Metoprolol has a short $t_{1/2}$ (3–5 h) and is only approved for the treatment of heart failure as the zero-order prolonged-release formulation that has been used in the successful outcome trials (*metoprolol succinate CR/XL*; Ponikowski et al., 2016; Yancy et al., 2017). Standard extended-release formulations (*metoprolol tartrate*) exhibit much larger daily fluctuations of plasma concentrations and an insufficient 24-h trough-peak ratio when given twice daily. A principal disadvantage of *metoprolol* is its dependency on the polymorphic cytrochrome P450 (CYP) 2D6 for its metabolism. CYP2D6 "poor metabolizers," about 8% of the Caucasian population, exhibit C_{Pmax} levels of *metoprolol* 5-fold higher than those of standard metabolizers; in a prospective longitudinal study, that difference correlated with 2-fold differences in heart rate responses (Rau et al., 2009). *Bisoprolol* has a sufficiently long plasma $t_{1/2}$ (10–12 h) for once-daily dosing and is not metabolized by CYP2D6. *Carvedilol* has a shorter $t_{1/2}$ (6–10 h) and requires twice-daily dosing. An advantageous peculiarity of *carvedilol* is that it dissociates only slowly from β receptors and therefore acts longer than its plasma $t_{1/2}$ suggests. *Carvedilol* metabolism depends on CYP2D6, but less so than *metoprolol*. *Nebivolol* plasma concentrations are 10- to 15-fold higher in CYP2D6 poor metabolizers, but this is without clinical consequence, likely because the first metabolite is similarly active as the parent compound. *Nebivolol* is not approved in the U.S. for the treatment of heart failure (only for hypertension), but it is approved in 71 countries worldwide, including Europe (patients >70 years of age).

Clinical Use. All patients with symptomatic heart failure (stage C, NYHA II–IV) and all patients with left ventricular dysfunction (stage B, NYHA I) after myocardial infarction should be treated with a β blocker. The therapy with β blockers should be initiated only in clinically stable patients at very low doses, generally one-eighth of the final target dose, and titrated upward every 4 weeks. Even when initiated properly, a tendency to retain fluid exists that may require diuretic dose adjustment. The improvement of left ventricular function generally takes 3 to 6 months, and in this period, patients should be carefully monitored.

The β blockers should not be administered in new-onset or acutely decompensated heart failure. If patients are hospitalized with acute decompensation under current therapy with β blockers, doses may need to be reduced or the drug discontinued until clinical stabilization, after which therapy should be restarted.

Precautions. Formally, β blockers have long lists of adverse drug responses and contraindications. Practically, however, they are generally well tolerated if properly initiated. If doses are increased too rapidly, fall of blood pressure, fluid retention, and dizziness are common and require dose reduction.

TABLE 33–3 ■ β BLOCKERS APPROVED AND CLINICALLY EVALUATED FOR THE THERAPY OF HFrEF

β BLOCKER	β_1 SELECTIVE	VASODILATION	HALF-LIFE (h)	START DOSE (mg)	TARGET DOSE (mg)	CYP2D6 DEPENDENCE[a]
Bisoprolol	Yes	No	10–12	1 × 1.25	1 × 10	No
Carvedilol	No	Yes	6–10	2 × 3.125	2 × 25	Yes
Metoprolol succinate[b]	Yes	No	>12[b]	1 × 12.5[b]	1 × 200	Yes
Nebivolol	Yes	Yes	10	1 × 1.25	1 × 10	Yes

[a]CYP2D6 indicates dependence on polymorphic cytochrome P450 metabolism; likely less relevant for nebivolol as first metabolite is active.
[b]Clinical studies in heart failure have mainly used metoprolol succinate in a slow-release formulation (zero order of kinetics); metoprolol itself has a half-life of 3–5 h.

The major cardiovascular responses associated with use of β blockers are the following:

- *Heart rate lowering,* a desirable effect that indicates proper dosing (no decrease indicates insufficient dosing). A reasonable target resting heart rate is 60 to 70 beats/min.
- *AV block* (beware preexisting conduction disturbance; consider pacemaker implantation).
- *Bronchoconstriction.* Asthma is a contraindication for all β blocker use; however, chronic obstructive lung disease is not, because the β_2 receptor–dependent dynamic range is low in these patients, and studies have documented safety. Nonetheless, only β_1-selective compounds should be used in patients with chronic obstructive pulmonary disease.
- *Peripheral vasoconstriction (cold extremities).* Initial vasoconstriction turns into vasodilation under chronic therapy with β blockers. Cold extremities are generally not a problem in patients with heart failure. Yet, patients with peripheral artery disease or symptoms of claudication or Raynaud disease should be carefully monitored and treated with *carvedilol* if a β blocker is employed.

Mineralocorticoid Receptor Antagonists

The third group of drugs with a documented life-prolonging effect in patients with heart failure are MRAs. They should be given in low doses to all patients in stage C (NYHA class II–IV), that is, with symptomatic HFrEF, even though the combination of ACEIs/ARBs and MRA is formally contraindicated due to the risk of hyperkalemia. The safety of a low-dose MRA (25 mg vs. the standard 100 mg of *spironolactone*) was demonstrated in a large, randomized trial in a patient cohort with severe heart failure (NYHA III–IV), with the MRA added to ACEIs, diuretics, and *digoxin* (Pitt, 2004). Later studies with *eplerenone* in less-severe heart failure essentially confirmed the efficacy of this class of drugs.

Mechanism of Action. The MRAs act as antagonists of nuclear receptors of aldosterone (see Figure 29–6). They are K^+-sparing diuretics (see discussion that follows) but gained more importance in the treatment of heart failure for their additional efficacy in suppressing the consequences of neurohumoral activation. Aldosterone, as the second major actor of the RAAS, promotes Na^+ and fluid retention, loss of K^+ and Mg^{2+}, sympathetic activation, parasympathetic inhibition, myocardial and vascular fibrosis, baroreceptor dysfunction, and vascular damage, all adverse effects in the setting of heart failure. Aldosterone plasma levels decrease under therapy with ACEIs or ARBs, but quickly increase again, a phenomenon called *aldosterone escape*. It is likely explained by incomplete blockade of the RAAS (e.g., AngI can be converted to AngII by chymase, in addition to ACE; see Chapter 30) and by the fact that aldosterone secretion is regulated not only by AngII but also by plasma concentrations of Na^+ and K^+. MRAs inhibit all the effects of aldosterone, of which reduction in fibrosis may be of particular importance.

Clinical Use; Adverse Responses. Currently, two steroidal MRAs are available, *spironolactone* and *eplerenone*. *Spironolactone* is a nonspecific steroid hormone receptor antagonist with similar affinity for progesterone and androgen receptors; it causes gynecomastia (painful breast swelling, 10% of patients) in men and dysmenorrhea in women. *Eplerenone* is selective for the mineralocorticoid receptor and therefore does not cause gynecomastia. A nonsteroidal MRA (*finerenone*) received FDA approval in 2021. It has a higher selectivity for mineralocorticoid over other steroid receptors and may cause relatively less hyperkalemia.

The most important ADR of MRAs is hyperkalemia. Under the well-controlled conditions of clinical trials, serious hyperkalemia (>5.5 mmol/L) occurred in 12% in the eplerenone group versus 7% in the placebo group (Zannad et al., 2011). Rates of hyperkalemia may be higher in clinical practice when risk conditions, comedication, and dose restrictions are not well controlled (Juurlink et al., 2004). Guidelines for the use of MRAs in patients with heart failure are as follows:

- Administer no more than 50 mg/d.
- Do not use if the GFR is less than 30 mL/min (creatinine ~2 mg/dL or higher).
- Be careful with elderly patients, in whom improvement in prognosis may be less relevant than prevention of serious side effects.
- Be careful with diabetics, who carry a higher risk of hyperkalemia.
- Do not combine with NSAIDs, which are contraindicated in heart failure but are frequently prescribed for chronic degenerative diseases of the musculoskeletal system.
- Do not combine with other K^+-sparing diuretics.

Angiotensin Receptor and Neprilysin Inhibitors

An addition to standard combination therapy of heart failure is *sacubitril/valsartan*. It is made by co-crystallizing the well-known ARB *valsartan* with *sacubitril*, a prodrug that, after deesterization, inhibits neprilysin, a peptidase mediating the enzymatic degradation and inactivation of natriuretic peptides (ANP, BNP, C-type natriuretic peptide [CNP]), bradykinin, and substance P. Thus, the drug combines inhibition of the RAAS with activation of a beneficial axis of neurohumoral activation, the natriuretic peptides. Consequently, the ARNI is expected to promote the beneficial effects of natriuresis, diuresis, and vasodilation of arterial and venous blood vessels and to inhibit thrombosis, fibrosis, cardiac myocyte hypertrophy, and renin release. Augmentation of ANP/BNP levels by inhibiting degradation is a better pharmacological principle than giving the agonist BNP (*nesiritide*; see under acute heart failure) directly because it enhances *endogenous* regulation of plasma and tissue levels. *Sacubitril/valsartan* causes smaller increases in bradykinin and substance P than *omapatrilat*, an earlier drug combining a neprilysin inhibitor and an ACEI (which itself and additionally inhibits degradation of these peptides). This difference may explain why *sacubitril/valsartan* is not associated with an increased rate of angioedema, the adverse effect that stopped the development of *omapatrilat*. A large head-to-head comparison study in patients with stable heart failure showed superiority of *sacubitril/valsartan* over *enalapril* (McMurray et al., 2014). It is currently recommended as a replacement for an ACEI or ARB in all patients with NYHA class II–III (U.S.; Yancy et al., 2017) or, in the ESC guidelines, for all patients still symptomatic under triple therapy including MRA (Ponikowski et al., 2016).

Treatment Principle II: Preload Reduction

Fluid overload with increased filling pressures (increased preload) and dilation of the ventricles in heart failure is the consequence of decreased kidney perfusion and activation of the RAAS. Normally, increased preload and stretch of the myofilaments increase contractile force in an autoregulatory manner, the positive force-length relationship or Frank-Starling mechanism. However, the failing heart in congestion operates at the flat portion of this relationship (Figure 33–4) and cannot generate sufficient force with increasing preload, leading to edema in the lungs and the periphery.

Diuretics increase Na^+ and water excretion by inhibiting transporters in the kidney and thereby improve symptoms of congestive heart failure (CHF) by moving patients to lower cardiac filling pressures along the same ventricular function curve. Diuretics are an integral part of the combination therapy of symptomatic forms of heart failure. Prognostic efficacy of diuretics in heart failure will remain an academic question, simply because randomization for a trial of diuretics would be ethically impermissible. Diuretics should *not* be given to patients without congestion because they activate the RAAS and may accelerate a vicious downward spiral. On the other hand, in severe heart failure, diuretic resistance may occur for various reasons and cause clinical deterioration (Table 33–4).

Loop Diuretics

Loop diuretics (*furosemide, torsemide, bumetanide*; Table 33–5) inhibit the Na^+-K^+-2Cl symporter in the ascending limb of the loop of Henle, where up to 15% of the primary filtrate (~150 L/d) is reabsorbed, explaining their strong diuretic action. The increase in Na^+ and fluid delivery to distal nephron segments has two consequences:

- It is sensed in the macula densa and normally activates tubuloglomerular feedback to decrease GFR. This autoregulation explains the quick

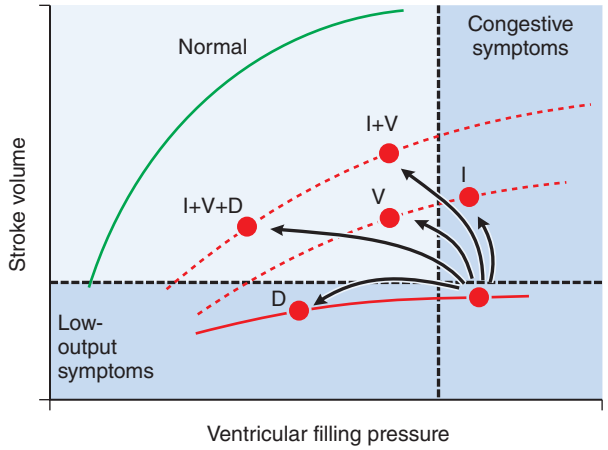

Figure 33–4 *Hemodynamic responses to pharmacologic interventions in heart failure.* The relationships between diastolic filling pressure (preload) and stroke volume (ventricular performance) are illustrated for a normal heart (green line; the Frank-Starling relationship) and for a patient with heart failure with systolic dysfunction (red line). Note that positive inotropic agents (I), such as CGs or *dobutamine*, move patients to a higher ventricular function curve (lower dashed line), resulting in greater cardiac work for a given level of ventricular filling pressure. Vasodilators (V), such as ACEIs or *nitroprusside*, also move patients to improved ventricular function curves while reducing cardiac filling pressures. Diuretics (D) improve symptoms of CHF by moving patients to lower cardiac filling pressures along the same ventricular function curve.

loss of efficacy of older diuretics of the carbonic anhydrase inhibitor class (e.g., *acetazolamide*), acting in the proximal tubule. Thiazides (see discussion that follows) are derived from this class and cause a small decrease in the GFR. Loop diuretics inhibit the feedback mechanism because it is mediated by the Na^+-K^+-2Cl symporter; they exhibit stable action and do not affect the GFR.

- It leads to increased ENaC-mediated reabsorption of Na^+ and, in exchange, to more K^+ excretion in the distal tubule, explaining the main side effect, hypokalemia.

The bioavailability of orally administered *furosemide* ranges from 40% to 70%. High drug doses are often required to initiate diuresis in patients with worsening symptoms or in those with impaired gastrointestinal (GI) absorption, as may occur in severely hypervolemic patients with CHF-induced GI edema. Oral bioavailabilities of *bumetanide* and *torsemide* are greater than 80%, and as a result, these agents are more consistently absorbed than *furosemide*. *Furosemide* and *bumetanide* are short-acting drugs. The $t_{1/2}$ of *furosemide* in normal kidney function is about 1 h (increases in terminal kidney failure to >24 h). Rebound Na^+ retention normally requires dosing twice a day or more. *Bumetanide* reaches maximal plasma concentrations in 0.5 to 2 h and has a $t_{1/2}$ of 1 to 1.5 h. *Torsemide* has a slower onset of action (maximal effect 1–2 h after ingestion) and a plasma $t_{1/2}$ of 3 to 4 h. Kidney failure does not critically affect the elimination of *bumetanide* or *torsemide*. *Ethacrynic acid*, in contrast to other loop diuretics, thiazides, and thiazide-like diuretics, is not a sulfonamide and is generally reserved for patients with sulfa allergy. It acts like *furosemide* and causes ototoxicity at high doses.

TABLE 33–4 ■ CAUSES OF DIURETIC RESISTANCE IN HF

Noncompliance with medical regimen; excess dietary Na^+ intake
Decreased renal perfusion and glomerular filtration rate due to:
Excessive vascular volume depletion and hypotension due to aggressive diuretic or vasodilator therapy
Decline in cardiac output due to worsening heart failure, arrhythmias, or other primary cardiac causes
Selective reduction in glomerular perfusion pressure following initiation (or dose increase) of ACEI therapy
Nonsteroidal anti-inflammatory drugs
Primary renal pathology (e.g., cholesterol emboli, renal artery stenosis, drug-induced interstitial nephritis, obstructive uropathy)
Reduced or impaired diuretic absorption due to gut wall edema and reduced splanchnic blood flow

Thiazide Diuretics

Thiazide diuretics (*hydrochlorothiazide, chlorthalidone*; Table 33–5) have a limited role in heart failure for their low maximal diuretic effect and loss of efficacy at a GFR below 30 mL/min. Thiazide-like diuretics such as *metolazone* and *xipamide* (not available in the U.S.) retain their diuretic effect at low GFR and are therefore somewhat positioned in between loop diuretics and classical thiazides. Combination therapy of thiazides with loop diuretics is often effective in those refractory to loop diuretics alone ("sequential tubulus blockade"), as refractoriness is often caused by upregulation of the Na^+-Cl cotransporter in the distal convoluted tubule, the main target of thiazide diuretics (see Chapter 29). Thiazides are associated with a greater degree of K^+ wasting per fluid volume reduction than loop diuretics, and combination therapy requires particularly careful monitoring of K^+ loss.

K^+-Sparing Diuretics

K^+-Sparing diuretics (see Chapter 29) inhibit apical Na^+ channels in distal segments of the tubulus directly (ENaC; e.g., *amiloride*, *triamterene*) or reduce its gene expression (MRAs *spironolactone* and *eplerenone*). These agents are weak diuretics, but they are often used in the treatment of hypertension in combination with thiazides or loop diuretics to reduce K^+ and Mg^{2+} wasting. The prognostic efficacy of MRAs, which is at least partially independent of its K^+-sparing activity, makes *amiloride* and *triamterene* largely dispensable in the therapy of heart failure. They should not be combined with ACEIs and MRAs.

Treatment Principle III: Afterload Reduction

The failing heart is exquisitely sensitive to increased arterial resistance (i.e., afterload; Figure 33–5). Vasodilators, therefore, should have beneficial effects on patients with heart failure by reducing afterload and allowing the heart to expel blood against lower resistance. However, clinical trials with pure vasodilators were mainly disappointing, whereas inhibitors of the RAAS, vasodilators with a broader mode of action, were successful. Likely reasons include reflex tachycardia and tachyphylaxis (*prazosin*, ISDN) and negative inotropic effects (dihydropyridine calcium channel antagonists).

Hydralazine–Isosorbide Dinitrate

A remarkable exception is the therapeutic effect of a fixed combination of *hydralazine* and ISDN. In a pioneering trial, Cohn and colleagues showed moderate efficacy of this combination in patients with heart failure (Cohn et al., 1986). The benefit was restricted to improvement in the cohort of African Americans. In a second trial in African Americans only, the combination conferred a 43% survival benefit (Taylor et al., 2004). It was FDA approved in 2006, the first ethnically restricted approval.

As an orally available organic nitrate, ISDN, like *nitroglycerine* and isosorbide 5′-mononitrate (ISMN), preferentially dilates large blood vessels, for instance, venous capacitance and arterial conductance vessels (see Chapter 31). The main effect is "venous pooling" and reduction of diastolic filling pressure (preload) with little effect on systemic vascular resistance (which is regulated by small-to-medium arterioles). Sustained monotherapy is compromised by nitrate tolerance (i.e., loss of effect and induction of a pro-constrictory state with high levels of ROS). *Hydralazine* is a direct vasodilator whose mechanism of action remains unresolved (see Chapter 32). It was suggested that *hydralazine* prevents nitrate tolerance by reducing ROS-mediated inactivation of NO (Munzel et al., 2005), an action that could explain the efficacy of this drug combination in heart failure among African Americans. A test of this hypothesis in patients with NYHA class II–III heart failure (Chirkov et al., 2010)

TABLE 33–5 ■ PROPERTIES AND THERAPEUTIC DOSES OF DIURETICS FOR THE THERAPY OF HFrEF[a]

DIURETIC	START DOSE (mg)		COMMON DAILY DOSE (mg)		TIME TO START OF EFFECT (h)	HALF-LIFE (h)	ADVERSE EFFECTS AND INTERACTIONS
Loop diuretics							
Bumetanide	0.5–1		1–5		0.5	1–1.5	**Adverse effects:** Hypokalemia, hyponatremia, hypomagnesemia, hyperuricemia, hypocalcemia, nephrotoxicity, ototoxicity (loop diuretics), hypercalcemia (thiazides), glucose intolerance, sulfonamide hypersensitivity **Interactions:** Can increase lithium levels (PK) and cardiac glycoside toxicity (PD, hypokalemia), anion exchanger resins (PK), NSAIDs and glucocorticoids (PD) can decrease effect of diuretics
Furosemide	20–40		40–240		0.5	1	
Torsemide	5–10		10–20		1	3–4	
Thiazides							
Chlorthalidone	50		50–100		2	50	
Hydrochlorothiazide	25		12.5–100		1–2	6–8	
Potassium-sparing diuretics							
	+RAS blocker	−RAS blocker	+RAS blocker	−RAS blocker			**Adverse effects:** Hyperkalemia (all), gynecomastia, erectile dysfunction, and menstrual bleeding disorders (spironolactone) **Interactions:** Increased risk of hyperkalemia when given with ACE or ARB (note different dosing!), but also cyclosporine, NSAIDs **Contraindication:** Renal insufficiency with creatinine clearance <30 mL/min
Eplerenone, spironolactone	12.5–25	50	50	100–200	2–6	24–36	
Amiloride	2.5	5	5–10	10–20	2	10–24	
Triamterene	25	50	100	200	2	8–16	

PD, pharmacodynamics; PK, pharmacokinetic interaction.
[a]Dosing recommendations were adapted from ESC guidelines (Ponikowski et al., 2016).

failed to confirm the hypothesis. The relevant differences in responsiveness between African American and Caucasian patients with heart failure have not been explained.

The fixed-combination formulation contains 37.5 mg *hydralazine* and 20 mg ISDN and is uptitrated to a target dose of two tablets, thrice daily. Patients will also generally be taking a β blocker. Therefore, hypotension may be dose limiting. Frequent adverse effects include dizziness and headache. Adherence to the thrice-daily dosing regimen may impose practical problems (Cohn et al., 1986), and *hydralazine* doses greater than 200 mg have been associated with lupus erythematosus.

Vericiguat

A new addition to heart failure therapeutics is *vericiguat*, which was FDA approved in early 2021. It directly stimulates soluble guanylyl cyclase (GC) and sensitizes the enzyme to endogenous NO, like *riociguat* (approved for the treatment of pulmonary arterial hypertension; see Chapter 35), but with a longer half-life. GCs are established targets for natriuretic peptides (the membrane form, mGC) and NO and organic nitrates (the soluble form, sGC). A recent trial in patients with advanced heart failure and recent hospitalization showed that the addition of *vericiguat* (10 mg once daily) to a guideline-directed therapy (including 60% receiving triple therapy [renin-angiotensin system (RAS) inhibitor, β blocker, MRA] and 15% ARNI) reduced a composite endpoint of death from cardiovascular causes or first hospitalization for heart failure by 10% (Armstrong et al., 2020). As expected from an sGC stimulator, the rate of symptomatic hypotension was slightly higher in the *vericiguat* group.

Treatment Principle IV: Increasing Cardiac Contractility

The failing heart is unable to generate force sufficient to meet the needs of the body for perfusion of oxygenated blood (Figure 33–1). Historically, physicians attempted to stimulate force generation with positive inotropic drugs. Unfortunately, when used chronically, these agents do not improve life expectancy or cardiac performance. Rather, chronic use of positive inotropes is associated with excess mortality. Of the available inotropic agents, only cardiac glycosides are used in the treatment of chronic heart failure; this is for two reasons: long history of use (see historical perspective) and one large trial in patients with NYHA class II–III heart failure showing that *digoxin* reduced the rate of heart failure–associated hospitalizations without increasing mortality (Table 33–1).

Inotropic Agents and the Regulation of Cardiac Contractility

Cardiac myocytes contract and develop force in response to membrane depolarization and subsequent increases in intracellular Ca^{2+} concentrations (Figure 33–6). The mechanisms of this *excitation-contraction coupling* are the basis for understanding the mode of action of positive inotropic drugs and cardiac myocyte function in general. Positive inotropes and novel compounds in development act by increasing the concentration of free intracellular Ca^{2+} ($[Ca^{2+}]_i$). Ca^{2+} "sensitizers" (e.g., *levosimendan*) sensitize myofilaments to Ca^{2+}; that is, they shift the relationship between free Ca^{2+} concentration and force to the left.

Na^+/K^+ ATPase Inhibitors. Cardiac glycosides inhibit the plasma membrane Na^+/K^+ ATPase, a key enzyme that actively pumps Na^+ out and K^+ into the cell and thereby maintains the steep concentration gradients of Na^+ and K^+ across the plasma membrane. Inhibition of this enzyme slightly reduces the Na^+ gradient across the myocyte membrane, reducing the driving force for Ca^{2+} extrusion by the Na^+/Ca^{2+} exchanger (NCX), thereby providing more Ca^{2+} for storage in the SR to activate contraction. The details are explained by Figure 33–6 and its legend.

cAMP-Dependent Inotropes. The strongest stimulation of the heart is achieved by receptor-mediated stimulation of adenylyl cyclase. This explains the use of *dobutamine*, EPI, and NE in cardiogenic shock (see discussion that follows). Inhibition of cAMP degradation by PDE inhibitors such as *milrinone* or *enoximone* elevates cellular cAMP

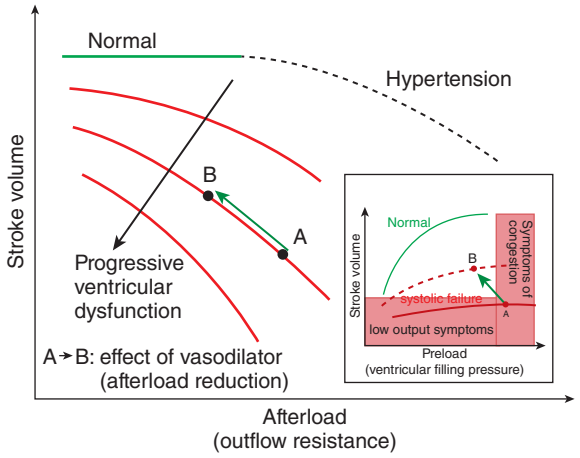

Figure 33–5 *Stroke volume versus afterload (outflow resistance): effects of heart failure. Increasing the resistance to ventricular outflow, a basic determinant of afterload, has little effect on stroke volume in normal hearts until high levels of outflow resistance (top curve).* However, in patients with systolic ventricular dysfunction (lower curves), an increase in outflow resistance elicits a noticeable decrease in cardiac performance (= stroke volume) that is progressive with increasing failure. Such an increase in outflow resistance can occur as a compensatory response by the SNS and RAAS to decreased cardiac function and depressed arterial pressure as a result of heart failure. A higher resistance to ventricular outflow increases peak pressure development in the left ventricle in opening the aortic valve, thereby increasing ventricular wall stress and end-systolic volume. This can cause end-diastolic volume to increase. In the normal heart, increasing ventricular stretch enhances cardiac contractile performance (stroke volume); this is the Frank-Starling effect (inset). However, in the failing heart, the positive contractile response embodied in the Frank-Starling effect is poor and provides only a small increase in stroke volume. Reducing outflow resistance with agents that reduce systemic vascular resistance, such as arterial vasodilators, can shift cardiac performance to a larger stroke volume in patients with myocardial dysfunction (from A to B). Such an increase in stroke volume may provide sufficient output and compensate for the decrease in systemic vascular resistance and moderate the fall in systemic arterial pressure due to the vasodilator. For details, see Figure 33–4 and the work of Klabunde (2015).

concentrations and activates the cAMP-PKA (protein kinase A) pathway and other cAMP-responsive systems (see Chapter 3). This concerted action results in higher peak Ca^{2+} concentrations in systole and thereby peak force (Figure 33–6). All cAMP-dependent inotropes hasten contraction (positive clinotropic effect) and relaxation (positive lusitropic effect), allowing sufficient perfusion of the ventricles in diastole under catecholamine stimulation and with the concomitant tachycardia. On the downside, acceleration of contraction during catecholamine stimulation, by promoting net Ca^{2+} entry per unit of time, increases the utilization of ATP (i.e., increases energy consumption) for Ca^{2+} reuptake into the SR via the sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA) and to restore the membrane potential by the activity of the Na^+/K^+ ATPase.

Myofilament Ca^{2+} Sensitizers. Calcium sensitizers increase the affinity of the myofilaments for Ca^{2+}, for example, by inducing a conformational change in troponin C (TnC). They enhance force for a given $[Ca^{2+}]_i$ and do not elevate $[Ca^{2+}]_i$ with its potentially deleterious proarrhythmic and energy-increasing consequences. On the other hand, increased myofilament Ca^{2+} sensitivity causes reduced dissociation of Ca^{2+} from the myofilaments in diastole and prolongation of relaxation ("negative lusitropic effect"). This effect can aggravate the already-compromised diastolic function in heart failure. It could also lead to delayed Ca^{2+} release from myofilaments in diastole and arrhythmias (Schober et al., 2012). Calcium sensitizers failed to improve prognosis in clinical trials of patients with chronic heart failure. However, *levosimendan* is approved in some countries for the treatment of acute heart failure. It has additional selective and potent inhibitory effects on PDE3, whose positive lusitropic consequence appears to antagonize the negative lusitropic effect of Ca^{2+} sensitization.

Agonists of G_q-coupled receptors (α_1, AT_1, ET_A) also increase myofilament Ca^{2+} sensitivity, likely due to increased myosin light chain phosphorylation. The positive inotropic effect is smaller than that of β receptor stimulation, develops more slowly, and is independent of cAMP.

Cardiac Glycosides

Actions and Therapeutic Use of Digoxin. ***Positive Inotropic Effect.*** Cardiac glycosides (CGs) at therapeutic concentrations mildly inhibit the cardiac Na^+/K^+ ATPase, causing an increase in intracellular $[Na^+]$. Increased $[Na^+]_i$ inhibits Ca^{2+} extrusion via the NCX, resulting in higher intracellular $[Ca^{2+}]$ and enhanced contractility (Figure 33–6). The increased contractility and hence cardiac output provides symptomatic relief in patients with heart failure (Figure 33–1). With the main trigger for neurohumoral activation removed, sympathetic nerve tone and, consequently, heart rate and peripheral vascular resistance drop. These decreases in preload and afterload reduce chamber dilation and thereby wall stress, a strong determinant of myocardial O_2 consumption. Increased renal perfusion lowers renin production and increases diuresis, further decreasing preload. It is not clear whether these potentially beneficial effects occur on top of current guideline-directed medical therapy (e.g., β blockers). Current guidelines list CGs as a third-line choice (Ponikowski et al., 2016) or not at all (Yancy et al., 2017; Figure 33–3).

Electrophysiological Actions. CGs at therapeutic concentrations shorten action potentials by accelerating the inactivation of L-type Ca^{2+} channels due to higher $[Ca^{2+}]_i$. Shorter action potentials (= refractory period) favor reentry arrhythmias, a reason that CGs promote atrial fibrillation. With the loss of intracellular K^+ and increase in intracellular Na^+, the resting membrane potential (determined largely by the K^+ current, now diminished) moves to less-negative values with two consequences. Diastolic depolarization and automaticity are enhanced, and, due to partial inactivation of Na^+ channels, impulse propagation is strongly reduced. Both phenomena promote reentry arrhythmias. At even higher CG concentrations, SR Ca^{2+} overload reaches a point at which Ca^{2+} is spontaneously released at amounts large enough to initiate Ca^{2+} waves and, via the NCX, depolarization of the cell (Figure 33–6). The typical ECG signs at this stage of CG intoxication are extrasystoles and bigeminies with a high risk of ventricular fibrillation.

Extracardiac Effects. CGs also inhibit Na^+/K^+ ATPase in other excitable tissues. (1) At low plasma concentrations, CGs stimulate vagal efferents and sensitize baroreceptor reflex mechanisms, causing increased parasympathetic and decreased sympathetic tone. The beneficial effect of *digoxin* at low plasma concentrations (Rathore et al., 2003), at which positive inotropic effects are minor, suggests that the neurohumoral actions of CGs may be therapeutically more relevant than the direct positive

HISTORICAL PERSPECTIVE

The British botanist William Withering (1741–1799) systematically described the actions of *Digitalis purpurea* in patients with heart failure ("dropsy") and gave exact dosing recommendations (Skou, 1986). Oswald Schmiedeberg (1833–1921), working in Strasbourg, France, isolated the first chemical entities from foxglove leaves; one of these entities was digitoxin. Until diuretics became available, CGs were the only heart failure drugs. CGs encompass many chemical entities, but only *digoxin* and its derivatives *β-acetyl digoxin, methyldigoxin*, and *digitoxin* are in clinical use in most countries. Until the 1980s, CGs were dosed according to therapeutic effects (e.g., improved diuresis [Withering considered CGs as diuretics], reduction of heart size [verifiable by X-ray], or alterations of the surface electrocardiogram [ECG]) and to symptoms of overdosing, such as nausea and altered color perception (yellow-green). Now, serum *digoxin* concentrations can be measured by radioimmunoassay. *Digoxin* has therapeutic efficacy (including a small survival benefit) only at serum concentrations between 0.5 and 0.8 ng/mL (Rathore et al., 2003). Concentrations greater than 1.2 ng/mL are associated with increased mortality. Serum *digoxin* concentrations greater than 0.8 ng/mL should be avoided.

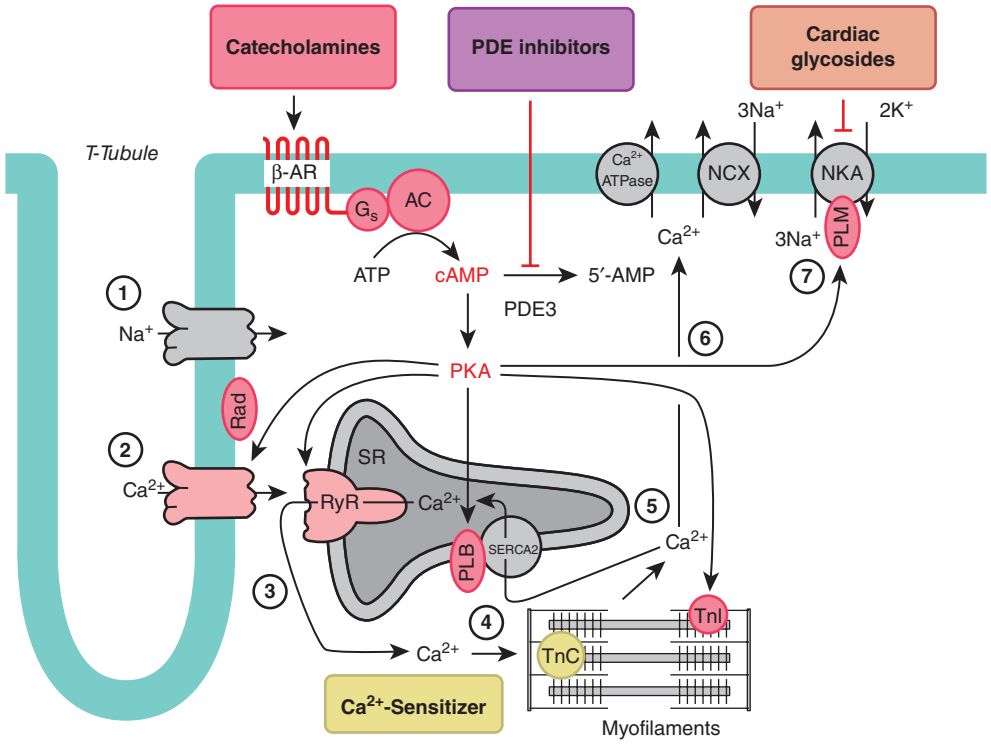

Figure 33–6 *Cardiac excitation-contraction coupling and its regulation by positive inotropic drugs.* The cardiac cycle is initiated by membrane depolarization, which causes the opening of voltage-dependent Na^+ (**1**) and L-type Ca^{2+} channels (**2**), permitting Na^+ and Ca^{2+} flow down their electrochemical gradients into the myocyte. Thus, Na^+ and Ca^{2+} enter the cardiac myocyte during each cycle of membrane depolarization, triggering the release, through the ryanodine receptor (RyR), of larger amounts of Ca^{2+} from internal stores in the SR (**3**). The resulting increase in intracellular Ca^{2+} interacts with troponin C (**4**) and activates interactions between actin and myosin that result in sarcomere shortening. The bulk of cytosolic Ca^{2+} (70%) is pumped back into the SR by a Ca^{2+}-ATPase, SERCA2 (**5**). The remainder is removed from the cell by a high-capacity NCX and, to a smaller extent, a sarcolemmal Ca^{2+}-ATPase (**6**). The NCX exchanges three Na^+ for a Ca^{2+}, using the electrochemical potential of Na^+ to drive Ca^{2+} extrusion. The electrochemical gradient for Na^+ across the sarcolemma is maintained by active transport of Na^+ out of the cell by the sarcolemmal Na^+/K^+ ATPase (NKA; **7**). The β adrenergic agonists (acting at β-AR, the β adrenergic receptor) and PDE inhibitors, by increasing intracellular cAMP levels, activate PKA, which phosphorylates the small GTPase Rad binding to and inhibiting the L-type Ca^{2+} channel (Liu et al., 2020), and regulatory components of the RyR, as well as phospholamban (PLB) on the SR and TnI (inhibitory subunit of troponin) in the sarcomere. As a result, Rad-mediated inhibition of L-type Ca^{2+} channels is released and the RyR2 Ca^{2+} channel open probability is increased; SERCA2 inhibition by PLB is released, with the result that SERCA2 accumulates Ca^{2+} into the SR faster, more avidly, and to a higher concentration; and relaxation occurs at slightly higher $[Ca^{2+}]_i$ due to slightly reduced sensitivity of the troponin complex to Ca^{2+}. The net effect of these phosphorylations is a positive inotropic effect: a faster rate of tension development to a higher level of tension, followed by a faster rate of relaxation (positive lusitropic effect). CGs, by inhibiting the NKA, reduce Na^+ extrusion from the cell, thereby permitting $[Na^+]_{in}$ to rise, reducing the inward gradient for Na^+ that drives Ca^{2+} extrusion by NCX. As a consequence, Ca^{2+} accumulates in the SR, and a positive inotropic effect follows, but without faster relaxation. See the text for details of additional effects of CGs. Note that, under steady-state conditions, the amount of Ca^{2+} leaving the cell exactly matches the amount entering it. As NCX exchanges three Na^+ for every Ca^{2+}, it creates a depolarizing current. This makes not only the direction of transport dependent on the chemical gradients of Na^+ and Ca^{2+} across the membrane but also on the membrane potential. Thus, the direction of Na^+-Ca^{2+} exchange may briefly reverse during depolarization, when the electrical gradient across the sarcolemma is transiently reversed. phospholemman (PLM) is a tonic inhibitor of the NKA, which supplies the driving force (an appropriately low $[Na^+]_{in}$) for maintaining low diastolic Ca^{2+}. Phosphorylation of PLM by PKA removes this inhibitory influence, thereby stimulating the activity of the NKA and limiting $[Na^+]_{in}$ and $[Ca^{2+}]_{in}$. This may reduce the tendency toward arrhythmias during adrenergic stimulation (see Pavlovic et al., 2013). Note that L-type Ca^{2+} channels, SERCA2, and NKA are all regulated indirectly by phosphorylation of inhibitory regulator proteins.

inotropic effects. (2) CGs at higher plasma concentrations increase Ca^{2+} concentrations in vascular smooth muscle cells and cause vasoconstriction. In patients with heart failure, vasodilation normally prevails due to the decrease in sympathetic nervous tone, but the direct vascular effect explains mesenteric artery ischemia or occlusion, a rare but severe adverse effect of CGs.

