 3-methoxyltyramine
NIA-AA: National Institute on Aging and Alzheimer's Association
NE: norepinephrine
NET: NE transporter
NMDA: *N*-methyl-D-aspartate
3-OMD: 3-*O*-methyl dopa
PD: Parkinson's disease
PET: positron emission tomography
PH: phenylalanine hydroxylase
REM: rapid eye movement
SNpc: substantia nigra pars compacta
SNpr: substantia nigra pars reticulate
SOD: superoxide dismutase
SSRI: selective serotonin reuptake inhibitor
STN: subthalamic nucleus
TAR: transactivation response element
TDP-43: TAR DNA-binding protein 43
TH: tyrosine hydrolase
VA/VL: ventroanterior and ventrolateral
VMAT2: vesicular monoamine transporter 2

as a trigger for neurodegenerative disorders. At least one toxin, MPTP, can induce a condition closely resembling PD. More recently, evidence has linked pesticide exposure with PD. Exposure of soldiers to neurotoxic chemicals has been implicated in ALS (as part of "Gulf War syndrome").

Approaches to Therapy

Certain themes are apparent in the pharmacological approaches described in this chapter. Many of the existing therapies are *neurochemical*, aiming to replace or compensate for damage to specific neurotransmitter systems that are selectively impaired. For example, dopaminergic therapy is a mainstay of PD therapy, and the primary agents used in AD aim to boost acetylcholinergic transmission. The goal of much current research is to identify therapies that are *neuroprotective* and can modify the underlying neurodegenerative process.

One target of neuroprotective therapies is *excitotoxicity, neural injury* that results from the presence of excess glutamate in the brain. *Glutamate* is used as a neurotransmitter to mediate most excitatory synaptic transmission in the mammalian brain. The presence of excessive amounts of glutamate can lead to excitotoxic cell death (see Chapter 16). The destructive effects of glutamate are mediated by glutamate receptors, particularly those of the NMDA type (see Table 16–2). Excitotoxic injury contributes to the neuronal death that occurs in acute processes such as stroke and head trauma. The role of excitotoxicity is less certain in the chronic neurodegenerative disorders; nevertheless, *glutamate antagonists* have been developed as neuroprotective therapies for neurodegeneration, with two such agents (*memantine* and *riluzole*, described later in the chapter) currently in clinical use.

Aging is the most important risk factor for all neurodegenerative diseases; a likely contributor to the effect of age is the progressive impairment in the capacity of neurons for oxidative metabolism with consequent production of reactive compounds such as hydrogen peroxide and oxygen radicals. These reactive species can lead to DNA damage, peroxidation of membrane lipids, and neuronal death. This has led to pursuit of drugs that can enhance cellular metabolism (such as the mitochondrial cofactor coenzyme Q_{10}) and antioxidant strategies as treatments to prevent or retard degenerative diseases.

The discovery of specific proteins that accumulate and aggregate in each of the neurodegenerative disorders has opened the door to new therapeutic approaches. *Aducanumab*, a monoclonal antibody targeting Aβ, is the first of these to be approved. There is intensive ongoing research to bring disease-modifying treatments, including antibodies and antisense oligonucleotides, that target α-synuclein, tau, TDP-43, and huntingtin into clinical care.

The immune system has been increasingly recognized to play a role in the neurodegenerative process in several neurodegenerative diseases, and much research is focused on identifying which parts of the immune system are active in AD, PD, ALS, and HD. While no therapies that target the immune system are approved currently for neurodegenerative diseases, the lessons learned from therapies targeting multiple sclerosis (see Chapter 39) will aid in the development of new immune-modulating therapies as disease-modifying treatments for neurodegenerative disorders.

Parkinson's Disease

Clinical Overview

Parkinsonism is a clinical syndrome with four cardinal features:

- Bradykinesia (slowness and poverty of movement)
- Muscular rigidity
- Resting tremor (which usually abates during voluntary movement)
- Impairment of postural balance, leading to disturbances of gait and to falling

The most common form of parkinsonism is idiopathic PD, first described by James Parkinson in 1817 as *paralysis agitans,* or the "shaking palsy." *The pathological hallmark of PD is the loss of the pigmented, dopaminergic neurons of the substantia nigra pars compacta, with the*

appearance of intracellular inclusions known as Lewy bodies. The principal component of the Lewy bodies is aggregated α-synuclein (Goedert et al., 2013). A loss of 70% to 80% of the DA-containing neurons accompanies symptomatic PD.

Without treatment, PD progresses over 5 to 10 years to a rigid, akinetic state in which patients are incapable of caring for themselves (Suchowersky et al., 2006). Death frequently results from complications of immobility, including aspiration pneumonia or pulmonary embolism. The availability of effective pharmacological treatment has radically altered the prognosis of PD; in most cases, good functional mobility can be maintained for many years. The life expectancy of adequately treated patients is increased substantially, but overall mortality remains higher than that of the general population.

While DA neuron loss is the most well-recognized feature of the disease, the disorder affects a wide range of other brain structures, including the brainstem, hippocampus, and cerebral cortex (Langston, 2006). There is increasing awareness of the "nonmotor" features of PD, which likely arise from pathology outside the DA system (Zesiewicz et al., 2010). Some nonmotor features may present before the characteristic motor symptoms: anosmia, or loss of the sense of smell; REM behavior disorder, a disorder of sleep with marked agitation and motion during periods of REM sleep; and disturbances of autonomic nervous system function, particularly constipation. Other nonmotor features are seen later in the disease and include depression, anxiety, and dementia. Features of cognitive impairment in PD include impaired attention, hallucinations, delusions, and executive and visuospatial dysfunction.

Several disorders other than idiopathic PD also may produce parkinsonism, including some relatively rare neurodegenerative disorders, stroke, and intoxication with DA receptor antagonists. Drugs that may cause parkinsonism include antipsychotics such as *haloperidol* and *chlorpromazine* (see Chapter 19) and antiemetics such as *prochlorperazine* and *metoclopramide* (see Chapter 54). The distinction between idiopathic PD and other causes of parkinsonism is important because parkinsonism arising from other causes usually is refractory to treatment.

Pathophysiology

The dopaminergic deficit in PD arises from a loss of the neurons in the substantia nigra pars compacta that provide innervation to the striatum (caudate and putamen). The current understanding of the pathophysiology of PD is based on the finding that the striatal DA content is reduced in excess of 80%, with a parallel loss of neurons from the substantia nigra, suggesting that replacement of DA could restore function. The direct and indirect pathway model of the function of the basal ganglia, described below, while incomplete, is still useful.

Dopamine Synthesis, Metabolism, and Receptors

Dopamine, a catecholamine, is synthesized in the terminals of dopaminergic neurons from tyrosine and stored, released, reaccumulated, and metabolized by processes described in Chapter 15 and summarized in Figure 21–1. The actions of DA in the brain are mediated by the DA receptor, of which there are two broad classes, D1 and D2, with five distinct subtypes, D_1–D_5. All the DA receptors are GPCRs. Receptors of the **D1 group** (D_1 and D_5 subtypes) couple to G_s and thence activate the cyclic AMP pathway. The **D2 group** (D_2, D_3, and D_4 receptors) couples to G_i to reduce the adenylyl cyclase activity and voltage-gated Ca^{2+} currents while activating K^+ currents. Each of the five DA receptors has a distinct anatomical pattern of expression in the brain. D_1 and D_2 proteins are abundant in the striatum and are the most important receptor sites with regard to the causes and treatment of PD. The D_4 and D_5 proteins are largely extrastriatal, whereas D_3 expression is low in the caudate and putamen but more abundant in the nucleus accumbens and olfactory tubercle.

Neural Mechanism of Parkinsonism: A Model of Basal Ganglia Function

Considerable effort has been devoted to understanding how the loss of dopaminergic input to the neurons of the neostriatum gives rise to the clinical features of PD (Hornykiewicz, 1973). The basal ganglia can be viewed as a modulatory side loop that regulates the flow of information from the cerebral cortex to the motor neurons of the spinal cord (Albin et al., 1989) (Figure 21–2).

The neostriatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of the cortex. Most neurons within the striatum are projection neurons that innervate other basal ganglia structures. A small but important subgroup of striatal neurons consists of interneurons that connect neurons within the striatum but do not project beyond its borders. ACh and neuropeptides are used as transmitters by these striatal interneurons.

The outflow of the striatum proceeds along two distinct routes, termed the *direct* and *indirect pathways* (Calabresi et al., 2014). The direct pathway is formed by neurons in the striatum that project directly to the output structures of the basal ganglia, the SNpr and the GPi; these, in turn, relay to the VA and VL thalamus, which provides excitatory input to the cortex. The neurotransmitter in both links of the direct pathway is GABA, which is inhibitory, so that *the net effect of stimulation of the direct pathway at the level of the striatum is to increase the excitatory outflow from the thalamus to the cortex.*

The indirect pathway is composed of striatal neurons that project to the GPe. This structure, in turn, innervates the STN, which provides outflow to the SNpr and GPi output structures. The first two links—the projections from striatum to GPe and GPe to STN—use the inhibitory transmitter GABA; however, the final link—the projection from STN to SNpr and GPi—is an excitatory glutamatergic pathway. Thus, *the net effect of stimulating the indirect pathway at the level of the striatum is to reduce the excitatory outflow from the thalamus to the cerebral cortex.* The balance of activity in the direct and indirect pathways is thought critical to the modulation of movement. The differential effect of DA on the direct and indirect pathways is the key feature of this model of basal ganglia function, which accounts for the symptoms observed in PD as a result of loss of dopaminergic neurons (Figure 21–3).

The dopaminergic neurons of the SNpc innervate all parts of the striatum; however, the target striatal neurons express distinct types of DA receptors. The striatal neurons giving rise to the direct pathway express primarily the *excitatory* D_1 DA receptor protein, whereas the striatal neurons forming the indirect pathway express primarily the *inhibitory* D_2 type. *Thus, DA released in the striatum tends to increase the activity of the direct pathway and reduce the activity of the indirect pathway, whereas the depletion that occurs in PD has the opposite effect. The net effect of the reduced dopaminergic input in PD is to increase markedly the inhibitory outflow from the SNpr and GPi to the thalamus and reduce excitation of the motor cortex.* This model explains some of the key clinical features in PD, such as bradykinesia. However, there are several limitations of this model of basal ganglia function. For example, this model fails to explain the resting tremor or levodopa-induced dyskinesia observed in PD. The anatomical connections in the basal ganglia are considerably more complex, and many of the pathways involved use several neurotransmitters. Limitations notwithstanding, the model is useful and has important implications for the rational design and use of pharmacological agents in PD.

Treatment

Current management of PD is primarily focused on the replacement of DA signaling that is depleted in the disorder. These therapies are effective at reducing the motor symptoms of PD, yet they do not slow the disease progression.

Levodopa

Levodopa (also called L-DOPA or L-3,4-dihydroxyphenylalanine), the metabolic precursor of DA, is the single most effective agent in the treatment of PD (Cotzias et al., 1969; Fahn et al., 2004). DA itself is not used as a therapeutic agent in PD due to its inability to cross the blood-brain barrier. *Levodopa*, however, crosses across the blood-brain barrier by a membrane transported for aromatic amino acids. The effects of *levodopa* result from its decarboxylation to DA in the CNS. When administered orally, *levodopa* is absorbed rapidly from the small bowel by the transport system for aromatic amino acids. Concentrations of the drug in plasma

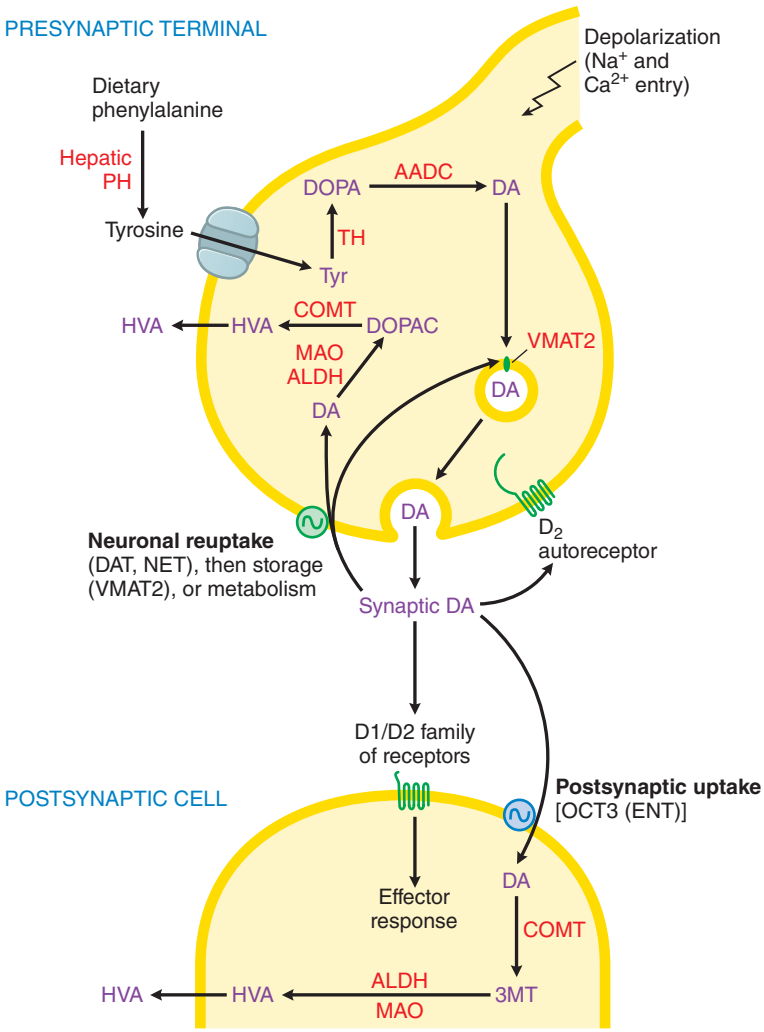

Figure 21–1 *Dopaminergic nerve terminal.* DA is synthesized from tyrosine in the nerve terminal by the sequential actions of TH and AADC. DA is sequestered by VMAT2 in storage granules and released by exocytosis. Synaptic DA activates presynaptic autoreceptors and postsynaptic D1 and D2 receptors. Synaptic DA may be taken up into the neuron via the DA and NE transporters (DAT, NET) or removed by postsynaptic uptake via the organic cation transporter, OCT3 (see Chapter 10). Cytosolic DA is subject to degradation by MAO and ALDH in the neuron and by COMT and MAO/ALDH in nonneuronal cells; the final metabolic product is HVA. See structures of neurotransmitters and metabolites in Figure 21–4.

usually peak between 0.5 and 2 h after an oral dose. The $t_{1/2}$ in plasma is short (1–3 h). The rate and extent of absorption of *levodopa* depend on the rate of gastric emptying, the pH of gastric juice, and the length of time the drug is exposed to the degradative enzymes of the gastric and intestinal mucosa. Administration of *levodopa* with high-protein meals delays absorption and reduces peak plasma concentrations. After entry across the blood-brain barrier by a membrane transporter for aromatic amino acids, *levodopa* is converted to DA by decarboxylation, primarily within the presynaptic terminals of dopaminergic neurons in the striatum. The DA produced is responsible for the therapeutic effectiveness of the drug in PD; after release, it is either transported back into dopaminergic terminals by the presynaptic uptake mechanism or metabolized by the actions of MAO and COMT (Figure 21–4).

In clinical practice, *levodopa* is almost always administered in combination with a peripherally acting inhibitor of AADC, such as *carbidopa* (used in the U.S.) or *benserazide* (available outside the U.S.), drugs that do not penetrate well into the CNS. If *levodopa* is administered alone, the drug is largely decarboxylated by enzymes in the intestinal mucosa and other peripheral sites so that relatively little unchanged drug reaches the cerebral circulation, and probably less than 1% penetrates the CNS. In addition, DA released into the circulation by peripheral conversion of *levodopa* produces undesirable effects, particularly nausea. Inhibition of peripheral decarboxylase markedly increases the fraction of administered *levodopa* that remains unmetabolized and available to cross the blood-brain barrier (Figure 21–5) and reduces the incidence of GI side effects and drug-induced orthostatic hypotension.

A daily dose of 75 mg *carbidopa* is generally sufficient to prevent the development of nausea. For this reason, the most commonly prescribed form of *carbidopa*/*levodopa* is the 25/100 form, containing 25 mg *carbidopa* and 100 mg *levodopa*. With this formulation, dosage schedules of three or more tablets daily provide acceptable inhibition of decarboxylase in most individuals.

Levodopa therapy can have a dramatic effect on motor signs and symptoms of PD. Early in the course of the disease, the degree of improvement in tremor, rigidity, and bradykinesia produced by *carbidopa*/*levodopa* may be nearly complete. Despite the short plasma $t_{1/2}$, *levodopa* dosing three to four times a day is sufficient to maintain a stable symptomatic benefit due to the storage of *levodopa* in surviving synaptic terminals. With long-term *levodopa* therapy, the "buffering" capacity is lost, and the patient's motor state may fluctuate dramatically with each dose of *levodopa*, producing the *motor complications* of *levodopa* (Pahwa et al., 2006).

A common problem is the development of the "wearing-off" phenomenon: Each dose of *levodopa* effectively improves mobility for a period of time, perhaps 1 to 2 h, but rigidity and akinesia return rapidly at the end of the dosing interval. Increasing the dose and frequency of administration can improve this situation, but this often is limited by the development of

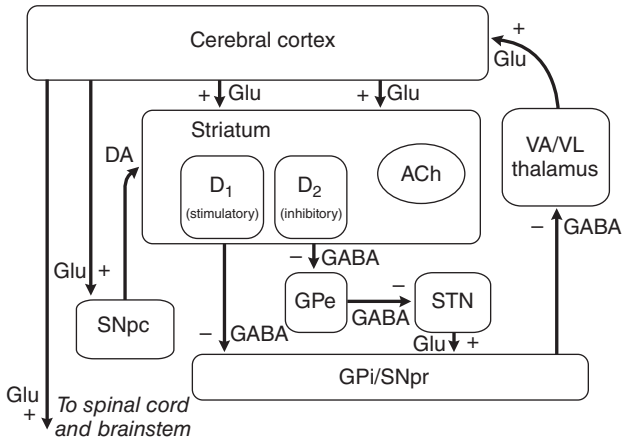

Figure 21–2 *Schematic wiring diagram of the basal ganglia.* The striatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of cerebral cortex. The striatum contains projection neurons expressing predominantly D_1 or D_2 DA receptors, as well as interneurons that use ACh as a neurotransmitter. Outflow from the striatum proceeds along two routes. The direct pathway, from the striatum to the SNpr and GPi, uses the inhibitory transmitter GABA. The indirect pathway, from the striatum through the GPe and the STN to the SNpr and GPi, consists of two inhibitory GABA-ergic links and one excitatory Glu projection. The SNpc provides dopaminergic innervation to the striatal neurons, giving rise to both the direct and the indirect pathways, and it regulates the relative activity of these two paths. The SNpr and GPi are the output structures of the basal ganglia and provide feedback to the cerebral cortex through the VA/VL nuclei of the thalamus.

dyskinesias, excessive and abnormal involuntary movements. In the later stages of PD, patients may fluctuate rapidly between being "off," having no beneficial effects from their medications, and being "on" but with disabling dyskinesias (the *on/off phenomenon*). A sustained-release formulation consisting of *carbidopa/levodopa* in an erodable wax matrix is helpful in some cases, but absorption of this older sustained-release formulation is not entirely predictable.

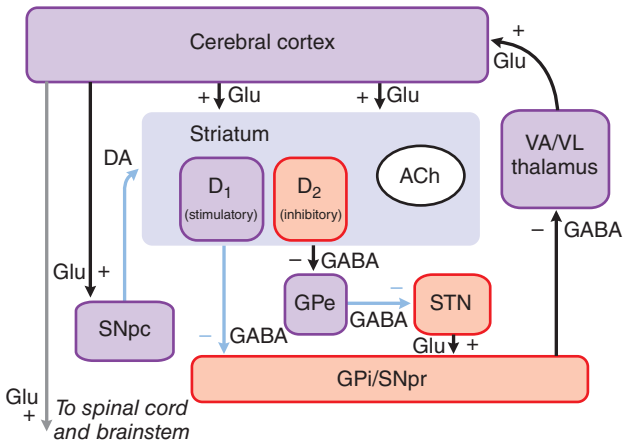

Figure 21–3 *The basal ganglia in PD.* The primary defect is destruction of the dopaminergic neurons of the SNpc. The striatal neurons that form the direct pathway from the striatum to the SNpr and GPi express primarily the *excitatory* D_1 DA receptor, whereas the striatal neurons that project to the GPe and form the indirect pathway express the *inhibitory* D_2 DA receptor. Thus, loss of the dopaminergic input to the striatum has a differential effect on the two outflow pathways; the direct pathway to the SNpr and GPi is less active (structures in purple), whereas the activity in the indirect pathway is increased (structures in red). The net effect is that neurons in the SNpr and GPi become more active. This leads to increased inhibition of the VA/VL thalamus and reduced excitatory input to the cortex. Light blue lines indicate primary pathways with reduced activity. (See Abbreviations list for definitions of anatomical abbreviations.)

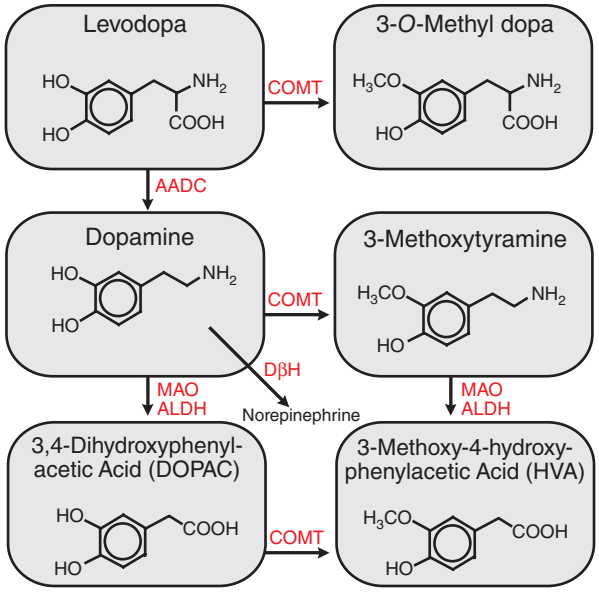

Figure 21–4 *Metabolism of levodopa (L-DOPA).*

Recently, several new formulations of *levodopa* intended to address the wearing off have been approved. A *carbidopa-levodopa* extended-release capsule contains both immediate- and extended-release beads that provide reduced off time in patients with motor fluctuations (Hauser et al., 2013). A *carbidopa-levodopa* intestinal gel is administered through a gastrostomy tube into the jejunum using a pump and can have a dramatic effect on reducing off time (Olanow et al., 2014). A *levodopa* inhalational powder is administered through an inhaler and is also effective for the treatment of off periods (LeWitt et al., 2019). Other *levodopa* formulations are under development, including subcutaneous delivery methods.

Does *levodopa* alter the course of the underlying disease or merely modify the symptoms? While the answer to this question is not entirely certain, the PD MED trial revealed that patients treated with *levodopa* early compared to DA agonists or MAO-B inhibitors had a slight but persistent benefit in mobility and activities of daily living at 7 years after initiation of therapy, although dyskinesia rates were higher among the levodopa group (PD MED Collaborative Group, 2014). Most practitioners have adopted a pragmatic approach, using *levodopa* only when the symptoms of PD cause functional impairment and other treatments are inadequate or not well tolerated.

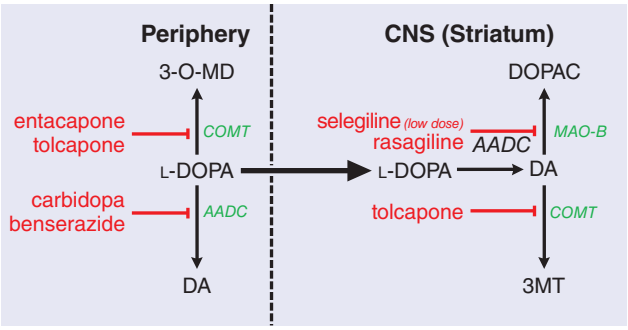

Figure 21–5 *Pharmacological preservation of levodopa (L-dopa) and striatal DA.* The principal site of action of inhibitors of COMT (e.g., *tolcapone, entacapone*, and *opicapone*) is in the peripheral circulation, where they block the *O*-methylation of L-dopa and increase the fraction of the drug available for delivery to the brain. Likewise, *carbidopa* and *benserazide* inhibit decarboxylation of L-dopa in the periphery, preserving it for delivery to the CNS. *Tolcapone* also has effects in the CNS. Inhibitors of MAO-B, such as low-dose *selegiline* and *rasagiline*, will act within the CNS to reduce oxidative deamination of DA, thereby enhancing vesicular stores.

A frequent and troubling adverse effect is the induction of hallucinations and confusion, especially in elderly patients or in patients with preexisting cognitive dysfunction. Conventional antipsychotic agents, such as the phenothiazines, are effective against *levodopa*-induced psychosis but may cause marked worsening of parkinsonism, probably through actions at the D_2 DA receptor, and should not be used in PD. An alternative approach has been to use "atypical" antipsychotic agents (see Chapter 19). The two atypical antipsychotics that are most effective and best tolerated in patients with advanced PD are *clozapine* and *quetiapine*. *Pimavanserin*, an inverse agonist at the serotonin $5HT2_A$ receptor, is FDA approved for the management of hallucinations and psychosis observed in PD. Monitoring of QT interval is important when using *pimavanserin* or atypical antipsychotics due to the risk of QT interval prolongation and resultant cardiac arrhythmias. Additionally, these drugs are associated with an increased rate of death when used in the elderly, a risk that must be weighed carefully against the risks created by hallucinations and psychosis. *Levodopa* (and the DA agonists, described in the next section) may also lead to the development of an impulse control disorder (ICD) (Weintraub et al., 2015). These include compulsive behaviors, gambling, and hypersexuality and can be destructive socially. PD also appears to be associated with an increased risk of suicidality, but whether this is associated with the disease or specific treatment is uncertain. Vigilance for signs of depression and suicidality should be practiced in all patients with PD.

Administration of *levodopa* with nonspecific inhibitors of MAO accentuates the actions of *levodopa* and may precipitate life-threatening hypertensive crisis and hyperpyrexia; nonspecific MAO inhibitors always should be discontinued at least 14 days before *levodopa* is administered (note that this prohibition does not include the MAO-B subtype-specific inhibitors *selegiline*, *rasagiline*, and *safinamide*). Abrupt withdrawal of *levodopa* or other dopaminergic medications may precipitate the *neuroleptic malignant syndrome* of confusion, rigidity, and hyperthermia, a potentially lethal adverse effect.

Dopamine Receptor Agonists

The DA receptor agonists in clinical use have durations of action substantially longer than that of *levodopa*; they are often used in the management of dose-related fluctuations in motor state and may be helpful in preventing motor complications (Parkinson Study Group, 2000). DA receptor agonists have been proposed to have the potential to modify the course of PD by reducing the endogenous release of DA as well as the need for exogenous *levodopa*, thereby reducing free radical formation. However, several clinical trials comparing DA receptor agonists to *levodopa* showed mixed results with regard to a protective advantage of DA receptor agonists compared to *levodopa* (Parkinson Study Group, 2002; PD MED Collaborative Group, 2014; Whone et al., 2003).

Two orally administered DA receptor agonists are commonly used for the treatment of PD: *ropinirole* and *pramipexole*. Both are well absorbed orally and have similar therapeutic actions. There is also a transdermal formulation of the DA agonist *rotigotine* available. *Ropinirole* and *pramipexole* have selective activity at D2 class sites (specifically at the D_2 and D_3 receptors). *Rotigotine* acts at D2 sites and also has activity at D1 sites. Like *levodopa*, these DA agonists can relieve the clinical symptoms of PD. The duration of action of the DA agonists (8–24 h) often is longer than that of *levodopa* (6–8 h), and they are particularly effective in the treatment of patients who have developed on/off phenomena. Both *ropinirole* and *pramipexole* are also available in once-daily sustained-release formulations, which are more convenient and may reduce adverse effects related to intermittent dosing. The transdermal delivery of *rotigotine* produces stable plasma drug levels over 24 h.

Pramipexole, *ropinirole*, and *rotigotine* may produce hallucinosis or confusion, similar to that observed with *levodopa*, and may cause nausea and orthostatic hypotension. These agents should be initiated at low dose and titrated slowly to minimize these effects. The DA agonists, as well as *levodopa* itself, are also associated with fatigue and somnolence. Patients should be warned about the potential for sleepiness, especially while driving. DA agonists cause a higher rate of ICD compared to levodopa, and screening for ICD is critical in patients treated with these drugs. Many practitioners prefer a DA agonist as initial therapy in younger patients to reduce the occurrence of motor complications. In older patients or those with substantial comorbidity, *levodopa*/*carbidopa* is generally better tolerated.

Apomorphine. *Apomorphine* is a dopaminergic agonist that can be administered by subcutaneous injection or as a sublingual formulation. It has a high affinity for D_4 receptors; moderate affinity for D_2, D_3, D_5, and adrenergic α_{1D}, α_{2B}, and α_{2C} receptors; and low affinity for D_1 receptors. *Apomorphine* is FDA approved as a "rescue therapy" for the acute intermittent treatment of off episodes in patients with a fluctuating response to dopaminergic therapy.

Apomorphine has the same side effects as the oral DA agonists. *Apomorphine* is highly emetogenic and requires pre- and posttreatment antiemetic therapy. Oral *trimethobenzamide*, at a dose of 300 mg, three times daily, should be started 3 days prior to the initial dose of *apomorphine* and continued at least during the first 2 months of therapy. Profound hypotension and loss of consciousness have occurred when *apomorphine* was administered with *ondansetron*; hence, the concomitant use of *apomorphine* with antiemetic drugs of the $5HT_3$ antagonist class is contraindicated. Other potentially serious side effects of *apomorphine* include QT prolongation, injection site reactions, and the development of a pattern of abuse characterized by increasingly frequent dosing leading to hallucinations, dyskinesia, and abnormal behavior. The sublingual formulation can cause oral sores and/or pain.

Because of these potential adverse effects, the use of *apomorphine* is appropriate only when other measures, such as oral DA agonists or COMT inhibitors, have failed to control the off episodes. *Apomorphine* injection should be initiated with a 2-mg test dose in a setting where the patient can be monitored carefully. If tolerated, it can be titrated slowly up to a maximum dosage of 6 mg. For effective control of symptoms, patients may require three or more injections daily. The starting dose for the sublingual formulation is 10 mg, and the dose can be titrated by 5-mg increments to a maximum of 30 mg/dose up to five doses total per day.

Catechol-O-Methyltransferase Inhibitors

Orally administered *levodopa* is largely converted by AADC to DA (see Figure 21–5), which causes nausea and hypotension. Addition of an AADC inhibitor such as *carbidopa* reduces the formation of DA but increases the fraction of *levodopa* that is methylated by COMT. COMT inhibitors block this peripheral conversion of *levodopa* to 3-*O*-methyl DOPA, increasing both the plasma $t_{1/2}$ of *levodopa* and the fraction of each dose that reaches the CNS. Additionally, centrally acting COMT inhibitors can block the metabolism of DA.

The COMT inhibitors *tolcapone* and *entacapone* reduce significantly "wearing-off" symptoms in patients treated with *levodopa*/*carbidopa* (Parkinson Study Group, 1997). The two drugs differ in their pharmacokinetic properties and adverse effects: *Tolcapone* has a relatively long duration of action and appears to act by inhibition of both central and peripheral COMT. *Entacapone* has a short duration of action (2 h) and principally inhibits peripheral COMT. Common adverse effects of both agents include nausea, orthostatic hypotension, vivid dreams, confusion, and hallucinations. An important adverse effect associated with *tolcapone* is hepatotoxicity, which has greatly limited its clinical use. At least three fatal cases of fulminant hepatic failure in patients taking *tolcapone* have been observed, leading to addition of a black-box warning to the label. *Tolcapone* should be used only in patients who have not responded to other therapies and with appropriate monitoring for hepatic injury. *Entacapone* has not been associated with hepatotoxicity. Both COMT inhibitors are given multiple times a day with each *levodopa* dose. *Entacapone* also is available in fixed-dose combinations with *levodopa*/*carbidopa*.

Opicapone is a new FDA-approved COMT inhibitor. Despite a short plasma $t_{1/2}$, its slow dissociation rate allows its use once daily. Its use with *levodopa* reduces off time comparable to *entacapone* (Ferreira et al., 2016).

Selective MAO-B Inhibitors

Two isoenzymes of MAO oxidize catecholamines: MAO-A and MAO-B. MAO-B is the predominant form in the striatum and is responsible for

most of the oxidative metabolism of DA in the brain. Selective MAO-B inhibitors are used for the treatment of PD: *selegiline*, *rasagiline*, and *safinamide*. *Selegiline* and *rasagiline* selectively and irreversibly inactivate MAO-B; *safinamide* is a reversible inhibitor of MAO-B. These agents exert modest beneficial effects on the symptoms of PD. The basis of this efficacy is, presumably, inhibition of the breakdown of DA in the striatum.

Selective MAO-B inhibitors do not substantially inhibit the peripheral metabolism of catecholamines and can be taken safely with *levodopa*. These agents also do not exhibit the "cheese effect," the potentially lethal potentiation of catecholamine action observed when patients on nonspecific MAO inhibitors ingest indirectly acting sympathomimetic amines such as the tyramine found in certain cheeses and wine.

Selegiline is generally well tolerated in younger patients for symptomatic treatment of early or mild PD. In patients with more advanced PD or underlying cognitive impairment, *selegiline* may accentuate the adverse motor and cognitive effects of *levodopa* therapy. Metabolites of *selegiline* include amphetamine and methamphetamine, which may cause anxiety, insomnia, and other adverse symptoms. *Selegiline* is available in an orally disintegrating tablet as well as a transdermal patch. Both delivery routes are intended to reduce hepatic first-pass metabolism and limit the formation of amphetamine metabolites.

Unlike *selegiline*, *rasagiline* does not give rise to undesirable amphetamine metabolites. *Rasagiline* monotherapy is effective in early PD. Adjunctive therapy with *rasagiline* significantly reduces *levodopa*-related wearing-off symptoms in advanced PD (Olanow et al., 2008). A clinical trial comparing early versus late start of *rasagiline* suggested that *rasagiline* may have disease-modifying effects (Olanow et al., 2009), although this benefit was not clearly maintained in a later follow-up study (Rascol et al., 2016). Selective MAO-B inhibitors are generally well tolerated, but their drug interactions can be troublesome. Similar to the nonspecific MAO inhibitors, *selegiline* can lead to the development of stupor, rigidity, agitation, and hyperthermia when administered with the analgesic *meperidine*. Although the mechanics of this interaction are uncertain, the guidance is clear: *Selegiline* or *rasagiline* should not be given in combination with *meperidine*. *Tramadol*, *methadone*, *propoxyphene dextromethorphan*, St. John's wort, and *cyclobenzaprine* are also contraindicated with MAO-B inhibitors. Although the development of the *serotonin syndrome* has been reported with coadministration of MAO-B inhibitors and antidepressants (tricyclic or serotonin reuptake inhibitors), this appears to be rare, and many patients are treated with this combination without difficulty. If concurrent treatment with MAO-B inhibitors and antidepressants is undertaken, close monitoring and use of low doses of the antidepressant are advisable (Panisset et al., 2014).

Safinamide is a novel MAO-B inhibitor that is FDA approved for adjunctive therapy to *levodopa* for off periods in PD. Unlike *selegiline* or *rasagiline*, *safinamide* does not irreversibly inhibit MAO-B, and it also reduces glutamate release (Muller, 2018). Dose adjustment is required in moderate hepatic dysfunction, and *safinamide* should be avoided in severe hepatic disease. Side effect profile and drug interactions are similar to those of other MAO-B inhibitors.

Muscarinic Receptor Antagonists

Antimuscarinic drugs currently used in the treatment of PD include *trihexyphenidyl* and *benztropine mesylate*, as well as the antihistaminic *diphenhydramine hydrochloride*, which also interacts at central muscarinic receptors. The biological basis for the therapeutic actions of muscarinic antagonists is not completely understood. They may act within the neostriatum through the receptors that normally mediate the response to intrinsic cholinergic innervation of this structure, which arises primarily from cholinergic striatal interneurons.

These drugs have relatively modest antiparkinsonian activity and are used only in the treatment of early PD or as an adjunct to dopamimetic therapy. Adverse effects result from their anticholinergic properties. Most troublesome are sedation and mental confusion. All anticholinergic drugs must be used with caution in patients with narrow-angle glaucoma (see Chapter 74), and in general, anticholinergics are not well tolerated in the elderly. The pharmacology and signaling mechanisms of muscarinic receptors are thoroughly covered in Chapter 11.

Amantadine

Amantadine, an antiviral agent used for the prophylaxis and treatment of influenza A (see Chapter 62), has antiparkinsonian activity. *Amantadine* appears to alter DA release in the striatum, has anticholinergic properties, and blocks NMDA glutamate receptors. It is used as initial therapy for mild PD. It also may be helpful as an adjunct in patients on *levodopa* with dose-related fluctuations and dyskinesias. *Amantadine* is usually administered at a dose of 100 mg, twice per day, and is well tolerated. Once-a-day formulations are now available. Side effects, including dizziness, lethargy, anticholinergic effects, and sleep disturbance, as well as nausea and vomiting, are mild and reversible.

Istradefylline

Istradefylline is an adenosine A_{2A} receptor antagonist that is FDA approved for adjunctive treatment for off periods in PD. A_{2A} receptors are highly colocalized with D_2 receptors in the striatum, and activation of A_{2A} receptor inhibits D_2 receptor signaling, possibly via heterodimerization of A_{2A} and D_2 receptors. Therefore, in the presence of adenosine tone, antagonism of A_{2A} receptors could promote motor function by boosting DA signaling in the striatum. *Istradefylline* is dosed once daily and generally well tolerated. The most common side effects include hallucinations, nausea, and dizziness. A few small, open-label trials suggest that this agent may also help nonmotor symptoms, such as urinary dysfunction, daytime sleepiness, and cognitive impairment (Torti et al., 2018).

Future Therapies

The ultimate goal in PD therapeutics is disease-modifying treatments that slow disease progression. Advances in the understanding of the mechanisms underlying neurodegeneration have led to novel therapies that are undergoing preclinical and clinical investigation. α-Synuclein, the key protein that becomes misfolded and aggregates in PD, is a key target under investigation, and monoclonal antibodies against α-synuclein are in phase II clinical studies. The excess kinase activity of LRRK2 is implicated in patients with LRRK2 mutations and possibly in sporadic PD. Several compounds that inhibit LRRK2 kinase activity are under clinical investigation. Compounds to promote the activity of β-glucocerebrosidase, the protein encoded by the risk gene *GBA*, or to reduce its substrate are also under investigation in clinical trials.

Clinical Summary

Pharmacological treatment of PD should be tailored to the individual patient (Connolly and Lang, 2014). Drug therapy is not obligatory in early PD; many patients can be managed for a time with exercise and lifestyle interventions. For patients with mild symptoms, MAO-B inhibitors, *amantadine*, or (in younger patients) anticholinergics are reasonable choices. In most patients, treatment with a dopaminergic drug, either *levodopa* or a DA agonist, is eventually required. Many practitioners prefer a DA agonist as initial therapy in younger patients to reduce the occurrence of motor complications, although the evidence supporting this practice is inconclusive. In older patients or those with substantial comorbidity, *levodopa/carbidopa* is generally better tolerated.

Alzheimer's Disease

Clinical Overview

The brain region most vulnerable to neuronal dysfunction and cell loss in AD is the medial temporal lobe, including the entorhinal cortex and hippocampus. The proteins that accumulate in AD are Aβ in amyloid plaques and tau in neurofibrillar tangles. AD has three major stages:

1. An asymptomatic "preclinical" stage during which accumulation of Aβ and tau begins
2. An MCI stage with episodic memory loss (repeated questions, misplaced items, etc.) that is not severe enough to impair daily function
3. A dementia stage with progressive loss of functional abilities

Death usually ensues within 6 to 12 years of onset, most often from a complication of immobility such as pneumonia or pulmonary embolism.

Alzheimer's disease has traditionally been a clinical diagnosis based on the presence of memory impairment and other cognitive impairments that are insidious, progressive, and not well explained by another disorder. In recent years, there has been steady progress toward the inclusion of biomarkers in the diagnostic criteria. This includes both *fluid biomarkers*, such as changes in Aβ and tau in the cerebrospinal fluid or plasma, and *imaging biomarkers*, such as hippocampal atrophy on structural magnetic resonance imaging, cortical hypometabolism on fluorodeoxyglucose PET scans, and amyloid or tau deposition on PET scans. Three agents, *florbetapir, flutemetamol*, and *florbetaben,* are FDA approved for determining whether individuals with cognitive impairment have Aβ deposition, which would suggest AD as a possible etiology. *Flortaucipir* is approved for tau PET imaging. Under the 2018 NIA-AA research framework, amyloid (A), tau (T), and neurodegeneration (N) biomarkers are used to classify individuals' "ATN" status, with amyloid biomarkers required for a diagnosis of AD (Jack et al., 2018).

Genetics

Mutations in three genes have been identified as causes of autosomal dominant, early-onset AD: *APP*, which encodes Aβ precursor protein, and *PSEN1* and *PSEN2,* encoding presenilin 1 and 2, respectively. All three genes are involved in the production of Aβ peptides. Aβ is generated by sequential proteolytic cleavage of APP by two enzymes, β-secretase and γ-secretase; the presenilins form the catalytic core of γ-secretase. The genetic evidence, combined with the fact that Aβ accumulates in the brain in the form of soluble oligomers and amyloid plaques and is toxic when applied to neurons, forms the basis for the amyloid hypothesis of AD pathogenesis. Many genes have been identified as having alleles that increase AD risk. By far the most important of these is *APOE*, which encodes the lipid carrier protein apoE. Individuals inheriting the ε4 allele of *APOE* have a 3-fold or more higher risk of developing AD. While these individuals make up less than one-fourth of the population, they account for more than half of all AD cases.

Pathophysiology

The pathological hallmarks of AD are amyloid plaques, which are extracellular accumulations of Aβ, and intracellular neurofibrillary tangles composed of the microtubule-associated protein tau. The deposition of amyloid plaques occurs first, and tangle burden accrues over time in a manner that correlates more closely with the development of cognitive impairment. In autosomal dominant AD, Aβ accumulates due to mutations that cause its overproduction; in sporadic late-onset AD, the reasons for amyloid accumulation are less clear. While amyloid plaques consist of highly ordered fibrils of Aβ, it appears that soluble Aβ oligomers, perhaps as small as dimers, are more highly pathogenic. Tau also aggregates, forming the paired helical filaments that make up neurofibrillary tangles. Posttranslational modifications of tau, including phosphorylation, proteolysis, and other changes, increase tau's propensity to aggregate. Mechanisms by which Aβ and tau induce neuronal dysfunction and death may include direct impairment of synaptic transmission and plasticity, excitotoxicity, oxidative stress, and neuroinflammation.

Neurochemistry

The most striking neurochemical disturbance in AD is a *deficiency of ACh*. The anatomical basis of the cholinergic deficit is atrophy and degeneration of subcortical cholinergic neurons. The selective deficiency of ACh in AD and the observation that central cholinergic antagonists (e.g., atropine) can induce a confusional state resembling the dementia of AD have given rise to the "cholinergic hypothesis" that a deficiency of ACh is critical in the genesis of the symptoms of AD. AD, however, is complex and also involves multiple neurotransmitter systems, including glutamate, 5HT, and neuropeptides, and there is destruction not only of cholinergic neurons but also of cortical and hippocampal targets that receive cholinergic input.

Treatment

Three classes of drugs are FDA approved for the treatment of AD: orally administered cholinesterase inhibitors, *memantine*, and intravenously delivered anti-Aβ antibodies to clear amyloid plaques. These treatments are often used in combination (Cummings et al., 2019).

Cholinesterase Inhibitors

Augmentation of cholinergic transmission has been the first-line AD treatment for decades. Three drugs, *donepezil, rivastigmine*, and *galantamine*, are widely used for this purpose (Table 21–1). All three are reversible antagonists of cholinesterases (see Chapter 12) and target the cholinergic deficit in AD. Cholinesterase inhibitors are indicated for symptomatic treatment of mild or moderate dementia due to AD. They are also widely used to treat other neurodegenerative diseases with cholinergic deficits, including dementia with Lewy bodies and vascular dementia. Their effect is generally modest, usually producing a 6- to 12-month delay in progression without a dramatic improvement in symptoms, after which clinical decline resumes. The drugs are generally well tolerated, with the most common side effects being GI distress, muscle cramping, and abnormal dreams. They should be used with caution in patients with bradycardia or syncope.

Memantine

Memantine is an uncompetitive antagonist of the NMDA-type glutamate receptor, used with the goal of blocking pathological NMDA receptor activation associated with excitotoxicity while permitting physiological activation associated with learning and memory. It is indicated for moderate-to-severe stages of dementia, as there is little evidence for its efficacy in earlier stages. Like the cholinesterase inhibitors, *memantine*

TABLE 21–1 ■ CHOLINESTERASE INHIBITORS USED FOR THE TREATMENT OF ALZHEIMER'S DISEASE

	DONEPEZIL	RIVASTIGMINE	GALANTAMINE
Enzymes inhibited[a]	AChE	AChE, BuChE	AChE
Mechanism	Noncompetitive	Noncompetitive	Competitive
Typical maintenance dose[b]	10 mg once daily	9.5 mg/24 h (transdermal) 3–6 mg twice daily (oral)	8–12 mg twice daily (immediate release) 16–24 mg/d (extended release)
FDA-approved indications	Mild-severe AD	Mild-moderate AD Mild-moderate PDD	Mild-moderate AD
Metabolism[c]	CYP2D6, CYP3A4	Esterases	CYP2D6, CYP3A4

[a]AChE is the major cholinesterase in the brain; BuChE is a serum and hepatic cholinesterase that is upregulated in AD brain.
[b]Typical starting doses are one-half of the maintenance dose and are given for the first month of therapy.
[c]Drugs metabolized by CYP2D6 and CYP3A4 are subject to increased serum levels when coadministered with drugs known to inhibit these enzymes, such as ketoconazole and paroxetine.

delays clinical deterioration temporarily. Adverse effects of *memantine* include mild headache or dizziness. The drug is excreted by the kidneys, and dosage should be reduced in patients with severe renal impairment.

Amyloid Immunotherapy

After 18 years without a new treatment option, the landscape of AD treatment changed dramatically in 2021 with FDA approval of the first disease-modifying therapy, *aducanumab*, a monoclonal antibody that reduces amyloid plaques (Sevigny et al., 2016). Passive immunotherapy targeting Aβ is based on the amyloid hypothesis, and FDA approval of *aducanumab* was via the Accelerated Approval Program, which allows early approval of treatments for serious conditions based on surrogate biomarkers, in this case amyloid plaque burden. Its approval was controversial because the data supporting clinical efficacy did not meet the level required for traditional FDA approval; accelerated approval requires a subsequent phase IV trial to establish clinical benefit. The labeled indication for *aducanumab* is AD at the mild cognitive impairment or mild dementia stage. Clinical trials of various amyloid immunotherapies suggest trends toward more effectiveness in earlier stages. This is consistent with the observation that amyloid plaques begin depositing approximately 15 years before symptom onset, and thus, by the moderate dementia stage when plaques may have been present for as long as 25 years, it may be too late to reverse Aβ-induced damage. The pivotal trials of *aducanumab* included patients with MCI or mild dementia due to AD and required a positive amyloid PET scan. In practice, CSF biomarker confirmation of amyloid positivity is also used as another means to identify potentially eligible patients. *Aducanumab* is given monthly by intravenous infusions and requires MRI safety scans before initiating treatment and at 6-month intervals. Amyloid-related imaging abnormalities (ARIAs) were observed in almost half of the patients in phase III trials and include localized areas of cerebral edema (ARIA-E) or microhemorrhages (ARIA-H). ARIAs are often asymptomatic and generally reversible with discontinuation of treatment but can cause headache, dizziness, nausea, and other neurological symptoms.

Treatment of Behavioral Symptoms

In addition to cognitive decline, behavioral and psychiatric symptoms in dementia (BPSD) are common, particularly in the middle stages of the disease. These symptoms include irritability and agitation, paranoia and delusional thinking, wandering, anxiety, and depression. Treatment can be difficult, and nonpharmacological approaches should generally be the first line.

A variety of pharmacological options are also available. Both cholinesterase inhibitors and *memantine* reduce some BPSD. However, their effects are modest and they do not treat some of the most troublesome symptoms, such as agitation. *Citalopram*, an SSRI (see Chapters 15 and 18), showed efficacy for agitation in a randomized clinical trial. Atypical antipsychotics, such as *risperidone*, *olanzapine*, *quetiapine*, and *ziprasidone* (see Chapter 19), are perhaps even more efficacious for agitation and psychosis in AD, but their use is often limited by adverse effects, including parkinsonism, sedation, and falls. In addition, the use of atypical antipsychotics in elderly patients with dementia-related psychosis has been associated with a higher risk of stroke and overall mortality, leading to an FDA black-box warning (Schneider et al., 2005). Benzodiazepines (see Chapter 22) can be used for occasional control of acute agitation but are not recommended for long-term management because of their adverse effects on cognition and other risks in the elderly population. The typical antipsychotic *haloperidol* (see Chapter 19) may be useful for aggression, but sedation and extrapyramidal symptoms limit its use to control acute episodes.

Clinical Summary

The typical patient with AD presenting in the early stages of disease should probably be treated with a cholinesterase inhibitor. Patients and families should be counseled that a realistic goal of therapy is to induce a temporary reprieve from progression, or at least a reduction in the rate of decline, rather than long-term recovery of cognition. If biomarkers indicate amyloid positivity, then amyloid immunotherapy can be considered. As the disease progresses, *memantine* can be added to the regimen. Behavioral symptoms are often treated with a serotonergic antidepressant or, if they are severe enough to warrant the risk of higher mortality, an atypical antipsychotic. Eliminating drugs likely to aggravate cognitive impairments, particularly anticholinergics, benzodiazepines, and other sedative/hypnotics, from the patient's regimen is another important aspect of AD pharmacotherapy.

Huntington's Disease

Clinical Overview

Huntington's disease is a dominantly inherited disorder characterized by the gradual onset of motor incoordination and cognitive decline in midlife (Bates et al., 2015). Symptoms develop insidiously, as a movement disorder manifested by brief, dance-like movements of the extremities, trunk, face, and neck (chorea), or psychiatric symptoms, or both. Fine-motor incoordination and impairment of rapid eye movements are early features. As the disorder progresses, the involuntary movements become more severe, dysarthria and dysphagia develop, and balance is impaired. The cognitive disorder manifests first as slowness of mental processing and difficulty in organizing complex tasks. Memory is impaired, but affected persons rarely lose their memory of family, friends, and the immediate situation. Patients usually lack insight into their own disease. Obsessive-compulsive behaviors and depression are common, and many patients have psychosis and behavioral disturbances. The risk of suicidality is high in HD. The outcome of HD is invariably fatal; over a course of 15 to 30 years, the affected person becomes totally disabled and unable to communicate, requiring full-time care; death ensues from the complications of immobility.

Genetics

Huntington's disease is an autosomal dominant disorder with nearly complete penetrance. The average age of onset is between 35 and 45 years, but the range varies from as early as age 2 to as late as the middle 80s. Although the disease is inherited equally from mother and father, more than 80% of those developing symptoms before age 20 inherit the defect from the father. Known homozygotes for HD show clinical characteristics identical to the typical HD heterozygote, indicating that the unaffected chromosome does not attenuate the disease symptomatology.

A region near the end of the short arm of chromosome 4 contains a polymorphic $(CAG)_n$ trinucleotide repeat that is significantly expanded in all individuals with HD. The expansion of this trinucleotide repeat is the genetic alteration responsible for HD. The range of CAG repeat length in normal individuals is between 9 and 34 triplets, with a median repeat length on normal chromosomes of 19. The repeat length in HD varies from 40 to over 100. Repeat length is correlated inversely with the age of onset of HD. The younger the age of onset, the higher is the probability of a large repeat number. The mechanism by which the expanded trinucleotide repeat leads to the clinical and pathological features of HD is unknown. The HD mutation lies within a large gene (10 kb) designated *HTT* (previously *IT15*) that encodes *huntingtin*, a protein of about 348,000 Da. The trinucleotide repeat, which encodes the amino acid glutamine, occurs at the 5′ end of HTT. Huntingtin has no sequence homology with other known proteins.

Pathophysiology

Huntington's disease is characterized by prominent neuronal loss in the striatum (caudate/putamen) of the brain. Atrophy of these structures proceeds in an orderly fashion, first affecting the tail of the caudate nucleus and then proceeding anteriorly from mediodorsal to ventrolateral. Interneurons and afferent terminals are largely spared, whereas the striatal projection neurons (the medium spiny neurons) are severely affected. This leads to large decreases in striatal GABA concentrations, whereas somatostatin and DA concentrations are relatively preserved. Significant loss of large pyramidal projection neurons in the deeper layers is also observed in the cortex.

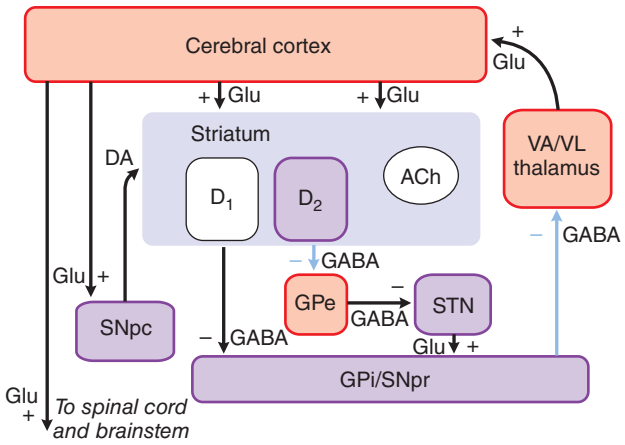

Figure 21–6 *The basal ganglia in Huntington's disease.* HD is characterized by loss of neurons from the striatum. The neurons that project from the striatum to the GPe and form the indirect pathway are affected earlier in the course of the disease than those that project to the GPi. This leads to a loss of inhibition of the GPe. The increased activity in this structure, in turn, inhibits the STN, SNpr, and GPi, resulting in a loss of inhibition to the VA/VL thalamus and increased thalamocortical excitatory drive. Structures in purple have reduced activity in HD, whereas structures in red have increased activity. Light blue lines indicate primary pathways of reduced activity. (See Abbreviations list for definitions of anatomical abbreviations.)

Selective vulnerability also appears to underlie the development of chorea. In most adult-onset cases, the medium spiny neurons that project to the GPi and SNpr (the indirect pathway) appear to be affected earlier than those projecting to the GPe (the direct pathway; see Figure 21–2). *The disproportionate impairment of the indirect pathway increases excitatory drive to the neocortex, producing involuntary choreiform movements* (Figure 21–6). In some individuals, rigidity rather than chorea is the predominant clinical feature; this is especially common in juvenile-onset cases. Here, the striatal neurons giving rise to both the direct and indirect pathways are impaired to a comparable degree.

Treatment

Symptomatic Treatment

None of the currently available medications slows the progression of the disease (Ross et al., 2014). Treatment is directed toward symptom management, particularly motor symptoms.

Tetrabenazine is used for the treatment of chorea associated with HD. *Tetrabenazine* and the related drug *reserpine* are inhibitors of VMAT2 and cause presynaptic depletion of catecholamines. *Tetrabenazine* is a reversible inhibitor; inhibition by *reserpine* is irreversible and may lead to long-lasting effects. Both drugs may cause hypotension and depression with suicidality; the shorter duration of effect of *tetrabenazine* simplifies clinical management. The recommended starting dose of *tetrabenazine* is 12.5 mg daily. Most patients can be managed with doses of 50 mg a day or less; however, *tetrabenazine* is extensively metabolized by CYP2D6. Genotyping for CYP2D6 may be needed to optimize therapy and is recommended for patients who require more than 50 mg daily. As might be expected with a drug that depletes DA stores, *tetrabenazine* can also cause parkinsonism. The recently approved deuterated tetrabenazine, *deutetrabenazine*, takes advantage of the stronger bonds that deuterium forms with carbon (the kinetic-isotope effect). The active deuterated dehydro-metabolites are VMAT2 inhibitors with longer half-lives than the corresponding products of *tetrabenazine* metabolism. *Deutetrabenazine* has therapeutic uses and an adverse effect profile similar to those of *tetrabenazine*, although *deutetrabenazine* may have a lower risk of depression.

Symptomatic treatment is needed for patients who are depressed, irritable, paranoid, excessively anxious, or psychotic. Depression can be treated effectively with standard antidepressant drugs with the caveat that drugs with substantial anticholinergic profiles can exacerbate chorea. SSRIs and selective serotonin and norepinephrine reuptake inhibitors (see Chapter 18) are effective treatments of depression and the irritability manifest in symptomatic HD. Paranoia, delusional states, and psychosis are treated with antipsychotic drugs, usually at lower doses than those used in primary psychiatric disorders (see Chapter 19). These agents also reduce cognitive function and impair mobility and thus should be used in the lowest doses possible and should be discontinued when the psychiatric symptoms resolve. In individuals with predominantly rigid HD, *clozapine, quetiapine* (see Chapter 19), or *carbamazepine* (see Chapter 20) may be more effective for the treatment of paranoia and psychosis. Acetylcholinesterase inhibitors have not been found to be effective for cognitive impairment in HD.

Many patients with HD exhibit worsening of involuntary movements as a result of anxiety or stress. In these situations, judicious use of sedative or anxiolytic benzodiazepines can be helpful. In juvenile-onset cases where rigidity rather than chorea predominates, DA agonists have had variable success in the improvement of rigidity. These individuals also occasionally develop myoclonus and seizures that can be responsive to *clonazepam*, *valproate*, and other anticonvulsants (see Chapter 20).

Encouraged by the success of genetic approaches for other neurogenetic disorders, such as spinal muscular atrophy, biomedical scientists are investigating genetic-based therapies for HD. Antisense oligonucleotides (ASO) to promote degradation of mutant and/or wild-type *HTT* RNA are in development in preclinical and clinical studies. A phase I/IIA clinical trial showed the safety of a non–allele-specific ASO and reduction of CSF huntingtin levels (Tabrizi et al., 2019). Other genetic approaches under investigation include RNA interference and splicing inhibitors.

Amyotrophic Lateral Sclerosis

Clinical Overview

Amyotrophic lateral sclerosis (ALS or Lou Gehrig disease) is a disorder of the motor neurons of the ventral horn of the spinal cord (lower motor neurons) and the cortical neurons that provide their afferent input (upper motor neurons). The disorder is characterized by rapidly progressive weakness, muscle atrophy and fasciculations, spasticity, dysarthria, dysphagia, and respiratory compromise. Many patients with ALS exhibit behavioral changes and cognitive dysfunction, and there is clinical, genetic, and neuropathological overlap between ALS and frontotemporal dementia spectrum disorders. ALS usually is progressive and fatal. Most patients die of respiratory compromise and pneumonia after 2 to 3 years, although some survive for many years.

Genetics and Pathophysiology

About 10% of ALS cases are familial (FALS), usually with an autosomal dominant pattern of inheritance. The most common genetic cause is a hexanucleotide repeat expansion in *C9ORF72*, which is responsible for up to 40% of FALS and around 5% of sporadic cases (Rohrer et al., 2015). Another 10% of FALS cases are due to mutations in the Cu/Zn *SOD1*. Mutations in the *TARDBP* gene encoding TDP-43 and in the *FUS/TLS* gene have been identified as causes of FALS. Both TDP-43 and FUS/TLS bind DNA and RNA and regulate transcription and alternative splicing. About 90% of ALS cases are sporadic. Of these, a few are caused by *de novo* mutations in *C9ORF72* (up to 7%), *SOD1*, *TDP-43*, *FUS/TLS*, or other genes, but for the majority of sporadic cases, the etiology remains unclear. The underlying pathophysiology remains under investigation, including roles for abnormal RNA processing, glutamate excitotoxicity, oxidative stress, and mitochondrial dysfunction (Mejzini et al., 2019).

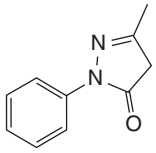
Treatment

Riluzole

Riluzole (2-amino-6-[trifluoromethoxy] benzothiazole) is an agent with complex actions in the nervous system. *Riluzole* is absorbed orally and is highly protein bound. It undergoes extensive metabolism in the liver by CYP-mediated hydroxylation and glucuronidation, with a $t_{1/2}$ of approximately 12 h. *In vitro* studies show that *riluzole* has both presynaptic and

postsynaptic effects; it inhibits glutamate release, blocks postsynaptic NMDA- and kainate-type glutamate receptors, and inhibits voltage-dependent Na^+ channels. The recommended dose is 50 mg twice daily, taken 1 h before or 2 h after a meal. *Riluzole* usually is well tolerated, although nausea or diarrhea may occur. Rarely, *riluzole* may produce hepatic injury with elevations of serum transaminases, and periodic monitoring of these is recommended. Meta-analyses of the available clinical trials indicated that *riluzole* extends survival by 2 to 3 months. Although the magnitude of the effect of *riluzole* on ALS is small, it represents a significant therapeutic milestone in the treatment of disease refractory to all previous treatments (Miller et al., 2012).

Edaravone



Edaravone

Edaravone was approved by the FDA in 2017 for the treatment of ALS, the first new drug approved for this indication since 1995. It is a small molecule with free radical scavenging properties that may reduce oxidative stress, although the exact mechanism of action is unknown. *Edaravone* has been used in Japan for acute stroke since 2001 and was FDA-approved for ALS under an orphan drug designation. A phase III study showed no benefit, but after *post hoc* subgroup analyses suggested an effect in early ALS, a subsequent trial enrolling only early-stage patients showed a smaller functional decline over 6 months in patients treated with *edaravone*. It is administered intravenously, with the first round daily for 14 days, followed by a 14-day holiday, then in subsequent cycles, 10 out of every 14 days followed by a 14-day holiday. The drug is metabolized to a glucuronide and a sulfate and excreted primarily in the urine as the glucuronide with a terminal $t_{1/2}$ of 4.5 to 6 h. At clinical doses, *edaravone* is not expected to inhibit major CYPs, UGTs, or drug transporters or to induce CYPs 1A2, 2B6, or 3A4; nor should inhibitors of these enzymes have substantial effects on the pharmacokinetics of *edaravone*. The infusion contains sodium bisulfite, which can cause hypersensitivity reactions. Other adverse effects include bruising, gait disorder, and headache.

Symptomatic Therapy of ALS: Spasticity

Spasticity is an important component of the clinical features of ALS and the feature most amenable to present forms of treatment. *Spasticity* is defined as an increase in muscle tone characterized by an initial resistance to passive movement of a joint, followed by a sudden relaxation (the so-called clasped-knife phenomenon). Spasticity results from loss of descending inputs to the spinal motor neurons, and the character of the spasticity depends on which nervous system pathways are affected. See further discussion of antispasticity agents in Chapter 13.

Baclofen. The best agent for the symptomatic treatment of spasticity in ALS is *baclofen*, a $GABA_B$ receptor agonist (see Figure 16–8). Initial doses of 5 to 10 mg/day are recommended, which can be increased to as much as 200 mg/day, if necessary. Alternatively, *baclofen* can be delivered directly into the space around the spinal cord using a surgically implanted pump and an intrathecal catheter. This approach minimizes the adverse effects of the drug, especially sedation, but it carries the risk of potentially life-threatening CNS depression.

Tizanidine. *Tizanidine* is an agonist of α_2 adrenergic receptors in the CNS. It reduces muscle spasticity, probably by increasing presynaptic inhibition of motor neurons. *Tizanidine* is primarily used in the treatment of spasticity in multiple sclerosis or after stroke, but it also may be effective in patients with ALS. Treatment should be initiated at a low dose of 2 to 4 mg at bedtime and titrated upward gradually. Drowsiness, asthenia, and dizziness may limit the dose that can be administered.

Other Agents. Benzodiazepines (see Chapter 22) such as *clonazepam* are effective antispasticity agents, but they may contribute to respiratory depression in patients with advanced ALS.

Dantrolene, approved in the U.S. for the treatment of muscle spasms, *is not used* in ALS because it can exacerbate muscular weakness. *Dantrolene* acts directly on skeletal muscle fibers, impairing Ca^{2+} release from the sarcoplasmic reticulum. It is effective in treating spasticity associated with stroke or spinal cord injury and in treating malignant hyperthermia (see Chapter 13). *Dantrolene* may cause hepatotoxicity, so it is important to monitor liver-associated enzymes before and during therapy with the drug.

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Anti-Parkinson: L-DOPA (DA precursor); Carbidopa (inhibits AADC, reduces the peripheral conversion of L-DOPA to DA)		
Carbidopa/levodopa	• Most effective symptomatic therapy for PD	• Therapeutic window narrows after several years of treatment: wearing off, dyskinesias, on/off phenomenon • Available as immediate-release tablets and orally disintegrated tablets (discontinued in the U.S.)
Carbidopa/levodopa sustained release	• Patients with PD with motor fluctuations on regular carbidopa/levodopa	• Bioavailability of immediate-release form, 75%
Carbidopa-levodopa extended-release capsules	• Patients with PD with motor fluctuations on regular carbidopa/levodopa	• Mixture of immediate- and extended-release beads
Carbidopa-levodopa intestinal gel	• Patients with PD with motor fluctuations on regular carbidopa/levodopa	• Requires placement of gastrostomy tube with jejunal extension • Useful for wearing-off issues
Levodopa inhalation formulation	• Patients with PD with motor fluctuations on regular carbidopa/levodopa	• Can be administered with carbidopa • Useful for wearing off
Anti-Parkinson: DA Agonists (longer acting than L-DOPA; can produce psychosis, impulse control disorder, sleepiness)		
Ropinirole	• PD • Restless legs syndrome	• Selective D2 receptor class agonist • Available in immediate release (3 times daily) and sustained release (once daily)
Pramipexole	• PD • Restless legs syndrome	• Selective D2 receptor class agonist • Available in immediate release (3 times daily) and sustained release (once daily)
Rotigotine	• PD • Restless legs syndrome	• D2 and D1 receptor class agonist • Transdermal formulation
Apomorphine	• Rescue therapy for acute intermittent treatment of off episodes	• Sublingual and subcutaneous formulations • Emetogenic, requires concurrent antiemetic • Sublingual form can cause oral pain and ulcers • Contraindicated with $5HT_3$ antagonists
Anti-Parkinson: COMT Inhibitors (reduce peripheral conversion of levodopa, increasing $t_{1/2}$ and CNS dose)		
Entacapone	• Adjunctive PD therapy given with each dose of levodopa, for wearing off	• Short $t_{1/2}$, inhibits peripheral COMT
Tolcapone	• Adjunctive PD therapy given with each dose of levodopa, for wearing off	• Long $t_{1/2}$, inhibits central and peripheral COMT • May be hepatotoxic; use only in patients not responding satisfactorily to other treatments; monitor liver function
Carbidopa/levodopa/entacapone	• PD, especially for wearing off on levodopa alone	• Fixed-dose combination formulation
Opicapone	• Adjunctive PD therapy for wearing off	• Once-a-day peripheral COMT inhibitor
Anti-Parkinson: MAO-B Inhibitors (reduce oxidative metabolism of dopamine in the CNS)		
Rasagiline	• PD, either as initial monotherapy or adjunct to levodopa	• Adjunct to reduce wearing off • Many drug interactions • Should not be given with meperidine • When administered with CYP1A2 inhibitors, C_p of rasagiline may double • Risk of serotonin syndrome
Selegiline	• PD, as adjunctive therapy in patients with deteriorating response to levodopa	• Generates amphetamine metabolites, which can cause anxiety and insomnia • MAO-B selectivity lost at doses >30–40 mg/day • Many drug interactions • Should not be given with meperidine • Risk of serotonin syndrome • Available in immediate-release, orally disintegrating tablet or transdermal patch
Safinamide	• PD, as adjunctive therapy to levodopa in patients with off periods	• Reversible MAO-B inhibition • Also has an effect on inhibiting glutamate release • Many drug interactions similar to rasagiline and selegiline • Risk of serotonin syndrome • Avoid in severe hepatic disease

Drug Facts for Your Personal Formulary: *Drugs for Neurodegenerative Disease (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Anti-Parkinson: Other		
Amantadine	• Early, mild PD • Levodopa-induced dyskinesias • Influenza	• Unclear mechanism of antiparkinsonian effects • Effective against dyskinesia • Available in immediate-release or long-acting formulation
Trihexyphenidyl	• PD, as adjunctive therapy	• Muscarinic receptor antagonist • Anticholinergic side effects
Benztropine	• PD, as adjunctive therapy	• Muscarinic receptor antagonist
Istradefylline	• Adjunctive treatment for off periods in PD	• Adenosine A_{2A} receptor antagonist • Side effects include hallucinations, nausea, and dizziness
Pimavanserin	• Treatment of delusions, hallucinations, and psychosis in PD	• Inverse serotonin $5HT2_A$ receptor agonist • QT interval monitoring required • Black-box label for increased rate of death in the elderly
Anti-Alzheimer: Acetylcholinesterase Inhibitors (boost cholinergic neurotransmission; first-line treatment)		
Donepezil	• Mild, moderate, severe AD dementia	• GI symptoms: main dose-limiting side effect • Bradycardia/syncope less common
Rivastigmine	• Mild-moderate AD dementia • Mild-moderate PD dementia	• Transdermal formulation available, with lower risk of GI side effects • Also inhibits BuChE
Galantamine	• Mild-moderate AD dementia	• GI symptoms: main dose-limiting side effect • Bradycardia/syncope less common than GI side effects
Anti-Alzheimer: Low-Affinity Uncompetitive NMDA Antagonist		
Memantine	• Moderate, severe AD dementia	• Reduces excitotoxicity through use-dependent blockade of NMDA receptors
Anti-Alzheimer: Amyloid Immunotherapy		
Aducanumab	• Reduces amyloid plaques; clinical efficacy uncertain	• Monthly intravenous infusion • Requires MRI monitoring for ARIA
Anti-Huntington		
Tetrabenazine Deutetrabenazine	• Chorea in HD	• Reversible VMAT2 inhibitor: depletes presynaptic catecholamines • Adverse effects: hypotension, depression with suicidality • Adjust dose for CYP2D6 status; 2D6 inhibitors (e.g., paroxetine, fluoxetine, quinidine, bupropion) ↑ exposure ~3-fold • Contraindications: concurrent or recent MAO inhibitor or reserpine
Anti-ALS		
Riluzole	• Extends survival in ALS up to 3 months	• Uncertain mechanism of action: inhibits glutamate release, blocks sodium channels and glutamate receptors
Edaravone	• Reduces progression in early stages of ALS	• Intensive intravenous administration regimen
Antispastic Agents		
Baclofen	• $GABA_B$ receptor agonist	• Sedation and CNS depression
Tizanidine	• α_2 Adrenergic receptor agonist	• Causes drowsiness; treatment is initiated with low dose and titrated upward
Benzodiazepines (e.g., clonazepam)	• See Chapter 22	• May contribute to respiratory depression
Dantrolene	• *Not used in ALS*, but for treating muscle spasm in stroke or spinal injury and for treating malignant hyperthermia	• May cause hepatotoxicity

Chapter 22

Hypnotics and Sedatives

S. John Mihic and Jody Mayfield

A *sedative* drug decreases activity, moderates excitement, and calms the recipient, whereas a *hypnotic* drug produces drowsiness and facilitates the onset and maintenance of a state of sleep that resembles natural sleep in its electroencephalographic characteristics and from which the recipient can be aroused easily. Sedation is a side effect of many drugs that are not considered general CNS depressants (e.g., antihistamines and antipsychotic agents). Although these and other agents can augment the effects of CNS depressants, they usually produce their desired therapeutic effects at concentrations lower than those causing substantial CNS depression. For example, benzodiazepine sedative-hypnotics do not produce generalized CNS depression. Although coma may occur at very high doses, neither surgical anesthesia nor fatal intoxication is produced by benzodiazepines unless other drugs with CNS depressant actions are concomitantly administered; an important exception is *midazolam*, which has been associated with decreased tidal volume and respiratory rate. Moreover, specific antagonists of benzodiazepines exist, such as *flumazenil*, which is used to treat cases of benzodiazepine overdose. This constellation of properties sets the benzodiazepine receptor agonists apart from other sedative-hypnotic drugs and imparts a measure of safety, such that benzodiazepines and the newer benzodiazepine receptor agonists (the "Z compounds") have largely displaced older agents for the treatment of insomnia and anxiety.

The CNS depressants discussed in this chapter include benzodiazepines, the Z compounds (e.g., *zolpidem* and *zaleplon*), barbiturates, and several sedative-hypnotic agents of diverse chemical structure. Many of the sedative-hypnotic drugs that do not specifically target the benzodiazepine receptor belong to a group of older, less-safe, sedative-hypnotic drugs that depress CNS function in a dose-dependent fashion, progressively producing a spectrum of responses from mild sedation to coma and death. These older sedative-hypnotic compounds share these properties with a large number of chemicals, including general anesthetics (see Chapter 21) and alcohols, most notably ethanol (see Chapter 27). The newer sedative-hypnotic agents, such as benzodiazepines and Z drugs, are safer in this regard.

HISTORICAL PERSPECTIVE

Humans have long sought sleep unburdened by worry and, to this end, have consumed many potions. In the mid-19th century, bromide was introduced specifically as a sedative-hypnotic. Chloral hydrate, paraldehyde, urethane, and sulfonal were used before the introduction of barbiturates (*barbital*, 1903; *phenobarbital*, 1912), of which about 50 were distributed commercially. Barbiturates attained such a high market share that fewer than a dozen other sedative-hypnotics were marketed successfully before 1960.

The partial separation of sedative-hypnotic-anesthetic properties from anticonvulsant properties characteristic of *phenobarbital* led to searches for agents with more selective effects on CNS functions. As a result, relatively nonsedating anticonvulsants, notably *phenytoin* and *trimethadione*, were developed in the late 1930s and early 1940s (see Chapter 20). The advent of *chlorpromazine* and *meprobamate* in the early 1950s, with their taming effects in animals, and the development of increasingly sophisticated methods for evaluating the behavioral effects of drugs, set the stage in the 1950s for the synthesis of *chlordiazepoxide*. Its introduction into clinical medicine in 1961 ushered in the era of benzodiazepines. Most benzodiazepines in the marketplace were selected for high anxiolytic potency relative to their depression of CNS function. However, all benzodiazepines possess sedative-hypnotic properties to varying degrees, which are exploited extensively clinically, especially to facilitate sleep. Mainly because of their remarkably low capacity to produce fatal CNS depression (i.e., high therapeutic indices), the benzodiazepines replaced barbiturates as the sedative-hypnotic agents of choice.

Abbreviations

ACh: acetylcholine
ALA: δ-aminolevulinic acid
AMPA: α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
COPD: chronic obstructive pulmonary disease
CYP: cytochrome P450
EEG: electroencephalogram
GABA: γ-aminobutyric acid
GI: gastrointestinal
GPCR: G protein-coupled receptor
MT: melatonin
OSA: obstructive sleep apnea
REM: rapid eye movement
SSRI: selective serotonin reuptake inhibitor

Benzodiazepines

All benzodiazepines in clinical use promote the binding of the major inhibitory neurotransmitter GABA to the $GABA_A$ receptor, a pentameric ligand-gated, anion-conducting channel (see Figures 16–5A and 16–11). Considerable heterogeneity exists among human $GABA_A$ receptors; this heterogeneity is thought to contribute to the myriad effects of these agents *in vivo*. Because receptor subunit composition governs the interactions of various allosteric modulators with these channels, considerable effort has been expended to find agents displaying selective actions on one or more subtypes of $GABA_A$ receptors. A number of distinct mechanisms of action, reflecting involvement of specific subunits of the $GABA_A$ receptor, likely contribute to distinct effects of various benzodiazepines—the sedative-hypnotic, muscle-relaxant, anxiolytic, amnesic, and anticonvulsant effects.

Although the benzodiazepines exert qualitatively similar clinical effects, quantitative differences in their pharmacodynamic spectra and pharmacokinetic properties have led to varying patterns of therapeutic application. While only the benzodiazepines used primarily for hypnosis are discussed in detail, this chapter describes the general properties of the group and important differences among individual agents (Figure 22–1) (see also Chapters 18 and 20).

The Molecular Target for Benzodiazepines

Benzodiazepines act at $GABA_A$ receptors by binding directly to a specific site that is distinct from the GABA binding site (see Figure 16–11).

The $GABA_A$ Receptor

The $GABA_A$ receptor is the major inhibitory receptor in the CNS. It is a transmembrane protein composed of five subunits that co-assemble around a central anion-conducting channel. Each subunit is composed of a large extracellular amino terminal domain, a transmembrane domain consisting of four transmembrane segments (M1–M4), an intracellular domain consisting of amino acids connecting M3 and M4, and a short carboxy terminus. The M2 segment of each subunit contributes to the formation of the central anion-conducting pore. GABA binds at the interfaces of α and β classes of subunits, while benzodiazepines bind at α/γ interfaces. The five subunits come from 19 isoforms, so the number of possible pentameric combinations is large. The number of pentamers actually expressed in nature is uncertain but likely numbers in the dozens. The $GABA_A$ receptor is a member of the cys-loop receptor superfamily, including also glycine, serotonin-3 ($5HT_3$), nicotinic acetylcholine (ACh) receptors, and the ACh binding protein.

The $GABA_A$ receptor pentamer contains a single benzodiazepine binding site, as well as other allosteric sites at which a variety of sedative-hypnotic-anesthetic agents exert modulatory effects on $GABA_A$ receptor function (see Chapter 16). The exact functional properties of the pentameric receptor depend on the subunit composition and arrangement of the individual subunits, and this heterogeneity likely contributes to the pharmacological diversity of benzodiazepine effects observed in behavioral, biochemical, and functional studies and to the selective effects of the Z compounds.

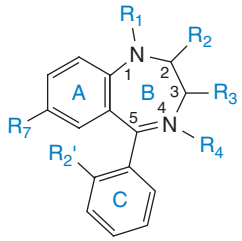

Figure 22–1 *Basic structure of benzodiazepines. Benzodiazepine* refers to the portion of this structure comprising the benzene ring (A) fused to a seven-member diazepine ring (B). Because all the important benzodiazepines contain a 5-aryl substituent (ring C) and a 1,4-diazepine ring, the term has come to mean the 5-aryl-1,4-benzodiazepines. Numerous modifications in the structure of the ring systems and substituents have yielded compounds with similar activities, including the benzodiazepine receptor antagonist *flumazenil*, in which ring C is replaced with a keto function at position 5 and a methyl substituent is added at position 4. A number of nonbenzodiazepine compounds (e.g., β-carbolines, *zolpidem*, *eszopiclone*) plus classic benzodiazepines and *flumazenil* bind to the benzodiazepine receptor, an allosteric site on the ionotropic $GABA_A$ receptor, a pentameric structure that forms a GABA-stimulated Cl^- channel.

Effects of Benzodiazepines on $GABA_A$ Receptor–Mediated Events

Benzodiazepines are allosteric modulators of $GABA_A$ receptor function (Sieghart, 2015). They increase the affinity of the $GABA_A$ receptor for GABA and thereby enhance GABA-induced Cl^- currents. Thus, in terms of channel kinetics, benzodiazepines increase the frequency of opening of the $GABA_A$ receptor Cl^- channel in the presence of GABA (Nestler et al., 2020; Sigel and Steinmann, 2012). Inverse agonists at the benzodiazepine binding site do just the opposite, reducing both GABA binding and the frequency of channel opening. Benzodiazepine antagonists (e.g., *flumazenil*) competitively block benzodiazepine agonist and inverse agonist binding and effect, but do not on their own affect responses elicited by agents that bind at the GABA binding site (Nestler et al., 2020; Sigel and Steinmann, 2012).

In pharmacodynamic terms, agonists at the benzodiazepine binding site shift the GABA concentration-response curve to the left, whereas benzodiazepine inverse agonists shift the curve to the right. Both these effects are blocked by antagonists (e.g., *flumazenil*) that bind at the benzodiazepine binding site. Application of a benzodiazepine site antagonist, in the absence of either an agonist or antagonist at this same site, has no effect on the GABA concentration-response curve. The behavioral and electrophysiological effects of benzodiazepines can also be reduced or prevented by prior treatment with antagonists at the GABA binding site (e.g., *bicuculline*). The remarkable safety profile of the benzodiazepines likely relates to the fact that their effects *in vivo* depend on the presynaptic release of GABA; applied in the absence of GABA, benzodiazepines do not directly activate $GABA_A$ receptors. In other words, benzodiazepines act exclusively as modulators of $GABA_A$ receptor function.

The behavioral and sedative effects of benzodiazepines can be ascribed in part to potentiation of GABAergic pathways that regulate the firing of monoamine-containing neurons known to promote behavioral arousal and mediation of the inhibitory effects of fear and punishment on behavior. Inhibitory effects on muscular hypertonia or the spread of seizure activity can be attributed to potentiation of inhibitory GABAergic circuits at various levels of the neuraxis. The magnitude of the effects produced by benzodiazepines varies widely, depending on such factors as the types of inhibitory circuits that are operating, the sources and intensity of

excitatory input, and the manner in which experimental manipulations are performed and assessed. Accordingly, benzodiazepines markedly prolong the period after brief activation of recurrent GABAergic pathways during which neither spontaneous nor applied excitatory stimuli can evoke neuronal discharge; this effect is reversed by the $GABA_A$ receptor antagonist *bicuculline* (see Figure 16–8).

Benzodiazepines Versus Barbiturates at the $GABA_A$ Receptor

The two classes of agents, barbiturates and benzodiazepines, differ markedly in their potencies. Barbiturates act to enhance $GABA_A$ receptor function at low micromolar concentrations, while benzodiazepines are considerably more potent, binding with nanomolar affinity. Both benzodiazepines and barbiturates bind to allosteric sites on the $GABA_A$ receptor pentamer and thereby enhance GABA-stimulated Cl^- channel function. However, barbiturates also have an additional effect: Higher concentrations of barbiturates directly activate $GABA_A$ receptors. Furthermore, when tested using equieffective concentrations of GABA, maximally effective concentrations of barbiturates produce several times greater enhancement of $GABA_A$ receptor function than maximally effective concentrations of benzodiazepines. These two phenomena almost certainly contribute to the profound and sometimes lethal CNS depression that barbiturates can cause. The lack of direct channel activation by benzodiazepines, their dependence on the presynaptic release of GABA at the $GABA_A$ receptor, and their limited abilities to enhance $GABA_A$ receptor function likely contribute to the safety of these agents as compared to barbiturates.

Pharmacological Properties of Benzodiazepines

The therapeutic effects of the benzodiazepines result from their actions on the CNS. The most prominent of these effects are sedation, hypnosis, decreased anxiety, muscle relaxation, anterograde amnesia, and anticonvulsant activity. Only two effects of these drugs result from peripheral actions: coronary vasodilation, seen after intravenous administration of therapeutic doses of certain benzodiazepines, and neuromuscular blockade, seen only with very high doses.

CNS Effects

While benzodiazepines depress activity at all levels of the neuraxis, some structures are affected differentially. All benzodiazepines have similar pharmacological profiles. Nevertheless, the drugs do differ in their pharmacokinetic and pharmacodynamic properties, and the clinical usefulness of individual benzodiazepines thus varies considerably. As the dose of a benzodiazepine is increased, sedation progresses to hypnosis and then to stupor. Although the clinical literature often refers to the "anesthetic" effects and uses of certain benzodiazepines, these drugs do not cause a true general anesthesia; awareness usually persists, and a failure to respond to a noxious stimulus sufficient to allow surgery cannot be achieved. Nonetheless, at "preanesthetic" doses, there is amnesia for events occurring subsequent to administration of the drug. Although many attempts have been made to separate the anxiolytic actions of benzodiazepines from their sedative-hypnotic effects, distinguishing between these behaviors is problematic. Accurate measurements of anxiety and sedation are difficult in humans, and the validity of animal models for measuring anxiety and sedation is uncertain.

Although analgesic effects of benzodiazepines have been observed in experimental animals, only transient analgesia is apparent in humans after intravenous administration. Such effects actually may involve the production of amnesia. Unlike barbiturates, benzodiazepines do not cause hyperalgesia.

Tolerance. Although most patients who chronically ingest benzodiazepines report that drowsiness wanes over a few days, tolerance to the impairment seen in some measures of psychomotor performance (e.g., visual tracking) is not usually observed. Whether tolerance develops to the anxiolytic effects of benzodiazepines remains debatable. Many patients use a fairly constant maintenance dose; increases or decreases in dosage appear to correspond with changes in their perceived problems or stresses. Conversely, other patients either do not reduce their dosages when stress is relieved or steadily escalate dosing. Such behavior may be associated with the development of drug dependence (see Chapter 28).

Some benzodiazepines induce muscle hypotonia without interfering with normal locomotion and can decrease rigidity in patients with cerebral palsy. *Clonazepam* in nonsedating doses causes muscle relaxation, but *diazepam* and most other benzodiazepines do not. Tolerance occurs to the muscle relaxant and ataxic effects of these drugs.

Experimentally, benzodiazepines inhibit seizure activity induced by either *pentylenetetrazol* or *picrotoxin* but suppress *strychnine*- and maximal electroshock–induced seizures only at doses that also severely impair locomotor activity. *Clonazepam, nitrazepam*, and *nordazepam* have greater selective anticonvulsant activity than do most other benzodiazepines. Benzodiazepines also suppress photic seizures in baboons and ethanol withdrawal seizures in humans. However, the development of tolerance to the anticonvulsant effects has limited the usefulness of benzodiazepines in the treatment of recurrent seizure disorders in humans (see Chapter 20).

Effects on the Electroencephalogram and Sleep Stages. The effects of benzodiazepines on the waking electroencephalogram (EEG) resemble those of other sedative-hypnotic drugs. Alpha rhythm activity is decreased, but there is an increase in low-voltage fast activity. Tolerance also occurs to these effects. With respect to sleep, some differences in the patterns of effects exerted by the various benzodiazepines have been noted, but benzodiazepine users usually report a sense of deep or refreshing sleep. Benzodiazepines decrease sleep latency, especially when first used, and diminish the number of awakenings and the time spent in stage 0 (a stage of wakefulness). They also produce an increased arousal threshold from sleep. Time in stage 1 (descending drowsiness) usually is decreased, and there is a prominent decrease in the time spent in slow-wave sleep (stages 3 and 4). Most benzodiazepines increase the latency from onset of spindle sleep to the first burst of rapid eye movement (REM) sleep. The time spent in REM sleep is usually shortened, but the number of cycles of REM sleep is typically increased, mostly late in the sleep time. *Zolpidem* and *zaleplon* suppress REM sleep less extensively than benzodiazepines and thus may be superior to benzodiazepines for use as hypnotics (Dujardin et al., 1998).

Despite the shortening of durations of stage 4 and REM sleep, benzodiazepine administration typically increases total sleep time, largely by increasing the time spent in stage 2, which is the major fraction of non-REM sleep. This effect is greatest in subjects with the shortest baseline total sleep time. In addition, despite the increased number of REM cycles, the number of shifts to lighter sleep stages (1 and 0) and the amount of body movement are diminished with benzodiazepine use. Nocturnal peaks in the secretion of growth hormone, prolactin, and luteinizing hormone are not affected. During chronic nocturnal use of benzodiazepines, the effects on the various stages of sleep usually decline within a few nights. When such use is discontinued, the pattern of drug-induced changes in sleep parameters may "rebound," and an increase in the amount and density of REM sleep may be especially prominent. If the dosage has not been excessive, patients usually will note only a shortening of sleep time rather than an exacerbation of insomnia.

Systemic Effects

Respiration. Hypnotic doses of benzodiazepines are without effect on respiration in normal subjects, but special care must be taken in the treatment of children and individuals with impaired hepatic or pulmonary function. At higher doses, such as those used for preanesthetic medication or for endoscopy, benzodiazepines slightly depress alveolar ventilation and cause respiratory acidosis as the result of a decrease in hypoxic rather than hypercapnic drive; these effects are exaggerated in patients with chronic obstructive pulmonary disease (COPD), and alveolar hypoxia, and CO_2 narcosis may result. These drugs can cause apnea during anesthesia or when given with opioids. Patients severely intoxicated with benzodiazepines require respiratory assistance only when they also have ingested another CNS depressant drug, most commonly ethanol.

Hypnotic doses of benzodiazepines may worsen sleep-related breathing disorders by adversely affecting control of the upper airway muscles or by decreasing the ventilatory response to CO_2. The latter effect may cause hypoventilation and hypoxemia in some patients with severe COPD. In patients with obstructive sleep apnea (OSA), hypnotic doses of benzodiazepines may decrease muscle tone in the upper airway and exaggerate the impact of apneic episodes on alveolar hypoxia, pulmonary hypertension, and cardiac ventricular load. Benzodiazepines may promote the appearance of episodes of apnea during REM sleep (associated with decreases in O_2 saturation) in patients recovering from a myocardial infarction; however, no impact of these drugs on survival of patients with cardiac disease has been reported.

Cardiovascular System. The cardiovascular effects of benzodiazepines are minor in normal subjects except in cases of severe intoxication (see previous discussion for adverse effects in patients with obstructive sleep disorders or cardiac disease). At preanesthetic doses, all benzodiazepines decrease blood pressure and increase heart rate. With *midazolam*, the effects appear to be secondary to a decrease in peripheral resistance; however, with *diazepam*, the effects are secondary to a decrease in left ventricular work and cardiac output. *Diazepam* increases coronary flow, possibly by an action to increase interstitial concentrations of adenosine, and the accumulation of this cardiodepressant metabolite also may explain the negative inotropic effects of the drug. In large doses, *midazolam* considerably decreases cerebral blood flow and O_2 assimilation.

Gastrointestinal (GI) Tract. Benzodiazepines are thought by some gastroenterologists to improve a variety of "anxiety-related" GI disorders. There is a paucity of evidence for direct actions. Although *diazepam* markedly decreases nocturnal gastric secretion in humans, other drug classes are considerably more effective in acid-peptic disorders (see Chapter 53).

ADME

All benzodiazepines are absorbed completely except *clorazepate*. *Clorazepate* is decarboxylated rapidly in gastric juice to *N*-desmethyldiazepam (nordazepam), which subsequently is absorbed completely. Drugs active at the benzodiazepine receptor may be divided into four categories based on their elimination $t_{1/2}$:

- Ultra-short-acting benzodiazepines
- Short-acting agents ($t_{1/2}$ <6 h), including *midazolam*, *triazolam*, *remimazolam*, the nonbenzodiazepine *zolpidem* ($t_{1/2}$ ~2 h), and *eszopiclone* ($t_{1/2}$, 5–6 h)
- Intermediate-acting agents ($t_{1/2}$, 6–24 h), including *estazolam* and *temazepam*
- Long-acting agents ($t_{1/2}$ >24 h), including *flurazepam*, *diazepam*, and *quazepam*

Flurazepam itself has a short $t_{1/2}$ (~2.3 h), but a major active metabolite, *N*-des-alkyl-flurazepam, is long-lived ($t_{1/2}$, 47–100 h); such features complicate the classification of certain benzodiazepines.

The benzodiazepines and their active metabolites bind to plasma proteins. The extent of binding correlates strongly with the oil:water partition coefficient and ranges from about 70% for *alprazolam* to nearly 99% for *diazepam*. The concentrations of these agents in the cerebrospinal fluid approximate the concentrations of free drugs in plasma. Uptake of benzodiazepines occurs rapidly into the brain and other highly perfused organs after intravenous administration (or oral administration of a rapidly absorbed compound); rapid uptake is followed by a phase of redistribution into tissues that are less well perfused but capacious, especially muscle and fat (see Table 2–2 and Figure 2–4). Redistribution is most rapid for benzodiazepines with the highest oil:water partition coefficients. The kinetics of redistribution of *diazepam* and other lipophilic benzodiazepines are complicated by enterohepatic circulation. These drugs cross the placental barrier and are also secreted into breast milk.

Most benzodiazepines are metabolized extensively by hepatic cytochrome P450 enzymes (CYPs), particularly CYPs 3A4 and 2C19. Some benzodiazepines, such as *oxazepam*, are not metabolized by CYPs but are conjugated directly by phase 2 enzymes. *Erythromycin, clarithromycin, ritonavir, itraconazole, ketoconazole, nefazodone*, and grapefruit juice are examples of CYP3A4 inhibitors (see Chapter 5) that can affect the rate of metabolism of benzodiazepines. Benzodiazepines do not significantly induce hepatic CYPs, so their chronic administration does not usually affect metabolism of benzodiazepines or other drugs. *Cimetidine* and oral contraceptives inhibit *N*-dealkylation and 3-hydroxylation of benzodiazepines. Ethanol, *isoniazid*, and *phenytoin* are less effective in this regard. These phase 1 reactions usually are reduced to a greater extent in elderly patients and in patients with chronic liver disease than are those reactions involving conjugation.

The active metabolites of some benzodiazepines are biotransformed more slowly than are the parent compounds; thus, the durations of action of many benzodiazepines bear little relationship to the $t_{1/2}$ of elimination of the parent drug. Conversely, the rate of biotransformation of drugs that are inactivated by the initial metabolic reaction is an important determinant of their durations of action; examples include *oxazepam*, *lorazepam*, *temazepam*, *triazolam*, and *midazolam*.

Benzodiazepine metabolism can seem daunting but can be organized around a few basic principles. Metabolism of the benzodiazepines occurs in three major stages. These stages and the relationships between the drugs and their metabolites are shown in Table 22–1.

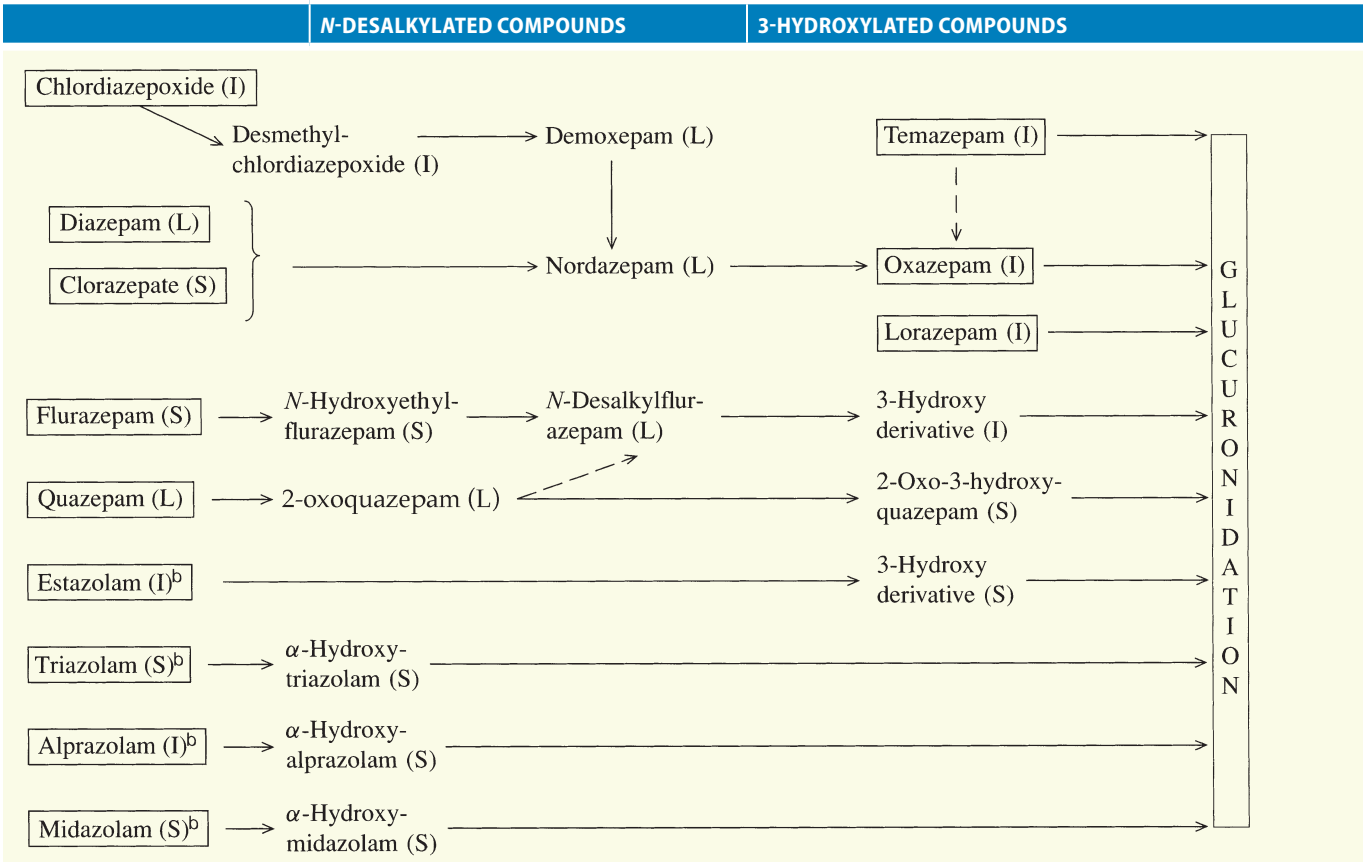
For benzodiazepines that bear a substituent at position 1 (or 2) of the diazepine ring, the *first phase* of metabolism involves modification or removal of the substituent. The eventual products are *N*-desalkylated compounds that are biologically active. Exceptions are *triazolam*, *alprazolam*, *estazolam*, and *midazolam*, which contain either a fused triazolo or an imidazolo ring and are α-hydroxylated.

The *second phase* of metabolism involves hydroxylation at position 3 and also usually yields an active derivative (e.g., *oxazepam* from *nordazepam*). The rates of these reactions are usually much slower than the first stage ($t_{1/2}$ >40–50 h), such that appreciable accumulation of hydroxylated products with intact substituents at position 1 does not occur. There are two significant exceptions to this rule: First, small amounts of temazepine accumulate during the chronic administration of *diazepam*; and second, following the replacement of S with O in *quazepam*, most of the resulting 2-oxoquazepam is hydroxylated slowly at position 3 without removal of the *N*-alkyl group. However, only small amounts of the 3-hydroxyl derivative accumulate during chronic administration of *quazepam* because this compound is conjugated at an unusually rapid rate. In contrast, the *N*-desalkylflurazepam that is formed by the "minor" metabolic pathway does accumulate during *quazepam* administration, and it contributes significantly to the overall clinical effect.

The *third major phase* of metabolism is the conjugation of the 3-hydroxyl compounds, principally with glucuronic acid; the $t_{1/2}$ values of these reactions usually are about 6 to 12 h, and the products invariably are inactive. Conjugation is the only major route of metabolism for *oxazepam* and *lorazepam* and is the preferred pathway for *temazepam* because of the slower conversion of this compound to *oxazepam*. *Triazolam* and *alprazolam* are metabolized principally by initial hydroxylation of the methyl group on the fused triazolo ring; the absence of a chlorine residue in ring C of *alprazolam* slows this reaction significantly. The products, sometimes referred to as *α-hydroxylated compounds,* are quite active but are metabolized rapidly, primarily by conjugation with glucuronic acid, such that there is no appreciable accumulation of active metabolites. The fused triazolo ring in *estazolam* lacks a methyl group and is hydroxylated to only a limited extent; the major route of metabolism involves the formation of the 3-hydroxyl derivative. The corresponding hydroxyl derivatives of *triazolam* and *alprazolam* also are formed to a significant extent. Compared with compounds without the triazolo ring, the rate of this reaction for all three drugs is unusually swift, and the 3-hydroxyl compounds are rapidly conjugated or oxidized further to benzophenone derivatives before excretion.

Midazolam is metabolized rapidly, primarily by hydroxylation of the methyl group on the fused imidazo ring; only small amounts of 3-hydroxyl compounds are formed. The α-hydroxylated compound, which has appreciable biological activity, is eliminated with a $t_{1/2}$ of 1 h

TABLE 22–1 ■ METABOLIC STAGES AND RELATIONSHIPS AMONG SOME OF THE BENZODIAZEPINES[a]



[a]Compounds enclosed in boxes are marketed in the U.S. The approximate half-lives of the various compounds are denoted in parentheses; S (short-acting), $t_{1/2}$ <6 h; I (intermediate-acting), $t_{1/2}$ = 6–24 h; L (long-acting), $t_{1/2}$ = >24 h. All compounds except clorazepate are biologically active; the activity of 3-hydroxydesalkylflurazepam has not been determined. Clonazepam (not shown) is an *N*-desalkyl compound, and it is metabolized primarily by reduction of the 7-NO_2 group to the corresponding amine (inactive), followed by acetylation; its $t_{1/2}$ is 20–40 h.
[b]See text for discussion of other pathways of metabolism.

after conjugation with glucuronic acid. Variable and sometimes substantial accumulation of this metabolite has been noted during intravenous infusion (Oldenhof et al., 1988).

The aromatic rings (A and C) of the benzodiazepines are hydroxylated only to a small extent. The only important metabolism at these sites is reduction of the 7-nitro substituents of *clonazepam*, *nitrazepam*, and *flunitrazepam*; the $t_{1/2}$ of these reactions are usually 20 to 40 h. The resulting amines are inactive and are acetylated to varying degrees before excretion.

Therapeutic Uses

Table 22–2 summarizes the therapeutic uses and routes of administration of benzodiazepines that are marketed in the U.S. Most benzodiazepines can be used interchangeably. For example, *diazepam* can be used to treat alcohol withdrawal symptoms, and most benzodiazepines work as hypnotics. Benzodiazepines that are useful as anticonvulsants have a long $t_{1/2}$, and rapid entry into the brain is required for efficacy in treatment of status epilepticus. Antianxiety agents, in contrast, should have a long $t_{1/2}$ despite the drawback of the risk of neuropsychological deficits caused by drug accumulation. For a hypnotic sleep medication, ideally there is a rapid onset of action when taken at bedtime, a sufficiently sustained action to maintain sleep throughout the night, and no residual action by the following morning. In practice, there are some disadvantages to the use of agents that have a relatively rapid rate of disappearance, such as *triazolam*, including the early morning insomnia experienced by some patients and a greater likelihood of rebound insomnia on drug discontinuation. With careful selection of dosage, *flurazepam* and other benzodiazepines with lower rates of elimination than *triazolam*'s can be used effectively.

Remimazolam is a benzodiazepine granted FDA approval in 2020 for the induction and maintenance of sedation during surgical procedures lasting 30 min or less. It has advantages over *midazolam*, another short-acting agent, possessing a faster onset and shorter duration of action; this shorter duration of action is due to rapid metabolism, yielding quicker patient recovery. Like other benzodiazepines, the effects of *remimazolam* can be reversed by *flumazenil*. Possible adverse reactions include hypoxia, diastolic hypotension, or diastolic or systolic hypertension.

Untoward Effects

At peak concentrations in plasma, hypnotic doses of benzodiazepines cause varying degrees of light-headedness, lassitude, increased reaction time, motor incoordination, impairment of mental and motor functions, confusion, and anterograde amnesia. Cognition appears to be affected less than motor performance. *All of these effects can greatly impair driving and other psychomotor skills, especially if combined with ethanol.* When the drug is given at the intended time of sleep, persistence of these effects into the following waking hours is adverse. These dose-related residual effects can be insidious because most subjects underestimate the degree of their impairment. Residual daytime sleepiness also may occur, even though successful drug therapy can reduce the daytime sleepiness resulting from chronic insomnia. The intensity and incidence of CNS toxicity generally increase with age (Monane, 1992). Other common side effects of benzodiazepines are weakness, headache, blurred vision, vertigo, nausea and vomiting, epigastric distress, and diarrhea; joint pains, chest pains, and incontinence are much rarer. Anticonvulsant benzodiazepines sometimes increase the frequency of seizures in patients with epilepsy.

TABLE 22–2 ■ THERAPEUTIC USES OF BENZODIAZEPINES

COMPOUND	ROUTES OF ADMINISTRATION	THERAPEUTIC USES[a]	COMMENTS	$t_{1/2}$ (h)[b]	USUAL SEDATIVE-HYPNOTIC DOSE, mg[c]
Alprazolam	Oral	Anxiety disorders, agoraphobia (OL)	Withdrawal symptoms may be especially severe	12 ± 2	—
Chlordiazepoxide	Oral, IM, IV	Anxiety disorders, management of alcohol withdrawal, preanesthetic medication (OL)	Long-acting and self-tapering because of active metabolites	10 ± 3.4	50–100, 1–4× daily[d] (once daily for sleep)
Clobazam	Oral	Adjunctive treatment of seizures associated with Lennox-Gastaut syndrome (U.S. approved use), other types of epilepsies, anxiety disorders	Active metabolite $t_{1/2}$ 71–82 h; tolerance develops to anticonvulsant effects; not recommended in patients with severe hepatic impairment; decrease dose and titrate in CYP2C19-poor metabolizers	36–42	—
Clonazepam	Oral	Seizure disorders, panic disorder, adjunctive treatment in acute mania and certain movement disorders (OL)	Tolerance develops to anticonvulsant effects	23 ± 5	0.25–0.5 (hypnotic)
Clorazepate	Oral	Anxiety disorders, seizure disorders, management of alcohol withdrawal	Prodrug; activity due to formation of nordazepam during absorption	2.0 ± 0.9	3.75–20, 2–4× daily[d]
Diazepam	Oral, IM, IV, rectal	Anxiety disorders, alcohol withdrawal, status epilepticus, skeletal muscle relaxation, preanesthetic medication, Ménière disease (OL)	Prototypical benzodiazepine	43 ± 13	5–10, every 4 h
Estazolam	Oral	Insomnia	Contains triazolo ring; adverse effects may be similar to those of triazolam	10–24	1–2
Flurazepam	Oral	Insomnia	Active metabolites accumulate with chronic use	74 ± 24	15–30
Lorazepam	Oral, IM, IV	Anxiety disorders, alcohol withdrawal, preanesthetic medication, seizure disorders	Metabolized solely by conjugation	14 ± 5	1–4
Midazolam	Oral, IV, IM	Preanesthetic and intraoperative medication, anxiety disorders (agitation, alcohol withdrawal, seizure disorders, OL)	Rapidly inactivated	1.9 ± 0.6	1–5[e]
Oxazepam	Oral	Anxiety disorders, alcohol withdrawal	Metabolized solely by conjugation	8.0 ± 2.4	15–30, 3–4× daily[d]
Quazepam	Oral	Insomnia	Active metabolites accumulate with chronic use	39	7.5–15
Remimazolam	IV	Used as a sedative during medical procedures lasting 30 min or less	Very rapidly inactivated	0.6-0.9	5
Temazepam	Oral	Insomnia	Metabolized mainly by conjugation	11 ± 6	7.5–30
Triazolam	Oral	Insomnia	Rapidly inactivated; may cause disturbing daytime side effects	2.9 ± 1.0	0.125–0.5

OL, off-label.

[a]The therapeutic uses are examples to emphasize that most benzodiazepines can be used interchangeably. In general, the therapeutic uses of a given benzodiazepine are related to its $t_{1/2}$ and may not match the marketed indications. The issue is addressed more extensively in the text.

[b]Half-life of active metabolite may differ. See Appendix II for additional information.

[c]For additional dosage information, see Chapter 24 (anesthesia), Chapter 18 (anxiety), and Chapter 20 (seizure disorders).

[d]Approved as a sedative-hypnotic only for management of alcohol withdrawal; doses in a nontolerant individual would be smaller.

[e]Recommended doses vary considerably depending on specific use, condition of patient, and concomitant administration of other drugs.

A wide variety of serious allergic, hepatotoxic, and hematologic reactions to the benzodiazepines may occur, but the incidence is low; these reactions have been associated with the use of *flurazepam*, *triazolam*, and *temazepam*. Large doses taken just before or during labor may cause hypothermia, hypotonia, and mild respiratory depression in the neonate. Abuse by the pregnant mother can result in a withdrawal syndrome in the newborn.

Adverse Psychological Effects

Benzodiazepines may at times cause paradoxical effects. *Flurazepam* occasionally increases the incidence of nightmares—especially during the first week of use—and sometimes causes garrulousness, anxiety, irritability, tachycardia, and sweating. Amnesia, euphoria, restlessness, hallucinations, sleepwalking, sleep-talking, other complex behaviors, and hypomanic behavior have been reported to occur during use of various benzodiazepines. Bizarre uninhibited behavior may occur in some users, hostility and rage in others; collectively, these are sometimes referred to as *disinhibition* or *dyscontrol reactions*. Paranoia, depression, and suicidal ideation also occasionally may accompany the use of these agents. Such paradoxical or disinhibition reactions are rare and appear to be dose related. Because of reports of an increased incidence of confusion and abnormal behaviors, *triazolam* has been banned in the U.K. The FDA has declared *triazolam* to be safe and effective in low doses of 0.125 to 0.25 mg.

Chronic benzodiazepine use poses a risk for development of dependence and abuse (Woods et al., 1992). Mild dependence may develop in many patients who have taken therapeutic doses of benzodiazepines on a regular basis for prolonged periods, but not to the same extent as seen with older sedatives and other recognized drugs of abuse (see Chapter 28; Uhlenhuth et al., 1999). Withdrawal symptoms may include temporary intensification of the problems that originally prompted their use (e.g., insomnia or anxiety). Dysphoria, irritability, sweating, unpleasant dreams, tremors, anorexia, and faintness or dizziness also may occur, especially when withdrawal of the benzodiazepine occurs abruptly. Hence, it is prudent to taper the dosage gradually when therapy is to be discontinued. Despite their adverse effects, benzodiazepines are relatively safe drugs, and fatalities are rare unless other drugs are taken concomitantly. Ethanol is a common contributor to deaths involving benzodiazepines, but true coma is uncommon in the absence of another CNS depressant. Although overdosage with a benzodiazepine rarely causes severe cardiovascular or respiratory depression, therapeutic doses of benzodiazepines can further compromise respiration in patients with COPD or OSA. Benzodiazepine abuse of a different sort includes the use of *flunitrazepam* (Rohypnol; not licensed for use in the U.S.) as a "date rape drug."

Drug Interactions

Except for additive effects with other sedative or hypnotic drugs, reports of clinically important deleterious pharmacodynamic interactions between benzodiazepines and other drugs have been infrequent. In some cases, benzodiazepines are used in the premedication of surgical or dental patients before the induction of anesthesia, largely to decrease anxiety, but also to produce light sedation. In this case, the amnestic effects of benzodiazepines are desirable. *Midazolam*, with its very fast onset of action and an inactive metabolite, is the preoperative anxiolytic currently used predominantly. An unwanted pharmacodynamic interaction involves the use of *valproate* and benzodiazepines in combination, which may cause psychotic episodes. An example of a pharmacokinetic interaction is ethanol increasing the rate of absorption of benzodiazepines and thus the associated CNS depression.

Novel Benzodiazepine Receptor Site Agonists

Hypnotics in this class are commonly referred to as "Z compounds." They include *zolpidem*, *zaleplon*, *zopiclone* (not marketed in the U.S.), and *eszopiclone*, which is the S(+) enantiomer of *zopiclone* (Huedo-Medina et al., 2012) and is available in the U.S. Although the Z compounds are structurally unrelated to each other and to benzodiazepines, their therapeutic efficacy as hypnotics is due to agonist effects at the benzodiazepine site of the $GABA_A$ receptor (Hanson et al., 2008). Compared to benzodiazepines, Z compounds are less effective as anticonvulsants or muscle relaxants, which may be related to their relative selectivity for $GABA_A$ receptors containing the α_1 subunit. Over the last decade, Z compounds have largely replaced benzodiazepines in the treatment of insomnia. Z compounds were initially promoted as having less potential for dependence and abuse than traditional benzodiazepines. However, based on postmarketing clinical experience with *zopiclone* and *zolpidem*, tolerance and physical dependence can be expected during long-term use, especially with higher doses. The Z drugs are classified as schedule IV drugs in the U.S., indicating abuse liability concerns similar to those of benzodiazepines. The clinical presentation of overdose with Z compounds is similar to that of benzodiazepine overdose and can be treated with the benzodiazepine receptor site antagonist *flumazenil*.

Zaleplon

Zaleplon is a member of the pyrazolopyrimidine class. *Zaleplon* preferentially binds to the benzodiazepine binding site on $GABA_A$ receptors containing the α_1 receptor subunit. It is absorbed rapidly and reaches peak plasma concentrations in about 1 h. Its bioavailability is about 30% because of presystemic metabolism. *Zaleplon* is metabolized largely by aldehyde oxidase and to a lesser extent by CYP3A4. Its $t_{1/2}$ is short, about 1 h. *Zalepon*'s oxidative metabolites are converted to glucuronides and eliminated in urine. Less than 1% of *zaleplon* is excreted unchanged; none of *zaleplon*'s metabolites is pharmacologically active. *Zaleplon* is usually administered in 5-, 10-, or 20-mg doses (Dooley and Plosker, 2000). *Zaleplon*-treated subjects with either chronic or transient insomnia experience shorter periods of sleep onset latency.

Zolpidem

Zolpidem is an imidazopyridine sedative-hypnotic. The actions of *zolpidem* are also due to agonist effects at the benzodiazepine receptor site on $GABA_A$ receptors and generally resemble those of benzodiazepines. The drug normally has little effect on the stages of sleep in human subjects. It is effective in shortening sleep latency and prolonging total sleep time in patients with insomnia. After discontinuation of *zolpidem*, the beneficial effects on sleep reportedly persist for up to 1 week, but mild rebound insomnia on the first night of withdrawal may occur. *Zolpidem* is approved only for the short-term treatment of insomnia; however, tolerance and physical dependence are rare (Morselli, 1993). At therapeutic doses (5–10 mg), *zolpidem* infrequently produces residual daytime sedation or amnesia; the incidence of other adverse effects also is low. As with the benzodiazepines, overdoses of *zolpidem* do not produce severe respiratory depression unless other agents (e.g., ethanol) also are ingested. Hypnotic doses increase the hypoxia and hypercarbia of patients with OSA.

Zolpidem is absorbed readily from the GI tract; first-pass hepatic metabolism results in an oral bioavailability of about 70% (lower when the drug is ingested with food). *Zolpidem* is eliminated almost entirely by conversion to inactive products in the liver, largely through oxidation of the methyl groups on the phenyl and imidazopyridine rings to the corresponding carboxylic acids. Its plasma $t_{1/2}$ is typically about 2 h, but this value may increase 2-fold or more in those with cirrhosis and also tends to be greater in older patients, requiring adjustment of dosage. Although little or no unchanged *zolpidem* is found in the urine, elimination of the drug is slower in patients with chronic renal insufficiency; the increased elimination time is largely due to an increase in its apparent volume of distribution.

Zaleplon and Zolpidem Compared

Zaleplon and *zolpidem* are effective in relieving sleep-onset insomnia. Both drugs are FDA-approved for use for up to 7 to 10 days at a time. *Zaleplon* and *zolpidem* have sustained hypnotic efficacy without occurrence of rebound insomnia on abrupt discontinuation. *Zolpidem* has a $t_{1/2}$ of about 2 h, which is sufficient to cover most of a typical 8-h sleep period, and is presently approved for bedtime use only. *Zaleplon* has a shorter $t_{1/2}$ of about 1 h, which offers the possibility for safe dosing later in the night,

within 4 h of the anticipated rising time. *Zaleplon* and *zolpidem* differ in residual side effects; late-night administration of *zolpidem* has been associated with morning sedation, delayed reaction time, and anterograde amnesia, whereas *zaleplon* does not differ from placebo in those respects.

Eszopiclone

Eszopiclone is the active S(+) enantiomer of *zopiclone*. It exerts its sleep-promoting effects by enhancing $GABA_A$ receptor function via the benzodiazepine binding site. *Eszopiclone* is used for the long-term (~12 months) treatment of insomnia, for sleep maintenance, and to decrease the latency to onset of sleep (Melton et al., 2005; Rosenberg et al., 2005). It is available in 1-, 2-, or 3-mg tablets. In clinical studies, no tolerance was observed, and no signs of serious withdrawal, such as seizures or rebound insomnia, were seen on discontinuation of the drug; however, there are such reports for *zopiclone*, the racemate used outside the U.S. Mild withdrawal signs, consisting of abnormal dreams, anxiety, nausea, and upset stomach can occur (≤2%). A minor reported adverse effect of *eszopiclone* is a bitter taste. *Eszopiclone* is absorbed rapidly after oral administration, with a bioavailability of about 80%, and shows wide distribution throughout the body. It is 50% to 60% bound to plasma proteins, is metabolized by CYPs 3A4 and 2E1, and has a $t_{1/2}$ of about 6 h.

Management of Patients After Long-Term Benzodiazepine Therapy

If a benzodiazepine has been used regularly for more than 2 weeks, its use should be tapered rather than discontinued abruptly. In some patients taking hypnotics with a short $t_{1/2}$, it is easier to switch first to a hypnotic with a long $t_{1/2}$ and then to taper. The onset of withdrawal symptoms from medications with a long $t_{1/2}$ may be delayed. Consequently, the patient should be warned about the symptoms associated with withdrawal effects.

Flumazenil: A Benzodiazepine Receptor Antagonist

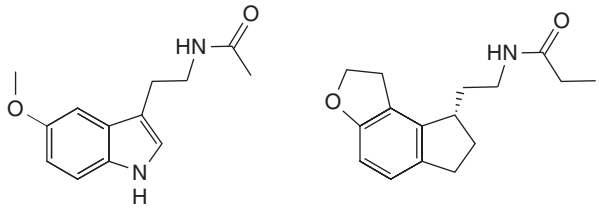
Flumazenil is an imidazobenzodiazepine that binds with high affinity to the benzodiazepine binding site on the $GABA_A$ receptor, where it competitively antagonizes the binding and allosteric effects of benzodiazepines and other ligands, including the Z drugs (Hoffman and Warren, 1993). *Flumazenil* antagonizes both the electrophysiological and behavioral effects of agonist and inverse-agonist benzodiazepines and β-carbolines.

Flumazenil is available only for intravenous administration. Administration of a series of small injections is preferred to a single bolus injection. A total of 1 mg *flumazenil* given over 1 to 3 min usually is sufficient to abolish the effects of therapeutic doses of benzodiazepines. Additional courses of treatment with *flumazenil* may be needed within 20 to 30 min should sedation reappear. The duration of clinical effects usually is only 30 to 60 min. Although absorbed rapidly after oral administration, less than 25% of the drug reaches the systemic circulation owing to extensive first-pass hepatic metabolism. *Flumazenil* is eliminated almost entirely by hepatic metabolism to inactive products with a $t_{1/2}$ of about 1 h. Oral doses are apt to cause headache and dizziness.

The primary indications for the use of *flumazenil* are the management of suspected benzodiazepine overdose and the reversal of sedative effects produced by benzodiazepines administered during general anesthesia and diagnostic or therapeutic procedures. *Flumazenil* administration should also be considered in cases in which the patient has consumed a combination of sedatives, as long as one of them is a benzodiazepine site agonist, such as in cases of combined ethanol and benzodiazepine overdose. However, *flumazenil* is not effective in treating single-drug overdoses with barbiturates, ethanol, opioids, or tricyclic antidepressants. Indeed, the administration of *flumazenil* in these settings may be associated with the onset of seizures, especially in patients poisoned with tricyclic antidepressants. *Flumazenil* may precipitate seizures or other withdrawal signs in patients taking benzodiazepines for protracted periods and in whom tolerance or dependence may have developed.

Melatonin Congeners

Melatonin is a circadian signaling molecule. In some fish and amphibians, melatonin modulates skin coloration through an action on melanin-containing pigment granules in melanophores. In humans, melatonin, not to be confused with the pigment melanin, is the principal indoleamine in the pineal gland, where it may be said to constitute a pigment of the imagination. The synthesis of melatonin in the pineal gland (by *N*-acetylation and *O*-methylation of serotonin; see Figure 15–2) is influenced by external factors, including environmental light. In mammals, melatonin induces pigment lightening in skin cells and suppresses ovarian functions; it also serves a role in regulating biological rhythms and has been studied as a treatment of jet lag and other sleep disturbances. Melatonin analogues have recently been approved for the treatment of insomnia.



MELATONIN RAMELTEON

Ramelteon

Ramelteon is a synthetic tricyclic analogue of melatonin, approved in the U.S. for the treatment of insomnia, specifically difficulties of sleep onset (Spadoni et al., 2011).

Mechanism of Action

Melatonin levels in the suprachiasmatic nucleus rise and fall in a circadian fashion, with concentrations increasing in the evening as an individual prepares for sleep and then reaching a plateau and ultimately decreasing as the night progresses. Two G protein–coupled receptors (GPCRs) for melatonin, MT_1 and MT_2, in the suprachiasmatic nucleus, each play a different role in sleep. Binding of agonists such as melatonin to MT_1 receptors promotes the onset of sleep; melatonin binding to MT_2 receptors shifts the timing of the circadian system. *Ramelteon* binds to both MT_1 and MT_2 receptors with high affinity, but, unlike melatonin, it does not bind appreciably to quinone reductase 2, the structurally unrelated MT_3 receptor. *Ramelteon* is not known to bind to any other classes of receptors, such as nicotinic ACh, neuropeptide, dopamine, and opioid receptors, or the benzodiazepine binding site on $GABA_A$ receptors.

Clinical Pharmacology

Prescribing guidelines suggest that an 8-mg tablet be taken about 30 min before bedtime. *Ramelteon* is rapidly absorbed from the GI tract. Because of the significant first-pass metabolism that occurs after oral administration, *ramelteon* bioavailability is less than 2%. The drug is largely metabolized by hepatic CYPs 1A2, 2C, and 3A4, with a $t_{1/2}$ of about 2 h in humans. Of the four metabolites, M-II acts as an agonist at MT_1 and MT_2 receptors and may contribute to the sleep-promoting effects of *ramelteon*.

Ramelteon is efficacious in combating both transient and chronic insomnia, with no tolerance occurring in its reduction of sleep onset latency even after 6 months of drug administration (Mayer et al., 2009). It is generally well tolerated by patients and does not impair next-day cognitive function. Sleep latency was consistently found to be shorter in patients given *ramelteon* compared with placebo controls. No evidence of rebound insomnia or withdrawal effects were noted on *ramelteon* withdrawal. Unlike most agents mentioned in this chapter, *ramelteon* is not a controlled substance since there is no evidence of abuse liability. Dizziness, nausea, drowsiness, and headache have been reported as adverse effects in a small minority of patients.

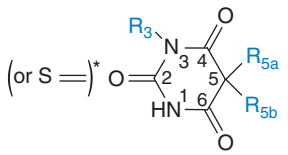
Tasimelteon

Tasimelteon is a selective agonist for MT_1 and MT_2 receptors. Although FDA approval was sought in the U.S. only for the treatment of non–24-h sleep-wake syndrome in totally blind patients experiencing circadian rhythm disorder (Johnsa and Neville, 2014), the FDA approved *tasimelteon* for use in both blind and nonblind individuals, although no clinical trials were performed in the latter group. In 2020, the FDA expanded the use of *tasimelteon* for the treatment of nighttime sleep disturbances in adults and children with Smith-Magenis syndrome, a rare neurodevelopmental disorder involving reversed circadian rhythm that makes nighttime sleep difficult. Discontinuation of *tasimelteon* use leads to a reversion to baseline sleep parameters within approximately 1 month.

Barbiturates

The barbiturates were once used extensively as sedative-hypnotic drugs. Except for a few specialized uses, they have been largely replaced by the much safer benzodiazepines and Z compounds. Table 22–3 lists the common barbiturates and their pharmacological properties.

Barbiturates are derivatives of this parent structure:



*O except in thiopental, where it is replaced by S.

Barbituric acid is 2,4,6-trioxohexahydropyrimidine. This compound lacks central depressant activity, but the presence of alkyl or aryl groups at position 5 confers sedative-hypnotic and sometimes other activities. Barbiturates in which the oxygen at C2 is replaced by sulfur are called *thiobarbiturates*. These compounds are more lipid soluble than the corresponding *oxybarbiturates*. In general, structural changes that increase lipid solubility decrease duration of action, decrease latency to onset of activity, accelerate metabolic degradation, and increase hypnotic potency.

The Pharmacological Properties of Barbiturates

The barbiturates reversibly depress the activity of all excitable tissues to varying extents. The CNS is particularly sensitive, but even when barbiturates are given in anesthetic concentrations, direct effects on peripheral excitable tissues are weak. However, serious deficits in cardiovascular and other peripheral functions occur in acute barbiturate intoxication.

ADME

For sedative-hypnotic use, the barbiturates usually are administered orally (see Table 22–2). Na^+ salts are absorbed more rapidly than the corresponding free acids, especially from liquid formulations. The onset of action varies from 10 to 60 min and is delayed by the presence of food. Intramuscular injections of solutions of the Na^+ salts should be placed deeply into large muscles to avoid the pain and possible necrosis that can result at more superficial sites. The intravenous route usually is reserved for the management of status epilepticus (*phenobarbital sodium*) or for the induction or maintenance of general anesthesia (e.g., *thiopental* or *methohexital*).

Barbiturates distribute widely in the body and readily cross the placenta. The highly lipid-soluble barbiturates such as *thiopental* and *methohexital*, used to induce anesthesia, undergo rapid redistribution after intravenous injection. Redistribution into less-vascular tissues, especially muscle and fat, leads to a decline in the concentration of barbiturate in the plasma and brain. With *thiopental* and *methohexital*, this results in the awakening of patients within 5 to 15 min of the injection of the usual anesthetic doses (see Figures 2–4 and 24–3).

Except for the less lipid-soluble *aprobarbital* and *phenobarbital*, nearly complete metabolism or conjugation of barbiturates in the liver precedes their renal excretion. The oxidation of radicals at C5 is the most important biotransformation that terminates biological activity. In some instances (e.g., *phenobarbital*), *N*-glycosylation is an important metabolic pathway. Other biotransformations include *N*-hydroxylation, desulfuration of thiobarbiturates to oxybarbiturates, opening of the barbituric acid ring, and *N*-dealkylation of *N*-alkyl barbiturates to active metabolites (e.g., *mephobarbital* to *phenobarbital*). About 25% of *phenobarbital* and nearly all of *aprobarbital* are excreted unchanged in the urine. Their renal excretion can be increased greatly by osmotic diuresis or alkalinization of the urine.

TABLE 22–3 ■ THERAPEUTIC USES OF BARBITURATES

COMPOUND	ROUTES OF ADMINISTRATION	THERAPEUTIC USES	COMMENTS	$t_{1/2}$ (h)
Amobarbital	IM, IV	Insomnia, preoperative sedation, emergency management of seizures	Only Na^+ salt for injection is sold in the U.S.	10–40
Butabarbital	Oral	Insomnia, preoperative sedation, daytime sedation	Redistribution shortens duration of action of single dose to 8 h	35–50
Mephobarbital (not licensed for use in the U.S.)	Oral	Seizure disorders, daytime sedation	Second-line anticonvulsant	10–70
Methohexital	IV	Induction and maintenance of anesthesia	Only Na^+ salt available; single dose provides 5–7 min of anesthesia	3–5
Pentobarbital	Oral, IM, IV, rectal (only injectable form is marketed in the U.S.)	Insomnia, preoperative and procedural sedation, emergency management of seizures	Administer only Na^+ salt parenterally	15–50
Phenobarbital	Oral, IM, IV	Seizure disorders, status epilepticus, daytime sedation (hyperbilirubinemia, off-label use)	First-line anticonvulsant; only Na^+ salt administered parenterally	80–120
Secobarbital	Oral	Insomnia, preoperative sedation	Only Na^+ salt available	15–40
Thiopental (not currently produced or marketed in the U.S.)	IV	Induction/maintenance of anesthesia, preoperative sedation, emergency management of seizures, intracranial pressure	Only Na^+ salt available; single dose provides brief period of anesthesia	8–10 ($t_{1/2}$ of anesthetic effects is short due to redistribution)

OL of lab l u:

The metabolic elimination of barbiturates is more rapid in young people than in the elderly and infants, and half-lives are increased during pregnancy partly because of the expanded volume of distribution. Chronic liver disease, especially cirrhosis, often increases the $t_{1/2}$ of the biotransformable barbiturates. Repeated administration, especially of *phenobarbital*, shortens the $t_{1/2}$ of barbiturates that are metabolized as a result of the induction of microsomal enzymes in the liver.

The barbiturates commonly used as hypnotics in the U.S. have $t_{1/2}$ *values such that the drugs are not fully eliminated in 24 h (see Table 22–3). Thus, these barbiturates will accumulate during repeated administration unless appropriate adjustments in dosage are made. Furthermore, the persistence of the drug in plasma during the day favors the development of tolerance and abuse.*

CNS Effects

Actions on the $GABA_A$ Receptor

Enhancement of inhibition occurs primarily at synapses where neurotransmission is mediated by GABA acting at $GABA_A$ receptors. Barbiturates bind to an allosteric site on the $GABA_A$ receptor distinct from the benzodiazepine site (see Figure 16–11); binding leads to an increase in the mean open time of the GABA-activated Cl^- channel, with no effect on frequency. At higher concentrations, barbiturates directly activate channel opening, even in the absence of GABA (Nestler et al., 2020). Barbiturates also reportedly inhibit excitatory α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainate receptors (Marszalec and Narahashi, 1993) and inhibit glutamate release via an effect on voltage-activated Ca^{2+} channels. Barbiturates also produce significantly greater enhancement of $GABA_A$ receptor function than even maximally effective concentrations of benzodiazepines.

Effects in the CNS

Barbiturates enhance GABA-mediated inhibitory transmission throughout the CNS; nonanesthetic doses preferentially suppress polysynaptic responses. Facilitation is diminished, and inhibition usually is enhanced. The site of inhibition is either postsynaptic, as at *cortical and cerebellar pyramidal cells* and in the *cuneate nucleus, substantia nigra*, and *thalamic relay neurons*, or presynaptic, as in the *spinal cord*.

Barbiturates can produce all degrees of depression of the CNS, ranging from mild sedation to general anesthesia in a dose-dependent manner (see Chapter 24). Certain barbiturates, particularly those containing a 5-phenyl substituent (e.g., *phenobarbital* and *mephobarbital*), have selective anticonvulsant activity (see Chapter 20). The antianxiety properties of the barbiturates are inferior to those exerted by the benzodiazepines.

Except for the anticonvulsant activities of *phenobarbital* and its congeners, the barbiturates possess a low degree of selectivity and a low therapeutic index. Pain perception and reaction are relatively unimpaired until the moment of unconsciousness, and in small doses, barbiturates increase reactions to painful stimuli. Hence, they cannot be relied on to produce sedation or sleep in the presence of even moderate pain.

Effects on Stages of Sleep

Hypnotic doses of barbiturates increase the total sleep time and alter the stages of sleep in a dose-dependent manner. Like the benzodiazepines, barbiturates decrease sleep latency, the number of awakenings, and the durations of REM and slow-wave sleep. During repetitive nightly administration, some tolerance to the effects on sleep occurs within a few days, and the effect on total sleep time may be reduced by as much as 50% after 2 weeks of use. Discontinuation leads to rebound increases in all the sleep parameters initially decreased by barbiturates.

Tolerance, Abuse, and Dependence

With chronic administration of gradually increasing doses, pharmacodynamic tolerance continues to develop over a period of weeks to months, depending on the dosage schedule, whereas pharmacokinetic tolerance reaches its peak in a few days to a week. Tolerance to the euphoric, sedative, and hypnotic effects occurs more readily and is greater than that to the anticonvulsant and lethal effects; thus, as tolerance increases, the therapeutic index decreases. Pharmacodynamic tolerance to barbiturates confers cross-tolerance to all general CNS depressant drugs, including ethanol. Like other CNS depressant drugs, barbiturates are abused, and some individuals develop physical dependence (see Chapter 28).

Effects on Peripheral Nerve Structures

Barbiturates selectively depress transmission in autonomic ganglia and reduce nicotinic excitation by choline esters. This effect may account, at least in part, for the fall in blood pressure produced by intravenous oxybarbiturates and by severe barbiturate intoxication. At skeletal neuromuscular junctions, the blocking effects of both *tubocurarine* and *decamethonium* are enhanced during barbiturate anesthesia. These actions probably result from the capacity of barbiturates at hypnotic or anesthetic concentrations to inhibit current flow through nicotinic ACh receptors. Several distinct mechanisms appear to be involved, and little stereoselectivity is evident.

Systemic Effects

Respiration

Barbiturates depress both the respiratory drive and the mechanisms responsible for the rhythmic character of respiration. The neurogenic drive is essentially eliminated by a dose three times greater than that used normally to induce sleep. Such doses also suppress the hypoxic drive and, to a lesser extent, the chemoreceptor drive. However, the margin between the lighter planes of surgical anesthesia and dangerous respiratory depression is sufficient to permit the ultra-short-acting barbiturates to be used, with suitable precautions, as anesthetic agents.

The barbiturates only slightly depress protective reflexes until the degree of intoxication is sufficient to produce severe respiratory depression. Coughing, sneezing, hiccoughing, and laryngospasm may occur when barbiturates are employed as intravenous anesthetic agents.

Cardiovascular System

When given orally in sedative or hypnotic doses, barbiturates do not produce significant overt cardiovascular effects. In general, the effects of *thiopental* anesthesia on the cardiovascular system are benign in comparison with those of the volatile anesthetic agents; there usually is either no change or a fall in mean arterial pressure (see Chapter 24). Barbiturates can blunt cardiovascular reflexes by partial inhibition of ganglionic transmission, most evident in patients with congestive heart failure or hypovolemic shock. Because barbiturates also impair reflex cardiovascular adjustments to inflation of the lung, positive-pressure respiration should be used cautiously and only when necessary to maintain adequate pulmonary ventilation in patients who are anesthetized or intoxicated with a barbiturate.

Additional cardiovascular changes often noted when *thiopental* and other intravenous thiobarbiturates are administered after conventional preanesthetic medication include decreased renal and cerebral blood flow with a marked fall in CSF pressure. Although cardiac arrhythmias are observed only infrequently, intravenous anesthesia with barbiturates can increase the incidence of ventricular arrhythmias, especially when *epinephrine* and *halothane* also are present. Anesthetic concentrations of barbiturates depress the function of Na^+ channels and at least two types of K^+ channels. However, direct depression of cardiac contractility occurs only when doses several times those required to cause anesthesia are administered.

GI Tract

The oxybarbiturates tend to decrease the tone of the GI musculature and the amplitude of rhythmic contractions; the locus of action is partly peripheral and partly central. A hypnotic dose does not significantly delay gastric emptying in humans. The relief of various GI symptoms by sedative doses is probably largely due to the central depressant action.

Liver

The effects vary with the duration of exposure to the barbiturate. *Acutely,* the barbiturates interact with several CYPs and inhibit the biotransformation of a number of other drugs and endogenous substrates, such as steroids; other substrates may reciprocally inhibit barbiturate biotransformations (see Chapter 5).

Chronic administration of barbiturates markedly increases the protein and lipid content of the hepatic smooth endoplasmic reticulum, as well as the activities of glucuronyl transferase and CYPs 1A2, 2C9, 2C19, and 3A4. The induction of these enzymes increases the metabolism of a number of drugs (including barbiturates) and endogenous substances, including steroid hormones, cholesterol, bile salts, and vitamins K and D. The self-induced increase in barbiturate metabolism partly accounts for tolerance to barbiturates. The inducing effect is not limited to the microsomal enzymes; for example, there are increases in δ-aminolevulinic acid (ALA) synthase, a mitochondrial enzyme, and aldehyde dehydrogenase, a cytosolic enzyme. The effect of barbiturates on ALA synthetase can cause dangerous disease exacerbations in persons with intermittent porphyria.

Kidneys

Severe oliguria or anuria may occur in acute barbiturate poisoning largely as a result of the marked hypotension.

Therapeutic Uses

The major uses of individual barbiturates are listed in Table 22–3. As with the benzodiazepines, the selection of a particular barbiturate for a given therapeutic indication is based primarily on pharmacokinetic considerations. Benzodiazepines and other compounds have largely replaced barbiturates as sedatives.

Untoward Effects

Aftereffects

Drowsiness may last for only a few hours after a hypnotic dose of barbiturate, but residual CNS depression sometimes is evident the following day, and subtle distortions of mood and impairment of judgment and fine motor skills may be demonstrable. Residual effects also may take the form of vertigo, nausea, vomiting, or diarrhea or sometimes may be manifested as overt excitement.

Paradoxical Excitement

In some persons, barbiturates produce excitement rather than depression, and the patient may appear to be inebriated. This type of idiosyncrasy is relatively common among geriatric and debilitated patients and occurs most frequently with *phenobarbital* and *N*-methylbarbiturates. Barbiturates may cause restlessness, excitement, and even delirium when given in the presence of pain, and may worsen a patient's perception of pain.

Hypersensitivity

Allergic reactions occur, especially in persons with asthma, urticaria, angioedema, or similar conditions. Hypersensitivity reactions include localized swellings, particularly of the eyelids, cheeks, or lips, and erythematous dermatitis. Rarely, exfoliative dermatitis may be caused by *phenobarbital* and can prove fatal; the skin eruption may be associated with fever, delirium, and marked degenerative changes in the liver and other parenchymatous organs.

Other

Because barbiturates enhance porphyrin synthesis, they are absolutely contraindicated in patients with acute intermittent porphyria or porphyria variegata. Hypnotic doses in the presence of pulmonary insufficiency are contraindicated. Rapid intravenous injection of a barbiturate may cause cardiovascular collapse before anesthesia ensues. Blood pressure can fall to shock levels; even slow intravenous injection of barbiturates often produces apnea and occasionally laryngospasm, coughing, and other respiratory difficulties.

Drug Interactions

Barbiturates combine with other CNS depressants to cause severe depression; interactions with ethanol and with first-generation antihistamines are common. *Isoniazid*, *methylphenidate*, and monoamine oxidase inhibitors also increase the CNS depressant effects of barbiturates.

Barbiturates competitively inhibit the metabolism of certain other drugs; however, the greatest number of drug interactions results from induction of hepatic CYPs (as described previously) and the accelerated disappearance of many drugs and endogenous substances from the body. Hepatic enzyme induction enhances metabolism of endogenous steroid hormones, which may cause endocrine disturbances, and enhances metabolism of oral contraceptives, which may increase the likelihood of unwanted pregnancy. Barbiturates also induce the hepatic generation of toxic metabolites of chlorocarbons (chloroform, trichloroethylene, carbon tetrachloride) and consequently promote lipid peroxidation, which facilitates periportal necrosis of the liver caused by these agents.

Barbiturate Poisoning

The incidence of barbiturate poisoning has declined markedly, largely as a result of their decreased use as sedative-hypnotic agents. Most of the cases are the result of attempts at suicide, but some are from accidental poisonings in children or drug abusers. The lethal dose of barbiturate varies, but severe poisoning is likely to occur when more than 10 times the full hypnotic dose has been ingested at once. The lethal dose becomes lower if alcohol or other depressant drugs are present. In severe intoxication, the patient is comatose; respiration is affected early. Breathing may be either slow or rapid and shallow. Eventually, blood pressure falls because the effect of the drug and of hypoxia on medullary vasomotor centers; depression of cardiac contractility and sympathetic ganglia also contributes. Pulmonary complications (e.g., atelectasis, edema, and bronchopneumonia) and renal failure are likely to be the fatal complications of severe barbiturate poisoning.

The treatment of acute barbiturate intoxication is based on general supportive measures, which are applicable in most respects to poisoning by any CNS depressant. The use of CNS stimulants is contraindicated. If renal and cardiac functions are satisfactory and the patient is hydrated, forced diuresis and alkalinization of the urine will hasten the excretion of *phenobarbital*. See Chapter 9, Drug Toxicity and Poisoning.

Miscellaneous Sedative-Hypnotic Drugs

Many drugs with diverse structures have been used for their sedative-hypnotic properties, including *ramelteon, chloral hydrate, meprobamate*, and *paraldehyde* (no longer licensed in the U.S.). With the exception of *ramelteon* and *meprobamate*, the pharmacological actions of these drugs generally resemble those of the barbiturates:

- They all are general CNS depressants that can produce profound hypnosis with little or no analgesia.
- Their effects on the stages of sleep are similar to those of the barbiturates.
- Their therapeutic indices are low, and acute intoxication, which produces respiratory depression and hypotension, is managed similarly to barbiturate poisoning.
- Their chronic use can result in tolerance and physical dependence.
- The syndrome after chronic use can be severe and life threatening.

Chloral Hydrate

Chloral hydrate may be used to treat patients with paradoxical reactions to benzodiazepines. *Chloral hydrate* is reduced rapidly to the active compound trichloroethanol (CCl_3CH_2OH), largely by hepatic alcohol dehydrogenase. Its pharmacological effects probably are caused by trichloroethanol, which can exert barbiturate-like effects on $GABA_A$ receptor channels *in vitro*. *Chloral hydrate* is regulated as a schedule IV controlled substance.

In the U.S., *chloral hydrate* is best known as a literary hypnotic, the "knockout drops" added to a strong alcoholic beverage to produce a "Mickey Finn" or "Mickey," a cocktail given to an unwitting imbiber to render the person malleable or unconscious, most famously Sam Spade in Dashiell Hammett's 1930 novel, *The Maltese Falcon*.

Meprobamate

Meprobamate, a *bis*-carbamate ester, was introduced as an antianxiety agent in 1955 and this remains its only approved use in the U.S.;

it has abuse liability and is regulated as a schedule IV drug. Marketing authorization for *meprobamate* was withdrawn in the European Union in 2012 and in Canada in 2013 due to concerns related to its side effects. *Meprobamate* also became popular as a sedative-hypnotic agent but was later largely replaced by benzodiazepines in this role. The pharmacological properties of *meprobamate* resemble those of the benzodiazepines in a number of ways. *Meprobamate* can release suppressed behaviors in experimental animals at doses that cause little impairment of locomotor activity, and although it can cause CNS depression, it cannot produce anesthesia. Large doses of *meprobamate* cause severe respiratory depression, hypotension, shock, and heart failure. *Meprobamate* appears to have a mild analgesic effect in patients with musculoskeletal pain, and it enhances the analgesic effects of other drugs.

Meprobamate is well absorbed when administered orally. Nevertheless, an important aspect of intoxication with *meprobamate* is the formation of gastric bezoars consisting of undissolved *meprobamate* tablets; treatment may require endoscopy, with mechanical removal of the bezoar. Most of the drug is metabolized in the liver by side-chain hydroxylation and glucuronidation; the kinetics of elimination may depend on dose. The $t_{1/2}$ of *meprobamate* may be prolonged during its chronic administration. The major unwanted effects of the usual sedative doses of *meprobamate* are drowsiness and ataxia; larger doses impair learning and motor coordination and prolong reaction time. *Meprobamate* enhances the CNS depression produced by other drugs. After long-term medication, abrupt discontinuation evokes a withdrawal syndrome usually characterized by anxiety, insomnia, tremors, and, frequently, hallucinations; generalized seizures occur in about 10% of cases.

Carisoprodol, a skeletal muscle relaxant whose active metabolite is *meprobamate*, also has abuse potential and has become a popular "street drug." *Carisoprodol* is designated as a schedule IV controlled substance in the U.S.

Other Agents

Etomidate is used in the U.S. and other countries as an intravenous anesthetic, often in combination with *fentanyl*. It is advantageous because it lacks pulmonary and vascular depressant activity, although it has a negative inotropic effect on the heart. Its pharmacology and anesthetic uses are described in Chapter 24.

Clomethiazole has sedative, muscle relaxant, and anticonvulsant properties. Given alone, its effects on respiration are slight, and the therapeutic index is high. However, deaths from adverse interactions with ethanol are relatively frequent.

Propofol is a rapidly acting and highly lipophilic diisopropylphenol used in the induction and maintenance of general anesthesia (see Chapter 24), as well as in the maintenance of long-term sedation. *Propofol* has found use in intensive care sedation in adults (McKeage and Perry, 2003), for sedation during GI endoscopy procedures, and during transvaginal oocyte retrieval.

Nonprescription Hypnotic Drugs

The antihistamines *diphenhydramine* and *doxylamine* are FDA approved as ingredients in over-the-counter nonprescription sleep aids. With an elimination $t_{1/2}$ of about 9 to 10 h, these antihistamines can be associated with prominent residual sleepiness the morning after when taken as a sleep aid the night before.

New and Emerging Agents

Suvorexant

Suvorexant, an inhibitor of orexin 1 and 2 receptors, is FDA-approved for the treatment of insomnia (Winrow and Renger, 2014). Orexins, produced by neurons in the lateral hypothalamus and projecting broadly throughout the CNS, play a major role in regulation of the sleep cycle. These neurons are quiescent during sleep but are active during wakefulness; thus, orexins promote wakefulness, while antagonists at orexin receptors enhance REM and non-REM sleep. *Suvorexant* decreases sleep onset latency and is superior to placebo in sleep maintenance. One 10-mg dose should be taken within 30 min of going to bed if at least 7 h remain until the projected time of awakening. The most common adverse reaction is daytime somnolence, and there is a possibility of the worsening of depression or suicidal ideation. *Suvorexant* is a schedule IV controlled substance.

Lemborexant

Lemborexant, another orexin 1/2 receptor antagonist, was granted FDA approval in 2019. Doses ranging from 2.5 to 10 mg are efficacious in the treatment of insomnia with minimal next-morning residual drowsiness in most patients (Murphy et al., 2017). *Lemborexant* has a $t_{1/2}$ of 17 to 19 h. As with *suvorexant*, the most common adverse reaction is somnolence, especially at higher doses. Like *suvorexant*, it is a schedule IV controlled drug. Importantly, orexin receptor antagonists do not produce the anterograde amnesia seen with benzodiazepines and the Z drugs.

Doxepin

Doxepin, a tricyclic antidepressant, enhances subjective measures of sleep quality and is indicated for the treatment of difficulties with sleep maintenance (Yeung et al., 2015). It acts presumably via antagonism of H_1 receptor function when administered in low doses, although it also may act as an antagonist of the norepinephrine transporter and an antagonist of muscarinic, α_1 adrenergic, and $5HT_{2A}$ receptors. *Doxepin* should be taken in initial doses of 6 mg (3 mg in elderly patients) within 30 min of bedtime. Abnormal thinking and behavior have been observed following its use, and it can worsen suicidal ideation and depression. *Doxepin* is FDA-approved for the treatment of sleep maintenance insomnia.

Pregabalin

Pregabalin, an anxiolytic agent that binds to Ca^{2+} channel $\alpha_2\delta$ subunits, has proved useful in clinical trials (Holsboer-Trachsler and Prieto, 2013); *pregabalin* slightly decreased sleep onset latency and increased the proportion of time spent in slow-wave sleep. *Pregabalin* appears to be an effective treatment of the insomnia seen in patients suffering from a generalized anxiety disorder. *Pregabalin* is designated as a schedule V controlled substance.

Ritanserin

Ritanserin and other $5HT_{2A/2C}$ receptor antagonists show a capacity to promote slow-wave sleep in patients with chronic primary insomnia or generalized anxiety disorder (Monti, 2010). *Ritanserin* is not licensed for use in the U.S.

Agomelatine

Agomelatine, a melatonin receptor agonist and a $5HT_{2C}$ receptor antagonist, is prescribed for the treatment of depression and may aid in ameliorating sleep disturbances often associated with depression. *Agomelatine* is not licensed for use in the U.S. but is approved for medical use in Europe and Australia.

Management of Insomnia

Insomnia is one of the most common complaints in general medical practice. A number of pharmacological agents are available for the treatment of insomnia. The "perfect" hypnotic would allow sleep to occur with normal sleep architecture. It would not cause next-day effects, either of rebound anxiety or of continued sedation. It would not interact with other medications. It could be used chronically without causing dependence or rebound insomnia on discontinuation. Controversy in the management of insomnia revolves around two issues:

- Pharmacological versus nonpharmacological treatment
- Use of short-acting versus long-acting hypnotics

The side effects of hypnotic medications must be weighed against the sequelae of chronic insomnia, which include a 4-fold increase in serious accidents (Balter and Uhlenhuth, 1992). Regular moderate exercise

or even small amounts of exercise often are effective in promoting sleep. In addition to appropriate pharmacological treatment, the management of insomnia should correct identifiable causes, address inadequate sleep hygiene, eliminate performance anxiety related to falling asleep, provide entrainment of the biological clock so that maximum sleepiness occurs at the hour of attempted sleep, and suppress the use of alcohol and over-the-counter sleep medications.

Categories of Insomnia

- *Transient insomnia* lasts less than 3 days and usually is caused by a brief environmental or situational stressor. If hypnotics are prescribed, they should be used at the lowest dose and for only 2 to 3 nights. Note that benzodiazepines given acutely before important life events, such as examinations, may result in impaired performance.
- *Short-term insomnia* lasts from 3 days to 3 weeks and usually is caused by a personal stressor such as illness, grief, or job problems. Hypnotics may be used adjunctively for 7 to 10 nights and are best used intermittently during this time, with the patient skipping a dose after 1 to 2 nights of good sleep.
- *Long-term insomnia* lasts for more than 3 weeks; a specific stressor may not be identifiable.

Insomnia Accompanying Major Psychiatric Illnesses

The insomnia caused by major psychiatric illnesses often responds to specific pharmacological treatment of that illness. For example, in major depressive episodes with insomnia, selective serotonin reuptake inhibitors (SSRIs), which may cause insomnia as a side effect, usually will result in improved sleep because they treat the depressive syndrome. In a patient whose depression is responding to an SSRI but has persistent insomnia as a side effect of the medication, judicious use of evening *trazodone* may improve sleep, as well as augment the antidepressant effect of the reuptake inhibitor. However, the patient should be monitored for priapism, orthostatic hypotension, and arrhythmias.

Adequate control of anxiety disorders often produces adequate resolution of the accompanying insomnia. Sedative use in patients with anxiety disorders is decreasing because of a growing appreciation of the effectiveness of other agents, such as β adrenergic receptor antagonists (see Chapter 14) for performance anxiety and SSRIs for obsessive-compulsive disorder and perhaps generalized anxiety disorder. The profound insomnia in patients with acute psychosis owing to schizophrenia or mania usually responds to dopamine receptor antagonists (see Chapters 15 and 19). Benzodiazepines often are used adjunctively in this situation to reduce agitation and improve sleep.

Insomnia Accompanying Other Medical Illnesses

For long-term insomnia owing to other medical illnesses, adequate treatment of the underlying disorder, such as congestive heart failure, asthma, or COPD, may resolve the insomnia. Adequate pain management in conditions of chronic pain will treat both the pain and the insomnia and may make hypnotics unnecessary. *Adequate attention to sleep hygiene, including reduced caffeine intake, avoidance of alcohol, adequate exercise, and regular sleep and wake times, often will reduce the insomnia.*

Conditioned (Learned) Insomnia

In those who have no major psychiatric or other medical illness and in whom attention to sleep hygiene is ineffective, attention should be directed to conditioned (learned) insomnia. These patients have associated the bedroom with activities consistent with wakefulness rather than sleep. In such patients, all other activities associated with waking, even such quiescent activities as reading and watching television, should be done outside the bedroom.

Sleep-State Misperception

Some patients complain of poor sleep but have been shown to have no objective polysomnographic evidence of insomnia. They are difficult to treat.

Long-Term Insomnia

Nonpharmacological treatments are important for all patients with long-term insomnia. These include education about sleep hygiene, relaxation training, and behavioral modification approaches, such as sleep restriction and stimulus-control therapies.

Long-term hypnotic use leads to a decrease in effectiveness and may produce rebound insomnia on discontinuance. Almost all hypnotics change sleep architecture. The barbiturates reduce REM sleep; the benzodiazepines reduce slow-wave non-REM sleep and, to a lesser extent, REM sleep. While the significance of these findings is not clear, there is an emerging consensus that slow-wave sleep is particularly important for physical restorative processes. REM sleep may aid in the consolidation of learning. The blockade of slow-wave sleep by benzodiazepines may partly account for their diminishing effectiveness over the long term, and it also may explain their effectiveness in blocking sleep terrors, a disorder of arousal from slow-wave sleep.

Long-acting benzodiazepines can cause next-day confusion, whereas shorter-acting agents can produce rebound next-day anxiety. Paradoxically, the acute amnestic effects of benzodiazepines may be responsible for the patient's subsequent report of restful sleep. Anterograde amnesia may be more common with *triazolam*. Hypnotics should not be given to patients with sleep apnea, especially the obstructive type, because these agents decrease upper airway muscle tone while also decreasing the arousal response to hypoxia.

Insomnia in Older Patients

The elderly, like the very young, tend to sleep in a *polyphasic* (multiple sleep episodes per day) pattern rather than the *monophasic* pattern characteristic of younger adults. This pattern makes assessment of adequate sleep time difficult.

Changes in the pharmacokinetic profiles of hypnotic agents occur in the elderly because of reduced body water, reduced renal function, and increased body fat, leading to a longer $t_{1/2}$ for benzodiazepines. A dose that produces pleasant sleep and adequate daytime wakefulness during week 1 may produce daytime confusion and amnesia by week 3 as the drug level continues to rise, particularly with long-acting hypnotics. For example, the benzodiazepine *diazepam* is highly lipid soluble and is excreted by the kidney. Because of the increase in body fat and the decrease in renal excretion that typically occur from age 20 to 80, the $t_{1/2}$ of the drug may increase 4-fold over this span.

Injudicious use of hypnotics in the elderly can produce daytime cognitive impairment and thereby impair overall quality of life. Once an older patient has been taking benzodiazepines for an extended period, whether for daytime anxiety or for nighttime sedation, terminating the drug can be a long, involved process. Attempts at drug withdrawal may not be successful, and it may be necessary to leave the patient on the medication, with adequate attention to daytime side effects.

Prescribing Guidelines for Managing Insomnia

Hypnotics that act at $GABA_A$ receptors—benzodiazepine hypnotics and the newer agents *zolpidem*, *zopiclone*, and *zaleplon*—are preferred to barbiturates; the $GABA_A$ receptor agents have a higher therapeutic index, smaller effects on sleep architecture, and less abuse potential. Compounds with a shorter $t_{1/2}$ are favored in patients with sleep-onset insomnia but without significant daytime anxiety who need to function at full effectiveness during the day. These compounds also are appropriate for the elderly because of a decreased risk of falls and respiratory depression. However, the patient and physician should be aware that early morning awakening, rebound daytime anxiety, and amnestic episodes also may occur. These undesirable side effects are more common at higher doses of the benzodiazepines.

Benzodiazepines with longer $t_{1/2}$ values are favored for patients who have significant daytime anxiety. These benzodiazepines also are appropriate for patients receiving treatment of major depressive episodes because the short-acting agents can worsen early morning awakening. However, longer-acting benzodiazepines can be associated with next-day cognitive impairment or delayed daytime cognitive impairment (after 2–4 weeks of treatment) as a result of drug accumulation with repeated administration.

Older agents—barbiturates, chloral hydrate, *and* meprobamate—*should be avoided for the management of insomnia. They have high abuse potential and are dangerous in overdose.*

Drug Facts for Your Personal Formulary: *Sedative-Hypnotic Agents*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Benzodiazepines—synergistic with other CNS depressants, especially ethanol; see Table 22–2		
Alprazolam	Anxiety disorders, agoraphobia	Withdrawal symptoms may be especially severe
Chlordiazepoxide	Anxiety disorders, alcohol withdrawal, preanesthetic medication	Long-acting and self-tapering because of active metabolites
Clobazam	Adjunctive treatment of seizures associated with Lennox-Gastaut syndrome, other epilepsy and anxiety disorders	Active metabolite has long half-life Decrease dose and titrate in CYP2C19-poor metabolizers Tolerance develops to anticonvulsant effects
Clonazepam	Seizure disorders, adjunctive treatment in acute mania and certain movement disorders	Tolerance develops to anticonvulsant effects
Clorazepate	Anxiety disorders, seizure disorders	Prodrug; activity due to formation of nordazepam during absorption
Diazepam	Anxiety disorders, alcohol withdrawal, status epilepticus, skeletal muscle relaxation, preanesthetic medication	Prototypical benzodiazepine
Estazolam	Insomnia	Contains triazolo ring; adverse effects may be similar to those of triazolam
Flurazepam	Insomnia	Active metabolites accumulate with chronic use
Lorazepam	Anxiety disorders, alcohol withdrawal, preanesthetic medication	Metabolized solely by conjugation
Midazolam	Preanesthetic and intraoperative medication	Rapidly inactivated
Oxazepam	Anxiety disorders, alcohol withdrawal	Metabolized solely by conjugation
Quazepam	Insomnia	Active metabolites accumulate with chronic use
Remimazolam	Preanesthetic and intraoperative medication	Very rapidly inactivated
Temazepam	Insomnia	Metabolized mainly by conjugation
Triazolam	Insomnia	Rapidly inactivated; may cause disturbing daytime side effects
"Z Compounds"—nonbenzodiazepines with agonist effects at the benzodiazepine site of $GABA_A$ receptors; these agents have largely replaced benzodiazepines for treating insomnia		
Zaleplon	Insomnia	Very short elimination half-life
Zolpidem	Insomnia	Short-term (2–6 week) treatment of insomnia
Eszopiclone	Insomnia	S(+) enantiomer of zopiclone
Benzodiazepine Antagonist		
Flumazenil	Benzodiazepine overdose (benzodiazepine and β-carboline antagonist)	Headache, dizziness; do not use in tricyclic antidepressant poisoning (seizures!)
Miscellaneous and Emerging Agents		
Ramelteon	Insomnia	Melatonin receptor agonist; significant first-pass effect
Tasimelteon	Circadian rhythm disorder in blind patients	Melatonin receptor agonist
Suvorexant	Insomnia	Orexin receptor antagonist; needs at least 7 h after 10-mg dose before awakening
Lemborexant	Insomnia	Orexin receptor antagonist
Doxepin	Depression, insomnia	Tricyclic antidepressant; sedating effects likely occur through H_1 receptor antagonism; beware of abnormal behavior, suicide ideation, depression; use half dose in the elderly
Propofol	Induction/maintenance of anesthesia, procedural sedation	Rapid recovery
Pregabalin (β-isobutyl–GABA)	Nerve/muscle pain, fibromyalgia, seizures	Schedule V substance, abuse potential; some concern for suicide ideation and angioedema

Drug Facts for Your Personal Formulary: *Sedative-Hypnotic Agents* (*continued*)

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Barbiturates—synergistic with other CNS depressants, especially ethanol; induce CYPs; respiratory depressants; see Table 22–3		
Amobarbital	Insomnia, preoperative sedation, emergency management of seizures	• IM and IV • Short-acting (3–8 h)
Butobarbital	Insomnia, preoperative sedation, daytime sedation	• Oral • Fast onset of action • Short-acting (3–8 h)
Mephobarbital (not licensed for use in U.S.)	Seizure disorders, daytime sedation	• Oral • Short-acting (3–8 h)
Methohexital	Induction and maintenance of anesthesia	• IV • Ultra-short-acting (5–15 min)
Pentobarbital	Insomnia, preoperative and procedural sedation, emergency management of seizures	• Oral, IM, IV, or rectal • Administer Na^+ salt parenterally • Short-acting (3–8 h)
Phenobarbital	Seizure disorders, status epilepticus, daytime sedation	• Oral, IM, IV • First-line anticonvulsant (see Chapter 20); administer Na^+ salt parenterally • Long-acting (days)
Secobarbital	Insomnia, preoperative sedation	• Oral • Short-acting (3–8 h)
Thiopental	Induction and maintenance of anesthesia, preoperative sedation, emergency management of seizures, intracranial hypertension	• IV single dose provides brief period of anesthesia • Ultra-short-acting (5–15 min)

Chapter 23

Opioid Analgesics

Emily M. Jutkiewicz and John R. Traynor

Introduction to Opioids and Receptors

Pain is a common component of many clinical pathologies, and management of pain is a vital clinical need. Drugs such as *morphine* and *oxycodone* acting at opioid receptors remain the mainstay of pain treatment, despite the safety concerns associated with the long-term use of these drugs, which has led to addiction and death from their misuse and the worldwide opioid crisis. Morphine and related drugs exert their pharmacological effects by acting at opioid receptors. Opioid receptors are 7-transmembrane G protein-coupled receptors (GPCRs; see Chapter 3) and comprise a family of four types, the mu (μ), delta (δ), kappa (κ) opioid receptors, which we will refer to as the classical or canonical opioid receptors, and the nociceptin (NOP) receptor (NOPr), which has close structural homology to the classical opioid receptors but distinct ligands and pharmacology. In this chapter, we will use mu, delta, kappa, and NOPr to describe the receptors. The mu-opioid receptor is mainly responsible for the pain-relieving actions and, importantly, also the unwanted effects, of all clinically useful opioid analgesics, which generally mimic the pharmacology of morphine. Consequently, this chapter will focus mainly on this receptor and its ligands and their pharmacology, with some mention of the pharmacology of drugs acting at the delta, kappa, and NOPr receptors.

The original opioid drugs (*morphine* and *codeine*) are components of opium, the dried resin from the seed head of the opium poppy, *Papaver somniferum*. Opium also contains thebaine, which has no opioid activity but serves as a precursor for the synthesis of additional opioid drugs. Also present in opium are *papaverine* (1%), a smooth muscle relaxant, and *noscapine* (6%), which has been used as an antitussive. *Morphine*, *codeine*, and structurally related compounds found in opium, together with semisynthetic derivatives such as *oxycodone* that bind to the mu-opioid receptor, are termed opiates. In contrast, an opioid is any agent that binds to the ligand-binding (orthosteric) site of members of the opioid receptor family. Consequently, the term opioid is a broader definition and covers the opiates, fully synthetic drugs, such a *methadone* and *fentanyl*, and endogenous opioid peptides, including the enkephalins, endorphins, and dynorphins, which are the naturally occurring neurotransmitters acting at opioid receptors. Opioid drugs are often referred to as narcotic analgesics or narcotics, derived from the Greek word *narkotikos* for "benumbing" or "stupor," because of their sedative properties and ability to cause sleep in the presence of pain.

Opioid Receptors

Types of Opioid Receptors

The three types of classical opioid receptors, mu, delta, and kappa, share extensive sequence homology (55%–58%) and belong to the class A or rhodopsin family of GPCRs (see Figures 3–14 and 23–1). As such they

Abbreviations

AC: adenylyl cyclase
ACTH: corticotropin; formerly adrenocorticotropic hormone
ADH: antidiuretic hormone
COPD: chronic obstructive pulmonary disease
CSF: cerebrospinal fluid
CYP: cytochrome P450
DAMGO: [D-Ala^2,MePhe^4,Gly(ol)^5]enkephalin
EEG: electroencephalogram
FSH: follicle-stimulating hormone
GABA: γ-aminobutyric acid
GI: gastrointestinal
GPCR: G protein-coupled receptor
GRK: GPCR kinase
HPA: hypothalamic-pituitary-adrenal
5HT: serotonin
LH: luteinizing hormone
6-MAM: 6-monoacetylmorphine
MAO: monoamine oxidase
MAPK: mitogen-activated protein kinase
NE: norepinephrine
NMDA: *N*-methyl-D-aspartate
NOP: nociceptin/orphanin FQ (N/OFQ)
NOPr: NOP receptor
NSAID: nonsteroidal anti-inflammatory drug
PAG: periaqueductal gray
PCA: patient-controlled analgesia
PKC: protein kinase C
POMC: proopiomelanocortin
TM: transmembrane

transduce agonist responses into the cell via members of the $G_{i/o}$ and G_z families of heterotrimeric G proteins. NOPr was added to the opioid receptor family based on its close sequence homology (48%–49%). However, neither opioid drugs nor the enkephalins, endorphins, or dynorphin bind to this receptor, and agonists for the NOPr do not exhibit the same pharmacology as the opioids. A previous definition of opioid receptors required that they be sensitive to the specific opioid antagonist *naloxone*, but with the addition of the NOPr to this family, this is no longer the case. The opioid receptors appear early in vertebrate evolution (Stevens, 2009). The gene for the human mu-opioid receptor (*OPRM1*) has been mapped to chromosome 6, for the delta-opioid receptor (*OPRD1*) to chromosome 1, for the kappa-opioid receptor (*OPRK1*) to chromosome 8, and for the NOPr (*OPRL1*) to chromosome 20 (Dreborg et al., 2009).

Opioid Receptor Distribution

As defined by the distribution of receptor protein, message, ligand binding, and the pharmacological effects initiated by opioids, opioid receptors are widely distributed in the periphery and central nervous system (Mansour et al., 1988) and are found both pre- and/or postsynaptically.

Mu-opioid receptors are found in regions of the brain involved in the control of both the sensory and affective components of pain as well as modulation of many other behaviors. This includes both superficial and deeper layers of the neocortex, caudate-putamen, nucleus accumbens, ventral tegmental area, thalamus, hippocampus, amygdala, raphe nucleus, periaqueductal gray (PAG), medulla and pons, and dorsal horn of the spinal cord.

The distribution of *kappa-opioid receptors* is consistent with the roles of the kappa-opioid system in regulation of diuresis, food intake, pain perception, and neuroendocrine functioning, including response to stress. Major regions expressing kappa-opioid receptors are the caudate-putamen, nucleus accumbens, amygdala, hypothalamus, and pituitary. Kappa-opioid receptors are also found in the found in the PAG, raphe nuclei, pons and medulla, and dorsal horn of the spinal cord, but there is very little expression in the cortex.

Delta-opioid receptors are expressed in regions related to olfactory areas of the brain as well as the neocortex, caudate-putamen, nucleus accumbens, and amygdala. There are low levels in the dorsal horn of the spinal cord. The delta-opioid receptor is involved in modulation of pain and mood.

NOPr receptors are the most widely distributed of the opioid receptors. The receptor is found in most regions of the brain and spinal cord, in areas related to the physiological actions of this system in the modulation of pain and reward as well as anxiety and stress, memory, and feeding behaviors (Ozawa et al., 2015).

Opioid receptors are also present on a variety of nonneuronal cells, including macrophages (peripheral and central microglia) and astrocytes (Dannals, 2013; Yaksh, 1987) and in the enteric nervous system of the gastrointestinal (GI) tract (Galligan and Akbarali, 2014). Delta-opioid receptors in the heart may afford cardioprotection.

Opioid Receptor Signaling

Following agonist occupation of opioid receptors and subsequent activation of heterotrimeric G proteins, both the α subunits and βγ dimers bind to downstream proteins to provide a complex pattern of intracellular signals (Figure 23–2). Signaling is similar for all members of the opioid receptor family (Al-Hasani and Bruchas, 2011).

The a_i subunits directly inhibit the enzyme adenylyl cyclase (AC) to reduce levels of cyclic AMP and so inhibit the phosphorylation of many proteins that are controlled by protein kinase A–dependent regulation as well as cyclic AMP–dependent calcium influx. Chronic treatment with opioid agonists leads to a loss of responsiveness of AC and an "overshoot" of cycle AMP production when the opioid is removed. The βγ dimer inhibits voltage-gated Ca^{2+} channels on presynaptic terminals, leading to reduced Ca^{2+} influx and an inhibition of transmitter release (Weiss and Zamponi, 2021). For example, inhibition of γ-aminobutyric acid (GABA) release in the ventrolateral periaqueductal gray leads to activation of descending antinociceptive pathways and, in the ventral tegmental area, enhances dopamine release in the nucleus accumbens, an important component of the reward pathway. The βγ dimers also act to open K^+ channels, including G protein-coupled inwardly rectifying potassium (GIRK) channels, which leads to hyperpolarization and reduced neuronal firing. Both effects are important for analgesic actions of the opioid drugs. The release of βγ subunits also lead to activation of the mitogen-activated protein kinase (MAPK) cascades, a diverse family of kinases that modulate many cellular responses by phosphorylation, including cell differentiation, ion channel function, and scaffolding of intracellular proteins. Other enzymes such as protein kinase C (PKC) and phospholipase C can be activated by βγ subunits. An important role for βγ dimers is the recruitment of G protein receptor kinases (GRKs), specifically GRK2 and 3, to phosphorylate the receptor. This is an initial step in receptor desensitization and leads to the recruitment of β-arrestin necessary for receptor internalization prior to degradation or as a prerequisite for recycling of refreshed receptors to the cell membrane to receive another signal. The receptor can be phosphorylated by members of the GRK family that do not require recruitment by the βγ or by PKC. However, β-arrestin also functions to scaffold and activate MAPK pathways.