Indirect Actions. The vagotonic and sympatholytic effects of CGs cause bradycardia and AV prolongation (negative dromotropic effect) and can promote atrial flutter and fibrillation. Fibrillation is explained by the acetylcholine-induced shortening of atrial action potentials, which is further enhanced by the direct CG effect described previously. On the other hand, CGs are therapeutically used for frequency control of permanent atrial fibrillation because of their negative dromotropic effects.

Interactions with K^+, Ca^{2+}, and Mg^{2+}. Hyperkalemia reduces and hypokalemia increases the binding affinity of CG to the Na^+/K^+ ATPase. In addition, hypokalemia reduces repolarizing K^+ currents, with the consequence of increased spontaneous diastolic depolarization and automaticity. Hypokalemia is therefore a major risk factor for arrhythmogenic effects of CGs. Hypercalcemia as well as hypomagnesemia favor SR Ca^{2+} overload and spontaneous Ca^{2+} release events. Control of serum electrolytes is therefore mandatory.

Adverse Effects. The therapeutic index of CG is extremely narrow, as documented in the DIG trial: plasma concentrations between 0.5 and 0.8 ng/mL are associated with beneficial effects, and concentrations of 1.2 ng/mL and greater are associated with a tendency toward increased mortality (Rathore et al., 2003). The most frequent and most serious adverse effects are arrhythmias. In CG overdosing, patients exhibit arrhythmias (90%), GI symptoms (~55%), and neurotoxic symptoms (~12%). The most frequent causes of toxicity are renal insufficiency and overdosing.

Cardiac toxicity in healthy persons presents as extreme bradycardia, atrial fibrillation, and AV block, whereas ventricular arrhythmias are rare. In patients with structural heart disease, frequent signs of CG toxicity are ventricular extrasystoles, bigeminy, ventricular tachycardia, and fibrillation. In principle, however, every type of arrhythmia can

be CG induced. GI adverse effects are anorexia, nausea, and vomiting, mainly because of CG effects on chemosensors in the area postrema. Spastic contraction of the mesenteric artery can rarely lead to severe diarrhea and life-threatening necrosis of the intestine. Headache, fatigue, and sleeplessness can be early symptoms of CG toxicity.

Typical, albeit not too common (10%), are visual effects: altered color perception and coronas (halos). Some have speculated that the visual effects of digitalis intoxication contributed to the qualities of late paintings by Vincent van Gogh, who may have been treated for neurological complaints with foxglove by Dr. Paul Gachet, whose portraits by van Gogh (painted in June 1890) show the doctor seated next to a sprig of the plant, a natural source of CGs and used widely in the 19th century (Lee, 1981).

Therapy of CG Toxicity. Cessation of CG medication normally suffices as therapy of CG toxicity. However, severe arrhythmias, such as extreme bradycardia or complex ventricular arrhythmias, require active therapy.

- Extreme sinus bradycardia, sinoatrial block, or AV block grade II or III: Atropine (0.5–1 mg) IV. If not successful, a temporary pacemaker may be necessary.
- Tachycardic ventricular arrhythmias and hypokalemia: K^+ infusion (40–60 mmol/d). Consider that high K^+ can aggravate AV conduction defects.
- An effective antidote for *digoxin* toxicity is antidigoxin immunotherapy. Purified Fab fragments from ovine antidigoxin antisera are usually dosed by the estimated total dose of *digoxin* ingested to achieve a fully neutralizing effect.

Treatment Principle V: Heart Rate Reduction

Heart rate is a strong determinant of cardiac energy consumption, and higher heart rates in patients with heart failure are associated with poor prognosis (Bohm et al., 2010). Partial agonists at β receptors such as *xamoterol* increase nocturnal heart rate (i.e., they prevent the physiological dip) and are associated with excess mortality in patients with heart failure (Xamoterol Study Group, 1990). Conversely, β blockers lower heart rate and improve survival prognosis.

Ivabradine

The circumstantial evidence for beneficial effects of heart rate lowering led to the development of *ivabradine*, a selective inhibitor of cardiac pacemaker channels (hyperpolarization-activated, cyclic nucleotide–gated cation channels [HCNs]). *Ivabradine* is used for the treatment of heart failure and stable angina pectoris in patients not tolerating β blockers or in whom β blockers did not sufficiently lower heart rate (<70 beats/min; guideline class IIa recommendation, Figure 33–3). Approval was based on a study showing a decrease in hospitalization and heart failure mortality, but not total or cardiovascular mortality (Swedberg et al., 2010). Of note, the effect of *ivabradine* was not superior to that of *digoxin* in an earlier study (Digitalis Investigation Group, 1997). In a study in patients with stable angina (85% on β blockers), *ivabradine* conferred no benefit but led to phosphenes (typical transient enhanced brightness in a restricted area of the visual field) and increased the rate of bradycardia, atrial fibrillation, and QT prolongation (Fox et al., 2014), casting doubts about the role of the compound in ischemic heart disease.

Treatment Principle VI: SGLT2 Inhibition

The most recent addition to the combination drug treatment of patients with heart failure came unexpectedly. Studies in patients with diabetes mellitus showed that SGLT2 inhibitors (*empagliflozin, canagliflozin*), developed to increase the excretion of glucose by the kidneys, improved overall and particularly heart failure–related outcomes (Zinman et al., 2015). A trial in patients with heart failure and reduced EF confirmed the beneficial effect of this class and showed that it occurred independently of the presence of diabetes (McMurray et al., 2019). *Dapagliflozin* was the first SGLT2 inhibitor approved for the treatment of heart failure in the U.S. in 2020. The mechanism of the salutary effect on the prognosis of patient with heart failure is not well understood. SGLT2 is not present in the heart, and therefore, it is likely that the primary effect of inhibition of glucose reuptake in the kidney tubulus causes improved diuresis and preload reduction ("a better diuretic effect"). Alternatively, evidence suggests that the class of SGLT2 inhibitors exerts beneficial off-target effects such as inhibition of the sodium hydrogen exchanger (Packer, 2017) or the later sodium influx (Philippaert et al., 2021). This new finding with SGLT2 inhibitors may open new angles for drug development to treat heart failure. The exact place of SGLT2 inhibitors in guideline-directed medical therapy (Figure 33–3) has not yet been defined.

Drug Treatment of Acutely Decompensated Heart Failure

Acutely decompensated heart failure is a leading cause of hospitalization in patients older than 65 and represents a sentinel prognostic event in the natural course of the disease, with a high recurrence rate and a 1-year mortality rate of about 30%. Even in decompensated heart failure, about 50% of patients exhibit preserved left ventricular function (HFpEF). The HFpEF cohort is older, is more likely to be female and hypertensive, and has less coronary artery disease than the HFrEF cohort. Therapeutically, it is important to quickly identify and treat specific reasons for decompensation. Besides acute myocardial ischemia, these include uncorrected high blood pressure, atrial fibrillation and other arrhythmias, pulmonary embolism, and kidney failure. Pharmacological reasons for acute decompensation include nonadherence to heart failure medication and Na^+/fluid restriction, negative inotropic drugs (e.g., *verapamil, diltiazem, nifedipine*), and NSAIDs, especially cyclooxygenase 2–specific inhibitors.

The therapy of acutely decompensated heart failure aims at fast symptom relief, short-term survival, fast recompensation, and reduction of readmission rates. Treatment is less evidence-based than therapy for chronic heart failure, and no single drug given to patients experiencing acute decompensation has shown improvement in the long-term prognosis. The main principles (besides nonpharmacological treatment modalities such as O_2 and noninvasive or [rarely] invasive ventilatory support) are diuretics and vasodilators, with positive inotropes in selected cases and mechanical support systems as an ultimate step.

Diuretics

Patients with dyspnea and signs of fluid overload/congestion should be promptly treated with an intravenous loop diuretic such as *furosemide* that exerts an acute vasodilator and slightly delayed but still fast diuretic effect. Optimal doses and regimens need to be adapted to the clinical picture. An intravenous bolus of 40 to 80 mg *furosemide* is a common starting dose, often continued by an infusion of *furosemide* at a daily dose equal to the (oral) daily dose prescribed before hospitalization. Doses may need to be escalated according to symptoms and diuresis. Additional use of a thiazide diuretic in small doses can break a relative resistance to loop diuretics but requires careful monitoring of K^+ losses. Excessive doses of *furosemide* must be avoided because they can cause hypotension, a reduction in GFR, electrolyte disturbance, and further neurohumoral activation.

Vasodilators

Vasodilators such as *nitroglycerin* and *nitroprusside* reduce preload and afterload. The reduction in preload (= diastolic filling pressure) moves the patient to the left on the stroke volume-preload relationship, like the effect of diuretic-induced volume reduction (Figure 33–4). The accompanying reduction in chamber dimension reduces wall stress and thus O_2 consumption. The additional reduction in afterload allows the heart to expel blood against a lower output resistance (Figure 33–4). These mechanisms explain why vasodilators (which have no inotropic efficacy and lower blood pressure) increase stroke volume. Yet, robust evidence for symptomatic benefit or improved clinical outcome is lacking. They are probably best suited for patients with hypertension and should be avoided in patients with systolic blood pressure less than 110 mmHg (Ponikowski et al., 2016). The main risk is hypotension, which is negatively associated with favorable outcomes in patients with acutely decompensated heart failure (Patel et al., 2014).

Nesiritide, recombinant human BNP, dilates arterial and venous blood vessels by stimulating the membrane-bound GC to produce more cGMP.

By this mechanism, it decreases preload and afterload and reduces pulmonary capillary wedge pressure. It was initially approved for the treatment of acutely decompensated heart failure in the U.S., but not in several European countries. Early clinical studies and a meta-analysis raised concerns that the use of *nesiritide* was associated with an increased risk for renal failure and death when compared to a noninotrope control therapy (Sackner-Bernstein et al., 2005). This risk was not confirmed in a more recent study (O'Connor et al., 2011), but beneficial effects (dyspnea relief) were modest. Based on this study, *nesiritide* is not recommended for routine use in patients with acute heart failure. In 2018, the manufacture of *nesiritide* was discontinued.

Positive Inotropic Agents

Stimulating the heart's force of contraction in a situation of critically diminished cardiac output may appear to be the most intuitive intervention. Yet, inotropes in acutely decompensated heart failure are associated with worse outcome and should therefore be restricted to patients with critically low cardiac output and perfusion of vital organs. Hypotension with a systolic pressure less than 85 mm Hg has been suggested as a practical limit (Ponikowski et al., 2016). Reasons for the adverse consequences of positive inotropes are probably complex. All inotropic agents increase cardiac energy expenditure (greater and faster force development ⇒ more ATP consumption ⇒ greater O_2 demand), which carries the risk of diffuse cardiac myocyte death. In acutely decompensated heart failure, the risk is exaggerated by the low perfusion pressure, any preexisting coronary artery disease, and the likely presence of cardiac myocyte hypertrophy and myocyte–endothelial cell mismatch. Tachycardia, aggravated by many inotropes, adds to the problem by strongly increasing energy expenditure and reducing the time for coronary perfusion in diastole. All positive inotropes increase the risk of arrhythmias.

Dobutamine

Dobutamine is the β adrenergic agonist of choice for the management of patients with acute CHF with systolic dysfunction. *Dobutamine* has relatively well-balanced cardiac and vascular actions: stimulation of cardiac output with less tachycardia than EPI and with a concomitant decrease in pulmonary artery wedge pressure. *Dobutamine* is a racemic mixture of (–) and (+) enantiomers. The (–) enantiomer is a potent agonist at α_1 adrenergic receptors and a weak agonist at β_1 and β_2 receptors. The (+) enantiomer is a potent β_1 and β_2 agonist without much activity at α_1 adrenergic receptors. *Dobutamine* has no activity at dopamine receptors. At infusion rates that result in a positive inotropic effect in humans, the β_1 adrenergic effect in the myocardium predominates. In the vasculature, the α_1 adrenergic agonist effect of the (–) enantiomer appears to be offset by the vasodilating effects of the (+) enantiomer at β_2 receptors. Thus, the principal hemodynamic effect of *dobutamine* is an increase in stroke volume from positive inotropy, augmented by a small decrease in systemic vascular resistance and, therefore, afterload. Lowering of pulmonary artery capillary pressure is considered an advantage compared to other catecholamines, as is the smaller chronotropic effect (reasons for which are not clear).

Continuous *dobutamine* infusions are typically initiated at 2 to 3 μg/kg/min and uptitrated until the desired hemodynamic response is achieved. Pharmacologic tolerance may limit infusion efficacy beyond 4 days; therefore, addition or substitution of a PDE3 inhibitor may be necessary to maintain adequate circulatory support. The major side effects of *dobutamine* are tachycardia and supraventricular/ventricular arrhythmias, which may require a reduction in dosage. The concurrent use of β blockers is a common cause of blunted clinical responsiveness to *dobutamine*. It can be overcome by higher doses in case of *bisoprolol* and *metoprolol*, but not as easily for *carvedilol*, which has a very slow dissociation rate.

Epinephrine

The natural sympathetic agonist is mainly produced by the adrenal gland and systemically released. It is a balanced β_1, β_2, and α_1 adrenergic agonist and has a similar net hemodynamic effect as *dobutamine*, but with a stronger tachycardic effect, which makes it a second-choice inotrope in acutely decompensated heart failure.

Norepinephrine

The main sympathetic neurotransmitter released from sympathetic nerve endings is a potent β_1 and α_1 agonist and weak β_2 receptor agonist. This profile causes the positive inotropism accompanied by prominent vasoconstriction and increased afterload. Vasoconstriction of coronary blood vessels promotes ischemia; increased afterload may impede cardiac output (Figure 33–4). However, the stronger blood pressure–increasing effect of NE may be needed in persistent hypotension despite adequate cardiac filling pressures. Moreover, the increase in mean blood pressure leads to a reflex increase in parasympathetic nervous tone that can antagonize the direct tachycardic effect of NE and cause bradycardia.

Dopamine

The pharmacologic and hemodynamic effects of dopamine (DA) vary with concentration. Low doses (≤2 μg/kg lean body mass/min) induce cAMP-dependent vascular smooth muscle vasodilation by direct stimulation of D2 receptors. Activation of D2 receptors on sympathetic nerves in the peripheral circulation also inhibits NE release and reduces α adrenergic stimulation of vascular smooth muscle, particularly in splanchnic and renal arterial beds. This is the pharmacological basis for the "low-dose DA infusion" historically used to increase renal blood flow and maintain an adequate GFR and diuresis in hospitalized patients with CHF with impaired renal function refractory to diuretics. However, mainly negative clinical studies argue against the validity of this concept (Chen et al., 2013; Vargo et al., 1996). At intermediate infusion rates (2–5 μg/kg/min), DA directly stimulates cardiac β receptors to enhance myocardial contractility. At higher infusion rates (5–15 μg/kg/min), α adrenergic receptor stimulation–mediated peripheral arterial and venous constriction occurs. The complex profile and negative clinical data on low-dose infusion make DA a second or third choice in the treatment of heart failure.

Phosphodiesterase Inhibitors

The cAMP-PDE inhibitors decrease cellular cAMP degradation, resulting in elevated levels of cAMP. This results in positive inotropic and chronotropic effects in the heart and dilation of resistance and capacitance vessels, effectively decreasing preload and afterload (thus the term *inodilator*). PDE inhibitors may be more advantageous than catecholamines in patients on β blockers and in patients with high systemic or pulmonary artery resistance. Hypotension is often dose limiting; tachycardic and arrhythmogenic effects are like those of catecholamines.

Milrinone and Enoximone. Parenteral formulations of *milrinone* and *enoximone* are used for short-term circulation support in advanced CHF. *Enoximone* (not available in the U.S.) is a relative selective inhibitor of PDE3, the cGMP-inhibited cAMP PDE and main isoform involved in inotropic control in human heart. *Milrinone* inhibits human heart PDE3 and PDE4 with similar potency (Bethke et al., 1992). By increasing intracellular cAMP concentrations, they have similar actions as the β receptor agonists *dobutamine* and EPI but tend to lower systemic and pulmonary vascular resistance more than do the catecholamines. It should be kept in mind that PDE inhibitors potentiate the actions of β receptor agonists, both beneficial and detrimental. The loading dose of *milrinone* is ordinarily 25 to 75 μg/kg, and the continuous infusion rate ranges from 0.375 to 0.75 μg/kg/min. Bolus doses of *enoximone* at 0.5 to 1.0 mg/kg over 5 to 10 min are followed by an infusion of 5 to 20 μg/kg/min. The elimination half-lives of *milrinone* and *enoximone* in normal individuals are 0.5 to 1 h and 2 to 3 h, respectively, but can be increased in patients with severe CHF.

Myofilament Calcium Sensitizers (Levosimendan, Pimobendan)

In some countries but not in the U.S., calcium sensitizers are approved for the short-term treatment of acutely decompensated heart failure (e.g., *levosimendan* in Sweden, *pimobendan* in Japan). Calcium sensitizers increase the sensitivity of contractile myofilaments to Ca^{2+} by binding to and inducing a conformational change in the thin-filament regulatory protein troponin C. This causes an increased force for a given cytosolic Ca^{2+} concentration, theoretically without raising the $[Ca^{2+}]_{cytosol}$. However, a variety of other effects have been ascribed to *pimobendan* and *levosimendan*, including inhibition of PDE, inhibition of the production of

proinflammatory cytokines, and opening of ATP-dependent potassium channels (Maack et al., 2019). Clinical data provide evidence for symptomatic benefit and reductions in the length of stay in the hospital but do not support a better safety profile of *levosimendan* compared to catecholamines or classical PDE inhibitors (Mebazaa et al., 2007). Increased rates of arrhythmia and death are likely related to the PDE3 inhibitor activity of these compounds.

Other Drugs Used in Heart Failure

The vasopressin receptor antagonist *tolvaptan* is FDA approved for the treatment of therapy-resistant hyponatremia, a common and difficult-to-treat complication in decompensated heart failure. *Tolvaptan* is also approved to slow kidney function decline in adults at risk of rapidly progressing autosomal dominant polycystic kidney disease. Unfortunately, studies in an unselected cohort of patients with heart failure failed to show convincing beneficial effects of *tolvaptan*. Severe thirst and dehydration are common side effects. *Heparin* or other anticoagulants are routinely used in hospitalized patients with heart failure to prevent thromboembolism.

Role of Standard Combination Therapy

Most patients hospitalized with acutely decompensated heart failure have preexisting heart failure and respective maintenance therapy. Guidelines suggest reviewing a patient's existing therapy on admission to determine whether recent changes in the medication could be causally related to an exacerbation of cardiac disease. If not, the standard heart failure medication (ACEI/ARB, β blocker, MRA, diuretic) should be continued in the absence of hemodynamic instability or contraindications (Yancey et al., 2017; Figure 33–3).

Lessons From Heart Failure Drug Development

Heart failure is an attractive but difficult indication for drug development. The number of drug development failures over the past two decades largely exceeded that of successes, indicating our incomplete understanding of the pathophysiology of heart failure, but sometimes also signaling problematic trial design. Even negative trials have helped to better understand the disease. Examples of drugs that have been tested in large prospective trials and failed are listed in Table 33–6.

Lessons From Failed Drugs

The failure of *positive inotropic agents* (PDE inhibitors, catecholamines, calcium sensitizers, mixed-acting compounds such as *flosequinan* or *vesnarinone*; Cohn et al., 1998) to improve long-term outcome of patients with heart failure has induced a paradigm shift toward drugs that unload the heart and reduce neurohumoral activation, the current standard. It demonstrated that further stimulating the failing heart may transiently improve symptoms but increase mortality. Unfortunately, reducing the hemodynamic load without protecting the heart from the adverse consequences of the activated SNS and RAAS also seems inefficient, as exemplified by the neutral effect of the α_1 receptor antagonist *prazosin* in the VeHeFT-I trial (Cohn et al., 1986). *Moxonidine*, a centrally acting α_2/imidazole agonist with similar sympatholytic actions as *clonidine*, should theoretically have similar efficacy to β blockers, but a larger prospective trial showed *moxonidine* increased mortality (Cohn et al., 2003). It is unclear whether doses and dose titration were too aggressive or whether the principle of central sympatholysis is unsafe in heart failure. Multiple lines of laboratory and clinical evidence suggested that heart failure has an important inflammatory component; yet, two blockers of tumor necrosis factor (TNF), *infliximab* and *etanercept,* induced harm rather than benefit in patients with chronic heart failure (Chung et al., 2003; Mann et al., 2004).

Endothelin 1, a potent vasoconstrictor, is upregulated in heart failure and could play an adverse role in heart failure, like that of AngII. Nonselective ET receptor antagonists such as *bosentan* had striking efficacy in postinfarct rodent models and are successfully used in pulmonary hypertension (see Chapter 35). However, *bosentan* showed no efficacy in patients with chronic heart failure (Packer et al., 2005). *Omapatrilat*, a dual inhibitor of ACE and neprilysin, can decrease AngII and increase ANP/BNP, conditions promoting vasodilation, diuresis, and antihypertrophic effects; however, expectations that *omapatrilat* would be more efficacious than an ACEI in heart failure were not confirmed in a prospective study (Packer et al., 2002).

Several clinical trials have tested the idea that adding an ARB or the renin inhibitor *aliskiren* to standard therapy that includes an ACEI would be beneficial by more completely inhibiting the RAAS. Except for one trial (McMurray et al., 2003), studies of these combinations consistently showed a lack of benefit and an increase in adverse effects, particularly decreased renal function and hyperkalemia. The premise was that if some inhibition of the RAAS is good, more would be better; perhaps the premise was wrong.

Statins were proposed to have anti-inflammatory, antihypertrophic, and proangiogenic effects independent of their cholesterol-lowering effect (Liao and Laufs, 2005). Trials testing this hypothesis by adding statins to standard treatment of chronic heart failure demonstrated that the combination was safe but had no added beneficial effect on mortality (Kjekshus et al., 2007). An antagonist of the V_2 vasopressin receptor *tolvaptan* was ineffective in patients with chronic stable heart failure (Udelson et al., 2007). The discrepancy to several positive preclinical and early clinical studies suggests that the vasopressin axis of the neurohumoral activation program in heart failure may be sufficiently addressed by standard combination therapy, leaving no room for further improvement.

Lessons From Treating Acute Heart Failure

The drugs currently recommended (*furosemide, nitroglycerin, dobutamine*) for the treatment of acutely decompensated heart failure have

TABLE 33–6 ■ AGENTS FOR HF THAT FAILED IN CLINICAL TRIALS

DRUG (type)	YEAR OF PUBLICATION	REASON FOR FAILURE
Milrinone (PDE inhibitor)	1991	Increased mortality
Pimobendan (PDE inhibitor)	1996	Trend toward increased mortality
Flosequinan (unclear)	1993	Increased mortality
Vesnarinone (unclear)	1998	Increased mortality, arrhythmias
Moxonidine (central antisympathetic)	1998	Increased mortality
Infliximab (TNFα blocker)	2003	Increased mortality
Etanercept (TNFα blocker)	2004	Trend toward increased mortality
Bosentan (ET receptor blocker)	2005	Liver toxicity, trend toward benefit over time (?)
Etomoxir (CPT1 blocker)	2007	Liver toxicity
Omapatrilat (dual ACEI and neprilysin inhibitor)	2002	Angioedema, no clear benefit
ARB + ACEI	2003 and 2008	No benefit, more angioedema and renal side effects
Rosuvastatin (HMG-CoA reductase inhibitor)	2007	No benefit
Tolvaptan (vasopressin V2 receptor blocker)	2009	No benefit
Rolofylline (adenosine A_1 receptor blocker)	2009	No benefit, seizures

CPT1, carnitine palmitoyltransferase 1; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A.

never been tested in adequately powered prospective clinical trials. All novel drugs tested either in comparison to standard inotropes or noninotropes or as an add-on have failed to show convincing superiority or benefit in terms of symptoms, duration of hospitalization, and 30-day mortality. The A_1 adenosine receptor antagonist *rolophylline* should produce several beneficial effects on the kidney, including inhibition of tubular reabsorption of Na^+ and water, dilation of the afferent arteriole, and inhibition of tubular-glomerular feedback, but its addition to standard therapy in patients with acute heart failure with impaired kidney function produced no salutary renal or cardiac effects and caused unacceptable adverse effects such as seizures, a typical side effect of central A_1 adenosine antagonism known also from theophylline (Massie et al., 2010).

Recent Developments; Novel Approaches

Numerous pharmacological and nonpharmacological treatment options are being tested in preclinical and clinical studies (https://www.clinicaltrials.gov). They range from cell and gene therapies to food supplements (vitamins, polyunsaturated fatty acid) and intravenous iron to classical small molecules. In the CUPID2 trial, gene therapy, in the form of an intracoronary infusion of adeno-associated virus 1/SERCA2 to improve the defective diastolic uptake of Ca^{2+} into the sarcoplasmic reticulum, did not provide any benefit in HFrEF (Greenberg et al., 2016). *Serelaxin*, recombinant human *relaxin 2*, is a naturally occurring peptide with 53 amino acids discovered in 1926 as an ovarian hormone inducing relaxation of the uterus during pregnancy. Its actions on the cardiovascular system include increased arterial compliance, cardiac output, and renal blood flow, characteristics of a promising drug for the treatment of acutely decompensated heart failure. However, the promising results of an earlier study (Teerlink et al., 2013) were not confirmed in a larger phase III trial (Metra et al., 2019).

Heart failure is often associated with anemia, a predictor of a poor prognosis. Yet, correction of anemia by an erythropoietin derivative, *darbepoetin alpha*, did not affect any clinical end point but increased the rate of thromboembolic events and ischemic strokes in patients with heart failure and mild-to-moderate anemia (Swedberg et al., 2013). However, intravenous iron, added to standard therapy in patients with NYHA class II–III heart failure, iron deficiency, and hemoglobin levels of 9.5 to 13.5 g/dL, improved quality of life, NYHA class, and physical exercise capacity (Anker et al., 2009). The beneficial effects seemed to be independent of the presence of anemia and may be related to other roles of iron in the body. In patients hospitalized for acute heart failure and signs of iron deficiency, intravenous iron reduced the rate of heart failure hospitalizations but had no effect on cardiovascular death (Ponikowski et al., 2020).

Myosin Modulators

There are two new small molecule drugs entering clinical use that alter the rate or extent of myosin's interaction with actin to produce force: *mavacamten* and *omacamtiv mecarbil*.

Mavacamten was FDA-approved in 2022 for treating patients with symptomatic obstructive hypertrophic cardiomyopathy (HCM). HCM is often caused by mutations in genes encoding sarcomeric proteins (e.g., cardiac myosin) and the mutations commonly result in sarcomeric hypercontractility. *Mavacamten* is an allosteric and reversible inhibitor selective for cardiac myosin and hence directly targets the underlying pathophysiology of HCM. Specifically, *mavacamten* reduces the number of myosin heads that can enter "on actin" (power-generating) states, thus reducing the probability of force-producing (systolic) and residual (diastolic) cross-bridge formation. Excess myosin actin cross-bridge formation and decreased fraction of myosin in the super-relaxed state are mechanistic hallmarks of HCM. *Mavacamten* shifts the overall myosin population towards an energy-sparing, recruitable, super-relaxed state. Due to its inherent negative inotropic effects and hence the risk for causing heart failure, *mavacamten* is available only through the manufacturers Risk Evaluation and Mitigation Strategy (REMS) Program, and patients must be closely monitored by echocardiography. Use of *mavacamten* is restricted to HCM patients with a left ventricular ejection fraction above 55%, and the drug should be stopped if left ventricular ejection fraction falls below 50% or if the patient experiences heart failure symptoms. *Mavacamten* is extensively metabolized, primarily through CYP2C19, which is inhibited by drugs such as fluconazole and several antidepressants. Concomitant use of such drugs will increase *mavacamten* serum concentrations. In CYP2C19 poor metabolizers (~5% of Caucasians, 15-20% of Asians), its half-life increases from 6-9 days to 23 days. Given its narrow therapeutic indication and likelihood for drug-drug interactions, patients receiving *mavacamten* will have to be closely monitored.

Omacamtiv mecarbil is also an allosteric myosin modulator but has opposite effects to mavacamten in that it promotes force generation. *Omacamtiv mecarbil* is being evaluated as a positive inotropic agent for use in patients with systolic heart failure (HFrEF). Its clinical utility remains to be determined

Drug Facts for Your Personal Formulary: *Heart Failure Drugs*

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Inhibitors of the Renin-Angiotensin System		
ACE Inhibitors Benazepril Captopril Enalapril Lisinopril Quinapril Ramipril	• Heart failure • Hypertension • Diabetic nephropathy	• First choice in treating heart failure • Short-acting captopril only for initiation of therapy; enalapril requires twice-daily dosing • Cough in 5%–10% of patients, angioedema • Hypotension, hyperkalemia, skin rash, neutropenia, anemia, fetopathic syndrome, rare hepatic failure, rare agranulocytosis • Contraindicated in combination with neprilysin inhibitors and in patients with renal artery stenosis; caution in patients with impaired renal function or hypovolemia
Fosinopril Trandolapril Perindopril		• Both hepatic and renal elimination, caution in patients with renal or hepatic impairment
Angiotensin Receptor Blockers Candesartan, Eprosartan Irbesartan, Losartan Olmesartan, Telmisartan Valsartan	• Hypertension • Heart failure • Diabetic nephropathy	• Only in cases of intolerance to ACEI • Unwanted effects as ACEI, but less cough or angioedema • No evidence for superiority over ACEI • In combination with ACEI more harm than benefit

Drug Facts for Your Personal Formulary: *Heart Failure Drugs (continued)*

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
β Blockers		
Bisoprolol Carvedilol Metoprolol Nebivolol	• Heart failure • Hypertension • Widely used for angina, prevention of arrhythmias, rate control in atrial fibrillation, migraine	• First choice in the treatment of heart failure • Start low (1/10 target dose), go slow (2- to 4-weekly doubling) • Adverse effects: bradycardia, AV block, bronchospasm, peripheral vasoconstriction, worsening of acute heart failure, depression, worsening of psoriasis • Polymorphic CYP2D6 metabolism (metoprolol, carvedilol, nebivolol)
Mineralocorticoid Receptor Antagonists		
Eplerenone Spironolactone Finerenone	• Heart failure • Hypertension • Hyperaldosteronism, hypokalemia, ascites • Chronic kidney disease in diabetic patients (finerenone)	• First choice in treating symptomatic heart failure • Low doses (25–50 mg) • Most serious side effect is hyperkalemia • Spironolactone causes painful breast swelling and impotence in men, dysmenorrhea in women due to binding to sex hormone receptors • Finerenone reduces heart failure events and renal function decline in diabetic patients with chronic kidney disease
Neprilysin Inhibitor/Angiotensin Receptor Blocker		
Sacubitril/valsartan	• Heart failure	• Superior to the ACEI enalapril • May become first choice in treating heart failure • ↓ Degradation of natriuretic peptides, ↑ their beneficial actions • Hypotension, angioedema, hyperkalemia, contraindicated with ACEIs
Diuretics		
Thiazide Type Chlorothiazide Hydrochlorothiazide *Thiazide-like* Chlorthalidone Indapamide Metolazone	• Edema associated with congestive heart failure, liver cirrhosis, chronic kidney disease, and nephrotic syndrome • Hypertension • Nephrogenic diabetes insipidus • Kidney stones caused by Ca^{2+} crystals	• Symptomatic treatment of milder forms of heart failure • Loose efficacy at GFR <30–40 mL/min (exception indapamide and metolazone) • Potentiate effect of loop diuretics in severe heart failure (sequential tubulus blockade) • Risk for hypokalemia and arrhythmia when combined with QT-prolonging drugs • Sulfonamide hypersensitivity, photosensitivity
Loop Diuretics Bumetanide Ethacrynic acid Furosemide Torsemide	• Acute pulmonary edema (intravenous) • Edema associated with congestive heart failure, liver cirrhosis, chronic kidney disease, and nephrotic syndrome • Hyponatremia • Hypercalcemia • Hypertension with renal insufficiency	• Symptomatic treatment of severe heart failure and acute decompensation • Often required in treating severe chronic heart failure, twice-daily dosing or more • Torsemide may be superior to furosemide in heart failure • Risk for hypokalemia and arrhythmia when combined with QT-prolonging drugs • Nephrotoxicity, ototoxicity, sulfonamide hypersensitivity (except ethacrynic acid) • Ethacrynic acid as a reserve for patients with sulfa allergy
Vasodilators		
• ISDN/hydralazine	• Heart failure in African Americans	• Approved only for African Americans • Headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, angina pectoris; ⇒ use in combination with β blocker • Contraindicated with PDE5 inhibitors • Drug-induced lupus-like syndrome; other immunological reactions
Positive Inotropes		
• Digoxin • Digitoxin	• Heart failure • Atrial fibrillation	• Not first choice in treating heart failure • Low therapeutic index: proarrhythmic, nausea, diarrhea, visual disturbances • Digoxin kidney dependent, digitoxin not • Half-life 1.5 (digoxin) or 7 days (digitoxin) • Plasma concentration: 0.5–0.8 ng/mL (digoxin) or 10–25 ng/mL (digitoxin)
Heart Rate Reduction		
Ivabradine	• Heart failure	• Not first choice in treating heart failure • May exert benefits in patients not tolerating β blockers or having heart rate >75 under β blockers • Unwanted effects: bradycardia, QT prolongation, atrial fibrillation, phosphenes

Drug Facts for Your Personal Formulary: *Heart Failure Drugs (continued)*

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Intravenous Vasodilators: Acute decompensated heart failure		
Nitroglycerin Sodium nitroprusside	• Acute decompensated heart failure	• May ↑ cardiac output in acute congestion (↑ filling pressure and dilation) via ↓ preload and afterload • NO releaser, stimulates soluble guanylyl cyclase • Avoid if systolic blood pressure <110 mmHg • Nitroglycerine: headache, rebound hypertension • Nitroprusside: cyanide toxicity, methemoglobinemia
Intravenous Positive Inotropes: Acutely decompensated heart failure		
Dobutamine Dopamine Epinephrine Norepinephrine	• Acute decompensated heart failure	• β_1 Receptor–mediated stimulation of cardiac output and, depending on drug, complex vascular actions • Last option in patients with systolic blood pressure <85 mmHg • ↑ Cardiac energy consumption and risk of arrhythmia • Use of catecholamines correlates with poor prognosis; use lowest possible doses for shortest possible time • Dobutamine causes less tachycardia than EPI and less afterload increase than NE • Role of low-dose dopamine unclear
Enoximone Milrinone	• Acute decompensated heart failure	• PDE3/4 inhibitors, ↑ cellular cAMP • ↑ Cardiac output and dilate blood vessels ("inodilator") • May be used in patients on β blockers and with high peripheral and pulmonary arterial resistance • Blood pressure decrease is dose limiting • Risks and prognostic effects: same as catecholamines (above)
Levosimendan (not available in the U.S.)	• Acute decompensated heart failure	• Combined Ca^{2+} sensitizer (troponin C binding) and PDE3 inhibitor • ↑ Cardiac output and ↓ vascular resistance ("inodilator") • Advantages over catecholamines or simple PDE inhibitors unclear

Chapter 34 Antiarrhythmic Drugs

Bjorn C. Knollmann, Dan M. Roden, and Katherine T. Murray

Cardiac cells undergo depolarization and repolarization about 60 times per minute to form and propagate cardiac action potentials. The shape and duration of each action potential are determined by the activity of ion channel protein complexes in the membranes of individual cells, and the genes encoding most of these proteins and their regulators have now been identified. Action potentials in turn provide the primary signals to release Ca^{2+} from intracellular stores (sarcoplasmic reticulum) and to thereby initiate contraction. Thus, each normal heartbeat results from the highly integrated electrophysiological behavior of multiple proteins on the surface and within multiple cardiac cells. Disordered cardiac rhythm can arise from influences such as inherited variation in ion channels or other genes, ischemia, sympathetic stimulation, or myocardial scarring. Available antiarrhythmic drugs suppress arrhythmias by modulating flow through specific ion channels or by altering autonomic function. An increasingly sophisticated understanding of the molecular basis of normal and abnormal cardiac rhythm may lead to identification of new targets for antiarrhythmic drugs and perhaps improved therapies (Al-Khatib et al., 2018).

Arrhythmias can range from incidental, asymptomatic clinical findings to life-threatening abnormalities. Mechanisms underlying cardiac arrhythmias have been identified in cellular and animal experiments. For some human arrhythmias, precise mechanisms are known, and treatment can be targeted specifically to those mechanisms. In other cases, mechanisms can only be inferred, and the choice of drugs is based largely on results of prior experience. Antiarrhythmic drug therapy has two goals: termination of an ongoing arrhythmia or prevention of an arrhythmia. Unfortunately, antiarrhythmic drugs not only may help control arrhythmias but also can cause them, even during long-term therapy. Thus, prescribing antiarrhythmic drugs requires that precipitating factors be excluded or minimized, that a precise diagnosis of the type of arrhythmia (and its possible mechanisms) be made, that the prescriber has reason to believe that drug therapy will be beneficial, and that the risks of drug therapy can be minimized.