Opioid Receptor Ligands

Endogenous Opioid Peptides

There are three families of endogenous opioid peptides, the enkephalins, endorphins (principally β-endorphin), and dynorphins, which act at the classical opioid receptors. These peptides share the common amino-terminal sequence of Tyr-Gly-Gly-Phe-(Met or Leu), which may be followed by various C-terminal extensions (Table 23–1). Thus, Leu- and Met-enkephalin are simple pentapeptides, whereas extended forms of these, as well as the dynorphins, contain up to 17 amino acids, and the endorphins are up to 31 amino acid residues in length. There

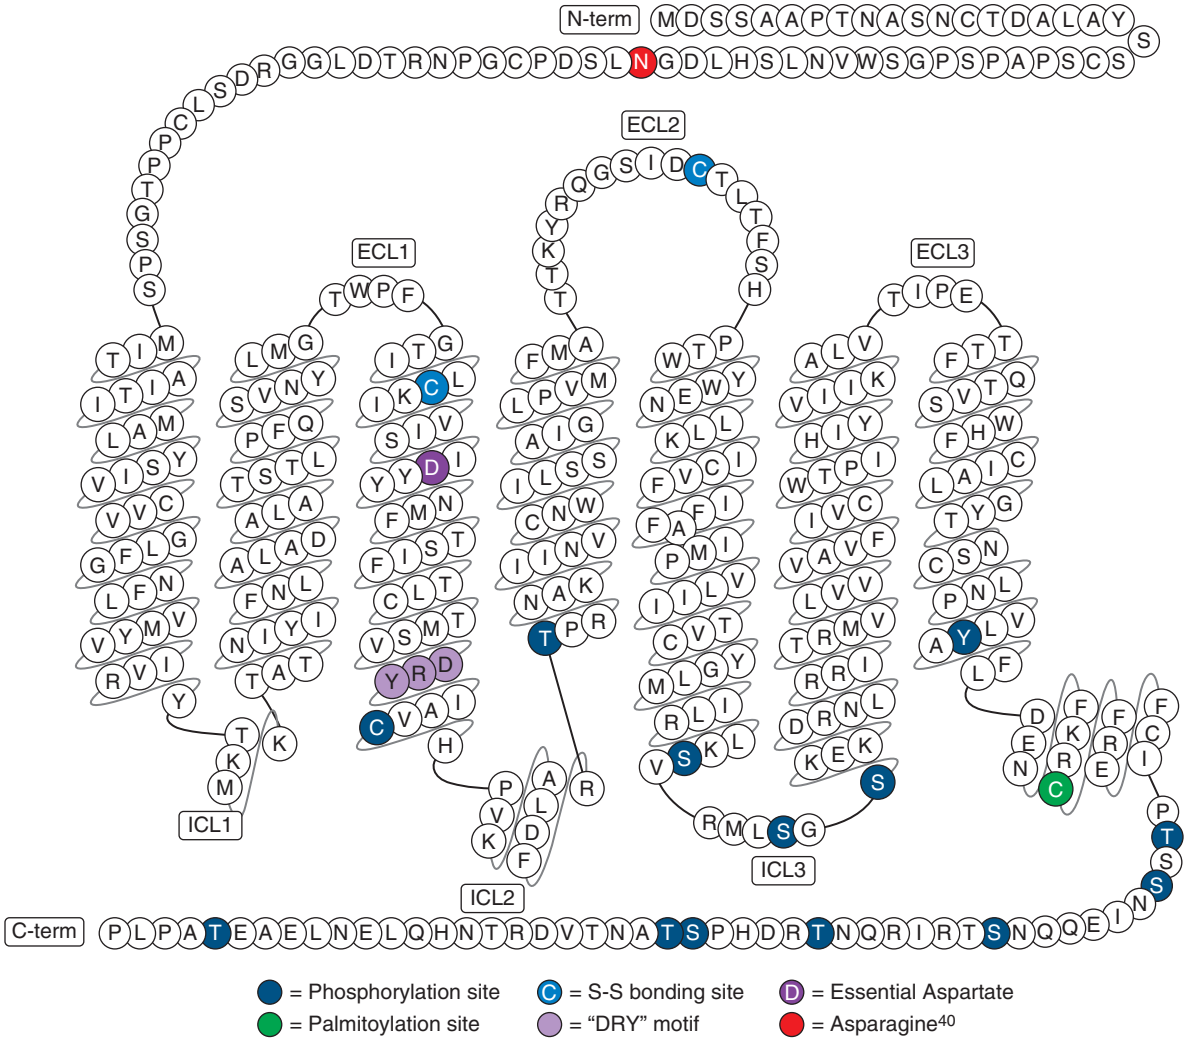

Figure 23–1 *General structure of an opioid receptor.* This diagram is of the mu-opioid receptor, but other opioid receptors have the same general structure and the typical characteristics of a G protein-coupled receptor (GPCR). Along the external amino terminus there are several aspartate (N) residues that are potential glycosylation sites. There are seven transmembrane (TM) regions joined by intracellular and extracellular loops (ICL and ECL, respectively), a long intracellular carboxy tail, and tyrosine (Y) and serine (S) phosphorylation sites in the areas where arrestins interact. There is a conserved aspartate (D) for binding to the tertiary N atom found in all opioid drugs and a disulfide linkage between two cysteine residues. The Na^+ binding site is in the TM bundle just below the orthosteric site.

is some specificity of the peptides for the different opioid receptors, but because of this structural similarity, there is a considerable degree of overlap. β-Endorphin is mu-opioid receptor preferring, and the dynorphins are considered the endogenous ligands for the kappa-opioid receptor. The simpler enkephalins are less selective for delta > mu receptors but do not bind to or activate the kappa-opioid receptor. None of these ligands bind to NOPr. Nociceptin (a 17-amino acid peptide), also known as orphanin F/Q or N/OFQ, which has an N-terminal amino acid sequence of Phe-Gly-Gly-Phe, is the endogenous ligand for NOPr, and has no activity at the classical opioid receptors (Lambert, 2008). The endomorphins are two opioid peptides with high affinity and selectivity for the mu-opioid receptor. Although originally discovered in mammalian brain tissues, the precursor peptides for these have never been identified, and the origin of the endomorphins remains unknown. It is therefore up for debate as to whether these are truly endogenous opioids. In total, there are more than 20 opioid peptides acting at the four opioid receptors.

The opioid peptides are derived from their large precursor proteins by complex cleavage with distinct trypsin-like enzymes (Figure 23–3). Preproopiomelanocortin (pre-POMC) provides POMC, which contains the sequence for β-endorphin. In addition, the POMC sequence is also processed into a variety of nonopioid peptides, including adrencorticotropin (ACTH), α-melanocyte-stimulating hormone, and β-lipotropin. Although β-endorphin contains the sequence for Met-enkephalin at its amino terminus, it is not converted to this peptide. Preproenkephalin contains the sequences for one copy of Leu-enkephalin and four copies of Met-enkephalin. Preprodynorphin contains three dynorphin peptides of differing lengths that all begin with the Leu-enkephalin sequence: dynorphin A, dynorphin B, and neoendorphin. Prepronociceptin contains the sequence of the 17-amino acid peptide nociceptin (also known as orphanin FQ or N/OFQ).

Not all cells that express a given opioid prohormone precursor store and release the same mixture of opioid peptides. This results from differential posttranslational processing of the prohormones into peptides of different lengths or even breakdown of larger opioid peptides into smaller fragments; for example, dynorphins contain the Leu-enkephalin sequence. Moreover, processing can be altered in response to physiological demands, leading to the release of a different mix of posttranslationally derived peptides.

Opioid peptides are present in areas of the central nervous system (CNS) related to the processing of pain information (e.g., spinal cord dorsal horn, the spinal trigeminal nucleus, and the PAG), to the modulation of affective behavior (e.g., amygdala, hippocampus, locus coeruleus, and frontal cerebral cortex), to the modulation of motor control (e.g., caudate nucleus and globus pallidus), to the regulation of the autonomic nervous system (e.g., medulla), and to neuroendocrinological functions (e.g., median eminence). Opioid peptides are found in the plasma, and this reflects release from secretory systems such as the pituitary, adrenals, and exocrine glands of the stomach and intestine.

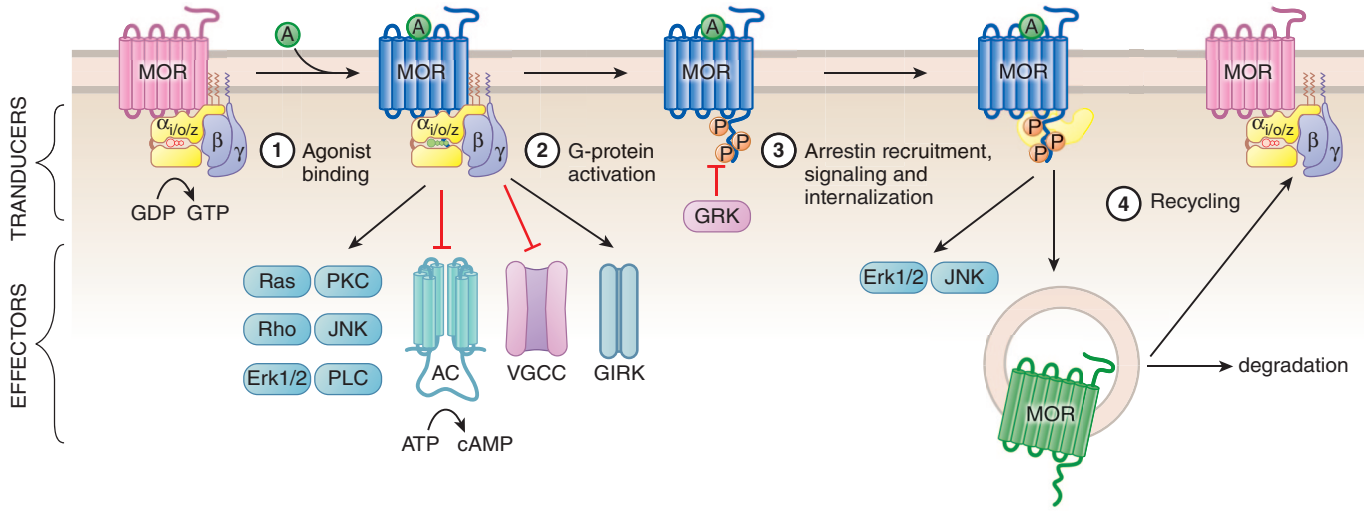

Figure 23–2 *Simplified scheme of opioid receptor signaling.* In the presence of an opioid agonist (green circle), inactive receptor (red, Ri) is converted to active receptor (blue, Ra) (Step 1). This causes the α subunit of the G protein heterotrimer to exchange GDP for GTP which leads to dissociation of the α and βγ subunits that go on to modulate various downstream effectors, including kinases (e.g., PKC, ERK, and JNK [c-Jun N-terminal kinase]), small GTPases (Ras and Rho), phospholipase C (PLC), ion channels (voltage-gated calcium channels [VGCC] and G protein-coupled K^+ channels [GIRKs]), enzymes, and their secondary messengers (step 2). Signaling is terminated by phosphorylation of the receptor by G protein receptor kinases (GRK), followed by arrestin recruitment, and internalization (step 3). In addition, arrestins can scaffold signaling pathways. Finally, internalized receptor (green) is targeted for either degradation or recycling to the plasma membrane (step 4). MOR, mu-opioid receptor.

Exogenous Opioid Receptor Ligands

Opioid receptor ligands are defined by their selectivity (or otherwise) for a particular opioid receptor and their functional properties as agonists, partial agonists, antagonists, biased agonists, or allosteric modulators, as defined below.

Agonists. Agonists bind to the orthosteric site to activate the receptors, leading to modulation of a wide variety of cell signaling cascades and resultant effects on physiology. Since clinically used drugs may have varying degrees of activity at other opioid receptors, highly selective agonists have been developed. For the classical opioid receptors, these are derivatives of the endogenous opioid peptides, DAMGO and DPDPE, for mu- and delta-opioid receptors, respectively, and dynorphin itself for the kappa-opioid receptor (see Table 23–1). Selective small-molecule agonists are also useful as tools for preclinical *in vivo* research. These include *morphine* for mu-, SNC80 for delta-, and U69593 and its derivatives for kappa-opioid receptors. Nociceptin itself and the small-molecule Ro64-6198 are used as selective agonists for the NOPr (Figure 23–4).

Partial Agonists. Partial agonists also bind to the orthosteric site of receptors but are not capable of eliciting the same level of response as seen with full agonists, even with escalating doses (i.e., these drugs have reduced level of efficacy or "ceiling" to the magnitude of their action). However, this definition is system dependent. For example, in preclinical pain models in rodents where the nociceptive insult can be varied in intensity, even *morphine* can be observed to be a partial agonist, compared to, for example, *fentanyl*. Similarly, *buprenorphine* acts as partial agonist at the mu-opioid receptor in preclinical models, but in the pain clinic, it is effective in managing postoperative pain. However, the partial agonist nature of *buprenorphine* does mean it has a ceiling effect and so inhibits respiration (a dangerous side effect of opioid full agonists) to a lesser extent than *morphine* or *oxycodone* and thus may be a safer alternative. Partial agonists used in the clinic are not selective for specific opioid receptors. For example, *buprenorphine* acts at all opioid receptors, including weak agonist activity at NOPr, and *pentazocine* is a partial agonist at both mu- and kappa-opioid receptors. Partial agonists are sometimes termed *agonist-antagonists* because they have agonist actions but also antagonize the effects of opioid agonists that have higher efficacy, such as hydromorphone. As such, partial agonists can precipitate withdrawal in opioid-dependent patients.

Antagonists. These drugs are competitive antagonists and prevent the binding of opioids to the orthosteric site on opioid receptors. They have no activity themselves, but their pharmacology derives solely from blocking the actions of opioid agonists. Commonly used opioid antagonists are *naloxone* and *naltrexone*. These compounds bind to all classical opioid receptors with similar affinity, although as mentioned above, they do not bind to the NOPr.

Antagonists for specific opioid receptors have been developed for research purposes. These include peptides, such as the somatostatin analogue CTOP (D-Phe-Cys-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH_2) as a mu-opioid receptor antagonist and a derivative of enkephalin (ICI-174864) as a selective delta-opioid receptor antagonist. In addition, chemical manipulation of *naltrexone* and its derivatives has given rise to the selective mu-opioid receptor antagonist *cyprodime*, the selective delta-opioid receptor antagonist *naltrindole*, and the selective kappa-opioid receptor antagonist nor-BNI (see Figure 23–4). JD-Tic is also a commonly used and highly selective antagonist at the kappa-opioid receptor.

Inverse Agonists. The opioid receptors, like other membrane-bound GPCRs, are not static structures but continually move through a series of conformations, including conformations that are able to activate intracellular signaling pathways. This gives the receptors a basal level of activity, in the absence of an agonist, and the receptors are said to be *constitutively active*. Inverse agonists are compounds that stabilize receptors in inactive conformations and so inhibit constitutive activity (see Chapter 3). Of the opioid receptors, the delta-opioid receptor shows high constitutive activity in cellular models. The selective delta-opioid receptor antagonist ICI-174864 also inhibits constitutive activity of the receptor and therefore is more accurately defined as an inverse agonist.

Biased Agonists. Intracellular signaling downstream of opioid receptors is highly complex (see Figure 23–2). Most agonists activate all of these downstream pathways equally. However, biased agonists are compounds that preferentially activate a particular pathway or pathways over other pathways. The most observed bias is between agonists that activate pathways downstream of G proteins as opposed to those downstream of β-arrestin. This became a hot area of research in opioid pharmacology following preclinical experiments that showed β-arrestin pathways might be responsible for certain unwanted effects of opioid agonists, particularly constipation and respiratory depression, while G protein pathways

were important for the analgesic effects. Although more recent studies have not supported this concept (Gillis et al., 2020), the idea that selective pharmacology could be gained in this way remains attractive. One compound designated as a G protein-biased agonist, namely *oliceridine*, has received approval for intravenous use in hospital settings in situations where other medications do not work, although the safety profile of *oliceridine* is no better than *morphine*.

Allosteric Modulators. These are compounds that act at opioid receptors but at a site distinct from the orthosteric site. Positive allosteric modulators quantitatively alter the action of opioids occupying the orthosteric binding site. As such, they can promote the activity of endogenous opioid peptides to provide antinociception and so may have the potential to provide analgesia without the side effects associated with traditional opioid agonists. Negative allosteric modulators inhibit the actions of opioid agonists but unlike *naloxone* and *naltrexone* are not competitive. Thus far, positive and negative allosteric modulators are only in the early preclinical stages of investigation (Livingston and Traynor, 2018).

Opioid Receptor Structure and Activation

The opioid receptors belong to the family of class A GPCRs (see Chapter 3) and comprise an extracellular N-terminus, seven transmembrane (TM) alpha-helical structures joined by two extracellular loops and three intracellular loops and an intracellular C-terminal domain (see Figure 23–1). Two conserved cysteine residues in the first and second extracellular loops form a disulfide bridge to stabilize ECL2. The extracellular loops are also N-glycosylated, which regulates export of newly synthesized receptors to the cell surface as well as internalization and degradation. These loops may also occlude access of ligands to the orthosteric binding site, thus altering ligand affinity. A short proximal section of the C-terminus is attached to the membrane by a palmitoyl group and forms an additional small alpha-helix. The intracellular loops and C-terminus interact with signaling partners within the cell membrane and inside the cell, in particular G proteins and β-arrestins, and also serve as substrates for phosphorylation by GRKs and other kinases, which is an important component of signal termination.

The structure of all four opioid receptor types has been solved using either X-ray crystallographic or single-particle cryogenic electron microscopy methods, although less information is available about the loops and C-terminus because of the flexibility of these regions. The amino acid residues making up the TM domains, which contain the orthosteric binding site, are similar across all of the receptors, although NOPr is more distant from the classical opioid receptors. The opioid receptor agonists and endogenous opioid peptides bind similarly in the orthosteric site of opioid receptors. For example, at the mu-opioid receptor the nitrogen atom and phenolic OH in morphine-like molecules or in the Tyr moiety of the endogenous opioid peptides, form a salt bridge with a negatively charged aspartate residue in TM3 that is conserved across GPCRs, and a water-mediated interaction with a histidine in TM6, respectively. These same residues are involved with ligands binding to the delta- and kappa-opioid receptors. Synthetic opioids that are not based on the enkephalin or morphine structure, for example, *methadone* and *fentanyl*, bind in the same orthosteric site but with different interactions between the ligand and the receptors. In addition, the larger endogenous peptides extend out of the orthosteric pocket toward the extracellular domains; these additional interactions determine the selectivity of the peptides. For example, the kappa-opioid receptor selective peptide dynorphin has several basic arginine residues that interact with negatively charged residues on the N-terminus of the kappa receptor but are absent on the N-terminus of the other opioid receptors.

Opioid receptors, like all GPCRs, are flexible proteins that exist in multiple conformational states, but in the simplest model, there is an inactive ensemble of conformations (R) and an ensemble of active conformations (R*). The inactive conformations, which do not activate intracellular partners, such as heterotrimer G proteins, are stabilized by the presence of an Na^+ ion, which forms a network with amino acids deep in TM domains beneath the orthosteric site, and a "DRY" motif (Asp [or Glu]-Arg-Tyr) at the junction of TM3 and ICL2, which forms an "ionic lock," and holds the receptor in an inactive conformation. Active receptor (R*) ensembles are formed in the presence of agonist and intracellular binding partner through changes in several conserved "molecular switch" regions, including opening of the DRY-mediated ionic lock as well as collapse of the Na^+ binding site. These changes lead to an outward movement of TM6 relative to other TM domains. This opens a binding site for the C-terminus of the G_α subunit of the heterotrimeric G protein, leading to activation of the G protein. The G protein and orthosteric binding sites are allosterically linked. Thus, agonist binding increases G protein affinity and G protein binding increases agonist affinity. Most of this mechanism has been determined through experiments with the β_2 adrenergic receptor but applies equally well to opioid receptors (Weis and Kobilka, 2018).

Opioid Receptor Variants and Receptor Complexes

There is growing evidence for increasing complexity of opioid receptor function. For example, there are several nonsynonymous variants of the mu-opioid receptor found in the human population (Ravindranathan et al., 2009). Of these, the single polynucleotide polymorphism in the gene of the opioid receptor (*OPRM1*) A118G, giving a receptor in which

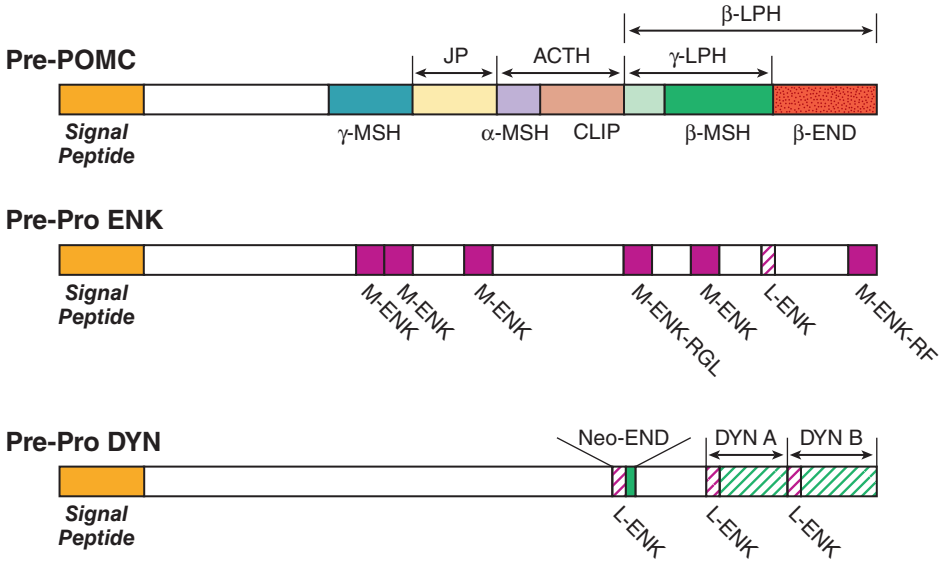

Figure 23–3 *Opioid peptide precursors.* Opioid peptides derive from precursor proteins that may also contain nonopioid peptides. *Pre-POMC* is a good example. Proteolytic processing of a pre-pro form by a signal peptidase removes the signal peptide; then, various prohormone convertases (endoproteases) attack at dibasic sequences, yielding α-, β-, and γ-melanocyte-stimulating hormone (MSH), ACTH, corticotropin-like intermediate lobe peptide (CLIP), β- and γ-lipotropin (LPH), and β-endorphin (β-END). In a similar manner, *pre-pro enkephalin (ENK)* yields Leu-enkephalin (L-ENK) and Met-enkephalin (M-ENK) and two extended derivatives, M-ENK-Arg-Gly-Leu and M-ENK-Arg-Phe. *Pre-pro dynorphin (DYN)* yields α neoendorphin (α-NEO) and dynorphin A and B (DYN A and DYN B), each of which contains the Leu-enkephalin sequence (Tyr-Gly-Gly-Phe-Leu) at its amino terminus. JP, joining peptide. *Pre-pronociceptin* (not shown) contains one copy of nociceptin peptide. For details of the proteolytic processing of POMC, see Figure 50–1.

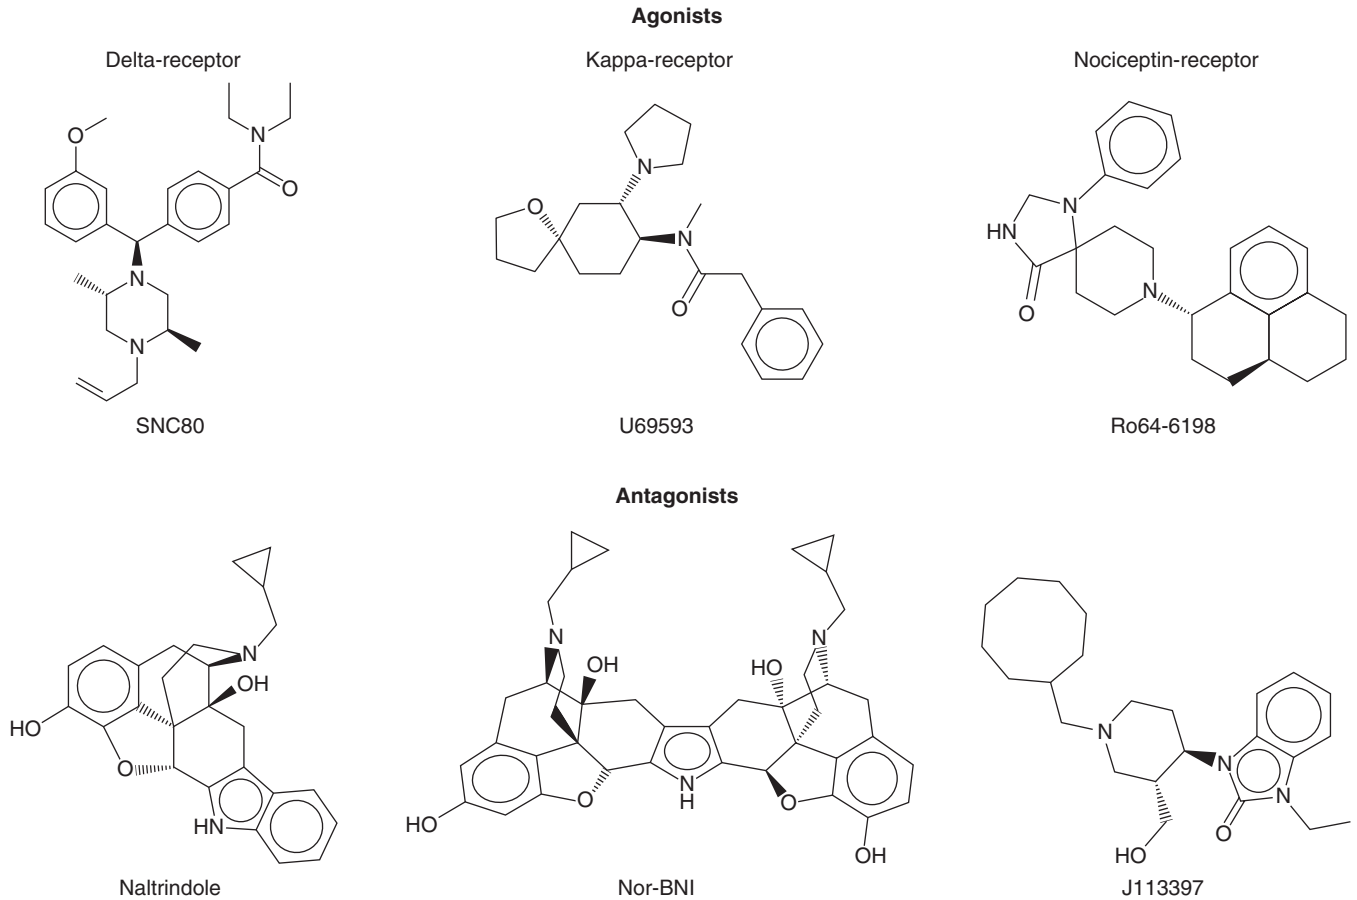

Figure 23–4 *Examples of compounds acting at kappa, delta, and nociceptin receptor.*

BOX 23–1 ■ Pharmacology of Kappa-, Delta-, and NOP-Receptor Agonists

Kappa-opioid receptor agonists have analgesic effects (e.g., *butorphanol*, *pentazocine*) but are not typically employed for long-term analgesic therapy because they can produce dysphoric and psychotomimetic effects. Agonists acting at the kappa-opioid receptor inhibit the release of oxytocin and antidiuretic hormone and cause prominent diuresis. Some kappa-opioid receptor agonists, such as salvinorin A from *Salvia divinorum*, are used recreationally and have hallucinogenic effects in humans. There is evidence that kappa-opioid receptor antagonists may have antidepressant effects in depressed patients (Jacobson et al., 2020).

Agonists at delta-opioid receptors have antinociceptive effects in animal models of neuropathic and chronic pain but have not yet found clinical utility because of preclinical and clinical evidence of proconvulsant activity. Delta-opioid receptor agonists also have antidepressant-like, anxiolytic effects and anti-parkinsonian effects in preclinical models (Dripps and Jutkiewicz, 2018).

NOPr agonists can be pro- or anti-analgesic depending on their site of action and the animal species. NOPr agonists, unlike mu-opioid receptor agonists, are not rewarding and do not cause respiratory depression, so compounds with activity at both mu-opioid receptors and NOPrs are being investigated as potentially safer analgesics. The system has been implicated in regulation of body weight and stress-related mood disorders. Molecules targeting NOPr may find use in the management of anxiety and/or depression and substance abuse (Witkin et al., 2014).

Some selective agonists and antagonists for these receptors are shown in Figure 23–4.

asparagine in position 40 of the N-terminus (Fig 23–1) is replaced by aspartate, has received the most attention. This single nucleotide polymorphism is found in approximately 40% of Asian populations, 16% of Europeans, and 3% of African Americans (Zerbino et al., 2018) and has been linked to dependence on opioids and other drugs of abuse (Halikere et al., 2020).

Many splice variants of the mu-opioid receptor have been reported and may show a differential pharmacology, although the roles and level of expression of these are not well known (Gretton and Droney, 2014). In addition, opioid receptors can form receptor complexes with themselves (homomers) or with other opioid receptors or indeed many other GPCRs, giving receptor complexes with the potential for a very diverse pharmacology (Fujita et al., 2014). These aspects have potential clinical significance since drugs targeting splice variants or complex receptor heteromers could have safer pharmacological profiles. Although the basis of much research, no clinical candidates targeting these entities have yet emerged.

Pharmacology of Clinically Employed Opioid Drugs

Clinically used opioid agonists are generally selective for mu-opioid receptors and produce their therapeutic and adverse effects through activation of these receptors. Even so, the drugs have a highly complex pharmacology. The exact nature of observed physiological responses induced by opioid agonists is due to the wide distribution of mu-opioid receptors across the CNS and in the periphery, their degree of efficacy (e.g., whether they are full or partial agonists), and the level of selectivity of each drug for mu-opioid over other opioid receptors or, indeed, other targets. Opioid drugs are relatively receptor selective at lower doses but may interact with additional receptor types when given at high doses, especially as doses are escalated to overcome tolerance. Mu-opioid receptor agonists produce analgesia, affect mood and rewarding behavior, and alter respiratory, cardiovascular, GI, and neuroendocrine function. The pharmacology of the non-mu-opioid receptor systems is briefly highlighted in Box 23–1.

Pharmacology of the Prototypical Mu-Opioid Agonist Morphine

Analgesia

Opioid drugs acting at the mu-opioid receptor, as exemplified by *morphine*, are used to treat different types of pain (Box 23–2). When therapeutic doses of *morphine* are administered, patients report their pain to be less intense or entirely absent. Patients often report pain is still present, but they feel less discomfort. In addition to relief of distress, some patients may experience euphoria. Analgesia can be readily achieved without loss of consciousness, although drowsiness commonly occurs. *Morphine* at

BOX 23–2 ■ Pain States and Mechanisms

Meaningful discussion of the action of analgesic agents must recognize that all pain is not the same and that a number of variables contribute to a patient's pain reporting and therefore to the effect of the analgesic. Heuristically, one may think of pain as several distinct sets of events (Yaksh et al., 2015).

Acute Nociception

Acute activation of small, high-threshold sensory afferents (Aδ and C fibers) generates transient, stimulus-dependent inputs into the spinal cord, which in turn leads to activation of dorsal horn neurons that project contralaterally to the thalamus and thence to the somatosensory cortex. A parallel spinofugal projection runs through the medial thalamus and thence to portions of the limbic cortex, such as the anterior cingulate. The output produced by acutely activating these ascending systems is sufficient to evoke pain reports. Examples of such stimuli include a hot coffee cup, a needlestick, or an incision.

Tissue Injury

Following tissue injury or local inflammation (e.g., local skin burn, toothache, rheumatoid joint), an ongoing pain state arises that is characterized by burning, throbbing, or aching and an abnormal pain response termed *hyperalgesia*, which can be evoked by otherwise innocuous or mildly aversive stimuli (tepid bathwater on a sunburn; moderate extension of an injured joint). This pain typically reflects the effects of active factors such as prostaglandins, bradykinin, cytokines, serine proteases, and H^+ ions, among many mediators. Such mediators are released locally into the injury site and have the capacity, through eponymous receptors on the terminals of small, high-threshold afferents (Aδ and C fibers), to activate these sensory afferents and to reduce the stimulus intensity required for their activation (e.g., peripheral sensitization). In addition, the ongoing afferent traffic initiated by the tissue injury and inflammation leads to activation of spinal facilitatory cascades, yielding a greater output to the brain for any given afferent input. This facilitation is thought to underlie hyperalgesic states, for example, central sensitization. Such tissue injury/inflammation-evoked pain is often referred to as *nociceptive* pain (Figure 23–5) (Sorkin and Wallace, 1999). Examples of such states would be burn, postincision pain, abrasion of the skin, musculoskeletal injury, or inflammation of the joint.

Nerve Injury

Injury to a peripheral nerve yields complex anatomical and biochemical changes in the nerve and spinal cord that induce *spontaneous dysesthesias* (shooting, burning pain) and *allodynia*

(hurt from a light touch). Nerve injury pain state may not depend on the activation of small afferents but may be initiated by low-threshold sensory afferents (e.g., Aβ fibers). Such nerve injuries result in the development of ectopic activity arising from neuromas formed by nerve injury and the dorsal root ganglia of the injured axons as well as changes in dorsal horn sensory processing. Such changes include activation of nonneuronal (glial) cells and loss of constitutive inhibitory circuits, such that low-threshold afferent input carried by Aβ fibers evokes a pain state (West et al., 2015). Examples of such nerve injury–inducing events include mononeuropathies secondary to nerve trauma or compression (carpal tunnel syndrome) and the postherpetic state (shingles). Polyneuropathies such as those occurring in diabetes or after chemotherapy (as for cancer) can also lead to ongoing dysesthesias and evoked hyperpathias. These pain states are said to be *neuropathic* (Figure 23–6). Many clinical pain syndromes, such as found in cancer, typically represent a combination of these inflammatory and neuropathic mechanisms.

Neuropathic pain is typically considered to respond less well to opioid analgesics than acute pain, and higher doses are required. There is a growing perception that, in the face of chronic tissue injury or inflammation (e.g., arthritis), there can be a transition from an inflammatory to a neuropathic pain phenotype.

Sensory Versus Affective Dimensions of Pain

Information generated by a high-intensity peripheral stimulus initiates activity in pathways activating higher-order systems that reflect the aversive magnitude of the stimulus. Painful stimuli have the certain ability to generate strong emotional components that reflect a distinction between pain as a specific sensation subserved by distinct neurophysiological structures (the *sensory discriminative* dimension) and pain such as suffering (the original sensation plus the reactions evoked by the sensation: the *affective motivational* dimension of the pain experience) (Melzack and Casey, 1968). Opioid drugs have potent effects on both components of the pain experience.

analgesic doses does not have anticonvulsant activity and usually does not cause slurred speech, emotional lability, or significant impairment of motor coordination. Lower doses of *morphine* can produce reductions in the affective response to pain but not the perceived intensity of the pain experience; higher, clinically effective doses reduce both perceived intensity and affective responses to the pain (Price et al., 1985).

The relief of pain by morphine-like opioid agonists is relatively selective in that other senses are generally not affected, including light touch and proprioception. Continuous dull pain (as generated by tissue injury and inflammation) is relieved more effectively than sharp intermittent pain, such as that associated with the movement of an inflamed joint. With sufficient amounts of opioid agonist, it is possible to relieve even the severe piercing pain associated with, for example, acute renal or biliary colic, although opioids can induce spasm in the sphincter of Oddi and may exacerbate the pain (see section on the GI tract, below).

When an analgesic dose of *morphine* is administered to normal, pain-free individuals, the experience may be unpleasant, and nausea and vomiting are common. Individuals may experience drowsiness, difficulty in mentation, apathy, and lessened physical activity. As the dose is increased, the subjective, analgesic, and toxic effects, including respiratory depression, become more pronounced.

The analgesic actions of opioid drugs are mediated by actions in the brain, spinal cord, and in some instances the periphery. These are summarized in Figure 23–7.

Supraspinal Actions. Direct microinjections of *morphine* into specific brain regions can produce potent analgesia that is reversible by the mu-opioid receptor antagonists, such a *naloxone*. The best characterized of these sites is the mesencephalic PAG region. *Morphine* and other mu-opioid receptor agonists inhibit release of the inhibitory transmitter GABA from tonically active PAG systems that regulate activity in projections to the medulla. PAG projections to the medulla activate medullospinal release of norepinephrine (NE) and serotonin (5HT) at the level of the spinal dorsal horn, which attenuate dorsal horn excitability (Yaksh, 1997).

Spinal Action. Opioid drugs delivered spinally (intrathecally or epidurally) induce powerful analgesia that is reversed by low doses of systemic *naloxone* (Yaksh, 1997). Mu-opioid receptors are largely limited to the *substantia gelatinosa* of the superficial dorsal horn, the region in which small, high-threshold sensory afferents terminate. A significant proportion of mu-opioid receptors are associated with small peptidergic primary afferent C fibers; the remainder are on local dorsal horn neurons. Mu-opioid receptor agonists act presynaptically on small, high-threshold primary afferents to *inhibit the opening of voltage-sensitive Ca^{2+} channels*,

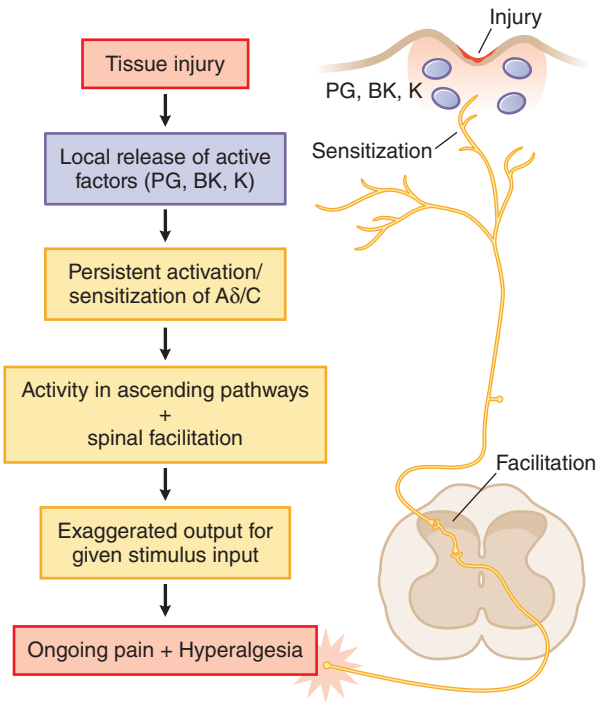

Figure 23–5 *Mechanisms of tissue injury–evoked nociception.* BK, bradykinin; K, potassium; PG, prostaglandins.

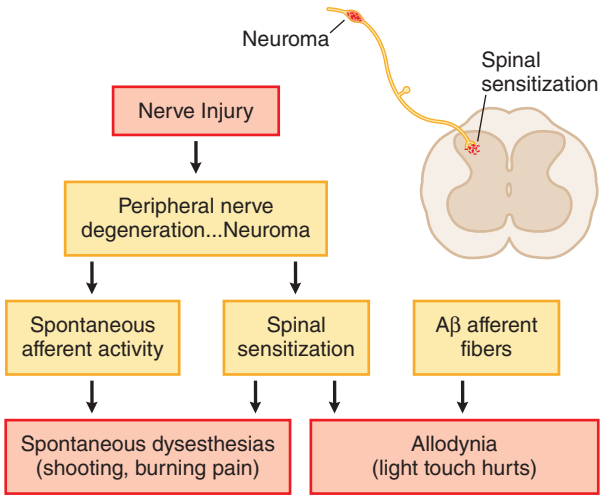

Figure 23–6 *Mechanisms of nerve injury–evoked nociception.*

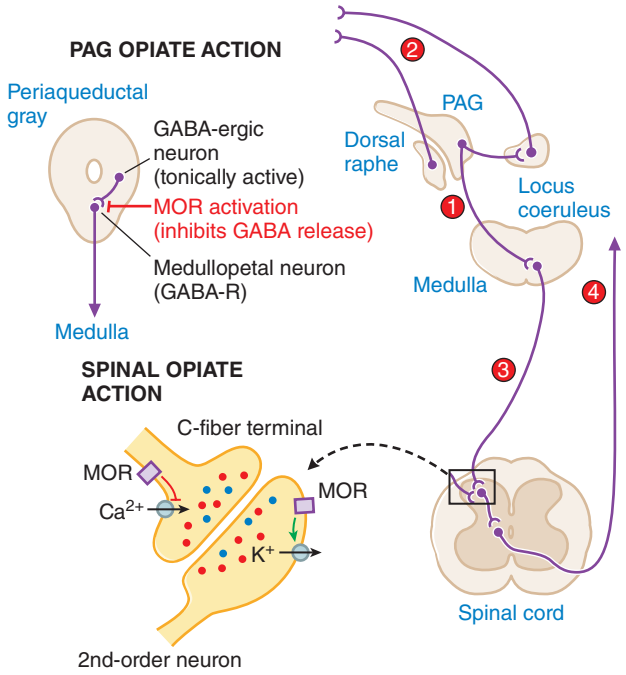

Figure 23–7 *Mechanisms of opioid action in producing analgesia.* **Top left:** Schematic of organization of opiate action in the periaqueductal gray area (PAG). **Top right:** Opioid-sensitive pathways in the PAG. Opioid actions via the mu-opioid receptor block the release of GABA from tonically active systems that otherwise regulate the projections to the medulla (1), leading to an activation of PAG outflow that results in activation of forebrain (2) and spinal (3) monoamine receptors that regulate spinal cord projections (4), which provide sensory input to higher centers and mood. **Bottom left:** Schematic of primary afferent synapse with second-order dorsal horn spinal neuron, showing pre- and postsynaptic opiate receptors coupled to Ca^{2+} and K^+ channels, respectively. Opioid receptor binding is highly expressed in the superficial spinal dorsal horn (substantia gelatinosa). These receptors are located presynaptically on the terminals of small primary afferents (C fibers) and postsynaptically on second-order neurons. Presynaptically, activation of mu-opioid receptors blocks the opening of the voltage-sensitive Ca^{2+} channel, which otherwise initiates transmitter release. Postsynaptically, mu-receptor activation enhances opening of K^+ channels, leading to hyperpolarization. Thus, an opioid agonist acting at these sites jointly serves to attenuate the afferent-evoked excitation of the second-order neuron.

thereby preventing transmitter release. A postsynaptic action is demonstrated by the ability of opioid analgesics to block excitation of dorsal horn neurons evoked by glutamate, partly by *hyperpolarizing the neurons through the activation of K^+ channels*, making them less likely to fire. Morphine selectively depresses the discharge of spinal dorsal horn neurons evoked by small (high-threshold) but not large (low-threshold) afferent nerve fibers. Overall, the capacity of spinal opioids to reduce the release of excitatory neurotransmitters from C fibers and to decrease the excitability of dorsal horn neurons accounts for the powerful and selective effect of the drugs on spinal nociceptive processing.

Peripheral Action. Direct application of high concentrations of opioid analgesics to a peripheral nerve can produce a local anesthetic-like action that is not reversed by *naloxone*. Conversely, at peripheral sites under conditions of inflammation where there is an increased terminal sensitivity leading to an exaggerated pain response (e.g., hyperalgesia), direct injection of opioids produces a local action that can exert a normalizing effect on the exaggerated thresholds. The effects may be on peripheral afferent terminals or on inflammatory cells that release products that sensitize the nerve terminal, or both (Stein and Machelska, 2011).

Opioid-Induced Hyperalgesia

A paradoxical increase in pain state can be observed following acute (hours to days) or chronic opioid drug exposure. This increase may be reflected by unexplained increases in pain reports, increased levels of pain with increasing drug dosages, or a diffuse sensitivity unassociated with the original pain (Lee et al., 2011). The mechanisms of this increased pain profile are not understood, although evidence suggests that inflammatory responses may be involved through Toll-like receptor 4 activation on microglia, upregulation of proinflammatory cytokines, chemokines, cyclooxygenase, and prostaglandin E_2, and other neuropeptides, such as cholecystokinin, neuropeptide FF, and nociceptin (Mercadante et al., 2019).

Respiratory Effects

Although effects of mu-opioid receptor agonists on respiration are readily demonstrated in preclinical models, significant respiratory depression rarely occurs in the clinic with standard analgesic doses, unless there are mitigating factors where opioid drugs should be used with caution, for example, in patients with asthma, chronic obstructive pulmonary disease (COPD), pulmonary hypertension, decreased respiratory reserve, preexisting respiratory depression, hypoxia, or hypercapnia. Moreover, it should be stressed that *respiratory depression is the primary cause of deaths in opioid overdose in individuals who misuse and abuse opioids.*

Mu-opioid receptor agonists depress all phases of respiratory activity, including rate, minute volume, and tidal exchange, and produce irregular and aperiodic breathing. The diminished respiratory volume is due primarily to a slower rate of breathing, which after ingestion of toxic amounts of opioids, may fall to three to four breaths per minute. Morphine-like opioid agonists depress respiration through several mechanisms involving mu-opioid receptors. Respiratory rate and tidal volume depend on intrinsic rhythm generators located in the ventrolateral medulla. These systems generate a "respiratory rhythm" that is driven by afferent input reflecting the partial pressure of arterial O_2 as measured by chemosensors in the carotid and aortic bodies and CO_2 as measured by chemosensors in the brainstem. Morphine-like opioid agonists reduce respiration in part by a direct depressant effect on rhythm generation, with changes in respiratory pattern and rate observed at lower doses than changes in tidal volume. A key factor is the depression of the ventilatory response to increased CO_2. This effect is mediated by depression of the excitability of brainstem chemosensory neurons. Also, opioids will depress ventilation otherwise driven by hypoxia through an effect on carotid and aortic body chemosensors. Importantly, hypoxic stimulation of chemoreceptors may still be effective when opioids have decreased the responsiveness to CO_2, and inhalation of O_2 may remove the residual drive resulting from the elevated PO_2 and produce apnea (Pattinson, 2008). In addition to the effect on respiratory rhythm and chemosensitivity, mu-opioid receptor agonists can have mechanical effects on airway function by increasing chest wall rigidity and diminishing upper airway patency (Lalley, 2008).

Studies comparing *morphine* and morphine-like opioids with respect to the ratio of analgesic versus respiratory-depressant activity have found that when equianalgesic doses are used, there is no significant difference. Maximal respiratory depression occurs within 5 to 10 min of intravenous administration of *morphine* or within 30 to 90 min of intramuscular or subcutaneous administration. Maximal respiratory-depressant effects occur more rapidly with more lipid-soluble agents. After therapeutic doses, respiratory minute volume may be reduced for as long as 4 to 5 h. Agents that have persistent kinetics, such as *methadone*, must be carefully monitored, particularly after dose incrementation. Respiratory depression produced by any mu-opioid receptor agonist can be reversed with an opioid antagonist. It is important to remember that most opioid antagonists have a relatively short duration of action as compared with agonists such as *morphine* or *methadone*, and fatal "re-narcotization" can occur if vigilance is not exercised and if more antagonist is not added as needed.

Factors Exacerbating Opioid-Induced Respiratory Depression. Several factors can increase the risk of opioid-related respiratory depression even at therapeutic doses. These include the following:

Other Medications. The combination of opioid drugs with other depressant medications, such as general anesthetics, tranquilizers, alcohol, or sedative-hypnotics produces additive depression of respiratory activity.

Sleep. Natural sleep produces a decrease in the sensitivity of the medullary center to CO_2, and the depressant effects of *morphine* and sleep are at least additive. Obstructive sleep apnea is a risk factor for increasing the likelihood of fatal respiratory depression.

Age. Newborns can show significant respiratory depression and desaturation; this may be evident in lower Apgar scores if opioids are administered parenterally to women within 2 to 4 h of delivery because of transplacental passage of opioids. Elderly patients are at greater risk of depression because of reduced lung elasticity, chest wall stiffening, and decreased vital capacity.

Disease. Opioids may cause a greater depressant action in patients with chronic cardiopulmonary or renal diseases because they can manifest a desensitization of their response to increased CO_2.

COPD. Enhanced respiratory depression can be noted in patients with COPD and sleep apnea secondary to diminished hypoxic drive.

Pain Relief. Because pain stimulates respiration, removal of the painful condition (as with the analgesia resulting from the therapeutic use of the opioid) will reduce the ventilatory drive and lead to apparent respiratory depression.

Although respiratory depression is not considered to be a favorable therapeutic effect of opioids, their ability to suppress respiratory drive is used as therapeutic advantage to treat dyspnea resulting, for example, in patients with COPD, where air hunger leads to extreme agitation, discomfort, and gasping; opioid analgesics will suppress the gasping and decease the panic of the patient. Similarly, opioid drugs find use in patients who require artificial ventilation (Clemens and Klaschik, 2007).

Sedation

Mu-opioid receptor agonists can produce drowsiness and cognitive impairment. Such depression can augment respiratory impairment. These effects are most typically noted following initiation of opioid drug therapy or after dose incrementation. Importantly, these effects on arousal resolve over a few days due to the development of tolerance to the sedative effects. As with respiratory depression, the degree of drug effect can be enhanced by a variety of predisposing patient factors, including dementia, encephalopathies, brain tumors, and other depressant medications, including sleep aids, antihistamines, alcohol, antidepressants, and anxiolytics (Cherny, 1996).

Neuroendocrine Effects

The regulation of the release of hormones and factors from the pituitary is under complex regulation by opioid receptors in the hypothalamic-pituitary-adrenal (HPA) axis. Broadly considered, morphine-like opioid agonists reduce the release of a large number of HPA hormones (Armario, 2010). However, withdrawal from opioids stimulates the HPA axis (Houshyar et al., 2001; Nava et al., 2006).

Sex Hormones

In males, acute opioid agonist treatment reduces plasma cortisol, testosterone, and gonadotrophins. Inhibition of adrenal function is reflected by reduced cortisol production and reduced adrenal androgens (dehydroepiandrosterone). In females, morphine administration will produce lower luteinizing hormone (LH) and follicle-stimulating hormone (FSH) release. In both males and females, chronic therapy can result in endocrinopathies, including hypogonadotropic hypogonadism. In men, this may cause decreased libido and, with extended exposure, reduced secondary sex characteristics. In women, these exposures are associated with menstrual cycle irregularities. These changes are reversible with removal of the drug.

Prolactin. Prolactin release from the anterior pituitary is under inhibitory control by dopamine released from neurons of the arcuate nucleus. Mu-opioid receptor agonists act presynaptically on these dopamine-releasing terminals to inhibit neurotransmitter release and thereby increase plasma prolactin levels.

ADH and Oxytocin. The effects of opioids on ADH and oxytocin release are complex. These hormones are synthesized in the perikarya of the magnocellular neurons in the paraventricular and supraoptic nuclei of the hypothalamus and released from the posterior pituitary (see Chapter 46). *Morphine* and morphine-like drugs bring about the liberation of ADH by acting on the hypothalamic-hypophysial system. In addition, mu-opioid receptor agonists may yield a hypotension secondary to histamine release, which would promote ADH release. Endogenous and exogenous mu-opioid receptor agonists modulate oxytocin release from the posterior pituitary, which is used to provide rest and sedation during stressed prodromal stages of labor (Morris et al., 2010).

Miosis

Mu-opioid receptor agonists induce pupillary constriction (miosis) in the awake state and block pupillary reflex dilation during anesthesia. The parasympathetic outflow from the *Edinger-Westphal nucleus* activates parasympathetic outflow through the ciliary ganglion to the pupil, producing constriction. This outflow is locally regulated by GABAergic interneurons. Opioid agonists block this GABAergic interneuron-mediated inhibition, leading to increased parasympathetic outflow (Larson, 2008). At high doses of agonists, the miosis is marked, and pinpoint pupils are pathognomonic; however, marked mydriasis will occur with the onset of asphyxia. While some tolerance to the miotic effect develops, regular opioid users with high circulating concentrations of opioids continue to have constricted pupils. Therapeutic doses of *morphine* increase accommodative power and lower intraocular tension in normal and glaucomatous eyes (Larson, 2008).

Seizures and Convulsions

In older children and adults, moderately high doses of mu-opioid receptor agonists produce electroencephalogram (EEG) slowing. In the newborn, *morphine* can produce epileptiform activity and occasionally seizure activity (Young and da Silva, 2000). Mechanisms likely involved in these excitatory actions include inhibition of inhibitory interneurons. Morphine-like drugs indirectly excite certain groups of neurons, such as hippocampal pyramidal cells, by inhibiting the inhibition (disinhibition) exerted by GABAergic interneurons (McGinty, 1988). It has been suggested that opioid receptors may couple through both inhibitory and stimulatory G proteins, with the inhibitory coupling but not the excitatory coupling showing tolerance with continued exposures (King et al., 2005).

The metabolites of several opioids (morphine-3-glucuronide, normeperidine) have been implicated in seizure activity (Seifert and Kennedy, 2004; Smith, 2000). Withdrawal syndrome from an opioid-dependent state in the adult and in the infant born to an opioid-dependent mother can lead to prominent EEG activation, tremor, and rigidity. Anticonvulsant agents may not always be effective in suppressing such opioid-induced seizures.

Cough

Cough is a protective reflex evoked by airway stimulation. It involves rapid expression of air against a transiently closed glottis. The reflex is complex, involving the central and peripheral nervous systems as well as the smooth muscle of the bronchial tree. *Morphine*, *codeine*, and related opioids depress the cough reflex at least in part by a direct effect on a cough center in the medulla; this cough suppression can be achieved without altering the protective glottal function (Chung and Pavord, 2008). There is no obligatory relationship between depression of respiration and depression of coughing, and effective antitussive agents are available that do not depress respiration (opioid- and opiate-based antitussives are discussed later in the chapter).

Nausea and Vomiting

These are side effects of morphine-like drugs caused by direct stimulation of the chemoreceptor trigger zone for emesis in the *area postrema* of the medulla. All clinically useful mu-opioid receptor agonists produce

some degree of nausea and vomiting. Nausea and vomiting are relatively uncommon in recumbent patients given therapeutic doses of *morphine*, but nausea occurs in about 40% and vomiting in 15% of ambulatory patients given analgesic doses. *Morphine* and related analgesics produce an increase in vestibular sensitivity. A component of nausea is likely also due to the gastric stasis that occurs postoperatively and that is exacerbated by analgesic doses of *morphine* (Greenwood-Van Meerveld, 2007).

Cardiovascular System

In the supine patient, therapeutic doses of morphine-like opioids have no major effect on blood pressure or cardiac rate and rhythm. Such doses can, however, produce peripheral vasodilation, reduced peripheral resistance, and an inhibition of baroreceptor reflexes. Thus, when supine patients assume the head-up position, orthostatic hypotension and fainting may occur. The peripheral arteriolar and venous dilation produced by *morphine* involves several mechanisms, including morphine-induced *release of histamine* from mast cells and *blunting of reflex vasoconstriction* caused by increased P_{CO_2}. High doses of mu-opioid receptor agonists used as anesthetic induction agents, such as *fentanyl* and *sufentanil*, have only modest effects on hemodynamic stability, in part because they do not cause release of histamine (Monk et al., 1988).

Morphine may exert its therapeutic effect in the treatment of angina pectoris and acute myocardial infarction by decreasing preload, inotropy, and chronotropy, thus favorably altering determinants of myocardial O_2 consumption. *Morphine* also produces cardioprotective effects and can mimic the phenomenon of ischemic preconditioning, whereby a short ischemic episode paradoxically protects the heart against further ischemia. This effect appears to be mediated through a mitochondrial ATP-sensitive K^+ channel in cardiac myocytes. Morphine-like opioids should be used with caution in patients who have decreased blood volume because these agents can aggravate hypovolemic shock. *Morphine* should be used with great care in patients with cor pulmonale; deaths after therapeutic doses have been reported. Concurrent use of certain CNS depressants (phenothiazines, ethanol, benzodiazepines) may increase the risk of *morphine*-induced hypotension. Cerebral circulation is not affected directly by therapeutic doses of opioids. However, opioid-induced respiratory depression and CO_2 retention can result in cerebral vasodilation and an increase in cerebrospinal fluid (CSF) pressure. This pressure increase does not occur when P_{CO_2} is maintained at normal levels by artificial ventilation.

Skeletal Muscle Tone

At therapeutic doses required for analgesia, opioid agonists have little effect on motor tone or function. However, high doses of opioids, as used for anesthetic induction, produce muscular rigidity. Myoclonus, ranging from mild twitching to generalized spasm, is an occasional side effect that has been reported with all clinically used opioid agonists and is particularly prevalent in patients receiving high doses. The increased muscle tone is mediated centrally. High doses of spinal opioids can increase motor tone, possibly through an inhibition of inhibitory interneurons in the ventral horn of the spinal cord. Intracranial delivery of opioids can initiate rigidity in animal models, possibly reflecting increased extrapyramidal activity.

Gastrointestinal Tract

Opioids have effects on all aspects of GI function. Between 40% and 95% of patients treated with opioid agonists develop constipation and changes in bowel function (Benyamin et al., 2008). Opioid receptors are densely distributed in enteric neurons between the myenteric and submucosal plexuses and on a variety of secretory cells. The importance of these peripheral systems in altering GI motility is demonstrated by the therapeutic efficacy of peripherally limited agonists such as *loperamide* as antidiarrheals and the utility of peripherally limited opioid antagonists such as *methylnaltrexone* to reverse the constipation induced by systemic opioid agonists.

Esophagus. The esophageal sphincter is under control of brainstem reflexes that activate cholinergic motor neurons originating in the esophageal myenteric plexus. This system regulates passage of material from the esophagus to the stomach and prevents regurgitation; conversely, it allows relaxation in the act of emesis. *Morphine* inhibits lower esophageal sphincter relaxation induced by swallowing and by esophageal distension; the effect is believed to be centrally mediated because peripherally restricted opioids such as *loperamide* do not alter esophageal sphincter tone (Sidhu and Triadafilopoulos, 2008).

Stomach. *Morphine* increases tonic contracture of the antral musculature and upper duodenum and reduces resting tone in the musculature of the gastric reservoir, thereby prolonging gastric emptying time and increasing the likelihood of esophageal reflux. Passage of the gastric contents through the duodenum may be delayed by as much as 12 h. This also results in retardation of orally administered medications. *Morphine* and other opioid agonists usually decrease secretion of HCl. Activation of opioid receptors on parietal cells enhances secretion, but indirect effects, including increased secretion of somatostatin from the pancreas and reduced release of acetylcholine, appear to be dominant in most circumstances (Kromer, 1988).

Intestine. *Morphine* reduces propulsive activity in the small and large intestines and diminishes intestinal secretions. Opioid agonists suppress rhythmic inhibition of muscle tone, leading to concurrent increases in basal tone in the circular muscle of the small and large intestines. This results in enhanced high-amplitude phasic contractions, which are nonpropulsive (Wood and Galligan, 2004). The upper part of the small intestine, particularly the duodenum, is affected more than the ileum. A period of relative atony may follow the period of elevated basal tone. Intestinal secretion arises from activation of enterocytes by local cholinergic submucosal plexus secretomotor neurons. Opioids act on secretomotor neurons to inhibit their excitatory output to the enterocytes and thereby reduce intestinal secretion (Kromer, 1988). The reduced rate of passage of the intestinal contents, along with reduced intestinal secretion, leads to increased water absorption, increasing viscosity of the bowel contents, and constipation. The tone of the anal sphincter is augmented greatly, and reflex relaxation in response to rectal distension is reduced. Patients who take opioid agonists chronically remain constipated.

Biliary Tract. *Morphine* constricts the sphincter of Oddi, and the pressure in the common bile duct may rise more than 10-fold within 15 min. Fluid pressure also may increase in the gallbladder and produce symptoms that may vary from epigastric distress to typical biliary colic. All opioids can cause biliary spasm. Some patients with biliary colic experience exacerbation rather than relief of pain when given opioids. Spasm of the sphincter of Oddi probably is responsible for elevations of plasma amylase and lipase that sometimes occur after *morphine* administration. *Atropine* only partially prevents *morphine*-induced biliary spasm, but opioid antagonists prevent or relieve it.

Ureter and Urinary Bladder

Morphine inhibits the urinary voiding reflex and increases the tone of the external sphincter with a resultant increase in the volume of the bladder. Tolerance develops to these effects of opioids on the bladder. Clinically, opioid-mediated inhibition of micturition can be of such clinical severity that catheterization is sometimes required after therapeutic doses of *morphine*, particularly with spinal drug administration. The inhibition of systemic opioid effects on micturition is reversed by peripherally restricted antagonists (Rosow et al., 2007).

Uterus

Morphine may prolong labor. If the uterus has been made hyperactive by oxytocics, *morphine* tends to restore the contractions to normal.

Mast Cell Degranulation and Histamine Release

Many mu-opioid receptors agonists, including *morphine* and *meperidine*, evoke mast cell degranulation and histamine release. This action can cause bronchoconstriction, vasodilation, urticaria, other types of skin rashes, and pruritus. The effect on mast cells is not blocked by antagonists such as *naloxone* and so it not mu-opioid receptor mediated, but rather a due to their interaction with the Mas-related G

protein-coupled receptor X2 (MRGPRX2; see Chapter 43 and McNeil, 2021a and 2021b) expressed in mast cells and small-diameter neurons in the dorsal root ganglia and trigeminal ganglia (Lansu et al., 2017). Mu-opioid agonists, such as *fentanyl*, do not activate this receptor and are associated with a lower incidence of histamine release.

Skin

Therapeutic doses of *morphine* cause dilation of cutaneous blood vessels. The skin of the face, neck, and upper thorax frequently becomes flushed. Pruritus commonly follows systemic administration of *morphine*. Itching is readily seen with *morphine* mainly due to histamine release. The systemic action is sensitive to antihistamines (*diphenhydramine*) and correlates with the mast cell degranulating properties of the opioid. Neither the pruritus nor the degranulation is reversed by opioid antagonists (Barke and Hough, 1993). Pruritus also can be seen following epidural or intrathecal opioid administration through a centrally mediated, *naloxone*-reversible mechanism (Kumar and Singh, 2013).

Immune System

Opioids modulate immune function by direct effects on immune cells and indirectly through centrally mediated neuronal mechanisms (Vallejo et al., 2004). The acute central immunomodulatory effects of opioids may be mediated by activation of the sympathetic nervous system; the chronic effects of opioids may involve modulation of the HPA axis. Direct effects on immune cells may involve variants of the classical neuronal opioid receptors. Proposed mechanisms for the immune-suppressive effects of *morphine* on neutrophils include nitric oxide–dependent inhibition of nuclear factor-κB activation and activation of MAPKs. Evidence suggests that several opioid drugs, including *morphine*, may interact with Toll-like receptor 4 to activate a variety of immunocytes (Hutchinson et al., 2007). Overall, however, opioid agonists are modestly immunosuppressive, and increased susceptibility to infection and tumor spread have been observed. In some situations, immune effects appear more prominent with acute administration than with chronic administration, which could have important implications for the care of the critically ill.

Temperature Regulation

Opioids alter the equilibrium point of the hypothalamic heat-regulatory mechanisms such that body temperature usually falls slightly. Mu-opioid receptor agonists acting in the CNS result in slightly increased thresholds for sweating and significantly lower the threshold temperatures for evoking vasoconstriction and shivering.

Chronic Effects of Mu-Opioid Drugs: Tolerance, Dependence, and Opioid Use Disorder

Acute or short-term opioid receptor activation produces the typical pharmacological pattern described above. However, repeated or prolonged mu-opioid receptor activation by agonists leads to the development of tolerance and physical dependence. Tolerance to opioids refers to the loss of the effectiveness of the opioid agonist with continuous or repeated administration (over days to weeks to months), requiring the administration of larger doses to produce the expected therapeutic effects. Physical dependence is most noticeable when an opioid agonist is withheld or in the presence of an antagonist, and symptoms of opioid withdrawal, such as diarrhea, hyperalgesia, restlessness, and increases in heart rate and respiration, are observed. There are a number of mechanisms thought to contribute to tolerance to and physical dependence on opioid agonists.

Tolerance

Mechanisms underlying tolerance may include loss of opioid receptors, changes in intracellular cascades (e.g., reduced inhibition of AC), as well as changes at the organ system level (e.g., loss of sedative and analgesic effects) (Christie, 2008). Different physiological responses can develop tolerance at markedly different rates. At the organ system level, some endpoints show little or no tolerance development (pupillary miosis); some show moderate tolerance (constipation, emesis, analgesia, sedation); and some show rapid tolerance (euphoria). The amount of tolerance that develops is generally thought to be due to the number of "spare" receptors present at the level of the organ or neural circuit mediating a response.

In general, cross-tolerance to different mu-opioid receptor agonists occurs. However, for reasons that are not clear, this cross-tolerance is neither absolute nor complete. This lack of complete cross-tolerance between agonists forms the basis for the clinical strategy of "opioid rotation" in pain therapy (Smith and Peppin, 2014).

Dependence

Dependence represents a state of adaptation manifested by a withdrawal syndrome produced by cessation of drug exposure (e.g., by drug abstinence) or administration of an antagonist (e.g., *naloxone*). Dependence is specific to the drug class and is receptor-mediated. At the organ system level, opioid withdrawal is manifested by significant somatomotor and autonomic outflow (reflected by agitation, hyperalgesia, hyperthermia, hypertension, diarrhea, pupillary dilation, and release of virtually all pituitary and adrenomedullary hormones) and by affective symptoms (dysphoria, anxiety, and depression). Consistent with the phenomenon of cross-tolerance, drugs interacting with the same opioid receptor will suppress the withdrawal observed in organisms dependent on another drug acting on the same receptor (e.g., *morphine* and *methadone*). A state of opioid withdrawal is highly aversive, and avoiding withdrawal is thought to contribute to persistent opioid-taking behavior.

Opioid Use Disorder

In the late 1990s and early 2000s, opioid misuse and abuse as well as overprescribing led to an opioid epidemic in which opioid overdose deaths increased dramatically. From 1999 to 2019, nearly half a million people have died from an opioid overdose, including prescription and illicit opioids. Opioid use disorder is a behavioral pattern characterized by compulsive use of a drug. The positive, rewarding effects of opioids are the driving component for initiating the recreational use of opioids and is subject to the development of tolerance. Given the aversive nature of withdrawal symptoms, avoidance and alleviation of withdrawal symptoms may become a primary motivation for continued drug-taking (Kreek and Koob, 1998). When the drive to acquire the drug leads to drug-seeking behaviors that occur despite the physical, emotional, or societal damage suffered by the drug seeker, then the obsession or compulsion to acquire and use the drug is considered to reflect an opioid use disorder. In animals, this may be manifested by a willingness to tolerate stressful conditions to acquire drug delivery. Importantly, drug dependence is not synonymous with drug addiction. Tolerance and dependence are physiological responses seen in all patients but are not necessarily predictors of opioid misuse and abuse. For example, cancer pain often requires prolonged treatment with high doses of opioids, leading to tolerance and dependence, but not necessarily opioid abuse.

Mechanisms of Tolerance, Dependence, Withdrawal, and Abuse Liability

The mechanisms underlying chronic tolerance and dependence/withdrawal are controversial. There are multiple molecular, cellular, and circuit-level mechanisms that may account for changes in homeostasis and the effects of mu-opioid receptor agonists. Figure 23–2 shows some of the receptor-effector signaling pathways that may contribute to the adaptive signaling changes that occur with immediate and long-term opioid agonist action (desensitization, tolerance, dependence, withdrawal).

Receptor Desensitization, Internalization, and Downregulation

In the face of a transient activation (minutes to hours), receptor desensitization occurs that is specific for that receptor and disappears with a time course parallel to the clearance of the agonist. Short-term desensitization probably involves phosphorylation of the receptors resulting in an uncoupling of the receptor from its G protein and/or internalization of the receptor (Williams et al., 2013). This process likely contributes to the termination of agonist activity.

Acute desensitization and/or receptor internalization may play a role in the initiation of chronic tolerance but is not sufficient to explain the persistent changes observed. Moreover, receptor desensitization and downregulation may be agonist specific. For instance, *morphine*, unlike other mu-opioid receptor agonists, does not promote significant mu-opioid receptor phosphorylation or internalization. Endocytosis and sequestration of receptors do not invariably lead to receptor degradation but can also result in receptor dephosphorylation and recycling to the surface of the cell. Agonists that cause rapid internalization of opioid receptors also rapidly desensitize signaling, but sensitivity can be at least partially restored by recycling of "reactivated" opioid receptors.

Adaptation of Intracellular Signaling Mechanisms

Assessment of the coupling of mu-opioid receptors to cellular effects, such as inhibition of AC, activation of inwardly rectifying K^+ channels, inhibition of Ca^{2+} currents (see Figure 23–2), and inhibition of neurotransmitter release demonstrates functional uncoupling of receptor occupancy from effector function. Importantly, chronic application of opioids initiates adaptive counterregulatory changes. A common example of such cellular processes is the rebound increase in cellular cyclic AMP levels produced by "superactivation" of AC and upregulation of the amount of enzyme as a result of long-term exposure to an opioid followed by its abrupt withdrawal (Williams et al., 2013).

System-Level Counteradaptation

The loss of analgesic effects with chronic opioid agonist exposure may reflect an enhanced excitability of linked systems. Thus, tolerance to the analgesic effects of chronically administered mu-opioid receptor agonists may result from an activation of bulbospinal pathways that increases the excitability of spinal dorsal horn pain transmission linkages. With chronic opioid exposure, opioid receptor occupancy will lead to the activation of PKC, which can phosphorylate and enhance the activation of local *N*-methyl-D-aspartate (NMDA) glutamate receptors. These receptors are considered to play an important role as an excitatory link in enhanced pain processing. Blockade of these receptors can at least partially attenuate the loss of analgesic efficacy with continued opioid exposure. Such system-level counteradaptation mechanisms may apply to specific circuits (e.g., pain modulation) but not necessarily to other effects of opioids (e.g., sedation or miosis) (Christie, 2008). These changes may be mechanistically important in opioid-induced hyperalgesia, by which higher doses of opioids may lead to a paradoxical increase in pain processing (Fletcher and Martinez, 2014).

Differential Tolerance Development and Fractional Occupancy Requirements

A difficulty in explaining tolerance relates to the differential rates of the development of tolerance. It is unclear why responses such as miosis show no tolerance development over extended exposure (indeed, miosis is considered symptomatic in drug overdose of highly tolerant patients), whereas analgesia and sedation are likely to show a reduction. One possibility is that tolerance represents a functional uncoupling of some fraction of the receptor population and that different physiological end points require activation of different fractions of their coupled receptors to produce a given physiological effect. Functional data suggest that opioid receptors may interact, forming homo- and heterodimers, and that such complexes may alter receptor signaling and trafficking and contribute to tolerance to *morphine* and possibly to disease states (Massotte, 2015; Zhang et al., 2015).

Mechanisms of the Reinforcing Effects of Mu-Opioid Receptor Agonists

The mechanisms by which opioids produce euphoria, tranquility, and other alterations of mood (including rewarding properties) are complex and not entirely understood. Neural systems that mediate opioid reinforcement overlap with, but are distinct from, those involved in physical dependence and analgesia (Koob and Le Moal, 2008). Behavioral and pharmacological data point to a pivotal role of the mesocorticolimbic dopamine system that projects to the nucleus accumbens in drug-induced reward and motivation (Figure 23–8). Increased dopamine release in this region is considered to underlie a positive reward state. The reinforcing effects of opioids are thought to be mediated partly via inhibition of local GABAergic neuronal activity in the ventral tegmental area, which otherwise acts to inhibit DA outflow, thus causing disinhibition of dopamine release.

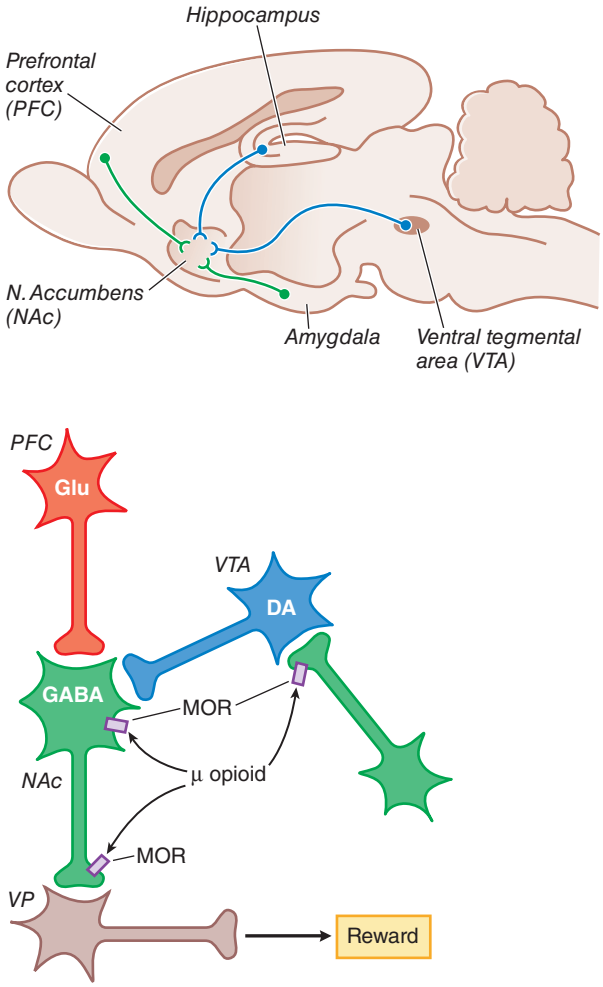

Figure 23–8 *Pathways underlying rewarding properties of opioid drugs.* **Upper panel:** This sagittal section of rat brain shows dopamine (DA) and GABA inputs from the ventral tegmental area (VTA) and prefrontal cortex (PFC), respectively, into the nucleus accumbens (NAc). **Lower panel:** Neurons are labeled with their primary neurotransmitters. At a cellular level, mu-opioid receptor agonists reduce excitability and transmitter release at the sites indicated by inhibiting Ca^{2+} influx and enhancing K^+ current. Thus, opioid-induced inhibition in the VTA on GABAergic interneurons or in the NAc reduce GABA-mediated inhibition and increase outflow from the ventral pallidum (VP), which appears to correlate with a positive reinforcing state (enhanced reward).

Adverse Effects and Precautions Affecting Patient Responses to Mu-Opioids

As can be seen from their complex pharmacology, *morphine* and related mu-opioid receptor agonists, aside from their action as analgesics, produce a wide spectrum of effects reflecting the wide distribution of opioid receptors across organ systems that can affect patient responses and susceptibilities.

Compromised Respiratory Function

Due to their respiratory-depressant actions, *morphine* and related opioid drugs must be used cautiously in patients with compromised respiratory function such as emphysema, kyphoscoliosis, severe obesity, or cor pulmonale. Although many patients with such conditions seem to be functioning within normal limits, they are already using compensatory mechanisms, such as increased respiratory rate. Many have chronically elevated levels of plasma carbon dioxide and may be less sensitive to its respiratory-stimulating actions.

Pain State

Patient in severe pain may tolerate larger doses of *morphine*. However, as the pain subsides, such patients may become sedated and even show respiratory depression as the stimulatory effects of pain on these parameters are diminished.

Asthma and Allergic Responses

Due to its histamine-releasing properties, *morphine* can precipitate or exacerbate asthmatic attacks and should be avoided in patients with a history of asthma. Other mu-opioid agonists, such as *fentanyl*, may be better choices for such patients.

Opioid analgesics may also evoke allergic phenomena, but a true allergic response is uncommon. The effects are manifested as urticaria and fixed eruptions; contact dermatitis in nurses and pharmaceutical workers also occurs. Wheals at the site of injection of *morphine*, *codeine*, and related drugs are likely secondary to histamine release. Anaphylactoid reactions have been reported after intravenous administration of *codeine* and *morphine*, but such reactions are rare. In people who use intravenous opioid *heroin*, such reactions may contribute to sudden death, episodes of pulmonary edema, and other complications.

Head Injury

While head injury per se does not constitute an absolute contraindication to the use of mu-opioid agonists, the possibility of exaggerated depression of respiration and the potential need to control ventilation of the patient must be considered. Because opioids may produce mental clouding and side effects such as miosis and vomiting, which are important signs in following the clinical course of patients with head injuries, the advisability of their use must be weighed carefully against these risks.

Liver or Kidney Disease

Most opioid analgesics are metabolized by the liver and should be used with caution in patients with hepatic disease. Renal disease significantly alters the pharmacokinetics of several drugs, including *morphine*, *codeine*, *dihydrocodeine*, and *meperidine*. Morphine-6-glucuronide may accumulate with continued dosing with *morphine* or *codeine*, and symptoms of opioid overdose may result. When repeated doses of *meperidine* or *propoxyphene* are given to such patients, the accumulation of metabolites may cause tremor and seizures and cardiac toxicity, respectively. Note, propoxyphene has been withdrawn in the U.S. and Europe due its narrow therapeutic window, in particular cardiac toxicity.

Blood-Brain Barrier

Morphine is hydrophilic, so proportionately less *morphine* normally crosses into the CNS than with more lipophilic opioids. In neonates or when the blood-brain barrier is compromised, lipophilic opioids may give more predictable clinical results than *morphine*.

Age and Sex

In adults, the duration of analgesia produced by *morphine* increases progressively with age; however, the degree of analgesia that is obtained with a given dose is similar. There is a growing body of data on gender differences in responses to pain and analgesics (Mogil, 2012). Females exhibit the majority of chronic pain syndromes, and surveys examining sex differences in acute pain models report either no sex difference or greater sensitivity in females (Loyd and Murphy, 2014).

Hypovolemia and Hypotension

Reduced blood volume causes patients to be considerably more susceptible to the vasodilating effects of *morphine* and related drugs. These agents must be used cautiously in patients with hypotension from any cause.

Morphine and Structurally Related Agonists

Chemistry and Structure-Activity Relationships

The structures of *morphine*, *codeine* (3-O-methylated morphine), and some of their analogues and antagonists are shown in Figure 23–9. *Heroin*, or 3,6-diacetylmorphine, is a semisynthetic derivative of *morphine*. Methylation of the phenolic hydroxyl at position 3, as in *codeine*, or acetylation of this hydroxyl, as in *heroin*, drastically reduces binding to the mu-opioid receptor; these compounds are converted *in vivo* to morphine and 6-acetyl morphine, respectively, to afford analgesia.

Thebaine, which is O-methylated at both the 3- and 6-hydroxyl groups and contains an additional double C=C bond, has no activity at opioid receptors but is used to synthesize 14-hydroxyl-derivatives, such as the potent agonists *oxymorphone* and *oxycodone* as well as the antagonists *naltrexone* and *naloxone*. *Thebaine* is also the precursor for the synthesis of the partial agonist *buprenorphine* and the highly potent full agonist *etorphine*, which is 1000 times more potent than *morphine* and restricted to veterinary use. The tertiary N atom in the morphine-like agonists is substituted with a methyl group (as in *morphine*); replacement of this with an allyl or cyclopropyl methyl group lowers efficacy (as with *buprenorphine*) and provides the antagonists *naloxone* and *naltrexone*.

In addition, structurally distinct, fully synthetic opioid analgesics have been developed to attain the holy grail of an opioid analgesic without respiratory depression or addiction liability (Figure 23–10). These include simplified versions of the *morphine* structure such as the morphinans (e.g., *levorphanol*) and benzomorphans (e.g., *pentazocine*), as well as the *methadone* and the *fentanyl* family of compounds, which lack a phenolic hydroxyl group. Despite these structural differences, all opioid analgesics bind to the same orthosteric site on the mu-opioid receptor as *morphine* and so have very similar pharmacology. On the other hand, structural modifications such as those described above can provide opioid drugs with different affinities for the various types of receptors, agonist versus antagonist activity, and altered distribution, metabolism, and pharmacokinetic profiles.

Morphine

ADME

Absorption. In general opioid drugs are moderately well absorbed from the GI tract; absorption through the rectal mucosa also occurs, and a few opioid analgesics (e.g., *morphine, hydromorphone*) are available in suppositories. The more lipophilic opioids are absorbed readily through the nasal or buccal mucosa. Those with the greatest lipid solubility also can be absorbed transdermally, for example *fentanyl* and *buprenorphine* are available as patches. Opioids, particularly *morphine*, have been widely used for spinal delivery to produce direct analgesia at this site. These agents display useful transdural movement adequate to permit their use epidurally.

With many opioids, *morphine* being a prime example, the effect of a given dose is less after oral administration than after parenteral administration. This is due to a significant degree and variability of first-pass metabolism in the liver, particularly glucuronidation of the hydroxyl groups. For example, the bioavailability of oral preparations of *morphine* is only about 25%, but if this is taken into consideration together with the clearance rate, adequate relief of pain can be achieved with oral administration of *morphine*. Satisfactory analgesia in patients with cancer is associated with a broad range of steady-state concentrations of *morphine* in plasma (16–364 ng/mL) (Neumann et al., 1982). *Codeine*, in which the 3-hydroxy group is protected by O-methylation, has a much better oral bioavailability, although as mentioned above, it has to be converted to *morphine in vivo* to be effective as an analgesic. The duration of action is often longer with drugs given by the oral route.

When *morphine* and most other opioids are given intravenously, they act promptly. However, after subcutaneous administration, the more lipid-soluble opioids act more rapidly than *morphine* because of differences in the rates of absorption and entry into the CNS. Overall, compared with more lipid-soluble opioids such as *codeine*, *heroin*, *methadone*, and *fentanyl*, *morphine* crosses the blood-brain barrier at a considerably lower rate.

Distribution and Metabolism. After a therapeutic dose, approximately one-third of *morphine* in the plasma is protein bound. *Morphine* itself does not persist in tissues, and 24 h after the last dose, tissue concentrations are low. The major pathway for the metabolism of *morphine* and related drugs is conjugation with glucuronic acid to give

Figure 23–9 *Structures of morphine-related opioid agonists and antagonists.*

morphine-6-glucuronide and morphine-3-glucuronide; small amounts of morphine-3,6-diglucuronide are formed. N-demethylation of *morphine* to normorphine is a minor metabolic pathway. Although meant as a process for excretion, the more polar 3- and 6-glucuronides can cross the blood-brain barrier to exert significant clinical effects (Christrup, 1997). Indeed, morphine-6-glucuronide has pharmacological actions indistinguishable from those of *morphine* and if given systemically is reported to be approximately twice as potent as *morphine* in animal models and in humans (Osborne et al., 1992), although it has been reported that Chinese populations may be less sensitive to *morphine* as a result of decreased production of morphine-6-glucuronide (Caraco et al., 1999). In patients undergoing treatment with chronic oral *morphine*, plasma levels of morphine-6-glucuronide exceed those of *morphine* such that the 6-glucuronide accounts for a significant portion of analgesia and most of *morphine*'s effects. Morphine-6-glucuronide is excreted by the kidney, and in renal failure, the levels of this metabolite can accumulate, possibly explaining *morphine*'s potency and long duration in patients with compromised renal function.

In adults, the $t_{1/2}$ of *morphine* is about 2–3 h; the $t_{1/2}$ of morphine-6-glucuronide is somewhat longer. Children achieve adult renal function values by 6 months of age. In elderly patients, lower doses of *morphine* are recommended based on a smaller volume of distribution and the general decline in renal function (Owens et al., 1983). In contrast to the 6-glucuronide derivative, morphine-3-glucuronide, another important metabolite, has very-low-affinity opioid receptors, but it has been suggested this may contribute to the excitatory effects of *morphine* (Smith, 2000).

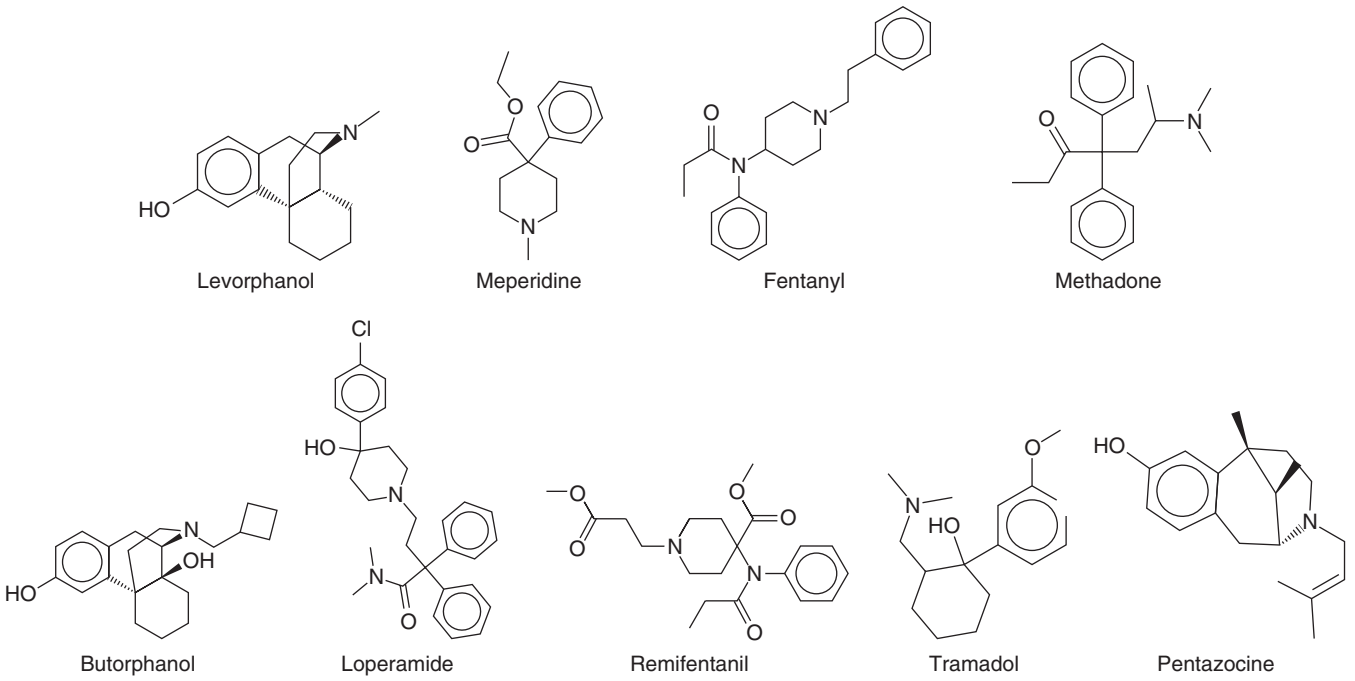

Figure 23–10 *Structures of opioid analgesics structurally different from morphine.*

Excretion. *Morphine* is eliminated by glomerular filtration, primarily as morphine-3-glucuronide; 90% of the total excretion of *morphine* takes place the first day after administration. Very little *morphine* is excreted unchanged. Enterohepatic circulation of *morphine* and its glucuronides accounts for the presence of small amounts of *morphine* in feces and urine for several days after the last dose.

Codeine

The half-life of *codeine* in plasma is 2 to 4 h. Metabolites of *codeine* are excreted chiefly as inactive forms in the urine. However, *codeine* in which the 3-hydroxy group is protected by O-methylation has a much better oral bioavailability (60%) due to lower first-pass metabolism, although as mentioned above, it has to be converted to *morphine in vivo* to be effective as an analgesic since the 3-methoxy group drastically reduces affinity for the mu-opioid receptor (see receptor structure above). Approximately 10% of administered *codeine* is O-demethylated to *morphine*, and so free and conjugated *morphine* can be found in the urine after therapeutic doses of *codeine*. The conversion of *codeine* to *morphine* is carried out by the enzyme CYP2D6. There are many known different polymorphisms of CYP2D6, resulting in poor, intermediate, and ultra-rapid metabolizers (Ingelman-Sunberg, 2004). Moreover, the frequency of variants differs across ethnic groups. This means caution is required in the use of *codeine* since an inability to convert *codeine* to *morphine* makes *codeine* ineffective as an analgesic for about 10% of the Caucasian population (Eichelbaum and Evert, 1996). Conversly, ultra-rapid metabolism can lead to problems due to higher than predicted serum *morphine* levels. In breastfeeding mothers, the ultra-rapid conversion of *codeine* can result in unsafe levels of *morphine* in breast milk, resulting in serious adverse effects in breastfed infants that can lead to death.

It is therefore vitally important to consider the possibility of metabolic enzyme polymorphism in any patient who experiences toxicity or does not receive adequate analgesia from *codeine* or other opioid prodrugs (e.g., *hydrocodone*, *oxycodone*, and *tramadol*) (Johansson and Ingelman-Sundberg, 2011).

Heroin

Heroin (diacetylmorphine) is rapidly hydrolyzed to 6-mono-acetylmorphine (6-MAM), which in turn is hydrolyzed to *morphine*. *Heroin* and 6-MAM are more lipid soluble than *morphine* and so enter the brain quicker. Since *heroin* binds very poorly to the mu-opioid receptor due to lack of a free 3-hydroxyl group, *morphine* and 6-MAM are responsible for the pharmacological actions of *heroin*, making *heroin* a prodrug. *Heroin* is excreted mainly in the urine, largely as free and conjugated *morphine* (Rook et al., 2006).

Hydromorphone

Hydromorphone is a semisynthetic derivative of *morphine* and displays all of the same actions. It is more lipid soluble than *morphine*, resulting in an increased onset of action, and is several times more potent. The drug is formulated in parenteral, rectal, subcutaneous, and oral preparations and as a nebulized formulation and is given off-label by epidural or intrathecal routes. *Hydromorphone* is metabolized in the liver to hydromorphone-3-glucoronide.

Oxymorphone, Oxycodone, and Hydrocodone

Oxymorphone is a potent mu-opioid receptor agonist with an onset of analgesia after parenteral dosing of about 5 to 10 min and a duration of action of 3 to 4 h. *Oxymorphone* is extensively metabolized in the liver and excreted as the 3- and 6-glucuronides. It is approximately equipotent to *oxycodone*, with an onset of action of 10 to 30 min and duration of 4 to 6 h. Hepatic CYPs 2D6 and 3A4 convert *hydrocodone* to hydromorphone and norhydrocodone, respectively. *Hydrocodone* has a serum half-life of about 4 h.

Oxycodone is available as immediate-release formulations with or without nonsteroidal anti-inflammatory drugs (NSAIDs) and as controlled-release preparations. Parenteral formulations are available in the U.K. for intravenous or intramuscular administration. *Oxycodone* undergoes hepatic metabolism to produce the more potent oxymorphone. *Oxycodone* is one of the most commonly abused opioid drugs.

Hydrocodone is used orally for relief of moderate-to-severe pain and is employed in a liquid formulation as a cough suppressant. It is approximately equipotent to *oxycodone*, with an onset of action of 10 to 30 min and duration of 4 to 6 h. Hepatic CYPs 2D6 and 3A4 convert *hydrocodone* to hydromorphone and norhydrocodone, respectively. *Hydrocodone* has a serum half-life of about 4 h.

Morphinans

Levorphanol

This drug is available for intravenous, intramuscular, and oral administration. The pharmacological effects of *levorphanol* closely parallel those

of *morphine*. Compared to *morphine*, this agent is about seven times more potent and may produce less nausea and vomiting. *Levorphanol* is metabolized less rapidly than *morphine* and has a $t_{1/2}$ of 12 to 16 h; repeated administration at short intervals may thus lead to accumulation of the drug in plasma (Prommer, 2014). The D-isomer (dextrorphan) is devoid of analgesic action but has inhibitory effects at NMDA receptors.

Piperidine and Phenylpiperidine Analgesics

Meperidine

CNS Actions. *Meperidine* produces a pattern of effects similar but not identical to those already described for *morphine* (Latta et al., 2002), including analgesia and respiratory depression, leading to accumulation of CO_2, which in turn leads to cerebrovascular dilation, increased cerebral blood flow, and elevation of CSF pressure.

Meperidine can sometimes cause CNS excitation, characterized by tremors, muscle twitches, and seizures. These effects are due largely to accumulation of a metabolite, normeperidine. Meperidine has local anesthetic properties, particularly noted after epidural administration.

Cardiovascular Effects. The effects of *meperidine* on the cardiovascular system generally resemble those of *morphine*. Intramuscular administration of therapeutic doses of *meperidine* does not affect heart rate significantly, but intravenous administration frequently produces a marked increase in heart rate. Meperidine is a strong releaser of histamine.

Actions on Smooth Muscle, GI Tract, and Uterus. *Meperidine* does not cause as much constipation as *morphine*, even when given over prolonged periods; this may be related to its greater ability to enter the CNS, thereby producing analgesia at lower systemic concentrations. As with other opioids, clinical doses of *meperidine* slow gastric emptying sufficiently to delay absorption of other drugs significantly. The uterine muscles of a nonpregnant woman usually are mildly stimulated by *meperidine*. Administered before an oxytocic, *meperidine* does not exert any antagonistic effect. Therapeutic doses given during active labor do not delay the birth process; in fact, frequency, duration, and amplitude of uterine contractions may be increased.

ADME. *Meperidine* is absorbed by all routes of administration. The peak plasma concentration usually occurs at about 45 min, but the range is wide. After oral administration, only about 50% of the drug escapes first-pass metabolism to enter the circulation, and peak concentrations in plasma occur in 1 to 2 h. *Meperidine* is metabolized chiefly in the liver, with a $t_{1/2}$ of about 3 h. Metabolites are the *N*-demethyl product, normeperidine, and the hydrolysis product, meperidinate, both of which may be conjugated before excretion. In patients with cirrhosis, the bioavailability of *meperidine* is increased to as much as 80%, and the $t_{1/2}$ of both *meperidine* and the metabolite normeperidine ($t_{1/2}$ ~15–20 h) are prolonged. Only a small amount of *meperidine* is excreted unchanged.

Therapeutic Use. The major use of *meperidine* is for analgesia. The analgesic effects of *meperidine* are detectable about 15 min after oral administration, peak in 1 to 2 h, and subside gradually. The onset of analgesic effect is faster (within 10 min) after subcutaneous or intramuscular administration, and the effect reaches a peak in about 1 h, corresponding closely to peak concentrations in plasma. In clinical use, the duration of effective analgesia is about 1.5 to 3 h. Peak respiratory depression is observed within 1 h of intramuscular administration, and there is a return toward normal starting at about 2 h. In general, 75 to 100 mg *meperidine hydrochloride* given parenterally is approximately equivalent to 10 mg *morphine*. In terms of total analgesic effect, *meperidine* is about one-third as effective when given orally as when administered parenterally.

Single doses of *meperidine* can be effective in the treatment of postanesthetic shivering. *Meperidine*, 25 to 50 mg, is used frequently with antihistamines, corticosteroids, *acetaminophen*, or NSAIDs to prevent or ameliorate infusion-related rigors and shaking chills that accompany the intravenous administration of agents such as *amphotericin B*, *interleukin-2*, *trastuzumab*, and *alemtuzumab*.

Meperidine crosses the placental barrier and, even in reasonable analgesic doses, causes a significant increase in the percentage of babies who show delayed respiration, decreased respiratory minute volume, or decreased O_2 saturation or who require resuscitation. Fetal and maternal respiratory depression induced by *meperidine* can be treated with *naloxone*. *Meperidine* produces less respiratory depression in the newborn than does an equianalgesic dose of *morphine* or *methadone* (Fishburne, 1982).

Untoward Effects, Precautions, and Contraindications. The overall incidence of untoward effects is similar to that observed after equianalgesic doses of *morphine*, although constipation, urinary retention, and nausea may be less common. Patients who experience nausea and vomiting with *morphine* may not do so with *meperidine*; the converse also may be true. In patients or individuals who are tolerant to the depressant effects of *meperidine*, large doses repeated at short intervals may produce an excitatory syndrome that includes hallucinations, tremors, muscle twitches, dilated pupils, hyperactive reflexes, and convulsions. These excitatory symptoms are due to the accumulation of the long-lived metabolite normeperidine, which has a $t_{1/2}$ of 15 to 20 h, compared to 3 h for *meperidine*. Decreased renal or hepatic function increases the likelihood of toxicity. As a result of these properties, *meperidine* is not recommended for the treatment of chronic pain because of concerns over the toxicity of its metabolite. It should not be used for longer than 48 h or in doses greater than 600 mg/day.

Interactions With Other Drugs. Severe reactions may follow the administration of *meperidine* to patients being treated with monoamine oxidase (MAO) inhibitors. There are two basic types of interaction. The more prominent is an excitatory reaction ("serotonin syndrome") with delirium, hyperthermia, headache, hyper- or hypotension, rigidity, convulsions, coma, and death. This reaction may be due to the capacity of *meperidine* to block neuronal reuptake of serotonin, resulting in serotonergic overactivity. In the second type of interaction, several MAO inhibitors are substrates or inhibitors of hepatic CYPs and reduce *meperidine* metabolism, creating a condition resembling acute narcotic overdose. *Meperidine* and its congeners are contraindicated in patients taking MAO inhibitors or within 14 days after discontinuation of an MAO inhibitor.

Chlorpromazine increases the respiratory-depressant effects of *meperidine*, as do tricyclic antidepressants (but not *diazepam*). Concurrent administration of drugs such as *promethazine* or *chlorpromazine* also may greatly enhance *meperidine*-induced sedation without slowing clearance of the drug. Treatment with *phenobarbital* or *phenytoin* increases systemic clearance and decreases oral bioavailability of *meperidine*. As with *morphine*, concomitant administration of amphetamine has been reported to enhance the analgesic effects of *meperidine* and its congeners while counteracting sedation.

Diphenoxylate

Diphenoxylate is a *meperidine* congener that has a constipating effect in humans. Its only approved use is for the treatment of diarrhea, in combination with *atropine sulfate*. *Diphenoxylate* is unusual in that even its salts are virtually insoluble in aqueous solution, thus reducing the probability of abuse by the parenteral route. The recommended daily dosage of *diphenoxylate* for the treatment of diarrhea in adults is 20 mg in divided doses. *Difenoxin*, the main metabolite of *diphenoxylate*, is also marketed in a fixed dose with *atropine* for the management of diarrhea.

Loperamide

Like *diphenoxylate*, this agent slows GI motility by effects on the circular and longitudinal muscles of the intestine (Kromer, 1988). Part of its antidiarrheal effect may be due to a reduction of GI secretory processes (see Chapter 50). In controlling chronic diarrhea, *loperamide* is as effective as *diphenoxylate* and little tolerance develops to its constipating effect. Concentrations of drug in plasma peak about 4 h after ingestion. The apparent elimination $t_{1/2}$ is 7 to 14 h. *Loperamide* is poorly absorbed after oral administration and, in addition, does not penetrate well into the brain due to the exporting activity of P-glycoprotein, which is widely expressed in the brain endothelium. The usual dosage is 4 to 8 mg/day; the daily dose should not exceed 16 mg (Regnard et al., 2011). The most common

side effect is abdominal cramps. *Loperamide* is unlikely to be abused parenterally because of its low solubility; large doses of *loperamide* given to human volunteers do not elicit pleasurable effects typical of opioids.

Fentanyl and Its Analogues

The beneficial and unwanted effects of *fentanyl* and its various analogues, such as *alfentanil*, *sufentanil*, and *remifentanil*, are similar to those of other mu-opioid receptor agonists. Differences between this class of drugs and other mu-opioids are highlighted below. In addition, the rapid pharmacokinetics of the compounds distinguishes them from other mu-opioid agonists and makes them important in anesthetic practice. As described below, they have a relatively short time to peak analgesic effect, rapid termination of effect after small bolus doses, cardiovascular safety, and capacity to significantly reduce the dosing requirement for the volatile anesthetics.

Pharmacology of Fentanyl-Like Compounds

Abuse Liability. *Fentanyl* and its derivatives have a high potential for misuse, and many illicit derivatives of *fentanyl* have found their way onto the street and in large part have fueled the opioid crisis and the high death rate from opioid overdose. Moreover, self-administration by chewing of *fentanyl* patches can be deadly. Practitioners must be aware of this potential and, as with all controlled substances, keep careful control of *fentanyl* stocks. Opioid use disorder is discussed later in the chapter.

Analgesia. *Fentanyl* and its congeners are extremely potent analgesics and typically exhibit a very short duration of action when given parenterally.

Respiratory Depression. Respiratory depression is similar to that observed with *morphine*, but onset is more rapid and of shorter duration that *morphine* but extended after large doses or long infusions. Delayed respiratory depression also can be seen after the use of *fentanyl* or *sufentanil*, possibly due to enterohepatic circulation. Life-threatening wooden chest syndrome caused by rigidity in the diaphragm, chest wall, and upper airways is common after the high doses of *fentanyl* and analogues used in anesthetic induction. Rigidity can be treated with depolarizing or nondepolarizing neuromuscular-blocking agents while controlling the patient's ventilation, but care must be taken to make sure that the patient is not simply immobilized and aware.

Cardiovascular System. *Fentanyl* and its derivatives decrease heart rate through vagal activation and may modestly decrease blood pressure. However, because the drugs do not release histamine directly, depressant effects on the myocardium are minimal. For this reason, high doses of *fentanyl* or *sufentanil* are commonly used as the primary anesthetic for patients undergoing cardiovascular surgery or for patients with poor cardiac function.

ADME

The fentanyl-like drugs are highly lipid soluble and rapidly cross the blood-brain barrier. This is reflected in the $t_{1/2}$ for equilibration between the plasma and CSF of about 5 min for *fentanyl* and *sufentanil*. As *fentanyl* is poorly absorbed from the GI tract, the optimal absorption is through buccal administration. The levels in plasma and CSF decline rapidly owing to redistribution of *fentanyl* from highly perfused tissue groups to other tissues, such as muscle and fat. As saturation of less well-perfused tissue occurs, the duration of effect of *fentanyl* and *sufentanil* approaches the length of their elimination $t_{1/2}$, 3 to 4 h. *Fentanyl* and *sufentanil* undergo hepatic metabolism and renal excretion. With the use of higher doses or prolonged infusions, the drugs accumulate, these clearance mechanisms become progressively saturated, and *fentanyl* and *sufentanil* become longer acting. *Remifentanil* is very rapidly metabolized by esterases in plasma and is discussed separately below.

Therapeutic Uses

Fentanyl and *sufentanil* have wide popularity as anesthetic adjuvants (see Chapter 24), administered intravenously and epidurally. After systemic delivery, *fentanyl* is about 100 times more potent than *morphine*; *sufentanil* is about 1000 times more potent than *morphine*. The time to peak analgesic effect after intravenous administration of *fentanyl* and *sufentanil* (~5 min) is notably less than that for *morphine* and *meperidine* (~15 min). Recovery from analgesic effects also occurs more quickly. However, with larger doses or prolonged infusions, the duration of action is similar to that of longer-acting opioids.

The use of *fentanyl* in chronic pain treatment has become widespread. Transdermal patches that provide sustained release of *fentanyl* for 48 to 72 h are available. However, factors promoting increased absorption (e.g., fever) can lead to relative overdosage and increased side effects. Transbuccal absorption from buccal tablets or lollipop-like lozenges permits rapid absorption and has found use in the management of acute incident pain and for the relief of breakthrough cancer pain. *Fentanyl* should only be used in opioid-tolerant patients, defined as consuming more than 60 mg of oral *morphine* equivalent.

Epidural use of *fentanyl* and *sufentanil* for postoperative or labor analgesia is popular. A combination of epidural opioids with local anesthetics permits reduction in the dosage of both components.

Remifentanil

Remifentanil has a more rapid onset of analgesic action than *fentanyl* or *sufentanil*. Analgesic effects occur within 1 to 1.5 min following intravenous administration. Peak respiratory depression after bolus doses of *remifentanil* occurs after 5 min. *Remifentanil* is metabolized by plasma esterases, with a $t_{1/2}$ of 8 to 20 min; thus, elimination is independent of hepatic metabolism or renal excretion. Age and weight can affect clearance of *remifentanil*. After 3- to 5-h infusions of *remifentanil*, recovery of respiratory function can be seen within 3 to 5 min; full recovery from all effects of *remifentanil* occurs within 15 min. The primary metabolite, remifentanil acid, has 0.05% to 0.025% of the potency of the parent compound and is excreted renally.

Remifentanil hydrochloride is useful for short, painful procedures that require intense analgesia and blunting of stress responses; the drug is routinely given by continuous intravenous infusion because of its short duration of action, which allows for easy management of drug levels. When postprocedural analgesia is required, *remifentanil* alone is a poor choice. In this situation, either a longer-acting opioid or another analgesic modality should be combined with *remifentanil* for prolonged analgesia, or another opioid should be used. *Remifentanil* is not used intraspinally (epidural or intrathecal administration) because of its formulation with glycine, an inhibitory neurotransmitter in the dorsal horn of the spinal cord (Stroumpos et al., 2010).

Methadone

Methadone is a long-acting mu-opioid receptor agonist with pharmacological properties qualitatively similar to those of *morphine*. *Methadone* has a chiral center and is used clinically as the racemate, although the analgesic activity is almost entirely the result of its content of l-methadone, which is 8 to 50 times more potent than the d-isomer. d-Methadone binds very poorly to the mu-opioid receptor and so also lacks significant respiratory depressant action and addiction liability, although it does possesses antitussive activity (Fredheim et al., 2008).

Propoxyphene is a methadone analogue that was used to treat mild-to-moderate pain. As mentioned earlier, the U.S. FDA recommended removal of the drug (trade name: Darvon) from the U.S. market in 2010 due to reports of cardiac toxicity.

Pharmacological Effects

Important properties of *methadone* are its analgesic activity, its efficacy by the oral route, its extended duration of action in suppressing withdrawal symptoms in physically dependent individuals, and its tendency to show persistent effects with repeated administration. Miotic and respiratory-depressant effects can be detected for more than 24 h after a single dose; on repeated administration, marked sedation is seen in some patients. Effects on cough, bowel motility, biliary tone, and the secretion of pituitary hormones are qualitatively similar to those of *morphine*.

ADME

Methadone is absorbed well from the GI tract and can be detected in plasma within 30 min of oral ingestion; it reaches peak concentrations at

about 4 h. Peak concentrations occur in brain within 1 to 2 h of subcutaneous or intramuscular administration, and this correlates well with the intensity and duration of analgesia. *Methadone* also can be absorbed from the buccal mucosa. *Methadone* undergoes extensive biotransformation in the liver. The major metabolites are pyrrolidine and pyrroline derivatives that result from N-demethylation and cyclization and are excreted in the urine and the bile along with small amounts of unchanged drug. The amount of *methadone* excreted in the urine is increased when the urine is acidified. The $t_{1/2}$ of *methadone* is long, 15 to 40 h. *Methadone* appears to be firmly bound to protein in various tissues, including brain. After repeated administration, there is gradual accumulation in tissues. When administration is discontinued, low concentrations are maintained in plasma by slow release from extravascular binding sites. This process may explain why withdrawal symptoms following *methadone* are less severe than with *morphine* but last longer, resulting in a relatively mild but protracted withdrawal syndrome.

Therapeutic Uses

Although an effective analgesic, the primary use of *methadone hydrochloride* is detoxification and maintenance therapy treatment for opioid use disorder. Because it is a full agonist with all the properties of *morphine*, this takes place within certified treatment programs. Outside treatment programs, *methadone* is used for the management of chronic pain. The onset of analgesia occurs 10 to 20 min after parenteral administration and 30 to 60 min after oral medication. The typical oral dose is 2.5 to 10 mg repeated every 8 to 12 h as needed depending on the severity of the pain and the response of the patient. Care must be taken when increasing the dosage because of the prolonged $t_{1/2}$ of the drug and its tendency to accumulate over a period of several days with repeated dosing. The peak respiratory-depressant effects of *methadone* typically occur later and persist longer than peak analgesia, so it is necessary to exercise vigilance and strongly caution patients against self-medicating with CNS depressants, particularly during treatment initiation and dose titration. *Methadone* should not be used in labor. Despite its longer plasma $t_{1/2}$, the duration of the analgesic action of single doses is essentially the same as that of *morphine*. With repeated use, cumulative effects are seen, so either lower dosages or longer intervals between doses become possible. *Methadone*, like other opioids, will produce tolerance and dependence. Development of physical dependence during the long-term administration of *methadone* can be demonstrated following abrupt drug withdrawal or by administration of an opioid antagonist. Likewise, subcutaneous administration of *methadone* to those with an opioid use disorder produces euphoria equal in duration to that caused by *morphine*, and its overall abuse potential is comparable with that of *morphine*.

Adverse Effects

Side effects are similar to those described for *morphine*. *Rifampin* and *phenytoin* accelerate the metabolism of *methadone* and can precipitate withdrawal symptoms. Unlike other opioids, *methadone* is associated with the prolonged QT syndrome and is additive with agents known to prolong the QT interval.

Partial Agonists

These compounds exhibit clinically useful analgesia but with less respiratory depression and addictive potential. The compounds are generally not selective for the mu-opioid receptor over delta- or kappa-opioid receptors as compared with high-efficacy mu-opioid receptor agonists.

Buprenorphine

Pharmacology. *Buprenorphine* is a highly lipophilic mu-opioid agonist that is 25 to 50 times more potent than *morphine* but less efficacious. The pharmacology of *buprenorphine* is qualitatively similar to *morphine*. Administered sublingually, *buprenorphine* (0.4–0.8 mg) produces satisfactory analgesia in postoperative patients. The main therapeutic use of *buprenorphine* is as for the management of opioid use disorder. *Buprenorphine* also functions as a delta- and kappa-opioid antagonist and a weak partial agonist at NOPr.

ADME. Concentrations of *buprenorphine* in blood peak within 5 min of intramuscular injection and within 1 to 2 h of oral or sublingual administration. The plasma $t_{1/2}$ is about 3 h. However, the $t_{1/2}$ for dissociation of *buprenorphine* from the mu receptor is approximately 170 min, as opposed to 7 min for *fentanyl*, so plasma levels of *buprenorphine* may not parallel clinical effects.

Buprenorphine is metabolized to norbuprenorphine by CYP3A4 and should not be taken with known inhibitors of CYP3A4 (e.g., azole antifungals, macrolide antibiotics, and HIV protease inhibitors) or drugs that induce CYP3A4 activity (e.g., certain anticonvulsants and *rifampin*). Both N-dealkylated and conjugated metabolites are detected in the urine, but most of the drug is excreted unchanged in the feces. When *buprenorphine* is discontinued, a withdrawal syndrome develops that is delayed in onset for 2 to 14 days and persists for 1 to 2 weeks.

Therapeutic Uses

Analgesia. *Buprenorphine*, formulated as an injection, sublingual tablets, or skin patch, is used as an analgesic. About 0.3 mg IM *buprenorphine* is equianalgesic to 10 mg IM *morphine*. Some of the subjective and respiratory-depressant effects are unequivocally slower in onset and last longer than those of *morphine*. The respiratory depression and other effects of *buprenorphine* can be prevented by prior administration of *naloxone*, but they are not readily reversed by *naloxone* once the effects have been produced, probably due to the high affinity of buprenorphine and its slow dissociation from mu-opioid receptors. As a partial agonist, *buprenorphine* antagonizes the respiratory depression produced by anesthetic doses of *fentanyl* without completely reversing opioid pain relief. *Buprenorphine* can also precipitate withdrawal in patients who have been receiving higher efficacy mu-opioid agonists for several weeks.

Opioid Use Disorder. Due to its extended length of action at the mu-opioid receptor and its partial mu-opioid agonist activity, *buprenorphine* is used for the management of patients suffering from opioid use disorder (Greenwald et al., 2014). The drug controls opioid craving and also serves to block the actions of higher-efficacy opioids the addicted patient might take. For this use, *buprenorphine* is administered in a fixed-dose combination with *naloxone* to prevent misuse and diversion but may be given alone to pregnant women or patients with *naloxone* allergy. Induction doses start at 2 to 4 mg daily and stabilize at approximately 12 to 16 mg/day. Because *buprenorphine* can precipitate withdrawal in individuals with an opioid use disorder, detoxification is needed before starting treatment. The complex pharmacology of *buprenorphine* with actions at mu-, delta-, and kappa-opioid receptors and nociceptin receptors may contribute to its effectiveness for the management of opioid dependence. Because it is safer than *methadone*, U.S. physicians can treat up to 275 patients with the *buprenorphine-naloxone* combination in an outpatient setting after completing a short training course.

Pentazocine

Pentazocine was synthesized in an effort to develop an effective analgesic with little or no abuse potential.

Pentazocine is a partial agonist at both mu- and kappa-opioid receptors. The pattern of CNS effects produced by *pentazocine* is similar to those of the morphine-like opioids, including analgesia, sedation, and respiratory depression. An oral dose of about 50 mg *pentazocine* results in analgesia equivalent to that produced by a 60-mg oral dose of *codeine*. Due to its partial agonist nature, ceiling effects for analgesia and respiratory depression are observed at doses above 50 to 100 mg of *pentazocine*. However, the analgesic actions of the drug are thought to be mediated by its kappa-opioid receptor action. Consistent with kappa-opioid receptor activation, high doses of *pentazocine* (60–90 mg) elicit dysphoric and psychotomimetic effects. The cardiovascular responses to *pentazocine* differ from those seen with typical mu-opioid receptor agonists in that high doses cause an increase in blood pressure and heart rate. *Pentazocine* does not antagonize the respiratory depression produced by *morphine*. However, when given to patients who are dependent on *morphine* or other mu-opioid receptor agonists, *pentazocine* may precipitate withdrawal.

Therapeutic Use. *Pentazocine lactate* injection is indicated for the relief of mild-to-moderate pain and is also used as a preoperative medication

and as a supplement to anesthesia. *Pentazocine* tablets for oral use are only available in fixed-dose combinations with *acetaminophen* or *naloxone*. Combination of *pentazocine* with *naloxone* reduces the potential misuse of tablets as a source of injectable *pentazocine*.

Nalbuphine

Like *pentazocine, nalbuphine* is a partial agonist at kappa- and mu-opioid receptors with effects that qualitatively resemble those of *pentazocine*; however, *nalbuphine* produces fewer dysphoric side effects than *pentazocine* (Schmidt et al., 1985).

An intramuscular dose of 10 mg *nalbuphine* is equianalgesic to 10 mg *morphine*, with similar onset and duration of analgesic and subjective effects. *Nalbuphine* depresses respiration as much as equianalgesic doses of *morphine*; however, like *pentazocine*, *nalbuphine* exhibits a ceiling effect such that increases in dosage beyond 30 mg produce no further respiratory depression or analgesia. In contrast to *pentazocine* and *butorphanol* (see below), 10 mg *nalbuphine* given to patients with stable coronary artery disease does not produce an increase in cardiac index, pulmonary arterial pressure, or cardiac work, and systemic blood pressure is not significantly altered; these indices also are relatively stable when *nalbuphine* is given to patients with acute myocardial infarction. *Nalbuphine* produces few side effects at doses of 10 mg or less; sedation, sweating, and headache are the most common. At much higher doses (70 mg), psychotomimetic side effects (e.g., dysphoria, racing thoughts, and distortions of body image) can occur. *Nalbuphine* is metabolized in the liver and has a plasma $t_{1/2}$ of 2 to 3 h. *Nalbuphine* is 20% to 25% as potent when administered orally as when given intramuscularly. Prolonged administration of *nalbuphine* can produce physical dependence. The withdrawal syndrome is similar in intensity to that seen with *pentazocine*.

Therapeutic Use. *Nalbuphine* is used to produce analgesia. Because it is a partial agonist, administration to patients who have been receiving morphine-like opioids may create difficulties unless a brief drug-free interval is interposed.

Butorphanol

Butorphanol has a profile of actions similar to those of *pentazocine* and *nalbuphine*.

In postoperative patients, a parenteral dose of 2 to 3 mg *butorphanol* produces analgesia and respiratory depression approximately equal to that produced by 10 mg *morphine* or 80 to 100 mg *meperidine*. The plasma $t_{1/2}$ of *butorphanol* is about 3 h. Like *pentazocine*, analgesic doses of *butorphanol* produce an increase in pulmonary arterial pressure and in the work of the heart; systemic arterial pressure is slightly decreased. The major side effects of *butorphanol* are drowsiness, weakness, sweating, feelings of floating, and nausea. While the incidence of psychotomimetic side effects is lower than that with equianalgesic doses of *pentazocine*, they are qualitatively similar. Physical dependence can occur.

Therapeutic Use. *Butorphanol* is used for the relief of acute pain (e.g., postoperative) and, because of its potential to antagonize other mu-opioid receptor agonists, should not be used in combination with higher-efficacy agents. Because of its side effects on the heart, it is less useful than *morphine* or *meperidine* in patients with congestive heart failure or myocardial infarction. A nasal formulation is available and has proven to be effective in pain relief, including migraine pain (Gillis et al., 1995); this method of administration is associated with drowsiness and dizziness.

Other Opioid Agonists

Tramadol

Pharmacology and Therapeutic Use. The analgesic effect of *tramadol* is due to weak mu-opioid receptor activity and inhibition of uptake of NE and 5HT. The affinity of *tramadol* for the mu-opioid receptor is only 1/6000 that of *morphine*, but the O-demethylated metabolite of *tramadol* is two to four times more potent than the parent drug and may account for part of the analgesic effect. *Tramadol* is supplied as a racemate that is more effective than either enantiomer alone. The (+)-enantiomer binds with higher affinity to the mu-opioid receptor and inhibits 5HT uptake. The (–)-enantiomer is more active on NE uptake and stimulates α_2 adrenergic receptors.

In the treatment of mild-to-moderate pain, *tramadol* is as effective as *morphine*. However, for the treatment of severe or chronic pain, *tramadol* is less effective. *Tramadol* is as helpful as *meperidine* in the treatment of labor pain and may cause less neonatal respiratory depression (Grond and Sablotzki, 2004). *Tramadol* is also available as long-acting formulations and in a fixed-dose combination with *acetaminophen*.

Side effects of *tramadol* include nausea, vomiting, dizziness, dry mouth, sedation, and headache. Respiratory depression appears to be less than with equianalgesic doses of *morphine* and is reversed by *naloxone*; the degree of constipation is less than that seen after equivalent doses of *codeine*. *Tramadol* can cause seizures and possibly exacerbate seizures in patients with predisposing factors. *Tramadol* should not be used in patients taking MAO inhibitors, selective serotonin reuptake inhibitors, or other drugs that lower the seizure threshold. Precipitation of withdrawal necessitates that *tramadol* be tapered prior to discontinuation.

ADME. *Tramadol* is 68% bioavailable after a single oral dose. *Tramadol* undergoes extensive hepatic metabolism by a number of enzymes, including CYPs 2D6 and 3A4, and by conjugation with subsequent renal excretion. The elimination $t_{1/2}$ is 6 h for *tramadol* and 7.5 h for its active metabolite. Analgesia begins within an hour of oral dosing and peaks within 2 to 3 h. The duration of analgesia is about 6 h.

Tapentadol

Tapentadol is structurally and mechanistically similar to *tramadol*. It is a weak inhibitor of monoamine reuptake but has a significantly more potent activity at mu-opioid receptors. Serotonin syndrome is a risk, especially when *tapentadol* is used concomitantly with selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, tricyclic antidepressants, or MAO inhibitors that impair serotonin metabolism. *Tapentadol* is metabolized largely by glucuronidation.

Oliceridine

This is the first mu-opioid receptor biased agonist to be approved by the FDA. However, although showing bias in preclinical studies, the compound has the same pharmacological profile and contraindications as *morphine*. It is approved only for use in adults to manage severe acute pain that requires an intravenous opioid and where alternative treatments do not provide adequate pain relief.

Dosage and Routes of Opioid Analgesic Administration

Dosing information for commonly used opioid drugs is provided in Tables 23–2 and 23–3. Information on *morphine* equivalent doses for various opioid drugs is provided in Table 23–4.

In addition to the traditional oral and parenteral formulations for opioids, many other methods of administration have been developed to improve therapeutic efficacy while minimizing side effects. These include the following:

Patient-Controlled Analgesia (PCA). The patient has limited control of the dosing of opioid from an infusion pump programmed within tightly mandated parameters. This permits better alignment between pain control and individual differences in pain perception and responsiveness to opioids and gives the patient a greater sense of control over the pain.

Spinal Delivery. Administration of opioids into the epidural or intrathecal spaces provides more direct access to the first pain-processing synapse in the dorsal horn of the spinal cord. The management of chronic pain with spinal opioids has been addressed by the use of chronically implanted intrathecal catheters connected to subcutaneously implanted refillable pumps (Yaksh et al., 2017). Epidural administration of opioids is popular in the management of postoperative

TABLE 23–2 ■ DOSING DATA FOR CLINICALLY EMPLOYED OPIOID ANALGESICS

DRUG	APPROXIMATE EQUIANALGESIC ORAL DOSE	APPROXIMATE EQUIANALGESIC PARENTERAL DOSE	RECOMMENDED STARTING DOSE (Adults >50 kg)		RECOMMENDED STARTING DOSE (Children and Adults <50 kg)	
			ORAL	PARENTERAL	ORAL	PARENTERAL
Morphine	30 mg/3–4 h	10 mg/3–4 h	15 mg/3–4 h	5 mg/3–4 h	0.3 mg/kg/3–4 h	0.1 mg/kg/3–4 h
Codeine	130 mg/3–4 h	75 mg/3–4 h	30 mg/3–4 h	30 mg/2 h (IM/SC)	0.5 mg/kg/3–4 h	Not recommended
Hydromorphone	6 mg/3–4 h	1.5 mg/3–4 h	2 mg/3–4 h	0.5 mg/3–4 h	0.03 mg/kg/3–4 h	0.005 mg/kg/3–4 h
Hydrocodone (typically with acetaminophen)	30 mg/3–4 h	Not available	5 mg/3–4 h	Not available	0.1 mg/kg/3–4 h	Not available
Levorphanol	4 mg/6–8 h	2 mg/6–8 h	4 mg/6–8 h	2 mg/6–8 h	0.04 mg/kg/6–8 h	0.02 mg/kg/6–8 h
Meperidine	300 mg/2–3 h	100 mg/3 h	Not recommended	50 mg/3 h	Not recommended	0.75 mg/kg/2–3 h
Methadone	10 mg/6–8 h	10 mg/6–8 h	5 mg/12 h	Not recommended	0.1 mg/kg/12 h	Not recommended
Oxycodone	20 mg/3–4 h	Not available	5 mg/3–4 h	Not available	0.1 mg/kg/3–4 h	Not available
Oxymorphone	10 mg/3–4 h	1 mg/3–4 h	5 mg/3–4 h	1 mg/3–4 h	0.1 mg/kg/3–4 h	Not recommended
Tramadol	100 mg	100 mg	50–100 mg/6 h	50–100 mg/6 h	Not recommended	Not recommended
Fentanyl Transdermal 72-h patch (25 µg/h) = morphine 50 mg/24 h						
Buprenorphine	Not available	0.3–0.4 mg/6–8 h	Not available	0.4 mg/6–8 h	Not available	0.004 mg/kg/6–8 h
Butorphanol	Not available	2 mg/3–4 h	Not available	2 mg/3–4 h	Not available	Not recommended
Nalbuphine	Not available	10 mg/3–4 h	Not available	10 mg/3–4 h	Not available	0.1 mg/kg/3–4 h
Oliceridine	Not available	1–3mg/1–3h	Not available	1–2 mg	Not available	

These data are merely guidelines. Clinical response must be the guide for each patient, with consideration to hepatic and renal function, disease, age, concurrent medications (their effects and dose limitations [acetaminophen, 3 g/day for adults]), and other factors that could modify pharmacokinetics and drug response. Recommended start doses are approximately but not precisely equianalgesic and are driven by doses available from manufacturers. Transdermal fentanyl is contraindicated for acute pain and in patients receiving <60 mg oral morphine equivalent per day. Use Table 23–4 for converting morphine to methadone dosing.
For morphine, hydromorphone, and oxymorphone, rectal administration is an alternate route for patients unable to take oral medications, but equianalgesic doses may differ from oral and parenteral doses because of pharmacokinetic differences.
Doses listed for patients with body weight less than 50 kg cannot be used as initial starting doses in babies less than 6 months of age; consult the *Clinical Practice Guideline #1, Acute Pain Management: Operative or Medical Procedures and Trauma* (cited below), section on neonates, for recommendations.

AHCPR Clinical Practice Guidelines, No. 1: Acute Pain Management: Operative or Medical Procedures and Trauma. Agency for Health Care Policy and Research, Rockville, MD, **1992**.

TABLE 23–3 ■ EPIDURAL OR INTRATHECAL OPIOIDS FOR THE TREATMENT OF ACUTE (BOLUS) OR CHRONIC (INFUSION) PAIN

DRUG	SINGLE DOSE (mg)[a]	INFUSION RATE (mg/h)[b]	ONSET (min)	DURATION OF EFFECT OF SINGLE DOSE (h)[c]
Epidural				
Morphine	1–6	0.1–1.0	30	6–24
Meperidine	20–150	5–20	5	4–8
Methadone	1–10	0.3–0.5	10	6–10
Hydromorphone	1–2	0.1–0.2	15	10–16
Fentanyl	0.025–0.1	0.025–0.10	5	2–4
Sufentanil	0.01–0.06	0.01–0.05	5	2–4
Alfentanil	0.5–1	0.2	15	1–3
Subarachnoid (Intrathecal)				
Morphine	0.1–0.3		15	8–24+
Fentanyl	0.005–0.025		5	3–6

[a]Low doses may be effective when administered to the elderly or when injected in the thoracic region.
[b]If combining with a local anesthetic, consider using 0.0625% bupivacaine.
[c]Duration of analgesia varies widely; higher doses produce longer duration. With the exception of epidural/intrathecal morphine or epidural sufentanil, all other spinal opioid use is considered to be off-label.

TABLE 23–4 ■ MORPHINE MILLIGRAM EQUIVALENT (MME) DOSES FOR COMMONLY PRESCRIBED OPIOIDS

OPIOID	CONVERSION FACTOR[a]
Codeine	0.15
Fentanyl transdermal (in μg/h)	2.4
Hydrocodone	1
Hydromorphone	4
Methadone	
1–20 mg/day	4
21–40 mg/day	8
41–60 mg/day	10
≥61–80 mg/day	12
Morphine	1
Oxycodone	1.5
Oxymorphone	3

[a]Multiply the dose for each opioid by the conversion factor to determine the dose in MMEs. For example, tablets containing hydrocodone 5 mg and acetaminophen 300 mg taken four times a day would contain a total of 20 mg of hydrocodone daily, equivalent to 20 MME daily; extended-release tablets containing oxycodone 10 mg taken twice a day would contain a total of 20 mg of oxycodone daily, equivalent to 30 MME daily. Note the following precautions: (1) All doses are in milligrams/day except for fentanyl, which is micrograms/hour. (2) Equianalgesic dose conversions are only estimates and cannot account for individual variability in genetics and pharmacokinetics. (3) Do not use the calculated dose in MMEs to determine the doses to use when converting one opioid to another; when converting opioids, the new opioid is typically dosed at substantially lower than the calculated MME dose to avoid accidental overdose due to incomplete cross-tolerance and individual variability in opioid pharmacokinetics. (4) Use particular caution with methadone dose conversions because the conversion factor increases at higher doses. (5) Use particular caution with fentanyl because it is dosed in micrograms/hour instead of milligrams/day, and its absorption is affected by heat and other factors.

pain and causes less respiratory depression due to lower systemic levels. Similarly, this delivery method is popular for providing analgesia during labor and delivery because of reduced placental transfer and less potential for respiratory depression of the newborn. In addition, intraspinal narcotics often are combined with other agents that include local anesthetics, N-type Ca^{2+} channel blockers, α_2 adrenergic agonists, and $GABA_B$ agonists, allowing the use of lower concentrations of these agents (Yaksh et al., 2017). However, epidural and intrathecal opioids have their own dose-dependent side effects, such as pruritus, nausea, vomiting, respiratory depression, and urinary retention.

Rectal Administration. This is an alternative for patients with difficulty swallowing or other oral pathology and who prefer a less invasive route than parenteral administration. This route is not well tolerated by most children.

Oral Transmucosal Administration. Opioids can be absorbed through the oral mucosa more rapidly than through the stomach. Bioavailability is greater owing to avoidance of first-pass metabolism, and lipophilic opioids are absorbed better by this route than are more hydrophilic compounds such as *morphine*. For example, a variety of formulations of *fentanyl* are available for this route.

Transnasal Administration. A transnasal *fentanyl* spray is FDA approved for the treatment of breakthrough cancer pain. Administration is well tolerated, and pain relief occurs rapidly

Butorphanol has been employed intranasally. *Naloxone* is commonly given by this route for overdose rescue, as described above.

Transdermal Administration. Transdermal *fentanyl* patches are approved for use in sustained pain. This modality is well suited for cancer pain treatment because of its ease of use, prolonged duration of action, and stable blood levels. Dermatological side effects from the patches, such as rash and itching, usually are mild. Individuals with an opioid use disorder have been known to chew the patches and receive an overdose, sometimes with fatal outcomes, following rapid and efficient buccal and sublingual absorption. Fever and external heat sources (heating pads, hot baths) can increase absorption of *fentanyl* and potentially lead to an overdose.

Opioid Rotation

Changing to a different opioid when the patient fails to achieve benefit, or side effects become limiting before analgesia is sufficient, is widely employed. Failure or intolerance of one opioid cannot necessarily predict the patient's response or acceptance to another (Quang-Cantagrel et al., 2000). Practically, opioid rotation involves incrementing the dose of a given opioid agonist (e.g., *morphine*) to a level limited by side effects and insufficient analgesia and then substituting an alternate opioid medication at an equieffective dose. Care must be taken to titrate the doses and monitor the patient closely during such drug transitions.

Combination Therapy

In general, the use of combinations of drugs with the same pharmacokinetic profile is not warranted (e.g., *morphine* plus *methadone*). The same holds if the drugs have overlapping targets and opposing effects (e.g., combining an agonist with an agent with a partial agonist). On the other hand, certain opioid combinations are useful. For example, in a chronic pain state with periodic incident or breakthrough pain, the patient might receive a slow-release formulation of *morphine* for baseline pain relief, and the acute incident (breakthrough) pain may be managed with a rapid-onset/short-lasting formulation such as buccal *fentanyl*. For inflammatory or nociceptive pain, opioids may be usefully combined with other analgesic agents, such as *acetaminophen* or other NSAIDs. In the case of neuropathic pain, other drug classes may be useful alone or in combination with an opioid. For example, antidepressants that block amine reuptake, such as *amitriptyline* or *duloxetine*, and anticonvulsants such as *gabapentin* may enhance the analgesic effect and may be synergistic in some pain states.

Opioid Antagonists

A variety of agents bind competitively to one or more of the opioid receptors, display little or no intrinsic activity, and robustly antagonize the effects of receptor agonists. Relatively minor changes in the structure of an opioid ligand can convert an agonist into an antagonist at one or more types of opioid receptors. Simple substitutions transform *morphine* to *nalorphine*, *levorphanol* to *levallorphan*, and *oxymorphone* to *naloxone* or *naltrexone*. Other congeners, especially *naloxone* and *naltrexone*, appear to be devoid of agonist actions and interact with the canonical opioid receptors types (mu-, delta-, and kappa-opioid receptors), albeit with somewhat different affinities. Importantly, *naloxone* and *naltrexone* do not bind to the nociceptin receptor. The majority of these agents are relatively lipid soluble and have excellent CNS penetration after systemic delivery (Barnett et al., 2014). However, a number of antagonists only bind to opioid receptors mainly at peripheral (non-CNS) sites due to their poor bioavailability, such as *methylnaltrexone*. These opioid receptor antagonists are used to manage opioid-induced constipation (Becker et al., 2007).

Alvimopan is a mu-opioid receptor antagonist with distribution restricted to the periphery. Following oral administration, a deamidated metabolite of *alvimopan* slowly and variably appears in the bloodstream and is attributed to activity of the intestinal microbiome. Like *alvimopan*, the metabolite is an antagonist with high affinity for the mu-opioid receptor. Both parent drug and metabolite have terminal half-lives of 10 to 18 h. *Alvimopan* is FDA-approved for treatment of postoperative ileus in patients with less than 7 days of opioid exposure immediately prior to

beginning *alvimopan*. Due to increased incidence of myocardial infarction with prolonged use, *alvimopan* is for short-term use (15 doses) only.

Nalmefene (not marketed in the U.S.) is a relatively pure mu-opioid receptor antagonist that is more potent than *naloxone*.

Therapeutic Uses

Opioid antagonists have obvious therapeutic utility in the treatment of opioid overdose but are also used to treat opioid-induced constipation and alcohol use disorder. Opioid antagonists displace opioid agonists from the mu-opioid receptor and thus reverse the effects of agonists. Under ordinary circumstances, these opioid antagonists produce few effects in the absence of an exogenous agonist. However, under certain conditions (e.g., pain, shock, alcohol use), when the endogenous opioid systems are activated, the administration of an opioid antagonist alone may have effects.

Treatment of Opioid Overdoses

Opioid antagonists, particularly *naloxone*, have an established use in the treatment of opioid-induced toxicity, especially respiratory depression. Its specificity is such that reversal by *naloxone* is virtually diagnostic for the involvement of an opioid agonist. *Naloxone* acts rapidly to reverse the respiratory depression. The duration of action of *naloxone* is relatively short, and it often must be given repeatedly or by continuous infusion to prevent re-narcotization. *Naloxone* nasal spray (Narcan®) is widely available for emergency use in a nonhospital setting. It should be noted that *naloxone* or any opioid antagonist may precipitate withdrawal in dependent subjects, causing undesirable effects such as diarrhea, hypertension/tachycardia, and pain. Opioid antagonists also have been employed effectively to decrease neonatal respiratory depression secondary to the intravenous or intramuscular administration of opioids to the mother. In the neonate, the initial dose is 10 μg/kg given intravenously, intramuscularly, or subcutaneously.

Management of Constipation

The peripherally limited antagonists *methylnaltrexone* and *naloxegol* have important roles in the management of constipation and reduced GI motility present in the patient undergoing chronic opioid therapy for chronic pain, *methadone* maintenance, and following abdominal surgery. Treatment with such agents facilitates recovery of normal bowel function and leaves the analgesic activity of the postoperative opioid intact, which is mostly mediated by the CNS (Vaughan-Shaw et al., 2012).

Management of Opioid and Alcohol Use Disorders

An extended-release formulation of *naltrexone* is approved for the treatment of opioid and alcohol use disorder. The extended-release matrix is delivered by intramuscular injection and given by a practitioner once per month. To reduce the risk of eliciting withdrawal symptoms, patients should wait 7 to 14 days since their last dose of an opioid agonist before starting *naltrexone* treatment. In opioid use disorder, *naltrexone* will prevent opioid agonists from binding to and activating mu-opioid receptors, preventing opioid-induced euphoria and, hopefully, relapse to opioid use. In all patients taking this medication, *naltrexone* will block the centrally mediated analgesic effects and peripherally mediated GI slowing produced by mu-opioid receptor agonists.

Miscellaneous

Naltrexone in combination with *bupropion* is also FDA-approved as an adjunct for weight management in patients with obesity. *Samidorphan*, an analogue of *naltrexone*, has been recently approved as a combination with *olanzapine* for the management of schizophrenia. The antagonist has been shown to reduce weight gain in patients on *olanzapine*.

Pharmacological Properties

Effects in the Absence of Opioid Agonist

Subcutaneous doses of *naloxone* up to 12 mg produce no discernible effects in humans, and doses of 24 mg cause only slight drowsiness. *Naltrexone* also is a relatively pure antagonist but with a longer duration of action and greater bioavailability following oral administration. The effects of opioid receptor antagonists are usually both subtle and limited, likely reflecting the low levels of tonic activity and organizational complexity of the opioid systems in various physiological systems. Opioid receptor antagonism in humans is associated with variable effects, ranging from no effect to mild hyperalgesia. In some, but not all, studies, opioid antagonists are reported to block the analgesic effects produced by acupuncture, exercise, mindfulness meditation, positive mood, magnetic stimulation, and placebo medications, suggesting that the endogenous opioid system may play a role in these analgesic effects (Bruehl et al., 2020; Ciampi de Andrade et al., 2011; Flaten, 2014; Frangos et al., 2021; Staud and Price, 2006).

Endogenous opioid peptides participate in the regulation of pituitary secretion by exerting tonic inhibitory effects on the release of certain hypothalamic hormones (see Chapter 46). Thus, the administration of *naloxone* or *naltrexone* increases the secretion of gonadotropin-releasing hormone and corticotropin-releasing hormone and elevates the plasma concentrations of LH, FSH, and ACTH, as well as the steroid hormones produced by their target organs. *Naloxone* stimulates the release of prolactin in women. Endogenous opioid peptides probably have some role in the regulation of feeding or energy metabolism; however, *naltrexone* does not accelerate weight loss in very obese subjects, even though short-term administration of opioid antagonists reduces food intake in lean and obese individuals. Long-term administration of antagonists may increase the density of opioid receptors in the brain and causes a temporary exaggeration of responses to the subsequent administration of opioid agonists.

Effects in the Presence of Opioid Agonists

Antagonistic Effects. Small doses (0.4–0.8 mg) of *naloxone* given intramuscularly or intravenously prevent or promptly reverse the effects of receptor agonists. In patients with respiratory depression, an increase in respiratory rate is seen within 1 to 2 min. Sedative effects are reversed, and blood pressure, if depressed, returns to normal. Higher doses of *naloxone* are required to antagonize the respiratory-depressant effects of *buprenorphine*, *fentanyl*, and other high-affinity opioid receptor agonists; 1 mg *naloxone* intravenously completely blocks the effects of 25 mg *heroin*. *Naloxone* reverses the psychotomimetic and dysphoric effects of agonist-antagonist agents such as *pentazocine*, but much higher doses (10–15 mg) are required. The duration of antagonistic effects depends on the dose but usually is 1 to 4 h. Antagonism of opioid effects by *naloxone* often is accompanied by an "overshoot" phenomenon. For example, respiratory rates depressed by opioids transiently become higher than before the period of depression. Rebound release of catecholamines may cause hypertension, tachycardia, and ventricular arrhythmias. Pulmonary edema also has been reported after *naloxone* administration.

Effects in Opioid-Dependent Patients

In subjects who are dependent on morphine-like opioids, small subcutaneous doses of *naloxone* (0.5 mg) precipitate a moderate-to-severe withdrawal syndrome similar to that seen after abrupt withdrawal of opioids, except that the syndrome appears within minutes of administration and subsides in about 2 h. The severity and duration of the syndrome are related to the dose of the antagonist and to the degree and type of dependence. Higher doses of *naloxone* will precipitate a withdrawal syndrome in patients dependent on *pentazocine*, *butorphanol*, or *nalbuphine*. In dependent patients, peripheral side effects of opioids, notably reduced GI motility and constipation, can be reversed by *methylnaltrexone*, with subcutaneous doses (0.15 mg/kg) producing reliable bowel movements and no evidence of centrally mediated withdrawal signs (Thomas et al., 2008). *Naloxone* produces an overshoot phenomenon suggestive of early acute physical dependence 6 to 24 h after even a single dose of a mu-opioid receptor agonist.

ADME

Although absorbed readily from the GI tract, *naloxone* undergoes extensive first-pass metabolism and is almost completely metabolized by the liver (primarily by conjugation with glucuronic acid) before reaching the systemic circulation and thus must be administered parenterally. The $t_{1/2}$ of *naloxone* is about 1 h, but its clinically effective duration of action can be even less.

Compared with *naloxone*, *naltrexone* is more effective by the oral route, and has a duration of action that approaches 24 h after moderate oral doses. Peak concentrations in plasma are reached within 1 to 2 h and then decline with an apparent $t_{1/2}$ of about 3 h. *Naltrexone* is metabolized to 6-naltrexol, which is a weaker antagonist with a longer $t_{1/2}$, about 13 h. *Naltrexone* is more potent than *naloxone*, and 100-mg oral doses given to patients dependent on opioids produce concentrations in tissues sufficient to block the euphorigenic effects of 25-mg IV doses of *heroin* for 48 h. *Methylnaltrexone* is similar to *naltrexone*; it is converted to methyl-6-naltrexol isomers and eliminated primarily via active renal secretion. The $t_{1/2}$ of *methylnaltrexone* is about 8 h.

Acute Opioid Toxicity

Acute opioid toxicity may result from clinical overdosage, accidental overdosage, or attempts at suicide. Occasionally, a delayed toxicity may occur from the injection of an opioid into chilled skin areas or in patients with low blood pressure and shock. The drug is not fully absorbed; therefore, a subsequent dose may be given. When normal circulation is restored, an excessive amount may be absorbed suddenly.

The triad of coma, pinpoint pupils, and depressed respiration suggests opioid poisoning. The patient is stuporous or, if a large overdose has been taken, may be in a profound coma. The respiratory rate will be very low, or the patient may be apneic and possibly cyanotic. Body temperature falls, and the skin becomes cold and clammy. The skeletal muscles are flaccid, the jaw is relaxed, and the tongue may fall back and block the airway. Convulsions occasionally may be noted in infants and children. When death occurs, it is nearly always from respiratory failure.

The first step in treatment is to establish a patent airway and ventilate the patient. *Naloxone* is used to reverse the severe respiratory depression. *Naloxone* can be given IM, SC, or IV or by first responders and the public using a nasal spray (Narcan®) containing 4 mg *naloxone*. Administration can be repeated every 2 to 3 min if the person does not respond after the first dose. This may be particularly needed with very potent opioids such as the *fentanyl* derivatives. The duration of action of *naloxone* is shorter than that of many opioid agonists; hence, patients can slip back into coma. Steps for responding to an opioid overdose can be found in the Substance Abuse and Mental Health Administration's *Opioid Overdose Prevention Toolkit* (https://store.samhsa.gov/product/Opioid-Overdose-Prevention-Toolkit/SMA18-4742; accessed June 29, 2022).

Additional Therapeutic Uses of Opioids

Dyspnea

Morphine is used to alleviate the dyspnea of acute left ventricular failure and pulmonary edema, and the patient's response to intravenous *morphine* may be dramatic. The mechanism underlying this pronounced relief is not clear. It may involve an alteration of the patient's reaction to impaired respiratory function and an indirect reduction of the work of the heart owing to reduced fear and apprehension. However, it is more probable that the major benefit is due to cardiovascular effects, such as decreased peripheral resistance secondary to histamine release and an increased capacity of the peripheral and splanchnic vascular compartments. *Nitroglycerin*, which also causes vasodilation, may be superior to *morphine*. Nonetheless, opioids generally are contraindicated in pulmonary edema unless severe pain is also present.

Anesthetic Adjuvants

High doses of opioids, notably *fentanyl* and analogues, are widely used as the primary anesthetic agents in many surgical procedures. They have powerful minimum alveolar concentration ("MAC")-sparing effects; for example, they reduce the concentrations of volatile anesthetic otherwise required to produce an adequate anesthetic depth. Although respiration is so depressed that physical assistance is required, patients can retain consciousness. Therefore, when an opioid is the primary anesthetic, an agent that results in unconsciousness and produces amnesia, such as the benzodiazepines or lower concentrations of volatile anesthetics, is also employed. High doses of opioid as employed in the operating room setting also result in prominent rigidity of the chest wall and masseters, requiring concurrent treatment with muscle relaxants to permit intubations and ventilation.

Opioid-Related Antitussive Agents

As mentioned earlier, mu-opioid receptor agonists, particularly *codeine*, are effective in suppressing the cough reflex, although for *codeine*, this action may not involve opioid receptors. In addition, *dextromethorphan* and *pholcodine* are structurally compounds that do not bind to or have activity at opioid receptors and produce antitussive activity through other mechanisms.

Dextromethorphan (D-3-methoxy-*N*-methylmorphinan) as the D-isomer has no analgesic or addictive properties and does not act through mu-opioid receptors. Rather, the drug acts centrally to elevate the threshold for coughing. Its effectiveness in patients with pathological cough has been demonstrated in controlled studies; its potency is nearly equal to that of *codeine*, but *dextromethorphan* produces fewer subjective and GI side effects. In therapeutic dosages, the drug does not inhibit ciliary activity, and its antitussive effects persist for 5 to 6 h. The average adult dosage of *dextromethorphan hydrobromide* is 10 to 20 mg every 4 h or 30 mg every 6 to 8 h, not to exceed 120 mg daily. The drug is marketed for over-the-counter sale in liquids, syrups, capsules, soluble strips, lozenges, and freezer pops or in combinations with antihistamines, expectorants, and decongestants. An extended-release *dextromethorphan* suspension is approved for twice-daily administration. The toxicity of *dextromethorphan* is low, although the compound does inhibit neuronal serotonin uptake and must be avoided in patients taking MAO inhibitors as it can cause "serotonin syndrome."

Extremely high doses of *dextromethorphan* are misused because it acts at NMDA receptors and can cause hallucinations, euphoria, significant perceptual distortions, and even dissociative effects, as well as significantly impair motor functioning and coordination.

Pholcodine [3-*O*-(2-morpholinoethyl) morphine] is used clinically in many countries outside the U.S. *Pholcodine* is at least as effective as *codeine* as an antitussive; it has a long $t_{1/2}$ and can be given once or twice daily.

Overall Summary and Conclusions

Failure to adequately manage pain can have important negative consequences on physiological function, such as autonomic hyperreactivity (increased blood pressure, increased heart rate, suppression of GI motility, and reduced secretions) and reduced mobility (leading to deconditioning, muscle wasting, joint stiffening, and decalcification), and can contribute to deleterious changes in the psychological state (depression, helplessness syndromes, and anxiety). By many hospital-accrediting organizations, and by law in many states, appropriate pain assessment and adequate pain management are standard of care, with pain considered the "fifth vital sign."

Mu-opioid receptor agonists are highly effective for treating moderate-to-severe, acute pain. Chronic use of mu-opioid receptor agonists leads to the development of tolerance, physical dependence, and potentially, opioid use disorder. The extensive overuse of mu-opioid receptor agonists for chronic pain and other medical conditions has contributed to the opioid epidemic that began at the start of the

TABLE 23–5 ■ WORLD HEALTH ORGANIZATION ANALGESIC LADDER

Step 1: Mild-to-Moderate Pain

Nonopioid ± adjuvant agent

- Acetaminophen or an NSAID should be used, unless contraindicated. Adjuvant agents are those that enhance analgesic efficacy, treat concurrent symptoms that exacerbate pain, or provide independent analgesic activity for specific types of pain.

Step 2: Mild-to-Moderate Pain or Pain Uncontrolled After Step 1

Short-acting opioid as required ± nonopioid ATC ± adjuvant agent

- Morphine, oxycodone, or hydromorphone should be added to acetaminophen or an NSAID for maximum flexibility of opioid dose.

Step 3: Moderate-to-Severe Pain or Pain Uncontrolled After Step 2

Sustained-release/long-acting opioid ATC or continuous infusion + short-acting opioid as required ± nonopioid ± adjuvant agent

- Sustained-release oxycodone, morphine, oxymorphone, or transdermal fentanyl is indicated.

ATC, around the clock.

21st century. Drug overdose has become the leading cause of accidental death in the U.S., driven by opioid misuse and abuse (National Institute on Drug Abuse, 2021; Rudd et al., 2016). Thus, there has been a growing concern over the appropriate use of opioids in pain management. The three-step ladder promoted by the World Health Organization encourages the use of more conservative therapies before initiating opioid therapy (Table 23–5). Weaker opioids can be supplanted by stronger opioids in cases of moderate and severe pain. The Centers for Disease Control and Prevention (CDC) also provides guidelines for chronic opioid treatment (Dowell et al., 2016; see *Guidelines for Prescribing Opiates for Chronic Pain*, available at: https://www.cdc.gov/drugoverdose/pdf/prescribing/Guidelines_Factsheet-a.pdf) and for the treatment of acute pain conditions (see *Clinical Guidance for Selected Common Acute Pain Conditions*, available at: https://www.cdc.gov/acute-pain/index.html).

While all of the currently available, clinically used opioid analgesics activate the orthosteric binding site on the mu-opioid receptor, targeting other opioid receptor types, combinations of opioid receptor types, or allosteric binding sites on the mu-opioid receptor may produce analgesia with less liability for opioid misuse and abuse. In addition, endogenous opioids and opioid receptors may be involved in modulating homeostatic and disease states other than pain, such as mood, reward, obesity, and movement disorders. This is becoming an active area of research and discovery.

Drug Facts for Your Personal Formulary: *Opioid Agonists and Antagonists*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Agonists		
Morphine Hydromorphone Oxycodone Hydrocodone	• Potent mu-agonists • Strong analgesic in moderate-to-severe pain states • Morphine is a useful adjunct in pulmonary edema and general anesthesia	• ↓ GI motility ⇒ constipation • Hydrocodone, oxycodone formulated with NSAIDs • Hydrocodone, oxycodone, and fentanyl are more potent than morphine • Oxycodone and hydrocodone popular drugs of abuse
Fentanyl	• Potent mu-agonist analgesic • Administered orally (buccal tablet, sublingual tablet/spray, oral lozenge), intravenous (push/infusion), intramuscular, topical, topical iontophoretic, spinal	• Rapid onset, short duration of action • Longer effective $t_{1/2}$ than sufentanil > alfentanil > remifentanil
Sufentanil Alfentanil Remifentanil	• Like fentanyl • Rapid onset, short duration of action • Administered intravenously	• Sufentanil and alfentanil also given epidurally • Remifentanil: ultrashort acting
Meperidine	• Mu-agonist analgesic • Rapid onset, intermediate duration of action	• Not for extended use due to accumulation of seizure-inducing metabolite • Potent histamine releaser
Methadone	• Potent mu-agonist analgesic like morphine • Rapid onset, long duration of action • Maintenance therapy for opioid use disorder in specialized clinics/rehab programs	• Long oral $t_{1/2}$, ~27 h ⇒ potential for accumulation with too frequent repeated delivery • NMDA receptor antagonist
Codeine	• Low potency; prodrug for morphine • Useful for mild-to-moderate pain • Administered orally	• Useful antitussive • Activated *in vivo* to morphine by CYP2D6 • CYP2D6 polymorphisms cause large individual differences in analgesia, no analgesic effect in 10% of Caucasians
Levorphanol	• Opioid agonist • Rapid onset, modest duration of analgesia • Administered orally	• Less selective for mu over delta or kappa receptors than morphine • Long elimination $t_{1/2}$, ~14 h ⇒ potential for accumulation with too frequent repeated delivery • 5HT/NE reuptake inhibitor; NMDA receptor antagonist • Adverse effects: delirium, hallucinations
Peripherally Restricted Agonist		
Loperamide	• Mu-opioid agonist • Effective antidiarrheal • Administered orally	• Loperamide crosses blood-brain barrier poorly; can be formulated with simethicone

Drug Facts for Your Personal Formulary: *Opioid Agonists and Antagonists (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Agonist Restricted by Coformulation		
Diphenoxylate	• Mu-opioid agonist • Effective antidiarrheal • Administered orally	• Diphenoxylate will cross the blood-brain barrier, so it is formulated with atropine, the anticholinergic effects of which (weakness, nausea) discourage abuse
Partial Agonists; Agonist/Antagonist Combinations		
Buprenorphine	• Mild-to-moderate pain • Less respiratory depression than full agonists • Administered by intramuscular, intravenous, sublingual, transdermal, buccal film, transdermal patch • Coformulated with naloxone for maintenance therapy for opioid use disorder (to prevent diversion). Prescribed from clinicians' offices with appropriate training	• Partial agonist at mu receptor, antagonist at kappa and delta receptors • Slow dissociation from mu-opioid receptors • Delivery to a patient on a full opioid agonist may initiate withdrawal (may be done therapeutically in management of heroin addiction)
Butorphanol Nalbuphine Pentazocine	• Kappa/mu partial agonists • Analgesia to mild-to-moderate pain	• Delivery to patient on a full opioid agonist may initiate withdrawal • Pentazocine is also formulated with naloxone
Other Agonists		
Tramadol	• Analgesia for moderate pain • Weak mu-agonist and a 5HT/NE uptake inhibitor • Available as a fixed-dose combination with acetaminophen	• Potential for seizures • Serotonin syndrome risk • As an adjunct to other opioids for chronic pain
Tapentadol	• Analgesia for moderate pain • Weak mu-agonist and a 5HT/NE uptake inhibitor	• Serotonin syndrome risk
Oliceridine	• Analgesia • IV use in hospital setting only	• Partial agonist • G protein bias
Central Antitussives		
Dextromethorphan	• ↓ Cough reflex; receptor mechanisms unclear • Administered orally • Available as an extended-release formulation	• Serotonin syndrome risk • Has no analgesic or addictive properties
Codeine	• See codeine listing, above	• See codeine listing, above
Antagonists		
Naloxone	• Antagonist at mu, delta, and kappa receptors • Rapid onset, moderately short acting • Rapidly reverses central and peripheral opioid effects • Used in treating opioid overdose • Autoinjector and nasal sprays available for emergency administration	• $t_{1/2}$ ~64 min • Re-narcotization may occur with long-lasting agonists as naloxone is metabolized • May induce moderate hyperalgesia • Known as Narcan®; used by emergency medical technicians to revive comatose opioid abusers • Nasally administered version can be used by nonspecialists (i.e., the general public) to reverse overdose
Naltrexone Nalmefene	• Antagonists at mu, delta, and kappa receptors • Rapid onset, longer acting than naloxone • Reverse central and peripheral opioid effects • Used in treating alcohol and opioid dependence	• Start only after 7–10 days of abstinence from opioids to reduce risk withdrawal symptoms • Long-term use of naltrexone ⇒ hypersensitivity to opioids • Naltrexone: formulated with bupropion for managing obesity and with morphine for severe pain; contraindicated in hepatitis and liver failure (black-box warning: excessive doses cause hepatocellular injury)
Samidorphan	• Mu-opioid receptor antagonist • Only approved for use with olanzapine in treatment of schizophrenia	• Higher affinity that naltrexone • Improved oral bioavailability • Kappa- and delta-opioid receptor partial agonism
Peripherally Restricted Antagonists		
Methylnaltrexone	• Antagonist at mu, delta, and kappa receptors • Reverses peripheral opioid effects (e.g., opioid-induced constipation) but not analgesia	• Does not cross blood-brain barrier; thus, not useful in treating addiction or reversing CNS effects of opioids
Alvimopan	• Antagonist at mu, delta, and kappa receptors • Penetrates poorly into CNS • FDA approved for ileus	• Reverses peripheral opioid effects only

Chapter 24 General Anesthetics and Therapeutic Gases

Jerry Ingrande, Matthew L. Pearn, and Hemal H. Patel

General anesthetics depress the CNS to a sufficient degree to permit the performance of surgery and unpleasant procedures. General anesthetics have low therapeutic indices and thus require great care in administration. The selection of specific drugs and routes of administration to produce general anesthesia is based on the pharmacokinetic properties and on the secondary effects of the various drugs. The practitioner should consider the context of the proposed diagnostic or surgical procedure and the individual patient's characteristics and associated medical conditions when choosing appropriate anesthetic agents.

General Principles of Surgical Anesthesia

The administration of general anesthesia is driven by three general objectives:

1. *Minimizing the potentially deleterious direct and indirect effects of anesthetic agents and techniques.*
2. *Sustaining physiologic homeostasis during surgical procedures* that may involve major blood loss, tissue ischemia, reperfusion of ischemic tissue, fluid shifts, exposure to a cold environment, and impaired coagulation.
3. *Improving postoperative outcomes* by choosing techniques that block or treat components of the surgical stress response that may lead to short- or long-term sequelae.

Hemodynamic Effects of General Anesthesia

The most prominent physiological effect of anesthesia induction is a decrease in systemic arterial blood pressure. The causes include direct vasodilation, myocardial depression, or both; a blunting of baroreceptor control; and a generalized decrease in central sympathetic tone. Agents vary in the magnitude of their specific effects, but in all cases, the hypotensive response is enhanced by underlying volume depletion or preexisting myocardial dysfunction.

Respiratory Effects of General Anesthesia

Nearly all general anesthetics reduce or eliminate both ventilatory drive and the reflexes that maintain airway patency. Therefore, ventilation generally must be assisted or controlled for at least some period during surgery. The gag reflex is lost, and the stimulus to cough is blunted. Lower esophageal sphincter tone also is reduced, so both passive and active regurgitation may occur. Endotracheal intubation has been a major reason for a decline in the number of aspiration deaths during general anesthesia. Muscle relaxation is valuable during the induction of general anesthesia where it facilitates management of the airway, including endotracheal intubation. Neuromuscular blocking agents commonly are used to effect such relaxation (see Chapter 13). Alternatives to an endotracheal tube include a face mask and a laryngeal mask, an inflatable mask placed in the oropharynx forming a seal around the glottis. Airway management techniques are based on the anesthetic procedure, the need for neuromuscular relaxation, and the physical characteristics of the patient.

Hypothermia

Patients commonly develop hypothermia (body temperature <36°C) during surgery. The reasons include low ambient temperature, exposed body cavities, cold intravenous fluids, altered thermoregulatory control, and reduced metabolic rate. Metabolic rate and total body O_2 consumption decrease with general anesthesia by about 30%, reducing heat generation. Hypothermia may lead to an increase in perioperative morbidity. Prevention of hypothermia is a major goal of anesthetic care.

Nausea and Vomiting

Nausea and vomiting continue to be significant problems following general anesthesia and are caused by the action of anesthetics on the chemoreceptor trigger zone and the brainstem vomiting center, which are modulated by 5-hydroxytryptamine (5HT), histamine, acetylcholine (ACh), dopamine (DA), and neurokinin 1 (NK1) (see Figure 54–6). The $5HT_3$ receptor antagonists *ondansetron*, *dolasetron*, and *palonosetron* (see Chapters 15 and 54) are effective in suppressing nausea and vomiting. Common preventive strategies include anesthetic induction with *propofol*; the combined use of *droperidol*, *metoclopramide*, and *dexamethasone*; and avoidance of nitrous oxide (N_2O). A new subclass of antiemetic drugs includes NK1 antagonists (e.g., *aprepitant*, *rolapitant*).

Abbreviations

ACh: acetylcholine
ADME: absorption, distribution, metabolism, excretion
CBF: cerebral blood flow
CMR: cerebral metabolic rate
CMRO_2: cerebral metabolic rate of O_2 consumption
CNS: central nervous system
DA: dopamine
ED_{50}: median effective dose
EEG: electroencephalogram
FIO_2: inspired O_2 fraction
GABA: γ-aminobutyric acid
GFR: glomerular filtration rate
Hb: hemoglobin
5HT: 5-hydroxytryptamine (serotonin)
ICP: intracranial pressure
IV: intravenous
LD_{50}: median lethal dose
MAC: minimum alveolar concentration
MI: myocardial infarction
MOC: methoxycarbonyl
NK1: neurokinin 1
NMDA: *N*-methyl-D-aspartate
PaCO_2: arterial CO_2 tension
PO_2: partial pressure of O_2
PRIS: propofol infusion syndrome
RBF: renal blood flow
VLPO: ventrolateral preoptic

Other Emergent and Postoperative Phenomena

Hypertension and tachycardia are common during emergence from anesthesia as the sympathetic nervous system regains its tone and is enhanced by pain. Myocardial ischemia can appear or worsen during emergence in patients with coronary artery disease. Emergence excitement occurs in 5% to 30% of patients and is characterized by tachycardia, restlessness, crying, moaning, and thrashing. Neurological signs, including delirium, spasticity, hyperreflexia, and Babinski sign, are often manifest in the patient emerging from anesthesia. Postanesthesia shivering occurs frequently because of core hypothermia. A small dose of *meperidine* (12.5 mg) lowers the shivering trigger temperature and effectively stops the activity. The incidence of all these emergence phenomena is greatly reduced with opioids and α_2 adrenergic agonists (*dexmedetomidine*).

Airway obstruction may occur during the postoperative period because of residual anesthetic effects. Pulmonary function is reduced following all types of anesthesia and surgery, and hypoxemia may occur. In the immediate postoperative period, pulmonary function reduction can be compounded by the respiratory suppression associated with opioids used for pain control. Regional anesthetic techniques are an important part of a perioperative approach that employs local anesthetic wound infiltration; epidural, spinal, and plexus blocks; and nonsteroidal anti-inflammatory drugs, opioids, α_2 adrenergic receptor agonists, and NMDA (*N*-methyl-D-aspartate) receptor antagonists.

Actions and Mechanisms of General Anesthetics

The Anesthetic State

The components of the anesthetic state include:

- *Amnesia*
- *Analgesia*
- *Unconsciousness*
- *Immobility* in response to noxious stimulation
- *Attenuation of autonomic responses* to noxious stimulation

The potency of general anesthetic agents is measured by determining the concentration of general anesthetic that *prevents* movement in response to surgical stimulation. For inhalational anesthetics, anesthetic potency is measured in *minimum alveolar concentration* (*MAC) units*, with *1 MAC* defined as *the minimum alveolar concentration* that prevents movement in response to surgical stimulation in 50% of subjects. The strengths of MAC as a measurement are the following:

- Alveolar concentrations can be monitored continuously by measuring end-tidal anesthetic concentration using infrared spectroscopy or mass spectrometry.
- MAC provides a direct correlate of the free concentration of the anesthetic at its site(s) of action in the central nervous system (CNS).
- MAC is a simple-to-measure end point that reflects an important clinical goal.

End points other than immobilization also can be used to measure anesthetic potency. For example, the ability to respond to verbal commands (MAC_{awake}) and the ability to form memories also have been correlated with alveolar anesthetic concentration. Verbal response and memory formation are suppressed at a fraction of MAC. The ratio of the anesthetic concentrations required to produce amnesia and immobility vary significantly among different inhalational anesthetic agents.

Generally, the potency of intravenous agents is defined as the free plasma concentration (at equilibrium) that produces loss of response to surgical incision (or other end points) in 50% of subjects.

Mechanisms of Anesthesia

The molecular and cellular mechanisms by which general anesthetics produce their effects have remained one of the great mysteries of pharmacology. The leading unitary theory was that anesthesia is produced by perturbation of the physical properties of cell membranes. This thinking was based largely on the observation that the anesthetic potency of a gas correlated with its solubility in olive oil. This correlation is referred to as the Meyer-Overton rule. Clear exceptions to the Meyer-Overton rule (Franks, 2006) suggest protein targets that may account for anesthetic effect. Increasing evidence supports the hypothesis that different anesthetic agents produce specific components of anesthesia by actions at different molecular targets. Given these insights, the unitary theory of anesthesia has been largely discarded.

Molecular Mechanisms of General Anesthetics

Most intravenous general anesthetics act predominantly through $GABA_A$ receptors and perhaps through some interactions with other ligand-gated ion channels such as NMDA receptors and two-pore K^+ channels. $GABA_A$ receptors (GABA-gated chloride channels; see Figures 16–5 and 16–11) are sensitive to a wide variety of anesthetics, including the halogenated inhalational agents, many intravenous agents (*propofol*, barbiturates, and *etomidate*; see Figure 24–1), and neurosteroids. At clinical concentrations, general anesthetics increase the sensitivity of the $GABA_A$ receptor to GABA (γ-aminobutyric acid), thereby enhancing inhibitory neurotransmission and depressing nervous system activity. The action of anesthetics on the $GABA_A$ receptor probably is mediated by binding of the anesthetics to specific allosteric sites on the $GABA_A$ receptor protein (but they do not compete with GABA for its binding site). The capacity of *propofol* and *etomidate* to inhibit the response to noxious stimuli is mediated by a specific site on β_3 subunits of certain $GABA_A$ receptors, whereas the sedative effects of these anesthetics represent effects on channels containing β_2 subunits.

Structurally related to the $GABA_A$ receptors are other ligand-gated ion channels, including *glycine receptors* and neuronal *nicotinic ACh receptors* (see Figures 16–5, 16–6, and 16–9). Glycine-gated Cl^- channels (glycine receptors) may play a role in mediating inhibition by anesthetics of responses to noxious stimuli. Inhalational anesthetics enhance the capacity of glycine to activate glycine receptors, which play an important role in inhibitory neurotransmission in the spinal cord and brainstem. *Propofol*, neurosteroids, and barbiturates also potentiate glycine-activated currents, whereas *etomidate* and *ketamine* do not. Subanesthetic concentrations of the inhalational anesthetics inhibit some classes of neuronal

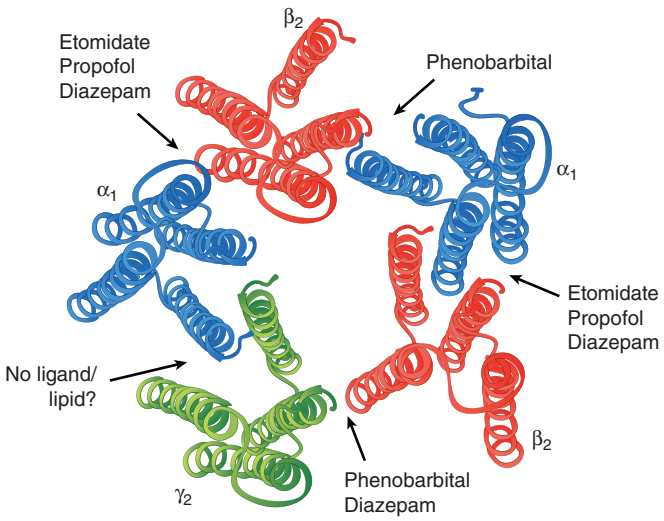

Figure 24–1 *Anesthetics and GABA$_A$ interaction sites.* Structure of a predominant synaptic isoform of the GABAA receptor obtained by cryo-electron microscopy (Kim et al, 2020). View is from the synaptic perspective looking down the ion channel axis. Five subunits (two α_1, two β_2 and one γ_2) arrange like barrel staves to form a central chloride-conducting pore. The neurotransmitter GABA binds at β-α subunit interfaces in the extracellular domain. Shown here is a cross-section of the transmembrane domain, which houses interaction sites for common intravenous general anesthetics and diazepam. Binding of these anesthetics potentiates the receptor's response to GABA, thereby increasing fast synaptic inhibitory signaling. (Figure provided by Professor Ryan Hibbs, Department of Neuroscience, University of Texas Southwestern Medical Center, Dallas, TX) For a side view of the interaction sites, see Figure 16-11. For details about the subunit organization of pentameric ligand-gated ion channels, see Figure 13-1.

nicotinic ACh receptors, which seem to mediate other components of anesthesia such as analgesia or amnesia.

Ketamine, nitrous oxide, *cyclopropane*, and *xenon* are the only general anesthetics that do not have significant effects on GABA$_A$ or glycine receptors. These agents inhibit a different type of ligand-gated ion channel, the NMDA receptor (see Figure 16–9 and Table 16–2). NMDA receptors are glutamate-gated cation channels that are somewhat selective for Ca^{2+} and are involved in long-term modulation of synaptic responses (long-term potentiation) and glutamate-mediated neurotoxicity.

Halogenated inhalational anesthetics activate some members of a class of K^+ channels known as *two-pore domain channels*; other two-pore domain channel family members are activated by xenon, N_2O, and *cyclopropane*. These channels are located in both presynaptic and postsynaptic sites. The postsynaptic channels may be the molecular locus through which these agents hyperpolarize neurons.

Cellular Mechanisms of Anesthesia

General anesthetics produce two important physiological effects at the cellular level:

1. Inhalational anesthetics can hyperpolarize neurons. Neuronal hyperpolarization may affect pacemaker activity and pattern-generating circuits.
2. Both inhalational and intravenous anesthetics have substantial effects on synaptic transmission and much smaller effects on action potential generation or propagation.

Inhalational anesthetics inhibit excitatory synapses and enhance inhibitory synapses in various preparations. The inhalational anesthetics inhibit neurotransmitter release. Inhalational anesthetics also can act postsynaptically, altering the response to released neurotransmitter. These actions are thought to be due to specific interactions of anesthetic agents with neurotransmitter receptors.

Intravenous anesthetics produce a narrower range of physiological effects. Their predominant actions are at the synapse, where they have profound and relatively specific effects on the postsynaptic response to released neurotransmitter. Most of the intravenous agents act predominantly by enhancing inhibitory neurotransmission, whereas ketamine predominantly inhibits excitatory neurotransmission at glutamatergic synapses.

Anatomic Sites of Anesthetic Action

In principle, general anesthetics could interrupt nervous system function at myriad levels, including peripheral sensory neurons, the spinal cord, the brainstem, and the cerebral cortex. Most anesthetics cause, with some exceptions, a global reduction in cerebral metabolic rate (CMR) and in cerebral blood flow (CBF). A consistent feature of general anesthesia is a suppression of metabolism in the thalamus (Alkire et al., 2008), which serves as a major relay by which sensory input from the periphery ascends to the cortex. Suppression of thalamic activity may serve as a switch between the awake and anesthetized states (Franks, 2008). General anesthesia also suppresses activity in specific regions of the cortex, including the mesial parietal cortex, posterior cingulate cortex, precuneus, and inferior parietal cortex.

Similarities between natural sleep and the anesthetized state suggest that anesthetics might also modulate endogenous sleep-regulating pathways, which include ventrolateral preoptic (VLPO) and tuberomammillary nuclei. VLPO projects inhibitory GABAergic fibers to ascending arousal nuclei, which in turn project to the cortex, forebrain, and subcortical areas and release histamine, 5HT, orexin, norepinephrine, and ACh to mediate wakefulness. Intravenous and inhalational agents with activity at GABA$_A$ receptors can increase the inhibitory effects of VLPO, thereby suppressing consciousness. *Dexmedetomidine*, an α_2 adrenergic agonist, also increases VLPO-mediated inhibition by suppressing the inhibitory effect of locus ceruleus neurons on VLPO. Finally, both intravenous and inhalational anesthetics depress hippocampal neurotransmission, a probable locus for their amnestic effects.

Parenteral Anesthetics

Parenteral anesthetics are the most common drugs used for anesthetic induction of adults. Their lipophilicity, coupled with the relatively high perfusion of the brain and spinal cord, results in rapid onset and short duration after a single bolus dose. These drugs ultimately accumulate in fatty tissue. Each of these anesthetics has its own unique properties and side effects (Tables 24–1 and 24–2). *Propofol* is advantageous for procedures where rapid return to a preoperative mental status is desirable. *Etomidate* usually is reserved for patients at risk for hypotension or myocardial ischemia. *Ketamine* is best suited for patients with asthma

TABLE 24–1 ■ PHARMACOLOGICAL PROPERTIES OF PARENTERAL ANESTHETICS

DRUG	IV INDUCTION DOSE (mg/kg)	MINIMAL HYPNOTIC LEVEL (μg/mL)	INDUCTION DOSE DURATION (min)	$t_{1/2}\beta$ (h)	*CL* (mL/min/kg)	PROTEIN BINDING (%)	V_{ss} (L/kg)

or for children undergoing short, painful procedures. *Thiopental* has a long-established track record of safety; however, clinical use is limited currently by availability.

Pharmacokinetic Principles

Parenteral anesthetics are small, hydrophobic, substituted aromatic or heterocyclic compounds (Figure 24–2). Hydrophobicity is the key factor governing their pharmacokinetics. After a single intravenous bolus, these drugs preferentially partition into the highly perfused and lipophilic tissues of the brain and spinal cord, where they produce anesthesia within a single circulation time. Subsequently, blood levels fall rapidly, resulting in drug redistribution out of the CNS back into the blood. The anesthetic then diffuses into less-perfused tissues, such as muscle and viscera, and at a slower rate into the poorly perfused but very hydrophobic adipose tissue. Termination of anesthesia after single boluses of parenteral anesthetics primarily reflects redistribution out of the CNS rather than metabolism (see Figure 2–4).

After redistribution, anesthetic blood levels fall according to a complex interaction between the metabolic rate and the amount and lipophilicity of the drug stored in the peripheral compartments. Thus, parenteral anesthetic half-lives are "context sensitive," and the degree to which a $t_{1/2}$ is contextual varies greatly from drug to drug, as might be predicted based on their differing hydrophobicities and metabolic clearances (Figure 24–3; Table 24–1). For example, after a single bolus of *thiopental*, patients usually emerge from anesthesia within 10 min; however, a patient may require more than a day to awaken from a prolonged *thiopental* infusion. Most individual variability in sensitivity to parenteral anesthetics can be accounted for by pharmacokinetic factors. For example, in patients with lower cardiac output, the relative perfusion of the brain and the fraction of anesthetic dose delivered to the brain are higher; thus, patients in septic shock or with cardiomyopathy usually require lower doses of parenteral anesthetics. The elderly also typically require a smaller parenteral anesthetic dose, primarily because of a smaller initial volume of distribution.

Specific Parenteral Agents

Propofol

Propofol is the most used parenteral anesthetic in the U.S. The clinical pharmacological properties of *propofol* are summarized in Table 24–1.

The active ingredient in *propofol*, 2,6-diisopropylphenol, is an oil at room temperature and insoluble in aqueous solutions. *Propofol* is formulated for intravenous administration as a 1% (10-mg/mL) emulsion in 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide. In the U.S., disodium EDTA (0.05 mg/mL) or sodium metabisulfite (0.25 mg/mL) is added to inhibit bacterial growth. *Propofol* should be administered within 4 h of its removal from sterile packaging; unused drug should be discarded. The lipid emulsion formulation of *propofol* is associated with significant pain on injection and with hyperlipidemia.

Clinical Use and ADME. The induction dose of *propofol* in a healthy adult is 2 to 2.5 mg/kg. Dosages should be reduced in the elderly and in the presence of other sedatives and increased in young children. Because of its reasonably short elimination $t_{1/2}$, *propofol* often is used for maintenance of anesthesia as well as for induction. For short procedures, small boluses (10%–50% of the induction dose) every 5 min or as needed are effective. An infusion of *propofol* (50–200 μg/kg/min) produces a more stable drug level and is better suited for longer-term anesthetic maintenance. Sedating doses of *propofol* are 20% to 50% of those required for general anesthesia.

Propofol has a context-sensitive $t_{1/2}$ of about 10 min with an infusion lasting 3 h and about 30 min for infusions lasting up to 8 h (see Figure 24–3). *Propofol*'s shorter duration of action after infusion can be explained by its very high clearance, coupled with the slow diffusion of drug from the peripheral to the central compartment. *Propofol* is metabolized in the liver by conjugation to sulfate and glucuronide to less-active metabolites that are renally excreted. *Propofol* is highly protein bound, and its pharmacokinetics, like those of the barbiturates, may be affected by conditions that alter serum protein levels. Clearance of *propofol* is reduced in the elderly. In neonates, *propofol* clearance is also reduced. By contrast, in young children, a more rapid clearance in combination with a larger central volume may necessitate larger doses of *propofol* for induction and maintenance of anesthesia.

Side Effects

Nervous System. The sedation and hypnotic actions of *propofol* are mediated by its action on $GABA_A$ receptors; agonism at these receptors results in an increased Cl^- conduction and hyperpolarization of neurons. *Propofol* suppresses the electroencephalogram (EEG) and, in sufficient doses, can produce burst suppression of the EEG. *Propofol* decreases the cerebral metabolic rate of O_2 consumption ($CMRo_2$), CBF, and intracranial and intraocular pressures by about the same amount as *thiopental*. *Propofol* can be used in patients at risk for cerebral ischemia; however, no human outcome studies have been performed to determine its efficacy as a neuroprotectant.

Cardiovascular System. *Propofol* produces a dose-dependent decrease in blood pressure that is significantly greater than that produced by *thiopental*. The fall in blood pressure can be explained by both vasodilation and possibly mild depression of myocardial contractility. *Propofol* appears to blunt the baroreceptor reflex and reduce sympathetic nerve activity. *Propofol* should be used with caution in patients at risk for, or intolerant of, decreases in blood pressure.

Respiratory System. *Propofol* produces a slightly greater degree of respiratory depression than *thiopental*. Patients given *propofol* should be monitored to ensure adequate oxygenation and ventilation. *Propofol* appears to

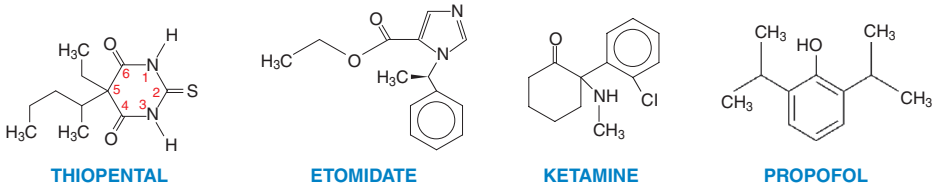

Figure 24–2 *Structures of some parenteral anesthetics.*

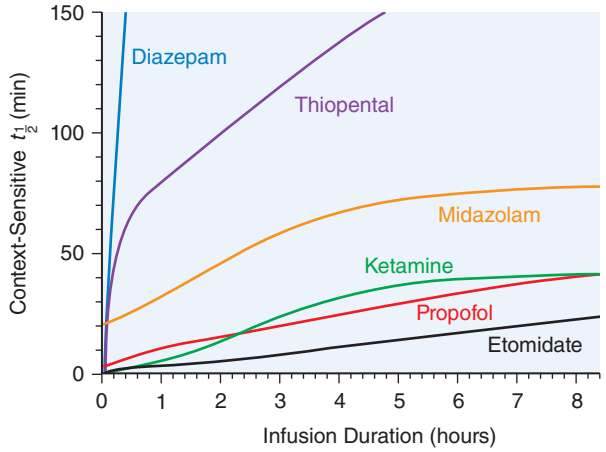

Figure 24–3 *Context-sensitive half-time of general anesthetics.* The duration of action of single intravenous doses of anesthetic/hypnotic drugs is similarly short for all and is determined by redistribution of the drugs away from their active sites (see Figure 2–4). However, after prolonged infusions, drug half-lives and durations of action are dependent on a complex interaction between the rate of redistribution of the drug, the amount of drug accumulated in fat, and the drug's metabolic rate. This phenomenon has been termed the *context-sensitive half-time*; that is, the $t_{1/2}$ of a drug can be estimated only if one knows the context—the total dose and over what time period it has been given. Note that the half-times of some drugs such as *etomidate*, *propofol*, and *ketamine* increase only modestly with prolonged infusions; others (e.g., *diazepam* and *thiopental*) increase dramatically. (Reproduced with permission from Reves JG, Glass PSA, Lubarsky DA, et al. Intravenous anesthetics. In: Miller RD, et al., eds. *Miller's Anesthesia*. 7th ed. Churchill Livingstone, Philadelphia, **2010**, 718. Copyright © Elsevier.)

be less likely than barbiturates to provoke bronchospasm and may be the induction agent of choice in patients with asthma. The bronchodilator properties of *propofol* may be attenuated by the metabisulfite preservative in some *propofol* formulations.

Other Side Effects. *Propofol* has a significant antiemetic action. *Propofol* elicits pain on injection that can be reduced with *lidocaine* and the use of larger arm and antecubital veins. A rare but potentially fatal complication, *propofol infusion syndrome* (PRIS), has been described primarily in prolonged, higher-dose infusions of *propofol* in young or head-injured patients (Kam and Cardone, 2007). PRIS is characterized by metabolic acidosis, hyperlipidemia, rhabdomyolysis, and liver enlargement.

Etomidate

Etomidate is a substituted imidazole that is supplied as the active d-isomer. *Etomidate* is poorly soluble in water and is formulated as a 2-mg/mL solution in 35% propylene glycol. Unlike *thiopental*, *etomidate* does not induce precipitation of neuromuscular blockers or other drugs frequently given during anesthetic induction.

Clinical Use and ADME.

Etomidate is primarily used for anesthetic induction of patients at risk for hypotension. Induction doses of *etomidate* (see Table 24–1) are accompanied by a high incidence of pain on injection and myoclonic movements. *Lidocaine* effectively reduces the pain of injection, while myoclonic movements can be reduced by premedication with either benzodiazepines or opiates. *Etomidate* is pharmacokinetically suitable for off-label infusion for anesthetic maintenance (10 µg/kg/min) or sedation (5 µg/kg/min); however, long-term infusions are not recommended because of side effects.

An induction dose of *etomidate* has a rapid onset; redistribution limits the duration of action. Metabolism occurs in the liver, primarily to inactive compounds. Elimination is both renal (78%) and biliary (22%). Compared to *thiopental*, the duration of action of *etomidate* increases less with repeated doses (see Figure 24–3).

Side Effects

Nervous System. *Etomidate* produces hypnosis and has no analgesic effects. The effects of *etomidate* on CBF, metabolism, and intracranial pressures are similar to those of *thiopental* (without dropping mean arterial blood pressure). *Etomidate* produces increased EEG activity in epileptogenic foci and has been associated with seizures.

Cardiovascular System. Cardiovascular stability after induction is a major advantage of *etomidate* over either *propofol* or barbiturates. Induction doses of *etomidate* typically produce a small increase in heart rate and little or no decrease in blood pressure or cardiac output. *Etomidate* has little effect on coronary perfusion pressure while reducing myocardial O_2 consumption.

Respiratory and Other Side Effects. The degree of respiratory depression due to *etomidate* appears to be less than that due to *thiopental*. Like *methohexital*, *etomidate* may induce hiccups; it does not significantly stimulate histamine release. *Etomidate* has been associated with nausea and vomiting. The drug also inhibits adrenal biosynthetic enzymes required for the production of cortisol and some other steroids. Although the hemodynamic profile of *etomidate* may be advantageous, potential negative effects on steroid synthesis raise concerns about its use in trauma and critically ill patients (van den Heuvel et al., 2013) and obviate *etomidate* use for long-term infusion. A rapidly metabolized and ultra-short-acting analogue, *methoxycarbonyl-etomidate*, retains the favorable pharmacological properties of *etomidate* but does not produce adrenocortical suppression after bolus dosing (Cotton and Claing, 2009).

Ketamine

Ketamine is an arylcyclohexylamine and congener of *phencyclidine*. *Ketamine* is supplied as a mixture of the R+ and S– isomers even though the S– isomer is more potent and has fewer side effects. Although more lipophilic than *thiopental*, *ketamine* is water-soluble.

Clinical Use and ADME.

Ketamine is useful for anesthetizing patients at risk for hypotension and bronchospasm and for certain pediatric procedures. However, significant side effects limit its routine use. *Ketamine* rapidly produces a hypnotic state quite distinct from that of other anesthetics. Patients have profound analgesia, unresponsiveness to commands, and amnesia but may have their eyes open, move their limbs involuntarily, and breathe spontaneously. This cataleptic state has been termed *dissociative anesthesia*. The administration of *ketamine* has been shown to reduce the development of tolerance to long-term opioid use. *Ketamine* typically is administered intravenously but also is effective by intramuscular, oral, and rectal routes. *Ketamine* does not elicit pain on injection or true excitatory behavior as described for *methohexital*, although involuntary movements produced by *ketamine* can be mistaken for anesthetic excitement. Low-dose *ketamine* has potential use in depression (Rasmussen et al., 2013). Subanesthetic doses of *ketamine* can desensitize central pain pathways and modulate opioid receptors. It may be used perioperatively to reduce opioid requirements as part of a multimodal analgesic regimen (Bell et al., 2006). Currently, *ketamine* is also being explored as an antidepressant (see Figure 18–2).

The onset and duration of an induction dose of *ketamine* are determined by the same distribution/redistribution mechanisms operant for all the other parenteral anesthetics. *Ketamine* is metabolized to norketamine by hepatic CYPs (mainly by 3A4; less by 2B6 and 2D9). Norketamine, with approximately 20% of the activity of *ketamine*, is hydroxylated and excreted in urine and bile. *Ketamine*'s large volume of distribution and rapid clearance make it suitable for continuous infusion (see Table 24–1 and Figure 24–3).

Side Effects

Nervous System. *Ketamine* has indirect sympathomimetic activity and produces distinct behavioral effects. The *ketamine*-induced cataleptic state is accompanied by nystagmus with pupillary dilation, salivation, lacrimation, and spontaneous limb movements with increased overall muscle tone. Patients are amnestic and unresponsive to painful stimuli. *Ketamine* produces profound analgesia, a distinct advantage over other parenteral anesthetics. Unlike other parenteral anesthetics, *ketamine* increases CBF and intracranial pressure (ICP) with minimal alteration of cerebral metabolism. The effects of *ketamine* on CBF can be readily attenuated by the simultaneous administration of sedative-hypnotic agents.

Emergence delirium, characterized by hallucinations, vivid dreams, and delusions is frequent consequence of *ketamine* that can result in

serious patient dissatisfaction and can complicate postoperative management. Benzodiazepines reduce the incidence of emergence delirium.

Cardiovascular System. Unlike other anesthetics, induction doses of *ketamine* typically increase blood pressure, heart rate, and cardiac output. The cardiovascular effects are indirect and are most likely mediated by inhibition of both central and peripheral catecholamine reuptake. *Ketamine* has direct negative inotropic and vasodilating activity, but these effects usually are overwhelmed by the indirect sympathomimetic action. Thus, *ketamine* is a useful drug, along with *etomidate*, for patients at risk for hypotension during anesthesia. However, it is important to note that in chronically ill patients with depleted sympathetic tone, the direct negative inotropic and vasodilating actions of *ketamine* may be unmasked. While not arrhythmogenic, *ketamine* increases myocardial O_2 consumption and is not an ideal drug for patients at risk for myocardial ischemia.

Respiratory System. The respiratory effects of *ketamine* are perhaps the best indication for its use. Induction doses of *ketamine* produce small and transient decreases in minute ventilation, but respiratory depression is less severe than with other parenteral anesthetics. *Ketamine* is a potent bronchodilator and is particularly well suited for anesthetizing patients at high risk for bronchospasm.

Barbiturates

Barbiturates are derivatives of barbituric acid with either an oxygen or a sulfur at the 2-position (see Figure 24–2 and Chapters 20 and 22). The three barbiturates most commonly used in clinical anesthesia are *sodium thiopental* (not currently marketed in the U.S.), *thiamylal* (currently licensed in the U.S. only for veterinary use), and *methohexital*. *Sodium thiopental* was used most frequently for inducing anesthesia.

Barbiturates are supplied as racemic mixtures despite enantioselectivity in their anesthetic potency. Barbiturates are formulated as the sodium salts with 6% sodium carbonate and reconstituted in water or isotonic saline to alkaline solutions ($10 < pH < 11$). *Mixing barbiturates with drugs in acidic solutions during anesthetic induction can result in precipitation of the barbiturate as the free acid; thus, standard practice is to delay the administration of other drugs until the barbiturate has cleared the intravenous tubing.*

The pharmacological properties and other therapeutic uses of the barbiturates are presented in Chapter 22. Table 22–3 lists the common barbiturates with their clinical pharmacological properties.

Clinical Use and ADME. Recommended intravenous dosing for parenteral barbiturates in a healthy young adult is given in Table 24–1. The availability of *thiopental* is limited currently by the lack of an FDA-licensed product and the prohibition of its import due to controversy over its use in administration of the death penalty by lethal injection.

The principal mechanism limiting anesthetic duration after single doses is redistribution of these hydrophobic drugs from the brain to other tissues. However, after multiple doses or infusions, the duration of action of the barbiturates varies considerably depending on their clearances. See Table 24–1 for pharmacokinetic parameters.

Methohexital differs from the other two intravenous barbiturates in its much more rapid clearance; thus, it accumulates less during prolonged infusions. Because of their slow elimination and large volumes of distribution, prolonged infusions or very large doses of *thiopental* and *thiamylal* can produce unconsciousness lasting several days. All three barbiturates are primarily eliminated by hepatic metabolism and subsequent renal excretion of inactive metabolites; a small fraction of *thiopental* undergoes desulfuration to the longer-acting hypnotic *pentobarbital*. Hepatic disease or other conditions that reduce serum protein concentrations will increase the initial free concentration and hypnotic effect of an induction dose.

Side Effects

Nervous System. Barbiturates suppress the EEG and can produce EEG burst suppression. They reduce the CMR, as measured by $CMRo_2$, in a dose-dependent manner. As a consequence of the decrease in $CMRo_2$, CBF and ICP are similarly reduced. Presumably, their CNS depressant activity contributes to their anticonvulsant effects (see Chapter 20). *Methohexital* can increase ictal activity, and seizures have been described in patients who received doses sufficient to produce burst suppression of the EEG, properties that make *methohexital* a good choice for anesthesia in patients who undergo electroconvulsive therapy.

Cardiovascular System. The anesthetic barbiturates produce dose-dependent decreases in blood pressure. The effect is due primarily to vasodilation, particularly venodilation, and to a lesser degree to a direct decrease in cardiac contractility. Typically, heart rate increases as a compensatory response to a lower blood pressure, although barbiturates also blunt the baroreceptor reflex. *Thiopental* maintains the ratio of myocardial O_2 supply to demand in patients with coronary artery disease within a normal blood pressure range. Hypotension can be severe in patients with an impaired ability to compensate for venodilation, such as those with hypovolemia, cardiomyopathy, valvular heart disease, coronary artery disease, cardiac tamponade, or β adrenergic blockade. None of the barbiturates has been shown to be arrhythmogenic.

Respiratory System. Barbiturates are respiratory depressants. Induction doses of *thiopental* decrease minute ventilation and tidal volume, with a smaller and inconsistent decrease in respiratory rate. Reflex responses to hypercarbia and hypoxia are diminished by anesthetic barbiturates; at higher doses or in the presence of other respiratory depressants such as opiates, apnea can result. Compared to *propofol*, barbiturates produce a higher incidence of wheezing in asthmatics, attributed to histamine release from mast cells during induction of anesthesia.

Other Side Effects. Short-term administration of barbiturates has no clinically significant effect on the hepatic, renal, or endocrine systems. True allergies to barbiturates are rare; however, direct drug-induced histamine release is occasionally seen. Barbiturates can induce fatal attacks of porphyria in patients with acute intermittent or variegate porphyria and are contraindicated in such patients. *Methohexital* can produce pain on injection to a greater degree than *thiopental*. Inadvertent intra-arterial injection of thiobarbiturates can induce a severe inflammatory and potentially necrotic reaction that can threaten limb survival. *Methohexital*, and to a lesser degree other barbiturates, can produce excitatory symptoms on induction, such as cough, hiccup, muscle tremors, twitching, and hypertonus.

Novel Parenteral Anesthetics

Remimazolam

Remimazolam is an intravenous sedative-hypnotic that was recently approved by the FDA. The basic chemical structure is that of *midazolam*, with an attached carboxylic ester linkage. The ester linkage results in rapid metabolism by nonspecific esterases in the plasma, much like what occurs with *remifentanil*. The drug therefore combines the pharmacological effects of *midazolam* and metabolic kinetics of *remifentanil*. *Remimazolam* is administered for procedural sedation. Like other benzodiazepines, *remimazolam* is an agonist of the $GABA_A$ receptor. At low doses, the drug acts as an anxiolytic; higher doses result in sedation.

Like other intravenously administered sedative-hypnotics, the distribution of *remimazolam* is highly dependent on cardiac output, with the majority of drug being distributed to the vessel-rich regions. *Remimazolam* is rapidly metabolized via ester hydrolysis, a process that follows first-order kinetics, and does not become saturated at clinically used concentrations of the drug. There is no accumulation of drug. The drug has an extremely short context sensitivity, and prolonged infusions do not result in prolonged, residual effects. Because elimination is organ-independent (occurs via plasma esterase activity), the drug can be safely used in patients with hepatic and/or renal impairment.

The recommended dose of *remimazolam* when given as a single injection for procedural sedation is 2.5 to 5 mg IV. Peak sedative effects should occur 3 to 5 min following a single IV dose. Infusion rates ranging from 1 to 5 mg/min can be used for maintenance of sedation. Alternatively, repeated boluses of 1.25 to 2.5 mg every 2 min can be given.

Use of *remimazolam* as the sole hypnotic agent as part of balanced general anesthesia is under investigation. Similarly, while the short

context sensitivity of *remimazolam* may make it an ideal drug for prolonged sedation (i.e., intensive care unit sedation), there are few studies outlining its use for such an indication. Current manufacturer recommendations indicate that the drug should be used for procedures lasting 30 min or less. The side effect profile of *remimazolam* mimics that of other benzodiazepines.

Propofol Derivatives

Modifications of *propofol* and/or its emulsion are being investigated to mitigate *propofol*-induced venoirritation after a bolus. Emulsions with a higher ratio of medium-chain triglycerides to long-chain triglycerides have been shown to alleviate pain on injection.

Fospropofol is a water-soluble ester prodrug of *propofol* that is hydrolyzed by alkaline phosphatase to yield *propofol*, phosphate, and formaldehyde. It produces less pain on injection compared to *propofol*. Furthermore, since it does not contain lipid, egg products, or preservatives, it does not have the concerns of bacterial infection or hyperlipidemia associated with *propofol* emulsions. *Fospropofol* produces dose-dependent sedation and can be administered in otherwise-healthy individuals at 2 to 8 mg/kg IV (delivered either as a bolus or by a short infusion over 5–10 min). The optimum dose for sedation is about 6.5 mg/kg. This results in a loss of consciousness in about 10 min. The duration of the sedative effect is approximately 45 min. *Fospropofol* was recently discontinued for clinical use in the U.S. due to its prolonged onset of action (time to peak effect, 8–13 min), slow recovery, and significant perianal pruritis associated with its administration.

Etomidate Derivatives

Derivatives of *etomidate* have been investigated that either lesson or eliminate adrenocortical suppression. *Methoxycarbonyl etomidate* (MOC-etomidate) contains an ester moiety that is rapidly metabolized. MOC-etomidate does not produce prolonged adrenocortical suppression. Its metabolite is metabolically active and has an adrenocortical inhibition potency that is approximately 300-fold lower than its parent compound (Mahmoud and Mason, 2018).

The substitution of nitrogen on the *etomidate* imidazole ring with a methylene group creates *carboetomidate*. *Carboetomidate* maintains the same hypnotic efficacy associated with *etomidate*; however, there is an approximately 2000-fold lower adrenocortical inhibition associated with *carboetomidate*. This drug also inhibits 5HT receptors, and therefore, may also have decreased emetogenic potential.

Inhalational Anesthetics

A wide variety of gases and volatile liquids can produce anesthesia. The structures of the currently used inhalational anesthetics are shown in Figure 24–4. The inhalational anesthetics have therapeutic indices (median lethal dose [LD_{50}]/median effective dose [ED_{50}]) that range from 2 to 4, making these among the most dangerous drugs in clinical use. The toxicity of these drugs is largely a function of their side effects, and each of the inhalational anesthetics has a unique side effect profile. Hence, the selection of an inhalational anesthetic often is based on balancing a patient's pathophysiology with drug side effect profiles.

Table 24–3 lists the widely varying physical properties of the inhalational agents in clinical use. Ideally, an inhalational agent would produce rapid induction of anesthesia and rapid recovery following discontinuation.

Pharmacokinetic Principles

Inhalational agents behave as gases rather than as liquids and thus require different pharmacokinetic constructs for analyzing their uptake and distribution. Inhalational anesthetics distribute between tissues (or between blood and gas) such that equilibrium is achieved when the partial pressure of anesthetic gas is equal in the two tissues. When a person has breathed an inhalational anesthetic for a sufficiently long time that all tissues are equilibrated with the anesthetic, the partial pressure of the anesthetic in all tissues will be equal to the partial pressure of the anesthetic in inspired gas. While the partial pressure of the anesthetic may be equal in all tissues, the concentration of anesthetic in each tissue will be different. Indeed, anesthetic partition coefficients are defined as the ratio of anesthetic concentration in two tissues when the partial pressures of anesthetic are equal in the two tissues. Blood:gas, brain:blood, and fat:blood partition coefficients for the various inhalational agents are listed in Table 24–3. These partition coefficients show that inhalational anesthetics are more soluble in some tissues (e.g., fat) than they are in others (e.g., blood). In clinical practice, equilibrium is achieved when the partial pressure in inspired gas is equal to the partial pressure in end-tidal (alveolar) gas. For inhalational agents that are not very soluble in blood or any other tissue, equilibrium is achieved quickly, as illustrated for nitrous oxide in Figure 24–5. If an agent is more soluble in a tissue such as fat, equilibrium may take many hours to reach. This occurs because fat represents a huge anesthetic reservoir that will be filled slowly because of the modest blood flow to fat. Anesthesia is produced when anesthetic partial pressure in brain is equal to or greater than MAC. Because the brain is well perfused, anesthetic partial pressure in brain becomes equal to the partial pressure in alveolar gas (and in blood) over the course of several minutes. Therefore, anesthesia is achieved shortly after alveolar partial pressure reaches MAC.

Elimination of inhalational anesthetics is largely a reversal of uptake. For inhalational agents with high blood and tissue solubility, recovery will be a function of the duration of anesthetic administration. This occurs because the accumulated amounts of anesthetic in the fat reservoir will prevent blood (and therefore alveolar) partial pressures from falling rapidly. Patients will be arousable when alveolar partial pressure reaches MAC_{awake}, a partial pressure somewhat lower than MAC (see Table 24–3).

Specific Inhalational Agents

Isoflurane

Isoflurane is a volatile liquid at room temperature and is neither flammable nor explosive in mixtures of air or O_2. *Isoflurane* is a commonly used inhalational anesthetic worldwide.

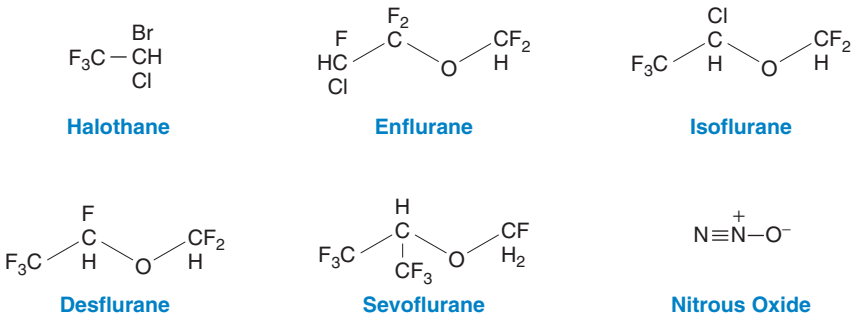

Figure 24–4 *Structures of inhalational general anesthetics.* Note that all inhalational general anesthetic agents except *nitrous oxide* and *halothane* are ethers and that fluorine replaces chlorine in the development of the halogenated agents. All structural differences are associated with important differences in pharmacological properties.

TABLE 24–3 ■ PROPERTIES OF INHALATIONAL ANESTHETIC AGENTS

AGENT	MAC[a] (vol%)	MAC_{AWAKE}[b] (vol%)	VAPOR PRESSURE (mmHg, 20°C)	PARTITION COEFFICIENT AT 37°C			% RECOVERED AS METABOLITES
				BLOOD/GAS	BRAIN/BLOOD (Brain/Gas)	FAT/BLOOD (Fat/Gas)	
Isoflurane[c]	1.05–1.28	0.4	238	1.43	2.6	45 (91)	0.17
Enflurane	1.68	0.4	175	1.91	1.4	36 (98)	2.4
Sevoflurane	1.4–3.3	0.6	157	0.63–0.69	1.7 (1.2)	48 (50)	3.5
Desflurane	5.2–9.2	2.4	669	0.424	1.3 (0.54)	27 (19)	<0.02
N_2O[c]	105	60.0	Gas	0.47	1.1	2.3	0.004
Xe	55–71	32.6	Gas	0.115	—	(1.9)	0

[a]MAC values are expressed as volume percent, the percentage of the atmosphere that is anesthetic. An MAC value greater than 100% means that hyperbaric conditions would be required.
[b]MAC_{AWAKE} is the concentration at which appropriate responses to commands are lost.
[c]EC_{50} for memory suppression (vol%): isoflurane, 0.24; N_2O, 52.5; values not available for other agents.

Clinical Use and ADME. *Isoflurane* is typically used for maintenance of anesthesia *after induction* with other agents because of its pungent odor. Induction of anesthesia can be achieved in less than 10 min with an inhaled concentration of 1.5% to 3% *isoflurane* in O_2; this concentration is reduced to 1% to 2% (~1–2 MAC) for maintenance of anesthesia. The use of adjunct agents such as opioids or nitrous oxide reduces the concentration of *isoflurane* required for surgical anesthesia.

Isoflurane has a blood:gas partition coefficient substantially lower than that of *enflurane*. Consequently, induction with *isoflurane* and recovery from *isoflurane* are relatively faster. More than 99% of inhaled *isoflurane* is excreted unchanged by the lungs. *Isoflurane* does not appear to be a mutagen, teratogen, or carcinogen.

Side Effects

Cardiovascular System. *Isoflurane* produces a concentration-dependent decrease in arterial blood pressure; cardiac output is well maintained; hypotension is the result of decreased systemic vascular resistance. *Isoflurane* produces vasodilation in most vascular beds, with pronounced effects in skin and muscle, and is a potent coronary vasodilator, simultaneously producing increased coronary blood flow and decreased myocardial O_2 consumption. *Isoflurane* significantly attenuates baroreceptor function. Patients anesthetized with *isoflurane* generally have mildly elevated heart rates as a compensatory response to reduced blood pressure; however, rapid changes in *isoflurane* concentration can produce both transient tachycardia and hypertension due to *isoflurane*-induced sympathetic stimulation.

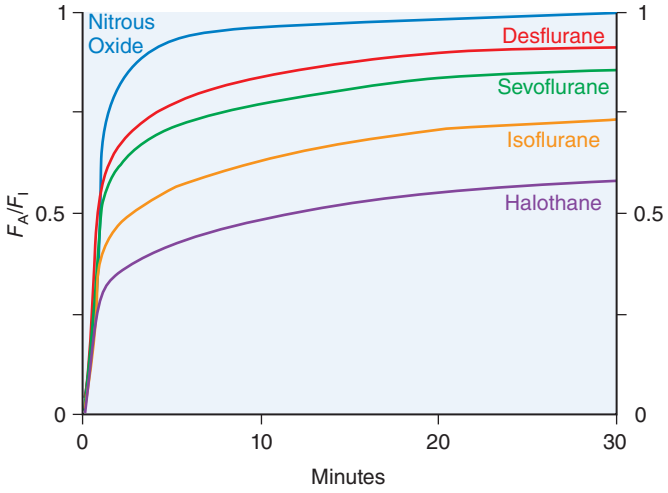

Figure 24–5 *Uptake of inhalational general anesthetics.* The rise in end-tidal alveolar (F_A) anesthetic concentration toward the inspired (F_I) concentration is most rapid with the least-soluble anesthetics (*nitrous oxide* and *desflurane*) and slowest with the most soluble anesthetic, *halothane*. All data are from human studies. (Reproduced with permission from Eger EI II. Inhaled anesthetics: uptake and distribution. In: Miller RD et al., eds. *Miller's Anesthesia*. 7th ed. Churchill Livingstone, Philadelphia, **2010**, 540. Copyright © Elsevier.)

Respiratory System. *Isoflurane* produces concentration-dependent depression of ventilation. This drug is particularly effective at depressing the ventilatory response to hypercapnia and hypoxia. Although *isoflurane* is a bronchodilator, it also is an airway irritant and can stimulate airway reflexes during induction of anesthesia, producing coughing and laryngospasm.

Nervous System. *Isoflurane* dilates the cerebral vasculature, producing increased CBF (Drummond et al., 1983). There is a modest risk of an increase in ICP in patients with preexisting intracranial hypertension. *Isoflurane* reduces $CMRO_2$ in a dose-dependent manner.

Muscle. *Isoflurane* produces some relaxation of skeletal muscle by its central effects. It also enhances the effects of both depolarizing and nondepolarizing muscle relaxants. Like other halogenated inhalational anesthetics, *isoflurane* relaxes uterine smooth muscle and is not recommended for analgesia or anesthesia for labor and vaginal delivery.

Kidney. *Isoflurane* reduces renal blood flow and glomerular filtration rate (GFR), resulting in a small volume of concentrated urine.

Liver and Gastrointestinal Tract. Splanchnic and hepatic blood flows are reduced with increasing doses of *isoflurane* as systemic arterial pressure decreases. There are no reported incidences of hepatic toxicity.

Sevoflurane

Sevoflurane is a clear, colorless, volatile liquid at room temperature and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or O_2. However, *sevoflurane* can undergo an exothermic reaction with desiccated CO_2 absorbent to produce airway burns or spontaneous ignition, explosion, and fire. *Sevoflurane must not be used with an anesthesia machine in which the CO_2 absorbent has been dried by prolonged gas flow through the absorbent. The reaction of sevoflurane with desiccated CO_2 absorbent also can produce CO, which can result in serious patient injury.*

Clinical Use and ADME. *Sevoflurane* is widely used for maintenance of anesthesia after intravenous induction. *Sevoflurane* is the preferred volatile anesthetic for inhalational induction of anesthesia due to its pleasant smell, rapid onset, and lack of irritation to the airway. Thus, it has largely replaced *halothane* (not available in the U.S.) as the preferred agent for anesthetic induction in adult and pediatric patients. Induction of anesthesia is rapidly achieved using inhaled concentrations of 2% to 4% *sevoflurane*. *Sevoflurane* has properties that make it an ideal induction agent.

The low solubility of *sevoflurane* in blood and other tissues provides for rapid induction of anesthesia and rapid changes in anesthetic depth following changes in delivered concentration. Approximately 5% of absorbed *sevoflurane* is metabolized by hepatic CYP2E1, with the predominant product being hexafluoroisopropanol. Hepatic metabolism of

sevoflurane also produces inorganic fluoride. Interaction of *sevoflurane* with soda lime produces decomposition products that may be toxic, such as compound A, pentafluoroisopropenyl fluoromethyl ether (see kidney discussion under Side Effects).

Side Effects

Cardiovascular System. *Sevoflurane* produces concentration-dependent decreases in arterial blood pressure (due to systemic vasodilation) and cardiac output. *Sevoflurane* does not produce tachycardia and thus may be a preferable agent in patients prone to myocardial ischemia.

Respiratory System. *Sevoflurane* produces a concentration-dependent reduction in tidal volume and increase in respiratory rate in spontaneously breathing patients. The increased respiratory frequency does not compensate for reduced tidal volume, with the net effect being a reduction in minute ventilation and an increase in $Paco_2$. *Sevoflurane* is not irritating to the airway and is a potent bronchodilator. As a result, *sevoflurane* is the most effective clinical bronchodilator of the inhalational anesthetics.

Nervous System. *Sevoflurane* produces effects on cerebral vascular resistance, $CMRo_2$, and CBF that are similar to those produced by *isoflurane* and *desflurane*. *Sevoflurane* can increase ICP in patients with poor intracranial compliance, the response to hypocapnia is preserved during sevoflurane anesthesia, and increases in ICP can be prevented by hyperventilation. In children, *sevoflurane* is associated with delirium on emergence from anesthesia. This delirium is short lived and without any reported adverse long-term sequelae.

Muscle. *Sevoflurane* produces skeletal muscle relaxation and enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents.

Kidney. Controversy has surrounded the potential nephrotoxicity of compound A, which is produced by interaction of *sevoflurane* with the CO_2 absorbent soda lime. Biochemical evidence of transient renal injury has been reported in human volunteers (Eger et al., 1997). Large clinical studies have shown no evidence of increased serum creatinine, blood urea nitrogen, or any other evidence of renal impairment following *sevoflurane* administration. *The FDA recommends that sevoflurane be administered with fresh gas flows of 1 to 2 L/min, with sevoflurane exposures not exceeding 2 MAC-hours to minimize exposure to compound A.*

Liver and Gastrointestinal Tract. *Sevoflurane* is not known to cause hepatotoxicity or alterations of hepatic function tests.

Desflurane

Desflurane is a highly volatile liquid at room temperature (vapor pressure = 669 mmHg) and must be stored in tightly sealed bottles. Delivery of a precise concentration of *desflurane* requires the use of a specially heated vaporizer that delivers pure vapor that then is diluted appropriately with other gases (O_2, air, or N_2O). *Desflurane* is nonflammable and nonexplosive in mixtures of air or O_2.

Clinical Use and ADME.

Desflurane irritates the tracheobronchial tree and can provoke coughing, salivation, and bronchospasm. Anesthesia therefore usually is induced with an intravenous agent, with *desflurane* subsequently administered for maintenance of anesthesia. Maintenance of anesthesia usually requires inhaled concentrations of 6% to 8% (~1 MAC). Lower concentrations of *desflurane* are required if it is coadministered with nitrous oxide or opioids.

Desflurane has a very low blood:gas partition coefficient (0.42) and also is not very soluble in fat or other peripheral tissues. Thus, the alveolar and blood concentrations rapidly rise to the level of inspired concentration, providing rapid induction of anesthesia and rapid changes in depth of anesthesia following changes in the inspired concentration. Emergence from *desflurane* anesthesia also is rapid. *Desflurane* is minimally metabolized; more than 99% of absorbed *desflurane* is eliminated unchanged through the lungs.

Side Effects

Cardiovascular System. *Desflurane* produces hypotension primarily by decreasing systemic vascular resistance. Cardiac output is well preserved, as is blood flow to the major organ beds (splanchnic, renal, cerebral, and coronary) (Eger, 1994). Transient tachycardia is often noted with abrupt increases in *desflurane*'s delivered concentration, a result of this *desflurane*-induced stimulation of the sympathetic nervous system. The hypotensive effects of *desflurane* do not wane with increasing duration of administration.

Respiratory System. *Desflurane* causes a concentration-dependent increase in respiratory rate and a decrease in tidal volume. At low concentrations (<1 MAC), the net effect is to preserve minute ventilation. *Desflurane* concentrations greater than 1 MAC depress minute ventilation, resulting in elevated arterial CO_2 tension ($Paco_2$). *Desflurane* is a bronchodilator. However, it also is a strong airway irritant and can cause coughing, breath-holding, laryngospasm, and excessive respiratory secretions. *Because of its irritant properties, desflurane is not used as the primary anesthetic for induction of anesthesia.*

Nervous System. *Desflurane* decreases cerebral vascular resistance and $CMRo_2$. Burst suppression of the EEG is achieved with approximately 2 MAC; at this level, $CMRo_2$ is reduced by approximately 50%. Under conditions of normocapnia and normotension, *desflurane* produces an increase in CBF and can increase ICP in patients with poor intracranial compliance. The vasoconstrictive response to hypocapnia is preserved during *desflurane* anesthesia; increases in ICP thus can be prevented by hyperventilation.

Muscle, Kidney, Liver, and Gastrointestinal Tract. *Desflurane* produces direct skeletal muscle relaxation as well as enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents. Consistent with its minimal metabolic degradation, *desflurane* has no reported nephrotoxicity or hepatotoxicity.

Desflurane and Carbon Monoxide. Inhaled anesthetics are administered via a system that permits unidirectional flow of gas and rebreathing of exhaled gases. To prevent rebreathing of CO_2 (which can lead to hypercarbia), CO_2 absorbers are incorporated into the anesthesia delivery circuits. With almost complete desiccation of the CO_2 absorbents, substantial quantities of carbon monoxide can be produced. This effect is greatest with *desflurane* and can be prevented by the use of well-hydrated, fresh CO_2 absorbent.

Halothane

Halothane is a volatile liquid at room temperature and must be stored in a sealed container. Because *halothane* is a light-sensitive compound, it is marketed in amber bottles with thymol added as a preservative. Mixtures of *halothane* with O_2 or air are neither flammable nor explosive.

Clinical Use and ADME.

Halothane has been used for maintenance of anesthesia. Concerns over hepatic toxicity have limited its use in developed countries. *Halothane* can produce fulminant hepatic necrosis (*halothane hepatitis*) in approximately 1 in 10,000 patients receiving *halothane* and "is referred to as halothane *hepatitis*" (Summary of the National Halothane Study, 1966). This syndrome (with a 50% fatality rate) is characterized by fever, anorexia, nausea, and vomiting, developing several days after anesthesia, and can be accompanied by a rash and peripheral eosinophilia. *Halothane* hepatitis may be the result of an immune response to hepatic proteins that become trifluoroacetylated as a consequence of *halothane* metabolism. *Halothane* has a low cost and is still widely used in developing countries. Due to its side effect profile and the availability of safer agents with more favorable pharmacokinetic profiles, *halothane* is no longer marketed in the U.S. Those interested in further information on *halothane* should consult previous recent editions of this book.

Enflurane

Enflurane is a clear, colorless liquid at room temperature and has a mild, sweet odor. Like other inhalational anesthetics, it is volatile and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or oxygen.

Clinical Use and ADME.

Enflurane is primarily utilized for maintenance rather than induction of anesthesia. Surgical anesthesia can be induced with *enflurane* in less than 10 min with an inhaled concentration of 2%

to 4.5% in oxygen and maintained with concentrations from 0.5% to 3%. *Enflurane* concentrations required to produce anesthesia are reduced when it is coadministered with nitrous oxide or opioids. Concerns over *enflurane*'s ability to decrease seizure threshold and potentially produce nephrotoxicity have limited its clinical utility in developed countries (Mazze et al., 1977).

Because of its relatively high blood:gas partition coefficient, induction of anesthesia and recovery from *enflurane* are relatively slow. *Enflurane* is metabolized to a modest extent, with 2% to 8% of absorbed *enflurane* undergoing oxidative metabolism by hepatic CYP2E1. Fluoride ions are a by-product of *enflurane* metabolism, but plasma fluoride levels are low and nontoxic. Patients taking *isoniazid* exhibit enhanced metabolism of *enflurane* with consequent elevation of serum fluoride.

Side Effects. *Enflurane* causes a decrease in arterial blood pressure, the result of vasodilation and depression of myocardial contractility, with minimal effects on heart rate. The drug is an effective bronchodilator and produces a pattern of rapid shallow breathing. Due to its actions as a cerebral vasodilator, *enflurane* can increase ICP. It can produce seizure activity and should not be used in patients with seizure disorders. *Enflurane* relaxes skeletal and uterine muscle. As with other anesthetic gases, *enflurane* reduces renal blood flow, GFR, and urinary output.

Nitrous Oxide

Nitrous oxide is a colorless, odorless gas at room temperature. N_2O is sold in steel cylinders and must be delivered through calibrated flowmeters provided on all anesthesia machines. N_2O is neither flammable nor explosive, but it does support combustion as actively as oxygen does when it is present in proper concentration with a flammable anesthetic or material.

Clinical Use and ADME. N_2O is a weak anesthetic agent that has significant analgesic effects. Surgical anesthetic depth is only achieved under hyperbaric conditions. By contrast, analgesia is produced at concentrations as low as 20%. The analgesic property of N_2O is a function of the activation of opioidergic neurons in the periaqueductal gray matter and the adrenergic neurons in the locus ceruleus. N_2O is frequently used in concentrations of approximately 50% to provide analgesia and mild sedation in outpatient dentistry. N_2O cannot be used at concentrations above 80% because this limits the delivery of adequate O_2. Because of this limitation, N_2O is used primarily as an adjunct to other inhalational or intravenous anesthetics.

Nitrous oxide is very insoluble in blood and other tissues. This results in rapid equilibration between delivered and alveolar anesthetic concentrations and provides for rapid induction of anesthesia and rapid emergence following discontinuation of administration. The rapid uptake of N_2O from alveolar gas serves to concentrate coadministered halogenated anesthetics; this effect (the "second gas effect") speeds induction of anesthesia. On discontinuation of N_2O administration, N_2O gas can diffuse from blood to the alveoli, diluting O_2 in the lung. This can produce an effect called *diffusional hypoxia*. *To avoid hypoxia, 100% O_2 rather than air should be administered when N_2O is discontinued.* Almost all (99.9%) of the absorbed N_2O is eliminated unchanged by the lungs.

Side Effects

Cardiovascular System. Although N_2O produces a negative inotropic effect on heart muscle *in vitro*, depressant effects on cardiac function generally are not observed in patients because of the stimulatory effects of N_2O on the sympathetic nervous system. The cardiovascular effects of N_2O also are heavily influenced by the concomitant administration of other anesthetic agents. When N_2O is coadministered with halogenated inhalational anesthetics, one observes increases in heart rate, arterial blood pressure, and cardiac output. In contrast, when N_2O is coadministered with an opioid, one generally sees decreases in arterial blood pressure and cardiac output. N_2O also increases venous tone in both the peripheral and the pulmonary vasculature. The effects of N_2O on pulmonary vascular resistance can be exaggerated in patients with preexisting pulmonary hypertension; thus, the drug generally is not used in these patients.

Respiratory System. N_2O causes modest increases in respiratory rate and decreases in tidal volume in spontaneously breathing patients. Even modest concentrations of N_2O markedly depress the ventilatory response to hypoxia. Thus, it is prudent to monitor arterial O_2 saturation directly in patients receiving or recovering from N_2O.

Nervous System. N_2O can significantly increase CBF and ICP. This cerebral vasodilatory capacity of N_2O is significantly attenuated by the simultaneous administration of intravenous agents such as opiates and *propofol*. By contrast, the combination of N_2O and inhaled agents results in greater vasodilation than the administration of the inhaled agent alone at equivalent anesthetic depth.

Muscle. N_2O does not relax skeletal muscle and does not enhance the effects of neuromuscular blocking drugs.

Kidney, Liver, and Gastrointestinal Tract. N_2O is not known to have nephrotoxic or hepatotoxic effects.

Other Adverse Effects. A major problem with N_2O is that it will exchange with N_2 in any air-containing cavity in the body. Moreover, because of their differential blood:gas partition coefficients, N_2O will enter the cavity faster than N_2 escapes, thereby increasing the volume or pressure in this cavity. Examples of air collections that can be expanded by N_2O include a pneumothorax, an obstructed middle ear, an air embolus, an obstructed loop of bowel, an intraocular air bubble, a pulmonary bulla, and intracranial air. N_2O should be avoided in these clinical settings.

Nitrous oxide interacts with the cobalt of vitamin B_{12}, thereby preventing vitamin B_{12} from acting as a cofactor for methionine synthase (Sanders and Maze, 2007). Inactivation of methionine synthase can produce signs of vitamin B_{12} deficiency, including megaloblastic anemia and peripheral neuropathy, a particular concern in patients with malnutrition, vitamin B_{12} deficiency, or alcoholism. The clinical use of N_2O is controversial due to its potential metabolic effects related to increased homocysteine and changes in DNA and protein synthesis (Ko et al., 2014). For this reason, N_2O is not used as a chronic analgesic or as a sedative in critical care settings.

Anesthetic Adjuncts

A general anesthetic is usually given with adjuncts to augment specific components of anesthesia, permitting lower doses of general anesthetics with fewer side effects.

Benzodiazepines

Benzodiazepines (see Chapters 18 and 22) can produce anesthesia similar to that of barbiturates; they are more commonly used for sedation rather than general anesthesia because prolonged amnesia and sedation may result from anesthetizing doses. As adjuncts, benzodiazepines are used for anxiolysis, amnesia, and sedation prior to induction of anesthesia or for sedation during procedures not requiring general anesthesia. The benzodiazepine most frequently used in the perioperative period is *midazolam*, followed distantly by *diazepam* and *lorazepam*.

Midazolam is water soluble and typically is administered intravenously but also can be given orally, intramuscularly, or rectally; oral *midazolam* is particularly useful for sedation of young children. *Midazolam* produces minimal venous irritation (as opposed to *diazepam* and *lorazepam*, which are formulated in propylene glycol and are painful on injection, sometimes producing thrombophlebitis). *Midazolam* has the pharmacokinetic advantage, particularly over lorazepam, of being more rapid in onset and shorter in duration of effect. Sedative doses of *midazolam* (0.01–0.05 mg/kg IV) reach peak effect in about 2 min and provide sedation for approximately 30 min. Elderly patients tend to be more sensitive to and have a slower recovery from benzodiazepines. *Midazolam* is metabolized principally by hepatic CYP3A4, and drug interactions with inducers, inhibitors, and substrates of that CYP are predictable. Either for prolonged sedation or for general anesthetic maintenance, *midazolam* is more suitable than other benzodiazepines for infusion, although *midazolam*'s duration of action ($t_{1/2}$) does significantly increase with prolonged infusions (see Figure 24–3). Benzodiazepines reduce CBF and cerebral metabolism, but

at equianesthetic doses are less effective than barbiturates in this respect. Benzodiazepines modestly decrease blood pressure and respiratory drive, occasionally resulting in apnea.

α_2 Adrenergic Agonists

Dexmedetomidine is a selective α_2 adrenergic receptor agonist (Kamibayashi and Maze, 2000) used for short-term (<24 h) sedation of critically ill adults and for sedation prior to and during surgical or other medical procedures in nonintubated patients. Activation of α_{2A} adrenergic receptors by *dexmedetomidine* produces both sedation and analgesia.

The recommended loading dose is 1 μg/kg given over 10 min, followed by infusion at a rate of 0.2 to 0.7 μg/kg/h. Reduced doses should be considered in patients with risk factors for severe hypotension. *Dexmedetomidine* is highly protein bound and is metabolized primarily in the liver; the glucuronide and methyl conjugates are excreted in the urine. Common side effects of *dexmedetomidine* include hypotension and bradycardia, attributed to decreased catecholamine release by activation peripherally and in the CNS of the α_{2A} receptor. Nausea and dry mouth also are common untoward reactions. At higher drug concentrations, the α_{2B} subtype is activated, resulting in hypertension and a further decrease in heart rate and cardiac output. *Dexmedetomidine* provides sedation and analgesia with minimal respiratory depression. However, *dexmedetomidine* does not appear to provide reliable amnesia, and additional agents may be needed.

Analgesics

Analgesics typically are administered with general anesthetics to reduce anesthetic requirements and minimize hemodynamic changes produced by painful stimuli. Nonsteroidal anti-inflammatory drugs, cyclooxygenase 2 inhibitors, and acetaminophen (see Chapter 42) sometimes provide adequate analgesia for minor surgical procedures. However, opioids are the primary analgesics used during the perioperative period because of the rapid and profound analgesia they produce. *Fentanyl*, *sufentanil*, *alfentanil*, *remifentanil*, *meperidine*, *hydromorphone*, and *morphine* are the major parenteral opioids used in the perioperative period. The primary analgesic activity of each of these drugs is produced by agonist activity at μ opioid receptors (see Chapter 23).

The choice of a perioperative opioid is based primarily on duration of action because, at appropriate doses, all produce similar analgesia and side effects. *Remifentanil* has an ultrashort duration of action (<10 min), accumulates minimally with repeated doses, and is particularly well suited for procedures that are briefly painful. Single doses of *fentanyl*, *sufentanil*, and *alfentanil* all have similar intermediate durations of action (40, 60, and 15 min, respectively), but recovery after prolonged administration varies considerably.

The frequency and severity of nausea, vomiting, and pruritus after emergence from anesthesia are increased by all opioids to about the same degree. A useful side effect of *meperidine* is its capacity to reduce shivering, a common problem during emergence from anesthesia; other opioids are not as efficacious against shivering, perhaps due to less κ receptor agonism. Finally, opioids often are administered intrathecally and epidurally for management of acute and chronic pain (see Chapter 23). Neuraxial opioids with or without local anesthetics can provide profound analgesia for many surgical procedures; however, respiratory depression and pruritus usually limit their use to major operations.

Neuromuscular Blocking Agents

The practical aspects of the use of neuromuscular blockers as anesthetic adjuncts are briefly described here. The detailed pharmacology of this drug class is presented in Chapter 13.

Depolarizing (e.g., *succinylcholine*) and nondepolarizing (e.g., *vecuronium*) muscle relaxants often are administered during the induction of anesthesia to relax muscles of the jaw, neck, and airway and thereby facilitate laryngoscopy and endotracheal intubation. Barbiturates will precipitate when mixed with muscle relaxants and should be allowed to clear from the intravenous line prior to injection of a muscle relaxant. The action of nondepolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an acetylcholinesterase inhibitor, such *as neostigmine* or *edrophonium* (see Chapter 12), in combination with a muscarinic receptor antagonist (e.g., *glycopyrrolate* or *atropine*; see Chapter 11) to offset the muscarinic activation resulting from esterase inhibition. *Sugammadex* is a modified gamma cyclodextrin molecule that specifically binds and encapsulates *rocuronium* and *vecuronium*, resulting in a rapid reversal of *rocuronium*- and *vecuronium*-induced neuromuscular block (Ledowski, 2015).

Anesthetic Administration in Special Populations

Obesity

Obesity is associated with numerous physiological and anthropometric changes that affect the pharmacokinetics of anesthetic drugs, namely increases in cardiac output, fat mass, and lean body mass. Increases in adipose tissue serve to increase the apparent volume of distribution at steady state, thereby increasing context sensitivity of anesthetics after prolonged administration. Emergence from anesthesia may be delayed after repeated drug administration or long infusion times.

However, the initial distribution and dilution of drug in the first minutes of drug administration (i.e., the front-end kinetics) are affected by cardiac output and regional blood flow. Since cardiac output is preferentially distributed to the metabolically active lean tissue, lean body weight rather than total body weight should be used to calculate initial loading doses (Ingrande et al., 2011). In fact, elegant physiological pharmacokinetic models have demonstrated that dose adjustments of *thiopental* based on lean body weight or based on cardiac output result in the same peak plasma concentration (Wada et al., 1997).

The excess adiposity associated with obesity alters the pharmacodynamics of anesthetics. Obese patients may be more sensitive to upper airway obstruction after the administration of sedatives and/or opioids, especially given the high prevalence of obstructive sleep apnea and obesity hypoventilation syndrome in this population. Doses of sedatives and opioids should be decreased accordingly when these drugs are used for conscious sedation. Extreme caution should be given if these classes of drugs are given concurrently due to drug synergism.

Advanced Age

Physiological changes associated with aging alter the pharmacokinetics of anesthetics in elderly patients. Advanced age is associated with reduced lean body mass and increased body fat, both of which affect volume of distribution. Hepatic blood flow and hepatic mass are reduced, thereby reducing hepatic clearance and impairing anesthetic drug metabolism. Kidney function may be impaired, reducing drug elimination. Reduced drug metabolism coupled with depressed drug elimination means loading should be reduced and drug readministration should occur less frequently in this population.

There is a decrease in cardiac output associated with aging. This reduces drug distribution and clearance of anesthetics. The age-related changes in cardiovascular function increase the cardio-depressant risk associated with anesthetics in this population. The reduction in cardiac output may delay the onset of action of most anesthetic agents and also may reduce peripheral drug distribution with lower apparent volume of distribution.

In addition to these pharmacokinetic changes, the pharmacodynamics of anesthetics are altered in the elderly. Elderly subjects are more sensitive to the sedative-hypnotic effects of benzodiazepines and intravenous induction agents (Vuyk, 2003). A single study showed that induction doses of *propofol* can be up to 44% lower in elderly patients compared to their younger counterparts (Peacock et al., 1992). Hence, doses of anesthetics may need to be lowered in the elderly.

Pediatrics

Changes in body composition affect the pharmacokinetics of anesthetics in pediatric patients. In general, neonates and infants have a higher amount of adipose tissue and extracellular water compared to children of older ages. Therefore, the apparent volumes of distribution of both

lipophilic drugs and hydrophilic drugs in children are inversely proportional to age. Total protein, albumin, and alpha-1 acid glycoprotein levels are decreased in neonates. Free fractions of anesthetics are therefore higher in this population. The high amount of free drug and the higher ratio of cerebral to systemic blood flow may increase the CNS concentration of a given drug in neonates compared to older children (Ku and Smith, 2015). After approximately 1 year of age, the concentrations of albumin and alpha-1 acid glycoprotein reach adult levels.

Compared to adults, infants and children have an increased liver blood flow, which may increase hepatic metabolism. However, drug metabolism and elimination are generally slower in neonates owing to immature expression of CYPs and reduced GFR. Expression of CYPs is lowest at birth and increases with increasing age. Likewise, GFR is lowest at birth and rises to adult values by 6 to 12 months of age. However, reduced renal clearance secondary to the decreased GFR may be offset due to the reduced protein binding and increased free fraction of drug.

Therapeutic Gases

Oxygen

Oxygen is essential to life. Hypoxia is a life-threatening condition in which O_2 delivery is inadequate to meet the metabolic demands of the tissues. Hypoxia may result from alterations in tissue perfusion, decreased O_2 tension in the blood, or decreased O_2 carrying capacity. In addition, hypoxia may result from restricted O_2 transport from the microvasculature to cells or impaired utilization within the cell. An inadequate supply of O_2 ultimately results in the cessation of aerobic metabolism and oxidative phosphorylation, depletion of high-energy compounds, cellular dysfunction, and death.

Normal Oxygenation

Oxygen makes up 21% of air, which at sea level represents a partial pressure of 21 kPa (158 mmHg). While the fraction (percentage) of O_2 remains constant regardless of atmospheric pressure, the partial pressure of O_2 (Po_2) decreases with lower atmospheric pressure. Ascent to elevated altitude reduces the uptake and delivery of O_2 to the tissues, whereas increases in atmospheric pressure (e.g., hyperbaric therapy or breathing at depth) raise the Po_2 in inspired air and increase gas uptake. As the air is delivered to the distal airways and alveoli, the Po_2 decreases by dilution with CO_2 and water vapor and by uptake into the blood.

Under ideal conditions, when ventilation and perfusion are well matched, the alveolar Po_2 will be about 14.6 kPa (110 mmHg). The corresponding alveolar partial pressures of water and CO_2 are 6.2 kPa (47 mmHg) and 5.3 kPa (40 mmHg), respectively. Under normal conditions, there is complete equilibration of alveolar gas and lung capillary blood, and the Po_2 in end-capillary blood is typically within a fraction of a kilopascal of that in the alveoli. The Po_2 in arterial blood, however, is further reduced by venous admixture (shunt), the addition of mixed venous blood from the pulmonary artery, which has a Po_2 of about 5.3 kPa (40 mmHg). Together, the diffusional barrier, ventilation-perfusion mismatches, and the shunt fraction are the major causes of the alveolar-to-arterial O_2 gradient, which is normally 1.3 to 1.6 kPa (10–12 mmHg) when air is breathed and 4.0 to 6.6 kPa (30–50 mmHg) when 100% O_2 is breathed. O_2 is delivered to the tissue capillary beds by the circulation and again follows a gradient out of the blood and into cells. Tissue extraction of O_2 typically reduces the Po_2 of venous blood by an additional 7.3 kPa (55 mmHg). Although the Po_2 at the site of cellular O_2 utilization—the mitochondria—is not known, oxidative phosphorylation can continue at a Po_2 of only a few millimeters of mercury.

In the blood, O_2 is carried primarily in chemical combination with hemoglobin and is to a small extent dissolved in solution. The quantity of O_2 combined with hemoglobin depends on the Po_2, as illustrated by the sigmoidal oxyhemoglobin dissociation curve (Figure 24–6). Hemoglobin is about 98% saturated with O_2 when air is breathed under normal circumstances, and it binds 1.3 mL of O_2 per gram when fully saturated. The steep slope of this curve with falling Po_2 facilitates unloading of O_2 from

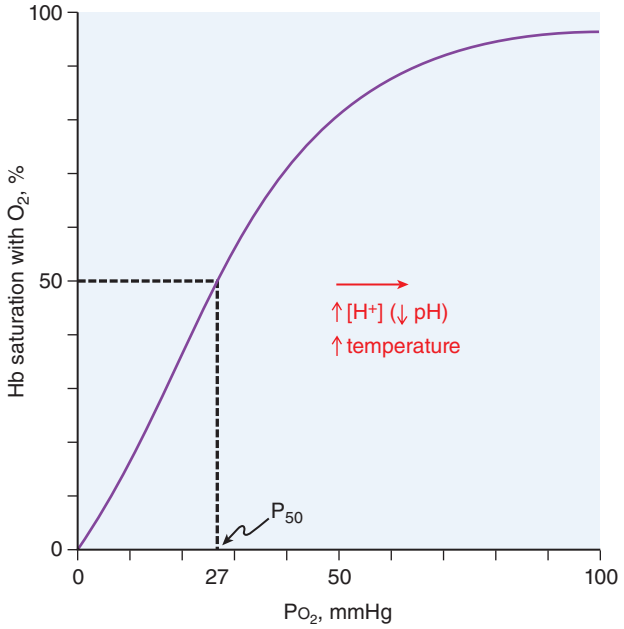

Figure 24–6 *Oxyhemoglobin dissociation curve for whole blood.* The relationship between Po_2 and hemoglobin (Hb) saturation is shown. The P_{50}, or the Po_2 resulting in 50% saturation, is indicated. An increase in temperature or a decrease in pH (as in working muscle) shifts this relationship to the right, reducing the hemoglobin saturation at the same Po_2 and thus aiding in the delivery of O_2 to the tissues.

hemoglobin at the tissue level and reloading when desaturated mixed venous blood arrives at the lung. Shifting of the curve to the right with increasing temperature, increasing Pco_2, and decreasing pH, as is found in metabolically active tissues, lowers the O_2 saturation for the same Po_2 and thus delivers additional O_2 where and when it is most needed. However, the flattening of the curve with higher Po_2 indicates that increasing blood Po_2 by inspiring O_2-enriched mixtures can increase the amount of O_2 carried by hemoglobin only minimally. Because of the low solubility of O_2 (0.226 mL/L per kPa or 0.03 mL/L per mmHg at 37°C), breathing 100% O_2 can increase the amount of O_2 dissolved in blood by only 15 mL/L, less than one-third of normal metabolic demands. However, if the inspired Po_2 is increased to 3 atm (304 kPa) in a hyperbaric chamber, the amount of dissolved O_2 is sufficient to meet normal metabolic demands even in the absence of hemoglobin (Table 24–4).

Oxygen Deprivation. *Hypoxemia* generally implies a failure of the respiratory system to oxygenate arterial blood. Classically, there are five causes of hypoxemia:

- Low F_{IO_2} (inspired O_2 fraction)
- Hypoventilation
- Ventilation-perfusion mismatch
- Shunt or venous admixture
- Increased diffusion barrier

The term *hypoxia* denotes insufficient oxygenation of the tissues. In addition to failure of the respiratory system to oxygenate the blood adequately, a number of other factors can contribute to hypoxia at the tissue level. These may be divided into categories of O_2 delivery and O_2 utilization. O_2 delivery decreases globally when cardiac output falls or locally when regional blood flow is compromised, such as from a vascular occlusion (e.g., stenosis, thrombosis, or microvascular occlusion) or increased downstream pressure (e.g., compartment syndrome, venous stasis, or venous hypertension). Decreased O_2 carrying capacity of the blood likewise will reduce O_2 delivery, such as occurs with anemia, carbon monoxide poisoning, or hemoglobinopathy. Finally, hypoxia may occur when transport of O_2 from the capillaries to the tissues is decreased (edema) or utilization of the O_2 by the cells is impaired (CN^- toxicity).

TABLE 24–4 ■ THE CARRIAGE OF OXYGEN IN BLOOD[a]

ARTERIAL Po_2 kPa (mmHg)	ARTERIAL O_2 CONTENT (mL O_2/L)			MIXED VENOUS Po_2 kPa (mmHg)	MIXED VENOUS O_2 CONTENT (mL O_2/L)			EXAMPLES
	DISSOLVED	BOUND TO Hb	TOTAL		DISSOLVED	BOUND TO Hb	TOTAL	
4.0 (30)	0.9	109	109.9	2.7 (20)	0.6	59	59.6	High altitude; respiratory failure breathing air
12.0 (90)	2.7	192	194.7	5.5 (41)	1.2	144	145.2	Normal person breathing air
39.9 (300)	9.0	195	204	5.9 (44)	1.3	153	154.3	Normal person breathing 50% O_2
79.7 (600)	18	196	214	6.5 (49)	1.5	163	164.5	Normal person breathing 100% O_2
239 (1800)	54	196	250	20.0 (150)	4.5	196	200.5	Normal person breathing hyperbaric O_2

[a]This table illustrates the carriage of oxygen in the blood under a variety of circumstances. As arterial O_2 tension increases, the amount of dissolved O_2 increases in direct proportion to the Po_2, but the amount of oxygen bound to Hb reaches a maximum of 196 mL O_2/L (100% saturation of Hb at 15 g/dL). Further increases in O_2 content require increases in dissolved oxygen. At 100% inspired O_2, dissolved O_2 still provides only a small fraction of total demand. Hyperbaric oxygen therapy is required to increase the amount of dissolved oxygen to supply all or a large part of metabolic requirements. Note that, during hyperbaric oxygen therapy, the hemoglobin in the mixed venous blood remains fully saturated with O_2. The figures in this table are approximate and are based on the assumptions of 15 g/dL Hb, 50 mL O_2/L whole-body oxygen extraction, and constant cardiac output. When severe anemia is present, arterial Po_2 remains the same, but arterial content is lower; oxygen extraction continues, resulting in lower O_2 content and tension in mixed venous blood. Similarly, as cardiac output falls significantly, the same oxygen extraction occurs from a smaller volume of blood and results in lower mixed venous oxygen content and tension.

Effects of Hypoxia

Cellular and Metabolic Effects. At the molecular level, nonlethal hypoxia produces a marked alteration in gene expression, mediated in part by hypoxia-inducible factor 1α (Guimarães-Camboa et al., 2015).

When the mitochondrial Po_2 falls below about 0.13 kPa (1 mmHg), aerobic metabolism stops, and the less-efficient anaerobic pathways of glycolysis become responsible for the production of cellular energy. End products of anaerobic metabolism, such as lactic acid, are released into the circulation in measurable quantities. Energy-dependent ion pumps slow, and transmembrane ion gradients dissipate. Intracellular concentrations of Na^+, Ca^{2+}, and H^+ increase, finally leading to cell death. The time course of cellular demise depends on the relative metabolic demands, oxygen storage capacity, and anaerobic capacity of the individual organs. Restoration of perfusion and oxygenation prior to hypoxic cell death paradoxically can result in an accelerated form of cell injury (ischemia-reperfusion syndrome), which is thought to result from the increased generation of highly reactive oxygen free radicals.

Cell and Organ Survival. Ultimately, hypoxia results in the cessation of aerobic metabolism, exhaustion of high-energy intracellular stores, cellular dysfunction, and death. The time course of cellular demise depends on the tissue's relative metabolic requirements, O_2 and energy stores, and anaerobic capacity. Survival times (the time from the onset of circulatory arrest to significant organ dysfunction) range from 1 to 2 min in the cerebral cortex to around 5 min in the heart and 10 min in the kidneys and liver, with the potential for some degree of recovery if reperfused. Revival times (the duration of hypoxia beyond which recovery is no longer possible) are about four to five times longer.

Organ System Effects. Less-severe degrees of hypoxia have progressive physiological effects on different organ systems (Nunn, 2005).

Respiratory System. Hypoxia stimulates the carotid and aortic baroreceptors to cause increases in both the rate and the depth of ventilation. Minute volume almost doubles when normal individuals inspire gas with a Po_2 of 6.6 kPa (50 mmHg). Dyspnea is not always experienced with simple hypoxia but occurs when the respiratory minute volume approaches half the maximal breathing capacity; this may occur with minimum exertion in patients in whom maximal breathing capacity is reduced by lung disease. In general, little warning precedes the loss of consciousness resulting from hypoxia.

Cardiovascular System. Hypoxia causes reflex activation of the sympathetic nervous system by both autonomic and humoral mechanisms, resulting in tachycardia and increased cardiac output. Peripheral vascular resistance, however, decreases primarily through local autoregulatory mechanisms, with the net result that blood pressure generally is maintained unless hypoxia is prolonged or severe. In contrast to the systemic circulation, hypoxia causes pulmonary vasoconstriction and hypertension, an extension of the normal regional vascular response that matches perfusion with ventilation to optimize gas exchange in the lung (hypoxic pulmonary vasoconstriction).

CNS. The CNS is least able to tolerate hypoxia. Hypoxia is manifest initially by decreased intellectual capacity and by impairment of judgment and psychomotor ability. This state progresses to confusion and restlessness and ultimately to stupor, coma, and death as the arterial Po_2 decreases below 4 to 5.3 kPa (30–40 mmHg). Victims often are unaware of this progression.

Adaptation to Hypoxia

Long-term hypoxia results in adaptive physiological changes; these have been studied most thoroughly in persons exposed to high altitude. Adaptations include increased numbers of pulmonary alveoli, increased concentrations of hemoglobin in blood and myoglobin in muscle, and a decreased ventilatory response to hypoxia. Short-term exposure to high altitude produces similar adaptive changes. In susceptible individuals, however, acute exposure to high altitude may produce *acute mountain sickness*, a syndrome characterized by headache, nausea, dyspnea, sleep disturbances, and impaired judgment progressing to pulmonary and cerebral edema. Mountain sickness is treated with rest and analgesics when mild or supplemental O_2, descent to lower altitude, or an increase in ambient pressure when more severe. *Acetazolamide* (a carbonic anhydrase inhibitor) and *dexamethasone* also may be helpful. The syndrome usually can be avoided by a slow ascent to altitude, adequate hydration, and prophylactic use of *acetazolamide* or *dexamethasone*.

Examples of "normal" hypoxia are widespread, and the comparative physiology of hypoxic tolerance offers clues to the mechanisms involved. Aspects of fetal and newborn physiology are strongly reminiscent of adaptive mechanisms found in hypoxia-tolerant animals (Guimarães-Camboa et al., 2015; Mortola, 1999), including shifts in the oxyhemoglobin dissociation curve (fetal hemoglobin), reductions in metabolic rate and body temperature (hibernation-like mode), reductions in heart rate and circulatory redistribution (as in diving mammals), and redirection of energy utilization from growth to maintenance metabolism. These adaptations probably account for the relative tolerance of the fetus and neonate to both chronic (uterine insufficiency) and short-term hypoxia.

Oxygen Inhalation

Physiological Effects. O_2 inhalation is used primarily to reverse or prevent the development of hypoxia. However, when O_2 is breathed in

excessive amounts or for prolonged periods, secondary physiological changes and toxic effects can occur.

Respiratory System. Inhalation of O_2 at 1 atm or above causes a small degree of respiratory depression in normal subjects, presumably as a result of loss of tonic chemoreceptor activity. However, ventilation typically increases within a few minutes of O_2 inhalation because of a paradoxical increase in the tension of CO_2 in tissues. This increase results from the increased concentration of oxyhemoglobin in venous blood, which causes less-efficient removal of carbon dioxide from the tissues. Expansion of poorly ventilated alveoli is maintained in part by the nitrogen content of alveolar gas; nitrogen is poorly soluble and thus remains in the air spaces while O_2 is absorbed. High O_2 concentrations delivered to poorly ventilated lung regions dilute the nitrogen content and can promote absorption atelectasis (partial or complete collapse of the lung), occasionally resulting in an increase in shunt and a paradoxical worsening of hypoxemia after a period of O_2 administration.

Cardiovascular System. Heart rate and cardiac output are slightly reduced when 100% O_2 is breathed; blood pressure changes little. Elevated pulmonary artery pressures in patients living at high altitude who have chronic hypoxic pulmonary hypertension may reverse with O_2 therapy or return to sea level. In neonates with congenital heart disease and left-to-right shunting of cardiac output, O_2 supplementation must be regulated carefully because of the risk of further reducing pulmonary vascular resistance and increasing pulmonary blood flow.

Metabolism. Inhalation of 100% O_2 does not produce detectable changes in O_2 consumption, CO_2 production, respiratory quotient, or glucose utilization.

Oxygen Administration

Oxygen is supplied as a compressed gas in steel cylinders; purity of 99% is *medical grade*. For safety, O_2 cylinders and piping are color coded (green in the U.S.), and some form of mechanical indexing of valve connections is used to prevent the connection of other gases to O_2 systems.

Oxygen is delivered by inhalation except during extracorporeal circulation, when it is dissolved directly into the circulating blood. A closed delivery system with an endotracheal tube produces an airtight seal to the patient's airway, and complete separation of inspired from expired gases can precisely control F_{IO_2}. In all other systems, such as nasal cannulas and face masks, the actual delivered F_{IO_2} will depend on the ventilatory pattern (i.e., rate, tidal volume, inspiratory-expiratory time ratio, and inspiratory flow) and delivery system characteristics.

Monitoring of Oxygenation. Monitoring and titration are required to meet the therapeutic goal of O_2 therapy and to avoid complications and side effects. Although cyanosis is a physical finding of substantial clinical importance, it is not an early, sensitive, or reliable index of oxygenation. Noninvasive monitoring of arterial O_2 saturation can be achieved using transcutaneous pulse oximetry, in which O_2 saturation is measured from the differential absorption of light by oxyhemoglobin and deoxyhemoglobin and the arterial saturation determined from the pulsatile component of this signal. Pulse oximetry measures hemoglobin saturation and not P_{O_2}. It is not sensitive to increases in P_{O_2} that exceed levels required to saturate the blood fully. Pulse oximetry is useful for monitoring the adequacy of oxygenation during procedures requiring sedation or anesthesia, rapid evaluation and monitoring of potentially compromised patients, and titrating O_2 therapy in situations where toxicity from O_2 or side effects of excess O_2 are of concern. A specific tool for measuring cerebral oxygenation is near-infrared spectroscopy (Guarracino, 2008).

Complications of Oxygen Therapy. In addition to the potential to promote absorption atelectasis and depress ventilation, high flows of dry O_2 can dry out and irritate mucosal surfaces of the airway and the eyes, as well as decrease mucociliary transport and clearance of secretions. Humidified O_2 thus should be used when prolonged therapy (>1 h) is required. Finally, any O_2-enriched atmosphere constitutes a fire hazard, and appropriate precautions must be taken. Hypoxemia can occur despite the administration of supplemental O_2. Therefore, it is essential that both O_2 saturation and adequacy of ventilation be assessed frequently.

Therapeutic Uses of Oxygen

Correction of Hypoxia. The primary therapeutic use of O_2 is to correct hypoxia. Hypoxia is most commonly a manifestation of an underlying disease, and administration of O_2 thus should be viewed as temporizing therapy. Efforts must be directed at correcting the cause of the hypoxia. Hypoxia resulting from most pulmonary diseases can be alleviated at least partially by administration of O_2, allowing time for definitive therapy to reverse the primary process.

Reduction of Partial Pressure of an Inert Gas. Because nitrogen constitutes some 79% of ambient air, it also is the predominant gas in most gas-filled spaces in the body. In situations such as bowel distension from obstruction or ileus, intravascular air embolism, or pneumothorax, it is desirable to reduce the volume of air-filled spaces. Because nitrogen is relatively insoluble, inhalation of high concentrations of O_2 (and thus low concentrations of nitrogen) rapidly lowers the total-body partial pressure of nitrogen and provides a substantial gradient for the removal of nitrogen from gas spaces. Administration of O_2 for air embolism is also beneficial because it helps to relieve localized hypoxia distal to the vascular obstruction. In the case of *decompression sickness*, or *bends*, lowering the inert gas tension in blood and tissues by O_2 inhalation prior to or during barometric decompression reduces the supersaturation that occurs after decompression so that bubbles do not form.

Hyperbaric Oxygen Therapy. O_2 can be administered at greater than atmospheric pressure in hyperbaric chambers (Thom, 2009). Clinical uses of hyperbaric O_2 therapy include the treatment of trauma, burns, radiation damage, infections, nonhealing ulcers, skin grafts, spasticity, and other neurological conditions. Hyperbaric O_2 may be useful in generalized hypoxia. In carbon monoxide poisoning, hemoglobin and myoglobin become unavailable for O_2 binding because of the high affinity of these proteins for carbon monoxide. High P_{O_2} facilitates competition of O_2 for hemoglobin binding sites as carbon monoxide is exchanged in the alveoli. In addition, hyperbaric O_2 increases the availability of dissolved O_2 in the blood (see Table 24–4). Adverse effects of hyperbaric O_2 therapy include middle ear barotrauma, CNS toxicity, seizures, lung toxicity, and aspiration pneumonia.

Hyperbaric O_2 therapy has two components: increased hydrostatic pressure and increased O_2 pressure. Both factors are necessary for the treatment of decompression sickness and air embolism. The hydrostatic pressure reduces bubble volume, and the absence of inspired nitrogen increases the gradient for elimination of nitrogen and reduces hypoxia in downstream tissues. Increased O_2 pressure at the tissue is the primary therapeutic goal for other indications for hyperbaric O_2. A small increase in P_{O_2} in ischemic areas enhances the bactericidal activity of leukocytes and increases angiogenesis. Repetitive brief exposures to hyperbaric O_2 may enhance therapy for chronic refractory osteomyelitis, osteoradionecrosis, crush injury, or the recovery of compromised skin and tissue grafts. Increased O_2 tension can be bacteriostatic and useful in the treatment of the spread of infection with *Clostridium perfringens* and clostridial myonecrosis (gas gangrene).

Oxygen Toxicity

Oxygen can have deleterious actions at the cellular level. O_2 toxicity may result from increased production of hydrogen peroxide and reactive intermediates such as superoxide anion, singlet oxygen, and hydroxyl radicals that attack and damage lipids, proteins, and other macromolecules, especially those in biological membranes. A number of factors limit the toxicity of oxygen-derived reactive agents, including enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, which scavenge toxic oxygen by-products, and reducing agents such as iron, glutathione, and ascorbate. These factors, however, are insufficient to limit the destructive actions of oxygen when patients are exposed to high concentrations over an extended time period. Tissues show differential sensitivity to oxygen toxicity, which is likely the result of differences in both their production of reactive compounds and their protective mechanisms.

Respiratory Tract. The pulmonary system is usually the first to exhibit toxicity, a function of its continuous exposure to the highest O_2 tensions

in the body. Subtle changes in pulmonary function can occur within 8 to 12 h of exposure to 100% O_2. Increases in capillary permeability, which will increase the alveolar/arterial O_2 gradient and ultimately lead to further hypoxemia, and decreased pulmonary function can be seen after only 18 h of exposure. Serious injury and death, however, require much longer exposures. Pulmonary damage is directly related to the inspired O_2 tension, and concentrations of less than 0.5 atm appear to be safe over long time periods. The capillary endothelium is the most sensitive tissue of the lung. Endothelial injury results in loss of surface area from interstitial edema and leaks into the alveoli.

Nervous System. Retinopathy of prematurity is an eye disease in premature infants involving abnormal vascularization of the developing retina that can result from O_2 toxicity or relative hypoxia. CNS problems are rare, and toxicity occurs only under hyperbaric conditions where exposure exceeds 200 kPa (2 atm). Symptoms include seizures and visual changes, which resolve when O_2 tension is returned to normal. In premature neonates and those who have sustained *in utero* asphyxia, hyperoxia and hypocapnia are associated with worse neurological outcomes.

Carbon Dioxide

Carbon dioxide is produced by metabolism at approximately the same rate as O_2 is consumed. At rest, this value is about 3 mL/kg/min, but it may increase dramatically with exercise. CO_2 diffuses readily from the cells into the blood, where it is carried partly as bicarbonate ion (HCO_3^-), partly in chemical combination with hemoglobin and plasma proteins, and partly in solution at a partial pressure of about 6 kPa (46 mmHg) in mixed venous blood. CO_2 is transported to the lung, where it is normally exhaled at the rate it is produced, leaving a partial pressure of about 5.2 kPa (40 mmHg) in the alveoli and in arterial blood. An increase in P_{CO_2} results in respiratory acidosis and may be due to decreased ventilation or the inhalation of CO_2, whereas an increase in ventilation results in decreased P_{CO_2} and respiratory alkalosis. Because CO_2 is freely diffusible, the changes in blood P_{CO_2} and pH soon are reflected by intracellular changes in P_{CO_2} and pH and by widespread effects in the body, especially on respiration, circulation, and the CNS.

Respiration

Carbon dioxide is a rapid, potent stimulus to ventilation in direct proportion to the inspired CO_2. CO_2 stimulates breathing by acidifying central chemoreceptors and the peripheral carotid bodies. Elevated P_{CO_2} causes bronchodilation, whereas hypocarbia causes constriction of airway smooth muscle; these responses may play a role in matching pulmonary ventilation and perfusion.

Circulation

The circulatory effects of CO_2 result from the combination of its direct local effects and its centrally mediated effects on the autonomic nervous system. The direct effect of CO_2 on the heart, diminished contractility, results from pH changes and a decreased myofilament Ca^{2+} responsiveness. The direct effect on systemic blood vessels results in vasodilation. CO_2 causes widespread activation of the sympathetic nervous system. The results of sympathetic nervous system activation generally are opposite to the local effects of carbon dioxide. The sympathetic effects consist of increases in cardiac contractility, heart rate, and vasoconstriction (see Chapter 12). The balance of opposing local and sympathetic effects, therefore, determines the total circulatory response to CO_2. The net effect of CO_2 inhalation is an increase in cardiac output, heart rate, and blood pressure. In blood vessels, however, the direct vasodilating actions of CO_2 appear more important, and total peripheral resistance decreases when the P_{CO_2} is increased. CO_2 also is a potent coronary vasodilator. Cardiac arrhythmias associated with increased P_{CO_2} are due to the release of catecholamines.

Hypocarbia results in opposite effects: decreased blood pressure and vasoconstriction in skin, intestine, brain, kidney, and heart. These actions are exploited clinically in the use of hyperventilation to diminish intracranial hypertension.

CNS

Hypercarbia depresses the excitability of the cerebral cortex and increases the cutaneous pain threshold through a central action. This central depression has therapeutic importance. For example, in patients who are hypoventilating from narcotics or anesthetics, increasing P_{CO_2} may result in further CNS depression, which in turn may worsen the respiratory depression. This positive-feedback cycle can have lethal consequences.

Methods of Administration

Carbon dioxide is marketed in gray metal cylinders as the pure gas or as CO_2 mixed with O_2. It usually is administered at a concentration of 5% to 10% in combination with O_2 by means of a face mask. Another method for the temporary administration of CO_2 is by rebreathing, such as from an anesthesia breathing circuit or from something as simple as a paper bag.

Therapeutic Uses

Carbon dioxide is used for insufflation during endoscopic procedures (e.g., laparoscopic surgery) because it is highly soluble and does not support combustion. CO_2 can be used to flood the surgical field during cardiac surgery. Because of its density, CO_2 displaces the air surrounding the open heart so that any gas bubbles trapped in the heart are CO_2 rather than insoluble N_2. It is used to adjust pH during cardiopulmonary bypass procedures when a patient is cooled.

Hypocarbia still has some uses in anesthesia; it constricts cerebral vessels, decreasing brain size slightly, and thus may facilitate the performance of neurosurgical operations. While short-term hypocarbia is effective for this purpose, sustained hypocarbia has been associated with worse outcomes in patients with head injury. Hypocarbia should be instituted with a clearly defined indication and normocarbia should be reestablished as soon the indication for hypocarbia no longer applies.

Nitric Oxide

Nitric oxide (NO) is a free radical gas now known as a critical endogenous cell-signaling molecule with an increasing number of potential therapeutic applications.

Endogenous NO is produced from L-arginine by NO synthases (neural, inducible, and endothelial) (see Chapter 3). In the vasculature, basal production of NO by endothelial cells is a primary determinant of resting vascular tone. NO causes vasodilation of smooth muscle cells and inhibition of platelet aggregation and adhesion. Impaired NO production is implicated in atherosclerosis, hypertension, cerebral and coronary vasospasm, ischemia-reperfusion injury, and inflammation and in mediating central nociceptive pathways. NO is rapidly inactivated in the circulation by oxyhemoglobin and by the reaction of NO with the heme iron, leading to the formation of nitrosyl-hemoglobin. Small quantities of methemoglobin are also produced, and these are converted to the ferrous form of heme iron by cytochrome b5 reductase. The majority of inhaled NO is excreted in the urine in the form of nitrate.

Therapeutic Uses

Inhaled NO selectively dilates the pulmonary vasculature (Cooper, 1999) and has potential as a therapy for numerous diseases associated with increased pulmonary vascular resistance. Inhaled NO is FDA-approved for only one indication, persistent pulmonary hypertension of the newborn.

Diagnostic Uses

Inhaled NO can be used during cardiac catheterization to evaluate the pulmonary vasodilating capacity of patients with heart failure and infants with congenital heart disease. Inhaled NO also is used to determine the diffusion capacity (D_L) across the alveolar-capillary unit. NO is more effective than CO_2 in this regard because of its greater affinity for hemoglobin and its higher water solubility at body temperature. NO is produced from the nasal passages and from the lungs of normal human subjects and can be detected in exhaled gas. The measurement of fractional exhaled NO is a noninvasive marker for airway inflammation with utility in the assessment of respiratory tract diseases, including asthma, respiratory tract infection, and chronic lung disease.

Toxicity

Administered at low concentrations (0.1–50 ppm), inhaled NO appears to be safe and without significant side effects. Pulmonary toxicity can occur with levels higher than 50 to 100 ppm. NO is an atmospheric pollutant; the Occupational Safety and Health Administration places the 7-hour exposure limit at 50 ppm. Part of the toxicity of NO may be related to its further oxidation to NO_2 in the presence of high concentrations of O_2.

The development of methemoglobinemia is a significant complication of inhaled NO at higher concentrations, and rare deaths have been reported with overdoses of NO. Methemoglobin concentrations should be monitored intermittently during NO inhalation. Inhaled NO can inhibit platelet function and has been shown to increase bleeding time in some clinical studies, although bleeding complications have not been reported. In patients with impaired function of the left ventricle, NO has a potential to further impair left ventricular performance by dilating the pulmonary circulation and increasing the blood flow to the left ventricle, thereby increasing left atrial pressure and promoting pulmonary edema formation.

The most important requirements for safe NO inhalation therapy include:

- Continuous measurement of NO and NO_2 concentrations using either chemiluminescence or electrochemical analyzers
- Frequent calibration of monitoring equipment
- Intermittent analysis of blood methemoglobin levels
- The use of certified tanks of NO
- Administration of the lowest NO concentration required for therapeutic effect

Methods of Administration

Courses of treatment of patients with inhaled NO are highly varied, extending from 0.1 to 40 ppm in dose and for periods of a few hours to several weeks in duration. The determination of a dose-response relationship on a frequent basis should assist in the titration of the optimum dose of NO. Commercial NO systems are available that will accurately deliver inspired NO concentrations between 0.1 and 80 ppm and simultaneously measure NO and NO_2 concentrations.

Helium

Helium is an inert gas whose low density, low solubility, and high thermal conductivity provide the basis for its medical and diagnostic uses. Helium can be mixed with O_2 and administered by mask or endotracheal tube. Under hyperbaric conditions, it can be substituted for the bulk of other gases, resulting in a mixture of much lower density that is easier to breathe.

The primary uses of helium are in pulmonary function testing, the treatment of respiratory obstruction, laser airway surgery, as a label in imaging studies, and for diving at depth. Helium is also suited for determinations of residual lung volume, functional residual capacity, and related lung volumes. These measurements require a highly diffusible nontoxic gas that is insoluble and does not leave the lung by the bloodstream so that, by dilution, the lung volume can be measured. Helium can be added to O_2 to reduce turbulence due to airway obstruction because the density of helium is less than that of air, and the viscosity of helium is greater than that of air. Mixtures of helium and O_2 reduce the work of breathing. Helium has high thermal conductivity, making it useful during laser surgery on the airway. Laser-polarized helium is used as an inhalational contrast agent for pulmonary magnetic resonance imaging. Helium also has potential as a cytoprotective agent (Smit et al., 2015).

Hydrogen Sulfide

Hydrogen sulfide (H_2S), which has a characteristic rotten egg smell, is a colorless, flammable, water-soluble gas that is primarily considered as a toxin due to its capacity to inhibit mitochondrial respiration through blockade of cytochrome c oxidase. Inhibition of respiration can be toxic; however, if depression of respiration occurs in a controlled manner, it may allow nonhibernating species exposed to inhaled H_2S to enter a state akin to suspended animation (i.e., a slowing of cellular activity to a point at which metabolic processes are inhibited but not terminal) and thereby increase tolerance to stress. H_2S activates ATP-dependent K^+ channels, has vasodilating properties, and serves as a free radical scavenger. H_2S can protect against whole-body hypoxia, lethal hemorrhage, and ischemia-reperfusion injury in various organs, including the kidney, lung, liver, and heart. Currently, effort is under way for development of gas-releasing molecules that could deliver H_2S and other therapeutic gases to diseased tissue. H_2S in low quantities may have the potential to limit cell death (Lefer, 2007).

Drug Facts for Your Personal Formulary: *General Anesthetics and Therapeutic Gases*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Parenteral Anesthetics		
Propofol Etomidate Ketamine Thiopental	• Anesthetic induction • Rapid-onset and short-duration anesthetics used in procedures for rapid return to preoperative mental status	• Highly lipophilic → entry to brain and spinal cord, accumulation in fatty tissues • Propofol dosage: ↓ in elderly due to reduced clearance, ↑ in young children due to rapid clearance • PRIS: rare complication associated with prolonged and high-dose propofol infusion in young or head-injured patients • Etomidate: preferred for patients at risk of hypotension or MI; produces hypnosis, no analgesic effects; ↑ EEG activity, associated with seizures • Ketamine: suited for patients at risk for hypotension and asthma and for pediatric procedures; increases HR, BP, cardiac output, CBF, and ICP; emergence delirium, hallucinations, vivid dreams limit use
Barbiturates Methohexital Thiopental	• Anesthetic induction	• Respiratory and EEG depressants • Methohexital: more rapid clearance than other barbiturates • Thiopental: action terminated by redistribution; good safety record; not available in the U.S. • Intra-arterial injection of thiobarbiturates → severe inflammatory and potentially necrotic reaction

Drug Facts for Your Personal Formulary: *General Anesthetics and Therapeutic Gases (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Inhalational Anesthetics		
Isoflurane	• Maintenance of anesthesia • Commonly used inhalational anesthetic	• Highly volatile at RT; not flammable in air or O_2 • ↓ Ventilation and RBF (renal blood flow); ↑ CBF • Induces hypotension and ↑ coronary blood flow, thus ↓ myocardial O_2 consumption • ↓ Baroreceptor function • Excreted unchanged by the lungs
Enflurane	• Maintenance of anesthesia	• Volatile at RT; store in tightly sealed bottles • Slow induction and recovery • ↓ Arterial BP due to vasodilation and ↓ myocardial contractility • Possible effects: ↑ ICP, seizure activity
Sevoflurane	• Preferred agent for anesthetic induction • Used for outpatient anesthesia (not irritating airway; induction and recovery are rapid)	• Reacts exothermically with desiccated CO_2 absorbent • Ideal induction agent (pleasant smell, rapid onset) • ↓ Arterial pressure and cardiac output; potent bronchodilator • Preferred for patients with myocardial ischemia • Compound A, product of interaction of sevoflurane with the CO_2-absorbent soda lime, is nephrotoxic
Desflurane	• Used for outpatient surgery (rapid onset, rapid recovery)	• Highly volatile at RT; store in tightly sealed bottles • Nonflammable in mixtures of air or O_2 • An airway irritant
Halothane	• Maintenance of anesthesia	• Highly volatile at RT, light sensitive; store in tightly sealed amber bottles with thymol (preservative) • Possible hepatic toxicity has limited its use and is no longer available in the U.S.
Nitrous oxide (N_2O)	• Weak anesthetic agent used for its significant analgesic effects	• Colorless and odorless gas at RT; used as adjunct to other anesthetics • Will expand volume of air-containing cavities → avoid use in obstructions of ear and bowel and in intraocular and intracranial air bubbles, etc. • To avoid diffusional hypoxia, administer 100% O_2 rather than air when discontinuing N_2O • Can increase CBF and ICP • Clinical use controversial due to potential metabolic effects related to ↑ homocysteine and changes in DNA and protein synthesis
Anesthetic Adjuncts • Augment anesthetic effects of general anesthesia		
Benzodiazepines Midazolam, diazepam, lorazepam	• Used for anxiolysis, amnesia, preanesthetic sedation, and sedation during procedures not requiring general anesthesia	• Midazolam most commonly used, followed distantly by diazepam and lorazepam (see Chapters 18 and 22)
α_2 Adrenergic agonists Dexmedetomidine	• Short-term (<24 h) sedation of critically ill adults • Sedation prior to and during surgical or medical procedures in nonintubated patients	• Activation of the α_{2A} adrenergic receptor by dexmedetomidine → sedation and analgesia • Side effects: hypotension and bradycardia due to decreased catecholamine release in the CNS; nausea and dry mouth
Analgesics *Opioids* Fentanyl, sufentanil, alfentanil, remifentanil, meperidine, morphine	• To reduce anesthetic requirement and minimize hemodynamic changes due to painful stimuli	• Opioids are the primary analgesics during perioperative period; the choice of opioid is based on duration of action (see Chapter 23) • Opioids often are administered intrathecally and epidurally for management of acute and chronic pain
NSAIDs Acetaminophen		• NSAIDs and acetaminophen are used for minor surgical procedures to control postoperative pain
Neuromuscular Blocking Agents Succinylcholine (depolarizing) Atracurium, vecuronium, et al. (nondepolarizing, competitive)	• Skeletal muscle relaxant	• Action of nondepolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an AChE inhibitor (e.g., neostigmine or edrophonium; see Chapter 12), in combination with a muscarinic receptor antagonist

Drug Facts for Your Personal Formulary: *General Anesthetics and Therapeutic Gases (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Therapeutic Gases		
Oxygen	• Used primarily to reverse or prevent the development of hypoxia	• Excessive O_2 ↓ ventilation • Monitoring and titration are required to avoid complications and side effects • HR and cardiac output are slightly ↓ when 100% O_2 is breathed • High flows of dry O_2 can dry out and irritate mucosal surfaces of the airway and the eyes; humidified O_2 should be used for prolonged therapy (>1 h) • O_2-enriched atmosphere constitutes a fire hazard; take precautions
Carbon dioxide	• Insufflation during endoscopic procedures • Flooding the surgical field during cardiac surgery • Adjusting pH during cardiopulmonary bypass	• CO_2 is highly soluble, noncombustible, denser than air • ↑ P_{CO_2} → respiratory acidosis • Effects on cardiovascular system: combination of direct CNS and reflex sympathetic effects; net effect: ↑ cardiac output, HR, and BP
Nitric oxide	• Inhaled NO is used to dilate pulmonary vasculature in persistent pulmonary hypertension of the newborn	• Cell-signaling molecule; induces vasodilation • Pulmonary toxicity can occur with levels >50–100 ppm • Use lowest NO concentration required for therapeutic effect • Monitor blood methemoglobin levels intermittently during inhalation therapy
Helium	• Pulmonary function testing, treatment of respiratory obstruction, laser airway surgery • As a label in imaging studies	• Mixtures of He and O_2 reduce the work of breathing • Potential as a cytoprotective agent • For diving at depth
Hydrogen sulfide	• Potential therapeutic use for protection against effects of hypoxia	

AChE, acetylcholinesterase; BP, blood pressure; HR, heart rate; MI, myocardial infarction; NSAID, nonsteroidal anti-inflammatory drug; RT, room temperature.

Chapter 25 Local Anesthetics

William A. Catterall and Kenneth Mackie

Local anesthetics bind reversibly to a specific receptor site within the pore of the Na^+ channels in nerves and block ion movement through this pore. When applied locally to nerve tissue in appropriate concentrations, local anesthetics can act on any part of the nervous system and on every type of nerve fiber, reversibly blocking the action potentials responsible for nerve conduction. Thus, a local anesthetic in contact with a nerve trunk can cause both sensory and motor paralysis in the area innervated. These effects of clinically relevant concentrations of local anesthetics are reversible with recovery of nerve function and no evidence of damage to nerve fibers or cells in most clinical applications.

HISTORY

The first local anesthetic, *cocaine*, was serendipitously discovered to have anesthetic properties in the late 19th century. *Cocaine* occurs in abundance in the leaves of the coca shrub (*Erythroxylon coca*). For centuries, Andean natives have chewed an alkali extract of these leaves for its stimulatory and euphoric actions. When, in 1860, Albert Niemann isolated *cocaine*, he tasted his newly isolated compound, noted that it numbed his tongue, and a new era began. Sigmund Freud studied *cocaine*'s physiological actions, and Carl Koller introduced *cocaine* into clinical practice in 1884 as a topical anesthetic for ophthalmological surgery. Shortly thereafter, Halstead popularized its use in infiltration and conduction block anesthesia. Subsequently, Einhorn and others developed synthetic substitutes in an attempt to avoid the toxic and addictive qualities of *cocaine*.

Chemistry and Structure-Activity Relationship

Cocaine is an ester of benzoic acid and the complex alcohol 1-carbomethoxy, 3-hydroxytropane (Figure 25–1). Because of its toxicity and addictive properties (see Chapter 28), a search for synthetic substitutes for *cocaine* began in 1892 with the work of Einhorn and colleagues, resulting in the synthesis of *procaine*, which became the prototype for local anesthetics for nearly half a century. The most widely used agents today are *lidocaine*, *bupivacaine*, and *tetracaine*.

Typical local anesthetics contain hydrophilic and hydrophobic moieties that are separated by an intermediate ester or amide linkage. A broad range of compounds containing these minimal structural features can satisfy the requirements for action as local anesthetics. The hydrophilic group usually is a tertiary amine but also may be a secondary amine; the hydrophobic moiety must be aromatic. The nature of the linking group determines some of the pharmacological properties of these agents. For example, plasma esterases readily hydrolyze local anesthetics with an ester link.

The structure-activity relationship and the physicochemical properties of local anesthetics have been well reviewed (Courtney and Strichartz, 1987). Hydrophobicity increases both the potency and the duration of action of the local anesthetics; association of the drug at hydrophobic sites enhances the partitioning of the drug to its sites of action and decreases the rate of metabolism by plasma esterases and hepatic enzymes. In addition, the receptor site for these drugs on Na^+ channels is thought to be hydrophobic (see Mechanism of Action), so that receptor affinity for anesthetic agents is greater for the more hydrophobic drugs. Hydrophobicity also increases toxicity, so that the therapeutic index is decreased for more hydrophobic drugs.

Molecular size influences the rate of dissociation of local anesthetics from their receptor sites. Smaller drug molecules can escape from the receptor site more rapidly. This characteristic is important in rapidly firing cells, in which local anesthetics bind during action potentials and dissociate during the period of membrane repolarization. Rapid binding of local anesthetics during action potentials causes the frequency and voltage dependence of their action.

Abbreviations

ACh: acetylcholine
CSF: cerebrospinal fluid
CYP: cytochrome P450
EDTA: ethylenediaminetetraacetic acid
NE: norepinephrine
NET: norepinephrine transporter
TRP: transient receptor potential
TRPV channel: TRP vanilloid subtype channel

Mechanism of Action

Cellular Site of Action

Local anesthetics act at the cell membrane to prevent the generation and the conduction of nerve impulses. Conduction block can be demonstrated in squid giant axons from which the axoplasm has been removed.

Local anesthetics block conduction by decreasing or preventing the large transient increase in the permeability of excitable membranes to Na^+ that normally is produced by a slight depolarization of the membrane (see Chapters 10, 13, and 16; Strichartz and Ritchie, 1987). This action of local anesthetics is due to their direct interaction with voltage-gated Na^+ channels. As the anesthetic action progressively develops in a nerve, the threshold for electrical excitability gradually increases, the rate of rise of the action potential declines, impulse conduction slows, and the safety factor for conduction decreases. These factors decrease the probability of propagation of the action potential, and nerve conduction eventually fails.

Local anesthetics can bind to other membrane proteins (Butterworth and Strichartz, 1990). In particular, they can block K^+ channels (Strichartz and Ritchie, 1987). However, because the interaction of local anesthetics with K^+ channels requires higher concentrations of drug, blockade of conduction is not accompanied by any large or consistent change in resting membrane potential.

Quaternary analogues of local anesthetics block conduction when applied internally to perfused giant axons of squid but are relatively ineffective when applied externally. These observations suggest that the site at which local anesthetics act, at least in their charged form, is accessible only from the inner surface of the membrane (Narahashi and Frazier, 1971; Strichartz and Ritchie, 1987). Therefore, local anesthetics applied externally first must cross the membrane before they can exert a blocking action.

The Local Anesthetic Receptor Site on Na^+ Channels

The major mechanism of action of these drugs involves their interaction with a specific binding site within the Na^+ channel (Butterworth and Strichartz, 1990). The Na^+ channels of the mammalian brain are complexes of glycosylated transmembrane proteins with an aggregate molecular size in excess of 300,000 Da; the individual subunits are designated α (260,000 Da) and β_1 to β_4 (33,000–38,000 Da). The large α subunit of the Na^+ channel contains four homologous domains (I–IV); each domain consists of six transmembrane segments in α-helical conformation (S1–S6; Figure 25–2) and an additional, membrane-reentrant pore (*P*) loop. The Na^+-selective transmembrane pore of the channel resides in the center of a nearly symmetrical structure formed by the four homologous domains. The voltage dependence of channel opening reflects conformational changes that result from the movement of "gating charges" within the voltage sensor module of the Na^+ channel in response to changes in the transmembrane potential. The gating charges are located in the S4 transmembrane helices, which are hydrophobic and positively charged, containing arginine or occasionally lysine residues at every third position. These residues are thought to move perpendicular to the plane of the membrane under the influence of the transmembrane potential, initiating a series of conformational changes in all four domains, which leads to the open state of the channel (Figure 25–2) (Catterall et al., 2000, 2020).

The transmembrane pore of the Na^+ channel is surrounded by the S5 and S6 transmembrane helices and the short membrane-associated segments between them that form the *P* loop. Amino acid residues in these short segments are the most critical determinants of the ion conductance and selectivity of the channel.

After it opens, the Na^+ channel inactivates within a few milliseconds due to closure of an inactivation gate. This functional gate is formed by the short intracellular loop of protein that connects homologous domains III and IV. This loop folds over the intracellular mouth of the transmembrane pore during the process of inactivation and binds to an inactivation gate "receptor" on the intracellular surface of the pore module.

Amino acid residues important for local anesthetic binding are found in the S6 segments in domains I, III, and IV (Ragsdale et al., 1994; Yarov-Yarovoy et al., 2002). Hydrophobic amino acid residues near the center of the S6 segments interact directly with bound local anesthetics, locating

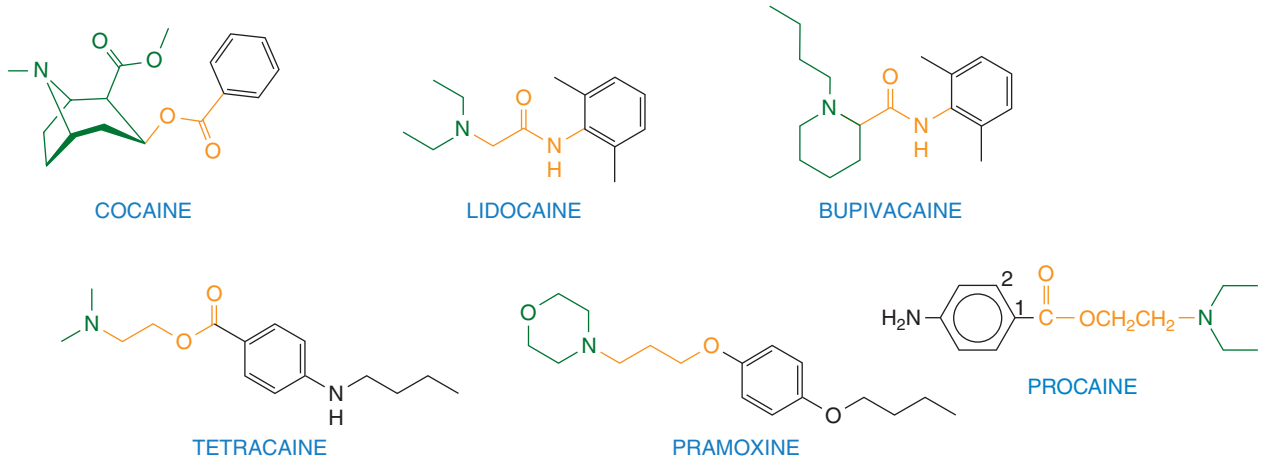

Figure 25–1 *Structural formulas of selected local anesthetics.* Most local anesthetics consist of a hydrophobic (aromatic) moiety (black), a linker region (orange), and a substituted amine (hydrophilic region, green). The structures at the top are grouped by the nature of the linker region. *Procaine* is a prototypic ester-type local anesthetic; esters generally are rapidly hydrolyzed by plasma esterases, contributing to the relatively short duration of action of drugs in this group. *Lidocaine* is a prototypic amide-type local anesthetic; these structures generally are more resistant to clearance and have longer durations of action. There are exceptions, including *benzocaine* (poorly water soluble; used only topically) and the structures with a ketone, an amidine, and an ether linkage. *Chloroprocaine* has a chlorine atom on C2 of the aromatic ring of *procaine*.

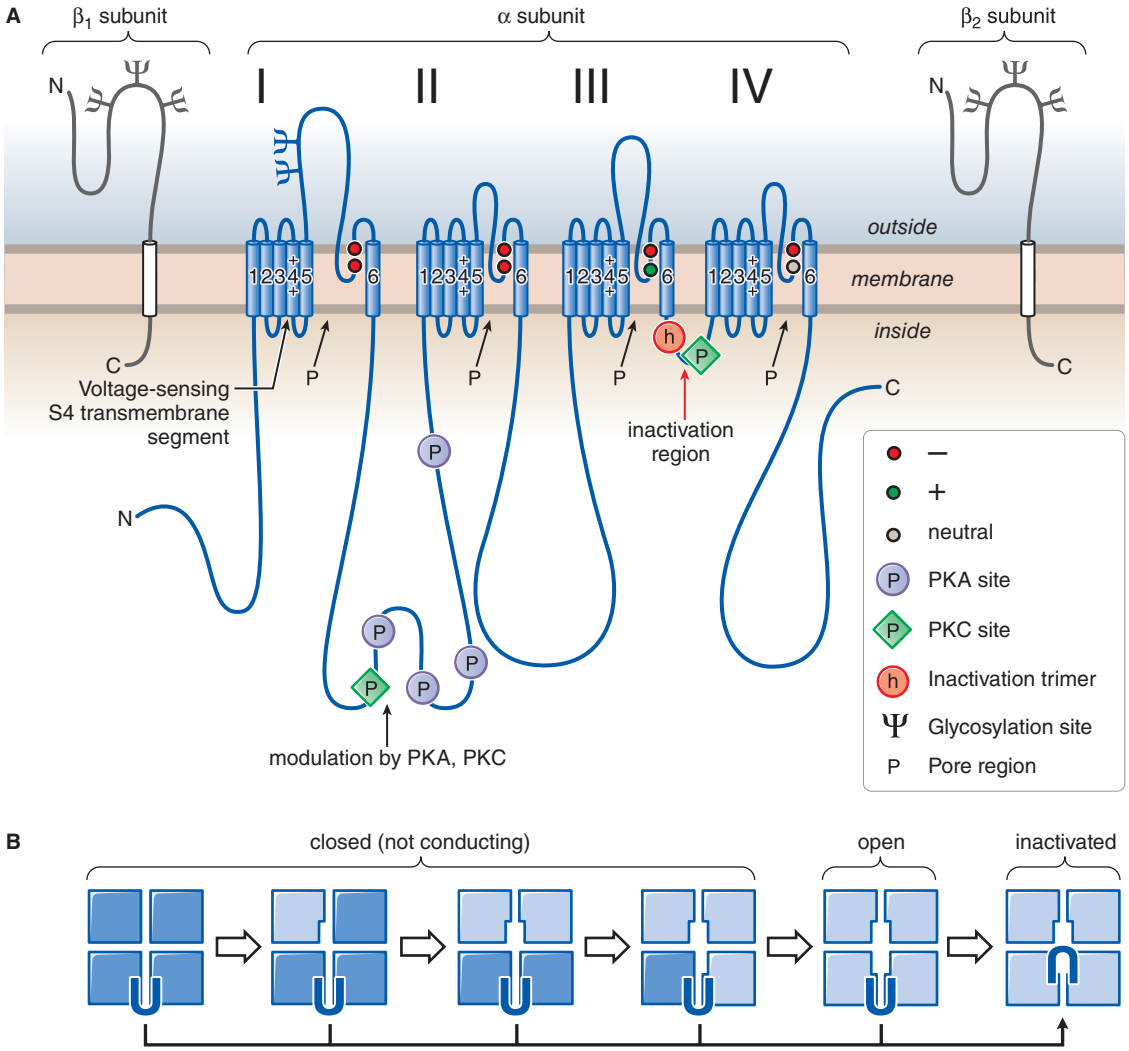

Figure 25–2 *Molecular organization and function of voltage-gated Na^+ channels.* **A.** A two-dimensional representation of the α (center), β_1 (left), and β_2 (right) subunits of the voltage-gated Na^+ channel from mammalian brain. The polypeptide chains are represented by continuous lines with length approximately proportional to the actual length of each segment of the channel protein. Cylinders represent regions of transmembrane α helices. ψ indicates sites of demonstrated *N*-linked glycosylation. Note the repeated structure of the four homologous domains (I–IV) of the α subunit. **Voltage Sensing**. The S4 transmembrane segments in each homologous domain of the α subunit serve as voltage sensors. (+) represents the positively charged amino acid residues at every third position within these segments. Electrical field (negative inside) exerts a force on these charged amino acid residues, pulling them toward the intracellular side of the membrane; depolarization allows them to move outward and initiate a conformational change that opens the pore. **Pore**. The S5 and S6 transmembrane segments and the short membrane-associated loop between them (*P* loop) form the walls of the pore in the center of an approximately symmetrical square array of the four homologous domains (see **B**). The amino acid residues indicated by circles in the *P* loop are critical for determining the conductance and ion selectivity of the Na^+ channel and its ability to bind the extracellular pore-blocking toxin tetrodotoxin (TTX) and saxitoxin. **Inactivation**. The short intracellular loop connecting homologous domains III and IV serves as the fast inactivation gate of the Na^+ channel. It is thought to fold into the intracellular surface of the pore domain and occlude the pore within a few milliseconds after it opens. Three hydrophobic residues (isoleucine-phenylalanine-methionine [IFM]) at the position marked **h** appear to serve as an inactivation particle, binding to the intracellular surface of the pore module and binding to an inactivation gate receptor there. **Modulation**. The gating of the Na^+ channel can be modulated by protein phosphorylation. Phosphorylation of the inactivation gate between homologous domains III and IV by protein kinase C (PKC) slows inactivation. Phosphorylation of sites in the intracellular loop between homologous domains I and II by either PKC or protein kinase A (PKA) reduces Na^+ channel activation. (Adapted with permission from Catterall WA. From ionic currents to molecular mechanisms: the structure and function of voltage-gated sodium channels. *Neuron*, **2000**, *26*:13–25. Copyright © Elsevier). **B.** The four homologous domains of the Na^+ channel α subunit are illustrated as a square array, as viewed looking down on the membrane. The sequence of conformational changes that the Na^+ channel undergoes during activation and inactivation is diagrammed. On depolarization, each of the four homologous domains sequentially undergoes a conformational change to an activated state. After all four domains have activated, the Na^+ channel can open. Within a few milliseconds after opening, the inactivation gate between domains III and IV closes into the intracellular surface of the pore module and binds there, preventing further ion conductance (see Catterall, 2000).

the local anesthetic receptor site in the center of the transmembrane pore of the Na^+ channel, with part of its structure contributed by amino acids in the S6 segments of domains I, III, and IV (Figure 25–3A). Ancestral Na^+ channels in bacteria comprise four identical subunits, each similar to one of the four domains of the mammalian Na^+ channel α subunit and containing a similar voltage sensor and pore-lining segment. In schematic terms, a voltage-gated Na^+ channel is composed of a funnel-shaped extracellular *vestibule* that feeds sodium ions into a narrow *selectivity filter*, which opens onto a large, water-filled *central cavity* that has an intracellular exit *gate* (Figure 25–3B). Functionally, the channel can exist in a cycle of multiple states, controlled by the local effects of the membrane potential on the positive gating charges in the S4 transmembrane segments in domains I–IV of the channel protein, as shown in Figure 25–2A. These states are *resting/closed, intermediate/closed, open,* and *inactivated*.

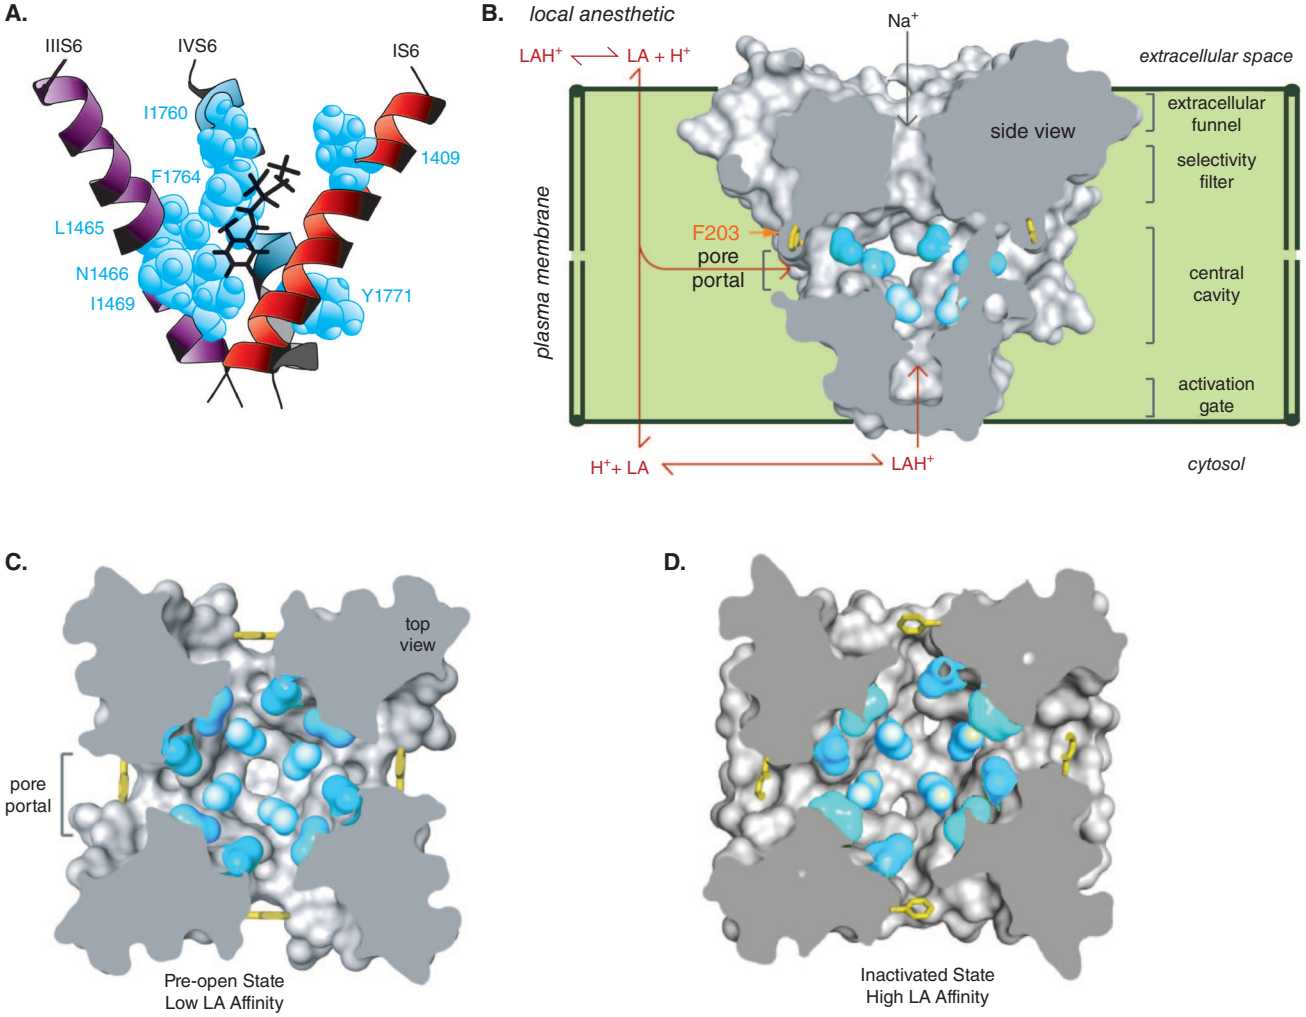

Figure 25–3 *A structural view of the interaction of a local anesthetic (LA) with a voltage-gated Na^+ channel.* **A.** Functional model of the receptor site for LAs with *etidocaine* bound (black sticks) and amino acid residues in the pore-lining S6 segments in domains I, III, and IV (light blue balls), whose mutation causes loss of LA block. **B.** LA access and binding. LAs bind in the center of the pore region depicted by the light blue balls. LAs exist in charged and uncharged forms at physiological pH, in accordance with the Henderson-Hasselbalch relationship (see Figure 2–3). The uncharged species, LA, can diffuse across the membrane, possibly interacting with the channel protein en route. Within the cell, LA equilibrates with H^+; the charged form, LAH^+, binds in the channel with greater affinity than does the uncharged species. The resting/closed conformation of the channel has a relatively low affinity for LA. Depolarization initiates a conformational change that opens the intracellular activation gate, allowing rapid inward sodium conductance through the pore and rapid access of LAs to their receptor site in a high-affinity conformation. Thus, stimulation of a nerve by an action potential enhances LA binding. With a low frequency of stimulation, LA has time to dissociate and the channels reliably return to their resting state (low affinity for LA). With a high frequency of stimulation, as in nociceptive sensory afferents after a wound, there is insufficient time for LA to fully dissociate; thus, the fraction of channels liganded by LA increases in the continued presence of LA, leading to greater and greater conduction blockade. **C.** Top view of a cross-section through the bacterial Na^+ channel Na_VAb highlighting the positions of amino acid residues that bind LAs in light blue (Payandeh et al., 2011). A portal or fenestration in the side of the pore provides a slow route of drug access from the membrane. **D.** Top view. The LA receptor site (light blue) undergoes a substantial conformational change in the inactivated state, which increases binding of LAs.

The three-dimensional structure of an ancestral Na^+ channel (Payandeh et al., 2011) revealed the arrangement of its transmembrane segments and the positions of the amino acid residues in the local anesthetic binding site in the pore, as represented by light blue balls (Figure 25–3C, D).

Recently, the complete structures of mammalian Na^+ channels have been determined at high resolution by cryogenic electron microscopy, including the peripheral nerve Na^+ channel $Na_V1.7$ (Figure 25–4). This structure reveals the functional components of the peripheral nerve Na^+ channel in atomic detail and shows a conservation of structure of the core transmembrane region of Na^+ channels from bacteria to mammals (Payandeh et al., 2011; Shen et al., 2019).

Frequency and Voltage Dependence

The degree of block produced by a given concentration of local anesthetic depends on how the nerve has been stimulated and on its resting membrane potential. Thus, a resting nerve is much less sensitive to a local anesthetic than one that is repetitively stimulated; higher frequency of stimulation and more positive membrane potential cause a greater degree of anesthetic block. These frequency- and voltage-dependent effects of local anesthetics occur because the charged form of the local anesthetic molecule gains access to its binding site within the pore primarily when the Na^+ channel is open and because the local anesthetic binds more tightly to and stabilizes the inactivated state of the Na^+ channel (Butterworth and Strichartz, 1990; Courtney and Strichartz, 1987; Hille, 1977). Remarkably, the conformation of the local anesthetic receptor site is changed considerably in the inactivated state (Payandeh et al., 2012; Figure 25–3D), revealing how preferential binding to inactivated Na^+ channels may occur. The frequency and voltage dependence of local anesthetic inhibition of Na^+ channels contribute to the selectivity of drug action because rapidly fired action potentials that signal intense pain are blocked preferentially compared to more slowly fired action potentials that communicate other sensory information.

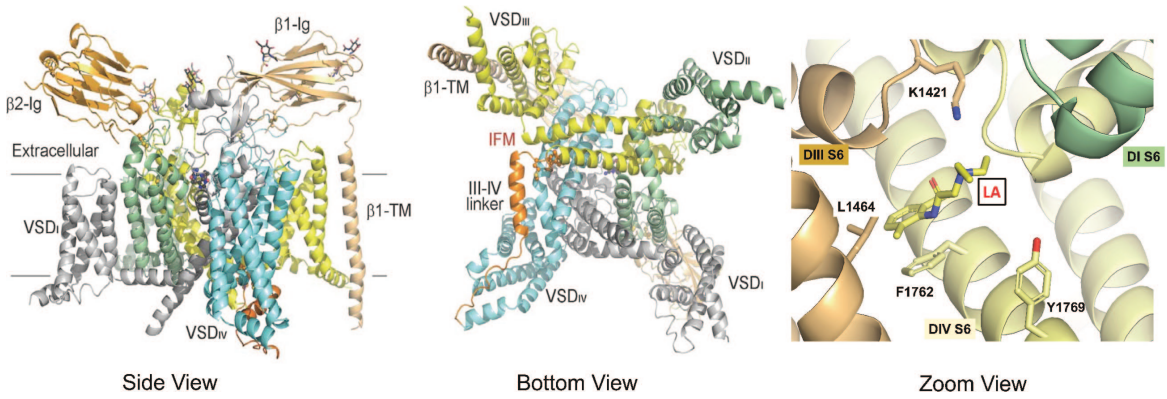

Figure 25–4 *Three-dimensional structure of a Na⁺ channel.* The three-dimensional structure of the sensory nerve Na⁺ channel $Na_V1.7$ determined by cryogenic electron microscopy (Shen et al., 2019). **Left panel:** This side view shows the organization of the 24 transmembrane segments of the four homologous domains of the Na⁺ channel α subunits (domain I, gray; domain II, green; domain III, yellow; domain IV, blue) and the binding positions of the β1 and β2 subunits (β1, light tan; β2, dark tan). **Center panel:** This bottom view highlights the domain III–IV linker and the pore-blocking IFM motif of the fast inactivation gate (dark tan). **Right panel:** This zoom view is a model of *lidocaine* (local anesthetic [LA]) bound in its receptor site in the pore, based on structures of $Na_V1.7$ and $Na_V1.5$, the primary cardiac Na⁺ channel (Jiang et al., 2020; Shen et al., 2019). Amino acid numbering is that from $Na_V1.5$. In contrast to this binding position of LAs, the potent marine neurotoxins tetrodotoxin and saxitoxin bind in the extracellular funnel with high affinity ($K_d \sim 10^{-9}$ M) and block the pore (Jiang et al., 2020; Shen et al., 2019). β2-Ig, beta-2 subunit immunoglobulin-like domain; D# S6, Domain # (Roman numerals I through IV) transmembrane segment 6; IFM, fast inactivation Ile/Phe/Met (IFM) motif; VSD, voltage-sensing domain. Side and bottom views: From Shen H, et al. Structures of human $Na_V1.7$ channel in complex with auxiliary subunits and animal toxins. *Science*, **2019**, *363*:1303-1308. Reprinted with permission from AAAS.

Local anesthetics exhibit frequency and voltage dependence to different extents depending on their pK_a, lipid solubility, molecular size, and binding to different channel states. In general, the frequency dependence of local anesthetic action depends critically on the rate of dissociation from the receptor site in the pore of the Na⁺ channel. A high frequency of stimulation is required for rapidly dissociating drugs so that drug binding during the action potential exceeds drug dissociation between action potentials. Dissociation of smaller and more hydrophobic drugs is more rapid, so a higher frequency of stimulation is required to yield frequency-dependent block. Frequency-dependent block of ion channels is also important for the actions of antiarrhythmic drugs (see Chapter 34).

Differential Sensitivity of Nerve Fibers

For most patients, treatment with local anesthetics causes the sensation of pain to disappear first, followed by loss of the sensations of temperature, touch, deep pressure, and finally motor function (Table 25–1). Classical experiments with intact nerves showed that the δ wave in the compound action potential, which represents slowly conducting, small-diameter myelinated fibers, was reduced more rapidly and at lower concentrations of cocaine than was the α wave, which represents rapidly conducting, large-diameter fibers (Gasser and Erlanger, 1929). In general, autonomic fibers, small unmyelinated C fibers (mediating pain sensations), and small myelinated Aδ fibers (mediating pain and temperature sensations) are blocked before the larger myelinated Aγ, Aβ, and Aα fibers (mediating postural, touch, pressure, and motor information) (Raymond and Gissen, 1987). *The differential rate of block exhibited by fibers mediating different sensations is of considerable practical importance in the use of local anesthetics.*

The precise mechanisms responsible for this apparent specificity of local anesthetic action on pain fibers are not fully known, but several factors may contribute. Although sensitivity to local anesthetic block

TABLE 25–1 ■ SUSCEPTIBILITY OF NERVE TYPES TO LOCAL ANESTHETICS

CLASSIFICATION	ANATOMIC LOCATION	MYELIN	DIAMETER (μm)	CONDUCTION VELOCITY (m/s)	FUNCTION	CLINICAL SENSITIVITY TO BLOCK
A fibers						
A α	Afferent to and efferent from muscles and joints	Yes	6–22	10–85	Motor and proprioception	+
A β						++
A γ	Efferent to muscle spindles	Yes	3–6	15–35	Muscle tone	++
A δ	Sensory roots and afferent peripheral nerves	Yes	1–4	5–25	Pain, temperature, touch	+++
B fibers	Preganglionic sympathetic	Yes	<3	3–15	Vasomotor, visceromotor, sudomotor, pilomotor	++++
C fibers						
Sympathetic	Postganglionic sympathetic	No	0.3–1.3	0.7–1.3	Vasomotor, visceromotor, sudomotor, pilomotor	++++
Dorsal root	Sensory roots and afferent peripheral nerves	No	0.4–1.2	0.1–2	Pain, temperature, touch	++++

increases with decreasing fiber size, consistent with high sensitivity for pain sensation mediated by small fibers (Gasser and Erlanger, 1929), no clear correlation of the concentration dependence of local anesthetic block with fiber diameter is observed when the orientation of nerve fibers allows direct measurement of action potentials (Fink and Cairns, 1984; Franz and Perry, 1974; Huang et al., 1997). Therefore, it is unlikely that the fiber size *per se* determines the sensitivity to local anesthetic block under steady-state conditions. However, the spacing of nodes of Ranvier increases with the size of nerve fibers. Because a fixed number of nodes must be blocked to prevent conduction, small fibers with closely spaced nodes of Ranvier may be blocked more rapidly during treatment of intact nerves because the local anesthetic reaches a critical length of nerve more rapidly. Differences in tissue barriers and location of smaller C fibers and Aδ fibers in nerves also may influence the rate of local anesthetic action. Different combinations of Na^+ channel subtypes are also expressed in these nerve fibers, but all of these Na^+ channels have similar affinity for block by local anesthetics.

Effect of pH

Local anesthetics tend to be only slightly soluble as unprotonated amines. Therefore, they generally are marketed as water-soluble salts, usually hydrochlorides. Because local anesthetics are weak bases (typical pK_a values range from 8 to 9), their hydrochloride salts are mildly acidic. This property increases the stability of the local anesthetic esters and the catecholamines added as vasoconstrictors. Under usual conditions of administration, the pH of the local anesthetic solution rapidly equilibrates to that of the extracellular fluids.

Although the unprotonated species of the local anesthetic is necessary for diffusion across cellular membranes, it is the cationic species that interacts preferentially with Na^+ channels. The results of experiments on anesthetized mammalian nonmyelinated fibers support this conclusion (Ritchie and Greengard, 1966). In these experiments, conduction could be blocked or unblocked merely by adjusting the pH of the bathing medium to 7.2 or 9.6, respectively, without altering the amount of anesthetic present. The primary role of the cationic form also was demonstrated by Narahashi and Frazier, who perfused the extracellular and axoplasmic surface of the giant squid axon with tertiary and quaternary amine local anesthetics and found that the quaternary amines were active only when perfused intracellularly (Narahashi and Frazier, 1971). However, the unprotonated molecular forms also possess anesthetic activity (Butterworth and Strichartz, 1990).

Prolongation of Action by Vasoconstrictors

The duration of action of a local anesthetic is proportional to the time of contact with nerve. Consequently, maneuvers that keep the drug at the nerve prolong the period of anesthesia. For example, *cocaine* inhibits the neuronal membrane transporters for catecholamines, thereby potentiating the effect of norepinephrine (NE) at α adrenergic receptors in the vasculature, resulting in vasoconstriction and reduced *cocaine* absorption in vascular beds where α adrenergic effects predominate (see Chapters 10 and 14). In clinical practice, a vasoconstrictor, usually *epinephrine*, is often added to local anesthetics. The vasoconstrictor performs a dual service. By decreasing the rate of absorption, it localizes the anesthetic at the desired site and allows the drug's elimination to keep pace with its entry into the systemic circulation, thereby reducing the drug's systemic toxicity. Note, however, that *epinephrine* dilates skeletal muscle vascular beds via actions at β_2 adrenergic receptors and therefore has the potential to increase systemic toxicity of anesthetic deposited in muscle tissue.

Some of the vasoconstrictor agents may be absorbed systemically, occasionally to an extent sufficient to cause untoward reactions (see the next section). There also may be delayed wound healing, tissue edema, or necrosis after local anesthesia. These effects seem to occur partly because sympathomimetic amines increase the O_2 consumption of the tissue; this, together with the vasoconstriction, leads to hypoxia and local tissue damage. Thus, the use of vasoconstrictors in local anesthetic preparations for anatomical regions with limited collateral circulation is avoided.

Undesired Effects of Local Anesthetics

In addition to blocking conduction in nerve axons in the peripheral nervous system, local anesthetics interfere with the function of all organs in which conduction or transmission of impulses occurs. Thus, these agents affect the CNS, autonomic ganglia, neuromuscular junctions, and all forms of muscle (for a review, see Covino, 1987; Garfield and Gugino, 1987; Gintant and Hoffman, 1987). The danger of such adverse reactions is proportional to the concentration of local anesthetic achieved in the circulation. In general, for local anesthetics with chiral centers, the *S*-enantiomer is less toxic than the *R*-enantiomer (McClure, 1996).

CNS

Following absorption, local anesthetics may cause CNS stimulation, producing restlessness and tremor that may progress to clonic convulsions. In general, the more potent the anesthetic, the more readily convulsions may be produced. Alterations of CNS activity are thus predictable from the local anesthetic agent in question and the blood concentration achieved. Central stimulation is followed by depression; death usually is caused by respiratory failure.

The apparent stimulation and subsequent depression produced by applying local anesthetics to the CNS presumably is due solely to depression of neuronal activity; a selective depression of inhibitory neurons likely accounts for the excitatory phase *in vivo*. Rapid systemic administration of local anesthetics may produce death with no or only transient signs of CNS stimulation. Under these conditions, the concentration of the drug probably rises so rapidly that all neurons are depressed simultaneously. Airway control, along with ventilatory and circulatory support, are essential features of treatment in the late stage of intoxication. Intravenously administered benzodiazepines are the drugs of choice for both the prevention and the arrest of convulsions. Neither *propofol* nor a rapidly acting barbiturate is preferred; both are more likely to produce cardiovascular depression than a benzodiazepine (see Chapter 20).

Although drowsiness is the most frequent complaint that results from the CNS actions of local anesthetics, *lidocaine* may produce dysphoria or euphoria and muscle twitching. Moreover, *lidocaine* may produce a loss of consciousness that is preceded only by symptoms of sedation (Covino, 1987). Whereas other local anesthetics also show the effect, *cocaine* has a particularly prominent effect on mood and behavior. These effects of *cocaine* and its potential for abuse are discussed in Chapter 28.

Cardiovascular System

Following systemic absorption, local anesthetics act on the cardiovascular system. The primary site of action is the myocardium, where decreases in electrical excitability, conduction rate, and force of contraction occur. In addition, most local anesthetics cause arteriolar dilation. Untoward cardiovascular effects usually are seen only after high systemic concentrations are attained and CNS symptoms are evident. However, on rare occasions, lower doses of some local anesthetics will cause cardiovascular collapse and death, probably due to either an action on the pacemaker or the sudden onset of ventricular fibrillation. Ventricular tachycardia and fibrillation are relatively uncommon consequences of local anesthetics other than *bupivacaine*. The antiarrhythmic effects of local anesthetics such as *lidocaine* and *procainamide* are discussed in Chapter 34. Finally, it should be stressed that untoward cardiovascular effects of local anesthetic agents may result from their inadvertent intravascular administration, especially if *epinephrine* is also present.

Smooth Muscle

Local anesthetics depress contractions in the intact bowel and in strips of isolated intestine (Zipf and Dittmann, 1971). They also relax vascular and bronchial smooth muscle, although low concentrations initially may produce contraction (Covino, 1987). Spinal and epidural anesthesia, as well as instillation of local anesthetics into the peritoneal cavity, cause sympathetic nervous system paralysis, which can result in increased tone

of gastrointestinal musculature (described under Clinical Uses). Local anesthetics may increase the resting tone and decrease the contractions of isolated human uterine muscle; however, uterine contractions are seldom depressed directly during intrapartum regional anesthesia.

Neuromuscular Junction and Ganglia

Local anesthetics also affect transmission at the neuromuscular junction. At concentrations at which the muscle responds normally to direct electrical stimulation, *procaine* can block the response of skeletal muscle to maximal motor-nerve volleys and to acetylcholine (ACh). Similar effects occur at autonomic ganglia. These effects are due to block of nicotinic ACh receptors by high concentrations of the local anesthetic (Charnet et al., 1990; Neher and Steinbach, 1978).

Hypersensitivity

Rare individuals are hypersensitive to local anesthetics. The reaction may manifest itself as an allergic dermatitis or a typical asthmatic attack (Covino, 1987). It is important to distinguish allergic reactions from toxic side effects and from the effects of coadministered vasoconstrictors. Hypersensitivity seems to occur more frequently with local anesthetics of the ester type and frequently extends to chemically related compounds. For example, individuals sensitive to *procaine* also may react to structurally similar compounds (e.g., *tetracaine*) through reaction to a common metabolite. Although allergic responses to agents of the amide type are uncommon, solutions of such agents may contain preservatives such as methylparaben that may provoke an allergic reaction (Covino, 1987). Local anesthetic preparations containing a vasoconstrictor also may elicit allergic responses due to the sulfite added as an antioxidant for the catecholamine/vasoconstrictor.

Metabolism

Local anesthetics of the ester type (e.g., *tetracaine*) are hydrolyzed and inactivated primarily by a plasma esterase, probably plasma cholinesterase. The liver also participates in hydrolysis of local anesthetics. Because spinal fluid contains little or no esterase, anesthesia produced by the intrathecal injection of an anesthetic agent will persist until the local anesthetic agent has been absorbed into the circulation. The amide-linked local anesthetics are, in general, degraded by the hepatic CYPs, with the initial reactions involving *N*-dealkylation and subsequent hydrolysis (Arthur, 1987). However, with *prilocaine*, the initial step is hydrolytic, forming *o*-toluidine metabolites that can cause methemoglobinemia. The extensive use of amide-linked local anesthetics in patients with severe hepatic disease requires caution.

Toxicity

The metabolic fate of local anesthetics is of great practical importance because toxicity can result from an imbalance between their rates of absorption and elimination. The rate of absorption of many local anesthetics into the systemic circulation can be considerably reduced by the incorporation of a vasoconstrictor agent in the anesthetic solution. However, the rate of degradation of local anesthetics varies greatly, and this is a major factor in determining the safety of a particular agent. Because toxicity is related to the concentration of free drug, binding of the anesthetic to proteins in the serum and to tissues reduces toxicity. For example, in intravenous regional anesthesia of an extremity, about half of the original anesthetic dose still is tissue bound 30 min after the restoration of normal blood flow (Arthur, 1987). Reversing the effects of local anesthetic systemic toxicity is a clinical challenge. One developing approach is promising and unusual: intravenous lipid emulsion therapy (Weinberg, 2012). Whether the lipids simply provide a favorable milieu of micelles into which lipophilic drugs can partition or the effect involves more complex biochemical pathways is not yet clear (Ok et al., 2018).

Plasma binding sites serve to moderate local anesthetic levels in blood. The amide-linked local anesthetics bind extensively (55%–95%) to plasma proteins, particularly α_1-acid glycoprotein. Many factors increase (e.g., cancer, surgery, trauma, myocardial infarction, smoking, and uremia) or decrease (e.g., oral contraceptives) the level of this glycoprotein, thereby changing the amount of anesthetic delivered to the liver for metabolism and thus influencing systemic toxicity. Age-related changes in protein binding of local anesthetics also occur. The neonate is relatively deficient in plasma proteins that bind local anesthetics and thereby is more susceptible to toxicity. Plasma proteins are not the sole determinant of local anesthetic availability. Uptake by the lung also may play an important role in the distribution of amide-linked local anesthetics. Finally, reduced cardiac output slows delivery of the amide compounds to the liver, reducing their metabolism and prolonging their plasma half-lives.

Local Anesthetics and Related Agents

Cocaine

Chemistry

Cocaine, an ester of benzoic acid and methylecgonine, occurs in abundance in the leaves of the coca shrub. Ecgonine is an amino alcohol base closely related to tropine, the amino alcohol in *atropine*. It has the same fundamental structure as the synthetic local anesthetics (see Figure 25–1).

Pharmacological Actions and Preparations

The clinically desired actions of *cocaine* are the blockade of nerve impulses as a consequence of its local anesthetic properties and local vasoconstriction secondary to inhibition of the NE transporter (NET) (see Table 10–5). Toxicity and its potential for abuse have steadily decreased the clinical uses of *cocaine*. Its high toxicity is due to reduced catecholamine uptake in both the central and peripheral nervous systems and the resulting prolongation of transmitter dwell time in the synaptic cleft. *Cocaine*'s euphoric properties are due primarily to inhibition of catecholamine uptake, particularly dopamine, in the CNS. Other local anesthetics do not block the uptake of NE and do not produce the sensitization to catecholamines, vasoconstriction, or mydriasis characteristic of *cocaine*. Currently, *cocaine* is used primarily for topical anesthesia of the upper respiratory tract, where its combination of both vasoconstrictor and local anesthetic properties provides anesthesia and shrinking of the mucosa. *Cocaine hydrochloride* is provided as a 1%, 4%, or 10% solution for topical application. For most applications, the 1% or 4% preparation is preferred to reduce toxicity. Because of its abuse potential, *cocaine* is listed as a schedule II controlled substance by the U.S. Drug Enforcement Administration.

Lidocaine

Lidocaine, an aminoethylamide (Figure 25–1), is the prototypical amide local anesthetic.

Pharmacological Actions and Preparations

Lidocaine produces faster, more intense, longer lasting, and more extensive anesthesia than does an equal concentration of *procaine*. *Lidocaine* is an alternative choice for individuals sensitive to ester-type local anesthetics.

A *lidocaine* transdermal patch is used for relief of pain associated with postherpetic neuralgia. The combination of *lidocaine* (2.5%) and *prilocaine* (2.5%) under an occlusive dressing (EMLA, others) is used as an anesthetic prior to venipuncture, skin graft harvesting, and infiltration of anesthetics into genitalia. *Lidocaine* in combination with *tetracaine* in a formulation that generates a "peel" is approved for topical local analgesia prior to superficial dermatological procedures such as filler injections and laser-based treatments. *Lidocaine* in combination with *tetracaine* is also supplied in a formulation that generates heat on exposure to air, which is used prior to venous access and superficial dermatological procedures such as excision, electrodessication, and shave biopsy of skin lesions. The mild warming is intended to increase skin temperature by up to 5°C for the purpose of enhancing delivery of local anesthetic into the skin.

ADME

Lidocaine is absorbed rapidly after parenteral administration and from the gastrointestinal and respiratory tracts. Although it is effective when used without any vasoconstrictor, *epinephrine* decreases the rate of absorption, thereby decreasing the probability of toxicity and prolonging the duration of action. In addition to preparations for injection, *lidocaine* is formulated for topical, ophthalmic, mucosal, and transdermal use.

Lidocaine is dealkylated in the liver by CYPs to monoethylglycine xylidide and glycine xylidide, which can be metabolized further to monoethylglycine and xylidide. Both monoethylglycine xylidide and glycine xylidide retain local anesthetic activity. In humans, about 75% of the xylidide is excreted in the urine as the further metabolite 4-hydroxy-2,6-dimethylaniline (Arthur, 1987).

Toxicity

The side effects of *lidocaine* seen with increasing dose include drowsiness, tinnitus, dysgeusia, dizziness, and twitching. As the dose increases, seizures, coma, and respiratory depression and arrest will occur. Clinically significant cardiovascular depression usually occurs at serum *lidocaine* levels that produce marked CNS effects. The metabolites monoethylglycine xylidide and glycine xylidide may contribute to some of these side effects.

Clinical Uses

Lidocaine has a wide range of clinical uses as a local anesthetic; it has utility in almost any application where a local anesthetic of intermediate duration is needed. *Lidocaine* also is used as an antiarrhythmic agent (see Chapter 34).

Bupivacaine

Bupivacaine has a wide range of clinical uses as a local anesthetic; it has utility in almost any application where a local anesthetic of long duration is needed.

Pharmacological Actions and Preparations

Bupivacaine is a widely used amide local anesthetic; its structure is similar to that of *lidocaine* except that the amine-containing group is a butyl piperidine (Figure 25–1). *Bupivacaine* is a potent agent capable of producing prolonged anesthesia. Its long duration of action plus its tendency to provide more sensory than motor block has made it a popular drug for providing prolonged analgesia during labor or the postoperative period. By taking advantage of indwelling catheters and continuous infusions, *bupivacaine* can be used to provide several days of effective analgesia. Recently, a liposomal *bupivacaine* preparation has been FDA-approved. While safe and effective, its clinical superiority over conventional *bupivacaine* has not been demonstrated (Hussain et al., 2021).

ADME

Bupivacaine is more slowly absorbed than *lidocaine*, so plasma levels increase more slowly following a *bupivacaine* nerve block or epidural. Conversely, *bupivacaine* levels fall more slowly following cessation of a continuous *bupivacaine* infusion than would be predicted from single-injection pharmacokinetics. *Bupivacaine* is primarily metabolized in the liver by CYP3A4 to pipecolylxylidine, which is then glucuronidated and excreted.

Toxicity

Bupivacaine is more cardiotoxic than equieffective doses of *lidocaine*. Clinically, this is manifested by severe ventricular arrhythmias and myocardial depression after inadvertent intravascular administration. Although *lidocaine* and *bupivacaine* both rapidly block cardiac Na^+ channels during systole, *bupivacaine* dissociates much more slowly than *lidocaine* during diastole, so a significant fraction of Na^+ channels at physiological heart rates remains blocked with *bupivacaine* at the end of diastole (Clarkson and Hondeghem, 1985). Thus, the block by *bupivacaine* is cumulative and substantially more than predicted by its local anesthetic potency. At least a portion of the cardiac toxicity of *bupivacaine* may be mediated centrally; direct injection of small quantities of *bupivacaine* into the medulla can produce malignant ventricular arrhythmias (Thomas et al., 1986). *Bupivacaine*-induced cardiac toxicity can be difficult to treat, and its severity is enhanced by coexisting acidosis, hypercarbia, and hypoxemia, emphasizing the importance of prompt airway control in resuscitation from *bupivacaine* overdose.

Local Anesthetics Suitable for Injection

The number of synthetic local anesthetics is so large that it is impractical to consider them all here. Some local anesthetic agents are too toxic to be given by injection. Their use is restricted to topical application to the eye (see Chapter 74), the mucous membranes, or the skin (see Chapter 75). Many local anesthetics are suitable, however, for infiltration or injection to produce nerve block; some of these also are useful for topical application. The discussion below presents the main categories of local anesthetics; agents are listed alphabetically.

Articaine

Articaine is approved in the U.S. for dental and periodontal procedures. Although it is an amide local anesthetic, it also contains an ester, whose hydrolysis terminates its action. Thus, *articaine* exhibits rapid onset (1–6 min) and duration of action of about 1 h.

Chloroprocaine

Chloroprocaine is a chlorinated derivative of *procaine*. Its major assets are its rapid onset and short duration of action and its reduced acute toxicity due to rapid metabolism (plasma $t_{1/2}$ ~ 25 sec). Enthusiasm for its use has been tempered by reports of prolonged sensory and motor block after epidural or subarachnoid administration of large doses. This toxicity appears to have been a consequence of low pH and the use of sodium metabisulfite as a preservative in earlier formulations. There are no reports of neurotoxicity with newer preparations of *chloroprocaine* that contain calcium ethylenediaminetetraacetic acid (EDTA) as the preservative, although these preparations are not recommended for intrathecal administration. A higher-than-expected incidence of muscular back pain following epidural anesthesia with *2-chloroprocaine* has also been reported (Stevens et al., 1993). This back pain is thought to be due to tetany in the paraspinous muscles, which may be a consequence of Ca^{2+} binding by the EDTA included as a preservative; the incidence of back pain appears to be related to the volume of drug injected and its use for skin infiltration.

Mepivacaine

Mepivacaine is an intermediate-acting amino amide with pharmacological properties resembling those of *lidocaine*. *Mepivacaine*, however, is more toxic to the neonate and thus is not used in obstetrical anesthesia. The increased toxicity of *mepivacaine* in the neonate is related to ion trapping of this agent because of the lower pH of neonatal blood and the pK_a of *mepivacaine*, rather than to its slower metabolism in the neonate. *Mepivacaine* appears to have a slightly higher therapeutic index in adults than does *lidocaine*. Its onset of action is similar to, and its duration slightly longer (~20%) than, that of *lidocaine* in the absence of a coadministered vasoconstrictor. *Mepivacaine* is not effective as a topical anesthetic.

Prilocaine

Prilocaine is an intermediate-acting amino amide. It has a pharmacological profile similar to that of *lidocaine*. The primary differences are that it causes little vasodilation and thus can be used without a vasoconstrictor; its increased volume of distribution reduces its CNS toxicity, making it suitable for intravenous regional blocks (described further in the chapter). The use of *prilocaine* is largely limited to dentistry because the drug is unique among the local anesthetics in its propensity to cause methemoglobinemia. This effect is a consequence of the metabolism of the aromatic ring to *o*-toluidine. Development of methemoglobinemia is dependent on the total dose administered, usually appearing after a dose of 8 mg/kg. If necessary, it can be treated by the intravenous administration of *methylene blue* (1–2 mg/kg).

Ropivacaine

The cardiac toxicity of *bupivacaine* stimulated interest in developing a less-toxic, long-lasting local anesthetic. One result of that search was the development of the amino ethylamide *ropivacaine*; the *S*-enantiomer was

chosen because it has a lower toxicity than the *R*-isomer (McClure, 1996). *Ropivacaine* is slightly less potent than *bupivacaine* in producing anesthesia. *Ropivacaine* appears to be suitable for both epidural and regional anesthesia, with a duration of action similar to that of *bupivacaine*. Interestingly, it seems to be even more motor-sparing than *bupivacaine*.

Procaine

Procaine is no longer marketed in the U.S. as a single entity. It is an ingredient of some long-acting intramuscular formulations of *penicillin*.

Tetracaine

Tetracaine is a long-acting amino ester. It is significantly more potent and has a longer duration of action than *procaine*. *Tetracaine* may exhibit increased systemic toxicity because it is more slowly metabolized than the other commonly used ester local anesthetics. Currently, it is widely used in spinal anesthesia when a drug of long duration is needed. *Tetracaine* also is incorporated into several topical anesthetic preparations. With the introduction of *bupivacaine*, *tetracaine* is rarely used in peripheral nerve blocks because of the large doses often necessary, its slow onset, and its potential for toxicity.

Agents Used Primarily to Anesthetize Mucous Membranes and Skin

Some agents are useful as topical anesthetic agents on the skin or mucous membranes, although too irritating or too ineffective to be applied to the eye. These preparations are effective in the symptomatic relief of anal and genital pruritus, poison ivy rashes, and numerous other acute and chronic dermatoses. They sometimes are combined with a glucocorticoid or antihistamine and are available in a number of proprietary formulations.

Dibucaine

Dibucaine is a quinoline derivative. Its toxicity resulted in its removal from the U.S. market as an injectable preparation. It retains wide popularity outside the U.S. as a spinal anesthetic. It currently is available as an over-the-counter ointment for cutaneous use.

Dyclonine

Dyclonine hydrochloride is readily absorbed through the skin and mucous membranes. Its onset is rapid; its duration of action is short. *Dyclonine* is an active ingredient in a number of over-the-counter medications, including sore throat lozenges, a patch for cold sores, and a 0.75% solution.

Pramoxine

Pramoxine hydrochloride is a surface anesthetic agent that is not a benzoate ester. Its distinct chemical structure may help minimize the danger of cross-sensitivity reactions in patients allergic to other local anesthetics. *Pramoxine* produces satisfactory surface anesthesia and is reasonably well tolerated on the skin and mucous membranes. It is too irritating to be used on the eye or in the nose, but an otic solution containing chloroxylenol is marketed. Many preparations, including creams, lotions, sprays, gel, wipes, and foams, usually containing 1% *pramoxine*, are available for topical application.

Anesthetics With Low Aqueous Solubility

Some local anesthetics have low aqueous solubility and consequently are absorbed too slowly to cause classical local anesthetic toxicity. These compounds can be applied directly to wounds and ulcerated surfaces, where they remain localized for long periods of time, producing a sustained anesthetic action. Chemically, they are esters of para-aminobenzoic acid lacking the terminal amino group possessed by the previously described local anesthetics. The most important member of the series is *benzocaine* (ethyl aminobenzoate), which is incorporated into a large number of topical preparations. *Benzocaine* can cause methemoglobinemia (see the discussion of methemoglobinemia in the section on *prilocaine*); consequently, dosing recommendations must be followed carefully.

Agents for Ophthalmic Use

Anesthesia of the cornea and conjunctiva can be obtained readily by topical application of local anesthetics. However, most of the local anesthetics that have been described are too irritating for ophthalmological use. The two compounds used most frequently today are *proparacaine* and *tetracaine*. In addition to being less irritating during administration, *proparacaine* has the advantage of bearing little antigenic similarity to the other benzoate local anesthetics. Thus, it sometimes can be used in individuals sensitive to the amino ester local anesthetics.

For use in ophthalmology, these local anesthetics are instilled a single drop at a time. If anesthesia is incomplete, successive drops are applied until satisfactory conditions are obtained. The duration of anesthesia is determined chiefly by the vascularity of the tissue; thus, it is longest in normal cornea and shortest in inflamed conjunctiva. In the latter case, repeated instillations may be necessary to maintain adequate anesthesia. Long-term administration of topical anesthesia to the eye has been associated with retarded healing, pitting, sloughing of the corneal epithelium, and predisposition of the eye to inadvertent injury. Thus, these drugs should not be prescribed for self-administration. For issues of drug delivery, pharmacokinetics, and toxicity unique to drugs for ophthalmic use, see Chapter 74.

Biological Toxins: Tetrodotoxin and Saxitoxin

The two biological toxins, tetrodotoxin and saxitoxin, block the pore of the Na^+ channel. Tetrodotoxin is found in the gonads and other visceral tissues of some fish of the order Tetraodontiformes (to which the Japanese *fugu*, or puffer fish, belongs); it also occurs in the skin of some newts of the family Salamandridae and of the Costa Rican frog *Atelopus*. *Saxitoxin* is elaborated by the dinoflagellates *Gonyaulax catenella* and *G. tamarensis* and retained in the tissues of clams and other shellfish that eat these organisms. Given the right conditions of temperature and light, the *Gonyaulax* may multiply so rapidly as to discolor the ocean, causing the condition known as *red tide*. Shellfish feeding on *Gonyaulax* at this time become extremely toxic to humans and are responsible for periodic outbreaks of paralytic shellfish poisoning (Sakai and Swanson, 2014; Stommel and Watters, 2004). Although these toxins are chemically distinct, they have similar mechanisms of action. Both toxins, in nanomolar concentrations, specifically block the outer mouth of the pore of Na^+ channels in the *membranes* of excitable cells. As a result, the action potential is blocked. The receptor site for these toxins is formed by amino acid residues in the *P* loop of the Na^+ channel α subunit (Figure 25–2) in all four domains (Catterall, 2000; Shen et al., 2019; Terlau et al., 1991). Not all Na^+ channels are equally sensitive to tetrodotoxin; some Na^+ channels in cardiac myocytes and dorsal root ganglion neurons are resistant, and a tetrodotoxin-resistant Na^+ channel is expressed when skeletal muscle is denervated. Tetrodotoxin and saxitoxin are exceedingly potent; the minimal lethal dose of each in the mouse is about 8 μg/kg. Both toxins have caused fatal poisoning in humans due to paralysis of the respiratory muscles; therefore, the treatment of severe cases of poisoning requires support of respiration. Blockade of vasomotor nerves, together with a relaxation of vascular smooth muscle, seems to be responsible for the hypotension that is characteristic of tetrodotoxin poisoning. Early gastric lavage and pressor support also are indicated. If the patient survives paralytic shellfish poisoning for 24 h, the prognosis is good.

Clinical Uses of Local Anesthetics

Local anesthesia is the loss of sensation in a body part without the loss of consciousness or the impairment of central control of vital functions. It offers two major advantages over general anesthesia. First, physiological perturbations associated with general anesthesia are avoided. Second, neurophysiological responses to pain and stress can be modified beneficially. However, local anesthetics have the potential to produce deleterious side effects. Proper choice of a local anesthetic and care in its use are the primary determinants in avoiding these problems.

There is a poor relationship between the amount of local anesthetic injected and peak plasma levels in adults. Furthermore, peak plasma levels vary widely depending on the area of injection. They are highest with interpleural or intercostal blocks and lowest with subcutaneous

infiltration. Thus, recommended maximum doses serve only as general guidelines. This discussion summarizes the pharmacological and physiological consequences of the use of local anesthetics categorized by method of administration. A more comprehensive discussion of their use and administration is presented in textbooks on regional anesthesia (Cousins et al., 2008).

Topical Anesthesia

Anesthesia of mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract can be produced by direct application of aqueous solutions of salts of many local anesthetics or by suspension of the poorly soluble local anesthetics. *Tetracaine* (2%), *lidocaine* (2%–10%), and *cocaine* (1%–4%) typically are used. *Cocaine* is used only in the nose, nasopharynx, mouth, throat, and ear, where it uniquely produces vasoconstriction as well as anesthesia. The shrinking of mucous membranes decreases operative bleeding while improving surgical visualization. Comparable vasoconstriction can be achieved with other local anesthetics by the addition of a low concentration of a vasoconstrictor such as *phenylephrine* (0.005%). *Epinephrine*, topically applied, has no significant local effect and does not prolong the duration of action of local anesthetics applied to mucous membranes because of poor penetration. *Maximal safe total dosages* for topical anesthesia in a healthy 70-kg adult are 300 mg for *lidocaine*, 150 mg for *cocaine*, and 50 mg for *tetracaine*.

Peak anesthetic effect following topical application of *cocaine* or *lidocaine* occurs within 2 to 5 min (3–8 min with *tetracaine*), and anesthesia lasts for 30 to 45 min (30–60 min with *tetracaine*). Anesthesia is entirely superficial; it does not extend to submucosal structures. This technique does not alleviate joint pain or discomfort from subdermal inflammation or injury.

Local anesthetics are absorbed rapidly into the circulation following topical application to mucous membranes or denuded skin. Thus, topical anesthesia always carries the risk of systemic toxic reactions. Systemic toxicity has occurred even following the use of local anesthetics to control discomfort associated with severe diaper rash in infants. Absorption is particularly rapid when local anesthetics are applied to the tracheobronchial tree. Concentrations in blood after instillation of local anesthetics into the airway are nearly the same as those following intravenous injection. Surface anesthetics for the skin and cornea have been described earlier in the chapter.

Eutectic mixtures of local anesthetics *lidocaine* (2.5%)/*prilocaine* (2.5%) (EMLA) and *lidocaine* (7%)/*tetracaine* (7%) (Pliaglis) bridge the gap between topical and infiltration anesthesia. The efficacy of each of these combinations lies in the fact that the mixture has a melting point less than that of either compound alone, existing at room temperature as an oil that can penetrate intact skin. These creams produce anesthesia to a maximum depth of 5 mm and are applied as a cream on intact skin under an occlusive dressing in advance (~30–60 min) of any procedure. These mixtures are effective for procedures involving skin and superficial subcutaneous structures (e.g., venipuncture and skin graft harvesting). Beware: the component local anesthetics will be absorbed into the systemic circulation, potentially producing toxic effects. Guidelines are available to calculate the maximum amount of cream that can be applied and area of skin covered. These mixtures must not be used on mucous membranes or abraded skin, as rapid absorption across these surfaces may result in systemic toxicity.

Infiltration Anesthesia

Infiltration anesthesia is the injection of local anesthetic directly into tissue without taking into consideration the course of cutaneous nerves. Infiltration anesthesia can be so superficial as to include only the skin. It also can include deeper structures, including intra-abdominal organs, when these too are infiltrated.

The duration of infiltration anesthesia can be approximately doubled by the addition of *epinephrine* (5 μg/mL) to the injection solution; *epinephrine* also decreases peak concentrations of local anesthetics in blood. *Epinephrine-containing solutions are generally not injected into tissues supplied by end arteries—for example, fingers and toes, ears, the nose, and the penis—because of a concern that the resulting vasoconstriction may cause gangrene.* Similarly, *epinephrine* should be avoided in solutions injected intracutaneously. Because *epinephrine* also is absorbed into the circulation, its use should be avoided in those for whom adrenergic stimulation is undesirable.

The local anesthetics most frequently used for infiltration anesthesia are *lidocaine* (0.5%–1%) and *bupivacaine* (0.125%–0.25%). When used without *epinephrine*, up to 4.5 mg/kg of *lidocaine* or 2 mg/kg of *bupivacaine* can be employed in adults. When *epinephrine* is added, these amounts can be increased by one-third. Tumescent anesthesia is a special case of infiltration anesthesia for which large doses and volumes of *lidocaine* and *epinephrine* are administered (Holt, 2017).

Infiltration anesthesia and other regional anesthetic techniques have the advantage of providing satisfactory anesthesia without disrupting normal bodily functions. The chief disadvantage of infiltration anesthesia is that relatively large amounts of drug must be used to anesthetize relatively small areas. This is no problem with minor surgery. When major surgery is performed, however, the amount of local anesthetic that is required makes systemic toxic reactions likely. The amount of anesthetic required to anesthetize an area can be reduced significantly and the duration of anesthesia increased markedly by specifically blocking the nerves that innervate the area of interest. This can be done at one of several levels: subcutaneously, at major nerves, or at the level of the spinal roots.

Field Block Anesthesia

Field block anesthesia is produced by subcutaneous injection of a solution of local anesthetic to anesthetize the region distal to the injection. For example, subcutaneous infiltration of the proximal portion of the volar surface of the forearm results in an extensive area of cutaneous anesthesia that starts 2 to 3 cm distal to the site of injection. The same principle can be applied with particular benefit to the scalp, the anterior abdominal wall, and the lower extremity.

The drugs, concentrations, and doses recommended are the same as for infiltration anesthesia. The advantage of field block anesthesia is that less drug can be used to provide a greater area of anesthesia than when infiltration anesthesia is used. Knowledge of the relevant neuroanatomy obviously is essential for successful field block anesthesia.

Nerve Block Anesthesia

Injection of a solution of a local anesthetic into or about individual peripheral nerves or nerve plexuses produces even greater areas of anesthesia than do the techniques already described. Blockade of mixed peripheral nerves and nerve plexuses also usually anesthetizes somatic motor nerves, producing skeletal muscle relaxation, which is essential for some surgical procedures. The areas of sensory and motor block usually start several centimeters distal to the site of injection. Brachial plexus blocks are particularly useful for procedures on the upper extremity and shoulder. Intercostal nerve blocks are effective for anesthesia and relaxation of the anterior abdominal wall. Cervical plexus block is appropriate for surgery of the neck. Sciatic and femoral nerve blocks are useful for surgery distal to the knee. Other useful nerve blocks prior to surgical procedures include blocks of individual nerves at the wrist and at the ankle, blocks of individual nerves such as the median or ulnar nerve at the elbow, and blocks of sensory cranial nerves.

There are four major determinants of the onset of sensory anesthesia following injection near a nerve:

1. Proximity of the injection to the nerve
2. Concentration and volume of drug
3. Degree of ionization of the drug
4. Time

Local anesthetic is never intentionally injected into the nerve; this would be painful and could cause nerve damage. Instead, the anesthetic agent is deposited as close to the nerve as possible, a placement that can

be assisted by ultrasound visualization of the nerve. Thus, the local anesthetic must diffuse from the site of injection into the nerve on which it acts. The rate of diffusion is determined chiefly by the concentration of the drug, its degree of ionization (ionized local anesthetic diffuses more slowly), its hydrophobicity, and the physical characteristics of the tissue surrounding the nerve. Higher concentrations of local anesthetic will provide a more rapid onset of peripheral nerve block. The utility of higher concentrations, however, is limited by systemic toxicity and by direct neural toxicity of concentrated local anesthetic solutions. For a given concentration, local anesthetics with lower pK_a values tend to have a more rapid onset of action because more drug is uncharged at neutral pH. For example, the onset of action of *lidocaine* occurs in about 3 min; 35% of *lidocaine* is in the basic form at pH 7.4. In contrast, the onset of action of *bupivacaine* requires about 15 min; only 5% to 10% of *bupivacaine* is uncharged at this pH. Increased hydrophobicity might be expected to speed onset by increased penetration into nerve tissue. However, it also will increase binding to tissue lipids. Furthermore, the more hydrophobic local anesthetics also are more potent (and toxic) and thus must be used at lower concentrations, decreasing the concentration gradient for diffusion. Tissue factors also play a role in determining the rate of onset of anesthetic effects. The amount of connective tissue that must be penetrated can be significant in a nerve plexus compared to isolated nerves and can slow or even prevent adequate diffusion of local anesthetic to the nerve fibers.

Duration of nerve block anesthesia depends on the physical characteristics of the local anesthetic used and the presence or absence of vasoconstrictors. Especially important physical characteristics are lipid solubility and protein binding. Local anesthetics can be broadly divided into three categories:

- Those with a short (20- to 45-min) duration of action in mixed peripheral nerves, such as *procaine*
- Those with an intermediate (60- to 120-min) duration of action, such as *lidocaine* and *mepivacaine*
- Those with a long (400- to 450-min) duration of action, such as *bupivacaine*, *ropivacaine*, and *tetracaine*

Block duration of the intermediate-acting local anesthetics such as *lidocaine* can be prolonged by the addition of *epinephrine* (5 µg/mL). The degree of block prolongation in peripheral nerves following the addition of *epinephrine* appears to be related to the intrinsic vasodilating properties of the local anesthetic and thus is most pronounced with *lidocaine*.

The types of nerve fibers that are blocked when a local anesthetic is injected about a mixed peripheral nerve depend on the concentration of drug used, nerve fiber size, internodal distance, and frequency and pattern of nerve impulse transmission (see the previous sections on Frequency and Voltage Dependence and Differential Sensitivity of Nerve Fibers). Anatomical factors are similarly important. A mixed peripheral nerve or nerve trunk consists of individual nerves surrounded by an investing epineurium. The vascular supply usually is centrally located. When a local anesthetic is deposited about a peripheral nerve, it diffuses from the outer surface toward the core along a concentration gradient. Consequently, nerves in the outer mantle of the mixed nerve are blocked first. These fibers usually are distributed to more proximal anatomical structures than are those situated near the core of the mixed nerve and often are motor. If the volume and concentration of local anesthetic solution deposited about the nerve are adequate, the local anesthetic eventually will diffuse inward in amounts adequate to block even the most centrally located fibers. Lesser amounts of drug will block only nerves in the mantle and the smaller and more sensitive central fibers. Furthermore, because removal of local anesthetics occurs primarily in the core of a mixed nerve or nerve trunk, where the vascular supply is located, the duration of blockade of centrally located nerves is shorter than that of more peripherally situated fibers.

The choice of local anesthetic and the amount and concentration administered are determined by the nerves and the types of fibers to be blocked, the required duration of anesthesia, and the size and health of the patient. For blocks of 2 to 4 h, *lidocaine* (1%–1.5%) can be used in the amounts recommended previously (see Infiltration Anesthesia). *Mepivacaine* (up to 7 mg/kg of a 1%–2% solution) provides anesthesia that lasts about as long as that from *lidocaine*. *Bupivacaine* (2–3 mg/kg of a 0.25%–0.375% solution) can be used when a longer duration of action is required. Alternatively, addition of 5 µg/mL *epinephrine* slows systemic absorption and therefore prolongs duration and lowers the plasma concentration of the intermediate-acting local anesthetics.

Peak plasma concentrations of local anesthetics depend on the amount injected, the physical characteristics of the local anesthetic, whether *epinephrine* is used, the rate of blood flow to the site of injection, and the surface area exposed to local anesthetic. This is of particular importance in the safe application of nerve block anesthesia because the potential for systemic reactions is related to peak free serum concentrations. For example, peak concentrations of *lidocaine* in blood following injection of 400 mg without *epinephrine* for intercostal nerve blocks average 7 µg/mL; the same amount of *lidocaine* used for block of the brachial plexus results in peak concentrations in blood of about 3 µg/mL (Covino and Vassallo, 1976). Therefore, the amount of local anesthetic that can be injected must be adjusted according to the anatomical site of the nerve(s) to be blocked to minimize untoward effects. Addition of *epinephrine* can decrease peak plasma concentrations by 20% to 30%. Multiple nerve blocks (e.g., intercostal block) or blocks performed in vascular regions require reduction in the amount of anesthetic that can be given safely because the surface area for absorption or the rate of absorption is increased.

Intravenous Regional Anesthesia (Bier Block)

The Bier block technique relies on using the vasculature to bring the local anesthetic solution to the nerve trunks and endings. In this technique, an extremity is exsanguinated with an Esmarch (elastic) bandage, and a proximally located tourniquet is inflated to 100 to 150 mmHg above the systolic blood pressure. The Esmarch bandage is removed, and the local anesthetic is injected into a previously cannulated vein. Typically, complete anesthesia of the limb ensues within 5 to 10 min. Pain from the tourniquet and the potential for ischemic nerve injury limit tourniquet inflation to 2 h or less. However, the tourniquet should remain inflated for at least 15 to 30 min to prevent toxic amounts of local anesthetic from entering the circulation following deflation. *Lidocaine*, 40 to 50 mL (0.5 mL/kg in children) of a 0.5% solution without *epinephrine*, is the drug of choice for this technique. For intravenous regional anesthesia in adults using a 0.5% solution without *epinephrine*, the dose administered should not exceed 4 mg/kg.

The attractiveness of the Bier block lies in its simplicity. Its primary disadvantages are that it can be used only for a few anatomical regions, sensation (pain) returns quickly after tourniquet deflation, and premature release or failure of the tourniquet can produce toxic levels of local anesthetic (e.g., 50 mL of 0.5% *lidocaine* contains 250 mg of *lidocaine*). For the last reason and because its longer duration of action offers no advantage, the more cardiotoxic agent *bupivacaine* is not recommended for this technique. Intravenous regional anesthesia is used most often for surgery of the forearm and hand but can be adapted for the foot and distal leg.

Spinal Anesthesia

Spinal anesthesia follows the injection of local anesthetic into the cerebrospinal fluid (CSF) in the lumbar space. For a number of reasons, including the ability to produce anesthesia of a considerable fraction of the body with a dose of local anesthetic that produces negligible plasma levels, spinal anesthesia remains one of the most popular forms of anesthesia. In most adults, the spinal cord terminates above the second lumbar vertebra; between that point and the termination of the thecal sac in the sacrum, the lumbar and sacral roots are bathed in CSF. Thus, in this region, there is a relatively large volume of CSF within which to inject drug, thereby minimizing the potential for direct nerve trauma.

The following is a brief discussion of the physiological effects of spinal anesthesia relating to the pharmacology of the local anesthetics. See more specialized texts (Cousins et al., 2008) for additional details.

Physiological Effects of Spinal Anesthesia

Most of the physiological side effects of spinal anesthesia are a consequence of the sympathetic blockade produced by local anesthetic block of the sympathetic fibers in the spinal nerve roots. A thorough understanding of these physiological effects is necessary for the safe and successful application of spinal anesthesia. Although some effects may be deleterious and require treatment, others can be beneficial for the patient or can improve operating conditions.

Most sympathetic fibers leave the spinal cord between T1 and L2 (see Figure 10–1). Although local anesthetic is injected below these levels in the lumbar portion of the dural sac, cephalad spread of the local anesthetic occurs with all but the smallest volumes injected. This cephalad spread is of considerable importance in the practice of spinal anesthesia and potentially is under the control of numerous variables, of which patient position and baricity (density of the drug relative to the density of the CSF) are the most important (Greene, 1983). The degree of sympathetic block is related to the height of sensory anesthesia; often, the level of sympathetic blockade is several spinal segments higher because the preganglionic sympathetic fibers are more sensitive to low concentrations of local anesthetic. The effects of sympathetic blockade involve both the actions (now partially unopposed) of the parasympathetic nervous system and the response of the unblocked portion of the sympathetic nervous system. Thus, as the level of sympathetic block ascends, the actions of the parasympathetic nervous system are increasingly dominant, and the compensatory mechanisms of the few unblocked sympathetic nervous system are diminished. As most sympathetic nerve fibers leave the cord at T1 or below, few additional effects of sympathetic blockade are seen with cervical levels of spinal anesthesia. The consequences of sympathetic blockade will vary among patients as a function of age, physical conditioning, and disease state. Interestingly, sympathetic blockade during spinal anesthesia appears to be minimal in healthy children.

Clinically, the most important effects of sympathetic blockade during spinal anesthesia are on the cardiovascular system. At all but the lowest levels of spinal blockade, some vasodilation will occur. Vasodilation is more marked on the venous than on the arterial side of the circulation, resulting in blood pooling in the venous capacitance vessels. This reduction in circulating blood volume is well tolerated at low levels of spinal anesthesia in healthy patients. With an increasing level of block, this effect becomes more marked, and venous return becomes gravity dependent. If venous return decreases too much, cardiac output and organ perfusion decline precipitously. Venous return can be increased by a modest (10°–15°) head-down tilt or by elevating the legs.