Principles of Cardiac Electrophysiology

The flow of ions across cell membranes generates the currents that make up cardiac action potentials. Factors that determine the magnitude of individual currents and their modulation by drugs include transmembrane potential, time since depolarization, and the presence of specific ligands (Priori et al., 1999). Further, because the function of many channels is time and voltage dependent, even a drug that targets a single ion channel may, by altering the trajectory of the action potential, alter the function of other channels. Most antiarrhythmic drugs affect more than one ion current, and many exert ancillary effects, such as modification of cardiac contractility or autonomic nervous system function. Thus, antiarrhythmic drugs usually exert multiple actions and can be beneficial or harmful in individual patients (Priori et al., 1999; Roden, 1994).

The Cardiac Cell at Rest: A K^+-Permeable Membrane

Ions move across cell membranes in response to electrical and concentration gradients, not through the lipid bilayer but through specific ion channels or transporters. The normal cardiac cell at rest maintains a transmembrane potential approximately 80 to 90 mV negative to the exterior; this gradient is established by pumps, especially the Na^+, K^+–ATPase, and fixed anionic charges within cells. There are both electrical and concentration gradients that would move Na^+ ions into resting cells (Figure 34–1). However, Na^+ channels, which allow Na^+ to move along this gradient, are closed in the cardiac cell at rest, so Na^+ does not enter normal resting

Abbreviations

AF: atrial fibrillation
AV: atrioventricular
β blocker: β adrenergic receptor antagonist
CPVT: catecholaminergic polymorphic ventricular tachycardia
DAD: delayed afterdepolarization
DC: direct current
EAD: early afterdepolarization
ECG: electrocardiogram
ERP: effective refractory period
GX: glycine xylidide
ICD: implantable cardioverter-defibrillator
LQTS: long QT syndrome
NCX: Na^+-Ca^{2+} exchanger
PSVT: paroxysmal supraventricular tachycardia
RV: right ventricle
RyR2: ryanodine receptor type 2
SA: sinoatrial
SR: sarcoplasmic reticulum
VF: ventricular fibrillation
VT: ventricular tachycardia
WPW: Wolff-Parkinson-White

cardiac cells. In contrast, a specific type of K^+ channel protein (inward rectifier channels) remains open at negative resting potentials. Hence, K^+ can move through these channels across the cell membrane at negative potentials in response to either electrical or concentration gradients (Figure 34–1). For each individual ion, there is an equilibrium potential E_x at which there is no net driving force for the ion to move across the membrane. E_x can be calculated using the Nernst equation:

$$E_x = -(RT/FZx)\ \ln([x]_i/[x]_o) \qquad \text{(Equation 34–1)}$$

where Zx is the valence of the ion, T is the absolute temperature, R is the gas constant, F is Faraday's constant, $[x]_o$ is the extracellular concentration of the ion, and $[x]_i$ is the intracellular concentration. For typical values for K^+, $[K]_o$ = 4 mM and $[K]_i$ = 150 mM, the calculated K^+ equilibrium potential E_K is –96 mV. There is thus no net force driving K^+ ions into or out of a cell when the transmembrane potential is –96 mV, which is close to the resting potential. If $[K]_o$ is elevated to 10 mM, as might occur in diseases such as renal failure or myocardial ischemia, the calculated E_K rises to –70 mV. In this situation, there is excellent agreement between changes in theoretical E_K owing to changes in $[K]_o$ and the actual measured transmembrane potential, indicating that the normal cardiac cell at rest is permeable to K^+ (because inward rectifier channels are open) and that $[K]_o$ is the major determinant of resting potential.

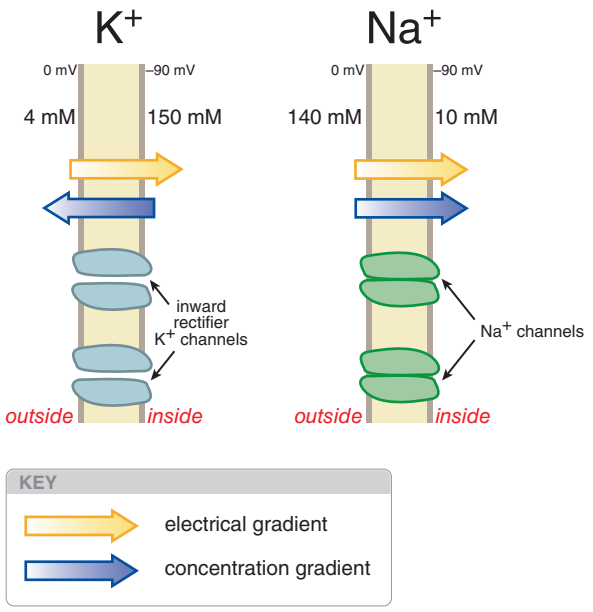

Figure 34–1 *Electrical and chemical gradients for K^+ and for Na^+ in a resting cardiac cell.* Inward rectifier K^+ channels are open (left), allowing K^+ ions to move across the membrane and the transmembrane potential to approach E_K. In contrast, Na^+ does not enter the cell despite a large net driving force because Na^+ channel proteins are in the closed conformation (right) in resting cells.

The Cardiac Action Potential

Transmembrane current through voltage-gated ion channels is the primary determinant of cardiac action potential morphology and duration. Channels are macromolecular complexes consisting of a pore-forming transmembrane structure (which may be a single protein, often termed an α subunit, or a multimer), as well as function-modifying β subunits and other accessory proteins. Common features of the pore-forming structure include a voltage-sensing domain (for voltage-gated channels), a selectivity filter, a conducting pore, and an inactivating particle (Figure 34–2). In response to changes in local transmembrane potential, ion channels undergo conformational changes, allowing for, or preventing, the flow of ions through the conducting pore along their electrochemical gradient, generally in time-, voltage-, and/or ligand-dependent fashion.

To initiate an action potential, a cardiac myocyte at rest is depolarized above a threshold potential, usually via gap junctions by a neighboring myocyte. On membrane depolarization, Na^+ channel proteins, $Na_V1.5$, change conformation from the "closed" (resting) state to the "open" (conducting) state (Figure 34–2), allowing up to 10^7 Na^+ ions/sec to enter each cell and moving the transmembrane potential toward E_{Na} (+65 mV). This surge of Na^+ ions lasts only about a millisecond, after which the Na^+ channel protein rapidly changes conformation from the open state to an "inactivated," nonconducting state (Figure 34–2). The maximum upstroke slope of phase 0 (dV/dt_{max}, or V_{max}) of the action potential (Figure 34–3) is largely governed by Na^+ current and is a major determinant of conduction velocity of a propagating action potential. Under normal conditions, Na^+ channels, once inactivated, cannot reopen until they reassume the closed conformation. However, a small population of Na^+ channels may continue to open during the action potential plateau in some cells (Figure 34–3), providing further inward current, often termed "late" Na^+ current. As the cell membrane repolarizes, the negative membrane potential moves Na^+ channel proteins from inactivated to closed conformations, from which they are again available to open and depolarize the cell. The relationship between Na^+ channel availability and transmembrane potential is an important determinant of conduction and refractoriness in many cells, as discussed in the material that follows.

The changes in transmembrane potential generated by the inward Na^+ current produce, in turn, a series of openings (and in some cases

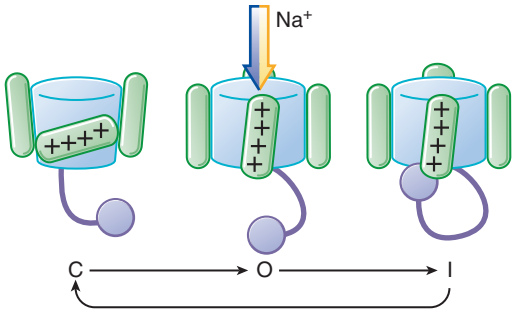

Figure 34–2 *Voltage-dependent conformational changes determine current flow through Na^+ channels.* At hyperpolarized potentials, the channel is in a closed conformation, and no current can flow (left, C). As depolarization begins, the voltage sensor (indicated here as ++++) moves, thus altering channel conformation and opening the pore, allowing conduction (middle, O). As depolarization is maintained, an intracellular particle blocks current flow, making the channel nonconducting in the inactivated state (right, I).

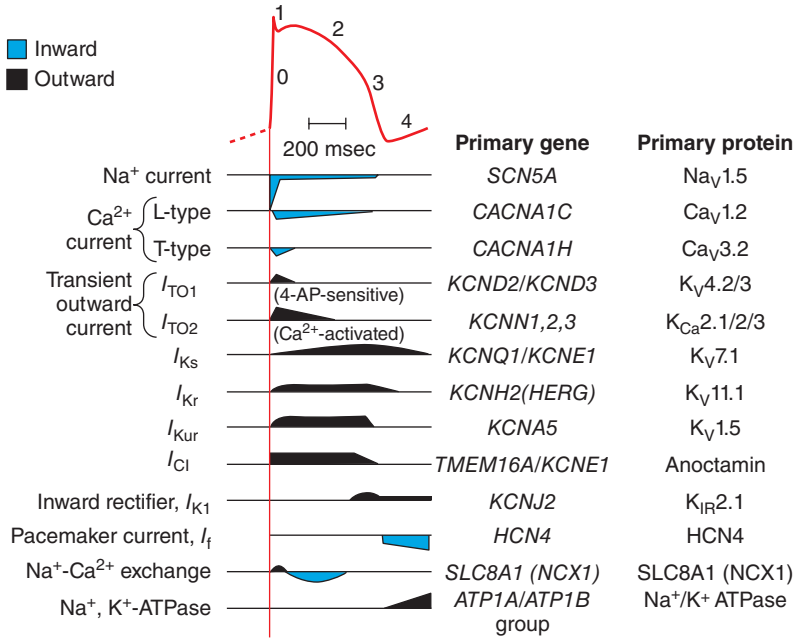

Figure 34–3 *The relationship between an action potential from the ventricular conducting system and the time course of the currents that generate it.* The current magnitudes are not to scale; the peak Na^+ current is ordinarily 50 times larger than any other current, although the portion that persists into the plateau (phase 2) is small. Multiple types of Ca^{2+} current, transient outward current I_{TO}, and delayed rectifier I_K have been identified. Each represents a different channel protein, usually associated with ancillary (function-modifying) subunits. 4-Aminopyridine (4-AP) is a widely used *in vitro* blocker of K^+ channels. I_{TO2} may be a Cl^- current in some species or a Ca-activated K current generated by apamin-sensitive "small" K channels ($K_{Ca}2.1/2/3$). Components of I_K have been separated on the basis of how rapidly they activate: slowly (I_{Ks}), rapidly (I_{Kr}), or ultrarapidly (I_{Kur}); I_{Kur} is found predominantly in atria. The voltage-activated, time-independent current may be carried by Cl^- (I_{Cl}) or K^+ (I_{Kp}, *p* for plateau). The genes encoding the major pore-forming proteins are listed in the right-hand column, followed by the protein name. *KCNE1*, a β subunit of the *KCNQ1* channel required for I_{Ks}, serves also as an auxiliary subunit of the *TMEM16A* channel, a Ca-activated Cl channel, and induces a voltage-dependent Cl current in the absence of intracellular calcium elevation (Ávalos Prado et al., 2021).

subsequent inactivation) of other channels (Figure 34–3). For example, when a cell is depolarized by the Na^+ current, "transient outward" K^+ channels, $K_V4.2$ and $K_V4.3$, quickly change conformation to enter an open, or conducting, state; because the transmembrane potential at the end of phase 0 is positive to E_K, the opening of transient outward channels results in an outward, or repolarizing, K^+ current (termed I_{TO}), which contributes to the phase 1 "notch" seen in some action potentials (e.g., more prominent in epicardium than in endocardium). Transient outward K^+ channels, like Na^+ channels, inactivate rapidly. During the phase 2 plateau of a normal cardiac action potential, inward, depolarizing currents, primarily through voltage-gated L-type Ca^{2+} channels, $Ca_V1.2$, are balanced by outward, repolarizing currents primarily through K^+ ("delayed rectifier") channels. Delayed rectifier currents (collectively termed I_K) increase with time, whereas Ca^{2+} currents inactivate (and so decrease with time); as a result, cardiac cells repolarize (phase 3) several hundred milliseconds after the initial Na^+ channel opening. Figure 34–3 summarizes the major inward and outward currents generated during the action potential by ion channels and electrogenic ion transporters in the heart.

A common mechanism whereby drugs prolong cardiac action potentials and provoke arrhythmias is inhibition of a specific delayed rectifier current, I_{Kr}, generated by expression of *KCNH2* (formerly termed *HERG* [human ether-a-go-go related gene]). The ion channel protein, $K_V7.1$, generated by *KCNH2* expression differs from other ion channels in important structural features (i.e., pore-lining aromatic residues) that make it much more susceptible to drug block; understanding these structural constraints is an important first step to designing drugs lacking I_{Kr}-blocking properties. Avoiding $I_{Kr}/K_V7.1$ channel block has become a major issue in drug development (Roden, 2004).

Maintenance of Intracellular Ion Homeostasis

With each action potential, the cell interior gains Na^+ and Ca^{2+} ions and loses K^+ ions. Figure 34–4 illustrates the major ion channels and membrane transporters regulating ion homeostasis of cardiac myocytes. An ATP-requiring Na^+-K^+ exchange mechanism, or pump, is activated in most cells to maintain intracellular homeostasis. This Na^+, K^+–ATPase extrudes three Na^+ ions for every two K^+ ions shuttled from the exterior of the cell to the interior (Figure 34–4); as a result, the act of pumping itself is electrogenic, generating a net outward (repolarizing) current.

Normally, intracellular Ca^{2+} is maintained at low levels (~100 nM). In cardiac myocytes, the entry of Ca^{2+} during each action potential through L-type Ca^{2+} channels is a signal to the sarcoplasmic reticulum (SR) to release its Ca^{2+} stores and thus initiate Ca^{2+}-dependent contraction, a process termed excitation-contraction coupling. The efflux of Ca^{2+} from the SR occurs through ryanodine receptor Ca^{2+} release channels (RyR2) and subsequent removal of intracellular Ca^{2+} occurs by both the SR Ca^{2+} uptake pump, which moves Ca^{2+} ions back into the SR, and an electrogenic Na^+-Ca^{2+} exchanger (NCX) on the cell surface, which exchanges three Na^+ ions from the exterior for each Ca^{2+} ion extruded (Figure 34–4).

Genetic Arrhythmia Diseases

Rare congenital arrhythmia diseases such as the long QT syndrome (LQTS) and catecholaminergic polymorphic ventricular tachycardia (CPVT) can cause sudden death due to fatal arrhythmias, often in young subjects. The identification of disease genes not only has resulted in improved care of affected patients and their families but also has contributed importantly to our understanding of the normal action potential, arrhythmia mechanisms, and potential antiarrhythmic drug targets (Knollmann and Roden, 2008). Figure 34–4 illustrates which ion channels have been linked to congenital arrhythmia diseases. For example, mutations in the cardiac Na^+ channel gene *SCN5A* can cause one form of LQTS by destabilizing fast inactivation, increasing late Na^+ current, and thereby prolonging action potentials and thus the QT interval (as discussed in material that follows). Drugs inhibiting this abnormal current may be antiarrhythmic in this form of LQTS (Remme and Wilde, 2013), and drugs increasing late Na^+ current may cause arrhythmias (Lu et al.,

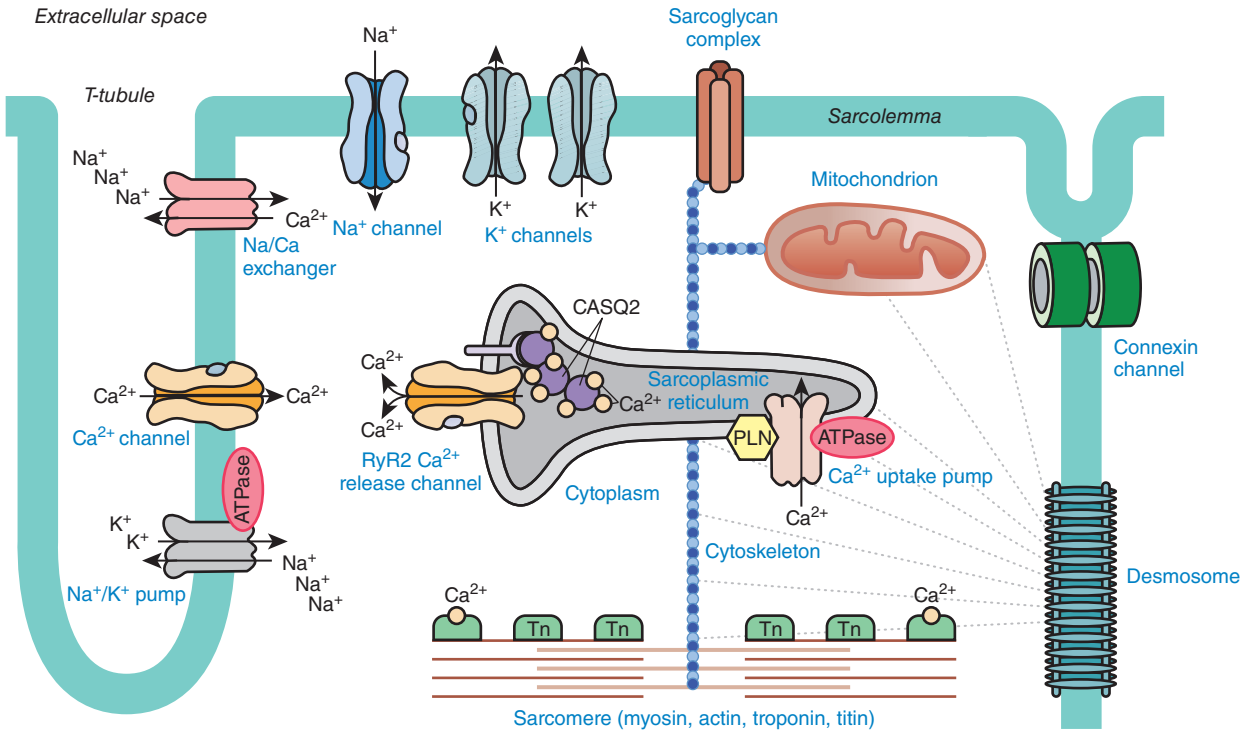

Figure 34–4 *Excitation-contraction coupling and ion homeostasis in a ventricular cardiomyocyte.* Shown are the protein complexes, myocyte architecture, and intracellular organelles involved in cardiac excitation-contraction coupling. The initial event in the cardiac cycle is membrane depolarization, which occurs with ion entry through connexin channels from a neighboring cardiomyocyte (right) followed by opening of voltage-gated Na^+ channels and Na^+ entry (top). The resultant rapid depolarization of the membrane inactivates Na^+ channels and opens both K^+ channels and Ca^{2+} channels. Entry of Ca^{2+} into the cell triggers the release of Ca^{2+} from the sarcoplasmic reticulum through the RyR2 Ca^{2+} release channel. Ca^{2+} then binds to the troponin complex and activates the contractile apparatus (the sarcomere, bottom). Cellular relaxation occurs on removal of Ca^{2+} from the cytosol by the Ca^{2+}-uptake pumps of the sarcoplasmic reticulum and by Na/Ca exchange with the extracellular fluid. Intracellular Na^+ homeostasis is achieved by the Na/K pump. The molecular components that are required for normal electrophysiological activity, contractile function, and cell-cell adhesion (the latter mediated by desmosomes) all need to be positioned correctly within the cell and anchored to each other and the cytoskeleton.

2012; Yang et al., 2014). Inhibitors may include not only antiarrhythmics such as *mexiletine* or *flecainide*, which are discussed in this chapter, but also the antianginal agent *ranolazine* (see Chapter 31), which is a late Na^+ current blocker.

Similarly, mutations in the *RyR2* gene encoding an intracellular Ca^{2+} release channel (or less commonly in other genes regulating RyR2 function) cause CPVT by generating "leaky" RyR2 channels, perturbing intracellular Ca^{2+} homeostasis, and causing delayed afterdepolarization (DAD)-dependent arrhythmias described further in this chapter. Intriguingly, some arrhythmias in acquired heart disease have been attributed to increased late Na^+ current or leaky RyR2 channels. Thus, studies in the rare congenital arrhythmia syndromes may point to new avenues for drug development in more common arrhythmias in acquired heart disease (Knollmann and Roden, 2008; Priori et al., 1999). Drugs such as *flecainide* and *propafenone* that inhibit these abnormal RyR2 channels (Kryshtal et al., 2021) appear to prevent CPVT in mouse models and in humans (Kannankeril et al., 2017; Watanabe et al., 2009). However, as discussed below, these drugs are also sodium channel blockers and are thus not used in patents with many forms of acquired heart disease. In malignant hyperthermia, a disease caused by leaky RyR1 calcium release channels in skeletal muscle, the RyR1 blocker *dantrolene* can be effective, and it has also been investigated in arrhythmias caused by leaky RyR2 channels (Roden and Knollmann, 2014). These precedents have propelled efforts to develop more selective RyR2 blockers (Batiste et al., 2019; Zhou et al., 2011).

Action Potential Heterogeneity in the Heart

The general description of the action potential and the currents that underlie it must be modified for certain cell types (Figure 34–5), primarily due to variability in the expression of ion channels and electrogenic ion transport pumps. The resultant diversity of action potentials in different regions of the heart plays a role in understanding the pharmacological profiles of antiarrhythmic drugs. In the ventricle, action potential duration varies across the wall of each chamber, as well as apicobasally, largely as a consequence of varying densities of repolarizing currents. In the neighboring His-Purkinje conduction system, action potentials are longer, probably due to decreased K^+ currents, increased late Na^+ current, and differences in intercellular Ca^{2+} handling (Dun and Boyden, 2008).

Atrial cells have shorter action potentials than ventricular cells because of larger early repolarization currents such as I_{TO}. Atrial cells also express an additional repolarizing K^+ channel ($I_{K\text{-}Ach}$) that is activated by the neurotransmitter acetylcholine and accounts for action potential shortening with vagal stimulation. Although some cells of the sinus and atrioventricular (AV) nodes likely have small Na^+ current, depolarization is primarily achieved by inward current generated by opening of Ca^{2+} channels. In addition, these cells, as well as cells from the conducting system, normally display the phenomenon of spontaneous diastolic, or phase 4, depolarization and thus spontaneously reach threshold for regeneration of action potentials. The rate of spontaneous firing usually is fastest in sinus node cells, which therefore serve as the natural pacemaker of the heart. The slow diastolic depolarization that underlies pacemaker activity is generated by a nonselective channel () that conducts both Na^+ and K^+ (funny current, I_f) and is activated at hyperpolarized membrane potentials (Cohen and Robinson, 2006). In diseased cells, pacemaker-like activity can arise from spontaneous Ca^{2+} release from the SR, followed by membrane depolarization due to activation of NCX.

Certain ion channels are expressed only in some tissues or become active only under specific pathophysiologic conditions. For example, the T-type Ca^{2+} channel may be important in diseases such as hypertension and play a role in pacemaker activity (Ono and Iijima, 2010). A T-type–selective Ca^{2+} channel antagonist, *mibefradil* was commercially available briefly in the late 1990s but was withdrawn because

of concerns over potentially life-threatening pharmacokinetic interactions with many other drugs. A second example is a small-conductance K^+ channel activated by intracellular Ca^{2+} (SK channel) and blocked by apamin (Zhang et al., 2021). SK channels are prominently expressed in healthy atrial myocytes and pacemaking cells compared to ventricular cells. However, SK channels are upregulated in ventricular myocytes in heart failure and pulmonary veins in atrial fibrillation (AF). Therefore, the SK channel has been implicated mechanistically in atrial and ventricular arrhythmias and may represent a novel therapeutic target. A third example is a channel that transports Cl^- ions and results in repolarizing currents (I_{Cl}) (Duan, 2013); some of these are observed only in association with pathophysiological conditions. A final example is the K^+ channels that are quiescent when intracellular ATP stores are normal and become active when these stores are depleted. Such ATP-inhibited K^+ channels may become particularly important in repolarizing cells during states of metabolic stress such as myocardial ischemia (Tamargo et al., 2004).

Impulse Propagation and the Electrocardiogram

Normal cardiac impulses originate in the sinus node. Impulse propagation in the heart depends on the magnitude of the depolarizing current (usually Na^+ current) and the geometry and density of cell-cell electrical connections (Kleber and Saffitz, 2014). Cardiac cells are relatively long and thin and well coupled through specialized gap junction proteins at their ends (connexins; Figure 34–4), whereas lateral ("transverse") gap junctions are sparser. As a result, impulses spread along cells two to three times faster than across cells. This "anisotropic" (direction-dependent) conduction may be a factor in the genesis of certain arrhythmias described in the material that follows (Priori et al., 1999).

Once impulses leave the sinus node, they propagate rapidly throughout the atria, resulting in atrial systole and the P wave of the surface electrocardiogram (ECG) (Figure 34–5). Propagation slows markedly through the AV node, where the inward current mediating the phase 0 upstroke (through Ca^{2+} channels) is much smaller than the Na^+ current in atria, ventricles, or the subendocardial conducting system. This conduction delay, represented as the PR interval on the ECG, allows the atrial contraction to propel blood into the ventricle, thereby optimizing cardiac output.

Once impulses exit the AV node, they enter the conducting system, where Na^+ currents are larger than in any other tissue, and propagation is correspondingly faster, up to 0.75 m/sec longitudinally. Activation spreads from the His-Purkinje system on the endocardium of the ventricles throughout the rest of the ventricles, stimulating coordinated ventricular contraction. This electrical activation manifests itself as the QRS complex on the ECG. Ventricular repolarization is represented on the surface ECG as the T wave. The time from initial depolarization in the ventricle until the end of repolarization is termed the QT interval. Lengthening of ventricular action potentials prolongs the QT interval and may be associated with arrhythmias in LQTS and other settings. QT interval is rate dependent, and various formulae are commonly used to generate a rate-corrected value (QTc). The most common is the Bazett formula: QTc = QT/(RR^0.5), where RR is the cardiac cycle length expressed in seconds.

Refractoriness and Conduction Failure

In atrial, ventricular, and His-Purkinje cells, if restimulation occurs early during the plateau of an action potential, no Na^+ channels are available to open, so no inward current results, and no new action potential is generated: At this point, the cell is termed *refractory* (Figure 34–6). On the other hand, if such a stimulus occurs after the cell has repolarized completely, Na^+ channels have recovered from inactivation, and a normal Na^+ channel–dependent upstroke results with the same amplitude as the previous upstroke (Figure 34–6A). When a stimulus occurs during phase 3 of the action potential, the upstroke of the premature action potential is slower and of smaller magnitude. The magnitude depends on the number of Na^+ channels that have recovered from inactivation (Figure 34–6A), which in turn is dependent on the membrane potential. Thus, refractoriness is determined by the voltage-dependent recovery of Na^+ channels from inactivation.

Refractoriness frequently is measured by assessing whether premature stimuli applied to tissue preparations (or the whole heart) result

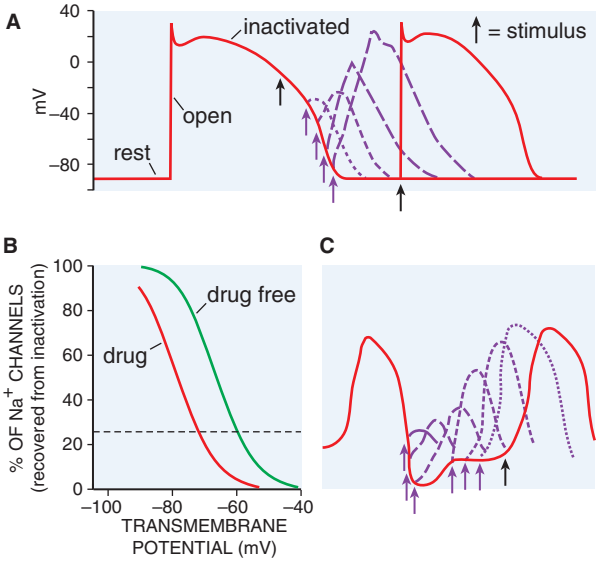

Figure 34–6 *Qualitative differences in responses of slow- and fast-response tissues to premature stimuli.* **A.** With a very early premature stimulus (black arrow) in ventricular myocardium, all Na^+ channels still are in the inactivated state, and no upstroke results. As the action potential repolarizes, Na^+ channels recover from the inactivated to the resting state (see Figure 34–2), from which opening can occur. The phase 0 upstroke slopes of the premature action potentials (purple) are greater with later stimuli because recovery from inactivation is voltage dependent. **B.** The relationship between transmembrane potential and degree of recovery of Na^+ channels from inactivation. The dotted line indicates 25% recovery. Most Na^+ channel–blocking drugs shift this relationship to the left, so in the presence of drug, fewer channels have recovered from inactivation at any potential. **C.** In Ca^{2+}-dependent slow-response tissues such as the AV node, premature stimuli delivered even after full repolarization of the action potential are depressed; recovery from inactivation is time dependent.

in propagated impulses. While the magnitude of the Na^+ current is one major determinant of propagation of premature beats, cellular geometry also is important in multicellular preparations. Propagation from cell to cell requires current flow from the first site of activation and consequently can fail if inward current is insufficient to drive activation in many neighboring cells. The *effective refractory period* (ERP) is the longest interval at which a premature stimulus fails to generate a propagated response and often is used to describe drug effects in intact tissue.

The situation is different in tissue whose depolarization is largely controlled by Ca^{2+} channel current, such as the AV node. Because Ca^{2+} channels have a slower recovery from inactivation, these tissues are often referred to as *slow response* (Figure 34–6C), in contrast to *fast response* in the remaining cardiac tissues. Even after a Ca^{2+} channel–dependent action potential has repolarized to its initial resting potential, not all Ca^{2+} channels are available for reexcitation because recovery from inactivation of these channels depends not only on voltage but also on the time since repolarization. Therefore, an extrastimulus applied shortly after repolarization is complete generates a reduced Ca^{2+} current, which may propagate slowly to adjacent cells prior to extinction. An extrastimulus applied later will result in a larger Ca^{2+} current and faster propagation. Thus, in Ca^{2+} channel–dependent tissues, which include not only the AV node but also tissues whose underlying characteristics have been altered by factors such as myocardial ischemia, refractoriness is prolonged, and propagation occurs slowly. Conduction that exhibits such dependence on the timing of premature stimuli is termed *decremental*. Slow conduction in the heart, a critical factor in the genesis of reentrant arrhythmias (see further discussion), also can occur when Na^+ currents are depressed by disease or membrane depolarization (e.g., elevated $[K]_o$), resulting in decreased steady-state Na^+ channel availability (Figure 34–6B).

Mechanisms of Cardiac Arrhythmias

An arrhythmia is by definition a perturbation of the normal sequence of impulse initiation and propagation. Failure of impulse initiation, in the sinus node, may result in slow heart rates (bradyarrhythmias), whereas failure in the normal propagation of action potentials from atrium to ventricle results in dropped beats (commonly referred to as heart block) and usually reflects an abnormality in either the AV node or the His-Purkinje system. These abnormalities may be caused by drugs (Table 34–1) or by structural heart disease; in the latter case, permanent cardiac pacing may be required.

Abnormally rapid heart rhythms (tachyarrhythmias) are common clinical problems that may be treated with antiarrhythmic drugs. Three major underlying mechanisms have been identified: enhanced automaticity, triggered automaticity, and reentry. These are often interrelated mechanisms as abnormal beats arising from one mechanism can elicit a second; for example, a triggered automatic beat can initiate reentry.

Enhanced Automaticity

Enhanced automaticity may occur in cells that normally display spontaneous diastolic depolarization—the sinus and AV nodes and the His-Purkinje system. β Adrenergic stimulation, hypokalemia, and mechanical stretch of cardiac muscle cells increase phase 4 slope and so accelerate pacemaker rate, whereas *acetylcholine* reduces pacemaker rate both by decreasing phase 4 slope and by hyperpolarization (making the maximum diastolic potential more negative). In addition, automatic behavior may occur in sites that ordinarily lack spontaneous pacemaker activity; for example, depolarization of ventricular cells (e.g., by ischemia) may produce "abnormal" automaticity. When impulses propagate from a region of enhanced normal or abnormal automaticity to excite the rest of the heart, more complex arrhythmias may result from the induction of reentry.

Afterdepolarizations and Triggered Automaticity

Under some pathophysiological conditions, a normal cardiac action potential may be interrupted or followed by an abnormal depolarization (Figure 34–7). If this abnormal depolarization reaches threshold, it may, in turn, give rise to secondary upstrokes that can propagate and create abnormal rhythms. These abnormal secondary upstrokes occur only after an initial normal, or "triggering," upstroke and thus are termed *triggered rhythms*.

Two major forms of triggered rhythms are recognized. In the first case, under conditions of intracellular or SR Ca^{2+} overload (e.g., myocardial ischemia, adrenergic stress, *digitalis* intoxication, or CPVT), a normal action potential may be followed by a *DAD* (Figure 34–7A); as discussed previously, spontaneous SR Ca^{2+} release activating NCX current is a common mechanism underlying DADs (Wit, 2018). If this afterdepolarization reaches threshold, a secondary triggered beat or beats may occur. DAD amplitude is increased *in vitro* by rapid pacing, and clinical arrhythmias corresponding to DAD-mediated triggered beats are more frequent when the underlying sinus heart rate is rapid or in the presence of β adrenergic stimulation (Priori et al., 1999).

In the second type of triggered activity, the key abnormality is marked prolongation of the cardiac action potential. When this occurs, phase 3 repolarization may be interrupted by an early afterdepolarization (EAD) (Figure 34–7B). EAD-mediated triggering *in vitro* and clinical arrhythmias are most common when the underlying heart rate is slow, extracellular K^+ is low, and certain drugs that prolong action potential duration (antiarrhythmics and others) are present. EAD-related triggered upstrokes probably reflect inward current through Ca^{2+} channels or possibly the NCX and/or Na^+ channels (Wit, 2018). Due to their intrinsically longer action potential, EADs are induced more readily in Purkinje cells and in endocardial than in epicardial cells.

When cardiac repolarization is markedly prolonged, polymorphic ventricular tachycardia with a long QT interval, termed *torsades de pointes*, may occur. This arrhythmia is thought to be caused by EADs, which trigger functional reentry (discussed next) owing to heterogeneity of action potential durations across the ventricular wall (Priori et al., 1999). Congenital LQTS, a disease in which torsades de pointes causes syncope or death, is most often caused by mutations in the genes encoding the Na^+

TABLE 34–1 ■ DRUG-INDUCED CARDIAC ARRHYTHMIAS

ARRHYTHMIA	DRUG	LIKELY MECHANISM	TREATMENT*	CLINICAL FEATURES
Sinus bradycardia, AV block	Digoxin	↑Vagal tone	Antidigoxin antibodies, temporary pacing	Atrial tachycardia may also be present
Sinus bradycardia, AV block	Verapamil, diltiazem	Ca^{2+} channel block	Ca^{2+}, temporary pacing	
Sinus bradycardia	β *Blockers*	Sympatholytic	Isoproterenol	
AV block	Clonidine Methyldopa		Temporary pacing	
Sinus tachycardia Any other tachycardia	β Blocker withdrawal	Upregulation of β receptors with chronic therapy; β blocker withdrawal →↑β effects	β Blockade	Hypertension, angina also possible
↑Ventricular rate in atrial flutter	Quinidine Flecainide Propafenone	Conduction slowing in atrium, with enhanced (quinidine) or unaltered AV conduction	AV nodal blockers	QRS complexes often widened at fast rates
↑Ventricular rate in atrial fibrillation in patients with WPW syndrome	Digoxin Verapamil	↓Accessory pathway refractoriness	IV procainamide DC cardioversion	Ventricular rate can exceed 300 beats/min and lead to VF
Multifocal atrial tachycardia	Theophylline	↑Intracellular Ca^{2+} and DADs	Withdraw theophylline ?Verapamil	Often in advanced lung disease
Polymorphic VT with ↑QT interval (torsades de pointes)	Quinidine Sotalol Procainamide Disopyramide Dofetilide Ibutilide "Noncardioactive" drugs (see text) Amiodarone (rare)	EAD-related triggered activity	Magnesium Isoproterenol Cardiac pacing	Hypokalemia, bradycardia frequent Related to ↑ plasma concentrations, except for quinidine
Frequent or difficult to terminate VT ("incessant" VT)	Flecainide Propafenone Quinidine (rarer)	Conduction slowing in reentrant circuits	Na^+ bolus reported effective in some cases	Most often in patients with advanced myocardial scarring
Atrial tachycardia with AV block; ventricular bigeminy, others	Digoxin	DAD-related triggered activity (± ↑ vagal tone)	Antidigoxin antibodies	Coexistence of abnormal impulses with abnormal sinus or AV nodal function
Ventricular fibrillation	Inappropriate use of IV verapamil	Severe hypotension and/or myocardial ischemia	Cardiac resuscitation (DC cardioversion)	Misdiagnosis of VT as PSVT and inappropriate use of verapamil

*In each of these cases, recognition and withdrawal of the offending drug(s) are mandatory; ↑, increase; ↓, decrease; ?, unclear.

channels (10%) or the channels underlying the repolarizing currents I_{Kr} and I_{Ks} (80%–90%) (Figure 34–4; Roden and Knollmann, 2014).

Reentry

Reentry occurs when a cardiac impulse travels in a path such as to return to its original site and reactivate the original site, thus perpetuating rapid reactivation independent of normal sinus node function. Key features enabling reentrant excitation are a pathway; heterogeneity of electrophysiologic properties, notably refractoriness, along the pathway; and slow conduction.

Anatomically Defined Reentry

The prototypical example of reentry is the Wolff-Parkinson-White (WPW) syndrome in which patients have an accessory connection between the atrium and ventricle (Figure 34–8). With each sinus node depolarization, impulses can excite the ventricle via the normal structures (AV node) or the accessory pathway, and this often results in an unusual and characteristic QRS complex in normal sinus rhythm. Importantly, the electrophysiological properties of the AV node and accessory pathways are different: Accessory pathways usually consist of nonnodal tissue with longer refractory periods and without decremental conduction. Thus, with a premature atrial beat (e.g., from abnormal automaticity), conduction may fail in the accessory pathway but continue, albeit slowly, in the AV node and then through the His-Purkinje system; there, the propagating impulse may encounter the ventricular end of the accessory pathway when it is no longer refractory. The likelihood that the accessory pathway is no longer refractory increases as AV nodal conduction slows, demonstrating how slow conduction enables reentry. When the impulse reenters the atrium, it then can reenter the ventricle via the AV node, reenter the atrium via the accessory pathway, and so on (Figure 34–8).

Reentry of this type, referred to as *AV reentrant tachycardia*, is determined by the following:

1. The presence of an anatomically defined circuit
2. Heterogeneity in refractoriness among regions in the circuit
3. Slow conduction in one part of the circuit

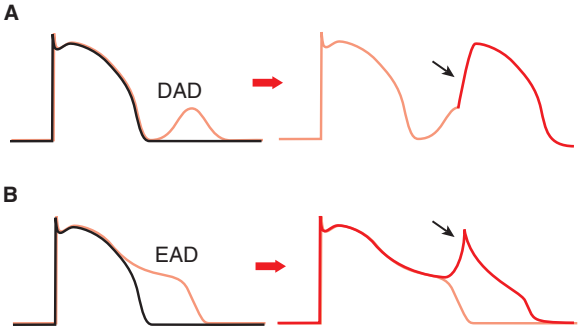

Figure 34–7 *Afterdepolarizations and triggered activity.* **A.** Delayed afterdepolarization (DAD) arising after full repolarization. DADs are typically caused by spontaneous Ca^{2+} release from the SR under conditions of Ca^{2+} overload. This increased cytosolic Ca^{2+} is removed from the cytosol by the electrogenic Na-Ca exchanger (see Figure 34–4), which produces Na^+ influx and causes a cell membrane depolarization in the form of a DAD. A DAD that reaches threshold results in a triggered upstroke (black arrow, right). **B.** Early afterdepolarization (EAD) interrupting phase 3 repolarization. Multiple ion channels and transporters can contribute to EADs (e.g., Na^+ channel, L-type Ca^{2+} channel, Na-Ca exchanger). Under some conditions, triggered beat(s) can arise from an EAD (black arrow, right).

Similar "anatomically defined" reentry commonly occurs in the region of the AV node (*AV nodal reentrant tachycardia*), in the atrium (*atrial flutter*), and in scarred ventricle (*ventricular tachycardia*). The term *paroxysmal supraventricular tachycardia* (PSVT) includes both AV reentry and AV nodal reentry, which share many clinical features.

While antiarrhythmic drugs or electrical cardioversion are used to terminate reentry acutely (discussed further in the chapter and in Table 34–2), anatomically defined reentry is often treated with radio-frequency ablation because its consistent pathway often makes it possible to identify and ablate critical segments of this pathway effectively, curing the patient and obviating the need for long-term drug therapy. Radio-frequency ablation is carried out through a catheter advanced to the interior of the heart and requires minimal convalescence.

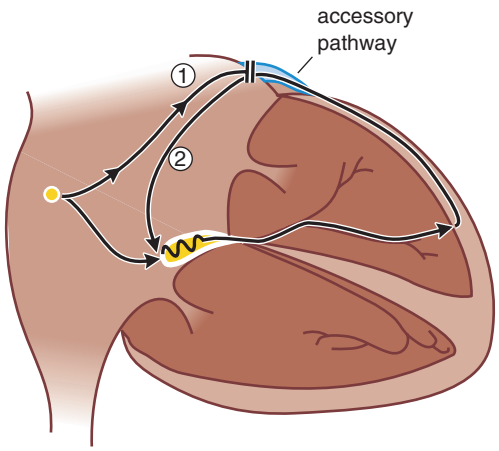

Figure 34–8 *Atrioventricular reentrant tachycardia in the WPW syndrome.* In these patients, an accessory AV connection is present (light blue). A premature atrial impulse blocks in the accessory pathway (1) and propagates slowly through the AV node and conducting system. On reaching the accessory pathway (by now no longer refractory) via the ventricle, the impulse reenters the atrium (2), where it then can reenter the ventricle via the AV node and become self-sustaining (see Figure 34–10C). AV nodal–blocking drugs readily terminate this tachycardia. Recurrences can be prevented by drugs that prevent atrial premature beats, by drugs that alter the electrophysiological characteristics of tissue in the circuit (e.g., they prolong AV nodal refractoriness), and by nonpharmacological ablation techniques that selectively destroy the accessory pathway.

Functionally Defined Reentry

Reentry also may occur in the absence of a distinct, anatomically defined pathway (Figure 34–9). For example, a premature beat from within the ventricular wall may encounter refractory tissue in only one direction, allowing for conduction throughout the rest of the wall until the originally refractory area recovers, reexcites, and then propagates back through the original location of the premature beat. Another example is localized ischemia or other electrophysiological perturbations that result in an area of sufficiently slow conduction in the ventricle that impulses exiting from that area find the rest of the myocardium reexcitable, in which case reentry may ensue. AF and ventricular fibrillation (VF) are extreme examples of "functionally defined" reentry: Cells are reexcited as soon as they are repolarized sufficiently to allow enough Na^+ channels to recover from inactivation. The abnormal activation pathway subsequently provides abnormal spatial heterogeneity of repolarization that can cause other reentrant circuits to form. In AF, these can persist for years, and rotor-like activity can sometimes be recorded, presumably reflecting single or multiple reentrant circuits that can be transiently stable or meander around the atrium.

Common Arrhythmias and Their Mechanisms

The primary tool for diagnosis of arrhythmias is the ECG. More sophisticated approaches sometimes are used, such as recording from specific regions of the heart during artificial induction of arrhythmias by specialized pacing techniques. Table 34–2 lists common arrhythmias, their likely mechanisms, and approaches that should be considered for their acute termination and for long-term therapy to prevent recurrence. Examples of some arrhythmias discussed here are shown in Figure 34–10. Some arrhythmias, notably VF, are treated not pharmacologically but with direct current (DC) cardioversion—the application of a large electric current across the chest. This technique also can be used to immediately restore normal rhythm in less serious cases when the arrhythmia is ongoing (i.e., not starting and stopping spontaneously); if the patient is conscious, a brief period of general anesthesia is required. Implantable cardioverter-defibrillators (ICDs), devices that are capable of detecting ventricular tachycardia (VT) or VF and automatically delivering a defibrillating shock, are used increasingly in patients judged to be at high risk for VF. Often, drugs are used with these devices if defibrillating shocks, which are painful, occur frequently.

Mechanisms of Antiarrhythmic Drug Action

Antiarrhythmic drugs almost invariably have multiple effects in patients, and their effects on arrhythmias can be complex. A drug can modulate other targets in addition to its primary site of action. At the same time, a single arrhythmia may result from multiple underlying mechanisms (e.g., torsades de pointes [Figure 34–10H] can result either from increased late sodium current or decreased repolarizing potassium currents). Thus, antiarrhythmic therapy should be tailored to target the most relevant underlying arrhythmia mechanism, where it is known. Drugs may be antiarrhythmic by suppressing the initiating mechanism or by altering reentrant circuits. In some cases, drugs may suppress an initiator but nonetheless promote reentry (see discussion that follows).

Drugs may slow automatic rhythms by altering any of the four determinants of spontaneous pacemaker discharge (Figure 34–11): (1) increase maximum diastolic potential, (2) decrease phase 4 slope, (3) increase threshold potential, or (4) increase action potential duration. *Adenosine* and acetylcholine may increase maximum diastolic potential, and β blockers (β adrenergic receptor antagonists) (see Chapter 14) may decrease phase 4 slope. Blockade of Na^+ or Ca^{2+} channels usually results in altered threshold, and blockade of cardiac K^+ channels prolongs the action potential.

Antiarrhythmic drugs may suppress arrhythmias owing to DADs or EADs by two major mechanisms:

1. inhibition of the development of afterdepolarizations (usually due to RyR2-mediated SR Ca^{2+} release); and
2. interference with the inward current (usually through Na^+ or Ca^{2+} channels), which is responsible for the upstroke

TABLE 34–2 ■ A MECHANISTIC APPROACH TO ANTIARRHYTHMIC THERAPY

ARRHYTHMIA	COMMON MECHANISM	ACUTE THERAPY[a]	CHRONIC THERAPY[a]
Premature atrial, nodal, or ventricular depolarizations	Unknown	None indicated	None indicated
Atrial fibrillation	Disorganized "functional" reentry Continual AV node stimulation and irregular, often rapid, ventricular rate	1. Control ventricular response: AV node block[b] 2. Restore sinus rhythm: DC cardioversion	1. Control ventricular response: AV nodal block[b] 2. Maintain normal rhythm: K+ channel block, Na+ channel block with $\tau_{recovery}$ >1 sec
Atrial flutter	Stable reentrant circuit in the right atrium Ventricular rate often rapid and irregular	Same as atrial fibrillation	Same as atrial fibrillation AV nodal–blocking drugs especially desirable to avoid ↑ ventricular rate Ablation in selected cases[c]
Atrial tachycardia	Enhanced automaticity, DAD-related automaticity, or reentry within atrium	Same as atrial fibrillation Adenosine sometimes effective	Same as atrial fibrillation Ablation of tachycardia "focus"[c]
AV nodal reentrant tachycardia (PSVT)	Reentrant circuit within or near AV node	*Adenosine AV nodal block[b] Less commonly: ↑ vagal tone (digitalis, edrophonium, phenylephrine)	*AV nodal block Flecainide Propafenone *Ablation[c]
Arrhythmias associated with WPW syndrome: 1. AV reentry (PSVT) 2. Atrial fibrillation with atrioventricular conduction via accessory pathway	Reentry (Figure 34–8) Very rapid rate due to nondecremental properties of accessory pathway	Same as AV nodal reentry *DC cardioversion *Procainamide	K^+ channel block Na^+ channel block with $\tau_{recovery}$ >1 sec *Ablation[c] *Ablation[c] K^+ channel block Na^+ channel block with $\tau_{recovery}$ >1 sec (AV nodal blockers can be harmful)
VT in patients with remote myocardial infarction	Reentry near the rim of the healed myocardial infarction	Amiodarone Procainamide Lidocaine Bretylium DC cardioversion	*ICD[d] Amiodarone K^+ channel block Na^+ channel block
VT in patients without structural heart disease	DADs triggered by ↑ sympathetic tone	Adenosine[e] Verapamil[e] β Blockers[e] *DC cardioversion	Verapamil[e] β Blockers[e]
VF	Disorganized reentry	*Defibrillation Amiodarone Procainamide Lidocaine Bretylium	*ICD[d] Amiodarone K^+ channel block Na^+ channel block
Torsades de pointes, congenital or acquired (often drug related)	EAD-related triggered activity	Magnesium Isoproterenol Pacing	β Blockade Pacing

*Indicates treatment of choice. [a]Acute drug therapy is administered intravenously; chronic therapy implies long-term oral use. [b]AV nodal block can be achieved clinically by adenosine, Ca^{2+} channel block, β adrenergic receptor blockade, or increased vagal tone (a major antiarrhythmic effect of digitalis glycosides). [c]Ablation is a procedure in which tissue responsible for the maintenance of a tachycardia is identified by specialized recording techniques and then selectively destroyed, usually by high-frequency radio waves delivered through a catheter placed in the heart. [d]ICD, implanted cardioverter-defibrillator: a device that can sense VT or VF and deliver pacing and/or cardioverting shocks to restore normal rhythm. [e]These may be harmful in reentrant VT and so should be used for acute therapy only if the diagnosis is secure.

Thus, arrhythmias owing to DADs in CPVT may be inhibited by β blockers (which block development of DAD by reducing SR Ca^{2+} uptake and thereby decreasing SR Ca^{2+} load and the likelihood of spontaneous Ca^{2+} release from the SR), *verapamil* (which blocks the development of DAD by reducing Ca^{2+} influx into the cell and hence SR Ca^{2+} load), or Na^+ channel–blocking drugs which elevate the threshold required to produce the abnormal pacemaker. In CPVT, combined RyR2 and Na^+ channel block by agents such as *flecainide* or *propafenone* is more effective than *verapamil*. Some manifestations of digital intoxication (see later) are DAD mediated, but other arrhythmia mechanisms could be present in which calcium channel blockers such as *verapamil* are not useful and may even be harmful in this setting. Similarly, two approaches are used in arrhythmias related to EAD-triggered beats (Tables 34–1 and 34–2). EADs can be inhibited by shortening action potential duration; in

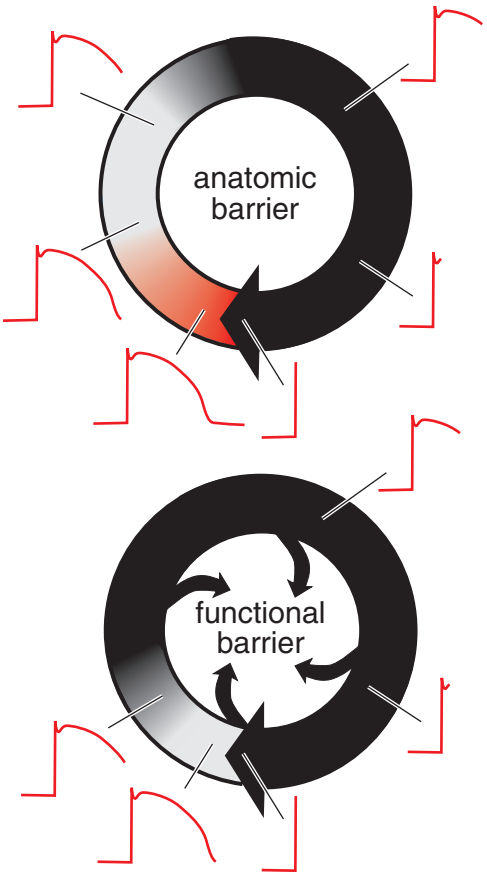

Figure 34–9 *Two types of reentry.* The border of a propagating wavefront is denoted by a heavy black arrowhead. In anatomically defined reentry (top), a fixed pathway is present (e.g., Figure 34–8). The black area denotes tissue in the reentrant circuit that is completely refractory because of the recent passage of the propagating wavefront; the gray area denotes tissue in which depressed upstrokes can be elicited (see Figure 34–6A), and the dark red area represents tissue in which restimulation would result in action potentials with normal upstrokes. The dark red area is termed an *excitable gap*. In functionally defined, or "leading circle," reentry (bottom), there is no anatomic pathway and no excitable gap. Rather, the circulating wavefront creates an area of inexcitable tissue at its core. In this type of reentry, the circuit does not necessarily remain in the same anatomic position during consecutive beats. During mapping of excitation sequences in the heart, this type of activity may be manifest as one or more "rotors."

practice, heart rate is accelerated by *isoproterenol* infusion or by pacing. Triggered beats arising from EADs can be inhibited by Mg^{2+} without normalizing repolarization *in vitro* or clinical QT interval largely by block of Ca^{2+} channels. In most forms of congenital LQTS, torsades de pointes occurs with adrenergic stress; therapy includes β adrenergic blockade (which does not shorten the QT interval but may prevent EADs) as well as pacing to shorten action potentials.

In anatomically determined reentry, drugs may terminate the arrhythmia by blocking propagation of the action potential. Conduction usually fails in a "weak link" in the circuit. In the example of the WPW-related arrhythmia described previously, the weak link is the AV node, and drugs that prolong AV nodal refractoriness and slow AV nodal conduction, such as Ca^{2+} channel blockers, β blockers, or *adenosine*, are likely to be effective. On the other hand, slowing conduction in functionally determined reentrant circuits may change the pathway without extinguishing the circuit. In fact, the effect of conduction slowing in this setting is variable. In some patients, conduction slowing drugs promote the development of reentrant arrhythmias, while in others, conduction slows sufficiently to extinguish propagation. Prolongation of refractoriness is another likely approach for terminating functionally determined reentry (Knollmann and Roden, 2008; Priori et al., 1999; Task Force, 1991). In atrial and ventricular myocytes, refractoriness can be prolonged by delaying the recovery of Na^+ channels from inactivation. Drugs that act by blocking Na^+ channels generally shift the voltage dependence of recovery from block (Figure 34–6B) and so prolong refractoriness (Figure 34–12).

Drugs that increase action potential duration without direct action on Na^+ channels (e.g., by blocking delayed rectifier currents) also prolong refractoriness (Figure 34–12). Particularly in sinoatrial (SA) or AV nodal tissues, Ca^{2+} channel blockade prolongs refractoriness. Drugs that interfere with cell-cell coupling also theoretically should increase refractoriness in multicellular preparations. Arrhythmia-prone hearts often display abnormal anatomy and histology, notably enhanced fibrosis, and some evidence suggests anti-inflammatory or antifibrotic interventions could thus be antiarrhythmic by preventing these changes.

State-Dependent Ion Channel Block

Knowing the structural and molecular determinants of ion channel permeation and drug block has provided key information for analyzing the actions of available and new antiarrhythmic compounds (MacKinnon, 2003). A key concept is that ion channel–blocking drugs bind to specific sites on the ion channel proteins to modify function (e.g., decrease current). The affinity of the ion channel protein for the drug on its target site generally varies as the ion channel protein shuttles among functional conformations (or ion channel "states"; see Figure 34–2). Physicochemical characteristics, such as molecular weight and lipid solubility, are important determinants of this state-dependent binding. State-dependent binding has been studied most extensively in the case of Na^+ channel–blocking drugs. Most useful agents of this type block open or inactivated Na^+ channels and have little affinity for channels in the resting state. Most Na^+ channel blockers bind to a local anesthetic binding site in the pore of the cardiac sodium channel protein $Na_V1.5$ (Fozzard et al., 2005). Thus, during each action potential, drugs bind to Na^+ channels and block them, and with each diastolic interval, drugs dissociate, and the block is released. Allosteric mechanisms have also been described whereby drug binding to a site distant from the pore nevertheless alters channel conformation and thus permeation though the pore.

As illustrated in Figure 34–13, the dissociation rate is a key determinant of steady-state block of Na^+ channels. When heart rate increases, the time available for dissociation decreases, and steady-state Na^+ channel block increases. The rate of recovery from block also slows as cells are depolarized, as in ischemia. This explains the finding that Na^+ channel blockers depress Na^+ current, and hence conduction, to a greater extent in ischemic tissues than in normal tissues. Open- versus inactivated-state block also may be important in determining the effects of some drugs. Increased action potential duration, which results in a relative increase in time spent in the inactivated state, may increase block by drugs that bind to inactivated channels, such as lidocaine. This likely explains why inactivation state Na^+ channels blockers are relatively ineffective in atrial tissue where action potentials are shorter.

The rate of recovery from block often is expressed as a time constant ($\tau_{recovery}$, the time required to complete approximately 63% of an exponentially determined process). In the case of drugs such as *lidocaine*, $\tau_{recovery}$ is so short (<<1 sec) that recovery from block is very rapid, and substantial Na^+ channel block occurs only in rapidly driven tissues, particularly in ischemia. Conversely, drugs such as *flecainide* have such long $\tau_{recovery}$ values (>10 sec) that roughly the same numbers of Na^+ channels are blocked during systole and diastole. As a result, slowing of conduction occurs at therapeutic concentrations even in normal tissues at normal rates. This is manifest on the ECG as prolongation of PR and QRS durations.

Classifying Antiarrhythmic Drugs

Classifying drugs by common electrophysiological properties emphasizes the connection between basic electrophysiological actions and antiarrhythmic effects (Vaughan Williams, 1970). To the extent that the clinical actions of drugs can be predicted from their basic electrophysiological properties, such classification schemes have merit. However, as each compound is better characterized in a range of *in vitro* and *in vivo* test systems, it becomes apparent that differences in pharmacological effects occur even among drugs that share the same classification, some of which

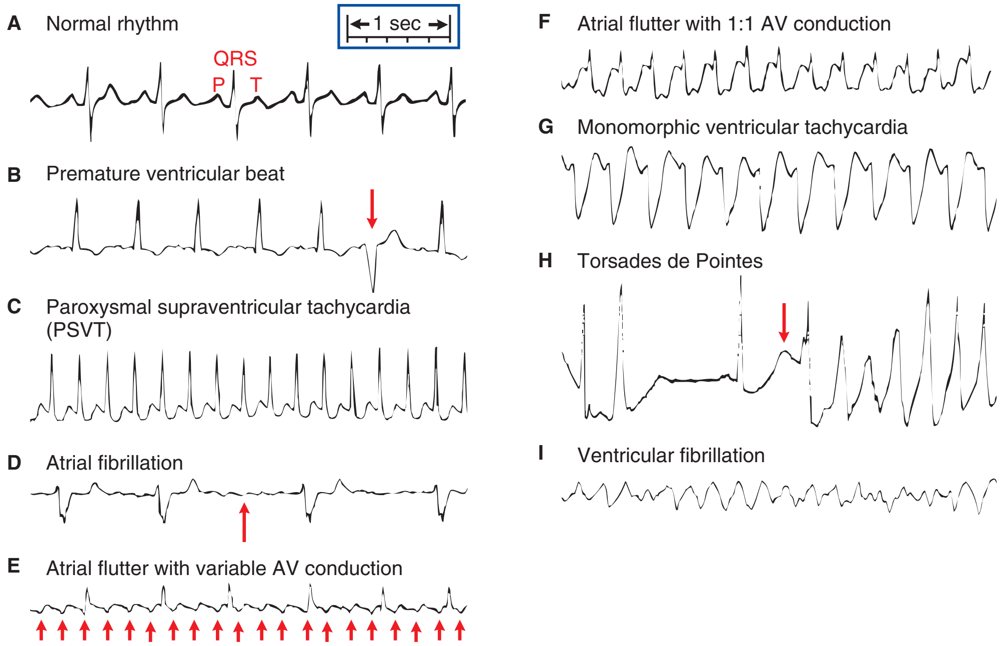

Figure 34–10 *Electrocardiograms showing normal and abnormal cardiac rhythms.* The P, QRS, and T waves in normal sinus rhythm are shown in panel **A**. Panel **B** shows a premature beat arising in the ventricle (arrow). PSVT is shown in panel **C**; this is most likely reentry using an accessory pathway (see Figure 34–8) or reentry within or near the AV node. In atrial fibrillation (panel **D**), there are no P waves, and the QRS complexes occur irregularly (and at a slow rate in this example); electrical activity between QRS complexes shows small undulations (arrow) corresponding to fibrillatory activity in the atria. In atrial flutter (panel **E**), the atria beat rapidly, approximately 250 beats per min (arrows) in this example, and the ventricular rate is variable. If a drug that slows the rate of atrial flutter is administered, 1:1 AV conduction (panel **F**) can occur. In monomorphic VT (panel **G**), identical wide QRS complexes occur at a regular rate, 180 beats per min. The electrocardiographic features of the torsades de pointes syndrome (panel **H**) include a very long QT interval (>600 ms in this example, arrow) and VT in which each successive beat has a different morphology (polymorphic VT). Panel **I** shows the disorganized electrical activity characteristic of VF.

may be responsible for the observed clinical differences in responses to drugs of the same broad "class" (Table 34–3).

An alternative way of approaching antiarrhythmic therapy is to attempt to classify arrhythmia mechanisms and then target drug therapy to the electrophysiological mechanism most likely to terminate or prevent the arrhythmia (Priori et al., 1999; Task Force, 1991) (Table 34–2). This approach has been further enhanced by an increasing understanding of arrhythmia mechanisms in genetic diseases such as LQTS and CPVT, so a genetic framework represents a complementary approach for improving antiarrhythmic drug development and therapy (Knollmann and Roden, 2008).

Na^+ Channel Block

The extent of Na^+ channel block depends critically on heart rate and membrane potential, as well as on drug-specific physicochemical characteristics that determine $\tau_{recovery}$ (Figure 34–13). Na^+ channels are blocked at rapid heart rates in diseased tissue with a rapid-recovery drug such as *lidocaine* or even at normal rates in normal tissues with a slow-recovery drug such as *flecainide*. When Na^+ channels are blocked, threshold for excitability is decreased; that is, greater membrane depolarization is required to open enough Na^+ channels to overcome K^+ currents at the resting membrane potential and elicit an action potential. This change in threshold probably contributes to the clinical finding that Na^+ channel blockers tend to increase both pacing threshold and the energy required to defibrillate the fibrillating heart. These deleterious effects may be important if antiarrhythmic drugs are used in patients with pacemakers or implanted defibrillators. Na^+ channel block decreases conduction velocity in fast-response tissue and increases QRS duration. Usual doses of *flecainide* prolong QRS intervals by 25% or more during normal rhythm, whereas *lidocaine* increes QRS intervals only at very fast heart rates. Drugs with $\tau_{recovery}$ values greater than 10 sec (e.g., *flecainide*) also tend to prolong the PR interval; this is likely due to block of fast-response tissue in the region of the AV node, although additional Ca^{2+} channel block is also possible. Drug effects on the PR interval are also highly modified by autonomic effects. For example, *quinidine* tends to shorten the PR interval largely as a result of its vagolytic properties. Action potential duration is either unaffected or shortened by Na^+ channel block; some Na^+ channel–blocking drugs do prolong cardiac action potentials but by other mechanisms, usually K^+ channel block (Table 34–3).

By increasing threshold, Na^+ channel block decreases automaticity (Figure 34–11B) and can potentially inhibit triggered activity arising from DADs or EADs. Many Na^+ channel blockers also decrease phase 4 slope (Figure 34–11A). In anatomically defined reentry, Na^+ channel blockers may decrease conduction sufficiently to extinguish the propagating reentrant wavefront. However, as described previously, conduction slowing owing to Na^+ channel block may exacerbate reentry. Block of Na^+ channels also shifts the voltage dependence of recovery from inactivation (Figure 34–6B) to more negative potentials, thereby tending to increase refractoriness. Thus, whether a given drug exacerbates or suppresses reentrant arrhythmias depends on the balance between its effects on refractoriness and on conduction in a particular reentrant circuit. *Lidocaine* and *mexiletine* are not useful in AF or atrial flutter, likely because they have short $\tau_{recovery}$ values and predominantly block inactivated channels. Conversely, *quinidine, flecainide, propafenone*, and similar agents are effective in some patients. Many of these agents owe part of their antiarrhythmic activity to blockade of K^+ channels and possibly also RyR2 block (*flecainide*, *propafenone*).

Na^+ Channel Blocker Toxicity

Conduction slowing in potential reentrant circuits can account for toxicity of drugs that block the Na^+ channel (Table 34–1). For example, Na^+ channel block decreases conduction velocity and hence slows atrial flutter rate. However, normal AV nodal function permits a greater number of impulses to penetrate the ventricle, and heart rate may actually increase (Figure 34–10). Thus, with Na^+ channel blocker therapy, atrial flutter rate may drop from 300 per min, with 2:1 or 4:1 AV conduction (i.e., a heart rate of 150 or 75 beats per min, respectively), to 220 per min, but with 1:1 transmission to the ventricle (i.e., a heart rate of 220 beats per min), with potentially disastrous consequences. This form of drug-induced arrhythmia is especially common during treatment with *flecainide* or *propafenone*,

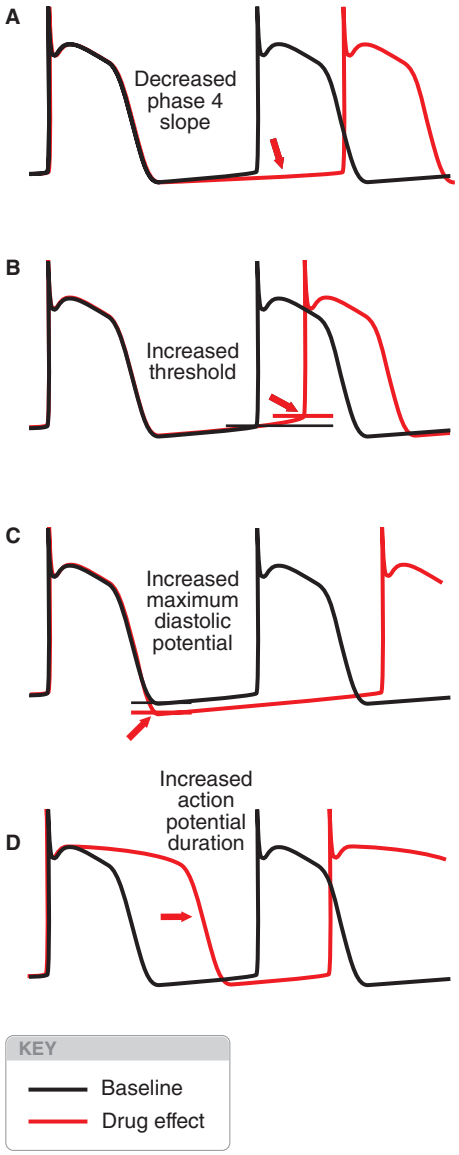

Figure 34–11 *Four ways to reduce the rate of spontaneous discharge.* The horizontal lines in panels **B** and **C** mark the threshold potentials for triggering an action potential before and after drug application.

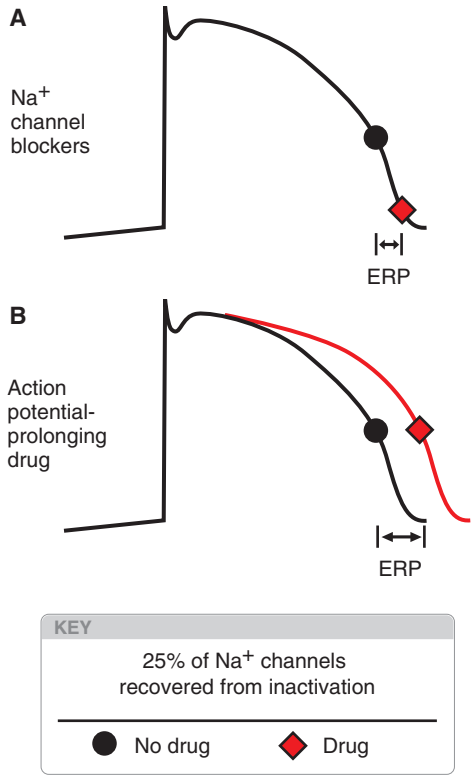

Figure 34–12 *Two ways to increase refractoriness.* In this figure, the black dot indicates the point at which a sufficient number of Na^+ channels (an arbitrary 25%; see Figure 34–6B) have recovered from inactivation to allow a premature stimulus to produce a propagated response in the absence of a drug. Block of Na^+ channels (**A**) shifts voltage dependence of recovery (see Figure 34–6B) and so delays the point at which 25% of channels have recovered (red diamond), prolonging the ERP. Note that if the drug also dissociates slowly from the channel (see Figure 34–13), refractoriness in fast-response tissues actually can extend beyond full repolarization ("postrepolarization refractoriness"). Drugs that prolong the action potential (**B**) also will extend the point at which an arbitrary percentage of Na^+ channels have recovered from inactivation, even without directly interacting with Na^+ channels.

and occasionally *amiodarone*; it can also occur with *quinidine*, which also increases AV nodal conduction through its vagolytic properties. Therapy with Na^+ channel blockers in patients with reentrant ventricular tachycardia after a myocardial infarction can increase the frequency and severity of arrhythmic episodes. Although the mechanism is unclear, a likely explanation is that slowed conduction allows the reentrant wavefront to persist within the tachycardia circuit. Such drug-exacerbated arrhythmia can be difficult to manage, and deaths owing to intractable drug-induced VT have been reported. In this setting, Na^+ infusion may be beneficial. Drug-exacerbated VT or VF also likely accounts for increased mortality with Na^+ channel blockers compared to placebo in patients convalescing from acute myocardial infarction in the CAST trial (Echt et al., 1991). Several Na^+ channel blockers (e.g., *procainamide* and *quinidine*) have been reported to exacerbate neuromuscular paralysis by D-tubocurarine (see Chapter 13).

Action Potential Prolongation

Most drugs that prolong the action potential do so by blocking I_{Kr} (Roden et al., 1993), although increased late Na^+ current also produces this effect (Lu et al., 2012; Yang et al., 2014). Both drug effects increase action potential duration and reduce normal automaticity (Figure 34–11D). Increased action potential duration, seen as an increase in QT interval, increases refractoriness (Figure 34–12) and therefore should be an effective way of treating reentry (Task Force, 1991). Experimentally, K^+ channel block produces a series of desirable effects: reduced defibrillation energy requirement, inhibition of VF owing to acute ischemia, and increased contractility (Roden, 1993; Singh, 1993). As shown in Table 34–3, many K^+ channel–blocking drugs also interact with β adrenergic receptors (*sotalol*) or other channels (e.g., *amiodarone* and *quinidine*). Amiodarone and sotalol appear to be at least as effective as drugs with predominant Na^+ channel–blocking properties in both atrial and ventricular arrhythmias. "Pure" action potential–prolonging drugs (e.g., *dofetilide* and *ibutilide*) are also available (Murray, 1998; Torp-Pedersen et al., 1999).

Toxicity of Drugs That Prolong the Action Potential

Most of these agents disproportionately prolong cardiac action potentials and the QT interval when underlying heart rate is slow and can cause torsades de pointes (Table 34–1, Figure 34–10). While this effect is usually seen with QT-prolonging antiarrhythmic drugs, it can occur more rarely with drugs that are used for noncardiac indications. For such agents, the risk of torsades de pointes may not become apparent until after widespread use postmarketing, and recognition of this risk has been a common cause for drug withdrawal (Roden, 2004). Sex hormones modify cardiac ion channels and help account for the clinically observed increased incidence of drug-induced torsades de pointes in women (Tadros et al., 2014). Testosterone deficiency, often in men being treated for prostate cancer, has also been recognized as a cause of torsades de pointes (Salem et al., 2018).

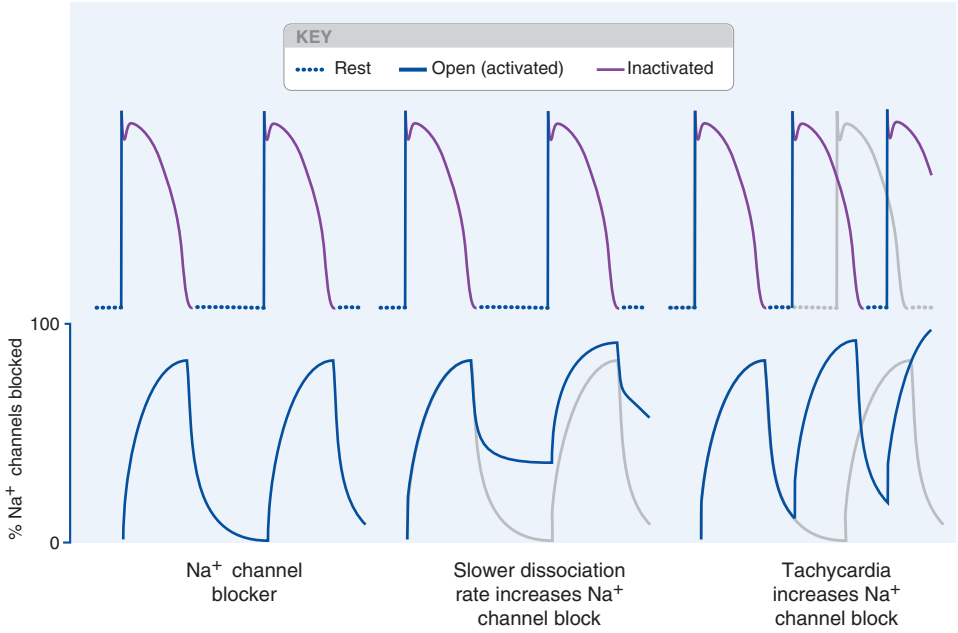

Figure 34–13 *Recovery from block of Na⁺ channels during diastole.* This recovery is the critical factor determining extent of steady-state Na^+ channel block. Na^+ channel blockers bind to (and block) Na^+ channels in the open or inactivated states, resulting in phasic changes in the extent of block during the action potential. As shown in the middle panel, a decrease in the rate of recovery from block increases the extent of block. Different drugs have different rates of recovery, and depolarization reduces the rate of recovery. The right panel shows increasing heart rate, which results in relatively less time spent in the rest state and also increases the extent of block. (Reproduced with permission from Roden DM, et al. Ca^{2+} Channel Block

The major electrophysiological effects resulting from block of cardiac Ca^{2+} channels are in nodal tissues. Dihydropyridines such as *nifedipine*, which are used commonly in angina and hypertension (see Chapters 31 and 32), preferentially block Ca^{2+} channels in vascular smooth muscle; their cardiac electrophysiological effects, such as heart rate acceleration, result principally from reflex sympathetic activation secondary to peripheral vasodilation. Only *verapamil* and *diltiazem* block Ca^{2+} channels in cardiac cells at clinically used doses. These drugs generally slow sinus rate (Figure 34–11A), although hypotension, if marked, can cause reflex sympathetic activation and tachycardia. The velocity of AV nodal conduction decreases, so the PR interval increases. AV nodal block occurs because of decremental conduction, as well as increased AV nodal refractoriness. These effects form the basis of the antiarrhythmic actions of Ca^{2+} channel blockers in reentrant arrhythmias whose circuit involves the AV node, such as AV reentrant tachycardia (Figure 34–8).

Another important indication for antiarrhythmic therapy is to reduce the ventricular rate in atrial flutter or AF. Parenteral *verapamil* and *diltiazem* are approved for temporary control of rapid ventricular rate in atrial flutter or AF and for rapid conversion of PSVT to sinus rhythm (where their use has largely been supplanted by adenosine). Oral *verapamil* or *diltiazem* may be used to control the ventricular rate in chronic atrial flutter or AF and for prophylaxis of repetitive PSVT. Unlike β blockers, Ca^{2+} channel blockers have not been shown to reduce mortality after myocardial infarction (Singh, 1990).