At high levels of spinal blockade, the cardiac accelerator fibers, which exit the spinal cord at T1–T4, will be blocked. This is detrimental in patients dependent on elevated sympathetic tone to maintain cardiac output (e.g., during congestive heart failure or hypovolemia), and it also removes one of the compensatory mechanisms available to maintain organ perfusion during vasodilation. Thus, as the level of spinal block ascends, the rate of cardiovascular compromise can accelerate if not carefully observed and treated. Sudden asystole also can occur, presumably because of loss of sympathetic innervation in the continued presence of parasympathetic activity at the sinoatrial node (Caplan et al., 1988). In the usual clinical situation, blood pressure serves as a surrogate marker for cardiac output and organ perfusion. Treatment of hypotension usually is warranted when the blood pressure decreases to about 30% of *resting* values.

Therapy is aimed at maintaining brain and cardiac perfusion and oxygenation. To achieve these goals, administration of oxygen, fluid infusion, manipulation of patient position, and the administration of vasoactive drugs are all options. In practice, patients typically are administered a bolus (500–1000 mL) of fluid prior to the induction of spinal anesthesia in an attempt to prevent some of the deleterious effects of spinal blockade. Because the usual cause of hypotension is decreased venous return, possibly complicated by decreased heart rate, drugs with preferential venoconstrictive and chronotropic properties are preferred. For this reason, *ephedrine*, 5–10 mg intravenously, often is the drug of choice. In addition to the use of *ephedrine* to treat deleterious effects of sympathetic blockade, direct-acting α_1 adrenergic receptor agonists such as *phenylephrine* (see Chapter 14) can be administered by either bolus or continuous infusion.

A beneficial effect of spinal anesthesia partially mediated by the sympathetic nervous system is on the intestine. Sympathetic fibers originating from T5 to L1 inhibit peristalsis; thus, their blockade produces a small, contracted intestine. This, together with flaccid abdominal musculature, produces excellent operating conditions for some types of bowel surgery. The consequences of spinal anesthesia on the respiratory system are mostly mediated by effects on the skeletal musculature. Paralysis of the intercostal muscles will reduce a patient's ability to cough and clear secretions, which may produce dyspnea in patients with bronchitis or emphysema. Respiratory arrest during spinal anesthesia seldom occurs due to paralysis of the phrenic nerves or to toxic levels of local anesthetic in the CSF of the fourth ventricle; it is much more likely to be due to medullary ischemia secondary to hypotension.

Pharmacology

Currently in the U.S., the drugs most commonly used in spinal anesthesia are *lidocaine*, *tetracaine*, and *bupivacaine*. The choice of local anesthetic is primarily determined by the desired duration of anesthesia. General guidelines are to use *lidocaine* for short procedures, *bupivacaine* for intermediate-to-long procedures, and *tetracaine* for long procedures. As mentioned, the factors contributing to the distribution of local anesthetics in the CSF have received much attention because of their importance in determining the height of block. The most important pharmacological factors include the amount, and possibly the volume, of drug injected and its baricity. The speed of injection of the local anesthesia solution also may affect the height of the block, just as the position of the patient can influence the rate of distribution of the anesthetic agent and the height of blockade achieved (described in the next section). For a given preparation of local anesthetic, administration of increasing amounts leads to a fairly predictable increase in the level of block attained. For example, 100 mg of *lidocaine*, 20 mg of *bupivacaine*, or 12 mg of *tetracaine* usually will result in a T4 sensory block. More complete tables of these relationships can be found in standard anesthesiology texts.

Epinephrine often is added to spinal anesthetics to increase the duration or intensity of block. *Epinephrine*'s effect on duration of block is dependent on the technique used to measure duration. A commonly used measure of block duration is the length of time it takes for the block to recede by two dermatomes from the maximum height of the block, while a second is the duration of block at some specified level, typically L1. In most studies, addition of 200 μg of *epinephrine* to *tetracaine* solutions prolongs the duration of block by both measures. However, addition of *epinephrine* to *lidocaine* or *bupivacaine* does not affect the first measure of duration but does prolong the block at lower levels. In different clinical situations, one or the other measure of anesthesia duration may be more relevant, and this must be kept in mind when deciding whether to add *epinephrine* to spinal local anesthetics.

The mechanism of action of vasoconstrictors in prolonging spinal anesthesia is uncertain. It has been hypothesized that these agents decrease spinal cord blood flow, decreasing clearance of local anesthetic from the CSF, but this has not been convincingly demonstrated. *Epinephrine* and other α adrenergic agonists have been shown to decrease nociceptive transmission in the spinal cord, and studies in genetically modified mice suggested that α_{2A} adrenergic receptors play a principal role in this response (Stone et al., 1997). Such actions may contribute to the beneficial effects of *epinephrine*, *clonidine*, and *dexmedetomidine* when these agents are added to spinal local anesthetics.

Drug Baricity and Patient Position

The baricity of the local anesthetic injected will determine the direction of migration within the dural sac. Hyperbaric solutions will tend to settle in the dependent portions of the sac, while hypobaric solutions will tend to migrate in the opposite direction. Isobaric solutions usually will stay in the vicinity where they were injected, diffusing slowly in all directions. Consideration of the patient position during and after the performance of

the block and the choice of a local anesthetic of the appropriate baricity is crucial for a successful block during some surgical procedures. *Lidocaine* and *bupivacaine* are marketed in both isobaric and hyperbaric preparations and, if desired, can be diluted with sterile, preservative-free water to make them hypobaric.

Complications

Persistent neurological deficits following spinal anesthesia are extremely rare. Thorough evaluation of a suspected deficit should be performed in collaboration with a neurologist. Neurological sequelae can be both immediate and late. Possible causes include introduction of foreign substances (such as disinfectants, ultrasound gel, or talc) into the subarachnoid space, infection, hematoma, or direct mechanical trauma. Aside from drainage of an abscess or hematoma, treatment usually is ineffective; thus, avoidance and careful attention to detail while performing spinal anesthesia are necessary.

High concentrations of local anesthetic can cause irreversible block. After administration, local anesthetic solutions are diluted rapidly, quickly reaching nontoxic concentrations. However, there are several reports of transient or longer-lasting neurological deficits following *lidocaine* spinal anesthesia, particularly with 5% *lidocaine HCl* (i.e., ~180 mM) in 7.5% glucose (Forget et al., 2019).

Spinal anesthesia sometimes is regarded as contraindicated in patients with preexisting disease of the spinal cord. No experimental evidence exists to support this hypothesis. Nonetheless, it is prudent to avoid spinal anesthesia in patients with progressive diseases of the spinal cord. However, spinal anesthesia may be useful in patients with a fixed, chronic spinal cord injury.

A more common sequela following any lumbar puncture, including spinal anesthesia, is a postural headache with classic features. The incidence of headache decreases with increasing age of the patient and decreasing needle diameter. Headache following lumbar puncture must be thoroughly evaluated to exclude serious complications such as meningitis. Treatment usually is conservative, with bed rest and analgesics. If this approach fails, an epidural blood patch with the injection of autologous blood can be performed; this procedure is usually successful in alleviating postdural puncture headaches, although a second blood patch may be necessary. If two epidural blood patches are ineffective in relieving the headache, the diagnosis of postdural puncture headache should be reconsidered. Intravenous caffeine (500 mg as the benzoate salt administered over 4 h) also has been advocated for the treatment of postdural puncture headache; however, the efficacy of caffeine is less than that of a blood patch, and relief usually is transient.

Evaluation of Spinal Anesthesia

Spinal anesthesia is a safe and effective technique, especially during surgery involving the lower abdomen, the lower extremities, and the perineum. It often is combined with intravenous medication to provide sedation and amnesia. The physiological perturbations associated with low spinal anesthesia often have less potential harm than those associated with general anesthesia. The same does not apply for high spinal anesthesia. The sympathetic blockade that accompanies levels of spinal anesthesia adequate for mid- or upper abdominal surgery, coupled with the difficulty in achieving visceral analgesia, is such that equally satisfactory and safer operating conditions can be realized by combining the spinal anesthetic with a "light" general anesthetic or by the administration of a general anesthetic and a neuromuscular blocking agent.

Epidural Anesthesia

Epidural anesthesia is administered by injecting local anesthetic into the epidural space—the space bounded by the ligamentum flavum posteriorly, the spinal periosteum laterally, and the dura anteriorly. Epidural anesthesia can be performed in the sacral hiatus (caudal anesthesia) or in the lumbar, thoracic, or cervical regions of the spine. Its current popularity arises from the development of catheters that can be placed into the epidural space, allowing either continuous infusions or repeated bolus administration of local anesthetics. The primary site of action of epidurally administered local anesthetics is on the spinal nerve roots. However, epidurally administered local anesthetics also may act on the spinal cord and on the paravertebral nerves.

The selection of drugs available for epidural anesthesia is similar to that for major nerve blocks. As for spinal anesthesia, the choice of drugs to be used during epidural anesthesia is dictated primarily by the duration of anesthesia desired. However, when an epidural catheter is placed, short-acting drugs can be administered repeatedly, providing more control over the duration of block. *Bupivacaine*, 0.5% to 0.75%, is used when a long duration of surgical block is desired. Due to enhanced cardiotoxicity in pregnant patients, the 0.75% solution is not approved for obstetrical use. Lower concentrations—0.25%, 0.125%, or 0.0625%—of *bupivacaine*, often with 2 μg/mL of *fentanyl* added, frequently are used to provide analgesia during labor. They also are useful preparations for providing postoperative analgesia in certain clinical situations. *Lidocaine* 2% is the most frequently used intermediate-acting epidural local anesthetic. *Chloroprocaine*, 2% or 3%, provides rapid onset and a very short duration of anesthetic action. However, its use in epidural anesthesia has been clouded by controversy regarding its potential ability to cause neurological complications if the drug is accidentally injected into the subarachnoid space (discussed previously). The addition of *epinephrine* frequently prolongs the duration of action and reduces the toxicity of epidurally administered local anesthetics. Addition of *epinephrine* also makes inadvertent intravascular injection easier to detect and modifies the effect of sympathetic blockade during epidural anesthesia.

For each anesthetic agent, a relationship exists between the volume of local anesthetic injected epidurally and the segmental level of anesthesia achieved. For example, in 20- to 40-year-old, healthy, nonpregnant patients, each 1 to 1.5 mL of 2% *lidocaine* will give an additional segment of anesthesia. The amount needed decreases with increasing age and during pregnancy and in children. The concentration of local anesthetic used determines the type of nerve fibers blocked. The highest concentrations are used when sympathetic, somatic sensory, and somatic motor blockade are required. Intermediate concentrations allow somatic sensory anesthesia without muscle relaxation. Low concentrations will block only preganglionic sympathetic fibers. As an example, with *bupivacaine*, these effects might be achieved with concentrations of 0.5%, 0.25%, and 0.0625%, respectively. The total amounts of drug that can be injected with safety at one time are approximately those mentioned in the sections Nerve Block Anesthesia and Infiltration Anesthesia. Performance of epidural anesthesia requires a greater degree of skill than does spinal anesthesia. The technique of epidural anesthesia and the volumes, concentrations, and types of drugs used are described in detail in standard texts on regional anesthesia (Cousins et al., 2008).

A significant difference between epidural and spinal anesthesia is that the dose of local anesthetic used can produce high concentrations in blood following absorption from the epidural space. Peak concentrations of *lidocaine* in blood following injection of 400 mg (without *epinephrine*) into the lumbar epidural space average 3 to 4 μg/mL; peak concentrations of *bupivacaine* in blood average 1 μg/mL after the lumbar epidural injection of 150 mg. Addition of *epinephrine* (5 μg/mL) decreases peak plasma concentrations by about 25%. Peak blood concentrations are a function of the total dose of drug administered rather than the concentration or volume of solution following epidural injection (Covino and Vassallo, 1976). The risk of inadvertent intravascular injection is increased in epidural anesthesia, as the epidural space contains a rich venous plexus.

Another major difference between epidural and spinal anesthesia is that there is no zone of differential sympathetic blockade with epidural anesthesia; thus, the level of sympathetic block is close to the level of sensory block. Because epidural anesthesia does not result in the zones of differential sympathetic blockade observed during spinal anesthesia, cardiovascular responses to epidural anesthesia might be expected to be less prominent. In practice, this is not the case; the potential advantage of epidural anesthesia is offset by the cardiovascular responses to the high concentration of anesthetic in blood that occurs during epidural anesthesia. This is most apparent when *epinephrine* is added to the epidural

injection. The resulting concentration of *epinephrine* in blood is sufficient to produce significant β_2 adrenergic receptor–mediated vasodilation. As a consequence, blood pressure decreases, even though cardiac output increases due to the positive inotropic and chronotropic effects of *epinephrine* (see Chapter 14). The result is peripheral hyperperfusion and hypotension. Differences in cardiovascular responses to equal levels of spinal and epidural anesthesia also are observed when a local anesthetic such as *lidocaine* is used without *epinephrine*. This may be a consequence of the direct effects of high concentrations of *lidocaine* on vascular smooth muscle and the heart. The magnitude of the differences in responses to equal sensory levels of spinal and epidural anesthesia varies, however, with the local anesthetic used for the epidural injection (assuming no *epinephrine* is used). For example, local anesthetics such as *bupivacaine*, which are highly lipid soluble, are distributed less into the circulation than are less lipid-soluble agents such as *lidocaine*.

High concentrations of local anesthetics in blood during epidural anesthesia are of particular concern when this technique is used to control pain during labor and delivery. Local anesthetics cross the placenta, enter the fetal circulation, and at high concentrations may cause depression of the neonate. The extent to which they do so is determined by dosage, acid-base status, level of protein binding in both maternal and fetal blood, placental blood flow, and solubility of the agent in fetal tissue. These concerns have been lessened by the trend toward using more dilute solutions of *bupivacaine* for labor analgesia.

Epidural and Intrathecal Opiate Analgesia

Small quantities of opioid injected intrathecally or epidurally produce segmental analgesia (Yaksh and Rudy, 1976). This observation led to the clinical use of spinal and epidural opioids during surgical procedures and for the relief of postoperative and chronic pain (Cousins and Mather, 1984). As with local anesthesia, analgesia is confined to sensory nerves that enter the spinal cord dorsal horn in the vicinity of the injection. Presynaptic opioid receptors inhibit the release of substance P and other neurotransmitters from primary afferents, while postsynaptic opioid receptors decrease the activity of certain dorsal horn neurons in the spinothalamic tracts (Willcockson et al., 1986; see also Chapters 10 and 23). Because conduction in autonomic, sensory, and motor nerves is not affected by the opioids, blood pressure, motor function, and nonnociceptive sensory perception typically are not influenced by spinal opioids. The volume-evoked micturition reflex is inhibited, as manifested by urinary retention. Other side effects include pruritus, nausea, and vomiting in susceptible individuals. Delayed respiratory depression and sedation, presumably from cephalad spread of opioid within the CSF, occur infrequently with the doses of opioids currently used.

Spinally administered opioids by themselves do not provide satisfactory anesthesia for surgical procedures. Thus, opioids have found the greatest use in the treatment of postoperative and chronic pain, providing excellent analgesia following thoracic, abdominal, pelvic, or lower extremity surgery without the side effects associated with high doses of systemically administered opioids. For postoperative analgesia, spinally administered *morphine*, 0.2 to 0.5 mg, usually will provide 8 to 16 h of analgesia. Placement of an epidural catheter and repeated boluses or an infusion of opioid permits an increased duration of analgesia. *Morphine*, 2 to 6 mg every 6 h, commonly is used for bolus injections, while *fentanyl*, 20 to 50 µg/h, often combined with *bupivacaine* at 5 to 20 mg/h, is used for infusions. For cancer pain, repeated doses of epidural opioids can provide analgesia of several months' duration. The dose of epidural *morphine* is far less than the dose of systemically administered *morphine* that would be required to provide similar analgesia, thus reducing the complications that usually accompany the administration of high doses of systemic opioids, particularly sedation and constipation. Unfortunately, as with systemic opioids, tolerance will develop to the analgesic effects of epidural opioids, but this usually can be managed by increasing the dose.

Drug Facts for Your Personal Formulary: *Local Anesthetics*

Drugs	Therapeutic Uses or Duration	Clinical Pharmacology and Tips
Topical Anesthesia		
Lidocaine	• Superficial anesthesia of mucous membranes	• 2%–10% solution • ~30-min duration • Maximal healthy adult dose, ~4 mg/kg
Cocaine	• Superficial anesthesia of mucous membranes of nose, mouth, ear	• 1%–4% solution • ~30-min duration • Maximal healthy adult dose, ~1–3 mg/kg (maximum 400 mg); pediatric dose, <1 mg/kg • Vasoconstriction + anesthesia
Eutectic mixtures, oil, or cream: Lidocaine (2.5%)/prilocaine (2.5%) (EMLA) or Lidocaine (7%)/tetracaine (7%)	• Superficial anesthesia of cutaneous structures	• Effective to ~5-mm depth • Requires 30–60 min of contact to establish effective anesthesia • Should not be used on mucous membranes or abraded skin due to rapid absorption • Consult package insert for maximum dose
Infiltration Anesthesia		
Lidocaine	• Superficial anesthesia of cutaneous structures • Addition of dilute sodium bicarbonate (10:1—lidocaine: 8.4% sodium bicarbonate, ~0.75 mg/mL sodium bicarbonate) can lessen pain on injection	• 0.5%–1.0% solution • Maximal healthy adult dose, ~4 mg/kg • Addition of epinephrine (5 µg/mL) increases duration of action and maximal safe lidocaine dose
Bupivacaine	• Superficial anesthesia of cutaneous structures	• 0.125%–0.25% solution • Maximal healthy adult dose, ~2 mg/kg • Addition of epinephrine (5 µg/mL) increases duration of action and maximal safe bupivacaine dose

Drug Facts for Your Personal Formulary: *Local Anesthetics (continued)*

Drugs	Therapeutic Uses or Duration	Clinical Pharmacology and Tips
Nerve Block Anesthesia • Use with epinephrine-containing test dose • Risk of intravenous injection		
Articaine	• 1 h duration	• For dental and periodontal procedures • 4% solution, typically with epinephrine • Contains both an amide and ester, so degraded in both plasma and liver
Lidocaine, mepivacaine	• 1–2 h duration • Addition of epinephrine prolongs duration and increases maximal safe level of drug • Identification of blocked nerves (nerve stimulation or ultrasound) may increase safety and success of block	Safe doses depend on vascularity of tissue, generally: • Lidocaine: 1%–1.5%, maximal healthy adult dose, ~4 mg/kg • Mepivacaine: 1%–2%, maximal healthy adult dose, ~7 mg/kg (maximum 400 mg)
Bupivacaine, ropivacaine	• 6–8 h duration • Longer duration of sensory block with bupivacaine than with ropivacaine • Addition of epinephrine prolongs duration and increases maximal safe level of drug	Safe doses depend on vascularity of tissue, generally: • Bupivacaine: 0.25%–0.375%, maximal healthy adult dose, ~2–3 mg/kg (maximum 400 mg) • Ropivacaine: 0.5%–0.75%, maximal healthy adult dose, ~3–4 mg/kg (maximum 200 mg) • Infusions through a catheter placed adjacent to the nerve can provide sustained analgesia • Identification of blocked nerves (nerve stimulation or ultrasound) may increase safety and success of block
Epidural Anesthesia • Use with epinephrine-containing test dose • Risk of intravenous injection • Spread of block dependent on dose and volume injected • Epidural catheter allows repeated dosing • Consider coagulation status of patient		
Chloroprocaine	• Short duration • Epinephrine prolongs action	• 2%–3% solution • Possible increased incidence of postprocedure back pain
Lidocaine	• Intermediate duration • Epinephrine prolongs action	• 2% solution • Maximal healthy adult dose, ~4 mg/kg
Bupivacaine	• Long duration	• 0.5% solution • Maximal healthy adult dose, ~2–3 mg/kg
Ropivacaine	• Long duration	• 0.5%–1.0% solution • Maximal healthy adult dose, ~2–3 mg/kg • May have less toxicity than equiefficacious dose of bupivacaine
Spinal Anesthesia • Dose and baricity of anesthetic strongly influence spread • Addition of opioids can prolong analgesia • Consider coagulation status of patient		
Lidocaine	• Short duration (60–90 min)	• ~25–50 mg for perineal and lower extremity surgery • Association of spinal lidocaine with transient neurological symptoms
Tetracaine	• Long duration (210–240 min)	• Duration increased by epinephrine • ~5 mg for perineal surgery • ~10 mg for lower extremity surgery
Bupivacaine	• Long duration (210–240 min)	• ~10 mg for perineal and lower extremity surgery • 15–20 mg for abdominal surgery

Chapter 26 Cannabinoids

Matthew N. Hill and Kenneth Mackie

Introduction

The psychoactive and medicinal properties of *Cannabis* species have been appreciated for millennia. However, only recently have we developed an understanding of the compounds present in cannabis that produce these effects. The primary psychoactive compounds in cannabis are the phytocannabinoids, which are meroterpenoids typically synthesized from olivetolic acid and geranyl pyrophosphate. Δ^9-Tetrahydrocannabinol (THC) is the phytocannabinoid responsible for the characteristic psychoactivity of *Cannabis*. Another major phytocannabinoid, cannabidiol (CBD), may have distinct therapeutic benefits. The effects of other phytocannabinoids are less well understood. THC produces its effects by engaging the endocannabinoid system, an endogenous signaling system comprised of endogenous cannabinoids (endocannabinoids), endocannabinoid receptors, and the enzymes responsible for endocannabinoid synthesis and degradation. The endocannabinoid system is widespread throughout the body and is involved in regulation of stress, pain, reward, metabolism, and inflammation, among other physiological actions.

Endogenous Cannabinoids

The endocannabinoids (eCB) are defined as endogenously produced molecules that bind to cannabinoid receptors. The prototypical eCBs are arachidonate-derived signaling lipids that are produced by cells throughout most organ systems in the body but have been primarily studied within the nervous system (Blankman and Cravatt, 2013; Hillard, 2015, 2018). The lipophilic eCB molecules often associate with protein binding partners, such as fatty acid binding proteins or albumin in the blood, to facilitate transport through aqueous compartments. eCBs exert their actions through a family of receptors as discussed below.

Anandamide

The first eCB to be discovered was *N*-arachidonoylethanolamine (AEA; Figure 26–1) and was given the name *anandamide* in reference to the Sanskrit word *ānanda* for bliss (Blankman and Cravatt, 2013). AEA is an arachidonic acid molecule conjugated to an ethanolamine group. Within the brain, AEA is believed to be synthesized and mobilized in a varying, but continuous, manner and not undergo vesicular storage, a process often referred to as "on-demand" synthesis. AEA is a high-affinity (low nM) but low-efficacy agonist at the cannabinoid receptors, making it a partial agonist (Hillard, 2015), and is also known to act as an agonist at transient receptor potential channel vanilloid 1 (TRPV1) receptors at high concentrations (high nM–low µM range). Bulk levels of AEA exist at the low pmol/g brain weight concentration; microdialysis studies within the brain have found extracellular levels of AEA to be in the low nanomolar range. AEA concentrations within the blood are typically found in the low pmol/mL range; although the tissue depot source from which circulating AEA is derived is not well established, it likely involves a combination of genesis from blood cells and vascular, hepatic, and adipose tissue.

2-Arachidonoyl Glycerol

The second eCB to be discovered was 2-arachidonoyl glycerol (2-AG; Figures 26–1 and 26–2). 2-AG is an arachidonic acid molecule conjugated to a glycerol group. Within the brain, there is evidence for storage of 2-AG in membrane lipid rafts. Bulk 2-AG concentrations quantified from extracted brain tissue indicate that it is present in the low nmol/g range, which is about 1000-fold higher than AEA; however, extracellular levels determined through microdialysis studies indicate that 2-AG concentrations are only about 2- to 5-fold higher than AEA and found in a similar low nanomolar range. Based on this, it is predicted that about 90% of 2-AG in the brain exists as bulk 2-AG. This membrane-associated 2-AG may function as a storage reservoir for arachidonic acid, which is then utilized as a requisite substrate to form neuroinflammatory prostaglandins (Nomura et al., 2011). In contrast to AEA, 2-AG is a full agonist at the cannabinoid receptors, with an affinity in the nanomolar range, lower than that found for AEA (Hillard, 2015, 2018). Within the blood, circulating levels of 2-AG and AEA are in the lower pmol/mL range. As with AEA, the tissue source of circulating 2-AG is not well understood.

The Endocannabinoid-ome: Beyond AEA and 2-AG

While AEA and 2-AG are the most well-established and well-studied eCB molecules, other fatty acid ethanolamides, monoacyl glycerols, and even

Abbreviations

ABHD: α/β hydrolase domain-containing protein
AEA: anandamide
2-AG: 2-arachidonoyl glycerol
ALT: alanine aminotransferase
CBC: cannabichromene
CBCA: cannabichromenic acid
CBD: cannabidiol
CBDA: cannabidiolic acid
CBGA: cannabigerolic acid
CBN: cannabinol
CBNA: cannabinolic acid
COX-2: cyclooxygenase-2
DAG: diacylglycerol
DAGL: diacylglycerol lipase
eCB: endocannabinoid
FAAH: fatty acid amide hydrolase
GIRK: G protein-coupled inwardly rectifying K^+ channel
GPCR: G protein-coupled receptor
LTD: long-term depression
MAGL: monoacylglycerol lipase
MAP kinase: mitogen-activated protein kinase
NAPE-PLD: *N*-acyl phosphatidylethanolamine–specific phospholipase D
NArPE: *N*-arachidonoyl phosphatidylethanolamine
NREM: non–rapid eye movement
7-OH-CBD: 7-hydroxy-cannabidiol
11-OH-THC: 11-hydroxy-tetrahydrocannabinol
PAG: periaqueductal gray
PLC: phospholipase C
PPAR: peroxisome proliferator-activated receptor
REM: rapid eye movement
THC: Δ^9-tetrahydrocannabinol
THCA: Δ^9-tetrahydrocannabinolic acid
THCV: Δ^9-tetrahydrocannabivarin
TRPV1: transient receptor potential channel vanilloid 1
VTA: ventral tegmental area

peptides could represent additional members of the eCB family. Of these, the molecule hemopressin, a derivative of the alpha chain of hemoglobin, has garnered the most attention. Hemopressin has high affinity for cannabinoid receptors but, unlike AEA and 2-AG, appears to function as an inverse agonist (Hillard, 2015). The physiological relevance of hemopressin and the conditions under which it is synthesized and released are not well established. Other molecules, such as virodhamine and noladin ether, have been proposed as additional eCBs, but it is unclear whether these molecules are synthesized and released in a physiological manner *in vivo*. Thus, the discussion of the eCB system is focused exclusively on AEA and 2-AG. The pathways of synthesis and degradation for AEA and 2-AG are detailed in Figure 26–2 and discussed below.

Synthesis

Anandamide

The biosynthesis of AEA appears to involve several redundant pathways that all initiate from a common precursor, *N*-arachidonoyl phosphatidylethanolamine (NarPE). NarPE is formed via a Ca^{2+}-dependent enzymatic process, by an unknown *N*-acyl transferase, which removes arachidonic acid from the *sn-1* position of a membrane phospholipid donor and catalyzes the formation of an amide bond with the ethanolamine from phosphatidylethanolamine (Blankman and Cravatt, 2013). There are three pathways by which NarPE can be converted to AEA. The best established pathway is via hydrolysis by *N*-acyl phosphatidylethanolamine–specific phospholipase D (NAPE-PLD)–mediated liberation of phosphatidic acid from NarPE to produce AEA. Supporting the importance of the NAPE-PLD pathway, NAPE-PLD inhibitors reduce brain AEA levels up to 50% (Mock et al., 2020). NarPE can also be converted to lysoNArPE by α/β hydrolase domain-containing protein (ABHD) 4 or phospholipase A_2. LysoNArPE is deacylated to glycerolphospho-*N*-arachidonoylethanolamine (GP-AEA) and then converted to AEA by glycerophosphodiesterase 1 (GDE1). Finally, NarPE can be converted to a phospho-AEA by a phospholipase C (PLC)–like enzyme and then dephosphorylated to AEA by the tyrosine phosphatase PTPN22. This pathway of AEA biosynthesis may occur primarily in macrophages during inflammatory challenges.

2-Arachidonoyl Glycerol

The biosynthesis of 2-AG occurs via the enzyme diacylglycerol lipase (DAGL) (Gao et al., 2010). The DAGLα isoform is responsible for 2-AG biosynthesis in the CNS, whereas the DAGLβ isoform generates 2-AG in peripheral organs, such as the liver. 2-AG synthesis begins with the hydrolysis of *sn-2* arachidonoyl phosphatidylinositol 4,5-bisphosphate (PIP2) from membrane phospholipids by PLCβ to form diacylglycerol (DAG), which is then converted to 2-AG via DAGL-mediated hydrolysis of the ester bond at the *sn-1* position of DAG. Figure 26–2 also shows an alternative pathway.

Degradation

Anandamide

Anandamide is primarily degraded by fatty acid amide hydrolase (FAAH), which is widely expressed throughout the body. FAAH is a membrane protein associated with intracellular membranes of the endoplasmic reticulum and mitochondria. FAAH-mediated hydrolysis of AEA generates free arachidonic acid and ethanolamine. FAAH is constitutively active; its expression is regulated by reproductive and metabolic hormones; its enzymatic activity is regulated by protein kinase A and by stimulation of receptors linked to the G_s–adenylyl cyclase–cyclic AMP pathway. Within neurons, FAAH tends to be localized within somatodendritic compartments, and the intracellular transit of AEA from lipophilic membrane compartments to FAAH may be mediated by fatty acid binding proteins (Kaczocha et al., 2009). Genetic deletion or pharmacological inhibition of FAAH results in a large increase of AEA tissue content. In humans, a single nucleotide polymorphism, P129T, in the *FAAH* gene increases FAAH protein degradation, resulting in a reduction in FAAH expression and a consequential elevation in constitutive AEA signaling (Hillard, 2015). A second FAAH gene (*FAAH2*) exists in humans that is not present in rodents. Its relevance has yet to be elucidated, although an individual with significant psychiatric and neurological symptoms was identified to have a rare missense mutation in *FAAH2* (Sirrs et al., 2015). In addition to AEA, FAAH hydrolyses other fatty acid amides and *N*-acyl taurines. As a result, FAAH inhibition produces widespread alterations in lipid signaling species. AEA can also be oxidized by cyclooxygenase-2 (COX2), a reaction that generates bioactive prostaglandin ethanolamides.

2-Arachidonoyl Glycerol

2-Arachidonoyl glycerol is degraded by monoacylglycerol lipase (MAGL). Genetic deletion or pharmacological inhibition of MAGL results in a large increase of 2-AG tissue content throughout the whole body. MAGL-mediated hydrolysis generates free arachidonic acid and glycerol. In the brain, approximately 90% of 2-AG exists in membrane compartments where it acts as a reservoir for arachidonic acid. In response to inflammatory processes, MAGL rapidly catabolizes 2-AG to liberate arachidonic acid, which is then oxidized by COX-2 to generate neuroinflammatory prostaglandins (Nomura et al., 2011). Hence, inhibition of MAGL suppressed prostaglandin formation following inflammatory insults in the brain. MAGL is widely expressed throughout the nervous system and peripheral organs. Unlike FAAH, MAGL is localized to presynaptic compartments and not in the somatodendritic portion of neurons. Although MAGL activity can also be detected in the cytosolic fractions of cells, as with FAAH, membrane association of MAGL facilitates 2-AG hydrolysis. MAGL also hydrolyzes 1(3)- and 2-monoacylglycerols; thus, MAGL

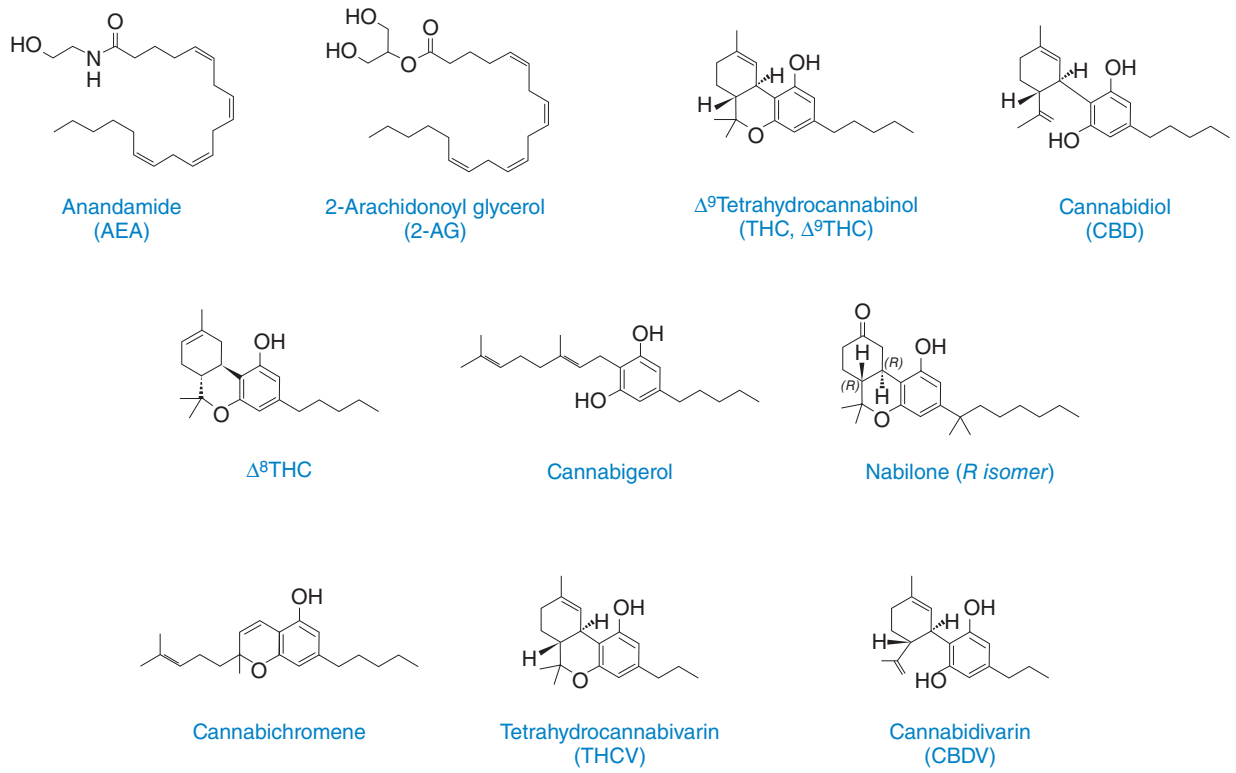

Figure 26–1 *Structures of selected cannabinoid molecules.* The endocannabinoids anandamide and 2-arachidonoyl glycerol have in common arachidonic acid and differ by being the amide of ethanolamine and ester of glycerol, respectively. The structures of the major phytocannabinoids, Δ^9-tetrahydrocannabinol (Δ^9THC) and cannabidiol, differ in the presence of the third ring in THC. The intermediate phytocannabinoid metabolite, cannabigerol, is monocyclic. Tetrahydrocannabivarin and cannabidivarin differ from THC and cannabidiol in having a propyl instead of pentyl side chain on the aromatic ring. Δ^8THC, cannabigerol, and cannabichromene are minor cannabinoids.

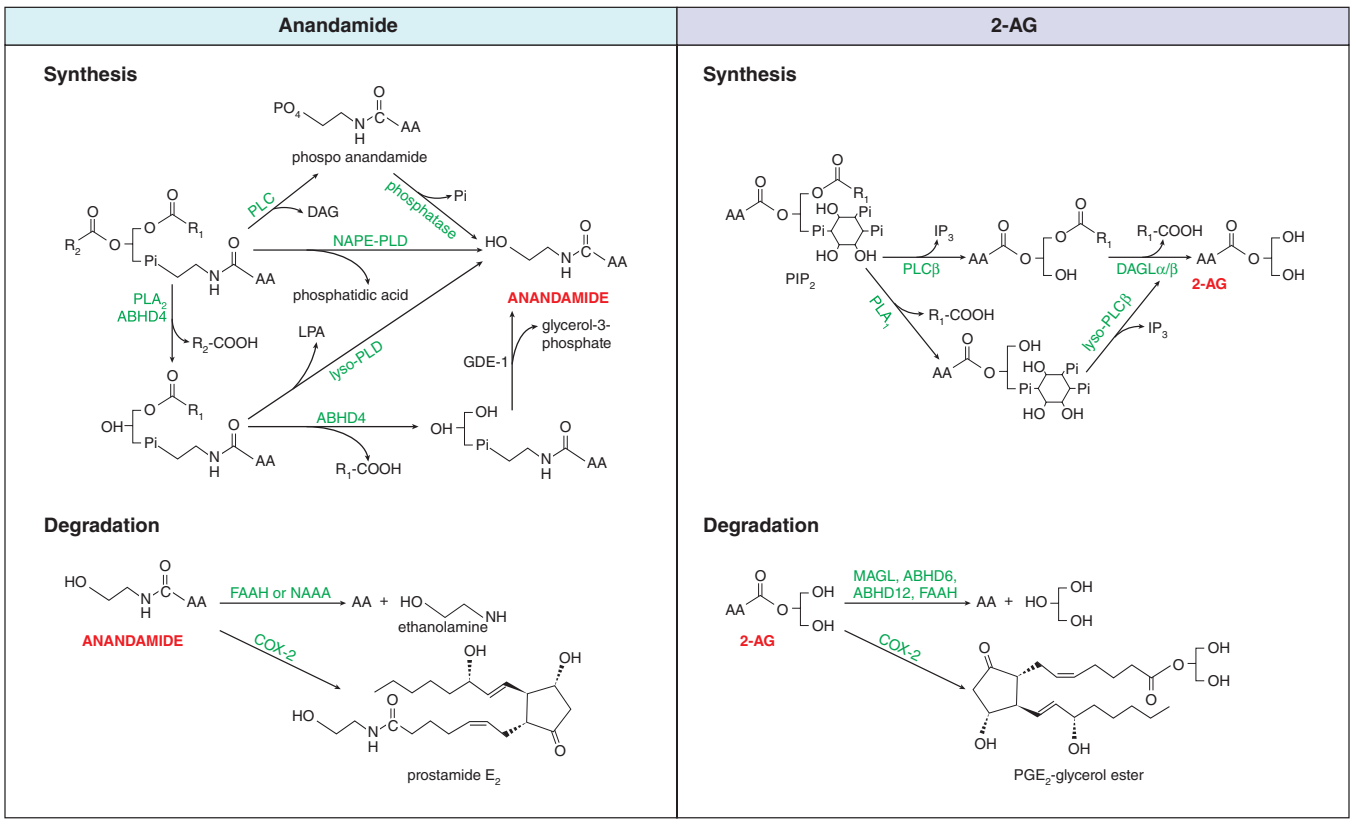

Figure 26–2 *Major synthetic and degradative pathways for anandamide and 2-arachidonoyl glycerol (2-AG).* **Left panel:** Primary synthetic and degradative pathways for anandamide. **Right panel:** Primary synthetic and degradative pathways for 2-AG. Only major pathways are shown. Enzymes are noted in green. AA, arachidonic acid; GDE-1, glycerophosphodiester phosphodiesterase 1; IP_3, inositol trisphosphate; LPA, lyso-phosphatidic acid; lyso-PLC, lyso-phospholipid–preferring phospholipase C; NAPE, *N*-acyl-ethanolamine-phospholipase; PIP_2, phosphatidylinositol bisphosphate; PLA, PLA_1, PLA_2, phospholipase A_1, A_2.

inhibition results in widespread elevations of lipid signaling species (Blankman and Cravatt, 2013). In addition to MAGL, hydrolases such as ABHD6 and ABHD12 can also degrade 2-AG. ABHD6 localizes to the somatodendritic compartment of neurons, which may regulate 2-AG hydrolysis prior to release from the cell, as opposed to MAGL, which is localized on presynaptic compartments and catabolizes 2-AG after it has exerted its action at cannabinoid receptors (Cao et al., 2019). ABHD12, on the other hand, has been estimated to be responsible for approximately 9% of 2-AG hydrolysis in the brain, and its gene transcripts have been identified within microglial cells of the brain. Inhibition of either ABHD6 or ABHD12 can impact 2-AG signaling but to a much lesser degree then seen after MAGL inhibition. 2-AG can also be oxygenated by COX2 to form prostaglandin glycerols, for which a physiological role has yet to be established (Hermanson et al., 2014).

Physiological Roles of Endocannabinoids

Mediators of Endocannabinoid Action

The lipophilic nature of THC delayed the identification of its mechanism of action for many years. The first convincing evidence that its actions were mediated by a G protein-coupled receptor (GPCR) came from the pioneering work of Allyn Howlett and colleagues (Howlett et al., 1990; Howlett and Abood, 2017). These studies showed that THC and related synthetic cannabinoids inhibited adenylyl cyclase via a pertussis toxin–sensitive GPCR and that this receptor was highly expressed in many brain regions, consistent with the psychotropic effects of THC. Subsequent autoradiographic mapping using high-affinity synthetic cannabinoids confirmed the widespread and high levels of this cannabinoid receptor across the brain (Herkenham et al., 1991). This receptor (now designated as the CB1 cannabinoid receptor) was cloned and its distribution, actions, and regulation characterized (Howlett et al., 2002). Within a few years, a second cannabinoid receptor, the CB2 receptor, was cloned from an immune cell line. The psychoactivity after consumption of cannabis is likely mediated by CB1 cannabinoid receptors, whereas the immune modulatory effects are likely CB2 cannabinoid receptor mediated (Mackie, 2008).

CB1 Cannabinoid Receptors

CB1 receptors are highly expressed in presynaptic terminals of a subset of cortical GABAergic interneurons (often coexpressing the neuromodulator, CCK) and at lower levels in many other nerve terminals (Hu and Mackie, 2015). The role of these presynaptic as well as somatic CB1 receptors in mediating synaptic plasticity and neuronal excitability is discussed below. CB1 receptor expression changes with age, potentially explaining effects of cannabinoids on the developing CNS (Bara et al., 2021). CB1 receptors are also expressed in nonneuronal cell types such as astrocytes and outside the brain in hepatocytes, adipocytes, skeletal muscle, and endocrine cells (Covelo et al., 2021; Fong and Heymsfield, 2009).

CB2 Cannabinoid Receptors

CB2 receptors are highly expressed in immune cells (including microglia) and are expressed at lower levels in other cell types such as neurons, endothelial cells, pericytes, and keratinocytes. CB2 receptors may mediate immunomodulatory effects of THC and could be important for reducing drug craving and pain.

CB1 and CB2 Receptor Signaling

CB1 and CB2 are GPCRs and usually couple to inhibitory G proteins and arrestins, although coupling to G_s to activate adenylyl cyclase or $G_{q/11}$ to activate PLC has been observed in some experimental conditions. As G_i-coupled receptors, the canonical CB1 and CB2 signaling pathways include inhibition of adenylyl cyclase and voltage-gated Ca^{2+} channels and activation of mitogen-activated protein kinases (MAP kinases) and inwardly rectifying K^+ channels (Howlett et al., 2002; Mackie, 2008). Both CB1 and CB2 receptors show functional selectivity or biased agonism, whereby certain ligands favor activating specific subsets of G proteins and/or arrestin signaling pathways. This functional selectivity needs to be considered when evaluating the behavioral and physiological consequences of structurally diverse cannabinoids acting at cannabinoid receptors, particularly CB2 receptors (Atwood et al., 2012).

Non-CB1/CB2 Targets of Endocannabinoids

Endocannabinoids and some synthetic ligands can engage other targets in addition to CB1 and CB2, including ion channels (discussed below), peroxisome proliferator-activated receptors (PPARs), and synthetic cannabinoid receptor ligands. Among PPARs, PPARα and PPARγ are activated by eCBs and may contribute to the pharmacological effects of cannabinoids (Pistis and O'Sullivan, 2017). Genes targeted by PPARs include those involved in the regulation of metabolism, inflammation, neuroprotection, and cellular differentiation.

eCBs as Retrograde Messengers. Endocannabinoids are major retrograde messengers in the nervous system and mediate several forms of synaptic plasticity (Chevaleyre et al., 2006; Ohno-Shosaku and Kano, 2014). As retrograde messengers, eCBs are synthesized "on demand" by the postsynaptic neuron and travel retrogradely across the synapse to activate presynaptic CB1 receptors, suppressing neurotransmission from CB1-expressing nerve terminals (Figure 26–3). Depending on the duration of eCB production, eCB-mediated synaptic plasticity may be transient or sustained (Figure 26–4). Both forms of plasticity involve stimulation of the postsynaptic neuron (by depolarization and Ca^{2+} influx via voltage-sensitive Ca^{2+} channels and/or activation of a $G_{q/11}$-linked GPCR and release of Ca^{2+} from intracellular stores). This activates diacylglycerol lipase α to produce 2-AG (Figures 26–2 and 26–3). Two well-described transient forms of eCB-mediated synaptic plasticity are *depolarization-stimulated suppression* of excitation (if excitatory transmission is suppressed) or depolarization-stimulated suppression of inhibition (if inhibitory transmission is suppressed) and *metabotropic-stimulated suppression* of excitation (if excitatory transmission is suppressed) or metabotropic-stimulated suppression of inhibition (if inhibitory transmission is suppressed). These transient forms of plasticity start within a second of stimulation of the postsynaptic neurons and can last for tens of seconds (Wilson et al., 2001).

Sustained low-frequency activity of excitatory synapses may lead to a persistent eCB-mediated long-term depression (LTD) (Chevaleyre et al., 2006). Induction of LTD depends on sustained eCB production. However, established LTD is maintained independent of eCBs or CB1 receptors. The network implications of eCB-mediated synaptic plasticity depend on the activity of the CB1-expressing synapse: If the synapse is not active, there will be little effect; it also depends on whether the inhibited synapse is excitatory or inhibitory in nature and the relationship between the inputs driving eCB synthesis and the presynaptic terminals expressing CB1 receptors (Soltesz et al., 2015).

Nonretrograde Effects of eCBs on Neuronal Excitability. In addition to their role as retrograde messengers, eCBs may modify neuronal excitability in diverse ways. The best characterized include:

- Direct modulation of ion channels
- Activation of G protein-coupled inwardly rectifying K^+ channels (GIRKs)
- Enhancement of a hyperpolarization-activated cation channel (I_h)

Endocannabinoids may directly modulate ion channels, including $5HT_3$, TRPV1, $GABA_A$, glycine, and others (Soderstrom et al., 2017). When relating *in vitro* reports to what occurs *in vivo*, it is important to appreciate that some of these reported effects only occur with high eCB concentrations that are unlikely to be reached *in vivo*. Levels of eCBs produced by intense neuronal activity activate somatic CB1 receptors to open GIRK channels to hyperpolarize the neuron (Bacci et al., 2004).

I_h is a cation channel regulating dendritic excitability and playing a central role in synaptic plasticity and learning. Enhancing I_h activity impairs learning, and I_h activation by CB1 receptors is a possible mechanism for THC impairment of learning. CB1 enhancement of I_h involves a signaling cascade consisting of c-Jun-N-terminal kinase 1 (JNK1), guanylyl cyclase, cyclic GMP, and hyperpolarization-activated cyclic nucleotide-gated (HCN) channels (Maroso et al., 2016).

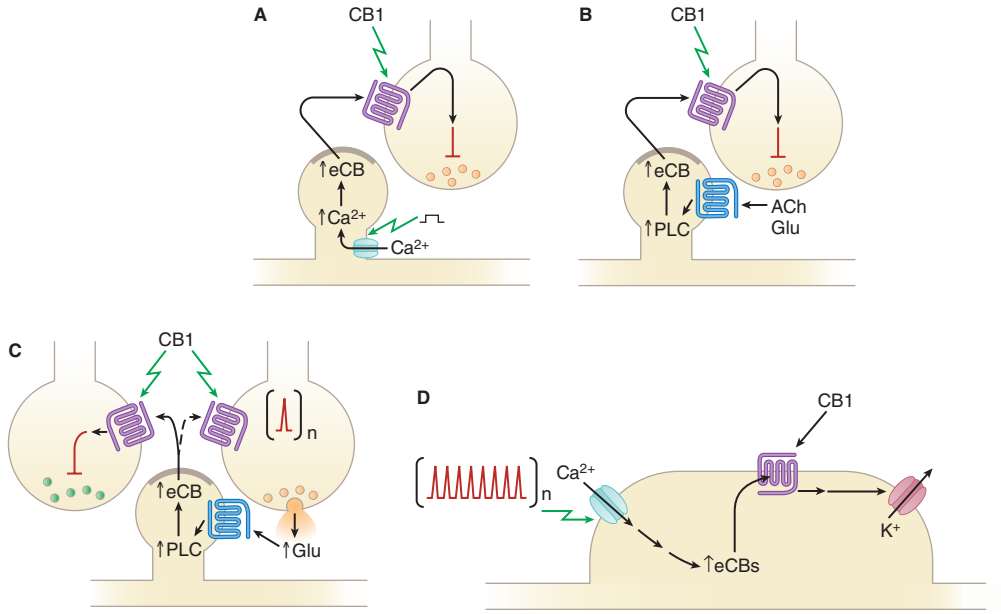

Figure 26–3 *Endocannabinoid-mediated synaptic plasticity and autocrine endocannabinoid signaling.* Unlike classical neurotransmitters, eCBs are "made on demand" following neuronal activity. Often, they are made in the postsynaptic cell and diffuse retrogradely to inhibit neurotransmitter from the presynaptic terminal (eCB-mediated synaptic plasticity; **A–C**). Occasionally, they act in an autocrine fashion (**D**). **A.** *Depolarization-induced suppression of inhibition/excitation (DSI/DSE).* Strong depolarization of the postsynaptic neuron leads to postsynaptic production of endocannabinoids, which diffuse retrogradely across the synapse. The endocannabinoids engage presynaptic CB1 receptors (), whose activation decreases synaptic vesicle release and synaptic transmission. If the presynaptic terminal is inhibitory, the phenomenon is denoted as DSI; if the presynaptic terminal is excitatory, the effect is termed DSE. **B.** *Metabotropic-induced suppression of excitation/inhibition (MSI/MSE).* In MSI/MSE, activation of postsynaptic GPCR → PLC pathways leads to the production of 2-AG, which diffuses retrogradely across the synapse to activate presynaptic CB1 receptors, suppressing synaptic transmission. If the presynaptic terminal is inhibitory, the phenomenon is denoted as MSI; if the presynaptic terminal is excitatory, it is referred to as MSE. Concurrent depolarization and GPCR → PLC activation can synergistically increase 2-AG production, resulting in a form of coincidence detection. **C.** *Homosynaptic and heterosynaptic endocannabinoid-mediated long-term depression (eLTD).* In homosynaptic eLTD, repeated stimulation (typically at a low frequency) of an excitatory terminal causes prolonged release of endocannabinoids from the postsynaptic neuron. This prolonged activation of presynaptic CB1 receptors induces a long-term depression of the excitatory terminal that extends long after the presynaptic stimulation has ceased. In heterosynaptic eLTD, LTD occurs at CB1-expressing synapses adjacent to the stimulated synapse. **D.** *Slow self-inhibition (SSI).* Classical SSI occurs when a CB1-expressing neuron is strongly stimulated (), producing endocannabinoids that activate somatic CB1 receptors, opening inwardly rectifying K^+ channels and leading to hyperpolarization and a prolonged inhibition of excitability. A paracrine variation on this autocrine theme occurs when the endocannabinoids diffuse away from the cell, activating somatic CB1 receptors on neighboring neurons and hyperpolarizing and suppressing firing in those neurons (Kreitzer et al., 2002).

Physiological Roles of Endocannabinoids

Stress and Its Resolution

Regular users of cannabis cite its ability to reduce stress and anxiety as a primary motivation for its use. Similarly, eCB signaling can reduce stress and anxiety. Research in both humans and rodents has found that exposure to stress results in the mobilization of eCBs, both in the brain and the periphery, and that glucocorticoids are an integral mediator in this response. This release of eCBs following stress is important for the termination of the stress response. As such, increasing eCB function can restrict or limit responses to stress. Within the brain, eCBs gate stress-induced excitation in brain regions such as the amygdala (Figure 26–5), which restricts the development of anxiety and the release of stress hormones (Gray et al., 2015; Morena et al., 2016). CB1 receptors are also localized to sympathetic nerve terminals in the periphery, and activation of these receptors by eCBs following stress exposure is important for restricting the autonomic response to stress. Exposure to chronic stress impairs eCB function. A loss of the ability of eCB signaling to restrict stress responses likely contributes to the development of stress-induced allostatic load (Morena et al., 2016). Human studies have found that the P129T genetic variant in FAAH, which reduces FAAH and elevates AEA signaling, is associated with lower levels of trait anxiety, enhanced top-down emotional control, improved inhibition of fear, and blunted neural and physiological responses to stress (Hariri et al., 2009; Petrie et al., 2021).

Reward

Intoxication with cannabis does produce a state of mild euphoria, and cannabis possesses addiction potential, albeit less than what is seen with drugs such as opiates. Rodents will self-administer cannabis vapor and will exert effort to seek cannabis vapor, both hallmark traits of substances that are reinforcing (Ferland and Hurd, 2020; Freels et al., 2020). The ability of cannabinoids to enhance reward is mediated by their actions in the ventral tegmental area (VTA; see Figure 26–5), a small brain nucleus with a high density of dopaminergic neurons. CB1 receptors in the VTA are primarily localized to the axon terminals of inhibitory GABA neurons that impinge upon VTA dopaminergic neurons. Activation of CB1 in the VTA inhibits GABA release, which disinhibits dopaminergic neurons, promoting the release of dopamine within the nucleus accumbens, a process known to be central for the encoding of rewarding salient events and for the motivation to engage in rewarding actions (Dubreucq et al., 2013; Wenzel and Cheer, 2018). Reinforcing stimuli, including both cocaine and voluntary exercise, require eCB signaling in the VTA to produce their rewarding effects. Disruption of eCB signaling inhibits motivation for rewarding stimuli and reduces engagement in pleasurable activities. In humans, the elevated AEA signaling associated with the P129T variant of FAAH increases neural reactivity of the nucleus accumbens to rewarding cues (Hariri et al., 2009). Pharmacological antagonism of CB1 receptors has been linked to the development of depression with anhedonia, an inability to experience pleasure (Christensen et al., 2007).

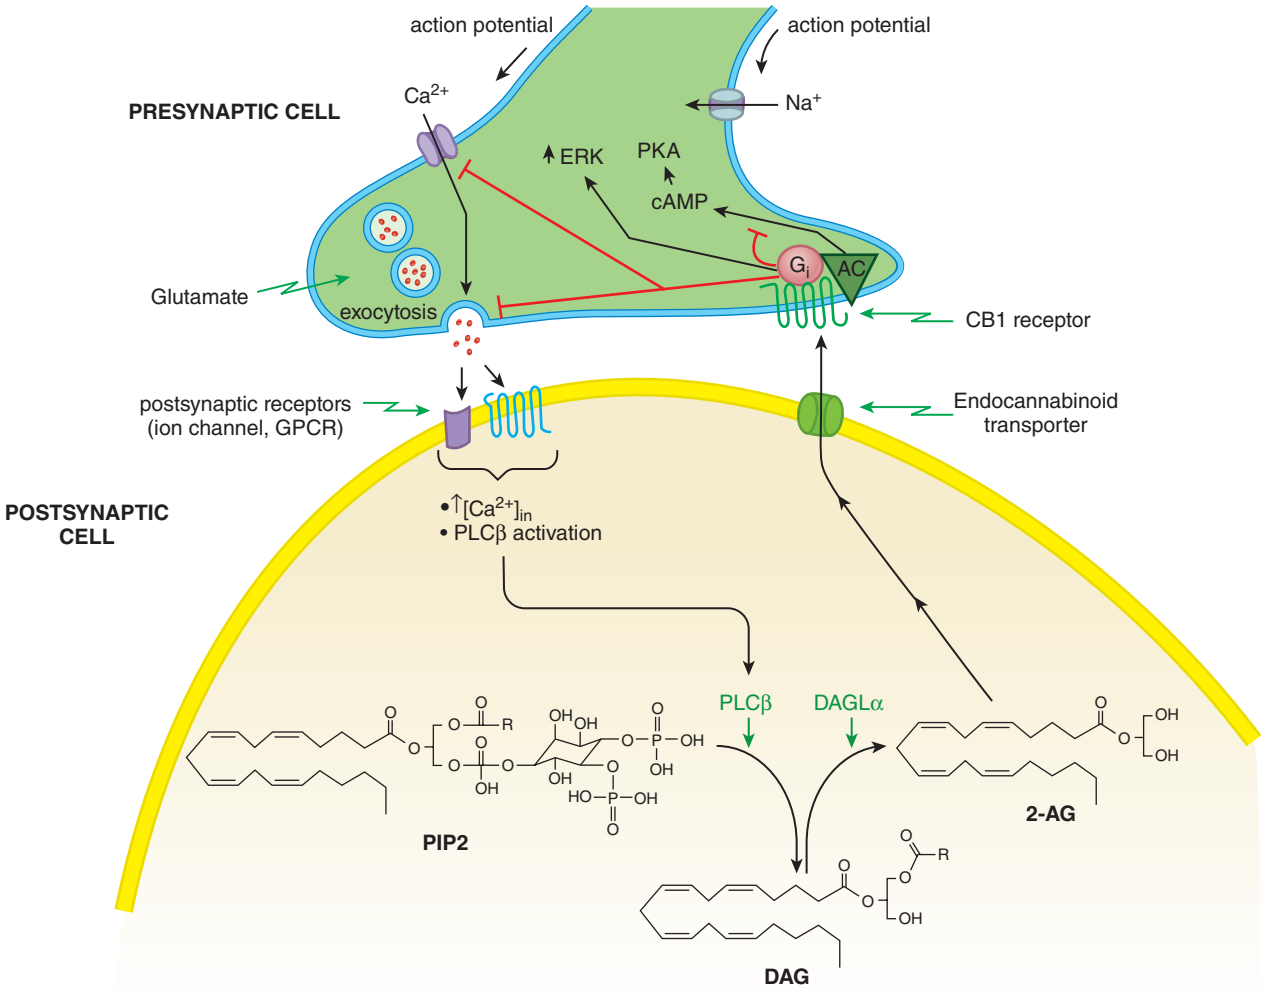

Figure 26–4 *2-Arachidonoyl glycerol (2-AG) synthesis and retrograde signaling in the CNS.* 2-AG acts as a retrograde messenger to limit presynaptic transmitter release. If the transmitter inhibited is excitatory, then feedback is negative. If the transmitter is inhibitory, then the feedback is positive. PIP2, phosphatidyl 4,5-bisphosphate.

Appetite and Metabolism

An increase in the consumption of sweet, palatable food, often referred to as "the munchies," is one of the prototypical effects of cannabis consumption in humans. eCB signaling is prominent within feeding circuits in the brain (see Figure 26–5). Within the hypothalamus, eCB levels fluctuate in response to nutritional status, where fasting elevates eCB levels and subsequent feeding and satiety decrease these levels (Lau et al., 2017). eCB signaling regulates feeding through regulation of the excitability of neurons within the arcuate nucleus of the hypothalamus, which are known to drive food intake (the AgRP/NPY neurons) and inhibit food intake (the POMC/MCH4 neurons). Thus, eCB signaling can rapidly increase or suppress food-seeking behavior and consumption. eCB signaling is also embedded into canonical hormonal cascades involved in regulating feeding. Leptin, a potent anorectic peptide produced by adipose tissue, rapidly suppresses hypothalamic eCB signaling to inhibit feeding. Hunger-stimulating hormones, such as ghrelin or glucocorticoids, promote food intake via recruitment of eCB signaling (Balsevich et al., 2018; Lau et al., 2017).

Peripheral eCB signaling also influences food intake and metabolic processes (Maccarrone et al., 2015; Ruiz de Azua and Lutz, 2019). Stimulation of cannabinoid receptors on vagal afferents and sympathetic nerve terminals can enhance food intake. Excess eCB activity in peripheral organs can have adverse effects on metabolic processes. Activation of hepatic CB1 receptors promotes the development of fatty liver and hepatic steatosis. Adipose tissue CB1 receptor activation can augment adipogenesis and fat accumulation. Elevated levels of endocannabinoids have been noted in rodent models of obesity and in human obese populations. Elevated eCB activity can promote the development of obesity and metabolic disorders; conversely, blockade of CB1 receptors produces anorectic effects, weight loss, and the prevention of metabolic consequences of obesity, such as insulin resistance and the development of type 2 diabetes in multiple species including humans (Lau et al., 2017; Ruiz de Azua and Lutz, 2019). Curiously, however, cannabis use in humans is generally not associated with obesity. Several large-scale population studies report that cannabis users have a lower body mass index and lower rates of obesity than noncannabis users. Because THC is a partial agonist at CB1 receptors, THC may occlude CB1 activation by 2-AG, a full agonist and thus limit some of the negative metabolic effects driven by elevated eCB function (Le Foll et al., 2013; Sidney, 2016).

Pain

Management of chronic pain and chemotherapy-induced nausea are the most common and most scientifically established therapeutic uses of cannabis in humans (Committee on the Health Effects of Marijuana, 2017; see also Chapter 54). CB1 receptors are distributed throughout multiple levels of pain circuits, including cortical, midbrain, spinal, and peripheral sites of action. CB1 receptors are synthesized within many dorsal root ganglion neurons and transported to peripheral afferent fibre nerve terminals. Peripheral eCB signaling can suppress pain initiation directly through activation of these receptors (Piomelli et al., 2014). eCBs also can act on CB1 receptors, and in some situations at TRPV1 receptors, within

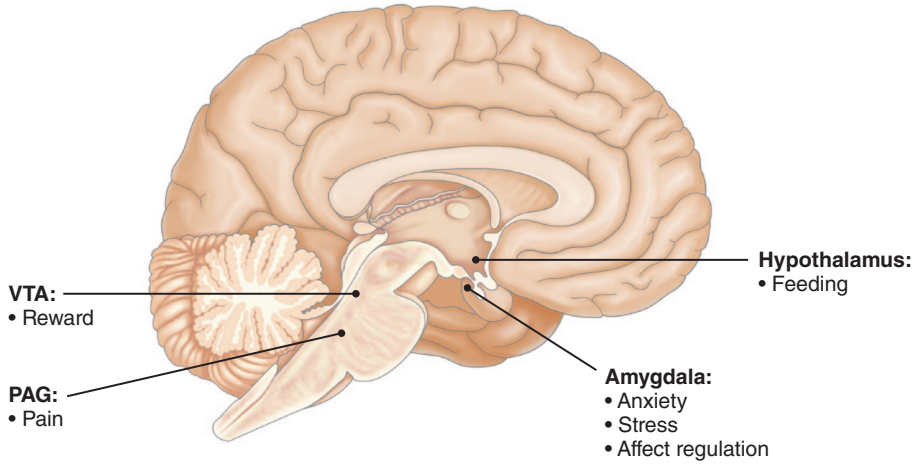

Figure 26–5 *Impact of endo- and phytocannabinoids on physiological processes in specific brain regions.* Cannabinoid signaling in the amygdala is the primary hub whereby endocannabinoids and THC influence anxiety states, stress responses, and affective processes. The capacity of cannabinoids to enhance rewarding stimuli has been localized to actions in the VTA. Cannabinoids increase feeding behavior through localized actions within hypothalamic nuclei. The analgesic effects of cannabinoids are driven through multiple pathways, including spinal and peripheral nerve pathways, but in the brain, the primary site of action is within the PAG.

spinal networks to influence pain processing (Woodhams et al., 2017). Cannabinoids can produce analgesia through activation of CB1 receptors within the periaqueductal gray (PAG; see Figure 26–5) and rostral ventromedial medulla of the descending pain circuit. eCBs act in higher-order brain circuits, primarily the cortical-amygdalar pathway, to influence pain processing, likely by influencing the affective component of pain. Exposure to noxious stimuli can enhance release of eCBs both in the periphery and within this distributed supraspinal pain circuit to act as endogenous regulators of pain initiation and sensitivity (Piomelli et al., 2014; Woodhams et al., 2017). Acute stress exposure produces transient analgesia via local release of eCBs within the PAG (Hohmann et al., 2005). A Scottish woman was discovered to possess both the P129T FAAH mutation as well as an upstream deletion in an FAAH pseudogene, which collectively resulted in robust elevations in AEA. These mutations were associated with a phenotype of pain insensitivity and accelerated healing (Habib et al., 2019).

Inflammation

CB2 receptors are primarily localized to immune cells and tissue, both in the periphery and in the brain. Most immune cells express CB2 receptors at varying levels, including T cells, monocytes, natural killer cells, and neutrophils, as well as microglia within the CNS. Activation of CB2 receptors on immune cells acts to reduce inflammation, primarily via the suppression of the release of proinflammatory cytokines, as well as by inhibiting cell proliferation and migration. Within the brain, CB2 receptors on microglia are rapidly induced by inflammation or damage and act to suppress the release of inflammatory cytokines and promote the release of anti-inflammatory cytokines. Within the periphery, CB2 receptors on T cells gate migration into tissues, such as the CNS, by reducing expression of adhesion factors. Deficits in T-cell CB2 receptors are associated with their enhanced infiltration into the CNS in pathological conditions such as multiple sclerosis (Malfitano et al., 2014). CB2-mediated activation of MAP kinases is integral to its ability to promote the release of anti-inflammatory cytokines and engage in reparative functions (Eljaschewitsch et al., 2006). CB1 receptors are also localized on some immune cells, but CB2 receptors appear to be the primary mechanism for most of the anti-inflammatory actions of eCBs.

eCB molecules can also regulate inflammation in the brain independently of cannabinoid receptors. 2-AG in the brain is predominately sequestered to cell membrane domains where it acts as a reservoir for arachidonic acid. In response to inflammatory stimuli, MAGL activity rapidly increases, metabolizing this membrane-associated 2-AG and liberating arachidonic acid, which is then converted to inflammatory prostaglandins via COX-2 (Nomura et al., 2011). MAGL localized within astrocytes (but not neurons) in the brain mediates the generation of neuroinflammatory molecules from 2-AG metabolism (Viader et al., 2015).

Sleep

The self-reported prosomnogenic effects of cannabis are often cited as a primary reason for continued consumption among recreational and medical cannabis users (Kesner and Lovinger, 2020). Cannabis can reduce the latency to onset of sleep and nighttime awakenings as well as promote non–rapid eye movement (NREM) sleep, while reducing the percentage of time spent in rapid eye movement (REM) sleep. eCB levels fluctuate in the brain and in the circulation in a circadian manner, and this diurnal cycle is disrupted following sleep. Elevating 2-AG signaling via MAGL inhibition similarly increases time spent sleeping and enhances NREM sleep while suppressing REM sleep (Kesner and Lovinger, 2020). Administration of a CB1 receptor antagonist promotes wakefulness and arousal and reduces NREM sleep. In humans, there have been multiple reports of sleep disruption following administration of the CB1 receptor antagonist *rimonabant*. eCB signaling may contribute to normative sleep-wake cycles.

Phytocannabinoids

Synthesis of THC and CBD by Cannabis

Our understanding of the synthetic pathways of the phytocannabinoids has expanded rapidly in the last decade. Details can be found in recent reviews (e.g., Gulck and Moller, 2020; Tahir et al., 2021) (Figure 26–6). Δ^9THC and its isomer, CBD (Figure 26–1), are synthesized in the trichomes of the cannabis plant, with the highest levels synthesized in the flowers of the female plant and lower levels produced in other aerial components and the male plant. Classic phytocannabinoid synthesis involves initial steps leading to the production of geranyl pyrophosphate and olivetolic acid. These are then joined by an aromatic prenyltransferase to form the initial phytocannabinoid, cannabigerolic acid (CBGA). CBGA then serves primarily as a substrate for Δ^9-tetrahydrocannabinolic acid (THCA) and cannabidiolic acid (CBDA) synthases, which catalyze the formation of THCA and CBDA. THCA and CBDA have little psychoactivity on their own but are important precursors. THCA and CBDA undergo decarboxylation (enhanced by gentle heating or light) to form biologically active THC and CBD, respectively. THCA and THC can also undergo spontaneous oxidation to form cannabinolic acid (CBNA) and cannabinol (CBN), with the latter lacking both the classic psychoactivity of THC and the biological activity of CBD. Interestingly, several other species of plants can also synthesize phytocannabinoids and closely related molecules with cannabimimetic effects (Gulck and Moller, 2020).

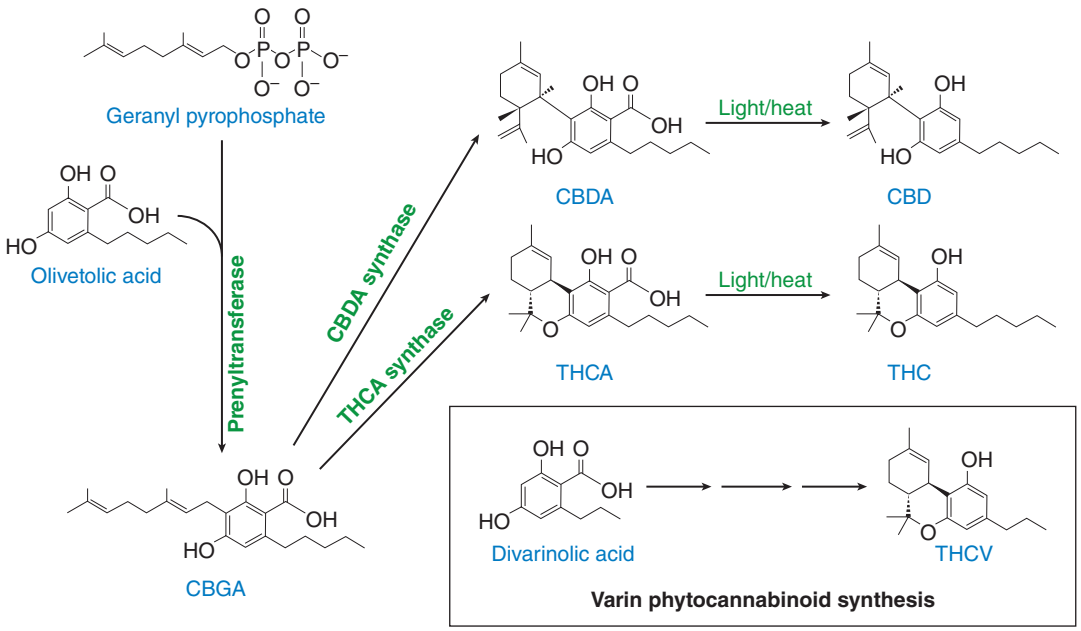

Figure 26–6 *Phytocannabinoid synthesis.* In the first committed step of phytocannabinoid synthesis, cannabigerolic acid synthase (CBGAS) prenylates olivetolic acid with geranyl pyrophosphate to produce cannabigerolic acid (CBGA). CBGA is then a substrate for THC synthase, CBD synthase, or CBC synthase, whose levels in experimental models can be varied by directed breeding programs. The synthases produce the acid forms of the phytocannabinoids (THCA, CBDA, and CBCA), which undergo nonenzymatic decarboxylation by light exposure or mild heating, yielding the more familiar THC, CBD, and CBC. *In the box:* Under growth conditions where butyl coenzyme A (CoA) is higher than hexanoyl CoA, divarinolic acid is produced (rather than olivetolic acid). Divarinolic acid is then synthesized to the varin cannabinoids, using the same enzymatic pathways that synthesize THC and CBD.

In addition to THC, CBD, and CBN, several "minor" cannabinoids may be synthesized in the plant under various growth conditions. Cannabichromenic acid (CBCA) is formed from CBGA by an incompletely characterized CBCA synthase and is subsequently decarboxylated to cannabichromene (CBC) (Gulck and Moller, 2020). Δ^8THC is a positional isomer of Δ^9THC and is likely a degradation product of Δ^9THC. Δ^8THC retains Δ^9THC psychoactivity.

A particularly interesting group of minor phytocannabinoids with a pharmacology distinct from Δ^9THC and CBD are the so-called varin cannabinoids, distinguished by their propyl side chain (see Figure 26–6). THC and CBD both contain a pentyl side chain derived from olivetolic acid. If the primary resorcinol available for the prenyltransferase is varinolic acid instead of olivetolic acid, then phytocannabinoids with propyl side chains result (tetrahydrocannabivarin acid and cannabidivarin acid, decarboxylated to Δ^9-tetrahydrocannabivarin [THCV] and cannabidivarin, respectively; see Figure 26–1). These varin phytocannabinoids have a pharmacology that distinguishes them from the pentyl phytocannabinoids, with THCV being a particularly potent CB1 cannabinoid receptor antagonist and a low-efficacy CB2 cannabinoid receptor agonist (McPartland et al., 2015).

Generally, the levels and activity of THCA and CBDA synthase in cannabis cultivars vary in a reciprocal fashion. Thus, plants that have been bred to have high THCA synthase activity will produce high levels of THC and low levels of CBD, while plants with high CBDA synthase activity will produce little THC. Selective breeding can result in a total THC content of dried plant material exceeding 30% (Swift et al., 2013). Importantly, the product specificities of THCA and CBDA synthases are not absolute. Therefore, plants producing high amounts CBD can also produce detectable levels of THC. This has important legal implications as cannabis plants with greater than 0.3% THC (w/w) are considered THC-producing in the U.S. and under current U.S. federal law are subject to U.S. Drug Enforcement Administration confiscation. Of note, CBD can be converted to THC under mildly acidic conditions, as might occur in the stomach, but whether this occurs in the human body under normal physiological conditions is not unequivocally established (Golombek et al., 2020).

In addition to phytocannabinoids, cannabis plants synthesize a range of other molecules, including terpenes and flavonoids. Terpenes give cannabis cultivars their distinctive aromas. Terpenes, built from isoprene units (2-methyl-1,3-butadiene), occur in myriad structures. The extent to which terpenes in cannabis contribute to or modify its psychoactivity or underlie its possible therapeutic benefits remains unknown (Booth et al., 2020).

Synthetic Cannabinoids

Considerable effort has been expended on synthesizing novel CB1 cannabinoid receptor agonists for therapeutic applications, such as analgesia. This has resulted in a rich medicinal chemistry of cannabinoid agonists of diverse structural classes. In parallel, widespread drug testing for THC (and its metabolites), coupled with the very long elimination half-life of THC metabolites, has motivated the recreational use of synthetic cannabinoids for individuals for whom a positive drug test may result in loss of their job. Because the structures of synthetic cannabinoids are often substantially different from THC, these compounds escape detection by common urine drug screens. This has led to the widespread recreational use of a wide variety of synthetic cannabinoids, known generically as "spice." In almost all cases, synthetic cannabinoids are high-efficacy CB1 agonists. In addition, their "off-target" activities have not been characterized, so they may engage an unpredictable repertoire of additional receptors, resulting in unpredictable psychoactivity. Finally, synthetic cannabinoids are typically prepared in illicit labs, with little quality control, so they may also be contaminated with unwanted molecular species.

Interactions Between eCBs, THC, and Synthetic Cannabinoids

The varying intrinsic efficacies of 2-AG, AEA, THC, and the synthetic cannabinoids used recreationally (the "spice" compounds) give rise to several possible interactions. For example, THC is a potent, low-efficacy

agonist at CB1 receptors, whereas 2-AG is a less potent but highly efficacious agonist. Thus, under conditions where either CB1 receptor density or postreceptor coupling is limited, THC may antagonize endogenous 2-AG signaling. Conversely, under circumstances of high CB1 receptor density and ample postreceptor coupling, THC and 2-AG could produce similar cellular effects. THC/2-AG interactions under the former condition may explain human behavioral data where even very high doses of the CB1 antagonist *rimonabant* weakly antagonize the subjective effects of THC, while *rimonabant* strongly attenuates THC-induced tachycardia (Huestis et al., 2001). Whether THC antagonizes, mimics, or augments eCB action likely varies across synapses. However, "spice" compounds are typically highly efficacious agonists, fully and indiscriminately activating CB1 receptors. With this property, "spice" compounds likely counter AEA signaling (AEA is a low-efficacy agonist). The very high efficacy of "spice" compounds (together with these compounds potentially engaging targets beyond CB1 and the presence of adulterants in the various "spice" formulations purchased by consumers) may explain their propensity to produce more frequent and more severe adverse effects than THC (Atwood et al., 2010; Deng et al., 2018; Huestis et al., 2001; Laaris et al., 2010; Straiker and Mackie, 2005).

Approved and Promising Pharmacological Applications

Dronabinol

Dronabinol is chemically synthesized THC formulated in sesame oil in a capsule and is also available as an oral solution.

Mechanism of Action

Dronabinol is a low-efficacy agonist of CB1 and CB2 cannabinoid receptors.

ADME

Dronabinol absorption from the gastrointestinal tract is high, as is first-pass metabolism, resulting in a bioavailability of only 10% to 20%. Peak plasma THC concentrations typically occur 1 to 3 h after oral administration. Concurrent food consumption slows time to peak THC plasma levels and increases exposure but does not affect peak plasma levels. THC undergoes successively oxidation at C11, leading to 11-hydroxy-tetrahydrocannabinol (11-OH-THC), followed by 11-nor-carboxy-THC. Notably, 11-OH-THC retains high activity at CB1 cannabinoid receptors. Thus, after oral consumption of *dronabinol*, levels of 11-OH-THC may be greater than those of THC, and most biological effects may be due to this metabolite. Excretion is primarily via the bile, with lesser amounts in the urine. THC metabolism is prolonged, with metabolites being detected in the feces and urine more than 5 weeks after a single dose. Most pharmacokinetic parameters for capsule and oral suspension forms of *dronabinol* are similar but not identical.

While inhalation is not an approved route of administration, it is important to note that the pharmacokinetics of THC vary dramatically if consumption occurs via the pulmonary route as opposed to oral ingestion in capsule form. For example, the bioavailability of inhaled (smoked) THC is 60% to 70%. For comparison, orally ingested THC produces blood levels in the range of 2 to 20 ng/mL, which peak around 60 to 90 min after ingestion and produce intoxication for up to 8 to 12 h (Huestis, 2005). Inhaled THC produces blood levels of THC that are dramatically higher, around 60 to 200 ng/mL, but peak quickly, around 15 min after inhalation, and rapidly return to baseline. However, frank intoxication persists for 90 to 240 min (Huestis, 2005).

Therapeutic Uses

Dronabinol is approved in the U.S. for the treatment of nausea and vomiting in patients receiving cancer chemotherapy who have not responded to conventional antiemetics as well as for anorexia associated with weight loss in patients with AIDS. See Chapter 54 for additional information on the use of *dronabinol* as an antiemetic agent.

Adverse Effects and Drug Interactions

The most common adverse effects reported with *dronabinol* involve the CNS and the cardiovascular system. CNS adverse effects include exacerbation of mania, depression, and schizophrenia as well as dizziness, fatigue, and cognitive impairment. Cardiovascular adverse effects include tachycardia and hypo- or hypertension. Abdominal pain and *increased* nausea and vomiting are occasionally reported with *dronabinol* use, which may be manifestations of cannabinoid hyperemesis syndrome. Care should be used in prescribing *dronabinol* to individuals who may be at greater risk for any of these adverse effects. Treatment includes holding or reducing the *dronabinol* dose or administration before sleep, depending on the nature and severity of the adverse effect. Phase 1 metabolism of *dronabinol* appears to be chiefly by CYP2C9 and CYP3A4, with the former having a greater contribution. Interactions with other drugs that may induce or inhibit these CYPs is likely. Conversely, high doses of THC may impair metabolism of drugs metabolized by these CYPs. CYP2C9 is highly polymorphic. Individuals who are homozygous for CYP2C9*3 (i.e., *3/*3) are classified as poor metabolizers and may be unusually susceptible to adverse drug responses when CYP2C9 is involved (see Chapter 7).

Pediatric and Geriatric Indications

Dronabinol is not approved for pediatric use. While there has been some interest in using *dronabinol* in treating agitation in dementia, it is not approved for this use.

Clinical Use

To treat nausea and vomiting associated with cancer chemotherapy after traditional pharmacological regimens are unsuccessful, *dronabinol* is begun at 5 mg/m^2 given 1 to 3 h before chemotherapy and then every 2 to 4 h after chemotherapy up to four to six doses per day. The first dose should be given at least 30 min prior to eating. Later doses can be given without regard to fed status; however, dosing relative to meals should be kept constant to facilitate titration. If the antiemetic response is inadequate, the dose can be increased in increments of 2.5 mg/m^2 to a maximum dose of 15 mg/m^2. CNS-related adverse effects increase significantly at higher doses, so patients must be carefully monitored for these and the dose decreased if necessary.

To treat anorexia associated with weight loss in AIDS, *dronabinol* is started at 2.5 mg twice a day, before lunch and before sleep. If the response is inadequate, the dose can be increased slowly to 5 mg twice daily, before lunch and in the evening. The maximum recommended dose is 10 mg twice daily. If CNS adverse effects are troublesome, the prelunch dose can be reduced or eliminated, keeping the evening dose. In Chapter 54, the section on Antinauseants and Antiemetics also presents information on the clinical use of *dronabinol* and *nabilone* (see below for discussion of *nabilone*).

Nabiximols

Nabiximols is a standardized extract from cannabis consisting of approximately equal amounts of THC and CBD and lesser amounts of minor cannabinoids, terpenes, and triglycerides. It is formulated as an ethanol-containing, peppermint-flavored, metered-dose oromucosal spray. It is not FDA-approved in the U.S. but is available in other countries.

Mechanism of Action

The THC in *nabiximols* is a low-efficacy agonist of CB1 and CB2 cannabinoid receptors. The CBD in *nabiximols* has the potential to interact with multiple targets (see section on CBD). The role of the minor constituents of *nabiximols* in its therapeutic efficacy is not known. There is the potential for a pharmacokinetic interaction between THC and CBD in *nabiximols* because of the overlapping CYPs involved in their metabolism.

ADME

Nabiximols pharmacokinetics are notably variable between patients, with mixed oromucosal and intestinal absorption contributing to this variability. Peak plasma THC concentrations typically occur 1 h after oromucosal administration. Peak plasma levels of THC and CBD can vary 10-fold between subjects receiving the same dose, and exposure may vary 3- to 4-fold. Co-consumption of food with *nabiximols* increases peak plasma

levels and exposure for both THC (~2-fold) and CBD (~4-fold). The pharmacokinetic variability emphasizes that patients receiving *nabiximols* should be consistent in taking the drug relative to their food consumption. Importantly, because of the oromucosal route of administration of *nabiximols*, peak levels of THC and CBD are achieved more slowly and are much lower than seen with inhaled cannabis or vaporized cannabinoid preparations. Metabolism of *nabiximols* is dominated by the metabolism of its two primary active components, THC and CBD. Details of their metabolism can be found in the sections on *dronabinol* and CBD, respectively. *Nabiximols* have been shown to inhibit CYP3A4 in a time-dependent fashion, even at clinically used doses. Thus, there is the potential for *nabiximols* to increase levels of other drugs metabolized by CYP3A4. Conversely, CYP3A4 inhibitors (e.g., *ketoconazole* and congeners) can substantially increase exposure to THC and CBD, and inducers of CYP3A4 (e.g., *rifampin*, St. John's wort) can decrease THC and CBD exposure. If the doses of drugs in these classes are increased or decreased when a patient is receiving *nabiximols*, their dosing should be reviewed.

Therapeutic Uses

Nabiximols is approved in several countries (but not the U.S.) for the treatment of moderate to severe spasticity and associated pain in multiple sclerosis. There is also interest in using *nabiximols* for treating chronic pain, although the clinical data on this indication are mixed.

Pediatric and Geriatric Indications

Nabiximols is not approved for pediatric use.

Adverse Effects and Drug Interactions

The most common adverse effects reported with *nabiximols* include dizziness, drowsiness, fatigue, and problems with memory/concentration; these effects likely arise from THC acting at CB1 cannabinoid receptors. Treatment for adverse effects involves holding or reducing the *nabiximols* dose, depending on the severity of the adverse effect. In clinical practice, these adverse effects are generally mild in intensity and diminish with continued use, suggesting that tolerance develops.

Clinical Use

Each dose (100-µL spray) of *nabiximols* contains 2.7 mg of THC and 2.5 mg of CBD. Typically, to minimize adverse effects, therapy is initiated with a single evening dose, with an additional evening dose every 2 days and morning doses, similarly titrated upward, added on the fifth day of treatment, to a maximum of 12 doses per day. Titration is stopped when adequate symptom relief is obtained or bothersome adverse effects occur. If adequate relief is not obtained after 4 weeks of treatment, treatment is generally stopped.

Cannabidiol

An oral solution of cannabis-derived CBD is FDA-approved for use in certain seizure disorders, as detailed below and in Chapter 20.

Mechanism of Action

The mechanism of action of CBD in reducing seizures remains unknown. Anxiolysis mediated by CBD appears to involve activation of serotonin $5HT_{1A}$ receptors. Anti-inflammatory actions of CBD seem to be mediated by a potentiation of adenosine signaling.

ADME

Peak plasma concentrations typically occur 3 to 5 hours after oral administration. Bioavailability of orally administered CBD is typically low and variable but is enhanced by concomitant fatty food consumption (3- to 15-fold increase in exposure). CBD half-life is long and variable (14–30+ h) and increases with chronic dosing.

Cannabidiol is primarily metabolized by hydroxylation of the C7 methyl group by CYP2C19, followed by oxidation to the C7 carboxylic acid by CYP3A4. The C7 hydroxyl cannabidiol metabolite (7-hydroxycannabidiol [7-OH-CBD]) is analogous to 11-OH-THC and appears to retain antiepileptic activity (Huestis, 2005). CBD metabolites are subject to phase II glucuronidation, primarily at the phenolic oxygen. CBD metabolites are excreted mostly via the feces with small amounts via urine.

Therapeutic Uses

Cannabidiol has been approved to treat medication-resistant seizures in Dravet and Lennox-Gastaut syndromes and tuberous sclerosis complex. Additional clinical trials are ongoing to determine its efficacy in other medication-resistant epilepsies. While there is evidence that acute administration of high doses of CBD reduces social anxiety disorder in certain settings, its efficacy for broadly treating anxiety disorders is not established (Wright et al., 2020). CBD has attracted interest as an antipsychotic agent, but its efficacy remains to be defined (Schoevers et al., 2020).

Adverse Effects and Drug Interactions

The most common adverse effects of CBD at the doses used to treat epilepsies include somnolence, fatigue, decreased appetite, diarrhea, and elevated hepatic transaminases. Liver transaminase elevations are dose-related, and alanine aminotransferase (ALT) elevations of greater than 3 times the upper limit of normal were observed in more than 10% of patients taking CBD at doses of 10 to 25 mg/kg per day. Approximately one-third of ALT elevations resolved despite continued administration of CBD. The risk of ALT elevation is almost doubled in patients receiving *valproate* (with or without *clobazam*) with CBD. Thus, in patients receiving CBD, serum transaminases and bilirubin should be monitored, particularly early in therapy or after a change in dose.

Due to the high doses of CBD administered as an antiepileptic, the likelihood that patients receiving CBD are also receiving multiple other drugs (which may induce or inhibit CYPs), and CBD interactions with several CYPs, CBD has a high potential to cause significant bidirectional drug-drug interactions. The best described is with the antiepileptic *clobazam*, where plasma levels of *clobazam* and its active metabolite, nor-clobazam, often increase dramatically following initiation of CBD therapy. This is consistent with CBD's inhibition of CYP3A4 and CYP2C19, which are responsible for metabolizing *clobazam* and nor-clobazam, respectively. Conversely, coadministration of CBD with *clobazam* increases 7-OH-CBD. *Clobazam* levels should be monitored when CBD is administered with *clobazam*. Coadministration of *valproate* with CBD does not increase *valproate* exposure but, as mentioned above, does increase the chance of liver transaminase elevation.

Pediatric and Geriatric Indications

In the U.S., *cannabidiol* is approved by the FDA for the treatment of seizures associated with Lennox-Gastaut syndrome, Dravet syndrome, or tuberous sclerosis complex in patients aged 1 year and older. In the E.U., the E.M.A. has granted orphan drug status for CBD to be used as adjunctive therapy with *clobazam* to treat seizures associated with Lennox-Gastaut or Dravet syndrome and as adjunctive therapy to treat seizures associated with tuberous sclerosis complex.

Clinical Use

For the treatment of seizures associated with Lennox-Gastaut or Dravet syndrome, CBD is typically started at 2.5 mg/kg twice daily. This is increased, as necessary, to 5 mg/kg twice daily after the initial week of treatment. If indicated, this dose can be increased to 10 mg/kg twice daily in weekly increments of 2.5 mg/kg per dose.

For the treatment of seizures associated with tuberous sclerosis complex, CBD is started at 2.5 mg/kg twice daily and increased in weekly increments of 2.5 mg/kg per dose to 12.5 mg/kg twice daily as tolerated.

It is important to note that the doses of CBD necessary to effectively treat seizures are much higher than the doses of CBD typically consumed from over-the-counter preparations available in the U.S.

Cannabidiol has also been examined for utility in other disease states. Several randomized clinical trials examined CBD as treatment for schizophrenia; results were mixed. In one study, 300 mg/day, but not 600 mg/day, of CBD improved cognitive impairment in schizophrenia (Hallak et al., 2010). Another study found that 800 mg/day of CBD was as effective as *amisulpride* but that CBD produced fewer negative side effects (e.g., extrapyramidal symptoms) than *amisulpride* (Leweke et al., 2012). The third trial found that 1000 mg/day of CBD improved positive symptoms but had no impact on negative symptoms (McGuire et al., 2018), while the fourth trial, which studied a dose of 600 mg/day, found no effect

on cognitive outcomes (Boggs et al., 2018). In persons with social anxiety disorder, one trial reported that a single dose of 600 mg of CBD did produce improvements in stress-induced anxiety and cognitive impairment (Bergamaschi et al., 2011). Another trial found that 3 consecutive days of administration of either 400 or 800 mg of CBD reduced craving and anxiety to drug cues in abstinent individuals with heroin use disorder (Hurd et al., 2019).

Note that in all clinical trials where efficacy of CBD has been reported, the doses are upward of 200 mg/day, with upper ranges reaching 1600 mg/day. This dose range is much higher than the doses that are typically used off-label by the general public, which tend to fall closer to 5 to 25 mg/day. Given the poor bioavailability of most oral CBD preparations, the lack of any identified pharmacological targets for CBD at the very low nanomolar concentrations that would be achieved by this dosing, and the failure to see clinical benefit in any trials using oral CBD at this low dose range, it seems highly unlikely that doses of CBD taken in this range are producing any biological impact on the individuals taking them. There is strong reason to believe that expectancy bias is having a robust impact on individuals claiming benefit from dosing of CBD at this level and that these effects are likely placebo effects.

Nabilone

Nabilone is a synthetic form of THC that is similar to, but structurally distinct from, THC itself (see Figure 26–1). *Nabilone* was previously FDA-approved and marketed in capsule form but has been discontinued in the U.S. since 2019 due to reports of serious hypersensitivity reactions.

Mechanism of Action

Nabilone has similar pharmacology to THC. It is a low-efficacy agonist of CB1 and CB2 cannabinoid receptors but is somewhat more efficacious than THC at activating both CB receptors.

ADME

Nabilone is taken orally and has high absorption from the gut (~96% absorption into bloodstream), with peak plasma levels occurring at around 2 h. As with THC, nabilone is subject to high first-pass metabolism, but over a dose range of 1 to 4 mg, the pharmacokinetics remain relatively linear. The distribution and metabolism of *nabilone* have not been well defined. *Nabilone* metabolism is primarily hepatic and likely involves several CYPs and hydroxylation sites on the dimethyl-heptyl side chain and formation of carboxylic analogues, similar to THC. There is also evidence that metabolites of *nabilone* are generated from the reduction of the ketone group on C9, producing several isomeric alcohols, which are primarily excreted in feces.

Therapeutic Uses

Nabilone is used in Canada, the United Kingdom, and Mexico for the treatment of chemotherapy-induced nausea and vomiting in patients who have not responded to conventional antiemetics. *Nabilone* has also been used off-label for the management of nightmares in individuals with posttraumatic stress disorder, for chronic neuropathic pain, cannabis withdrawal in hospitalized patients, and in the management of agitation in early dementia.

Adverse Effects and Drug Interactions

The most common adverse effects reported with *nabilone* involve the CNS and the cardiovascular system. CNS adverse side effects manifest as increased anxiety, nervousness, and panic and, in extreme rare cases, hallucinations and delusions. Sedation, dizziness, and impairments in normative cognitive function have also been seen, particularly at higher doses (≥5 mg). Cardiovascular adverse effects include mild tachycardia and postural hypotension at doses of 2.5 to 5 mg and above. Many of these adverse effects, particularly postural hypotension, may occur more frequently in elderly populations.

The metabolism of *nabilone* is not well established but likely involves the same CYP enzymes as those that metabolize THC. As such, there is a potential for drug interactions, although no major interactions have been identified. There are potential functional interactions with other substances that produce sedation or dizziness, such as benzodiazepines, opiates, some antidepressants (such as *quetiapine*), and alcohol.

Pediatric and Geriatric Indications

Nabilone is not approved for pediatric use. While there has been some interest in using *nabilone* in treating agitation in dementia, it is not approved for this use.

Clinical Use

To treat nausea and vomiting associated with cancer chemotherapy after traditional pharmacological regimens are unsuccessful, *nabilone* is begun at 1 to 2 mg given 1 to 3 h before chemotherapy. An initial dose may also be given the night prior to chemotherapy administration to offset nausea, and dosing may continue every 8 to 12 h for 24 h following chemotherapy (up to 48 h following chemotherapy if needed), without exceeding a total of 6 mg within 24 h. CNS-related adverse effects increase significantly at higher doses, so initial dosing is best at 1 mg to limit adverse side effects, with the dose increased up to 2 mg if not effective.

Off-label use of *nabilone* for control of nightmares in posttraumatic stress disorder consists of taking *nabilone* 1 h prior to bed, starting at a dose of 0.5 mg per night and titrating up to a maximal dose of 4 mg per night depending on efficacy and side effects. Similar dose ranges are used for off-label management of pain and for agitation in dementia.

Cannabinoid Drug Development

Peripherally Restricted CB1 Antagonists

Motivated by preclinical data showing that peripheral CB1 antagonism could be metabolically beneficial (Nogueiras et al., 2008) and on the assumption that the CB1 inhibitor *rimonabant* (see Box 26–1) induced anxiety and depression by a central mechanism, efforts have been directed toward the development and testing of *peripherally restricted* CB1 antagonists/inverse agonists. Several peripherally restricted CB1 antagonists are being evaluated in clinical trials to test whether they are effective therapy for obesity and the metabolic dysregulation accompanying obesity.

BOX 26–1 ■ Lessons From Clinical Trials and Postmarketing Surveillance

Cannabis consumption often causes an urge to consume calorically dense foods, a phenomenon colloquially known as "the munchies." Soon after the identification of CB1 cannabinoid receptors, several pharmaceutical companies initiated drug discovery programs to identify CB1 receptor antagonists, based on the reasoning that blocking CB1 receptors might decrease the consumption of highly palatable foods and be a novel pharmacological treatment for obesity. Among these companies, Sanofi-Aventis was the first to identify such an antagonist (specifically, an inverse agonist), designated as *rimonabant*.

In clinical trials, *rimonabant* produced a modest but consistent weight loss across diverse populations of obese subjects (Scheen, 2008). Interestingly, *rimonabant* improved metabolic parameters to a greater extent than predicted from the modest weight loss (Van Gaal et al., 2008). Further preclinical and clinical investigations supported the notion that *rimonabant*-induced weight loss was not a result of decreased food intake, which was only transient following initiation of the drug. Rather, weight loss was due to a sustained increase in energy expenditure brought about by antagonism by *rimonabant* of CB1 receptors on adipocytes, hepatocytes, and skeletal muscle (Addy et al., 2008; Kunos and Tam, 2011). Based on the favorable weight loss data, *rimonabant* was approved for use in the European Union as a treatment for obesity. However, concerns emerged that patients taking *rimonabant* were at a higher risk for anxiety, depression, and suicide. Because of these concerns, *rimonabant* failed to gain FDA approval and was withdrawn from the market in the European Union a few months later.

Endocannabinoid Catabolic Enzyme Inhibitors: FAAH and MAGL Inhibitors

A major approach within the cannabinoid field is the development of specific inhibitors that target the catabolism of eCB molecules: FAAH inhibition to potentiate AEA signaling and MAGL inhibition to potentiate 2-AG signaling (Blankman and Cravatt, 2013). MAGL inhibitors have been tested clinically by Pfizer and Abide/Lundbeck. The Pfizer compound did not go past phase I testing of brain penetrance. The Abide/Lundbeck MAGL inhibitor Lu AG06466 (formerly ABX1431) is currently in clinical trials but was ineffective in Tourette syndrome (Muller-Vahl et al., 2021). Given the ability of MAGL inhibition to modulate the generation of central inflammatory molecules (Nomura et al., 2011), ongoing clinical studies are focused on neurodegenerative diseases.

Compared to MAGL inhibitors, FAAH inhibitors have been more extensively tested. The first FAAH inhibitor entering clinical development, PF-04457845, was developed by Pfizer. It is a covalent, irreversible inhibitor of FAAH that produces up to 10-fold elevations in circulating AEA and related *N*-acyl ethanolamines for 24 h (Li et al., 2012). No serious adverse side effects were detected, and the compound had good CNS penetration and saturation of FAAH in the brain. The initial clinical study on osteoarthritic pain failed (Huggins et al., 2012). In 2019, a phase IIa trial with PF-04457845 showed safety and efficacy in treating cannabis withdrawal and dependence in men, with notable improvements in mood, anxiety, and sleep changes associated with withdrawal (D'Souza et al., 2019). This indication is currently being tested in a multisite trial (ClinicalTrials.gov identifier: NCT03386487). In 2020, an experimental trial in healthy humans showed that PF-04457845 reduced affective, autonomic, and physiological responses to stress and improved fear extinction (Mayo et al., 2020). Ongoing studies are examining the efficacy of FAAH inhibition in posttraumatic stress disorder.

The Janssen FAAH inhibitor, JNJ-42165279, is a reversible inhibitor of FAAH (Postnov et al., 2018). JNJ-42165279 was ineffective in individuals with anxious depression (ClinicalTrials.gov identifier: NCT02498392) but showed some benefit in patients with social anxiety disorder (Schmidt et al., 2021). Another FAAH inhibitor, SSR-411298, was tested for geriatric depression (ClinicalTrials.gov identifier: NCT00822744) and found to have no benefit.

Whether eCB-based drugs may have clinical utility remains to be determined. MAGL inhibitors hold promise for treating neuroinflammatory and neurodegenerative diseases, while FAAH inhibitors could be useful for the treatment of stress-related psychiatric disorders, such as social anxiety disorder and posttraumatic stress disorder, and for the management of cannabis use disorder.

Drug Facts for Your Personal Formulary: *Cannabinoids*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Cannabinoid receptor agonists		
Nabiximols (cannabidiol and THC)	• Spasticity associated with multiple sclerosis	• Oromucosal spray • Slow upward dose titration
Dronabinol	• Nausea/vomiting associated with chemotherapy • Appetite and weight loss in HIV infection	• Diverse CNS and cardiovascular adverse effects possible • Consider evening dosing to decrease adverse effects
Nabilone	• Nausea/vomiting associated with chemotherapy	• CNS and cardiovascular adverse effects and their treatment, similar to dronabinol
Cannabidiol		
Cannabidiol	• Decrease seizures associated with Lennox-Gastaut syndrome, Dravet syndrome, and tuberous sclerosis complex	• May elevate liver enzymes • Significant drug-drug interactions, particularly with clobazam • Bioavailability affected by food • Usual dose range, 10–20 mg/kg

Chapter 27 Ethanol

Jody Mayfield and S. John Mihic

Ethanol (CH_3CH_2OH), or beverage alcohol, is a two-carbon alcohol that is rapidly distributed in the body and brain. Ethanol alters many neurochemical systems and has rewarding and addictive properties. It is the oldest recreational drug and likely contributes to more morbidity, mortality, and public health costs than all illicit drugs combined. The 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) integrates alcohol abuse and alcohol dependence into a single disorder called *alcohol use disorder* (AUD), with mild, moderate, and severe subclassifications (American Psychiatric Association, 2013). In the DSM-5, all types of substance abuse and dependence have been combined into a single substance use disorder (SUD) on a continuum from mild to severe. A diagnosis of AUD requires that at least two of the 11 DSM-5 behaviors be present within a 12-month period (*mild AUD*: 2–3 criteria; *moderate AUD*: 4–5 criteria; *severe AUD*: 6–11 criteria). The four main behavioral effects of AUD are impaired control over drinking, negative social consequences, risky use, and altered physiological effects (tolerance, withdrawal). This chapter presents an overview of the prevalence and harmful consequences of AUD in the U.S., the systemic nature of the disease, neurocircuitry and stages of AUD, comorbidities, fetal alcohol spectrum disorders, genetic risk factors, and pharmacotherapies for AUD.

Human Consumption of Ethanol: A Brief History and Current Perspective

The use of alcoholic beverages is documented as far back as 10,000 BC. By about 3000 BC, the Greeks, Romans, and inhabitants of Babylon were incorporating ethanol into religious festivals, while also using it for pleasure and in medicinal practice. Over the last 2000 years, alcoholic beverages have been identified in most cultures, including pre-Columbian America about AD 200 and the Islamic world in the 8th century.

The dangers of heavy consumption of alcohol have long been recognized by almost all cultures. The increase in ethanol consumption in the 1800s, along with industrialization and the need for a dependable workforce, contributed to widespread organized efforts to discourage drunkenness, including a constitutional ban on the sale of alcoholic beverages in the U.S. from 1920 to 1933.

Today, AUD is one of the most prevalent psychiatric disorders worldwide. In the U.S., among adults 18 years and older, AUD is highly comorbid with other substance use and psychiatric disorders. In 2019, about 14.5 million people in the U.S. had AUD (Substance Abuse and Mental Health Services Administration, 2019). Roughly one-third of men (36%) and one-quarter of women (23%) will meet the criteria for a mild, moderate, or severe AUD in their lifetimes (Grant et al., 2015). Among ethnic groups, Native Americans have the highest prevalence of AUD. According to the Centers for Disease Control and Prevention (CDC), alcohol-related deaths are the third leading preventable cause of death in the U.S. (the first is tobacco and the second is poor diet and physical inactivity). Alcohol-impaired driving accounts for almost one-third of the overall driving fatalities. The cost of excessive drinking in the U.S. reached about $249 billion in 2010 (Sacks et al., 2015).

Binge drinking to a blood ethanol concentration (BEC) of 0.08% or above is the most common, costly, and deadly pattern of excessive drinking. This pattern of intake is defined as four or more drinks on the same occasion (within ~2 h) for females and five or more drinks for males and accounts for 77% of the total cost of excessive alcohol use in the U.S. (Sacks et al., 2015). In the past, AUD was more prevalent in men than

Abbreviations

ADH: alcohol dehydrogenase
ALDH: aldehyde dehydrogenase
AMPA: α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
APA: American Psychiatric Association
ARBD: alcohol-related birth defect
ARDS: acute respiratory distress syndrome
ARND: alcohol-related neurodevelopmental disorder
AUD: alcohol use disorder
BEC: blood ethanol concentration
CDC: U.S. Centers for Disease Control and Prevention
CYP: cytochrome P450
DSM-5: *Diagnostic and Statistical Manual of Mental Disorders* (5th edition)
FAS: fetal alcohol syndrome
GABA: γ-aminobutyric acid
GHB: γ-hydroxybutyric acid
GI: gastrointestinal
5HT: 5-hydroxytryptamine, serotonin
LPS: lipopolysaccharide
NMDA: *N*-methyl-D-aspartate
PTSD: posttraumatic stress disorder
SSRI: selective serotonin reuptake inhibitor
SUD: substance use disorder

women, but in the last decade, the difference between the sexes has narrowed for both AUD and binge drinking. In the 2019 National Survey on Drug Use and Health, more adults ages 18 and older reported binge drinking (~26%) in the past month than reported heavy alcohol use (~6%). Despite the high prevalence, morbidity, mortality, and socioeconomic costs, AUD often goes undiagnosed and untreated.

Blood Ethanol Concentration

Compared with other drugs, surprisingly large amounts of ethanol are required for physiological effects. Ethanol is consumed in gram quantities. In contrast, most other drugs with affinities for specific proteins are taken in milligram or microgram doses. The alcohol content of beverages typically ranges from 4% to 6% (volume/volume) for beer, 10% to 15% for wine, and 40% and higher for distilled spirits. The proof of an alcoholic beverage is twice its percentage of alcohol (e.g., 40% alcohol is 80 proof). A 12-oz bottle of beer (355 mL), a 5-oz glass of wine (148 mL), and a 1.5-oz "shot" of 40% liquor (44 mL) each contain about 14 g ethanol (the density of ethanol is 0.79 g/mL at 25°C) and constitute what is defined as a "standard drink" in the U.S.

Because the ratio of ethanol in end-expiratory alveolar air and blood is relatively consistent, BECs in humans are readily estimated by the measurement of ethanol levels in expired air; the partition coefficient for ethanol between blood and alveolar air is about 2100:1. In all states except Utah (0.05% w/v), the legally allowed BEC for operating a motor vehicle is 80 mg% (80 mg ethanol per 100 mL blood; 0.08% w/v), which is equivalent to a concentration of 17 mM ethanol in the blood. The consumption of one standard drink by a 70-kg person would produce a BEC of about 30 mg%. However, it is important to note that this is an estimation because the BEC is determined by multiple factors (e.g., rate of drinking, sex, body weight and water percentage, rates of metabolism and stomach emptying).

Metabolism of Ethanol

Absorption and Gastric Metabolism

After oral administration, ethanol is absorbed rapidly into the bloodstream from the stomach and small intestine and distributes into total body water (~0.65 L/kg body weight). Due to high surface area, absorption occurs more rapidly from the small intestine than from the stomach; delays in gastric emptying (e.g., due to the presence of food) slow ethanol absorption. Peak blood levels occur about 30 min after ingestion of ethanol if the stomach is empty. Because of first-pass metabolism by gastric and liver alcohol dehydrogenase (ADH), oral ingestion of ethanol leads to lower blood ethanol concentrations (BECs) than would be obtained if the same dose were administered intravenously. Compared with males, females have very little gastric ADH and consequently absorb more alcohol into their bloodstreams. In addition, the activities of liver ADH isozymes are lower in females. Thus, females generally metabolize ethanol more slowly than males. In addition, women are generally smaller and have lower body water percentages than men; this results in females reaching higher BECs than men after consuming the same amounts of alcohol.

Liver Metabolism

Only small amounts of ethanol are excreted in urine, sweat, and breath. The main enzymes involved in ethanol metabolism are ADH, catalase, and CYP2E1. CYPs 1A2 and 3A4 may also participate. Ethanol is metabolized primarily by sequential hepatic oxidation, first to acetaldehyde by ADH and then to acetic acid by aldehyde dehydrogenase (ALDH) (Figure 27–1). Each metabolic step requires NAD^+; thus, oxidation of 1 mol ethanol (46 g) to 1 mol acetic acid requires 2 mol NAD^+ (~1.3 kg). This greatly exceeds the supply of NAD^+ in the liver; thus, the bioavailability of NAD^+ limits ethanol metabolism to about 8 g/h (10 mL/h, 170 mmol/h) in a 70-kg adult. Ethanol metabolism proceeds via zero-order kinetics at BECs greater than 10 mg% and by first-order kinetics at BECs less than 10 mg%. Genetic variants of ADH and ALDH influence risk for developing AUD and are discussed later in the section on genetics.

In addition to limiting the rate of ethanol metabolism, the large increase in the hepatic NADH:NAD^+ ratio resulting from ethanol oxidation has other profound consequences. The function of NAD^+-requiring enzymes is impaired, resulting in accumulation of lactate, reduced activity of the tricarboxylic acid cycle, and accumulation of acetyl-CoA (which is produced from ethanol-derived acetic acid; Figure 27–1). The combination of increased NADH and elevated acetyl-CoA supports fatty acid synthesis and the storage and accumulation of triacylglycerides; ketone bodies then accrue, exacerbating lactic acidosis.

Although ADH is responsible for the majority of ethanol metabolism, CYP2E1 accounts for about 10%. This constituent of the microsomal ethanol-oxidizing system can be altered by acute or chronic ethanol consumption. Competition between ethanol and other drugs (e.g., *phenytoin* and *warfarin*) that are metabolized by CYP2E1 is observed after acute consumption of ethanol. CYP2E1 is also induced by chronic consumption of ethanol, and this is the primary mechanism for the development of pharmacokinetic tolerance to alcohol. This increased CYP2E1 activity also increases the clearance of other CYP2E1 substrates, leading to a requirement for increased dosing. The increased activity also increases susceptibility to certain toxins (e.g., CCl_4, which CYP2E1 metabolizes and thereby activates to the highly reactive trichloromethyl radical). Ethanol metabolism by the CYP2E1 pathway elevates $NADP^+$ and limits the availability of NADPH for the regeneration of reduced glutathione, thereby enhancing oxidative stress.

The mechanisms underlying hepatic disease resulting from heavy ethanol use probably reflect a complex combination of these metabolic factors, CYP2E1 induction (and enhanced activation of toxins and production of H_2O_2 and oxygen radicals), and possibly enhanced release of endotoxin as a consequence of ethanol's effect on gram-negative flora in the gastrointestinal (GI) tract. The often poor nutritional status of

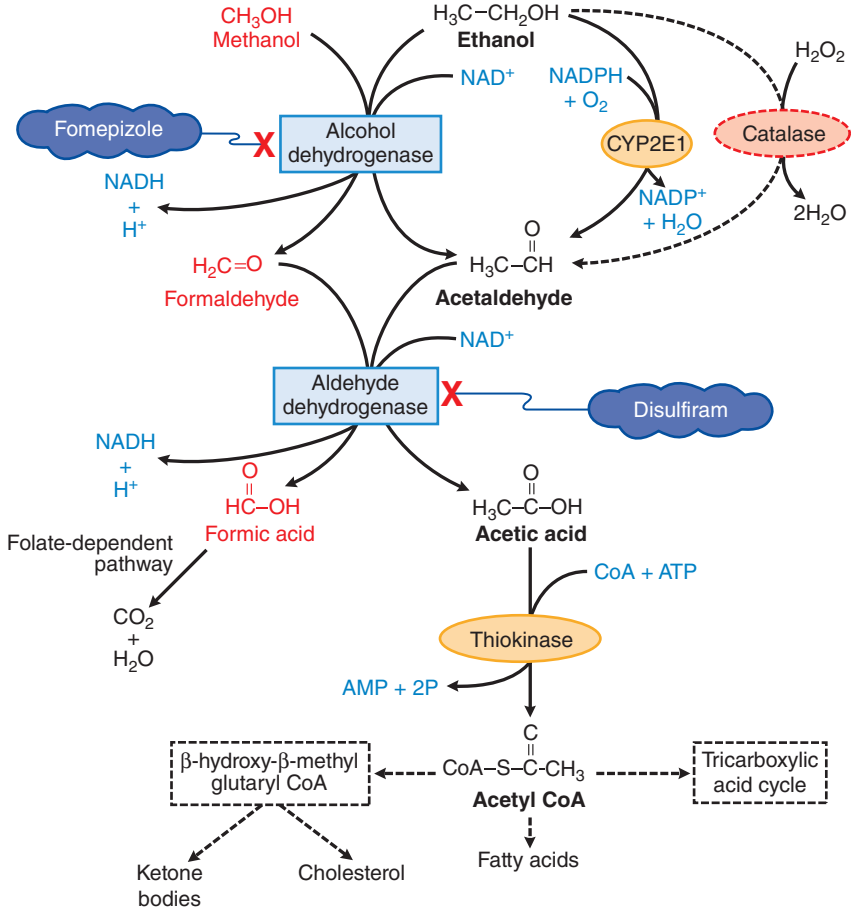

Figure 27–1 *Metabolism of ethanol and methanol.*

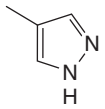
alcoholics (malabsorption and lack of vitamins A, D, and thiamine), suppressed of immune function, and a variety of other generalized effects likely compound the more direct adverse effects of excessive ethanol consumption. An overview of ethanol metabolism and how it can lead to tissue injury is found in the work of Molina et al. (2014).

Methanol

Methanol (CH_3OH), also known as methyl or wood alcohol, is an important industrial reagent and solvent found in products such as paint removers, shellac, and antifreeze. Methanol is added to industrial-use ethanol to make it unsafe for human consumption. Ingestion of as little as 8 g (10 mL) of methanol produces toxicity ranging from blindness to death. The toxic effects take about 12 or more hours to manifest themselves and are dependent on methanol metabolism to formaldehyde and formic acid (see Figure 27–1). Methanol poisoning consists of headache, GI distress, and pain (partially related to pancreatic necrosis), difficulty breathing, restlessness, and blurred vision. The visual disturbances occur from injury to ganglion cells of the retina and the optic nerve by formic acid, which produces inflammation, atrophy, and potential bilateral blindness. Severe metabolic acidosis can develop due to the accumulation of formic acid, and respiratory depression may be severe, resulting in coma or death.

Methanol is rapidly absorbed via the eyes, oral administration, inhalation, and through the skin, with the last two routes most relevant in industrial settings. Absorption of methanol taken orally typically occurs within 30 to 60 min. Methanol is metabolized by ADH to formaldehyde, which is then metabolized to formic acid by ALDH. Competition between methanol and ethanol for ADH is the basis for using ethanol to treat methanol poisoning because ethanol slows the rate of formic acid production, lessening the toxicity associated with methanol consumption.



FOMEPIZOLE

Fomepizole (4-methylpyrazole), an ADH inhibitor (Figure 27–1) that is administered alone, or in combination with hemodialysis, is also used to treat methanol or ethylene glycol poisoning. Plasma levels of 0.8 mg/L are effective in inhibiting ADH. *Fomepizole* should not be used with ethanol because it prolongs the half-life of ethanol. Treatment of methanol poisoning also consists of using sodium bicarbonate to combat acidosis.

Effects of Ethanol on Physiological Systems

The Wisdom of Shakespeare

William Shakespeare described the acute pharmacological effects of imbibing ethanol in the Porter scene (act 2, scene 3) of *Macbeth*. The Porter, awakened from an alcohol-induced sleep by Macduff, explains three effects of alcohol and then wrestles with a fourth effect that combines the contradictory aspects of soaring overconfidence with physical impairment:

Porter: … and drink, sir, is a great provoker of three things.

Macduff: What three things does drink especially provoke?

Porter: Marry, sir, nose-painting [*cutaneous vasodilation*], sleep [*CNS depression*], and urine [*inhibition of antidiuretic hormone (vasopressin) secretion, exacerbated by volume loading*]. Lechery, sir, it provokes and

unprovokes: it provokes the desire, but it takes away the performance; therefore, much drink may be said to be an equivocator with lechery: it makes him, and it mars him; it sets him on, and it takes him off; it persuades him, and disheartens him; makes him stand to, and not stand to [*the imagination desires what the corpus cavernosum cannot deliver*]; in conclusion, equivocates him in a sleep, and, giving him the lie, leaves him.

Research findings have since provided the physiological correlates for Shakespeare's enumeration (see the bracketed additions to the Porter's words in the preceding paragraph). The most noticeable consequences of the recreational use of ethanol still are well summarized by the gregarious and garrulous Porter, whose delighted and devilish demeanor demonstrates a frequently observed influence of modest concentrations of ethanol on the CNS.

Central Nervous System

Ethanol is primarily a CNS depressant. Ingestion of low to moderate amounts of ethanol, like that of other sedative/hypnotics such as barbiturates and benzodiazepines, can have anxiolytic actions and produce behavioral disinhibition. Individual signs of intoxication vary from expansive and vivacious effects to uncontrolled mood swings and emotional outbursts that may have violent components. With more severe intoxication, CNS function becomes progressively more impaired, ultimately to the point of general anesthesia. Due to respiratory depression, there is little margin between the concentrations yielding the anesthetic and lethal effects of ethanol.

Acute Intoxication and Treatment

Many factors influence the BEC, including body weight, body composition, and the rate of absorption from the GI tract. In women, with a generally lower volume of distribution for ethanol, BECs may be about 30% to 50% higher than in men for the same quantity consumed.

Signs of intoxication typical of CNS depression are observed in most people after two or three drinks, with the most prominent effects seen at times of peak BEC, about 30 to 60 min following consumption on an empty stomach. These symptoms include an initial stimulatory effect (perhaps due to inhibition of CNS inhibitory systems), giddiness, muscle relaxation, and impaired judgment. Higher blood levels (~80 mg/dL or ~17 mM) are associated with slurred speech, incoordination, unsteady gait, and impaired attention; levels between 80 and 200 mg/dL are associated with more intense mood lability and greater cognitive deficits, potentially accompanied by aggressiveness and anterograde amnesia (an "alcoholic blackout," i.e., loss of memory of events that transpired while intoxicated). BECs greater than 200 mg/dL can produce nystagmus and sedation, while levels of 300 mg/dL and higher produce failing vital signs, coma, and death. Heavy drinkers, who have developed significant pharmacodynamic tolerance, will display markedly less impairment at these BECs. All of these symptoms are likely to be exacerbated and occur at a lower BEC if ethanol is taken with other CNS depressants (e.g., benzodiazepines or barbiturates) or with any drug or medication that promotes sedation and incoordination (e.g., antihistamines). Also see the section on Drug Interactions later in the chapter.

The treatment of acute ethanol intoxication is based on the severity of respiratory and CNS depression. If respiratory depression is not severe, careful observation is the primary treatment. Patients with evidence of respiratory depression should be intubated to protect the airway and to provide ventilatory assistance; stomach lavage can also be considered if absorption is not yet complete. Because it is freely miscible with water, ethanol can be removed from the blood by hemodialysis. The usual protocol involves observing the patient in the emergency room for 4 to 6 h while the ingested ethanol is metabolized. The symptoms associated with diabetic coma, drug intoxication, cardiovascular accidents, and skull fractures are similar and may be confused with profound alcohol intoxication. Testing for breath odor in a case of suspected intoxication can be misleading because there can be other causes of similar breath odor (e.g., diabetic ketoacidosis or other metabolic acidosis). Determining blood ethanol levels is necessary to confirm the absence or presence of alcohol intoxication, and diabetes or other underlying conditions should also be considered in patients with positive BECs. There is no safe pharmacological treatment to increase the rate of ethanol metabolism.

Chronic Effects and Treatment

The transient effects of heavy ethanol consumption that produce a "hangover"—the next-morning syndrome of headache, thirst, nausea, hyperexcitability, and cognitive impairment—may reflect ethanol withdrawal, dehydration, or mild acidosis. Insomnia is a common and persistent problem in AUD, even after weeks of abstinence (Brower, 2015), and should be treated because it may contribute to relapse. Ethanol affects respiration and muscle relaxation, and heavy drinking can produce sleep apnea, especially in older dependent individuals. Treatment of insomnia must take into account possible pharmacodynamic interactions of ethanol with another CNS depressant.

Ethanol-induced cognitive impairment may be related to changes in synaptic plasticity (e.g., long-term potentiation and long-term depression), like those reported in preclinical studies of the hippocampus, prefrontal cortex, striatum, and nucleus accumbens (Abrahao et al., 2017). AUD causes shrinkage of the brain due to loss of both white and gray matter, and chronic heavy drinking increases the risk of developing *alcoholic dementia*. The cognitive deficits and brain atrophy observed after a heavy drinking period partially reverse over the weeks to months following abstinence. Chronic alcohol abuse also reduces overall brain metabolism, which reverses during detoxification.

Wernicke-Korsakoff syndrome is a degenerative neurological disorder that encompasses Wernicke encephalopathy and Korsakoff syndrome. These two closely related disorders often occur together, with most individuals developing encephalopathy first. Some researchers believe these are different stages of the same disorder. The disorder is caused by thiamine deficiency and is most commonly seen in those with AUD. It may also result independently of AUD, from malnutrition or conditions that cause nutritional deficiencies. The classic triad of symptoms are confusion, ataxia, and eye abnormalities (double vision, nystagmus, ophthalmoplegia); however, it is underdiagnosed because of a wide range of symptoms that overlap with other conditions (Chandrakumar et al., 2018). In its early stages, symptoms of Wernicke encephalopathy are usually reversible with high doses of thiamine, but the mental impairments in Korsakoff syndrome respond more slowly and incompletely. Untreated Wernicke encephalopathy leads to death in up to 20% of cases, and about 75% of those who survive the encephalopathy go on to develop Korsakoff psychosis, characterized by memory impairment, apathy, anterograde and retrograde amnesia, and confabulation (Chandrakumar et al., 2018; Thomson et al., 2012). Wernicke-Korsakoff syndrome is a medical emergency, and early treatment with intravenous thiamine (followed by oral maintenance treatment) is essential to reverse the Wernicke symptoms and prevent progression or reduce the severity of the Korsakoff state.

Molecular Targets: Neurotransmitter and Neuromodulator Systems

Ethanol alters the release of neurotransmitters and neuropeptides and modulates pre-, post-, and extrasynaptic activity through diverse molecular targets (reviewed in Abrahao et al., 2017). The dopaminergic system and the endogenous opioid system are sensitive to low concentrations of ethanol and play key roles in mediating its rewarding effects, although ethanol is not believed to directly act at either opioid or dopamine receptors. Ethanol perturbs the balance between excitatory and inhibitory transmission, for example, by enhancing the function of inhibitory cys-loop ligand-gated ion channels (e.g., $GABA_A$ and glycine) or inhibiting the function of excitatory ionotropic glutamate receptors (e.g., *N*-methyl-D-aspartate [NMDA], α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA], kainate) (Table 27–1). GIRK, $5HT_3$(serotonin) receptor-gated, and L-type Ca^{2+} channels are also sensitive to ethanol at low concentrations. Table 27–1 shows the overall effects of acute ethanol on some of the neurotransmitter and neuromodulator systems that are involved in the neurocircuitry of addiction.

TABLE 27–1 ■ MOLECULAR SITES OF ETHANOL ACTION

LIGAND- AND VOLTAGE-GATED ION CHANNELS	EFFECTS OF ACUTE ETHANOL
$GABA_A$ receptor-operated channels	Enhancement
Glycine receptor-operated channels	Enhancement
Glutamate receptor-operated channels (e.g., NMDA, AMPA, kainate)	Inhibition
Nicotinic acetylcholine receptor-operated channels	Subunit-specific
$5HT_3$ receptor-operated channels	Enhancement
G protein–coupled inwardly rectifying K^+ (GIRK) channels	Enhancement
Large conductance, Ca^{2+}-activated K^+ channels (BK)	Enhancement
L-type Ca^{2+} channels	Inhibition

The enhancement or inhibition of channel function recorded here represents an overall consensus of acute ethanol effects. Sensitivity and overall effects may depend on ethanol concentration, time of exposure, channel subunit composition, brain region, cell type, posttranslational modifications, and other factors.

Putative ethanol binding sites in many of the channel proteins in Table 27–1 have been identified through molecular modeling of high-resolution crystal structures (reviewed in Cui and Koob, 2017). Unlike other drugs, ethanol has a relatively weak affinity for its molecular targets; however, the ease with which ethanol is distributed and diffuses through membranes greatly broadens its targets and long-term neurobiological effects. Considering this, it is not surprising that the molecular mechanisms responsible for alcohol intoxication, reward, and dependence remain poorly understood.

Neurocircuitry and Stages of AUD

AUD is the chronically relapsing and compulsive use of alcohol, comprising three interacting stages that progressively worsen over time: binge-intoxication, withdrawal-negative affect, and preoccupation-anticipation ("craving"). The neurocircuitry of the basal ganglia is thought to mediate the neurobiological basis of the binge-intoxication stage, including the facilitation of incentive salience, a form of motivational salience associated with reward. The basal ganglia are associated with key functions, including voluntary motor control and procedural learning related to routine behaviors or habits. Release of dopamine and opioid peptides in the ventral striatum (nucleus accumbens) is associated with the reinforcing actions of alcohol (Volkow et al., 2007). Endocannabinoid signaling may also contribute to the motivational and reinforcing properties of ethanol, and ethanol drinking alters endocannabinoid levels and cannabinoid receptor 1 expression in brain nuclei in addiction pathways (Pava and Woodward, 2012). Alcohol use facilitates incentive salience by imparting motivational properties to previously neutral stimuli. Activation of the ventral striatum leads to recruitment of basal ganglia–globus pallidus–thalamic–cortical loops that engage the dorsal striatum habit formation, hypothesized to be the beginning of compulsive-like responding for drugs.

Tolerance rapidly develops to the rewarding effects of alcohol and is defined as a reduced behavioral or physiological response to the same dose of drug, or the requirement of a higher dose to obtain the same effect (see Chapter 28); this may be pharmacokinetic and/or pharmacodynamic in nature. The major forms of pharmacodynamic (functional) tolerance are *acute* and *chronic*. Acute functional tolerance, also known as the Mellanby effect, occurs within hours of alcohol administration and is due to CNS adaptations to its effects. This is demonstrated by comparing behavioral impairment at the same BECs on the ascending limb of the absorption phase of the BEC–time curve and on the descending limb of the curve, as metabolism reduces the BEC. Behavioral impairment and subjective feelings of intoxication are much greater at a given BEC on the ascending than on the descending limb. Chronic tolerance also develops in the long-term heavy drinker. In contrast to acute tolerance, chronic tolerance has both pharmacodynamic and pharmacokinetic elements, the latter due to induction of alcohol-metabolizing enzymes, primarily CYP2E1. In general, the maximum pharmacokinetic tolerance attained would be a doubling of the normal metabolic rate.

Dependence is defined by a withdrawal syndrome observed several hours to days after alcohol consumption is terminated. The symptoms and severity are determined by the amount and duration of drinking and include major motivational changes, sleep disruption, autonomic nervous system (sympathetic) activation, tremors, and, in severe cases, seizures. In addition, 2 or more days after withdrawal, some individuals experience *delirium tremens*, characterized by hallucinations, delirium, tachycardia, and a potentially fatal fever or cardiac arrhythmia. Individuals with AUD also show evidence of negative emotional states during acute withdrawal that persist into protracted abstinence; such states include symptoms related to anxiety, dysphoria, and depression. Persistent depression/anxiety-like symptoms are important treatment considerations. Delirium tremens require management as a medical emergency in an intensive care unit or another inpatient setting. Patients should be kept in a quiet and comfortable environment, and their vital signs routinely monitored. Electrolyte, fluid, and nutritional deficiencies must be corrected. Long-acting benzodiazepines such as *diazepam* or *chlordiazepoxide* are the treatments of choice, but *phenobarbital*, *dexmedetomidine*, or *propofol* may be used in benzodiazepine-refractory patients. Comorbidities are common in delirium tremens patients, especially liver dysfunction, and this may affect benzodiazepine dosing regimens. Lastly, clinical management of delirium tremens would be incomplete if it is not done in the context of anticipated treatment of the patient's underlying AUD. Two processes are thought to form the neurobiological basis for the withdrawal–negative affect stage: decreased functioning in reward systems in the ventral striatum and recruitment of the stress systems in the extended amygdala. As dependence develops, brain stress systems, involving corticotropin-releasing factor, norepinephrine, and dynorphin, are recruited (Koob, 2014), producing a powerful motivation for drug seeking.

The preoccupation-anticipation ("craving") stage involves dysregulation of prefrontal cortex circuits, causing loss of executive control. The completion of complex tasks in the AUD brain may involve two opposing systems. A "go" system (the anterior cingulate cortex and dorsolateral prefrontal cortex) engages habits via the basal ganglia, while the "stop" system (the ventrolateral prefrontal cortex and orbitofrontal cortex) inhibits the basal ganglia incentive salience and the extended amygdala stress system (Koob, 2015). Individuals with AUD show impairments in decision making, spatial information, and behavioral inhibition, all of which drive craving. Craving can be divided into "reward" craving (drug seeking induced by drugs or stimuli linked to drugs) and "relief" craving (drug seeking induced by an acute stressor or a state of stress) (Heinz et al., 2003). Thus, deficits in prefrontal cortical control of basal ganglia and extended amygdala function may explain individual differences in the predisposition to and perpetuation of addiction. Residual dysregulation of the neurocircuits mediating incentive salience and stress responsivity help perpetuate compulsive drug taking and relapse.

Endocrine System

The endocrine system comprises glands that produce and secrete hormones into the blood, affecting almost every cell and organ, and regulating many processes, including metabolism, energy, electrolyte balance, stress response, growth, development, and reproduction. The endocrine system also controls communication between the immune and nervous systems and is essential for maintaining homeostasis. Acute and chronic ethanol differentially alters endocrine function via the hypothalamic-pituitary-adrenal axis, the hypothalamic-pituitary-gonadal axis, the hypothalamic-pituitary-thyroid axis, the hypothalamic-pituitary-growth hormone/insulin-like growth factor-1 axis, and the hypothalamic-posterior pituitary axis (Rachdaoui and Sarkar, 2017). Chronic ethanol intake disrupts hormones from the endocrine portions of the pancreas and adipose tissue and the pituitary hormone prolactin, causing

hyperprolactinemia. The hormonal disturbances contribute to many conditions, such as thyroid and cardiovascular disease, immune and reproductive dysfunction, cancer, diabetes, and psychological disorders.

Sexual and Reproductive Function

Many drugs of abuse, including ethanol, have disinhibiting effects that may initially increase libido. Despite the notion that ethanol enhances sexual function, the opposite effect generally prevails, as Shakespeare's Porter noted. Sexual dysfunction in AUD includes decreased sexual arousal, increased ejaculatory latency, and decreased orgasmic pleasure. Hyperprolactinemia can decrease fertility in men and women with AUD by leading to hypogonadism, reduced sperm production, impotence, and menstrual cycle irregularities. Ethanol's adverse effects on the hypothalamic-pituitary-gonadal axis also contribute to decreased libido and fertility, gonadal atrophy, and menstrual irregularities.

Bone

Maintaining healthy bone requires a balanced bone remodeling process, where old bone is removed by osteoclasts and new bone is formed by osteoblasts. Chronic heavy drinking disrupts this balance by inhibiting bone formation and interfering with bone resorption (Maurel et al., 2012). Binge or heavy drinking is particularly concerning during adolescence and in young adults when it can dramatically compromise bone health. As bone mass and bone mineral density decrease, the risk of osteoporosis and fractures increase. In addition to bone loss from the direct effects of alcohol on both osteoblasts and osteoclasts, there are indirect mechanisms, such as poor vitamin D metabolism and Ca^{2+} absorption. Hormonal deficiencies in men and women with AUD are also contributing factors. Testosterone, an anabolic hormone important for production of osteoblasts, is decreased, and reduced estrogen levels increase bone fragility. Elevated levels of cortisol and parathyroid hormone in AUD also decrease bone formation.

Body Temperature

Ingestion of ethanol causes an initial feeling of warmth due to enhanced cutaneous vasodilatation. Heat is transferred from the body core to the periphery, and the core temperature falls due to ethanol's effect on the central temperature-regulating mechanism in the hypothalamus. Intake of high quantities of ethanol may lead to pronounced decreases in body temperature, especially in cold ambient temperatures. Alcohol is a major risk factor contributing to deaths from hypothermia.

Kidneys

Ethanol inhibits the release of vasopressin (antidiuretic hormone) from the posterior pituitary gland, resulting in enhanced diuresis. This dehydrating effect can lead to headaches and nausea. Alcohol-dependent individuals in withdrawal exhibit increased vasopressin release and a consequential retention of water, as well as dilutional hyponatremia.

Cardiovascular System

There is a complex relationship between ethanol consumption and cardiovascular disease, a leading cause of death and disability. Heavy alcohol use greatly increases risk for cardiovascular disease. Although observational studies have suggested lower risk in light to modest drinkers, the perceived benefit may be the product of healthier lifestyles in this group. Drinking recommendations from clinicians should remain guarded given that risk depends on dose and many other factors (e.g., sex, age, drinking patterns, lifestyle factors, and genetic risk), that there is the potential for other ethanol-related problems, and that there is a lack of randomized controlled trials on ethanol's long-term effects on cardiovascular function.

Serum Lipoproteins

A common risk factor for cardiovascular disease is the composition of lipids in the blood. Low alcohol consumption may have positive effects on lipid profiles by increasing high-density lipoprotein cholesterol (see Chapter 37), which transports cholesterol to the liver for elimination, and by decreasing total cholesterol, triglycerides, and low-density lipoprotein cholesterol, which causes cholesterol to accumulate in the arteries. The overall decrease in cholesterol accumulation in arterial walls decreases cardiovascular disease.

Hypertension and Stroke

In general, alcohol-risk relationships for hypertension tend to be J-shaped in women, with decreased risk found at low doses (Piano, 2017). However, based on a meta-analysis, women drinking more than 20 g ethanol/day and men drinking more than 30 g/day showed increased risk of hypertension. Even small increases in blood pressure can increase mortality from coronary artery disease and from stroke. In men and women, approximately one to two drinks per day may have no effect on or slightly reduce stroke events; however, greater daily alcohol consumption increases stroke risk (Piano, 2017).

Cardiac Arrhythmias and Cardiomyopathy

Arrhythmias like atrial fibrillation are a serious consequence of consuming large amounts of alcohol, particularly during binge drinking. Atrial fibrillation is one of the most common arrhythmias and is strongly associated with cardiovascular events such as stroke. Alcoholic cardiomyopathy is an acquired form of dilated cardiomyopathy associated with long-term, heavy alcohol consumption (Piano, 2017). It is characterized by a dilated left ventricle and increased mass, normal or reduced left ventricular wall thickness, and reduced ejection fraction in advanced stages. Cardiomyopathy may be caused by oxidative stress, cell death, impaired mitochondrial function, altered fatty acid metabolism and transport, and increased protein breakdown.

Lungs

The lungs are often overlooked as a site of ethanol action. However, individuals with AUD are more likely to develop pneumonia, tuberculosis, respiratory syncytial virus infection, and acute respiratory distress syndrome (ARDS) (Simet and Sisson, 2015). ARDS is quite deadly in a healthy person, and someone with AUD is at even greater risk. ARDS can occur in young AUD patients, whereas cirrhosis or other alcohol-related diseases take much longer to develop. The increased susceptibility to pulmonary infections, injury, and inflammation is caused by impaired immune responses. For example, alcohol impairs neutrophil production and release, lymphocyte function (e.g., T-cell function), ciliary function in airways, and the function of alveolar macrophages. Thus, the "alcoholic lung" is immunocompromised and under oxidative stress. The lungs then become depleted of the vital antioxidant glutathione.

Skeletal Muscle

Skeletal muscle dysfunction (myopathy) is a very common clinical manifestation in AUD, but it often goes unrecognized (Simon et al., 2017). Approximately 50% of chronic drinkers may develop alcoholic myopathy, which is five times more common than the incidence of liver cirrhosis. Cirrhosis may also influence the development of myopathy, and myopathy worsens the clinical outcome. The decreased muscle mass in alcohol-induced myopathy results from an imbalance in protein synthesis and degradation. In particular, there is decreased protein synthesis of myofibrillar and sarcoplasmic proteins. Some of the specific anabolic and catabolic mechanisms that are implicated in muscle wasting in AUD may involve decreased mammalian target of rapamycin–mediated protein synthesis and excessive protein degradation via the ubiquitin proteosome pathway and the autophagic-lysosomal system (Simon et al., 2017). Functional improvements in muscle strength occur over time following abstinence or reduced drinking. Optimizing nutritional status can also improve muscle function.

Digestive System

The body priorities metabolizing alcohol over other functions. As ethanol is absorbed and metabolized, it can damage the organs of the digestive

system and increase the risk of several cancers (discussed in a later section). Heavy drinking damages the mucosa of the esophagus, stomach, and intestines, disrupts gastric and intestinal barriers, impairs nutrient and protein absorption, impairs immune responses, and causes gastritis, pancreatitis, and liver diseases. The gut dysbiosis caused by ethanol has widespread inflammatory consequences.

Esophagus and Stomach

Ethanol directly damages the mucosa of the esophagus and stomach. It lowers esophageal sphincter pressure, impairs motility, and alters gastric acid secretion. AUD patients may develop gastroesophageal reflux disease, ulcers, or acute and chronic gastritis. Heavy drinking is also a predisposing factor for Mallory-Weiss syndrome, which is characterized by mucosal tears at the gastroesophageal junction and upper GI bleeding. Proton pump inhibitors and histamine H_2 antagonists are used to decrease gastric acidity.

Intestines

Ethanol damages the intestinal mucosa directly and indirectly by altering the microbiota and impairing mucosal immune function. Many individuals with AUD have chronic diarrhea caused by malabsorption in the small intestine. The rectal fissures and pruritus ani that are associated with heavy drinking are likely related to chronic diarrhea. Diarrhea is caused by structural and functional changes in the small intestine; for example, the intestinal mucosa has flattened villi, and digestive enzyme levels often are decreased. These changes are usually reversible after a period of abstinence.

Pancreas

Heavy alcohol use is the most common cause of both acute and chronic pancreatitis in the U.S. Acute alcoholic pancreatitis is characterized by the abrupt onset of abdominal pain, nausea, vomiting, and increased levels of serum or urine pancreatic enzymes. Treatment usually consists of intravenous fluid replacement (often with nasogastric suction) and opioid pain medication. Similar to alcoholic cirrhosis, chronic pancreatitis results from progressive cellular destruction and fibrosis and develops after recurrent episodes of acute pancreatitis. Ethanol metabolites and by-products like reactive oxygen species directly injure pancreatic acinar cells, causing stellate cells to produce extracellular matrix, which leads to the atrophy-fibrosis sequelae characteristic of chronic pancreatitis. Compared with the liver, the ability to oxidize ethanol in the pancreas is low. However, during chronic alcohol abuse, the pancreas has a much greater capacity than the liver for nonoxidative metabolism of ethanol to fatty acid ethyl esters (Rasineni et al., 2020). Inhibition of hepatic ADH during chronic drinking and the resulting increased production of fatty acid ethyl esters in the pancreas may be a major mechanism in the pathogenesis of chronic pancreatitis. The clinical symptoms are pain, malnutrition, and diabetes mellitus. Insulin may be needed to control the hyperglycemia (see Chapter 51), and pancreatic enzyme capsules containing lipase, amylase, and proteases can treat malabsorption (see Chapter 54).

Liver

As the main organ involved in ethanol metabolism, the liver is a well-known target for the pathological effects of chronic ethanol. According to the CDC in 2018, about 43% of deaths due to liver disease among individuals ages 12 and older involved alcohol. Over time, the dose-dependent effects progress from fat accumulation (steatosis) to fatty liver accompanied by inflammation (steatohepatitis), to collagen deposition (fibrosis), to fibrous scarring and loss of liver cells (cirrhosis). However, heavy drinkers may develop cirrhosis without first developing hepatitis.

Ethanol perturbs most aspects of hepatic lipid metabolism (You and Arteel, 2019), and the accumulation of fat in the liver is an early event that can develop over a few days. The generation of excess NADH, via metabolism of ethanol and acetaldehyde by ADH and ALDH, inhibits the tricarboxylic acid cycle and the oxidation of fat, leading to steatosis (see Figure 27–1). Fibrosis, resulting from tissue necrosis and chronic inflammation, is the underlying cause of alcoholic cirrhosis. Fatty liver disease is common in those with AUD, while a minority will go on to develop cirrhosis.

Patients with alcohol-related liver disease show changes in the composition of their gut microbiomes, increased intestinal permeability, and increased circulating levels of the gut-derived microbial endotoxin LPS (lipopolysaccharide). LPS is an important trigger for steatosis, inflammation, and fibrosis by stimulating the generation of reactive oxygen species and a cascade of events that culminate in the transcription of proinflammatory cytokines.

Fatty liver disease and acute alcoholic hepatitis are usually reversible with abstinence. In severe cases of alcoholic hepatitis or cirrhosis, abstinence may stop or delay disease progression, but cirrhosis is usually terminal if the patient does not receive a liver transplant.

Hematological Effects

While nutritional deficiencies can play a role in alcohol-related anemias, alcohol also directly interferes with red blood cell production. Heavy drinking is associated with different anemias (e.g., macrocytic and sideroblastic anemias). Thrombocytopenia is common in heavy drinkers and can complicate alcohol withdrawal syndrome (Silczuk and Habrat, 2020). Leukopenia is also commonly found in AUD and increases susceptibility to infections.

Immune System

Ethanol disrupts innate and adaptive immune signaling, further increasing the risk of infection and causing systemic inflammation that can damage organs and increase cancer risk. Immune responses are central to the pathogenesis of alcoholic liver disease. In addition to effects on granulocytes (leukopenia), ethanol alters lymphocyte composition, decreases T-cell mitogenesis, and changes immunoglobulin production. Individuals with AUD have weakened resistance to infections (e.g., to *Klebsiella* pneumonia and tuberculosis). The function of alveolar macrophages and neutrophils in the airways is impaired, causing damage that may not be evident until the patient encounters a secondary respiratory infection. As a consequence of ethanol's harmful effects on the gut microbiome and the integrity of the GI tract, gut microbes escape into the bloodstream where they go on to trigger or exacerbate immune and proinflammatory responses in different tissues and organs. The immune dysfunction is not confined to peripheral injury or illness. It is not clear whether peripheral responses are required to induce neuroinflammation or if ethanol also has direct proinflammatory effects in the brain.

Neuroimmune System

The impact of immune signaling in the brain on the neurobiological and behavioral changes in AUD or other CNS diseases has been an area of focus over the past decade (Erickson et al., 2019). Chronic ethanol consumption increases the levels of circulating innate immune signaling molecules (e.g., proinflammatory cytokines) that are capable of reaching the brain, where they elicit long-lasting neuroimmune responses through the transcription of immune-related genes and the activation of astrocytes and microglia. These cells are the principal immune mediators in the brain, responding to and releasing molecules like cytokines and chemokines. Neurons also mediate immune responses and express immune-related genes. Although microglia are the resident macrophages in the brain, there is new appreciation for how they directly communicate with neurons. The transition of microglia to reactive states is a diverse process with different functional states that may dictate healthy CNS function or trigger neuroinflammatory processes in psychiatric and neurodegenerative diseases. Drugs that inhibit neuroimmune/proinflammatory signaling have opened new avenues for therapeutics and are currently being studied for their potential to reduce alcohol drinking.

Cancers

Ethanol is a procarcinogen and increases the risk of several types of cancers (National Cancer Institute, 2020). People who drink 50 g (~3.5 drinks) or more of alcohol daily are at two to three times greater risk of cancers of the oral cavity, pharynx, and larynx; tobacco use further escalates these risks. Compared with non- or occasional drinkers, this

level of drinking is associated with a 1.5 times greater risk of developing colorectal cancer. AUD is a major risk factor for esophageal squamous cell carcinoma, as is genetic deficiency of ALDH2. AUD is a primary cause of liver cancer. Epidemiological studies show a higher risk of breast cancer in women who are heavy drinkers. A notable complication in the treatment of cancer patients with AUD is that ethanol can interfere in the metabolism of some chemotherapeutic agents. The effects of acetaldehyde, a demonstrated carcinogen in animal models, and oxidative stress are widely cited mechanisms for the increased rate of carcinogenesis among individuals with AUD. Evidence also points to a role for aberrant DNA methylation patterns and other epigenetic modifications that control genome activity as mechanisms in alcohol-induced cancer development and progression. Epigenetics refers to processes that affect gene expression without changes in DNA sequence.

Teratogenic Effects: Fetal Alcohol Spectrum Disorders

Ethanol is the most common teratogen in humans. Ethanol from a mother's blood passes freely to her baby through the umbilical cord, and it can be assumed that embryo or fetal BECs will be similar to maternal levels. Children born to mothers who are heavy drinkers display mental deficits and a common pattern of distinct dysmorphology known as FAS (fetal alcohol syndrome). The diagnosis of FAS is typically based on the observance of a triad of abnormalities associated with a history of prenatal ethanol exposure (Dorrie et al., 2014):

- A cluster of craniofacial abnormalities
- CNS dysfunction (structural or functional)
- Pre- or postnatal growth deficiencies (weight or height)

Fetal alcohol spectrum disorder is not a diagnostic term used by clinicians but rather an umbrella term that encompasses all of the disabilities caused by prenatal alcohol exposure. For example, children who do not meet all the criteria for a diagnosis of FAS may show physical or mental deficits consistent with partial phenotypes, including *partial FAS, alcohol-related neurodevelopmental disorder (ARND), and alcohol-related birth defect (ARBD)* (Dorrie et al., 2014). The DSM-5 characterizes *neurobehavioral disorder associated with prenatal alcohol exposure* as a condition associated with problems in thinking, behavior, and life skills (Hagan et al., 2016). The incidence of FAS is about 0.5 to 2 per 1000 live births in the general U.S. population, while the incidence of FAS, ARND, and ARBD combined is at least 1%. Early diagnosis and treatment intervention are important for these children. Higher rates of FAS occur in children born to African and Native American women. Children of binge-drinking mothers show severe mental and behavioral deficits, likely due to the high peak BECs (Dorrie et al., 2014).

The FAS craniofacial abnormalities associated with maternal drinking in the first trimester consist of microcephaly, shortened palpebral fissures, thin upper lip, smooth philtrum, and epicanthal folds. Magnetic resonance imaging studies demonstrate decreased volumes in the basal ganglia, corpus callosum, cerebrum, and cerebellum that correlate with the facial abnormalities. CNS dysfunction attributed to *in utero* ethanol exposure consists of hyperactivity; attention and mental deficits; learning disabilities; language, memory, and motor disorders; and psychiatric conditions. FAS is the number one preventable cause of cognitive and attention deficits in the Western world, with afflicted children consistently scoring lower than their peers on a variety of IQ tests. Although the evidence is not conclusive, it has been suggested that even moderate alcohol consumption (28 g/day) in the second trimester of pregnancy is correlated with impaired academic performance of children at age 6. Maternal age also may be a factor: Pregnant women over age 30 who drink alcohol create greater risks to their children than do younger women who consume similar amounts of alcohol. In addition, the intake of high amounts of alcohol, particularly during the first trimester, greatly increases the chances of spontaneous abortion. Alcohol use is risky throughout pregnancy, and there is no known safe amount. Current recommendations are to drink no alcohol during pregnancy.

Clinical Uses of Ethanol

For the treatment of poisoning by methanol or ethylene glycol, *fomepizole* is the first-line treatment, but systemically administered ethanol is also used; it acts at ADH to competitively slow the metabolism of methanol to formaldehyde and thence formic acid (see Figure 27–1). Dehydrated alcohol injected in close proximity to nerves or sympathetic ganglia is used to relieve long-lasting pain related to trigeminal neuralgia, inoperable carcinoma, and other conditions. Epidural, subarachnoid, and lumbar paravertebral injections of ethanol are also administered for inoperable pain. For example, lumbar paravertebral ethanol injections destroy sympathetic ganglia and thereby cause vasodilation, provide pain relief, and promote healing of lesions in patients with vascular disease of the lower extremities.

Drug Interactions

There are hundreds of over-the-counter and prescription medications that can interact adversely with ethanol. Ethanol increases the risk of liver damage or internal bleeding associated with *aspirin* or other nonsteroidal anti-inflammatory drug use. Due to synergistic effects in the CNS, caution must be taken when administering sedatives in patients who have ingested heavy doses of ethanol or other CNS depressants. Acute ethanol intoxication decreases general anesthetic requirements, and elective surgery should be postponed in intoxicated patients. In contrast, chronic ethanol drinking increases anesthetic requirements largely due to pharmacodynamic cross-tolerance. An additional complication is the use of neuromuscular blockers and sedative/anesthetic agents in patients with AUD presenting with compromised liver function. This is particularly true for patients administered *succinylcholine* and benzodiazepines.

Pharmacokinetic interactions between ethanol and other drugs must also be considered. *Acute administration* of ethanol inhibits the function of enzymes responsible for metabolizing a variety of different drugs, including *codeine*, *morphine*, *phenytoin*, some benzodiazepines, *tolbutamide*, and *warfarin*, among others. One in five prescription opioid deaths involves alcohol, and mixing these drugs increases risk of overdose and death. Because ethanol is a substrate for CYP2E1, any drug being metabolized by this CYP isozyme will be metabolized at a slower rate in the presence of ethanol. In contrast, the *chronic administration* of ethanol acts as an enzyme inducer, particularly of CYP2E1, increasing the rate of metabolism of *phenytoin*, *warfarin*, *propranolol*, and benzodiazepines. Activation of CYP2E1 in heavy drinkers can change *acetaminophen* into a toxic chemical and exacerbate hepatoxicity (see Figure 9–4).

Comorbidity of Alcohol Use Disorder With Other Psychiatric Disorders

Patients diagnosed with a mood or anxiety disorder are about twice as likely to suffer from a drug abuse disorder and vice versa. AUD is comorbid with other SUDs, major depressive and bipolar disorders, certain phobias, and antisocial and borderline personality disorders. AUD or other SUDs also co-occur with schizophrenia. Interestingly, there is a common neuroimmune link among AUD and some comorbid psychiatric disorders, suggesting a rationale for the development of therapeutics that target the key neuroimmune pathways. Although selective serotonin reuptake inhibitors (SSRIs) have not been shown to be effective treatments for AUD in those without a mental health disorder, SSRIs and other antidepressants may decrease alcohol intake when AUD and depression co-occur. If alcohol use occurs as a consequence of depression, treating the underlying problem can decrease drinking.

Exposure to traumatic events, and the debilitating, long-term anxiogenic symptoms that often result, are a cornerstone of posttraumatic stress disorder (PTSD). Classic symptoms include:

- Intrusion or reexperiencing the event
- Avoidance of internal and external reminder

- Negative changes in mood and cognition
- Hyperarousal and reactivity

PTSD increases the risk of developing AUD or other SUDs. There is a high prevalence of comorbid AUD and PTSD in the U.S., and, not surprisingly, a dual diagnosis exacerbates the symptoms of each disorder and worsens the prognosis for recovery. AUD and PTSD share considerable overlap in neural substrates and neuropathologies (Gilpin and Weiner, 2017). The SSRIs *sertraline* and *paroxetine* are FDA-approved for PTSD, but few studies have examined their efficacy in patients with PTSD and AUD. In one clinical trial, *sertraline* modestly improved PTSD symptoms and drinking measures but only in a subset of patients with early-onset PTSD and less severe AUD (Gilpin and Weiner, 2017). Verplaetse et al. (2018) have reviewed different treatment interventions for comorbid PTSD and AUD. For example, *naltrexone* (FDA-approved for AUD and discussed later) has modest effects on alcohol outcomes but does not significantly improve PTSD symptoms. Randomized clinical trials are needed to study potential drug combinations in these comorbid diseases.

Alcohol Use Disorder and Genetics

As with other complex trait disorders, the development and progression of AUD are influenced by multiple genetic and environmental factors, including stressors such as emotional, physical, or sexual abuse and drinking patterns within one's culture and peer group. The heritability of AUD is estimated to be 50% to 60%, as judged by family and twin studies.

Among the genetic variants identified, the most significant are in the ethanol-metabolizing enzymes. Linkage analyses show that genes clustered in the *ADH* region affect risk for alcohol dependence (Edenberg et al., 2006). For example, the *ADH1B*2* variant is found in high frequencies in Asian populations and may protect against AUD. It results in faster metabolism of ethanol and a transient higher blood level of acetaldehyde, which is associated with a lower risk for heavy drinking, but a higher risk for esophageal, head, and neck cancers in those who drink. The *ADH1B*3* single nucleotide polymorphism found in individuals of African descent is also associated with lower incidence of AUD.

ALDH2 is the most efficient isozyme in humans for the metabolism of ethanol-derived acetaldehyde. Low levels of acetaldehyde are rewarding and stimulating, while high blood levels produce toxic reactions such as vomiting, diarrhea, and unstable blood pressure; thus, variation in ALDH2 activity could affect the rewarding or aversive properties of ethanol. The genetic variant *ALDH2*2* encodes for an enzyme that cannot fully convert acetaldehyde to acetate; and in those who drink, acetaldehyde (a group 1 carcinogen) can accumulate to toxic levels, increasing risk of esophageal, head, and neck cancers. Approximately 10% of East Asians are homozygous for *ALDH2*2* and develop severe adverse reactions after the consumption of one drink or less. Similar effects occur if ethanol is consumed with the ALDH inhibitor *disulfiram* (the first pharmacotherapy for AUD, discussed in the next section of this chapter). Almost 40% of East Asians are heterozygous for *ALDH2*2* and experience facial flushing and enhanced sensitivity to alcohol but do not necessarily report adverse responses. Because ALDH2 deficiency poses increased risk of carcinogenesis, those individuals who drink should not dismiss mild responses to alcohol as inconsequential.

As gene discovery efforts continue to progress, findings from a large sample size show the polygenicity of alcohol use phenotypes and enrichment of candidate genes in tissues from cortical and subcortical regions known to be involved in AUD or SUDs (Liu et al., 2019). Many classical neurotransmitter and neuromodulator risk genes for AUD have been identified in genome-wide association studies, as well as robust changes in genes involved in brain stress and immune signaling. A genome-wide meta-analysis in individuals of European ancestry identified new risk loci for problematic alcohol use and also found genetic correlations with other substance use and psychiatric traits, particularly major depressive disorder (Zhou et al., 2020).

TABLE 27–2 ■ FDA-APPROVED MEDICATIONS FOR TREATING ALCOHOL USE DISORDER

MEDICATION	USUAL DOSE	MECHANISM/EFFECT
Disulfiram	250 mg/d (range of 125–500 mg/d)	• Inhibits ALDH with resulting ↑ acetaldehyde in the presence of ethanol. Abstinence is reinforced to avoid the adverse reaction.
Naltrexone (oral)	50 mg/d	• Opioid receptor antagonist; may ↓ drinking by ↓ the rewarding and reinforcing properties of alcohol.
Naltrexone (IM)	380 mg/4 weeks	• Same mechanism and effect as oral naltrexone. Long-acting depot formulation may improve bioavailability and patient compliance.
Acamprosate	666 mg three times daily	• May modulate glutamate and GABA neurotransmission; may work best in patients who are abstinent at treatment initiation.

Pharmacotherapies for Alcohol Use Disorder

In the U.S., the lifetime prevalence rate for AUD is estimated to be 29% (Grant et al., 2015). Despite evidence-based treatment options, however, AUD often goes undiagnosed and untreated. There are still only a few FDA-approved drugs for AUD: *disulfiram*, *naltrexone* (oral and long-acting injectable), and *acamprosate* (Table 27–2). *Disulfiram* inhibits ALDH and thereby alters the pharmacokinetics of ethanol; the other agents have neurobiological mechanisms. They have reasonable efficacy, with effect sizes similar to those of antidepressant drugs. However, they are prescribed in less than 9% of patients (Kranzler and Soyka, 2018).

Benzodiazepines are the treatment of choice for management of acute alcohol withdrawal (see Table 27–2) and to prevent the progression from minor withdrawal symptoms to major ones, such as seizures and delirium tremens (see Chapter 28).

Disulfiram

Disulfiram (tetraethylthiuram disulfide) was the first drug approved to treat alcohol abuse but is not considered a first-line treatment today. It inhibits ALDH and rapidly increases the blood acetaldehyde concentration by 5 to 10 times the level measured when ethanol is administered alone. *Disulfiram* irreversibly inactivates cytosolic and mitochondrial forms of ALDH to varying degrees. It is unlikely that *disulfiram*, itself, is responsible for ALDH inactivation *in vivo*. Several active metabolites, especially diethylthiomethylcarbamate, behave as suicide-substrate inhibitors of ALDH *in vitro*; these metabolites reach significant concentrations in plasma following the administration of *disulfiram*.

Alcohol consumption by individuals previously treated with *disulfiram* gives rise to marked signs and symptoms of acetaldehyde poisoning. At BECs of 5 to 10 mg%, mild effects are noted, increasing markedly in severity as the BEC reaches 50 mg%. If the patient attains a BEC of 125 to 150 mg%, loss of consciousness may occur. Within 5 to 10 min, the face feels hot and soon becomes flushed and scarlet in appearance. As the vasodilation spreads over the whole body, intense throbbing is felt in the head and neck, and a pulsating headache may develop. Respiratory difficulties, nausea, vomiting, sweating, thirst, chest pain, hypotension, orthostatic syncope, weakness, vertigo, blurred vision, and confusion are observed. The facial flush is then replaced by pallor, and blood pressure may fall to levels seen in shock. Thus, the use of *disulfiram* requires careful medical supervision and patient education and should only be attempted in motivated patients committed to maintaining abstinence. Patient must

learn to avoid disguised forms of alcohol that may be present in sauces, fermented vinegar, cough syrups, and even aftershave lotions. *Disulfiram* does not reduce craving; its effectiveness is based on the fear of adverse effects in the presence of ethanol, resulting in poor patient compliance.

Disulfiram should not be administered until the patient has abstained from alcohol for at least 12 h. The FDA-approved dosage is 250 to 500 mg/day. Unless sedation (the most common side effect) is prominent, the daily dose should be taken in the morning, the time when the resolve not to drink may be strongest. Sensitization to alcohol may last as long as 14 days after the last dose because of the slow rate of restoration of ALDH. It should be used with caution in patients with liver disease and is contraindicated in those with cardiovascular disease.

Disulfiram or its metabolites can inhibit many enzymes with sulfhydryl groups, producing a wide spectrum of biological effects. Hepatic CYPs are inhibited, thereby interfering with the metabolism of *phenytoin*, *chlordiazepoxide*, barbiturates, *warfarin*, and other drugs.

Naltrexone

Naltrexone, an opioid receptor antagonist, is approved for AUD in both oral and extended-release injectable forms. *Naltrexone* is chemically related to *naloxone* but has higher bioavailability and a longer duration of action when administered orally. It is also approved for treatment of opioid dependence (see Chapters 23 and 28). *Naltrexone* reduces endogenous opioid activity in mesolimbic reward pathways and may reduce the reinforcing effects of alcohol by blunting opioid-mediated dopamine transmission. *Naltrexone* is typically prescribed after no opioids have been taken for 7 to 10 days at a dose of 50 mg/day (see Table 27–2). The extended-release intramuscular formulation (380 mg) may increase bioavailability and overcome problems with medication adherence. It is approved for monthly injection in those who can abstain from alcohol in an outpatient setting before starting *naltrexone*. *Naltrexone* is underutilized in clinical practice, although current American Psychiatric Association (APA) guidelines recommend it as a first-line drug.

A meta-analysis shows that oral *naltrexone* reduces risk of relapse to any drinking and to binge drinking (reviewed in Kranzler and Soyka, 2018). Both oral (50 mg/day) and injectable (380 mg, single injection) *naltrexone* increased the likelihood of no binge drinking in a 1-month pilot study of male veterans (Busch et al., 2017).

Naltrexone is well tolerated, the most common adverse effect being nausea. Other side effects are headache, dizziness, anxiety, and insomnia. Patients should also be monitored for development of depression. Hepatotoxicity is associated with oral doses exceeding 300 mg; the drug is contraindicated in patients with liver failure or acute hepatitis and should be used with caution in patients with active liver disease. One potential concern with intramuscular *naltrexone* is injection-site reactions. *Naltrexone* blocks the effects of opioid analgesics and can cause withdrawal in an opioid-dependent patient. It can be used following detoxification to prevent relapse in patients with opioid use disorder. If opioids are needed for pain management, higher doses may be required and should be administered under medical supervision.

Acamprosate

Acamprosate (*N*-acetylhomotaurine) is FDA-approved for AUD and may have a better outcome in patients who are abstinent at treatment initiation. The mechanism of action of *acamprosate* has not yet been elucidated. It is generally well tolerated, with diarrhea being the main side effect. A meta-analysis of randomized clinical trials showed that *acamprosate* is associated with reduced risk of drinking in abstinent patients but does not reduce the likelihood of binge drinking (Jonas et al., 2014). The FDA-approved dose is 1998 mg/day, divided into three doses, which may limit patient compliance (see Table 27–2). *Acamprosate* is contraindicated in patients with renal failure.

Other Drugs With Repurposing Potential

The following drugs are not FDA-approved for AUD but are approved in other countries or are being used off-label, or there is emerging evidence of their possible clinical utility.

Baclofen, a $GABA_B$ receptor agonist, is a skeletal muscle relaxant used to reduce spasticity. It is approved to treat AUD in France and is indicated for use in patients not responsive to other treatments. There is increased risk of sedation when combining *baclofen* with alcohol. In a meta-analysis of randomized clinical trials, *baclofen* was associated with a delay in return to drinking and a greater likelihood of abstinence, especially in those with higher daily alcohol use at baseline (reviewed in Kranzler and Soyka, 2018). Although some results have been promising, evidence overall is uncertain regarding its use, particularly as a first-line treatment. For a review of *baclofen* in treating AUD, see de Beaurepaire et al., 2019.

Nalmefene (an analogue of *naltrexone*) is a mu- and delta-opioid receptor antagonist with partial agonist activity at kappa receptors. Compared with *naltrexone*, *nalmefene* has a longer half-life, greater bioavailability, and decreased risk of liver toxicity. The European Medicines Agency has recommended *nalmefene* for as-needed use (18 mg) to reduce heavy drinking. Such targeted use may be beneficial in high-risk situations or in problem drinkers who are not medication compliant or may otherwise not seek treatment. In a meta-analysis of randomized clinical trials, *nalmefene* was associated with a slight reduction in the number of binge-drinking days and in total alcohol consumption at 6 months (reviewed in Kranzler and Soyka, 2018).

Gabapentin is an anticonvulsant and GABA analogue that inhibits the α2δ-1 subunit of voltage-gated Ca^{2+} channels. It is primarily used to treat neuropathic pain, restless leg syndrome, and as an adjunctive treatment for partial-onset seizures. It is prescribed off-label for anxiety and other psychiatric disorders. APA guidelines suggest using it to treat AUD after first trying *naltrexone* or *acamprosate*. In one clinical trial, *gabapentin* (particularly at 1800 mg/day) increased the rate of abstinence and prevented binge drinking (reviewed in Kranzler and Soyka, 2018). *Gabapentin* is also associated with decreased alcohol craving and is used to treat mild to moderate alcohol withdrawal (Ahmed et al., 2019). For additional information on *gabapentin*, see Chapter 20.

Topiramate is an anticonvulsant that modulates voltage-gated sodium channels and GABA and glutamate activity in the CNS. It is FDA-approved for seizure disorders and migraine prevention and is used off-label as an adjunct therapy for chronic weight management. As with *gabapentin*, current APA guidelines suggest using *topiramate* as a second-line treatment for AUD, typically after trying *naltrexone* or *acamprosate*. A meta-analysis of randomized clinical trials showed *topiramate* is associated with a greater number of abstinent days and reduced number of binge-drinking days (reviewed in Kranzler and Soyka, 2018). Paresthesia and dysgeusia are the most common side effects.

Sodium oxybate, the sodium salt of γ-hydroxybutyric acid (GHB), is FDA-approved to treat cataplexy and excessive daytime sleepiness in narcolepsy. *Sodium oxybate* is approved in Italy and Austria to prevent relapse and to treat alcohol withdrawal (Caputo et al., 2016; van den Brink et al., 2018). It is structurally similar to GABA and thought to act by mimicking the effects of ethanol at $GABA_A$ and $GABA_B$ receptors, increasing dopamine levels in the mesocorticolimbic circuitry, and reducing craving. Because GHB is a recreational ("street") drug, there has been concern regarding its abuse potential and pharmacodynamic interactions with alcohol; however, this has not been an issue in clinical settings in patients without polydrug use and psychiatric comorbidities.

There are a number of other drugs being studied for their potential to treat AUD. ***Varenicline***, which is approved for smoking cessation, also reduces craving and alcohol consumption in some studies. *Varenicline* is a partial agonist at α3β4, α4β2, and α6β2 subtypes of nicotinic acetylcholine receptors (nAChRs) and acts as a high-efficacy agonist at α7 nAChRs. For more information on *varenicline*, consult Chapter 13. Other compounds in under investigation for the treatment of AUD in at least some subgroups of patients include the dopamine receptor partial agonist *aripiprazole*, the NMDA receptor antagonist *ifenprodil*, and the α_1 adrenergic receptor antagonists *prazosin* and *doxazosin*. Drugs that target immune and inflammatory pathways are also being studied for their potential to treat AUD. For example, *apremilast* (an inhibitor of phosphodiesterase type 4 and an anti-inflammatory drug approved to treat psoriasis)

decreased alcohol drinking in a human laboratory study. Lastly, *suvorexant*, an antagonist of OX_1 and OX_2 orexin receptors that is used to treat insomnia, may reduce relapse drinking by treating the sleep disruptions commonly found in AUD.

Treatment Outlook

Compared with other psychiatric disorders, there is a significant gap in pharmacotherapies for AUD. In the U.S., fewer than 1 in 10 individuals with a 12-month diagnosis of AUD receive any treatment. This is particularly concerning because, as described throughout this chapter, AUD is a systemic disease targeting the central and peripheral nervous systems, the digestive tract, the heart and vascular system, the lungs, bone and skeletal muscle, and the endocrine and immune systems. AUD is one of the leading causes of preventable morbidity and mortality.

Despite the overall modest effect sizes of available drugs, they do benefit some patients beyond what psychosocial treatment alone can accomplish. Clinicians are urged to address this public health burden by increasing screening measures and discussing evidence-based treatments (pharmacological and psychosocial) for patients who meet the criteria for AUD. Screening for other comorbid psychiatric illnesses in AUD individuals is also critical. As with any polygenic disease, the goal should be to initiate treatment earlier, before there is prolonged history of abuse with neurobiological or inflammatory insults. Although abstinence has traditionally been the main goal, reducing risky drinking behavior may be a valid treatment outcome for some. Evidence for this comes from patients in clinical trials who reported that alcohol-related problems increase with their number of days of binge drinking. New tools are being used in the search for new treatments, such as combining transcriptomic and computational approaches to find existing drugs that will target the dysregulated genes and biological pathways in AUD (Ferguson et al., 2019). Identifying improved pharmacotherapies and broadening access to treatment are major goals in the fight against this systemic disease.

Drug Facts for Your Personal Formulary: *Drugs Used to Treat Alcohol Use Disorder or Methanol Poisoning*

FDA-Approved Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Disulfiram 250–500 mg/day	• AUD (for patients committed to sustained abstinence)	• ALDH inhibitor. • Causes adverse effects from increased acetaldehyde when taken with alcohol. • Requires medical supervision and patient education. • Poor patient compliance.
Naltrexone Oral: 50 mg/day (50–100 mg) IM: 380 mg every 4 weeks (150–400 mg)	• AUD • Opioid use disorder (after opioid detoxification)	• Opioid receptor antagonist. • Available in oral and extended-release injectable formulations. • Contraindicated in patients with liver disease or taking opioids concurrently. • 2018 APA guidelines recommend use as a first-line treatment.
Acamprosate 1998 mg/day	• AUD	• May restore glutamate and GABA imbalances in the brain. • Safer for patients with hepatic disease; contraindicated in patients with severe cardiovascular disease. • 2018 APA guidelines recommend use as a first-line treatment.
Benzodiazepines	• Management of alcohol withdrawal • Anxiety/panic/seizure disorders • Insomnia • Anesthetic premedication	• ↑ GABA binding at $GABA_A$ receptors. • Chlordiazepoxide, lorazepam, diazepam, oxazepam, midazolam, and clorazepate are used in the U.S. to manage alcohol withdrawal symptoms.
Fomepizole	• Methanol or ethylene glycol poisoning	• ADH inhibitor.
Drugs Not FDA-Approved for AUD but Approved Elsewhere or Found Clinically Useful		
Gabapentin	• AUD (off-label) • Anticonvulsant • Neuropathic pain • Restless leg syndrome	• Blocks voltage-gated Ca^{2+} channels. • 2018 APA guidelines suggest use in AUD, typically after first trying naltrexone or acamprosate.
Topiramate	• AUD (off-label) • Anticonvulsant • Migraine prevention	• Acts on voltage-gated sodium channels and $GABA_A$ and glutamate receptors. • 2018 APA guidelines suggest use in AUD, typically after first trying naltrexone or acamprosate.
Nalmefene	• Approved for AUD in European Union (18 mg/day, as needed) • Opioid overdose/dependence	• Opioid receptor antagonist. • Less liver toxicity and longer acting than naltrexone. • Once approved for opioid overdose but now discontinued in the U.S.
Baclofen	• Approved for AUD in France • Spasticity	• $GABA_B$ receptor agonist, skeletal muscle relaxant, and antispasmodic agent.
Sodium oxybate	• Approved for AUD in Italy and Austria • Cataplexy • Narcolepsy	• GABA analogue and form of GHB. • Acts on $GABA_B$ and extrasynaptic $GABA_A$ receptors.

Chapter 28

Drug Use Disorders and Addiction

Christine Konradi and Yasmin L. Hurd

A Brief History of the Use of Psychoactive and Addictive Substances

Addictive and hallucinogenic substances have been used throughout mankind's cultural history. Traditionally, these substances have been used by healers for medicinal purposes and by priests in religious ceremonies. Hallucinogenic plants and mushrooms were used in pre-Columbian Mesoamerican cultures, opium has been known to man since prehistoric times, and alcoholic substances have been widely socially accepted for thousands of years. The advent of chemistry and pharmaceutical companies in the 19th century allowed for the analysis of psychoactive substances in coca leaves and poppy seeds, leading to the extraction and identification of the active ingredients and the synthesis of new compounds that were modeled after the botanical material. The hope was to find substances that could cure medical conditions and relieve pain without some of the addictive or adverse properties of the botanical extracts. Cocaine, morphine, and heroin were synthesized, and, although it seems absurd from today's vantage point, were marketed as less addictive and more beneficial for addiction treatment. Morphine was a blessing during the American Civil War, as it was 100 years later during the U.S. involvement in Vietnam, and in both wars, many soldiers developed dependencies.

Regulatory Responses in the U.S. to Issues of Purity, Use, and Misuse of Drugs

Initial steps to regulate pharmaceuticals were introduced with the Pure Food and Drugs Act in 1906. That act stipulated that active ingredients be listed on the label of a drug's packaging and that drugs could not fall below purity levels established by the U.S. Pharmacopeia (National Formulary). However, addictive drugs continued to be legally available without prescriptions as long as they were properly labeled. In 1908, with opium dens in most major cities, the first Opium Commissioner was appointed, and in 1914, the Harrison Narcotics Act was enacted. It regulated and taxed the production, importation, and distribution of heroin and cocaine. For the first time, doctors and pharmacists had to keep records of prescriptions.