Verapamil and Diltiazem

The major adverse effect of intravenous *verapamil* or, less commonly, *diltiazem* is hypotension, particularly with bolus administration. This was a particular problem when the drugs were used mistakenly in patients with VT (in which Ca^{2+} channel blockers usually are not effective) misdiagnosed as PSVT; the drugs are now rarely used for this indication. Hypotension also is frequent in patients receiving other vasodilators and in patients with underlying left ventricular dysfunction, which the drugs can exacerbate. Severe sinus bradycardia or AV block also occurs, especially in susceptible patients, such as those also receiving β blockers. With oral therapy, these adverse effects tend to be less severe. Constipation is a frequent side effect of oral *verapamil*.

Verapamil is prescribed as a racemate. L-*Verapamil* is the more potent Ca^{2+} channel blocker. However, with oral therapy, the L-enantiomer undergoes more extensive first-pass hepatic metabolism. For this reason, a given concentration of *verapamil* prolongs the PR interval to a greater extent when administered intravenously (where concentrations of the L- and D-enantiomers are equivalent) than when administered orally. *Diltiazem* also undergoes extensive first-pass hepatic metabolism, and both drugs have metabolites that exert Ca^{2+} channel–blocking actions. In clinical practice, adverse effects during therapy with *verapamil* or *diltiazem* are determined largely by *underlying* heart disease and concomitant therapy; plasma concentrations of these agents are not routinely measured. Both drugs can increase serum digoxin concentration, although the magnitude of this effect is variable; excess slowing of ventricular response may occur in patients with AF.

Blockade of β Adrenergic Receptors

β Adrenergic stimulation increases the magnitude of the Ca^{2+} current and slows its inactivation; increases the magnitude of the repolarizing current I_{Ks}; increases pacemaker current (thereby increasing sinus rate; DiFrancesco, 1993); increases the Ca^{2+} stored in the SR by activating the SR Ca^{2+} uptake pump (thereby increasing likelihood of spontaneous Ca^{2+} release and DADs); and under pathophysiological conditions, can increase both DAD- and EAD-mediated arrhythmias. The increases in plasma epinephrine associated with severe stress (e.g., acute myocardial infarction or resuscitation after cardiac arrest) lower serum K^+, especially in patients receiving chronic diuretic therapy. β Blockers inhibit adrenergic effects and can be antiarrhythmic by reducing heart rate, decreasing intracellular Ca^{2+} overload, and inhibiting afterdepolarization-mediated automaticity. Epinephrine-induced hypokalemia appears to be mediated by β_2 adrenergic receptors and is blocked by "noncardioselective" antagonists such as *propranolol* (see Chapter 14). In acutely ischemic tissue, β blockers increase the energy required to fibrillate the heart, an

TABLE 34–3 ■ MAJOR ELECTROPHYSIOLOGIC ACTIONS OF ANTIARRHYTHMIC DRUGS

DRUG	Na^+ CHANNEL BLOCK		K^+ CHANNEL BLOCK, ↑APD	Ca^{2+} CHANNEL BLOCK	RyR2 CHANNEL BLOCK	AUTONOMIC EFFECTS	OTHER EFFECTS
	$\tau_{recovery}$[1], SECONDS	STATE DEPENDENCE[1]					
Lidocaine	0.1	I > O					
Phenytoin	0.2	I

Digoxin						✓: Vagal stimulation	✓: Inhibition of Na^+, K^+–ATPase
Adenosine						✓: Adenosine receptor activation	✓: Activation of K^+ current
Magnesium				✓	(x)		

✓ Indicates an effect that is important in mediating the clinical action of a drug. (x) Indicates a demonstrable effect whose relationship to drug action in patients is less well established. [a]Indicates drugs prescribed as racemates, and the enantiomers are thought to exert similar electrophysiological effects. [b]Indicates racemates for which clinically relevant differences in the electrophysiological properties of individual enantiomers have been reported (see text). One approach to classifying antiarrhythmic drugs is provided in Vaughan Williams (1970):

Class	*Major action*
I	Na^+ channel block
II	β Adrenergic receptor blockade
III	Action potential prolongation (usually by K^+ channel block)
IV	Ca^{2+} channel block

Drugs are listed here according to this scheme. It is important to bear in mind, however, that many drugs exert multiple effects that contribute to their clinical actions. It is occasionally clinically useful to subclassify Na^+ channel blockers by their rates of recovery from drug-induced block ($\tau_{recovery}$) under physiological conditions. Because this is a continuous variable and can be modulated by factors such as depolarization of the resting potential, these distinctions can become blurred: class Ib, $\tau_{recovery}$ <1 sec; class Ia, $\tau_{recovery}$ 1–10 sec; class Ic, $\tau_{recovery}$ > 10 sec. These class and subclass effects are associated with distinctive ECG changes, characteristic "class" toxicities, and efficacy in specific arrhythmia syndromes (see text). [1]These data are dependent on experimental conditions, including species and temperature. The $\tau_{recovery}$ values cited here are from Courtney (1987). APD, action potential duration; O, open-state blocker; I, inactivated-state blocker.

antiarrhythmic action. These effects may contribute to the reduced short-term and long-term mortality observed in trials of chronic therapy with β blockers after myocardial infarction (Singh, 1990).

As with Ca^{2+} channel blockers and *digitalis*, β blockers increase AV nodal conduction time (increased PR interval) and prolong AV nodal refractoriness; hence, they are useful in terminating reentrant arrhythmias that involve the AV node and in controlling ventricular response in AF or atrial flutter. β Blockers may be useful in arrhythmias triggered by physical or emotional stress, such as in many patients with LQTS and all patients with CPVT syndrome (Roden and Spooner, 1999). β Blockers are also reportedly effective in controlling arrhythmias owing to Na^+ channel blockers; this effect may be due in part to slowing of the heart rate, which then decreases the extent of rate-dependent conduction slowing by Na^+ channel block.

Adverse effects of β blockade include fatigue, bronchospasm, hypotension, impotence, depression, aggravation of heart failure, worsening of symptoms owing to peripheral vascular disease, and masking of the symptoms of hypoglycemia in diabetic patients (see Chapter 14). In patients

with arrhythmias owing to excess sympathetic stimulation (e.g., pheochromocytoma, *clonidine* withdrawal, or cocaine toxicity), β blockers can result in unopposed α adrenergic stimulation, with resulting severe hypertension or α adrenergic–mediated arrhythmias. In such patients, arrhythmias should be treated with both α and β blockers or with a drug such as *labetalol* that combines α- and β-blocking properties. Abrupt discontinuation of chronic β-blocker therapy can lead to "rebound" symptoms, including hypertension, increased angina, and arrhythmias; thus, β blockers are tapered over 2 weeks prior to discontinuation of chronic therapy (see Chapters 14 and 31–33).

Selected β Blockers

It is likely that most β blockers share antiarrhythmic properties. Some, such as *propranolol*, also exert Na^+ channel–blocking effects at high concentrations. Similarly, drugs with intrinsic sympathomimetic activity may be less useful as antiarrhythmics (Singh, 1990). *Acebutolol* is as effective as *quinidine* in suppressing ventricular ectopic beats, an arrhythmia that many clinicians no longer treat. *Sotalol* (see its discussion in a separate section) is more effective for many arrhythmias than other β blockers, probably because of its K^+ channel–blocking actions. *Esmolol* (see separate discussion that follows) is a β_1-selective agent that has a very short elimination half-life. Intravenous esmolol is useful in clinical situations in which immediate β adrenergic blockade is desired. Some β blockers (e.g., *propranolol*, *metoprolol*) are CYP2D6 substrates; thus, efficacy may vary across individuals (see Chapter 7). *Nadolol* and *propranolol* appear more effective than other β blockers when β blockade is needed in congenital arrhythmia syndromes such as CPVT or LQTS (Ahn et al., 2017; Chockalingam et al., 2012).

Principles in the Clinical Use of Antiarrhythmic Drugs

Drugs that modify cardiac electrophysiology often have a very narrow margin between the doses required to produce a desired effect and those associated with adverse effects. Moreover, antiarrhythmic drugs can induce new arrhythmias with possibly fatal consequences. Nonpharmacological treatments, such as cardiac pacing, electrical defibrillation, or ablation of targeted regions, are indicated for some arrhythmias; in other cases, no therapy is required, even though an arrhythmia is detected. Therefore, the fundamental principles of therapeutics described here must be applied to optimize antiarrhythmic therapy.

1. Identify and Remove Precipitating Factors

Factors that commonly precipitate cardiac arrhythmias include hypoxia, electrolyte disturbances (especially hypokalemia), myocardial ischemia, and certain drugs. Antiarrhythmics, including cardiac glycosides, are not the only drugs that can precipitate arrhythmias (Table 34–1). For example, *theophylline* can cause multifocal atrial tachycardia, which sometimes can be managed simply by reducing the dose of *theophylline*. Torsades de pointes can arise during therapy not only with action potential–prolonging antiarrhythmics but also with other "noncardiovascular" drugs that do not affect ion channels (Roden, 2004). The incidence can vary from 1% to 3% in patients receiving *sotalol* or *dofetilide* and can be very rare (<1/50,000) with some noncardiovascular drugs. Drugs with a very wide range of clinical indications have been implicated: These include some antibiotics (including antibacterials, antiprotozoals, antivirals, and antifungals), antipsychotics, antihistamines, antidepressants, and *methadone*. The website Crediblemeds.org maintains a list of drugs (and levels of evidence) that have been implicated in this adverse effect.

2. Establish the Goals of Treatment

Some Arrhythmias Should Not Be Treated: The CAST Example

Abnormalities of cardiac rhythm are readily detectable by a variety of recording methods. However, the mere detection of an abnormality does not equate with the need for therapy. This was illustrated in CAST. The presence of asymptomatic ventricular ectopic beats is a known marker for increased risk of sudden death owing to VF in patients convalescing from myocardial infarction. In CAST, patients with recent myocardial infarction whose ventricular ectopic beats were suppressed by the potent Na^+ channel blocker *encainide* (no longer marketed) or *flecainide* were randomly assigned to receive those drugs or placebo. Unexpectedly, the mortality rate was 2- to 3-fold higher among patients treated with the drugs than in those treated with placebo (Echt et al., 1991). While the explanation for this effect is not known, several lines of evidence suggest that, in the presence of these drugs and myocardial scarring, transient episodes of myocardial ischemia or sinus tachycardia can cause marked conduction slowing (because these drugs have a very long $\tau_{recovery}$), resulting in fatal reentrant ventricular tachyarrhythmias.

One consequence of this pivotal clinical trial was to reemphasize the concept that therapy should be initiated only when a clear benefit to the patient can be identified. When symptoms are obviously attributable to an ongoing arrhythmia, there usually is little doubt that termination of the arrhythmia will be beneficial; when chronic therapy is used to prevent recurrence of an arrhythmia, the risks may be greater (Roden, 1994). *Among the antiarrhythmic drugs discussed here, only β adrenergic blockers* (Connolly, 1999) *demonstrably reduce mortality during long-term therapy*.

Symptoms Due to Arrhythmias

Some patients with an arrhythmia may be asymptomatic; in this case, establishing any benefit for treatment will be difficult. Some patients may present with presyncope, syncope, or even cardiac arrest, which may be due to brady- or tachyarrhythmias. Other patients may present with a sensation of irregular heartbeats (i.e., palpitations) that can be minimally symptomatic in some individuals and incapacitating in others. The irregular heartbeats may be due to intermittent premature contractions or to sustained arrhythmias such as AF (which results in an irregular ventricular rate) (Figure 34–10). Finally, patients may present with symptoms owing to decreased cardiac output attributable to arrhythmias. The most common symptom is breathlessness either at rest or on exertion. Occasionally, sustained or frequent tachycardias may produce no "arrhythmia" symptoms (e.g., palpitations) but will depress contractile function; these patients may present with heart failure due to "tachycardia-induced cardiomyopathy," a condition that can be reversed by treating the arrhythmia.

Choosing Among Therapeutic Approaches

In choosing among available therapeutic options, it is important to establish clear therapeutic goals. For example, three options are available in patients with AF: (1) reduce the ventricular response using AV nodal–blocking agents such as *digitalis*, *verapamil*, *diltiazem*, or β blockers (Table 34–1); (2) restore and maintain normal rhythm using drugs such as *flecainide* or *amiodarone*; or (3) decide not to implement antiarrhythmic therapy, especially if the patient truly is asymptomatic. Most patients with AF also benefit from anticoagulation to reduce stroke incidence regardless of symptoms (Dzeshka and Lip, 2015) (see Chapter 36).

Factors that contribute to the choice of therapy include not only symptoms but also the type and extent of structural heart disease, the QT interval prior to drug therapy, the coexistence of conduction system disease, and the presence of noncardiac diseases (Table 34–4). In the rare patient with the WPW syndrome and AF, the ventricular response can be extremely rapid and can be accelerated paradoxically with *digitalis* or Ca^{2+} channel blockers; deaths owing to drug therapy have been reported under these circumstances.

The frequency and reproducibility of arrhythmia should be established prior to initiating therapy because inherent variability in the occurrence of arrhythmias can be confused with a beneficial or adverse drug effect. Techniques for this assessment include recording cardiac rhythm for prolonged periods or evaluating the response of the heart to artificially induced premature beats. It is important to recognize that drug therapy may be only partially effective. A marked decrease in the duration of paroxysms of AF may be sufficient to render a patient asymptomatic even if a low ventricular rate still can be detected.

TABLE 34–4 ■ PATIENT-SPECIFIC ANTIARRHYTHMIC DRUG CONTRAINDICATIONS

CONDITION	EXCLUDE/USE WITH CAUTION
Cardiac	
Heart failure	Disopyramide, flecainide
Sinus or AV node dysfunction	Digoxin, verapamil, diltiazem, β blockers, amiodarone
Wolff-Parkinson-White syndrome (risk of extremely rapid rate if atrial fibrillation develops)	Digoxin, verapamil, diltiazem
Infranodal conduction disease	Na^+ channel blockers, amiodarone
Aortic/subaortic stenosis	Bretylium
History of myocardial infarction	Flecainide
Prolonged QT interval	Quinidine, procainamide, disopyramide, sotalol, dofetilide, ibutilide, amiodarone, dronedarone
Cardiac transplant	Adenosine
Noncardiac	
Diarrhea	Quinidine
Prostatism, glaucoma	Disopyramide
Arthritis	Chronic procainamide
Lung disease	Amiodarone
Tremor	Mexiletine
Constipation	Verapamil
Asthma, peripheral vascular disease, hypoglycemia	β Blockers, propafenone

3. Minimize Risks

Antiarrhythmic Drugs Can Cause Arrhythmias

One well-recognized risk of antiarrhythmic therapy is the possibility of provoking new arrhythmias, with potentially life-threatening consequences. Antiarrhythmic drugs can provoke arrhythmias by different mechanisms (Table 34–1). These drug-provoked arrhythmias must be recognized because further treatment with antiarrhythmic drugs often exacerbates the problem, whereas withdrawal of the causative agent is curative. Thus, establishing a precise diagnosis is critical, and targeting therapies at underlying mechanisms of the arrhythmias may be required. For example, treating VT with *verapamil* not only may be ineffective but also can cause catastrophic cardiovascular collapse.

Monitoring of Plasma Concentration

Some adverse effects of antiarrhythmic drugs result from excessive plasma drug concentrations. Measuring plasma concentration and adjusting the dose to maintain the concentration within a prescribed therapeutic range may minimize some adverse effects. In many patients, serious adverse reactions relate to interactions involving antiarrhythmic drugs (often at usual plasma concentrations), transient factors such as electrolyte disturbances or myocardial ischemia, and the type and extent of the underlying heart disease (Roden, 1994). Factors such as generation of unmeasured active metabolites, variability in elimination of enantiomers (which may exert differing pharmacological effects), and disease- or enantiomer-specific abnormalities in drug binding to plasma proteins can complicate the interpretation of plasma drug concentrations.

Patient-Specific Contraindications

Another way to minimize the adverse effects of antiarrhythmic drugs is to avoid certain drugs in certain patient subsets altogether. For example, patients with a history of congestive heart failure are particularly prone to develop heart failure during *flecainide* or *disopyramide* therapy. In other cases, adverse effects of drugs may be difficult to distinguish from exacerbations of underlying disease. *Amiodarone* may cause interstitial lung disease; its use therefore is undesirable in a patient with advanced pulmonary disease in whom the development of this potentially fatal adverse effect would be difficult to detect. Specific diseases that constitute relative or absolute contraindications to specific drugs are listed in Table 34–4.

4. Consider the Electrophysiology of the Heart as a "Moving Target"

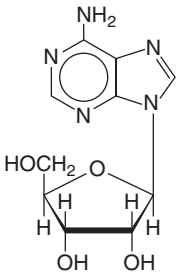
Cardiac electrophysiology varies dynamically in response to external influences such as changing electrolyte levels, autonomic tone, myocardial ischemia, and myocardial stretch (Priori et al., 1999). For example, myocardial ischemia results in changes in extracellular K^+ that make the resting potential less negative, inactivate Na^+ channels, decrease Na^+ current, and slow conduction. In addition, myocardial ischemia may activate channels that otherwise are quiescent, such as the ATP-inhibited K^+ channels. Thus, in response to myocardial ischemia, a normal heart may display changes in resting potential, conduction velocity, intracellular Ca^{2+} concentrations, and repolarization, any one of which then may create arrhythmias or alter response to antiarrhythmic therapy.

Antiarrhythmic Drugs

Summaries of important electrophysiological and pharmacokinetic features of the drugs considered here are presented in Tables 34–3 and 34–5. Ca^{2+} channel blockers and β blockers are discussed in Chapters 14 and 31 to 33. The drugs are presented in alphabetical order. Prescribing patterns have changed over the past several decades in part because fewer suppliers market older drugs, such as *quinidine* or oral *procainamide*, which are therefore increasingly difficult to obtain; this poses a problem for a small number of patients who may still benefit from treatment (Inama et al., 2010; Viskin et al., 2013).

Adenosine

Adenosine is a naturally occurring nucleoside that is administered as a rapid intravenous bolus for the acute termination of reentrant supraventricular arrhythmias (Link, 2012). Rare cases of VT in patients with otherwise-normal hearts are thought to be DAD mediated and can be terminated by *adenosine*. *Adenosine* also has been used to produce controlled hypotension during some surgical procedures and in the diagnosis of coronary artery disease. Intravenous ATP appears to produce effects similar to those of *adenosine*.



ADENOSINE

Pharmacological Effects

The effects of *adenosine* are mediated by its interaction with specific G protein-coupled adenosine receptors. *Adenosine activates* acetylcholine-sensitive K^+ current in the atrium and sinus and AV nodes, resulting in shortening of action potential duration, hyperpolarization, and slowing of normal automaticity (Figure 34–11C). *Adenosine* also inhibits the electrophysiological effects of increased intracellular cyclic AMP that occur with sympathetic stimulation. Because *adenosine* thereby reduces Ca^{2+}

TABLE 34–5 ■ PHARMACOKINETIC CHARACTERISTICS AND DOSES OF ANTIARRHYTHMIC DRUGS

DRUG	BIOAVAILABILITY		ELIMINATION						USUAL DOSES[c]	
	REDUCED FIRST-PASS METABOLISM	PROTEIN BINDING >80%	RENAL	HEPATIC	OTHER	ELIMINATION[a] $t_{1/2}$	ACTIVE METABOLITE(S)	THERAPEUTIC[b] PLASMA CONCENTRATION	LOADING DOSES	MAINTENANCE DOSES
Adenosine					✓	<10 sec			6–12 mg (IV)	
Amiodarone	↓ absorption	✓		✓		wks–mos	✓	0.5–2 μg/mL	400–1200 mg/d × 1–3 wk (IV: 1050 mg over 24 h)	100–300 mg/d; IV: 0.25 mg/min
Bretylium	↓ absorption		✓			7–15 h			150–300 mg (IV)	1–4 mg/min (IV)
Digoxin	~80%		✓			36 h		0.5–2.0 ng/mL	0.5–1 mg over 12–24 h	0.0625–0.25 mg q24h

Verapamil	↓ due to first-pass metabolism	✓		✓		3–7 h	✓		5–10 mg over ≥2 min (IV)	80–160 mg q8h; 180–480 mg q24h[d]

✓ Indicates an effect that affects the clinical action of the drug. (x) Indicates metabolite or route of elimination probably of minor clinical importance. [a]The elimination $t_{1/2}$ is one, but not the only, determinant of how frequently a drug must be administered to maintain a therapeutic effect and avoid toxicity (see Chapter 2). For some drugs with short elimination half-lives, infrequent dosing is nevertheless possible, e.g., verapamil. Formulations that allow slow release into the gastrointestinal tract of a rapidly eliminated compound (available for many drugs, including procainamide, disopyramide, verapamil, diltiazem, and propranolol) also allow infrequent dosing. [b]The therapeutic range is bounded by a plasma concentration below which no therapeutic effect is likely and an upper concentration above which the risk of adverse effects increases. Many serious adverse reactions to antiarrhythmic drugs can occur at "therapeutic" concentrations in susceptible individuals. When only an upper limit is cited, a lower limit has not been well defined. Variable generation of active metabolites may further complicate the interpretation of plasma concentration data (see Chapter 2). [c]Oral doses are presented unless otherwise indicated. Doses are presented as suggested ranges in adults of average build; lower doses are less likely to produce toxicity. Lower maintenance dosages may be required in patients with renal or hepatic disease. Loading doses are only indicated when a therapeutic effect is desired before maintenance therapy would bring drug concentrations into a therapeutic range—that is, for acute therapy (e.g., lidocaine, verapamil, adenosine) or when the elimination $t_{1/2}$ is extremely long (amiodarone). [d]Indicates suggested dosage using slow-release formulation. IV, intravenous. [e]Can be given as a q12h dosing schedule to improve convenience and compliance.

currents, it can be antiarrhythmic by increasing AV nodal refractoriness and by inhibiting DADs elicited by sympathetic stimulation.

Administration of an intravenous bolus of *adenosine* to humans transiently slows sinus rate and AV nodal conduction velocity and increases AV nodal refractoriness. A bolus of *adenosine* can produce transient sympathetic activation by interacting with carotid baroreceptors; a continuous infusion can cause hypotension.

Adverse Effects

A major advantage of *adenosine* therapy is that adverse effects are short-lived because the drug is transported into cells and deaminated so rapidly. Transient asystole (lack of any cardiac rhythm whatsoever) is common but usually lasts less than 5 sec and is in fact the therapeutic goal. Most patients feel a sense of chest fullness and dyspnea when therapeutic doses (6–12 mg) of *adenosine* are administered. Rarely, an *adenosine* bolus can precipitate AF, presumably by heterogeneously shortening atrial action potentials, or bronchospasm.

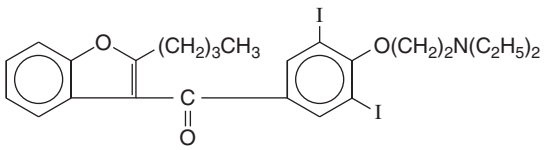
Clinical Pharmacokinetics

Adenosine is eliminated with a half-life of seconds by carrier-mediated uptake, which occurs in most cell types, including the endothelium, followed by metabolism by adenosine deaminase. *Adenosine* is an example of a drug whose efficacy requires a rapid bolus dose, preferably through a large central intravenous line; slow administration results in elimination of the drug prior to its arrival at the heart.

The effects of *adenosine* are potentiated in patients receiving *dipyridamole*, an adenosine-uptake inhibitor, and in patients with cardiac transplants owing to denervation hypersensitivity. Methylxanthines (see Chapters 16 and 44) such as *theophylline* and caffeine block adenosine receptors; therefore, larger-than-usual doses are required to produce an antiarrhythmic effect in patients who have consumed these agents in beverages or as therapy.

Amiodarone

Amiodarone exerts a multiplicity of pharmacological effects, none of which is clearly linked to its arrhythmia-suppressing properties. *Amiodarone* is a structural analogue of thyroid hormone, and some of its antiarrhythmic actions and its toxicity may be attributable to interaction with nuclear thyroid hormone receptors. *Amiodarone* is highly lipophilic, is concentrated in many tissues, and is eliminated extremely slowly; consequently, adverse effects may resolve very slowly. In the U.S., the drug is indicated for oral therapy in patients with recurrent VT or VF resistant to other drugs. In addition, the intravenous form is a first-line drug for management of VT or VF causing cardiac arrest (Dorian et al., 2002). Oral *amiodarone* had a modest beneficial effect on mortality in heart failure patients in a meta-analysis (Amiodarone Trials Meta-Analysis Investigators, 1997) but not in a later randomized clinical trial (Sudden Cardiac Death in Heart Failure Trial [SCD-HeFT] Investigators, 2005). Despite uncertainties about its mechanisms of action and the potential for serious toxicity, *amiodarone* is used widely in the treatment of common arrhythmias such as AF (Roy et al., 2000).



AMIODARONE

Pharmacological Effects

Studies of the acute effects of *amiodarone* in *in vitro* systems are complicated by its insolubility in water, necessitating the use of solvents such as dimethyl sulfoxide, which can have electrophysiological effects on its own. *Amiodarone's* effects may be mediated by perturbation of the lipid environment of the ion channels. *Amiodarone* blocks inactivated Na^+ channels and has a relatively rapid rate of recovery (time constant ≈ .6 sec` fr m block. It also dec ea es Ca^{2+} c rrent and transien outward delayed rectifier and inward rectifier K^+ currents and exerts a noncompetitive adrenergic-blocking effect. *Amiodarone* potently inhibits abnormal automaticity and, in most tissues, prolongs action potential duration. *Amiodarone* decreases conduction velocity by Na^+ channel block and by a poorly understood effect on cell-cell coupling that may be especially important in diseased tissue. Prolongations of the PR, QRS, and QT intervals and sinus bradycardia are frequent during chronic therapy. *Amiodarone* prolongs refractoriness in all cardiac tissues; Na^+ channel block and delayed repolarization owing to K^+ channel block, and inhibition of cell-cell coupling all may contribute to this effect.

Adverse Effects

Hypotension owing to vasodilation and depressed myocardial performance are frequent with the intravenous form of *amiodarone* and may be due in part to the solvent. While depressed contractility can occur during long-term oral therapy, it is unusual. Despite administration of high doses that would cause serious toxicity if continued long term, adverse effects are unusual during oral drug-loading regimens, which typically require several weeks. Occasional patients develop nausea during the loading phase, which responds to a decrease in daily dose.

Adverse effects during long-term therapy reflect both the size of daily maintenance doses and the cumulative dose, suggesting that tissue accumulation may be responsible. The most serious adverse effect during chronic *amiodarone* therapy is pulmonary fibrosis, which can be rapidly progressive and fatal. Underlying lung disease, doses of 400 mg/d or more, and recent pulmonary insults such as pneumonia appear to be risk factors. Serial chest X-rays or pulmonary function studies may detect early *amiodarone* toxicity but monitoring plasma concentrations has not been useful. With low doses, such as 200 mg/d or less as used in AF, pulmonary toxicity is less common (Zimetbaum, 2007). Other adverse effects during long-term therapy include corneal microdeposits (which are often asymptomatic), hepatic dysfunction, neuromuscular symptoms (most commonly peripheral neuropathy or proximal muscle weakness), photosensitivity, and hypo- or hyperthyroidism. The multiple effects of *amiodarone* on thyroid function are discussed further in Chapter 47. Treatment consists of withdrawal of the drug and supportive measures, including corticosteroids, for life-threatening pulmonary toxicity; reduction of dosage may be sufficient if the drug is deemed necessary and the adverse effect is not life threatening. While torsades de pointes and other drug-induced tachyarrhythmias can occur, they are unusual despite the marked QT prolongation and bradycardia typical of chronic therapy.

Clinical Pharmacokinetics

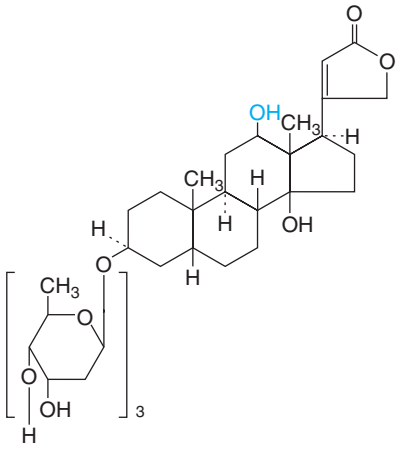
Amiodarone's oral bioavailability is about 30%, presumably due to poor absorption. This incomplete bioavailability is important in calculating equivalent dosing regimens when converting from intravenous to oral therapy. The drug distributes into lipid; heart tissue-to-plasma concentration ratios of greater than 20:1 and lipid-to-plasma ratios of greater than 300:1 have been reported. After the initiation of *amiodarone* therapy, increases in refractoriness, a marker of pharmacological effect, require several weeks to develop. *Amiodarone* undergoes hepatic metabolism by CYP3A4 to desethyl-amiodarone, a metabolite with pharmacological effects similar to those of the parent drug. When *amiodarone* therapy is withdrawn from a patient who has been receiving therapy for several years, plasma concentrations decline with a half-life of weeks to months. The mechanisms of *amiodarone* and desethyl-amiodarone elimination are not well established.

A therapeutic plasma *amiodarone* concentration range of 0.5 to 2 μg/mL has been proposed. However, efficacy apparently depends as much on duration of therapy as on plasma concentration, and elevated plasma concentrations do not predict toxicity. Because of *amiodarone's* slow accumulation in tissue, a high-dose oral loading regimen (e.g., 800–1600 mg/d) usually is administered for several weeks before maintenance therapy is started. If the presenting arrhythmia is life threatening, maintenance dosages of more than 300 mg/d can be used. On the other hand, maintenance doses of 200 mg/d or less are used if recurrence of an arrhythmia would be tolerated, as in patients with AF, because amiodarone slows the ventricular rate durin AF.

Dosage adjustments are not required in hepatic, renal, or cardiac dysfunction. *Amiodarone* potently inhibits the hepatic metabolism or renal elimination of many compounds. Mechanisms identified to date include inhibition of CYP3A4, CYP2C9, and P-glycoprotein (see Chapters 5 and 7). Dosages of *warfarin*, other antiarrhythmics (e.g., *flecainide*, *procainamide*, and *quinidine*), or *digoxin* usually require reduction during amiodarone therapy.

Bretylium

Bretylium is a quaternary ammonium compound that prolongs cardiac action potentials and interferes with reuptake of norepinephrine by sympathetic neurons; both actions may be antiarrhythmic (Heissenbuttel and Bigger, 1979). Intravenous *bretylium* to treat VF and prevent its recurrence became unavailable in 2011 and was reintroduced to the U.S. market in 2019 (see Table 34–5 for loading and maintenance doses).



DIGOXIN

Pharmacological Effects

Bretylium prolongs cardiac action potentials likely through block of K^+ channels. *Bretylium* has no effect on Na^+ channels, except at high concentrations, and no direct effect on automaticity. In animals and humans, administration of *bretylium* initially results in increased norepinephrine release from sympathetic neurons and inhibition of subsequent reuptake.

Adverse Effects

As a result of norepinephrine release, *bretylium* can produce transient hypertension and increased arrhythmias; this effect rarely is observed, since *bretylium* is used in critically ill patients who often are hemodynamically unstable. In theory, *bretylium* should be avoided in patients who are especially prone to increased arrhythmias with norepinephrine release, such as those with *digitalis* intoxication. In contrast, hypotension due to inhibition of norepinephrine reuptake is a common problem during *bretylium* therapy. *Bretylium*-induced hypotension should be managed with judicious fluid replacement if possible. Since *bretylium* effectively results in sympathetic denervation, the administration of normal doses of catecholamines such as dopamine may cause marked hypertension. *Bretylium* should be used only with great caution when the drug's vasodilating effects may be particularly hazardous, as in patients with aortic stenosis, carotid occlusive disease, or hypertrophic cardiomyopathy. The occurrence of torsades de pointes is unusual during *bretylium* therapy.

Clinical Pharmacokinetics

Bretylium is excreted unchanged by the kidneys without undergoing significant hepatic metabolism. Reduction of a maintenance infusion rate has been recommended in patients with renal failure, although adverse effects due to accumulation of *bretylium* in plasma have not been seen. A lag time of approximately 2 h has been reported between peak plasma *bretylium* concentrations and peak prolongation of ventricular refractoriness after an intravenous dose in dogs. This lag time suggests that *bretylium* is distributed to sites in peripheral tissues prior to exerting its pharmacological effect.

The hypotensive effects of *bretylium* are inhibited by coadministration of tricyclic antidepressants, which block *bretylium's* effects on sympathetic norepinephrine release and reuptake, while limited data suggest that its antiarrhythmic effects may be preserved.

Digoxin

Pharmacological Effects

Digitalis glycosides exert positive inotropic effects and have been used in heart failure; now, they are less commonly prescribed (see Chapter 33). Their inotropic action results from increased intracellular Ca^{2+}, which also forms the basis for arrhythmias related to cardiac glycoside intoxication. Cardiac glycosides increase phase 4 slope (i.e., increase the rate of automaticity), especially if $[K]_o$ is low. These drugs (e.g., *digoxin*) also exert prominent vagotonic actions, resulting in inhibition of Ca^{2+} currents in the AV node and activation of acetylcholine-mediated K^+ currents in the atrium. Thus, the major "indirect" electrophysiological effects of cardiac glycosides are hyperpolarization, shortening of atrial action potentials, and increases in AV nodal refractoriness. The last action accounts for the utility of *digoxin* in terminating reentrant arrhythmias involving the AV node and in controlling ventricular response in patients with AF. Cardiac glycosides may be especially useful in the last situation because many such patients have heart failure, which can be exacerbated by other AV nodal–blocking drugs such as Ca^{2+} channel blockers or β blockers. However, sympathetic drive is increased markedly in many patients with advanced heart failure, so *digitalis* is not very effective in decreasing the rate; on the other hand, even a modest decrease in rate can ameliorate heart failure.

Similarly, in other conditions in which high sympathetic tone drives rapid AV conduction (e.g., chronic lung disease and thyrotoxicosis), *digitalis* therapy may be only marginally effective in slowing the rate. In heart transplant patients, in whom innervation has been ablated, cardiac glycosides are ineffective for rate control. Increased sympathetic activity and hypoxia can potentiate *digitalis*-induced changes in automaticity and DADs, thus increasing the risk of *digitalis* toxicity. A further complicating feature in thyrotoxicosis is increased *digoxin* clearance.

The major ECG effects of cardiac glycosides are PR prolongation and a nonspecific alteration in ventricular repolarization (manifested by depression of the ST segment), whose underlying mechanism is not well understood.

Adverse Effects

Because of the low therapeutic index of cardiac glycosides, their toxicity is a common clinical problem (see Chapter 33). Arrhythmias, nausea, disturbances of cognitive function, and blurred or yellow vision are the usual manifestations. Elevated serum concentrations of *digitalis*, hypoxia (e.g., owing to chronic lung disease), and electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia, and hypercalcemia) predispose patients to *digitalis*-induced arrhythmias. While *digitalis* intoxication can cause virtually any arrhythmia, certain types of arrhythmias are characteristic. Arrhythmias that should raise a strong suspicion of *digitalis* intoxication are those in which DAD-related tachycardias occur along with impairment of sinus node or AV nodal function. Atrial tachycardia with AV block is classic, but ventricular bigeminy (sinus beats alternating with beats of ventricular origin), "bidirectional" VT (a rare entity), AV junctional tachycardias, and various degrees of AV block also can occur. With severe intoxication (e.g., with suicidal ingestion), severe hyperkalemia owing to poisoning of Na^+, K^+–ATPase and profound bradyarrhythmias, which may be unresponsive to pacing therapy, are seen. In patients with elevated serum *digitalis* levels, the risk of precipitating VF by DC cardioversion is likely increased; in those with therapeutic blood levels, DC cardioversion can be used safely.

Minor forms of cardiac glycoside intoxication may require no specific therapy beyond monitoring cardiac rhythm until symptoms and signs of toxicity resolve. Sinus bradycardia and AV block often respond to intravenous *atropine*, but the effect is transient. Mg^{2+} has been used successfully in some cases of *digitalis*-induced tachycardia. Any serious arrhythmia should be treated with *antidigoxin Fab fragments* (Digibind, Digifab), which are highly effective in binding *digoxin* and *digitoxin* and greatly enhance their renal excretion (see Chapter 33). Serum glycoside

concentrations rise markedly with antidigitalis antibodies, but these represent bound (pharmacologically inactive) drug. Temporary cardiac pacing may be required for advanced sinus node or AV node dysfunction. *Digitalis* exerts direct arterial vasoconstrictor effects, which can be especially deleterious in patients with advanced atherosclerosis who receive intravenous drug; mesenteric and coronary ischemia have been reported.

Clinical Pharmacokinetics

The only digitalis glycoside used in the U.S. is *digoxin*. *Digitoxin* (various generic preparations) also is used for chronic oral therapy outside the U.S. *Digoxin* tablets are incompletely (75%) bioavailable. In some patients, intestinal microflora may metabolize *digoxin*, markedly reducing bioavailability. In these patients, higher-than-usual doses are required for clinical efficacy; toxicity is a serious risk if antibiotics are administered that destroy intestinal microflora. Inhibition of P-glycoprotein (see further discussion) also may play a role in cases of toxicity. *Digoxin* is 20% to 30% protein bound.

The antiarrhythmic effects of *digoxin* can be achieved with intravenous or oral therapy. However, *digoxin* undergoes relatively slow distribution to effector site(s); therefore, even with intravenous therapy, there is a lag of several hours between drug administration and the development of measurable antiarrhythmic effects such as PR interval prolongation or slowing of the ventricular rate in AF. To avoid intoxication, a loading dose of approximately 0.6 to 1 mg *digoxin* is administered over 24 h. Measurement of postdistribution serum *digoxin* concentration and adjustment of the daily dose (0.0625–0.5 mg) to maintain concentrations of 0.5 to 2 ng/mL are useful during chronic *digoxin* therapy (Table 34–5). Some patients may require and tolerate higher concentrations but with an increased risk of adverse effects.