The temperance movement and Prohibition, solidified by the 18th Amendment, had the unintended consequences of encouraging organized crime, bootlegging, and poisonings with methanol-laced industrial alcohol. With the termination of Prohibition by the passage of the 21st Amendment, organized crime turned to trafficking in other addictive substances such as heroin, which was legally grown in Turkey for medicinal purposes. The Controlled Substances Act (CSA), enacted in 1970, was a response to the Counterculture Generation and the return of

Abbreviations

Δ9-THC: Δ-9-tetrahydrocannabinol
ADHD: attention-deficit/hyperactivity disorder
AIDS: acquired immune deficiency syndrome
AUD: alcohol use disorder
CBD: cannabidiol
CDC: U.S. Centers for Disease Control and Prevention
CRF: corticotropin-releasing factor
CSA: Controlled Substances Act
DA: dopamine

SUD: substance use disorder

TABLE 28–1 ■ DRUG SCHEDULING OF CONTROLLED SUBSTANCES

SCHEDULE	DEFINITION	EXAMPLES
I	Drugs with no currently accepted medical use and a high potential for abuse	Heroin, LSD[a], marijuana[a], MDMA, peyote, methaqualone
II	Drugs with a high potential for abuse, with use potentially leading to severe psychological or physical dependence	Combination products with <15 mg of hydrocodone per dosage unit (Vicodin), cocaine, methamphetamine, PCP, methadone, hydromorphone (Dilaudid), meperidine (Demerol), oxycodone (OxyContin), fentanyl, Dexedrine, Adderall, Ritalin
III	Drugs with a moderate to low potential for physical and psychological dependence	Products containing <90 mg of codeine per dosage unit (Tylenol with codeine), ketamine, anabolic steroids, testosterone
IV	Drugs with a low potential for abuse and low risk of dependence	Xanax, Soma, Darvon, Darvocet, Valium, Ativan, Talwin, Ambien, Tramadol
V	Drugs with lower potential for abuse than Schedule IV and consist of preparations containing limited quantities of certain narcotics. Schedule V drugs are generally used as antidiarrheals, antitussives, and analgesics.	Cough preparations with <200 mg of codeine or per 100 mL (Robitussin AC), Lomotil, Motofen, Lyrica, Parepectolin

MDMA, 3,4-methylenedioxy-methamphetamine.
[a]The absence of therapeutic properties is debated.

heroin-addicted soldiers from Vietnam. In its wake, the Drug Enforcement Administration (DEA) and the CSA were established. The CSA established federal drug policy under which the manufacture, importation, possession, use, and distribution of certain substances are regulated. Further, the CSA established classifications of drugs into five schedules, based on their accepted medical use and their likelihood to cause dependence (Table 28–1). The CSA also serves as the national implementing legislation for the Single Convention on Narcotic Drugs, an international treaty to prohibit production and supply of specific drugs. The DEA and the U.S. Food and Drug Administration (FDA) determine which substances are added to or removed from the various schedules.

In 1995, the slow-releasing opioid drug *OxyContin* was introduced by Purdue Pharma, and in 2001, The Joint Commission rolled out new pain management standards that consider pain as a fifth vital sign. The resultant exuberance of prescribing of opioids contributed to a new addiction epidemic, with the death toll from opioids rising to 75,000 annually (Centers for Disease Control and Prevention [CDC], 2021). Clearly addiction is a national problem in the U.S.

Neurobiological Mechanisms of Addiction

The interaction of a ligand with a receptor on a neuron activates an intracellular signal transduction pathway that leads to, among other things, a change in gene expression patterns and a modification of how that neuron communicates in the future. This type of response to neurotransmitters, hormones, and neurotrophic factors is the basis of memory formation. Without this level of neural plasticity, memory would not be possible (Figure 28–1).

Drugs are exogenous ligands that tap into the same process. Psychoactive drugs (i.e., drugs that have target sites in the brain and lead to alterations in perception, mood, consciousness, cognition, or behavior) can produce lasting neuroplastic changes. In the case of prescription drugs that treat neuropsychiatric disorders, the response is a desired adaptation. In the case of drugs of abuse, this neuroplasticity is a form of maladaptive memory. A characteristic of substance use disorders (SUDs) is the further change in brain circuits that may persist beyond detoxification and cause intense drug craving and relapse.

Addiction begins with the exposure to substances (e.g., cocaine) or presentation of behaviors (e.g., gambling) that directly and intensely affect brain function and perception. Many drugs of abuse activate the reward pathway in the brain, which involves a dopaminergic connection from the ventral tegmental area to the *nucleus accumbens*. Drugs can activate the reward system through a direct action on the dopaminergic neurons, as is the case with stimulants, or indirectly through neuronal circuits that regulate those neurons, as is the case with opioids. The mechanism of action of alcohol, sedatives, and hypnotics is less clear-cut and includes neurotransmitter systems such as γ-aminobutyric acid (GABA), glutamate, 5HT (5-hydroxytryptamine, serotonin), and others.

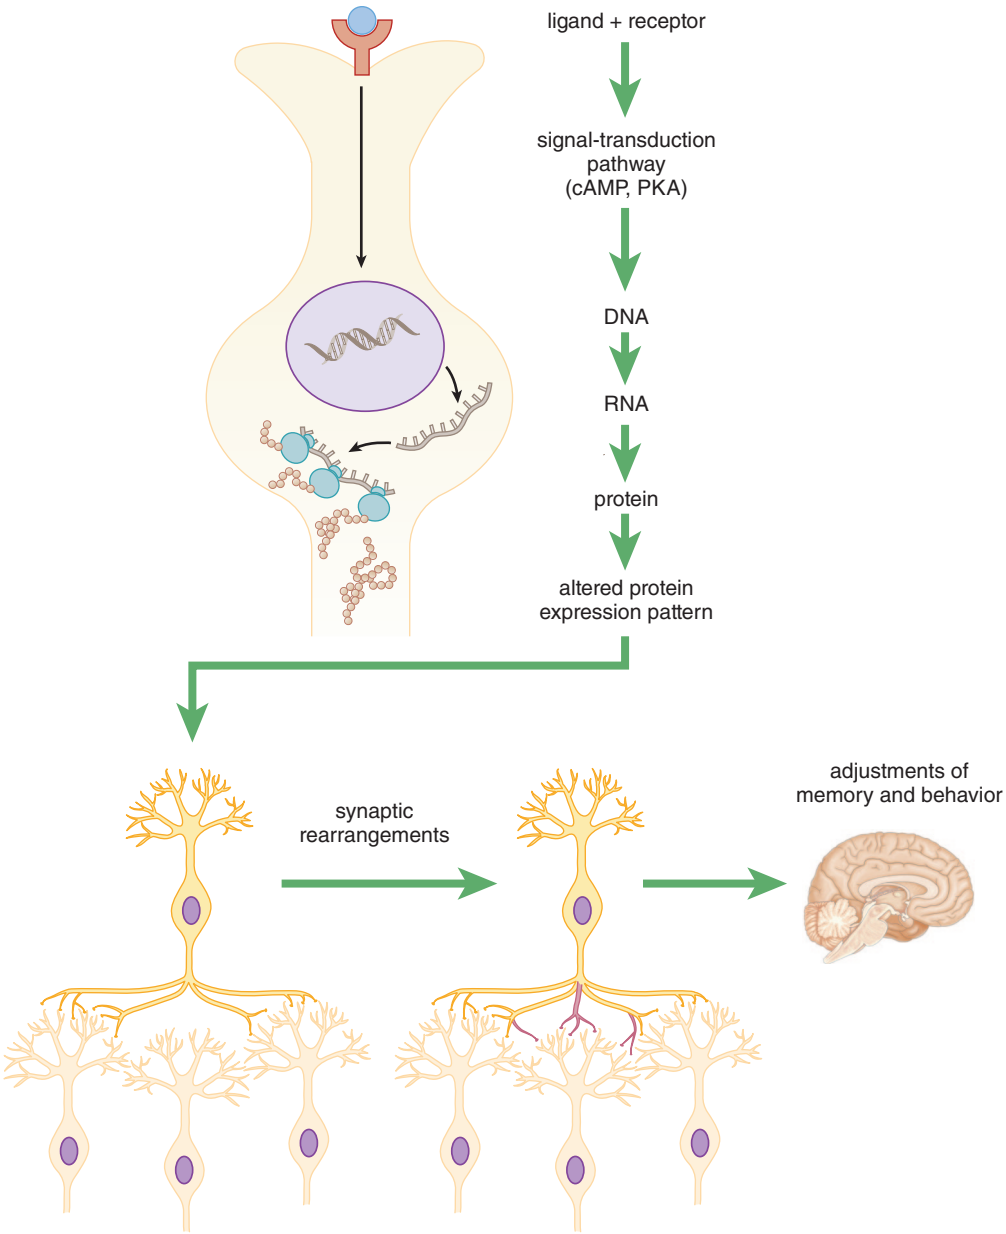

Figure 28–1 *From ligand-receptor interaction to long-term physical and behavioral changes in the CNS.* Drugs of abuse can alter the release of an endogenous ligand (i.e., release of DA, 5HT, NE) or serve as ligands themselves (e.g., THC isomers, opioids, nicotine, etc.). Interaction with a receptor initiates a cascade of signaling in the neuron that can involve ion channels, kinases, phosphatases, and other enzymes. Strong signals can be propagated to the nucleus where transcription factors are initiating mRNA synthesis to temporarily alter protein expression patterns. The newly synthesized proteins may change the physiology, structure, and connectivity of neurons. Some of this hard wiring of information generated by drugs might be irreversible and cannot be extinguished.

The reward system motivates normal behavior, and most humans simply enjoy the experience without an uncontrollable urge to repeat it. However, some individuals become drawn into compulsive repetition of the experience and develop SUDs or addictive behaviors, focusing on the immediate pleasure despite negative long-term consequences and neglecting important social, familial, and occupational responsibilities. The National Survey on Drug Use and Health reported that about 7% of Americans met the criteria for SUD in 2019 (Substance Abuse and Mental Health Services Administration, 2020) (Table 28–2), while about 10% have had SUDs at some time in their lives (Grant et al., 2016). This is lower than the approximately 17% of people above 18 years of age that used illicit drugs in 2019 or the approximately 25% of binge alcohol users in the month prior to the survey, underscoring that not all exposure to drugs leads to SUDs (Substance Abuse and Mental Health Services Administration, 2020).

Definitions and Pharmacological Phenomena

Using appropriate terminology is important to convey accurate patient information among healthcare professionals. Here are some of the most prevalent terms used in addiction research and treatment and their associated pharmacological phenomena.

Substance Use Disorders

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) bases the diagnosis of SUD on a pathological pattern of behaviors related to the use of a chemical substance (American Psychiatric Association, 2013). The individual has impaired control and may take the substance in larger amounts or over a longer period of time than was originally intended. An individual might report multiple

TABLE 28–2 ■ SUBSTANCE USE DISORDER FOR SPECIFIC SUBSTANCES IN 2019 (AS A PERCENTAGE OF THOSE AGE ≥12 YEARS IN U.S. POPULATION WHO MET CRITERIA FOR SUBSTANCE USE DISORDER)

Illicit Drugs	3.0
Marijuana	1.8
Cocaine	0.4
Heroin	0.2
Hallucinogens	0.1
Inhalants	0.0
Methamphetamine	0.4
Misuse of psychotherapeutics	0.8
Pain relievers	0.5
Stimulants	0.2
Tranquilizers or sedatives	0.2
Tranquilizers	0.2
Sedatives	0.1
Opioids	0.6
Illicit drugs other than marijuana	1.5
Alcohol	5.3
Both Illicit Drugs and Alcohol	0.9
Illicit Drugs or Alcohol	7.4
Illicit Drugs Only	2.1
Alcohol Only	4.4

unsuccessful efforts to decrease or discontinue use and spend a great deal of time obtaining the substance, using the substance, or recovering from its effects. Craving, defined as an intense desire or urge for the drug, is manifested particularly in an environment where the drug was previously obtained or used. Negative consequences associated with SUDs can be failure to fulfill obligations at work, school, or home; persistent or recurrent social or interpersonal problems; and withdrawal from family, recreational activities, and hobbies, which are replaced with use of the substance. Other hallmarks are risky overall behavior and risky use of the substance. Pharmacological criteria include the development of tolerance and withdrawal symptoms when levels of the substance decline (see below).

Addiction and Addictive Behaviors

Certain excessive behaviors can fit the same pathological criteria described in SUDs. These behavioral addictions include gambling, sex addiction, and shopping addiction. While SUD is a form of addiction, it is more appropriately labeled SUD in healthcare settings, which is considered a more neutral term. The American Society of Addiction Medicine defines addiction as a treatable, chronic medical disease involving complex interactions among brain circuits, genetics, the environment, and an individual's life experiences. People with addiction use substances or engage in behaviors that become compulsive and often continue despite harmful consequences.

Treatment outcomes for addiction and SUDs are generally as successful as those for other chronic diseases, such as diabetes or cardiovascular disease. While relapses are not uncommon, they fit into similar patterns as other chronic diseases that require healthy behavioral adaptations.

Tolerance

According to DSM-5, tolerance refers to the need of increased doses of a substance to achieve the desired effect or a reduction in effect even though the usual dose is consumed. Consider a stylized drug dose-response curve (Figure 28–2). As the dose of the drug increases, the observed effect of the drug increases. However, with tolerance, the curve shifts to the right due to the repeated use of the drug; that is, a given dose of the drug produces less effect.

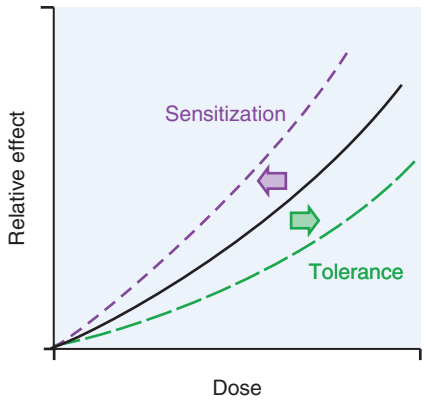

Figure 28–2 *Shifts in a dose-response curve with tolerance and sensitization.* The solid black curve describes the dose-response relationship to initial doses (the "control" curve). With tolerance, there is a shift of the curve to the right such that higher doses are required to achieve equivalent effects. With sensitization, the dose-response shifts leftward, and a given dose produces a greater effect than in the control case.

Tolerance can be life threatening in the case of opioids, for example, where the tolerance to respiratory depression does not develop at the same rate as the tolerance to sedating or euphoric effects. The discrepancy between tolerance to euphorigenic effects (rapid) and tolerance to effects on vital functions such as respiration and blood pressure (slow) can lead to potentially fatal overdoses as the user seeks the euphoria.

Pharmacologists define multiple aspects of tolerance:

- *Innate tolerance* refers to genetically determined lack of sensitivity to a drug the first time it is experienced.
- *Acquired tolerance* can be divided into three major types—*pharmacokinetic, pharmacodynamic*, and *learned tolerance*—and includes acute, reverse, and cross-tolerance.

Consider the following examples:

1. *Pharmacokinetic* or *dispositional tolerance* refers to changes in the distribution or metabolism of a drug after repeated administrations, such that a given dose produces a lower blood concentration than the same dose did on initial exposure. The most common mechanism is an increase in the rate of metabolism of the drug. For example, chronic administration of *phenobarbital* induces hepatic cytochrome P450 isoforms (CYPs) 1A2, 2C9, 2C19, and 3A4, thereby enhancing the metabolism of drugs that are substrates for these enzymes, including the barbiturate itself.
2. *Pharmacodynamic tolerance* refers to adaptive changes that have taken place within systems affected by the drug so that response to a given concentration of the drug is altered (usually reduced). Examples include drug-induced changes in receptor density or efficiency of receptor coupling to signal transduction pathways, such as upregulation of β adrenergic receptors during treatment of a hypertensive patient with a β receptor antagonist.
3. *Learned tolerance* refers to a reduction in the effects of a drug due to compensatory mechanisms that are acquired by past experiences.

- *Behavioral tolerance* is a type of learned tolerance. A common example is learning to walk a straight line despite the motor impairment produced by alcohol intoxication. At higher levels of intoxication, behavioral tolerance is overcome, and the behavioral deficits are obvious.
- *Conditioned tolerance* (situation-specific tolerance) develops when environmental cues or situations consistently are paired with the

administration of a drug. When a drug affects homeostatic balance by producing sedation and changes in blood pressure, pulse rate, gut activity, and so on, there is usually a reflexive counteraction or adaptation in the direction of maintaining the status quo. If a drug is always taken in the presence of specific environmental cues (e.g., smell of drug preparation and sight of syringe), these cues begin to predict the effects of the drug, and the adaptations begin to occur, which will prevent the full manifestation of the drug's effects (i.e., cause tolerance). This mechanism follows classical (Pavlovian) principles of learning and results in drug tolerance under circumstances where the drug is "expected."

- *Acute tolerance* refers to rapid tolerance developing with repeated use on a single occasion, such as in a "binge." For example, repeated doses of cocaine over several hours produce a decrease in response to subsequent doses of cocaine during the binge. This is the opposite of *sensitization*, observed with an intermittent-dosing schedule.
- *Sensitization* or *reverse tolerance* refers to an increase in response with repetition of the same dose of the drug. Sensitization results in a shift to the left of the dose-response curve (see Figure 28–2). Sensitization, in contrast to acute tolerance during a binge, requires a longer interval between doses, usually about 1 day. Sensitization often occurs with stimulants such as cocaine or amphetamine, but also occurs with other drugs.
- *Cross-tolerance* occurs when repeated use of a drug in a given category confers tolerance not only to that drug but also to other drugs in the same pharmacological category, such as opioid receptor agonists. Understanding cross-tolerance is important in the medical management of persons dependent on a drug. For example, a patient on methadone maintenance therapy might not experience analgesia elicited by morphine.
- *Detoxification* is a medically supervised withdrawal from the drug of abuse. It is often the first phase of treatment of drug dependence that involves the gradual decrease of the dose of the drug to reduce withdrawal symptoms, thereby weaning the patient from the drug. Detoxification can be accomplished with any medication in the same category as the initial drug of dependence. For example, users of heroin show cross-tolerance to other opioids. Thus, the detoxification of heroin-dependent patients can be accomplished with any medication that is an agonist at μ opioid receptors (MORs), such as *buprenorphine*.

Degrees of tolerance depend on the type of opioid, its half-life, and the route of administration. An addicted individual who is craving the "high" may risk overdose by not understanding the intricacies of the pharmacological profile of related drugs. This is especially dangerous when tolerance contributes to the individual progressing to more dangerous routes of administration (e.g., intravenous injection) or to highly potent opioids such as *fentanyl*. Accidental overdose has reached epidemic proportions and become so common in the U.S. that death in this manner now exceeds the toll for traffic accidents in young people (Rudd et al., 2016).

Allostasis and Physical Dependence

Physical dependence is a state that develops as a result of the adaptation (tolerance) produced by a resetting of homeostatic mechanisms in response to repeated drug use. The organism maintains "stability through change" by a process known as *allostasis* (McEwen, 1998). In the case of continued drug exposure, a person becomes physically dependent and requires continued administration of the drug to maintain normal function. If administration of the drug is stopped abruptly, there is a new imbalance, and the affected systems must readjust to a new equilibrium without the drug. An example is the rapid physical and emotional adaptation to opioid exposure that requires increasing doses of opioids to maintain the effect desired by the user (Figure 28–3).

Withdrawal Syndrome

DSM-5 describes withdrawal as a syndrome that occurs when blood or tissue concentrations of a substance decline in an individual who had maintained prolonged heavy use of that substance. The appearance of a withdrawal syndrome when administration of the drug is terminated is the only actual evidence of physical dependence. The types of withdrawal symptoms depend on the pharmacological category of the drug. For example, withdrawal of a stimulant causes sedation during withdrawal. Withdrawal of an opioid produces craving for the opioid and physical symptoms, such as nausea, vomiting, and diarrhea. Withdrawal associated with cannabis use disorder also includes somatic symptoms such as sweating, headache, and abdominal pain. Dependence and withdrawal have both physical and emotional presentations. Removal of a drug from the system often causes negative emotional states such as dysphoria, anxiety, and irritability. Significant

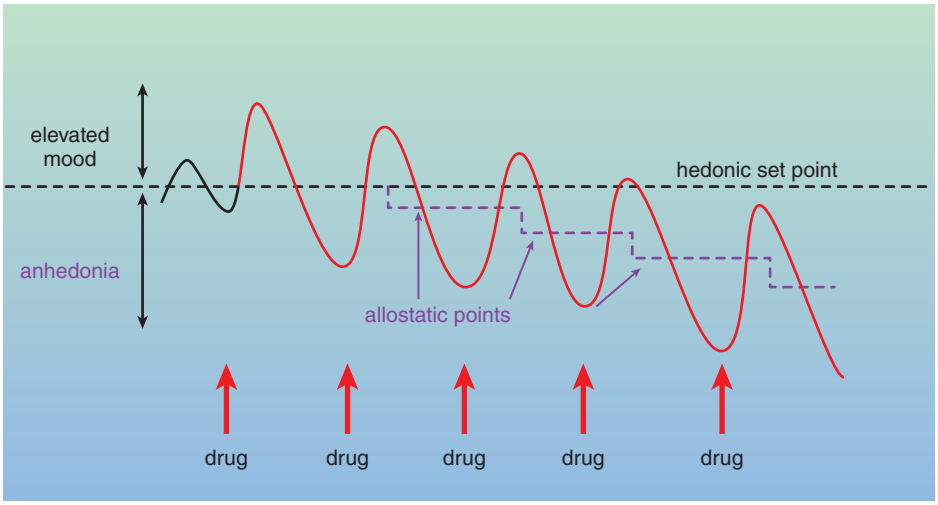

Figure 28–3 *Shifts in the hedonic set point during prolonged periods of opioid exposure.* Within the neuronal network, a balance is maintained between the multitude of receptors and their ligands. To protect the functional integrity, biological mechanisms are employed to counterbalance overactivity of any one system. Emotional experiences are rooted within this biological framework. The recalibration of interdependent elements to maintain a stable equilibrium explains why people with opioid use disorder (OUD) need to increase their drug intake over time to reach a similar emotional state to previous exposure experiences. With every exposure to opioids and the induced shift toward a state of elevated mood, the system counteracts downward toward equilibrium. When opioid levels fall, the counterbalancing measures are revealed as a drop in the hedonic setpoint and a reduced ability to feel pleasure (anhedonia). If drugs are taken in rapid succession, new allostatic points are established and the network is calibrated toward the presence of drugs. Eventually, drug use needs to be maintained to avoid the intense unpleasant emotional and physical consequences of withdrawal. (Figure adapted from Koob, 2015.)

withdrawal has not been documented in humans after repeated use of phencyclidine (PCP), other hallucinogens, and inhalants, which are not drugs that are generally used on a chronic daily basis.

Pharmacokinetic variables are of considerable importance to the amplitude and duration of the withdrawal syndrome. Short-acting substances tend to have a higher potential for the development of withdrawal symptoms, while longer-acting substances tend to have longer withdrawal duration. The longer the half-life of a substance, the longer is the time between cessation of drug taking and the onset of withdrawal symptoms, and the longer the withdrawal duration.

Tolerance, physical dependence, and withdrawal are all biological phenomena. They are the natural consequences of repeated, chronic drug use and can be reproduced in experimental animals. However, these symptoms in themselves do not imply that the individual is involved in drug misuse or addiction. *Patients who take medicines for appropriate medical indications and in correct dosages still may show tolerance, physical dependence, and withdrawal symptoms* if the drug is stopped abruptly rather than gradually. A physician prescribing a medication that normally produces tolerance must understand the difference between dependence and SUD and be mindful of withdrawal symptoms if the dose is reduced.

Reinforcement

The reinforcing properties of a drug can be propagated through positive reinforcement, negative reinforcement, or both.

- *Positive reinforcement* in the context of addiction refers to the capacity of drugs to produce positive effects that increase the likelihood that the individual will take the drug again. The more strongly reinforcing a drug is, the greater is the likelihood that the drug will be abused. The reinforcing properties of drugs are often associated with their capacity to increase neuronal activity in the brain mesolimbic reward pathway. Cocaine, amphetamine, ethanol, opiates, cannabinoids, and nicotine increase extracellular dopamine (DA) levels in the reward pathway, which consists of neurons arising in the ventral tegmental area that terminate in the ventral striatum, specifically the *nucleus accumbens* region. In contrast, drugs that block DA receptors generally produce bad feelings (i.e., *dysphoric effects*). Despite strong correlative findings, a precise causal relationship between DA and euphoria/dysphoria has not been established, and other findings emphasize additional roles of 5HT, glutamate, norepinephrine (NE), endogenous opioids, and GABA in mediating the reinforcing effects of drugs.
- *Negative reinforcement* is the process by which removal of an aversive stimulus increases the probability of a response. In the case of addiction, the aversive stimulus is the negative emotional state induced by drug withdrawal that reinforces drug taking. Various neurotransmitter systems have been implicated in negative reinforcement, such as the drug-induced increase in dynorphin, activation of κ opioid receptors (KOR), and corticotropin-releasing factor (CRF) hyperactivation during drug withdrawal (Koob, 2015; Zhou et al., 2019).

Relapse and Reinstatement

SUDs and addictions are chronic diseases. According to the National Institute on Drug Abuse (NIDA), more than 85% of people with addictions who stop using a drug reinstate drug use within a year. This is not due to physical symptoms, but to emotional craving. People in recovery are vulnerable to relapse when presented with cues associated with drug taking, in times of heightened stress, and when re-exposed to drugs after abstinence. While addiction is never considered "healed," lifelong remission and recovery are possible.

Substance-Induced Disorders

Substance-induced disorders are different from SUDs. They are defined by the development of a substance-specific syndrome due to the recent ingestion of a substance (i.e., intoxication). Clinically significant manifestations develop during or shortly after use of the substance. Substance intoxication is reversible and is common among those with SUDs but also occurs in individuals without SUD. In contrast, the development of substance-induced mental disorders is potentially severe and may in some cases leave persistent CNS syndromes.

An example is alcohol, which may produce depressive symptoms during intoxication, and anxiety syndromes during the acute withdrawal period. Stimulant substances and synthetic cannabinoids (manufactured drugs that activate cannabinoid receptors) can cause psychotic disorders or anxiety disorders, and depressive episodes during withdrawal.

Factors That Affect the Liability to Become Addicted

Most individuals who initiate use of a drug with addictive potential do not develop an SUD, although about 7% of persons aged 12 years or older met the criteria for SUD or alcohol use disorder (AUD) in 2019 (see Table 28–2). This trend increased slightly over the past 5 years due to an increased availability of, and addiction to, cannabis (Figure 28–4).

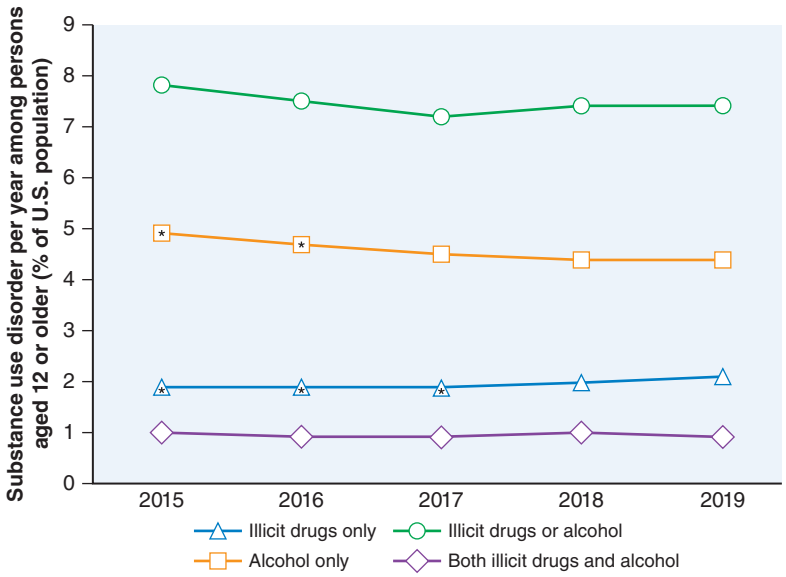

Figure 28–4 *Percentage of persons aged 12 years or older who met criteria for SUDs from 2015 to 2019 in the U.S.* Asterisk denotes the difference to 2019 at $p \leq 0.05$. (Data from Substance Abuse and Mental Health Services Administration, 2020.)

TABLE 28–3 ■ MULTIPLE SIMULTANEOUS VARIABLES AFFECTING ONSET AND CONTINUATION OF DRUG ABUSE AND ADDICTION

Agent (drug)
Availability
Purity/potency
Mode of administration
Chewing (absorption via oral mucous membranes)
Gastrointestinal
Intranasal
Subcutaneous and intramuscular
Intravenous
Inhalation
Speed of onset and termination of effects (pharmacokinetics: combination of agent and host)
Host (user)
Age at first exposure
Heredity (genetic vulnerability vs. genetic resilience)
Innate tolerance
Speed of developing tolerance
Likelihood of experiencing intoxication as pleasure
Absorption, distribution, metabolism, and elimination
Psychiatric symptoms
Prior experiences/expectations
Propensity for risk-taking behavior
Environment
Access to enforcers
Affordability of enforcers
Social setting
Community attitudes
Peer influence, role models
Employment or educational opportunities
Stressful environment
Conditioned stimuli: environmental cues become associated with drugs after repeated use in the same environment

TABLE 28–4 ■ USE, ADDICTION, AND RISK AMONG USERS OF TOBACCO, ETHANOL, AND ILLICIT DRUGS IN THE U.S., 1992–1994

AGENT	EVER USED[a] (%)	ADDICTION (%)	RISK OF ADDICTION (%)
Tobacco	75.6	24.1	31.9
Alcohol	91.5	14.1	15.4
Illicit drugs	51.0	7.5	14.7
Cannabis	46.3	4.2	9.1
Cocaine	16.2	2.7	16.7
Stimulants	15.3	1.7	11.2
Anxiolytics	12.7	1.2	9.2
Analgesics	9.7	0.7	7.5
Psychedelics	10.6	0.5	4.9
Heroin	1.5	0.4	23.1
Inhalants	6.8	0.3	3.7

[a]The ever-used and addiction percentages are those of the general population. The risk of addiction is specific to the drug indicated and refers to the percentage who met criteria for addiction among those who reported having used the agent at least once (i.e., each value in the rightmost column was obtained by expressing the number in the Addiction column as a percentage of the number in the Ever Used column, subject to errors of rounding).
Data *source*: Anthony et al., 1994. This study was repeated in 2001–2003: see Degenhardt et al., 2007.

Many variables operate simultaneously to influence the likelihood that a person initiating drug use will lose control and develop an addiction. These variables can be organized into three categories: agent (drug), host (user), and environment (Table 28–3).

Drug Variables

Pharmacokinetics in this instance refers to the onset, duration, and intensity of drug effects. It is influenced by properties related to the drug and by factors related to the user. *The abuse liability of a drug is correlated with the rate at which drug levels peak in the body*. Routes of administration that produce more rapid and efficient absorption into the bloodstream and brain—injecting, smoking, or "snorting"—tend to result in a more intense intoxication and are more reinforcing than oral administration. When coca leaves are chewed, cocaine is absorbed slowly; this produces low cocaine levels in the blood and few, if any, behavioral problems. Crack cocaine, on the other hand, is alkaloidal cocaine (free base) that can be readily vaporized by heating. Simply inhaling the vapors produces blood levels comparable to those resulting from intravenous cocaine owing to the large pulmonary surface area for absorption into the circulation following inhalation. Thus, inhalation of crack cocaine is much more addictive than chewing, drinking, or sniffing cocaine. The risk for developing addiction among those who try nicotine is about twice that for those who try cocaine (Table 28–4). This does not imply that the pharmacological addiction liability of nicotine is twice that of cocaine. Rather, the combination of variables listed in Table 28–3 in the categories of the Agent (e.g., mode of administration), Host, and Environment influence the development of addiction. For example, not only is nicotine smoked, which provides a rapid brain uptake, but nicotine is more accessible in society and can be administered more frequently than cocaine, thus increasing its addiction potential.

The influence of pharmacokinetics is fittingly illustrated by methylphenidate (MPH), the stimulant drug prescribed in attention-deficit/hyperactivity disorder (ADHD). Intravenous administration of MPH increases extracellular DA in the brain at a higher rate than cocaine and has similar reinforcing effects (i.e., self-report of feeling "high") as cocaine. The intravenous peak plasma concentration occurs almost immediately after dosing. In contrast, oral administration of MPH medication reaches peak plasma levels at a much lower speed and is rarely perceived as reinforcing, even though peak levels are eventually as high as after intravenous administration (Volkow et al., 2003). The recent availability of slow-release formulations of amphetamine compounds for the treatment of ADHD are another approach to prevent misuse of this group of drugs.

Host (User) Variables

Effects of drugs vary among individuals. Differences in genes that encode enzymes involved in drug transport, metabolism, elimination, and receptor-mediated responses may contribute to different effects of the drug across the addiction cycle (e.g., euphoria, reinforcement). For example, innate tolerance to alcohol due to enhanced metabolism may represent a biological trait that contributes to the development of alcoholism. While innate tolerance increases vulnerability to alcoholism, impaired metabolism may *protect* against it. Similarly, individuals who inherit a gene associated with slow nicotine metabolism may experience unpleasant effects when beginning to smoke and reportedly have a lower probability of becoming nicotine dependent (Thorgeirsson et al., 2010).

Psychiatric disorders constitute another category of host variables. People with anxiety, depression, insomnia, or even shyness may find that certain drugs give them relief (see Drug Summary Table). Alcohol and cannabis use are examples of self-medication. However, the apparent beneficial effects can be transient, and misuse of a drug may lead to tolerance and eventually compulsive, uncontrolled drug use. While psychiatric symptoms are seen commonly in drug abusers presenting for treatment, many of these symptoms begin *after* the person starts abusing drugs. Thus, drugs of abuse can produce more psychiatric symptoms than they relieve.

Age at first exposure is another critical factor. The majority of adults who end up with AUD or SUD had their first exposure to alcohol or drugs during adolescence. While the early initiation of drug taking could be part of an innate adolescent behavioral pattern such as risk-taking, the effect of drug exposure on the still-developing brain can facilitate use disorders and psychiatric disorders.

Drug use and vulnerability can differ between the sexes. Men are more likely than women to abuse illicit drugs and to overdose on drugs. However, females are as likely as males to develop SUDs and may be more susceptible to craving and relapse.

Environmental Variables

Initiating and continuing illegal drug use is influenced significantly by societal norms and peer pressure. A permissive environment, easy access to drugs, and community attitudes influence substance abuse. Drug policies such as marijuana legalization have the potential to increase SUDs, a viewpoint expressed in the theory of "gateway" drugs. However, while cannabis use in the states that legalized recreational marijuana did increase, there is no proven connection with other substance use trends (Figure 28–5).

People with adverse childhood experiences appear to account for a half to two-thirds of serious problems with drug use (Dube et al., 2003). Recent stressful situations can also lead to the initiation of drug taking, as well as cause drug reinstatement in abstinent persons with former SUDs. Similarly, environmental cues related to drug taking or re-exposure to small amounts of drugs or alcohol can lead to relapse.

Government Agencies Involved in Data Collection, Substance Use Disorder Research, and Drug Regulations

Much of what we know about drug use in the U.S. is collected by federal agencies or by projects funded by these agencies. The latest data are found on their websites, which provide access to current trends on a daily, weekly, and annual basis, including information on changing trends and novel illicit drugs that enter the U.S. market.

Synthetic cannabinoids and synthetic cathinones (e.g., ethylone) are the most common classes of new psychoactive substances, although opioids, phenethylamines, tryptamines, benzodiazepines, and piperazines are also of concern. With the influx of novel drugs and changes in the political landscape, trends are constantly changing (DEA Strategic Intelligence Section, 2021). For example, among people aged 12 or older, the percentage who used marijuana in the past year increased from 11.0% in 2002 to 17.5% in 2019. Over the same period, the percentage who used cocaine decreased from 2.5% to 2.0% (Substance Abuse and Mental Health Services Administration, 2020). According to the CDC, 70,630 drug overdose deaths occurred in the U.S. in 2019, accounting for 21.6 deaths per 100,000 persons. This number rose to approximately 85,000 drug overdose deaths in 2020, during the COVID-19 pandemic (Ahmad et al., 2021) (Figure 28–6). Drug overdose deaths are particularly driven by opioids and synthetic opioids. These data do not include deaths from excessive alcohol use, which results in around 29 deaths per 100,000. There can be no doubt that SUDs are a significant public health problem in the U.S. and that healthcare professionals and pharmacologists need timely information to make informed decisions about treatment and prevention of SUDs.

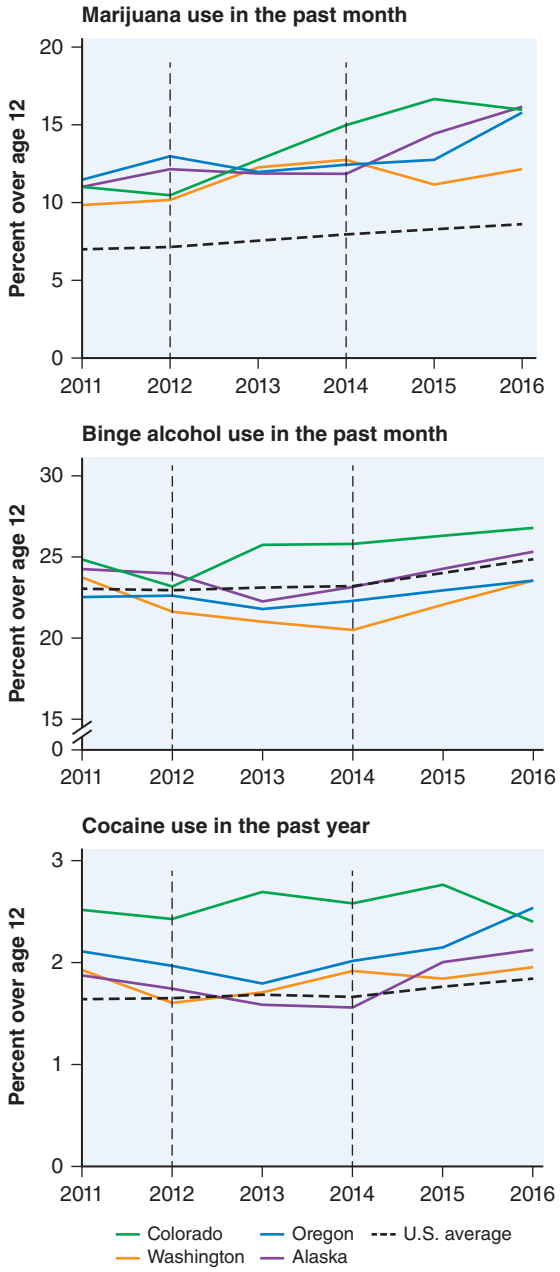

Figure 28–5 *No remarkable effects of marijuana legalization in four states on cocaine use and binge alcohol drinking.* Marijuana use was legalized in Colorado and Washington in 2012 and in Oregon and Alaska in 2014. Population age 12 and older was surveyed. Marijuana use and binge alcohol use were surveyed for 1 month of the year indicated, and cocaine use was surveyed for the entire year. Marijuana use was above the U.S. average in states that legalized recreational use and increased further after legalization. Binge alcohol use stayed within the U.S. national average, while cocaine use did not significantly change. (Data from Substance Abuse and Mental Health Services Administration, 2020.)

National Institute on Drug Abuse (NIDA) and National Institute on Alcohol Abuse and Alcoholism (NIAAA)

The National Institute on Drug Abuse (NIDA) supports research on drug use and its consequences (https://www.drugabuse.gov/). This includes understanding how drugs work in the brain and throughout the body, developing and testing new SUD treatment and prevention approaches, and tracking emerging drug use trends. NIDA funds the National Drug Early Warning System (NDEWS), a source with the most up-to-date

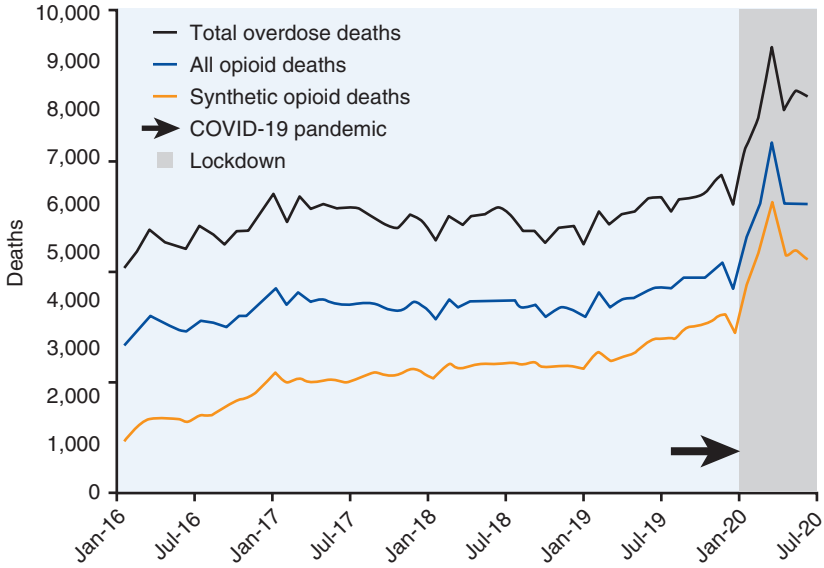

Figure 28–6 *The impact of the COVID-19 pandemic on overdose deaths in the U.S.* Numbers are fatalities per time unit. (Data from Ahmad et al., 2021.)

information on emerging substance use trends (Cottler et al., 2020). On the NDEWS website, pharmacologists can find information about novel psychoactive substances emerging in communities throughout the U.S. AUDs, though arguably among SUDs, are handled through a different entity, the National Institute on Alcohol Abuse and Alcoholism (NIAAA; https://www.niaaa.nih.gov/). AUD-relevant information is found on the NIAAA website, including the National Epidemiologic Survey on Alcohol and Related Conditions.

Substance Use and Mental Health Services Administration (SAMHSA)

SAMHSA, an agency within the U.S. Department of Health and Human Services, has the mission of reducing the impact of substance abuse and mental illness on U.S. communities and to improve SUD prevention, treatment, and recovery services (https://www.samhsa.gov/). Through the National Survey on Drug Use and Health, SAMHSA provides up-to-date information on tobacco, alcohol, and drug use (SAMHSA, 2020). Data collected in 2019 showed that 13.0% of people aged 12 or older (35.8 million people) used an illicit drug in the past month.

U.S. Drug Enforcement Administration (DEA), Controlled Substances Act, and Drug Schedules

The DEA, a branch of the Department of Justice, is charged with enforcing the controlled substances laws (https://www.dea.gov/). Drugs, other substances, and certain chemicals used to make drugs are classified into five distinct categories or schedules (see Table 28–1). Classification takes into consideration a drug's approved medical use and its abuse potential; new substances are added on a regular basis. The DEA publishes the annual National Drug Threat Assessment (NDTA), a comprehensive assessment of the threat posed to the U.S. by illicit drugs (DEA Strategic Intelligence Section, 2021). The NDTA also combines SUD-relevant information from the CDC, such as overdose deaths by specific drugs. Moreover, in its annual update, it lists new psychoactive substances that have entered the U.S.

Clinical and Pharmacological Topics: CNS Depressants

Alcohol is the most commonly used CNS depressant. Persons with SUDs frequently use multiple drugs in combination, most often in combination with ethanol, leading to combined SUDs and AUD (see Figure 28–4). When confronted with a patient exhibiting signs of overdose or withdrawal, these possible combinations will require different and specific treatments.

Alcohol (Ethanol) and Alcohol Use Disorder

More than 90% of American adults report experience with ethanol ("alcohol"), and over 50% report alcohol intake in the past month (Figure 28–7) (SAMHSA, 2020). While SAMHSA's annual numbers of AUD in persons 12 years and older are between 5% and 6%, studies in persons 18 years and older find even higher numbers and a lifetime prevalence of 29.1% (Grant et al., 2015). Alcohol use continues to be one of the deadliest substances, with liver disease and alcohol-related accidents causing approximately 95,000 deaths every year.

Ethanol is classified as a depressant because it produces sedation and sleep. However, the initial effects of alcohol, particularly at lower doses, are often perceived as stimulating owing to a suppression of inhibitory systems. Heavy use of ethanol causes the development of tolerance and physical dependence sufficient to produce an alcohol withdrawal syndrome when intake is stopped (Table 28–5).

Tolerance, Physical Dependence, and Withdrawal

The symptoms of mild intoxication by alcohol vary among individuals. Some experience motor incoordination and sleepiness. Others initially become stimulated. As the blood level increases, the sedating effects increase, with eventual coma and death occurring at high blood alcohol levels. The innate tolerance to alcohol varies greatly among individuals and is often traced to a family history of alcoholism (Hu et al., 2005). Experience with alcohol can produce greater tolerance (acquired tolerance) such that extremely high blood levels (300–400 mg/dL) may occur in alcoholics who do not appear grossly sedated. In these cases, the lethal dose does not increase proportionately to the sedating dose; thus, the margin of safety is decreased.

The development of tolerance and dependence by heavy drinkers often leads to drinking in the morning to restore blood alcohol levels diminished during the night. The alcohol withdrawal syndrome generally depends on the amount of the average daily dose and usually is "self-medicated" by resumption of alcohol ingestion. Withdrawal symptoms are experienced frequently but usually are not severe or life threatening unless they occur in conjunction with other problems, such as infection, trauma, malnutrition, or electrolyte imbalance. In the context of such complications, the syndrome of *delirium tremens* becomes likely, especially after a long period of heavy drinking in people with an AUD, which under the most severe situation can lead to seizures and death.

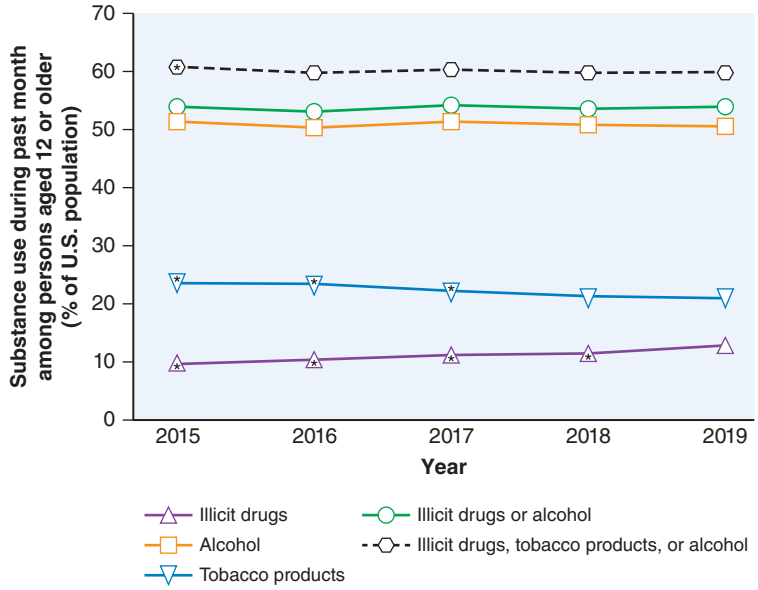

Figure 28–7 *Experience with substance use during 1 month annually among persons aged 12 or older in the U.S. from 2015 to 2019.* Asterisk denotes the difference to 2019 at $p \leq 0.05$. (Data from Substance Abuse and Mental Health Services Administration, 2020; data retrieved June 4, 2021.)

AUD produces cross-tolerance to other sedatives, such as benzodiazepines. This tolerance is present in abstinent alcoholics, but while drinking, it can enhance the properties of other sedatives. This is particularly true for benzodiazepines, which are relatively safe when given alone but are potentially lethal in combination with alcohol. The chronic use of alcohol and other sedatives is associated with the development of depression and the risk of suicide. Cognitive deficits have been reported in individuals with AUD even when tested while sober. These deficits usually improve with abstinence. More severe memory impairments are caused by neurological disorders due to nutritional deficiencies (e.g., thiamine deficiency) common in those with excessive alcohol consumption. Medical complications of alcohol abuse and dependence include liver disease, cardiovascular disease, endocrine and gastrointestinal effects, and malnutrition, in addition to the CNS dysfunctions noted above. Ethanol readily crosses the placental barrier, producing fetal alcohol syndrome that can lead to intellectual disability in the offspring.

TABLE 28–5 ■ ALCOHOL WITHDRAWAL SYNDROME

Alcohol craving
Tremor, irritability
Nausea
Sleep disturbance
Tachycardia
Hypertension
Sweating
Perceptual distortion
Seizures (6–48 h after last drink)
Visual (and occasionally auditory or tactile) hallucinations (12–48 h after last drink)
Delirium tremens (48–96 h after last drink; rare in uncomplicated withdrawal)
Severe agitation, confusion
Fever, profuse sweating
Tachycardia, dilated pupils
Nausea, diarrhea

Data from Substance Abuse and Mental Health Services Administration, 2020.

Pharmacological Interventions

For treating AUD, the American Psychiatric Association recommends that treatment be initiated after a thorough clinical evaluation for co-occurring conditions and supplemented with behavioral therapies.

Detoxification. Although most mild cases of alcohol withdrawal never come to medical attention, severe cases require general evaluation; attention to hydration and electrolytes; vitamins, especially high-dose thiamine; and a sedating medication that has cross-tolerance with alcohol. To block or diminish the symptoms described in Table 28–5, a short-acting benzodiazepine such as *oxazepam* can be used at a dose of 15 to 30 mg every 6 to 8 h according to the stage and severity of withdrawal. However, benzodiazepines should be avoided in AUD beyond treatment of acute withdrawal (Reus et al., 2018). Anticonvulsants such as *carbamazepine* also have been shown to be effective in alcohol withdrawal.

Pharmacotherapy. Detoxification is the immediate goal, and doing so in a medically controlled setting will reduce negative effects of the withdrawal syndrome. Complete abstinence is the objective of long-term treatment, and this is best accomplished by a combination of relapse prevention, anticraving medication, and cognitive behavioral therapy. Various pharmacotherapies are available for treating AUD after detoxification. Of these, three are FDA-approved for AUD: *disulfiram*, *naltrexone*, and *acamprosate*.

Disulfiram has been useful in some programs that focus behavioral efforts to promote ingestion of the medication. *Disulfiram* blocks aldehyde dehydrogenase (see Chapter 27), resulting in the accumulation of acetaldehyde, which produces an unpleasant flushing reaction and nausea when alcohol is ingested. Knowledge that this unpleasant reaction will ensue may help the patient to resist the urge to resume drinking alcohol. However, *disulfiram* has not proven to be effective in controlled clinical trials because so many patients choose to stop taking the medication rather than the alcohol.

Naltrexone, an opioid receptor antagonist, blocks the endorphin activation properties of alcohol. *Naltrexone* is available in both PO (25, 50, or 100 mg) and extended-release IM formulations (e.g., Vivitrol; 380 mg IM injected every 4 weeks). Chronic administration of *naltrexone* decreases the rate of relapse to heavy drinking in randomized clinical trials. The effects varied from strong to weak, but overall, reduction in heavy drinking is a consistent finding (de Laat et al., 2021). *Naltrexone* works best in combination with behavioral treatment programs that encourage

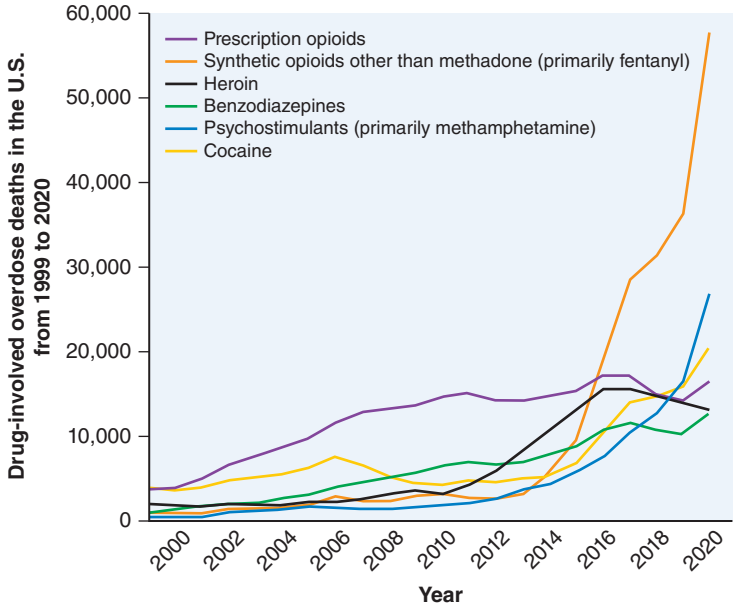

Figure 28–8 *Annual drug-involved overdose deaths in the U.S. between 1999 and 2020.* (Data retrieved from Centers for Disease Control and Prevention, National Center for Health Statistics. Multiple Cause of Death 1999–2020 on CDC WONDER Online Database, released in 2021. Data are from the Multiple Cause of Death Files, 1999–2020, as compiled from data provided by the 57 vital statistics jurisdictions through the Vital Statistics Cooperative Program. Accessed at http://wonder.cdc.gov/mcd-icd10.html on December 23, 2021.)

adherence to medication and abstinence from alcohol. *Naltrexone* is also approved for the treatment of opioid use disorder (OUD; see below).

Acamprosate, a mixed-acting antagonist at NMDA (*N*-methyl-D-aspartate) receptors and a positive allosteric modulator of $GABA_A$ receptors, appears to normalize the dysregulated neurotransmission associated with chronic ethanol intake, thereby attenuating one of the mechanisms that lead to relapse. *Acamprosate* is administered PO in delayed-release formulation (two 333-mg tablets three times a day). *Acamprosate* may also have neuroprotective actions.

Gabapentin has been studied off-label as an aid in the transition to the abstinent state, possibly by improvement in sleep and mood disturbance (PO 900–1800 mg/day). *Gabapentin,* also used as an anticonvulsant, indirectly reduces NMDA glutamate receptor function by disrupting voltage-dependent Ca^{2+} channels (see Chapters 16 and 20).

Topiramate, an anticonvulsant that inhibits carbonic anhydrase, can inhibit the reinforcing effect of alcohol. Like other therapeutic agents used in AUD, *topiramate* facilitates $GABA_A$ activity and suppresses glutamatergic activity.

Opioids and Opioid Use Disorder

Opioid agonists activate the MOR in pain pathways and are strong analgesics (see Chapter 23). They also stimulate the reward pathway, which makes them liable for misuse. Because of the high plasticity within the opioid system and the rapid adaptation to opioid exposure, these drugs have a high allostatic load (see Figure 28–3). Importantly, opioids inhibit the respiratory center in the brain, which explains the high risk of lethal overdose associated with their use.

Opioid Overdose

Nearly 70% of all drug overdose deaths in the U.S. in 2018 involved an opioid (DEA Strategic Intelligence Section, 2021; Wilson et al., 2020). The purity of street heroin in the U.S. has increased over the past decade from about 4% (4 mg heroin per 100-mg bag; range 0–8 mg/100 mg; the rest was nonopioid filler such as quinine) to a purity of 45% to 75% (45–75 mg heroin per 100-mg bag), with some samples testing as high as 90%. This increase in purity has led to increased levels of physical dependence among heroin addicts. Users who interrupt regular dosing now develop more severe withdrawal symptoms. The more potent supplies can be smoked or administered nasally (snorted), making heroin use accessible to people who would not insert a needle into their veins.

While deaths involving heroin have decreased by 4%, deaths due to other synthetic opioids such as *fentanyl* and *fentanyl analogues* are on the rise (Wilde et al., 2019) (Figure 28–8). *Fentanyl* is extremely powerful, 50 to 100 times more potent than *morphine* and 10 times more potent than heroin. *Fentanyl* is sometimes added to illicit drugs such as cocaine and to counterfeit "pharmaceutical" pills. Because of its extreme potency, *fentanyl* is a significant contributor to the increasing rates of overdose deaths in the U.S.

The most troubling issue with opioid dependence was initiated by changes in medical practice. At the turn of the 21st century, increasing interest in minimizing pain combined with intense marketing by the pharmaceutical industry changed prescription opioid practices. In some cases, clear overprescribing, especially of extended-release formulations of *oxycodone*, led to an epidemic of abuse, addiction, and overdose deaths (see Figure 28–8). Sales of *oxycodone* and *hydrocodone* peaked in 2012 (Figure 28–9), and opioid overdoses became a common cause of death in many communities. In the absence of FDA action, the CDC stepped in with prescribing guidelines (Dowell et al., 2016). States followed with prescription drug monitoring programs, electronic databases that track controlled substance prescriptions in each state.

With the stringent control of opioid prescriptions, heroin and other illegal synthetic opioids became the drugs of choice. Although there is no legal supply of heroin in the U.S., the drugs are brought into the country by transnational criminal organizations. Use of illegal opioids has increased significantly over the past 20 years, and a concomitant increase in overdose deaths has been observed. This public health crisis created by a combination of good intentions, financial opportunities, inadequate critical evaluation, and insufficient regulatory oversight serves as a cautionary tale how to approach and evaluate the opportunities and downsides of pharmacological therapies and treatments.

Opioid Tolerance, Dependence, and Withdrawal

Injection of a potent opioid produces a high and intense pleasure ("rush") often compared with sexual orgasm. There are some differences among the opioids in their acute effects; for instance, *morphine* and *codeine* produce a more prominent histamine-releasing effect (causing itching), whereas *meperidine* is notable for producing excitation or confusion.

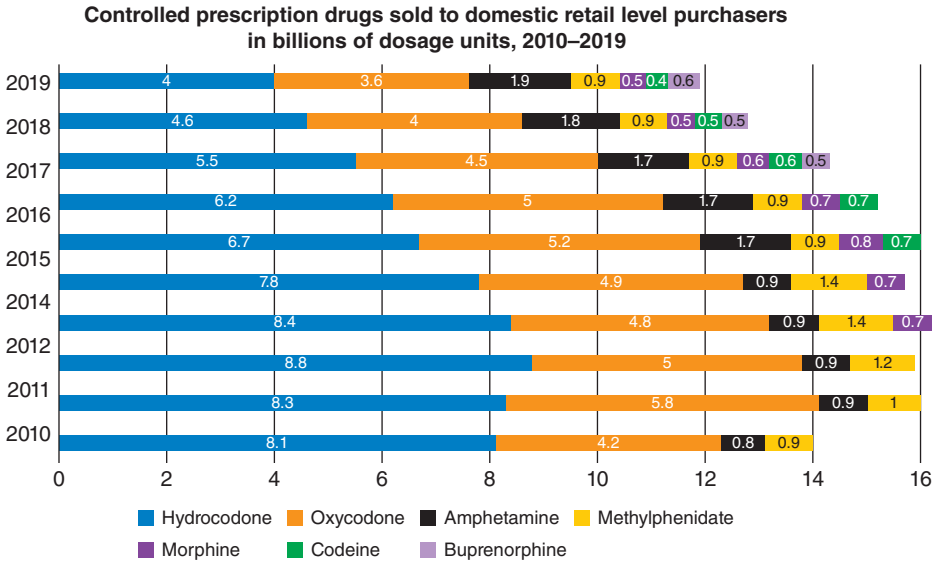

Figure 28–9 *Controlled prescription drugs sold to domestic retail level purchasers in billions of dosage units.* (Data from U.S. Drug Enforcement Administration, 2020 National Drug Threat Assessment, https://www.dea.gov/documents/2021/03/02/2020-national-drug-threat-assessment)

Even experienced opioid addicts, however, cannot distinguish between intravenously administered heroin and the common opioid *hydromorphone*, often used for pain management in hospitalized patients.

Heroin has high lipid solubility, crosses the blood-brain barrier quickly, and is deacetylated to the active metabolites 6-monoacetyl morphine and morphine. After the intense euphoria, which lasts from 45 sec to several minutes, there is a period of sedation and tranquility ("on the nod") lasting up to an hour. The effects of heroin wear off in 3 to 5 h, depending on the dose. Experienced users may inject two to four times daily. Thus, the heroin-addicted individual is constantly oscillating between being "high" and feeling the sickness of early withdrawal (as depicted in Figure 28–10). This produces many problems in the homeostatic systems regulated at least in part by endogenous opioids.

Tolerance develops early to the euphoria-producing effects of heroin and other opioids (Figure 28–3). While there is tolerance to the respiratory depressant, analgesic, sedative, and emetic properties, the levels of tolerance in the different systems vary. Thus, while increasing doses are needed to maintain a level of euphoria, reduced adaptations of the respiratory system to increasing doses can lead to death. Overdose is likely to occur when potency of the street sample is unexpectedly high or when the heroin is mixed with a more potent synthetic opioid such as *fentanyl*.

Addiction to heroin or other short-acting opioids produces behavioral disruptions and usually becomes incompatible with a productive life. Chronic heroin use is associated with pulmonary infections (especially tuberculosis), and when injected, it is associated with bacterial infections, skin abscesses, endocarditis, and viral infections such as hepatitis C and AIDS (acquired immunodeficiency syndrome).

Opioids are frequently used in combination with other drugs, such as heroin and cocaine ("speedball"). Users report improved euphoria with that combination, and there is evidence of reducing negative side effects of the other substance. For example, cocaine can reduce the signs of opiate withdrawal, and heroin may reduce the irritability seen in chronic users of cocaine.

Pharmacological Interventions for Opioid Use Disorders

Withdrawal and Detoxification. The first stage of treatment generally addresses physical dependence and detoxification. The opioid withdrawal syndrome (Table 28–6), though unpleasant, is not life threatening. It begins within 6 to 12 h after the last dose of a short-acting opioid and as long as 72 to 84 h after a long-acting opioid medication. The duration and

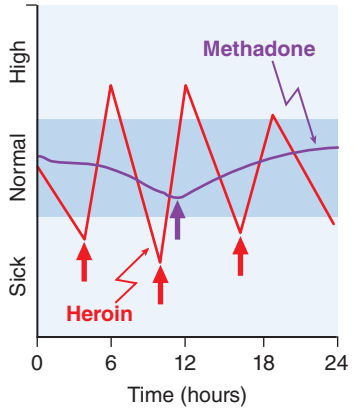

Figure 28–10 *Comparative time courses of response to heroin and methadone.* A person who injects heroin (↑) several times per day oscillates between being sick and being high (red line). In contrast, a *methadone* patient (purple line) remains in the "normal" range (blue band) with little fluctuation after dosing once per day. Ordinate values represent the subject's mental and physical state, not plasma levels of the drug.

TABLE 28–6 ■ CHARACTERISTICS OF OPIOID WITHDRAWAL

SYMPTOMS	SIGNS
Regular withdrawal	Pupillary dilation
Craving for opioids	Sweating
Restlessness, irritability	Piloerection ("gooseflesh")
Increased sensitivity to pain	Tachycardia
Nausea, cramps	Vomiting, diarrhea
Muscle aches	Increased blood pressure
Dysphoric mood	Yawning
Insomnia, anxiety	Fever
Protracted withdrawal	Cyclic changes in weight, pupil size, respiratory center sensitivity
Anxiety	
Insomnia	
Drug craving	

Data from Ahmad et al., 2021.

intensity of the syndrome relate to the $t_{1/2}$ of the agent. Thus, heroin withdrawal is brief (5–10 days) and intense, whereas *methadone* withdrawal is slower in onset and longer-lasting.

Opioid withdrawal signs and symptoms are normally treated pharmacologically. The most common approach consists of the transfer to a medically managed prescription opioid medication and then gradual dose reduction. Addiction to short-acting opioids such as heroin is most frequently treated with a long-acting opioid such as *methadone*, a full MOR agonist. The initial dose of *methadone* for the purposes of withdrawal is typically 20 to 30 mg. The first day's total dose can be determined by the response and then reduced by 20% per day during the course of detoxification. Although the duration of the *methadone* detoxification regimen is not correlated to better long-term outcomes, long-term maintenance of *methadone* treatment to prevent relapse and allow restoration of social connections is associated with better outcomes. *Buprenorphine*, a long-acting partial agonist with high affinity to the MOR, is also used to induce detoxification. Initial *buprenorphine* sublingual dose is typically 2 mg, and if well tolerated, subsequent 2-mg doses are administered every 1 to 2 h, titrating up to a total dose of 8 mg with gradual tapering during the course of detoxification.

A second approach during detoxification involves the use of oral *clonidine*, an α_2 adrenergic agonist that decreases adrenergic neurotransmission from the locus coeruleus. This medication is approved for the treatment of hypertension but is commonly used off-label to reduce symptoms of opioid withdrawal (0.1–0.3 mg PO every hour up to four doses). Many of the autonomic symptoms of opioid withdrawal, such as rhinorrhea and lacrimation, result from the loss of opioid suppression of the locus coeruleus system during the abstinence syndrome. *Clonidine* can alleviate many of these symptoms, although not the generalized aches and opioid craving. *Lofexidine*, a similar medication, is FDA-approved for use as an opioid withdrawal suppressant and administered PO at 3.2 mg/day split into four doses. With *clonidine* and *lofexidine*, the dose must be titrated according to the stage and severity of withdrawal; postural hypotension is a common side effect.

A third strategy for treating opioid withdrawal involves activation of the endogenous opioid system without medication. The techniques proposed include acupuncture and several methods of CNS activation such as transcranial magnetic stimulation, transcranial direct current stimulation, and auricular vagus nerve stimulation. These approaches may have therapeutic benefits by directly or indirectly modulating the neurocircuitry affected in OUD. While attractive theoretically, these strategies are not yet validated or currently implemented in the clinic.

Long-Term Management of OUDs. While in-patient detoxification is an important first start for treating OUDs, the probability of a quick return to compulsive opioid use is high if patients are discharged from the hospital after withdrawal from opioids without follow-up care. Numerous factors influence relapse. The withdrawal syndrome does not end in 5 to 7 days; a *protracted withdrawal syndrome* (see Table 28–6) can persist for up to 6 months. Physiological measures tend to oscillate, and the allostatic changes leave an extended mark of anxiety, insomnia, and drug craving (see Figure 28–3); during this phase, outpatient drug-free treatment has a very low probability of success, even when the patient has received intensive prior treatment while protected from relapse in a residential program.

Three medications have been approved for long-term OUD management by the FDA: *methadone*, *buprenorphine*, and extended-release *naltrexone*.

Opioid Agonist Treatment. Stabilization and maintenance on *methadone* is considered the most successful treatment of heroin addiction. *Methadone* is available as an oral solution, injectable solution, and tablet. Oral *methadone* has the strongest evidence for effectiveness and has a $t_{1/2}$ of 22 to 24 h. It is typically given as a liquid, with a starting dose of 20 mg/day and titrated up in increments to 60 to 80 mg/day. Patients who relapse repeatedly during drug-free treatment can be transferred directly to *methadone* without requiring detoxification. While treatment with *methadone* has the risk of diversion and misuse of medication, it is a safer alternative to short-acting potent opioids.

The introduction of *buprenorphine* represented a major change in the treatment of OUD. This medication produces minimal withdrawal symptoms when discontinued, has a low potential for overdose, and has a long duration of action. As a partial agonist, *buprenorphine* has ceiling effects on respiratory depression and thus is considered safer than *methadone* for agonist substitution treatment. However, it can precipitate withdrawal and patients need to be abstinent from other opioids before treatment is initiated. The period of abstinence is determined by the $t_{1/2}$ of the opioid the patient has been using. *Buprenorphine* is available as transmucosal tablets or film strips (4–16 mg/day). This is the first OUD treatment that can be prescribed or dispensed in a qualified physician's private office (upon obtaining a special federal waiver) rather than in a specialized clinic, as required for *methadone*. Although *buprenorphine* has a mild addictive potential, it can still be misused if it is snorted as a powder or dissolved and injected. As a solution to this problem, a combination of *buprenorphine* with *naloxone*, a short-acting MOR antagonist, is available. The oral bioavailability of *naloxone* is low (1%–3%), and thus, when *naloxone* is taken orally (sublingually), it is not effective; however, if the patient misuses the medication by injecting a solution of it, the *naloxone* component will block or diminish the subjective high that could be produced by *buprenorphine* alone. An alternative to daily *buprenorphine* is extended-release depot *buprenorphine*, which has shown greater patient satisfaction (Lintzeris et al., 2021).

Interestingly, supervised injectable opioid treatment (e.g., prescribed pharmaceutical heroin) is available in Canada and some European countries but not in the U.S. (Bell et al., 2020).

Opioid Antagonist Treatment. *Naltrexone* is an antagonist with a high affinity for MOR; it will competitively block the effects of heroin and other MOR agonists and is approved for both opioid dependence and alcohol dependence (see section on AUD). *Naltrexone* will not satisfy craving or relieve protracted withdrawal symptoms but will reduce opioid intake and overdose. An extended-release injectable depot version of *naltrexone* is available, since oral *naltrexone* has had limited effectiveness (Lott, 2018). As an MOR antagonist, *naltrexone* will precipitate withdrawal, so individuals who are being treated with *naltrexone* must abstain from all opioids for approximately 7 days before the treatment is initiated.

Naloxone, a full MOR antagonist, has a rapid onset of action that is useful as an emergency measure to acutely treat opioid overdoses. It is available as an injectable (0.4 and 1 mg/mL) and as a nasal spray (4 or 8 mg of *naloxone*) that can be administered even by persons not medically trained. *Naloxone* precipitates opioid withdrawal, which is unpleasant (Table 28–6) but lifesaving by reversing respiratory depression. Persons in opioid-induced respiratory distress must receive medical help since multiple doses of *naloxone* might be required over 24 h until opioid levels in the system decline. The *naloxone* will be competing against an unknown quantity of an MOR agonist; the $t_{1/2}$ of *naloxone* is 60 to 90 min, shorter than the half-lives of the effects of the abused opiates (see Chapter 23). This consideration is particularly critical with overdoses of highly potent opioid agonists such as *fentanyl*. Once a patient in overdose arrives at a medical center, the recommended dosing schedule with *naloxone* is 0.4 or 1 mg IV; dosing might require multiple administrations or continuous infusion (2.5 μg/kg/h) to prevent the occurrence of respiratory depression.

Benzodiazepines

Benzodiazepines, commonly used as sedatives and hypnotics (see Chapters 16 and 22), are, under some circumstances, also used acutely for alcohol detoxification. These agents are widely prescribed, and their abuse is not uncommon. Addiction to benzodiazepines is considered a "hypnotic, sedative, or anxiolytic use disorder." The proportion of patients who become tolerant and physically dependent on benzodiazepines increases after several months of use, and abrupt reduction of the dose or stopping the medication produces withdrawal symptoms (Table 28–7). Drug poisoning deaths by benzodiazepines are one of the

TABLE 28–7 ■ BENZODIAZEPINE WITHDRAWAL SYMPTOMS

Following moderate-dose usage
Anxiety, agitation
Increased sensitivity to light and sound
Paresthesias, strange sensations
Muscle cramps
Myoclonic jerks
Sleep disturbance
Dizziness
Following high-dose usage
Seizures
Delirium

decline (see Figure 28–7), but the number of deaths involving the combination of benzodiazepines and opioids has increased, likely due to the fact that both types of drugs suppress respiratory drive.

It can be difficult to distinguish benzodiazepine withdrawal symptoms from the reappearance of the anxiety symptoms for which the benzodiazepine was originally prescribed. Some patients may increase their dose over time as tolerance develops to the sedative effects. Antianxiety benefits, however, seem to continue long after tolerance to the sedating effects has developed. Other patients take the medication for years according to medical directions and function effectively because they take the medication. Patients with a history of alcohol or other drug abuse problems have an increased risk for the development of benzodiazepine abuse and should rarely, if ever, be treated with benzodiazepines on a chronic basis.

Pharmacological Interventions

Patients on long-term prescribed benzodiazepine treatments who wish to stop their medication are able to do so in an outpatient setting, but the process may take months of gradual dose reduction. Withdrawal symptoms may occur, but in most cases, the symptoms are mild. Patients who have been on low doses of benzodiazepines for years usually have no adverse effects. If symptoms of anxiety return, a nonbenzodiazepine such as *buspirone* may be prescribed. Some authorities recommend transferring the patient to a benzodiazepine with a long $t_{1/2}$ during detoxification; others recommend the use of anticonvulsants *carbamazepine* and *phenobarbital*. Intravenous administration of the selective $GABA_A$ receptor antagonist *flumazenil* is useful as an antidote in the treatment of benzodiazepine overdose and in reversing the postsurgical effects of long-acting benzodiazepines used as anesthetics.

Abusers of high doses of benzodiazepines usually require inpatient detoxification. Frequently, benzodiazepine abuse is part of a combined dependence involving alcohol, opioids, and cocaine. Detoxification can be a complex clinical pharmacological challenge requiring knowledge of the pharmacokinetics of each drug. One approach to complex detoxification is to focus on the nonopioid components while temporarily holding the opioid component constant with a low dose of *methadone* or *buprenorphine*. A long-acting benzodiazepine such as *diazepam* or *clorazepate* or a long-acting barbiturate such as *phenobarbital* can be used to block the sedative withdrawal symptoms. After detoxification, the prevention of relapse requires long-term outpatient rehabilitation similar to the treatment of alcoholism. No specific medications have been found to be useful in the rehabilitation of sedative abusers; specific psychiatric disorders such as depression or schizophrenia, if present, require appropriate medications.

Barbiturates

Barbiturates have sedative-hypnotic, anticonvulsant, anesthetic, and respiratory depressant effects. Barbiturates facilitate the activity of $GABA_A$ receptors at allosteric sites that are distinct from the benzodiazepine binding site (see Figure 16–11). Because of their higher abuse and overdose potential, barbiturates are less commonly prescribed than benzodiazepines. Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways, and treatment of abuse and addiction to barbiturates should be handled similarly to interventions for the abuse of alcohol and benzodiazepines. Because drugs in this category frequently are prescribed as hypnotics for patients complaining of insomnia, physicians should be aware of the problems that can develop when the hypnotic agent is withdrawn and of possible causes for insomnia that are treatable by other means. Insomnia is often a symptom of an underlying chronic problem, such as depression or respiratory dysfunction. Long-term prescription of sedative medications can change the physiology of sleep and should be avoided. When the sedative is stopped, there is a rebound effect with worsened insomnia. Whether from prescribed hypnotic or self-administered alcohol, medication-induced rebound insomnia requires detoxification by gradual dose reduction. Patients should be dissuaded from a bedtime drink of alcohol to relieve insomnia since alcohol can result in disordered sleep.

Nicotine

Nicotine and agents for smoking cessation are discussed in depth in Chapter 13. Because nicotine is the source of reinforcement of cigarette smoking, the most common cause of preventable death and disease in the U.S., it is arguably the most dangerous dependence-producing drug. Although more than 80% of smokers express a desire to quit, only 35% try to stop each year, and fewer than 5% are successful in unaided attempts to quit.

Tobacco (nicotine) use disorder is influenced by multiple variables. Nicotine itself produces reinforcement; users compare nicotine to stimulants such as cocaine or amphetamine, although its effects are of lower euphorigenic magnitude. To avoid the addictive effects of nicotine, one would need to smoke no more than 5 cigarettes daily. Many individuals who smoke cigarettes do not constrain themselves to such a small number. In 2019, approximately 11 million people smoked 16 or more cigarettes per day. Nicotine is absorbed readily through the skin, mucous membranes, and lungs. The pulmonary route produces discernible CNS effects in as little as 7 sec. Thus, each puff produces discrete positive reinforcement. With 10 puffs per cigarette, the 1-pack-per-day smoker reinforces the habit 200 times daily.

In dependent smokers, the urge to smoke correlates with a low blood nicotine level, as though smoking were a means to achieve a certain physiological nicotine level to avoid nicotine withdrawal symptoms (Table 28–8). As with other drugs of abuse, nicotine withdrawal involves both physical and mood-related symptoms such as craving, anxiety, depression, insomnia, constipation, or diarrhea. Like with many SUDs, depressed mood (dysthymic disorder, affective disorder) is associated with tobacco use disorder, but it is not known whether depression can predispose one to begin smoking or whether depression develops secondarily during the course of nicotine dependence.

Pharmacological Interventions

The nicotine withdrawal syndrome can be alleviated by nicotine replacement therapy (e.g., nicotine inhaler and nasal spray, nicotine gum or lozenge, or nicotine transdermal patch). Different methods of nicotine delivery provide different blood nicotine levels over varying time courses

TABLE 28–8 ■ NICOTINE WITHDRAWAL SYMPTOMS

Irritability, impatience, hostility
Anxiety
Dysphoric or depressed mood
Difficulty in concentrating
Restlessness
Decreased heart rate
Increased appetite or weight gain

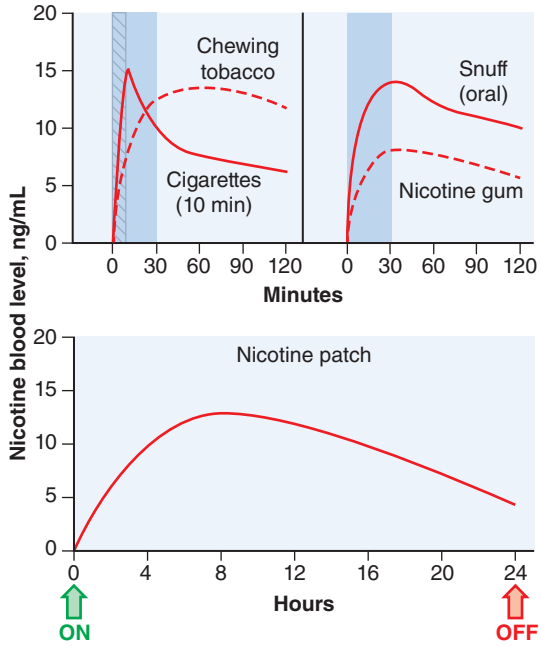

Figure 28–11 *Blood levels of nicotine resulting from different delivery systems.* In the upper panels, the shaded areas indicate the periods of nicotine delivery (30 min except for cigarettes, 10 min). In the lower panel, the arrows indicate the times of application and removal of a nicotine patch. These idealized curves are based on the findings of experiments by Benowitz et al. (1988) and Srivastava et al. (1991).

(Figure 28–11). These methods suppress the symptoms of nicotine withdrawal. Although these treatments result in more smokers achieving abstinence, most resume smoking over the ensuing weeks or months. A sustained-release preparation of the antidepressant *bupropion* (see Chapter 18) improves abstinence rates among smokers and remains a useful option. The cannabinoid CB_1 receptor inverse agonist *rimonabant* shows modest improvement of abstinence rates and reduces weight gain seen frequently in ex-smokers; unfortunately, *rimonabant* was linked to significant adverse depressive and neurological symptoms and is not approved for use in the U.S.

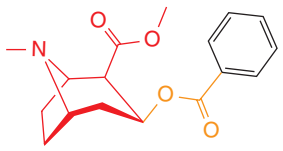
Varenicline, a partial agonist at the $\alpha_2\beta_4$ subtype of the nicotinic acetylcholine receptor, reduces cigarette craving and improves long-term abstinence rates. It has a high receptor affinity and blocks nicotine's access to the receptor. If the treated smoker relapses, there is little reward, and abstinence is more likely to be maintained. A systematic review and multiple treatment meta-analysis of various nicotine cessation replacement therapies showed *varenicline* to be the most effective over time (Mills et al., 2012). See Chapter 13 for more on the pharmacology of *varenicline*.

Clinical and Pharmacological Topics: Psychostimulants

Cocaine

In the U.S., the number of people aged 12 years or older who used cocaine in 2019 was 5.5 million (SAMHSA, 2020). Not all users, however, become addicted. Twenty percent of people who used cocaine met the criteria for SUD defined by the DSM-5 (American Psychiatric Association, 2013). A key factor in addiction is the widespread availability of relatively inexpensive cocaine in the alkaloidal form (free base, "crack"), suitable for smoking, and in the hydrochloride powder form, suitable for nasal or intravenous use.

The reinforcing effects of cocaine and its analogues correlate best with their effectiveness in inhibiting the dopamine transporter (DAT), which takes up DA from the synapse back into cells (see Figure 15–9). This leads to increased DA concentrations at brain sites mediating reward. However, cocaine also blocks both NE and 5HT reuptake, and chronic use of cocaine leads to changes in these neurotransmitter systems as well. Cocaine produces a dose-dependent increase in heart rate and blood pressure accompanied by increased arousal, improved performance on tasks of vigilance and alertness, and a sense of self-confidence and well-being. Higher doses produce euphoria, which has a brief duration and often is followed by a desire for more drug. Repeated doses of cocaine may lead to involuntary motor activity, stereotyped behavior, and paranoia. Irritability and increased risk of violence are found among heavy chronic users. The $t_{1/2}$ of cocaine in plasma is about 50 min, but inhalant (crack) users typically desire more cocaine after 10 to 30 min.



COCAINE

The major route for cocaine metabolism involves hydrolysis of its two ester groups. Tissue esterases and spontaneous hydrolysis remove the methyl ester to produce benzoylecgonine (30%–40%); removal of the benzoyl moiety by butyrylcholinesterase yields ecgonine methyl ester (~50%). Benzoylecgonine, produced on loss of the methyl group, is the major urinary metabolite and can be found in the urine for 2 to 5 days after a binge. As a result, the *benzoylecgonine test* is a valid method for verifying cocaine use; the metabolite can remain detectable in the urine of heavy users for up to 10 days.

Ethanol is frequently abused with cocaine, as it reduces the irritability induced by cocaine. Dual addiction to alcohol and cocaine is common. When cocaine and alcohol are taken concurrently, cocaine may be transesterified to cocaethylene, which is equipotent to cocaine in blocking DAT.

Addiction is the most common complication of cocaine abuse. In general, stimulants tend to be abused more irregularly than opioids, nicotine, and alcohol. Binge use is common, and a binge may last hours to days, terminating only when supplies of the drug are exhausted.

Toxicity

Risks of cocaine, beyond the potential for addiction, include cardiac arrhythmias, myocardial ischemia, myocarditis, aortic dissection, cerebral vasoconstriction, and seizures. Death from traumatic injuries is also associated with cocaine use. Cocaine may induce premature labor and *abruptio placentae*. Cocaine has been reported to produce a prolonged and intense orgasm if taken prior to intercourse, and users often indulge in compulsive and promiscuous sexual activity. However, chronic cocaine use reduces sexual drive. Chronic use is also associated with psychiatric disorders, including anxiety, depression, and psychosis.

Tolerance, Dependence, and Withdrawal

In intermittent users, the euphoric effect of cocaine is typically not subject to sensitization. In contrast, most experienced users become desensitized and, over time, require more cocaine to obtain euphoria (i.e., tolerance develops). Because cocaine typically is used intermittently, even heavy users go through frequent periods of withdrawal or "crash." The symptoms of withdrawal seen in users admitted to hospitals are listed in Table 28–9. Careful studies of cocaine users during withdrawal showed gradual diminution of these symptoms over 1 to 3 weeks. Residual depression, often seen after cocaine withdrawal, should be treated with antidepressant agents if it persists (see Chapter 18).

Pharmacological Interventions

The physiological aspects of cocaine withdrawal are generally mild. The major problem in treatment is not detoxification but helping the patient to resist the urge to resume compulsive cocaine use. At present, there are no medications approved by the FDA to treat cocaine addiction.

TABLE 28–9 ■ COCAINE WITHDRAWAL SYMPTOMS AND SIGNS

Dysphoria, depression
Sleepiness, fatigue
Cocaine craving
Bradycardia

Data from U.S. Drug Enforcement Administration, 2020 National Drug Threat Assessment, https://www.dea.gov/documents/2021/03/02/2020-national-drug-threat-assessment

Behavioral therapy is the treatment of choice, with medication indicated for specific coexisting disorders such as depression. However, researchers are exploring a variety of neuropharmacological targets. Animal models suggest that enhancing GABAergic inhibition can reduce reinstatement of cocaine self-administration, and a controlled clinical trial of *topiramate*, a medication approved to treat epilepsy and prevent migraines, showed a significant reduction in cocaine use or craving. *Topiramate* also reduced the relapse rate in individuals with AUD, prompting current studies in patients dually dependent on cocaine and alcohol (Johnson et al., 2013). *Baclofen*, a $GABA_B$ agonist, was found in a single-site trial to reduce relapse in cocaine addicts but was not effective in a multisite trial. *Modafinil*, a mild stimulant approved for treating narcolepsy and thought to be a weak inhibitor of DAT, has, in several clinical trials for use in cocaine withdrawal, reduced the euphoria produced by cocaine and relieved cocaine withdrawal symptoms (Morgan et al., 2016). *Modafinil* is also currently being tested in clinical trials as a treatment for methamphetamine, alcohol, and other SUDs.

A novel approach being considered for cocaine addiction employs a vaccine that produces anticocaine antibodies capable of preventing cocaine from reaching the brain. Conjugates of cocaine, cocaine metabolites, and cocaine analogues are rendered antigenic by conjugating them to proteins that elicit immune responses that will remove cocaine from the bloodstream. Preclinical trials and phase I trials are currently ongoing (Havlicek et al., 2020).

Amphetamine and Related Agents

Subjective effects similar to those of cocaine are produced by *amphetamine*, *dextroamphetamine*, *methamphetamine*, *phenmetrazine*, *methylphenidate*, and *diethylpropion*. Amphetamines increase synaptic DA, NE, and 5HT primarily by stimulating presynaptic release of stored neurotransmitter (see Chapter 10). Amphetamine-related agents are most often used to treat ADHD, although they do not seem to function as gateway drugs. Intravenous or smoked methamphetamine produces an abuse/dependence syndrome similar to that of cocaine, although clinical deterioration may progress more rapidly. Methamphetamine addiction has become a major public health problem in the U.S. Behavioral and medical treatments for methamphetamine addiction are similar to those used for cocaine, with behavioral therapies as the most effective treatment.

MDMA ("Ecstasy") and MDA

MDMA (3,4-methylenedioxy-methamphetamine) and MDA (methylenedioxy-amphetamine) are synthetic phenylethylamines that have stimulant as well as psychedelic effects. Acute effects are dose dependent and include feelings of energy, altered sense of time, and pleasant sensory experiences with enhanced perception. Negative effects include tachycardia, dry mouth, jaw clenching, and muscle aches. At higher doses, visual hallucinations, agitation, hyperthermia, and panic attacks have been reported. A typical oral dose is one or two 100-mg tablets, producing effects lasting 3 to 6 h, although dosage and potency of street samples are variable (~100 mg of active drug per tablet). Some people do report withdrawal symptoms that include fatigue, loss of appetite, depression, and trouble concentrating.

Caffeine

Caffeine, a mild stimulant, is the most widely used psychoactive drug in the world. It is present in soft drinks, coffee, tea, cocoa, chocolate, and numerous prescription and over-the-counter drugs.

Caffeine is an antagonist at adenosine A_{2A} receptors. It also inhibits cyclic nucleotide phosphodiesterases, mildly increases NE and DA release, and enhances neural activity in numerous brain areas. Caffeine is absorbed from the digestive tract, is distributed rapidly throughout all tissues, and easily crosses the placental barrier. Caffeine is metabolized largely by CYP1A2, with a mean biological $t_{1/2}$ of approximately 5 h, a number that can vary widely. For instance, tobacco smoking reduces the $t_{1/2}$ by approximately 40%; oral contraceptives double it; *fluvoxamine* increases caffeine's half-life 10-fold. Many of caffeine's effects are believed to be due to its competitive antagonism at adenosine A_{2A} receptors. Adenosine is a neuromodulator (see Chapter 16) that caffeine resembles structurally. The mild sedating effects that occur when adenosine activates adenosine receptor subtypes can be antagonized by caffeine. Tolerance to the stimulating effects of caffeine occurs rapidly. Thus, a mild withdrawal syndrome can be produced by abruptly discontinuing the intake of as little as one to two cups of coffee per day. Caffeine withdrawal consists of feelings of fatigue and sedation. With higher doses, headaches and nausea have been reported during withdrawal; vomiting is rare.

Clinical and Pharmacological Topics: Hallucinogens

Hallucinogens are a class of drugs that cause a distortion of reality in the user. While these chemicals are found in certain plants and mushrooms, with historical evidence of their use dating back thousands of years, many are also produced synthetically today. Hallucinogens are divided into two categories: classic hallucinogens (psychedelics such as d-lysergic acid diethylamide [LSD], peyote, psilocybin, ayahuasca, dimethyltryptamine [DMT], and 251-NBOMe) and dissociative drugs (e.g., ketamine, PCP, *Salvia divinorum*). Dissociative drugs do not produce the same psychedelic experience ("trip") as psychedelics but tend to conjure up feelings of detachment. Pharmacologically, many classical hallucinogens act on the serotonergic system, while dissociative drugs act predominantly on the glutamatergic and GABA system. Salvinorin A, the main compound in *S. divinorum*, is different and has a profound effect on KORs.

While hallucinogens are rarely addictive, they seem to play a role in triggering mental disorders such as schizophrenia, yet they are also used to treat disorders such as depression and posttraumatic stress disorder (PTSD) (Galvao-Coelho et al., 2021; Gonzalez-Maeso et al., 2009). Claims about the potential of psychedelic drugs to enhance psychotherapy and to treat addictions are currently not supported by controlled studies.

Classic Hallucinogens

LSD (d-Lysergic Acid Diethylamide)

LSD is one of the most potent hallucinogenic drugs and is greater than 3000 times more potent than mescaline. LSD is sold on the illicit market in a variety of forms. A popular contemporary system involves postage stamp–size papers impregnated with varying doses of LSD (50–300 μg or more). The drug in these papers is absorbed through the oral epithelium.

Effects of hallucinogenic drugs are variable, even in the same individual on different occasions. LSD is absorbed rapidly after oral administration, with effects beginning at 40 to 60 min, peaking at 2 to 4 h, and gradually returning to baseline over 6 to 8 h. At a dose of 100 μg, LSD produces perceptual distortions and sometimes hallucinations; mood changes, including elation, paranoia, or depression; intense arousal; and sometimes a feeling of panic. Signs of LSD ingestion include pupillary dilation, increased blood pressure and pulse, flushing, salivation, lacrimation, and hyperreflexia. Visual effects are prominent. Colors seem more intense, and shapes may appear altered. The user may focus attention on unusual items, such as the pattern of hairs on the back of the hand. A "bad trip" usually consists of severe anxiety, although it also can be marked by periods of intense depression and suicidal thoughts. Visual disturbances usually are prominent. There are no documented toxic fatalities from LSD use, but fatal accidents and suicides have occurred during or shortly after intoxication.

Peyote (Mescaline)

Peyote is a small, spineless cactus with mescaline as its main ingredient. Mescaline can also be produced synthetically. Peyote has been used by natives in the southern part of North America as a part of religious ceremonies, dating back to approximately 4000 BCE. The top of the peyote cactus has disk-shaped buttons that are cut out, dried, and chewed or soaked in water to produce an intoxicating liquid. The DEA exempts peyote use from the CSA in connection with religious ceremonies of the Native American Church.

Psilocybin (4-Phosphoryloxy-N,N-Dimethyltryptamine)

Psilocybin is extracted from certain mushrooms found in tropical and subtropical regions of South America, Mexico, and the U.S. Similar to some other hallucinogenic drugs, psilocybin was ingested during religious ceremonies by indigenous cultures from Mexico and Central America, with historical evidence possibly dating back 6000 years. Psilocybin is consumed raw, mixed with food, or brewed into a tea and produces similar effects to those of LSD. Therapeutic use of psilocybin has been legalized in Oregon.

DMT (N,N-dimethyltryptamine)

DMT is a hallucinogenic chemical found naturally in several Amazonian plant species. It can also be synthesized in the laboratory. Synthetic DMT usually takes the form of a white crystalline powder and is typically vaporized or smoked in a pipe. *Ayahuasca* is a hallucinogenic brew made from Amazonian plants containing DMT along with a vine containing a monoamine oxidase inhibitor that prevents the normal breakdown of DMT in the digestive tract. Ayahuasca tea has traditionally been used for healing and religious purposes in indigenous South American cultures, mainly in the Amazon region, with evidence of its use dating back 1000 years.

251-NBOMe

251-NBOMe is a synthetic, highly potent $5HT_{2A}$ receptor agonist, with a common dose of the hydrochloride salt being 600 to 1200 µg. The drug was discovered in the early 21st century and has become a recreational drug. Routes of administration are similar to those for LSD. 251-NBOMe can cause tachycardia, hypertension, agitation, aggression, hallucinations, and seizures and has been linked to overdose deaths and injury-related deaths.

Tolerance, Physical Dependence, and Withdrawal of Classical Hallucinogens

Frequent, repeated use of psychedelic drugs is unusual; thus, tolerance is not commonly seen. Tolerance does develop to the behavioral effects of LSD after three or four daily doses, but no withdrawal syndrome has been observed.

Pharmacological Interventions

There are no FDA-approved medications that treat addiction to hallucinogens. However, because of the unpredictability of psychedelic drug effects, any use carries some risk. Users may require medical attention because of bad trips. Severe agitation may respond to *diazepam* (20 mg orally). "Talking down" by reassurance also is effective and is the management of first choice. Antipsychotic medications (see Chapter 19) may intensify the experience and thus are contraindicated. A particularly troubling aftereffect of LSD and similar drugs is the occasional occurrence of episodic visual disturbances. These originally were called "flashbacks" and resembled the experiences of prior LSD trips. Flashbacks belong to an official diagnostic category called the *hallucinogen persisting perception disorder*. The symptoms include false fleeting perceptions in the peripheral fields, flashes of color, geometric pseudohallucinations, and positive afterimages. The visual disorder appears stable in half the cases and represents an apparently permanent alteration of the visual system. Precipitants include stress, fatigue, emergence into a dark environment, marijuana, antipsychotic agents, and anxiety states.

Prolonged psychotic reactions lasting 2 days or more may occur after the ingestion of hallucinogens. Schizophreniform episodes may be precipitated in susceptible individuals, and there is some evidence that chronic use of these drugs is associated with the development of persistent psychotic disorders.

Dissociative Drugs

PCP (Phencyclidine)

PCP, an NMDA receptor antagonist, was developed originally as a general anesthetic in the 1950s and later was abandoned because of a high frequency of postoperative delirium with hallucinations. It was classified as a dissociative anesthetic because, in the anesthetized state, the patient remains conscious with staring gaze, flat facies, and rigid muscles. PCP became a drug of abuse in the 1970s, first in an oral form and then in a smoked version enabling a better regulation of the dose.

As little as 50 µg/kg produces emotional withdrawal, concrete thinking, and bizarre responses to projective testing. Catatonic posturing can resemble that of schizophrenia. A meta-analysis showed that hallucinogen-induced psychosis transitioned to a schizophrenia diagnosis in 26% of cases (Murrie et al., 2020). Abusers taking higher doses may appear to be reacting to hallucinations and may exhibit hostile or assaultive behavior. Anesthetic effects increase with dosage; stupor or coma may occur with muscular rigidity, rhabdomyolysis, and hyperthermia. Intoxicated patients in the emergency room may progress from aggressive behavior to coma, with elevated blood pressure and enlarged, nonreactive pupils. PCP binds with high affinity to sites throughout the brain including the cortex and limbic structures, thus blocking NMDA-type glutamate receptors in regions mediating cognition and emotion (see Table 16–2 and Figure 16–9). Evidence suggests that NMDA receptors are involved in ischemic neuronal death caused by high levels of excitatory amino acids; as a result, PCP analogues that block NMDA receptors but with fewer psychoactive effects are of therapeutic interest.

Medical Intervention. Overdose must be treated by life support; there is no antagonist of PCP effects and no proven way to enhance excretion from the body, although acidification of the urine has been proposed. PCP-induced coma may last 7 to 10 days. The agitated or psychotic state produced by PCP can be treated with *diazepam*. Prolonged psychotic behavior requires antipsychotic medication. Because of the anticholinergic activity of PCP, antipsychotic agents with significant anticholinergic effects such as *chlorpromazine* should be avoided.

Ketamine

Ketamine, another NMDA receptor antagonist, appears to have higher potency for NMDA receptor subunits expressed on GABA interneurons (see Figure 18–2). It is a dissociative drug that is used in surgical anesthesia in children and animals and, more recently, as an antidepressant in adults. It is not used as an anesthetic in adults, due to its psychiatric side effects at higher doses, which led to its being investigated experimentally to understand the neurobiology of schizophrenia. Much of the ketamine sold on the street has been diverted from veterinary offices. Although it is manufactured as an injectable liquid, ketamine is generally evaporated to form a powder that is snorted or compressed into pills for illicit use. Because ketamine is odorless and tasteless and has amnesia-inducing properties, it is sometimes added to drinks to facilitate sexual assault.

Esketamine, the *S*-enantiomer of ketamine, is an FDA-approved rapid-acting antidepressant administered as a nasal spray for treatment-resistant depression. The effect is transient and might require maintenance therapy if other antidepressants are ineffective. Since ketamine is known to cause dependence in some persons, caution is still warranted to prevent potential addiction. For this reason, esketamine must be administered under the direct supervision of a healthcare provider.

Salvia divinorum

Salvia divinorum is a plant species related to the common sage. A number of terpenoids have been extracted from the plant, including *salvinorin A*, a potent naturally occurring hallucinogen. Salvinorin A is a KOR agonist and also has activity at the dopamine receptor. The KOR actions are somewhat antithetical to those of KOR agonists such as dizocilpine, a psychoric

and involved in negative reinforcement. Not surprisingly, the experience of salvinorin A is often considered dysphoric by the user but offset by the desired hallucinogenic effects.

Tolerance, Physical Dependence, and Withdrawal of Dissociative Drugs

Of the dissociatives, only PCP is documented to have the potential to be addictive. While behavioral treatments can be successful for a variety of SUDs, it is not clear if they are effective to treat addiction to hallucinogens.

Pharmacological Interventions Pharmacological interventions are used to treat various symptoms associated with use of dissociative drugs, but no approved medications are on the market to treat addiction to these drugs.

Clinical and Pharmacological Topics: Cannabinoids

Cannabis plants have been cultivated for centuries for presumed medicinal and psychoactive properties. Cannabis contains over 113 cannabinoids with varying degrees of psychopharmacological properties. Of these, Δ-9-tetrahydrocannabinol (Δ9-THC) is the main psychoactive cannabinoid that produces most of the characteristic euphorigenic effects of marijuana. In the U.S., marijuana use remains prohibited by federal law, but as of 2021, more than half of all states have various degrees of legalization, ranging from medical use only, to decriminalization, to full legalization. The greater availability of cannabinoid products has led to increased marijuana use and a greater number of marijuana-associated auto accidents. The issues of whether and how to control the use of marijuana have not been resolved, and there is a likelihood that marijuana will be decriminalized on the federal level. The potencies of available botanical forms have generally not been standardized, and the dangers inherent in inhaling a smoke replete with organic molecules have not been defined for marijuana.

Δ9-THC

Cannabinoids such as Δ9-THC target the endogenous cannabinoid system that consists of ligand/receptor/signaling networks described in Chapter 26. The pharmacological effects of Δ9-THC vary with the dose, route of administration, experience of the user, vulnerability to psychoactive effects, and setting of use. Intoxication with marijuana produces changes in mood, perception, and motivation, but the effects most frequently sought are a "high" and a "mellowing out." Effects vary with dose, but typically last about 2 h. During the high, cognitive functions, perception, reaction time, learning, and memory are impaired. Coordination and tracking behavior may be impaired for several hours beyond the perception of the high. Marijuana also produces complex behavioral changes such as giddiness and increased hunger. Unpleasant reactions such as panic or hallucinations and even acute psychosis may occur. These reactions are seen commonly with higher doses and with oral ingestion, since the delayed impact of ingested Δ9-THC (15–60 min) entices people to keep consuming edibles in the belief that they are ineffective. Numerous clinical reports suggest that marijuana use may precipitate a recurrence of psychosis in people with a history of schizophrenia. Cannabis has a high conversion rate from drug-induced psychosis to schizophrenia, at 34% (Murrie et al., 2020). One of the most controversial putative effects of marijuana is the production of an "amotivational syndrome." This syndrome is not an official diagnosis but has been used to describe young people who drop out of social activities and show little interest in school, work, or other goal-directed activity. At the cellular level, there is no evidence that marijuana damages brain cells or produces any permanent functional changes. There is evidence that cannabinoids and the CB_1 receptor, the most abundant GPCR in the mammalian brain, have neuroprotective potential (Antonazzo et al., 2019).

TABLE 28–10 MARIJUANA WITHDRAWAL SYNDROME

Restlessness
Irritability
Mild agitation
Insomnia
Sleep electroencephalogram disturbance
Nausea, cramping

Marijuana has medicinal effects, including antiemetic properties that relieve side effects of chemotherapy. It also has muscle-relaxing effects, anticonvulsant properties, and the capacity to reduce the elevated intraocular pressure of glaucoma. These medical benefits can come at the cost of the psychoactive effects that potentially impair normal activities. *Dronabinol* is an approved synthetic formulation of Δ9-THC (see Chapters 26 and 54).

Tolerance, Dependence, and Withdrawal

Tolerance to most of the effects of marijuana can develop rapidly after only a few doses but also disappears rapidly. Withdrawal symptoms are observed in people with cannabis use disorder (Table 28–10), who use marijuana on a daily basis and then suddenly stop. Negative affective states associated with cannabis withdrawal symptoms include irritability, anxiety, decreased appetite, and disrupted sleep. Presently no FDA-approved medications are available for cannabis use disorder. Several pharmacological interventions under investigation are substitution therapies with exogenous cannabinoid agonists that target the CB_1 receptor, including *dronabinol* and *nabilone*. Heavy users may suffer from accompanying depression and thus may respond to antidepressant medication.

Cannabidiol

Cannabidiol (CBD) is another prominent cannabinoid in cannabis plants. As of 2021, CBD derived from cannabis remains a schedule I drug (see Table 28–1). However, CBD from hemp extract (which contains <0.3% THC) is not regulated and is widely available throughout the U.S. In contrast to Δ9-THC, CBD is not psychoactive and is not an agonist at cannabinoid receptors (Laprairie et al, 2015; Zou and Kumar, 2018). The mechanisms of action of CBD are not well understood but are multifold and include negative allosteric modulation of the cannabinoid receptor, competitive antagonism at the GPR-55 receptor (initially considered an atypical cannabinoid receptor), partial agonism at $5HT_{1A}$ receptors, and agonism at transient receptor potential cation channel subfamily V member 1 (TRPV1). Studies about potential medicinal uses in pain, epilepsy, anxiety, mood disorders, neurodegenerative disorders, and other conditions are currently ongoing, including CBD as a potential treatment for OUD (Hurd et al., 2019). Chapter 26 presents more details about cannabinoids.

Drug Summary Table—Chapter 28

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Drugs of Abuse		
Amphetamine	Used to treat: • ADHD • Obesity • Narcolepsy • Improving cognition and working memory	• High doses can cause psychosis • Increases monoamines (particularly DA) in the neuronal synapse
Barbiturates	• Anxiolytics • Anticonvulsants • Hypnotics • Anti-migraine drugs • Anesthetics in surgical settings	• GABA receptor modulators • Inferior to benzodiazepines • Can cause physical dependance • Danger of overdose death • Increased fatality when combined with other CNS depressants
Benzodiazepines	• Anxiolytics • Anticonvulsants • Sedatives • Hypnotics	• GABA receptor modulators • Are relatively safe when taken alone but can be fatal when combined with other CNS depressants • Can cause physical dependance
Cannabinoids (Δ9-THC)	• Antiemetic (particularly during chemotherapy)	• Δ9-THC partial agonist at the CB_1 cannabinoid receptor • Δ9-THC has psychoactive effects; may cause anxiety at higher doses, and reduce anxiety at lower doses • Associated with transition to schizophrenia • No known lethal effects
Cocaine	• Topical use as local anesthetic in otolaryncology and tear duct surgery	• Can cause strokes and heart attacks • Associated with high mortality rates • Cobalt thiocyanate test used for quick detection of cocaine has a high false-positivity rate • Increases monoamines (particularly DA) in neuronal synapses
Ethanol (alcohol)	• External antiseptic • Antidote to ethylene glycol (antifreeze) and methanol	• Creates toxic metabolites • Common mutation in aldehyde dehydrogenase in East Asia causes a toxic alcohol flush reaction • Leading cause of preventable death
Heroin	• No approved medical use	• Metabolized in the brain into 6-monoacetylmorphine and morphine • Extremely addictive • Together with fentanyl a leading cause of SUD deaths • Rapid neurobiological adaptations require increased doses to avoid withdrawal symptoms • Causes respiratory depression • Increased fatalities when combined with CNS depressants • Metabolites activate MORs
MDMA	• No approved medical use	• "Party-drug," used in raves • High doses can cause psychosis • increases monoamines (particularly 5HT) in the synapse
Methaqualone	• Hypnotic • Sedative • Anxiolytic	• GABA agonist • Similar to barbiturates • Widespread use as recreational drug between 1960 and 1980 • Increases fatality when combined with other CNS depressants
Methylphenidate	Used to treat: • ADHD • Narcolepsy • Improves cognition and working memory	• Similar to amphetamine • Increases monoamines (particularly DA and NE) in the synapse
Nicotine	• Might have benefits in Parkinson's disease, schizophrenia, dementia, depression, and ADHD • Used in nicotine batches to help people quit smoking	• Binds to nicotinic acetylcholine receptors • Highly addictive • Leading cause of preventable death

Drug Summary Table—Chapter 28 (*continued*)

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Drugs used in the treatment of addiction		
Acamprosate	• Used to treat AUD	• Mechanism of action not fully understood but may act as a NMDA receptor antagonist/GABA receptor modulator • Should not be administered to persons with impaired kidneys • May cause depression, anxiety and GI symptoms
Baclofen	• May be used to treat AUD, but evidence is not conclusive • Used to treat spasticity	• $GABA_B$ receptor agonist • Discontinuation can lead to a withdrawal syndrome
Benzodiazepines	• Used to treat alcohol withdrawal syndrome during detoxification	• Increased fatality when combined with alcohol or other CNS depressants! • Not used for prolonged AUD treatment • See under "Drugs of Abuse"
Buprenorphine	• OUD maintenance treatment • OUD induction of treatment • Analgesic • Administered PO, IV, IM, transmucosal, transdermal, or implant	• Partial agonist at MOR, antagonist at KOR • Is combined with naloxone in maintenance treatment to prevent intravenous abuse • Side effects include respiratory depression, somnolence • Concomitant use with CNS depressants amplifies side effects and can be lethal
Bupropion	• Improves abstinence rate in smokers • Atypical antidepressant	• May cause insomnia
Carbamazepine	• Might be used during detoxification • Anticonvulsant	• Sodium channel blocker • Should not be combined with alcohol use
Cannabidiol	• FDA-approved as an anticonvulsant • Being considered as a potential treatment of OUD	• Negative allosteric modulator at the CB_1 receptor • Currently, Schedule I if derived from cannabis plant, but unscheduled if obtained from hemp plant (>0.3% THC).
Clonidine	• Used off label to reduce symptoms of opioid and alcohol withdrawal • Treats hypertension • Treats ADHD	• α_2 adrenergic receptor agonist • May cause insomnia
Disulfiram	• Used to treat AUD	• Inhibits aldehyde dehydrogenases (see also "Ethanol" and toxic flush reaction) • Very unpleasant when alcohol is consumed • Poor compliance
Flumazenil	• Antidote in the treatment of benzodiazepine overdose • Reversing the post-surgical effects of long-acting benzodiazepines used as anesthetics	• $GABA_A$ receptor antagonist
Gabapentin	• Alcohol detoxification • Treats neuropathic pain • Anticonvulsant	
Lofexidine	• Reduces symptoms of opioid withdrawal • Treats hypertension	• α_2 adrenergic receptor agonist
Methadone	• Used in OUD detoxification and in opioid maintenance therapy • May be used as analgesic	• Opioid receptor agonist • Schedule II drug • On WHO list of essential medicines • Side effects similar to other opioids
Modafinil	• Off-label use in cocaine, alcohol, methamphetamine and amphetamine withdrawal • May increase rate of abstinence • Used to treat ADHD • Used to treat Narcolepsy	• Schedule IV controlled substance in the US • Increases wakefulness

Drug Summary Table—Chapter 28 (*continued*)

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Drugs used in the treatment of addiction (cont.)		
Naloxone	• Used for the acute treatment of opioid overdose • Available as nasal spray • Combined with buprenorphine in buprenorphine maintenance therapy	• Rapid-acting competitive opioid receptor antagonist • Precipitates opioid withdrawal • May have to be administered repeatedly over 24 hours • Side effects may include agitation, nausea, vomiting, and tachycardia
Naltrexone	• Used in the management of OUD and AUD	• Opioid receptor antagonist • May precipitate opioid withdrawal and should not be used before opioid detoxification • Side effects may include nausea, anxiety, and insomnia
Oxazepam	• AUD detoxification • Anxiolytic	• Short-acting benzodiazepine
Phenobarbital	• Might be used during drug detoxification • Anticonvulsant	• Barbiturate • On WHO list of essential medicines
Rimonabant	• Some improvement in nicotine abstinence rate • Not approved in the U.S.!	• Cannabinoid CB_1 receptor inverse agonist • Serious adverse effects
Topiramate	• May reduce craving for cocaine and alcohol • Used to treat AUD • Anticonvulsant • Prevention of migraines	• Carbonic anhydrase inhibitor • Increased risk of kidney stones
Varenicline	• Treatment of tobacco use disorder	• Selective partial agonist at $\alpha_4\beta_2$ nicotinic acetylcholine receptors • May cause nausea
Opioid medications used in pain treatment		
Buprenorphine	• OUD treatment • Analgesic • Administered PO, IV, IM, transmucosal, transdermal, or implant	• Partial agonist at MOR, antagonist at KOR • Side effects include respiratory depression, somnolence • Concomitant use with CNS depressants amplify side effects and can be lethal
Fentanyl	• Analgesic • Administered PO, IV, IM, transmucosal, sublingual, transdermal	• Leading cause of drug-related deaths in the U.S. • Respiratory depressant • Side effects include nausea, vomiting, sedation and constipation • On WHO list of essential medicines in cancer pain • 100 times more potent than morphine • Analogues such as carfentanil 10,000 times more potent than morphine
Hydrocodone	• Analgesic • Antitussive • Administered PO	• Similar side effects to oxycodone • Histamine release and itching • Full MOR agonist • Should not be combined with CNS depressants
Morphine	• Analgesic • Administered PO, IV, IM • Is also smoked	• Side effects include respiratory depression, nausea, vomiting, hypotension
Oxycodone	• Analgesic • can be administered PO, IV, IM, or intranasally	• A slow-release formulation, Oxycontin, has been subjected to criticism as a significant contributor to the opioid epidemic • Side effects include euphoria, constipation, nausea, drowsiness, hypotension, and respiratory depression • Should not be combined with CNS depressants

Drug Summary Table—Chapter 28 (*continued*)

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Hallucinogens		
251-NBOMe	• No approved medical use	
Ayahuasca	• No approved medical use	• The most prevalent teas are brewed from *banisteriopsis caapi* and *psychotria viridis* • DMT and an MAOI are the main ingredients • Can cause severe vomiting
DMT	• No approved medical use	
Ketamine	• Anesthetic • Antidepressant	• Esketamine prescribed for treatment resistant depression under medical supervision • Widely used by veterinarians for surgical anesthesia • Can cause psychosis
LSD	• No approved medical use	• Can impair mental function • 1/10th as harmful as alcohol • May trigger psychosis and panic attacks
PCP	• No approved medical use	• May trigger hallucinogen-induced psychosis and transition to schizophrenia
Peyote (Mescaline)	• No approved medical use	• Regularly used and legal in the Native American Church
Psilocybin	• No approved medical use	• Misidentification of poisonous mushrooms resembling psilocybin could lead to unintentional, potentially fatal poisoning
Salvia divinorum	• No approved medical use	• As of 2021, not regulated under the U.S. Controlled Substances Act, though might be regulated in individual states

Modulation of Pulmonary, Renal, and Cardiovascular

This page intentionally left blank

Chapter 29 Drugs Affecting Renal Excretory Function

Edwin K. Jackson

The kidney filters the extracellular fluid volume across the renal glomeruli an average of 12 times a day, and the renal nephrons precisely regulate the fluid volume of the body and its electrolyte content via processes of secretion and reabsorption. Disease states such as hypertension, heart failure, renal failure, nephrotic syndrome, and cirrhosis may disrupt this balance. Diuretics increase the rate of urine flow and Na^+ excretion and are used to adjust the volume or composition of body fluids in these disorders. Precise regulation of body fluid osmolality is also essential. It is controlled by a finely tuned homeostatic mechanism that operates by adjusting both the rate of water intake and the rate of solute-free water excretion by the kidneys—that is, water balance. Abnormalities in this homeostatic system can result from genetic diseases, acquired diseases, or drugs and may cause serious and potentially life-threatening deviations in plasma osmolality.

Part I of this chapter first describes renal physiology, then introduces diuretics with regard to mechanism and site of action, effects on urinary composition, and effects on renal hemodynamics, and then integrates diuretic pharmacology with a discussion of mechanisms of edema formation and the role of diuretics in clinical medicine. Specific therapeutic applications of diuretics are presented in Chapters 32 (hypertension) and 33 (heart failure). *Part II* of this chapter describes the vasopressin system that regulates water homeostasis and plasma osmolality and factors that perturb those mechanisms and examines pharmacological approaches for treating disorders of water balance.

Part I: Renal Physiology and Diuretic Drug Action

Renal Anatomy and Physiology

The basic urine-forming unit of the kidney is the nephron. The initial part of the nephron, the renal (Malpighian) corpuscle, consists of a capsule (Bowman's capsule) and a tuft of capillaries (the glomerulus) residing within the capsule. The glomerulus receives blood from an afferent arteriole, and blood exits the glomerulus via an efferent arteriole. Ultrafiltrate produced by the glomerulus collects in the space between the glomerulus and capsule (Bowman's space) and enters a long tubular portion of the nephron, where the ultrafiltrate is reabsorbed and conditioned. Each human kidney is composed of about 1 million nephrons. Figure 29–1 illustrates subdivisions of the nephron.

Glomerular Filtration

In the glomerular capillaries, a portion of plasma water is forced through a filter that has three basic components: the fenestrated capillary endothelial cells, a basement membrane lying just beneath the endothelial cells, and the filtration slit diaphragms formed by epithelial cells that cover the basement membrane on its urinary space side. Solutes of small size flow with filtered water (solvent drag) into Bowman's space, whereas formed elements and macromolecules are retained by the filtration barrier.

Overview of Nephron Function

The kidney filters large quantities of plasma, reabsorbs substances that the body must conserve, and leaves behind or secretes substances that must be eliminated. The changing architecture and cellular differentiation along the length of a nephron are crucial to these functions (Figure 29–1). Together, the two kidneys in humans produce about 120 mL of ultrafiltrate/min, yet only 1 mL of urine/min; more than 99% of the glomerular ultrafiltrate is reabsorbed at a high energy cost. The kidneys consume 7% of total-body O_2 intake despite comprising only 0.5% of body weight.

The proximal tubule is contiguous with Bowman's capsule and takes a winding path until finally forming a straight portion that dives into the renal medulla. Normally, about 65% of filtered Na^+ is reabsorbed in the proximal tubule. This part of the tubule is highly permeable to water, and thus, reabsorption is essentially isotonic. Between the outer and inner strips of the outer medulla, the tubule abruptly changes morphology to become the descending thin limb (DTL), which penetrates the inner medulla, makes a hairpin turn, and then forms the ascending thin limb (ATL). At the juncture between the inner and outer medulla, the tubule once again changes morphology and becomes the thick ascending limb (TAL). Together, the proximal straight tubule, DTL, ATL, and TAL segments are known as the *loop of Henle*.

The DTL is highly permeable to water, yet its permeabilities to NaCl and urea are low. In contrast, the ATL is permeable to NaCl and urea but is impermeable to water. The TAL actively reabsorbs NaCl but is impermeable to water and urea. Approximately 25% of filtered Na^+ is reabsorbed in the loop of Henle, mostly in the TAL, which has a large reabsorptive capacity. The TAL passes between the afferent and efferent arterioles and makes contact with the afferent arteriole by means of a cluster of specialized columnar epithelial cells known as the *macula densa*. The macula

Abbreviations

ACTH: corticotropin (previously adrenocorticotropic hormone)
ADH: antidiuretic hormone
AIP: aldosterone-induced protein
Ang: angiotensin (e.g., AngII and AngIII)
ANP: atrial natriuretic peptide
ATL: ascending thin limb
AVP: arginine vasopressin
BNP: brain natriuretic peptide
cGMP: cyclic guanosine monophosphate
CHF: congestive heart failure
CKD: chronic kidney disease
CNGC: cyclic nucleotide-gated cation channel
CNP: C-type natriuretic peptide
CNT: connecting tubule
COX: cyclooxygenase
DAG: diacyglycerol
DCT: distal convoluted tubule
DDAVP: 1-deamino-8-D-AVP (desmopressin)
DI: diabetes insipidus
DTL: descending thin limb
ECFV: extracellular fluid volume
ENaC: epithelial Na^+ channel
ENCC1 or TSC: the absorptive Na^+-Cl^- symporter
ENCC2, NKCC2, or BSC1: the absorptive Na^+-K^+-$2Cl^-$ symporter
ENCC3, NKCC1, or BSC2: the secretory Na^+-K^+-$2Cl^-$ symporter
GFR: glomerular filtration rate
GPCR: G protein-coupled receptor
IMCD: inner medullary collecting duct
IP_3: inositol trisphosphate
LOX: lipoxygenase
MR: mineralocorticoid receptor
NP: natriuretic peptide
NPR: natriuretic peptide receptor (e.g., NPRA, B, or C)
NSAID: nonsteroidal anti-inflammatory drug
OAT: organic anion transporter
PG: prostaglandin
PK: protein kinase (e.g., PKA, PKB, PKG)
PL: phospholipase (e.g., PLC, PLD)
PTH: parathyroid hormone
PVN: paraventricular nucleus
RAS: renin-angiotensin system
RBF: renal blood flow
SGLT2: sodium-glucose cotransporter type 2
SIADH: syndrome of inappropriate secretion of ADH
SON: supraoptic nucleus
TAL: thick ascending limb
TGF: tubuloglomerular feedback
VP: vasopressin
VRUT: vasopressin-regulated urea transporter
vWD: von Willebrand disease

densa is strategically located to sense concentrations of NaCl leaving the loop of Henle. If the concentration of NaCl is too high, the macula densa sends a chemical signal (perhaps adenosine or ATP) to the afferent arteriole of the same nephron, causing it to constrict, thereby reducing the glomerular filtration rate (GFR). This homeostatic mechanism, known as *tubuloglomerular feedback (TGF)*, protects the organism from salt and volume wasting. The macula densa also regulates renin release from the adjacent juxtaglomerular cells in the wall of the afferent arteriole.

Approximately 0.2 mm past the macula densa, the tubule changes morphology once again to become the DCT. Like the TAL, the DCT actively transports NaCl and is impermeable to water. Because these characteristics impart the capacity to produce dilute urine, the TAL and the DCT are collectively called the *diluting segment of the nephron*, and the tubular fluid in the DCT is hypotonic regardless of hydration status. However, unlike the TAL, the DCT does not contribute to the countercurrent-induced hypertonicity of the medullary interstitium (described in material that follows).

The collecting duct system (segments 10–14 in Figure 29–1) is an area of fine control of ultrafiltrate composition and volume. It is here that final adjustments in electrolyte composition are made, via the adrenal steroid *aldosterone*. Vasopressin (also called ADH) modulates water permeability in this part of the nephron as well. The more distal portions of the collecting duct pass through the renal medulla, where the interstitial fluid is markedly hypertonic. In the absence of ADH, the collecting duct system is impermeable to water, and dilute urine is excreted. In the presence of ADH, the collecting duct system is permeable to water, and water is reabsorbed. The movement of water out of the tubule is driven by the steep concentration gradient that exists between tubular fluid and medullary interstitium.

The hypertonicity of the medullary interstitium plays a vital role in the capacity of mammals and birds to concentrate urine, which is accomplished by the unique topography of the loop of Henle and the specialized permeabilities of the loop's subsegments. The "passive countercurrent multiplier hypothesis" proposes that active transport in the TAL concentrates NaCl in the interstitium of the outer medulla. Because this segment of the nephron is impermeable to water, active transport in the ascending limb dilutes the tubular fluid. As the dilute fluid passes into the collecting duct system, water is extracted if, and only if, ADH is present. Because the cortical and outer medullary collecting ducts have low permeability to urea, urea is concentrated in the tubular fluid. The IMCD, however, is permeable to urea, so urea diffuses into the inner medulla, where it is trapped by countercurrent exchange in the vasa recta (medullary capillaries that run parallel to the loop of Henle). Because the DTL is impermeable to salt and urea, the high urea concentration in the inner medulla extracts water from the DTL and concentrates NaCl in the tubular fluid of the DTL. As the tubular fluid enters the ATL, NaCl diffuses out of the salt-permeable ATL, thus contributing to the hypertonicity of the medullary interstitium.

General Mechanism of Renal Epithelial Transport

There are multiple mechanisms by which solutes may cross cell membranes (see also Chapter 4). The kinds of transport achieved in a nephron segment depend mainly on which transporters are present and whether they are embedded in the luminal or basolateral membrane. Figure 29–2 presents a general model of renal tubular transport that can be summarized as follows:

1. Na^+, K^+-ATPase (sodium pump) in the basolateral membrane transports Na^+ into the intercellular and interstitial spaces and K^+ into the cell, establishing an electrochemical gradient for Na^+ across the cell membrane directed inward.
2. Na^+ can diffuse down this Na^+ gradient across the luminal membrane via Na^+ channels and via membrane symporters that use the energy stored in the Na^+ gradient to transport solutes out of the tubular lumen and into the cell (e.g., Na^+-glucose, Na^+-$H_2PO_4^-$, and Na^+-amino acid) and antiporters (e.g., Na^+-H^+) that move solutes into the lumen as Na^+ moves down its gradient and into the cell.
3. Na^+ exits the basolateral membrane into intercellular and interstitial spaces mainly via the Na^+ pump.
4. The action of Na^+-linked symporters in the luminal membrane causes the concentration of substrates for these symporters to rise in the epithelial cell. These substrate/solute gradients then permit simple diffusion or mediated transport (e.g., symporters, antiporters, uniporters, and channels) of solutes into the intercellular and interstitial spaces.
5. Accumulation of Na^+ and other solutes in the intercellular space creates a small osmotic pressure differential across the epithelial cell.

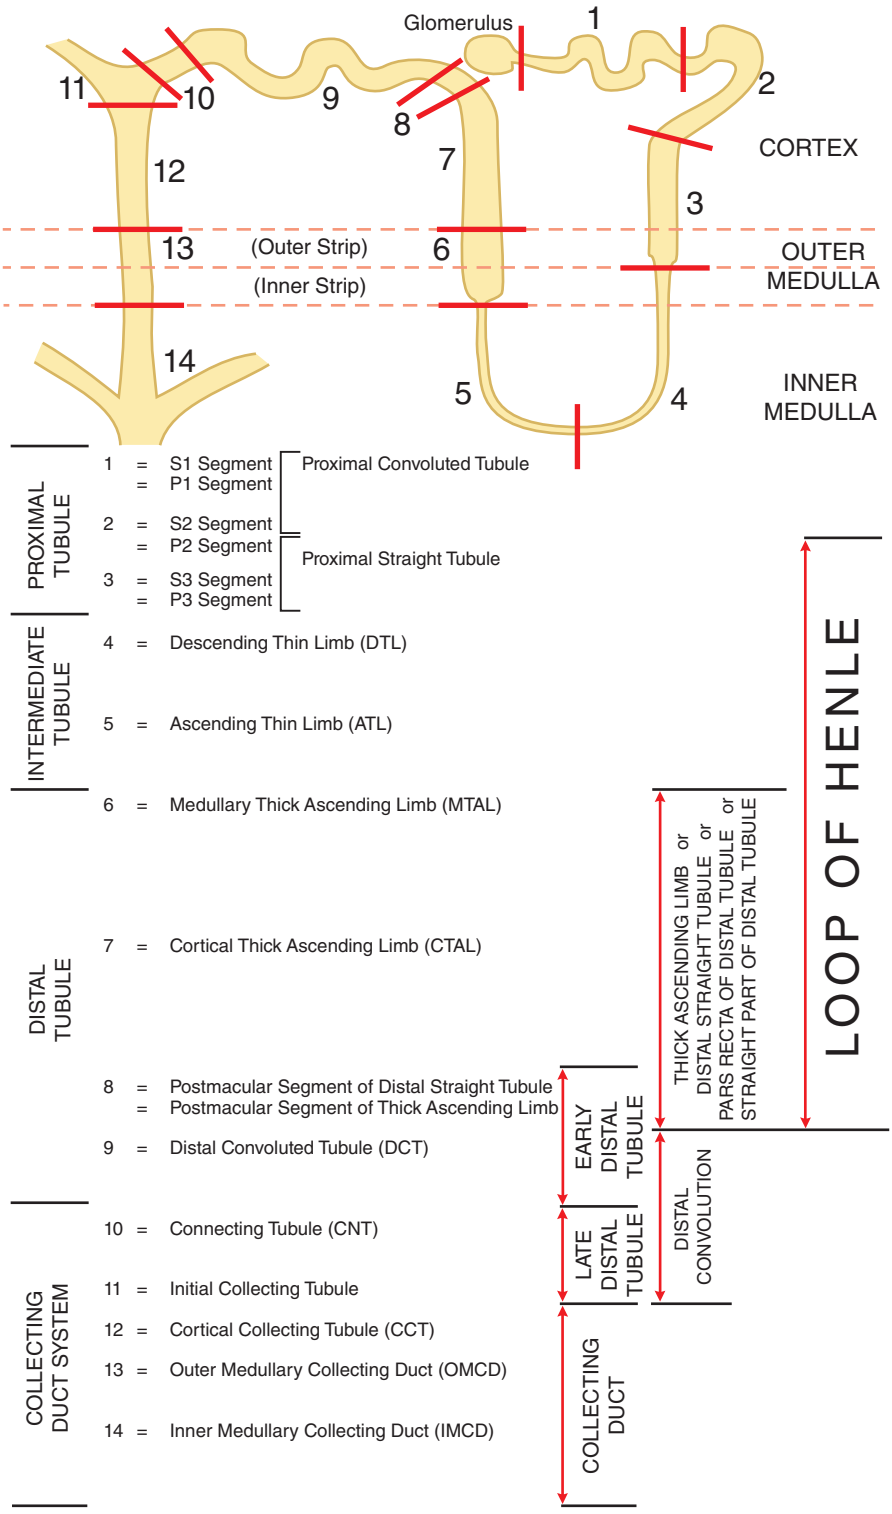

Figure 29–1 *Anatomy and nomenclature of the nephron.*

In water-permeable epithelium, water moves into the intercellular spaces driven by the osmotic pressure differential. Water moves through aqueous pores in both the luminal and the basolateral cell membranes, as well as through tight junctions (paracellular pathway). Bulk water flow carries some solutes into the intercellular space by solvent drag.

6. Movement of water into the intercellular space concentrates other solutes in the tubular fluid, resulting in an electrochemical gradient for these substances across the epithelium. Membrane-permeable solutes then move down their electrochemical gradients into the intercellular space by both the transcellular (e.g., simple diffusion, symporters, antiporters, uniporters, and channels) and paracellular pathways. Membrane-impermeable solutes remain in the tubular lumen and are excreted in the urine with an obligatory amount of water.
7. As water and solutes accumulate in the intercellular space, hydrostatic pressure increases, thus providing a driving force for bulk water flow. Bulk water flow carries solute out of the intercellular space into the interstitial space and, finally, into the peritubular capillaries.

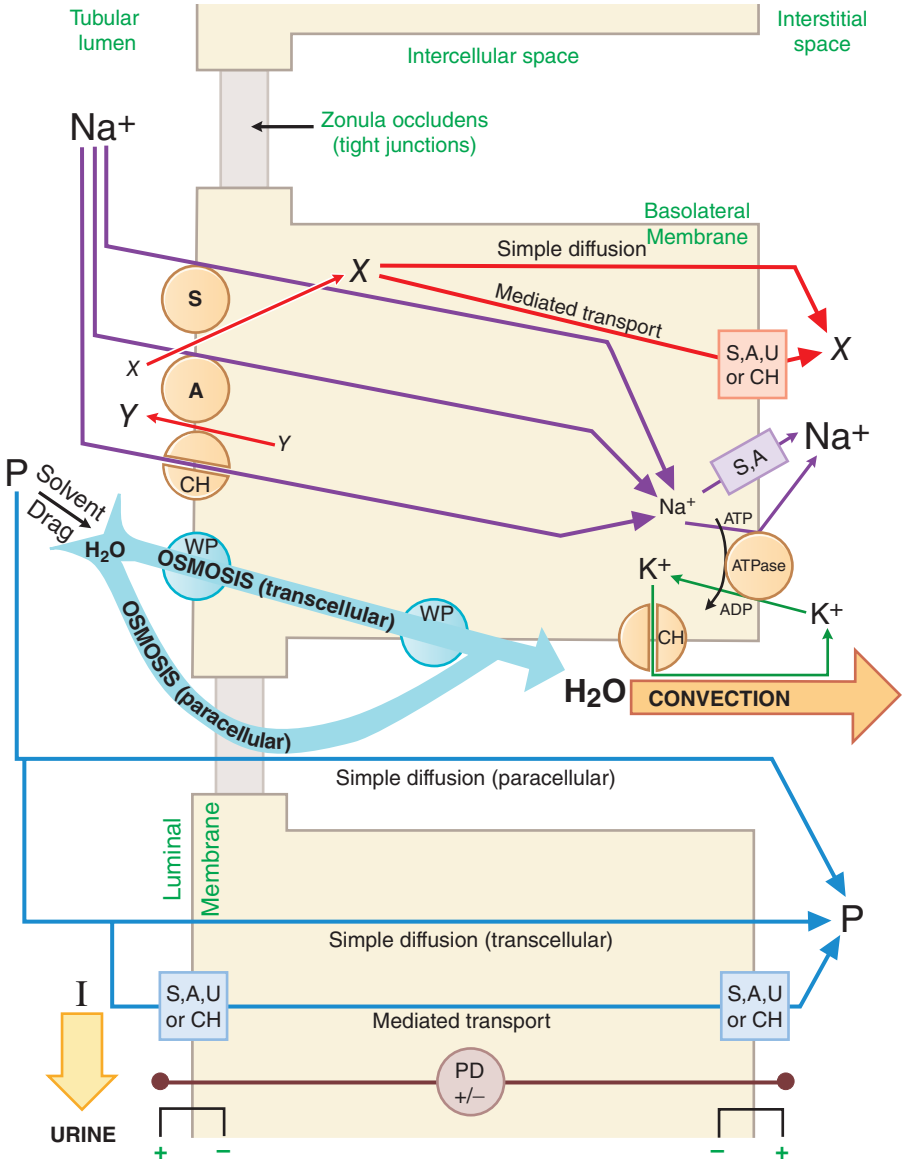

Figure 29–2 *Generic mechanism of renal epithelial cell transport* (see text for details). A, antiporter; ATPase, Na^+, K^+-ATPase (sodium pump); CH, ion channel; *I*, membrane-impermeable solutes; *P*, membrane-permeable solutes; PD, potential difference across indicated membrane or cell; S, symporter; U, uniporter; WP, water pore; *X* and *Y*, transported solutes.

Organic Acid and Organic Base Secretion

The kidney is a major organ involved in the elimination of organic chemicals from the body. Organic molecules may enter the renal tubules by glomerular filtration or may be actively secreted directly into tubules. The proximal tubule has a highly efficient transport system for organic acids and an equally efficient but separate transport system for organic bases. Current models for these secretory systems are illustrated in Figure 29–3. Both systems are powered by the sodium pump in the basolateral membrane, involve secondary and tertiary active transport, and use a facilitated diffusion step. There are many organic acid and organic base transporters (see Chapter 4). A family of organic anion transporters (OATs) links countertransport of organic anions with dicarboxylates (Figure 29–3A).

Renal Handling of Specific Anions and Cations

Reabsorption of Cl^- generally follows reabsorption of Na^+. In segments of the tubule with low-resistance tight junctions (i.e., "leaky" epithelium), such as the proximal tubule and TAL, Cl^- movement can occur paracellularly. Cl^- crosses the luminal membrane by antiport with formate and oxalate (proximal tubule), symport with Na^+/K^+ (TAL), symport with Na^+ (DCT), and antiport with HCO_3^- (collecting duct system). Cl^- crosses the basolateral membrane via symport with K^+ (proximal tubule and TAL), antiport with Na^+/HCO_3^- (proximal tubule), and Cl^- channels (TAL, DCT, collecting duct system).

Of filtered K^+, 80% to 90% is reabsorbed in the proximal tubule (diffusion and solvent drag) and TAL (diffusion), largely through the paracellular pathway. The DCT and collecting duct system secrete variable amounts of K^+ by a channel-mediated pathway. Modulation of the rate of K^+ secretion in the collecting duct system, particularly by aldosterone, allows urinary K^+ excretion to be matched with dietary intake. The transepithelial potential difference V_T, lumen positive in the TAL and lumen negative in the collecting duct system, drives K^+ reabsorption and secretion, respectively.

Most of the filtered Ca^{2+} (~70%) is reabsorbed by the proximal tubule by passive diffusion through a paracellular route. Another 25% of filtered Ca^{2+} is reabsorbed by the TAL in part by a paracellular route driven by the lumen-positive V_T and in part by active transcellular Ca^{2+} reabsorption modulated by parathyroid hormone (PTH) (see Chapter 52). Most of

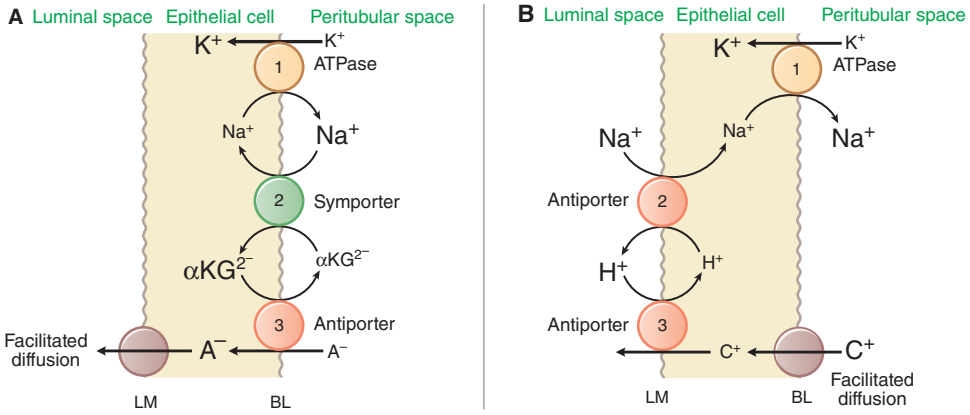

Figure 29–3 *Mechanisms of organic acid* (**A**) *and organic base* (**B**) *secretion in the proximal tubule.* The numbers 1, 2, and 3 refer to primary, secondary, and tertiary active transport, respectively. A^-, organic acid (anion); C^+, organic base (cation); αKG^{2-}, α-ketoglutarate but also other dicarboxylates. BL and LM indicate basolateral and luminal membranes, respectively.

the remaining Ca^{2+} is reabsorbed in DCT by a transcellular pathway. The transcellular pathway in the TAL and DCT involves passive Ca^{2+} influx across the luminal membrane through Ca^{2+} channels (TRPV5, transient receptor potential cation channel V5), followed by Ca^{2+} extrusion across the basolateral membrane by a Ca^{2+}-ATPase. Also, in DCT and CNT, Ca^{2+} crosses the basolateral membrane by Na^+-Ca^{2+} exchanger (antiport). P_i is largely reabsorbed (80% of filtered load) by the proximal tubule. The Na^+-P_i symporter uses the free energy of the Na^+ electrochemical gradient to transport P_i into the cell. The Na^+-P_i symporter is inhibited by PTH.

The renal tubules reabsorb HCO_3^- and secrete protons (tubular acidification), thereby participating in acid-base balance. These processes are described in the section on carbonic anhydrase inhibitors.

Principles of Diuretic Action

Diuretics are drugs that increase the rate of urine flow; clinically useful diuretics also increase the rate of Na^+ excretion (natriuresis) and of an accompanying anion, usually Cl^-. Most clinical applications of diuretics are directed toward reducing extracellular fluid volume by decreasing total-body NaCl content.

Although continued diuretic administration causes a sustained net deficit in total-body Na^+, the time course of natriuresis is finite because renal compensatory mechanisms bring Na^+ excretion in line with Na^+ intake, a phenomenon known as *diuretic braking*. These compensatory mechanisms include activation of the sympathetic nervous system, activation of the renin-angiotensin-aldosterone axis, decreased arterial blood pressure (which reduces pressure natriuresis), renal epithelial cell hypertrophy, increased renal epithelial transporter expression, and perhaps alterations in natriuretic hormones such as atrial natriuretic peptide (ANP). The net effects on extracellular volume and body weight are shown in Figure 29–4.

Diuretics may modify renal handling of other cations (e.g., K^+, H^+, Ca^{2+}, and Mg^{2+}), anions (e.g., Cl^-, HCO_3^-, and $H_2PO_4^-$), and uric acid. In addition, diuretics may alter renal hemodynamics indirectly. Table 29–1 compares the general effects of the major diuretic classes.

Inhibitors of Carbonic Anhydrase

There are three orally administered carbonic anhydrase inhibitors—*acetazolamide, dichlorphenamide,* and *methazolamide* (Table 29–2).

Mechanism and Site of Action

Proximal tubular epithelial cells are richly endowed with the zinc metalloenzyme carbonic anhydrase, which is found in the luminal and basolateral membranes (type IV carbonic anhydrase), as well as in the cytoplasm (type II carbonic anhydrase) (Figure 29–5). Carbonic anhydrase plays a role in $NaHCO_3$ reabsorption and acid secretion.

In the proximal tubule, the free energy in the Na^+ gradient established by the basolateral Na^+ pump is used by a Na^+-H^+ antiporter (Na^+-H^+ exchanger type 3) in the luminal membrane to transport H^+ into the tubular lumen in exchange for Na^+. In the lumen, H^+ reacts with filtered HCO_3^- to form H_2CO_3, which decomposes rapidly to CO_2 and water in the presence of carbonic anhydrase in the brush border. Carbonic anhydrase reversibly accelerates this reaction several thousand–fold. CO_2 is lipophilic and rapidly diffuses across the luminal membrane into the

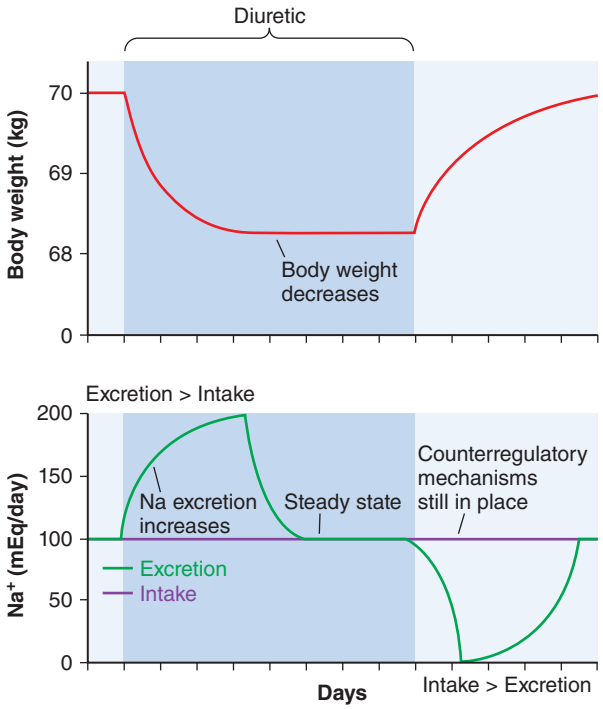

Figure 29–4 *Changes in extracellular fluid volume (ECFV) and weight with diuretic therapy.* The period of diuretic administration is shown in the shaded box along with its effects on body weight in the upper part of the figure and Na^+ excretion in the lower half of the figure. Initially, when Na^+ excretion exceeds intake, body weight and ECFV decrease. Subsequently, a new steady state is achieved where Na^+ intake and excretion are equal but at a lower ECFV and body weight. This results from activation of the RAAS and SNS, "the braking phenomenon." When the diuretic is discontinued, body weight and ECFV rise during a period when Na^+ intake exceeds excretion. A new steady state is then reached as stimulation of the RAAS and SNS wanes. RAAS, renin-angiotensin-aldosterone system; SNS, sympathetic nervous system.

TABLE 29–1 ■ EXCRETORY AND RENAL HEMODYNAMIC EFFECTS OF DIURETICS[a]

DIURETIC MECHANISM (Primary site of action)	CATIONS					ANIONS			URIC ACID		RENAL HEMODYNAMICS			
	Na^+	K^+	H^+[b]	Ca^{2+}	Mg^{2+}	Cl^-	HCO_3^-	$H_2PO_4^-$	*ACUTE*	*CHRONIC*	RBF	GFR	FF	TGF
Inhibitors of CA (proximal tubule)	+	++	–	NC	V	(+)	++	++	I	–	–	–	NC	+
Osmotic diuretics (loop of Henle)	++	+	I	+	++	+	+	+	+	I	+	NC	–	I
Inhibitors of Na^+-K^+-$2Cl^-$ symport (thick ascending limb)	++	++	+	++	++	++	+[c]	+[c]	+	–	V(+)	NC	V(–)	–
Inhibitors of Na^+-Cl^- symport (distal convoluted tubule)	+	++	+	V(–)	V(+)	+	+[c]	+[c]	+	–	NC	V(–)	V(–)	NC
Inhibitors of renal epithelial Na^+ channels (late distal tubule, collecting duct)	+	–	–	–	–	+	(+)	NC	I	–	NC	NC	NC	NC
Antagonists of mineralocorticoid receptors (late distal tubule, collecting duct)	+	–	–	I	–	+	(+)	I	I	–	NC	NC	NC	NC

[a]Except for uric acid, changes are for acute effects of diuretics in the absence of significant volume depletion, which would trigger complex physiological adjustments.
[b]H^+ includes titratable acid and NH_4^+.
[c]In general, these effects are restricted to those individual agents that inhibit carbonic anhydrase. However, there are notable exceptions in which symport inhibitors increase bicarbonate and phosphate (e.g., metolazone, bumetanide). ++, +, (+), –, NC, V, V(+), V(–), and I indicate marked increase, mild-to-moderate increase, slight increase, decrease, no change, variable effect, variable increase, variable decrease, and insufficient data, respectively. For cations and anions, the indicated effects refer to absolute changes in fractional excretion. CA, carbonic anhydrase; FF, filtration fraction; GFR, glomerular filtration rate; RBF, renal blood flow; TGF, tubuloglomerular feedback.

TABLE 29–2 ■ INHIBITORS OF CARBONIC ANHYDRASE

DRUG	RELATIVE POTENCY	ORAL AVAILABILITY	$t_{1/2}$ (hours)	ROUTE OF ELIMINATION

ID, insufficient data; M, metabolism; R, renal excretion of intact drug.

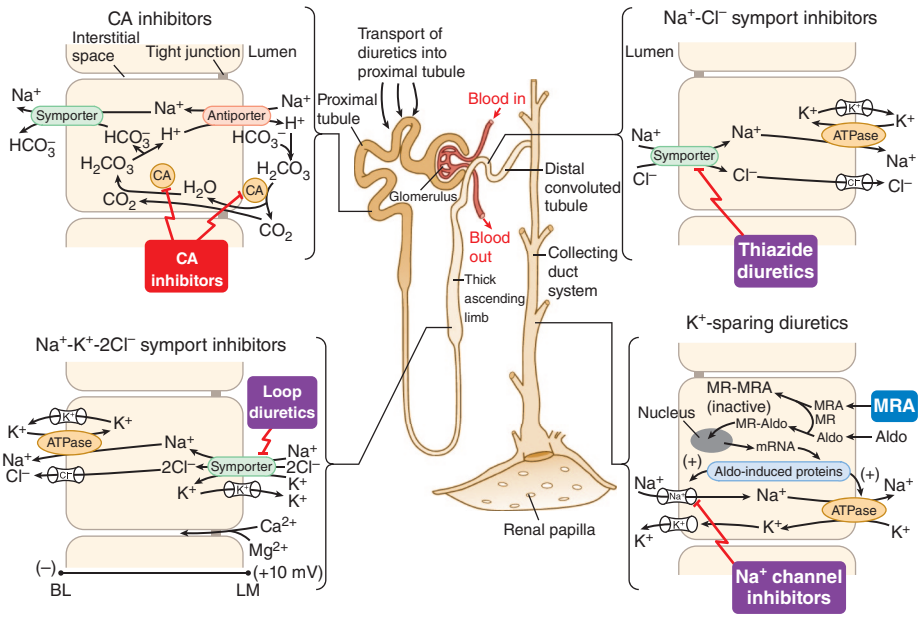

Figure 29–5 *Sites and mechanisms of action of diuretics.* Three important features are noteworthy: (1) Transport of solute across epithelial cells in all nephron segments involves highly specialized proteins, which for the most part are apical and basolateral membrane integral proteins. (2) Diuretics target and block the action of epithelial proteins involved in solute transport. (3) The site and mechanism of action of a given class of diuretics are determined by the specific protein inhibited by the diuretic. BL, basolateral membrane; CA, carbonic anhydrase; LM, luminal membrane; MR, mineralocorticoid receptor; MRA, mineralocorticoid receptor antagonist.

epithelial cell, where it reacts with water to form H_2CO_3, a reaction catalyzed by cytoplasmic carbonic anhydrase. Continued operation of the Na^+-H^+ antiporter maintains a low proton concentration in the cell, so H_2CO_3 ionizes spontaneously to form H^+ and HCO_3^-, creating an electrochemical gradient for HCO_3^- across the basolateral membrane. The electrochemical gradient for HCO_3^- is used by a Na^+-HCO_3^- symporter (also known as the Na^+-HCO_3^- cotransporter) in the basolateral membrane to transport $NaHCO_3$ into the interstitial space. The net effect of this process is transport of $NaHCO_3$ from the tubular lumen to the interstitial space, followed by movement of water (isotonic reabsorption). Removal of water concentrates Cl^- in the tubular lumen, and consequently, Cl^- diffuses down its concentration gradient into the interstitium by the paracellular pathway.

Carbonic anhydrase inhibitors potently inhibit both the membrane-bound and cytoplasmic forms of carbonic anhydrase and can cause nearly complete elimination of $NaHCO_3$ reabsorption in the proximal tubule. However, due to the large excess of carbonic anhydrase activity in proximal tubules, a large fraction of the enzyme activity must be inhibited before an effect on electrolyte excretion is observed. Although the proximal tubule is the major site of action of carbonic anhydrase inhibitors, carbonic anhydrase is also involved in secretion of titratable acid in the collecting duct system, which is a secondary site of action for this class of drugs.

Effects on Urinary Excretion

Inhibition of carbonic anhydrase is associated with a rapid rise in urinary HCO_3^- excretion to about 35% of filtered load. This, along with inhibition of titratable acid and NH_4^+ secretion in the collecting duct system, results in an increase in urinary pH to about 8 and development of metabolic acidosis. However, even with a high degree of inhibition of carbonic anhydrase, 65% of HCO_3^- is rescued from excretion. The loop of Henle has large reabsorptive capacity and captures most of the Cl^- and a portion of the Na^+. Thus, only a small increase in Cl^- excretion occurs, with HCO_3^- being the major anion excreted along with the cations Na^+ and K^+. The fractional excretion of Na^+ may be as much as 5%, and the fractional excretion of K^+ can be as much as 70%. The increased excretion of K^+ is in part secondary to increased delivery of Na^+ to the distal nephron, as described in the section on inhibitors of Na^+ channels. The effects of carbonic anhydrase inhibitors on renal excretion are self-limiting, probably because the resulting metabolic acidosis decreases the filtered load of HCO_3^- to the point that the uncatalyzed reaction between CO_2 and water is sufficient to achieve HCO_3^- reabsorption.

Effects on Renal Hemodynamics

By inhibiting proximal reabsorption, carbonic anhydrase inhibitors increase delivery of solutes to the macula densa. This triggers TGF, which increases afferent arteriolar resistance and reduces renal blood flow (RBF) and GFR.

Other Actions

Carbonic anhydrase inhibitors have extrarenal sites of action. Carbonic anhydrase in the ciliary processes of the eye mediates formation of HCO_3^- in aqueous humor. Inhibition of carbonic anhydrase decreases the rate of formation of aqueous humor and consequently reduces intraocular pressure. *Acetazolamide* frequently causes paresthesias and somnolence, suggesting an action of carbonic anhydrase inhibitors in the CNS. The efficacy of *acetazolamide* in epilepsy is due in part to the production of metabolic acidosis; however, direct actions of *acetazolamide* in the CNS also contribute to its anticonvulsant action. Due to interference with carbonic anhydrase activity in erythrocytes, carbonic anhydrase inhibitors increase CO_2 levels in peripheral tissues and decrease CO_2 levels in expired gas. *Acetazolamide* causes vasodilation by opening vascular Ca^{2+}-activated K^+ channels; however, the clinical significance of this effect is unclear.

ADME

See Table 29–2 for pharmacokinetic data.

Therapeutic Uses

The efficacy of carbonic anhydrase inhibitors as single agents is low. The combination of *acetazolamide* with diuretics that block Na^+ reabsorption at more distal sites in the nephron causes a marked natriuretic response in patients with low basal fractional excretion of Na^+ (<0.2%) who are resistant to diuretic monotherapy. Even so, the long-term usefulness of carbonic anhydrase inhibitors often is compromised by the development of metabolic acidosis. The major indication for carbonic anhydrase inhibitors is open-angle glaucoma (Scozzafava and Supuran, 2014). Two products developed specifically for this use are *dorzolamide* and *brinzolamide*, which are available only as ophthalmic drops. Carbonic anhydrase inhibitors also may be employed for secondary glaucoma and preoperatively in acute-angle closure glaucoma to lower intraocular pressure before surgery (see Chapter 74). Orally administered *acetazolamide* is also used for the treatment of glaucoma (see Chapter 74) and absence seizures (see Chapter 20). *Acetazolamide* can provide symptomatic relief in patients with *high-altitude illness* or *mountain sickness* (Ritchie et al., 2012). Carbonic anhydrase inhibitors are also useful in patients with familial periodic paralysis. *Dichlorphenamide* is now approved for treating this syndrome. The mechanism for the beneficial effects of carbonic anhydrase inhibitors in altitude sickness and familial periodic paralysis may relate to the induction of a metabolic acidosis. Carbonic anhydrase inhibitors can be useful for correcting metabolic alkalosis, especially one caused by diuretic-induced increases in H^+ excretion. Other off-label uses include normal-pressure hydrocephalus, idiopathic intracranial hypertension, prevention of cystine renal calculi, and respiratory stimulant in stable hypercapnic chronic obstructive pulmonary disease.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Serious toxic reactions to carbonic anhydrase inhibitors are infrequent; however, these drugs are sulfonamide derivatives and, like other sulfonamides, may cause bone marrow depression, skin toxicity, sulfonamide-like renal lesions, and allergic reactions. With large doses, many patients exhibit drowsiness and paresthesias. Most adverse effects, contraindications, and drug interactions are secondary to urinary alkalinization or metabolic acidosis, including (1) diversion of ammonia of renal origin from urine into the systemic circulation, a process that may induce or worsen hepatic encephalopathy (the drugs are contraindicated in patients with hepatic cirrhosis); (2) calculus formation and ureteral colic due to precipitation of calcium phosphate salts in alkaline urine; (3) worsening of metabolic or respiratory acidosis (the drugs are contraindicated in patients with hyperchloremic acidosis or severe chronic obstructive pulmonary disease); and (4) reduction of the urinary excretion rate of weak organic bases. As such, caution is advised for patients receiving concomitant high-dose salicylates.

Osmotic Diuretics

Osmotic diuretics (Table 29–3) are freely filtered at the glomerulus, undergo limited reabsorption by the renal tubule, and are relatively inert

TABLE 29–3 ■ OSMOTIC DIURETICS

DRUG	ORAL AVAILABILITY	$t_{1/2}$ (hours)	ROUTE OF ELIMINATION
Glycerin	Orally active	0.5–0.75	~80% M, ~20% U
Isosorbide[a]	Orally active	5–9.5	R

[b]In renal failure, 6–36 h.

pharmacologically. Osmotic diuretics are administered in doses large enough to significantly increase the osmolality of plasma and tubular fluid. Of the osmotic diuretics listed, only *glycerin* and *mannitol* are currently available in the U.S.

Mechanism and Site of Action

Osmotic diuretics act in both the proximal tubule and the loop of Henle, with the latter the primary site of action. In the proximal tubule, osmotic diuretics act as nonreabsorbable solutes that limit the osmosis of water into the interstitial space and thereby reduce the luminal Na^+ concentration to the point that net Na^+ reabsorption ceases. By extracting water from intracellular compartments, osmotic diuretics expand extracellular fluid volume, decrease blood viscosity, and inhibit renin release. These effects increase RBF, and the increase in renal medullary blood flow removes NaCl and urea from the renal medulla, thus reducing medullary tonicity. A reduction in medullary tonicity causes a decrease in the extraction of water from the DTL, which in turn limits the concentration of NaCl in the tubular fluid entering the ATL. This latter effect diminishes the passive reabsorption of NaCl in the ATL. In addition, osmotic diuretics inhibit Mg^{2+} reabsorption in the TAL.

Effects on Urinary Excretion

Osmotic diuretics increase urinary excretion of nearly all electrolytes, including Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-, and phosphate.

Effects on Renal Hemodynamics

Osmotic diuretics increase RBF by a variety of mechanisms, but total GFR is not significantly altered.

ADME

Pharmacokinetic data on the osmotic diuretics are gathered in Table 29–3. Where available, *glycerin* and *isosorbide* can be given orally, whereas *mannitol* and *urea* must be administered intravenously (with the exception that *mannitol* powder is used by inhalation for diagnosis of bronchial hyperreactivity).

Therapeutic Uses

One use for *mannitol* is in the treatment of dialysis disequilibrium syndrome. Excessively removing solutes from the extracellular fluid by hemodialysis results in a reduction in the osmolality of extracellular fluid. Consequently, water moves from the extracellular compartment into the intracellular compartment, causing hypotension and CNS symptoms (headache, nausea, muscle cramps, restlessness, CNS depression, and convulsions). Osmotic diuretics increase the osmolality of the extracellular fluid compartment and thereby shift water back into the extracellular compartment. By increasing the osmotic pressure of plasma, osmotic diuretics extract water from the eye and brain. Osmotic diuretics are used to control intraocular pressure during acute attacks of glaucoma and for short-term reductions in intraocular pressure both preoperatively and postoperatively in patients who require ocular surgery. Also, *mannitol* is used to reduce cerebral edema and brain mass before and after neurosurgery and to control intracranial pressure in patients with traumatic brain injury (Wakai et al., 2013). A spray-dried form of *mannitol* is FDA approved for managing cystic fibrosis in adults; by hydrating airways, *mannitol* improves mucus clearance. *Mannitol* is also FDA approved for the diagnosis of bronchial hyperreactivity (by oral inhalation) and for antihemolytic urologic irrigation during transurethral procedures. *Mannitol* is often used to treat or prevent acute kidney injury; however, it is questionable whether *mannitol* improves renal outcomes (Nigwekar and Waikar, 2011).

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Osmotic diuretics are distributed in the extracellular fluid and contribute to the extracellular osmolality. Thus, water is extracted from intracellular compartments, and the extracellular fluid volume becomes expanded. In patients with heart failure or pulmonary congestion, this may cause frank pulmonary edema. Extraction of water also causes hyponatremia, which may explain the common adverse effects, including headache, nausea, and vomiting. Conversely, loss of water more than electrolytes can cause hypernatremia and dehydration. Osmotic diuretics are contraindicated in patients who are anuric due to severe renal disease. *Urea* may cause thrombosis or pain if extravasation occurs, and it should not be administered to patients with impaired liver function because of the risk of elevation of blood ammonia levels. Both *mannitol* and *urea* are contraindicated in patients with active cranial bleeding. Glycerin is metabolized and can cause hyperglycemia.

Inhibitors of Na^+-K^+-$2Cl^-$ Symport: Loop Diuretics, High-Ceiling Diuretics

The loop diuretics inhibit activity of the Na^+-K^+-$2Cl^-$ symporter in the TAL of the loop of Henle, hence the moniker *loop diuretics*. Although the proximal tubule reabsorbs about 65% of filtered Na^+, diuretics acting only in the proximal tubule have limited efficacy because the TAL has the capacity to reabsorb most of the unabsorbed material from the proximal tubule. In contrast, inhibitors of Na^+-K^+-$2Cl^-$ symport in the TAL, sometimes called *high-ceiling diuretics*, are highly efficacious because (1) about 25% of the filtered Na^+ load normally is reabsorbed by the TAL, and (2) nephron segments past the TAL do not possess the resorptive capacity to rescue the flood of unabsorbed material exiting the TAL.

Of the inhibitors of Na^+-K^+-$2Cl^-$ symport (Table 29–4), only *furosemide*, *bumetanide*, *ethacrynic acid*, and *torsemide* are available in the U.S. *Furosemide* and *bumetanide* contain a sulfonamide moiety. *Ethacrynic acid* is a phenoxyacetic acid derivative; *torsemide* is a sulfonylurea. *Furosemide* and *bumetanide* are available as oral and injectable formulations. *Torsemide* is available as an oral formulation; *ethacrynate sodium* is available as an injectable solution and *ethacrynic acid* as an oral tablet.

Mechanism and Site of Action

These agents act primarily in the TAL, where the flux of Na^+, K^+, and Cl^- from the lumen into epithelial cells is mediated by a Na^+-K^+-$2Cl^-$ symporter

TABLE 29–4 ■ INHIBITORS OF Na^+-K^+-$2Cl^-$ SYMPORT (LOOP DIURETICS, HIGH-CEILING DIURETICS)

DRUG	RELATIVE POTENCY	ORAL AVAILABILITY	$t_{1/2}$ (hours)	ROUTE OF ELIMINATION

[a]Metabolism of furosemide occurs predominantly in the kidney.
[b]Not available in the U.S.

(Figure 29–5). Inhibitors of this symporter block its function (Bernstein and Ellison, 2011; Wile, 2012), bringing salt transport in this segment of the nephron to a virtual standstill. There is evidence that these drugs attach to the Cl^- binding site located in the symporter's transmembrane domain; however, more recent studies challenge this view. Inhibitors of Na^+-K^+-$2Cl^-$ symport also inhibit Ca^{2+} and Mg^{2+} reabsorption in the TAL by abolishing the transepithelial potential difference that is the dominant driving force for reabsorption of these cations.

Na^+-K^+-$2Cl^-$ symporters are found in many secretory and absorbing epithelia. There are two varieties of Na^+-K^+-$2Cl^-$ symporters. The "absorptive" symporter (called *ENCC2, NKCC2*, or *BSC1*) is expressed only in the kidney, is localized to the apical membrane and subapical intracellular vesicles of the TAL, and is regulated by the cyclic AMP/PKA pathway. The "secretory" symporter (called *ENCC3, NKCC1*, or *BSC2*) is a "housekeeping" protein that is expressed widely and, in epithelial cells, is localized to the basolateral membrane. The affinity of loop diuretics for the secretory symporter is somewhat less than for the absorptive symporter (e.g., 4-fold difference for *bumetanide*). Mutations in the Na^+-K^+-$2Cl^-$ symporter cause a form of inherited hypokalemic alkalosis called Bartter syndrome.

Effects on Urinary Excretion

Loop diuretics increase urinary Na^+ and Cl^- excretion profoundly (i.e., up to 25% of the filtered Na^+ load) and markedly increase Ca^{2+} and Mg^{2+} excretion. *Furosemide* has weak carbonic anhydrase–inhibiting activity and thus increases urinary excretion of HCO_3^- and phosphate. All inhibitors of Na^+-K^+-$2Cl^-$ symport increase urinary K^+ and titratable acid excretion. This effect is due in part to increased Na^+ delivery to the distal tubule (the mechanism by which increased distal Na^+ delivery enhances K^+ and H^+ excretion is discussed in the section on Na^+ channel inhibitors). Other mechanisms contributing to enhanced K^+ and H^+ excretion include flow-dependent enhancement of ion secretion by the collecting duct, nonosmotic vasopressin release, and activation of the renin-angiotensin system (RAS) axis.

Acutely, loop diuretics increase uric acid excretion; their chronic administration results in reduced uric acid excretion. Chronic effects of loop diuretics on uric acid excretion may be due to enhanced proximal tubule transport or secondary to volume depletion or to competition between diuretic and uric acid for the organic acid secretory mechanism in the proximal tubule. Asymptomatic hyperuricemia is a common consequence of loop diuretics, but painful episodes of gout are rarely reported (Bruderer et al., 2014). By blocking active NaCl reabsorption in the TAL, inhibitors of Na^+-K^+-$2Cl^-$ symport interfere with a critical step in the mechanism that produces a hypertonic medullary interstitium. Therefore, loop diuretics block the kidney's ability to concentrate urine. Also, because the TAL is part of the diluting segment, inhibitors of Na^+-K^+-$2Cl^-$ symport markedly impair the kidney's ability to excrete a dilute urine during water diuresis.

Effects on Renal Hemodynamics

If volume depletion is prevented by replacing fluid losses, inhibitors of Na^+-K^+-$2Cl^-$ symport generally increase total RBF and redistribute RBF to the midcortex. The mechanism of the increase in RBF is not known but may involve PGs: nonsteroidal anti-inflammatory drugs (NSAIDs) attenuate the diuretic response to loop diuretics in part by preventing prostaglandin (PG)-mediated increases in RBF. Loop diuretics block TGF by inhibiting salt transport into the macula densa so that the macula densa no longer detects NaCl concentrations in the tubular fluid. Therefore, unlike carbonic anhydrase inhibitors, loop diuretics do not decrease the GFR by activating TGF. Loop diuretics are powerful stimulators of renin release. This effect is due to interference with NaCl transport by the macula densa and, if volume depletion occurs, to reflex activation of the sympathetic nervous system and stimulation of the intrarenal baroreceptor mechanism.

Other Actions

Loop diuretics, particularly *furosemide*, acutely increase systemic venous capacitance and thereby decrease left ventricular filling pressure. This effect, which may be mediated by PGs and requires intact kidneys, benefits patients with pulmonary edema even before diuresis ensues. High doses of inhibitors of Na^+-K^+-$2Cl^-$ symport can inhibit electrolyte transport in many tissues. This effect is clinically important in the inner ear and can result in ototoxicity, particularly in patients with preexisting hearing impairment.

ADME

Table 29–4 presents some pharmacokinetic properties of the agents. Because these drugs are bound extensively to plasma proteins, delivery of these drugs to tubules by filtration is limited. However, they are secreted efficiently by the organic acid transport system in the proximal tubule and thereby gain access to the Na^+-K^+-$2Cl^-$ symporter in the luminal membrane of the TAL. For loop diuretics, this involves OAT1 and OAT3 on the basolateral membrane and multidrug resistance-associated protein 4 (MRP-4) on the luminal membrane (Ellison, 2019). Approximately 65% of *furosemide* is excreted unchanged in urine, and the remainder is conjugated to glucuronic acid in the kidney. Thus, in patients with renal disease, the elimination $t_{1/2}$ of *furosemide* is prolonged. *Bumetanide* and *torsemide* have significant hepatic metabolism, so liver disease can prolong the elimination $t_{1/2}$ of these loop diuretics. Oral bioavailability of *furosemide* varies (10%–100%). In contrast, oral availabilities of *bumetanide* and *torsemide* are reliably high.

As a class, loop diuretics have short elimination half-lives; prolonged-release preparations are not available. Consequently, often the dosing interval is too short to maintain adequate levels of loop diuretics in the tubular lumen. Note that *torsemide* has a longer $t_{1/2}$ than other agents available in the U.S. As the concentration of loop diuretic in the tubular lumen declines, nephrons begin to avidly reabsorb Na^+, which often nullifies the overall effect of the loop diuretic on total-body Na^+. This phenomenon of "postdiuretic Na^+ retention" can be overcome by restricting dietary Na^+ intake or by more frequent administration of the loop diuretic.

Therapeutic Uses

A major use of loop diuretics is in the treatment of acute pulmonary edema. A rapid increase in venous capacitance in conjunction with brisk natriuresis reduces left ventricular filling pressures and thereby rapidly relieves pulmonary edema. Loop diuretics also are used widely for treatment of chronic congestive heart failure (CHF) when diminution of extracellular fluid volume is desirable to minimize venous and pulmonary congestion (see Chapter 33). Diuretics cause a significant reduction in mortality and the risk of worsening heart failure, as well as an improvement in exercise capacity. Although *furosemide* is the most commonly used loop diuretic for the treatment of heart failure, patients with heart failure have fewer hospitalizations and better quality of life with *torsemide* than with *furosemide*, perhaps because of its more reliable absorption and due to other ancillary pharmacological effects (Buggey et al., 2015).

Although diuretics are used widely for treatment of hypertension (see Chapter 32), in patients with normal renal function, Na^+-K^+-$2Cl^-$ symport inhibitors are not considered first-line diuretics for the treatment of hypertension. This is due to the lower antihypertensive efficacy of loop diuretics in such patients and the lack of data demonstrating a reduction in cardiovascular events. However, in patients with a low GFR (<30 mL/min) or with resistant hypertension, loop diuretics are the diuretics of choice.

The edema of nephrotic syndrome often is refractory to less-potent diuretics, and loop diuretics often are the only drugs capable of reducing the massive edema associated with this renal disease. Loop diuretics also are employed in the treatment of edema and ascites of liver cirrhosis; however, care must be taken not to induce volume contraction. In patients with a drug overdose, loop diuretics can be used to induce forced diuresis to facilitate more rapid renal elimination of the offending drug. Loop diuretics, combined with isotonic saline administration to prevent volume depletion, are used to treat hypercalcemia. Loop diuretics interfere with the kidney's capacity to produce concentrated urine. Consequently, loop diuretics combined with hypertonic saline are useful for the

treatment of life-threatening hyponatremia. Loop diuretics also are used to treat edema associated with chronic kidney disease (CKD), in which the dose-response curve may be right shifted, requiring higher doses of the loop diuretic.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Most adverse effects are due to abnormalities of fluid and electrolyte balance. Overzealous use of loop diuretics can cause serious depletion of total-body Na^+. This may manifest as hyponatremia or extracellular fluid volume depletion associated with hypotension, reduced GFR, circulatory collapse, thromboembolic episodes, and, in patients with liver disease, hepatic encephalopathy. Increased Na^+ delivery to the distal tubule, particularly when combined with activation of the RAS, leads to increased urinary K^+ and H^+ excretion, causing a hypochloremic alkalosis. If dietary K^+ intake is not sufficient, hypokalemia may develop, and this may induce cardiac arrhythmias, particularly in patients taking cardiac glycosides. Increased Mg^{2+} and Ca^{2+} excretion may result in hypomagnesemia (a risk factor for cardiac arrhythmias) and hypocalcemia (rarely leading to tetany). Loop diuretics should be avoided in postmenopausal osteopenic women, in whom increased Ca^{2+} excretion may have deleterious effects on bone metabolism.

Loop diuretics can cause ototoxicity that manifests as tinnitus, hearing impairment, deafness, vertigo, and a sense of fullness in the ears. Hearing impairment and deafness are usually, but not always, reversible. Ototoxicity occurs most frequently with rapid intravenous administration and least frequently with oral administration. To avoid ototoxicity, the rate of *furosemide* infusions should not exceed 4 mg/min. *Ethacrynic acid* appears to induce ototoxicity more often than do other loop diuretics and should be reserved for use only in patients who cannot tolerate other loop diuretics (e.g., due to sulfa allergies). Loop diuretics also can cause hyperuricemia (occasionally leading to gout) and hyperglycemia (infrequently precipitating diabetes mellitus) and can increase plasma levels of low-density lipoprotein (LDL) cholesterol and triglycerides while decreasing plasma levels of high-density lipoprotein (HDL) cholesterol. Other adverse effects include skin rashes, photosensitivity, paresthesias, bone marrow depression, and GI disturbances. Contraindications to the use of loop diuretics include severe Na^+ and volume depletion, hypersensitivity to sulfonamides (for sulfonamide-based loop diuretics), and anuria unresponsive to a trial dose of loop diuretic.

Drug interactions may occur when loop diuretics are administered with the following:

- Aminoglycosides, *carboplatin*, *paclitaxel*, and others (synergism of ototoxicity)
- Digitalis glycosides (increased *digitalis*-induced arrhythmias)
- *Lithium* (increased plasma levels of Li^+)
- *Propranolol* (increased plasma levels of *propranolol*)
- Sulfonylureas (hyperglycemia)
- *Cisplatin* (increased risk of diuretic-induced ototoxicity)
- NSAIDs (blunted diuretic response and salicylate toxicity with high doses of salicylates)
- *Probenecid* (blunted diuretic response)
- Thiazide diuretics (synergism of diuretic activity of both drugs, leading to profound diuresis)
- *Amphotericin B* (increased potential for nephrotoxicity and intensification of electrolyte imbalance)

Inhibitors of Na^+-Cl^- Symport: Thiazide-Type and Thiazide-Like Diuretics

The term *thiazide diuretics* generally refers to all inhibitors of Na^+-Cl^- symport, so named because the original inhibitors of Na^+-Cl^- symport were benzothiadiazine derivatives. The class now includes diuretics that are benzothiadiazine derivatives (*thiazide* or *thiazide-type diuretics*) and drugs that are pharmacologically similar to thiazide diuretics but differ structurally (*thiazide-like diuretics*). Table 29–5 lists diuretics in this drug class that are currently available in the U.S.