The elimination half-life of *digoxin* ordinarily is about 36 h, so maintenance doses are administered once daily. Renal elimination of unchanged drug accounts for about 80% of *digoxin* elimination. *Digoxin* doses should be reduced (or dosing interval increased) and serum concentrations monitored closely in patients with impaired excretion owing to renal failure or in patients who are hypothyroid. *Digitoxin* undergoes primarily hepatic metabolism and may be useful in patients with fluctuating or advanced renal dysfunction. *Digitoxin* metabolism is accelerated by drugs such as *phenytoin* and *rifampin* that induce hepatic metabolism. *Digitoxin's* elimination half-life is even longer than that of *digoxin* (about 7 days); it is highly protein bound, and its therapeutic range is 10 to 30 ng/mL.

Amiodarone, *dronedarone*, *quinidine*, *verapamil*, *diltiazem*, *cyclosporine*, *itraconazole*, *propafenone*, and *flecainide* decrease *digoxin* clearance by inhibiting P-glycoprotein, the major route of *digoxin* elimination (Fromm et al., 1999). New steady-state *digoxin* concentrations are approached after four to five half-lives (i.e., in about a week). *Digitalis* toxicity results so often with *quinidine* or *amiodarone* that it is routine to decrease the dose of *digoxin* if these drugs are started. In all cases, *digoxin* concentrations should be measured regularly and the dose adjusted if necessary. Hypokalemia, which can be caused by many drugs (e.g., diuretics, *amphotericin B*, and corticosteroids), will potentiate *digitalis*-induced arrhythmias.

Disopyramide

Disopyramide exerts electrophysiological effects very similar to those of *quinidine*, but the drugs have different adverse effect profiles. *Disopyramide* can be used to maintain sinus rhythm in patients with atrial flutter or AF and to prevent recurrence of VT or VF. Because of its negative inotropic effects, it is sometimes used in hypertrophic cardiomyopathy. *Disopyramide* is prescribed as a racemate.

Pharmacological Actions and Adverse Effects

The *in vitro* electrophysiological actions of *S*-(+)-disopyramide are similar to those of quinidine. The *R*-(–)-enantiomer produces similar Na^+ channel block but does not prolong cardiac action potentials. Unlike *quinidine*, racemic *disopyramide* does not antagonize α adrenergic receptors but does exert prominent anticholinergic actions that account for many of its adverse effects. These include precipitation of glaucoma, constipation, dry mouth, and urinary retention in the elderly man with prostatism but also occurs in females. *Disopyramide* can cause torsades de pointes and commonly depresses contractility, which can precipitate heart failure. In patients with hypertrophic cardiomyopathy, this depression contractility may be exploited to therapeutic advantage to decrease dynamic outflow tract obstruction (Sherrid and Arabadjian, 2012).

Clinical Pharmacokinetics

Disopyramide is well absorbed. Binding to plasma proteins is concentration dependent, so a small increase in total concentration may represent a disproportionately larger increase in free drug concentration. *Disopyramide* is eliminated by both hepatic metabolism (to a weakly active metabolite) and renal excretion of unchanged drug. The dose should be reduced in patients with renal dysfunction. Higher-than-usual dosages may be required in patients receiving drugs that induce hepatic metabolism, such as *phenytoin*.

Dofetilide

Dofetilide prolongs action potentials and the QT interval by potently blocking the I_{Kr} channel. Increased late Na^+ current, likely due to inhibition of phosphoinositide 3–kinase (Yang et al., 2014), may also contribute. The drug has virtually no extracardiac pharmacological effects. *Dofetilide* is effective in maintaining sinus rhythm in patients with AF. In the DIAMOND studies (Torp-Pedersen et al., 1999), *dofetilide* did not affect mortality in patients with advanced heart failure or in those convalescing from acute myocardial infarction.

Adverse Effects

Torsades de pointes occurred in 1% to 3% of patients in clinical trials where strict exclusion criteria (e.g., hypokalemia) were applied, doses were adjusted based on renal function, and continuous ECG monitoring was used to detect marked QT prolongation in the hospital. Other adverse effects were no more common than with placebo during premarketing clinical trials.

Clinical Pharmacokinetics

Most of a dose of *dofetilide* is excreted unchanged by the kidneys. In patients with mild-to-moderate renal failure, decreases in dosage based on creatinine clearance are required to minimize the risk of torsades de pointes. The drug should not be used in patients with advanced renal failure or with inhibitors of renal cation transport. *Dofetilide* also undergoes minor hepatic metabolism.

Dronedarone

Dronedarone is a noniodinated benzofuran derivative of *amiodarone* that is FDA-approved for the treatment of AF and atrial flutter. In randomized placebo-controlled trials, it was effective in maintaining sinus rhythm and reducing the ventricular response rate during episodes of AF (Patel et al., 2009). Compared to *amiodarone*, *dronedarone* treatment is associated with significantly fewer adverse events but is significantly less effective in maintaining sinus rhythm. *Dronedarone* decreased hospital admissions compared to placebo in patients with a history of AF (Hohnloser et al., 2009). In other studies, however, the drug increased mortality in patients with permanent AF (Connolly et al., 2011) and in those with severe heart failure (Kober et al., 2008).

Pharmacological Effects

Like *amiodarone*, *dronedarone* is a blocker of multiple ion currents, including the rapidly activating delayed rectifier K^+ current (I_{Kr}), the slowly activating delayed rectifier K^+ current (I_{Ks}), the inward rectifier K^+ current (I_{K1}), the acetylcholine-activated K^+ current, the peak Na^+ current, and the L-type Ca^{2+} current. It has stronger antiadrenergic effects than *amiodarone*.

Adverse Effects and Drug Interactions

The most common adverse reactions are diarrhea, nausea, abdominal pain, vomiting, and asthenia. *Dronedarone* causes dose-dependent prolongation of the QTc interval, but torsades de pointes is rare. *Dronedarone* is metabolized by CYP3A and is a moderate inhibitor of CYP3A,

CYP2D6, and P-glycoprotein. Potent CYP3A4 inhibitors such as *ketoconazole* may increase *dronedarone* exposure by as much as 25-fold. Consequently, *dronedarone* should not be coadministered with potent CYP3A4 inhibitors (e.g., antifungals, macrolide antibiotics). Coadministration with other drugs metabolized by CYP2D6 (e.g., *metoprolol*) or P-glycoprotein (e.g., *digoxin*) may result in increased drug concentrations. *Dronedarone* may cause severe liver injury; the FDA has suggested monitoring of hepatic enzymes for the first 6 months of therapy.

Esmolol

Esmolol is a β_1-selective agent that is metabolized by erythrocyte esterases and so has a very short elimination half-life (9 min). Intravenous *esmolol* is useful in clinical situations in which immediate β adrenergic blockade is desired (e.g., for rate control of rapidly conducted AF). Because of *esmolol's* very rapid elimination, adverse effects due to β adrenergic blockade—should they occur—dissipate rapidly when the drug is stopped. Although methanol is a metabolite of *esmolol*, methanol intoxication has not been a clinical problem. The pharmacology of *esmolol* is described in further detail in Chapter 13.

Flecainide

The effects of *flecainide* therapy are thought to be attributable to the drug's very long $\tau_{recovery}$ from Na^+ channel block. Suppression of DADs triggered by RyR2 Ca^{2+} release also contributes to *flecainide's* antiarrhythmic effect (Kryshtal et al., 2021). In CAST, *flecainide* increased mortality in patients convalescing from myocardial infarction (Echt et al., 1991). However, it continues to be used for arrhythmias in patients in whom structural heart disease is absent (Henthorn et al., 1991); this includes the maintenance of sinus rhythm in patients with supraventricular arrhythmias (i.e., AF) and incessant ventricular ectopy. Clinical case series suggested long-term *flecainide* efficacy in two congenital ventricular arrhythmia syndromes: type 3 LQTS due to mutations that cause late Na^+ currents and CPVT due to mutations that cause "leaky" RyR2 SR Ca^{2+} release channels. As discussed previously and supported by data from a recent randomized clinical trial (Kannankeril et al., 2017), *flecainide* has become the drug of choice for preventing arrhythmias in CPVT patients uncontrolled by β blockers.

Pharmacological Effects

Flecainide blocks Na^+ currents, spontaneous SR Ca^{2+} release, and delayed rectifier K^+ current (I_{Kr}) *in vitro* at similar concentrations. It also blocks Ca^{2+} currents *in vitro*. Action potential duration is shortened in Purkinje cells, probably owing to block of late-opening Na^+ channels, but is prolonged in ventricular cells, probably owing to block of delayed rectifier current. *Flecainide* does not cause EADs *in vitro* but has been associated with rare cases of torsades de pointes. In atrial tissue, *flecainide* disproportionately prolongs action potentials at fast rates, an especially desirable antiarrhythmic drug effect; this effect contrasts with that of *quinidine*, which prolongs atrial action potentials to a greater extent at slower rates. *Flecainide* prolongs the duration of PR, QRS, and QT intervals even at normal heart rates. *Flecainide* is also an open channel blocker of RyR2 Ca^{2+} release channels and prevents arrhythmogenic Ca^{2+} release from the SR and hence DADs in isolated myocytes (Hilliard et al., 2010). The RyR2 channel block by *flecainide* directly targets the underlying molecular defect in patients with mutations in the RyR2 gene and the cardiac calsequestrin gene, which may explain why *flecainide* suppresses ventricular arrhythmias in patients with CPVT refractory to β blocker therapy (Kannankeril et al., 2017; Watanabe et al., 2009). Recent experimental work suggests that RyR2 block is the principal mechanism of *flecainide* action in CPVT (Kryshtal et al., 2021).

Adverse Effects

Flecainide produces few subjective complaints in most patients; dose-related blurred vision is the most common noncardiac adverse effect. It can exacerbate congestive heart failure in patients with depressed left ventricular performance. The most serious adverse effects are provocation or exacerbation of potentially lethal arrhythmias. These include acceleration of ventricular rate in patients with atrial flutter, increased frequency of episodes of reentrant VT, and increased mortality in patients convalescing from myocardial infarction. *Flecainide* also can cause heart block in patients with conduction system disease. Overdose causes very wide QRS complexes and hemodynamic collapse; intravenous sodium bicarbonate has been used in this setting. As discussed previously, it is likely that all these effects can be attributed to Na^+ channel block.

Clinical Pharmacokinetics

Flecainide is well absorbed. The elimination $t_{1/2}$ is shorter with urinary acidification (10 h) than with urinary alkalinization (17 h), but it is nevertheless sufficiently long to allow dosing twice daily (Table 34–5). Elimination occurs by both renal excretion of unchanged drug and hepatic metabolism to inactive metabolites. The latter is mediated by the polymorphically distributed enzyme CYP2D6 (see Pharmacogenetics in Chapter 7). However, even in patients in whom this pathway is absent due to genetic polymorphism or inhibition by other drugs (e.g., *quinidine* or *fluoxetine*), renal excretion ordinarily is sufficient to prevent drug accumulation. In the rare patient with renal dysfunction and lack of active CYP2D6, *flecainide* may accumulate to toxic plasma concentrations. *Flecainide* is a racemate, but there are no differences in the electrophysiological effects or disposition kinetics of its enantiomers. Some reports have suggested that plasma *flecainide* concentrations greater than 1 μg/mL should be avoided to minimize the risk of *flecainide* toxicity; however, in susceptible patients, the adverse electrophysiological effects of *flecainide* therapy can occur at therapeutic plasma concentrations.

Ibutilide

Ibutilide is an I_{Kr} blocker that can also activate an inward Na^+ current (Murray, 1998). The action potential–prolonging effect of the drug may arise from either mechanism. *Ibutilide* is administered as a rapid infusion (1 mg over 10 min) for the immediate conversion of AF or atrial flutter to sinus rhythm. The drug's efficacy rate is higher in patients with atrial flutter (50%–70%) than in those with AF (30%–50%). In AF, the conversion rate is lower in those in whom the arrhythmia has been present for weeks or months compared with those in whom it has been present for days. The major toxicity with *ibutilide* is torsades de pointes, which occurs in up to 6% of patients and requires immediate cardioversion in up to one-third of these patients. The drug undergoes extensive first-pass metabolism, so it is not used orally. It is eliminated by hepatic metabolism and has a $t_{1/2}$ of 2 to 12 h (average 6 h).

Lidocaine

Lidocaine is a local anesthetic that also is useful in the acute intravenous therapy of ventricular arrhythmias. When *lidocaine* was administered to all patients with suspected myocardial infarction, the incidence of VF was reduced. However, survival to hospital discharge tended to be decreased, perhaps because of *lidocaine*-exacerbated heart block or congestive heart failure. Therefore, *lidocaine* no longer is administered routinely to all patients in coronary care units.

Pharmacological Effects

Lidocaine blocks both open and inactivated cardiac Na^+ channels. *In vitro* studies suggested that *lidocaine*-induced block reflects an increased likelihood that the Na^+ channel protein assumes a nonconducting conformation in the presence of drug (Balser et al., 1996). Recovery from block is rapid, so *lidocaine* exerts greater effects in depolarized (e.g., ischemic) or rapidly driven tissues. *Lidocaine* is not useful in atrial arrhythmias, possibly because atrial action potentials are so short that the Na^+ channel is in the inactivated state only briefly compared with diastolic (recovery) times, which are relatively long. In some studies, *lidocaine* increased current through inward rectifier channels, but the clinical significance of this effect is not known. *Lidocaine* can hyperpolarize Purkinje fibers depolarized by low $[K]_o$ or stretch; the resulting increased conduction velocity may be antiarrhythmic in reentry.

Lidocaine decreases automaticity by reducing the slope of phase 4 and altering the threshold for excitability. Action potential duration usually is unaffected or is shortened; such shortening may be due to block of the

few Na^+ channels that inactivate late during the cardiac action potential. *Lidocaine* usually exerts no significant effect on PR or QRS duration; QT is unaltered or slightly shortened. The drug exerts little effect on hemodynamic function, although rare cases of *lidocaine*-associated exacerbations of heart failure have been reported, especially in patients with very poor left ventricular function. For additional information on *lidocaine*, see Chapter 25 on local anesthetics.

Adverse Effects

When a large intravenous dose of *lidocaine* is administered rapidly, seizures can occur. When plasma concentrations of the drug rise slowly above the therapeutic range, as may occur during maintenance therapy, tremor, dysarthria, and altered levels of consciousness are more common. Nystagmus is an early sign of *lidocaine* toxicity.

Clinical Pharmacokinetics

Lidocaine is well absorbed but undergoes extensive though variable first-pass hepatic metabolism; thus, oral use of the drug is inappropriate. In theory, therapeutic plasma concentrations of *lidocaine* may be maintained by intermittent intramuscular administration, but the intravenous route is preferred (Table 34–5). *Lidocaine's* metabolites, glycine xylidide (GX) and monoethyl GX, are less potent as Na^+ channel blockers than the parent drug. GX and *lidocaine* appear to compete for access to the Na^+ channel, suggesting that with infusions during which GX accumulates, *lidocaine's* efficacy may be diminished. With infusions lasting longer than 24 h, the clearance of *lidocaine* falls—an effect that may result from competition between parent drug and metabolites for access to hepatic drug-metabolizing enzymes.

Plasma concentrations of *lidocaine* decline biexponentially after a single intravenous dose, indicating that a multicompartment model is necessary to analyze *lidocaine* disposition. The initial drop in plasma *lidocaine* following intravenous administration occurs rapidly, with a $t_{1/2}$ of about 8 min, and represents distribution from the central compartment to peripheral tissues. The terminal elimination $t_{1/2}$ of about 2 h represents drug elimination by hepatic metabolism. *Lidocaine's* efficacy depends on maintenance of therapeutic plasma concentrations in the central compartment. Therefore, the administration of a single bolus dose of *lidocaine* can result in transient arrhythmia suppression that dissipates rapidly as the drug is distributed and concentrations in the central compartment fall. To avoid this distribution-related loss of efficacy, a loading regimen of 3 to 4 mg/kg over 20 to 30 min is used (e.g., an initial 100 mg followed by 50 mg every 8 min for three doses). Subsequently, stable concentrations can be maintained in plasma with an infusion of 1 to 4 mg/min, which replaces drug removed by hepatic metabolism. The time to steady-state *lidocaine* concentrations is approximately 8–10 h. If the maintenance infusion rate is too low, arrhythmias may recur hours after the institution of apparently successful therapy. On the other hand, if the rate is too high, toxicity may result. In either case, routine measurement of plasma *lidocaine* concentration at the time of expected steady state is useful in adjusting maintenance infusion rate.

In heart failure, the central volume of distribution is decreased, so the total loading dose should be decreased. Because *lidocaine* clearance also is decreased, the rate of the maintenance infusion should be decreased. *Lidocaine* clearance also is reduced in hepatic disease, during treatment with *cimetidine* or β blockers, and during prolonged infusions. Frequent measurement of plasma *lidocaine* concentration and dose adjustment to ensure that plasma concentrations remain within the therapeutic range (1.5–5 μg/mL) are necessary to minimize toxicity in these settings. *Lidocaine* is bound to the acute-phase reactant α_1-acid glycoprotein. Diseases such as acute myocardial infarction are associated with increases in α_1-acid glycoprotein and protein binding and hence a decreased proportion of free drug. These findings may explain why some patients require and tolerate higher-than-usual total plasma *lidocaine* concentrations to maintain antiarrhythmic efficacy.

Magnesium

The intravenous administration of 1 to 2 g $MgSO_4$ is effective in preventing recurrent episodes of torsades de pointes, even if the serum Mg^{2+} concentration is normal (Brugada, 2000). However, controlled studies of this effect have not been performed. The mechanism of action is likely related to block of L-type Ca^{2+} currents responsible for the triggered upstroke arising from EADs (black arrow, Figure 34–7B). Following its administration, the QT interval is not shortened. Mg^{2+} is also an inhibitor of RyR2 Ca^{2+} release channels *in vitro*, which may explain why intravenous Mg^{2+} has been used successfully in arrhythmias related to *digitalis* intoxication.

Large placebo-controlled trials of intravenous Mg^{2+} to improve outcome in acute myocardial infarction have yielded conflicting results (ISIS-4 Collaborative Group, 1995; Woods and Fletcher, 1994). While oral Mg^{2+} supplements may be useful in preventing hypomagnesemia, there is no evidence that chronic Mg^{2+} ingestion exerts a direct antiarrhythmic action.

Mexiletine

Mexiletine is an analogue of *lidocaine* that has been modified to reduce first-pass hepatic metabolism and permit chronic oral therapy. The electrophysiological actions are similar to those of *lidocaine*. Tremor and nausea, the major dose-related adverse effects, can be minimized by taking the drug with food.

Mexiletine undergoes hepatic metabolism, which is inducible by drugs such as *phenytoin*. *Mexiletine* is approved for treating ventricular arrhythmias; combinations of *mexiletine* with *quinidine* or *sotalol* may increase efficacy while reducing adverse effects. *In vitro* studies and clinical case series have suggested a role for *mexiletine* (or *flecainide*; see previous discussion) in correcting the aberrant late inward Na^+ current in type 3 congenital LQTS (Roden and Knollmann, 2008).

Procainamide

Procainamide is an analogue of the local anesthetic *procaine* (see Figure 25–1). It exerts electrophysiological effects similar to those of *quinidine* but lacks *quinidine's* vagolytic and α adrenergic–blocking activity. *Procainamide* is better tolerated than *quinidine* when given intravenously. Loading and maintenance intravenous infusions are used in the acute therapy of many supraventricular and ventricular arrhythmias. However, long-term oral treatment is poorly tolerated and often is stopped owing to adverse effects.

Pharmacological Effects

Procainamide is a blocker of open Na^+ channels with an intermediate $\tau_{recovery}$ from block. It also prolongs cardiac action potentials in most tissues, probably by blocking outward K^+ current(s). *Procainamide* decreases automaticity, increases refractory periods, and slows conduction. The major metabolite, *N*-acetyl procainamide, lacks the Na^+ channel–blocking activity of the parent drug but is equipotent in prolonging action potentials. Because the plasma concentrations of *N*-acetyl procainamide often exceed those of *procainamide*, increased refractoriness and QT prolongation during chronic *procainamide* therapy may be partly attributable to the metabolite. However, it is the parent drug that slows conduction and produces QRS interval prolongation. Although hypotension may occur at high plasma concentrations, this effect usually is attributable to ganglionic blockade rather than to any negative inotropic effect, which is minimal.

Adverse Effects

Hypotension and marked slowing of conduction are major adverse effects of high concentrations (>10 μg/mL) of *procainamide*, especially during acute intravenous loading. Dose-related nausea is frequent during oral therapy and may be attributable in part to high plasma concentrations of *N*-acetyl procainamide. Torsades de pointes can occur, particularly when plasma concentrations of *N*-acetyl procainamide rise to greater than 30 μg/mL. *Procainamide* produces potentially fatal bone marrow aplasia in 0.2% of patients; the mechanism is not known, but high plasma drug concentrations are not suspected.

During long-term therapy, most patients will develop biochemical evidence of the drug-induced lupus syndrome, such as circulating antinuclear antibodies. Therapy need not be interrupted merely because of the

presence of antinuclear antibodies. However, 25% to 50% of patients eventually develop symptoms of the lupus syndrome; common early symptoms are rash and small-joint arthralgias. Other symptoms of lupus, including pericarditis with tamponade, can occur, although renal involvement is unusual. The lupus-like symptoms resolve on cessation of therapy or during treatment with *N*-acetyl procainamide (see discussion that follows).

Clinical Pharmacokinetics

Procainamide is eliminated rapidly ($t_{1/2}$ ~3–4 h) by both renal excretion of unchanged drug and hepatic metabolism. The major pathway for hepatic metabolism is conjugation by *N*-acetyl transferase, whose activity is determined genetically, to form *N*-acetyl procainamide. *N*-Acetyl procainamide is eliminated by renal excretion ($t_{1/2}$ ~6–10 h) and is not significantly converted back to *procainamide*. Because of the relatively rapid elimination rates of both the parent drug and its major metabolite, oral *procainamide* usually is administered as a slow-release formulation. In patients with renal failure, *procainamide* or *N*-acetyl procainamide can accumulate to potentially toxic plasma concentrations. Reduction of *procainamide* dose and dosing frequency and monitoring of plasma concentrations of both compounds are required in this situation. Because the parent drug and metabolite exert different pharmacological effects, the past practice of using the sum of their concentrations to guide therapy is inappropriate.

In individuals who are "slow acetylators," the *procainamide*-induced lupus syndrome develops more often and earlier during treatment than among rapid acetylators. In addition, the symptoms of *procainamide*-induced lupus resolve during treatment with *N*-acetyl procainamide. Both of these findings support results of *in vitro* studies suggesting that it is chronic exposure to the parent drug (or an oxidative metabolite) that results in the lupus syndrome; these findings also provided one rationale for the further development of *N*-acetyl procainamide and its analogues as antiarrhythmic agents (Roden, 1993).

Propafenone

Propafenone is a Na^+ channel blocker with a relatively slow time constant for recovery from block (Funck-Brentano et al., 1990). Some data suggest that, like *flecainide*, *propafenone* also blocks K^+ channels. Its major electrophysiological effect is to slow conduction in fast-response tissues. The drug is prescribed as a racemate; while the enantiomers do not differ in their Na^+ channel–blocking properties, *S*-(+)-propafenone is a β adrenergic receptor antagonist. *Propafenone* prolongs PR and QRS durations. Chronic therapy with oral *propafenone* is used to maintain sinus rhythm in patients with supraventricular tachycardias, including AF. *R*-(−)propafenone blocks RyR2 channels and may be used as an alternative to *flecainide* in CPVT (Hwang et al., 2011).

Adverse Effects

Adverse effects during *propafenone* therapy include acceleration of ventricular response in patients with atrial flutter, increased frequency or severity of episodes of reentrant VT, exacerbation of heart failure, and the adverse effects of β adrenergic blockade, such as sinus bradycardia and bronchospasm (see previous discussion and Chapter 14).

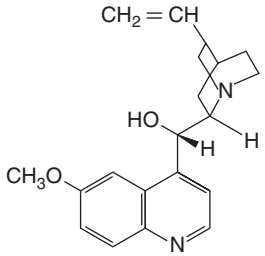
Clinical Pharmacokinetics

Propafenone is well absorbed and is eliminated primarily by CYP2D6-mediated hepatic metabolism (see Chapter 5). In most subjects ("extensive metabolizers"), *propafenone* undergoes extensive first-pass hepatic metabolism to 5-hydroxy propafenone, a metabolite equipotent to *propafenone* as a Na^+ channel blocker but much less potent as a β adrenergic receptor antagonist. A second metabolite, *N*-desalkyl propafenone, is formed by non-CYP2D6–mediated metabolism and is a less-potent blocker of Na^+ channels and β adrenergic receptors. CYP2D6-mediated metabolism of *propafenone* is saturable, so small increases in dose can increase plasma *propafenone* concentration disproportionately. In "poor metabolizer" subjects, in whom CYP2D6 activity is low or absent, first-pass hepatic metabolism is much less than in extensive metabolizers, and plasma *propafenone* concentrations will be much higher after an equal dose. The incidence of adverse effects during *propafenone* therapy is significantly higher in poor metabolizers.

CYP2D6 activity can be inhibited markedly by a number of drugs, including *quinidine* and *fluoxetine*. In extensive metabolizer subjects receiving such drugs or in poor metabolizer subjects, plasma *propafenone* concentrations of more than 1 μg/mL are associated with clinical effects of β adrenergic receptor blockade, such as reduction of exercise heart rate. It is recommended that dosage in patients with moderate-to-severe liver disease should be reduced to approximately 20% to 30% of the usual dose, with careful monitoring. It is not known if *propafenone* doses must be decreased in patients with renal disease. A slow-release formulation allows twice-daily dosing.

Quinidine

As early as the 18th century, the bark of the cinchona plant was used to treat "rebellious palpitations" (Levy and Azoulay, 1994). Studies in the early 20th century identified *quinidine*, a diastereomer of the antimalarial *quinine*, as the most potent of the antiarrhythmic substances extracted from the cinchona plant, and by the 1920s, *quinidine* was used as an antiarrhythmic agent. *Quinidine* is used to maintain sinus rhythm in patients with atrial flutter or AF and to prevent recurrence of VT or VF (Grace and Camm, 1998). *Quinidine* may be especially useful in preventing recurrent VF in unusual congenital arrhythmia syndromes such as Brugada syndrome or short QT syndrome (Inama et al., 2010; Viskin et al., 2013).



QUINIDINE

Pharmacological Effects

Quinidine blocks Na^+ current and multiple cardiac K^+ currents. It is an open-state blocker of Na^+ channels, with a $\tau_{recovery}$ in the intermediate (~3-sec) range. Thus, after therapeutic dosages, QRS duration increases modestly, usually by 10% to 20%. At therapeutic concentrations, *quinidine* commonly prolongs the QT interval up to 25%, but the effect is highly variable. At concentrations as low as 1 μM, *quinidine* blocks Na^+ current and the rapid component of delayed rectifier (I_{Kr}); higher concentrations block the slow component of delayed rectifier, inward rectifier, transient outward current, and L-type Ca^{2+} current.

Quinidine's Na^+ channel–blocking properties result in an increased threshold for excitability and decreased automaticity. As a consequence of its K^+ channel–blocking actions, *quinidine* prolongs action potentials in most cardiac cells, most prominently at slow heart rates. In some cells, such as midmyocardial cells and Purkinje cells, *quinidine* consistently elicits EADs at slow heart rates, particularly when $[K]_o$ is low (Priori et al., 1999). *Quinidine* prolongs refractoriness in most tissues, probably as a result of both prolongation of action potential duration and Na^+ channel blockade.

In intact animals and humans, *quinidine* also produces α adrenergic receptor blockade and vagal inhibition. Thus, the intravenous use of *quinidine* is associated with marked hypotension and sinus tachycardia. *Quinidine's* vagolytic effects tend to inhibit its direct depressant effect on AV nodal conduction, so the effect of drug on the PR interval is variable. Moreover, *quinidine's* vagolytic effect can result in increased AV nodal transmission of atrial tachycardias such as atrial flutter (Table 34–1).

Adverse Effects

Noncardiac. Diarrhea is the most common adverse effect during *quinidine* therapy, occurring in 30% to 50% of patients; the mechanism is not known. Diarrhea usually occurs within the first several days of *quinidine* therapy but can occur later. Diarrhea-induced hypokalemia may potentiate torsades de pointes due to *quinidine*.

Several immunological reactions can occur during *quinidine* therapy. The most common is thrombocytopenia, which can be severe but resolves rapidly with discontinuation of the drug. Hepatitis, bone marrow depression, and lupus syndrome occur rarely. None of these effects are related to elevated plasma *quinidine* concentrations.

Quinidine also can produce cinchonism, a syndrome that includes headache and tinnitus. In contrast to other adverse responses to *quinidine* therapy, cinchonism usually is related to elevated plasma *quinidine* concentrations and can be managed by dose reduction.

Cardiac. Of patients receiving *quinidine* therapy, 2% to 8% will develop marked QT interval prolongation and torsades de pointes. In contrast to effects of *sotalol*, *N*-acetyl procainamide, and many other drugs, *quinidine*-associated torsades de pointes generally occurs at therapeutic or even subtherapeutic plasma concentrations. The reasons for individual susceptibility to this adverse effect are not known.

At high plasma concentrations of *quinidine*, marked Na^+ channel block can occur, with resulting VT. This adverse effect occurs when very high doses of *quinidine* are used to try to convert AF to normal rhythm; this aggressive approach to *quinidine* dosing has been abandoned, and *quinidine*-induced VT is now unusual.

Quinidine can exacerbate heart failure or conduction system disease. However, in most patients with congestive heart failure, *quinidine* is well tolerated, perhaps because of its vasodilating actions.

Clinical Pharmacokinetics

Quinidine is well absorbed and is 80% bound to plasma proteins, including albumin and, like *lidocaine*, the acute-phase reactant α_1-acid glycoprotein. As with *lidocaine*, greater-than-usual doses (and total plasma *quinidine* concentrations) may be required to maintain therapeutic concentrations of free *quinidine* in high-stress states such as acute myocardial infarction. *Quinidine* undergoes extensive hepatic oxidative metabolism, and approximately 20% is excreted unchanged by the kidneys. One metabolite, 3-hydroxyquinidine, is nearly as potent as *quinidine* in blocking cardiac Na^+ channels and prolonging cardiac action potentials. Concentrations of unbound 3-hydroxyquinidine equal to or exceeding those of *quinidine* are tolerated by some patients. Other metabolites are less potent than *quinidine*, and their plasma concentrations are lower; thus, they are unlikely to contribute significantly to the clinical effects of *quinidine*.

There is substantial individual variability in the range of dosages required to achieve therapeutic plasma concentrations of 2 to 5 μg/mL. Some of this variability may be assay dependent because not all assays exclude *quinidine* metabolites. In patients with advanced renal disease or congestive heart failure, *quinidine* clearance is decreased only modestly. Thus, dosage requirements in these patients are similar to those in other patients.

Drug Interactions

Quinidine is a potent inhibitor of CYP2D6. As a result, the administration of *quinidine* to patients receiving drugs that undergo extensive CYP2D6-mediated metabolism may result in altered drug effects owing to accumulation of parent drug and failure of metabolite formation. For example, inhibition of CYP2D6-mediated metabolism of *codeine* to its active metabolite *morphine* results in decreased analgesia. On the other hand, inhibition of CYP2D6-mediated metabolism of *propafenone* results in elevated plasma *propafenone* concentrations and increased β adrenergic receptor blockade. *Quinidine* reduces the clearance of *digoxin* due to inhibition of P-glycoprotein–mediated *digoxin* transport (Fromm et al., 1999). *Dextromethorphan*, a CYP2D6 substrate that undergoes extensive first-pass bioinactivation, has shown promise in treatment of various neurological disorders, notably pseudobulbar affect. A combination of *dextromethorphan* and very-low-dose *quinidine* (30 mg) inhibits the first-pass metabolism, achieves higher systemic concentrations than monotherapy, and is now approved for use in pseudobulbar affect and neuropathic pain (Olney and Rosen, 2010).

Quinidine metabolism is induced by drugs such as *phenobarbital* and *phenytoin*. In patients receiving these agents, very high doses of *quinidine* may be required to achieve therapeutic concentrations. If therapy with the inducing agent is then stopped, *quinidine* concentrations may rise to very high levels, and its dosage must be adjusted downward. *Cimetidine* and *verapamil* also elevate plasma *quinidine* concentrations, but these effects usually are modest.

Drug Facts for Your Personal Formulary: *Antiarrhythmic Agents*

Antiarrhythmic Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Class IA: Na^+ Channel Blockers • Slow to intermediate off rate • Concomitant class III action (prolong QT)		
Procainamide	• Acute treatment of AF, VT, and VF • Chronic treatment to prevent AF, VT, and VF	• 40% of patients discontinue within 6 months of therapy due to side effects: hypotension (especially from intravenous use), nausea • QT prolongation and torsades de pointes due to accumulation of active *N*-acetyl metabolite • Lupus-like syndrome (25%–50% with chronic use), especially in genetic slow acetylators • Oral drug no longer available in the U.S.
Quinidine	• Chronic treatment to prevent AF, VT, and VF	• Diarrhea (30%–50% of patients); diarrhea-induced hypokalemia may potentiate torsades de pointes • Marked QT prolongation and high risk (~1%–5%) of torsades de pointes at therapeutic or subtherapeutic concentrations • Immune thrombocytopenia (~1%) • Cinchonism: tinnitus, flushing, blurred vision, dizziness, diarrhea • Potent inhibitor of *CYP2D6* and *ABCB1* (encoding P-glycoprotein): altered effects of digitalis, many antidepressants, and others
Disopyramide	• Chronic treatment to prevent AF, VT, and VF	• Anticholinergic effects (dry eyes, urinary retention, constipation) • Long QT (torsades de pointes) • Depression of contractility can precipitate or worsen heart failure; paradoxically, this can be useful in hypertrophic cardiomyopathy to reduce outflow tract obstruction

Drug Facts for Your Personal Formulary: *Antiarrhythmic Agents (continued)*

Antiarrhythmic Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Class IB: Na^+ Channel Blockers • Fast off rate • Little effect on ECG		
Lidocaine	• Acute treatment of VT and VF	• CNS: seizures and tinnitus • CNS: tremor, hallucinations, drowsiness, coma
Mexiletine	• Chronic treatment to prevent VT and VF	• Tremor and nausea
Class IC: Na^+ Channel Blockers • Slow off rate • Prolong PR and broaden QRS intervals		
Flecainide	• Chronic treatment to prevent PSVT, AF, VT, and VF in the absence of structural heart disease • Available in some countries for intravenous use in PSVT, AF • Useful in CPVT uncontrolled by β blockers	• RyR2-blocking effect important for antiarrhythmic efficacy • Much better tolerated than class IA or IB agents • Risk of severe proarrhythmia in patients with structural heart disease; increased mortality in patients with myocardial infarction (CAST) • Blurred vision • Can worsen heart failure
Propafenone	• Chronic treatment to prevent PSVT, AF, VT, and VF in the absence of structural heart disease • Available in some countries for intravenous use in PSVT, AF • Alternative to flecainide for CPVT	• RyR2-blocking effect important for antiarrhythmic efficacy • Also has β adrenergic–blocking effects (worsening of heart failure and bronchospasm), especially prominent in *CYP2D6* poor metabolizers • Risk of severe proarrhythmia in patients with structural heart disease
Class II: β Blockers		
Nadolol Propranolol Metoprolol Many others	• Chronic treatment to prevent arrhythmias in congenital LQTS and CPVT • Rate control in AF • Widely used for other indications (angina, hypertension, migraine, etc.)	• β Adrenergic–blocking effects (worsening of heart failure, bradycardia, bronchospasm) • Nadolol preferred by many for LQTS and CPVT
Esmolol	• Acute treatment to control rate in AF	• Ultrashort $t_{1/2}$, intravenous use only
Class III: K^+ Channel Blocker • Increase refractory period (prolong QT)		
Amiodarone	• Drug of choice for acute treatment of VT and VF and to slow ventricular rate and convert AF • Chronic treatment to prevent AF, VT, and VF	• Hypotension, depressed ventricular function and torsades de pointes (*rare*) with intravenous administration • Pulmonary fibrosis with chronic therapy, which can be fatal (requires periodic monitoring of lung function) • Many other adverse effects: corneal microdeposits, hepatotoxicity, neuropathies, photosensitivity, thyroid dysfunction • Note: tissue half-life of several months • Inhibitor of many drug-metabolizing and transport systems, with high potential for drug interactions
Dronedarone	• Chronic treatment to prevent AF	• Amiodarone analogue with lower efficacy than amiodarone • Gastrointestinal disturbances, risk for fatal hepatotoxicity • Increases mortality in patients with severe heart failure
Sotalol	• Chronic treatment to prevent AF, VT, and VF	• Also has β adrenergic–blocking effects • High risk (~1%–5%) of torsades de pointes
Dofetilide	• Chronic treatment to prevent AF	• Few adverse effects except high risk (~1%–5%) of torsades de pointes
Ibutilide	• Acute treatment to convert AF	• High risk (~1%–8%) of torsades de pointes
Class IV: Ca^{2+} Channel Blockers • Nondihydropyridine • Inhibit SA and AV nodes • Prolong PR		
Diltiazem Verapamil	• Acute intravenous use to convert PSVT and for rate control in AF • Chronic treatment to prevent PSVT and control rate in AF	• Hypotension (intravenous) • Sinus bradycardia or AV block especially in combination with β blockers • Constipation • Worsening of heart failure
Antiarrhythmic Drugs with Miscellaneous Mechanisms		
Adenosine (activates A receptors)	• Drug of choice for acute treatment PSVT	• Short $t_{1/2}$ (<5 sec) • Transient asystole • Transient dyspnea • Transient atrial fibrillation (rare)
$MgSO_4$	• Acute treatment of torsades de pointes	• Likely acts by blocking L-type Ca^{2+} channels
Digoxin (Na^+, K^+–ATPase inhibitor)	• Ventricular rate control in AF • Modest positive inotropic effect	• Adverse effects common and include gastrointestinal symptoms, visual/cognitive dysfunction, and arrhythmias, typically supraventricular arrhythmias with heart block or atrial or ventricular extrasystoles • Severe toxicities (e.g., with overdose) can be treated with antibody • Probably mortality neutral

Sotalol

Sotalol is a nonselective β adrenergic receptor antagonist that also prolongs cardiac action potentials by inhibiting delayed rectifier and possibly other K^+ currents (Hohnloser and Woosley, 1994). *Sotalol* is prescribed as a racemate; the L-enantiomer is a much more potent β adrenergic receptor antagonist than the D-enantiomer, but the two are equipotent as K^+ channel blockers. In the U.S., *sotalol* is approved for use in patients with both ventricular tachyarrhythmias and AF or atrial flutter. Clinical trials suggest that it is as effective as most Na^+ channel blockers in ventricular arrhythmias.