Mechanism and Site of Action

Thiazide diuretics inhibit NaCl transport in the DCT; the proximal tubule may represent a secondary site of action. Figure 29–5 illustrates the current model of electrolyte transport in the DCT. Transport is powered by a Na^+ pump in the basolateral membrane. Free energy in the electrochemical gradient for Na^+ is harnessed by a Na^+-Cl^- symporter in the luminal membrane that moves Cl^- into the epithelial cell against its electrochemical gradient. Cl^- then exits the basolateral membrane passively by a Cl^- channel. Thiazide diuretics inhibit the Na^+-Cl^- symporter (called *ENCC1* or *TSC*) that is expressed predominantly in kidney and localized to the apical membrane of DCT epithelial cells. Expression of the symporter is regulated by aldosterone. Mutations in the Na^+-Cl^- symporter cause a form of inherited hypokalemic alkalosis called Gitelman syndrome.

Effects on Urinary Excretion

Inhibitors of Na^+-Cl^- symport increase Na^+ and Cl^- excretion. However, thiazides are only moderately efficacious (i.e., maximum excretion of filtered Na^+ load is only 5%) because about 90% of the filtered Na^+ load is reabsorbed before reaching the DCT. Some thiazide diuretics also are weak inhibitors of carbonic anhydrase, an effect that increases HCO_3^- and phosphate excretion and probably accounts for their weak proximal tubular effects. Inhibitors of Na^+-Cl^- symport increase K^+ and titratable acid excretion by the same mechanisms discussed for loop diuresis. Acute thiazide administration increases uric acid excretion. However, uric acid excretion is reduced following chronic administration by similar mechanisms discussed for loop diuretics. Acute effects of inhibitors of Na^+-Cl^- symport on Ca^{2+} excretion are variable; when administered chronically, thiazide diuretics decrease Ca^{2+} excretion. The mechanism involves increased proximal reabsorption owing to volume depletion,

TABLE 29–5 ■ INHIBITORS OF Na^+-Cl^- SYMPORT (THIAZIDE DIURETICS)

DRUG	RELATIVE POTENCY	ORAL AVAILABILITY	$t_{1/2}$ (hours)	ROUTE OF ELIMINATION
Thiazide diuretics				
Bendroflumethiazide	10	~100%	3–3.9	~30% R, ~70% M
Chlorothiazide	0.1	9%–56% (dose-dependent)	~1.5	R
Hydrochlorothiazide	1	~70%	~2.5	R
Methyclothiazide	10	ID	ID	M
Thiazide-like diuretics				
Chlorthalidone	1	~65%	~47	~65% R, ~10% B, ~25% U
Indapamide	20	~93%	~14	M
Metolazone	10	~65%	8–14	~80% R, ~10% B, ~10% M

B, excretion of intact drug into bile; ID, insufficient data; M, metabolism; R, renal excretion of intact drug; U, unknown pathway of elimination.

as well as direct effects of thiazides to increase Ca^{2+} reabsorption in the DCT. Thiazide diuretics may cause mild magnesuria; long-term use of thiazide diuretics may cause magnesium deficiency, particularly in the elderly. Because inhibitors of Na^+-Cl^- symport inhibit transport in the cortical diluting segment, thiazide diuretics attenuate the kidney's ability to excrete dilute urine during water diuresis. However, because the DCT is not involved in the mechanism that generates a hypertonic medullary interstitium, thiazide diuretics do not alter the kidney's ability to concentrate urine during hydropenia. In general, inhibitors of Na^+-Cl^- symport do not affect RBF and only variably reduce GFR owing to increases in intratubular pressure. Thiazides have little or no influence on TGF.

ADME

Table 29–5 lists pharmacokinetic parameters of Na^+-Cl^- symport inhibitors. Note the wide range of half-lives for these drugs. As with loop diuretics, thiazides are secreted into the proximal tubule by the organic acid secretory pathway, which involves OAT1 and OAT3 on the basolateral membrane and multidrug resistance-associated protein 4 (MRP-4) on the luminal membrane (Ellison, 2019). Because thiazides must gain access to the tubular lumen to inhibit the Na^+-Cl^- symporter, drugs such as *probenecid* can attenuate the diuretic response to thiazides by competing for transport into the proximal tubule. However, plasma protein binding varies considerably among thiazide diuretics, and this parameter determines the contribution that filtration makes to tubular delivery of a specific thiazide.

Therapeutic Uses

Thiazide diuretics are used for the treatment of edema associated with diseases of the heart (CHF), liver (hepatic cirrhosis), and kidney (nephrotic syndrome, chronic renal failure, and acute glomerulonephritis). With the possible exceptions of *metolazone* and *indapamide*, most thiazide diuretics are ineffective when the GFR is less than 30 to 40 mL/min. Thiazide diuretics decrease blood pressure in hypertensive patients and are used widely for the treatment of hypertension in combination with other antihypertensive drugs (Tamargo et al., 2014) (see Chapter 32). Thiazide diuretics are inexpensive, as efficacious as other classes of antihypertensive agents, and well tolerated. Thiazides can be administered once daily, do not require dose titration, and have few contraindications. Moreover, thiazides have additive or synergistic effects when combined with other classes of antihypertensive agents. Although *hydrochlorothiazide* is the 10th most prescribed drug in the U.S. and is prescribed 20 times more often than *chlorthalidone* (Roush et al., 2015), there is strong evidence that *chlorthalidone* and other thiazide-like diuretics, such as *indapamide*, reduce blood pressure and cardiovascular events in hypertensive patients more so than does *hydrochlorothiazide* (Liang et al., 2017; Olde Engberink et al., 2015; Roush et al., 2015). This is likely due to the longer half-life of *thiazide-like* diuretics compared to *hydrochlorothiazide*, resulting in better 24-h control of arterial blood pressure by *chlorthalidone*.

Thiazide diuretics, which reduce urinary Ca^{2+} excretion, sometimes are employed to treat Ca^{2+} nephrolithiasis and may be useful for treatment of osteoporosis (see Chapter 52). Thiazide diuretics also are the mainstay for treatment of nephrogenic diabetes insipidus (DI), reducing urine volume by up to 50%. Although it may seem counterintuitive to treat a disorder of increased urine volume with a diuretic, thiazides reduce the kidney's ability to excrete free water: They increase proximal tubular water reabsorption (secondary to volume contraction) and block the ability of the DCT to form dilute urine. This last effect results in an increase in urine osmolality. Because other halides are excreted by renal processes similar to those for Cl^-, thiazide diuretics may be useful for the management of Br^- intoxication.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Thiazide diuretics rarely cause CNS (e.g., vertigo, headache), GI, hematological, and dermatological (e.g., photosensitivity, skin rashes, systemic lupus erythematosus) disorders. Thiazides are sulfonamides and can trigger sulfa allergic reactions. They can cause idiosyncratic acute transient myopia and acute angle-closure glaucoma (risk factors may include a history of sulfonamide allergy). The incidence of erectile dysfunction is greater with Na^+-Cl^- symport inhibitors than with several other antihypertensive agents (Grimm et al., 1997), but usually is tolerable. As with loop diuretics, most serious adverse effects of thiazides are related to abnormalities of fluid and electrolyte balance. These adverse effects include extracellular volume depletion, hypotension, hypokalemia, hyponatremia, hypochloremia, metabolic alkalosis, hypomagnesemia, hypercalcemia, and hyperuricemia. Thiazide diuretics have caused fatal or near-fatal hyponatremia (Rodenburg et al., 2013), and some patients are at recurrent risk of hyponatremia when rechallenged with thiazides.

Thiazide diuretics also decrease glucose tolerance and unmask latent diabetes mellitus (Scheen, 2018). The mechanism of impaired glucose tolerance appears to involve reduced insulin secretion and alterations in glucose metabolism. Hyperglycemia is reduced when K^+ or a K^+-sparing diuretic, such as *amiloride*, is given along with the thiazide diuretic (Brown et al., 2016). Importantly, thiazide-induced diabetes mellitus is not associated with the same cardiovascular disease risk as incident diabetes, and the benefits of thiazide diuretics outweigh the risks of worsening glucose control in both type 2 diabetics and those with new-onset diabetes (Scheen, 2018). Thiazide-induced hypokalemia also impairs the antihypertensive effect and cardiovascular protection afforded by thiazides in patients with hypertension. Thiazide diuretics also may increase plasma levels of low-density lipoprotein cholesterol, total cholesterol, and total triglycerides. Thiazide diuretics are contraindicated in individuals who are hypersensitive to sulfonamides. Thiazide diuretics may diminish the effects of uricosuric agents used to treat gout, sulfonylureas, and insulin and may increase the effects of anesthetics, *diazoxide*, digitalis glycosides, *lithium*, loop diuretics, and vitamin D. The effectiveness of thiazide diuretics may be reduced by NSAIDs, nonselective or selective COX-2 inhibitors, and bile acid sequestrants (reduced absorption of thiazides). *Amphotericin B* and corticosteroids increase the risk of hypokalemia induced by thiazide diuretics.

In a potentially lethal interaction, thiazide diuretic–induced K^+ depletion may contribute to fatal ventricular arrhythmias associated with drugs that prolong the QT interval (i.e., *quinidine*, *dofetilide*, *arsenic trioxide*; see also Chapter 34).

Inhibitors of Renal Epithelial Na^+ Channels: K^+-Sparing Diuretics

Triamterene and *amiloride* are the only two drugs of this class in clinical use. Both drugs cause small increases in NaCl excretion and usually are employed for their antikaliuretic actions to offset the effects of other diuretics that increase K^+ excretion. Consequently, *triamterene* and *amiloride*, along with *spironolactone* and *eplerenone* (described in the next section), often are classified as *potassium* (K^+)*–sparing diuretics.*

Mechanism and Site of Action

Both *triamterene* and *amiloride* are organic bases, are transported by the organic base secretory mechanism in the proximal tubule and have similar mechanisms of action (Figure 29–5). Principal cells in the late distal tubules and collecting ducts (particularly cortical collecting tubules) have, in their luminal membranes, ENaCs that provide a conductive pathway for Na^+ entry into the cell down the electrochemical gradient created by the basolateral Na^+ pump. The higher permeability of the luminal membrane for Na^+ depolarizes the luminal membrane but not the basolateral membrane, creating a lumen-negative transepithelial potential difference. This transepithelial voltage provides an important driving force for the secretion of K^+ into the lumen via K^+ channels (ROMK [Kir1.1] and BK channels) (Garcia and Kaczorowski, 2014) in the luminal membrane; however, the overall regulation of K^+ secretion in the late distal tubule and collecting duct involves multiple signaling mechanisms (Welling, 2013). Carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics increase Na^+ delivery to the late distal tubule and collecting duct, a situation that often is associated with increased K^+ and H^+ excretion.

Amiloride and *triamterene* block ENaCs in the luminal membrane of principal cells in late distal tubules and collecting ducts by binding to a site in the channel pore. ENaCs consist of three subunits (α, β, and γ)

TABLE 29–6 ■ INHIBITORS OF RENAL EPITHELIAL Na^+ CHANNELS (K^+-SPARING DIURETICS)

DRUG	RELATIVE POTENCY	ORAL BIOAVAILABILITY	$t_{1/2}$ (hours)	ROUTE OF ELIMINATION
Amiloride	1	15%–25%	~21	R
Triamterene	0.1	~50%	~4	M

M, metabolism; R, renal excretion of intact drug; however, triamterene is transformed into an active metabolite that is excreted in the urine.

(Kellenberger and Schild, 2015). Although the α subunit is sufficient for channel activity, maximal Na^+ permeability is induced when all three subunits are coexpressed in the same cell, probably forming a tetrameric structure consisting of two α subunits, one β subunit, and one γ subunit. Incompletely understood, complex mechanisms, including proteolytic cleavage, regulate epithelial Na^+ channel (ENaC) activation (Kellenberger and Schild, 2015).

Effects on Urinary Excretion

The late distal tubule and collecting duct have a limited capacity to reabsorb solutes; thus, Na^+ channel blockade in this part of the nephron increases Na^+ and Cl^- excretion rates only mildly (~2% of filtered load). Blockade of Na^+ channels hyperpolarizes the luminal membrane, reducing the lumen-negative transepithelial voltage. Because the lumen-negative potential difference normally opposes cation reabsorption and facilitates cation secretion, attenuation of the lumen-negative voltage decreases K^+, H^+, Ca^{2+}, and Mg^{2+} excretion rates. Volume contraction may increase reabsorption of uric acid in the proximal tubule; hence, chronic administration of *amiloride* and *triamterene* may decrease uric acid excretion. *Amiloride* and *triamterene* have little or no effect on renal hemodynamics and do not alter TGF.

ADME

Table 29–6 lists pharmacokinetic data for *amiloride* and *triamterene*. *Amiloride* is eliminated predominantly by urinary excretion of intact drug. *Triamterene* is metabolized in the liver to an active metabolite, 4-hydroxytriamterene sulfate, and this metabolite is excreted in urine. Therefore, *triamterene* toxicity may be enhanced in both hepatic disease and renal failure.

Therapeutic Uses

Because of the mild natriuresis induced by Na^+ channel inhibitors, these drugs seldom are used as sole agents in treatment of edema or hypertension; their major utility is in combination with other diuretics. Coadministration of a Na^+ channel inhibitor augments the diuretic and antihypertensive response to thiazide and loop diuretics. More important, the ability of Na^+ channel inhibitors to reduce K^+ excretion tends to offset the kaliuretic effects of thiazide and loop diuretics and results in normal plasma K^+ values.

Liddle syndrome (described later in this chapter) can be treated effectively with Na^+ channel inhibitors. Aerosolized *amiloride* has been shown to improve mucociliary clearance in patients with cystic fibrosis. By inhibiting Na^+ absorption from the surfaces of airway epithelial cells, *amiloride* augments hydration of respiratory secretions and thereby improves mucociliary clearance. *Amiloride* also is useful for *lithium*-induced nephrogenic DI because it blocks Li^+ transport into collecting tubule cells (Kortenoeven et al., 2009).

Toxicity, Adverse Effects, Contraindications, Drug Interactions

The most dangerous adverse effect of renal Na^+ channel inhibitors is hyperkalemia, which can be life threatening. Consequently, *amiloride* and *triamterene* are contraindicated in patients with hyperkalemia, as well as in patients at increased risk of developing hyperkalemia (e.g., patients with renal failure, patients receiving other K^+-sparing diuretics, patients taking angiotensin-converting enzyme inhibitors, or patients taking K^+ supplements). Even NSAIDs can increase the likelihood of hyperkalemia in patients receiving Na^+ channel inhibitors. Routine monitoring of the serum K^+ level is essential in patients receiving K^+-sparing diuretics. Cirrhotic patients are prone to megaloblastosis because of folic acid deficiency, and *triamterene*, a weak folic acid antagonist, may increase the likelihood of this adverse event. *Triamterene* also can reduce glucose tolerance and induce photosensitization and has been associated with interstitial nephritis and renal stones. Both drugs can cause CNS, GI, musculoskeletal, dermatological, and hematological adverse effects. The most common adverse effects of *amiloride* are nausea, vomiting, diarrhea, and headache; those of *triamterene* are nausea, vomiting, leg cramps, and dizziness.

Antagonists of Mineralocorticoid Receptors: Aldosterone Antagonists, K^+-Sparing Diuretics

Mineralocorticoids cause salt and water retention and increase K^+ and H^+ excretion by binding to specific mineralocorticoid receptors (MRs). Three MR antagonists are available in the U.S. (Table 29–7). *Spironolactone* and *eplerenone* have a steroidal structure, and *finerenone*, which was FDA approved in 2021, is a nonsteroidal MR antagonist. *Finerenone* and other nonsteroidal MR antagonists under development are sometimes referred to as "MR blockers" to differentiate them from *spironolactone* and *eplerenone*, which are widely called MR antagonists.

Mechanism and Site of Action

Epithelial cells in late distal tubule and collecting duct (particularly cortical collecting tubule) contain cytosolic MRs with high aldosterone affinity. When aldosterone binds to MRs, the MR-aldosterone complex translocates to the nucleus, where it regulates the expression of multiple gene products called aldosterone-induced proteins (AIPs) (Figure 29–6). AIPs affect the production, destruction, localization, and activation of multiple components of the system that mediates Na^+ reabsorption in late distal tubules and collecting ducts (Figure 29–6A). Consequently, transepithelial NaCl transport is enhanced, and the lumen-negative transepithelial voltage is increased. The latter effect increases the driving force for K^+ and H^+ secretion into the tubular lumen.

Drugs such as *spironolactone*, *eplerenone*, and *finerenone* competitively inhibit the binding of aldosterone to the MR. Unlike the MR-aldosterone complex, the MR-MRA antagonist complex is not able to induce the synthesis of AIPs. Because *spironolactone*, *eplerenone*, and *finerenone* block the biological effects of aldosterone, these agents also are referred to as *aldosterone antagonists*. MR antagonists are the only diuretics that do not require access to the tubular lumen to induce diuresis.

TABLE 29–7 ■ MINERALOCORTICOID RECEPTOR ANTAGONISTS (ALDOSTERONE ANTAGONISTS, K^+-SPARING DIURETICS)

DRUG	ORAL AVAILABILITY	$t_{1/2}$ (hours)	ROUTE OF ELIMINATION
Spironolactone	~65%	~1.6	M
Canrenone[a]	80%	3.7–22	M
Potassium canrenoate[a]	100%	3.7–22	M
Eplerenone	69%	~5	M
Finerenone	44%	~2	M

M, metabolism.
[a]Not available in the U.S.

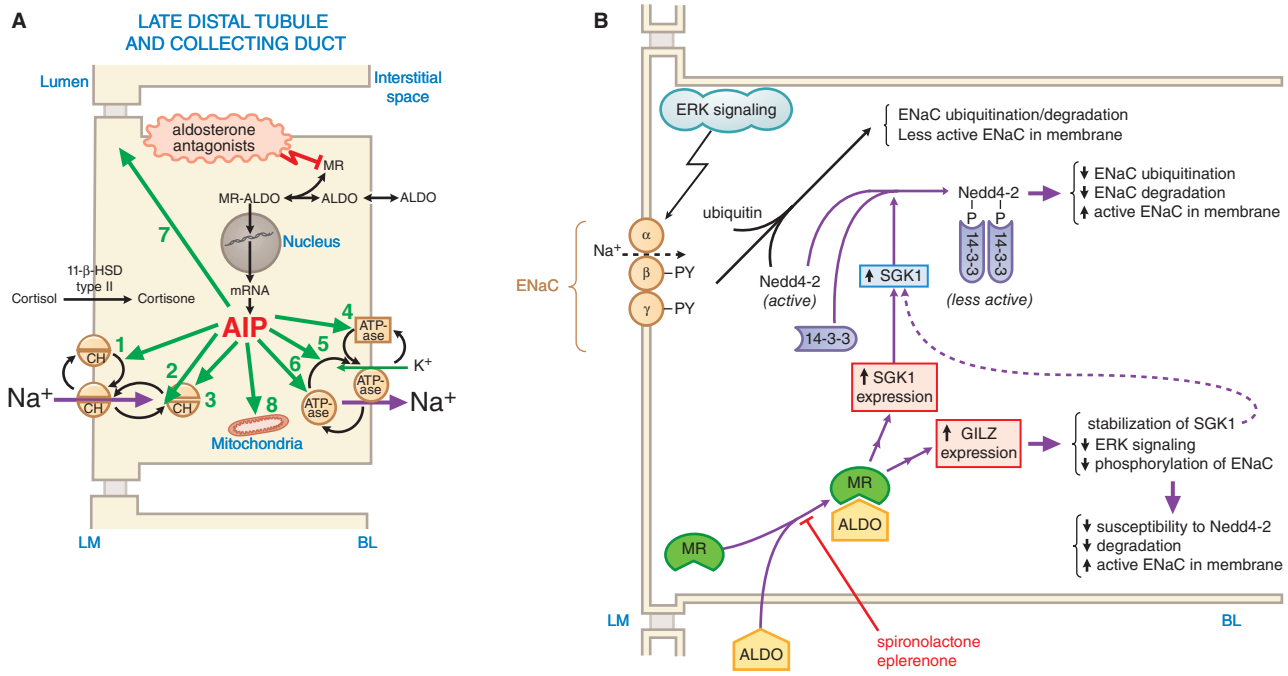

Figure 29–6 *Effects of aldosterone on late distal tubule and collecting duct and diuretic mechanism of aldosterone antagonists.*

A. ***Overview of aldosterone's influences on Na⁺ retention.*** Via interaction with the mineralocorticoid receptor (MR), aldosterone affects several renal pathways that handle Na^+. Key to numbered items influenced by aldosterone (ALDO):

1. Activation of membrane-bound Na^+ channels
2. Na^+ channel (ENaC) removal from the membrane inhibited
3. *De novo* synthesis of Na^+ channels
4. Activation of membrane-bound Na^+,K^+-ATPase
5. Redistribution of Na^+,K^+-ATPase from cytosol to membrane
6. *De novo* synthesis of Na^+,K^+-ATPase
7. Changes in permeability of tight junctions
8. Increased mitochondrial production of ATP

Cortisol also has affinity for the mineralocorticoid receptor but is inactivated in the cell by 11-β-hydroxysteroid dehydrogenase (HSD) type II.

B. ***Details of aldosterone's influences on membrane ENaC.*** ERK signaling phosphorylates components of ENaC, making them susceptible to interaction with Nedd4-2, a ubiquitin-protein ligase that ubiquitinates ENaC, leading to its degradation. The Nedd4-2 interaction with ENaC occurs via several proline-tyrosine-proline (PY) motifs of ENaC. ALDO enhances expression of the serum and glucocorticoid-regulated kinase-1 (SGK1) and the glucocorticoid-induced leucine zipper protein (GILZ; TSC22D3). SGK1 phosphorylates and inactivates Nedd4-2; 14-3-3 dimers bind to the phosphorylated sites in Nedd4-2 and stabilize them. Phosphorylated Nedd4-2 no longer interacts well with the PY motifs of ENaC. As a result, ENaC is not ubiquitinated and remains in the membrane, leading to increased Na^+ entry into the cell. GILZ stabilizes SGK1, enhancing its effects, and decreases ERK signaling and ENaC phosphorylation, events that prime ENaC for degradation; these effects all lead to less ubiquitination and more active ENaC in the cell membranes of the distal tubule and collecting duct. For details see Ronzaud and Staub (2014) and Ronchetti et al. (2015). AIP, aldosterone-induced proteins; ALDO, aldosterone; CH, ion channel; BL, basolateral membrane; LM, luminal membrane; MR, mineralocorticoid receptor.

Both the β and γ subunits of ENaC have a specific region in their C terminus called the PY motif. The PY motif interacts with the ubiquitin ligase Nedd4-2 (Figure 29–6B), a protein that ubiquitinates ENaC and targets it for destruction by the proteasome. Aldosterone increases the expression of serum and glucocorticoid-stimulated kinase 1 (SKG-1); SGK-1 phosphorylates and inactivates Nedd4-2. Thus, aldosterone results in attenuated internalization and proteasome-mediated degradation of ENaC, leading to increased expression of ENaC in the luminal membrane. Liddle syndrome, an autosomal-dominant, monogenic disease characterized by sodium retention and severe hypertension, is caused by mutations in the PY motif of either the β or γ subunit of ENaC, leading to MR-independent overexpression of ENaC. Thus, Liddle syndrome is responsive to ENaC inhibitors but not to MR antagonists.

Effects on Urinary Excretion

The effects of MR antagonists on urinary excretion are similar to those induced by renal ENaC inhibitors. However, unlike Na^+ channel inhibitors, the clinical efficacy of MR antagonists is a function of endogenous aldosterone levels. The higher the endogenous aldosterone level, the greater the effects of MR antagonists on urinary excretion. MR antagonists have little or no effect on renal hemodynamics and do not alter TGF.

Other Actions

Spironolactone has some affinity toward progesterone and androgen receptors and thereby induces side effects such as gynecomastia, impotence, and menstrual irregularities. Owing to its 9,11-epoxide group, *eplerenone* has very low affinity for progesterone and androgen receptors (<1% and <0.1%, respectively) compared with *spironolactone*. Nonsteroidal MR blockers (e.g., *finerenone*) also have very low affinity for progesterone and androgen receptors. High *spironolactone* concentrations can interfere with steroid biosynthesis by inhibiting steroid hydroxylases, but these effects have limited clinical relevance.

ADME

Spironolactone is absorbed partially (~65%), is metabolized extensively (even during its first passage through the liver), undergoes enterohepatic recirculation, and is highly protein bound. Although *spironolactone* per se has a short $t_{1/2}$ (~1.6 h), it is metabolized to a number of active compounds (including canrenone; see discussion that follows) that have long

half-lives. The $t_{1/2}$ of *spironolactone* is prolonged to 9 h in patients with cirrhosis. *Eplerenone* and *finerenone* have good oral availability and are eliminated primarily by metabolism by CYP3A4 to inactive metabolites, with a $t_{1/2}$ of about 5 h for *eplerenone* and 2 h for *finerenone*. Canrenone and K^+-canrenoate also are in clinical use (not available in the U.S.). Canrenoate is not active but is *converted* to canrenone. Due to first-pass metabolism in the gut wall and liver, *finerenone* has an oral availability of only 44%.

Therapeutic Uses

The MR antagonists often are coadministered with thiazide or loop diuretics in the treatment of edema and hypertension. Such combinations result in increased mobilization of edema fluid while causing lesser perturbations of K^+ homeostasis. MR antagonists are particularly useful in the treatment of resistant hypertension due to primary hyperaldosteronism (adrenal adenomas or bilateral adrenal hyperplasia) and of refractory edema associated with secondary aldosteronism (cardiac failure, hepatic cirrhosis, nephrotic syndrome, and severe ascites). MR antagonists are considered diuretics of choice in patients with hepatic cirrhosis. MR antagonists, added to standard therapy, substantially reduce morbidity and mortality in patients with heart failure with reduced ejection fraction (see Chapter 33) (D'Elia and Krum, 2014).

In patients with heart failure with reduced ejection fraction, MR antagonists reduce overall and cardiac mortality, sudden cardiac death, cardiac hospitalizations, and progression of heart failure and are recommended for patients with mild to marked heart failure severity (Flatt et al., 2016). In patients with heart failure with preserved ejection fraction, the use of MR antagonists remains controversial. In such patients, MR antagonists improve left ventricular diastolic function but do not improve exercise capacity, mortality, or hospitalization for heart failure (Edelmann et al., 2013; Li et al., 2018; Pitt et al., 2014). MR antagonists also may reduce ventricular arrhythmias and sudden cardiac death.

MR antagonists reduce proteinuria in patients with CKD, and the use of these drugs in kidney diseases is under intense investigation (Bauersachs et al., 2015). The nonsteroidal MR blocker *finerenone* improves a composite of renal outcomes and cardiovascular outcomes in patients with CKD and type 2 diabetes (Bakris et al., 2020). The improvement in cardiovascular outcomes with *finerenone* in type 2 diabetics with CKD is independent of preexisting atherosclerotic cardiovascular disease (Filippatos et al., 2020). *Finerenone* is FDA approved to decrease the risk of renal function decline, nonfatal myocardial infarction, hospitalization for heart failure, and death due to cardiovascular disease in adult patients with CKD associated with type 2 diabetes. In 2021, *finerenone* was FDA approved to reduce the risk of end-stage kidney disease, cardiovascular death, and heart failure in diabetic patients with CKD.

Spironolactone, but not *eplerenone*, is widely considered to be an antiandrogenic compound and has been used to treat hirsutism and acne; however, evidence for efficacy is weak (Brown et al., 2009), and these uses are not FDA approved. Biochemical studies suggested that *spironolactone* is a partial agonist of androgen receptors (Nirdé et al., 2001) and can exert antiandrogenic or androgenic effects depending on context (e.g., the prevailing levels of endogenous androgenic steroids). Indeed, a case report describes *spironolactone*-induced worsening of prostate cancer attributed to androgen receptor stimulation (Sundar and Dickinson, 2012).

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Hyperkalemia is the principal risk of MR antagonists. Therefore, these drugs are contraindicated in patients with hyperkalemia and in those at increased risk of developing hyperkalemia. *Eplerenone* and *finerenone* are contraindicated in patients with creatinine clearance ≤30 mL/min and ≤25 mL/min, respectively. The starting dose of *finerenone* should be decreased from 20 mg to 10 mg in patients with creatinine clearance ≤60 mL/min. MR antagonists also can induce metabolic acidosis in cirrhotic patients. Salicylates may reduce the tubular secretion of canrenone and decrease diuretic efficacy of *spironolactone*. *Spironolactone* may alter the clearance of cardiac glycosides. Owing to its affinity for other steroid receptors, *spironolactone* may cause gynecomastia, impotence, decreased libido, and menstrual irregularities. *Spironolactone* also may induce diarrhea, gastritis, gastric bleeding, and peptic ulcers (the drug is contraindicated in patients with peptic ulcers). CNS adverse effects include drowsiness, lethargy, ataxia, confusion, and headache. *Spironolactone* may cause skin rashes and, rarely, Stevens-Johnson syndrome, toxic epidermal necrolysis, drug rash with eosinophilia and systemic symptoms, and blood dyscrasias. Strong inhibitors of CYP3A4 (e.g., *ketoconazole*, *itraconazole*) may increase plasma levels of *eplerenone* and *finerenone*, and such drugs should not be administered to patients taking *eplerenone* or *finerenone* and vice versa. Other than hyperkalemia and GI disorders, the rate of adverse events for *eplerenone* is similar to that of placebo.

Inhibitors of Sodium-Glucose Symport: SGLT2 Inhibitors, Gliflozins

Inhibitors of sodium-glucose cotransporter type 2 (SGLT2), also referred to as gliflozins, were developed for management of diabetes mellitus and are described in detail in Chapter 51. SGLT2 inhibitors are also efficacious diuretics. *Canagliflozin*, *dapagliflozin*, *empagliflozin,* and *ertugliflozin* are approved for treatment of diabetes in the U.S. *Ipragliflozin*, *luseogliflozin*, *remogliflozin*, and *tofogliflozin* are SGLT2 inhibitors used outside the U.S. Chemically, gliflozins consist of a glucose sugar (unmodified or modified) with a substituted diarylmethylene group attached to the β-position of the anomeric carbon.

Mechanism and Site of Action

SGLT2 is a low-affinity, yet high-capacity, sodium-glucose symporter (cotransporter) that is expressed in the apical membrane of the proximal tubule and is responsible for the reabsorption of approximately 90% of filtered glucose across the apical membrane (Ansary et al., 2019). SGLT1 is a high-affinity, but low-capacity, sodium-glucose cotransporter that is also expressed in the apical membrane of the proximal tubule but only reabsorbs approximately 10% of filtered glucose. Both SGLT2 and SGLT1 exploit the electrochemical gradient of Na^+ across the apical membrane to provide the free energy required to reabsorb the large quantities of glucose—the glomerular filtration barrier does not retain glucose—that are delivered to the proximal tubule via the ultrafiltrate. The transport of intracellular glucose across the renal epithelial basolateral membrane is mediated by the facilitative glucose transporter GLUT2. At prescribed doses, gliflozins selectively block SGLT2 and thereby reduce the reabsorption of filtered glucose by up to 50%. Because little glucose is reabsorbed by the more distal segments of the nephron, glucose that exits the proximal tubule functions as an osmotic diuretic, similar to *mannitol*. Because SGLT2 normally accounts for approximately 5% of total renal Na^+ reabsorption, inhibition of SGLT2 also decreases the reabsorption of Na^+ by the proximal tubule and thus delivers additional Na^+ to downstream nephron segments. Thus, the gliflozins, by inhibiting SGLT2, engage a dual or "hybrid" mechanism of diuretic action that combines an osmotic diuresis, due to increased glucose excretion, with attenuation of Na^+ reabsorption in the proximal tubule (Sarzani et al., 2020).

Effects on Urinary Excretion

In rats, acute administration of *luseogliflozin* increases glucose excretion by 450-fold, urine flow by 5-fold, and sodium excretion by 7-fold, but does not affect K^+ excretion (Ansary et al., 2017). Numerous preclinical and clinical studies confirm the diuretic and natriuretic effects of gliflozins (Ansary et al., 2019).

Effects on Renal Hemodynamics

In patients with diabetes mellitus, often there exists a state of glomerular hyperfiltration due to decreased vascular resistance of afferent arterioles and increased vascular resistance of efferent arterioles resulting in increased glomerular hydrostatic pressure (Cherney et al., 2014; Škrtić et al., 2014). Theoretically, by increasing NaCl delivery to the TAL, gliflozins should trigger TGF and thereby increase preglomerular vascular resistance and decrease glomerular hypertension. Indeed, *empagliflozin* decreases RBF and hyperfiltration in type 1 diabetics (Cherney et al.,

2014), a response that is accompanied by an increase in the calculated preglomerular vascular resistance and a decrease in the estimated glomerular hydrostatic pressure (Škrtić et al., 2014).

Other Actions

Due to their diuretic and natriuretic effects, chronic treatment with gliflozins reduces plasma volume by approximately 7% and decreases systolic and diastolic blood pressures by approximately 2 to 4 and 1 to 2 mm Hg, respectively (Sarzani et al., 2020). The antihypertensive effects of gliflozins are mostly secondary to their diuretic activity.

ADME

Canagliflozin, *dapagliflozin*, *empagliflozin*, and *ertugliflozin* are readily absorbed (oral availabilities >65%), are highly protein bound (>85%), and have long $t_{1/2}$s (ranging from 11 to 17 h). The major route of elimination is via hepatic metabolism followed by excretion of metabolites in the urine and feces.

Therapeutic Uses

The role of gliflozins in the treatment of diabetes mellitus is described in detail in Chapter 51. Gliflozins combined with *metformin* are recommended as the preferred treatment regimen for type 2 diabetes. In type 2 diabetics, gliflozins reduce cardiovascular morality, nonfatal stroke, nonfatal myocardial infarction, hospitalization for heart failure, and total mortality (Neal et al., 2017; Wiviott et al., 2019; Zinman et al., 2015). In type 2 diabetes, gliflozins also protect against declining renal function, end-stage kidney disease, death due to kidney disease, and acute kidney injury (Neuen et al., 2019). The antihypertensive actions of gliflozins likely account for some of the beneficial effects of gliflozins to reduce cardiovascular disease and CKD. Relief of glomerular hypertension may also contribute to the effectiveness of gliflozins to prevent diabetic kidney disease. Because AngII preferentially constricts the postglomerular microcirculation, RAS blockers reduce postglomerular vascular resistance. The combination of a gliflozin and a RAS blocker may synergize to reduce glomerular hypertension and protect against diabetic nephropathy (Sarzani et al., 2020). The protective actions of gliflozins on the heart and kidneys may also be due in part to reduced hyperglycemia, inflammation, oxidative stress, and sympathetic nervous system activity (Ni et al., 2020; Sarzani et al., 2020).

Diuretics that act in the more distal segments of the nephron often upregulate transport systems in the proximal tubule, a phenomenon that contributes to diuretic resistance. This provides a rationale for combining gliflozins with loop or thiazide diuretics to provide for sequential nephron blockade to overcome diuretic resistance (Wilcox et al., 2020). Indeed, clinical studies demonstrate that gliflozins augment natriuresis induced by loop diuretics (Griffin et al., 2020; Wilcox et al., 2020). In patients with heart failure with reduced ejection fraction, a disease in which most patients are treated with loop diuretics, gliflozins reduce cardiovascular death and hospitalization regardless of presence or absence of diabetes (McMurray et al., 2019; Petrie et al., 2020).

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Reproductive and urinary tract infections, although mild to moderate in severity, are not uncommon in patients treated with gliflozins. This may be due to elevated glucose concentrations in the urine, which provide a favorable environment for bacterial and fungal infections. Although rare, gliflozins can induce ketoacidosis, and serum ketone body levels and pH should be monitored. Gliflozins can reduce bone density and increase risk of bone fractures. Accordingly, gliflozins should be used with caution in patients at elevated risk of bone fractures. In some clinical trials, gliflozins appeared to increase the risk of lower limb amputation. However, a meta-analysis of randomized trials failed to reproduce this finding. Whether gliflozins as a class increase risk of amputation remains unclear. There is some evidence of gliflozin-induced tumorgenicity in animals and patients; however, at present, this remains controversial. Other adverse effects of gliflozins are related to their main pharmacological effects and include hypoglycemia, polyuria, dehydration, hyperphosphatemia, hypermagnesemia and hyperkalemia, hypovolemia, and hypotension. Gliflozins are contraindicated in patients with severe renal impairment and end-stage renal disease. Regarding drug interactions, β-adrenoceptor blockers may mask symptoms of hypoglycemia, and fluoroquinolones, angiotensin-converting enzyme inhibitors, and other antidiabetic agents can increase the risk of hypoglycemia in patients taking gliflozins.

Inhibitors of the Nonspecific Cation Channel: Natriuretic Peptides

Four natriuretic peptides (NPs) are relevant with respect to human physiology: ANP, brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin. The IMCD is a major site of action of NPs.

Three NPs—ANP, BNP, and CNP—share a common homologous 17-member amino acid ring formed by a disulfide bridge between cysteine residues, although they are products of different genes. Urodilatin, also structurally similar, arises from altered processing of the same precursor molecule as ANP and has four additional amino acids at the N terminus. ANP and BNP are produced by the heart in response to wall stretch; CNP is of endothelial and renal cell origin; urodilatin is found in the kidney and urine. Natriuretic peptide receptors (NPRs), classified as types A, B, and C, are membrane monospans. NPRA (binds ANP and BNP) and NPRB (binds CNP) have intracellular domains with guanylate cyclase activity and a protein kinase element. NPRC (binds all NPs) has a truncated intracellular domain and may help with NP clearance. The various NPs have somewhat overlapping effects, causing natriuresis, inhibition of production of renin and aldosterone, and vasodilation (the result of cGMP elevation in vascular smooth muscle). A human recombinant BNP, *nesiritide*, with the same 32–amino acid structure as the endogenous peptide produced by the ventricular myocardium, is available for clinical use in some countries but was discontinued in the U.S.

Mechanism and Site of Action

The IMCD is the final site along the nephron where Na^+ is reabsorbed. Up to 5% of the filtered Na^+ load can be reabsorbed here. The effects of nesiritide and other NPs are mediated via effects of cGMP on Na^+ transporters (Figure 29–7). Two types of Na^+ channels are expressed in IMCD.

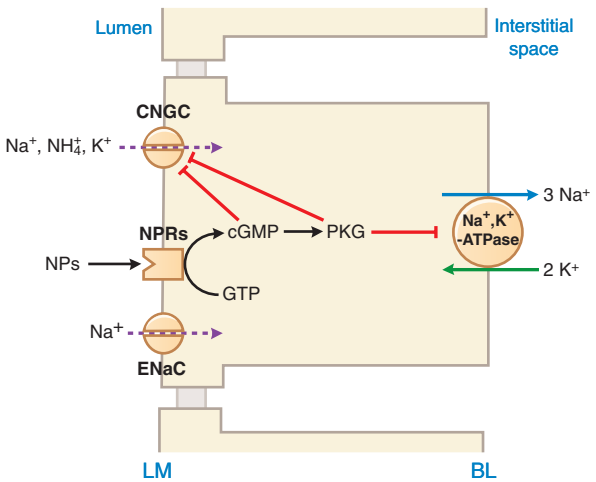

Figure 29–7 *The inner medullary collecting duct Na^+ transport and its regulation.* Na^+ enters the IMCD cell in one of two ways: via ENaC and through a CNGC that transports Na^+, K^+, and NH_4^+ and is gated by cGMP. Na^+ then exits the cell via the Na^+,K^+-ATPase. The CNGC is the primary pathway for Na^+ entry and is inhibited by NPs. NPs bind to cell surface NPRs A, B, and C. The A and B receptors are isoforms of particulate guanylyl cyclase that synthesize cGMP. The CNGC is inhibited by cGMP directly and indirectly through PKG. PKG activation also inhibits Na^+ exit via the Na^+,K^+-ATPase. ENaC is a low-conductance (4-pS) highly selective Na^+ channel that plays a minor role in IMCD Na^+ transport (see Figure 29–6). BL, basolateral membrane; LM, luminal membrane.

The *first* is a high-conductance, 28-pS, nonselective cyclic nucleotide-gated cation channel (CNGC). This channel is inhibited by intracellular cGMP and by NPs via their capacity to stimulate membrane-bound guanylyl cyclase activity and elevate cellular cGMP. The *second* type of Na^+ channel expressed in the IMCD is the low-conductance, 4-pS, highly selective Na^+ channel ENaC. The majority of Na^+ reabsorption in the IMCD is mediated via CNGC.

Effects on Urinary Excretion and Renal Hemodynamics

Nesiritide inhibits Na^+ transport in both the proximal and distal nephron, but its primary effect is in the IMCD. Urinary Na^+ excretion increases with *nesiritide*, but the effect may be attenuated by upregulation of Na^+ reabsorption in upstream segments of the nephron. GFR increases in response to *nesiritide* in normal subjects, but in treated patients with CHF, GFR may increase, decrease, or remain unchanged.

Other Actions

Administration of *nesiritide* decreases systemic and pulmonary resistances and left ventricular filling pressure and induces a secondary increase in cardiac output.

ADME

Natriuretic peptides are administered intravenously. *Nesiritide* has a distribution $t_{1/2}$ of 2 min and a mean terminal $t_{1/2}$ of 18 min. Clearance occurs via at least two mechanisms: internalization and subsequent degradation mediated by NPCR, and metabolism by extracellular proteases (Potter, 2011). There is no need to adjust the dose for renal insufficiency.

Therapeutic Uses

Human recombinant ANP (*carperitide*, available only in Japan) and BNP (*nesiritide*, no longer available in the U.S.) are the therapeutic agents of this class. In patients with acute decompensated CHF who have dyspnea with minimal activity or at rest, *nesiritide* reduces pulmonary capillary wedge pressure and improves short-term symptoms of dyspnea. However, the ASCEND-HF trial found that *nesiritide* does not change mortality and rehospitalization and has only a small effect on dyspnea (O'Connor et al., 2011). Thus, *nesiritide* is not recommended for routine use in the broad population of patients with acute heart failure (O'Connor et al., 2011).

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Nesiritide can cause hypotension, and there are concerns about adverse renal effects. However, the ASCEND-HF trial did not demonstrate worsening of renal function in *nesiritide*-treated patients with heart failure (O'Connor et al., 2011).

Adenosine Receptor Antagonists

There are four adenosine receptor subtypes (A_1, A_{2A}, A_{2B}, and A_3). A_1, A_{2A}, and A_{2B} receptors regulate aspects of renal physiology. The A_1 receptor is expressed in the proximal tubule and stimulates reabsorption of Na^+. Consequently, antagonists of A_1 receptors cause diuresis/natriuresis, yet are K^+ sparing. Several naturally occurring methylxanthines (e.g., caffeine, theophylline, and theobromine) are A_1 receptor antagonists (albeit nonselective) and consequently cause diuresis. *Pamabrom* is a mild diuretic consisting of a one-to-one mixture of 8-bromotheophylline and 2-amino-2-methyl-1-propanol; 8-bromotheophylline, a methylxanthine, is the active component of *pamabrom*. *Pamabrom* is the diuretic ingredient in several over-the-counter products marketed for relief of premenstrual syndrome. Little is known regarding the pharmacology, diuretic mechanism of action, and efficacy of *pamabrom*. However, because 8-bromotheophylline is a methylxanthine, it is possible that the mild diuresis induced by *pamabrom* is related to blockade of renal A_1 receptors.

Emerging Diuretics

Discoveries over the past few decades have revealed many of the intricate molecular mechanisms that regulate reabsorption and secretion by renal epithelial cells. Several components of these regulatory mechanisms are being targeted to create novel diuretics that may overcome diuretic resistance and improve patient outcomes (Cheng et al., 2017). Signal transduction kinases such as with-no-lysine kinases (WNKs), Ste20-related proline/alanine-rich kinase (SPAK), and oxidative stress-responsive 1 (OSR1) regulate the activity or expression of the Na^+-K^+-$2Cl^-$ symporter, the Na^+-Cl^- symporter, or ENaC, and inhibitors of these proteins may become useful diuretics. Transport by some renal epithelial cells requires the activity of basolateral Cl^- channels (ClC-Kb), apical inwardly rectifying K^+ channels (Kir1.1, aka ROMK), basolateral inwardly rectifying K^+ channels (Kir4.1), or basolateral Cl^--HCO_3^- antiporters (pendrin). Blockers of these channels may also become useful diuretics with unique properties. 8-Aminoguanosine and 8-aminoguanine increase sodium and glucose excretion while markedly reducing K^+ excretion, a unique diuretic profile that is likely due in part to inhibition of purine nucleoside phosphorylase (Jackson et al., 2016, 2018).

Clinical Use of Diuretics

Site and Mechanism of Diuretic Action

An understanding of the sites and mechanisms of action of diuretics enhances comprehension of the clinical aspects of diuretic pharmacology. Figure 29–5 provides a summary view of the sites and mechanisms of actions of diuretics.

The Role of Diuretics in Clinical Medicine

Figure 29–8 illustrates interrelationships among renal function, Na^+ intake, water homeostasis, distribution of extracellular fluid volume, and mean arterial blood pressure and suggests three fundamental strategies for mobilizing edema fluid:

- Correction of the underlying disease
- Restriction of Na^+ intake
- Administration of diuretics

Figure 29–9 presents a useful synthesis, Brater's algorithm, a logically compelling algorithm for diuretic therapy (specific recommendations for drug, dose, route, and drug combinations) in patients with edema caused by renal, hepatic, or cardiac disorders (Brater, 1998).

The clinical situation dictates whether a patient should receive diuretics and what therapeutic regimen should be used (type of diuretic, dose, route of administration, and speed of mobilization of edema fluid). Massive pulmonary edema in patients with acute left-sided heart failure is a medical emergency requiring rapid, aggressive therapy, including intravenous administration of a loop diuretic. In this setting, use of oral diuretics is inappropriate. Conversely, mild pulmonary and venous congestion associated with chronic heart failure is best treated with an oral loop or thiazide diuretic, the dosage of which should be titrated carefully to maximize the benefit-to-risk ratio. Loop and thiazide diuretics decrease morbidity and mortality in patients with heart failure (Faris et al., 2002). MR antagonists also demonstrate reduced morbidity and mortality in patients with heart failure receiving optimal therapy with other drugs.

Periodic administration of diuretics to cirrhotic patients with ascites may eliminate the necessity for or reduce the interval between paracenteses, adding to patient comfort and sparing protein reserves that are lost during paracenteses. Although diuretics can reduce edema associated with chronic renal failure, increased doses of more powerful loop diuretics usually are required. In nephrotic syndrome, diuretic response often is disappointing. In chronic renal failure and cirrhosis, edema will not pose an immediate health risk but can greatly reduce quality of life. In such cases, only partial removal of edema fluid should be attempted, and fluid should be mobilized slowly using a diuretic regimen that accomplishes the task with minimal perturbation of normal physiology.

Diuretic resistance refers to the condition in which the rate of diuresis/natriuresis is inadequate despite administration of what should be an adequate diuretic regimen (Cox and Testani, 2020). Diuretic resistance remains a major clinical challenge. Considerable attention has been directed toward the mechanisms of, and approaches to overcoming, diuretic resistance (Cox and Testani, 2020; Mullens et al., 2019; Wilcox et al., 2020). Pre-nephron (e.g., reduced RBF, hypoalbuminemia, excessive sodium intake, NSAIDs) or intra-nephron factors may contribute to diuretic resistance. Intra-nephron mechanisms are classified as pre–loop

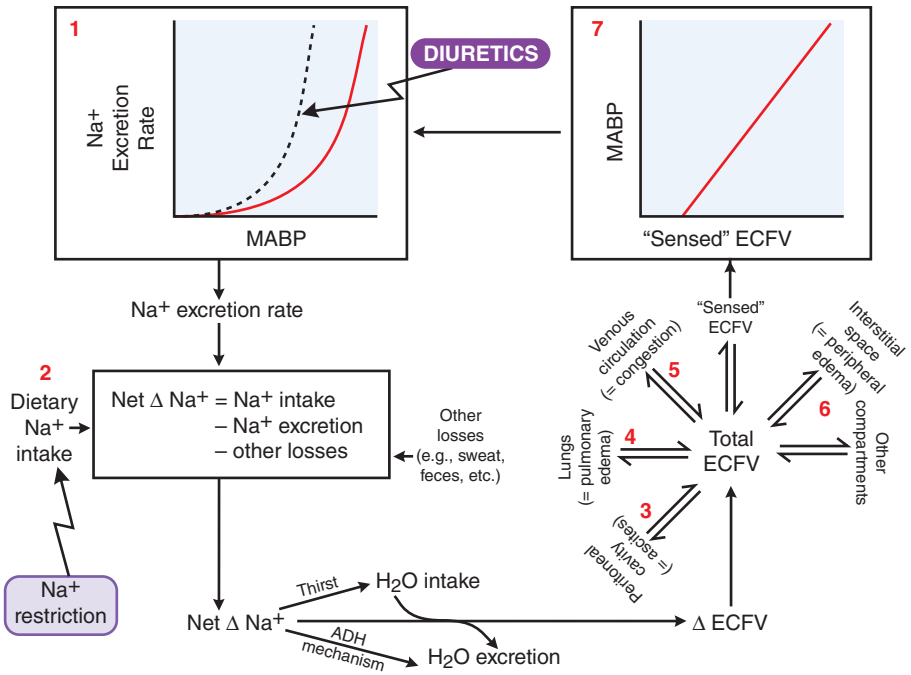

Figure 29–8 *Interrelationships among renal function, Na+ intake, water homeostasis, distribution of extracellular fluid volume, and mean arterial blood pressure.* Starting at upper left panel (#1), read this figure counterclockwise. Complex interrelationships exist among the cardiovascular system, kidneys, CNS, and capillary beds such that perturbations at one of these sites can affect all other sites. A primary law of the kidney is that Na^+ excretion is a steep function of mean arterial blood pressure (MABP) such that small increases in MABP cause marked increases in Na^+ excretion; this is known as the "pressure-natriuresis" relationship (upper left). Over any given time interval, the net change in total-body Na^+ is the dietary Na^+ intake minus the urinary excretion rate and other losses (lower left). If the pressure-natriuresis curve is right-shifted, a net positive Na^+ balance occurs, and the extracellular Na^+ concentration increases, thus stimulating water intake (thirst) and reducing urinary water output (via ADH release). These changes expand the extracellular fluid volume (ECFV), and the enlarged ECFV is distributed among many body compartments (lower right). ECFV on the arterial side of the circulation pressurizes the arterial tree ("sensed" ECFV) and increases MABP (upper right), thus increasing Na^+ excretion (and completing the loop). This loop cycles until net Na^+ accumulation is zero; i.e., in the long run, Na^+ intake must equal Na^+ loss.

These considerations explain the fundamental mechanisms of edema formation:

1. Rightward shift of renal pressure natriuresis curve.
2. Excessive dietary Na^+ intake.
3. Increased distribution of ECFV to peritoneal cavity (e.g., liver cirrhosis with increased hepatic sinusoidal hydrostatic pressure) leading to ascites formation.
4. Increased distribution of ECFV to lungs (e.g., left-sided heart failure with increased pulmonary capillary hydrostatic pressure) leading to pulmonary edema.
5. Increased distribution of ECFV to venous circulation (e.g., right-sided heart failure) leading to venous congestion.
6. Peripheral edema caused by altered Starling forces causing increased distribution of ECFV to interstitial space (e.g., diminished plasma proteins in nephrotic syndrome, severe burns, and liver disease).
7. Increased MABP resulting from "sensed" ECFV on the arterial side of the heart.

These perturbations leading to edema can be addressed by: **A.** Correcting the underlying disease; **B.** Administering diuretics to left-shift the renal pressure-natriuresis relationship; **C.** Restricting dietary Na^+ intake.

of Henle (e.g., increased sodium reabsorption by the proximal tubule, reduced GFR, albuminuria, competition for diuretic transport into the proximal tubule), loop of Henle (e.g., decreased response of the TAL to diuretics), or post–loop of Henle (e.g., hypertrophy and hyperfunction of the distal tubule) (Cox and Testani, 2020). NSAID coadministration is a common preventable cause of diuretic resistance. PG production, especially PGE_2, is an important counterregulatory mechanism in states of reduced renal perfusion (e.g., volume contraction, CHF, cirrhosis), characterized by activation of the renin-angiotensin-aldosterone system and sympathetic nervous system. NSAID administration can block PG-mediated effects that counterbalance the renin-angiotensin-aldosterone system and sympathetic nervous system, resulting in salt and water retention. Diuretic resistance also occurs with COX-2–selective inhibitors.

In chronic renal failure, a reduction in RBF decreases delivery of diuretics to the kidney, and accumulation of endogenous organic acids competes with loop diuretics for transport at the proximal tubule. Consequently, diuretic concentration at the active site in the tubular lumen is limini he l. In nephrotic svnd' om e, bindin g of diuretics to lum nal albu-nin w s t ou ght o 'imit resp on e; ow v , th e 'alic t of hi onc nt has been challenged. In hepatic cirrhosis, nephrotic syndrome, and heart failure, nephrons may have diminished diuretic responsiveness because of increased proximal tubular Na^+ reabsorption, leading to diminished Na^+ delivery to distal nephrons.

Faced with resistance to loop diuretics, the clinician has several options:

- Bed rest may restore drug responsiveness by improving the renal circulation.
- An increase in dose of loop diuretic may restore responsiveness; however, nothing is gained by increasing the dose above that which causes a near-maximal effect (the ceiling dose) of the diuretic.
- Administration of smaller doses more frequently or a continuous intravenous infusion of a loop diuretic will increase the length of time that an effective diuretic concentration is at the active site.
- Use of combination therapy to sequentially block more than one site in the nephron may result in a synergistic interaction between two diuretics. F or example, a combination of a loop diuretic w ith a K -s ar i g or a th ia de d ur tic m y i prov th ra peu ic res onse;

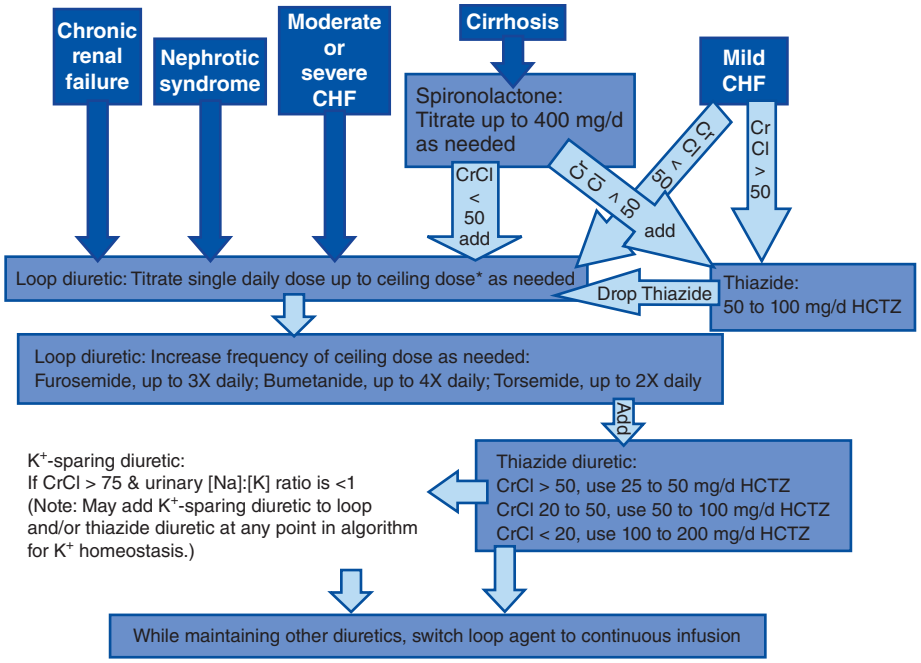

Figure 29–9 *"Brater's algorithm" for diuretic therapy of chronic renal failure, nephrotic syndrome, CHF, and cirrhosis.* Follow algorithm until adequate response is achieved. If adequate response is not obtained, advance to the next step. For illustrative purposes, the thiazide diuretic used is hydrochlorothiazide (HCTZ). An alternative thiazide-type diuretic may be substituted with dosage adjusted to be pharmacologically equivalent to the recommended dose of HCTZ. *Do not combine two K^+-sparing diuretics due to the risk of hyperkalemia.* CrCl indicates creatinine clearance in milliliters per minute, and ceiling dose refers to the smallest dose of diuretic that produces a near-maximal effect. *Ceiling doses of loop diuretics and dosing regimens for continuous intravenous infusions of loop diuretics are disease-state specific. Doses are for adults only.

however, nothing is gained by the administration of two drugs of the same type. Thiazide diuretics with significant proximal tubular effects (e.g., metolazone) are particularly well suited for sequential blockade when coadministered with a loop diuretic.

- Reducing salt intake will diminish postdiuretic Na^+ retention, which can nullify previous increases in Na^+ excretion.
- Scheduling of diuretic administration shortly before food intake will provide effective diuretic concentration in the tubular lumen when salt load is highest.

Part II: Water Homeostasis and the Vasopressin System

Vasopressin Physiology

Arginine vasopressin (ADH in humans) is the main hormone that regulates body fluid osmolality. The hormone is released by the posterior pituitary whenever water deprivation causes an increased plasma osmolality or whenever the cardiovascular system is challenged by hypovolemia or hypotension. Vasopressin acts primarily in the renal collecting duct to increase the permeability of the cell membrane to water, thus permitting water to move passively down an osmotic gradient across the collecting duct into the extracellular compartment.

Vasopressin is a potent vasopressor/vasoconstrictor. It is also a neurotransmitter; among its actions in the CNS are apparent roles in the secretion of corticotropin (ACTH) and in regulation of the cardiovascular system, temperature, and other visceral functions. Vasopressin also promotes release of coagulation factors by vascular endothelium and increases platelet aggregability.

Anatomy of the Vasopressin System

The antidiuretic mechanism in mammals involves two anatomical components: a CNS component for synthesis, transport, storage, and release of vasopressin and a renal collecting duct system composed of epithelial cells that respond to vasopressin by increasing their water permeability. The CNS component of the antidiuretic mechanism is called the *hypothalamoneurohypophyseal system* and consists of neurosecretory neurons with perikarya located predominantly in two specific hypothalamic nuclei, the supraoptic nucleus (SON) and paraventricular nucleus (PVN). Long axons of magnocellular neurons in SON and PVN terminate in the neural lobe of the posterior pituitary (neurohypophysis), where they release vasopressin and oxytocin (see Figure 46–1).

Synthesis of Vasopressin

Vasopressin and oxytocin are synthesized mainly in the perikarya of magnocellular neurons in the SON and PVN. However, parvicellular neurons in the PVN also synthesize vasopressin, as do some non-CNS cells (see discussion that follows). Vasopressin synthesis appears to be regulated solely at the transcriptional level. In humans, a 168–amino acid prepro-hormone (Figure 29–10) is synthesized and then packaged into membrane-associated granules. The prohormone contains three domains: vasopressin (residues 1–9), vasopressin-neurophysin (residues 13–105), and vasopressin-glycopeptide (residues 107–145). The vasopressin domain is linked to the vasopressin-neurophysin domain through a GLY-LYS-ARG-processing signal, and the vasopressin-neurophysin is linked to the vasopressin-glycopeptide domain by an ARG-processing signal. In secretory granules, an endopeptidase, exopeptidase, monooxygenase, and lyase act sequentially on the prohormone to produce vasopressin, vasopressin-neurophysin (sometimes referred to as neurophysin II), and vasopressin-glycopeptide. The synthesis and transport of vasopressin depend on the preprohormone conformation. In particular, vasopressin-neurophysin binds vasopressin and is critical for correct processing, transport, and storage of vasopressin. Genetic mutations in either the signal peptide or vasopressin-neurophysin give rise to central DI.

Vasopressin also is synthesized by the heart and adrenal gland. In the heart, elevated wall stress increases vasopressin synthesis several-fold and may contribute to impaired ventricular relaxation and coronary vasoconstriction. Vasopressin synthesis in the adrenal medulla stimulates catecholamine secretion from chromaffin cells and may promote adrenal cortical growth and stimulate aldosterone synthesis.

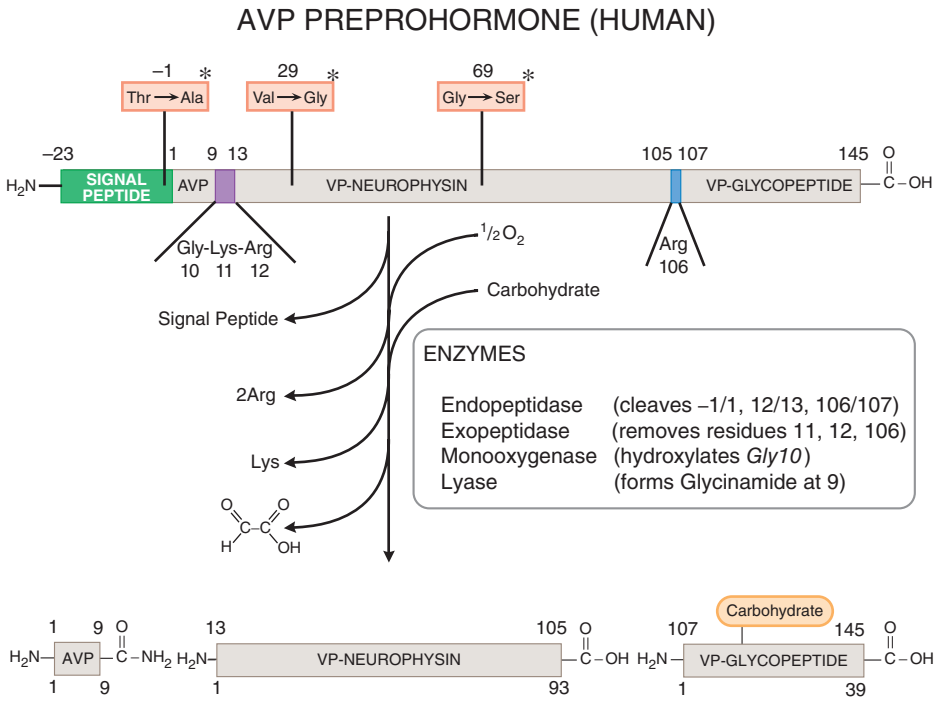

Figure 29–10 *Processing of human arginine vasopressin (AVP) preprohormone.* More than 40 mutations in the single gene on chromosome 20 that encodes AVP preprohormone give rise to central DI. *Boxes indicate mutations leading to central DI. DI, diabetes insipidus; VP, vasopressin.

Regulation of Vasopressin Secretion

Hyperosmolality. An increase in plasma osmolality is the principal physiological stimulus for vasopressin secretion by the posterior pituitary. The osmolality threshold for secretion is about 280 mOsm/kg. Below the threshold, vasopressin is barely detectable in plasma, and above the threshold, vasopressin levels are a steep and relatively linear function of plasma osmolality. Indeed, a 2% elevation in plasma osmolality causes a 2- to 3-fold increase in plasma vasopressin levels, which in turn causes increased solute-free water reabsorption, with an increase in urine osmolality. Increases in plasma osmolality above 290 mOsm/kg lead to an intense desire for water (thirst). Thus, the vasopressin system affords the organism longer thirst-free periods and, in the event that water is unavailable, allows the organism to survive longer periods of water deprivation. Above a plasma osmolality of approximately 290 mOsm/kg, plasma vasopressin levels exceed 5 pM. Since urinary concentration is maximal (~1200 mOsm/kg) when vasopressin levels exceed 5 pM, further defense against hypertonicity depends mainly on water intake rather than on decreases in urinary water loss.

Hepatic Portal Osmoreceptors. An oral salt load activates hepatic portal osmoreceptors, leading to increased vasopressin release. This mechanism augments plasma vasopressin levels even before the oral salt load increases plasma osmolality.

Hypovolemia and Hypotension. Vasopressin secretion is regulated hemodynamically by changes in effective blood volume or arterial blood pressure. Regardless of the cause (e.g., hemorrhage, Na^+ depletion, diuretics, heart failure, hepatic cirrhosis with ascites, adrenal insufficiency, or hypotensive drugs), reductions in effective blood volume or arterial blood pressure are associated with high circulating vasopressin concentrations. However, unlike osmoregulation, hemodynamic regulation of vasopressin secretion is exponential; that is, small decreases (5%) in blood volume or pressure have little effect on vasopressin secretion, whereas larger decreases (20%–30%) can increase vasopressin levels to 20 to 30 times normal (exceeding the vasopressin concentration required to induce maximal antidiuresis). Vasopressin is one of the most potent vasoconstrictors known, and the vasopressin response to hypovolemia or hypotension serves as a mechanism to stave off cardiovascular collapse during periods of severe blood loss or hypotension. Hemodynamic regulation of vasopressin secretion does not disrupt osmotic regulation; rather, hypovolemia/hypotension alters the set point and slope of the plasma osmolality–plasma vasopressin relationship.

Neuronal pathways that mediate hemodynamic regulation of vasopressin release are different from those involved in osmoregulation. Baroreceptors in the left atrium, left ventricle, and pulmonary veins sense blood volume (filling pressures), and baroreceptors in the carotid sinus and aorta monitor arterial blood pressure. Nerve impulses reach brainstem nuclei predominantly through the vagal trunk and glossopharyngeal nerve; these signals are ultimately relayed to the SON and PVN.

Hormones and Neurotransmitters. Vasopressin-synthesizing magnocellular neurons have a large array of receptors on both perikarya and nerve terminals; therefore, vasopressin release can be accentuated or attenuated by chemical agents acting at both ends of the magnocellular neuron (Iovino et al., 2014). Also, hormones and neurotransmitters can modulate vasopressin secretion by stimulating or inhibiting neurons in nuclei that project, either directly or indirectly, to the SON and PVN (Iovino et al., 2014). Because of these complexities, modulation of vasopressin secretion by most hormones or neurotransmitters is unclear. Several agents stimulate vasopressin secretion, including acetylcholine (by nicotinic receptors), histamine (by H_1 receptors), dopamine (by both D_1 and D_2 receptors), glutamine, aspartate, cholecystokinin, neuropeptide Y, substance P, vasoactive intestinal polypeptide, PGs, and AngII. Inhibitors of vasopressin secretion include ANP, γ-aminobutyric acid, and opioids (particularly dynorphin via κ receptors). The effects of AngII have received the most attention. AngII synthesized in the brain and circulating AngII may stimulate vasopressin release. Inhibition of the conversion of AngII to AngIII blocks AngII-induced vasopressin release, suggesting that AngIII is the main effector peptide of the brain RAS controlling vasopressin release.

Pharmacological Agents. Several drugs alter urine osmolality by stimulating or inhibiting vasopressin secretion. In most cases, the mechanism is not known. Stimulators of vasopressin secretion include *vincristine*, *cyclophosphamide*, tricyclic antidepressants, *nicotine*, *epinephrine*, and high doses of *morphine*. *Lithium*, which inhibits the renal effects of vasopressin, also enhances vasopressin secretion. Inhibitors of vasopressin

secretion include *ethanol* (see also Chapter 27), *phenytoin*, low doses of *morphine*, glucocorticoids, *fluphenazine*, *haloperidol*, *promethazine*, *oxilorphan*, and *butorphanol*. *Carbamazepine* has a renal action to produce antidiuresis in patients with central DI but inhibits vasopressin secretion by a central action.

Vasopressin Receptors

Cellular vasopressin effects are mediated mainly by interactions of the hormone with the three types of receptors: V_{1a}, V_{1b}, and V_2. All are GPCRs. The V_{1a} receptor is the most widespread subtype of vasopressin receptor; it is found in vascular smooth muscle, adrenal gland, myometrium, bladder, adipocytes, hepatocytes, platelets, renal medullary interstitial cells, vasa recta in the renal microcirculation, epithelial cells in the renal cortical collecting duct, spleen, testis, and many CNS structures. V_{1b} receptors have a more limited distribution and are found in the anterior pituitary, several brain regions, pancreas, and adrenal medulla. V_2 receptors are located predominantly in principal cells of the renal collecting duct system but also are present on epithelial cells in TAL and on vascular endothelial cells.

Figure 29–11 summarizes the current model of V_1 receptor-effector coupling. Vasopressin binding to V_1 receptors activates the G_q-PLC-IP_3 pathway, thereby mobilizing intracellular Ca^{2+} and activating PKC, ultimately causing biological effects that include immediate responses (e.g., vasoconstriction, glycogenolysis, platelet aggregation, and ACTH release) and growth responses in smooth muscle cells.

Principal cells in renal collecting duct have V_2 receptors on their basolateral membranes that couple to G_S to stimulate adenylyl cyclase activity (Figure 29–12). The resulting activation of the cyclic AMP/PKA pathway triggers an increased rate of insertion of water channel–containing vesicles (WCVs) into the apical membrane and a decreased rate of endocytosis of WCVs from the apical membrane. Because WCVs contain preformed functional water channels (aquaporin 2), their net shift into apical membranes in response to V_2 receptor stimulation greatly increases water permeability of the apical membrane (Nejsum, 2005) (Figures 29–12 and 29–13).

V_2 receptor activation also increases urea permeability by 400% in the terminal portions of the IMCD. V_2 receptors increase urea permeability by activating a vasopressin-regulated urea transporter (termed *VRUT*, *UT1*, or *UTA1*), most likely by PKA-induced phosphorylation. Kinetics of vasopressin-induced water and urea permeability differ, and vasopressin-induced regulation of VRUT does not entail vesicular trafficking to the plasma membrane.

V_2 receptor activation also increases Na^+ transport in TAL and collecting duct. Increased Na^+ transport in TAL is mediated by three mechanisms that affect the Na^+-K^+-$2Cl^-$ symporter: rapid phosphorylation of the symporter, translocation of the symporter into the luminal membrane, and increased expression of symporter protein. The multiple mechanisms by which vasopressin increases water reabsorption are summarized in Figure 29–14.

Renal Actions of Vasopressin

Several sites of vasopressin action in kidney involve both V_1 and V_2 receptors. V_1 receptors mediate contraction of mesangial cells in the glomerulus and contraction of vascular smooth muscle cells in vasa recta and efferent arterioles. V_1 receptor–mediated reduction of inner medullary blood flow contributes to the maximum concentrating capacity of the kidney. V_1 receptors also stimulate PG synthesis by medullary interstitial cells. Because PGE_2 inhibits adenylyl cyclase in collecting ducts, stimulation of PG synthesis by V_1 receptors may counterbalance V_2 receptor–mediated antidiuresis. V_1 receptors on principal cells in cortical collecting ducts may inhibit V_2 receptor–mediated water flux by activation of PKC. V_2 receptors mediate the most prominent response to vasopressin, which is increased water permeability of the collecting duct at concentrations as low as 50 fM. Thus, V_2 receptor–mediated effects of vasopressin occur

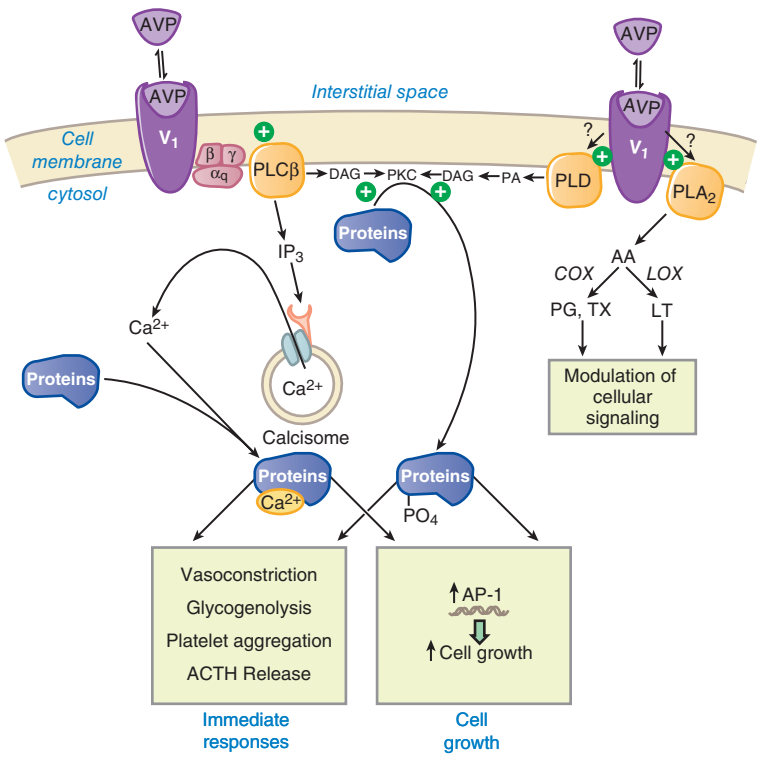

Figure 29–11 *Mechanism of V_1 receptor-effector coupling.* Binding of AVP to V_1 vasopressin receptors (V_1) stimulates membrane-bound phospholipases. Stimulation of G_q activates the PLCβ-IP_3/DAG-Ca^{2+}-PKC pathway. Activation of V_1 receptors also causes influx of extracellular Ca^{2+} by an unknown mechanism. PKC and Ca^{2+}/calmodulin-activated protein kinases phosphorylate cell-type–specific proteins, leading to cellular responses. A further component of the AVP response derives from the production of eicosanoids secondary to the activation of PLA_2; the resulting mobilization of arachidonic acid (AA) provides substrate for eicosanoid synthesis by the cyclooxygenase (COX) and lipoxygenase (LOX) pathways, leading to local production of prostaglandin (PG), thromboxane (TX) and leukotriene (LT), which may activate many signaling pathways, including those linked to G_S and G_q. AVP, arginine vasopressin; DAG, diacyglycerol; PA, phosphatidic acid; PKC, protein kinase C; PLA, phospholipase A; PLC, phospholipase C; PLD, phospholipase D.

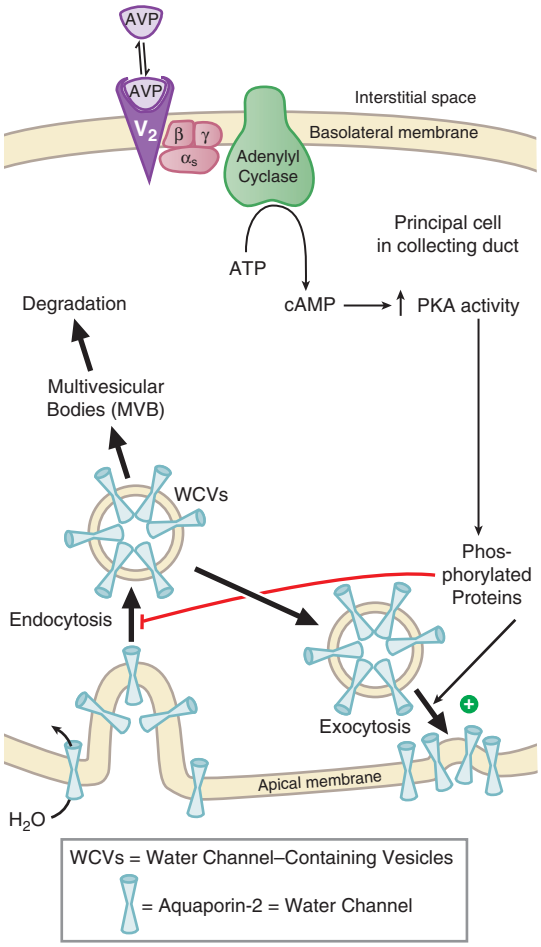

Figure 29–12 *Mechanism of V_2 receptor-effector coupling.* Binding of AVP to the V_2 receptor activates the G_S-adenylyl cyclase-cAMP-PKA pathway and shifts the balance of aquaporin 2 trafficking toward the apical membrane of the principal cell of the collecting duct, thus enhancing water permeability. Although phosphorylation of *Ser256* of aquaporin 2 is involved in V_2 receptor signaling, other proteins located in both the water channel–containing vesicles and the apical membrane of the cytoplasm also may be involved.

at concentrations far lower than are required to engage V_1 receptor–mediated actions. Other renal actions mediated by V_2 receptors include increased urea transport in the IMCD and increased Na^+ transport in the TAL; both effects contribute to the urine-concentrating ability of the kidney. V_2 receptors also increase Na^+ transport in cortical collecting ducts, and this may synergize with aldosterone to enhance Na^+ reabsorption during hypovolemia.

Pharmacological Modification of the Antidiuretic Response to Vasopressin

The NSAIDs, particularly *indomethacin*, enhance the antidiuretic response to vasopressin. Because PGs attenuate antidiuretic responses to vasopressin and NSAIDs inhibit PG synthesis, reduced PG production probably accounts for potentiation of vasopressin's antidiuretic response. *Carbamazepine* and *chlorpropamide* (not available in the U.S.) also enhance antidiuretic effects of vasopressin by unknown mechanisms. In rare instances, *chlorpropamide* can induce water intoxication. Several drugs inhibit the antidiuretic actions of vasopressin. *Lithium* is of particular importance because of its use in the treatment of manic-depressive disorders (Kishore and Ecelbarger, 2013). Acutely, Li^+ appears to reduce V_2 receptor–mediated stimulation of adenylyl cyclase. Also, Li^+ increases plasma levels of PTH, a partial antagonist to vasopressin. In most patients, the antibiotic *demeclocycline* attenuates the antidiuretic effects of vasopressin, probably owing to decreased accumulation and action of cyclic AMP (Kortenoeve et al., 2013).

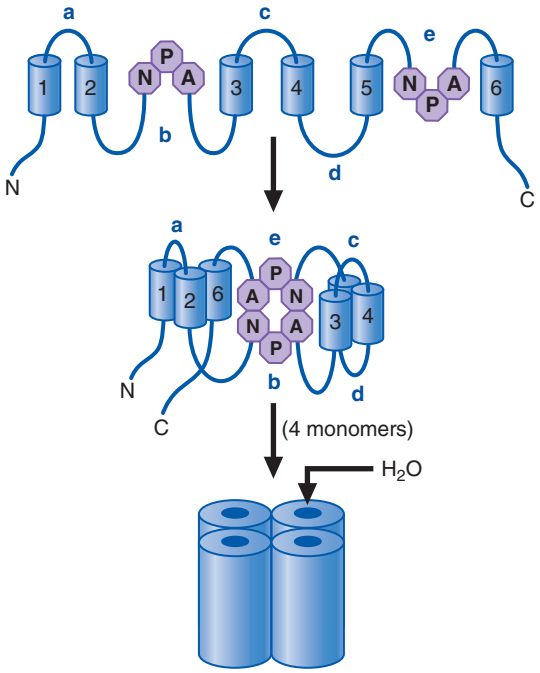

Figure 29–13 *Structure of aquaporins.* Aquaporins have six transmembrane domains, and the NH_2 and COOH termini are intracellular. Loops b and e each contain an asparagine-proline-alanine (NPA) sequence. Aquaporins fold with transmembrane domains 1, 2, and 6 in close proximity and transmembrane domains 3, 4, and 5 in juxtaposition. The long b and e loops dip into the membrane, and the NPA sequences align to create a pore through which water can diffuse. Most likely, aquaporins form a tetrameric oligomer. At least seven aquaporins are expressed at distinct sites in the kidney. Aquaporin 1, abundant in the proximal tubule and DTL, is essential for concentration of urine. Aquaporin 2, exclusively expressed in the principal cells of the connecting tubule and collecting duct, is the major vasopressin-regulated water channel. Aquaporin 3 and aquaporin 4 are expressed in the basolateral membranes of collecting duct principal cells and provide exit pathways for water reabsorbed apically by aquaporin 2. Aquaporin 7 is in the apical brush border of the straight proximal tubule. Aquaporins 6 to 8 are also expressed in kidney; their functions remain to be clarified. Vasopressin regulates water permeability of the collecting duct by influencing the trafficking of aquaporin 2 from intracellular vesicles to the apical plasma membrane (Figure 29–12). AVP-induced activation of the cAMP-PKA pathway also enhances expression of aquaporin 2 mRNA and protein; chronic dehydration thus causes upregulation of aquaporin 2 and water transport in the collecting duct.

Nonrenal Actions of Vasopressin

Cardiovascular System. The cardiovascular effects of vasopressin are complex. Vasopressin is a potent vasoconstrictor (V_1 receptor mediated), and resistance vessels throughout the circulation may be affected. Vascular smooth muscle in the skin, skeletal muscle, fat, pancreas, and thyroid gland appears most sensitive, with significant vasoconstriction also occurring in the GI tract, coronary vessels, and brain. Despite the potency of vasopressin as a direct vasoconstrictor, vasopressin-induced pressor responses *in vivo* are minimal and occur only with vasopressin concentrations significantly higher than those required for maximal antidiuresis. To a large extent, this is due to circulating vasopressin actions on V_1 receptors to inhibit sympathetic efferents and potentiate baroreflexes. In addition, V_2 receptors cause vasodilation in some blood vessels.

Vasopressin helps to maintain arterial blood pressure during episodes of severe hypovolemia/hypotension. The effects of vasopressin on the heart (reduced cardiac output and heart rate) are largely indirect and result from coronary vasoconstriction, decreased coronary blood flow, and alterations in vagal and sympathetic tone. Some patients with coronary insufficiency experience angina even in response to the relatively small amounts of vasopressin required to control DI, and vasopressin

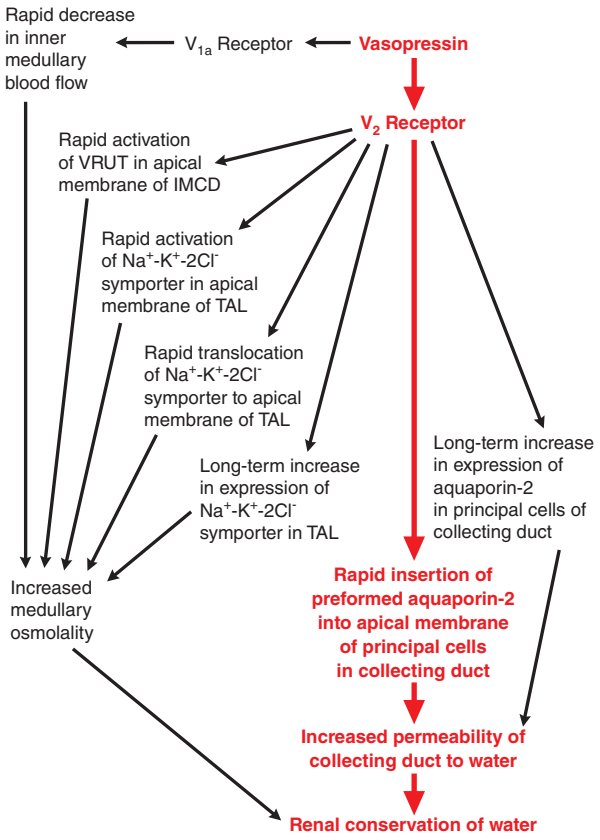

Figure 29–14 *Mechanisms by which vasopressin increases the renal conservation of water.* Red and black arrows denote major and minor pathways, respectively.

induced myocardial ischemia has led to severe reactions and even death.

CNS. Vasopressin likely plays a role as a neurotransmitter or neuromodulator. Although vasopressin can modulate CNS autonomic systems controlling heart rate, arterial blood pressure, respiration rate, and sleep patterns, the physiological significance of these actions is unclear. While vasopressin is not the principal corticotropin-releasing factor, vasopressin may provide for sustained activation of the hypothalamic-pituitary-adrenal axis during chronic stress. Studies in both laboratory animals and humans indicated that vasopressin and oxytocin are key regulators of social and emotional behaviors (Benarroch, 2013). CNS effects of vasopressin appear to be mediated predominantly by V_1 receptors.

Blood Coagulation. Activation of V_2 receptors by *desmopressin* or *vasopressin* increases circulating levels of procoagulant factor VIII and of von Willebrand factor. These effects are mediated by extrarenal V_2 receptors. Presumably, vasopressin stimulates the secretion of von Willebrand factor and factor VIII from storage sites in vascular endothelium. However, because release of von Willebrand factor does not occur when *desmopressin* is applied directly to cultured endothelial cells or to isolated blood vessels, intermediate factors are likely to be involved.

Other Nonrenal Effects. At high concentrations, vasopressin stimulates smooth muscle contraction in the uterus (by oxytocin receptors) and GI tract (by V_1 receptors). Vasopressin is stored in platelets, and activation of V_1 receptors stimulates platelet aggregation. Also, activation of V_1 receptors on hepatocytes stimulates glycogenolysis.

Vasopressin Receptor Agonists

Several vasopressin-like peptides occur naturally across the animal kingdom (Table 29–8); all are nonapeptides. In all mammals except swine, the neurohypophyseal peptide is 8-arginine vasopressin, and the terms vasopressin, AVP, and ADH are used interchangeably. There are also a

number of synthetic peptides with receptor-subtype specificity and one nonpeptide agonist.

Many vasopressin analogues were synthesized with the goal of increasing duration of action and selectivity for vasopressin receptor subtypes (V_1 vs. V_2 receptors, which mediate pressor responses and antidiuretic responses, respectively). Thus, the antidiuretic-to-vasopressor ratio for the V_2-selective agonist, DDAVP, also called *desmopressin*, is about 3000 times greater than that for vasopressin; thus, desmopressin is the preferred drug for the treatment of central DI. Substitution of valine for glutamine in position 4 further increases the antidiuretic selectivity, and the antidiuretic-to-vasopressor ratio for deamino [Val^4, D-Arg^8]AVP is about 11,000 times greater than that for vasopressin.

Increasing V_1 selectivity has proved more difficult than increasing V_2 selectivity. Vasopressin receptors in the adenohypophysis that mediate vasopressin-induced ACTH release are neither classical V_1 nor V_2 receptors. Because vasopressin receptors in the adenohypophysis appear to share a common signal-transduction mechanism with classical V_1 receptors and because many vasopressin analogues with vasoconstrictor activity release ACTH, V_1 receptors have been subclassified into V_{1a} (vascular/hepatic) and V_{1b} (pituitary) receptors (also called V_3 receptors). There are selective agonists for V_{1a} and V_{1b} receptors.

The chemical structure of oxytocin is closely related to that of vasopressin: Oxytocin is [Ile^3, Leu^8]AVP. With such structural similarities, it is not surprising that vasopressin and oxytocin agonists and antagonists can bind to each other's receptors. Therefore, most of the available peptide vasopressin agonists and antagonists have some affinity for oxytocin receptors; at high doses, they may block or mimic the effects of oxytocin.

Diseases Affecting the Vasopressin System

Diabetes Insipidus

Diabetes insipidus is a disease of impaired renal water conservation owing either to inadequate vasopressin secretion from the neurohypophysis (central DI) or to insufficient renal vasopressin response (nephrogenic DI). Very rarely, DI can be caused by an abnormally high degradation rate of vasopressin by circulating vasopressinases. Pregnancy may accentuate or reveal central or nephrogenic DI by increasing plasma levels of vasopressinase and by reducing renal sensitivity to vasopressin. Patients with DI excrete large volumes (>30 mL/kg per day) of dilute (<200 mOsm/kg) urine and, if their thirst mechanism is functioning normally, are polydipsic. Central DI can be distinguished from nephrogenic DI by administration of *desmopressin*, which will increase urine osmolality in patients with central DI but have little or no effect in patients with nephrogenic DI. DI can be differentiated from primary polydipsia by measuring plasma osmolality, which will be low to low-normal in patients with primary polydipsia and high to high-normal in patients with DI.

Central DI. Head injury, either surgical or traumatic, in the region of the pituitary or hypothalamus may cause central DI. Postoperative central DI may be transient, permanent, or triphasic (recovery followed by permanent relapse). Other causes include hypothalamic or pituitary tumors, cerebral aneurysms, CNS ischemia, and brain infiltrations and infections. Central DI may also be idiopathic or familial. Familial central DI usually is autosomal dominant (chromosome 20), and vasopressin deficiency occurs several months or years after birth and worsens gradually. Autosomal dominant central DI is linked to mutations in the vasopressin preprohormone gene that cause the prohormone to misfold and oligomerize improperly. Accumulation of mutant vasopressin precursor causes neuronal death, hence the dominant mode of inheritance. Rarely, familial central DI is autosomal recessive owing to a mutation in the vasopressin peptide itself that gives rise to an inactive vasopressin mutant.

Antidiuretic peptides are the primary treatment of central DI, with *desmopressin* the peptide of choice. For patients with central DI who cannot tolerate antidiuretic peptides because of side effects or allergic reactions, other treatment options are available. *Chlorpropamide*, an oral sulfonylurea, potentiates the action of small or residual amounts of circulating vasopressin and will reduce urine volume in more than half of all patients with central DI. Doses of 125 to 500 mg daily appear effective in patients with partial central DI. If polyuria is not controlled satisfactorily with *chlorpropamide* alone, addition of a thiazide diuretic to the regimen usually results in an adequate reduction in urine volume. *Carbamazepine* (800–1000 mg daily in divided doses) also reduces urine volume in patients with central DI. Long-term use may induce serious adverse effects; therefore, *carbamazepine* is used rarely to treat central DI. These agents are not effective in nephrogenic DI, which indicates that functional V_2 receptors are required for the antidiuretic effect. Because *carbamazepine* inhibits and *chlorpropamide* has little effect on vasopressin secretion, it is likely that *carbamazepine* and *chlorpropamide* act directly on the kidney to enhance V_2 receptor–mediated antidiuresis.

Nephrogenic DI. Nephrogenic DI may be congenital or acquired. Hypercalcemia, hypokalemia, postobstructive renal failure, Li^+, *foscarnet*, *clozapine*, *demeclocycline*, and other drugs can induce nephrogenic DI. As many as one in three patients treated with Li^+ may develop nephrogenic DI. X-linked nephrogenic DI is caused by mutations in the gene encoding the V_2 receptor, which maps to Xq28. Mutations in the V_2 receptor gene may cause impaired routing of the V_2 receptor to the cell surface, defective coupling of the receptor to G proteins, or decreased receptor affinity for vasopressin. Autosomal recessive and dominant nephrogenic DI result from inactivating mutations in aquaporin 2. These findings indicate that aquaporin 2 is essential for the antidiuretic effect of vasopressin in humans.

Although the mainstay of treatment of nephrogenic DI is assurance of an adequate water intake, drugs also can be used to reduce polyuria. *Amiloride* blocks Li^+ uptake by the Na^+ channel in the collecting duct system and may be effective in patients with mild-to-moderate concentrating defects. Thiazide *diuretics* reduce the polyuria of patients with DI and often are used to treat nephrogenic DI. In infants with nephrogenic DI, use of thiazides may be crucial because uncontrolled polyuria may exceed the child's capacity to imbibe and absorb fluids. It is possible that the natriuretic action of thiazides and resulting extracellular fluid volume depletion play an important role in thiazide-induced antidiuresis. The antidiuretic effects appear to parallel the thiazide's ability to cause natriuresis, and the drugs are given in doses similar to those used to mobilize edema fluid. In patients with DI, a 50% reduction of urine volume is a good response to thiazides. Moderate restriction of Na^+ intake can enhance the antidiuretic effectiveness of thiazides.

Several case reports have described the effectiveness of *indomethacin* in the treatment of nephrogenic DI; however, other PG synthase inhibitors (e.g., *ibuprofen*) appear to be less effective. The mechanism of the effect may involve a decrease in GFR, an increase in medullary solute concentration, or enhanced proximal fluid reabsorption. Also, because PGs attenuate vasopressin-induced antidiuresis in patients with at least a partially intact V_2 receptor system, some of the antidiuretic response to indomethacin may be due to diminution of the PG effect and enhancement of vasopressin effects on the principal cells of the collecting duct.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

Syndrome of inappropriate secretion of ADH (SIADH) is a disease of impaired water excretion with accompanying hyponatremia and hypoosmolality, caused by the *inappropriate* secretion of vasopressin. Clinical manifestations of plasma hypotonicity resulting from SIADH may include lethargy, anorexia, nausea and vomiting, muscle cramps, coma, convulsions, and death. A multitude of disorders can induce SIADH, including malignancies, pulmonary diseases, CNS injuries/diseases (e.g., head trauma, infections, and tumors), and general surgery.

Three drug classes are commonly implicated in drug-induced SIADH: psychotropic medications (e.g., selective serotonin reuptake inhibitors, *haloperidol*, and tricyclic antidepressants), sulfonylureas (e.g., *chlorpropamide*), and vinca alkaloids (e.g., *vincristine* and *vinblastine*). Other drugs strongly associated with SIADH include *clonidine*, *cyclophosphamide*, *enalapril*, *felbamate*, *ifosfamide*, *methyldopa*, *pentamidine*, and *vinorelbine*. Many other drugs have been implicated. In a normal individual, an elevation in plasma vasopressin per se does not induce plasma hypotonicity because the person simply stops drinking owing to an osmotically

induced aversion to fluids. Therefore, plasma hypotonicity only occurs when excessive fluid intake (oral or intravenous) accompanies inappropriate secretion of vasopressin.

Treatment of hypotonicity in the setting of SIADH includes water restriction, intravenous administration of hypertonic saline, loop diuretics (which interfere with kidney's concentrating ability), and drugs that inhibit the effect of vasopressin to increase water permeability in collecting ducts. To inhibit vasopressin's action in collecting ducts, *demeclocycline*, a tetracycline, has been the preferred drug, but *tolvaptan* and *conivaptan*, V_2 receptor antagonists, are now available (see next section and Table 29–9).

Although Li^+ can inhibit the renal actions of vasopressin, it is effective in only a minority of patients, may induce irreversible renal damage when used chronically, and has a low therapeutic index. Therefore, Li^+ should be considered for use only in patients with symptomatic SIADH who cannot be controlled by other means or in whom tetracyclines are contraindicated (e.g., patients with liver disease). It is important to stress that the majority of patients with SIADH do not require therapy because plasma Na^+ stabilizes in the range of 125 to 132 mM; such patients usually are asymptomatic. Only when symptomatic hypotonicity ensues, generally when plasma Na^+ levels drop below 120 mM, should therapy with demeclocycline be initiated. Due to symptoms resulting from hypotonicity, which causes an influx of water into cells with resulting cerebral swelling, the goal of therapy is simply to increase plasma osmolality toward normal.

Other Water-Retaining States

In patients with CHF, cirrhosis, or nephrotic syndrome, *effective* blood volume often is reduced, and hypovolemia frequently is exacerbated by the liberal use of diuretics. Because hypovolemia stimulates vasopressin release, patients may become hyponatremic owing to vasopressin-mediated retention of water. The development of potent orally active V_2 receptor antagonists and specific inhibitors of water channels in the collecting duct has provided a new therapeutic strategy not only in patients with SIADH but also in the more common setting of hyponatremia in patients with heart failure, liver cirrhosis, and nephrotic syndrome.

Clinical Use of Vasopressin Agonists

Two antidiuretic peptides are available for clinical use in the U.S.:

- *Vasopressin* (synthetic 8-L-arginine vasopressin) is available as a sterile aqueous solution; it may be administered intravenously, subcutaneously, intramuscularly, intranasally, intraosseously (off label), intraarterially, or endotracheally (off label; unreliable).
- *Desmopressin acetate* (synthetic DDAVP) is available as a sterile aqueous solution packaged for intravenous or subcutaneous injection, in a solution for intranasal administration with either a nasal spray pump or rhinal tube delivery system, and in tablets for oral administration.

Therapeutic Uses

The therapeutic uses of *vasopressin* and its congeners can be divided into two main categories according to the vasopressin receptor involved: V_1 receptor mediated and V_2 receptor mediated.

V_1 receptor–mediated therapeutic applications are based on the rationale that V_1 receptors cause GI and vascular smooth muscle contraction. *Vasopressin is the main agent used.* Vasodilatory shock is the only FDA-approved indication for *vasopressin*. *Vasopressin* levels in patients with vasodilatory shock are inappropriately low, and such patients are highly sensitive to the pressor actions of V_1 receptor agonists. Current recommendations for treatment of septic shock are to employ fluids and *norepinephrine* as first-line treatments, with the addition of *vasopressin* when necessary to achieve target blood pressure or to avoid excessive doses of *norepinephrine* (Demiselle et al., 2020; Shi et al., 2020). The use of

vasopressin in other shock states, for example hemorrhagic (Gupta et al., 2017) and cardiogenic (Karami et al., 2020) shock, remains controversial. *Vasopressin* combined with *epinephrine* and steroids showed improved outcomes after in-hospital cardiac arrest (Layek et al., 2014). However, due to lack of external validation, current guidelines do not recommend this combination for treatment of cardiac arrest (Vallentin et al., 2020).

V_1 receptor–mediated GI smooth muscle contraction has been used to treat postoperative ileus and abdominal distension and to dispel intestinal gas before abdominal roentgenography to avoid interfering gas shadows. V_1 receptor–mediated vasoconstriction of the splanchnic arterial vessels reduces blood flow to the portal system and thereby attenuates pressure and bleeding in esophageal varices. Although endoscopic variceal banding ligation is the treatment of choice for bleeding esophageal varices, V_1 receptor agonists have been used in an emergency setting until endoscopy can be performed. Simultaneous administration of *nitroglycerin* with V_1 receptor agonists may attenuate the cardiotoxic effects of V_1 agonists while enhancing their beneficial splanchnic effects. Also, V_1 receptor agonists have been used during abdominal surgery in patients with portal hypertension to diminish the risk of hemorrhage during the procedure. V_1 receptor–mediated vasoconstriction has been used to reduce bleeding during acute hemorrhagic gastritis, burn wound excision, cyclophosphamide-induced hemorrhagic cystitis, liver transplant, cesarean section, and uterine myoma resection.

V_2 receptor–mediated therapeutic applications are based on the rationale that V_2 receptors cause water conservation and stimulate release of blood coagulation factors. *Desmopressin is the standard drug of choice.* Central, but not nephrogenic, DI can be treated with V_2 receptor agonists, and polyuria and polydipsia usually are well controlled by these agents. Some patients experience transient DI (e.g., in head injury or surgery in the area of the pituitary); however, therapy for most patients with DI is lifelong. *Desmopressin* is the drug of choice for the vast majority of patients. The duration of effect from a single intranasal dose is from 6 to 20 h; twice-daily administration is effective in most patients. The usual intranasal dosage in adults is 10 to 40 μg daily either as a single dose or divided into two or three doses. In view of the high cost of the drug and the importance of avoiding water intoxication, the schedule of administration should be adjusted to the minimal amount required. In some patients, chronic allergic rhinitis or other nasal pathology may preclude reliable peptide absorption following nasal administration. Oral administration of *desmopressin* in doses of 0.1 to 1.2 mg/d provides adequate *desmopressin* blood levels to control polyuria. Subcutaneous or intravenous administration of 2 to 4 μg daily of *desmopressin* also is effective in central DI.

Vasopressin has little, if any, place in the long-term therapy of DI because of its short duration of action and V_1 receptor–mediated side effects. *Vasopressin* can be used as an alternative to *desmopressin* in the initial diagnostic evaluation of patients with suspected DI and to control polyuria in patients with DI who recently have undergone surgery or experienced head trauma. Under these circumstances, polyuria may be transient, and long-acting agents may produce water intoxication.

Desmopressin is used in bleeding disorders. In most patients with type I von Willebrand disease (vWD) and in some with type IIn vWD, *desmopressin* will elevate von Willebrand factor and shorten bleeding time. However, *desmopressin* generally is ineffective in patients with types IIa, IIb, and III vWD. *Desmopressin* may cause a marked transient thrombocytopenia in individuals with type IIb vWD and is contraindicated in such patients. *Desmopressin* also increases factor VIII levels in patients with mild-to-moderate hemophilia A. *Desmopressin* is not indicated in patients with severe hemophilia A, those with hemophilia B, or those with factor VIII antibodies. In patients with renal insufficiency, *desmopressin* shortens bleeding time and increases circulating levels of factor VIII coagulant activity, factor VIII–related antigen, and ristocetin cofactor. It also induces the appearance of larger von Willebrand factor multimers. *Desmopressin* is effective in some patients with liver cirrhosis- or drug-induced (e.g., *heparin*, *hirudin*, and antiplatelet agents) bleeding disorders. *Desmopressin*, given intravenously at a dose of 0.3 μg/kg, increases factor VIII and von Willebrand factors for more than 6 h. *Desmopressin* can be given at intervals of 12 to 24 h depending on the clinical response and severity of bleeding. Tachyphylaxis to *desmopressin* usually occurs after several days (owing to depletion of factor VIII and von Willebrand factor storage sites) and limits its usefulness to preoperative preparation, postoperative bleeding, excessive menstrual bleeding, and emergency situations.

Another V_2 receptor–mediated therapeutic application is the use of *desmopressin* for primary nocturnal enuresis. Bedtime administration of *desmopressin* tablets provides a high response rate that is sustained with long-term use and that accelerates the cure rate. Intranasal *desmopressin* is no longer recommended for the treatment of primary nocturnal enuresis because of increased risk of hyponatremia. *Desmopressin* also relieves post–lumbar puncture headache, probably by causing water retention and thereby facilitating rapid fluid equilibration in the CNS.

ADME

When *vasopressin* and *desmopressin* are given orally, they are inactivated quickly by trypsin. Inactivation by peptidases in various tissues (particularly liver and kidney) results in a plasma $t_{1/2}$ of *vasopressin* of 17 to 35 min. Following intramuscular or subcutaneous injection, antidiuretic effects of *vasopressin* last 2 to 8 h. The $t_{1/2}$ of *desmopressin* is 75 min to 3.5 h.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Most adverse effects are mediated through V_1 receptor activation on vascular and GI smooth muscle; such adverse effects are much less common and less severe with *desmopressin* than with *vasopressin*. After injection of large doses of *vasopressin*, marked facial pallor due to cutaneous vasoconstriction is observed commonly. Increased intestinal activity is likely to cause nausea, belching, cramps, and an urge to defecate. *Vasopressin* should be administered with extreme caution in individuals suffering from vascular disease, especially coronary artery disease. Other cardiac complications include arrhythmia and decreased cardiac output. Peripheral vasoconstriction and gangrene were encountered in patients receiving large doses of *vasopressin*.

The major V_2 receptor–mediated adverse effect is water intoxication. Many drugs, including *carbamazepine*, *chlorpropamide*, *morphine*, tricyclic antidepressants, and NSAIDs, can potentiate the antidiuretic effects of these peptides. Several drugs, such as Li^+, *demeclocycline*, and *ethanol*, can attenuate the antidiuretic response to *desmopressin*. *Desmopressin* and *vasopressin* should be used cautiously in disease states in which a rapid increase in extracellular water may impose risks (e.g., in angina, hypertension, and heart failure) and should not be used in patients with acute renal failure. Patients receiving *desmopressin* to maintain hemostasis should be advised to reduce fluid intake. Also, it is imperative that these peptides not be administered to patients with primary or psychogenic polydipsia because severe hypotonic hyponatremia will ensue. Mild facial flushing and headache are the most common adverse effects. Allergic reactions ranging from urticaria to anaphylaxis may occur with *desmopressin* or *vasopressin*. Intranasal administration may cause local adverse effects in the nasal passages, such as edema, rhinorrhea, congestion, irritation, pruritus, and ulceration.

Clinical Use of Vasopressin Antagonists

Table 29–9 summarizes the selectivity of vasopressin receptor antagonists. Only *tolvaptan* and *conivaptan* are currently available in the U.S.

Therapeutic Uses

When the kidney perceives the arterial blood volume to be low (as in the disease states of CHF, cirrhosis, and nephrosis), AVP perpetuates a state of total-body salt and water excess. V_2 receptor antagonists or "aquaretics" may have a therapeutic role in these conditions, especially in patients with concomitant hyponatremia. They are also effective in hyponatremia associated with SIADH. Aquaretics increase renal free water excretion with little or no change in electrolyte excretion. Because they do not affect Na^+ reabsorption, they do not stimulate the TGF mechanism with its associated consequence of reducing GFR.

Drug Facts for Your Personal Formulary: *Diuretics and Agents Regulating Renal Excretion*

Drug	Major Therapeutic Uses	Clinical Pharmacology and Tips
Carbonic Anhydrase Inhibitors		
Acetazolamide Dichlorphenamide	• Glaucoma • Epilepsy • Altitude sickness • Diuretic resistance • Metabolic alkalosis • Familial periodic paralysis	• Ineffective as diuretic monotherapy because effects on renal excretion are self-limiting • Dichlorphenamide drug of choice for familial periodic paralysis
Osmotic Diuretics		
Mannitol	• Elevated intraocular pressure • Elevated intracranial pressure • Dialysis disequilibrium syndrome • Diagnosis of bronchial hyperreactivity • Urologic irrigation • Management of some overdoses • Cystic fibrosis in adults	• Frequently used to treat or prevent acute kidney injuries, efficacy unclear • Expansion of extracellular fluid volume may cause pulmonary edema
Inhibitors of Na^+-K^+-$2Cl^-$ Symport (Loop Diuretics; High-Ceiling Diuretics)		
Bumetanide Ethacrynic acid Furosemide Torsemide	• Acute pulmonary edema • Edema associated with congestive heart failure, liver cirrhosis, chronic kidney disease, and nephrotic syndrome • Hyponatremia • Hypercalcemia • Hypertension	• Higher doses needed with impaired renal function • Torsemide superior to furosemide in heart failure • Increased risk of ototoxicity with ethacrynic acid compared to other loop diuretics • Risk for hypokalemia and arrhythmia when combined with QT-prolonging drugs • Ethacrynic acid first choice in sulfa allergy
Inhibitors of Na^+-Cl^- Symport (Thiazide Diuretics)		
Thiazide type Chlorothiazide Hydrochlorothiazide Methyclothiazide (not available in the U.S.) ***Thiazide-like*** Chlorthalidone Indapamide Metolazone	• Hypertension • Edema associated with congestive heart failure, liver cirrhosis, chronic kidney disease, and nephrotic syndrome • Nephrogenic diabetes insipidus	• Among first choice for treating hypertension • Thiazide-like have longer half-lives than thiazide-type and thus may be superior for hypertension • Higher doses needed for treating edema in patients with impaired renal function • Frequently combined with a loop diuretic to effect "sequential blockade" of tubular transport • Risk for hypokalemia and arrhythmia when combined with QT-prolonging drugs • Cause metabolic disturbances (e.g., elevate plasma glucose and cholesterol) • May cause severe hyponatremia in some patients
Inhibitors of Renal Epithelial Na^+ Channels (K^+-Sparing Diuretics)		
Amiloride Triamterene	• Hypertension • Edema associated with congestive heart failure, liver cirrhosis, and chronic kidney disease • Liddle syndrome • Lithium-induced nephrogenic diabetes insipidus	• Low efficacy as monotherapy for edema • Frequently combined with loop or thiazide diuretics to prevent hypokalemia and increase diuresis • Risk of hyperkalemia in renal insufficiency or when combined with angiotensin-converting enzyme inhibitors or angiotensin receptor antagonists
Mineralocorticoid Receptor Antagonists (Aldosterone Antagonists; K^+-Sparing Diuretics)		
Eplerenone Spironolactone Finerenone (nonsteroidal MR antagonist)	• Hypertension • Edema associated with congestive heart failure, liver cirrhosis, chronic kidney disease • Primary hyperaldosteronism • Acute myocardial infarction (eplerenone) • Heart failure (in combination with standard therapy) • Polycystic ovary disease • Chronic kidney disease in diabetic patients (finerenone)	• Endogenous aldosterone levels determine efficacy • Can be combined with loop or thiazide diuretics to prevent hypokalemia and increase diuresis • Diuretics of choice for hypertension due to primary hyperaldosteronism and for edema due to secondary aldosteronism (e.g., heart failure, hepatic cirrhosis) • Finerenone reduces cardiovascular mortality and declining renal function in diabetic patients • High risk for hyperkalemia in chronic renal failure • Eplerenone and finerenone contraindicated with potent inhibitors of CYP3A4 (e.g., ketoconazole, itraconazole) • Spironolactone active metabolite has long half-life requiring slow dose adjustments (over days)

Drug Facts for Your Personal Formulary: *Diuretics and Agents Regulating Renal Excretion (continued)*

Drug	Major Therapeutic Uses	Clinical Pharmacology and Tips
Sodium-Glucose Symport Antagonists (SGLT2 Inhibitors; Gliflozins)		
Canagliflozin Dapagliflozin Empagliflozin, others	• Diabetes mellitus type 2 • Heart failure with reduced ejection fraction	• Reduction of cardiovascular mortality and declining renal function in diabetic patients • Augment natriuresis induced by loop diuretics • Rare necrotizing fasciitis of perineum • Hepatic metabolism, long half-life
Vasopressin Receptor Agonist		
V_1 receptor agonist Vasopressin	• Postoperative abdominal distention • Abdominal roentgenography • Bleeding • Cardiac arrest • Hypovolemic shock	• Contraindicated in nephrogenic diabetes insipidus • Not for long-term therapy of central diabetes insipidus • Use with extreme caution in patients with vascular disease
V_2 receptor agonist Desmopressin (DDAVP)	• Central diabetes insipidus • Primary nocturnal enuresis • Prevention of blood loss in patients with specific bleeding disorders	• Contraindicated in nephrogenic diabetes insipidus • Drug of choice for central diabetes insipidus • Can be administered orally at high doses • Major adverse effect is water intoxication
Vasopressin Receptor Antagonists		
Conivaptan Tolvaptan	• Treatment of hypervolemic and euvolemic hyponatremia	• Risk of too rapid correction with serious consequences (osmotic demyelination syndrome) • Close monitoring of serum Na^+ required

Tolvaptan is a selective oral V_2 receptor antagonist FDA approved for clinically significant hypervolemic and euvolemic hyponatremia. *Tolvaptan* is also approved to slow kidney function decline in adults at risk of rapidly progressing autosomal dominant polycystic kidney disease. *Conivaptan* is a nonselective V_{1a} receptor/V_2 receptor antagonist that is FDA approved for the treatment of hospitalized patients with euvolemic and hypervolemic hyponatremia. *Conivaptan* is available only for intravenous infusion. In heart failure patients, V_2 receptor antagonists improve decongestion and serum sodium and in the short term provide symptomatic improvement (Vinod et al., 2017); however, this does not translate into short-term or long-term improvements in important clinical outcomes such as mortality or hospitalization (Gunderson et al., 2019). The interaction of *tolvaptan* with loop diuretics is currently being studied in several clinical trials (Gunderson et al., 2019).

ADME

Tolvaptan has a $t_{1/2}$ of 2.8 to 12 h, and less than 1% is excreted in the urine. *Tolvaptan* is a substrate and inhibitor of P-glycoprotein and is eliminated entirely by CYP3A4 metabolism. *Conivaptan* is highly protein bound, has a terminal elimination $t_{1/2}$ of 5 to 12 h, is metabolized via CYP3A, and is partially excreted by the kidney.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

The most dangerous adverse effect of V_2 receptor antagonists is due to their pharmacological action to increase free water excretion. This may correct hyponatremia too rapidly, resulting in serious and even fatal consequences (osmotic demyelination syndrome). Indeed, *tolvaptan* is labeled with a black-box warning against too rapid correction of hyponatremia and with the recommendation to initiate therapy in a hospital setting capable of close monitoring of serum Na^+. V_2 receptor antagonists should not be used with hypertonic saline. Antagonism of V_2 receptors can also cause polyuria, which likely explains the increased incidence of dehydration, hypotension, dizziness, pyrexia, increased thirst, and xerostomia with this class of drugs. Both *tolvaptan* and *conivaptan* can cause GI adverse effects. *Tolvaptan* can cause liver damage; therefore, administration of *tolvaptan* generally should be limited to 30 days, and *tolvaptan* should not be used in patients with liver disease. Both *tolvaptan* and *conivaptan* can induce headaches, hypokalemia, and hyperglycemia, and both are contraindicated in anuria (no benefit) and in patients receiving drugs that inhibit CYP3A4 (e.g., *clarithromycin*, *ketoconazole*). *Tolvaptan* and *conivaptan* are contraindicated in hypovolemic hyponatremia. *Tolvaptan* may increase the rate of hyperkalemia when it is given with angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and potassium-sparing diuretics.

Chapter 30 Renin and Angiotensin

Krishna Sriram and Paul A. Insel

THE RENIN-ANGIOTENSIN SYSTEM

The renin-angiotensin system (RAS) participates in the pathophysiology of numerous clinical disorders, including diabetic nephropathy, hypertension, congestive heart failure, and myocardial infarction (MI). This role has led to extensive study of the RAS and development of multiple ways to inhibit its actions. This chapter discusses the physiology, biochemistry, and cellular and molecular biology of classical and novel RAS components and pathways. The chapter also discusses the pharmacology and clinical utility of drugs that inhibit the RAS. Therapeutic applications of drugs covered in this chapter are also discussed in Chapters 31 to 33. The RAS is sometimes identified as the renin-angiotensin-aldosterone system. *Aldosterone*, a mineralocorticoid, is discussed in Chapter 50.

HISTORY

In 1898, Tiegerstedt and Bergman found that saline extracts of the kidney (ren-) contained a pressor substance that they named *renin*. In 1934, Goldblatt and colleagues found that renal artery constriction produced persistent hypertension in dogs. In 1940, Braun-Menéndez and colleagues in Argentina and Page and Helmer in the U.S. reported that renin was an enzyme that acted on a plasma protein substrate to catalyze the formation of a pressor peptide, which the Argentinian investigators named *hypertensin* and Page and Helman named *angiotonin*. This peptide was ultimately renamed *angiotensin,* and its plasma substrate was called *angiotensinogen*.

In the 1950s, two forms of angiotensin (Ang) were identified: a decapeptide (AngI) and an octapeptide (AngII) formed by the cleavage of AngI by angiotensin-converting enzyme (ACE), a zinc metalloproteinase discovered by Skeggs in 1956. AngII was the more active form; its synthesis by Schwyzer and Bumpus in 1957 made it available for study. Later research showed that the kidneys are an important site of aldosterone action; angiotensin stimulates its production in humans, and renin secretion increases with depletion of Na^+. Thus, the RAS became recognized as a mechanism that stimulates aldosterone synthesis and secretion and an important homeostatic mechanism in the regulation of blood pressure (BP) and electrolyte composition.

In the early 1970s, polypeptides were discovered that either inhibited the formation of AngII or blocked AngII receptors. These inhibitors revealed important physiological and pathophysiological roles for the RAS and inspired the development of an efficacious class of antihypertensive drugs: orally active ACE inhibitors (ACEIs). Studies with ACEIs uncovered roles for the RAS in the pathophysiology of hypertension, heart failure, vascular disease, and renal failure. Selective and competitive antagonists of AngII receptors were subsequently developed that yielded *losartan*, the first orally active, highly selective, and potent nonpeptide AngII receptor antagonist (Dell'Italia, 2011). Many other AngII receptor antagonists have been developed, followed by *aliskiren*, a direct renin inhibitor.

Classical RAS

Through the actions of AngII, the RAS participates in BP regulation, aldosterone release, Na^+-reabsorption from renal tubules, electrolyte and fluid homeostasis, and cardiovascular remodeling. AngII is derived from angiotensinogen in two proteolytic steps. First, the enzyme renin, released into the circulation from the juxtaglomerular (JG) cells, specialized smooth muscle cells in glomerular arterioles in the kidneys, cleaves the decapeptide AngI from the amino terminus of angiotensinogen (renin substrate). Then, ACE (also referred to as ACE1 for clarity), located on the endothelial cell lining of the vasculature (and in other cell types throughout the body), removes the carboxy-terminal dipeptide of AngI to produce the octapeptide AngII. Other enzymes, in particular chymase (expressed in mast cells and cardiac myocytes, among others), also participate in conversion of AngI to AngII. Figure 30–1 summarizes these enzymatic steps. AngII acts by binding to two distinct seven-membrane–spanning G protein-coupled receptors (GPCRs), AT_1 (also known as AGTR1) and AT_2 (also known as AGTR2). AGTR1, the more widely expressed and studied of the AngII GPCRs, is thought to mediate the majority of RAS-mediated physiological and pathophysiological effects.

Abbreviations

ACE: angiotensin-converting enzyme
ACEI: angiotensin-converting enzyme inhibitor
Ac-SDKP: *N*-acetyl-seryl-aspartyl-lysyl-proline
ACTH: corticotropin (formerly adrenocorticotropic hormone)
Ang: angiotensin
ARDS: acute respiratory distress syndrome
ARNi: angiotensin receptor–neprilysin inhibitors
ARB: angiotensin receptor blocker
BP: blood pressure
cAMP: cyclic AMP
CoV: coronavirus
COVID-19: coronavirus disease 2019
COX: cyclooxygenase
DRI: direct renin inhibitor
ECM: extracellular matrix
GFR: glomerular filtration rate
GI: gastrointestinal
GPCR: G protein-coupled receptor
GRK: G protein-coupled receptor kinases
HFrEF: heart failure with reduced ejection fraction
IRAP: insulin-regulated aminopeptidase
JG: juxtaglomerular
LDL: low-density lipoprotein
MD: macula densa
MI: myocardial infarction
MRGPRD: Mas-related G protein–coupled receptor D
NE: norepinephrine
NO: nitric oxide
NOS: nitric oxide synthase
NSAID: nonsteroidal anti-inflammatory drug
PAI-1: plasminogen activator inhibitor type 1
PG: prostaglandin
PI_3K: phosphoinositide 3-kinase
PL: phospholipase
PRA: plasma renin activity
PRC: plasma renin concentration
(pro)renin: renin and prorenin
PRR: (pro)renin receptor
RAS: renin-angiotensin system
RBF: renal blood flow
ROS: reactive O_2 species
SARS: severe acute respiratory syndrome
TGF: transforming growth factor
TPR: total peripheral resistance

Hence, the renin-ACE-AGTR1 axis represents an important opportunity for pharmacological intervention. The effects of ACE-AngII-AGTR1 signaling are counteracted by actions of ACE2, which converts AngI and AngII to other angiotensin peptides, whose actions generally oppose those of AngII. AGTR2 is widely expressed in many cell/tissue types throughout the body, especially in the vasculature, the heart, adipose tissue, and various endocrine tissues.

Newer Paradigms in the RAS

Discoveries regarding the RAS indicated that it was not only an endocrine system but also a paracrine, autocrine/intracrine hormonal system with several new components and pathways. The RAS includes local (tissue) RAS; alternative pathways for AngII synthesis (*ACE independent* and *renin independent*); a second ACE, ACE2, which converts AngI to peptides that include Ang(1–7), which acts primarily via the MAS1 receptor (a GPCR), whose activation opposes the vasoconstrictor effects of the ACE-AngII-AT_1 receptor axis; multiple biologically active angiotensin peptides such as Ang(1–9), AngIII, Ang(3–7), angiotensin A, and alamandine; multiple receptors for angiotensin (AT_1, AT_2, AT_4; MAS1; and MRGPRD [Mas-related G protein–coupled receptor D]); and the (pro)renin receptor (PRR). Differential activation of these multiple arms of the RAS may underlie pathophysiological outcomes in cardiovascular and renal disease (Campbell, 2014; Santos, 2014) and have been implicated in the pathobiology of coronavirus disease 2019 (COVID-19) (Sriram and Insel, 2020a).

Components of the Renin-Angiotensin System

Renin

Renin is the major determinant of the rate of AngII production; its secretion is regulated by several mechanisms (Figures 30–2 and 30–3). Renin is synthesized, stored, and secreted by exocytosis into the renal arterial circulation by the JG cells located in the walls of the afferent arterioles that enter the glomeruli. Renin, an aspartyl protease, cleaves the bond between residues 10 and 11 at the amino terminus of angiotensinogen to generate AngI. The active form of renin is a glycoprotein that contains 340 amino acids. The precursor gene for renin (*REN*) is also expressed in certain types of reproductive tissue, smooth muscle, numerous epithelial cell types (including alveolar epithelial cells, pancreatic ductal cells), and endothelial cells, indicating the possibility of localized RAS activation as many of these tissues/cells also express other RAS components.

Prorenin can be activated in two ways: *proteolytically,* by proconvertase 1 or cathepsin B enzymes that remove 43 amino acids (propeptide) from its amino terminus to uncover the active site of renin, and *nonproteolytically,* when prorenin binds to the PRR, resulting in conformational changes that unfold the propeptide and expose the active catalytic site of the enzyme (Nguyen and Danser, 2008). Both renin and prorenin are stored in the JG cells and, when released, circulate in the blood. The concentration of prorenin in the circulation is about 10-fold greater than that of the active enzyme. The $t_{1/2}$ of circulating renin is about 15 min.

Control of Renin Secretion

Renin is secreted by the granular cells within the JG apparatus and is regulated by the following pathways (Figure 30–2):

1. The macula densa (MD)
2. Intrarenal baroreceptors
3. β_1 Adrenergic receptors

The Macula Densa

The MD, which is adjacent to the JG cells, is important for salt and water regulation by the RAS. The MD is composed of specialized columnar epithelial cells in the wall of the cortical thick ascending limb that passes between the afferent and efferent arterioles of the glomerulus (see Chapter 29). The MD cells sense changes in the fluid composition in the tubule and send chemical (paracrine) signals to the JG cells that regulate renin release. Increases or decreases in NaCl flux across the MD inhibit or stimulate renin release, respectively.

Adenosine, ATP, and prostaglandins (PGs) modulate renin release (Figure 30–3). ATP and adenosine inhibit renin release when NaCl transport increases. ATP acts via P2Y2 receptors to enhance Ca^{2+} release, and adenosine acts via the A_1 adenosine receptor to inhibit adenylyl cyclase activity and cyclic AMP (cAMP) production. PGE_2 and PGI_2 stimulate renin release when NaCl transport decreases by enhancing cAMP formation. PG production is increased by inducible cyclooxygenase 2 (COX-2) and nNOS. Chronic dietary Na^+ restriction increases COX-2 and nNOS expression in MD cells; inhibition of either COX-2 or nNOS inhibits renin release (Peti-Peterdi and Harris, 2010).

Regulation by the MD is more dependent on the luminal concentration of Cl^- than Na^+. NaCl transport into the MD is mediated by the Na^+-K^+-$2Cl^-$ symporter (Figure 30–3). The half-maximal concentrations of Na^+

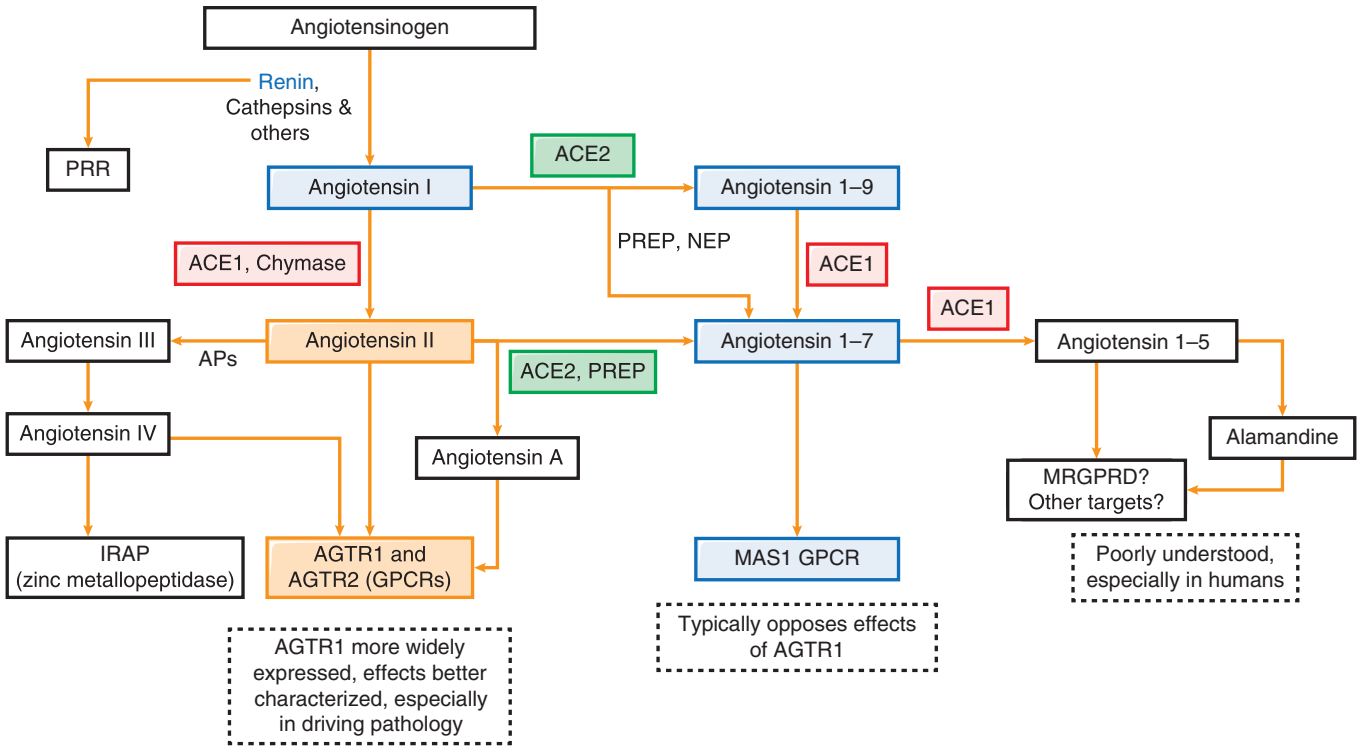

Figure 30–1 *The RAS components and signaling pathway.* AGTR1 and 2, angiotensin II receptors 1 and 2; AP, aminopeptidase; PREP, prolyl endopeptidase; NEP, neprilysin, which also contributes to Ang(1–9) and AngII degradation (not shown), to a lesser degree than ACE1 or ACE2.

and Cl^- required for transport via this symporter are 2 to 3 and 40 mEq/L, respectively. Because the luminal concentration of Na^+ at the MD usually is much greater than the level required for half-maximal transport, physiological variations in luminal Na^+ concentrations at the MD have little effect on renin release (i.e., the symporter remains saturated with respect to Na^+). Conversely, physiological changes in Cl^- concentrations (20–60 mEq/L) profoundly affect MD-mediated renin release.

Intrarenal Baroreceptors

Increases and decreases in BP or renal perfusion pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The immediate stimulus is believed to be reduced tension within the afferent arteriole wall. Release of renal PGs and biomechanical coupling via stretch-activated ion channels may also contribute to renin release mediated by intrarenal baroreceptors.

β_1 Adrenergic Receptors

β_1 Adrenergic receptors are primarily regulated by the release of norepinephrine (NE) from postganglionic sympathetic nerves; activation of β_1 receptors on JG cells increases cAMP and enhances renin secretion. Treatment with β blockers reduces renin secretion and plasma renin activity (PRA).

Feedback Regulation

Renin release is subject to feedback regulation (Figures 30–2 and 30–3). Increased renin secretion enhances the formation of AngII, which stimulates AT_1 receptors on JG cells to inhibit renin release, an effect termed *short-loop negative feedback*. Inhibition of renin release by AngII-dependent increase in BP is termed *long-loop negative feedback*. AngII increases arterial BP via AT_1 receptors, a response that inhibits renin release by:

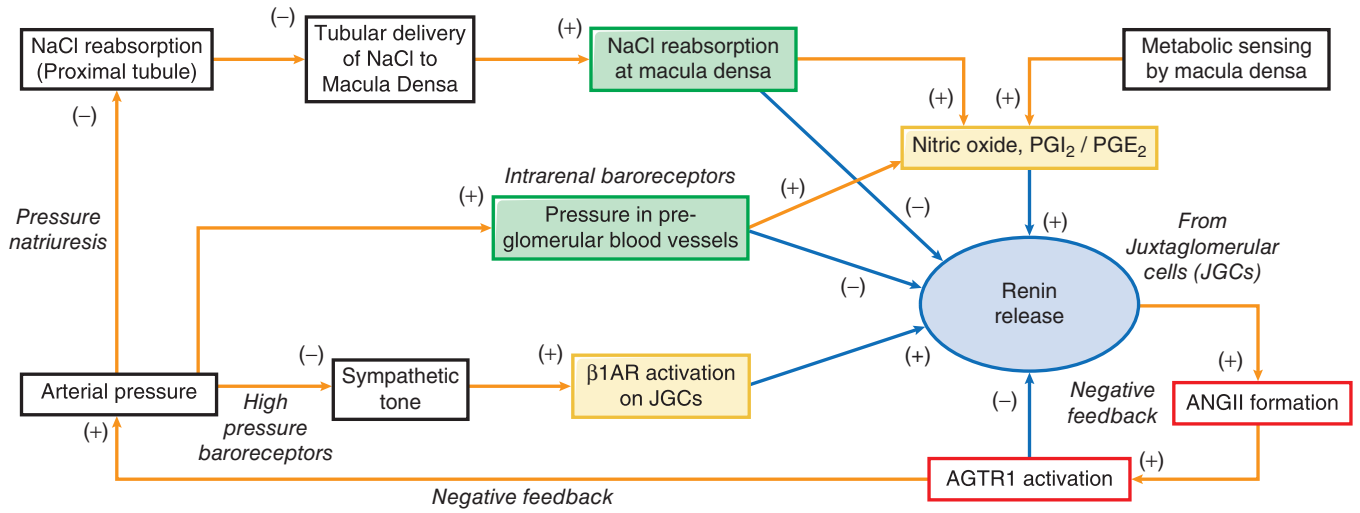

Figure 30–2 *Physiological pathways, feedback loops, and pharmacological regulation of the RAS.* Schematic portrayal of the three major physiological pathways regulating renin release. β1AR, β_1 adrenergic receptor. See text for details.

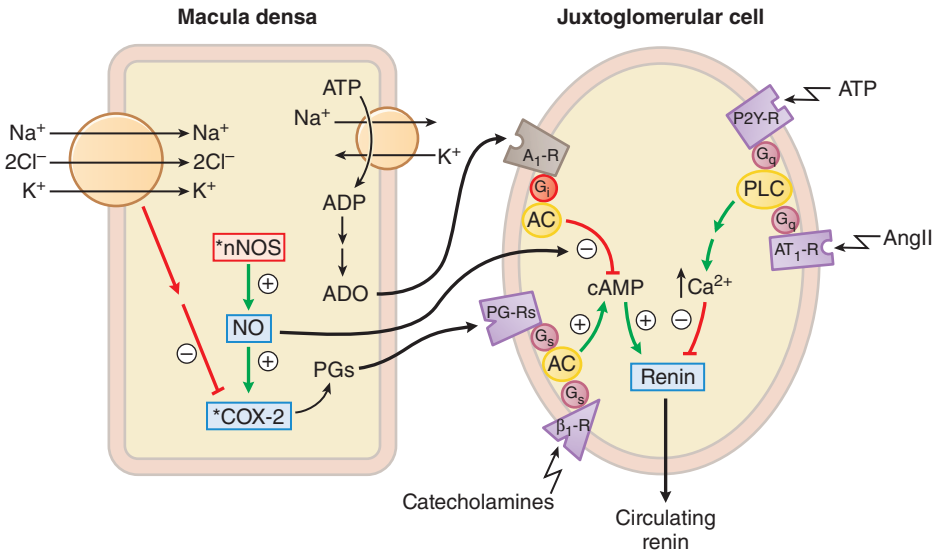

Figure 30–3 *Regulation of JG cell renin release by the macula densa (MD).* Mechanisms by which the MD regulates renin release. Changes in tubular delivery of NaCl to the MD cause signals to be conveyed to the JG cells (JGCs). Sodium depletion increases nNOS and COX-2 in the MD to enhance production of PGs. PGs and catecholamines stimulate adenylyl cyclase activity and cAMP production and hence renin release from the JGCs. Increased NaCl transport depletes ATP and increases adenosine (ADO) levels. Adenosine diffuses to the JGCs and inhibits cAMP production and renin release via G_i-coupled A_1 receptors. Increased NaCl transport in the MD augments the efflux of ATP, which may inhibit renin release by binding to P2Y receptors and activating the $G_{q/11}$-PLC-IP_3-Ca^{2+} pathway in JGCs. Circulating AngII also inhibits renin release on JGCs via G_{q11}-coupled AT_1 receptors. *Expression upregulated by chronic Na^+ depletion.

1. Activating high-pressure baroreceptors, thereby reducing renal sympathetic tone
2. Increasing pressure in the preglomerular vessels
3. Reducing NaCl reabsorption in the proximal tubule (pressure natriuresis), which increases tubular delivery of NaCl to the MD

Drugs That Affect Renin Secretion

Renin release is influenced by arterial BP, dietary salt intake, and pharmacological agents. Loop diuretics stimulate renin release and increase plasma renin concentration (PRC) by decreasing arterial BP and by blocking the reabsorption of NaCl at the MD. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit PG synthesis and thereby decrease renin release. ACEIs, angiotensin receptor blockers (ARBs), and renin inhibitors interrupt both the short- and long-loop negative-feedback mechanisms and thereby increase renin release and PRC. Centrally acting sympatholytic drugs, as well antagonists of β_1 adrenergic receptors, decrease renin secretion by reducing β_1 adrenergic receptor activation of JG cells.

Angiotensinogen

Angiotensinogen, the substrate for renin, is a globular glycoprotein. AngI is cleaved by renin from the amino terminus of angiotensinogen. Human angiotensinogen contains 452 amino acids and is synthesized as preangiotensinogen, which has a 24– or 33–amino acid signal peptide. *AGT*, the precursor gene for angiotensinogen, is expressed in the liver and at substantial levels in the heart, brain, and smooth muscle cells, among others. Angiotensinogen is synthesized and secreted primarily by the liver, although angiotensinogen transcripts occur in many tissues, including the heart, kidneys, pancreas, lungs, adipocytes, and certain regions of the CNS. Synthesis of angiotensinogen is stimulated by inflammation, insulin, estrogens, glucocorticoids, thyroid hormone, and AngII. Pregnancy-related increases in estrogen increase plasma angiotensinogen levels several-fold.

Circulating levels of angiotensinogen are approximately equal to the K_m of renin for its substrate (~1 μM). Consequently, the rate of AngII synthesis, and therefore BP, can be influenced by changes in angiotensinogen levels. Oral contraceptives that contain estrogen increase circulating levels of angiotensinogen and can induce hypertension. Urinary angiotensinogen levels, considered an index for local intrarenal RAS activation, are elevated in patients with hypertension and progressive renal disease (Nishiyama and Kobori, 2018).

A missense mutation (M235T) in the angiotensinogen gene increases angiotensinogen plasma levels and has been implicated as a possible risk factor in several conditions (e.g., hypertension, preeclampsia, hypertrophic cardiomyopathy, and chronic kidney disease).

Angiotensin-Converting Enzyme

Angiotensin-converting enzyme (ACE, ACE1, kininase II, dipeptidyl carboxypeptidase, CD143, and several others) is a glycoprotein ectoenzyme with an apparent molecular weight of 170 kDa. Human ACE contains 1277 amino acid residues and has two homologous domains, each with a catalytic site and a Zn^{2+}-binding region. ACE has a large amino-terminal extracellular domain, a short carboxyl-terminal intracellular domain, and a 22–amino acid transmembrane hydrophobic region. ACE cleaves dipeptide units from substrates with diverse amino acid sequences. Preferred substrates have one free carboxyl group in the carboxyl-terminal amino acid, and proline must not be the penultimate amino acid; thus, the enzyme does not degrade AngII. ACE inactivates bradykinin and other potent vasodilator peptides. Slow conversion of AngI to AngII occurs in plasma, but rapid metabolism occurs *in vivo*, largely from the activity of membrane-bound ACE on the luminal surface of vascular endothelial cells (Guang et al., 2012).

An insertion/deletion polymorphism in intron 16 of the *ACE* gene produces large variation in serum ACE levels. The deletion allele, associated with higher levels of serum ACE and increased metabolism of bradykinin, may confer an increased risk of several disorders, including hypertension (and associated chronic kidney disease), and complications of pregnancy.

Angiotensin-Converting Enzyme 2

ACE2, a carboxypeptidase, cleaves one amino acid from the carboxyl terminal to convert AngII to Ang(1–7) and can convert AngI to Ang(1–9), which is then converted to Ang(1–7) by ACE, neprilysin, and endopeptidases (Santos, 2014). ACE2 contains a single catalytic domain that is

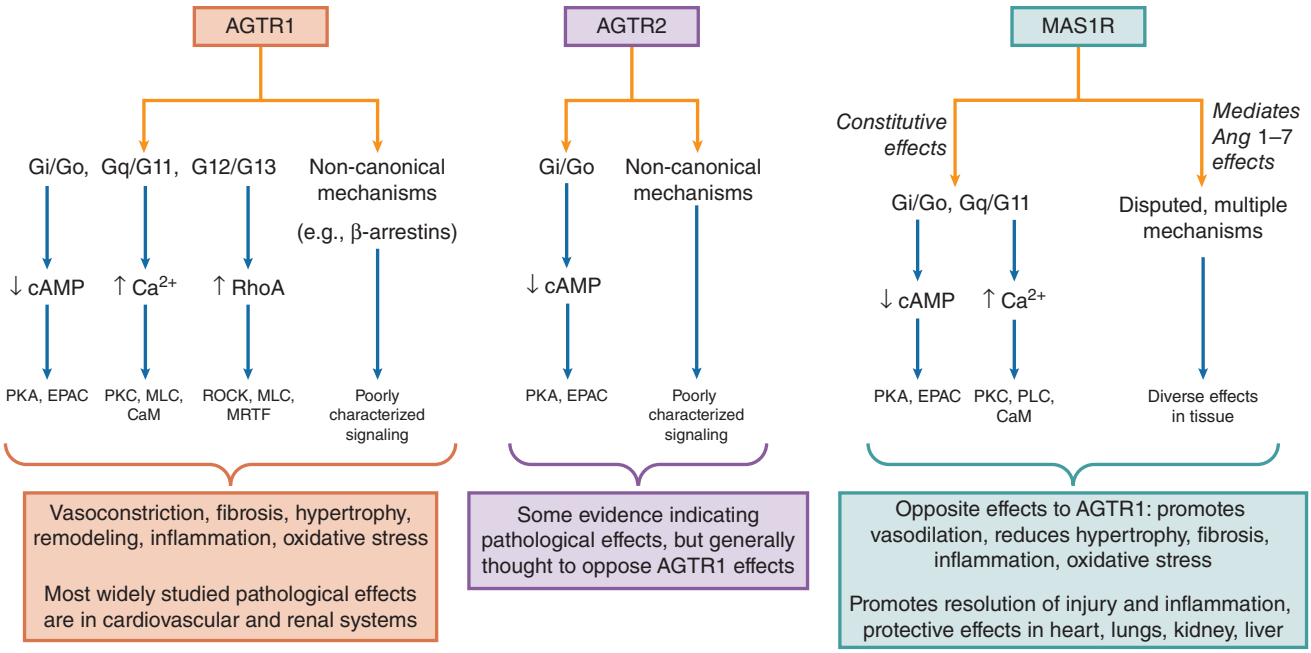

Figure 30–4 *Schematic diagram of opposing arms in the RAS.* Therapeutic interventions aim to inhibit the ACE-AngII-AT_1 receptor axis (orange) and enhance the ACE2-Ang(1–7)-Mas receptor axis (green). CaM, calmodulin; MLC, myosin light chain; MRTF, myocardin-related transcription factor A; PKA/PKC, protein kinase A/C; PLC, phospholipase C; ROCK, Rho kinase.

42% identical to the two catalytic domains of ACE. AngII is the preferred substrate for ACE2, with 400-fold higher affinity than AngI (Guang et al., 2012).

ACE2 opposes the actions of AngII by at least two mechanisms:

1. Decrease in AngII levels by metabolizing it to Ang(1–7), thus limiting effects of AngII
2. Increases in Ang(1–7), which via MAS1, opposes AngII actions (Figures 30–1 and 30–4)

ACE2 is not inhibited by standard ACEIs and has no effect on bradykinin. Reduced expression or deletion of ACE2 is associated with hypertension, defects in cardiac contractility, and elevated levels of AngII. Overexpression of the ACE2 gene decreases BP and prevents AngII-induced cardiac hypertrophy in hypertensive rats. ACE2 is protective against diabetic nephropathy through the Ang(1–7)/Mas receptor pathway (Varagic et al., 2014). Ang(1–9), which is generated from AngI by ACE2, may have vasodilating and protective effects by activating AT_2 receptors (Etelvino et al., 2014).

ACE2 metabolizes numerous peptides (including apelin, neurotensin, and ghrelin) and is a receptor for severe acute respiratory syndrome (SARS) coronaviruses (CoVs), including SARS-CoV-1 and SARS-CoV-2. The interaction with coronavirus spike proteins has led to efforts to use soluble ACE2 as a therapy to block entry and mitigate morbidity from coronavirus infections (Monteil et al., 2020).

Alternative Pathways for Angiotensin II Biosynthesis

AngII can be generated by ACE-independent pathways. Angiotensinogen is converted to AngI, or directly to AngII by cathepsin G and tonin. Enzymes that convert AngI to AngII include cathepsin G, chymostatin-sensitive AngII-generating enzyme, and chymase. Chymase contributes to tissue conversion of AngI and Ang(1–12) to AngII, particularly in the heart and kidneys. Mast cells are the major source of chymase (Ferrario et al., 2014).

Angiotensinases

Angiotensinases include aminopeptidases, endopeptidases, carboxypeptidases, and other peptidases that metabolize angiotensin peptides; none s spec ic.

Angiotensin Peptides and Their Receptors

Table 30–1 shows the sequence of the RAS peptides, and Table 30–2 lists the peptides, their receptors, and overall effects of the receptor-peptide interactions.

AngII-AT_1 Receptor Axis

Angiotensin II binds to the GPCRs AT_1 and AT_2. The hypertensive, renal, and hypertrophic effects of AngII are mediated by AT_1 receptors. Numerous polymorphisms have been identified in the AT_1 receptor gene, one of which (A1166C) has been associated with hypertension, hypertrophic cardiomyopathy, coronary artery vasoconstriction, and susceptibility to diabetic nephropathy (Zhuang et al., 2018). Preeclampsia may be associated with AT_1 polymorphisms or AT_1 agonistic autoantibodies, but this is a controversial area (Gathiram and Moodley, 2020).

AngII-AT_1 Receptor-Effector Coupling. AT_1 receptors link to numerous signal transduction systems to produce effects that vary with cell type and are a combination of primary and secondary responses. AT_1 receptors couple to several heterotrimeric G proteins, (e.g., $G_{q/11}$, $G_{12/13}$, and G_i) and are substrates for phosphorylation and desensitization by G

TABLE 30–1 ■ ANGIOTENSIN PEPTIDES AND THEIR SEQUENCES

PEPTIDE/PROTEIN	SEQUENCE
Angiotensinogen	Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu- | - (~450 amino acids)
Angiotensin I	Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu
Angiotensin 1–9	Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His
Angiotensin 1–7	Asp-Arg-Val-Tyr-Ile-His-Pro
Angiotensin 1–5	Asp-Arg-Val-Tyr-Ile
Angiotensin II	Asp-Arg-Val-Tyr-Ile-His-Pro-Phe
Angiotensin A	Ala-Arg-Val-Tyr-Ile-His-Pro-Phe
Angiotensin III	Arg-Val-Tyr-Ile-His-Pro-Phe
Angiotensin IV	Va'-Tyr-Ile-His-Pro-Phe

protein-coupled receptor kinases (GRKs), interacting with β-arrestin, prior to being internalized.

In most cell types, AT_1 receptors couple to $G_{q/11}$ to activate the phospholipase (PL) Cβ-IP_3-Ca^{2+} pathway. Secondary responses to $G_{q/11}$ activation include activation of PKC, PLA_2, and PLD, eicosanoid production, Ca^{2+}-dependent and MAP kinases, and Ca^{2+}-calmodulin–dependent activation of nitric oxide synthase (NOS). Activation of G_i may occur and will reduce the activity of adenylyl cyclase, lowering cellular cAMP content. However, there also is evidence for $G_{q/11} \rightarrow G_s$ cross talk such that activation of the AT_1-$G_{q/11}$-PLC pathway can enhance cAMP production. The βγ subunits of G_i and activation of $G_{12/13}$ lead to activation of tyrosine kinases and low-molecular-weight ("small") G proteins such as Rho. Ultimately, the Jak/STAT pathway may be activated and transcriptional regulatory factors induced. By these mechanisms, AngII influences gene expression, including of genes that regulate cell growth and production of extracellular matrix (ECM) components. AngII/AT_1 also stimulate the activity of a membrane-bound NADH/NADPH oxidase that generates reactive oxygen species (ROS). ROS may contribute to certain biochemical effects (e.g., activation of MAP kinase, tyrosine kinase, and phosphatases; inactivation of nitric oxide [NO]) and physiological effects (acute effects on renal function, chronic effects on BP, vascular hypertrophy and inflammation) of AngII (Garrido and Griendling, 2009). The role of these many signaling pathways in mediating biological responses to AngII varies in different tissues and cell types. The AT_1 receptor is structurally flexible and may be activated by mechanical stress independent of AngII binding (Kim et al., 2012). Function of the AT_1 receptor may be modified by homodimerization or heterodimerization with GPCRs that include AT_2, bradykinin B_2, β_2 adrenergic, and apelin receptors (Takezako et al., 2017).

AngII-AT_2 Receptor Axis

Activation of the AT_2 receptors counteracts many of the effects of the AT_1 receptors by having antiproliferative, anti-inflammatory, vasodilatory, natriuretic, and antihypertensive effects (Figure 30–4). AT_2 receptors are more widely distributed in fetal tissues than in adults. AT_2 receptor expression is increased and AT_2 receptors have been implicated in cardiovascular and renal disorders (Jones et al., 2008; Kaschina et al., 2017; Ocaranza et al., 2020; Santos et al., 2019). AT_2 receptor signaling is mediated by G protein-dependent ($G_{i\alpha2}$ and $G_{i\alpha3}$) and G protein-independent pathways. Effects of AT_2 receptor activation include activation of phosphotyrosine phosphatases that inhibit MAP kinases and ERK1/2; inhibition of Ca^{2+} channel functions; and increases in NO, cyclic GMP, and bradykinin production. AT_2 receptors can bind AT_1 receptors to antagonize and reduce their expression. AT_2 receptors can also form heterodimers with bradykinin B_2 receptors, an interaction that can enhance NO production (Jones et al., 2008; Padia and Carey, 2013) and may dimerize with MAS receptors (Patel and Hussain, 2018).

Angiotensin (1–7)/Mas Receptor Axis

The ACE2/Ang(1–7)/Mas receptor axis is a negative regulator of the pressor, profibrotic, and anti-natriuretic effects of the ACE-AngII-AT_1 receptor axis of the RAS (Figure 30–4). Ang(1–7) is generated in several ways (Figure 30–1), including from:

- AngII by ACE2;
- AngII by carboxypeptidases;
- AngI by endopeptidases; and
- AngI in two steps: by ACE2 to Ang(1–9) and then to Ang(1–7) by ACE or neprilysin.

The antihypertensive effects of Ang(1–7) occur via binding to Mas receptors, but Ang(1–7) can also bind and activate AT_2 receptors (Gironacci et al., 2014). Activation of Mas receptors by Ang(1–7) induces vasodilation, stimulates a phosphoinositide 3-kinase (PI_3K)/Akt pathway that promotes NO production, potentiates the vasodilatory effects of bradykinin, and inhibits AngII-induced activation of ERK1/2 and NFκB. Ang(1–7) has antiangiogenic, antiproliferative, and antithrombotic effects and is renoprotective and cardioprotective in cardiac ischemia and heart failure (Fraga-Silva et al., 2013; Santos et al., 2019). Activation of Mas receptors in the brain is associated with improved memory and cognition (Gironacci et al., 2014). Mice with knockout of the *Mas* gene have increased vascular resistance and cardiac dysfunction (Santos et al., 2019).

TABLE 30–2 ■ RAS PEPTIDES AND THEIR RECEPTORS

RECEPTOR	RAS PEPTIDE	EFFECT
AT_1	AngII, AngIII, AngA, Ang(1–12)	Vasoconstriction, hypertrophy, proliferation, angiogenesis, fibrosis, inflammation, nephropathy
AT_2	AngII, AngIII, Ang(1–7), Ang(1–9), AngA	Vasodilation, anti-hypertrophy, reduction of fibrosis, natriuresis; some contradictory pathological effects
MAS1	Ang(1–7)	Vasodilation, anti-hypertrophy, reduction of fibrosis, resolution of inflammation and injury, natriuresis
MRGPRD	Alamandine	Less well understood; believed to have similar effects to MAS1: vasodilation, anti-hypertrophy, reduction of fibrosis
IRAP	AngIV, Ang(3–7)	Neuroprotection, cognition, renal vasodilation, natriuresis
PRR	Prorenin, renin	Hypertrophy, fibrosis, apoptosis

The capacity of Ang(1–7) to counterbalance actions of AngII may depend on the relative activities of ACE-AngII-AT_1 receptors and ACE2-Ang(1–7)-Mas receptors (Figure 30–4 and Table 30–2; Forrester et al., 2018; Ocaranza et al., 2020; Santos et al., 2019). Enhancing the ACE2-Ang(1–7)-Mas receptor pathway using ACE2 activators or Mas receptor agonists could provide new ways to modulate the RAS in cardiovascular and renal disease and other settings.

Angiotensin III

Angiotensin III, also called Ang(2–8), can be formed by the action of aminopeptidase A on AngII or by the action of ACE on Ang(2–10). AngIII binds to both AT_1 and AT_2 receptors, causing effects qualitatively like those of AngII. AngII and AngIII stimulate aldosterone secretion with equal potency; however, AngIII is less efficacious in elevating BP (25%) and stimulating the adrenal medulla (10%). Data from model systems imply that AngIII and the shorter angiotensin-derived peptides have significant activity, especially at the AT_2 receptor, and that there may be instances where AngIII is the active endogenous ligand (Bosnyak et al., 2011).

Angiotensin IV/AT_4 Receptor Axis

Angiotensin IV [Ang(3–8)] is formed from AngIII through the catalytic action of aminopeptidase N. Central and peripheral actions of AngIV are mediated through a specific AT_4 receptor that was identified as IRAP (insulin-regulated aminopeptidase) (Figure 30–1 and Table 30–2). This single transmembrane protein receptor colocalizes with the glucose transporter type 4. AT_4 receptors are detectable in numerous tissues, e.g., heart, vasculature, adrenal cortex, and brain regions, that process sensory and motor functions. AngIV-dependent AT_4 receptor activation regulates cerebral blood flow, is neuroprotective, and facilitates long-term potentiation, memory consolidation, and cognition (Wright et al., 2013). AngIV binding to the AT_4 receptor inhibits the catalytic activity of IRAP and enables accumulation of neuropeptides linked to memory potentiation. Other actions include renal vasodilation, natriuresis, neuronal differentiation, inflammation, and ECM remodeling. AngIV analogues have been developed as potential therapeutics for Alzheimer's disease and head injury (Wright and Harding, 2019).

Other Physiologically Active Angiotensin Peptides

Other biologically active angiotensin peptides and their receptors have been identified (Tables 30–1 and 30–2). These peptides include

Ang (1-9), alamandine, AngA, Ang(3-7), and proangiotensin/Ang(1–12) (Ferrario et al., 2014; Forrester et al., 2018; Ocaranza et al., 2020; Santos et al., 2019). Ang(1–9) is generated from AngI by ACE2, carboxypeptidase A, and cathepsin. Ang(1–9) has cardioprotective and antipressor effects reportedly mediated through binding to AT_2 receptors and the release of NO (Etelvino et al., 2014) and may have a role in heart failure (Basu et al., 2017). Alamandine is produced from Ang(1–7) by the decarboxylation of the N-terminal Asp_1 residue into Ala_1. Alamandine acts through MrgD, a GPCR, to mediate vasodilatory and antifibrotic effects similar to Ang(1–7). Alamandine is an ACE substrate and may be an ACEI. Alamandine is elevated in patients with chronic renal disease (Etelvino et al., 2014).

Angiotensin A is an octapeptide produced by decarboxylation of the Asp_1 residue of AngII into Ala_1. AngA binds to both AT_1 and AT_2 receptors and has effects similar to, but less potent than, AngII. AngA is reported to be elevated in patients with end-stage renal disease (Ferrario et al., 2014). Ang(3–7) is generated from AngIV and binds AT_4 receptors (Wright et al., 2013). Proangiotensin or Ang(1–12) is generated from angiotensinogen through a non-renin pathway and can be converted to AngII by chymase. Ang(1–12) can bind to the AT_1 receptors and may be a precursor for autocrine/intracrine production of AngII (Ferrario et al., 2014).

Local (Tissue) Renin-Angiotensin System

Local RAS is a tissue-based AngII-producing system that plays a role in hypertrophy, inflammation, remodeling, and apoptosis. ACE is present on the luminal face of vascular endothelial cells throughout the circulation; circulating (pro)renin can bind the PRR in the arterial wall in tissues to locally generate AngII (Campbell, 2014; Paul et al., 2006). Tissue RAS is also an autocrine and intracrine mechanism that can generate AngII and other angiotensin peptides independently of the renal/hepatic-based system (Nehme et al., 2019). Many tissues—including the brain, pituitary, blood vessels, heart, lung, kidney, and adrenal gland—express renin, angiotensinogen, ACE and ACE2, chymase, PRR, angiotensin I, II, III, IV, Ang(1–7), and AT_1, AT_2, and Mas receptors (Campbell, 2014; Ferrario et al., 2014). Activation of the local RAS components is tissue specific and may affect pathophysiology. However, the existence and role of tissue RAS in the brain remain controversial (Saravi et al., 2021). The potential role of local RAS and impact of RAS inhibition in solid tumors is an emerging area of interest (Almutlaq et al., 2021).

RAS components, in particular AngII, can be upregulated during inflammation and tissue injury. This underscores the role of AngII in pathobiology, with inflammation/injury driving RAS activity, which further promotes inflammation in a positive feedback loop (Sriram and Insel, 2020a). Evidence for local RAS activity is most notable in the heart, vasculature, and lungs (Campbell, 2014; Forrester et al., 2018).

The (Pro)Renin Receptor

(Pro)renin/PRR binding enhances tissue-RAS activity and exerts organ-specific localized actions that can be independent of AngII production (Ichihara and Yatabe, 2019; Ramkumar and Kohan, 2019). PRR is widely expressed in tissues throughout the body. The PRR gene is on the X chromosome and named *ATP6ap2* (ATPase-6 accessory protein 2). Knockout of the PRR gene is lethal, indicating its important role in development. Human mutations in the PRR gene are associated with intellectual disability and epilepsy (Nguyen and Danser, 2008). Human PRR, an approximately 37 kDa (350–amino acid) transmembrane protein, possesses an N-terminal extracellular domain that binds (pro)renin, a transmembrane domain, and a cytosolic domain associated with vacuolar-H^+-ATPase (V-ATPase) activity. Nephron-specific deletion of PRR in mice does not affect the RAS but produces renal concentration defects and distal renal tubular acidosis because of decreased V-ATPase activity (Trepiccione et al., 2016). Moreover, mice that overexpress human PRR in neurons have an ERK and NOX-4–dependent, angiotensin-independent increase in BP in response to intracerebroventricular infusion of (pro)renin (Peng et al., 2018). Together, such findings support the idea that (pro)renin and PRR can produce effects independent of the RAS.

The PRR binds (pro)renin with nanomolar affinity and high specificity, increases catalytic activity of renin, and induces activation of (pro)renin by unfolding its pro-segment, exposing the enzymatic cleft. Bound, activated (pro)renin catalyzes the conversion of angiotensinogen to AngI and, in turn, AngII formation. PRR binding of (pro)renin also induces AngII-independent signaling events, including activation of ERK1/2, p38, tyrosine kinases, COX-2, transforming growth factor (TGF)-β gene expression, and plasminogen activator inhibitor type 1 (PAI-1) (Ichihara and Yatabe, 2019; Nguyen and Danser, 2008; Peters, 2017). Such effects are not blocked by ACEIs or AT_1 receptor antagonists and may contribute to fibrosis, nephrosis, and end-organ damage (Kaneshiro et al., 2007).

Circulating plasma concentrations of (pro)renin are elevated 100-fold in diabetic patients and associated with increased risk of nephropathy, renal fibrosis, and retinopathy (Nguyen and Danser, 2008). Blockade of PRR by a peptide antagonist, known as "handle region peptide," reportedly protected animals from diabetic nephropathy and retinopathy, but the efficacy and specificity of this peptide have not been confirmed by others (Danser, 2015).

As noted above, in addition to its RAS-mediated actions, the PRR participates in RAS-independent functions, including as an accessory protein essential for V-ATPase activity, which is required for intracellular acidity, receptor-mediated endocytosis, and activation of lysosomal and autophagosomal enzymes. Cardiomyocyte-specific and podocyte-specific PRR knockout mice develop lethal organ-specific failure due to loss of V-ATPase and dysregulation of intracellular acidification and autophagy (Binger and Muller, 2013). PRR also participates in the activation of Wnt/β-catenin and Wnt/planar cell polarity signaling pathways and antagonizes ELABELA/apelin actions (Chen and Xu, 2020). Recent work has implicated PRR as a novel biomarker and potential therapeutic target for a variety of cancers (Wang J et al., 2020). PRR reportedly can regulate low-density lipoprotein (LDL) uptake and metabolism and may have a role in disorders of glucose and lipid metabolism (Ramkumar and Kohan, 2019). Silencing PRR expression in hepatocytes decreased cellular LDL uptake by decreasing expression of LDL receptor and sortelin 1 protein, a regulator of LDL uptake and metabolism and a PRR-interacting protein (Lu et al., 2016).

Functions and Effects of Angiotensin II

Angiotensin II increases total peripheral resistance (TPR) and alters renal function and cardiovascular structure (Figure 30–5). Modest increases in plasma AngII concentration acutely raise BP; on a molar basis, AngII is about 40 times more potent than NE: the EC_{50} of AngII for acutely raising arterial BP is approximately 0.3 nM. Intravenous injection of a moderate dose of AngII raises systemic BP within seconds, but it peaks rapidly and returns to normal within minutes (Figure 30–6). This rapid pressor response to AngII is due to an increase in TPR—a response that helps maintain arterial BP in the face of acute hypotensive challenges (e.g., blood loss or vasodilation). Although AngII increases cardiac contractility directly (by opening voltage-gated Ca^{2+} channels in cardiac myocytes) and increases heart rate indirectly (by facilitating sympathetic tone, enhancing adrenergic neurotransmission, and provoking adrenal catecholamine release), the rapid increase in arterial BP activates a baroreceptor reflex that decreases sympathetic tone and increases vagal tone. Thus, depending on the physiological state, AngII may increase, decrease, or not change cardiac contractility, heart rate, and cardiac output. Changes in cardiac output therefore contribute little, if at all, to the rapid pressor response induced by AngII.

AngII also causes a slow pressor response that helps to stabilize arterial BP over the long term. A continuous infusion of initially subpressor doses of AngII gradually increases arterial BP; the maximum effect requires days to achieve. This slow pressor response probably is mediated by a decrease in renal excretory function that shifts the renal pressure–natriuresis curve to the right (see the next section). AngII stimulates the synthesis of endothelin 1 and superoxide anion, which may contribute to the slow pressor response.

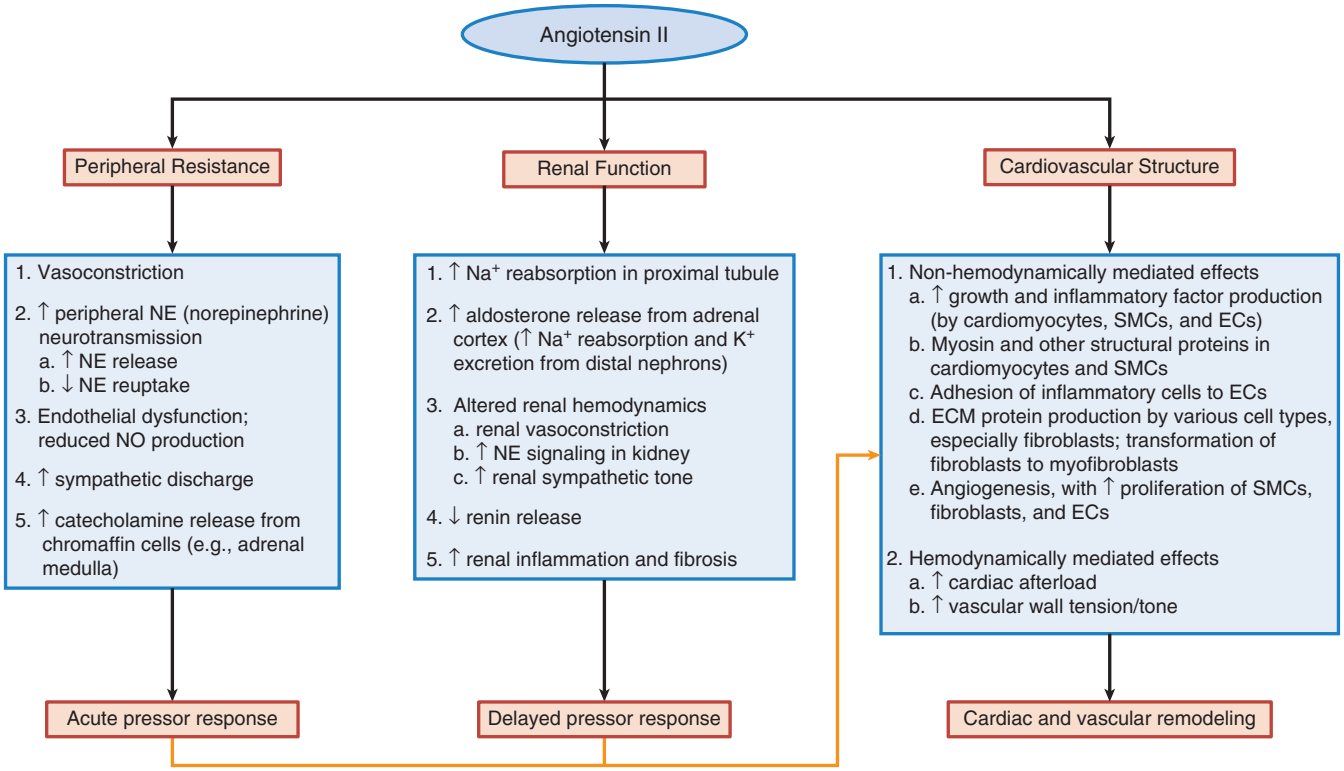

Figure 30–5 *Major physiological effects of AngII.* AngII exerts physiological and pathological effects on both the renal and cardiovascular systems, providing a rationale for the therapeutic benefits of RAS inhibition. EC, endothelial cell; SMC, smooth muscle cell.

In addition to its effects on arterial BP, AngII stimulates remodeling of the cardiovascular system, causing hypertrophy of vascular and cardiac cells and increased synthesis and deposition of collagen by cardiac fibroblasts, as discussed in subsequent sections of this chapter.

Mechanisms by Which Angiotensin II Increases Total Peripheral Resistance

AngII increases peripheral resistance by direct and indirect effects on blood vessels.

Direct Vasoconstriction

AngII constricts precapillary arterioles and, to a lesser extent, postcapillary venules by activating AT_1 receptors on vascular smooth muscle cells and stimulating the $G_{q/11}$-PLC-IP_3-Ca^{2+} pathway. AngII also exerts vasoconstrictive effects due to signaling in endothelial cells, likely due to the presence of AGTR1 receptors in caveolae. AGTR1 activation is associated with an increase in ROS production and a decrease in endothelial NOS activity, contributing to endothelial dysfunction (Eguchi et al., 2018; Forrester et al., 2018; Gomolak and Didion, 2014). Direct vasoconstriction is strongest in the kidneys, somewhat less in the splanchnic bed, much less in vessels of the brain, and even weaker in pulmonary and skeletal muscle vessels. Nevertheless, high circulating concentrations of AngII may decrease cerebral and coronary blood flow. The effects of AngII on vasoconstriction may also be mediated by AGTR2 receptors, though this is controversial (Forrester et al., 2018).

Enhancement of Peripheral Noradrenergic Neurotransmission

Angiotensin II, binding to AT_1 receptors, augments NE release from sympathetic nerve terminals by inhibiting the reuptake of NE into nerve terminals and by enhancing the vascular response to NE (see Chapter 14). High concentrations of the peptide directly stimulate ganglion cells.

Effects on the CNS

Angiotensin II increases sympathetic tone. Small amounts of AngII infused into the vertebral arteries increase arterial BP via effects of AngII on circumventricular nuclei that are not protected by the blood-brain barrier (e.g., area postrema, subfornical organ, organum vasculosum of the lamina terminalis). Circulating AngII also attenuates baroreceptor-mediated reductions in sympathetic discharge, thereby increasing arterial BP. The CNS is affected by bloodborne AngII and AngII formed within the brain, which contains all components of the RAS. AngII also has a centrally mediated dipsogenic (thirst) effect and enhances vasopressin release from the neurohypophysis.

Release of Catecholamines from the Adrenal Medulla

AngII stimulates the release of catecholamines from the adrenal medulla by promoting Ca^{2+} entry secondary to depolarization of chromaffin cells.

Mechanisms by Which Angiotensin II Regulates Renal Function

Angiotensin II has pronounced effects on renal function, reducing the urinary excretion of Na^+ and water while increasing the excretion of K^+. The overall effect of AngII on the kidneys is to shift the renal pressure–natriuresis curve to the right (Figure 30–7), as discussed subsequently.

Direct Effects of AngII on Na^+ Reabsorption in the Renal Tubules

Very low concentrations of AngII stimulate Na^+/H^+ exchange in the proximal tubule—an effect that increases Na^+, Cl^-, and bicarbonate reabsorption (see also Chapter 29). Approximately 20% to 30% of the bicarbonate handled by the nephron may be affected by this mechanism. AngII also increases the expression of the Na^+-glucose symporter in the proximal tubule. Paradoxically, high concentrations of AngII may inhibit proximal tubule Na^+ transport. AngII also directly stimulates the Na^+-K^+-$2Cl^-$ symporter in the thick ascending limb. The proximal tubule secretes angiotensinogen, and the connecting tubule releases renin, so a paracrine tubular RAS may contribute to Na^+ reabsorption.

Release of Aldosterone from the Adrenal Cortex

Angiotensin II stimulates the zona glomerulosa of the adrenal cortex to increase the synthesis and secretion of aldosterone and augments

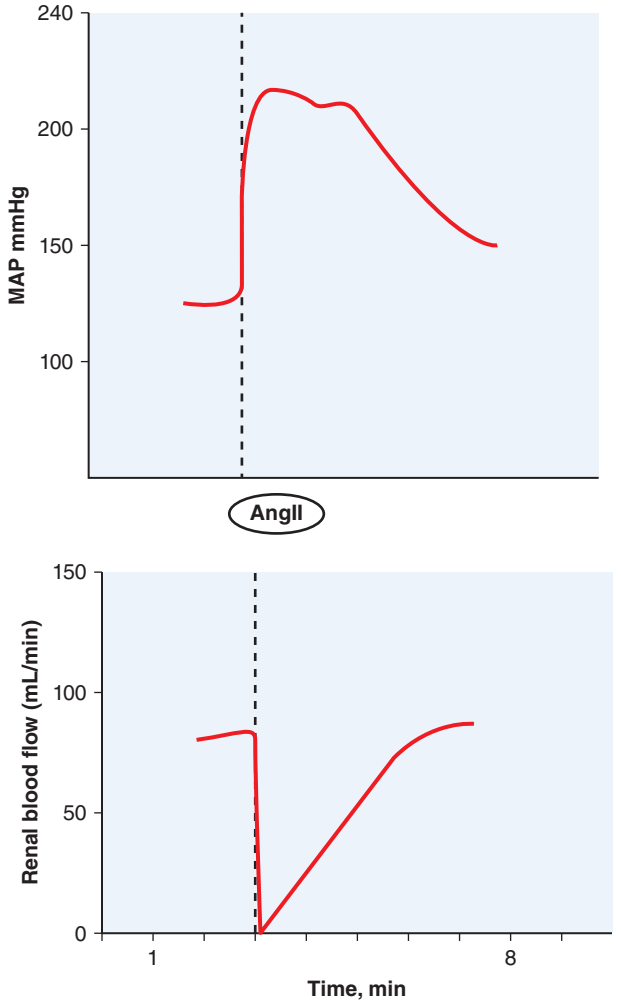

Figure 30–6 *Effect of an intravenous bolus of AngII on arterial BP and RBF.* Angiotensin was added at the time indicated by the dashed vertical line.

responses to other stimuli (e.g., corticotropin [ACTH], K^+). Increased output of aldosterone is elicited by AngII concentrations that have little or no acute effect on BP. Aldosterone acts on the distal and collecting tubules to cause retention of Na^+ and excretion of K^+ and H^+. The stimulant effect of AngII on aldosterone synthesis and release is enhanced under conditions of hyponatremia or hyperkalemia and is reduced when concentrations of Na^+ and K^+ in the plasma are altered in the opposite directions.

Altered Renal Hemodynamics

Angiotensin II reduces renal blood flow (RBF) and renal excretory function by directly constricting the renal vascular smooth muscle, by enhancing renal sympathetic tone (a CNS effect), and by facilitating renal adrenergic transmission (an intrarenal effect). AngII-induced vasoconstriction of preglomerular microvessels is enhanced by endogenous adenosine via signal transduction systems activated by AT_1 and the adenosine A_1 receptor, respectively.

Angiotensin II influences the glomerular filtration rate (GFR) by several mechanisms:

- Constriction of the afferent arterioles, which reduces intraglomerular pressure and reduces GFR
- Contraction of mesangial cells, which decreases the capillary surface area within the glomerulus available for filtration and thereby decreases GFR
- Constriction of efferent arterioles, which increases intraglomerular pressure and tends to increase GFR

Normally, AngII slightly reduces GFR; however, with renal artery hypotension, the effects of AngII on the efferent arteriole predominate

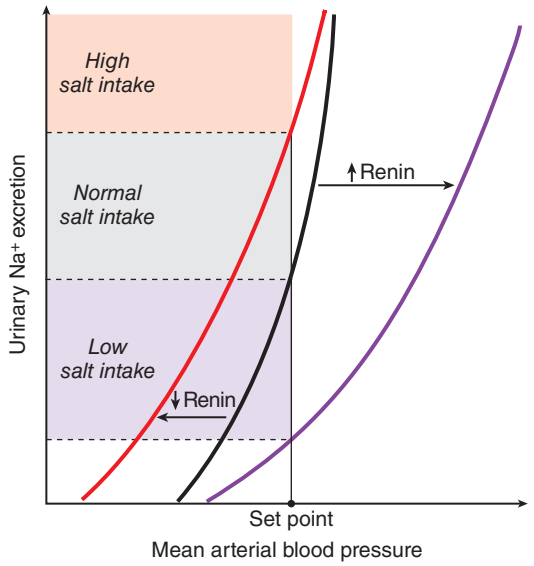

Figure 30–7 *Pressure-natriuresis curve: effects of Na^+ intake on renin release (AngII formation) and arterial BP.* Inhibition of the RAS will cause a large drop in blood pressure in Na^+-depleted individuals. (Modified with permission from Jackson EK, Branch RA, Margolius HS, Oates JA. Physiological functions of the renal prostaglandin, renin, and kallikrein systems. In: Seldin DW, Giebisch GH, eds. *The Kidney: Physiology and Pathophysiology*. Vol 1. Lippincott Williams & Wilkins, Philadelphia, **1985**, 624.)

so that AngII increases GFR. Thus, blockade of the RAS may cause acute renal failure in patients with bilateral renal artery stenosis or in patients with unilateral stenosis who have only a single kidney.