Sotalol prolongs action potential duration throughout the heart and QT interval on the ECG. It decreases automaticity, slows AV nodal conduction, and prolongs AV refractoriness by blocking both K^+ channels and β adrenergic receptors, but it exerts no effect on conduction velocity in fast-response tissue. *Sotalol* causes EADs and triggered activity *in vitro* and can cause torsades de pointes, especially when the serum K^+ concentration is low. Unlike the situation with *quinidine*, the incidence of torsades de pointes (1.5%–2% incidence) seems to depend on the dose of *sotalol*; indeed, torsades de pointes is the major toxicity with *sotalol* overdose. Occasional cases occur at low dosages, often in patients with renal dysfunction, because *sotalol* is eliminated by renal excretion of unchanged drug. The other adverse effects of *sotalol* therapy are those associated with β adrenergic receptor blockade (see previous discussion and Chapter 14).

Chapter 35 Treatment of Pulmonary Arterial Hypertension

Dustin R. Fraidenburg, Ankit A. Desai, Ayako Makino, and Jason X.-J. Yuan

Introduction to Pulmonary Hypertension

The pulmonary circulation plays a unique and essential role in gas exchange and oxygenation of venous blood in the lungs. It is a low-resistance and low-pressure circulatory system; the mean pulmonary arterial pressure (PAP) in healthy control subjects is 14.0 ± 3.3 mmHg. PAP is a function of cardiac output and pulmonary vascular resistance (PVR). Pulmonary hypertension (PH) is defined as a mean PAP greater than 20 mmHg at rest, measured by right heart catheterization (Simonneau et al., 2019). PH can be a primary disorder of the pulmonary vasculature, commonly referred to as pulmonary arterial hypertension (PAH), or can occur as a complication of other cardiopulmonary, vascular, and systemic diseases. Based on shared pathophysiological and pathological characteristics as well as response to therapy, PH is classified into five major groups (Simonneau et al., 2019), as shown in Box 35–1.

Pulmonary Arterial Hypertension

Idiopathic PAH is a rare, progressive, and fatal disease in which vascular changes in the small arteries and arterioles result in progressive increases in PVR, resulting in increased PAP (Kuhr et al., 2012; McLaughlin et al., 2009; Morrell et al., 2009). A heritable form of PAH is caused by heterozygous germline mutations in *BMPR2*, the gene encoding bone morphogenetic protein receptor type 2, a member of the transforming growth factor-β (TGF-β) superfamily (Morrell et al., 2019). Around 70% to 80% of heritable cases of PAH and 10% to 20% of idiopathic PAH cases are caused by mutations in *BMPR2*. Less common PAH genes include *TBX4*, *ACVRL1*, *ENG*, *SMAD9*, and *KCNK3* (0.4%). In patients with PAH, elevated afterload increases stress on the RV, often leading to right heart dysfunction and failure, the major cause of morbidity and mortality in this population (Voelkel et al., 2012). The median survival in untreated disease is 2.8 years, yet with modern therapies, the median survival has been estimated to be about 9 years (Benza et al., 2012). This group of patients is the most well-studied subset of PH and the primary target of available therapeutics.

Pulmonary Hypertension Associated With Other Disease States

Other PH groups represent most cases of PH (see textbox). The presence of PH in these more common diseases portends a much poorer prognosis, often identifying people with multiple comorbidities, late-stage presentations, or more severe disease. While recognition of PH in heart disease carries important prognostic implications, to date, there are no approved targeted therapies for PH in this disease state. Similarly, in lung diseases, the presence of PH is an important risk factor and

BOX 35–1 ■ Classification of Pulmonary Hypertension

Pulmonary arterial hypertension (PAH)
- Idiopathic PAH
- Heritable PAH due to genetic variants
  - *BMPR2* (most common)
  - *TBX4*, *ACVRL1*, *ENG*, *SMAD9*, *KCNK3*
- Drug- and toxin-induced PAH
- PAH associated with:
  - Connective tissue disease
  - HIV infection
  - Portal hypertension
  - Congenital heart disease
  - Schistosomiasis
- PAH long-term responders to calcium channel blockers
- PAH with overt features of venous/capillary involvement
- PAH of the newborn syndrome

PH due to left heart disease
- Heart failure
- Valvular heart disease
- Congenital/acquired cardiovascular conditions leading to postcapillary hypertension

PH due to lung diseases and/or hypoxia
- Obstructive lung disease
- Restrictive lung disease
- Hypoxia without lung disease
- Developmental lung disorders

PH due to pulmonary artery obstructions
- Chronic thromboembolic pulmonary hypertension (CTEPH)
- Other pulmonary artery obstructions

PH with unclear and/or multifactorial mechanisms
- Hematological disorders
- Systemic and metabolic disorders
- Complex congenital heart disease

Abbreviations

BCRP: breast cancer resistance protein
BNP: B-type natriuretic peptide
$[Ca^{2+}]_{cyt}$: cytosolic free Ca^{2+} concentration
CCB: calcium channel blocker
CTEPH: chronic thromboembolic pulmonary hypertension
CYP: cytochrome P450
DAG: diacylglycerol
EC: endothelial cell
ECE: endothelin-converting enzyme
EGF: epidermal growth factor
ER: endoplasmic reticulum
ERA: endothelin receptor antagonist
ET-1: endothelin 1
FDA: U.S. Food and Drug Administration
GPCR: G protein-coupled receptor
IP_3: inositol triphosphate
IPR: prostacyclin receptor
mGC: membrane (or particulate) guanylate cyclase
NO: nitric oxide
NO_2: nitric dioxide
PA: pulmonary artery
PAH: pulmonary arterial hypertension
PAP: pulmonary arterial pressure
PASMC: pulmonary artery smooth muscle cell
PDE: phosphodiesterase
PDGF: platelet-derived growth factor
PGI_2: prostacyclin, prostaglandin I_2
Pgp : P-glycoprotein
PH: pulmonary hypertension
PKA: protein kinase A
PKC: protein kinase C
PKG: protein kinase G
PLC: phospholipase C
PVR: pulmonary vascular resistance
REMS: Risk Evaluation and Mitigation Strategy
ROC: receptor-operated Ca^{2+} channel
RV: right ventricle
sGC: soluble guanylate cyclase
SR: sarcoplasmic reticulum
SVR: systemic vascular resistance
TGF-β: transforming growth factor-β
TKR: tyrosine kinase receptor
VDCC: voltage-dependent Ca^{2+} channel
VEGF: vascular endothelial growth factor
VIP: vasoactive intestinal peptide
V/Q: ventilation/perfusion
VSM: vascular smooth muscle

portends a worse prognosis, but until 2021, there were no approved therapies targeting PH in these populations. Inhaled *treprostinil* is now FDA-approved for treating PH associated with interstitial lung disease, with use and dosing that mirror those in PAH (Waxman et al., 2021). However, in other forms of respiratory disease, there are no currently approved therapies for PH. In patients identified to have chronic thromboembolic pulmonary hypertension (CTEPH), a subtype of PH due to pulmonary artery obstructions, surgical pulmonary thromboendarterectomy is the treatment of choice. Patients determined to be poor surgical candidates or those with persistent PH following surgery respond to pulmonary vasodilator therapy (Fedullo et al., 2011; Ghofrani et al., 2013a).

Routes of Drug Delivery to the Pulmonary Circulation

The pulmonary circulation permits delivery of drugs through multiple routes. The pulmonary circulation runs in series with the systemic circulation, receiving the entire cardiac output in each cardiac cycle. Thus, exposure of pulmonary tissue to drugs is excellent and reliable. Continuous intravenous infusion is used to deliver high concentrations of drugs that exhibit short half-lives to the pulmonary circulation while avoiding first-pass metabolism. Alternatively, drug administration by subcutaneous pump may be used to lower the risk of adverse effects. Oral delivery remains a safe, effective, and reliable route for many classes of drugs used to treat PAH. The small pulmonary arteries and precapillary arterioles are also unique in their close proximity to the alveoli and lower airways. Hence, inhalational delivery of therapeutic compounds can directly target the lung vasculature and pulmonary circulation, limit systemic side effects, and preferentially affect well-ventilated parts of the lung to improve ventilation-perfusion matching (see Chapter 44).

Mechanisms of Pulmonary Arterial Hypertension

Pulmonary arterial hypertension is thought to arise from pathophysiological and pathobiological changes in the small pulmonary arteries and arterioles. Regardless of the initial etiological trigger, the putative mechanisms contributing to elevated PVR and PAP include:

- Sustained pulmonary vasoconstriction
- Concentric pulmonary vascular remodeling
- *In situ* thrombosis
- Pulmonary vascular wall stiffening

Each of these mechanisms (Figure 35–1) can contribute to the development and progression of PAH and forms the basis for drug therapy for this disease. Accordingly, an effective therapy for PAH would (1) cause pulmonary vasodilation; (2) exert antiproliferative or proapoptotic effects on highly proliferative cells in the pulmonary vascular wall (e.g., fibroblasts, myofibroblasts, and smooth muscle cells); (3) prevent or resolve *in situ* thrombosis in small arteries and precapillary arterioles; (4) exert antifibrotic effects to attenuate extracellular matrix stiffness; and (5) reduce pulmonary vascular wall stiffness due to myogenic tone and inflammation/cholesterol-associated membrane stiffness (Humbert et al., 2019; Mandegar et al., 2004; Morrell et al., 2009).

Although the cellular and molecular mechanisms leading to these changes in the pulmonary vasculature are complex, an imbalance of vasoactive mediators, mitogenic and angiogenic factors, and pro- and antiapoptotic proteins plays an important role in PAH development. Relative deficiencies of vasodilators such as nitric oxide (NO) and prostacyclin deleteriously accompany an excess of vasoconstrictors such as endothelin 1 (ET-1) and thromboxane A_2. NO released by the vascular endothelial cell (EC) normally promotes the production of cyclic GMP in the pulmonary artery smooth muscle cell (PASMC), resulting in PASMC relaxation and pulmonary vasodilation. Prostacyclin, also known as prostaglandin I_2 (PGI_2), is also released from the EC and promotes the synthesis of cAMP, causing PASMC relaxation and pulmonary vasodilation. In addition, NO and PGI_2 both have antiproliferative and anticoagulant effects that inhibit concentric pulmonary vascular wall thickening and *in situ* thrombosis. ET-1 is a potent vasoconstrictor secreted by ECs; it exerts vasoconstrictive and proliferative effects on PASMCs. Other vasoactive mediators such as thromboxane A_2, serotonin, and vasoactive intestinal peptide (VIP) appear to play a role in the development of PAH, but the therapeutic potential of targeting these substances has not been well established. Table 35–1 summarizes the changes in these vasoactive mediators and the potential contributions of those changes to the development of PAH.

Sustained vasoconstriction and pulmonary vascular remodeling also result from functional and transcriptional changes in membrane receptors and ion channels on the surface of PASMCs. Several G protein-coupled

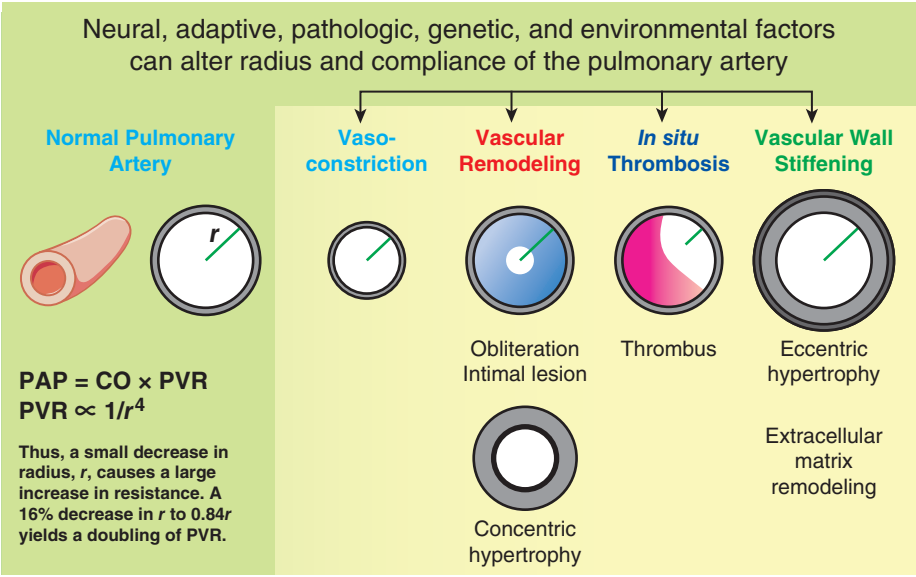

Figure 35–1 *Major pathogenic components in the development of PAH.* Vascular remodeling occurs as changes in the intraluminal radius with or without changes in the vascular wall thickness. Changes in intraluminal radius of small pulmonary arteries and arterioles have dramatic effects on the PVR. Pathogenic factors contributing to the development and progression of PAH include sustained vasoconstriction, concentric pulmonary vascular remodeling, *in situ* thrombosis, and vascular wall stiffening.

receptors (GPCRs) and tyrosine kinase receptors (TKRs) are implicated in the development and progression of PAH (Morrell et al., 2009; Schermuly et al., 2011). Increased cytosolic $[Ca^{2+}]$ is an important common pathway by which receptor activation and downstream cellular signaling cascades exert their effects in the pulmonary vasculature. A rise in cytosolic free Ca^{2+} concentration ($[Ca^{2+}]_{cyt}$) in PASMCs is a major trigger for PASMC contraction and an important mediator for PASMC proliferation, migration, and vascular remodeling. Furthermore, ion channels, particularly Ca^{2+}-permeable cation channels and K^+-permeable channels (e.g., KCNA5 and KCNK3) in the plasma membrane of PASMCs, can directly influence $[Ca^{2+}]_{cyt}$ (Mandegar et al., 2004). Changes in activity and expression of ion channels and transporters, such as voltage-dependent Ca^{2+} channel (VDCC), receptor-operated Ca^{2+} channel (ROC), store-operated Ca^{2+} channels, and the Na^+-Ca^{2+} exchanger, are implicated in the development of PAH; all are potential therapeutic targets. Down-regulation of K^+-permeable channels in PASMCs leads to membrane depolarization and opening of VDCCs, enhancing Ca^{2+} influx, with a consequent increase in $[Ca^{2+}]_{cyt}$ and further sustained vasoconstriction and vascular remodeling (Kuhr et al., 2012).

TABLE 35–1 ■ ROLES OF VASOACTIVE MEDIATORS IN PAH

Clinical Use of Drugs for Pulmonary Hypertension

Treatment of PAH must include a proper assessment of symptoms, functional classification, and RV performance for optimal selection of appropriate agents. The most widely used criterion for initiating treatment is the presence of symptoms and impairments in functional capacity, as measured by functional classification. This classification measures the physical limitations imposed on a particular patient from the disease, progressing from class I through class IV (from no impairment through mounting functional limitation to inability to perform physical activity). Clinical trials suggest that class II patients may benefit from therapy, with greater benefit seen in class III. While the overall number of class IV patients is low, these patients with the most severe functional impairments fare far worse. RV dysfunction results from increased PVR, in part, and is the major contributor to morbidity and mortality in this population; therefore, assessment of the RV often is used in conjunction with functional assessment to guide therapy (Figure 35–2).

Goals of treatment include improvement in symptoms, such as dyspnea, fatigue, chest pain, or syncope; improved functional capacity, including 6-min walk distance; and improvement in pulmonary hemodynamics and RV function. Oral formulations, either endothelin receptor antagonists (ERAs), phosphodiesterase (PDE) inhibitors, or soluble guanylate cyclase (sGC) stimulators are usually employed as first-line agents due to ease of use. Treatment of more severe cases generally involves parenteral therapy with *prostacyclin* and prostacyclin analogues (i.e., *epoprostenol* or *treprostinil*), considered the most potent pulmonary vasodilators that also have antiproliferative and antifibrotic effects, yet controversy exists on the initial treatment of patients with moderate-to-severe functional limitations. Sequential combination therapy with the addition of separate classes of medications until treatment goals are achieved is often utilized for severe or progressive disease (Ghofrani and Humbert, 2014). This approach is commonly used in clinical trials and has incremental clinical benefits when agents with different mechanisms of action are combined sequentially. Modest effects with single agents may be enhanced with the use of up-front combinations and could lead to more dramatic improvements in both symptoms and hemodynamics (Galie et al., 2016; Sitbon et al., 2014). Combination therapy is now recommended for initial therapy of all treatment-naïve PAH patients with functional class II or III symptoms (Klinger et a , 2019).

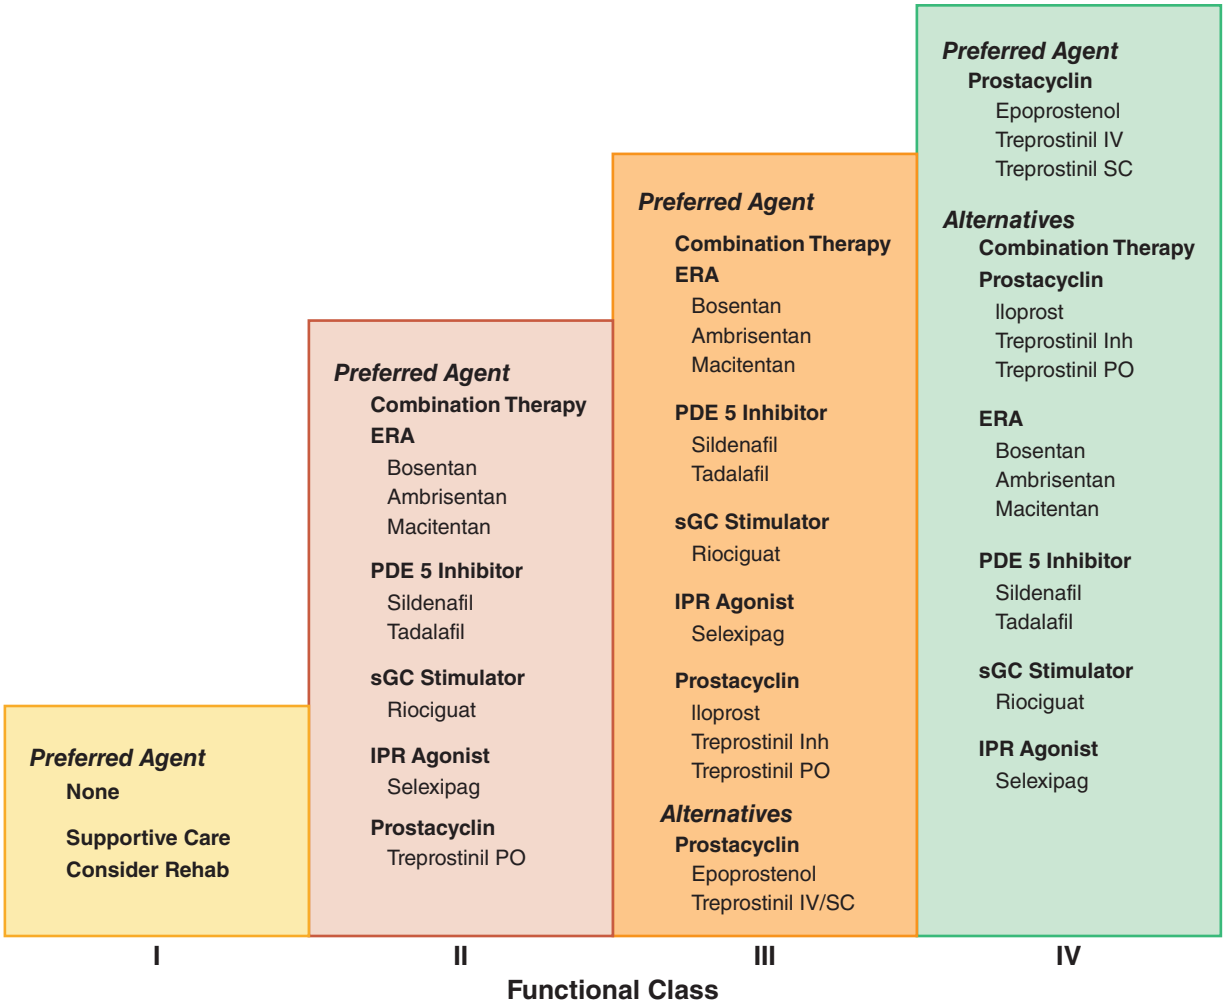

Figure 35–2 *Clinical use of PAH drugs based on functional class.* Treatment of PAH is generally based on the patient's functional classification at the time of presentation. Four functional classes have been defined for PAH: (I) no symptoms or functional limitation; (II) slight limitation of physical activity; (III) marked limitation of physical activity; and (IV) symptoms with any activity or at rest. In patients with no functional limitation, there is no specific therapy that has shown benefit in clinical trials. Expert guidelines recommend only supportive care and physical rehabilitation in this group. Patients with symptoms consistent with functional classes II and III have the best evidence for therapeutic benefits. Current guidelines suggest that up-front combination therapy, using *ambrisentan* and *tadalafil* in particular, should be considered in all treatment-naïve patients in these categories unless they are unwilling or unable to tolerate this therapy (Klinger et al., 2019). First-line therapeutics include oral agents such as endothelin receptor antagonists (ERAs), PDE5 inhibitors, sGC stimulators, oral or inhaled PGI_2 analogues, and the IPR agonist *selexipag*. The most severely limited patients, those in functional class IV, or those with evidence of right heart dysfunction should be started on the most potent vasodilators, which include the intravenous and subcutaneous formulations of PGI_2 analogues. Sequential combination therapy using agents from multiple mechanistic classes should be considered if patients are not meeting treatment goals.

Although PH often complicates other diseases of the heart and lungs (see Box 35–1), efficacy of drug therapy had been documented only for primary PAH and CTEPH. In 2021, inhaled *treprostinil* was shown to improve functional capacity in patients with PH associated with interstitial lung disease and was also associated with lower risk of clinical worsening, improved biomarker levels, and fewer exacerbations of underlying lung disease (Waxman et al., 2021). Supportive care therapies described in other chapters include volume management with diuretics (e.g., *furosemide*), anticoagulants (e.g., *warfarin*) for patients at high risk for thrombotic disease, supplemental oxygen therapy for hypoxic patients, and inotropic therapy (e.g., *milrinone*) to improve cardiac contractility in patients with RV dysfunction.

Pharmacotherapy for Pulmonary Arterial Hypertension

Pharmacotherapy for PAH targets the major pathogenic mechanisms of the disease—pulmonary vascular remodeling (e.g., concentric pulmonary vascular thickening and intraluminal obliteration), sustained pulmonary vasoconstriction, *in situ* thrombosis, and pulmonary vascular wall stiffening—with the goals of attenuating the development and progression of PAH and reversing these pathological changes in patients with established PAH. Currently available PAH therapeutics are classified based on their cellular and molecular mechanisms (Humbert and Ghofrani, 2016):

- NO and stimulators of cGMP and PKG signaling
- Membrane receptor agonists
- Membrane receptor antagonists
- Ion channel blockers and openers

Stimulators of cGMP and PKG Signaling

Nitric oxide is synthesized mainly in vascular ECs and diffuses into vascular smooth muscle cells (PASMCs) to activate sGC. Activated sGC generates cGMP, which in turn is hydrolyzed by cyclic nucleotide PDE5 to 5′-GMP (Figure 35–3). cGMP is an intracellular second messenger that signals through (1) cGMP-dependent PKG, the principal downstream mediator of cGMP, and (2) cyclic nucleotide–gated and hyperpolarization-activated cyclic nucleotide–gated channels (Craven and

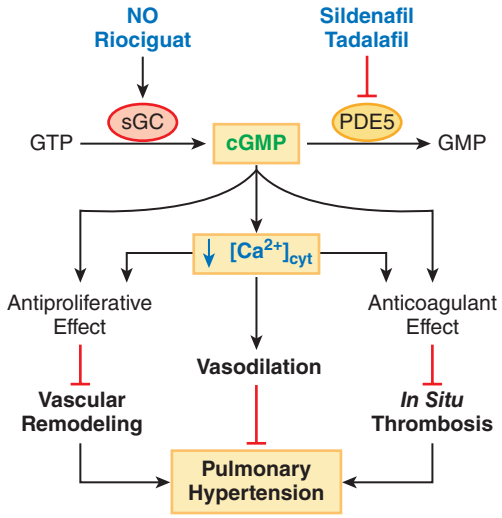

Figure 35–3 *Stimulators of NO/cGMP signaling.* NO activates sGC to produce cGMP, which has vasodilating effects through decreased $[Ca^{2+}]_{cyt}$ as well as anticoagulant and antiproliferative effects that are both dependent and independent of $[Ca^{2+}]_{cyt}$. cGMP is degraded primarily by PDE5 in PASMCs, which is targeted by the PDE5 inhibitors *sildenafil* and *tadalafil*.

Zagotta, 2006). Increased cellular cGMP exerts relaxant and antiproliferative effects on PASMCs and myofibroblasts through activation of cGMP-gated K^+ channels, inhibition of Ca^{2+}-permeable channels (e.g., L-type VDCCs, transient receptor potential cation channels), and attenuation of several specific intracellular signaling cascades that are related to cell proliferation, growth, and migration (the cAMP-PKA pathway exerts similar effects). The drugs currently available for the treatment of PAH in this category include inhaled NO, activators of sGC, and inhibitors of PDE5.

The enzymic catalysts of cGMP formation in tissues are soluble (sGC) and particulate (pGC) or plasma membrane (mGC) GC. NO stimulates sGC, while the natriuretic peptides stimulate mGC (see Chapter 3 for information on the structure and mechanisms of activation of these enzymes). The sGC is the source of cGMP synthesis on which therapeutic agents for PAH rely. In the lung, activation of the cGMP-PKG pathway causes relaxation of smooth muscle, inhibits proliferation of bronchial and vascular smooth muscle cells, and has an antiproliferative effect (and can induce apoptosis) in pulmonary vascular smooth muscle cells and ECs (Figure 35–3).

Nitric Oxide

Nitric oxide is biosynthesized from the terminal nitrogen of L-arginine by nitric oxide synthase (see Chapter 3). Endogenous NO levels are reduced in patients with PAH, PH associated with connective tissue disease, chronic obstructive pulmonary disease, and interstitial lung disease (Girgis et al., 2005; Kawaguchi et al., 2006).

ADME. NO is a soluble gas. *Inhaled NO* is a gaseous blend of NO and N_2. NO must be compressed and stored with an inert gas such as N_2 to minimize the exposure to O_2, decreasing the risk of the accumulation of nitric dioxide (NO_2). Inhaled NO increases the PaO_2 by preferentially vasodilating better-ventilated lung regions from poorly inflated lung areas (i.e., with low ventilation/perfusion [V/Q] ratios). Inhaled NO is generally administered continuously or with a pulsing device that is rapidly triggered with the onset of inspiration; careful monitoring of response is warranted (Griffiths and Evans, 2005). Inhaled NO is a selective pulmonary vasodilator. Its acute and relatively specific effects on PAP and PVR are due to its route of administration and short half-life (2–6 sec), which is primarily a result of the rapid inactivation of NO by hemoglobin binding and oxidation to nitrite; the nitrite interacts with oxyhemoglobin, leading to the formation of nitrate and met-hemoglobin (Bueno et al., 2013). Nitrate has been identified as the predominant NO metabolite excreted in the urine, accounting for more than 70% of the NO dose inhaled (Ichinose et al., 2004).

Clinical Use. NO can acutely lower PAP and PVR without significantly altering systemic arterial pressure. Inhaled NO is used for the treatment of term and near-term neonates with persistent PH of the newborn and acute hypoxemic respiratory failure (Abman, 2013). Acute vasodilator testing is another well-established but off-label use of inhaled NO in adult patients with PAH. Vasodilator testing is performed in the course of deciding whether a patient might derive clinical benefit from Ca^{2+} channel blockade therapy (e.g., *nifedipine*) (Abman, 2013). In the treatment of PAH, a 30% decrease in PVR during the inhalation of NO (10 ppm for 10 min) has been used to identify an association with vascular responsiveness and a favorable response to calcium channel blockers (CCBs) in a small cohort of patients with PAH (McLaughlin et al., 2009).

Adverse Effects and Precautions. High doses of inhaled NO (500–1000 ppm) can be lethal. However, NO doses of less than 40 ppm are well tolerated chronically for up to 6 months and do not cause methemoglobinemia in adults who have normal methemoglobin reductase activity (Griffiths and Evans, 2005). In neonates, methemoglobin accumulation has been investigated during the first 12 h of exposure to 0, 5, 20, and 80 ppm of inhaled NO (Abman, 2013). In the study, methemoglobin concentrations increased during the first 8 h of NO exposure. The mean methemoglobin level remained below 1% in the placebo group and in the 5- and 20-ppm groups but reached approximately 5% in the 80-ppm inhaled NO group.

Drug interactions between properly dosed NO and other medications are not expected, but side effects may include noisy breathing, hematuria, or possibly, atelectasis. Overdosage with inhaled NO manifests as elevations in methemoglobin and pulmonary toxicities associated with inspired NO_2, including acute respiratory distress syndrome. Elevations in methemoglobin reduce the O_2 delivery capacity of the circulation. Based on clinical studies, NO_2 levels greater than 3 ppm or methemoglobin levels greater than 7% are treated by reducing the dose of, or discontinuing, inhaled NO therapy (Abman, 2013). Methemoglobinemia that does not resolve after reduction or discontinuation of inhaled NO therapy can be treated with intravenous vitamin C, intravenous methylene blue, or blood transfusion, based on the clinical situation.

Inhaled NO gas has limitations: Dosing must be individualized and frequently adjusted; delivery is cumbersome and expensive; off-target effects from reactive nitrogen species are possible; and rebound PH may appear when NO administration is interrupted. The oxidative product of NO metabolism, the inorganic anion nitrite, NO_2^-, is relatively stable compared to NO ($t_{1/2}$ = 51 min); NO_2^- can be reduced back to NO under physiological and pathological hypoxia by enzymatic and nonenzymatic processes and thus can serve as an intravascular endocrine reservoir of potential NO bioactivity (Bueno et al., 2013). Other NO donor drugs such as *sodium nitroprusside* and *nitroglycerin* offer protective benefits in PVR or remodeling, but when administered intravenously, these drugs have limited use given their significant systemic vasodilating effects.

Riociguat

In patients with NO deficiency due to dysfunctional endothelial nitric oxide synthase or arginine insufficiency, activation of sGC increases signaling through the cGMP-PKG pathway and exerts a therapeutic effect (Hoeper et al., 2020; Stasch and Evgenov, 2013). *Riociguat*, a direct stimulator of sGC, has been approved to treat patients with PAH and CTEPH (Bishop, 2014; Ghofrani et al., 2013a, 2013b).

Mechanism of Action. *Riociguat* is the first-in-class stimulator of sGC. The agent exhibits a dual mode of action; it sensitizes sGC to endogenous NO, and it also directly stimulates sGC independently of NO.

ADME. The drug has excellent oral absorption, and the plasma concentration peaks approximately 1.5 h after oral intake (Stasch and Evgenov, 2013). Food does not affect the bioavailability of *riociguat*; its volume of distribution is about 30 L. *Riociguat* is metabolized by CYPs 1A1, 3A, 2C8, and 2J2. The action of CYP1A1 forms the major and active metabolite, M1, which is converted to an inactive *N*-glucuronide. The terminal elimination half-life is about 12 h in patients with PAH (7 h in healthy subjects) (Stasch and Evgenov, 2013).

Clinical Use. *Riociguat* at doses up to 2.5 mg given three times daily for 12 weeks increased walking distance and significantly delayed time to clinical worsening for patients with PAH (Ghofrani et al., 2013b). *Riociguat* was also effective in patients with CTEPH, for whom improvements in walking distance were apparent from week 2 onward (Ghofrani et al., 2013a).

Adverse Effects and Precautions. Concurrent use of *riociguat* with *nitroglycerin* or PDE5 inhibitors can cause severe hypotension and syncope. Serious adverse effects include embryo-fetal toxicity, hypotension, and bleeding. Other common adverse reactions include headache, dyspepsia, dizziness, nausea, diarrhea, vomiting, anemia, reflux, constipation, palpitations, nasal congestion, epistaxis, dysphagia, abdominal distension, and peripheral edema (Ghofrani et al., 2013a, 2013b; Stasch and Evgenov, 2013). *Riociguat* is contraindicated in PH associated with idiopathic interstitial pneumonias and may cause pulmonary edema in patients with pulmonary veno-occlusive disease. Drug interactions include antacids, smoking, strong CYP3A inducers, and strong CYP and Pgp/BCRP inhibitors. *Riociguat* is not recommended in patients with creatinine clearance less than 15 mL/min, on dialysis, or with severe hepatic impairment. Due to the potential for teratogenicity, there is an FDA-mandated Risk Evaluation and Mitigation Strategy (REMS) program for female patients.

PDE5 Inhibitors

Cyclic nucleotide PDEs comprise a superfamily of enzymes that hydrolyze 3′-5′ cyclic nucleotides to their cognate 5′ monophosphates (Omori and Kotera, 2007). PDE5, an isoform that is relatively specific for cGMP, is abundant in PASMCs (Kass et al., 2007). The physiological importance of PDE5 in the regulation of vascular tone has been most effectively demonstrated by the successful clinical use of its specific inhibitors in the treatment of erectile dysfunction and PAH (Galie et al., 2005; Ravipati et al., 2007).

Sildenafil. ***Mechanism of Action.*** *Sildenafil*, which structurally mimics the purine ring of cGMP, is a competitive and selective inhibitor of PDE5. *Sildenafil* has a relatively high selectivity (>1000-fold) for human PDE5 over other PDEs. By inhibiting cGMP hydrolysis, *sildenafil* elevates cellular levels of cGMP and augments signaling through the cGMP-PKG pathway, *provided guanylyl cyclase is active*.

ADME. The drug is rapidly absorbed and reaches a peak plasma concentration 1 h after oral administration. *Sildenafil* is cleared by the hepatic CYP3A (major route) and CYP2C9 (minor). *Sildenafil* and its major active metabolite, *N*-desmethyl sildenafil, have terminal half-lives of about 4 h. Both the parent compound and the major metabolite are highly bound to plasma proteins (96%) (Cockrill and Waxman, 2013). Metabolites are predominantly excreted into the feces (73%–88%) and to a lesser extent into the urine; unmetabolized drug is not detected in urine or feces (Muirhead et al., 2002). Clearance is reduced in the elderly (>65 years), leading to an increase in area-under-the-curve values for the parent drug and the *N*-desmethyl metabolite.

Clinical Use and Adverse Effects and Precautions. *Sildenafil*, 20 mg three times per day, improves exercise capacity, functional class, and hemodynamics. In addition to improved exercise capacity and hemodynamic parameters, *sildenafil* (initiated at 20 mg three times daily, titrated to 40–80 mg three times daily) plus long-term *epoprostenol* therapy also resulted in delayed time to clinical worsening of PAH in clinical studies.

Dose adjustments for reduced renal and hepatic function are usually not necessary except for severe hepatic and renal impairment (Cockrill and Waxman, 2013). Concomitant administration of potent CYP3A inducers (e.g., *bosentan*) will generally cause substantial decreases in plasma levels of *sildenafil* (Schwartz and Kloner, 2010). The mean reduction in the bioavailability of *sildenafil* (80 mg three times a day) when coadministered with *epoprostenol* is 28% but is not thought to be clinically relevant. CYP3A inhibitors (e.g., protease inhibitors used in human immunodeficiency virus therapy, *erythromycin*, and *cimetidine*) inhibit *sildenafil* metabolism, thereby prolonging the $t_{1/2}$ and elevating blood levels of *sildenafil*. Consistent with its mechanism of action on cGMP signaling, *sildenafil* and other PDE5 inhibitors potentiate the hypotensive effects of nitrate vasodilators, producing dangerously low blood pressure. Thus, the administration of PDE5 inhibitors to patients receiving nitrates in any form is contraindicated. In any event, the patient's underlying cardiovascular status and concurrent use of hypotensive agents (e.g., nitrate vasodilators, α adrenergic antagonists) must be considered prior to use of this class of drugs. Important, but rare, adverse effects include permanent vision loss, hearing impairment, and priapism. *Sildenafil* use is not recommended in children as chronic use has been associated with mortality (Barst et al., 2014). Use of PDE5 inhibitors is not recommended in PH secondary to sickle cell disease as use has been associated with serious vaso-occlusive crises (Machado et al., 2011).

Headache (16%) and flushing (10%) are the most frequently reported side effects. Patients taking *sildenafil* or *vardenafil* may notice a transient blue-green tinting of vision due to inhibition of retinal PDE6, which is involved in phototransduction (see Chapter 74).