Mechanisms by Which Angiotensin II Alters Cardiovascular Structure

Pathological alterations involving cardiovascular hypertrophy and remodeling increase morbidity and mortality. The cells involved include vascular smooth muscle cells, cardiac myocytes, endothelial cells, immune cells, and fibroblasts. AngII induces hypertrophy of cardiac myocytes; stimulates the migration, proliferation, and hypertrophy of vascular smooth muscle and endothelial cells; increases ECM production by vascular smooth muscle cells; and increases ECM production by cardiac fibroblasts. Moreover, AngII promotes the release of proinflammatory factors (e.g., cytokines and chemokines) that induce paracrine effects on neighboring cells (e.g., TGF-β produced by cardiac myocytes stimulates transformation of fibroblasts into myofibroblasts). The recruitment of immune cells contributes further to this pro-remodeling, inflammatory, and hypertrophic phenotype. Secreted factors from immune cells contribute to cardiac myocyte hypertrophy along with pathological effects in other cell types. AngII signaling also enhances coagulopathy through interaction with the coagulation cascade and increases immune cell adhesion to endothelial cells, thus further enhancing vascular pathology. Hence, cardiac remodeling by AngII results from a complex interplay of multiple cell types (Figure 30–8) (Forrester et al., 2018; Sriram and Insel, 2020a). In addition, AngII alters ECM formation and degradation indirectly by increasing aldosterone production and mineralocorticoid receptor activation. The adverse cardiovascular remodeling induced by AngII can be reduced but not entirely eliminated by mineralocorticoid receptor antagonists.

Hemodynamically Mediated Effects of Angiotensin II on Cardiovascular Structure

In addition to the direct effects of AngII on cardiovascular structure, changes in cardiac preload (volume expansion owing to Na^+ retention) and afterload (increased arterial BP) probably contribute to cardiac hypertrophy and remodeling. Arterial hypertension also contributes to hypertrophy and remodeling of blood vessels.

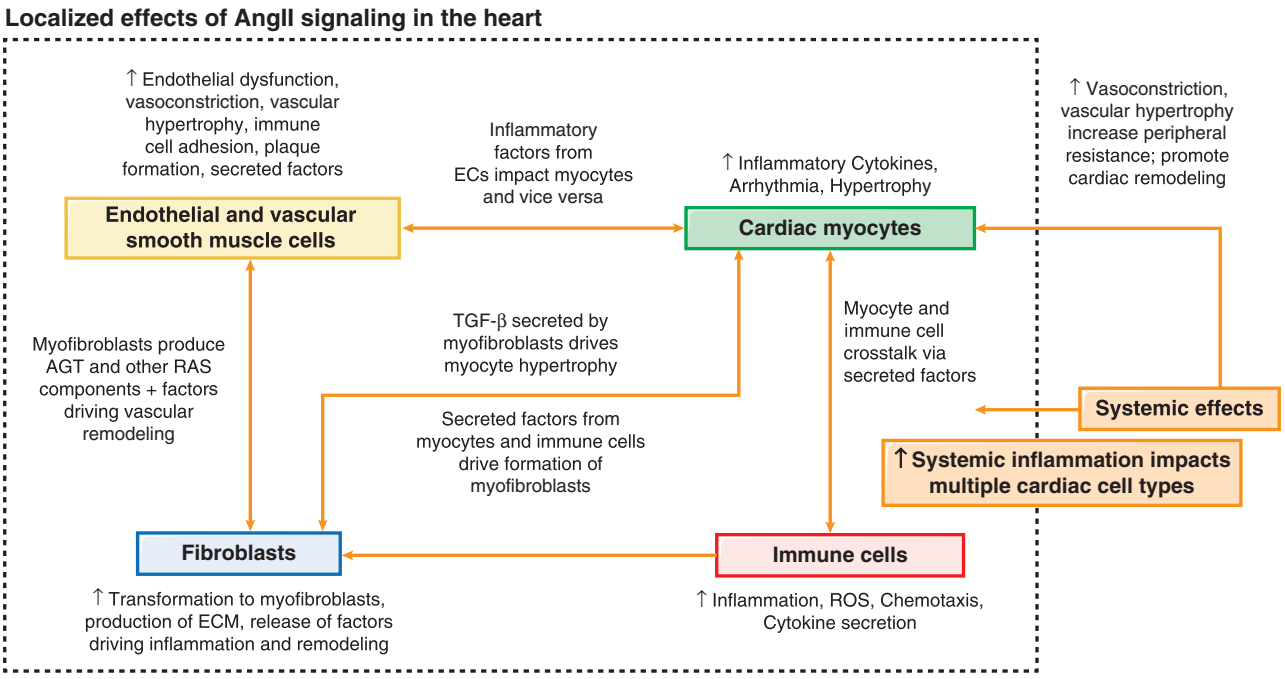

Figure 30–8 *Impact of AngII signaling on cell types that contribute to cardiac hypertrophy.* The effects of AngII involve the interaction of multiple cell types and processes that include inflammation, remodeling, and hypertrophy, with cardiac myocytes interacting with other cells via secreted factors. Besides these localized effects are systemic effects of AngII—increased peripheral resistance and systemic inflammation—that contribute to hypertrophy. AGT, angiotensinogen; ECs, endothelial cells; ECM, extracellular matrix; ROS, reactive oxygen species.

Role of the RAS in Long-Term Maintenance of Arterial Blood Pressure Despite Extremes in Dietary Na^+ Intake

Arterial BP is a major determinant of Na^+ excretion. This is illustrated graphically by plotting urinary Na^+ excretion versus mean arterial BP (Figure 30–7), a plot known as the *renal pressure–natriuresis curve*. Over the long term, Na^+ excretion must equal Na^+ intake; therefore, the set point for long-term levels of arterial BP can be obtained as the intersection of a horizontal line representing Na^+ intake with the renal pressure–natriuresis curve. The RAS plays a major role in maintaining a constant set point for long-term levels of arterial BP despite extreme changes in dietary Na^+ intake. When dietary Na^+ intake is low, renin release is stimulated, and AngII acts on the kidneys to shift the renal pressure–natriuresis curve to the right. Conversely, when dietary Na^+ is high, renin release is inhibited, and the withdrawal of AngII shifts the renal pressure–natriuresis curve to the left. When modulation of the RAS is blocked by drugs, changes in salt intake markedly affect long-term levels of arterial BP.

Other Effects of the RAS

Expression of the RAS is required for the development of normal kidney morphology, particularly the maturational growth of the renal papilla. AngII causes a marked anorexigenic effect and weight loss; high circulating levels of AngII may contribute to the anorexia, wasting, and cachexia of heart failure (Yoshida et al., 2013).

The RAS in SARS Infections and Pulmonary Pathobiology

The COVID-19 pandemic has brought attention to the biology of coronaviruses. Understanding how coronaviruses infect humans can provide insights into therapeutic approaches focused on mitigating host pathobiology. ACE2 is the viral receptor for SARS-CoV-1 (which causes SARS) and SAR-CoV-2 (which causes COVID-19). The viral spike proteins bind to ACE2, followed by viral endocytosis and subsequent infection (Sriram and Insel, 2020a). Given the high expression of ACE2 in respiratory epithelia, particularly in alveolar pneumocytes (especially type II pneumocytes), both SARS viruses can cause severe alveolar injury, leading to acute respiratory distress syndrome (ARDS) and systemic organ failure in the most serious cases.

Interaction of the SARS-CoV spike proteins with ACE2 is thought to be a critical component of SARS-CoV pathobiology. This interaction leads to ACE2 internalization and decrease in ACE2 activity (along with a decrease in ACE2 gene expression). The functional activities of ACE2 in the RAS pathway are thus blunted (Figures 30–1 and 30–4) (reviewed in Sriram and Insel, 2020a). The result is an imbalance in the actions of ACE1 versus ACE2 with respect to the peptides they generate and receptors that are activated: less ACE2 relative to ACE1 implies greater abundance of AngII (with less degradation of AngII by ACE2) and, hence, increased activation of AngII receptors (in particular AGTR1, which is highly expressed in many pulmonary cell types) and less activation of MAS1. This imbalance leads to a bias toward the injury- and inflammation-promoting effects of AngII, including apoptosis in the alveolar epithelium, fibrosis by fibroblasts, and inflammatory and remodeling effects in endothelial cells that mediate alveolar-capillary communication. A positive feedback loop of inflammation and injury occurs, which can produce severe pathology when coupled with a rapid immune/inflammatory response (Figure 30–9; Sriram and Insel, 2020a, 2021). Such inflammatory signaling can couple with coagulation signaling, leading to "thromboinflammation," a characteristic of SARS infections and other forms of ARDS (Sriram and Insel, 2021). Studies with SARS-infected ACE2-knockout mice (Kuba et al., 2005) and with nonreplicating viral particles expressing ACE2-binding spike proteins (Lei et al., 2021) are examples of evidence supporting this mechanism.

Concerns emerged in the early stages of the COVID-19 pandemic that RAS inhibitors may be harmful by enhancing ACE2 expression, thereby promoting viral entry of SARS-CoV-2. However, subsequent analysis of data for ACE2 expression in animals and humans treated with RAS inhibitors questioned the validity of this idea (reviewed in Sriram and Insel, 2020b). Subsequent epidemiological studies in COVID-19 patients have indicated either no effect or a beneficial effect of using RAS inhibitors (e.g., Lopes et al., 2021; Zhang et al., 2020). Thus, patients prescribed

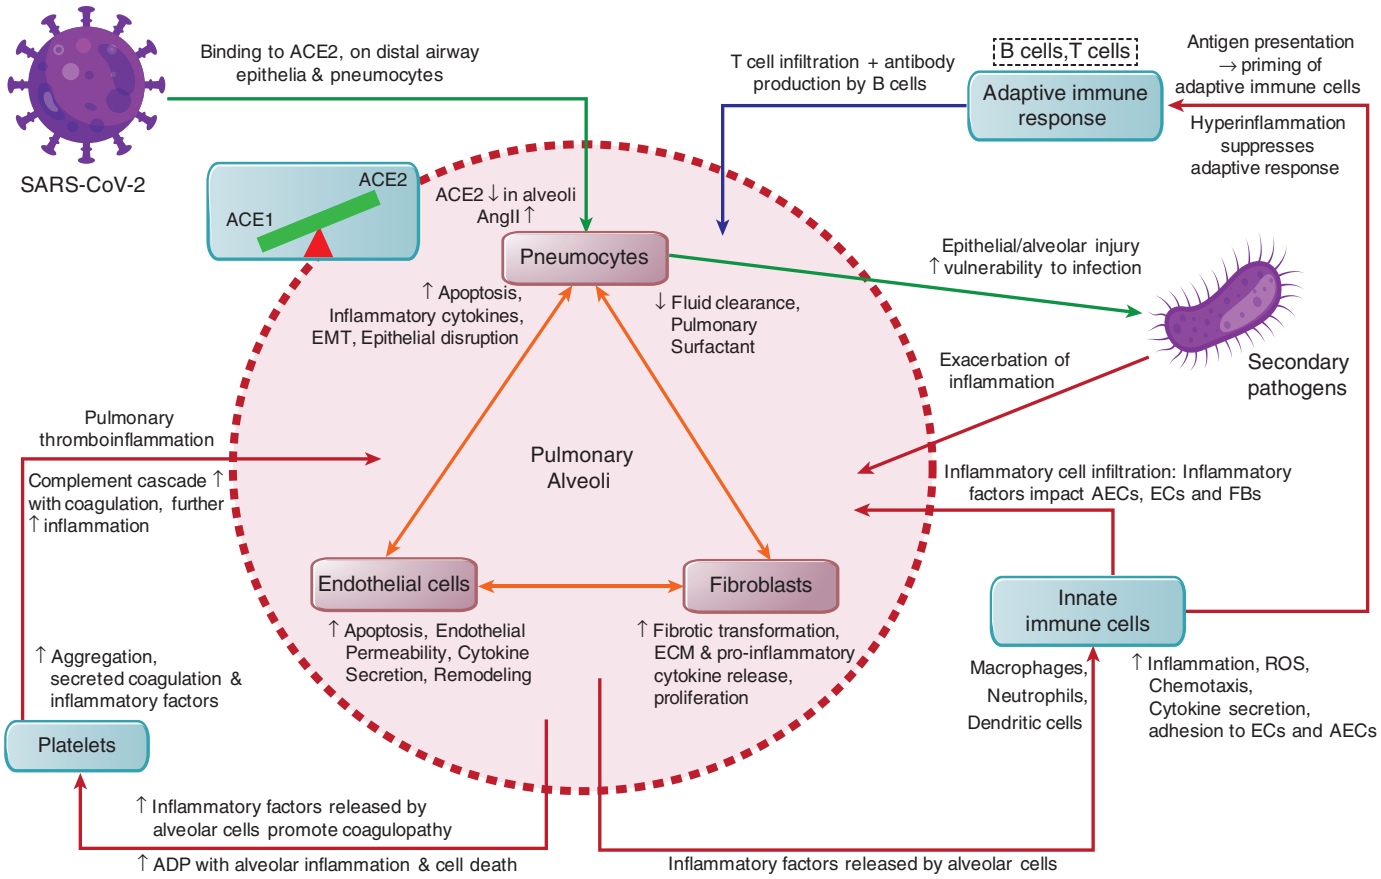

Figure 30–9 *A model for how COVID-19 pulmonary pathobiology is mediated by dysregulation of RAS signaling.* SARS-CoV-2 binds to ACE2, with resulting functional inhibition of ACE2 resulting in an imbalance of ACE1- versus ACE2-mediated effects, with proinflammatory effects of the ACE1-AngII-AGTR1 axis promoting pathobiology. ADP, adenosine diphosphate; AECs alveolar epithelial cells; ECM, extracellular matrix; EMT, epithelial mesenchymal transition; FBs, fibroblasts; ROS, reactive oxygen species.

RAS inhibitors should remain on these drugs, irrespective of COVID-19. In addition, RAS inhibitors are being explored as therapeutic agents for COVID-19 (e.g., Sriram et al., 2020; Zhang et al., 2020).

Angiotensin II has also been implicated as a contributor to other lung diseases, such as pulmonary fibrosis, pulmonary hypertension, and ARDS, due to the range of pathological effects on pulmonary cell types shown in Figure 30–9 (Sriram and Insel, 2020a; Wang et al., 2019). Accordingly, inhibitors of RAS signaling, including ACEIs, ARBs, and novel molecules such as soluble ACE2 (discussed subsequently), are under investigation for use in such conditions.

Effects of RAS on Immune Cells

Angiotensin II has effects on immune cells, primarily via AGTR1 receptors that promote inflammation, enhancing tissue injury, remodeling, and fibrosis, especially in the heart, vascular smooth muscle, and kidneys (Crowley and Rudemiller, 2017; Forrester et al., 2018). Most notable is the activation of macrophages (promoting macrophage infiltration, ROS production, and proinflammatory cytokine release). Similar effects occur in T cells, in particular, $CD4^+$ cells; AngII also enhances T-cell proliferation. Proinflammatory effects of the RAS have been noted in the CNS, likely via AGTR1 activation of macrophages (Hammer et al., 2017). AGTR1 activation may induce differentiation of hematopoietic stem cells and monocytes, promoting a migratory, proinflammatory, and adhesive phenotype. These effects are in addition to the ability of activated immune cells to stimulate expression of angiotensinogen (particularly in the liver and kidney), further enhancing AngII production and establishing a pathological feedback loop (Satou et al., 2018). Despite the evidence for AngII as a promoter of a proinflammatory, pathological phenotype, certain paradoxical effects have been noted. These include the ability of AGTR1 activation on immune cells to suppress inflammation (Crowley and Rudemiller, 2017), suggesting a possible biphasic response, dependent on the physiological context. The use of RAS inhibitors for treating inflammatory conditions, such as arthritis, atherosclerosis, and pancreatitis, is an active area of research (Ranjbar et al., 2019).

Besides actions of AGTR1, ACE may have effects on immune cell function independent of AngII signaling, including by cleaving certain peptide antigens presented to $CD8^+$ T cells, leading to modulation of immune surveillance—a phenomenon that is poorly understood and merits further study (Crowley and Rudemiller, 2017). Limited evidence indicates a potential anti-inflammatory role for AGTR2 and MAS1 receptors on immune cells that may counteract the effects of AGTR1 (Forrester et al., 2018; Santos et al., 2019).

Inhibitors of the Renin-Angiotensin System

Drugs that interfere with the RAS play a prominent role in the treatment of cardiovascular disease. Besides β_1 blockers that inhibit renin release, the following three classes of inhibitors of the RAS are utilized therapeutically (Figure 30–10):

1. ACE inhibitors
2. Angiotensin II receptor blokcers
3. Direct renin inhibitors

All these drug classes reduce the actions of AngII and lower BP, but each class has different effects on components of the RAS (Table 30–3). Angiotensin II receptor blockers can be combined with a neprilysin inhibitor, as shown in Figure 30–10, and discussed in subsequent sections. Representative structures of agents that inhibit the RAS and reduce effects of AngII are shown in Figure 30–12, near the end of this chapter.

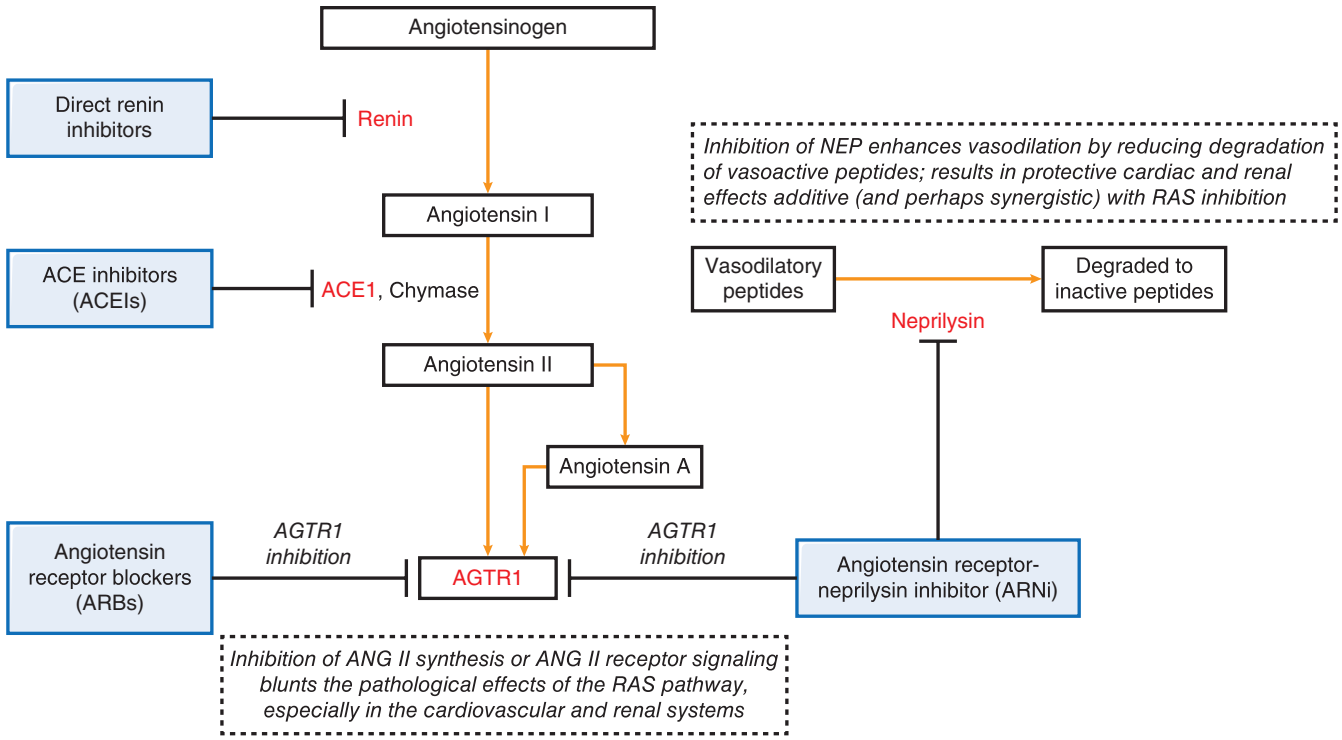

Figure 30–10 *Classes of RAS inhibitors with currently approved drugs.* NEP, neprilysin.

Novel Agents for Targeting the RAS Pathway

Besides approved inhibitors of the canonical RAS pathway, other novel agents have been identified as antagonists of the RAS, or that curb its pathological effects. As described earlier, MAS1 is considered the primary receptor by which Ang(1–7) exerts effects that counter those of AngII, providing a rationale for the therapeutic use of Ang(1–7) analogues and/or MAS1 agonists. Numerous preclinical studies have been conducted using Ang(1–7) (including a purified synthetic form, TXA127), along with early clinical trials in humans that indicate excellent drug tolerance (Sriram et al., 2020). AVE 0991, a small-molecule, nonpeptide MAS1 agonist has also been tested in preclinical animal studies, but not as yetin humans. Thus, clinical testing of MAS1 as a target is in its very early stages.

An alternative means of targeting the RAS pathway and the pathological effects of AngII is to promote ACE2 activity and in turn enhance the generation of peptides that signal via MAS1 and counteract actions of AngII. Soluble, recombinant human ACE2 (rhACE2) has been tested in preclinical studies, reducing inflammation and injury in various cell and tissue types, both *ex vivo* and *in vivo* (Sriram and Insel, 2020a; Sriram et al., 2020). A synthetic rhACE2, GSK2586881, has been tested in early-stage clinical trials for pulmonary hypertension (ClinicalTrials.gov identifier: NCT03177603) and acute lung injury (NCT01597635), with limited therapeutic benefit but excellent drug safety. rhACE2 is also being tested in COVID-19, as both a decoy for the virus and to directly ameliorate inflammation and injury, especially in the lung.

Biased agonists of AGTR1 may represent another novel means to mitigate pathological effects of AngII/AGTR1. TRV027 is an example of one such biased AGTR1 agonist that has been tested in preclinical models and patients. This compound and other AGTR1 biased agonists are discussed in greater detail below in the section on ARBs. Agonists for AGTR2 are also in development. Such agonists exerted anti-inflammatory and antifibrotic effects in preclinical studies and have been well tolerated in early-stage clinical trials (Colafella et al., 2019). Figure 30–11 summarizes novel compounds that target the RAS pathway.

Angiotensin-Converting Enzyme Inhibitors

HISTORY

In the 1960s, Ferreira and colleagues found that venom from the Brazilian pit viper (*Bothrops jararaca*) contains factors that intensify vasodilator responses to bradykinin. These bradykinin-potentiating factors are peptides that inhibit kininase II, an enzyme that inactivates bradykinin. Erdös and coworkers established that ACE and kininase II are the same enzyme, which catalyzes both the synthesis of AngII and the destruction of bradykinin. A nonapeptide, teprotide, the snake venom peptide that inhibits kininase II and ACE, was synthesized and tested in human subjects. It lowered BP in many patients with essential hypertension and exerted beneficial effects in patients with heart failure. Captopril, an orally effective ACE inhibitor, was developed by analysis of the inhibitory action of teprotide, inference about the action of ACE on its substrates, and analogy with carboxypeptidase A, which is inhibited by D-benzylsuccinic acid. Ondetti, Cushman, and colleagues argued that inhibition of ACE might be produced by succinyl amino acids corresponding to the dipeptide cleaved by ACE. This led to the synthesis of carboxy alkanoyl and mercapto alkanoyl derivatives that are potent competitive inhibitors of ACE.

Pharmacological Effects

The ACEIs block the conversion of AngI to AngII. Inhibition of AngII production lowers BP and enhances natriuresis. ACE has many substrates; thus, its inhibition has multiple consequences, including inhibition of bradykinin degradation, which has beneficial antihypertensive and protective effects. ACEIs increase the circulating levels of the stem cell regulator Ac-SDKP (*N*-acetyl-seryl-aspartyl-lysyl-proline), which may contribute to the cardioprotective effects of ACEIs. ACEIs increase renin release and the rate of formation of AngI by interfering with both short- and long-loop negative feedbacks on renin release (Figure 30–2). The AngI that accumulates is directed into alternative metabolic routes, resulting in increased production of vasodilator peptides [e.g., Ang(1–9) and Ang(1–7)] (Figure 30–1).

Clinical Pharmacology

The ACEIs can be classified into three broad groups based on chemical structure:

1. Sulfhydryl-containing ACEIs structurally related to *captopril*
2. Dicarboxyl-containing ACEIs structurally related to *enalapril* (e.g., *lisinopril*, *benazepril*, *quinapril*, *moexipril*, *ramipril*, *trandolapril*, *perindopril*; Figure 30–12)
3. Phosphorus-containing ACEIs structurally related to *fosinopril*

Many ACEIs are ester-containing prodrugs that are 100 to 1000 times less potent but have better oral bioavailability than the active molecules. Currently, 11 ACEIs are available for clinical use in the U.S. They differ with regards to potency, pharmacokinetics, and whether ACE inhibition is primarily an effect of the drug or an active metabolite.

All ACEIs block the conversion of AngI to AngII and have similar therapeutic indications, adverse effect profiles, and contraindications. Because hypertension usually requires long-term treatment, quality-of-life issues are an important consideration in comparing antihypertensive drugs. With the exception of *fosinopril*, *trandolapril*, and *quinapril* (which display balanced elimination by the liver and kidneys), ACEIs are predominantly cleared by the kidneys. Impaired renal function thus significantly diminishes the plasma clearance of most ACEIs, and dosages of these drugs should be reduced in patients with renal impairment. *Elevated PRA renders patients hyperresponsive to ACEI-induced hypotension. Thus, initial dosages of all ACEIs should be reduced in patients with high plasma levels of renin (e.g., patients with heart failure and during salt depletion, including diuretic use).* ACEIs differ markedly in tissue distribution; it is possible that this difference could be exploited to selectively inhibit certain local (tissue) RAS.

Captopril. *Captopril* is a potent ACE inhibitor (K_i = 1.7 nM). Orally administered *captopril* is absorbed rapidly and has a bioavailability of approximately 75% but is reduced by 25% to 30% with food. Peak concentrations in plasma occur within an hour, and the drug is cleared rapidly ($t_{1/2}$ of ~2 h). Most of the drug is eliminated in urine, 40% to 50% as *captopril*, and the rest as captopril disulfide dimers and captopril–cysteine disulfide. The oral dose of *captopril* ranges from 6.25 to 150 mg 2 to 3 times daily, with 6.25 mg thrice daily or 25 mg twice daily appropriate to initiate therapy for heart failure or hypertension, respectively.

Enalapril. *Enalapril maleate* is a prodrug that is hydrolyzed by esterases in the liver to produce enalaprilat, the active dicarboxylic acid. *Enalaprilat* is a potent inhibitor of ACE (K_i = 0.2 nM). *Enalapril* is absorbed rapidly when given orally; its oral bioavailability is approximately 60% and not reduced by food. Peak concentrations of *enalapril* in plasma occur within

an hour; *enalaprilat* concentrations peak after 3 to 4 h. *Enalapril* has a $t_{1/2}$ of approximately 1.3 h, but *enalaprilat*, because of tight binding to ACE, has a plasma $t_{1/2}$ of approximately 11 h. Intact *enalapril* and *enalaprilat* are excreted by the kidneys. The oral dosage of *enalapril* ranges from 2.5 to 40 mg daily, with 2.5 and 5 mg daily appropriate to initiate therapy for heart failure and hypertension, respectively.

Enalaprilat. *Enalaprilat* is not absorbed orally but is available for intravenous administration when oral therapy is not appropriate. For hypertensive patients, the dosage is 0.625 to 1.25 mg given intravenously over 5 min. This dosage may be repeated every 6 h.

Lisinopril. *Lisinopril* is the lysine analogue of *enalaprilat*; unlike *enalapril*, *lisinopril* itself is active. *In vitro*, *lisinopril* is a slightly more potent ACE inhibitor than is *enalaprilat*. *Lisinopril* is absorbed slowly, variably, and incompletely (~30%) after oral administration (and not reduced by food); peak concentrations in plasma are achieved in about 7 h. It is excreted unchanged by the kidney with a plasma $t_{1/2}$ of about 12 h. The oral dosage of *lisinopril* ranges from 5 to 40 mg daily (single or divided dose), with 5 and 10 mg daily appropriate for the initiation of therapy for heart failure and hypertension, respectively. A daily dose of 2.5 mg with close medical supervision is recommended for patients with heart failure who are hyponatremic or have renal impairment.

Benazepril. Cleavage of the ester moiety by hepatic esterases transforms *benazepril*, a prodrug, into *benazeprilat*. *Benazepril* is absorbed rapidly but incompletely (37%) after oral administration (only slightly reduced by food). *Benazepril* is nearly completely metabolized to *benazeprilat* and to the glucuronide conjugates of *benazepril* and *benazeprilat*, which are excreted into the urine and bile; peak concentrations of *benazepril* and *benazeprilat* in plasma are achieved in 0.5 to 1 and 1 to 2 h, respectively. *Benazeprilat* has an effective plasma $t_{1/2}$ of 10 to 11 h. Except for the lungs, *benazeprilat* does not accumulate in tissues. The oral dosage of *benazepril* ranges from 5 to 80 mg daily (single or divided dose).

Fosinopril. Cleavage of the ester moiety by hepatic esterases transforms *fosinopril* into *fosinoprilat*. *Fosinopril* is absorbed slowly and incompletely (36%) after oral administration (the rate but not extent is reduced by food). *Fosinopril* is largely metabolized to *fosinoprilat* (75%) and to its glucuronide conjugate, which are excreted in both the urine and the bile. Peak concentrations of *fosinoprilat* in plasma occur in about 3 h. *Fosinoprilat* has an effective plasma $t_{1/2}$ of approximately 11.5 h, which is not significantly altered by renal impairment. The oral dosage of *fosinopril* ranges from 10 to 80 mg daily (single or divided dose). The initial dose is reduced to 5 mg daily in patients with Na^+ or water depletion or renal failure.

Trandolapril. An oral dose of *trandolapril* is absorbed without reduction by food and produces plasma levels of *trandolapril* (10% bioavailability) and *trandolaprilat* (70% bioavailability). *Trandolaprilat* is approximately 8 times more potent than *trandolapril* as an ACEI. Glucuronides of *trandolapril* and de-esterification products are recovered in the urine (33%, mostly *trandolaprilat*) and feces (66%). Peak concentrations of *trandolaprilat* in plasma are achieved in 4 to 10 h.

Trandolaprilat displays biphasic elimination kinetics, with an initial $t_{1/2}$ of about 10 h (the major component of elimination), followed by a more prolonged $t_{1/2}$ (owing to slow dissociation of *trandolaprilat* from tissue ACE). Plasma clearance of *trandolaprilat* is reduced by renal and hepatic insufficiency. The oral dosage ranges from 1 to 8 mg daily (single or divided dose). The initial dose is 0.5 mg in patients who are taking a diuretic or who have renal impairment.

Quinapril. Cleavage of the ester moiety by hepatic esterases transforms *quinapril*, a prodrug, into *quinaprilat*, a conversion that is reduced in patients with diminished liver function. *Quinapril* is absorbed rapidly (with peak concentrations in 1 h); the rate, but not extent, of oral absorption (60%) may be reduced by food. *Quinaprilat* and other metabolites of *quinapril* are excreted in the urine (61%) and feces (37%). Peak concentrations of *quinaprilat* in plasma are achieved in about 2 h. The initial $t_{1/2}$ of *quinaprilat* is about 2 h; a prolonged terminal $t_{1/2}$ (~25 h) may be due to its high-affinity binding to tissue ACE. The oral dosage of *quinapril* ranges from 5 to 80 mg daily.

Ramipril. Orally administered *ramipril* is absorbed rapidly (peak concentrations in 1 h). The rate but not extent of its oral absorption (50%–60%) is reduced by food. *Ramipril* is metabolized to *ramiprilat* by hepatic esterases and to inactive metabolites that are excreted predominantly by the kidneys. Peak concentrations of *ramiprilat* in plasma are achieved in approximately 3 h. *Ramiprilat* displays triphasic elimination kinetics ($t_{1/2}$ values: 2–4, 9–18, and >50 h). This triphasic elimination is due to extensive distribution in tissues (initial $t_{1/2}$), clearance of free *ramiprilat* from plasma (intermediate $t_{1/2}$), and dissociation of *ramiprilat* from tissue ACE (long terminal $t_{1/2}$). The oral dosage of *ramipril* ranges from 1.25 to 20 mg daily (single or divided dose).

Moexipril. The antihypertensive activity of *moexipril* derives from its de-esterified metabolite, *moexiprilat*. *Moexipril* is absorbed incompletely; bioavailability as *moexiprilat* is about 13% and markedly decreased by food. The time to peak plasma concentration of *moexiprilat* is approximately 1.5 h; the elimination $t_{1/2}$ varies between 2 and 12 h. The recommended dosage range is 7.5 to 30 mg daily (single or divided doses) and is halved in patients taking diuretics or who have renal impairment.

Perindopril. *Perindopril erbumine* is a prodrug that is transformed to *perindoprilat* by hepatic esterases. The oral bioavailability of *perindopril* (75%) is not affected by food, but bioavailability of *perindoprilat* is reduced by about 35%. *Perindopril* is also converted to inactive metabolites that are excreted predominantly by the kidneys. Peak concentrations of *perindoprilat* in plasma are achieved in 3 to 7 h. *Perindoprilat* displays biphasic elimination kinetics with half-lives of 3 to 10 h (the major component of elimination) and 30 to 120 h (owing to slow dissociation of *perindoprilat* from tissue ACE). The oral dosage ranges from 2 to 16 mg daily (single or divided dose).

Therapeutic Uses of ACEIs

ACEIs are effective in the treatment of hypertension, cardiovascular disease, heart failure, and diabetic nephropathy.

ACEIs in Hypertension. Inhibition of ACE lowers systemic vascular resistance and mean, diastolic, and systolic BPs in hypertensive states except in primary aldosteronism (see Chapters 32 and 50) (Table 30–3). The initial change in BP tends to be positively correlated with PRA and AngII plasma levels prior to treatment. However, some patients may show a sizable reduction in BP that correlates poorly with pretreatment values of PRA. Perhaps increased local (tissue) production of AngII or increased responsiveness of tissues to normal levels of AngII makes some hypertensive patients sensitive to ACEIs despite normal PRA.

The long-term fall in systemic BP in hypertensive individuals treated with ACEIs is accompanied by a leftward shift in the renal pressure–natriuresis curve (Figure 30–7) and a reduction in TPR (from variable participation of different vascular beds). The kidney is a notable exception: Because renal vessels are extremely sensitive to vasoconstriction by AngII, ACEIs increase RBF via vasodilation of the afferent and efferent arterioles. Increased RBF occurs without increased GFR; thus, the filtration fraction is reduced.

The ACEIs produce systemic arteriolar dilation and increased compliance of large arteries, which contributes to a reduction of systolic pressure. Cardiac function in patients with uncomplicated hypertension generally is little changed, although stroke volume and cardiac output may increase slightly with sustained treatment. Baroreceptor function and cardiovascular reflexes are not compromised; responses to postural changes and exercise are little impaired. Even with substantial lowering of BP, heart rate and plasma catecholamine concentrations generally only increase slightly (if at all), perhaps reflecting an alteration of baroreceptor function with increased arterial compliance and decreased tonic influence of AngII on the sympathetic nervous system.

Aldosterone secretion is reduced, but not seriously impaired, by ACEIs. Aldosterone secretion is maintained at adequate levels by other steroidogenic stimuli, such as ACTH and K^+. Their activity on the zona glomerulosa of the adrenal cortex requires very small trophic or permissive amounts of AngII, which remain present because ACE inhibition is never complete. Excessive retention of K^+ and hyperkalemia can occur in patients taking supplemental K^+, in patients with renal impairment, or in patients taking other medications that reduce K^+ excretion.

ACEIs can normalize BP in approximately 50% of patients with mild-to-moderate hypertension. Ninety percent of such patients will be controlled by the combination of an ACEI and a Ca^{2+} channel blocker, a β_1 adrenergic receptor blocker, or a diuretic (see Chapter 32). Diuretics augment the antihypertensive response to ACEIs by rendering the patient's BP renin-dependent. Several ACEIs are marketed in fixed-dose combinations with a thiazide diuretic or Ca^{2+} channel blocker for the management of hypertension.

ACEIs in Left Ventricular Systolic Dysfunction. *Unless contraindicated, ACEIs should be given to all patients with impaired left ventricular systolic function whether or not they have symptoms of overt heart failure* (see Chapter 33). Several large clinical studies have demonstrated that inhibition of ACE in patients with systolic dysfunction prevents or delays the progression of heart failure, decreases the incidence of sudden death and MI, decreases hospitalization, and improves quality of life. Inhibition of ACE generally reduces afterload and systolic wall stress and increases cardiac output, cardiac index, and stroke volume. In systolic dysfunction, AngII decreases arterial compliance; this is reversed by ACE inhibition. Heart rate generally is reduced. Systemic BP falls, sometimes steeply at the outset, but tends to return toward initial levels. Renovascular resistance falls sharply and RBF increases. Natriuresis occurs because of improved renal hemodynamics, reduced stimulus to the secretion of aldosterone by AngII, and diminished direct renal effects of AngII. The decrease in excess volume of body fluids, venodilation, and increased capacity of the venous bed reduce venous return to the heart.

The response to ACEIs also involves reductions of pulmonary arterial pressure, pulmonary capillary wedge pressure, and left atrial and left ventricular filling volumes and pressures. Consequently, preload and diastolic wall stress are diminished. The improved hemodynamic performance results in increased exercise tolerance and suppression of the sympathetic nervous system. Cerebral and coronary blood flows usually are well maintained, even when systemic BP is reduced. In heart failure, ACEIs reduce ventricular dilation and tend to restore the heart to its normal elliptical shape. ACEIs may reverse ventricular remodeling via changes in preload/afterload by preventing the growth effects of AngII on myocytes and by attenuating cardiac fibrosis induced by AngII and aldosterone.

ACEIs in Acute MI. Beneficial effects of ACEIs in acute MI are observed especially in hypertensive and diabetic patients. Unless contraindicated

(e.g., cardiogenic shock or severe hypotension), ACEIs should be started during the acute phase of MI and can be administered along with thrombolytics, aspirin, and β adrenergic receptor antagonists (ACE Inhibitor Myocardial Infarction Collaborative Group, 1998). In high-risk patients (e.g., large infarct, systolic ventricular dysfunction), ACE inhibition should be continued long term (see Chapters 31 and 33).

ACEIs in Patients Who Are at High Risk of Cardiovascular Events. ACEIs benefit patients at high risk of cardiovascular events (Heart Outcomes Prevention Study Investigators, 2000). ACEIs decrease the rate of MI, stroke, and death in patients who do not have left ventricular dysfunction but have evidence of vascular disease or diabetes and one other risk factor for cardiovascular disease. In patients with coronary artery disease but without heart failure, ACE inhibition reduces cardiovascular disease death and MI (European Trial, 2003).

ACEIs in Diabetes Mellitus and Renal Failure. Diabetes mellitus is the leading cause of chronic renal disease. In patients with diabetic nephropathy, ACEIs prevent or delay disease progression. The renoprotective effects of ACEIs are in part independent of BP reduction. ACEIs can also decrease progression of retinopathy in type 1 diabetics and attenuate the progression of renal insufficiency in patients with nondiabetic nephropathies (Ruggenenti et al., 2010).

Several mechanisms participate in the renal protective effects of ACEIs. By decreasing arterial BP and dilating renal efferent arterioles, ACEIs reduce the increased glomerular capillary pressure that induces glomerular injury. ACEIs also increase the permeability selectivity of the filtering membrane, thereby diminishing exposure of the mesangium to proteinaceous factors that may stimulate mesangial cell proliferation and matrix production, which contribute to expansion of the mesangium in diabetic nephropathy. Because AngII is a growth factor, reduced intrarenal levels of AngII may attenuate mesangial cell growth and matrix production. ACEIs increase Ang(1–7) levels by preventing its metabolism by ACE; Ang(1–7), via Mas receptors, has protective and antifibrotic effects (Santos, 2014; Santos et al., 2019). In diabetes, AngII, via AT_1 receptors in renal podocytes, leads to activation of protein kinase signaling cascades, cytoskeletal rearrangements, retraction of podocyte processes, and reduction in proteins of the slit diaphragm, all resulting in increased permeability of the renal epithelium to proteins (proteinuria). ACEIs reduce these effects of AngII (Márquez et al., 2015).

Adverse Effects of ACEIs

The ACEIs are generally well tolerated. The drugs do not alter plasma concentrations of uric acid or Ca^{2+}, may improve insulin sensitivity and glucose tolerance in patients with insulin resistance, and decrease cholesterol and lipoprotein (a) levels in proteinuric renal disease.

Hypotension. A steep fall in BP may occur following the first dose of an ACEI in patients with elevated PRA. One should exercise care in patients who are salt depleted, on multiple antihypertensive drugs, or have congestive heart failure.

Cough. In 5% to 20% of patients, ACEIs induce a bothersome, dry cough mediated by the accumulation in the lungs of bradykinin, substance P, or PGs. Thromboxane antagonism, *aspirin*, and iron supplementation reduce cough induced by ACEIs. Dose reduction or switching to an ARB is sometimes effective. The cough disappears, usually within 4 days, if ACEIs are stopped.

Hyperkalemia. Significant K^+ retention is rarely encountered in patients with normal renal function. However, ACEIs may cause hyperkalemia in patients with renal insufficiency or diabetes or if used with K^+-sparing diuretics, K^+ supplements, β receptor blockers, or NSAIDs.

Acute Renal Failure. Inhibition of ACE can induce acute renal insufficiency in patients with bilateral renal artery stenosis, stenosis of the artery to a single remaining kidney, heart failure, or volume depletion owing to diarrhea or diuretics.

Angioedema. In 0.1% to 0.5% of patients, ACEIs induce rapid swelling in the nose, throat, mouth, glottis, larynx, lips, and/or tongue. Once ACEIs are stopped, angioedema disappears within hours; the patient's airway should be protected, and if necessary, *epinephrine*, an antihistamine, or a glucocorticoid should be administered. African Americans have a 4.5 times greater risk of ACEI-induced angioedema than Caucasians. Although rare, angioedema of the intestine (visceral angioedema) characterized by emesis, watery diarrhea, and abdominal pain has also been reported. ACEI-associated angioedema is a class effect: Patients who develop this adverse event should not be prescribed other ACEIs.

Fetopathic Potential. *If a pregnancy is diagnosed, it is imperative that ACEIs be discontinued.* ACEIs and ARBs have been associated with renal developmental defects when administered in the third trimester of pregnancy, and potentially earlier. The fetopathic effects may be due in part to fetal hypotension. This possible adverse effect should be discussed with women of childbearing potential, as should the necessity of birth control measures.

Skin Rash. The ACEIs occasionally cause a maculopapular rash that may itch but that may resolve spontaneously or with antihistamines.

Other Side Effects. Extremely rare but reversible side effects include dysgeusia (an alteration in or loss of taste), neutropenia (symptoms include sore throat and fever), glycosuria (spillage of glucose into the urine in the absence of hyperglycemia), anemia, and hepatotoxicity.

Drug Interactions. Antacids and other drugs (e.g., lanthanum, a phosphate binder) may reduce the bioavailability of ACEIs; capsaicin may worsen ACEI-induced cough; NSAIDs, including aspirin, may reduce the antihypertensive response to ACEIs; and K^+-sparing diuretics and K^+ supplements may exacerbate ACEI-induced hyperkalemia. ACEIs may increase plasma levels of digoxin and lithium and hypersensitivity reactions to allopurinol and other drugs. Coadministration of dipeptidyl peptidase-IV inhibitors (e.g., sitagliptin), alteplase, everolimus, and pregabalin may increase the risk of developing angioedema.

Angiotensin II Receptor Blockers

HISTORY

Attempts to develop therapeutically useful AngII receptor antagonists began in the 1970s. Initial efforts concentrated on angiotensin peptide analogues. Saralasin, 1-sarcosine, 8-isoleucine AngII, and other 8-substituted angiotensins are potent AngII receptor antagonists but are not of clinical value because they lack oral bioavailability and have (unacceptable) partial agonist activity. A breakthrough came in the 1980s with the synthesis of a series of imidazole-5–acetic acid derivatives that attenuated pressor responses to AngII in rats. Two compounds, S-8307 and S-8308, proved to be highly specific, albeit very weak, nonpeptide AngII receptor antagonists that were devoid of partial agonist activity (Dell'Italia, 2011). Through a series of stepwise modifications, *losartan*, an orally active, potent, and selective nonpeptide AT_1 receptor antagonist, was developed and approved for clinical use in the U.S. in 1995. Since then, seven additional AT_1 receptor antagonists (see Drug Facts for Your Personal Formulary table) have been approved. These AT_1 receptor antagonists are devoid of partial agonist activity, but structural modifications as minor as a methyl group can transform a potent antagonist into an agonist (Perlman et al., 1997).

Pharmacological Effects

AngII receptor blockers (ARBs) bind to AT_1 receptors with high affinity and are greater than 10,000-fold more selective for the AT_1 than the AT_2 receptor. Although binding of ARBs to AT_1 receptors is competitive, the inhibition by ARBs of biological responses to AngII often is functionally insurmountable. Insurmountable antagonism has the theoretical advantage of sustained receptor blockade even with increased levels of endogenous ligand and missed doses of drug. ARBs inhibit most biological effects of AngII, including: (1) vascular smooth muscle contraction; (2) rapid pressor responses; (3) slow pressor responses; (4) thirst;

(5) vasopressin release; (6) aldosterone secretion; (7) adrenal catecholamine release; (8) enhancement of noradrenergic neurotransmission; (9) increases in sympathetic tone; (10) changes in renal function; and (11) cellular hypertrophy and hyperplasia. ARBs reduce arterial BP in animals with renovascular and genetic hypertension, as well as in transgenic animals that overexpress the renin gene. ARBs, however, have little effect on arterial BP in animals with low-renin hypertension (e.g., rats with NaCl/deoxycorticosterone-induced hypertension) (Csajka et al., 1997).

Do ARBs Have Therapeutic Efficacy Equivalent to That of ACEIs?

Although ARBs and ACEIs both block the RAS, they differ in important aspects:

- *ARBs reduce AT_1 receptor activation more effectively than do ACEIs.* ACEIs reduce ACE-mediated biosynthesis of AngII but do not inhibit AngII generation via chymase and other ACE-independent AngII-producing pathways. ARBs block the actions of AngII via AT_1 receptors irrespective of the biochemical pathway leading to AngII formation.
- *Unlike ACEIs, ARBs permit activation of AT_2 receptors.* ACEIs increase renin release but block the conversion of AngI to AngII. ARBs also stimulate renin release; however, with ARBs, this translates into a several-fold increase in circulating levels of AngII. Because ARBs block AT_1 receptors, this increased level of AngII can activate AT_2 receptors.
- *ACEIs increase Ang(1–7) levels.* ACE is involved in the clearance of Ang(1–7), so inhibition of ACE increases Ang(1–7) levels. With ARBs, it is unclear if there is a clinically meaningful impact on Ang(1-7) levels.
- *ACEIs can increase the levels of ACE substrates, including bradykinin and Ac-SDKP.*

Whether the pharmacological differences between ARBs and ACEIs result in significant differences in therapeutic outcomes is an open question. Meta-analyses indicate some differences; thus, further investigation is needed. Such analyses indicate similar efficacy for treating primary hypertension, with an advantage for ARBs with respect to frequency of adverse events (Li et al., 2014; Chen et al., 2021). Meta-analysis of patients with heart failure with reduced ejection fraction (HFrEF) indicated that both drug classes improve heart failure at high doses, but only ARBs reduce heart failure–related hospitalization (Turgeon et al., 2019). ARBs are preferable to ACEIs in reducing risk of renal failure in diabetic patients with albuminuria (Wang et al., 2018). Clinical trial evidence does not support combination therapy with ARBs and ACEIs for patients with hypertension, heart failure, or nephropathy (Makani et al., 2013; ONTARGET Investigators, 2008; Saglimbene et al., 2018).

Clinical Pharmacology

Oral bioavailability of ARBs generally is low (<50%) except for *azilsartan* (~60%) and *irbesartan* (~70%), and protein binding is high (>90%).

Candesartan Cilexetil. *Candesartan cilexetil*, an inactive ester prodrug, is hydrolyzed to the active form, *candesartan*, during gastrointestinal (GI) tract absorption (Figure 30–12). Peak plasma levels are obtained 3 to 4 h after oral administration; the plasma $t_{1/2}$ is about 9 h. Plasma clearance of *candesartan* is by renal elimination (33%) and biliary excretion (67%). The plasma clearance of *candesartan* is affected by renal insufficiency but not by mild-to-moderate hepatic insufficiency. *Candesartan cilexetil* should be administered orally once or twice daily for a total daily dose of 4 to 32 mg.

Eprosartan (no longer available in the U.S.). Peak plasma levels are obtained 1 to 2 h after oral administration; the plasma $t_{1/2}$ is 5 to 9 h. *Eprosartan* is metabolized in part to a glucuronide conjugate. Clearance is by renal elimination and biliary excretion and is affected by both renal and hepatic insufficiency. The recommended dosage of *eprosartan* is 400 to 800 mg/d in one or two doses.

Irbesartan. Peak plasma levels are obtained about 1.5 to 2 h after oral administration; the plasma $t_{1/2}$ is 11 to 15 h. *Irbesartan* is metabolized in part to a glucuronide conjugate. The parent compound and its glucuronide conjugate are cleared by renal elimination (20%) and biliary excretion (80%). The plasma clearance of *irbesartan* is unaffected by either renal or mild-to-moderate hepatic insufficiency. The oral dosage of *irbesartan* is 150 to 300 mg once daily.

Losartan. Approximately 14% of an oral dose of *losartan* is converted by CYP2C9 and CYP3A4 to the 5-carboxylic acid metabolite, EXP 3174, which is more potent than *losartan* as an AT_1 receptor antagonist. Peak plasma levels of *losartan* and EXP 3174 occur approximately 1 to 3 h after oral administration; the plasma half-lives are 2.5 and 6 to 9 h, respectively. The plasma clearances of *losartan* and EXP 3174 are via the kidney and liver (metabolism and biliary excretion) and are affected by hepatic but not renal insufficiency. *Losartan* should be administered orally once or twice daily for a total daily dose of 25 to 100 mg. *Losartan* is a competitive antagonist of the thromboxane A_2 receptor and attenuates platelet aggregation. EXP 3179, another metabolite of *losartan* without angiotensin receptor effects, has multiple potential antioxidant and antifibrotic actions that may be mediated by inhibition of protein kinase C (Wenzel et al., 2009).

Olmesartan Medoxomil. *Olmesartan medoxomil*, an inactive ester prodrug, is hydrolyzed to the active form, *olmesartan*, during GI tract absorption. Peak plasma levels are obtained 1.4 to 2.8 h after oral administration; the plasma $t_{1/2}$ is 10 to 15 h. Plasma clearance of *olmesartan* is via renal elimination and biliary excretion. Although renal impairment and hepatic disease decrease the plasma clearance of *olmesartan*, no dose adjustment is required in patients with mild-to-moderate renal or hepatic impairment. The oral dosage of *olmesartan medoxomil* is 20 to 40 mg once daily.

Telmisartan. Peak plasma levels are obtained 0.5 to 1 h after oral administration; the plasma $t_{1/2}$ is about 24 h. *Telmisartan* is cleared from the circulation mainly by biliary secretion of intact drug. The plasma clearance of *telmisartan* is affected by hepatic but not renal insufficiency. The recommended oral dosage of *telmisartan* is 40 to 80 mg once daily.

Valsartan. Peak plasma levels occur 2 to 4 h after oral administration; food decreases absorption. The plasma $t_{1/2}$ is about 9 h. *Valsartan* is cleared from the circulation by the liver (~70% of total clearance); hepatic insufficiency reduces clearance. The oral dosage is 80 to 320 mg once daily.

Azilsartan Medoxomil. The prodrug is hydrolyzed in the GI tract into the active form, *azilsartan*. The drug is available in 40- and 80-mg once-daily doses. At the recommended dose of 80 mg once a day, *azilsartan medoxomil* is superior to *valsartan*, *olmesartan*, and *telmisartan* in lowering BP. Bioavailability of *azilsartan* is about 60% and is not affected by food. Peak plasma concentrations (C_{max}) are achieved within 1.5 to 3 h. The elimination $t_{1/2}$ is approximately 11 h. *Azilsartan* is metabolized mostly by CYP2C9 into inactive metabolites. Elimination of the drug is 55% in feces and 42% in urine. About 15% of the dose is eliminated unchanged in urine. Plasma clearance is not affected by renal or hepatic insufficiency.

Angiotensin Receptor–Neprilysin Inhibitors (ARNis). A combination of *sacubitril* and *valsartan*, marketed as Entresto (generic name: LCZ696), combines the AT_1 receptor antagonistic moiety of *valsartan* with the neprilysin inhibitor moiety of *sacubitril*. The complex (*sacubitril*, *valsartan*, Na^+, and water [1:1:3:2.5]) dissociates into *sacubitril* and *valsartan* after oral administration. *Sacubitril* is about 60% bioavailable and highly protein bound (94%–97%). *Sacubitril* is further metabolized by esterases into the active metabolite LBQ657, which has a $t_{1/2}$ of 11 h. The neprilysin inhibitor blocks the breakdown of natriuretic peptides (atrial natriuretic peptide, brain natriuretic peptide, and C-type natriuretic peptide), AngI and AngII, endothelin 1, adrenomedullin, and bradykinin. The drug combination lowers vascular resistance and increases blood flow. In a large randomized clinical trial, the drug combination was superior to *enalapril* and decreased the risk of deaths from cardiovascular causes and heart failure by 20% (McMurray et al., 2014).

Meta-analyses of clinical trials have further assessed the therapeutic benefit of ARNis, including in comparison with other RAS inhibitors. ARNis reduced hospitalization and death from heart failure compared to RAS inhibitors alone in patients with HFrEF (Solomon et al., 2016)

and promoted reversal of cardiac remodeling (Wang et al., 2019). Benefits of ARNis compared to ACE inhibition alone have also been observed in patients with decompensated HFrEF (PIONEER-HF trial; Ambrosy et al., 2020) and HFrEF after MI, including reduced heart failure hospitalization and mortality from cardiovascular events, albeit with an increased incidence of hypotension (PARADISE-MI trial; Jering et al., 2021). ARNis also appear to have advantages compared to ARBs in treating hypertension (Zhao et al., 2017) and greater BP-lowering effects than an ACEI or ARB for patients with both heart failure and chronic kidney disease (Kang et al., 2020). ARNis may have beneficial effects on renal function compared to ACEIs/ARBs in heart failure patients (Chen et al., 2020; Kang et al., 2020). A recent meta-analysis of clinical trials that included patients with heart failure with preserved ejection fraction indicates a reduced rate of hospitalization with ARNi treatment, although no reduction in mortality, an observation potentially confounded by challenges with patient classification (Kuno et al., 2020).

Entresto is approved for treatment of HFrEF at a recommended dose of 100 to 400 mg daily, divided into two doses. Entresto is contraindicated in patients with a history of angioedema during ACEI or ARB use. The drug should not be used in conjunction with an ARB (since Entresto contains an ARB) or ACEI (as combined neprilysin inhibition plus ACE inhibition likely increases the risk of angioedema). It also should not be used in conjunction with *aliskiren* in diabetic patients.

A New Class of ARBs in Development. The *β-arrestin–biased AT_1 receptor blocker* TRV027 (and others) binds to the AT_1 receptor and blocks G protein-coupled signaling while engaging β-arrestin. β-Arrestin, an adaptor protein, participates in receptor desensitization and internalization. In animal models, the β-arrestin–biased AT_1 receptor ligand increased myocyte contractility and protected against apoptosis (Kim et al., 2012). In phase II clinical studies, TRV027 decreased mean arterial pressure and was well tolerated. However, treatment with TRV027 did not improve clinical status in patients with acute heart failure (Pang et al., 2017).

Therapeutic Uses of ARBs

Angiotensin receptor blockers are approved for the treatment of hypertension. ARBs are renoprotective in type 2 diabetes mellitus and may be drugs of choice for renoprotection in diabetic patients.

Irbesartan and *losartan* are approved for diabetic nephropathy, *losartan* is approved for stroke prophylaxis, and *valsartan* and *candesartan* are approved for heart failure and to reduce cardiovascular mortality in clinically stable patients with left ventricular failure or left ventricular dysfunction following MI. ARBs and ACEIs have comparable efficacy in lowering BP, and ARBs have a favorable adverse effect profile. ARBs also are available as fixed-dose combinations with *hydrochlorothiazide* or *amlodipine* (see also Chapters 29, 32, and 33).

The Losartan Intervention for Endpoint (LIFE) Reduction in Hypertension Study demonstrated the superiority of an ARB compared with a β_1 adrenergic receptor antagonist in reducing stroke in hypertensive patients with left ventricular hypertrophy (Dahlöf et al., 2002). The ELITE (Evaluation of Losartan in the Elderly) study and a follow-up study (ELITE II) concluded that in elderly patients with heart failure, *losartan* is as effective as *captopril* in improving symptoms (Pitt et al., 2000). The VALIANT (Valsartan in Acute Myocardial Infarction) trial demonstrated that *valsartan* was as effective in reducing all-cause mortality as *captopril* in patients with MI complicated by left ventricular systolic dysfunction (Pfeffer et al., 2003). Both *valsartan* and *candesartan* reduce mortality and morbidity in patients with heart failure (Makani et al., 2013). ACEIs are used as first-line agents for the treatment of HFrEF. ARBs are used to treat such patients who cannot tolerate or have unsatisfactory responses to ACEIs. However, the more recent positive results from trials testing an ARNi (*sacubitril-valsartan* [Entresto]) have suggested that ARNis may be a standard of care in this setting (Rossignol et al., 2019).

Adverse Effects

ARBs are generally well tolerated. The incidence of angioedema and cough with ARBs is less than with ACEIs. ARBs have teratogenic potential and should be discontinued in pregnancy. ARBs can cause hypotension, oliguria, progressive azotemia, or acute renal failure in patients whose arterial BP or renal function is highly dependent on the RAS (e.g., renal artery stenosis). ARBs may cause hyperkalemia in patients with renal disease or those taking K^+ supplements or K^+-sparing diuretics. ARBs enhance the BP-lowering effect of other antihypertensive drugs, a desirable effect but one that may necessitate dosage adjustment. There are rare postmarketing reports of anaphylaxis, abnormal hepatic function, hepatitis, neutropenia, leukopenia, agranulocytosis, pruritus, urticaria, hyponatremia, alopecia, and vasculitis.

Direct Renin Inhibitors (DRIs)

Angiotensinogen is the only specific substrate for renin. DRIs inhibit the cleavage of AngI from angiotensinogen by renin, the rate-limiting enzymatic reaction for the generation of AngII. *Aliskiren* is the only DRI approved for clinical use.

HISTORY

Earlier inhibitors of renin were orally inactive peptide analogues of the prorenin propeptide or analogues of the renin-substrate cleavage site. Orally active, first-generation renin inhibitors (*enalkiren*, *zankiren*, CGP38560A, and *remikiren*) were effective in reducing AngII levels, but none of them succeeded in clinical trials due to their low potency, poor bioavailability, and short $t_{1/2}$. Low-molecular-weight renin inhibitors were designed based on molecular modeling and crystallographic structural information of renin-substrate interaction (Wood et al., 2003). This led to the development of *aliskiren*, a renin inhibitor that is approved for the treatment of hypertension. *Aliskiren* has BP-lowering effects akin to those of ACEIs and ARBs.

Pharmacological Effects

Aliskiren, a low-molecular-weight nonpeptide, is a competitive inhibitor of renin. It binds the active site of renin to block conversion of angiotensinogen to AngI, thus reducing the production of AngII. Aliskiren has a 10,000-fold higher affinity for renin (IC_{50} ~0.6 nM) than other aspartic peptidases. In healthy volunteers, *aliskiren* (40–640 mg/d) dose-dependently decreases BP, PRA, AngI, and AngII levels but increases PRC by 16- to 34-fold due to the loss of the short-loop negative feedback by AngII (Figure 30–2). *Aliskiren* also decreases plasma and urinary aldosterone levels and enhances natriuresis (Nussberger et al., 2002).

Clinical Pharmacology

Aliskiren is recommended as a single oral dose of 150 or 300 mg/d. Bioavailability of *aliskiren* is low (~2.5%), but its high affinity compensates for this low bioavailability. Peak plasma concentrations are reached within 3 to 6 h; the $t_{1/2}$ is 20 to 45 h. Steady state in plasma is achieved in 5 to 8 days. Plasma protein binding is 50% and is independent of concentration. *Aliskiren* is a substrate for P-glycoprotein, which contributes to low bioavailability. Fatty meals significantly decrease *aliskiren* absorption. Hepatic metabolism is minimal. Elimination is mostly as unchanged drug in feces; approximately 25% of the absorbed dose appears in the urine as the parent drug.

Therapeutic Uses of Aliskiren

Aliskiren is an efficacious antihypertensive agent (Musini et al., 2017; Wang GM et al., 2020; see Chapter 32), with similar efficacy as ACEIs and ARBs and similar rates of serious adverse events. Definitive evidence for its utility in blunting diabetic complications or in patients with heart failure has not been obtained (Zheng et al., 2017; Louvis and Coulson, 2018; Luo and Chen, 2019) and thus, *aliskiren* is not approved for these indications

Adverse Effects and Contraindications

Aliskiren is well tolerated. Adverse events are mild or comparable to placebo and include mild GI symptoms, such as diarrhea at high doses

Drug Facts for Your Personal Formulary: *Inhibitors of the RAS*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Angiotensin-Converting Enzyme Inhibitors • Inhibit the conversion of AngI to AngII		
Captopril Lisinopril Enalapril Benazepril Quinapril Ramipril Moexipril	• Hypertension • Acute myocardial infarction • Heart failure • Diabetic nephropathy	• Antihypertensive effects potentiated by inhibition of ACE-catalyzed degradation of bradykinin • Antihypertensive effects potentiated by increase in Ang(1–7) levels and activation of Ang(1–7)/Mas receptor pathway • Increase PRC and PRA • Adverse effects include cough in 5%–20% of patients, angioedema, hypotension, hyperkalemia, skin rash, neutropenia, anemia, fetopathic syndrome • Contraindicated in renal artery stenosis; use with caution in impaired renal function or hypovolemia • Contraindicated in pregnancy
Enalaprilat (IV)		• Intravenous administration
Fosinopril Trandolapril Perindopril		• Undergo both hepatic and renal elimination; use with caution in renal or hepatic impairment
Angiotensin Receptor Blockers • Block AT_1 receptors		
Losartan Valsartan Eprosartan Irbesartan Candesartan Olmesartan Telmisartan Azilsartan	• Hypertension • Heart failure • Diabetic nephropathy	• Increase PRC and PRA • Adverse effects include hyperkalemia and hypotension • Contraindicated in patients with renal insufficiency • Contraindicated in pregnancy
Angiotensin Receptor–Neprilysin Inhibitor Combination • Blocks AT_1 receptors and neprilysin		
Sacubitril-valsartan (Entresto)	• Heart failure	• Superior to ACEI in heart failure patients • Adverse effects and contraindications same as valsartan • Contraindicated in combination with other ARB or ACEI
Direct Renin Inhibitors • Inhibit renin and thus the conversion of angiotensinogen to AngI		
Aliskiren	• Hypertension	• Increases PRC but decreases PRA • Contraindicated in combination with ARB or ACEI • Contraindicated in diabetic nephropathy, pregnancy, or renal insufficiency

(600 mg daily), abdominal pain, dyspepsia, and gastroesophageal reflux; headache; dizziness; fatigue; upper respiratory tract infection; back pain; angioedema; and cough (much less common than with ACEIs). Other adverse effects include rash, hypotension, hyperkalemia in diabetics on combination therapy, elevated uric acid, renal stones, and gout. *Aliskiren* is contraindicated in pregnancy. Concomitant use with ACEIs and ARBs in patients with diabetes is contraindicated. *Aliskiren* should be avoided in patients with creatinine clearance less than 60 mL/min.

Drug Interactions. *Aliskiren* reduces absorption of *furosemide* by 50%. *Irbesartan* reduces the C_{max} of *aliskiren* by 50%. *Aliskiren* plasma levels are increased by drugs that inhibit P-glycoprotein, such as *ketoconazole*, *atorvastatin*, and *cyclosporine*. During *aliskiren* treatment, the PRA assay will be inhibited by persistence of *aliskiren* in this *ex vivo* reaction, whereas the renin concentration radioimmunoassay will not be inhibited.

Chapter 31

Treatment of Ischemic Heart Disease

Thomas Eschenhagen

Ischemic Heart Disease: A Short Introduction

Ischemic heart disease comprises pathologies that lead to myocardial ischemia, a pathological reduction in blood supply and, by extension, oxygenation of myocardial tissue. The main symptom of myocardial ischemia is angina pectoris. This stage of cell injury is, in principle, reversible. Myocardial infarction (MI) refers to the complete stoppage of blood supply and oxygenation, resulting in the onset of irreversible cell injury, also called cell death or necrosis (Oakes, 2021).

The pathophysiological understanding of ischemic heart disease has seen major changes over the past two decades—from a concept of localized calcification causing progressive constrictions of coronary arteries, ischemia, and exercise-induced angina pectoris to a systemic inflammatory disease of the arteries, including the coronaries (thus the name coronary artery disease [CAD]). A key finding in this change of paradigm was that most infarct-causing occlusions occur at small-to-medium plaques ("active plaques") by thrombosis rather than at hemodynamically relevant stenoses by progressive narrowing. Thus, in addition to the mere size of an obstructing plaque, the inflammatory activity of the atherosclerotic process, the stability of the plaque, and platelet reactivity appear to determine the prognosis (concept of the "vulnerable plaque"; Libby et al., 2002).

Atherosclerosis encompasses increased lipid deposition in the subendothelial space (early plaque), endothelial dysfunction with decreased production of nitric oxide (NO), less vasodilation and increased risk of platelet adhesion, influx of lipid scavenger cells (mainly macrophages), necrosis, sterile inflammation, proliferation of smooth muscle cells, and calcification and narrowing of the blood vessel by increasing plaque formation. If the endothelium covering the plaque or the cell layer enclosing the necrotic core of the plaque disrupts, thrombogenic materials such as collagen are presented to the bloodstream, causing platelet adhesion, fibrin deposition, thrombus formation, and closure of the blood vessel. It is increasingly recognized that platelets not only play a (mechanical) role in thrombus formation but also are an integral part of the immune response by stimulating neutrophil function (e.g., the formation of neutrophil extracellular traps [NETs]; Döring et al., 2017).

Triggering factors can be not only acute inflammation (e.g., influenza) but also blood pressure peaks during physical exercise or emotional stress (e.g., demonstrated during a life-threatening emergency and in avid fans during football games). Importantly, the process is dynamic, and the net thrombus formation is the result of the balance between thrombosis and thrombolysis by the fibrinolytic system (plasminogen). The degree and duration of coronary obstruction and thereby of the ischemia of downstream myocardium (and its size) determine the degree of necrosis of muscle tissue, that is, infarct size.

Taken together, important factors that determine the progress of CAD are the concentration of lipids in the blood, endothelial function, blood pressure (as a mechanical factor predisposing to plaque rupture), the activity of the inflammatory system, and the reactivity of pro- and antithrombotic systems. Patients with CAD, broadly, are advised to follow two sets of guidelines: (1) lifestyle (control body weight and blood pressure by exercising regularly, eating healthy, and not smoking), and (2) medications (take *aspirin*, statins, β adrenergic receptor antagonists [β blockers], and annual vaccinations against influenza). The widespread implementation of this combination drug regimen and the considerably improved treatment of acute coronary syndromes (ACSs) likely account for the continuous reduction in MIs and age-corrected cardiovascular lethality in Western countries (−42% between 2000 and 2011; Mozaffarian et al., 2015).

On the electrocardiogram (ECG), MI can be accompanied by ST-segment elevation (STEMI, indicating large transmural cell death) or not (non-STEMI, indicating smaller, not transmural cell death). The incidence of the classical large STEMI has been declining over the years as that of smaller non-STEMI has increased. While part of the latter may be explained by changes in definition (from ECG to a mainly troponin-based definition of MI), the observation raises the hypothesis that the dominant pathogenesis of acute coronary thrombosis may have changed from the rupture of lipid-rich, inflammatory plaques (in the prestatin era) to the erosion of stable plaques (Libby and Pasterkamp, 2015). Coronary imaging studies in patients treated for an ACS have shown that, over an observation period of 3.4 years, half of clinical events were associated with the large culprit lesion and half with nonculprit lesions. Although, in the latter, a "thin-capped" morphology and small lumen (signs of a "vulnerable plaque") were predictive of an event, only 5% of them gave rise to a clinical event (Stone et al., 2011). This indicates that the plaque phenotype is dynamic over time and that mechanisms beyond plaque rupture must play an additional role. These considerations have not yet led to new approved treatments but are the basis for active drug development. Examples of anti-inflammatory interventions with beneficial effects on the progression of CAD are the interleukin-1β antibody *canakinumab* (Ridker et al., 2017) and low-dose *colchicine* (Nidorf et al., 2020).

Antiplatelet agents, fibrinolytic drugs, anticoagulants, and statins (HMG-CoA [3-hydroxy-3-methylglutaryl coenzyme A] reductase inhibitors) are systematically discussed in Chapters 36 and 37. This chapter concentrates on the pharmacotherapy for angina pectoris and myocardial ischemia.

Abbreviations

ACE: angiotensin-converting enzyme
ACEI: angiotensin-converting enzyme inhibitor
ACS: acute coronary syndrome
ALDH2: mitochondrial aldehyde dehydrogenase
ARB: angiotensin receptor blocker
AV: atrioventricular
CAD: coronary artery disease
COX-1: cyclooxygenase isoform 1
CYP: cytochrome P450
ECG: electrocardiogram
EMA: European Medicines Agency
eNOS: endothelial NOS
FFA: free fatty acid
GI: gastrointestinal
Gp: glycoprotein
GTN: glyceryl trinitrate (nitroglycerin)
HCM: hypertrophic cardiomyopathy
HCN: hyperpolarization-activated cyclic nucleotide–gated
HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A
iNOS: inducible NOS
IP_3: inositol 1,4,5-trisphosphate
ISDN: isosorbide dinitrate
ISMN: isosorbide-5-mononitrate
LDL: low-density lipoprotein
MI: myocardial infarction
NET: neutrophil extracellular trap
nNOS: neuronal NOS
NO: nitric oxide
NOS: nitric oxide synthase
PAD: peripheral arterial disease
PDE: cyclic nucleotide phosphodiesterase
Pgp: P-glycoprotein
PLC: phospholipase C
rTPA: recombinant tissue plasminogen activator
SA: sinoatrial
STEMI: ST-segment elevation myocardial infarction
TxA_2: thromboxane A_2

Pathophysiology of Myocardial Ischemia

Myocardial ischemia leads to angina pectoris—chest pain behind the sternum, which, in the sense of the term, means a "strangling feeling in the chest." Myocardial ischemia is due to an imbalance in the myocardial oxygen supply-demand relationship. This imbalance may be caused by an increase in myocardial oxygen demand (which is determined by heart rate, ventricular contractility, and ventricular wall tension) or by a decrease in myocardial oxygen supply (primarily determined by coronary blood flow, but occasionally modified by the oxygen-carrying capacity of the blood), or sometimes by both (Figure 31–1). Because blood flow is proportional to the fourth power of the artery's luminal radius, the progressive decrease in vessel radius that characterizes coronary atherosclerosis can impair coronary blood flow and lead to symptoms of angina when myocardial O_2 demand increases, as with exertion (the so-called typical and most prevalent form of angina pectoris). In some patients, anginal symptoms may occur without any increase in myocardial O_2 demand, but rather as a consequence of an abrupt reduction in blood flow, as might result from coronary thrombosis (unstable angina or ACS) or localized vasospasm (variant or Prinzmetal angina). Regardless of the precipitating factors, the sensation of angina is similar in most patients. Typical angina is experienced as a heavy, pressing substernal discomfort (rarely described as a "pain"), often radiating to the left shoulder, flexor aspect of the left arm, jaw, or epigastrium. However, a significant minority of patients note discomfort in a different location or of a different character. Women, the elderly, and diabetics are more likely to experience myocardial ischemia with atypical symptoms. In most patients with typical angina, whose symptoms are provoked by exertion, the symptoms are relieved by rest or by administration of sublingual *nitroglycerin*.

Angina pectoris is a common symptom, affecting 8 million Americans (Mozaffarian et al., 2015). Angina pectoris may occur in a stable pattern over many years or may become unstable, increasing in frequency or severity and even occurring at rest. In typical stable angina, the pathological substrate is usually fixed atherosclerotic narrowing of an epicardial coronary artery, on which exertion or emotional stress superimposes an increase in myocardial O_2 demand. In variant angina, focal or diffuse coronary vasospasm episodically reduces coronary flow. Patients also may display a mixed pattern of angina with the addition of altered vessel tone on a background of atherosclerotic narrowing. In most patients with unstable angina, a local platelet deposition at an atherosclerotic plaque decreases coronary blood flow. As outlined above, this can occur as a result of a ruptured ("vulnerable") plaque or plaque erosion. Superimposed thrombosis may lead to the complete abrogation of blood flow.

Myocardial ischemia also may be *silent*, with electrocardiographic, echocardiographic, or radionuclide evidence of ischemia appearing in the absence of symptoms. While some patients have only silent ischemia, most patients who have silent ischemia have symptomatic episodes as well. The precipitants of silent ischemia appear to be the same as those of symptomatic ischemia. The *ischemic burden* (i.e., the total time a patient is ischemic each day) is greater in many patients than was recognized previously. In most trials, the agents that are efficacious in typical angina also are efficacious in reducing silent ischemia. β Blockers appear to be more

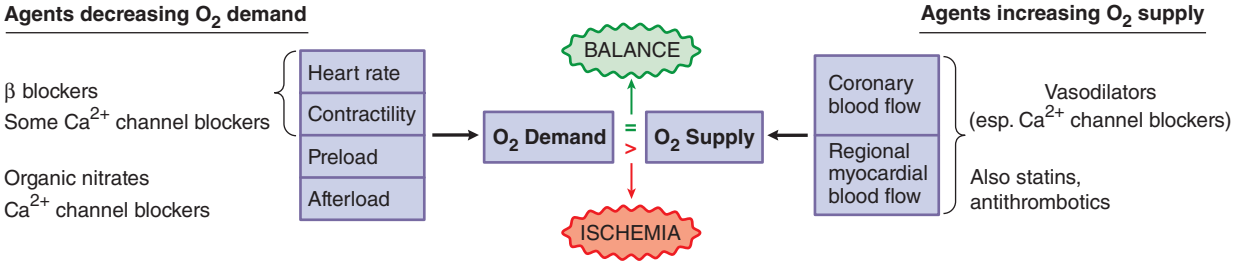

Figure 31–1 *Pharmacological modification of the major determinants of myocardial O_2 supply.* When myocardial O_2 requirements exceed O_2 supply, an ischemic episode results. This figure shows the primary hemodynamic sites of action of pharmacological agents that can reduce O_2 demand (left side) or enhance O_2 supply (right side). Some classes of agents have multiple effects. Stents, angioplasty, and coronary bypass surgery are mechanical interventions that increase O_2 supply. Both pharmacotherapy and mechanotherapy attempt to restore a dynamic balance between O_2 demand and O_2 supply.

effective than the Ca^{2+} channel blockers in the prevention of episodes. Therapy directed at abolishing all silent ischemia has not been shown to be of additional benefit over conventional therapy.

Pharmacotherapy of Ischemic Heart Disease

The principal pharmacological agents used in the treatment of angina are nitrovasodilators, β blockers (see Chapter 14), and Ca^{2+} channel blockers. In patients with typical exercise-induced angina due to CAD, these antianginal agents improve the balance of myocardial O_2 supply and O_2 demand principally by reducing myocardial O_2 demand: by decreasing heart rate, myocardial contractility, or ventricular wall stress. Increased O_2 supply by dilating the coronary vasculature may play an additional role and is the major effect of nitrovasodilators and Ca^{2+} channel blockers in variant angina.

By contrast, the principal therapeutic goal in ACSs with unstable angina is to prevent or reduce thrombus formation and increase myocardial blood flow; strategies include the use of antiplatelet agents and *heparin*, often accompanied by efforts to restore flow by mechanical means, including percutaneous coronary interventions using coronary stents, or (less commonly) emergency coronary bypass surgery. The principal therapeutic aim in variant or Prinzmetal angina is to prevent coronary vasospasm.

Antianginal agents may provide prophylactic or symptomatic treatment, but β blockers also reduce mortality, apparently by decreasing the incidence of sudden cardiac death associated with myocardial ischemia and infarction. The chronic use of organic nitrate vasodilators, which are highly efficacious in treatment of angina, is not associated with improvements in cardiac mortality, and some investigators have suggested that chronic use of *nitroglycerin* may have adverse cardiovascular effects (Parker, 2004).

Besides symptomatic relief from angina pain conferred by antianginal drugs, patients with CAD should be treated with drugs that can reduce the progression of atherosclerosis and reduce the risk of coronary thrombosis and MI. *Aspirin* is used routinely in patients with myocardial ischemia, and daily *aspirin* at low doses reduces the incidence of clinical events (Fihn et al., 2012). The optimal recommended dose is 75 to 100 mg/d (Collet et al., 2020). Oral ADP receptor antagonists such as *clopidogrel* are recommended as an alternative in patients with *aspirin* intolerance but should not routinely be used in addition to *aspirin* in patients with stable disease because of an unfavorable risk-benefit ratio (Fihn et al., 2012). However, recent guidelines recommend dual platelet inhibition in patients with high ischemic risk and without high bleeding risk (Collet et al., 2020). Dual platelet inhibition is routinely given in patients who underwent coronary artery stenting. The recommended time (generally 12 months) varies depending on the intervention (e.g., bare metal vs. drug-eluting stent) and the risk profile of patients. The newer ADP receptor antagonists *prasugrel* and *ticagrelor* have a more useful pharmacokinetic profile and seem to have a better benefit/risk ratio than clopidogrel in the postintervention treatment phase (Cannon et al., 2010; Wiviott et al., 2007) but are not generally recommended as alternatives to *clopidogrel* in patients with stable CAD. Concomitant treatment with a proton pump inhibitor is recommended in patients receiving single or dual antiplatelet therapy with a high risk of gastrointestinal bleeding (e.g., age >75; Knuuti et al., 2020; Li et al., 2017). Statins reduce mortality in patients with CAD. Although high-risk patients (including those with high plasma low-density lipoprotein (LDL) cholesterol levels) have the greatest absolute benefit, the relative risk reduction of approximately 25% appears largely independent of baseline cholesterol blood levels. Statins should therefore be given to all patients with CAD. Combination with *ezetimibe* or a PCSK9 inhibitor (antibody) should be considered in patients who are not reaching their LDL cholesterol goal with statins or statins plus *ezetimibe*, respectively, and are at very high ischemic risk (Knuuti et al., 2020). It is unclear whether angiotensin-converting enzyme (ACE) inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) (see Chapter 30) reduce mortality or other end points in patients with CAD when given routinely in addition to *aspirin*, statins, and β blockers, but they are recommended for subgroups of patients with CAD with reduced left ventricular systolic function, hypertension, diabetes, or chronic kidney disease (Collet et al., 2020).

Coronary artery bypass surgery and percutaneous coronary interventions such as angioplasty and coronary artery stent deployment commonly complement pharmacological treatment. In some subsets of patients, percutaneous or surgical revascularization may have a survival advantage over medical treatment alone (Kappetein et al., 2011). However, a large, randomized trial in patients with stable CAD and signs of recurrent ischemia failed to provide evidence for superiority of an early invasive strategy (Maron et al., 2020). Intracoronary drug delivery using drug-eluting coronary stents represents an intersection of mechanical and pharmacological approaches in the treatment of CAD.

Organic Nitrates

The organic nitrate agents are prodrugs that are sources of NO. NO activates the soluble isoform of guanylyl cyclase, thereby increasing intracellular levels of cGMP. In turn, cGMP promotes the dephosphorylation of the myosin light chain and the reduction of cytosolic Ca^{2+} and leads to the relaxation of smooth muscle cells in a broad range of tissues (see Figures 3–13, 3–17, and 48–7). The NO-dependent relaxation of vascular smooth muscle leads to vasodilation; NO-mediated guanylyl cyclase activation also inhibits platelet aggregation and relaxes smooth muscle in the bronchi and gastrointestinal (GI) tract.

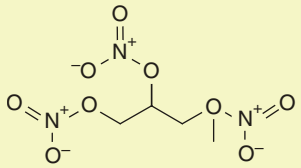
The broad biological response to nitrovasodilators reflects the existence of endogenous NO-modulated regulatory pathways. The endogenous synthesis of NO in humans is catalyzed by a family of nitric oxide synthases (NOSs) that oxidize the amino acid L-arginine to form NO, plus L-citrulline as a coproduct. There are three distinct mammalian NOS isoforms: *neuronal NOS (nNOS), endothelial NOS (eNOS),* and *inducible NOS (iNOS)* (see Chapter 3), and they are involved in processes as diverse as neurotransmission, vasomotion, and immunomodulation. In several vascular disease states, pathways of endogenous NO-dependent regulation appear to be deranged (Dudzinski et al., 2006).

HISTORICAL PERSPECTIVE

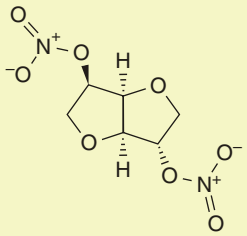
Nitroglycerin was first synthesized in 1846 by Sobrero, who observed that a small quantity placed on the tongue elicited a severe headache. The explosive properties of *nitroglycerin* also were soon noted, and control of this unstable compound for military and industrial use was not realized until Alfred Nobel devised a process to stabilize the *nitroglycerin* and patented a specialized detonator in 1863. The vast fortune that Nobel accrued from the *nitroglycerin* detonator patent provided the funds later used to establish the Nobel prizes. In 1857, T. Lauder Brunton of Edinburgh (no relation to the editor of this volume) administered *amyl nitrite*, a known vasodepressor, by inhalation and noted that anginal pain was relieved within 30 to 60 sec. The action of *amyl nitrite* was transitory, however, and the dosage was difficult to adjust. Subsequently, William Murrell surmised that the action of *nitroglycerin* mimicked that of *amyl nitrite* and established the use of sublingual *nitroglycerin* for relief of the acute anginal attack and as a prophylactic agent to be taken prior to exertion. The empirical observation that organic nitrates could dramatically and safely alleviate the symptoms of angina pectoris led to their widespread acceptance by the medical profession. Indeed, Alfred Nobel himself was prescribed *nitroglycerin* by his physicians when he developed angina in 1890. Basic investigations defined the role of NO in both the vasodilation produced by nitrates and endogenous vasodilation. The importance of NO as a signaling molecule in the cardiovascular system and elsewhere was recognized by the awarding of the 1998 Nobel Prize in Medicine/Physiology to the pharmacologists Robert Furchgott, Louis Ignarro, and Ferid Murad.

TABLE 31–1 ■ ORGANIC NITRATES AVAILABLE FOR CLINICAL USE

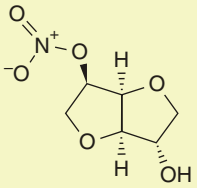
AGENT	PREPARATIONS, DOSES, ADMINISTRATION[a]	
Nitroglycerin (glyceryl trinitrate)	T: 0.3–0.6 mg as needed	O: 2.5–5 cm, topically every 4–8 h
	S: 0.4 mg per spray as needed	D: 1 disk (2.5–15 mg) for 12–16 h/d
	C: 2.5–9 mg 2–4 times daily	IV: 10–20 μg/min; ↑ 10 μg/min to max of 400 μg/min
	B: 1 mg every 3–5 h	
Isosorbide dinitrate	T: 2.5–10 mg every 2–3 h	T(O): 5–40 mg every 8 h
	T(C): 5–10 mg every 2–3 h	C: 40–80 mg every 12 h
Isosorbide-5-mononitrate	T: 10–40 mg twice daily	C: 60–120 mg daily



Nitroglycerin (glyceryl trinitrate, GTN)



Isosorbide dinitrate (ISDN)



Isosorbide-5-mononitrate (ISMN)

[a]B, buccal (transmucosal) tablet; C, sustained-release capsule or tablet; D, transdermal disk or patch; IV, intravenous injection; O, ointment; S, lingual spray; T, tablet for sublingual use; T(C), chewable tablet; T(O), oral tablet or capsule.

Chemistry

Organic nitrates are polyol esters of nitric acid, whereas organic nitrites are esters of nitrous acid (Table 31–1). Nitrate esters (—C—O—NO_2) and nitrite esters (—C—O—NO) are characterized by a sequence of carbon-oxygen-nitrogen, whereas nitro compounds possess carbon-nitrogen bonds (C—NO_2). Thus, glyceryl trinitrate (GTN; *nitroglycerin*) is not a nitro compound, and it is erroneously called *nitroglycerin*; however, this nomenclature is both widespread and official. Amyl nitrite is a highly volatile liquid that must be administered by inhalation and is of limited therapeutic utility. Organic nitrates of low molecular mass (such as GTN) are moderately volatile, oily liquids, whereas the high-molecular-mass nitrate esters (e.g., erythrityl tetranitrate, isosorbide dinitrate (ISDN), and isosorbide mononitrate) are solids. In the pure form (without an inert carrier such as lactose), *nitroglycerin* is explosive. The organic nitrates and nitrites, collectively termed *nitrovasodilators*, must be metabolized (reduced) to produce gaseous NO, which appears to be the active principle of this class of compounds. NO gas also can be directly administered by inhalation.

Pharmacological Properties

Mechanism of Action. Nitrites, organic nitrates, nitroso compounds, and a variety of other nitrogen oxide–containing substances (including *nitroprusside*; see further in the chapter) lead to the formation of the reactive gaseous free radical NO and related NO-containing compounds. NO gas also may be administered by inhalation. Surprisingly, more than 140 years after its introduction in the therapy of angina pectoris, the mode of action of organic nitrates is still incompletely understood (Mayer and Beretta, 2008). Established mechanisms of GTN bioactivation and action include a nonenzymatic reaction with L-cysteine, formation of nitrite and NO by ALDH2 (mitochondrial aldehyde dehydrogenase) (Chen et al., 2002), activation of soluble guanylyl cyclase, and generation of cGMP. The bioactivation of other nitrovasodilators such as ISDN and isosorbide-5-mononitrate (ISMN) is ALDH2 independent, suggesting the involvement of other enzymes, such as cytochrome P450s (CYPs), xanthine oxidoreductase, and cytosolic ALDH isoforms (Munzel et al., 2014). The action of NO on soluble guanylyl cyclase seems to be elicited in substantial part by S-nitrosothiol. The different ALDH2 dependence of GTN and ISDN is clinically relevant because individuals of Asian origin carry an inactive ALDH2 variant and do not respond adequately to GTN but do respond to ISDN (Stamler, 2008).

The NO-stimulated elevation of cGMP activates protein kinase G and modulates the activities of cyclic nucleotide PDEs (PDEs 2, 3, and 5) in a variety of cell types. In smooth muscle, the net result is reduced phosphorylation of myosin light chain, reduced Ca^{2+} concentration in the cytosol, and relaxation (see Figure 48–7). Reduced phosphorylation of myosin light chain is the result of decreased myosin light-chain kinase activity and increased myosin light-chain phosphatase activity and promotes vasorelaxation and smooth muscle relaxation in many tissues. cGMP is a substrate for PDE5, whose inhibition by *sildenafil* and related compounds potentiates the action of nitrovasodilators (see *Toxicity and Untoward Responses*).

Hemodynamic Effects. The nitrovasodilators promote relaxation of vascular smooth muscle. For reasons not understood, GTN dilates large blood vessels (>200-μm diameter) more potently than small vessels, explaining why low doses of GTN preferentially dilate veins and conductance arteries and leave the tone of the small-to-medium arterioles (that regulate resistance) unaffected. This profile has important consequences for the antianginal efficacy of nitrovasodilators. At low-to-medium doses, preferential venodilation decreases venous return, leading to a fall in left and right ventricular chamber size and end-diastolic pressures, reduced wall stress, and thereby reduced cardiac O_2 demand (see discussion that follows). Systemic vascular resistance and arterial pressure are not or only mildly decreased, leaving coronary perfusion pressure unaffected. Heart rate remains unchanged or may increase slightly in response to a decrease in blood pressure. Pulmonary vascular resistance and cardiac output are slightly reduced. Doses of GTN that do not alter systemic arterial pressure may still produce arteriolar dilation in the face and neck, resulting in a facial flush, or dilation of meningeal arterial vessels, causing headache.

Higher doses of organic nitrates cause further venous pooling and may decrease arteriolar resistance as well, thereby decreasing systolic and diastolic blood pressure and causing pallor, weakness, dizziness, and activation of compensatory sympathetic reflexes. This can happen to such an extent that coronary flow is compromised, and the sympathetic increase in myocardial O_2 demand overrides the beneficial action of the nitrovasodilators, leading to ischemia. In addition, sublingual *nitroglycerin* administration may produce bradycardia and hypotension, probably owing to activation of the Bezold-Jarisch reflex.

In patients with autonomic dysfunction and an inability to increase sympathetic outflow (multiple-system atrophy and pure autonomic failure are the most common forms, much less commonly seen in the autonomic dysfunction associated with diabetes), the fall in blood pressure consequent to the venodilation produced by nitrates cannot be compensated. In these clinical contexts, nitrates may reduce arterial pressure and coronary perfusion pressure significantly, producing potentially life-threatening hypotension (nitrate syncopy) and even aggravating angina.

ADME. As outlined previously, nitrovasodilators differ in their dependence on ALDH2 for bioactivation (note ALDH2 deficiency in many Asians). In addition, their pharmacokinetic profiles exhibit therapeutically relevant differences in sublingual resorption, onset of action, and half-life (Table 31–1).

Nitroglycerin. Peak concentrations of GTN are found in plasma within 4 min of sublingual administration; the drug has a $t_{1/2}$ of 1 to 3 min. The onset of action of GTN may be even more rapid if delivered as a sublingual spray rather than as a sublingual tablet. Glyceryl dinitrate metabolites, which have about one-tenth the vasodilator potency, appear to have half-lives of about 40 min.

Isosorbide Dinitrate. Sublingual administration of ISDN produces maximal plasma concentrations of the drug by 6 min, and the fall in concentration is rapid ($t_{1/2}$ of about 45 min). The primary initial metabolites, isosorbide-2-mononitrate and ISMN, have longer half-lives (3–6 h) and are presumed to contribute to the therapeutic efficacy of the drug. ISDN is therefore suitable both for standby and sustained therapy.

Isosorbide-5-Mononitrate. This agent is available in tablet form. ISMN does not undergo significant first-pass metabolism, so it has high bioavailability after oral administration, but its onset of action is too slow for acute treatment of angina.

Inhaled NO. Nitric oxide gas administered by inhalation appears to exert most of its therapeutic effects on the pulmonary vasculature because of the rapid inactivation of NO by hemoglobin in the blood. It is approved for the treatment of pulmonary hypertension in hypoxemic neonates, in whom it has reduced morbidity and mortality (Bloch et al., 2007).

Mechanisms of Antianginal Efficacy of Organic Nitrates

When GTN is injected directly into the coronary circulation of patients with CAD, anginal attacks (induced by electrical pacing) are not aborted even when coronary blood flow is increased. In contrast, sublingual administration of GTN does relieve anginal pain in the same patients, indicating that the major antianginal effect of nitrovasodilators is mediated by preload reduction rather than coronary artery dilation.

This interpretation is supported by studies in exercising patients showing that angina occurs at the same value of the *triple product* (Aortic pressure × Heart rate × Ejection time, which is roughly proportional to myocardial consumption of O_2) with or without *nitroglycerin*. Thus, the beneficial effect of *nitroglycerin* has to result from reduced cardiac O_2 demand rather than an increase in the delivery of O_2 to ischemic regions of myocardium. However, these results do not preclude the possibility that a favorable redistribution of blood flow to ischemic subendocardial myocardium may contribute to relief of pain in a typical anginal attack, and they do not preclude the possibility that direct coronary vasodilation may be the major effect of *nitroglycerin* in situations where vasospasm compromises myocardial blood flow.

Effects on Myocardial O_2 Requirements. The major determinants of myocardial O_2 consumption are left ventricular wall tension, heart rate, and myocardial contractility (Figure 31–1). Ventricular wall tension is affected by preload and afterload. *Preload* is determined by the diastolic pressure that distends the ventricle (ventricular end-diastolic pressure). Increasing end-diastolic volume augments the ventricular wall tension (by the law of Laplace, tension is proportional to pressure times radius). Increasing venous capacitance with nitrates decreases venous return to the heart, decreases ventricular end-diastolic volume, and thereby decreases O_2 consumption. An additional benefit of reducing preload is that it increases the pressure gradient for perfusion across the ventricular wall, which favors subendocardial perfusion. *Afterload* is the impedance against which the ventricle must eject. In the absence of aortic valvular disease, afterload is related to peripheral resistance. Decreasing peripheral arteriolar resistance reduces afterload and thus myocardial work and O_2 consumption. The nitrate-induced increase in distensibility of the large conductance arteries such as the aorta may play an additional role.

Nitrovasodilators preferentially decrease preload by dilating venous capacitance vessels. The decrease in afterload is generally small and mainly observed at higher doses. The effect on aortic stiffness appears complex (Soma et al., 2000). NO and nitrovasodilators can directly modulate the inotropic or chronotropic state of the heart via cGMP and its stimulatory effect on PDE2 (thereby reducing cAMP) or an inhibitory effect on the cAMP-specific PDE3 (thereby increasing cAMP). An inotropic response depends on the extent to which the cyclic nucleotide phosphodiesterase (PDE) isoforms are expressed in the appropriate cells and in the proper subcellular compartment (Steinberg and Brunton, 2001). Small NO concentrations favor a positive inotropic effect (Kojda et al., 1997); however, the effect size is small and its significance unclear. Because nitrates affect several of the primary determinants of myocardial O_2 demand, their net effect usually is to decrease myocardial O_2 consumption. In addition, an improvement in the lusitropic state of the heart may be seen with more rapid early diastolic filling. This may be secondary to the relief of ischemia rather than primary, or it may be due to a reflex increase in sympathetic activity. Nitrovasodilators also increase cGMP in platelets, with consequent inhibition of platelet function. While this may contribute to their antianginal efficacy, the effect appears to be modest. Earlier evidence for a negative interaction of nitrates with *heparin* were not reproduced in larger studies in patients (Koh et al., 1995).

Effects on Total and Regional Coronary Blood Flow. When considering the effect of vasodilators in the ischemic heart, it is important to realize that myocardial ischemia itself is a powerful stimulus to coronary vasodilation and part of an autoregulatory mechanism. In the presence of atherosclerotic coronary artery narrowing, ischemia distal to the lesion stimulates vasodilation of downstream resistance arterioles and thereby helps maintain adequate perfusion of the ischemic area under rest. If the stenosis is severe, much of the capacity to dilate is used to maintain resting blood flow. Further dilation may not be possible, neither under exercise nor with therapeutically applied vasodilators. In contrast, nonselective vasodilators such as adenosine or dipyridamole (which inhibits adenosine transmembrane transport and thereby increases extracellular concentrations) can worsen the perfusion of ischemic areas by dilating the relatively constricted arterioles of the healthy myocardium, leading to redistribution of blood flow away from the ischemic myocardium ("steal phenomenon"). Accordingly, dipyridamole is not used therapeutically but can be used as a stress test to provoke angina pectoris (Bodi et al., 2007). The same mechanism probably explains the potential of dihydropyridines with a fast onset of action such as nifedipine to provoke angina pectoris.

Nitrovasodilators, in contrast, do not have a major effect on the smaller resistance arteries (and therefore do not cause steal phenomena) but can dilate the large, epicardial sections of the coronary arteries upstream of a stenosis and also in a stenosis (concept of the "dynamic stenosis"; Brown et al., 1981) and thereby increase blood flow distal to the narrowing. Collateral flow to ischemic regions also is increased. As outlined previously, GTN also reduces wall stress that opposes blood flow to the subendocardium, which is particularly sensitive to ischemia.

In patients with angina owing to coronary artery spasm, the capacity of nitrovasodilators to dilate epicardial coronary arteries, particularly regions affected by spasm, is the primary mechanism of their beneficial effect.

Other Effects. The nitrovasodilators also relax smooth muscles of the bronchial tract, the gallbladder, biliary ducts, and sphincter of Oddi and the GI tract. Spontaneous motility is decreased by nitrates both *in vivo* and *in vitro*. The effect may be transient and incomplete *in vivo*, but abnormal "spasm" frequently is reduced. Indeed, many incidences of atypical chest pain and "angina" are due to biliary or esophageal spasm, and these also can be relieved by nitrates. Nitrates can also relax ureteral

and uterine smooth muscle, but these responses are of uncertain clinical significance.

Tolerance

Frequently repeated or continuous exposure to high doses of nitrovasodilators leads to tolerance, that is, marked attenuation in the magnitude of most of their pharmacological effects. The magnitude of tolerance is a function of dosage and frequency of use. Tolerance may result from a reduced capacity of the vascular smooth muscle to convert *nitroglycerin* to NO, *true vascular tolerance*, or to the activation of mechanisms extraneous to the vessel wall, *pseudotolerance* (Munzel et al., 1995). Multiple mechanisms have been proposed to account for nitrate tolerance, including volume expansion, neurohumoral activation, cellular depletion of sulfhydryl groups, and the generation of free radicals (Parker and Parker, 1998). A reactive intermediate formed during the generation of NO from organic nitrates may itself damage and inactivate the enzymes of the activation pathway (Munzel et al., 1995; Parker, 2004). Inactivation of ALDH2 (Sydow et al., 2004) and S-nitrosylation of soluble guanylyl cyclase (Sayed et al., 2008) are seen in models of nitrate tolerance and could explain cross-tolerance to different (nitro)vasodilators. Other changes observed in the setting of *nitroglycerin* tolerance include an enhanced response to vasoconstrictors such as angiotensin II, serotonin, and phenylephrine. Prolonged administration of GTN is associated with plasma volume expansion, which may be reflected by a decrease in hematocrit. Unfortunately, attempts to prevent nitrate tolerance based on these mechanisms (e.g., antioxidants, coapplication of vasodilators or diuretics) failed in clinical trials.

A clinically important lesson of research on nitrate tolerance is that prolonged treatment with nitrates may not only induce a loss of response to nitrates, but also actually increase the risk of angina in the interval (Parker et al., 1995). A special form of GTN tolerance is observed in individuals exposed to GTN in the manufacture of explosives. If protection is inadequate, workers may experience severe headaches, dizziness, and postural weakness during the first several days of employment ("Monday disease"). Tolerance then develops and can lead to organic nitrate dependence. Workers without demonstrable organic vascular disease have been reported to have an increase in the incidence of ACSs during the 24- to 72-h periods away from the work environment. It seems prudent not to withdraw nitrates abruptly from a patient who has received such therapy chronically.

Therapy should be designed to prevent tolerance. High doses should be avoided and therapy interrupted for 8 to 12 h daily, which allows the return of efficacy. In patients with exertional angina, it is usually most convenient to omit dosing at night either by adjusting dosing intervals of oral or buccal preparations or by removing cutaneous GTN. Patients whose anginal pattern suggests its precipitation by increased left ventricular filling pressures (e.g., in association with orthopnea or paroxysmal nocturnal dyspnea) may benefit from continuing nitrates at night and omitting them during a quiet period of the day. Some patients develop an increased frequency of nocturnal angina when a nitrate-free interval is employed using GTN patches; such patients may require another class of antianginal agent during this period. Continuous intravenous administration of GTN regularly induces tolerance and should therefore be avoided. Tolerance also has been seen with ISMN and ISDN; an eccentric twice-daily dosing schedule appears to maintain efficacy (Parker and Parker, 1998). *Molsidomine*, a direct NO donor, is approved in many European countries and is claimed to induce less tolerance than the organic nitrates, but the supporting evidence is weak. A clinical study failed to demonstrate beneficial effects of *molsidomine* on endothelial dysfunction (Barbato et al., 2015).

Toxicity and Untoward Responses

Untoward responses to the therapeutic use of organic nitrates are almost all secondary to actions on the cardiovascular system. Headache is common and can be severe, usually decreasing over a few days if treatment is continued and often controlled by decreasing the dose. Transient episodes of dizziness, weakness, and other manifestations associated with postural hypotension may develop, particularly if the patient is standing immobile, and may progress occasionally to loss of consciousness, a reaction that appears to be accentuated by alcohol. It also may be seen with very low doses of nitrates in patients with autonomic dysfunction. Even in severe nitrate syncope, positioning and other measures that facilitate venous return are the only therapeutic measures required. All the organic nitrates occasionally can produce drug rash.

Interaction of Nitrates With PDE5 Inhibitors. Erectile dysfunction is a frequently encountered problem whose risk factors parallel those of CAD. Thus, many men desiring therapy for erectile dysfunction already may be receiving (or may require, especially if they increase physical activity) antianginal therapy. The combination of sildenafil and other PDE5 inhibitors with organic nitrate vasodilators can cause extreme hypotension.

Cells in the corpus cavernosum produce NO during sexual arousal in response to nonadrenergic, noncholinergic neurotransmission (Burnett et al., 1992). NO stimulates the formation of cGMP, which leads to relaxation of smooth muscle of penile arteries that fill the corpus cavernosum, leading to engorgement of the corpus cavernosum and erection. The accumulation of cGMP is enhanced by inhibition of the cGMP-specific PDE5 family. *Sildenafil* and congeners inhibit PDE5 and have been demonstrated to improve erectile function in patients with erectile dysfunction. Not surprisingly, PDE5 inhibitors have assumed the status of widely used recreational drugs. *Sildenafil* is also FDA and European Medicines Agency (EMA) approved in patients with pulmonary arterial hypertension in whom the drug decreased pulmonary vascular resistance and enhanced exercise capacity. PDE5 inhibitors also are being studied in patients with congestive heart failure, but a large trial in patients with preserved ejection fraction failed (Redfield et al., 2013; Chapter 33). *Tadalafil* and *vardenafil* share similar therapeutic efficacy and side effect profiles with *sildenafil*; *tadalafil* has a longer time to onset of action and a longer therapeutic $t_{1/2}$ than the other PDE5 inhibitors (see Table 49–2). *Sildenafil* has been the most thoroughly characterized of these compounds, but all three PDE5 inhibitors are contraindicated for patients taking organic nitrate vasodilators, and the PDE5 inhibitors should be used with caution in patients taking α or β blockers (see Chapter 14).

The side effects of *sildenafil* and other PDE5 inhibitors are largely predictable based on their effects on PDE5. Headache, flushing, and rhinitis may be observed, as well as dyspepsia owing to relaxation of the lower esophageal sphincter. *Sildenafil* and *vardenafil* also weakly inhibit PDE6, the enzyme involved in photoreceptor signal transduction (see Figure 74–9), and can produce visual disturbances, most notably changes in the perception of color hue or brightness. In addition to visual disturbances, sudden one-sided hearing loss has also been reported. *Tadalafil* inhibits PDE11, a widely distributed PDE isoform, but the clinical importance of this effect is not clear. The most important toxicity of all these PDE5 inhibitors is hemodynamic. When given alone to men with severe CAD, these drugs induce only a modest (<10%) decrease of blood pressure (Herrmann et al., 2000). However, PDE5 inhibitors and nitrates act synergistically to cause profound increases in cGMP and dramatic reductions in blood pressure (>25 mm Hg). *PDE5 inhibitors should therefore not be prescribed to patients receiving any form of nitrate* (Cheitlin et al., 1999); in prescribing nitrates, the physician should warn the patient that PDE5 inhibitors and nitrates must not be used concurrently and that no PDE5 inhibitor should be used in the 24 h prior to initiating nitrate therapy. A period of longer than 24 h may be needed following administration of a PDE5 inhibitor for safe use of nitrates, especially with *tadalafil*, due to its prolonged $t_{1/2}$. If patients develop significant hypotension following combined administration of *sildenafil* and a nitrate, fluids and α adrenergic receptor agonists may be used for support.

Sildenafil, *tadalafil*, and *vardenafil* are metabolized via CYP3A4, and their toxicity may be enhanced in patients who receive inhibitors of this enzyme, including macrolide and imidazole antibiotics, and antiretroviral agents (see individual chapters and Chapter 7). PDE5 inhibitors also may prolong cardiac repolarization by blocking the I_{Kr}. Although these interactions and effects are important clinically, the overall incidence and profile of adverse events observed with PDE5 inhibitors, when used

without nitrates, are consistent with the expected background frequency of the same events in the treated population. In patients with CAD whose exercise capacity indicates that sexual activity is unlikely to precipitate angina and who are not currently taking nitrates, the use of PDE5 inhibitors can be considered.

Therapeutic Uses

Stable Angina Pectoris. Diseases that predispose to CAD and angina should be treated as part of a comprehensive therapeutic program with the primary goal being to prolong life. Conditions such as hypertension, anemia, thyrotoxicosis, obesity, heart failure, cardiac arrhythmias, and acute emotional stress can precipitate anginal symptoms in many patients. Patients should be counseled to stop smoking, lose weight, and maintain a low-fat, high-fiber diet; hypertension and hyperlipidemia should be corrected; and daily *aspirin* (or *clopidogrel* if *aspirin* is not tolerated) and statins (see Chapter 37) should be prescribed. Exposure to sympathomimetic agents (e.g., those in nasal decongestants and other sources) and serotonin receptor agonists used in the treatment of migraine (*sumatriptan* and similar) should be avoided. The use of drugs that modify the perception of pain is a poor approach to the treatment of angina because the underlying myocardial ischemia is not relieved.

Table 31–1 lists the preparations and dosages of the nitrites and organic nitrates. The rapidity of onset, the duration of action, and the likelihood of developing tolerance are related to the method of administration.

Short-Acting Nitrates for Standby Therapy. GTN is the most used drug for the rapid release of angina and can be applied as tablets, capsules, sublingual powder, spray, and aerosol. The onset of action is within 1 to 2 min (fastest with the spray), and the effects are undetectable by 1 h after administration. An initial dose of 0.3 mg GTN often relieves pain within 3 min. ISDN, but not ISMN, is an alternative to GTN. It has a slower onset of action (3–4 min) but a longer duration (>1 h). Anginal pain may be prevented when the drugs are used prophylactically immediately prior to exercise or stress. The smallest effective dose should be prescribed. Patients should be instructed to seek medical attention immediately if three tablets of GTN taken over a 15-min period do not relieve a sustained attack because this situation may be indicative of MI, unstable angina, or another cause of the pain.

Longer-Acting Nitrates for the Prophylaxis of Angina. Nitrates can also be used to provide prophylaxis against anginal episodes in patients who have more than occasional angina. However, such patients should be offered revascularizing therapy. Moreover, chronic treatment with nitrates is not associated with a prognostic benefit and may induce tolerance and endothelial dysfunction as discussed previously. Nitrates must therefore be considered a second choice compared to β blockers. Sustained-release oral preparations of ISDN, ISMN, and GTN are available. Sustained-release ISDN and ISMN are typically given in two doses administered 6 to 7 h apart, followed by a nitrate-free interval of at least 8 h.

Variant (Prinzmetal) Angina. The large coronary arteries normally contribute little to coronary resistance. However, in variant angina, coronary constriction results in reduced blood flow and ischemic pain. Multiple mechanisms have been proposed to initiate vasospasm, including endothelial cell injury. Whereas long-acting nitrates alone are occasionally efficacious in abolishing episodes of variant angina, additional therapy with Ca^{2+} channel blockers usually is required. Ca^{2+} channel blockers, but not nitrates, have been shown to influence mortality and the incidence of MI favorably in variant angina; they should generally be included in therapy.

Congestive Heart Failure. The utility of nitrovasodilators to relieve pulmonary congestion and to increase cardiac output in congestive heart failure is addressed in Chapter 33.

Unstable Angina Pectoris (Acute Coronary Syndromes [ACS], see discussion that follows). Resistance to nitrates classifies angina symptoms as "unstable" and is a characteristic feature of ACSs, typically caused by transient or permanent thrombotic occlusion of coronary vessels. Nitrates do not modify this process specifically and are second-line drugs.

Ca^{2+} Channel Blockers

Voltage-gated Ca^{2+} channels (L-type or slow channels) mediate the entry of extracellular Ca^{2+} into smooth muscle and cardiac myocytes and sinoatrial (SA) and atrioventricular (AV) nodal cells in response to electrical depolarization. In both smooth muscle and cardiac myocytes, Ca^{2+} is a trigger for contraction, albeit by different mechanisms. Ca^{2+} channel antagonists, also called *Ca^{2+} entry blockers* or *Ca^{2+} channel blockers*, inhibit Ca^{2+} influx. In vascular smooth muscle, this leads to relaxation, especially in arterial beds, in cardiac myocytes to negative inotropic effects. All Ca^{2+} channel blockers exert these two principal actions, but the ratio differs according to the class, as does the presence of chronotropic and dromotropic effects.

HISTORICAL PERSPECTIVE

The work in the 1960s of Fleckenstein and colleagues led to the concept that drugs can alter cardiac and smooth muscle contraction by blocking the entry of Ca^{2+} into myocytes (Fleckenstein et al., 1969). Godfraind and associates showed that the effect of the diphenylpiperazine analogues in preventing agonist-induced vascular smooth muscle contraction could be overcome by raising the concentration of Ca^{2+} in the extracellular medium (Godfraind et al., 1986). Hass and Hartfelder reported in 1962 that *verapamil*, a coronary vasodilator, possessed negative inotropic and chronotropic effects that were not seen with other vasodilatory agents, such as GTN. In 1967, Fleckenstein suggested that the negative inotropic effect resulted from inhibition of excitation-contraction coupling and that the mechanism involved reduced movement of Ca^{2+} into cardiac myocytes. *Verapamil* was the first clinically available Ca^{2+} channel blocker; it is a congener of *papaverine*. Many other Ca^{2+} entry blockers with a wide range of structures are now available.

Chemistry

The multiple Ca^{2+} channel blockers that are approved for clinical use have diverse chemical structures. Clinically used Ca^{2+} channel blockers include the phenylalkylamine *verapamil*, the benzothiazepine *diltiazem*, and numerous dihydropyridines, including *amlodipine*, *clevidipine*, *felodipine*, *isradipine*, *lercanidipine*, *nicardipine*, *nifedipine*, *nimodipine*, and *nisoldipine*. The structures and relative specificities of representative drugs are shown in Table 31–2. Although these drugs are commonly grouped together as "calcium channel blockers," there are fundamental differences among *verapamil*, *diltiazem*, and the dihydropyridines with respect to pharmacodynamics, drug interactions, and toxicities.

Mechanisms of Action

An increased concentration of cytosolic Ca^{2+} causes increased contraction in both cardiac and vascular smooth muscle cells. In cardiac myocytes, the entry of extracellular Ca^{2+} causes a larger Ca^{2+} release from intracellular stores (Ca^{2+}-induced Ca^{2+} release) and thereby initiates the contraction twitch. In smooth muscle cells, entry of Ca^{2+} plays a dominant role, but the release of Ca^{2+} from intracellular storage sites also contributes to contraction of vascular smooth muscle, particularly in some vascular beds. In contrast to cardiac muscle, smooth muscles typically contract tonically. Cytosolic Ca^{2+} concentrations can be increased by diverse contractile stimuli in vascular smooth muscle cells. Many hormones and autocoids increase Ca^{2+} influx through so-called receptor-operated channels, whereas increases in external concentrations of K^+ and depolarizing electrical stimuli increase Ca^{2+} influx through voltage-gated, or "potential operated," channels. The Ca^{2+} channel blockers produce their effects by binding to the α_1 subunit of the L-type voltage-gated Ca^{2+} channels and reducing Ca^{2+} flux through the channel. The vascular and cardiac effects of some of the Ca^{2+} channel blockers are summarized in the next section and in Table 31–2.

Voltage-gated channels contain domains of homologous sequence that are arranged in tandem within a single large subunit. In addition to the major channel-forming subunit (termed α_1), Ca^{2+} channels contain

several other associated subunits (termed α_2, β, γ, and δ) (Schwartz, 1992). Voltage-gated Ca^{2+} channels have been divided into at least three subtypes based on their conductances and sensitivities to voltage (Schwartz, 1992; Tsien et al., 1988). The channels best characterized to date are the L, N, and T subtypes. Only the L-type channel is sensitive to the dihydropyridine Ca^{2+} channel blockers. All approved Ca^{2+} channel blockers bind to the α_1 subunit of the L-type Ca^{2+} channel, which is the main pore-forming unit of the channel. This approximately 250,000-Da subunit is associated with a disulfide-linked $\alpha_2\delta$ subunit of about 140,000 Da and a smaller intracellular β subunit. The α_1 subunits share a common topology of four homologous domains, each of which is composed of six putative transmembrane segments (S1–S6). The α_2, δ, and β subunits modulate the α_1 subunit (see Figure 14–2). The phenylalkylamine Ca^{2+} channel blocker verapamil binds to transmembrane segment 6 of domain IV (IVS6), the benzothiazepine Ca^{2+} channel blocker diltiazem binds to the cytoplasmic bridge between domain III (IIIS) and domain IV (IVS), and the dihydropyridine Ca^{2+} channel blockers (*nifedipine* and several others) bind to transmembrane segments of both domains III and IV. These three separate receptor sites are linked allosterically.

Pharmacological Actions

Vascular Tissue. Depolarization of vascular smooth muscle cells depends primarily on the influx of Ca^{2+}. At least three distinct mechanisms may be responsible for contraction of vascular smooth muscle cells. First, voltage-gated Ca^{2+} channels open in response to depolarization of the membrane, and extracellular Ca^{2+} moves down its electrochemical gradient into the cell. After closure of Ca^{2+} channels, a finite period of time is required before the channels can open again in response to a stimulus. Second, agonist-induced contractions that occur without depolarization of the membrane result from stimulation of the G_q-phospholipase C (PLC)-IP_3 (inositol 1,4,5-trisphosphate) pathway, resulting in the release of intracellular Ca^{2+} from the sarcoplasmic reticulum (Chapter 3). Emptying of intracellular Ca^{2+} stores may trigger further influx of extracellular Ca^{2+} (store-operated Ca^{2+} entry), but its relevance in smooth muscle is unresolved. Third, receptor-operated Ca^{2+} channels allow the entry of extracellular Ca^{2+} in response to receptor occupancy. An increase in cytosolic Ca^{2+} results in enhanced binding of Ca^{2+} to calmodulin. The Ca^{2+}-calmodulin complex in turn activates myosin light-chain kinase, with resulting phosphorylation of the myosin light chain. Such phosphorylation promotes interaction between actin and myosin and leads to sustained contraction of smooth muscle. Ca^{2+} channel blockers inhibit the voltage-dependent Ca^{2+} channels in vascular smooth muscle and decrease Ca^{2+} entry. All Ca^{2+} channel antagonists relax arterial smooth muscle and thereby decrease arterial resistance, blood pressure, and cardiac afterload. Although experimentally large conductance veins of pig appear similarly or even more sensitive to Ca^{2+} channel blockers than arteries (Magnon et al., 1995), Ca^{2+} channel blockers do not affect cardiac preload significantly when given at normal doses in patients. This suggests that capacitance veins that determine venous return to the heart are resistant to the relaxing effect of Ca^{2+} channel antagonists.

Cardiac Cells. The mechanisms of excitation-contraction coupling in cardiac myocytes of the working myocardium differ from those in vascular smooth muscle in that increases in intracellular Ca^{2+} are fast and transient (Chapter 34). They are initiated by a fast and short (<5 msec) Na^+ influx through voltage-gated Na^+ channels that causes depolarization of the membrane and opening of L-type Ca^{2+} channels. Repolarizing K^+ currents terminate the cardiac action potential and Ca^{2+} influx. Within the cardiac myocyte, Ca^{2+} binds to troponin C, relieving the inhibitory effect of the troponin complex on the contractile apparatus and permitting productive interaction of actin and myosin, leading to contraction. By inhibiting Ca^{2+} influx, Ca^{2+} channel blockers reduce the peak size of the systolic Ca^{2+} transient and thereby produce a negative inotropic effect. Although this is true for all classes of Ca^{2+} channel blockers, the greater degree of peripheral vasodilation seen with the dihydropyridines is accompanied by a baroreceptor reflex–mediated increase in sympathetic tone sufficient to overcome the negative inotropic effect.

In the SA and AV nodes, depolarization largely depends on the movement of Ca^{2+} through the slow channel (and not on the opening of Na^+ channels as in working myocardium). The effect of a Ca^{2+} channel blocker on AV conduction and on the rate of the sinus node pacemaker depends on whether the agent delays the recovery of the slow channel (Schwartz, 1992). Although *nifedipine* reduces the slow inward current in a dose-dependent manner, it does not affect the rate of recovery of the slow Ca^{2+} channel. Although *nifedipine* has clear negative chronotropic effects in isolated preparations (at ~5-fold higher concentrations than needed for negative inotropy), at doses used clinically, *nifedipine* does not directly affect pacemaking or conduction through the AV node. Rather, it stimulates the heart indirectly by eliciting reflex sympathetic activation in response to a lowering of blood pressure (Figure 31–2).

In contrast, *verapamil* not only reduces the magnitude of the Ca^{2+} current through the slow channel but also decreases the rate of recovery of the channel. In addition, channel blockade caused by *verapamil* (and to a lesser

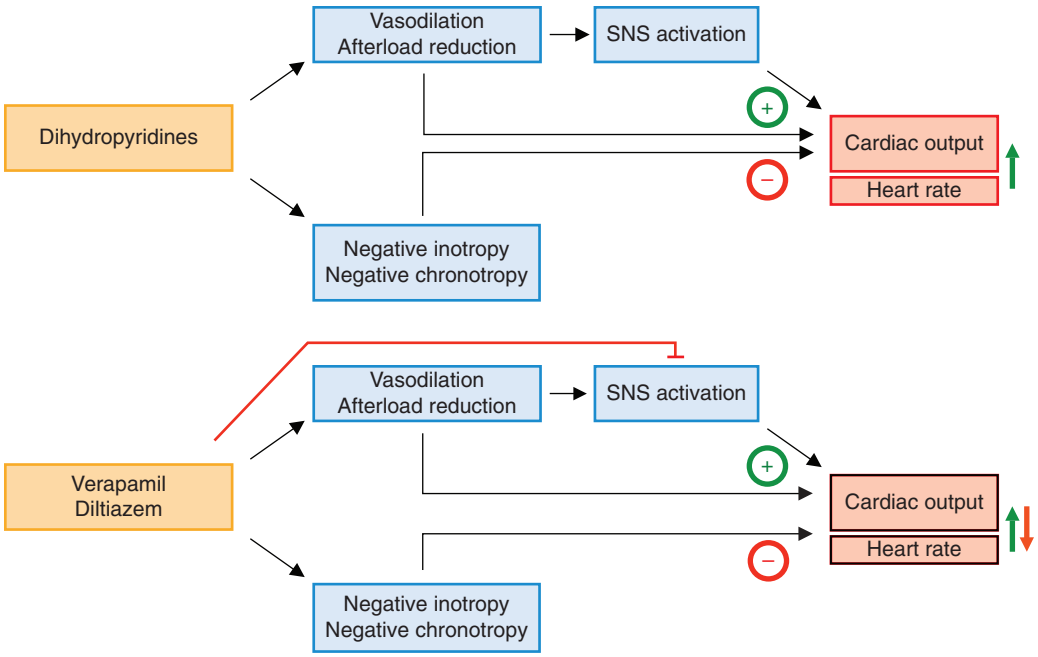

Figure 31–2 *Comparison of the integrated actions of Ca^{2+} channel blockers.* Due to different potencies and efficacies at various sites of action within the cardiovascular system, dihydropyridines produce integrated effects that are not identical to those of *verapamil* and *diltiazem*. *Verapamil* can have direct inhibitory effects on the sympathetic nervous system (SNS). The thickness of the arrow indicates the relative strength of the effect.

extent by *diltiazem*) is enhanced as the frequency of stimulation increases, a phenomenon known as *frequency dependence* or *use dependence*. *Verapamil* and *diltiazem* depress the rate of the sinus node pacemaker and slow AV conduction at clinically used doses; the latter effect is the basis for their use in the treatment of supraventricular tachyarrhythmias (see Chapter 34). *Verapamil* also inhibits fast Na^+ and repolarizing K^+ currents (I_{Kr}). The contribution of these actions to the clinical profile is unclear, but note that *verapamil*, despite the effect on I_{Kr}, has not been associated with torsades des pointes arrhythmias, as have other I_{Kr} blockers.

Integrated Cardiovascular Effects of Different Ca^{2+} Channel Antagonists. The hemodynamic profiles of the Ca^{2+} channel blockers approved for clinical use differ and depend mainly on the ratio of vasodilating and negative inotropic and chronotropic effects on the heart (Figure 31–2). The dihydropyridines dilate blood vessels at several-fold lower concentrations than those required for decreasing myocardial force; the ratio is close to one for *diltiazem* and *verapamil*. The published selectivity values differ widely, depending on the type of blood vessel and the mode of precontraction used for the comparison (Table 31–2 and Figure 31–3). The differences between the relatively vasoselective dihydropyridines and the essentially nonselective *diltiazem* and *verapamil* have important consequences because the decrease in arterial blood pressure elicits reflex sympathetic activation, resulting in the stimulation of heart rate, AV conduction velocity, and myocardial force, just the opposite of the direct effect of Ca^{2+} channel blockers. While direct and indirect effects normally balance each other in the case of *verapamil* and *diltiazem*, sympathetic stimulation often prevails in dihydropyridines, causing an increase in heart rate and contractility. Cardiac depressant effects of dihydropyridines may be unmasked, though, in the presence of β blockers and in patients with heart failure.

The dihydropyridines in clinical use—*amlodipine, clevidipine, felodipine, isradipine, lercanidipine, nicardipine, nifedipine, nimodipine,* and *nisoldipine*—share most pharmacodynamic properties. Differences regarding vascular selectivity or subvascular selectivity have been intensely studied in the past, but claims of large vasoselectivity factors were based on indirect comparisons (Godfraind et al., 1992). Overall, the clinical relevance of vasoselectivity ratios appears questionable; actual differences are probably not great (Figure 31–3). In any event, the drugs exert their antianginal effect mainly by peripheral arterial vasodilation and afterload reduction and not by coronary artery dilation (exception in variant angina).

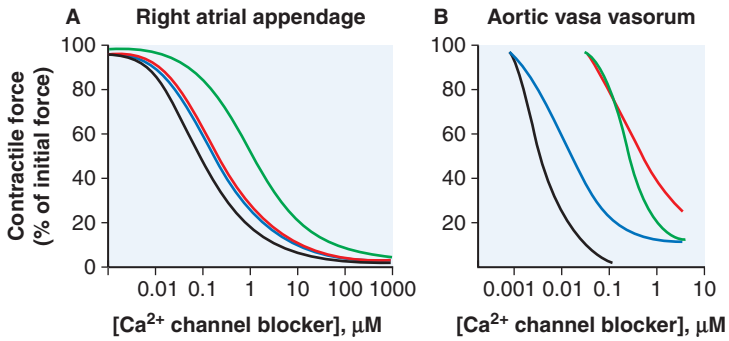

Figure 31–3 *Potency of Ca^{2+} channel blockers at different sites.* Effects were assessed on the contractile force of human right atrial appendages (**A**) and human arteries from aortic vasa vasorum precontracted with high-K^+ concentrations (**B**). *Felodipine* (black), *nifedipine* (blue), and *amlodipine* (green) are more potent on vascular muscle, inhibiting contraction of atrial muscle at concentrations about 10 times higher than those needed to reduce contraction in vascular tissue. *Verapamil* (red) inhibits atrial muscle force development at 20% of the concentration required to reduce contraction in vascular tissue. The vascular selectivity of the various Ca^{2+} channel blockers (EC_{50} [half-maximal effective concentration] on atrial appendage/EC_{50} on vasa vasorum) are as follows: felodipine, 12; nifedipine, ', amlo lip ne, 5; verapamil, 0.2. Fig ure is bas d on data of Angus e al., 2000.)

Verapamil, like the dihydropyridines, causes little effect on venous return and preload but has more direct negative inotropic and chronotropic effects than the dihydropyridines at doses that produce arteriolar dilation and afterload reduction (Figure 31–2). Thus, the consequences of a reflex increase in adrenergic tone are generally offset by the direct cardiodepressant effects of the drug. In patients without heart failure, oral administration of *verapamil* reduces peripheral vascular resistance and blood pressure with minimal changes in heart rate. Ventricular performance is not impaired and may improve, especially if ischemia limits its performance. In contrast, in patients with heart failure, intravenous *verapamil* can cause a marked decrease in contractility and left ventricular function. The antianginal effect of *verapamil*, like that of all Ca^{2+} channel blockers, is due primarily to a reduction in myocardial O_2 demand. The negative dromotropic effect has no relevance for the improvement of exercise but can cause second-degree AV block, particularly when given in combination with β blockers (contraindicated). *Diltiazem*'s effects lie in between those of dihydropyridines and *verapamil*.

The effects of Ca^{2+} channel blockers on diastolic ventricular relaxation (the lusitropic state of the ventricle) are complex. *Nifedipine*, *diltiazem*, and *verapamil* impaired parameters of ventricular relaxation in dogs, especially when given into the coronary arteries (Walsh and O'Rourke, 1985). However, reflex stimulation of sympathetic tone accelerates relaxation, which may outweigh a direct negative lusitropic effect. Likewise, a reduction in afterload will improve the lusitropic state. In addition, if ischemia is improved, the negative lusitropic effect will be reduced. The sum total of these effects in any given patient cannot be determined *a priori*.

ADME and Drug Interactions. Ca^{2+} channel blockers exhibit clinically relevant differences in pharmacokinetics (Figure 31–4). Immediate-release *nifedipine* is quickly absorbed after oral intake and produces only a briefly elevated blood level of the drug ($t_{1/2}$ ~1.8 h) that is associated with an abrupt decrease in blood pressure, reflex activation of the sympathetic nervous system, and tachycardia. This can cause a typical flush and can increase the risk of angina pectoris by abruptly decreasing coronary perfusion pressure concomitantly with tachycardia. Sustained-release preparations of *nifedipine* reduce fluctuations of plasma concentration. By contrast, *amlodipine* has slow absorption and a prolonged effect. With a plasma $t_{1/2}$ of 35 to 50 h, plasma levels and effect increase over 7 to 10 days of daily administration of a constant dose, resulting in a C_p with modest peaks and troughs. Such a profile allows the body to adapt and is associated with less reflex tachycardia. *Felodipine*, *nitrendipine*, *lercanidipine*, and *isradipine* have similar profiles for chronic treatment

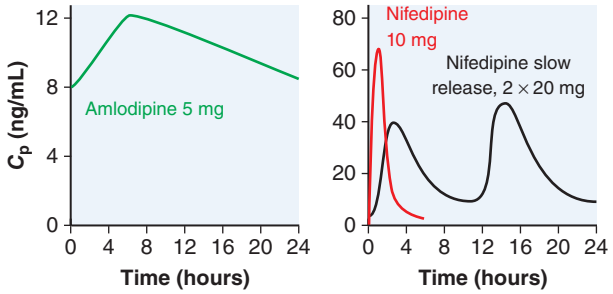

Figure 31–4 *Minimizing daily fluctuations in C_p values of Ca^{2+} channel blockers.* Graphs show plasma levels (C_p values) of *amlodipine* (left) and of *nifedipine* (right) in immediate-release (red) and slow-release (black) preparations; doses were administered at zero time. Plasma levels of *amlodipine* and *nifedipine* slow-release formulations were assessed after repeated application; thus, C_p values do not start at zero. Note the much smaller differences between trough and peak plasma concentrations in case of *amlodipine* compared to the rapid and brief pulse in plasma concentration of immediate-release *nifedipine* and the relatively large fluctuations even with the slow-release form of *nifedipine*. The plasma $t_{1/2}$ of *amlodipine* is about 39 h; that of *nifedipine* is about 1.8 h. A large fluctuation in C_p may result in adverse effects at the maximum and lack of efficacy at the minimum (see Figure 2–9A). (For original data, see Bainbridge et al., 1993; Debbas et al., 1986; and van Harten et al., 1987.)

(Table 31–2). *Clevidipine* is available in the U.S. and Switzerland for intravenous administration and has a very rapid ($t_{1/2}$ ~2 min) onset and offset of action. It is metabolized by esterases in blood. It may be useful in controlling blood pressure in severe or perioperative hypertension as an alternative to GTN, *sodium nitroprusside*, or *nicardipine*.

The bioavailability of all Ca^{2+} channel blockers is reduced, in some cases markedly, by first-pass metabolism by CYP3A4 enzymes in the intestinal epithelium and the liver. This has two consequences:

- The bioavailability of these drugs may be increased by strong inhibitors of CYP3A4, such as macrolide and imidazole antibiotics, antiretroviral agents, and grapefruit juice (see Chapter 5). Bioavailability is reduced by inducers of CYP3A4, such as *rifampin*, *carbamazepine*, and hypericum (St. John's wort).
- Some Ca^{2+} channel blockers (particularly *verapamil*) are strong CYP3A4 inhibitors and cause clinically relevant drug interactions with other CYP3A4 substrates, such as *simvastatin* and *atorvastatin*.

Moreover, *verapamil* is a relatively efficient inhibitor of the intestinal and renal ABC transport protein P-glycoprotein (Pgp) (also called MDR1 and ABCB1; see Chapter 5) and can thereby increase plasma levels of *digoxin*, *cyclosporine*, and *loperamide* and other agents that are exported by Pgp. The same mechanism operates at the blood-brain barrier, leading to high exposure of the central nervous system (cave central actions of *loperamide*). This high potential of *verapamil* for drug-drug interactions is a clear disadvantage and one of the reasons for its declining use. In patients with hepatic cirrhosis, the bioavailabilities and half-lives of the Ca^{2+} channel blockers may be increased, and dosage should be decreased accordingly. The half-lives of these agents also may be longer in older patients.

Toxicity and Untoward Responses. The profile of adverse reactions to the Ca^{2+} channel blockers varies among the drugs in this class. Immediate-release capsules of *nifedipine* often cause headache, flushing, and dizziness and can actually worsen myocardial ischemia. Dizziness and flushing are much less of a problem with the sustained-release formulations and with the dihydropyridines having a long $t_{1/2}$ and providing more constant plasma drug concentrations. Peripheral edema may occur in some patients with Ca^{2+} channel blockers but is not the result of generalized fluid retention; rather, it most likely results from increased hydrostatic pressure in the lower extremities owing to precapillary dilation and reflex postcapillary constriction (Epstein and Roberts, 2009). *Lercanidipine* appears to cause less peripheral edema than other dihydropyridines (Makarounas-Kirchmann et al., 2009). Other adverse effects of these drugs are due to actions in nonvascular smooth muscle. For example, Ca^{2+} channel blockers can cause or aggravate gastroesophageal reflux. Constipation is a common side effect of *verapamil* but occurs less frequently with other Ca^{2+} channel blockers. Urinary retention is a rare adverse effect. Uncommon adverse effects include rash and elevations of liver enzymes.

Although bradycardia, transient asystole, and exacerbation of heart failure have been reported with *verapamil*, these responses usually have occurred after intravenous administration of *verapamil* in patients with disease of the SA node, with AV nodal conduction disturbances, or in the presence of β blockade. The use of *verapamil* with a β blocker is contraindicated because of the increased propensity for AV block or severe depression of ventricular function. Patients with ventricular dysfunction, SA or AV nodal conduction disturbances, and systolic blood pressures below 90 mm Hg should not be treated with *verapamil* or *diltiazem*, particularly intravenously. *Verapamil* may also exacerbate AV nodal conduction disturbances observed with *digoxin*, both for pharmacodynamic and pharmacokinetic reasons (Pgp inhibition; see previous discussion). When used with *quinidine*, *verapamil* may cause excessive hypotension, again due to pharmacodynamic and pharmacokinetic reasons (*quinidine* is a CYP3A4 substrate and Pgp inhibitor).

Therapeutic Uses

Variant Angina. Variant angina results from reduced blood flow (a consequence of transient localized vasoconstriction) rather than increased

O_2 demand. Drug-induced causes (e.g., cocaine, amphetamines, *sumatriptan*, and related antimigraine drugs) should be excluded. Ca^{2+} channel blockers are effective in about 90% of patients (Collet et al., 2020). These agents are considered first-line treatment and may be combined with nitrovasodilators (Amsterdam et al., 2014).

Exertional Angina. Ca^{2+} channel blockers also are effective in the treatment of exertional, or exercise-induced, angina. Numerous double-blind, placebo-controlled studies have shown that these drugs decrease the number of anginal attacks and attenuate exercise-induced ST-segment depression, but evidence for life-prolonging efficacy is lacking. They are therefore considered the drugs of choice if β blockers do not achieve sufficient symptomatic benefit or are not tolerated (Knuuti et al., 2020).

The Ca^{2+} channel blockers reduce the *double product*, Heart rate × Systolic blood pressure, an approximate index of myocardial O_2 demand. Because these agents reduce the level of the double product at a given external workload and because the value of the double product at peak exercise is not altered, the beneficial effect of Ca^{2+} channel blockers likely derives from a decrease in O_2 demand rather than an increase in coronary flow.

Concurrent therapy of a dihydropyridine with a β blocker has proven more effective than either agent given alone in exertional angina, presumably because the β blocker suppresses reflex tachycardia. This concurrent drug therapy is particularly attractive because the dihydropyridines do not delay AV conduction and will not enhance the negative dromotropic effects associated with β receptor blockade. In contrast, the concurrent administration of *verapamil* or *diltiazem* with a β blocker is contraindicated for the potential for AV block, severe bradycardia, and decreased left ventricular function.

Unstable Angina (Acute Coronary Syndrome). In the past, Ca^{2+} channel blockers were routinely administered in patients presenting with unstable angina and ACS without persistent ST elevation. Reports about trends for harm with immediate-release *nifedipine* or *nifedipine* infusion in the absence of β blockers have led to the recommendation not to use dihydropyridines without concurrent therapy with β blockers. *Verapamil* and *diltiazem* are recommended only for patients who continue to show signs of ischemia, do not tolerate β blockers, have no clinically significant left ventricular dysfunction, and show no signs of disturbed AV conduction (Amsterdam et al., 2014).

Other Uses. The use of *verapamil* and *diltiazem* (but not dihydropyridines) as antiarrhythmic agents in supraventricular tachyarrhythmias is discussed in Chapter 34; their use for the treatment of hypertension is discussed in Chapter 32. Ca^{2+} channel blockers are contraindicated in patients with heart failure with reduced ejection fraction, but *amlodipine* and *felodipine* did not worsen the prognosis and can therefore be administered if indicated for other reasons (Chapter 33). *Verapamil* improves left ventricular outflow obstruction and symptoms in patients with hypertrophic cardiomyopathy (HCM). *Diltiazem* has shown early promising results in a clinical study in asymptomatic HCM mutation carriers (Ho et al., 2015). *Verapamil* also has been used in the prophylaxis of migraine headaches but is considered a second-choice drug. *Nimodipine* has been approved for use in patients with neurological deficits secondary to cerebral vasospasm after the rupture of a congenital intracranial aneurysm (Hanggi et al., 2017). *Nifedipine*, *diltiazem*, *amlodipine*, and *felodipine* appear to provide symptomatic relief in Raynaud disease. The Ca^{2+} channel blockers cause relaxation of the myometrium *in vitro* and may be effective in reducing preterm uterine contractions in preterm labor (see Chapter 48). A recent study suggests that *verapamil* can delay the progression of early stages of type 1 diabetes by improving the survival of pancreatic beta cells (Ovalle et al., 2018).

β Blockers

β Blockers are the only drug class that is effective in reducing the severity and frequency of attacks of exertional angina and in improving survival in patients who have had an MI. They are therefore recommended as first-line treatment of patients with stable CAD (Knuuti et al., 2020) and unstable angina/ACS (Hamm et al., 2011). Recent meta-analyses raised doubts about the mortality-reducing effects of β blockers in the MI reperfusion era (Bangalore et al., 2014); however, some of the results, such as the slightly increased heart failure frequency in patients receiving β blockers, contradicted numerous well-controlled prospective trials (see Chapter 33) and raised doubts about the validity of the analysis. Thus, the issue has not been definitively resolved. β Blockers are not useful for vasospastic angina and, if used in isolation, may worsen that condition. β Blockers appear equally effective in the treatment of exertional angina (Fihn et al., 2012; Knuuti et al., 2020), but very short-acting agents or drug formulations giving rise to large fluctuations of plasma concentrations (e.g., unformulated *metoprolol*) should be avoided for treatment of chronic CAD.

The effectiveness of β blockers in the treatment of exertional angina is attributable primarily to a fall in myocardial O_2 consumption at rest and during exertion. The decrease in myocardial O_2 consumption is due to a negative chronotropic effect (particularly during exercise), a negative inotropic effect, and a reduction in arterial blood pressure (particularly systolic pressure) during exercise. A decrease in heart rate prolongs the time of myocardial perfusion during diastole. Moreover, there is evidence that β blockers can increase blood flow toward ischemic regions by increasing coronary collateral resistance and preventing blood from being shunted away from the ischemic myocardium during maximal coronary vasodilation (Billinger et al., 2001), a "reverse steal or Robin Hood phenomenon" (see previous discussion).

Not all actions of β blockers are beneficial in all patients. The decreases in heart rate and contractility cause increases in the systolic ejection period and left ventricular end-diastolic volume; these alterations tend to increase O_2 consumption. However, the net effect of β blockade usually is to decrease myocardial O_2 consumption, particularly during exercise. In patients with limited cardiac reserve who are critically dependent on adrenergic stimulation, β blockade can result in profound decreases in left ventricular function. Despite this, several β blockers demonstrably reduce mortality in patients with congestive heart failure, and β blockers have become standard therapy for many such patients (see Chapters 14 and 33).

Numerous β blockers are approved for clinical use. β Blockers commonly used for the treatment of angina are β_1-selective and without intrinsic sympathomimetic activity (e.g., *atenolol, bisoprolol*, or *metoprolol*, Table 31–3). Chapter 14 presents their pharmacology in detail.

Antiplatelet, Anti-integrin, and Antithrombotic Agents

Antiplatelet agents represent the cornerstone of therapy for ACS (Amsterdam et al., 2014; Collet et al., 2020) and are systematically discussed in Chapter 36. They interfere either with two signaling pathways (thromboxane A2 [TxA2] and ADP) that cooperatively promote platelet aggregation in an auto- and paracrine manner or with a major common pathway of platelet aggregation, the glycoprotein (Gp) IIb/IIIa fibrinogen receptor. *Aspirin* inhibits platelet aggregation by irreversibly inactivating the thromboxane-synthesizing cyclooxygenase isoform 1 (COX-1) in platelets, thereby reducing production of TxA_2. *Aspirin*, given at doses of 160 to 325 mg at the onset of treatment of ACS, improves survival (Yeghiazarians et al., 2000). The thienopyridines are ADP receptor ($P2Y_{12}$ receptor) antagonists that block the pro-aggregatory effect of ADP, which is stored in vesicles within platelets and released when platelets adhere to prothrombotic structures. The pro-aggregatory synergism of TxA_2 and ADP on platelet aggregation and thrombus formation accounts for the potentiating effect of adding a thienopyridine to *aspirin*.

The addition of the thienopyridine *clopidogrel* to *aspirin* therapy reduces mortality in patients with ACS. Newer thienopyridines (*prasugrel, ticagrelor, cangrelor*) with favorable pharmacokinetic properties have been approved for the treatment of ACS. All three appear superior to *clopidogrel* in treating patients with ACS; contributing factors likely include faster onset of action and less variable pharmacokinetics. *Ticagrelor* is a direct, reversible $P2Y_{12}$ receptor antagonist, whereas *clopidogrel* and *prasugrel* are both prodrugs. The hepatic activation of *prasugrel* is more stable and faster than that of *clopidogrel*. *Cangrelor* is the first $P2Y_{12}$ receptor antagonist for intravenous application, producing very rapid inhibition of platelet aggregation. Recent guidelines recommend *ticagrelor* and

TABLE 31–3 ■ β BLOCKERS COMMONLY USED IN ISCHEMIC HEART DISEASE

AGENT	β_1-SELECTIVE	VASODILATION	HALF-LIFE (h)	STANDARD DOSE (mg)[a]	DOSE ADAPTATION IN KIDNEY FAILURE	CYP DEPENDENCE
Atenolol	Yes	No	6–10	1 × 50–100	Yes	No
Bisoprolol	Yes	No	10–12	2.5–10	No	No
Carvedilol	No	Yes	6–10	2 × 12.5–50	No	CYP2D6
Metoprolol succinate[b]	Yes	No	>12[b]	1 × 47.5–190	No	CYP2D6

[a]Doses of β blockers need to be individually adapted according to the heart rate response, which can vary widely between individuals. Evidence for fixed target doses such as in the treatment of heart failure are lacking for patients with ischemic heart disease. In general and particularly in the elderly, treatment should be started with the lowest dose, which is to be increased in 2- to 4-weekly intervals until heart rate decreases and angina pectoris symptoms improve.
[b]Metoprolol itself has a half-life of 3–5 h and is therefore not sufficiently long acting for the desired 24-h efficacy. It is therefore recommended to use only slow-release preparations. The numbers presented here apply to metoprolol succinate in a slow-release formulation (zero order of kinetics). β Blockers should never be stopped acutely, but their dose should be slowly reduced to avoid excessive increases in heart rate, relapse of angina pectoris, and cardiac arrhythmia such as atrial fibrillation.

prasugrel as the primary choice in patients with ACS and *clopidogrel* as an alternative in patients who cannot receive the former or are on oral anticoagulation therapy (e.g., for stroke prevention in atrial fibrillation). The place of *cangrelor* is not yet fully defined (Collet et al., 2020). *Cangrelor* is approved as adjunct treatment for reducing the risk of periprocedural MI, repeat coronary revascularization, and stent thrombosis in patients who have not been treated with a $P2Y_{12}$ platelet inhibitor and are not being given a GpIIb/IIIa inhibitor.

The optimal timing of the initiation of dual platelet treatment is controversial and depends on the likely clinical course. If conservative treatment is likely and the patient is not at an increased risk of bleeding, *aspirin* and a parenteral anticoagulant (see discussion that follows) should be given as soon as possible, with the addition of a $P2Y_{12}$ receptor antagonist as soon as the diagnosis of non-STEMI has been made. Dual platelet inhibition for 1 year is currently recommended for all patients after non-STEMI or STEMI and revascularization, independently of the type of revascularization and type of stent used (Collet et al., 2020). Due to the irreversible (*aspirin, clopidogrel*, and *prasugrel*) or prolonged (*ticagrelor*) modes of action, the risk of bleeding remains increased for extended periods after withdrawal of these drugs. Nonemergency major noncardiac surgeries should therefore be postponed for 5 (*ticagrelor*, *clopidogrel*) or 7 days (*prasugrel*, *aspirin*) after intake of the last dose.

Anti-integrin agents directed against the platelet integrin GpIIb/IIIa (including *abciximab*, *tirofiban*, and *eptifibatide*) are highly effective by blocking the final effector pathway of platelet aggregation; however, these agents have a small therapeutic index and must be administered parenterally. Meta-analyses of studies in patients with ACS showed that the use of GpIIb/IIIa inhibitors in addition to *heparin* was associated with about a 10% reduction in mortality, but with an increase in bleeding. Because most of these trials were conducted before the widespread use of the newer and more effective thienopyridines *prasugrel* and *ticagrelor*, the current value of the GpIIb/IIIa antagonists is not clear. Guidelines recommend them in patients on *prasugrel* or *ticagrelor* only in bailout situations (Amsterdam et al., 2014; Collet et al., 2020).

Heparin, in its unfractionated form and as low-molecular-weight *heparin* (e.g., *enoxaparin, dalteparin*), also reduces symptoms and prevents infarction in unstable angina (Yeghiazarians et al., 2000) and is currently recommended as first choice (Collet et al., 2020). *Fondaparinux*, a heparinoid pentasaccharide, antithrombin III–dependent factor Xa inhibitor, is recommended only in cases of an expected delay in mechanical coronary interventions. Thrombin inhibitors, such as *hirudin* or *bivalirudin*, directly inhibit even clot-bound thrombin, are not affected by circulating inhibitors, and function independently of antithrombin III. *Bivalirudin* provides no benefit over *heparin* in ACS (Valgimigli et al., 2015). Thrombolytic agents such as recombinant tissue plasminogen activator (rTPA) (*alteplase*) are of no benefit in unstable angina. The new oral anticoagulants (factor IIa inhibitor *dabigatran* and factor Xa inhibitors *rivaroxaban*, *apixaban*, and *edoxaban*) are recommended in patients with ACS and concomitant atrial fibrillation in addition to the dual antiplatelet therapy ("triple therapy"), but higher bleeding rates need to be considered (Collet et al., 2020). The addition of very-low-dose *rivaroxaban* (2 × 2.5 mg) to *aspirin* has been successfully tested for long-term prevention in patients with stable CAD (Eikelboom et al., 2017). *Vorapaxar*, first in its class, inhibits the protease-activated receptor-1 (PAR-1), the primary receptor for thrombin, which is a potent activator of platelets. *Vorapaxar* was shown to significantly reduce thrombotic cardiovascular events in patients with a history of MI or with peripheral artery disease.

Other Antianginal Agents

Ranolazine

Ranolazine is FDA and EMA approved as a second-line agent for the treatment of chronic angina. The drug may be used with a variety of other agents, including β blockers, Ca^{2+} channel blockers, ACEIs, ARBs, and therapeutic agents for lowering lipids and reducing platelet aggregation.

Mechanism of Action. The mechanism of *ranolazine*'s therapeutic efficacy in angina is uncertain. Its anti-ischemic and antianginal effects occur independently of reductions in heart rate and arterial blood pressure or changes in coronary blood flow. *Ranolazine* inhibits several cardiac ion fluxes, including I_{Kr} and I_{Na}. Preferential inhibition of late I_{Na} may explain its cardiac effects (Hasenfuss and Maier, 2008). The late I_{Na} contributes to arrhythmias in patients with the rare long QT 3 syndrome (see Chapter 34) and is increased in heart failure and ischemia. Reduction of the late I_{Na} could explain in part the elevated cytosolic Na^+ concentrations in cardiac myocytes in these conditions, leading to higher diastolic Ca^{2+} concentrations, Ca^{2+} overload, arrhythmias, and problems with diastolic relaxation.

Other mechanisms of action have been proposed. *Ranolazine* reduces cardiac fatty acid oxidation and stimulates glucose metabolism without inhibiting carnitine palmityl transferase 1 (McCormack et al., 1998). However, the effect is small, occurs at *ranolazine* concentrations more than 5-fold higher than do therapeutic effects, and can be assessed in the absence of fatty acid oxidation (Belardinelli et al., 2006). *Ranolazine* has weak β receptor blocking activity (Letienne et al., 2001) that may contribute to its antianginal activity.

Ranolazine did not improve the prognosis of patients with incomplete revascularization after percutaneous coronary intervention (Weisz et al., 2016), nor did it affect symptoms or measures of left ventricular diastolic function or dimensions in patients with HCM (Olivotto et al., 2018). These data question the therapeutic value of the compound.

ADME and Adverse Effects. *Ranolazine*, supplied as extended-release tablets, is administered without regard to meals at 500 to 1000 mg twice daily; higher doses are poorly tolerated. The drug's oral bioavailability is about 75%; inhibitors of Pgp (e.g., *digoxin*, *cyclosporine*; see Chapter 5) can increase absorption of *ranolazine* and increase exposure to both *ranolazine* and the competing drug. *Ranolazine*'s terminal $t_{1/2}$ is about 7 h; with repeated dosing, a steady-state C_p is reached in 3 days. *Ranolazine* is metabolized mainly by CYP3A4 and to a lesser extent by CYP2D6; unchanged drug (5%) and metabolites are excreted in the urine.

Ranolazine should not be used together with strong CYP3A4 inhibitors (e.g., macrolide and imidazole antibiotics, HIV protease inhibitors), and doses need to be limited when moderate CYP3A4 inhibitors such as *verapamil, diltiazem*, and *erythromycin* are used in combination. Inducers of CYP3A4 (e.g., *rifampin, carbamazepine*, and hypericum) can decrease *ranolazine* plasma levels, requiring dose adjustment. *Ranolazine* can affect plasma levels of other CYP3A4 substrates, including doubling levels of *simvastatin* and its active metabolite and requiring dose adjustment; dose reduction may be needed for other CYP3A4 substrates (e.g., *lovastatin*), especially for those with a narrow therapeutic range (e.g., *cyclosporine*, *tacrolimus*, *sirolimus*). Coadministration of *ranolazine* may increase exposure to other substrates of CYP2D6, such as tricyclic antidepressant drugs and antipsychotic agents.

The most frequent adverse effects are dizziness, headache, nausea, and constipation. Some CNS effects (e.g., dizziness, blurry vision, and confusional state) are reminiscent of class I antiarrhythmics. QT prolongation must be considered, but no torsades des pointes arrhythmias or related events have been reported.

Ivabradine

Ivabradine is EMA approved for treating stable angina and heart failure in patients in whom β blockers are not tolerated or are insufficiently effective in reducing heart rate and is FDA approved only for the treatment of heart failure (Chapter 33). *Ivabradine* is a selective blocker of hyperpolarization-activated hyperpolarization-activated cyclic nucleotide–gated (HCN) ion channels involved in the generation of automaticity in the SA node. By reducing the pacemaker current I_f through HCN channels, the compound dose dependently reduces heart rate and, differently from β blockers, does not affect cardiac contractile force. The antianginal effect is explained solely by reduction of heart rate and thereby O_2 demand (Figure 31–1).

A typical, often transient, side effect are phosphenes, transient enhanced lightness in restricted areas of the visual field, that are explained by effects on retinal HCN channels (3%–5% of cases). In a recent study in patients with chronic angina and normal left ventricular function, the addition of *ivabradine* to β blockers did not confer benefit but was associated with a trend for more cardiovascular end points and an increase in symptomatic bradycardia, atrial fibrillation, and QT prolongation (Fox et al., 2014). The data raise doubts about the hypothesis that heart rate reduction per se is associated with better cardiovascular outcome and has led to restrictions on use of *ivabradine* (e.g., contraindication for concurrent therapy with *verapamil* or *diltiazem*).

Nicorandil

Nicorandil is a nitrate ester of nicotinamide developed as an antianginal agent and currently is approved in many Asian and European countries for the treatment of stable angina pectoris. *Nicorandil* is not available in the U.S.

Mechanism of Action and Pharmacological Effects. *Nicorandil* has nitrate-like (cGMP-dependent) properties and acts as an agonist at ATP-sensitive potassium (K_{ATP}) channels. Its vasodilating action is potentiated by PDE5 inhibitors and only partially blocked by inhibitors of K_{ATP} channels, such as *glibenclamide*, suggesting that both properties participate in *nicorandil*'s effect. *Nicorandil* dilates both arterial and venous vascular beds, leading to decreases in afterload and preload of the heart. In the absence of direct effects on contractile force of the ventricles, the decrease in afterload causes cardiac output to increase. The last effect is stronger than that seen after administration of nitrovasodilators and partially explained by (reflex) tachycardia. Thus, the hemodynamic profile of *nicorandil* lies in between that of nitrovasodilators and dihydropyridine Ca^{2+} channel blockers. Its antianginal effect is described to be stable, but early studies reported a clear decrease or loss of antianginal effect after 2 weeks of oral treatment (Meany et al., 1989; Rajaratnam et al., 1999).

Experimental and clinical studies indicated that *nicorandil* has cardioprotective effects (Matsubara et al., 2000), mimicking that of ischemic preconditioning, a phenomenon where short periods of ischemia preceding prolonged stopping of perfusion (as in MI) reduce myocardial injury. While the exact mechanisms are not fully understood, a central role of nitoch ond'rial K_{ATP} channels i' as umed (A rdehali and O'Rou ke, 2005; Sato et al., 2000). Retrospective studies indicated a survival-prolonging effect of chronic treatment with *nicorandil* in patients with stable CAD, but sufficiently powered prospective studies are lacking.

ADME and Adverse Effects. *Nicorandil* is rapidly absorbed after sublingual or oral administration and has a short $t_{1/2}$ (1 h), which does not provide relevant trough levels at the usual regimen of twice-daily dosing at 20 mg/dose. Besides nitrate-like headache and hypotension (note contraindication of concurrent PDE5 inhibitors), *nicorandil* has been associated with the appearance of ulcerations. They were first described in 1997 (Boulinguez et al., 1997) as large, painful, buccal apthosis and seem to extend to a 40% to 60% increased risk of GI ulcerations and perforations (Lee et al., 2015).

Trimetazidine

Trimetazidine was developed as an antianginal agent. *Trimetazidine* is approved in several European countries but not in the U.S. Its effect is thought to be due to inhibition of long-chain 3-ketoacyl coenzyme A thiolase, the final enzyme in the free fatty acid (FFA) β-oxidation pathway. This leads to a partial shift from FFA to glucose oxidation in the heart, which provides less ATP but requires less O_2 and may therefore be beneficial in ischemia (Ussher et al., 2014). Numerous small studies provided evidence for the efficacy of the compound to reduce angina and increase exercise tolerance, particularly in patients with diabetes and heart failure (e.g., Tuunanen et al., 2008). However, a recent, adequately powered trial in patients after percutaneous coronary intervention showed no benefit of adding *trimetazidine* to standard care (Ferrari et al., 2020).

Trimetazidine can cause GI upset, nausea, and vomiting, and rarely, it has been associated with thrombocytopenia, agranulocytosis, and liver dysfunction. More important, *trimetazidine* may increase the risk of movement disorders such as Parkinson's disease, particularly in older patients with decreased kidney function. This serious effect has led to use restrictions by the EMA and the recommendation to use *trimetazidine* only as second-line treatment of stable angina in patients inadequately controlled by or intolerant to first-line antianginal therapies.

Therapeutic Strategies

Stable Coronary Artery Disease

Guidelines

Task forces from the American College of Cardiology and the American Heart Association (Fihn et al., 2012) and the European Society of Cardiology (Knuuti et al., 2020) have published guidelines that are useful in the selection of appropriate initial therapy for patients with chronic stable angina pectoris. All patients with CAD should receive at least one drug for angina relief in addition to fast- and short-acting nitrovasodilators (GTN, ISDN) and, for event prevention, *aspirin* and a statin. ACEIs should be considered in patients with CAD who have left ventricular dysfunction or diabetes (Table 31–4).

The evidence for clinically relevant differences between the three main classes of antianginal drugs is not compelling. A meta-analysis of publications that compared two or more antianginal therapies concluded that β blockers are associated with fewer episodes of angina per week and a lower rate of withdrawal due to adverse events than is *nifedipine*. However, differences did not extend to Ca^{2+} channel blockers other than *nifedipine*. Of note, no significant differences were observed in outcome between *long-acting* nitrates, Ca^{2+} channel blockers, and β blockers. Nevertheless, guidelines recommend that β blockers be considered first-line treatment of chronic angina relief; Ca^{2+} channel blockers with heart rate–lowering effects (*diltiazem, verapamil*) are alternatives. Dihydropyridines should be considered in patients who do not tolerate β blockers. In case of persistent angina, a combination of a dihydropyridine and a β blocker should be considered.

Second-Line Treatment

Longer-acting organic nitrates/nitrate formulation (e.g., cutaneous GTN) or *ranolazine* and, in non-U.S. countries, *ivabradine, trimetazidine*, and *nicorandil* may be considered as adjunct therapy in patients whose angina is not adequately controlled by first-line drugs. β Blockers can blo(k the

TABLE 31-4 ■ MANAGEMENT OF PATIENTS WITH STABLE CORONARY ARTERY DISEASE

TREATMENT LEVEL	ANGINA RELIEF	EVENT PREVENTION
All patients	Short-acting nitrates as standby medication	Education: Lifestyle management, control of risk factors
First-line treatment	β Blockers or diltiazem/verapamil	Aspirin + statins; consider ACEIs or ARBs
	Long-acting dihydropyridine if heart rate is low or there are issues of intolerance/contraindications	
	β Blockers + dihydropyridines if angina persists	
	For vasospastic angina, consider dihydropyridines or long-acting nitrates; avoid β blockers	
Second-line treatment (first line in some cases, according to comorbidities and tolerance)	Add or switch to ivabradine, long-acting nitrates, nicorandil, ranolazine,[a] or trimetazidine[a]	Consider clopidogrel in cases of aspirin intolerance
Invasive therapy	Consider angiography and stenting or coronary artery bypass grafting	

[a]In patients with diabetes mellitus.

baroreceptor-mediated reflex tachycardia and positive inotropic effects that may occur with nitrates, whereas nitrates, by increasing venous capacitance, can attenuate the increase in left ventricular end-diastolic volume associated with β blockade. Concurrent administration of nitrates also can alleviate the increase in coronary vascular resistance associated with blockade of β adrenergic receptors. *Ranolazine* and *trimetazidine* have a direct effect on the myocardium and likely act independently of hemodynamic effects. They can therefore be well combined with all other antianginal drugs where permitted. *Ivabradine* is a possible alternative to β blockers but is associated with toxicity when added to β blockers, *verapamil*, or *diltiazem* (Fox et al., 2014).

Ca^{2+} Channel Blockers and Nitrates. In severe exertional or vasospastic angina, the combination of a nitrate and a Ca^{2+} channel blocker may provide additional relief over that obtained with either type of agent alone. Because nitrates primarily reduce preload, whereas Ca^{2+} channel blockers reduce afterload, the net effect on reduction of O_2 demand should be additive; however, excessive vasodilation and hypotension can occur.

Acute Coronary Syndromes

The term *ACS* refers to chest pain with or without MI (i.e., myocardial necrosis). The latter diagnosis is essentially based on the presence or absence of increases in plasma levels of cardiac troponin (I or T). With tests becoming more and more sensitive, the number of MI diagnoses has increased, while that of unstable angina (i.e., chest pain without necrosis) has decreased. The term *unstable angina pectoris* is used for angina symptoms that present for the first time, change their usual pattern, occur at rest, or are resistant to nitrates.

Common to most clinical presentations of ACS is a disruption of a coronary plaque, leading to local platelet aggregation and thrombosis at the arterial wall, with subsequent partial or total occlusion of the vessel. Less commonly, vasospasm in minimally atherosclerotic coronary vessels may account for unstable angina. The pathophysiological principles that underlie therapy for exertional angina—which are directed at decreasing myocardial O_2 *demand*—have limited efficacy in the treatment of ACSs characterized by an insufficiency of myocardial O_2 (blood) *supply*. The most important interventions are as follows:

- Antiplatelet agents, including *aspirin* and thienopyridines (e.g., *clopidogrel, prasugrel,* or *ticagrelor*)
- Antithrombin agents such as *heparin* or *fondaparinux*
- Anti-integrin therapies that directly inhibit platelet aggregation mediated by glycoprotein GpIIb/IIIa
- Primary angioplasty with percutaneously deployed intracoronary stents or, if not possible for logistical reasons, fibrinolysis with rTPA (*alteplase*), *reteplase,* or *tenecteplase*.
- Coronary bypass surgery for selected patients

The β blockers reduce O_2 consumption and arrhythmias and have been associated with a moderate reduction in mortality in ACS but should be avoided in patients with compromised ventricular function or decreased blood pressure (Collet et al., 2020). Nitrates are useful in reducing vasospasm and in reducing myocardial O_2 consumption by decreasing ventricular wall stress. Intravenous administration of *nitroglycerin* allows high concentrations of the drug to be attained rapidly. Because *nitroglycerin* is degraded rapidly, the dose can be titrated quickly and safely using intravenous administration. If coronary vasospasm is present, intravenous *nitroglycerin* is likely to be effective, although the addition of a Ca^{2+} channel blocker may be required to achieve complete control in some patients. If a patient has consumed a PDE5 inhibitor within the preceding 24 h, there is a risk of profound hypotension, and nitrates should be withheld in favor of an alternate antianginal therapy.

While these principles apply to the entire group of patients with ACS, specific treatment algorithms and the value of different drug classes in ACS depend on the exact diagnosis and should be chosen according to recent guidelines (Collet et al., 2020).

STEMI is generally due to a complete obstruction of a large coronary artery. The mainstay in these patients is immediate reperfusion by primary angioplasty and stenting or, in the absence of invasive options, fibrinolytic therapy.

Non-STEMI can present with variable symptoms and electrocardiographic signs and is likely due to transient obstructions of larger coronary arteries or occlusion of small branches, leading to disseminated myocardial necrosis. Primary angioplasty is also indicated in these patients.

Unstable angina is differentiated from non-STEMI by the absence of increased plasma troponin concentrations. These patients have a better long-term prognosis and benefit less from early invasive procedures and intensified antiplatelet therapy. Mainstays are β blockers and nitrovasodilators (in the absence of contraindications such as hypotension). Short-acting Ca^{2+} channel blockers (e.g., *nifedipine*; see Figure 31–4) should normally be avoided in ACS because of a strong reflex activation of the sympathetic nervous system, but they are the first choice if vasospasm is the underlying cause.

Claudication and Peripheral Vascular Disease

Most patients with peripheral vascular disease also have CAD, and the therapeutic approaches for peripheral and coronary arterial diseases overlap (Gerhard-Herman et al., 2017). Mortality in patients with peripheral vascular disease is most commonly due to cardiovascular disease (Regensteiner and Hiatt, 2002), and treatment of CAD remains the central focus of therapy. Many patients with advanced peripheral arterial disease (PAD) are more limited by the consequences of peripheral ischemia than by myocardial ischemia. In the cerebral circulation, arterial disease may be manifest as stroke or transient ischemic attacks. The painful symptoms

of PAD in the lower extremities (claudication) typically are provoked by exertion, with increases in skeletal muscle O_2 demand exceeding blood flow that is impaired by proximal stenoses. When flow to the extremities becomes critically limiting, peripheral ulcers and rest pain from tissue ischemia can become debilitating.

Most of the therapies shown to be efficacious for treatment of CAD also have a salutary effect on progression of PAD (Hirsch et al., 2006). Antiplatelet therapy with *aspirin* (75–325 mg) or *clopidogrel* (75 mg), statins, and antihypertensive treatment are recommended in all patients with PAD (Gerhard-Herman et al., 2017). Oral anticoagulation is ineffective and increases bleeding risks. Interestingly, neither intensive treatment of diabetes mellitus nor antihypertensive therapy appears to alter the progression of symptoms of claudication. Other risk factor and lifestyle modifications remain cornerstones of therapy for patients with claudication; physical exercise, rehabilitation, and smoking cessation (possibly supported by drug treatment with *varenicline* or *bupropion*) have proven efficacy.

Cilostazol is specifically used in the treatment of lower extremity claudication. *Cilostazol* is an inhibitor of PDE3 and promotes accumulation of intracellular cAMP in many cells, including blood platelets. *Cilostazol*-mediated increases in cAMP inhibit platelet aggregation and promote vasodilation. The drug is metabolized by CYP3A4 and has important drug interactions with other drugs metabolized via this pathway (see Chapter 7). *Cilostazol* has been mainly studied in Asian populations and seems to improve symptoms of claudication, but the effect on cardiovascular mortality remains unclear (Bedenis et al., 2014). As a PDE3 inhibitor, *cilostazol* is in the same drug class as *milrinone*, which had been used orally as an inotropic agent for patients with heart failure. *Milrinone* therapy was associated with an increase in sudden cardiac death, and the oral form of the drug was withdrawn from the market. Concerns about several other inhibitors of PDE3 (*inamrinone, flosequinan*) followed. *Cilostazol* therefore is labeled as being contraindicated in patients with heart failure, although it is not clear that *cilostazol* itself leads to increased mortality in such patients. *Cilostazol* has been reported to increase nonsustained ventricular tachycardia; headache is the most common side effect.

Pentoxifylline is a methylxanthine derivative that is called a *rheologic modifier* for its effects on increasing the deformability of red blood cells. However, the effects of *pentoxifylline* on lower extremity claudication appear to be modest and not sufficiently supported by prospective evidence (Salhiyyah et al., 2015). Its use is not recommended anymore, similar to chelation therapy or B-complex vitamins (Gerhard-Herman et al., 2017). In contrast, all patients with PAD should be vaccinated against influenza.

Mechanopharmacological Therapy: Drug-Eluting Endovascular Stents

Intracoronary stents can ameliorate angina and reduce adverse events in patients with ACSs. However, the long-term efficacy of intracoronary stents is limited by subacute luminal restenosis within the stent, which, in bare metal stents, occurs in 20% to 30% of patients during the first 6 to 9 months of follow-up (Collet et al., 2020). The pathways that lead to "in-stent restenosis" are complex, but smooth muscle proliferation within the lumen of the stented artery is a common pathological finding. Local antiproliferative therapies at the time of stenting have been explored over many years; several drug-eluting stents and, more recently, biodegradable stents have been introduced in the market. The drugs currently used in intravascular stents are *paclitaxel*, *sirolimus* (*rapamycin*), and the two *sirolimus* derivatives *everolimus* and *zatarolimus*. *Paclitaxel* is a tricyclic diterpene that inhibits cellular proliferation by binding to and stabilizing polymerized microtubules. *Sirolimus* is a hydrophobic macrolide that binds to the cytosolic immunophilin FKBP12; the FKBP12-*sirolimus*

Drug Facts for Your Personal Formulary: *Coronary Artery Disease*

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Organic Nitrates		
Glyceryl trinitrate (GTN, nitroglycerin) Isosorbide dinitrate (ISDN) Isosorbide mononitrate (ISMN)	• Angina (sublingual) • Acute pulmonary edema (IV) • Acute hypertension (IV)	• NO-mediated vasodilation of large (venous, arterial) > small (resistance) vessels → preferential preload reduction without steal effect • Short-acting formulations of GTN or ISDN are standby drugs for all patients with CAD • First choice for vasospastic angina, along with Ca^{2+} channel blockers • Second choice for the prevention of exertional angina (longer-acting formulations) • Adverse effects: headache, dizziness, postural hypotension, syncope • Tolerance after >16 h (leave nitrate-free interval of >8 h) • Do not use concurrently with PDE5 inhibitor
Molsidomine	• Angina	• Direct NO donor • Second choice for the prevention of angina • Adverse effects same as above • No documented advantage over GTN/ISDN/ISMN
Inhaled NO	• Pulmonary hypertension in neonates	• Relatively selective effect on pulmonary vascular bed
Ca^{2+} Channel Blockers		
Dihydropyridines Amlodipine Felodipine Lercanidipine Nifedipine Nitrendipine ***Others*** Diltiazem Verapamil	• Angina • Hypertension • Rate control in atrial fibrillation (verapamil, diltiazem)	• Preferential arterial vasodilation → afterload reduction • First choice for vasospastic angina (dihydropyridines) • Second choice for preventing exertional angina • Immediate-release nifedipine and short-acting dihydropyridines can cause tachycardia and hypotension and trigger angina • Diltiazem and verapamil can ↓ heart rate and AV conduction; should not be used with β blockers • CYP3A4-mediated drug interactions with verapamil and diltiazem • Other unwanted effects: peripheral edema (dihydropyridines, less with lercanidipine), obstipation (verapamil)

Drug Facts for Your Personal Formulary: *Coronary Artery Disease (continued)*

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
β Blockers		
Atenolol Bisoprolol Carvedilol Metoprolol Nadolol Nebivolol Many others	• Angina • Heart failure • Hypertension • Widely used for other indications (prevention of arrhythmias, rate control in atrial fibrillation, migraine, etc.)	• First choice for prevention of exertional angina • Only antianginal drug class with proven prognostic benefits in CAD • Adverse effects: bradycardia, AV block, bronchospasm, peripheral vasoconstriction, worsening of acute heart failure, depression, worsening of psoriasis • Polymorphic CYP2D6 metabolism (metoprolol) • Additional vasodilation (carvedilol, nebivolol)
Ranolazine		
	• Angina	• Inhibits late Na^+ and other cardiac ion currents • Has weak β-blocking and metabolic effects • Second choice in the prevention of exertional angina • CYP3A4-dependent metabolism
Ivabradine		
	• Angina • Heart failure	• Selectively ↓ heart rate by inhibiting HCN currents in SA node • Second choice in the prevention of exertional angina; approved in patients not tolerating β blockers or having heart rate >75 under β blockers • Unwanted effects: bradycardia, QT prolongation, atrial fibrillation, phosphenes • Contraindication: combination with diltiazem or verapamil
Nicorandil		
	• Angina	• Dual nitrate-like and I_{KATP}-stimulatory action • Hemodynamic profile between nitrates and dihydropyridines; ↓ afterload more than nitrates • Second choice in the prevention of exertional angina • Adverse effects: hypotension, headache, buccal and GI ulcers • Do not combine with PDE5 inhibitor
Trimetazidine		
	• Angina	• Metabolic shift from fatty acid to glycolytic metabolism in the heart • Second choice in the prevention of exertional angina • May increase the incidence of Parkinson's disease
Antiplatelet, Anti-integrin, and Antithrombotic Drugs		
Aspirin $P2Y_{12}$ receptor antagonists (clopidogrel, prasugrel, ticagrelor cangrelor [IV])	• Prevention of thrombotic events (MI, stroke) • Acute coronary syndromes • Prevention of stent thrombosis	• ↓ Platelet aggregation by inhibiting COX-1–mediated TxA_2 production (aspirin) or ADP receptors ($P2Y_{12}$ receptor antagonists) • Oral use only: clopidogrel, prasugrel, ticagrelor • Irreversible action: aspirin, clopidogrel, prasugrel • Prodrugs: clopidogrel, prasugrel • Variable, CYP2C9-dependent metabolism (clopidogrel) • Withdraw 5–7 days before surgery • First choice in non-STEMI and STEMI • Dual platelet inhibition after stenting
Abciximab Eptifibatide Tirofiban	• Percutaneous coronary interventions	• Antibody (abciximab) or small molecule antagonists at platelet GpIIb/IIIa receptor • Parenteral use only • Highly efficient platelet inhibition • Therapeutic value in the era of highly effective dual platelet inhibition unclear
Heparin Low-molecular-weight heparins (e.g., enoxaparin, dalteparin)	• Acute coronary syndromes • Percutaneous coronary interventions	• Endogenous polysaccharide, inhibits thrombin (factor IIa) and factor Xa in an antithrombin III–dependent manner • Parenteral use only • Heparin: short $t_{1/2}$, complex pharmacokinetics, low bioavailability after subcutaneous injection • Low-molecular-weight heparin: longer half-life, renal excretion; accumulation in renal insufficiency • Heparin-induced thrombocytopenia
Fondaparinux	• Acute coronary syndromes • Percutaneous coronary interventions	• Synthetic pentasaccharide, antithrombin III–dependent, factor Xa inhibitor • Most favorable efficacy-safety ratio
Bivalirudin Lepirudin	• Percutaneous coronary interventions (bivalirudin) • Heparin-induced thrombocytopenia (HIT II) recombinant lepirudin	• Direct thrombin (factor IIa) inhibitors • Parenteral use only • Advantage of bivalirudin over heparin unclear

complex inhibits the protein kinase mTOR, the mammalian target of rapamycin (see Figure 39–2), thereby inhibiting cell cycle progression (see Figure 69–2). *Paclitaxel* and *sirolimus* differ markedly in their mechanisms of action but share common chemical properties as hydrophobic small molecules. Stent-induced damage to the vascular endothelial cell layer can lead to thrombosis. The inhibition of cellular proliferation by *paclitaxel* and *sirolimus* or derivatives affects vascular smooth muscle cell proliferation and thereby markedly reduces the rate of restenosis compared with bare metal stents. Drug-eluting stents are therefore recommended over bare metal stents independently of the type of intervention (Collet et al., 2020). Dual antiplatelet therapy (e.g., *aspirin* and *ticlopidine*) is recommended for 1 year after intracoronary stenting with drug-eluting stents, similar to bare metal stents. Evidence for the benefit of even longer periods is limited.

Chapter 32 Treatment of Hypertension

Thomas Eschenhagen

Epidemiology and Treatment Algorithms

Hypertension is the most common cardiovascular disease. Elevated arterial pressure causes hypertrophy of the left ventricle and pathological changes in the vasculature. As a consequence, hypertension is the principal cause of stroke; a major risk factor for coronary artery disease (CAD) and its associated complications, myocardial infarction (MI) and sudden cardiac death; and a major contributor to heart failure, renal insufficiency, and dissecting aneurysm of the aorta. The prevalence of hypertension increases with age; for example, about 50% of people between the ages of 60 and 69 years old have hypertension, and the prevalence further increases beyond age 70. According to a survey in the U.S., 81.5% of those with hypertension are aware they have it, 74.9% are being treated, yet only 52.5% are considered controlled (Go et al., 2014). The success of hypertension treatment programs, such as one organized in a large integrated healthcare delivery system in the U.S. (Jaffe et al., 2013), shows that these figures can be substantially improved by electronic hypertension registries tracking hypertension control rates, regular feedback to providers, development and frequent updating of an evidence-based treatment guideline, promotion of single-pill combination therapies, and follow-up blood pressure checks. Between 2001 and 2009, this program increased the number of patients with a diagnosis of hypertension by 78%, as well as the proportion of subjects meeting target blood pressure goals from 44% to more than 84% (Jaffe et al., 2013).

The definition of hypertension and treatment goals have evolved over the years according to results of intervention studies. The SPRINT study in nondiabetics with increased cardiovascular risk was prematurely stopped because the group of patients treated with antihypertensives to a systolic blood pressure target of 120 mmHg experienced a 25% lower rate of cardiovascular end points and total mortality than the group targeted to 140 mmHg (SPRINT Research Group, 2015). The rate of adverse effects such as hypotension and worsening of renal function were higher in the intensified treatment group, but this did not translate to a signal for real harm. The consequences of these results on the recent American Heart Association (AHA)/American College of Cardiology (ACC) (Whelton et al., 2018) and European Society of Cardiology (ESC) guidelines (Williams et al., 2018) slightly differ (Bakris et al., 2019; Table 32–1). In the U.S., hypertension is now defined as a blood pressure of 130/80 mmHg or higher, and in Europe, it is defined as a blood pressure of 140/90 mmHg or higher. These criteria characterize a group of patients whose risk of hypertension-related cardiovascular disease is high enough to merit medical attention. The risk of both fatal and nonfatal cardiovascular disease in adults is lowest with systolic blood pressures of less than 120 mmHg and diastolic blood pressures less than 80 mmHg; these risks increase incrementally as systolic and diastolic blood pressures rise. Recognition of this continuously increasing risk prevents a simple definition of hypertension (Table 32–1). Although many early clinical trials classified the severity of hypertension by diastolic pressure, progressive elevations of systolic pressure are similarly predictive of adverse cardiovascular events; at every level of diastolic pressure, risks are greater with higher levels of systolic blood pressure. Indeed, in patients more than 50 years old, systolic blood pressures predict adverse outcomes better than diastolic pressures. Pulse pressure, defined as the difference between systolic and diastolic pressure, may add additional predictive value (Franklin et al., 2009; Pastor-Barriuso et al., 2003). This may be at least in part due to higher-than-normal pulse pressure indicating adverse remodeling of blood vessels, representing an accelerated decrease in blood vessel compliance ("stiffening") normally associated with aging and atherosclerosis. Isolated systolic hypertension (increased systolic and normal diastolic blood pressure) in younger people (particularly men) is strongly associated with smoking. In elderly people, it indicates stiffening of the large arteries.

High blood pressure in the presence of pathological changes in certain target organs heralds a worse prognosis than the same level of blood pressure in a patient lacking these findings. For instance, retinal

Abbreviations

ACC: American College of Cardiology
ACE: angiotensin-converting enzyme
AHA: American Heart Association
Aldo: aldosterone
AngII: angiotensin II
ARB: angiotensin receptor blocker
AT_1: type 1 receptor for angiotensin II
AV: atrioventricular
β blocker: β adrenergic receptor antagonist
BP: blood pressure
CAD: coronary artery disease
COX-2: cyclooxygenase 2
DOPA: 3,4-dihydroxyphenylalanine
ENaC: epithelial Na^+ channel
ESC: European Society of Cardiology
GI: gastrointestinal
HDL: high-density lipoprotein
LDL: low-density lipoprotein
MI: myocardial infarction
MRA: mineralocorticoid receptor antagonist
NE: norepinephrine
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
RAS: renin-angiotensin system
SA: sinoatrial

hemorrhages, exudates, and papilledema in the eyes indicate a far worse short-term prognosis for a given level of blood pressure. Left ventricular hypertrophy defined by electrocardiogram, or more sensitively by echocardiography or cardiac magnetic resonance imaging, is associated with a substantially worse long-term outcome that includes a higher risk of sudden cardiac death. The risk of cardiovascular disease, disability, and death in hypertensive patients also is increased markedly by concomitant cigarette smoking, diabetes, or elevated low-density lipoprotein (LDL); the coexistence of hypertension with these risk factors increases cardiovascular morbidity and mortality to a degree that is compounded by each additional risk factor.

The purpose of treating hypertension is to decrease cardiovascular risk and to improve life expectancy. Effective pharmacological treatment of patients with hypertension decreases morbidity and mortality from cardiovascular disease, particularly the risk of stroke, heart failure, and CAD (Rosendorff et al., 2015). The reduction in risk of MI may be less significant.

Principles of Antihypertensive Therapy

Nonpharmacological therapy (lifestyle-related changes) is an important component of treatment of all patients with hypertension (Whelton et al., 2018; Williams et al., 2018). In some grade 1 hypertensives (Figure 32–1), blood pressure may be adequately controlled by a combination of weight loss (in overweight individuals), restricting sodium intake (to <5 g/d), increasing aerobic exercise (>30 min/d), moderating consumption of alcohol (ethanol/day ≤20–30 g in men [two drinks], ≤10–20 g in women [one drink]), smoking cessation, and increased consumption of fruits, vegetables, and low-fat dairy products.

The majority of patients require drug therapy for adequate blood pressure control (Figure 32–1). Current guidelines from cardiovascular societies differ slightly in their definitions and treatment targets, but the principles are the same (Bakris et al., 2019; Table 32–1). One of the important common recommendations is early use of single-pill combination therapy (Figure 32–2).

TABLE 32–1 ■ COMPARISON OF DEFINITIONS AND TREATMENT GOALS OF HYPERTENSION IN THE U.S. AND EUROPE

GUIDELINE DEFINITIONS OF HYPERTENSION	BLOOD PRESSURE (BP; mmHg)	
	U.S.	EUROPE
Office/clinic BP	≥130 systolic and/or ≥80 diastolic	≥140 systolic and/or ≥90 diastolic
Daytime mean	≥130 systolic and/or ≥80 diastolic	≥135 systolic and/or ≥85 diastolic
Nighttime mean	≥110 systolic and/or ≥65 diastolic	≥120 systolic and/or ≥70 diastolic
24-h mean	≥125 systolic and/or ≥75 diastolic	≥130 systolic and/or ≥80 diastolic
Home BP mean	≥130 systolic and/or ≥80 diastolic	≥135 systolic and/or ≥85 diastolic
BP targets for treatment	<130/80 mmHg	Systolic target <140 mmHg and close to 130 mmHg
Initial combination therapy	Initial single-pill combination in patients >20/10 mmHg above BP goal	Initial single-pill combination in patients ≥140/90 mmHg
BP requiring intervention	>130/80 mmHg	≥140/90 mmHg
Importance of home BP monitoring	• Take BP at home, twice in the morning and twice in the evening, in the week before clinic • Check BP machine annually	
Therapy	• Restrict β blockers to patients with comorbidities or other indications • Single-pill combinations as initial therapy	
Follow-up	• Detect poor adherence and focus on improvement • BP telemonitoring and digital health solutions recommended

Arterial pressure is the product of cardiac output and peripheral vascular resistance (Figure 32–3). Drugs lower blood pressure by actions on peripheral resistance, cardiac output, or both. Drugs may decrease the cardiac output by inhibiting myocardial contractility or by decreasing ventricular filling pressure. Reduction in ventricular filling pressure may be achieved by actions on the venous tone or on blood volume via renal effects. Drugs can decrease peripheral resistance by acting on smooth muscle to cause relaxation of resistance vessels or by interfering with the activity of systems that produce constriction of resistance vessels (e.g., the sympathetic nervous system, the renin-angiotensin system [RAS]). Lowering of body sodium content (by diuretics or low-salt diet) can indirectly lower peripheral resistance, possibly by reducing the response to vasoconstrictors and/or by reducing T-cell–mediated inflammation (Titze, 2015). In patients with isolated systolic hypertension, complex hemodynamics in a rigid arterial system contribute to increased blood pressure; drug effects may be mediated not only by changes in peripheral resistance but also via effects on large artery stiffness.

Antihypertensive drugs can be classified according to their sites or mechanisms of action (Table 32–2, Figure 32–3). The hemodynamic consequences of long-term treatment with antihypertensive agents (Table 32–3) provide a rationale for potential complementary effects of

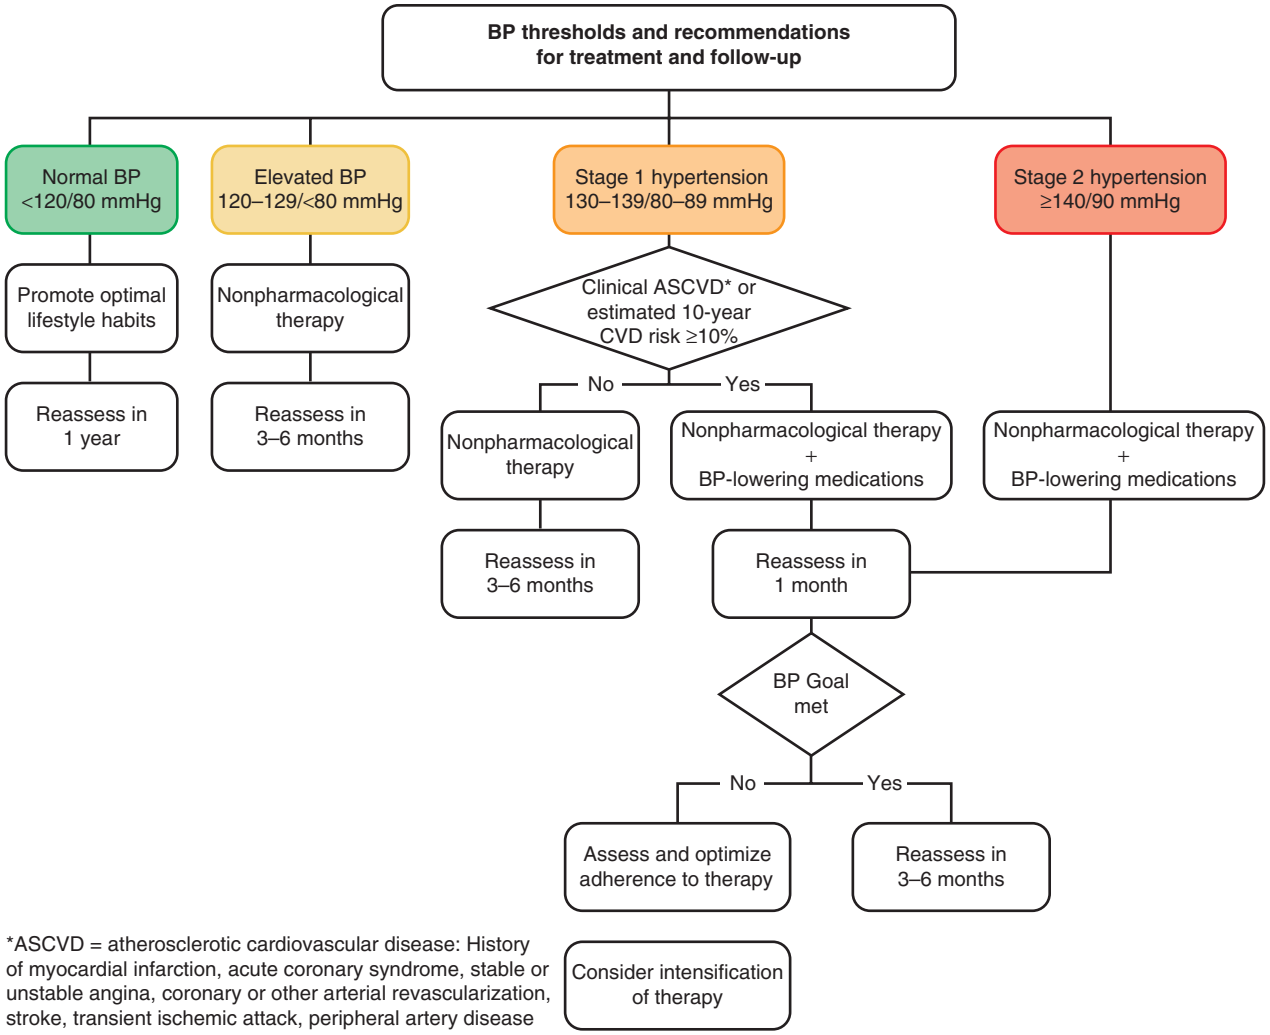

Figure 32–1 *Treatment algorithm for adults with hypertension.* Algorithm is based on recommendations of the American Heart Association and the American College of Cardiology (Whelton et al., 2018). *Patients with diabetes or chronic kidney disease are automatically put in the high-risk category. BP, blood pressure; CVD, cardiovascular disease.

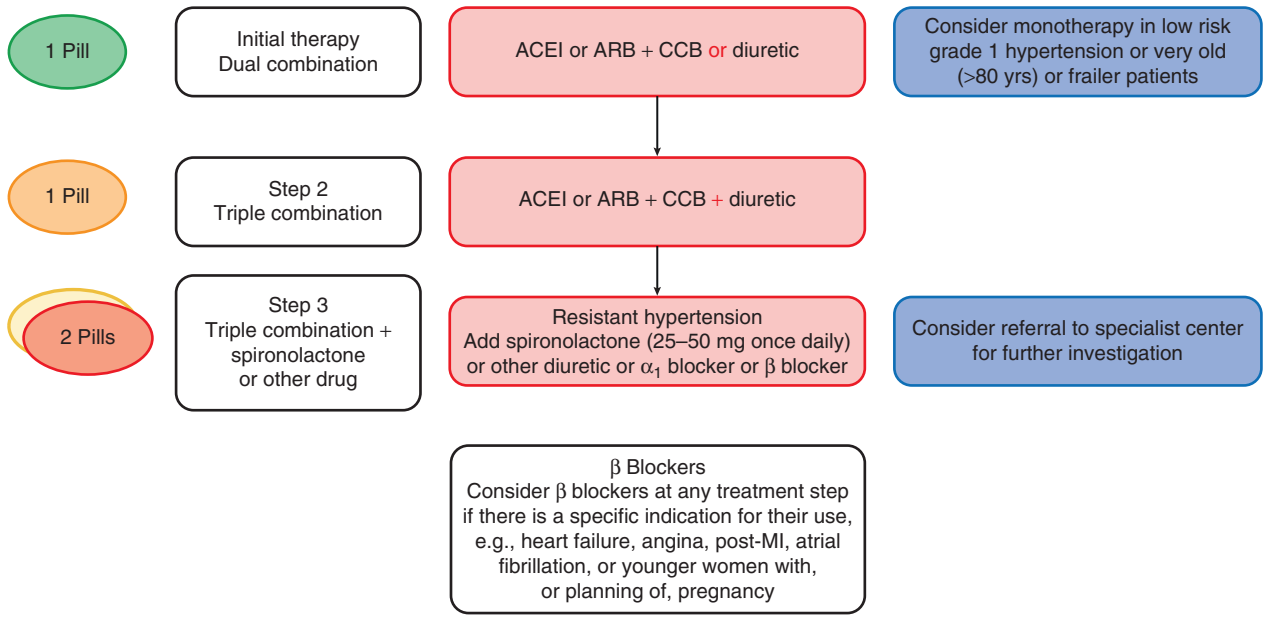

Figure 32–2 *Core drug treatment strategy for patients with uncomplicated hypertension.* The recommendation is based on the ESC guidelines for the treatment of hypertension (Williams et al., 2018). The algorithm is also appropriate for most patients with hypertension-mediated organ disease, cerebrovascular disease, diabetes, peripheral artery disease. ACEI, ACE inhibitor; CCB, calcium channel blocker.

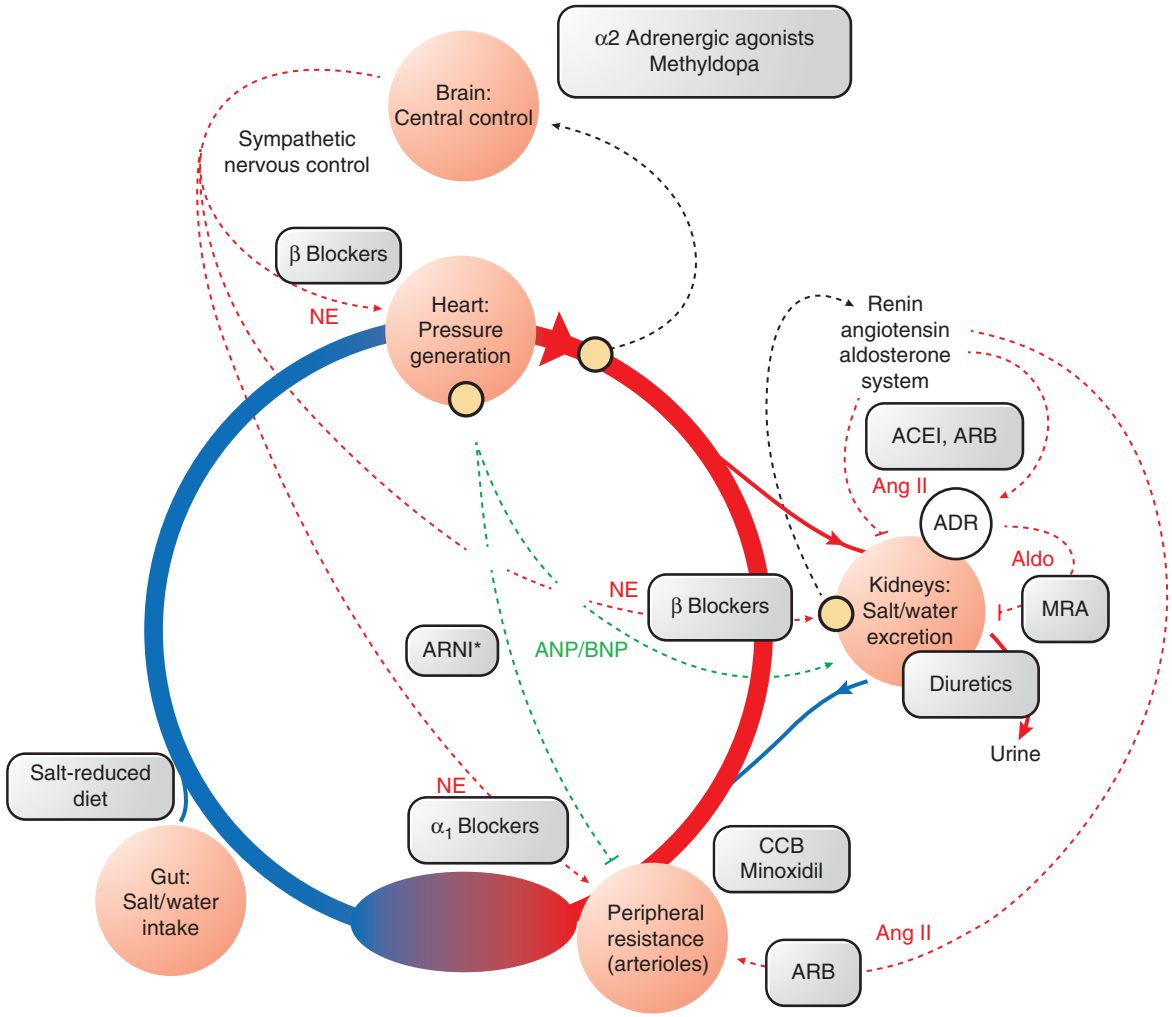

Figure 32–3 *Principles of blood pressure regulation and its modification by drugs.* Cardiac output and peripheral arteriolar resistance, the major determinants of arterial blood pressure, are regulated by myriad mechanisms, including the sympathetic nervous system (SNS) (main peripheral neurotransmitter NE), the balance between salt intake by the intestine (GI) and salt excretion by the kidneys, the renin-angiotensin-aldosterone system (RAAS) (main agonists AngII and aldosterone [Aldo]), and natriuretic peptides produced in the heart (atrial natriuretic peptide [ANP] and brain natriuretic peptide [BNP]). Sensors (yellow circles) provide afferent input on pressure in the heart and great vessels and on salt concentrations in the kidney. Note positive feedback between the SNS and RAAS via β_1-stimulated renin release and AngII-stimulated NE release (the latter not shown here for graphical reasons). Drug classes are indicated in grey boxes at their main site of action. Arrows indicate blood pressure-increasing (red) and -decreasing (green) effects. Neprilysin inhibitors (*sacubitril* in combination with *valsartan*, angiotensin receptor–neprilysin inhibitor [ARNI]) reduce blood pressure and are approved for heart failure (Chapter 33) but not for the treatment of hypertension. ACEI, ACE inhibitor; ADR, adrenal gland.*ARNI are not approved for the treatment of hypertension. CCB, calcium channel blocker.

concurrent therapy with two or more drugs. Concurrent use of drugs from different classes is a strategy for achieving effective control of blood pressure while minimizing dose-related adverse effects.

It generally is not possible to predict the responses of individuals with hypertension to any specific drug. For example, for some antihypertensive drugs, about two-thirds of patients will have a meaningful clinical response, whereas about one-third of patients will not respond to the same drug. Racial origin and age may have modest influence on the likelihood of a favorable response to a particular class of drugs. Polymorphisms in genes involved in the metabolism of antihypertensive drugs have been identified in the CYPs (phase I metabolism) and in phase II metabolism, such as catechol-*O*-methyltransferase (see Chapters 5 and 7). While these polymorphisms can change the pharmacokinetics of specific drugs quite markedly (e.g., five times higher plasma concentrations of metoprolol in CYP2D6 poor metabolizers), differences in efficacy are smaller (Rau et al., 2009) and of unknown clinical relevance. Polymorphisms that influence pharmacodynamic responses to antihypertensive drugs, including angiotensin-converting enzyme (ACE) inhibitors and diuretics, have also been identified, but evidence for clinically meaningful differences in drug response is sparse. Genome-wide scanning has identified several genetic variants associated with hypertension, but the effect sizes are much smaller than that of clinically established risk factors such as overweight.

While it is firmly established that the primary goal in the treatment of people with hypertension is the sustained reduction in mean blood pressure *per se* (Law et al., 2009), differences between antihypertensive drug classes may be relevant. This applies to unwanted effects and compliance, salutary effects on specific diseases, and most importantly, their efficacy to improve cardiovascular outcome. Current guidelines therefore differentiate among first-line antihypertensives (ACE inhibitors, angiotensin receptor blockers [ARBs], calcium channel blockers, and diuretics) that can be used in monotherapy or in different combinations, second-line drugs (*spironolactone*, β blockers [β adrenergic receptor antagonist], α_1 blockers; Figure 32–2), and antihypertensives for special indications (e.g., pregnancy, terminal kidney failure).

TABLE 32–2 ■ CLASSES OF ANTIHYPERTENSIVE DRUGS

Renin-angiotensin antagonists (Chapter 30)

- *Angiotensin-converting enzyme inhibitors*: benazepril, captopril,[a] enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, trandolapril
- *AngII receptor blockers*: candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, valsartan, azilsartan
- *Direct renin inhibitor*: aliskiren

Ca^{2+} channel blockers (Chapter 31): amlodipine, levamlodipine, clevidipine,[b] diltiazem, felodipine, isradipine, lercanidipine, nicardipine, nifedipine,[c] nisoldipine, verapamil

Diuretics (Chapter 29)

- *Thiazides and related agents*: chlorothiazide, chlorthalidone, hydrochlorothiazide, indapamide
- *Loop diuretics*: bumetanide, furosemide, torsemide
- *K^+-sparing diuretics*: amiloride, triamterene, MRA spironolactone

Sympatholytic drugs (Chapters 13 and 14)

- *Ganglionic blocking agents*: trimethaphan, mecamylamine
- *β Blockers*: atenolol, bisoprolol, esmolol,[b] nadolol, nebivolol, propranolol, acebutolol, betaxolol, metoprolol,[d] timolol
- *α Blockers*: prazosin, terazosin, doxazosin, phentolamine, metyrosine,[e] phenoxybenzamine[f]
- *Mixed α/β blockers*: labetalol, carvedilol
- *Centrally acting sympatholytic agents*: clonidine, guanfacine, methyldopa, moxonidine, reserpine

Vasodilators (Chapters 31 and 32)

- *Arterial*: diazoxide, fenoldopam, hydralazine, minoxidil
- *Arterial and venous*: nitroprusside

[a]Short duration of action makes captopril not a preferred choice for chronic treatment.
[b]Clevidipine and esmolol have an ultra-short half-life and are only approved for acute treatment.
[c]Only extended-release nifedipine is approved for hypertension.
[d]Only extended-release metoprolol (preferably as succinate salt with zero order of kinetics) should be used for the treatment of chronic hypertension.
[e]Metyrosine is a tyrosine hydroxylase inhibitor only indicated for pheochromocytoma, not for essential hypertension.
[f]Phenoxybenzamine is an irreversible inhibitor of α adrenergic receptors and is only approved in the treatment of pheochromocytoma.

Inhibitors of the Renin-Angiotensin System

Angiotensin II is an important regulator of cardiovascular function (see Chapter 30). The capacity to reduce the effects of angiotensin II (AngII) with pharmacological agents has been an important advance in the treatment of hypertension and its sequelae. Chapter 30 presents the basic physiology of the RAS and the pharmacology of inhibitors of the RAS. Table 30–2 summarizes the effects of a variety of antihypertensive agents on components of the RAS and warrants careful study. Drugs of this class are currently the most frequently prescribed antihypertensives worldwide.

Angiotensin-Converting Enzyme Inhibitors

The ability to reduce levels of AngII with orally effective ACE inhibitors represents an important advance in the treatment of hypertension. *Captopril* was the first such agent to be developed for the treatment of hypertension. Since then, *enalapril*, *lisinopril*, *quinapril*, *ramipril*, *benazepril*, *moexipril*, *fosinopril*, *trandolapril*, and *perindopril* have become available. These drugs are useful for the treatment of hypertension because of their efficacy and a favorable adverse effect profile that enhances patient adherence. Chapter 30 presents the pharmacology of ACE inhibitors in detail.

The ACE inhibitors appear to confer a special advantage in the treatment of patients with diabetes, slowing the development and progression of diabetic glomerulopathy. They also are effective in slowing the progression of other forms of chronic renal disease, such as glomerulosclerosis, which coexists with hypertension in many patients. An ACE inhibitor is the preferred initial agent in these patients. Patients with hypertension and ischemic heart disease are also candidates for treatment with ACE inhibitors. Administration of ACE inhibitors in the immediate post-MI period has been shown to improve ventricular function and reduce morbidity and mortality, particularly in patients with reduced left ventricular function (see Chapter 31).

The endocrine consequences of inhibiting the biosynthesis of AngII are of importance in several facets of hypertension treatment. Because ACE inhibitors blunt the rise in aldosterone concentrations in response to Na^+ loss, the normal role of aldosterone to oppose diuretic-induced natriuresis is diminished. Consequently, ACE inhibitors tend to enhance the efficacy of diuretic drugs. This means that even very small doses of diuretics may substantially improve the antihypertensive efficacy of ACE inhibitors; conversely, the use of high doses of diuretics together with ACE inhibitors may lead to excessive reduction in blood pressure and to Na^+ loss in some patients.

TABLE 32–3 ■ HEMODYNAMIC EFFECTS OF LONG-TERM ADMINISTRATION OF ANTIHYPERTENSIVE AGENTS

	HEART RATE	CARDIAC OUTPUT	TOTAL PERIPHERAL RESISTANCE	PLASMA VOLUME	PLASMA RENIN ACTIVITY
ACE inhibitors	↔	↔	↓	↔	↑
AT_1 receptor blockers	↔	↔	↓	↔	↑
Renin inhibitor	↔	↔	↓	↔	↓ (but renin ↑)
Ca^{2+} channel blockers	↓ or ↑	↓ or ↑	↓	–↑	–↑
Diuretics	↔	↔	↓	–↓	↑
Sympatholytic agents					
Centrally acting	– ↓	–↓	↓	– ↑	–↓
$α_1$ Blockers	–↑	–↑	↓	–↑	↔
β Blockers					
No ISA	↓	↓	–↓	–↑	↓
ISA[a]	↓↑	↔	↓	–↑	–↓
Arteriolar vasodilators	↑	↑	↓	↑	↑

↑, increased; ↓, decreased; –↑, increased or no change; –↓, decreased or no change; ↔, unchanged; ISA, intrinsic sympathomimetic activity.
[a]During rest, ISA may increase resting heart rate; during exercise, β adrenergic antagonism predominates, attenuating heart rate acceleration by NE. The profile has long-term adverse effects on the cardiovascular system, making these β blockers with ISA obsolete.

Attenuation of aldosterone production by ACE inhibitors also influences K^+ homeostasis; there is a small and clinically unimportant rise in serum K^+ when these agents are used alone in patients with normal renal function. However, substantial retention of K^+ can occur in some patients with renal insufficiency. Furthermore, the potential for developing hyperkalemia should be considered when ACE inhibitors are used with other drugs that can cause K^+ retention, including the K^+-sparing diuretics (*amiloride*, *triamterene*, and the MRAs *spironolactone* and *eplerenone*), nonsteroidal anti-inflammatory drugs (NSAIDs), K^+ supplements, and β blockers. Some patients with diabetic nephropathy may be at greater risk of hyperkalemia.

There are several cautions in the use of ACE inhibitors in patients with hypertension. Cough is a common (~5%) adverse effect and a reason to switch to ARBs. Angioedema of the head/neck and intestines is a rare but serious and potentially fatal adverse effect of the ACE inhibitors. Patients starting treatment with these drugs should be explicitly warned to discontinue their use with the advent of any signs of angioedema. Due to the risk of severe fetal adverse effects, ACE inhibitors are contraindicated during pregnancy, a fact that should be communicated to women of childbearing age.

In most patients, there is little or no appreciable change in glomerular filtration rate following the administration of ACE inhibitors. However, in renovascular hypertension, the glomerular filtration rate is generally maintained as the result of increased resistance in the postglomerular arteriole caused by AngII. Accordingly, in patients with bilateral renal artery stenosis or stenosis in a sole kidney, the administration of an ACE inhibitor will reduce the filtration fraction and cause a substantial reduction in glomerular filtration rate. The same mechanism of lowering the pressure in the filtrating vessels of the glomerulus probably participates in ACE inhibitor-induced slowing of the progression of chronic kidney disease. Serum creatinine levels and K^+ should be monitored in the first weeks after establishing therapy with an ACE inhibitor. Increases in serum creatinine greater than 20% predict the presence of renal artery stenosis (van de Ven et al., 1998) and are a reason to discontinue the treatment with ACE inhibitors.

ACE inhibitors lower blood pressure to some extent in most patients with hypertension. Following the initial dose of an ACE inhibitor, there may be a considerable fall in blood pressure in some patients; this response to the initial dose is a function of plasma renin activity prior to treatment. The potential for a large initial drop in blood pressure is the reason for using a low dose to initiate therapy, especially in patients who may have a very active RAS supporting blood pressure, such as patients with diuretic-induced volume contraction or congestive heart failure, both associated with an activated RAS. It should also be realized that, generally, no reason exists for normalizing blood pressure in a few days in patients with a lifelong disease. Attempts to do so increase the frequency of side effects and decrease compliance. With continuing treatment, there usually is a progressive fall in blood pressure that in most patients does not reach a maximum for several weeks. The blood pressure seen during chronic treatment is not strongly correlated with the pretreatment plasma renin activity. Young and middle-aged Caucasian patients have a higher probability of responding to ACE inhibitors; elderly African American patients as a group are more resistant to the hypotensive effect of these drugs. While most ACE inhibitors are approved for once-daily dosing for hypertension, a significant fraction of patients have a response that lasts less than 24 h and may require twice-daily dosing for adequate control of blood pressure (e.g., *enalapril, ramipril*). *Captopril*, with its very short duration of action, is not a good choice in the treatment of hypertension.

AT_1 Receptor Blockers

The importance of AngII in regulating cardiovascular function has led to the development of nonpeptide antagonists of the AT_1 (type 1 receptor for angiotensin II) subtype of AngII receptor. *Losartan, candesartan, irbesartan, valsartan, telmisartan, olmesartan, azilsartan*, and *eprosartan* (no longer marketed in the U.S.) have been approved for the treatment of hypertension. The pharmacology of ARBs is presented in detail in Chapter 30. By antagonizing the effects of AngII as competitive receptor antagonists, these agents relax smooth muscle and thereby promote vasodilation, increase renal salt and water excretion, reduce plasma volume, and decrease cellular hypertrophy. Given the central role of AT_1 receptors for the action of AngII, it is not surprising that ARBs have the same pharmacological profile as ACE inhibitors with one notable exception. ARBs do not inhibit the ACE-mediated degradation of bradykinin and substance P and thereby cause no cough.

Initial hopes for superiority of ARBs over ACE inhibitors have not been fulfilled. They were based on the idea that the AT_2 subtype elicits beneficial effects of AngII (e.g., antigrowth and antiproliferative responses). Because the AT_1 receptor mediates feedback inhibition of renin release, renin and AngII concentrations are increased during AT_1 receptor antagonism, leading to increased stimulation of uninhibited AT_2 receptors. Despite considerable interest, not much evidence supports any extra benefit from AT_1 blockade versus ACE inhibition, and attempts to show greater reductions in cardiovascular events by ARBs or by the combination of an ARB plus an ACE inhibitor over ACE inhibitor alone failed. ON-TARGET, one of the largest studies to date in patients with high vascular risk (70% hypertension), showed that *telmisartan* caused less cough and angioedema than *ramipril* (1.1% vs. 4.2%, and 0.1% vs. 0.3%, respectively) but had identical efficacy. The combination, although not more efficacious, was associated with greater worsening of renal function (13.5% vs. 10.2%), hypotension, and syncope (Yusuf et al., 2008).

Therapeutic Uses

The ARBs have a sufficient 24-h effect at once-daily dosing (except *losartan*). The full effect of ARBs on blood pressure typically is not observed until about 4 weeks after the initiation of therapy. If blood pressure is not controlled by an ARB alone, a second drug acting by a different mechanism (e.g., a diuretic or Ca^{2+} channel blocker) may be added. The combination of an ACE inhibitor and an ARB is not recommended for the treatment of hypertension.

Adverse Effects and Precautions

Adverse effects of ACE inhibitors that result from inhibiting AngII-related functions (see previous discussion and Chapter 30) also occur with ARBs. These include hypotension, hyperkalemia, and reduced glomerular filtration, including that associated with bilateral renal artery stenosis and stenosis in the artery of a solitary kidney. Hypotension is most likely to occur in patients whose blood pressure is highly dependent on AngII, including those with volume depletion (e.g., with diuretics), renovascular hypertension, cardiac failure, and cirrhosis; in such patients, initiation of treatment with low doses and attention to blood volume are essential. Hyperkalemia may occur in conjunction with other factors that alter K^+ homeostasis, such as renal insufficiency, ingestion of excess K^+, and the use of drugs that promote K^+ retention. Cough and angioedema occur rarely. ACE inhibitors and ARBs should not be administered during pregnancy and should be discontinued as soon as pregnancy is detected.

Direct Renin Inhibitors

Aliskiren, an orally effective direct renin inhibitor, is FDA approved for the treatment of hypertension. The detailed pharmacology of *aliskiren* is covered in Chapter 30. *Aliskiren* is an effective antihypertensive drug but has not been studied sufficiently in monotherapy of hypertension. A large study comparing a placebo or *aliskiren* added to a background of an ARB or an ACE inhibitor was stopped prematurely due to a trend toward increased cardiovascular events in the *aliskiren* treatment group (McMurray et al., 2012). The combination also induced more renal worsening, hypotension, and hyperkalemia. This mirrors previous studies with ARB/ACE inhibitor combinations and indicates that complete blockade of the RAS system results in more harm than benefit.

Pharmacology

The initial renin inhibitors were peptide analogues of sequences of renin itself or included the renin cleavage site in angiotensinogen. While effective in inhibiting renin and lowering blood pressure, these peptide analogues were effective only parenterally. However, *aliskiren* is effective following oral administration; it directly and competitively inhibits the catalytic activity of renin, leading to diminished production of AngI,

AngII, and aldosterone—with a resulting fall in blood pressure. *Aliskiren*, along with ACE inhibitors and ARBs, leads to an adaptive increase in the plasma concentrations of renin; however, because *aliskiren* inhibits renin activity, plasma renin activity does not increase as occurs with these other classes of drugs (Table 30–2). Nevertheless, the aldosterone escape known from ACE inhibitors and ARBs has also been observed under continuous treatment with *aliskiren* (Bomback et al., 2012).

ADME

Aliskiren is poorly absorbed, with an oral bioavailability of less than 3%. Taking the drug with a high-fat meal may substantially decrease plasma concentrations. *Aliskiren* has an elimination $t_{1/2}$ of at least 24 h. Elimination of the drug may be primarily through hepatobiliary excretion with limited metabolism via CYP3A4.

Therapeutic Uses

Given the unclear effectiveness and safety of *aliskiren* monotherapy, the place of this drug in the treatment of hypertension remains clouded. The combination of *aliskiren* with other RAS inhibitors is contraindicated.

Toxicity and Precautions

Aliskiren is generally well tolerated. Diarrhea may occur, especially at higher-than-recommended doses. The incidence of cough may be higher than for placebo but substantially less than found with ACE inhibitors. *Aliskiren* has been associated with several cases of angioedema in clinical trials (Frampton and Curran, 2007). Drugs acting on the RAS may damage the fetus and should not be used in pregnant women.

Ca^{2+} Channel Blockers

The Ca^{2+} channel–blocking agents are an important group of drugs for the treatment of hypertension. The general pharmacology of these drugs is presented in Chapter 31. The basis for their use in hypertension comes from the understanding that hypertension generally is the result of increased peripheral vascular resistance. Because contraction of vascular smooth muscle is dependent on the free intracellular concentration of Ca^{2+}, inhibition of transmembrane movement of Ca^{2+} through voltage-sensitive Ca^{2+} channels can decrease the total amount of Ca^{2+} that reaches intracellular sites. Indeed, all of the Ca^{2+} channel blockers lower blood pressure by relaxing arteriolar smooth muscle and decreasing peripheral vascular resistance. As a consequence of a decrease in peripheral vascular resistance, the Ca^{2+} channel blockers evoke a baroreceptor reflex–mediated sympathetic discharge. In the case of the dihydropyridines, tachycardia may occur from the adrenergic stimulation of the sinoatrial (SA) node; this response is generally quite modest except when the drug is administered rapidly. Tachycardia is typically minimal or absent with *verapamil* and *diltiazem* because of the direct negative chronotropic effect of these two drugs. Indeed, the concurrent use of a β blocker may magnify negative chronotropic effects of these drugs or cause heart block in susceptible patients. Consequently, the concurrent use of β blockers with either *verapamil* or *diltiazem* should be avoided.

The Ca^{2+} channel blockers are among the preferred drugs for the treatment of hypertension, both as monotherapy and in combination with other antihypertensives, because they have a well-documented effect on cardiovascular end points and total mortality. The combination of *amlodipine* and the ACE inhibitor *perindopril* proved superior to the combination of the β blocker *atenolol* and *hydrochlorothiazide* (Dahlof et al., 2005). *Amlodipine* was superior to *hydrochlorothiazide* as the combination partner for the ACE inhibitor *benazepril* (Jamerson et al., 2008).

The Ca^{2+} channel blockers most studied and used for the treatment of hypertension are long-acting dihydropyridines with sufficient 24-h efficacy at once-daily dosing (e.g., *amlodipine*, *felodipine*, *lercanidipine* [no longer available in the U.S.], and sustained-release formulations of others). Peripheral edema (ankle edema) is the main unwanted effect. Fewer patients appear to experience this harmless, but possibly distracting, side effect with newer compounds such as *lercanidipine* (Makarounas-Kirchmann et al., 2009), but the commonly used combination with RAS inhibitors has the same effect (Messerli et al., 2000). Immediate-release *nifedipine* and other short-acting dihydropyridines have no place in the treatment of hypertension. *Verapamil* and *diltiazem* also have short half-lives, more cardiac side effects, and a high drug interaction potential (*verapamil* > *diltiazem*) and are therefore not first-line antihypertensives.

Compared with other classes of antihypertensive agents, there may be a greater frequency of achieving blood pressure control with Ca^{2+} channel blockers as monotherapy in elderly subjects and in African Americans, population groups in which the low renin status is more prevalent. However, intrasubject variability is more important than relatively small differences between population groups. Ca^{2+} channel blockers are effective in lowering blood pressure and decreasing cardiovascular events in the elderly with isolated systolic hypertension (Staessen et al., 1997) and may be a preferred treatment in these patients.

Diuretics

An early strategy for the management of hypertension was to alter Na^+ balance by restriction of salt in the diet. Pharmacological alteration of Na^+ balance became practical with the development of the orally active thiazide diuretics (see Chapter 29). These and related diuretic agents have antihypertensive effects when used alone, and they enhance the efficacy of virtually all other antihypertensive drugs. Thus, this class of drugs remains important in the treatment of hypertension.

The exact mechanism for reduction of arterial blood pressure by diuretics is not certain. The initial action of thiazide diuretics decreases extracellular volume by interacting with a thiazide-sensitive NaCl cotransporter (*SLC12A3*) expressed in the distal convoluted tubule in the kidney, enhancing Na^+ and water excretion in the urine, which leads to a decrease in cardiac output. However, cardiac output returns to pretreatment values, and extracellular volume returns to almost normal due to compensatory responses such as activation of the RAS, while the hypotensive effect is maintained during long-term therapy due to decreased vascular resistance. The long-term vasodilation induced by thiazide diuretics must be secondary to their effect on the kidney, because no blood pressure–lowering effect of *chlorothiazide* was seen in nephrectomized dogs (Orbison, 1962). The fact that SLC12A3, the major drug target of thiazides, is expressed predominantly in the distal convoluted tubules and not in vascular smooth muscle or the heart further suggests that these drugs decrease peripheral resistance as an indirect effect of negative Na^+ balance. Accordingly, the hypotensive effect of a chronic treatment with thiazides has been reversed by a high-salt diet (Winer, 1961). That thiazides lose efficacy in treating hypertension in patients with coexisting renal insufficiency is compatible with this hypothesis. Moreover, carriers of rare functional mutations in SLC12A3 that decrease renal Na^+ reabsorption have lower blood pressure than appropriate controls (Ji et al., 2008); in a sense, this is an experiment of nature that may mimic the therapeutic effect of thiazides. Newer data suggest that large amounts of Na^+ can be stored in the body independently of changes in water content (challenging the dogma of strict coupling between Na^+ and water). High concentrations of Na^+ have been visualized in human skeletal muscle and skin of patients with Conn syndrome and were sensitive to adrenalectomy or *spironolactone* (Titze, 2015). Not all details are clear, but Na^+ accumulation in T cells and macrophages goes along with a proinflammatory state likely important in hypertension. It is well established that even small increases in intracellular Na^+ concentrations in cardiomyocytes have major effects on contractility (see Chapter 33; positive inotropic mechanism of digoxin). Similar mechanisms in smooth muscle cells could explain why chronic treatment with a thiazide markedly lowered the sensitivity to vasoconstrictors such as *phenylephrine* and AngII (Noveck, 1983).

Benzothiadiazines and Related Compounds

Benzothiadiazines ("thiazides") and related diuretics are the most frequently used class of antihypertensive agents in the U.S. Following the discovery of *chlorothiazide*, a number of oral diuretics were developed that have an arylsulfonamide structure and block the NaCl cotransporter. Some of these are not benzothiadiazines but have structural features and

molecular functions that are similar to the original benzothiadiazine compounds; consequently, they are designated as members of the thiazide class of diuretics. For example, *chlorthalidone* (also written as *chlortalidone*), one of the nonbenzothiadiazines, is widely used in the treatment of hypertension, as is *indapamide*.

Regimen for Administration of the Thiazide-Class Diuretics in Hypertension

Because members of the thiazide class have similar pharmacological effects, they generally have been viewed as interchangeable with appropriate adjustment of dosage (see Chapter 29). However, the pharmacokinetics and pharmacodynamics of these drugs differ, so they may not necessarily have the same clinical efficacy in treating hypertension. In a direct comparison, the antihypertensive efficacy of *chlorthalidone* was greater than that of *hydrochlorothiazide*, particularly during the night (Ernst et al., 2006), suggesting the much longer $t_{1/2}$ of *chlorthalidone* (>24 h) compared to *hydrochlorothiazide* (several hours) gave more stable blood pressure reductions. Meta-analyses confirmed the superiority of *chlorthalidone* over *hydrochlorothiazide* in long-term studies (Roush and Messerli, 2021). *Chlorthalidone* appears to be an underutilized drug in hypertensive patients requiring a diuretic.

Antihypertensive effects can be achieved in many patients with as little as 12.5 mg daily of *chlorthalidone* or *hydrochlorothiazide*. Furthermore, when used as monotherapy, the maximal daily dose of thiazide-class diuretics usually should not exceed 25 mg of *hydrochlorothiazide* or *chlorthalidone* (or equivalent). Even though more diuresis can be achieved with higher doses, some evidence suggests that doses higher than this are not generally more efficacious in lowering blood pressure in patients with normal renal function. Low doses of either thiazide reduce the risk of adverse effects such as K^+ wasting and inhibition of uric acid excretion, indicating an improved risk-to-benefit ratio at low doses of a thiazide. However, other studies suggested that low doses of *hydrochlorothiazide* have inadequate effects on blood pressure when monitored in a detailed manner (Lacourciere et al., 1995).

Clinical trials of antihypertensive therapy in the elderly demonstrated the best outcomes for cardiovascular morbidity and mortality when 25 mg of *hydrochlorothiazide* or *chlorthalidone* was the maximum dose given; if this dose did not achieve the target blood pressure reduction, a second drug was initiated (Dahlof et al., 1991). A case-control study found a dose-dependent increase in the occurrence of sudden death at doses of *hydrochlorothiazide* greater than 25 mg daily (Siscovick et al., 1994), supporting the hypothesis that higher diuretic doses are associated with increased cardiovascular mortality as long as hypokalemia is not corrected. Thus, if adequate blood pressure reduction is not achieved with the 25 mg daily dose of *hydrochlorothiazide* or *chlorthalidone*, the addition of a second drug is indicated rather than an increase in the dose of diuretic.

Urinary K^+ loss can be a problem with thiazides. ACE inhibitors and ARBs will attenuate diuretic-induced loss of K^+ to some degree, and this is a consideration if a second drug is required to achieve further blood pressure reduction beyond that attained with the diuretic alone. Because the diuretic and hypotensive effects of these drugs are greatly enhanced when they are given in combination, care should be taken to initiate combination therapy with low doses of each of these drugs (Vlasses et al., 1983). Administration of ACE inhibitors or ARBs together with other K^+-sparing agents or with K^+ supplements requires great caution; combining K^+-sparing agents with each other or with K^+ supplementation can cause potentially dangerous hyperkalemia in some patients.

In contrast to the limitation on the dose of thiazide-class diuretics used as monotherapy, the treatment of severe hypertension that is unresponsive to three or more drugs may require larger doses of the thiazide-class diuretics. Indeed, hypertensive patients may become refractory to drugs that block the sympathetic nervous system or to vasodilator drugs, because these drugs engender a state in which the blood pressure is very volume dependent. Therefore, it is appropriate to consider the use of thiazide-class diuretics in doses of 50 mg of daily *hydrochlorothiazide* equivalent when treatment with appropriate combinations and doses of three or more drugs fails to yield adequate control of the blood pressure. Alternatively, there may be a need to use higher-capacity diuretics such as *furosemide*, especially if renal function is not normal.

The effectiveness of thiazides as diuretics or antihypertensive agents is progressively diminished when the glomerular filtration rate falls below 30 mL/min. Exceptions are the thiazide-like diuretics *metolazone* and *xipamide*, which retain efficacy in patients with this degree of renal insufficiency. In the case of *xipamide*, this is explained by its access to the NaCl cotransporter from the blood side, which contrasts with classical thiazides reaching it via the tubular side.

Most patients will respond to thiazide diuretics with a reduction in blood pressure within about 4 to 6 weeks. Therefore, doses should not be increased more often than every 4 to 6 weeks. There is no way to predict the antihypertensive response from the duration or severity of the hypertension in a given patient, although diuretics are unlikely to be effective as sole therapy in patients with stage 2 hypertension (Table 32–1). Because the effect of thiazide diuretics is additive with that of other antihypertensive drugs, combination regimens that include these diuretics are common and rational. A wide range of fixed-dose combination products containing a thiazide are marketed for this purpose. Diuretics also have the advantage of minimizing the retention of salt and water that is commonly caused by vasodilators and some sympatholytic drugs. Omitting or underutilizing a diuretic is a frequent cause of "resistant hypertension."

Adverse Effects and Precautions

The adverse effects of diuretics are discussed in Chapter 29. Some of these determine whether a patient can tolerate and adhere to diuretic treatment.

The K^+ depletion produced by thiazide-class diuretics is dose dependent and variable among individuals, such that a subset of patients may become substantially K^+ depleted on diuretic drugs. Given chronically, even small doses lead to some K^+ depletion, which is a well-known risk factor for ventricular arrhythmias by reducing cardiac repolarization reserve. A reduction in the cardiac repolarization reserve has recently been used to explain that insults in a particular repolarization current do not necessarily result in QT interval prolongation, the principal clinical measure of repolarization (see Chapter 34). Hypokalemia directly reduces repolarization reserve by decreasing several K^+ conductances (inward rectifier I_{K1}, delayed rectifier I_{Kr}, and the transient outward current I_{to}) and increasing the binding activity of I_{Kr}-inhibiting drugs such as *dofetilide* (Yang and Roden, 1996). Hypokalemia also reduces the activity of the Na^+,K^+-ATPase (adenosine triphosphatase) (the Na^+ pump), causing intracellular accumulation of Na^+ and Ca^{2+}, further increasing the risk of afterdepolarizations (Pezhouman et al., 2015). Consequently, hypokalemia increases the risk of drug-induced polymorphic ventricular tachycardia (torsade de pointes; see Chapter 34) and the risk for ischemic ventricular fibrillation, the leading cause of sudden cardiac death and a major contributor to cardiovascular mortality in treated hypertensive patients. There is a positive correlation between diuretic dose and sudden cardiac death and an inverse correlation between the use of adjunctive K^+-sparing agents and sudden cardiac death (Siscovick et al., 1994). Thus, hypokalemia needs to be avoided by, for example, combining a thiazide with inhibitors of the RAS or with a K^+-sparing diuretic.

Thiazides have residual carbonic anhydrase–inhibiting activity, thereby reducing Na^+ reabsorption in the proximal tubule. The increased presentation of Na^+ at the macula densa leads to a reduced glomerular filtration rate via tubuloglomerular feedback. While this effect is clinically not meaningful in patients with normal renal function, it reduces diuretic effectiveness and may gain importance in patients with reduced kidney function. RAS inhibitors and Ca^{2+} channel blockers interfere with tubuloglomerular feedback, providing one explanation for the synergistic effect on blood pressure.

Erectile dysfunction is a troublesome adverse effect of the thiazide-class diuretics, and physicians should inquire specifically regarding its occurrence in conjunction with treatment with these drugs. Gout may be a consequence of the hyperuricemia induced by these diuretics. The occurrence of either of these adverse effects is a reason for considering

alternative approaches to therapy. However, precipitation of acute gout is relatively uncommon with low doses of diuretics. *Hydrochlorothiazide* may cause rapidly developing, severe hyponatremia in some patients. Thiazides inhibit renal Ca^{2+} excretion (in contrast to loop diuretics increasing it), occasionally leading to hypercalcemia; although generally mild, this can be more severe in patients subject to hypercalcemia, such as those with primary hyperparathyroidism. The thiazide-induced decreased Ca^{2+} excretion may be used therapeutically in patients with osteoporosis or hypercalciuria.

Thiazide diuretics have also been associated with changes in plasma lipids and glucose tolerance that have led to some concern. The clinical significance of the changes has been disputed because the clinical studies demonstrated comparable efficacy of the thiazide diuretic *chlortalidone* in reducing cardiovascular risk (ALLHAT Officers, 2002).

All thiazide-like drugs cross the placenta. While they have no direct adverse effects on the fetus, administration of a thiazide during pregnancy increases a risk of transient volume depletion that may result in placental hypoperfusion. Because the thiazides appear in breast milk, they should be avoided by nursing mothers.

Recent registry data from Denmark revealed an increased risk (10%–70%) of certain types of skin cancers (squamous skin cell carcinoma, nonmelanoma basal cell carcinoma) associated with the use of *hydrochlorothiazide* (Pedersen et al., 2018). The effect may be due to a photosensitizing effect and has led the FDA to require inclusion of that information on the label of all *hydrochlorothiazide*-containing drug formulations. It is not clear whether the risk extends to other thiazides.

Other Diuretic Antihypertensive Agents

The thiazide diuretics are more effective antihypertensive agents than are the loop diuretics, such as *furosemide* and *bumetanide*, in patients who have normal renal function. This differential effect is most likely related to the short duration of action of loop diuretics. In fact, a single daily dose of loop diuretics does not cause a significant net loss of Na^+ for an entire 24-h period because the strong initial diuretic effect is followed by a rebound mediated by activation of the RAS. Unfortunately, loop diuretics are frequently and inappropriately prescribed as a once-a-day medication in the treatment not only of hypertension, but also of congestive heart failure and ascites. The high efficacy of loop diuretics to produce a rapid and profound natriuresis can be detrimental for the treatment of hypertension. When a loop diuretic is given twice daily, the acute diuresis can be excessive and lead to more side effects than occur with a slower-acting, milder thiazide diuretic. Loop diuretics may be particularly useful in patients with azotemia or with severe edema associated with a vasodilator such as *minoxidil*.

K^+-Sparing Diuretics

Amiloride and *triamterene* are K^+-sparing diuretics that have little value as antihypertensive monotherapy but are important in combination with thiazides to antagonize urinary K^+ loss and the concomitant risk of ventricular arrhythmias. They act by reversibly inhibiting the epithelial Na^+ channel (ENaC) in the distal tubule membrane, the transporter responsible for the reabsorption of Na^+ in exchange for K^+. The importance of ENaC in hypertension is illustrated by the fact that an inherited form of hypertension, Liddle syndrome, is due to hyperactivity of ENaC. Gene expression of ENaC is mineralocorticoid sensitive, explaining the antihypertensive and K^+-sparing effect of another class of K^+-sparing diuretics, the MRAs *spironolactone* and *eplerenone*. In contrast to the immediate and short-term inhibition of ENaC by *amiloride* and *triamterene*, the action of MRAs is delayed for about 3 days and is long lasting because MRAs regulate the density of the channel protein in the tubule membrane.

The MRAs have a particular role in hypertension and heart failure (see Chapter 23) because small doses of *spironolactone* are often highly effective in patients with "resistant hypertension." First described decades ago (Ramsay et al., 1980), the concept was recently validated in a prospective, placebo-controlled trial comparing *spironolactone* (25–50 mg) with *bisoprolol* or *doxazosin* as add-ons in patients with uncontrolled hypertension despite triple standard antihypertensive therapy (Williams et al., 2015). *Spironolactone* had about a 2-fold larger blood pressure–lowering effect (8.7 vs. 4.8 and 4 mmHg, respectively). The efficacy of the mineralocorticoid receptor antagonist (MRA) *spironolactone* in resistant hypertension supports a primary role of Na^+ retention in this condition. Some of the effect may be related to the so-called aldosterone-escape phenomenon, or a return to pre-RAS-inhibitor plasma aldosterone levels with extended time of treatment, observed under treatment with RAS inhibitors. Primary hyperaldosteronism occurs in a significant fraction of patients with resistant hypertension (Calhoun et al., 2002). The addition of *spironolactone* at low dose is currently recommended as the third step in the ESC treatment algorithms (Figure 32–2).

Spironolactone has some significant adverse effects, especially in men (e.g., erectile dysfunction, gynecomastia, benign prostatic hyperplasia). *Eplerenone* is a more specific, though less-potent, MRA with reduced side effects.

All K^+-sparing diuretics should be used cautiously, with frequent measurements of plasma K^+ concentrations in patients predisposed to hyperkalemia (e.g., type 2 diabetics). Patients should be cautioned regarding the possibility that concurrent use of K^+-containing salt substitutes could produce hyperkalemia. Renal insufficiency is a relative contraindication to the use of K^+-sparing diuretics. Concomitant use of an ACE inhibitor or an ARB magnifies the risk of hyperkalemia with these agents.

Diuretic-Associated Drug Interactions

Because the antihypertensive effects of diuretics are additive with those of other antihypertensive agents, a diuretic commonly is used in combination with other drugs. The K^+- and Mg^{2+}-depleting effects of the thiazides and loop diuretics can potentiate arrhythmias that arise from digitalis toxicity. Corticosteroids can amplify the hypokalemia produced by the diuretics. NSAIDs (see Chapter 43) that inhibit the synthesis of prostaglandins reduce the antihypertensive effects of diuretics and all other antihypertensives. The renal effects of selective cyclooxygenase 2 (COX-2) inhibitors are similar to those of the traditional NSAIDs. NSAIDs and RAS inhibitors reduce plasma concentrations of aldosterone and can potentiate the hyperkalemic effects of a K^+-sparing diuretic. All diuretics can decrease the clearance of Li^+, resulting in increased plasma concentrations of Li^+ and potential toxicity.

Sympatholytic Agents

With the demonstration in 1940 that bilateral excision of the thoracic sympathetic chain could lower blood pressure, there was a search for effective chemical sympatholytic agents. Many of the early sympatholytic drugs were poorly tolerated and had limiting adverse side effects, particularly on mood. A number of sympatholytic agents are currently in use (Table 32–2). Antagonists of α and β adrenergic receptors have been mainstays of antihypertensive therapy but have recently lost their place as first-line therapy.

β Blockers

β Adrenergic receptor antagonists (β blockers) were not expected to have antihypertensive effects when they were first investigated in patients with angina, their primary indication. However, *pronethalol*, a drug that was never marketed, was found to reduce arterial blood pressure in hypertensive patients with angina pectoris. This antihypertensive effect was subsequently demonstrated for *propranolol* and all other β blockers. The basic pharmacology of these drugs is discussed in Chapter 14; characteristics relevant to their use in hypertension are described here.

Locus and Mechanism of Action

Antagonism of β adrenergic receptors affects the regulation of the circulation through a number of mechanisms, including a reduction in myocardial contractility and heart rate (i.e., cardiac output; see Figure 32–3). Antagonism of β_1 receptors of the juxtaglomerular complex reduces renin secretion and RAS activity. This action likely contributes to the

antihypertensive action. Some members of this large, heterogeneous class of drugs have additional effects unrelated to their capacity to bind to β adrenergic receptors. For example, *labetalol* and *carvedilol* are also α_1 blockers, and *nebivolol* promotes endothelial cell–dependent vasodilation via activation of nitric oxide (NO) production (Pedersen and Cockcroft, 2006) (see Figure 14–4).

Pharmacodynamic Differences

The β blockers vary in their selectivity for the β_1 receptor subtype, presence of partial agonist or intrinsic sympathomimetic activity, and vasodilating capacity. While all of the β blockers are effective as antihypertensive agents, these differences influence the clinical pharmacology and spectrum of adverse effects of the various drugs. The antihypertensive effect resides in antagonism of the β_1 receptor, while major unwanted effects result from antagonism of β_2 receptors (e.g., peripheral vasoconstriction, bronchoconstriction, hypoglycemia). Standard therapies are β_1 blockers without intrinsic sympathomimetic activity (e.g., *atenolol, bisoprolol, metoprolol*). They produce an initial reduction in cardiac output (mainly β_1) and a reflex-induced rise in peripheral resistance, with little or no acute change in arterial pressure. In patients who respond with a reduction in blood pressure, peripheral resistance gradually returns to pretreatment values or less. Generally, persistently reduced cardiac output and possibly decreased peripheral resistance account for the reduction in arterial pressure. Nonselective β blockers (e.g., *propranolol*) have stronger adverse effects on peripheral vascular resistance by also blocking β_2 receptors that normally mediate vasodilation. Vasodilating β blockers (e.g., *carvedilol, nebivolol*) may be preferred in patients with peripheral artery disease. Drugs with intrinsic sympathomimetic activity (e.g., *pindolol, xamoterol*) are not recommended for the treatment of hypertension or any other cardiovascular disease because they increase nighttime mean heart rate due to their direct partial agonistic activity.

Pharmacokinetic Differences

Lipophilic β blockers (*metoprolol, bisoprolol, carvedilol, propranolol*) appear to have more antiarrhythmic efficacy than the hydrophilic compounds (*atenolol, nadolol, labetalol*), possibly related to a central mode of action. Many β blockers have relatively short plasma half-lives and require more than once-daily dosing (*metoprolol, propranolol, carvedilol*), a significant disadvantage in the treatment of hypertension. They should generally be prescribed in sustained-release forms. *Bisoprolol* and *nebivolol* have $t_{1/2}$ values of 10 to 12 h and thus achieve sufficient trough levels at once-daily dosing. Hepatic metabolism of *metoprolol*, *carvedilol*, and *nebivolol* is CYP2D6 dependent. The relevance is probably greatest in case of *metoprolol*, for which CYP2D6 poor metabolizers (~7% of the Caucasian population) show 5-fold higher drug exposure and 2-fold higher heart rate decreases than the majority of extensive metabolizers (Rau et al., 2009).

Effectiveness in Hypertension

Meta-analyses have suggested that β blockers reduce the incidence of MI similar to other antihypertensives but are only about half as effective in preventing stroke (Lindholm et al., 2005). This has led to downgrading of this class of drugs in important guidelines (Whelton et al., 2018; Williams et al., 2018; Table 32–1, Figure 32–2). It has been argued that many of the studies supporting this conclusion were conducted with *atenolol*, which may not be the ideal β blocker. *Atenolol*, in contrast to *bisoprolol, carvedilol, metoprolol*, or *nebivolol*, has not been positively tested in heart failure trials. *Atenolol* may not lower central (aortic) blood pressure as effectively as it appears when conventionally measured in the brachial artery using a standard arm cuff (Williams et al., 2006), but it is not clear whether other β blockers have more favorable effects on central blood pressure, arterial stiffness, and endothelial dysfunction. Prospective studies of hypertensive agents have not compared different β blockers head-to-head; therefore, the clinical relevance of pharmacological differences in this heterogeneous drug class remains unclear. Regardless, β blockers as a class are associated with more side effects than ACE inhibitors/ARBs or calcium channel blockers, including increased incidence of diabetes and weight gain. Therefore, β blockers are only recommended in patients with a specific indication for their use (e.g., heart failure; Table 32–1) or in the third step of the treatment algorithm (Figure 32–2).

Adverse Effects and Precautions

The adverse effects of β blockers are discussed in Chapter 14. These drugs should be avoided in patients with reactive airway disease (e.g., asthma) or with SA or atrioventricular (AV) nodal dysfunction or in combination with other drugs that inhibit AV conduction, such as *verapamil*. The risk of hypoglycemic reactions may be increased in diabetics taking *insulin*, but type 2 diabetes is not a contraindication. β Blockers increase concentrations of triglycerides in plasma and lower those of high-density lipoprotein (HDL) cholesterol without changing total cholesterol concentrations. The long-term consequences of these effects are unknown. β Blockers may aggravate depression and psoriasis.

Sudden discontinuation of β blockers can produce a withdrawal syndrome, likely due to upregulation of β receptors during blockade, causing enhanced tissue sensitivity to endogenous catecholamines—potentially exacerbating the symptoms of CAD. The result, especially in active patients, can be rebound hypertension. Thus, β blockers should not be discontinued abruptly, except under close observation; dosage should be tapered gradually over 10 to 14 days prior to discontinuation.

Epinephrine can produce severe hypertension and bradycardia when a nonselective β blocker is present. The hypertension is due to the unopposed stimulation of α adrenergic receptors when vascular β_2 receptors are blocked. The bradycardia is the result of reflex vagal stimulation. Such paradoxical hypertensive responses to β blockers have been observed in patients with hypoglycemia or pheochromocytoma, during withdrawal from *clonidine*, following administration of *epinephrine* as a therapeutic agent, or in association with the illicit use of cocaine.

Therapeutic Uses

The β blockers provide effective therapy for all grades of hypertension. Marked differences in their pharmacokinetic properties should be considered; once-daily dosing is preferred for better compliance. Populations that tend to have a lesser antihypertensive response to β blockers include the elderly and African Americans. However, intraindividual differences in antihypertensive efficacy are generally much larger than statistical evidence of differences between racial or age-related groups. Consequently, these observations should not discourage the use of these drugs in individual patients in groups reported to be less responsive.

The β blockers usually do not cause retention of salt and water, and administration of a diuretic is not necessary to avoid edema or the development of tolerance. However, diuretics do have additive antihypertensive effects when combined with β blockers. The addition of a β blocker to first-line treatment with an ACE inhibitor/ARB or calcium channel blocker and diuretic is effective for patients who require a third antihypertensive drug (Figure 32–2). β Blockers (i.e., *bisoprolol, carvedilol, metoprolol*, or *nebivolol*) remain preferred drugs for hypertensive patients with conditions such as MI, ischemic heart disease, atrial fibrillation, or congestive heart failure and may be preferred for younger patients with signs of increased sympathetic drive.

α_1 Blockers

The availability of drugs that selectively block α_1 adrenergic receptors without affecting α_2 adrenergic receptors adds another group of antihypertensive agents. The pharmacology of these drugs is discussed in detail in Chapter 14. *Prazosin*, *terazosin*, and *doxazosin* are the agents available for the treatment of hypertension. *Phenoxybenzamine*, an irreversible α blocker ($\alpha_1 > \alpha_2$), is only used in the bridging treatment of catecholamine-producing tumors (pheochromocytoma).

Pharmacological Effects

Initially, α_1 blockers reduce arteriolar resistance and increase venous capacitance; this causes a sympathetically mediated reflex increase in heart rate and plasma renin activity. During long-term therapy, vasodilation persists, but cardiac output, heart rate, and plasma renin activity return to normal. Renal blood flow is unchanged during therapy with an α_1 blocker. The α_1 blockers cause a variable amount of postural

hypotension, depending on the plasma volume. Retention of salt and water occurs in many patients during continued administration, and this attenuates the postural hypotension. The α_1 blockers reduce plasma concentrations of triglycerides and total LDL cholesterol and increase HDL cholesterol. These potentially favorable effects on lipids persist when a thiazide-type diuretic is given concurrently. The long-term consequences of these small, drug-induced changes in lipids are unknown.

Therapeutic Uses

α_1 Blockers are not recommended as monotherapy for hypertensive patients, primarily as a consequence of the ALLHAT study (see further discussion). They are used primarily in conjunction with diuretics, β blockers, and other antihypertensive agents. β Blockers enhance the efficacy of α_1 blockers. α_1 Blockers are not the drugs of choice in patients with pheochromocytoma because a vasoconstrictor response to epinephrine can still result from activation of unblocked vascular α_2 adrenergic receptors. α_1 Blockers are attractive drugs for hypertensive patients with benign prostatic hyperplasia because they also improve urinary symptoms.

Adverse Effects

The use of *doxazosin* as monotherapy for hypertension increases the risk for developing congestive heart failure (ALLHAT Officers, 2002). This may be a class effect that represents an adverse effect of all of the α_1 blockers and has led to recommendations not to use this class of drugs in patients with heart failure. Interpretation of the outcome of the ALLHAT study is controversial, but the commonly held belief that the higher rate of apparent heart failure development in the groups of patients treated with a nondiuretic was caused by withdrawal of prestudy diuretics has not been substantiated (Davis et al., 2006).

A major precaution regarding the use of the α_1 blockers for hypertension is the so-called first-dose phenomenon, in which symptomatic orthostatic hypotension occurs within 30 to 90 min (or longer) of the initial dose of the drug or after a dosage increase. This effect may occur in up to 50% of patients, especially in patients who are already receiving a diuretic. After the first few doses, patients develop a tolerance to this marked hypotensive response.

Combined α_1 and β Blockers

Carvedilol (see Chapter 14) is a nonselective β blocker with α_1-antagonist activity. *Carvedilol* is approved for the treatment of hypertension and symptomatic heart failure. The ratio of α_1- to β-antagonist potency for *carvedilol* is approximately 1:10. The drug dissociates slowly from its receptor, explaining why the duration of action is longer than the short $t_{1/2}$ (2.2 h) and why its effect can hardly be overcome by catecholamines. *Carvedilol* undergoes oxidative metabolism and glucuronidation in the liver; the oxidative metabolism occurs via CYP2D6. As with *labetalol*, the long-term efficacy and side effects of *carvedilol* in hypertension are predictable based on its properties as a β and α_1 blocker. *Carvedilol* reduces mortality in patients with congestive heart failure (see Chapter 33). Due to the vasodilating effect, it is a β blocker of choice in patients with peripheral artery disease.

Labetalol (see Chapter 14) is an equimolar mixture of four stereoisomers. One isomer is an α_1 blocker, another is a nonselective β blocker with partial agonist activity, and the other two isomers are inactive. *Labetalol* has efficacy and adverse effects that would be expected with any combination of an α_1 and a β blocker. It has the disadvantages that are inherent in fixed-dose combination products: The extent of α_1 to β blockade is somewhat unpredictable and varies from patient to patient. *Labetalol* is FDA approved for eclampsia, preeclampsia, hypertension, and hypertensive emergencies. The main indication for *labetalol* is hypertension in pregnancy, for which it is one of the few compounds known to be safe (Magee et al., 2016).

Centrally Acting Sympatholytic Drugs

Methyldopa

Methyldopa, a centrally acting antihypertensive agent, is a prodrug that exerts its antihypertensive action via an active metabolite. Although used frequently as an antihypertensive agent in the past, *methyldopa*'s adverse effect profile limits its current use largely to treatment of hypertension in pregnancy, where it has a record for safety.

Methyldopa (α-methyl-3,4-dihydroxy-L-phenylalanine), an analogue of 3,4-dihydroxyphenylalanine (DOPA), is metabolized by the L-aromatic amino acid decarboxylase in adrenergic neurons to α-methyldopamine, which then is converted to α-methylnorepinephrine, the pharmacologically active metabolite. α-Methylnorepinephrine is stored in the secretory vesicles of adrenergic neurons, substituting for norepinephrine (NE), such that the stimulated adrenergic neuron now discharges α-methylnorepinephrine instead of NE. α-Methylnorepinephrine acts in the CNS to inhibit adrenergic neuronal outflow from the brainstem, probably by acting as an agonist at presynaptic α_2 adrenergic receptors in the brainstem, attenuating NE release and thereby reducing the output of vasoconstrictor adrenergic signals to the peripheral sympathetic nervous system.

ADME. Because *methyldopa* is a prodrug that is metabolized in the brain to the active form, its C_p has less relevance for its effects than that for many other drugs. C_{pmax} occurs 2 to 3 h following an oral dose. The drug is eliminated with a $t_{1/2}$ of about 2 h. *Methyldopa* is excreted in the urine primarily as the sulfate conjugate (50%–70%) and as the parent drug (25%). Other minor metabolites include methyldopamine, methylnorepinephrine, and their *O*-methylated products. The $t_{1/2}$ of *methyldopa* is prolonged to 4 to 6 h in patients with renal failure.

Despite its rapid absorption and short $t_{1/2}$, the peak effect of *methyldopa* is delayed for 6 to 8 h, even after intravenous administration, and the duration of action of a single dose is usually about 24 h; this permits once- or twice-daily dosing. The discrepancy between the effects of *methyldopa* and the measured concentrations of the drug in plasma is most likely related to the time required for transport into the CNS, conversion to the active metabolite storage of α-methyl NE, and its subsequent release in the vicinity of relevant α_2 receptors in the CNS. *Methyldopa* is a good example of a complex relationship between a drug's pharmacokinetics and its pharmacodynamics. Patients with renal failure are more sensitive to the antihypertensive effect of *methyldopa*, but it is not known if this is due to alteration in excretion of the drug or to an increase in transport into the CNS.

Therapeutic Uses. *Methyldopa* is a preferred drug for treatment of hypertension during pregnancy based on its effectiveness and safety for both mother and fetus (Magee et al., 2016). The usual initial dose of *methyldopa* is 250 mg twice daily; there is little additional effect with doses greater than 2 g/d. Administration of a single daily dose of *methyldopa* at bedtime minimizes sedative effects, but administration twice daily is required for some patients.

Adverse Effects and Precautions. *Methyldopa* produces sedation that is largely transient. A diminution in psychic energy may persist in some patients, and depression occurs occasionally. *Methyldopa* may produce dryness of the mouth. Other adverse effects include diminished libido, parkinsonian signs, and hyperprolactinemia that may become sufficiently pronounced to cause gynecomastia and galactorrhea. *Methyldopa* may precipitate severe bradycardia and sinus arrest.

Methyldopa also produces some adverse effects that are not related to its therapeutic action in the CNS. Hepatotoxicity, sometimes associated with fever, is an uncommon but potentially serious toxic effect of *methyldopa*. At least 20% of patients who receive *methyldopa* for a year develop a positive Coombs test (antiglobulin test) that is due to autoantibodies directed against the Rh antigen on erythrocytes. The development of a positive Coombs test is not necessarily an indication to stop treatment with *methyldopa*; however, 1% to 5% of these patients will develop a hemolytic anemia that requires prompt discontinuation of the drug. The Coombs test may remain positive for as long as a year after discontinuation of *methyldopa*, but the hemolytic anemia usually resolves within a matter of weeks. Severe hemolysis may be attenuated by treatment with glucocorticoids. Adverse effects that are even rarer include leukopenia, thrombocytopenia, red cell aplasia, lupus erythematosus–like syndrome, lichenoid and granulomatous skin eruptions, myocarditis, retroperitoneal fibrosis, pancreatitis, diarrhea, and malabsorption.

Clonidine and Moxonidine

The detailed pharmacology of the α_2 adrenergic agonists *clonidine* and *moxonidine* (no longer available in the U.S.) is discussed in Chapter 14. These drugs stimulate α_{2A} adrenergic receptors in the brainstem, resulting in a reduction in sympathetic outflow from the CNS (MacMillan et al., 1996). The hypotensive effect correlates directly with the decrease in plasma concentrations of NE. Patients who have had a spinal cord transection above the level of the sympathetic outflow tracts do not display a hypotensive response to *clonidine*. At doses higher than those required to stimulate central α_{2A} receptors, these drugs can activate α_{2B} receptors on vascular smooth muscle cells (MacMillan et al., 1996). This effect accounts for the initial vasoconstriction that is seen when given intravenously or overdoses of these drugs are taken. It may also be responsible for the loss of therapeutic effect that is observed with high doses. A major limitation in the use of these drugs is the paucity of information about their efficacy in reducing the risk of cardiovascular consequences of hypertension.

Pharmacological Effects. The α_2 adrenergic agonists lower arterial pressure by effects on both cardiac output and peripheral resistance. In the supine position, when the sympathetic tone to the vasculature is low, the major effect is a reduction in heart rate and stroke volume; however, in the upright position, when sympathetic outflow to the vasculature is normally increased, these drugs reduce vascular resistance. This action may lead to postural hypotension. The decrease in cardiac sympathetic tone leads to a reduction in myocardial contractility and heart rate that could promote congestive heart failure in susceptible patients.

Therapeutic Uses. The CNS effects are such that this class of drugs is not a leading option for monotherapy of hypertension. Indeed, there is no fixed place for these drugs in the treatment of hypertension. They effectively lower blood pressure in some patients who have not responded adequately to combinations of other agents. The greater clinical experience exists with *clonidine*. A study with *moxonidine* in patients with hypertension and paroxysmal atrial fibrillation indicated that the drug reduced the incidence of atrial fibrillation (Giannopoulos et al., 2014). *Clonidine* may be effective in reducing early morning hypertension in patients treated with standard antihypertensives. Overall, enthusiasm for α_2 receptor antagonists is diminished by the relative absence of evidence demonstrating reduction in risk of adverse cardiovascular events.

Clonidine has been used in hypertensive patients for the diagnosis of pheochromocytoma. The failure of *clonidine* to suppress the plasma concentration of NE to less than 500 pg/mL 3 h after an oral dose of 0.3 mg of *clonidine* suggests the presence of such a tumor. A modification of this test, wherein overnight urinary excretion of NE and epinephrine is measured after administration of a 0.3-mg dose of *clonidine* at bedtime, may be useful when results based on plasma NE concentrations are equivocal.

Adverse Effects and Precautions. Many patients experience persistent and sometimes intolerable adverse effects with these drugs. Sedation and xerostomia are prominent adverse effects. The xerostomia may be accompanied by dry nasal mucosa, dry eyes, and swelling and pain of the parotid gland. Postural hypotension and erectile dysfunction may be prominent in some patients. *Clonidine* may produce a lower incidence of dry mouth and sedation when given transdermally, perhaps because high peak concentrations are avoided. *Moxonidine* has additional activity at central imidazoline receptors and may produce less sedation than *clonidine*, but direct comparisons are lacking. Less-common CNS side effects include sleep disturbances with vivid dreams or nightmares, restlessness, and depression (note the use of α_2 adrenergic antagonists such as *mirtazapine* to treat depression). Cardiac effects related to the sympatholytic action of these drugs include symptomatic bradycardia and sinus arrest in patients with dysfunction of the SA node and AV block in patients with AV nodal disease or in patients taking other drugs that depress AV conduction. Some 15% to 20% of patients who receive transdermal *clonidine* may develop contact dermatitis.

Sudden discontinuation of *clonidine* and related α_2 adrenergic agonists may cause a withdrawal syndrome consisting of headache, apprehension, tremors, abdominal pain, sweating, and tachycardia. Arterial blood pressure may rise to levels above those present prior to treatment, but the withdrawal syndrome may occur in the absence of an overshoot in pressure. Symptoms typically occur 18 to 36 h after the drug is stopped and are associated with increased sympathetic discharge, as evidenced by elevated plasma and urine concentrations of catecholamines and metabolites. The frequency of occurrence of the withdrawal syndrome is not known, but withdrawal symptoms are likely dose related and more dangerous in patients with poorly controlled hypertension. Rebound hypertension also has been seen after discontinuation of transdermal administration of *clonidine* (Metz et al., 1987).

Treatment of the withdrawal syndrome depends on the urgency of reducing the arterial blood pressure. In the absence of life-threatening target organ damage, patients can be treated by restoring the use of *clonidine*. If a more rapid effect is required, *sodium nitroprusside* or a combination of an α and β blocker is appropriate. β Blockers should not be used alone in this setting because they may accentuate the hypertension by allowing unopposed α adrenergic vasoconstriction caused by activation of the sympathetic nervous system and elevated circulating catecholamines.

Because perioperative hypertension has been described in patients in whom *clonidine* was withdrawn the night before surgery, surgical patients who are being treated with an α_2 adrenergic agonist either should be switched to another drug prior to elective surgery or should receive their morning dose or transdermal *clonidine* prior to the procedure. All patients who receive one of these drugs should be warned of the potential danger of discontinuing the drug abruptly, and patients suspected of being noncompliant with medications should not be given α_2 adrenergic agonists for hypertension.

Adverse drug interactions with α_2 adrenergic agonists are rare. Diuretics predictably potentiate the hypotensive effect of these drugs. Tricyclic antidepressants may inhibit the antihypertensive effect of *clonidine*, but the mechanism of this interaction is not known.

Reserpine

Reserpine is an alkaloid extracted from the root of *Rauwolfia serpentina*, a climbing shrub indigenous to India. Ancient Hindu Ayurvedic writings describe medicinal uses of the plant; Sen and Bose described its use in the Indian biomedical literature. However, rauwolfia alkaloids were not used in Western medicine until the mid-1950s. *Reserpine* was the first drug found to interfere with the function of the sympathetic nervous system in humans, and its use began the modern era of effective pharmacotherapy of hypertension. *Reserpine* is no longer marketed in the U.S.

Mechanism of Action. *Reserpine* binds tightly to adrenergic storage vesicles in central and peripheral adrenergic neurons and remains bound for prolonged periods of time. The interaction inhibits the vesicular catecholamine transporter VMAT2, so that nerve endings lose their capacity to concentrate and store NE and dopamine. Catecholamines leak into the cytoplasm, where they are metabolized. Consequently, little or no active transmitter is released from nerve endings, resulting in a pharmacological sympathectomy. Recovery of sympathetic function requires synthesis of new storage vesicles, which takes days to weeks after discontinuation of the drug. Because *reserpine* depletes amines in the CNS as well as in the peripheral adrenergic neuron, it is probable that its antihypertensive effects are related to both central and peripheral actions.

Pharmacological Effects. Both cardiac output and peripheral vascular resistance are reduced during long-term therapy with *reserpine*.

ADME. Few data are available on the pharmacokinetic properties of *reserpine* because of the lack of an assay capable of detecting low concentrations of the drug or its metabolites. *Reserpine* that is bound to isolated storage vesicles cannot be removed by dialysis, indicating that the binding is not in equilibrium with the surrounding medium. Because of the irreversible nature of *reserpine* binding, the amount of drug in plasma is unlikely to bear any consistent relationship to drug concentration at the site of action. Free *reserpine* is entirely metabolized; therefore, none of the parent drug is excreted unchanged.

Toxicity and Precautions. Most adverse effects of *reserpine* are due to its effect on the CNS. Sedation and inability to concentrate or perform complex tasks are the most common adverse effects. More serious is the occasional psychotic depression that can lead to suicide. Depression usually appears insidiously over many weeks or months and may not be attributed to the drug because of the delayed and gradual onset of symptoms. *Reserpine* must be discontinued at the first sign of depression. *Reserpine*-induced depression may last several months after the drug is discontinued. The risk of depression is likely dose related. Depression is uncommon, but not unknown, with doses of 0.25 mg/d or less. The drug should never be given to patients with a history of depression. Other adverse effects include nasal stuffiness and exacerbation of peptic ulcer disease, which is uncommon with small oral doses.

Therapeutic Uses. *Reserpine* at low doses, in combination with diuretics, is effective in the treatment of hypertension, especially in the elderly. Several weeks are necessary to achieve maximum effect. In elderly patients with isolated systolic hypertension, *reserpine* (at 0.05 mg/d) was used as an alternative to *atenolol* together with a diuretic (Perry et al., 2000; SHEP Cooperative Research Group, 1991). However, with the availability of newer drugs that have proven life-prolonging effects and are well tolerated, the use of *reserpine* has largely diminished, and it is no longer recommended for the treatment of hypertension.

Vasodilators

Hydralazine

Hydralazine (1-hydrazinophthalazine) was one of the first orally active antihypertensive drugs to be marketed in the U.S.; however, the drug initially was used infrequently because of tachycardia and tachyphylaxis. With a better understanding of the compensatory cardiovascular responses that accompany use of arteriolar vasodilators, *hydralazine* was combined with sympatholytic agents and diuretics with greater therapeutic success. Nonetheless, its role in the treatment of hypertension has markedly diminished with the introduction of new classes of antihypertensive agents.

Mechanism of Action

Hydralazine directly relaxes arteriolar smooth muscle with little effect on venous smooth muscle. The molecular mechanisms mediating this action are not clear but may ultimately involve a reduction in intracellular Ca^{2+} concentrations. While a variety of changes in cellular signaling pathways are influenced by *hydralazine*, precise molecular targets that explain its capacity to dilate arteries remain uncertain. Potential mechanisms include inhibition of inositol trisphosphate–induced release of Ca^{2+} from intracellular storage sites, opening of high-conductance Ca^{2+}-activated K^+ channels in smooth muscle cells, and activation of an arachidonic acid, COX, and prostacyclin pathway that would explain sensitivity to NSAIDs (Maille et al., 2016).

Hydralazine-induced vasodilation is associated with powerful stimulation of the sympathetic nervous system, likely due to baroreceptor-mediated reflexes, resulting in increased heart rate and contractility, increased plasma renin activity, and fluid retention. These effects tend to counteract the antihypertensive effect of *hydralazine*.

Pharmacological Effects

Most of the effects of *hydralazine* are confined to the cardiovascular system. The decrease in blood pressure after administration of *hydralazine* is associated with a selective decrease in vascular resistance in the coronary, cerebral, and renal circulations, with a smaller effect in skin and muscle. Because of preferential dilation of arterioles over veins, postural hypotension is not a common problem; *hydralazine* lowers blood pressure similarly in the supine and upright positions.

ADME

Following oral administration, *hydralazine* is well absorbed via the gastrointestinal (GI) tract. *Hydralazine* is *N*-acetylated in the bowel and the liver, contributing to the drug's low bioavailability (16% in fast acetylators and 35% in slow acetylators). The rate of acetylation is genetically determined; about half of the U.S. population acetylates rapidly, and half does so slowly. The acetylated compound is inactive; thus, the dose necessary to produce a systemic effect is larger in fast acetylators. Because the systemic clearance exceeds hepatic blood flow, extrahepatic metabolism must occur. Indeed, *hydralazine* rapidly combines with circulating α-keto acids to form hydrazones, and the major metabolite recovered from the plasma is hydralazine pyruvic acid hydrazone. This metabolite has a longer $t_{1/2}$ than *hydralazine* but appears to be relatively inactive. Although the rate of acetylation is an important determinant of the bioavailability of *hydralazine*, it does not play a role in the systemic elimination of the drug, probably because hepatic clearance is so high that systemic elimination is principally a function of hepatic blood flow. The peak concentration of *hydralazine* in plasma and the peak hypotensive effect of the drug occurs within 30 to 120 min of ingestion. Although its $t_{1/2}$ in plasma is about 1 h, the hypotensive effect of *hydralazine* can last as long as 12 h. There is no clear explanation for this discrepancy.

Therapeutic Uses

Hydralazine is no longer a first-line drug in the treatment of hypertension on account of its relatively unfavorable adverse effect profile. The drug has a role as a combination pill containing *isosorbide dinitrate* (BiDil) in the treatment of heart failure (see Chapter 33). *Hydralazine* may have utility in the treatment of some patients with severe hypertension, can be part of evidence-based therapy in patients with congestive heart failure (in combination with nitrates for patients who cannot tolerate ACE inhibitors or ARBs), and may be useful in the treatment of hypertensive emergencies, especially preeclampsia, in pregnant women. *Hydralazine* should be used with great caution in elderly patients and in hypertensive patients with CAD because of the possibility of precipitating myocardial ischemia due to reflex tachycardia. The usual oral dosage of *hydralazine* is 25 to 100 mg twice daily. Off-label twice-daily administration is as effective as administration four times a day for control of blood pressure, regardless of acetylator phenotype. The maximum recommended dose of *hydralazine* is 200 mg/d to minimize the risk of drug-induced lupus syndrome.

Toxicity and Precautions

Two types of adverse effects occur after the use of *hydralazine*. The first, which are extensions of the pharmacological effects of the drug, include headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris. Myocardial ischemia can occur on account of increased O_2 demand induced by the baroreceptor reflex–induced stimulation of the sympathetic nervous system. Following parenteral administration to patients with CAD, the myocardial ischemia may be sufficiently severe and protracted to cause frank MI. For this reason, parenteral administration of *hydralazine* is not advisable in hypertensive patients with CAD, hypertensive patients with multiple cardiovascular risk factors, or older patients. In addition, if the drug is used alone, there may be salt retention with development of high-output congestive heart failure. When combined with a β blocker and a diuretic, *hydralazine* is better tolerated, although adverse effects such as headache are still commonly described and may necessitate discontinuation of the drug.

The second type of adverse effect is caused by immunological reactions, of which the drug-induced lupus syndrome is the most common. Administration of *hydralazine* also can result in an illness that resembles serum sickness, hemolytic anemia, vasculitis, and rapidly progressive glomerulonephritis. The mechanism of these autoimmune reactions is unknown, although it may involve the drug's capacity to inhibit DNA methylation (Arce et al., 2006). The drug-induced lupus syndrome usually occurs after at least 6 months of continuous treatment with *hydralazine*, and its incidence is related to dose, gender, acetylator phenotype, and race. In one study, after 3 years of treatment with *hydralazine*, drug-induced lupus occurred in 10% of patients who received 200 mg daily, 5% who received 100 mg daily, and none who received 50 mg daily (Cameron and Ramsay, 1984). The incidence is four times higher in women than in men,

and the syndrome is seen more commonly in Caucasians than in African Americans. The rate of conversion to a positive antinuclear antibody test is faster in slow acetylators than in rapid acetylators, suggesting that the native drug or a nonacetylated metabolite is responsible. However, the majority of patients with positive antinuclear antibody tests do not develop the drug-induced lupus syndrome, and *hydralazine* need not be discontinued unless clinical features (arthralgia, arthritis, and fever) of the syndrome appear. Discontinuation of the drug is all that is necessary for most patients with the *hydralazine*-induced lupus syndrome, but symptoms may persist in a few patients, and administration of corticosteroids may be necessary.

Hydralazine also can produce a pyridoxine-responsive polyneuropathy. The mechanism appears to be related to the ability of *hydralazine* to combine with *pyridoxine* to form a hydrazone. This side effect is unusual with doses of 200 mg/d or less.

K_{ATP} Channel Openers: Minoxidil

The 1965 discovery of the hypotensive action of *minoxidil* was a significant advance in the treatment of hypertension; the drug has proven to be efficacious in patients with the most severe and drug-resistant forms of hypertension.

Mechanism of Action

Minoxidil is not active *in vitro* but must be metabolized by hepatic sulfotransferase to the active molecule, minoxidil *N-O* sulfate; the formation of this active metabolite is a minor pathway in the metabolic disposition of *minoxidil*. Minoxidil sulfate relaxes vascular smooth muscle in isolated systems where the parent drug is inactive. Minoxidil sulfate activates the ATP-modulated K^+ channel permitting K^+ efflux and causes hyperpolarization and relaxation of smooth muscle.

Pharmacological Effects

Minoxidil produces arteriolar vasodilation with essentially no effect on the capacitance vessels; the drug resembles *hydralazine* and *diazoxide* in this regard. *Minoxidil* increases blood flow to skin, skeletal muscle, GI tract, and heart more than to the CNS. The disproportionate increase in blood flow to the heart may have a metabolic basis in that administration of *minoxidil* is associated with a reflex increase in myocardial contractility and in cardiac output. The cardiac output can increase markedly, as much as 3- to 4-fold. The principal determinant of the elevation in cardiac output is the action of *minoxidil* on peripheral vascular resistance to enhance venous return to the heart; by inference from studies with other drugs, the increased venous return probably results from enhancement of flow in the regional vascular beds, with a fast time constant for venous return to the heart (Ogilvie, 1985). The adrenergically mediated increase in myocardial contractility contributes to the increased cardiac output but is not the predominant causal factor.

The effects of *minoxidil* on the kidney are complex. *Minoxidil* is a renal artery vasodilator, but systemic hypotension produced by the drug occasionally can decrease renal blood flow. Renal function usually improves in patients who take *minoxidil* for the treatment of hypertension, especially if renal dysfunction is secondary to hypertension. *Minoxidil* is a potent stimulator of renin secretion. This effect is mediated by a combination of renal sympathetic stimulation and activation of the intrinsic renal mechanisms for regulation of renin release.

Discovery of K^+_{ATP} channels in a variety of cell types and in mitochondria is prompting consideration of K^+_{ATP} channel modulators as therapeutic agents in many cardiovascular diseases (Pollesello and Mebazaa, 2004). *Minoxidil*, similar to other K^+_{ATP} channel openers such as *diazoxide*, *pinacidil*, and *nicorandil*, may have protective effects on the heart during ischemia/reperfusion (Sato et al., 2004). *Pinacidil* and *nicorandil* are not available in the U.S. It also promotes the synthesis of vascular elastin in rats (Slove et al., 2013), a potentially interesting therapeutic effect.

ADME

Minoxidil is well absorbed from the GI tract. Although peak concentrations of *minoxidil* in blood occur 1 h after oral administration, the maximal hypotensive effect of the drug occurs later, possibly because formation of the active metabolite is delayed.

The bulk of the absorbed drug is eliminated as a glucuronide; about 20% is excreted unchanged in the urine. The extent of biotransformation of *minoxidil* to its active metabolite, minoxidil *N-O* sulfate, has not been evaluated in humans. *Minoxidil* has a plasma $t_{1/2}$ of 3 to 4 h, but its duration of action is 24 h and occasionally even longer. It has been proposed that persistence of *minoxidil* in vascular smooth muscle is responsible for this discrepancy, but without knowledge of the pharmacokinetic properties of the active metabolite, an explanation for the prolonged duration of action cannot be given.

Therapeutic Uses

Systemic *minoxidil* is best reserved for the treatment of severe hypertension that responds poorly to other antihypertensive medications, especially in male patients with renal insufficiency. *Minoxidil* has been used successfully in the treatment of hypertension in both adults and children. *Minoxidil* should never be used alone; it must be given concurrently with a diuretic to avoid fluid retention, with a sympatholytic drug (e.g., β blocker) to control reflex cardiovascular effects, and with an inhibitor of the RAS to prevent remodeling effects on the heart. The drug usually is administered either once or twice a day, but some patients may require more frequent dosing for adequate control of blood pressure. The initial daily dose of *minoxidil* may be as little as 1.25 mg, which can be increased gradually to 40 mg in one or two daily doses.

Adverse Effects and Precautions

The adverse effects of *minoxidil*, which can be severe, fall into three major categories: fluid and salt retention, cardiovascular effects, and hypertrichosis. Retention of salt and water results from increased proximal renal tubular reabsorption, which is secondary to reduced renal perfusion pressure and to reflex stimulation of renal tubular α adrenergic receptors. Similar antinatriuretic effects can be observed with the other arteriolar dilators (e.g., *diazoxide* and *hydralazine*). Although administration of *minoxidil* causes increased secretion of renin and aldosterone, this is not an important mechanism for retention of salt and water in this case. Fluid retention usually can be controlled by the administration of a diuretic. However, thiazides may not be sufficiently efficacious, and it may be necessary to use a loop diuretic, especially if the patient has any degree of renal dysfunction.

The cardiac consequences of the baroreceptor-mediated activation of the sympathetic nervous system during *minoxidil* therapy are similar to those seen with *hydralazine*; there is an increase in heart rate, myocardial contractility, and myocardial O_2 consumption. Thus, myocardial ischemia can be induced by *minoxidil* in patients with CAD. The cardiac sympathetic responses are attenuated by concurrent administration of a β blocker. The adrenergically induced increase in renin secretion also can be ameliorated by a β blocker or an ACE inhibitor, with enhancement of blood pressure control.

The increased cardiac output evoked by *minoxidil* has particularly adverse consequences in those hypertensive patients who have left ventricular hypertrophy and diastolic dysfunction. Such poorly compliant ventricles respond suboptimally to increased volume loads, with a resulting increase in left ventricular filling pressure. This probably is a major contributor to the increased pulmonary artery pressure seen with *minoxidil* (and *hydralazine*) therapy in hypertensive patients and is compounded by the retention of salt and water caused by *minoxidil*. Cardiac failure can result from *minoxidil* therapy in such patients; the potential for this complication can be reduced but not prevented by effective diuretic therapy. Pericardial effusion is an uncommon but serious complication of *minoxidil*. Mild and asymptomatic pericardial effusion is not an indication for discontinuing *minoxidil*, but the situation should be monitored closely to avoid progression to tamponade. Effusions usually clear when the drug is discontinued but can recur if treatment with *minoxidil* is resumed.

Flattened and inverted T waves frequently are observed in the electrocardiogram following the initiation of *minoxidil* treatment. These are not ischemic in origin and are seen with other drugs that activate

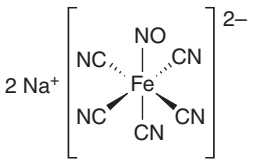
K^+ channels. *Pinacidil* is associated with a lowered ventricular fibrillation threshold and increased spontaneous ventricular fibrillation in the ischemic canine heart, while *minoxidil* had antiarrhythmic effects in the rabbit under ischemia/reperfusion. Whether such findings translate to events in humans is unknown.

Excess hair growth occurs in patients who receive *minoxidil* for an extended period and is probably a consequence of K^+ channel activation. Growth of hair occurs on the face, back, arms, and legs and is particularly offensive to women. Frequent shaving or depilatory agents can be used to manage this problem. Topical *minoxidil* is marketed over the counter for the treatment of male pattern baldness and hair thinning and loss on the top of the head in women. The topical use of *minoxidil* also can cause measurable cardiovascular effects in some individuals.

Other side effects of the drug are rare and include rashes, Stevens-Johnson syndrome, glucose intolerance, serosanguineous bullae, formation of antinuclear antibodies, and thrombocytopenia. *Minoxidil* is contraindicated in patients diagnosed with pheochromocytoma.

Sodium Nitroprusside

Although *sodium nitroprusside* has been known since 1850 and its hypotensive effect in humans was described in 1929, its safety and usefulness for the short-term control of severe hypertension were not demonstrated until the mid-1950s. Several investigators subsequently demonstrated that *sodium nitroprusside* also was effective in improving cardiac function in patients with left ventricular failure (see Chapter 33).



Sodium nitroprusside

Mechanism of Action

Nitroprusside is a nitrovasodilator that acts by releasing NO. NO activates the guanylyl cyclase–cyclic guanosine monophosphate–protein kinase G pathway, leading to vasodilation, mimicking the production of NO by vascular endothelial cells, which is impaired in many hypertensive patients. The mechanism of release of NO from *nitroprusside* is not clear and likely involves both enzymatic and nonenzymatic pathways. Tolerance develops to *nitroglycerin* but not to *nitroprusside*. The pharmacology of the organic nitrates, including *nitroglycerin*, is presented in Chapter 31.

Pharmacological Effects

Nitroprusside dilates both arterioles and venules, and the hemodynamic response to its administration results from a combination of venous pooling and reduced arterial impedance. In subjects with normal left ventricular function, venous pooling affects cardiac output more than does the reduction of afterload; cardiac output tends to fall. In contrast, in patients with severely impaired left ventricular function and diastolic ventricular distention, the reduction of arterial impedance is the predominant effect, leading to a rise in cardiac output (see Chapter 33).

Sodium nitroprusside is a nonselective vasodilator, and regional distribution of blood flow is little affected by the drug. In general, renal blood flow and glomerular filtration are maintained, and plasma renin activity increases. Unlike *minoxidil*, *hydralazine*, *diazoxide*, and other arteriolar vasodilators, *sodium nitroprusside* usually causes only a modest increase in heart rate and an overall reduction in myocardial O_2 demand.

ADME

Sodium nitroprusside is an unstable molecule that decomposes under strongly alkaline conditions or when exposed to light. The drug must be protected from light and given by continuous intravenous infusion to be effective. Its onset of action is within 30 sec; the peak hypotensive effect occurs within 2 min, and when the infusion of the drug is stopped, the effect disappears within 3 min.

Sodium nitroprusside is available in vials that contain 50 mg. The contents of the vial should be dissolved in 2 to 3 mL of 5% dextrose in water. Because the compound decomposes in light, only fresh solutions should be used, and the bottle should be covered with an opaque wrapping. The drug must be administered as a controlled continuous infusion, and the patient must be closely observed. Most hypertensive patients respond to an infusion of 0.25 to 1.5 μg/kg/min. Higher infusion rates are necessary to produce controlled hypotension in normotensive patients under surgical anesthesia. Patients who are receiving other antihypertensive medications usually require less *nitroprusside* to lower blood pressure. If infusion rates of 10 μg/kg/min do not produce adequate reduction of blood pressure within 10 min, the rate of administration of *nitroprusside* should be reduced to minimize potential toxicity.

The metabolism of *nitroprusside* by smooth muscle is initiated by its reduction, which is followed by the release of cyanide and then NO. Cyanide is further metabolized by hepatic rhodanase to form thiocyanate, which is eliminated almost entirely in the urine. The mean elimination $t_{1/2}$ for thiocyanate is 3 days in patients with normal renal function and much longer in patients with renal insufficiency.

Therapeutic Uses

Sodium nitroprusside is used primarily to treat hypertensive emergencies but also can be used in situations when short-term reduction of cardiac preload or afterload is desired. *Nitroprusside* has been used to lower blood pressure during acute aortic dissection; to improve cardiac output in congestive heart failure, especially in hypertensive patients with pulmonary edema that does not respond to other treatment (see Chapter 33); and to decrease myocardial O_2 demand after acute MI. In addition, *nitroprusside* is used to induce controlled hypotension during anesthesia to reduce bleeding in surgical procedures. In the treatment of acute aortic dissection, it is important to administer a β blocker with *nitroprusside* because reduction of blood pressure with *nitroprusside* alone can increase the rate of rise in pressure in the aorta because of increased myocardial contractility, thereby enhancing propagation of the dissection.

Toxicity and Precautions

The short-term adverse effects of *nitroprusside* are due to excessive vasodilation, with hypotension and its consequences. Close monitoring of blood pressure and the use of a continuous variable-rate infusion pump will prevent an excessive hemodynamic response to the drug in most cases.

Less commonly, toxicity may result from conversion of *nitroprusside* to cyanide and thiocyanate. Toxic accumulation of cyanide leading to severe lactic acidosis usually occurs when *sodium nitroprusside* is infused at a rate greater than 5 μg/kg/min but also can occur in some patients receiving doses on the order of 2 μg/kg/min for a prolonged period. The limiting factor in the metabolism of cyanide appears to be the availability of sulfur-containing substrates in the body (i.e., mainly thiosulfate). The concomitant administration of sodium thiosulfate can prevent accumulation of cyanide in patients who are receiving higher-than-usual doses of *sodium nitroprusside*; the efficacy of the drug is unchanged. The risk of thiocyanate toxicity increases when *sodium nitroprusside* is infused for more than 24 to 48 h, especially if renal function is impaired. Signs and symptoms of thiocyanate toxicity include anorexia, nausea, fatigue, disorientation, and toxic psychosis. The plasma concentration of thiocyanate should be monitored during prolonged infusions of *nitroprusside* and should not be allowed to exceed 0.1 mg/mL. Rarely, excessive concentrations of thiocyanate may cause hypothyroidism by inhibiting iodine uptake by the thyroid gland. In patients with renal failure, thiocyanate can be removed readily by hemodialysis. Patients with congenital (Leber) optic atrophy or with tobacco amblyopia have unusually high cyanide/thiocyanate ratios. These rare conditions are probably associated with defective or absent rhodanase, and *sodium nitroprusside* should be avoided in these patients.

Nitroprusside can worsen arterial hypoxemia in patients with chronic obstructive pulmonary disease because the drug interferes with hypoxic

pulmonary vasoconstriction and therefore promotes mismatching of ventilation with perfusion.

Diazoxide

Diazoxide was used in the treatment of hypertensive emergencies but fell out of favor at least in part due to the risk of marked falls in blood pressure when large bolus doses of the drug were used. Other drugs are now preferred for parenteral administration in the control of hypertension. *Diazoxide* also is administered orally to treat patients with various forms of hypoglycemia (see Chapter 51).

Nonpharmacological Therapy of Hypertension

Nonpharmacological approaches to the treatment of hypertension may suffice in patients with modestly elevated blood pressure. Such approaches also can augment the effects of antihypertensive drugs in patients with more marked initial elevations in blood pressure. The indications and efficacy of various lifestyle modifications in hypertension were reviewed in recent guidelines (Whelton et al., 2018; Williams et al., 2018).

- Reduction in body weight for people who are modestly overweight or frankly obese may be useful.
- Restricting sodium consumption lowers blood pressure in some patients.
- Restriction of ethanol intake to modest levels (daily consumption <20 g in women, <40 g in men) may lower blood pressure.
- Increased physical activity improves control of hypertension.
- Renal denervation may be effective in patients with well-defined resistant hypertension (Sardar et al., 2019).
- Bariatric surgery in grossly overweight individuals may normalize blood pressure and increase life expectancy (Schiavon et al., 2020).

Selection of Antihypertensive Drugs in Individual Patients

Choice of an antihypertensive drug should be driven by the likely benefit in an individual patient, considering concomitant diseases such as diabetes mellitus or CAD and problematic adverse effects of specific drugs. Costs have lost relevance because the most important antihypertensive drug classes (ACE inhibitors/ARBs, Ca^{2+} channel blockers, diuretics, and β blockers) are out of patent protection and available as low-cost generics.

After a long debate about blood pressure–independent effects of certain antihypertensive drug classes, there is a consensus that blood pressure lowering *per se* is the most important goal of antihypertensive treatment. This conclusion is based on a number of large comparative prospective trials that, overall, did not show major differences in outcome depending on drug class. Nevertheless, the current evidence for an overall better benefit/risk ratio of ACE inhibitors/ARBs, Ca^{2+} channel blockers, and diuretics (Table 32–4) has led to the recommendation in both American and European guidelines that these four classes of drugs should be preferred as first-line agents in patients with essential hypertension devoid of compelling indications for other drugs (Whelton et al., 2018; Williams et al., 2018; Figure 32–2). The guidelines and evidence for specific therapeutic benefit in special patient groups are the basis of recommendations for a compilation of drug choices in Table 32–4.

Several pharmacological principles should be considered for optimizing the antihypertensive drug regimen.

1. **Pharmacokinetics:** Hypertension is a chronic, often lifelong disease without major symptoms but with serious complications, making compliance to antihypertensive drugs a factor of utmost prognostic importance. Antihypertensives should be chosen that exhibit relatively even plasma concentrations at once-daily dosing, achieving sufficient 24-h control of blood pressure and trough-peak effect ratios greater than 50%. The longer the half-life, the less is the variation of plasma concentrations (e.g., *chlorthalidone* vs. *hydrochlorothiazide*). Drugs with stable pharmacokinetics, that is, low drug interaction potential and no pharmacogenetic influence, are preferred (e.g., *bisoprolol* vs. *metoprolol*).
2. **Drug combinations:** Two-thirds of patients with hypertension require two or more antihypertensives for sufficient blood pressure control. It is therefore recommended to start combining drugs at low-to-medium doses instead of increasing the dose of a single drug (Figure 32–2). Prescribing fixed drug combinations (e.g., a Ca^{2+} channel blocker + ACE inhibitor or an ACE inhibitor + diuretic) improves compliance.
3. **Strength of scientific evidence:** Data from large prospective trials provide a high level of confidence for a beneficial risk-benefit ratio and are a reason to use one drug over another.
4. **Pharmacodynamic considerations:** Although not formally tested in prospective trials, certain drug combinations make more sense than others. Thiazide diuretics increase the antihypertensive actions of all other classes, but their combination with RAS inhibitors makes particular sense as their K^+-sparing effect and thus their main risk are reduced by members of this class.
5. **Adverse drug effects and contraindications:** The major classes of antihypertensives are generally well tolerated and, in placebo-controlled trials, showed rates of adverse effects in the range of placebo with some notable exceptions that need to be taken into consideration when choosing a specific drug for a specific patient (Table 32–5). The rate of adverse effects such as hypotension or bradycardia can be largely reduced by starting antihypertensives at low doses and employing a slow dose-escalation strategy.

TABLE 32–4 ■ ANTIHYPERTENSIVE AGENTS PREFERRED IN SPECIFIC PATIENT POPULATIONS

MEDICAL CONDITION	PREFERRED ANTIHYPERTENSIVE AGENTS
Left ventricular hypertrophy	ACEI, ARB, CCB
Asymptomatic atherosclerosis	CCB
Microalbuminuria	ACEI, ARB
Renal dysfunction	ACEI, ARB
Previous stroke	ACEI, ARB, diuretics
Previous myocardial infarction	ACEI, ARB, BB
Coronary artery disease	ACEI, ARB, BB
Angina pectoris	BB, CCB
Heart failure	ACEI, ARB, BB, diuretics, MRA
Aortic aneurysm	BB
Atrial fibrillation, prevention	ACEI, ARB, BB
Atrial fibrillation, rate control	BB, CCB (nondihydropyridines)
End-stage renal disease, proteinuria	ACEI
Peripheral artery disease	ACEI, CCB
Isolated systolic hypertension	ACEI, ARB, CCB, diuretics
Metabolic syndrome	ACEI, ARB, CCB
Diabetes mellitus	ACEI, ARB, CCB, diuretics
Diabetes mellitus with proteinuria	ACEI, ARB
Hyperaldosteronism	MRA
Pregnancy	BB, CCB, α-methyldopa
Black ethnicity	CCB, diuretics

ACEI, ACE inhibitor; CCB, calcium channel blocker. The drug choices depicted represent a combined view from nine guidelines that differ; thus, the table is, necessarily, a didactic simplification (for details, consult Kjeldsen et al., 2014).

TABLE 32–5 ■ COMPELLING AND POSSIBLE CONTRAINDICATIONS[a] TO ANTIHYPERTENSIVE DRUGS

DRUG CLASS	COMPELLING CONTRAINDICATION	POSSIBLE CONTRAINDICATION/PRECAUTION
ACE inhibitors	Pregnancy Angioneurotic edema Hyperkalemia Bilateral renal artery stenosis	Women with childbearing potential
Angiotensin receptor blockers	Pregnancy Hyperkalemia Bilateral renal artery stenosis	Women with childbearing potential
Ca^{2+} channel blockers (dihydropyridines)		Tachycardia/arrhythmia Heart failure
Ca^{2+} channel blockers (verapamil, diltiazem)	AV block (grade 2–3) Severe left ventricular dysfunction Heart failure	Co-medication with CYP3A4- or P-glycoprotein–dependent drugs (e.g., statins, digoxin)
Diuretics (thiazides)	Gout	Metabolic syndrome Glucose intolerance Pregnancy Hypercalcemia Hypokalemia Erectile dysfunction
Mineralocorticoid receptor antagonists (MRA)	Hyperkalemia Serum creatinine >2.5 mg/dL in men, >2.0 mg/dL in women	Situations associated with higher risk of hyperkalemia (ACE inhibitor, ARB, diabetes)
β Blockers	Asthma AV block (grade 2–3)	Metabolic syndrome Glucose intolerance Athletes and physically active patients Chronic obstructive lung disease Psoriasis Depression
α Blockers	Heart failure	
Central sympatholytic drugs	Depression AV block (grade 2–3)	Erectile dysfunction Xerostomia

[a]*Possible contraindications and precautions* noted in column 3 are not formal contraindications, but rather patient characteristics that should be considered on an individual basis and that may mitigate against use of a class of drugs (e.g., metabolic syndrome and glucose intolerance for diuretics and β blockers). Similarly, some patients with chronic obstructive lung disease can be treated with β_1 blockers without deterioration of lung function, whereas other patients may experience significant bronchoconstriction with β blockers.

6. **Compelling indications:** Several compelling indications exist for specific antihypertensive agents on account of other serious, underlying cardiovascular disease (Table 32–4). These include heart failure, CAD, post-MI, chronic kidney disease, or diabetes. For example, a hypertensive patient with congestive heart failure ideally should be treated with a β blocker, ACE inhibitor/AT_1 receptor blocker, diuretic, and, in selected patients, *spironolactone* because of the benefit of these drugs in congestive heart failure, even in the absence of hypertension (see Chapter 33). Similarly, ACE inhibitors/ARBs should be first-line drugs in the treatment of diabetics with hypertension in view of these drugs' well-established benefits in diabetic nephropathy.
7. **Comorbidities:** Some patients have other diseases that could influence the choice of antihypertensive drugs. For example, a hypertensive patient with symptomatic benign prostatic hyperplasia might benefit from having an α_1 blocker as part of his therapeutic program because α_1 blockers are efficacious in both diseases. Similarly, a patient with recurrent migraine attacks might particularly benefit from use of a β blocker because a number of drugs in this class are efficacious in preventing migraine attacks. Women with a high risk of osteoporosis may benefit from the Ca^{2+}-increasing effect of thiazide diuretics. On the other hand, in pregnant hypertensives, some drugs that are otherwise little used (e.g., *labetalol, methyldopa*) may be preferred and popular drugs (e.g., ACE inhibitors) need to be avoided on account of concerns about safety.
8. **Second- and third-line hypertensives:** In most cases, hypertension can be well controlled by antihypertensives of the four major classes with or without *spironolactone* at low doses. However, patients with chronic kidney disease often require the additional use of drugs such as *hydralazine* or *minoxidil*. The place of *clonidine*/*moxonidine* or α_1 blockers in the treatment of hypertension is not well defined.

Acute Antihypertensive Treatment

The considerations mentioned apply to patients with hypertension who need treatment to reduce long-term risk, not patients in immediately life-threatening settings due to hypertension. While there are limited clinical trial data, clinical judgment favors rapidly lowering blood pressure in patients with life-threatening complications of hypertension, such as encephalopathy or pulmonary edema due to severe hypertension. However, rapid reduction in blood pressure has considerable risks for the patients; if blood pressure is decreased too quickly or extensively, cerebral blood flow may diminish due to adaptations in the cerebral circulation that protect the brain from the sequelae of very high blood pressures.

The temptation to treat patients merely on the basis of increased blood pressure should be resisted. Appropriate therapeutic decisions need to encompass how well a patient's major organs are reacting to the very high blood pressures. While many drugs have been used parenterally to rapidly decrease blood pressure in emergencies (including *nitroprusside, enalaprilat, esmolol, fenoldopam, labetalol, clevidipine* and *nicardipine*, *hydralazine*, and *phentolamine*), the clinical significance of differing actions of many of these drugs in this setting is largely unknown (Perez et al., 2009).

Resistant Hypertension

Some patients with hypertension fail to respond to recommended antihypertensive treatments. There are many potential explanations. To achieve stringent control of hypertension, many patients require two, three, or four appropriately selected drugs used at optimal doses. Exhibiting *an abundance of caution* and *therapeutic inertia*, clinicians may be reluctant to prescribe enough medications that exploit the drugs' full dose-response curves; conversely, patients may not adhere to the recommended pharmacological regimen. Sometimes, multiple drugs in the same therapeutic class that act by the same mechanism are combined; that is generally not a rational approach. Excess salt intake and the tendency of some antihypertensive drugs, especially vasodilators, to promote salt retention may mitigate falls in blood pressure; consequently, inadequate diuretic treatment commonly is found in patients with resistant hypertension. A relevant fraction of patients with resistant hypertension have primary hyperaldosteronism and benefit from the addition of daily *spironolactone* at 25 to 50 mg (Williams et al., 2015). Patients may take prescription drugs, over-the-counter drugs, or herbal preparations that oppose the actions of antihypertensive drugs (e.g., NSAIDs, sympathomimetic decongestants, *cyclosporine*, *erythropoietin*, *ephedra* [also called ma huang], or licorice). Illicit drugs such as cocaine and amphetamines may raise blood pressure. The physician must inquire about a patient's other medications and supplements and individualize the antihypertensive regimen.

Drug Facts for Your Personal Formulary: *Antihypertensives*

Antihypertensive Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Diuretics		
Thiazide type Chlorothiazide Hydrochlorothiazide ***Thiazide-like*** Chlorthalidone Indapamide Metolazone Xipamide	• Hypertension (HTN) • Edema associated with heart failure (HF), liver cirrhosis, chronic kidney disease, nephrotic syndrome • Nephrogenic diabetes insipidus • Kidney stones caused by Ca^{2+} crystals • Metolazone and xipamide (not approved in the U.S.) are also effective at glomerular filtration rate (GFR) <30 mL/min	• First choice for treating HTN • Chlorthalidone may be superior to hydrochlorothiazide in HTN • Lose efficacy at GFR <30–40 mL/min (exceptions: indapamide, metolazone, xipamide) • Potentiate effect of loop diuretics in HF (sequential tubular blockade) • Risk of hypokalemia and arrhythmia when combined with QT-prolonging drugs • Combine with ACE inhibitor (ACEI)/ARB or K^+-sparing diuretic/MRA to prevent hypokalemia
Loop diuretics Bumetanide Furosemide Torsemide	• Acute pulmonary edema • Edema associated with HF, liver cirrhosis, chronic kidney disease, nephrotic syndrome • Hyponatremia • Hypercalcemia • HTN	• Not first choice for treating HTN with normal renal function: action too short and followed by rebound • Indicated acutely in malignant HTN and GFR <30–40 mL/min • Torsemide may be superior to furosemide in HF • Risk of hypokalemia and arrhythmia when combined with QT-prolonging drugs
Sympatholytic Drugs		
β_1 Blockers Atenolol Bisoprolol Metoprolol Nebivolol Many others	• HTN • Heart failure (bisoprolol, metoprolol, nebivolol) • Widely used for other indications (angina, prevention of arrhythmias, rate control in atrial fibrillation, migraine, etc.)	• Not first choice in uncomplicated HTN; clear indication for angina, HF, atrial fibrillation, etc. • Bradycardia and AV block • Bronchospasm, peripheral vasoconstriction • Worsening of *acute* heart failure • Depression • Worsening of psoriasis • Polymorphic CYP2D6 metabolism (metoprolol) • Nebivolol NO-mediated vasodilation
Nonselective β blocker Propranolol	• HTN • Migraine	• Not first choice for treating HTN • Unwanted effects via blockade of β_2 receptors
α_1 Blockers Alfuzosin Doxazosin Prazosin Terazosin	• Benign prostate hyperplasia • HTN	• Not first choice for treating HTN • Higher rate of HF development (?) • Tachyphylaxis • Phenoxybenzamine (irreversible α_1/α_2 blockade) used in pheochromocytoma • Silodosin and tamsulosin are approved for the treatment of prostate hyperplasia and blood pressure–lowering effects need to be considered
α_1 and β blockers Carvedilol Labetalol	• HTN • Heart failure (carvedilol)	• β Blocker of choice in patients with peripheral artery disease • Among first choices for treating HF • Labetalol first choice for HTN in pregnancy
Central sympatholytic drugs Methyldopa Clonidine/moxonidine	• HTN	• Not first choice in treating HTN • Fatigue, depression • Nasal congestion

Antihypertensive Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Ca^{2+} Channel Blockers		
Dihydropyridines Amlodipine Felodipine Isradipine Lercanidipine Nifedipine (extended release) Nitrendipine ***Others*** Diltiazem, verapamil	• HTN • Angina • Rate control in atrial fibrillation (verapamil, diltiazem)	• Long-acting dihydropyridines among first choice in HTN • Diltiazem and verapamil: only if effects on heart rate and AV conduction are wanted, not in combination with β blockers; beware CYP3A4-mediated drug interactions
Inhibitors of the Renin-Angiotensin System		
ACE inhibitors Benazepril Captopril Enalapril Lisinopril Quinapril Ramipril Moexipril Fosinopril Trandolapril Perindopril	• HTN • Heart failure • Diabetic nephropathy	• Among first choice for treating HTN • Short-acting captopril only for initiation of therapy; enalapril and ramipril twice daily • Cough in 5%–10% of patients, angioedema • Hypotension, hyperkalemia, skin rash, neutropenia, anemia, fetopathic syndrome • Contraindications: pregnancy, renal artery stenosis; caution in patients with impaired renal function or hypovolemia • Fosinopril: hepatic and renal elimination, thus eliminated in patients with HF and low renal perfusion
Angiotensin receptor blockers Candesartan Eprosartan Irbesartan Losartan Olmesartan Telmisartan Valsartan Azilsartan	• HTN • Heart failure • Diabetic nephropathy	• Same as ACEI, less cough or angioedema • No evidence for superiority over ACEI • In combination with ACEI, more harm than benefit • Contraindicated in pregnancy
Direct renin inhibitors Aliskiren	• HTN	• Therapeutic value unclear; no evidence for superiority over ACEIs or ARBs • Combination with RAS inhibitors contraindicated
Vasodilators		
Hydralazine	• HTN • Heart failure in African Americans (fixed combination with isosorbide dinitrate)	• Not first choice in treating HTN • Adverse effects: headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris; generally combined with β blocker to reduce baroreceptor reflex effects • Use cautiously in patients with CAD • Lupus syndrome at high doses • Polymorphic metabolism (slow/fast acetylation)
Minoxidil	• HTN • Alopecia	• Reserve antihypertensive in patients with renal insufficiency • Water retention, tachycardia, angina, pericardial effusion • Use in combination with diuretic, β blocker, and RAS inhibitor • Hypertrichosis • Contraindicated in pheochromocytoma
Sodium nitroprusside	• Hypertensive emergencies	• Only short-term intravenously • Adverse effect: hypotension • Cyanide intoxication

Chapter 33 Therapy of Heart Failure

Thomas Eschenhagen

Heart failure is responsible for more than half a million deaths annually in the U.S. Its prevalence is stable in developed countries but increasing worldwide, mainly due to an adoption of western lifestyle and an aging population. Median survival rates after the first hospitalization associated with heart failure are worse than in most cancers but have improved over the past 30 years (1.3 to 2.3 years in men and 1.3 to 1.7 years in women) (Jhund et al., 2009). This positive survival trend was associated with a 2- to 3-fold higher prescription rate of angiotensin-converting enzyme (ACE) inhibitors (ACEIs) and angiotensin receptor blockers (ARBs), β receptor antagonists (β blockers), and mineralocorticoid receptor antagonists (MRAs), suggesting that improved drug therapy has contributed to enhanced survival of patients with heart failure. However, a more complex picture evolved over the past decade with an increasing incidence in people younger than 55 years of age, a decrease in heart failure with reduced ejection fraction (HFrEF); and an increase in heart failure with preserved ejection fraction (HFpEF; Chan et al., 2021; Tsao et al., 2018).

Pathophysiology of Heart Failure

Definitions

Heart failure is a state in which the heart is unable to pump blood at a rate commensurate with the requirements of the body's tissues or can do so only at elevated filling pressure. This leads to symptoms that define the heart failure syndrome clinically. Low output (forward failure) causes fatigue, dizziness, muscle weakness, and shortness of breath, which is aggravated by physical exercise. Increased filling pressure leads to congestion of the organs upstream of the heart (backward failure), clinically apparent as peripheral or pulmonary edema, maldigestion, and ascites.

Most patients with heart failure are diagnosed exclusively on the basis of symptoms; that is, their heart function has never been directly measured (e.g., by echocardiography). Under these circumstances, it is not possible to differentiate between HFrEF (or systolic heart failure) and HFpEF (or diastolic heart failure, see discussion that follows). Other diseases associated with similar symptoms can therefore be wrongly categorized as heart failure (e.g., chronic obstructive pulmonary disease).

Common Final Pathway of Multiple Cardiac Diseases

Heart failure is not a single disease entity but a clinical syndrome that represents the final pathway of multiple cardiac diseases. The most common reason for systolic heart failure today is ischemic heart disease causing either acute (myocardial infarction) or chronic loss of viable heart muscle mass. Other reasons include chronic arterial hypertension and valvular diseases (both are decreasing in incidence due to improved therapy), genetically determined primary heart muscle defects (cardiomyopathies), viral infections (cytomegalovirus and possibly parvovirus), and cardiotoxic agents. The last encompass excessive alcohol, cocaine, amphetamines, and cancer drugs such as *doxorubicin*, *trastuzumab* (the monoclonal antibody directed against the growth factor receptor Her-2/Erb-B2), and immune checkpoint inhibitors (see Section VII).

Pathophysiological Mechanisms

Systolic heart failure (i.e., HFrEF) is relatively well understood, whereas mechanisms underlying HFpEF are much less clear. The pathophysiology of heart failure involves four major interrelated systems (Figure 33–1):

- The heart itself
- The vasculature
- The kidney
- Neurohumoral regulatory circuits

The Heart Itself: Cardiomyopathy of the Overload

Any overload of the myocardium—loss of relevant muscle mass, which overloads the remaining healthy myocardium; chronic hypertension; or valvular defects—will eventually lead to the organ's failure to produce sufficient cardiac output. This concept can be extended to the genetically determined cardiomyopathies in which essentially any defect in an organelle of cardiac myocytes can lead to primary myocyte contractile dysfunction and then, secondarily, to the picture commonly seen in the

Abbreviations

ACC: American College of Cardiology
ACE: angiotensin-converting enzyme
ACEI: angiotensin-converting enzyme inhibitor
ADR: adverse drug reaction
AHA: American Heart Association
AngII: angiotensin II
ANP: atrial natriuretic peptide
ARB: AT_1 angiotensin receptor antagonist (blocker)
ARNI: angiotensin receptor–neprilysin inhibitor
AV: atrioventricular
AVP: arginine vasopressin
BNP: brain-type natriuretic peptide
CG: cardiac glycoside
CHF: congestive heart failure
CNP: C-type natriuretic peptide
CYP: cytochrome P450
DA: dopamine
ECG: electrocardiogram
EF: ejection fraction
eNOS: endothelial nitric oxide synthase
EPI: epinephrine
ESC: European Society of Cardiology
ET: endothelin
GC: guanylyl cyclase
GFR: glomerular filtration rate
GI: gastrointestinal
GPCR: G protein-coupled receptor
HCN: hyperpolarization-activated, cyclic nucleotide–gated cation channel
HFpEF: heart failure with preserved ejection fraction (diastolic heart failure)
HFrEF: heart failure with reduced ejection fraction (systolic heart failure)
iNOS: inducible nitric oxide synthase
ISDN: isosorbide 2,5′-dinitrate
ISMN: isosorbide 5′-mononitrate
MRA: mineralocorticoid receptor antagonist
NCX: Na^+/Ca^{2+} exchanger
NE: norepinephrine
NO: nitric oxide
NOS: nitric oxide synthase
NSAID: nonsteroidal anti-inflammatory drug
NYHA: New York Heart Association
PKA: protein kinase A
RAAS: renin-angiotensin-aldosterone system
RAS: renin-angiotensin system
ROS: reactive oxygen species
SERCA: sarco/endoplasmic reticulum Ca^{2+} ATPase
sGC: soluble guanylyl cyclase
SGLT2: sodium glucose co-transporter 2
SNS: sympathetic nervous system
SR: sarcoplasmic reticulum
TnC: troponin C
TNF: tumor necrosis factor

cardiomyopathy of the overload. Not surprisingly, the most common cardiomyopathies (dilated cardiomyopathy, hypertrophic cardiomyopathy) are due to mutations in genes encoding proteins of the contractile machinery, the sarcomere, proteins anchoring the sarcomere to the plasma membrane, or proteins mediating and maintaining cell-cell contact.

The overload (or the primary contractile defect) leads to alterations of the heart that can partially compensate but that come at a price. Because cardiac myocytes essentially stop replicating in the early postnatal period, the usual response to overload is not myocyte division but rather hypertrophy, growing in size and assembling more sarcomeres that can contribute to contractile force development. Whereas hypertrophy is principally a normal response to physiological needs such as body growth, pregnancy, and physical exercise ("physiological hypertrophy"), hypertrophy in response to chronic overload comes with features that make it a major risk factor for the development of heart failure ("pathological hypertrophy"). A direct consequence of cardiac myocyte hypertrophy is a reduced capillary/myocyte ratio (i.e., less O_2 and nutrient supply per myocyte), causing an energy deficit and metabolic reprogramming. Altered gene expression of ion channels, Ca^{2+}-regulating proteins, and contractile proteins can be interpreted as partially beneficial, energy-saving adaptations; on the other hand, the adaptations also aggravate contractile failure and favor arrhythmias. Concurrently, fibroblasts proliferate and deposit increased amounts of extracellular matrix (e.g., collagen). This fibrosis in heart failure also favors arrhythmias, increases the stiffness of the heart, and interrupts myocyte-to-myocyte communication (coordinated conduction and force transmission). Finally, overload leads to cardiac myocyte death by apoptosis or necrosis. Collectively, these adverse adaptations are called *pathological remodeling*.

Some of these alterations are direct, heart-intrinsic consequences of overload (e.g., hypertrophy, altered gene expression); others are secondary to neurohumoral activation and thereby susceptible to neurohumoral blocking agents (see discussion that follows and Figure 33–1).

The Vasculature

A critical parameter of cardiac function is the stiffness of the vasculature. It determines the resistance against which the heart must expel the blood. Vascular stiffness increases with aging. Heart failure may be the consequence of premature aging of the vasculature (Strait and Lakatta, 2012). Aging-induced loss of elasticity of the great blood vessels reduces their compliance, that is, the elasticity that permits vessels to extend in systole and contract in diastole. Good compliance reduces peak systolic pressure and increases diastolic pressure, which favors perfusion in diastole. It is negatively correlated with pulse pressure, that is, the difference between systolic and diastolic blood pressure, which is low in children and high in the elderly. Arterial hypertension and diabetes mellitus are the major reasons for premature stiffening of blood vessels, which imposes increased afterload to the heart and contributes to heart failure. Theoretically, stiffening and loss of compliance could be directly tackled by drugs (see section Recent Developments; Novel Approaches).

Another critical aspect of vascular function is the ability to adapt the vessel diameter to hemodynamic and neurohumoral stimuli, a function that is governed by cross talk between luminal endothelial and underlying smooth muscle cells (see Chapter 32). The main signaling pathway involves receptors that increase intracellular Ca^{2+} levels in endothelial cells, which activates endothelial nitric oxide synthase (eNOS) to produce nitric oxide (NO). This gaseous transmitter diffuses into smooth muscle cells and activates soluble guanylyl cyclase (sGC) to produce cGMP, which causes relaxation of vascular smooth muscle. Heart failure is always accompanied by endothelial dysfunction, which is a disturbed balance between vasodilating NO and proconstrictor reactive oxygen species (ROS). ROS, by inactivating the two critical enzymes eNOS and sGC and converting NO in peroxynitrite, a strong ROS, favor vasoconstriction. Several common cardiovascular drugs (ACEIs/ARBs, MRAs, statins) improve endothelial function by reducing ROS production. Cyclic nucleotide phosphodiesterase (PDE)5 inhibitors have similar consequences by inhibiting cGMP degradation in smooth muscle cells and thereby promoting relaxation. Stimulators of sGC like the recently approved new heart failure drug *vericiguat* dilate blood vessels by direct stimulation of the enzyme and sensitization to endogenous NO.

The Kidney

The kidney regulates Na^+ and H_2O excretion and thereby intravascular volume. Under normal conditions, autoregulatory and neurohumoral

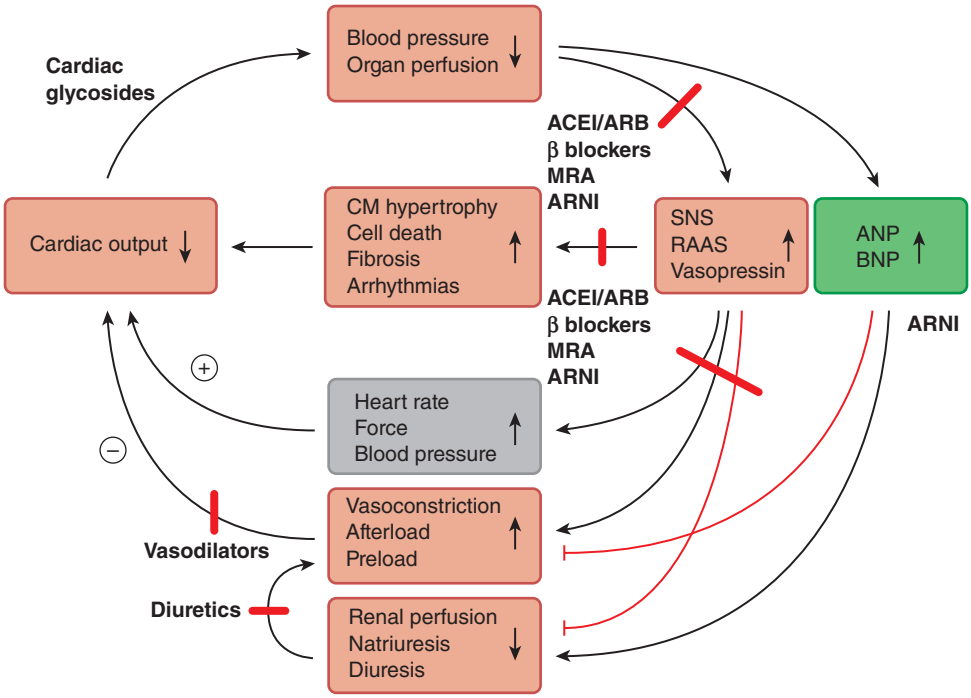

Figure 33–1 *Pathophysiologic mechanisms of systolic heart failure (HFrEF) and therapeutic interventions.* Any major decrease in cardiac contractile function leads to activation of neurohumoral systems, including the SNS, the RAAS, and vasopressin (antidiuretic hormone) secretion, which acutely stabilize blood pressure and organ perfusion by stimulating cardiac output, constricting resistance vessels, decreasing kidney perfusion, and increasing Na^+ and H_2O retention. Unfortunately, these responses are maladaptive, causing chronic overloading and overstimulation of the failing heart. Direct hypertrophic, proapoptotic, fibrotic, and arrhythmogenic effects of NE and AngII further accelerate the deleterious process. Note that the concomitant activation of the ANP/BNP system is the consequence of stretch and increased wall stress in the heart and has opposite and beneficial effects. See Abbreviations list at the beginning of the chapter.

mechanisms ensure an adequate glomerular filtration rate (GFR) and diuresis over a wide range of renal perfusion pressures. Prominent regulatory mechanisms with relevance for heart failure are (1) the angiotensin II (AngII)-mediated regulation of filtration rate by regulating the diameter of the efferent glomerular arteriole; (2) the regulation of kidney perfusion by a balance between constrictor-promoting effects of AngII (via AT_1 receptors) and vasopressin (arginine vasopressin [AVP], via V_1 receptors) and the vasodilating influence of prostaglandins (hence the deleterious effects of nonsteroidal anti-inflammatory drugs [NSAIDs]); (3) the aldosterone-mediated regulation of Na^+ reabsorption in the distal tubule; and (4) AVP-regulated water transport in the collecting ducts (via V_2 receptors). In heart failure, all mechanisms are dysregulated and constitute therapeutic targets of ACEIs/ARBs, MRAs, and diuretics. Newer agents, such as adenosine A_1 receptor antagonists and AVP receptor antagonists, have failed to exert therapeutic benefit in clinical studies.

Neurohumoral Regulation and HFrEF

The decrease in cardiac output in heart failure leads to the activation of the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone system (RAAS) and increases in plasma levels of AVP and endothelin (ET) (Figure 33–1). This concerted response ensures the perfusion of centrally important organs such as the brain and the heart (at the expense of kidney, liver, and skeletal muscle perfusion) in situations of acute blood loss. These responses are components of the "fight-or-flight response" and provide useful short-term physiological responses to alarm and danger. Chronically, however, neurohumoral activation exerts deleterious effects that constitute a vicious cycle in heart failure. Vasoconstriction initially not only stabilizes blood pressure but also increases afterload, which is the resistance against which the heart works to expel blood (see Figures 33–4 and 31–1). Because of the decreased contractile reserve, the failing heart is particularly sensitive to increases in afterload (see Figure 33–4); such increases further decrease cardiac output. Decreased kidney perfusion and increased aldosterone production reduce diuresis and promote volume overload, which increases cardiac preload, dilation, and ventricular wall stress, a major determinant of cardiac O_2 consumption. Tachycardic and positive inotropic actions of catecholamines not only acutely increase cardiac output but also promote arrhythmias and increase O_2 consumption in a failing, energy-depleted heart. AngII, norepinephrine (NE), and ET accelerate pathological cardiac remodeling (hypertrophy, fibrosis, and cell death). Aldosterone has prominent profibrotic actions. This spectrum of adverse consequences of chronic neurohumoral activation explains why inhibitors of these systems (ACEIs/ARBs, β blockers, and MRAs) exert long-term, life-prolonging effects in heart failure and are the cornerstones of current therapy.

Unexpectedly, ET and AVP receptor antagonists provide no beneficial effect in patients with heart failure, despite promising results in preclinical studies. Clinical trials suggested that neurohumoral activation in response to altered cardiac function may be sufficiently inhibited by the standard combination therapy, leaving no room for improvement from the addition of ET and AVP antagonists; however, recent data indicate that additional benefit may accrue via another therapeutic route: a drug combination called angiotensin receptor–neprilysin inhibitors (ARNIs). The FDA has approved a fixed-dose combination of the ARB *valsartan* with the neprilysin inhibitor *sacubitril*. *Valsartan* blocks AT_1 receptors, reducing the deleterious effects of AngII. *Sacubitril* inhibits the degradation of the natriuretic peptides atrial natriuretic peptide (ANP) and brain-type natriuretic peptide (BNP). The *valsartan/sacubitril* combination appears superior to the ACEI *enalapril*, reducing the rates of hospitalization and death from all cardiovascular causes in patients with HFrEF (Hubers and Brown, 2016).

This finding reflects the fact that neurohumoral activation in heart failure includes one system that exerts beneficial effects: the natriuretic peptides. Normally, ANP and BNP are expressed in the atria and released upon increased preload (stretch). During heart failure, ANP and BNP are also produced by the ventricles, such that plasma levels are elevated. Indeed, BNP is used as a biomarker of heart failure. ANP and BNP stimulate the plasma membrane guanylyl cyclase. In the kidney, elevated cGMP has diuretic effects. Elevated cellular cGMP mediates vasodilation in the vasculature and, in the heart, antihypertrophic, antifibrotic, and lusitropic effects related to phosphorylation of titin.

Enhancing these effects by inhibiting the degradation of ANP/BNP likely explains the clinical benefits of *sacubitril/valsartan*.

Heart Failure With Preserved Ejection Fraction

Systematic echocardiographic determination of left ventricular ejection fraction (EF) in thousands of patients with heart failure revealed that about 50% had no reduction; that is, they exhibited EF values greater than 50%. Still, patients had typical heart failure symptoms, including acute decompensation with pulmonary edema and a survival prognosis not much better or even identical to patients with reduced EF (HFrEF). These data point to a different pathophysiology in which abnormalities of the diastolic and not the systolic component of cardiac function prevail. Due to difficulties in defining diastolic function by standard techniques, the term *HFpEF* has been introduced and applies to patients with typical heart failure symptoms and "normal" (>50%) or only mildly reduced EF.

Even more than HFrEF, HFpEF is a multifactorial disease (Figure 33–2). HFpEF is typically associated with arterial hypertension, ischemic heart disease, diabetes mellitus, and obesity (metabolic syndrome); it is more frequent in women than men and shows a strong increase in prevalence with age (Shah et al., 2020). Hearts of patients with HFpEF are generally not dilated, wall thickness is enlarged (hypertrophy), and left atrial size often is enlarged as a sign of chronically elevated end-diastolic pressures. Central to the pathophysiology of HFpEF is, presumably, compromised diastolic relaxation of the left ventricle, which causes congestion of the lung, shortness of breath, or pulmonary edema. Clinical decompensation is often associated with strongly elevated blood pressure.

Molecular alterations include increased myocardial fibrosis (causing a permanent relaxation deficit) as well as more dynamic changes, such as reduced phosphorylation of titin, the sarcomeric protein that spans the large region from the Z to the M band. Titin contains several molecular spring domains whose elastic modulus determines the passive tension of cardiomyocytes, particularly at low-to-medium levels of stretch. Titin stiffness is determined by its isoforms and by cGMP-dependent phosphorylation, suggesting that agents that increase cellular cGMP might be beneficial in HFpEF. However, the PDE5 inhibitor *sildenafil*, which preserves and elevates cellular cGMP in some cells (see Chapters 3, 35, and 49), failed to show benefit (Redfield et al., 2013). This lack of efficacy is, unfortunately, also true for all other pharmacological interventions in HFpEF, including ACEIs, ARBs, and *spironolactone*. A new facet of HFpEF may be upregulation of inducible nitric oxide synthase (iNOS), the inducible isoform of nitric oxide synthase (NOS), in the myocardium, leading to increased nitrosylation and disturbance of the endoplasmic reticulum stress response (Schiattarella et al., 2019). The hypothesis is attractive as it is based on a mouse model integrating both hypertensive and metabolic stress, classical risk factors of HFpEF in humans. This hypothesis offers potential new therapy targets. Presently, exercise training is the only intervention that significantly increases exercise capacity (maximal oxygen consumption, peak VO_2) in HFpEF patients. In the absence of evidence-based clinical trial data, current therapy recommendations concentrate on optimal treatment of the underlying diseases, such as hypertension, diabetes, and obesity.

Heart Failure Staging

Heart failure was one of the first diseases for which guidelines described specific therapies for each stage of the disease. An early classification of the stages of heart failure was that of the New York Heart Association (NYHA), a classification still in use: class I (left ventricular dysfunction, no symptoms); class II (symptoms at medium-to-high levels of physical exercise); class III (symptoms at low levels of physical exercise); and class IV (symptoms at rest or daily life physical activities such as brushing teeth). The more recent guidelines of the American Heart Association (AHA) and American College of Cardiology (ACC) extended this classification by considering the following:

- Heart failure is part of the cardiovascular continuum with preventable risk factors (stage A).
- An asymptomatic stage exists that requires treatment to delay transition to symptomatic heart failure (stage B).
- Patients oscillate between different degrees of symptoms and therefore between class II and III (class C, which generally includes NYHA class II/III patients).

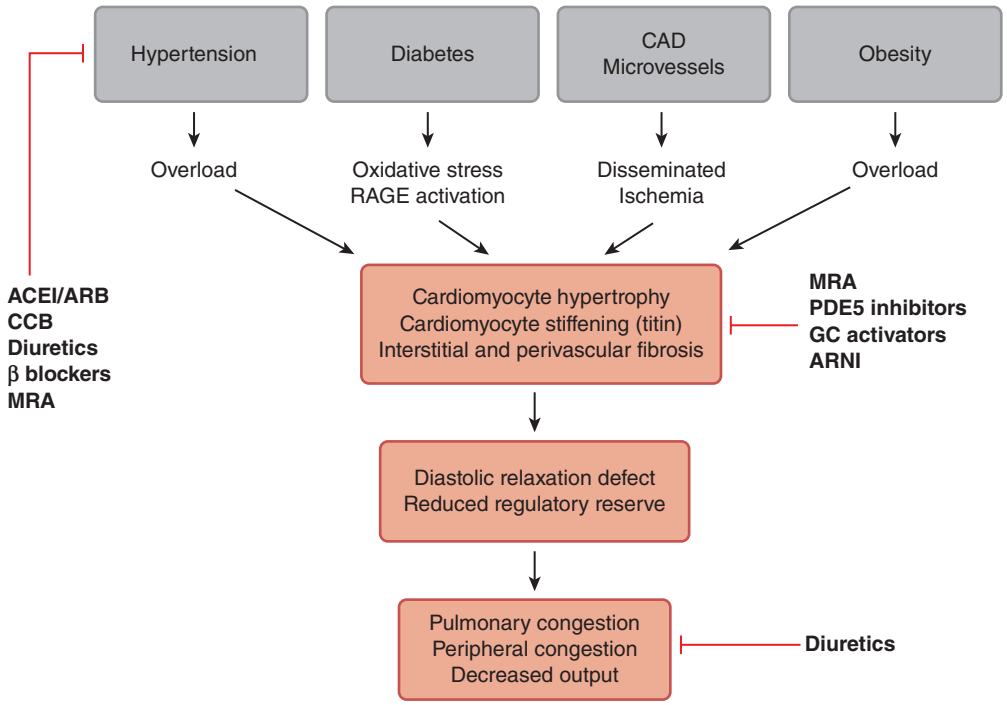

Figure 33–2 *Pathophysiological mechanisms of diastolic heart failure HFpEF and possible therapeutic interventions.* Unlike the case with HFrEF, the pharmacological agents shown have not been proven to have clinical efficacy toward HFpEF, although these agents can help to control underlying diseases, such as hypertension, diabetes, and obesity. Only exercise training has proven effective in increasing maximal exercise capacity. RAGE, receptor for advanced glycosylation end-products. CAD, coronary artery disease; CCB, calcium channel blocker.

- A final stage of the disease requires different treatment and special considerations, such as heart transplantation and left ventricular assist device implantation (stage D).

This chapter uses the AHA/ACC classification and considers the recent guidelines of the European Society of Cardiology (ESC) (Ponikowski et al., 2016), which provide more specific treatment algorithms, and the 2017 AHA/ACC update (Yancy et al., 2017). Treatment guidelines are summarized in Figure 33–3.

Prevention and Treatment

Ischemic heart disease, hypertension, and valvular diseases are the most prevalent causes of heart failure. People at high risk of heart failure (stage A) should be treated with drugs that mitigate the harmful effects of these diseases, in conjunction with appropriate lifestyle changes. Studies in thousands of patients have reproducibly shown that blood pressure lowering in hypertensive patients and lipid lowering with statins in dyslipidemic patients reduce not only the incidence of myocardial infarction and death but also the incidence of heart failure. The data are weaker for antidiabetic drugs, but consensus exists that blood glucose should be controlled with a hemoglobin A_{1C} goal of 7% to 7.5%.

Treatment of heart failure has seen a dramatic change over the past decades. Until the late 1980s, choice of drugs and dosing was symptom oriented and based on pathophysiological considerations of *acute* systolic heart failure. Treatment was mainly directed toward symptom relief and short-term improvement of hemodynamic function. Subsequent randomized clinical trials, which mainly tested effects of drugs on long-term morbidity (hospitalizations) and mortality, disproved many former beliefs. For example, positive inotropic drugs (sympathomimetics and PDE inhibitors) that exert acute symptomatic benefit reduce life expectancy when chronically administered. In contrast, β blockers decrease cardiac output acutely and may make people feel weak at the start of therapy but prolong life expectancy when given in increasing doses for extended periods. Vasodilators once seemed a logical choice for heart failure, but pure vasodilators such as the α_1 receptor antagonist *prazosin* or the nitrate isosorbide 2,5′-dinitrate (ISDN), in combination with the vasodilator *hydralazine*, do not positively affect the prognosis in Caucasians (see further discussion). Finally, successful trials can occur unexpectedly and before the mechanism of action is fully understood. A recent example is the beneficial effect of sodium glucose co-transporter 2 (SGLT2) inhibitors on outcome in patients with heart failure and without diabetes. Thus, clinical trials have established important principles for assessing efficacy of therapies for heart failure:

1. Drugs treating chronic heart failure should reduce the patient morbidity and mortality.
2. Short-term drug effects poorly predict the outcome of randomized clinical trials and optimal therapies for heart failure.
3. Considerations for stage of disease are critical.
4. New drugs for heart failure should be compared to the most effective current combination therapy, a principle often ignored in preclinical animal work.
5. Clinical trials often provide unexpected results, which then initiate research into advanced understanding of mechanisms.
6. Nonpharmacological treatment options such as cardiac resynchronization devices and intracardiac defibrillator/cardioverters are important for their documented lifesaving effect in selected patient populations.

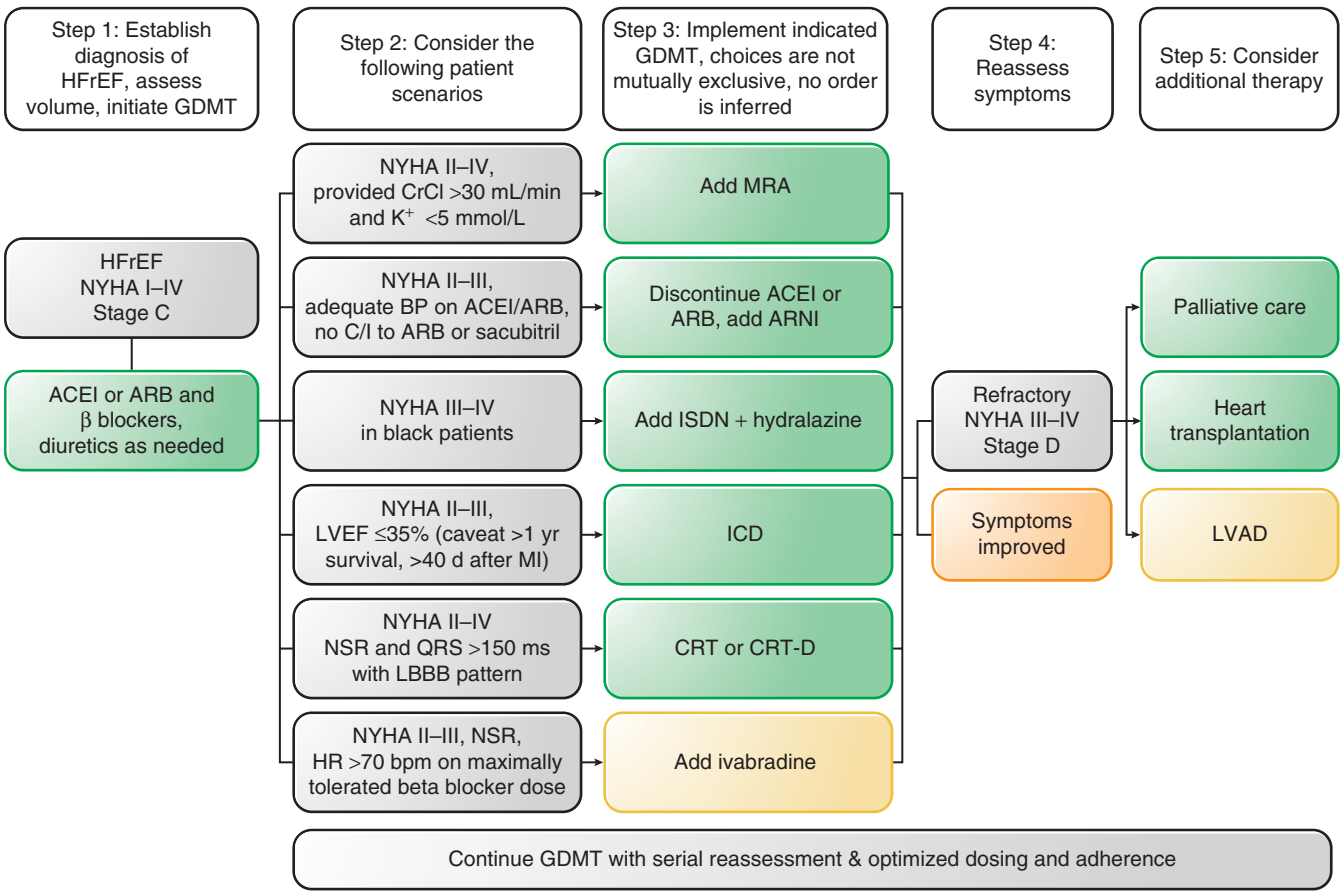

Figure 33–3 *AHA/ACC 2017 Heart Failure Treatment Guidelines (adapted from Yancy et al., 2017).* Colors indicate the guideline class of recommendation (green Ia—clinical efficacy established, yellow IIa—clinical efficacy likely). C/I, contraindication; CrCl, estimated creatinine clearance; CRT-D, cardiac resynchronization therapy device; GDMT, guideline-directed medical therapy; ICD, implantable cardioverter-defibrillator; LBBB, left bundle branch block; LVAD, left ventricular assist device; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NSR, normal sinus rhythm.

TABLE 33–1 ■ LANDMARK STUDIES IN THE TREATMENT OF PATIENTS WITH CHRONIC HFrEF

STUDY ACRONYM AND/OR AUTHOR	YEAR	STUDY POPULATION	NO. OF PATIENTS	BASELINE DRUGS (% of patients on each drug)	EFFECT ON ALL-CAUSE MORTALITY (vs. placebo or another drug)
Cohn et al.	1986	Men, impaired cardiac function and exercise capacity	642	CG, diuretics	ISDN/hydralazine, –34% Prazosin +/– vs. placebo (absolute mortality 19%/year)
CONSENSUS Trial Study Group	1987	Severe HF, NYHA class IV	253	Diuretics 100%, spironolactone 52%, CG 93%, vasodilators ~50%, BB 2%	Enalapril, –40% vs. placebo (absolute mortality 54%/year)
SOLVD Treatment	1991	NYHA II–III, EF <35%	2569	Diuretics 86%, CG 67%, vasodilators 51%, BB 7.5%	Enalapril, –16% vs. placebo (absolute mortality 13%/year)
SOLVD Prevention	1992	NYHA I, EF <35%	4228	Vasodilators 46%, diuretics 17%, CG 13%	Enalapril, –8% (n.s.) vs. placebo (absolute mortality 5%/year); HF development, –20%
DIG	1997	NYHA II–III	6800	Diuretics 81%, ACE 95%, nitrates 43%	Digoxin +/– vs. placebo (absolute mortality 11%/year); HF hospitalizations, –27%
RALES, Pitt et al.	1999	Severe HF, EF <35%	1663	Diuretics 100%, ACEI 94%, CG 72%, BB 10%	Spironolactone, –30% vs. placebo (absolute mortality 18%)
MERIT-HF	1999	NYHA II–IV	3991	Diuretics 90%, ACEI/ARB 95%, CG 63%	Metoprolol CR/XL, –34% vs. placebo (absolute mortality 11%/year)
PARADIGM, McMurray et al.	2014	NYHA II–IV	8442	Diuretics 80%, BB 93%, MRA 56%, CG 30%, ICD 15%, CRT 7%	Sacubitril/valsartan, –16% vs. enalapril (absolute mortality ~8%/year)
DAPA-HF	2019	NYHA II–IV	4744	Diuretics 93%, ACEI/ARB 85%, BB 96%, MRA 71%, CG 19%, ICD 26%, CRT 7%	Dapagliflozin, –17% vs. placebo (absolute mortality 9%/year)

BB, β blocker; CRT, cardiac resynchronization therapy; HF, heart failure; ICD, implantable cardioverter-defibrillator; n.s., nonsignificant.

Attention to these principles for assessing long-term efficacy of heart failure therapies has provided evidence-based principles of treatment.

HISTORICAL PERSPECTIVE

A series of landmark studies over three decades has established the current thinking on the treatment of patients with chronic HFrEF. These studies are not reviewed here, but interested readers may wish to consult the evidence that supports current therapies. These studies, often indicated by an acronym, are summarized in Table 33–1.

Drug Treatment of Chronic Systolic Heart Failure

Treatment Principle I: Neurohumoral Modulation

Dampening neurohumoral activation and its deleterious consequences on the heart, blood vessels, and kidney is the cornerstone of heart failure therapy. Therapy consists of ACEIs/ARBs, β blockers, MRAs, and neprilysin inhibitors (Figure 33–1). A systematic discussion of the drugs is found in Chapters 14, 29, 30, 31, and 32.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin II, the most active of the many angiotensin peptides, is largely derived from angiotensinogen in two proteolytic steps. First, *renin*, an enzyme released from the macula densa of the kidneys, cleaves the decapeptide AngI from the amino terminus of angiotensinogen (renin substrate) made by the liver. Then, ACE removes a carboxy-terminal dipeptide (His^9-Leu^{10}) from AngI, yielding the active octapeptide, AngII (see Chapter 30). Thus, ACEIs reduce circulating levels of AngII. All patients with heart failure (stages B and C; NYHA I–IV) should receive an ACEI.

Mechanism of Action. AngII interacts with two heptahelical G protein-coupled receptors (GPCRs), AT_1 and AT_2, and has four major cardiovascular actions that are all mediated by the AT_1 receptor:

- Vasoconstriction
- Stimulation of aldosterone release from the adrenal glands
- Direct hypertrophic and proliferative effects on cardiomyocytes and fibroblasts, respectively
- Stimulation of NE release from sympathetic nerve endings and the adrenal medulla

Physiological Effects. The ACEIs decrease AngII concentrations and thereby reduce its deleterious effects. Thus, ACEIs not only act as vasodilators but also reduce aldosterone levels and thereby act as an indirect diuretic, have direct antiremodeling effects on the heart, and produce sympatholytic effects (thus moderating the reflex tachycardia that accompanies vasodilation and the lowering of blood pressure).

The ACEIs have important renal effects. When renal perfusion pressure is reduced, AngII constricts renal efferent arterioles, and this serves to maintain glomerular filtration pressure and GFR. Thus, when renal perfusion pressure is compromised, inhibition of the RAAS may induce a sudden and marked decrease in GFR. For this reason, ACEIs are contraindicated in bilateral renal artery stenosis. Likewise, because patients with heart failure often have low renal perfusion pressures, aggressive treatment with ACEIs may induce acute renal failure. To avoid this, for patients with heart failure, ACEIs should be initiated at very low doses; blood pressure, blood creatinine, and K^+ levels should be monitored; and the ACEI dose slowly increased over weeks toward target levels (for agents that have been carefully evaluated in clinical trials; Table 33–2). The potentially dangerous acute effects become beneficial with long-term use of ACEIs because the (small) chronic lowering of glomerular pressures protects the glomerulus from fibrotic degeneration.

The ACEI-induced lowering of aldosterone levels causes reduced expression of the aldosterone-dependent epithelial Na^+ channel (ENaC)

TABLE 33–2 ■ ACEIs AND ARBs APPROVED AND CLINICALLY EVALUATED FOR THE THERAPY OF HfrEF[a]

DRUG	HALF-LIFE (h)	START DOSE (mg)	TARGET DOSE (mg)	IMPORTANT ADVERSE EFFECTS, INTERACTIONS, AND CONTRAINDICATIONS
ACEIs				
Captopril	1.7	3 × 6.25	3 × 50	**Adverse effects:** Cough (~5%), increase in serum creatinine (<25% normal, if >50%, think about renal artery stenosis), hyperkalemia, hypotension, angioedema; rare cholestatic jaundice, hepatic failure, agranulocytosis **Interactions:** Increased rate of hyperkalemia in combination with potassium-sparing diuretics, potassium supplements, cyclosporine, NSAIDs (PD), reduced efficacy in combination with NSAIDs (PD), increased lithium serum concentrations (PK) and hypoglycemic risk in combination with insulin or oral antidiabetics; increased effect in renal insufficiency (PK) **Contraindications:** Bilateral renal artery stenosis, therapy with neprilysin inhibitor (sacubitril)
Enalapril	11	2 × 2.5	2 × 20	
Lisinopril	13	1 × 2.5–5	1 × 20–35	
Ramipril	13–17	1 × 2.5	1 × 10	
Trandolapril	15–23	1 × 0.5	1 × 4	
ARBs				
Candesartan	9	1 × 4-8	1 × 32	**Adverse effects:** Similar to ACE, but less cough **Interactions and contraindications:** Same as for ACEI
Losartan	6-9	1 × 50	1 × 150	
Valsartan	6	2 × 40	2 × 160	

PD, pharmacodynamics; PK, pharmacokinetic interaction.
[a]Plasma half-lives partially apply to active metabolites (e.g., losartan).

in the distal tubule (see Figure 29–6). This target of K^+-sparing diuretics (see discussion that follows) normally mediates Na^+ reabsorption and K^+ excretion. Lower levels of ENaC lead to less absorption of Na^+ and less excretion of K^+. Thus, ACEIs favor hyperkalemia, which can be detrimental in patients with renal insufficiency but is normally beneficial for patients with heart failure who more often present with hypokalemia, a condition that promotes cardiac arrhythmias. ACEIs shift the balance of vascular smooth muscle tone toward vasodilation and thereby increase renal blood flow, another reason for their chronic protective effects on the kidney. This effect also explains why NSAIDs, which reduce the production of vasodilating prostaglandins, antagonize effects of ACEIs and should be avoided in patients with heart failure.

Other Actions, Good and Adverse. Angiotensin-converting enzyme has other actions, including the inactivation of bradykinin and substance P. ACEIs increase bradykinin and substance P levels, with two prominent consequences: cough, the most frequent adverse drug reaction (ADR) (~5%); and angioedema, a rare (~0.7%) but life-threatening condition presenting with swelling of the skin and mucous membranes of the throat and asphyxia (three times more common among people of African origin; McDowell et al., 2006). Experimental evidence suggests that increases in bradykinin contribute to the therapeutic efficacy of ACEIs and may explain why ARBs, which do not increase bradykinin (and therefore rarely cause cough), have not been consistently associated with improved survival in patients with HFrEF (Ponikowski et al., 2016).

The ACEIs are generally well tolerated in most patients. Important ADRs are the following:

- Dry cough, necessitating a change to ARBs
- Creatinine plasma concentration increase (<20%, normal; 20%–50%: careful observation and reduction of ACEI dosage; >50%, stop ACEI and consult specialist for evaluation of renal artery stenosis)
- Hyperkalemia (small increase normal, but requires careful observation in patients with diabetes, renal insufficiency, or comedication with MRAs, K^+-sparing diuretics, or NSAIDs)
- Angioedema (stop drug immediately and treat with antihistamines, corticosteroids, or, in severe case, epinephrine [EPI])
- Allergic skin reactions

Angiotensin Receptor Antagonists

The ARBs are systematically discussed in Chapter 30. They are highly selective, competitive receptor antagonists at the AT_1 receptor, which mediates the major effects of AngII. Therapeutic alternatives to ACEIs and second choice in all stages of heart failure in patients who do not tolerate ACEIs. Given the central role of the AT_1 receptor for the actions of AngII, it is not surprising that ARBs show the same pharmacological profile as ACEIs with the exception of not inducing cough. The unopposed activity of AT_2 receptor pathways in the presence of AT_1 blockade by an ARB seems to confer no therapeutic advantage to ARBs over ACEIs. Moreover, the addition of an ARB to therapy with an ACEI does not affect the prognosis of patients with heart failure but does increase hypotension, hyperkalemia, and renal dysfunction. A negative interaction between ACEIs and ARBs appears to extend to patients with higher renal risk. There is, therefore, no routine indication for this combination.

β Adrenergic Receptor Antagonists

Major Effects of β Adrenergic Antagonists. The sympathetic neurotransmitters NE (released at adrenergic nerve varicosities) and EPI (secreted by the adrenal medulla) are strong stimuli of heart function. They increase heart rate (positive chronotropic effect) and force of contraction (positive inotropic effect) and thereby augment cardiac output. They hasten the rate of force development (increased +dP/dt, positive clinotropy) and accelerate cardiac muscle relaxation (greater −dP/dt, positive lusitropic effect), which aids ventricular filling during diastole. Acceleration of the atrial-ventricular conduction rate (positive dromotropic effect) shortens the heart cycle and allows higher beating rates. Catecholamines enhance cardiac myocyte automaticity and lower the threshold for arrhythmias (positive bathmotropic effect). All these acute effects are mediated by β_1 receptors and, to a smaller extent, β_2 receptors. Extracardiac effects include bronchodilation (β_2), vasodilation (β_2) as well as vasoconstriction (α_1 receptors, which dominate at higher concentrations of catecholamines), stimulation of hepatic glycogen metabolism and gluconeogenesis (β_2), and, importantly, stimulation of renin release from the macula densa (β_1). Thus, activation of the SNS coactivates the RAAS, and, as outlined previously, activation of the RAAS activates the SNS by stimulation of NE release (see Chapters 14 and 30).

The β blockers competitively reduce β receptor–mediated actions of catecholamines and thus, depending on the activation level of the SNS, reduce heart rate and force, slow relaxation, slow atrioventricular (AV) conduction, suppress arrhythmias, lower renin levels, and, depending on their selectivity for the β_1 receptor, permit more or less bronchoconstriction, vasoconstriction, and lowering of hepatic glucose production.

Why Use β Blockers in Heart Failure? In light of the above actions, the efficacy of β blockers in heart failure came as a surprise and had to

overcome resistance in the medical community. How can a drug with cardiodepressant actions on heart function be beneficial in a clinical situation in which the heart is already dysfunctional and depending on catecholamines to maintain cardiac output? The first therapeutic application of β blockers at low doses was to a Swedish cohort of patients with heart failure with cardiac decompensation and heart rate greater than 120 beats/min; the goal was to reduce heart rate and cardiac energy consumption (Waagstein et al., 1975). The success of the experiment led to large clinical trials (i.e., MERIT-HF) that showed an impressive 35% prolongation of life expectancy in patients treated with β blockers (Table 33–1), on top of effects of ACEIs, diuretics, and *digoxin*.

Key to the understanding of the success of β blockers in heart failure were two lessons. *First*, therapy must be initiated in a clinically stable condition and at very low doses (one-eighth of target), and dose escalation requires time (e.g., doubling every 4 weeks in ambulatory settings; "start low, go slow"). Under these conditions, the heart has time to adapt to decreasing stimulation by catecholamines and to find a new equilibrium at a lower adrenergic drive. Importantly, β blockers do not fully block the receptors; rather, they are competitive antagonists that shift the concentration-response curve of catecholamines to the right (see Chapter 3).

Second, although the acute effects of catecholamines can be lifesaving, that level of β adrenergic stimulation applied chronically, as the SNS does in response to heart failure, is deleterious. Positive chronotropic, inotropic, and lusitropic effects culminate in overproportional increase in energy consumption. This is irrelevant in situations of acute blood loss or other stresses, but critical if persistent. The heart reacts to chronic sympathetic stimulation by a heart failure–specific gene program (e.g., downregulation of β adrenergic receptor density; upregulation of inhibitory G proteins; and decreases of sarcoplasmic reticulum [SR] Ca^{2+}-ATPase, the fast isoform of myosin heavy chain, and repolarizing K^+ currents), changes that come at the price of decreased dynamic range and increased propensity for arrhythmias. Reversal of the heart failure gene program by β blockers (Lowes et al., 2002) likely contributes to the paradoxical increase in left ventricular EF after 3 to 6 months of therapy and to the reduced rate of arrhythmogenic sudden cardiac death noted in large studies. In a simple view, β blockers protect the heart from the adverse long-term consequences of adrenergic overstimulation, for example, increased energy consumption, fibrosis, arrhythmias, and cell death. Lower heart rates not only save energy but also improve contractile function because the failing heart, in contrast to the healthy human heart, has a negative force-frequency relation (Pieske et al., 1995). In addition, β blockers improve perfusion of the myocardium by prolonging diastole, thereby reducing ischemia.

Available Agents. Four β blockers have been successfully tested in randomized clinical trials (Table 33–1): the β_1-selective agents *metoprolol* (MERIT-HF Investigators, 1999) and *bisoprolol* (CIBIS-II Investigators, 1999) and the third-generation agents with additional actions, *carvedilol* and *nebivolol*. *Carvedilol* is a nonselective β blocker and an α_1 receptor antagonist. *Nebivolol* (Flather et al., 2005) is β_1 selective and has additional vasodilatory actions that may be NO mediated (Chapter 14). The COMET trial (Poole-Wilson et al., 2003), the only randomized, prospective, head-to-head comparison of two β blockers, suggested a more favorable effect of *carvedilol* over *metoprolol* but used *metoprolol* in an unsuitable formulation (*metoprolol* tartrate instead of succinate in zero-order kinetics formulation) and at an insufficient dose. Subsequent observational studies and meta-analyses collectively did not confirm a clinically meaningful difference.

Pharmacokinetic Considerations. There are important pharmacokinetic differences among these β blockers (Table 33–3), distinctions that are relevant because successful therapy of heart failure (and most other chronic cardiovascular diseases) requires stable plasma concentrations over the entire day (trough levels before next dose application >50% of maximum).