Other PDE5 Inhibitors. *Vardenafil* is structurally similar to *sildenafil* and a potent inhibitor of PDE5. Although not FDA-approved for PAH in the U.S., its clinical efficacy in PAH appears similar to that of *sildenafil* (Cockrill and Waxman, 2013). *Tadalafil*, another PDE5 inhibitor used for the treatment of PAH, differs structurally from *sildenafil* and has a longer half-life. It is recommended to reduce the *tadalafil* starting dose or avoid use in patients with renal/hepatic impairment. *Tadalafil* is contraindicated with concurrent guanylate cyclase stimulators and has been associated with toxic skin reactions (Stevens-Johnson syndrome and exfoliative dermatitis). See Table 49–2 for comparative pharmacokinetic data of PDE5 inhibitors.

Prostacyclin Receptor Agonists

Prostacyclin (PGI_2) is synthesized in and released from vascular ECs (and other vascular cells) and exerts relaxant and antiproliferative effects on vascular smooth muscle cells. Similar to NO, endogenous PGI_2 is considered an endothelium-derived relaxing factor. Decreased PGI_2 synthesis occurs in patients with idiopathic PAH, a finding that provided the rationale for using PGI_2 and its analogues for treatment of PAH (Christman et al., 1992).

Mechanism of Action. Prostacyclin binds to the prostacyclin receptor (IPR) in the plasma membrane of PASMCs and activates the G_S-AC-cAMP-PKA pathway (Figure 35–4). PKA continues the signaling cascade by (1) decreasing $[Ca^{2+}]_{cyt}$ via activating K^+ channels (which causes membrane hyperpolarization and repolarization, leading to closure of VDCCs) and (2) inhibiting myosin light chain kinase, thereby causing smooth muscle relaxation and vasodilation (Olschewski et al., 2004; Yuan et al., 1996). Activated PKA can also exert an antiproliferative effect on PASMCs by inhibiting the signaling cascades of hedgehog, ERK/p21, and Akt/mTOR. Inhibition of cyclic nucleotide PDEs, mainly PDE3 and PDE4, enhances the cAMP-PKA–mediated relaxant and antiproliferative effects on vascular smooth muscle cells.

Epoprostenol (Prostacyclin)

Clinical Use, Adverse Effects, and Precautions. The first synthetic PGI_2, *epoprostenol*, has dose-dependent vasodilatory effects on both the systemic and pulmonary vasculature and increases cardiac output in patients with PAH (Rubin et al., 1982). *Epoprostenol*'s short half-life (3–5 min) requires the use of a drug delivery pump system for continuous intravenous infusion to achieve long-term efficacy in the treatment of PAH. In a clinical trial, *epoprostenol* treatment caused significant improvements in pulmonary hemodynamics, patient symptoms, and survival over a 12-week period (Barst et al., 1996).

Epoprostenol is light and temperature sensitive, although a more recent thermostable formulation is now available that permits its use at room temperature (20°C–25°C). This agent remains a mainstay of PAH treatment, particularly in advanced stages of the disease. Adverse effects of *epoprostenol* are similar for the entire class of PGI_2 analogues and

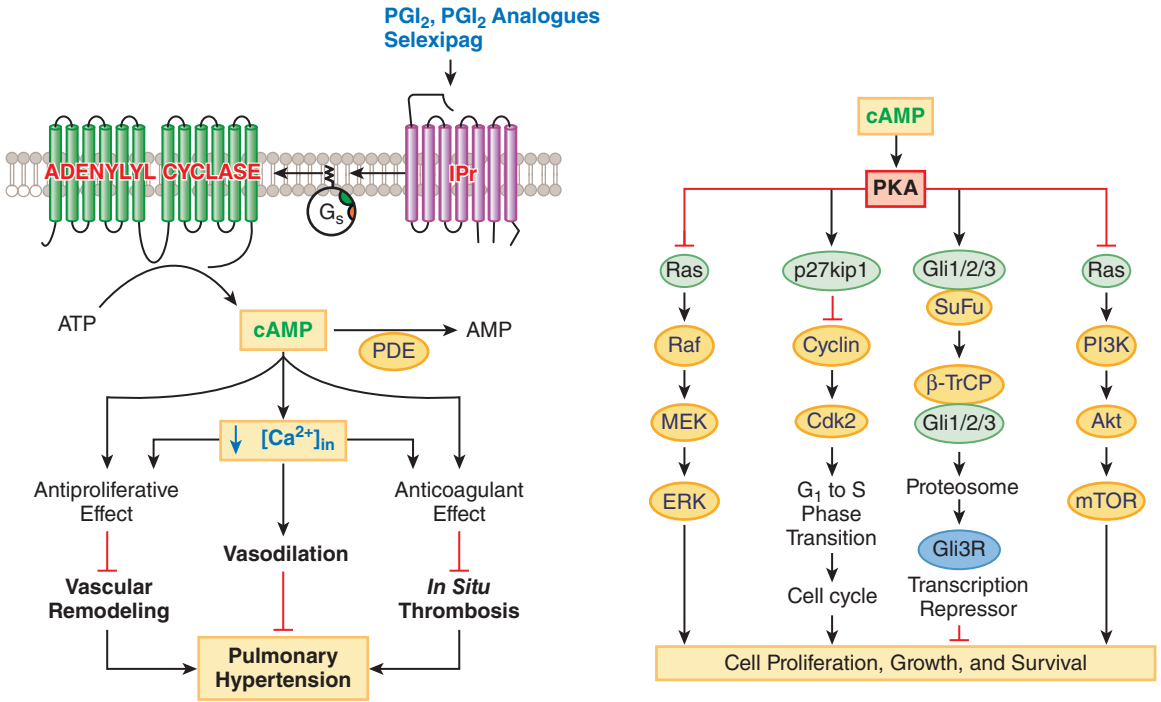

Figure 35–4 *Membrane receptor agonists that increase cAMP.* Therapies targeting the IPr, including PGI_2, PGI_2 analogues, and *selexipag*, increase cAMP through stimulation of its production by adenylyl cyclase. **A.** The vasodilating properties of cAMP are produced through decreased $[Ca^{2+}]_{cyt}$ as well as anticoagulant and antiproliferative effects that are both dependent and independent of $[Ca^{2+}]_{cyt}$. **B.** The antiproliferative effects of cAMP are manifested through numerous distinct pathways, many of which are currently under investigation as therapeutic targets.

include myalgias and pain in the extremities, jaw pain, nausea, headaches, abdominal discomfort, diarrhea, flushing, dizziness, and systemic hypotension. Side effects are generally dose-dependent, and slow titration is required for the drug to be sufficiently tolerated. *Epoprostenol* is contraindicated in heart failure with reduced ejection fraction. There is an increased risk for bleeding and for pulmonary edema.

Treprostinil

Clinical Use. *Treprostinil*, a PGI_2 analogue with longer half-life than that of *epoprostenol*, is available for continuous intravenous infusion, subcutaneous infusion, inhalation, and oral delivery. The risk of bacteremia or other catheter-related complications can be reduced by subcutaneous delivery. Subcutaneous *treprostinil* has similar efficacy to intravenous formulations of *epoprostenol* and *treprostinil* (Simonneau et al., 2002). Adverse effects related to delivery into the subcutaneous tissue of the lower abdomen are common, including pain and erythema in a majority of patients; these effects subside over time. Initial dose reduction is recommended in mild-to-moderate hepatic impairment and with concomitant use of strong CYP2C8 inhibitors. Use of treprostinil in patients with severe hepatic impairment has not been well studied.

Compared to intravenous *treprostinil*, the inhaled formulation has more potent pulmonary vasodilating effects, but patients can find the dosing scheme complex: Multiple breaths are taken through a nebulizer or inhaler four times a day and slowly titrated up to a maximum of 12 breaths four times a day. Inhaled *treprostinil* has comparable hemodynamic effects to inhaled *iloprost* in patients with PAH, though with a longer duration of effect. The most common adverse effect related to inhalation is transient coughing.

Monotherapy with extended-release oral formulations of *treprostinil* is effective in patients with PAH with moderate functional impairments (Jing et al., 2013). The dose is given three times daily, starting at 0.125 or 0.25 mg and titrating up every 3 days to the maximum tolerated dose or to adequate treatment effect. Serum concentrations at a steady dose of 3 mg three times daily are thought to approximate therapeutic levels of intravenous *treprostinil*. Sequential combination therapy with oral *treprostinil* added to existing monotherapy with either an endothelin receptor antagonist or PDE5 inhibitor reduced the risk of clinical worsening and was associated with improved PAH symptoms, improved functional class, and N-terminal pro-BNP levels compared to placebo (White et al., 2020). Note that the oral tablet shell does not dissolve and can lodge in intestinal blind-end pouches and diverticula, possibly causing appendicitis and diverticulitis.

Iloprost

Clinical Use, Adverse Effects, and Precautions. The first PGI_2 analogue available in an inhaled formulation, *iloprost*, was designed to target the pulmonary vasculature and lessen systemic side effects. Inhalation has potent vasodilatory effects on the pulmonary circulation, with less systemic vasodilation than intravenous PGI_2 (Olschewski et al., 1996). The effects of a single inhalation decline to baseline over 60 to 120 min, and current dosing strategies suggest 6 to 9 inhalations daily. The dose is generally titrated from 2.5 mg/inhalation to 5 mg after the first 2 to 4 weeks. *Iloprost* has minor CYP-dependent metabolism. Minor side effects common to the PGI_2 class include headache and jaw pain. Side effects specific to the inhaled formulation are cough, although this appears to resolve over time but may cause bronchospasm. Patients should avoid ingestion as well as contact with the skin and eyes. Drug interactions are limited to drugs with overlapping actions (e.g., vasodilation) and toxicities (e.g., risk for bleeding).

Selexipag

Selexipag is an orally active, selective IPR agonist that is chemically distinct and has different kinetic properties compared to PGI_2 analogues.

ADME. *Selexipag* is rapidly absorbed and hydrolyzed in the liver ($t_{1/2}$ = 1–2 h) to an active metabolite, ACT-333679 (Kaufmann et al., 2015). The active metabolite has a longer half-life, 10 to 14 h, allowing twice-daily dosing. *Selexipag* is a substrate of CYP2C8, CYP3A4, and P-glycoprotein.

Clinical Use, Adverse Effects, and Precautions. The drug is taken at a starting dose of 200 μg and titrated upward weekly to a maximum dose of 1600 μg twice daily. In phase III clinical trials, *selexipag* reduced

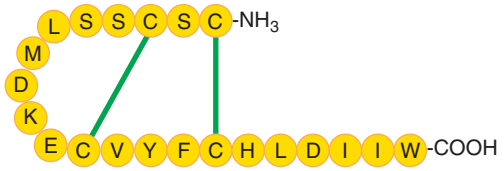
the risk of morbidity and mortality in patients with PAH (Simonneau et al., 2012; Sitbon et al., 2015). *Selexipag* is added to existing pulmonary vasodilator therapy in a majority of patients in the clinical trials for this agent. Adverse effects of *selexipag* are similar to those of PGI_2 analogues and include headache, jaw pain, nausea, dizziness, flushing, nasopharyngitis, and vomiting. Adverse effects appear to be more common when the drug is taken while fasting and wane over time. *Selexipag* is contraindicated with strong CYP2C8 inhibitors, and there are drug interactions with CYP2C8 inducers and inhibitors. Precaution should be taken with moderate or severe hepatic impairment, with dose reduction or avoidance of *selexipag*.

Beraprost

The first orally available PGI_2 analogue, *beraprost*, showed promise in early trials, but long-term trials showed no benefit over 12 months of therapy (Barst et al., 2003). As a result, *beraprost* is not approved for use in the U.S. or the European Union.

Endothelin and Endothelin Receptor Antagonists

Endothelin 1



Amino Acid Sequence of Human Endothelin 1

Biosynthesis. Endothelins are a trio of 21 amino acid peptides, each the product of a different gene, produced through a pre-pro and pro-peptide sequence by the endothelin-converting enzyme (ECE) types 1 and 2. ECE-1 is the rate-limiting step in ET-1 synthesis. Each mature ET peptide contains two disulfide bridges. ET-1, the predominant form, is encoded by the *EDN1* gene and produced in vascular ECs, although other cell types can also produce endothelin. A variety of cytokines, angiotensin II, and mechanical stress enhance ET-1 production. NO and PGI_2 reduce *EDN1* gene expression. ETs interact with two GPCRs, the ET_A and ET_B receptors, as described below. ET-1 is cleared by interaction with the ET_B receptor and via proteolytic degradation by neutral endopeptidase NEP24.11. Davenport and colleagues (2016) have reviewed key concepts of the biosynthesis, signaling, and pharmacology of ETs.

Endothelin Signaling. Endothelin 1 was discovered as a potent, endothelium-derived constricting factor (Yanagisawa et al., 1988). The constrictor response is mediated by the ET_A receptor, which is localized on PASMCs. The ET_B receptor is present on both PASMCs and pulmonary arterial endothelial cells. Binding of ET-1 to ET_A receptor on PASMCs activates the G_q-PLC-IP_3-Ca^{2+} and diacylglycerol (DAG) Ca^{2+}-PKC pathways (Figure 35–5 and Chapter 3). IP_3 activates the Ca^{2+} release channel on intracellular Ca^{2+} storage organelles, thereby mobilizing Ca^{2+} and increasing $[Ca^{2+}]_{cyt}$. The elevated cytosolic Ca^{2+} produces vasoconstriction (Figure 35–5). ET-1 is also a mitogenic factor that exerts proliferative effects on many types of cells, including vascular smooth muscle cells and myofibroblasts via intracellular signaling cascades (e.g., PI3K/Akt/mTOR and Ras/ERK/p21 pathways) (Davenport et al., 2016). The activation of ET_B receptors on ECs mediates vasodilation by increasing production of NO and PGI_2 and can inhibit ET-1 production.

Rationale for Antagonizing ET's Effects in PAH. Endothelin 1 is implicated as a contributory factor in idiopathic PAH (Giaid et al., 1993): Plasma ET-1 levels are increased up to 10-fold in patients with PAH and correlate well with severity of disease and the elevation of right atrial pressure. There are no clinically available specific inhibitors of ECE-1, the rate-limiting step in ET-1 synthesis, but several orally effective small-molecule antagonists of ET receptors have been developed. Despite the opposing effects of ET_A and ET_B receptor activation, pharmacological targeting of specific ET_A receptors has not led to significantly altered clinical responses compared to dual antagonism (e.g., antagonism of ET-1 binding to both ET_A and ET_B receptors) in treating PAH.

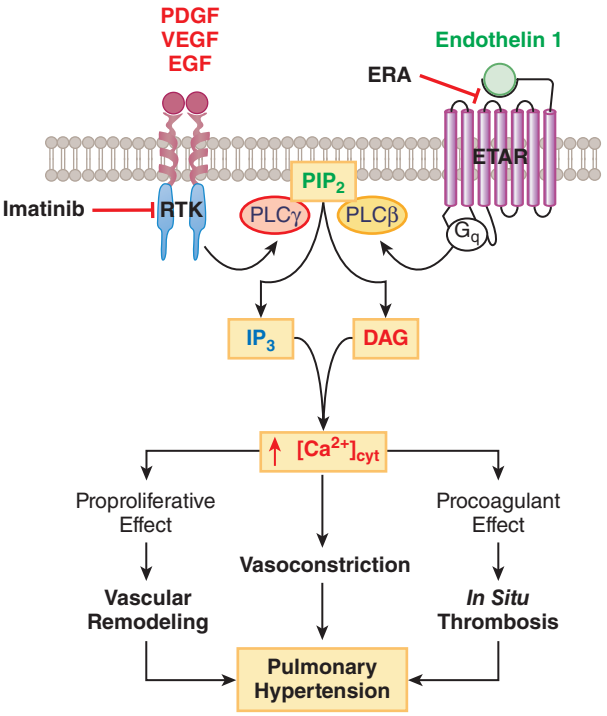


Figure 35–5 *Inhibition of receptor-mediated activation of PLC isoforms on pulmonary artery smooth muscle cells can reduce vasoconstriction.* Endothelin, acting via the ET_A-G_q-PLC_β-IP_3 pathway, can cause vasoconstriction, a response that endothelin receptor antagonists can inhibit. Growth factors such as PDGF, VEGF, and EGF, acting through receptor tyrosine kinases (RTKs), can activate PLC_γ and initiate contraction in a similar fashion; imatinib, a tyrosine kinase inhibitor (see Chapter 71), can inhibit the activation PLC_γ via RTKs, thereby reducing pulmonary artery contraction.

Endothelin Receptor Antagonists

Available ET receptor antagonists are *bosentan*, *macitentan*, and *ambrisentan*.

Commonalities. Endothelin antagonists generally share adverse effects. Common side effects of the class include headache, pulmonary edema, peripheral edema, anemia, and nasal congestion/pharyngitis, with a risk of testicular atrophy and infertility. *Bosentan* may increase liver transaminases, which should be monitored closely, and is contraindicated in patients with moderate-to-severe liver disease; the elevation of liver enzymes generally resolves after discontinuation of treatment. Given the concerns for hepatotoxicity in this class, *ambrisentan* and *macitentan* are not recommended in moderate or severe hepatic impairment.

The three available ET antagonists are metabolized by CYP3A4 and to some extent by CYPs 2C9 and 2C19. Repeated *bosentan* dosing elicits induction of CYPs 3A4 and 2C9, reducing exposure to drugs that are also metabolized by these CYPs (contraceptives, *warfarin*, some statins; coadministration with *cyclosporine* and *glyburide* is contraindicated); likewise, coadministration of *bosentan* or *macitentan* with a CYP inducer such as *rifampin* should be avoided. Inhibitors of these CYPs (e.g., *ketoconazole* and *ritonavir*) can increase *bosentan* and *macitentan* exposure (O'Callaghan et al., 2011).

The ET receptor antagonists are potent teratogens and should be used with caution in women of childbearing age. These agents must not be used in pregnant patients, and the FDA has mandated a REMS program due to hepatic (*bosentan*) and/or fetal toxicities (*bosentan*, *ambrisentan*, and *macitentan*). Documentation of a negative pregnancy test prior to initiation of therapy and a clear contraceptive plan are recommended,

and fertile women must use two acceptable methods of birth control while taking ET antagonists.

Bosentan. *Bosentan* is a nonpeptide, orally effective, competitive antagonist of ET_A and ET_B receptors. In patients with PAH with mild-to-severe functional impairment (functional classes II–IV), *bosentan* improves symptoms, functional capacity, and pulmonary hemodynamic parameters (Rubin et al., 2002). *Bosentan* is usually started at 62.5 mg twice daily, increasing to 125 mg twice daily after 4 weeks. *Bosentan* is metabolized by hepatic CYPs 2C9 and 3A4 with a $t_{1/2}$ of about 5 h, with excretion of metabolites in the bile. There is a drug interaction with hormonal contraceptives that can reduce the effectiveness of the contraceptives.

Macitentan. *Macitentan* is an orally active, competitive ET_A and ET_B receptor antagonist. At a dose of 10 mg daily, *macitentan* improves the time to disease progression or death in PAH and improves symptoms, functional capacity, and pulmonary hemodynamic measurements (Pulido et al., 2013). The drug is relatively well tolerated and has thus far not been associated with elevation of hepatic enzymes, but caution is recommended. *Macitentan* is metabolized by CYPs to an active metabolite; the $t_{1/2}$ of the parent compound is about 16 h and that of the active metabolite about 48 h, such that the metabolite contributes about 40% of the total pharmacologic activity over time.

Ambrisentan. Unlike *bosentan* and *macitentan*, *ambrisentan* is a relatively selective ET_A antagonist (~4000 times greater affinity for ET_A than ET_B). *Ambrisentan* is initiated at a dose of 5 mg daily and increased to a maximum of 10 mg daily. The $t_{1/2}$ is 9 h at steady state. Hepatic enzyme abnormalities are much less common than with *bosentan*, and if encountered, current recommendations suggest excluding all other causes of hepatotoxicity before discontinuing *ambrisentan*. Elimination is largely via nonrenal pathways that have not been extensively characterized. There is some metabolism by CYPs 3A4 and 2C19, followed by glucuronidation; thus, drug interactions might be expected, although clinically relevant interactions have not been reported. *Ambrisentan* is contraindicated in patients with idiopathic pulmonary fibrosis. Due to concerns of hepatotoxicity with the class, *ambrisentan* is not recommended in patients with moderate to severe hepatic impairment.

Receptor Tyrosine Kinase Inhibitors

Many growth factors and mitogenic factors are reportedly upregulated in tissues of patients with PAH. Elevations of ET-1, ATP, VIP, platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), fibroblast growth factor, and insulin-like growth factor in lung tissue, vascular smooth muscle cells, and peripheral blood have been assessed in PAH (Weiss et al., 2021). These myriad of mitogenic factors can activate TKRs, such as PDGF and EGF receptors. Activation of these receptors can induce cell proliferation, growth, migration, and contraction in PASMCs, pulmonary arterial endothelial cells, and pulmonary vascular fibroblasts. With these actions as a rationale, antagonists of TKRs have been tested as therapeutics for PAH.

Imatinib

Imatinib was initially developed as targeted treatment of chronic myelogenous leukemia by targeting the ABL TKR; the compound is now known to have many other targets, one of which is the PDGF receptor that has been linked to vascular smooth muscle hypertrophy in the development of PAH (Humbert et al., 1998). *Imatinib* as add-on therapy for refractory PAH has shown some efficacy in both case reports and a clinical trial, although serious adverse reactions, particularly subdural hematoma, are of concern (Hoeper et al., 2013). A proposed study of imatinib dosing, of factors affecting the response to imatinib (including patient genotype), and of potential biomarkers of imatinib's effecttiveness in PAH patients may provide definitive information on the tolerability and efficacy of imatinib in treating PAH (Wilkins et al., 2021).

Calcium Channels and Their Blockers

An increase in $[Ca^{2+}]_{cyt}$ in PASMCs causes pulmonary vasoconstriction and is an important stimulant of proliferation, migration, and vascular remodeling. $[Ca^{2+}]_{cyt}$ in PASMCs can be increased by Ca^{2+} influx through membrane Ca^{2+} channels and Ca^{2+} mobilization through the Ca^{2+} release channels in the membranes of the sarcoplasmic reticulum (SR) or endoplasmic reticulum (ER). $[Ca^{2+}]_{cyt}$ can be decreased in three ways: by Ca^{2+} extrusion via the ATP-dependent Ca^{2+} pump in the plasma membrane, export of Ca^{2+} by the Na^+/Ca^{2+} exchanger, and sequestration of cytosolic Ca^{2+} into the SR or ER by SR/ER Ca^{2+}-ATPase. There are three classes of Ca^{2+}-permeable channels functionally expressed in the plasma membrane of PASMCs: (1) VDCCs, (2) ROCs, and (3) store-operated Ca^{2+} channels. These are targets in the current therapy of PAH and putative targets for therapeutics of the future.

Voltage-Dependent Ca^{2+} Channel Blockers

A rare subset of patients (typically less than 5%–15% of all PAH confirmed by right heart catheterization) is considered vasoreactive, which is defined as a significant decrease in mean PAP (>10 mmHg drop to absolute mean PAP <40 mmHg) while preserving cardiac output during the administration of inhaled NO or intravenous injection of PGI_2 or *adenosine* (Rich and Brundage, 1987). Vasoreactive patients can achieve prolonged survival, sustained functional improvement, and hemodynamic improvement with CCB therapy (Hemnes et al., 2015; Rich and Brundage, 1987). The utility of CCB therapy in patients with vasoreactive PAH is supported by a series of well-designed observational studies (Hemnes et al., 2015; Rich and Brundage, 1987; Sitbon et al., 2005).

Clinical Use. Therapy with CCB can be initiated with a low dose of long-acting *nifedipine*, *amlodipine*, *diltiazem*, or *verapamil*. The dose is then increased to the maximal tolerated dose. Systemic blood pressure, heart rate, and oxygen saturation should be carefully monitored during titration. Sustained-release preparations of *nifedipine, verapamil*, and *diltiazem* are available that minimize the adverse effects of therapy, especially systemic hypotension. Patients who respond (defined as asymptomatic or minimal symptoms) to CCB therapy with a dihydropyridine or *diltiazem* are typically reassessed for sustained responses (Figure 35–6).

Adverse Effects and Precautions. Adverse effects are common with CCB therapy. Systemic vasodilation may cause hypotension, while pulmonary vasodilation may reduce hypoxic pulmonary vasoconstriction. Loss or inhibition of hypoxic pulmonary vasoconstriction can worsen

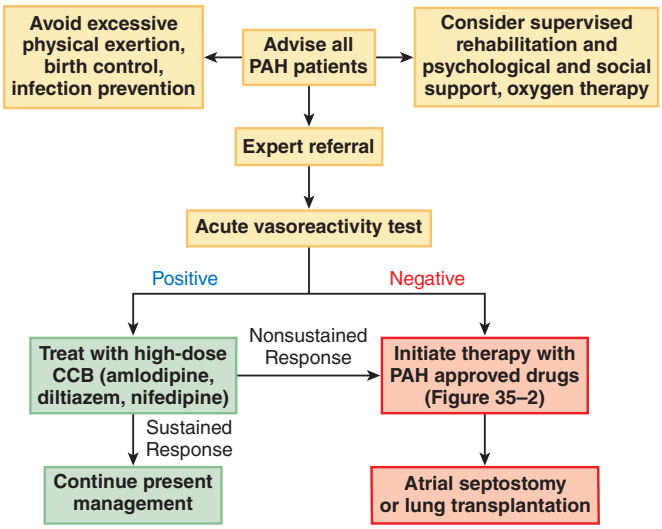

Figure 35–6 *Treatment algorithm for use of CCBs in PAH.* Vasoreactivity testing is used to identify the minority of patients who may have a substantial benefit from high-dose CCB therapy. These individuals must be monitored closely to ensure a sustained response. Patients without a positive vasodilator response should potentially be started on therapies approved for PAH based on symptoms at presentation. The patients with the most severe disease who fail to respond to therapy may need referral for surgical intervention to treat their disease.

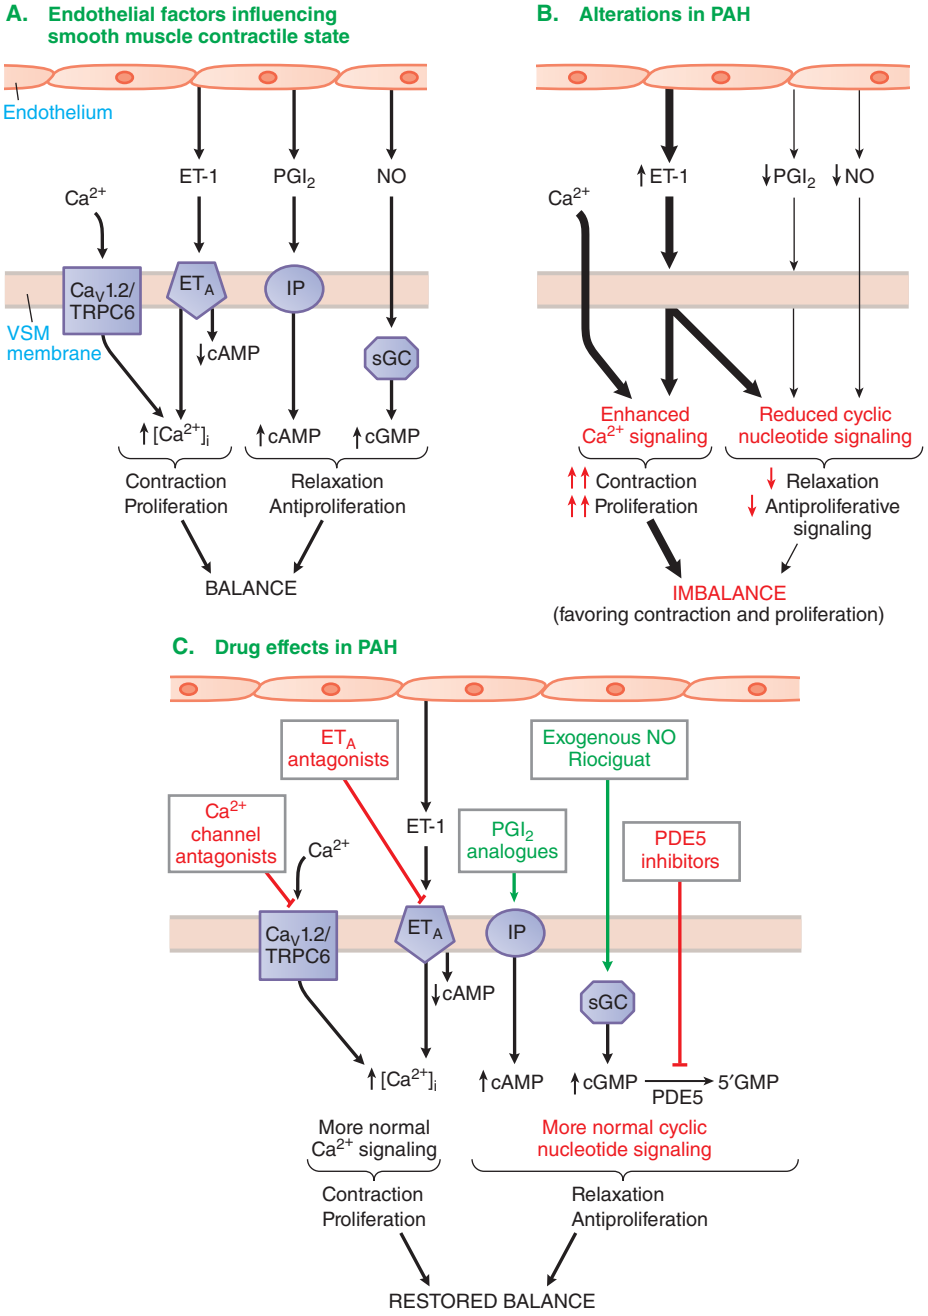

Figure 35–7 *Interactions between endothelium and vascular smooth muscle in PAH.* **A. Balance.** In normal pulmonary artery, there is a balance between constrictor and relaxant influences that may be viewed as competition between Ca^{2+} signaling pathways and cyclic nucleotide signaling pathways in vascular smooth muscle (VSM) cells. ET-1 binds to the ET_A receptor on VSM cells and activates the G_q-PLC-IP_3 pathway to increase cytosolic Ca^{2+}; ET-1 may also couple to G_i to inhibit cAMP production. As VSM cells depolarize, Ca^{2+} may enter via the L-type Ca^{2+} channel ($Ca_v1.2$) or transient receptor potential cation channel (TRPC6). ECs also produce relaxant factors, PGI_2 and NO. NO stimulates the sGC, causing accumulation of cGMP in VSM cells; PGI_2 binds to the IPR and stimulates cAMP production; elevation of these cyclic nucleotides promotes VSM relaxation (see Figure 35–3 and Chapters 44 and 49). **B. Imbalance.** In PAH, ET-1 production is enhanced, production of PGI_2 and NO is reduced, and the balance is shifted toward constriction and proliferation of VSM. **C. Restored balance**. In treating PAH, ET_A receptor antagonists can reduce the constrictor effects of ET-1, and Ca^{2+} channel antagonists can further reduce Ca^{2+}-dependent contraction. Exogenous PGI_2 and NO can be supplied to promote vasodilation (relaxation of VSM); the sGC can be activated pharmacologically (*riociguat*); inhibition of PDE5 can enhance the relaxant effect of elevated cGMP by inhibiting the degradation of cGMP. Thus, these drugs can reduce Ca^{2+} signaling and enhance cyclic nucleotide signaling, restoring the balance between the forces of contraction/proliferation and relaxation/antiproliferation. Remodeling and deposition of extracellular matrix by adjacent fibroblasts is influenced positively and negatively by the same contractile and relaxant signaling pathways, respectively. Effects of pharmacological agonists are noted by green arrows, and effects of antagonists by red T-bars.

V/Q mismatch and cause hypoxemia. CCBs may also be associated with deterioration of RV function because of their inhibitory effect on VDCC in cardiomyocytes. The pharmacology of CCBs is discussed in detail in Chapter 31.

PAH Drugs in Development

In addition to the PAH drugs in clinical use, there are many repurposed drugs and newly developed drugs that have therapeutic benefits in experimental models of PH. These agents have potential as future therapies for PAH:

- Long-acting treprostinil prodrug, treprostinil palmitil, for inhalation
- TGF-β/activin ligand trap (e.g., sotatercept)
- Antagonists of serotonin production, serotonin receptors, and transporters (e.g., LY393558, rodatristat ethyl)
- Allosteric antagonists of Ca^{2+}-sensing receptors (e.g., NPS2143 and calhex 231)
- Modulators of Ca^{2+}-activated and voltage-gated K^+ channels and ATP-sensitive K^+ channels (e.g., cromakalim)
- Inhibitors of the PI3K/Akt1/mTOR signaling cascades (e.g., perifosine, ipatasertib, and rapamycin derivatives sirolimus, temsirolimus, everolimus, deforolimus)
- Modulators of 5′ AMP-activated protein kinase (AMPK) (e.g., metformin)
- Inhibitors of pyruvate dehydrogenase kinase (e.g., JTT 251)
- Inhibitors of the Notch signaling pathway (e.g., DAPT and MK-0752)
- VIP (e.g., pemzivaptadil)
- Blockers of transient receptor potential cation channels (e.g., 2-APB, ML204, aniline-thiazoles, BI-749327)
- Extracellular elastase inhibitors (e.g., elafin and sivelestat)
- Rho kinase inhibitors (e.g., fasudil)
- Angiopoietin 1 inhibitors (e.g., trebananib)
- Inhibitors of bromodomain and extraterminal domain proteins (e.g., apabetalone)

Some of these drugs are already in phase III clinical trials; others are still in preclinical development.

A Pharmacologist's View of Signal Integration in PAH

As noted, an imbalance of vasoactive mediators, mitogenic and angiogenic factors, and pro- and antiapoptotic proteins plays an important role in PAH development. The pharmacological agents employed in PAH are focused on restoring the balance between contraction and proliferation on the one hand and relaxation and antiproliferation on the other, as summarized in Figure 35–7.

Drug Facts for Your Personal Formulary: *Pulmonary Hypertension Therapeutics*

Drug	Indication	Clinical Pharmacology and Tips
cGMP Signaling Modulators: PDE5 Inhibitors		
Sildenafil Tadalafil Vardenafil	• First-line therapy for moderate PAH (functional class II–III)	• Oral administration • Avoid nitrates and α adrenergic antagonists due to hypotension • Major side effects: epistaxis, headache, dyspepsia, vision or hearing loss, flushing, insomnia, dyspnea, priapism • Vardenafil, currently not recommended due to limited evidence for efficacy in PAH
cGMP Signaling Modulators: sGC Stimulator, Teratogenic (FDA-mandated REMS program for female patients)		
Riociguat	• First-line therapy for moderate PAH (functional class II–III)	• Oral administration • Efficacy confirmed in PAH patients and CTEPH patients • Side effects: headache, dyspepsia, edema, nausea, dizziness, syncope • Drug interactions with antacids, smoking, strong CYP3A inducers, and strong CYP and Pgp/BCRP inhibitors • Not recommended with severe renal impairment (creatinine clearance <15 mL/min or on dialysis) • Not recommended with severe hepatic impairment
IPr Agonists: Prostacyclin and Prostacyclin Analogues		
Epoprostenol	• First-line therapy for severe PAH (functional class IV)	• Administration by continuous IV infusion • Major side effects: jaw pain, hypotension, myalgia, flushing, nausea, vomiting, dizziness • Short half-life requires immediate medical attention to pump failure, contraindicated in heart failure • Increased risk for bleeding
Treprostinil	• Same as epoprostenol • First-line therapy for PH due to interstitial lung disease	• Available as IV, SC, inhaled, and oral preps • Longer half-life than epoprostenol with similar side effects • Local adverse effects of SC dose may improve over time • Substrate for CYP2C8 and CYP2C9, drug interaction with gemfibrozil and rifampin • Oral treprostinil tablet shell does not dissolve (can be seen in the stool and may lodge in intestinal blind-end pouch or diverticulum) • Initial dose reduction for mild-to-moderate hepatic impairment; limited data in severe hepatic impairment • Initial dose reduction with concomitant strong CYP2C8 inhibitors • Inhibits platelet aggregation and increases the risk of bleeding

Drug Facts for Your Personal Formulary: *Pulmonary Hypertension Therapeutics (continued)*

Drug	Indication	Clinical Pharmacology and Tips
Iloprost	• Alternative for epoprostenol in combination therapy for severe PAH (function class IV)	• Inhaled administration, at least 2 h apart • Side effects include flushing, hypotension, headache, nausea, throat irritation, cough, insomnia • May cause bronchospasm, pulmonary edema • Avoid systemic exposure (ingestion) as well as contact with the skin and eyes • Minor CYP-dependent metabolism
Selexipag	• Alternative for epoprostenol in combination therapy for severe PAH (functional class IV)	• Oral administration • Selective PGI_2 receptor agonist • Side effects include headache, jaw pain, nausea, diarrhea • Substrate of CYP2C8, CYP3A4, and Pgp • Drug interactions with CYP2C8 inducers/inhibitors • Contraindicated with strong CYP2C8 inhibitors • Dose reduction or avoidance recommended in moderate or severe hepatic impairment
Endothelin Receptor Antagonists: Oral Administration, Teratogenic (FDA-mandated REMS program)		
Bosentan	• First-line therapy for moderate PAH (functional class II–III) • Specific FDA indication for pediatric population aged 3 years or older with idiopathic or congenital PAH	• Monitor liver function and hemoglobin levels • Metabolized by CYP2C9, CYP3A4, and CYP2C19 • Drug interaction with hormonal contraceptives (reduced effectiveness of contraceptives) • Side effects: liver impairment, palpitations, itching, edema, anemia, respiratory infections
Ambrisentan	• First-line therapy for moderate PAH (functional class II–III)	• Side effects: edema, nasal congestion, constipation, flushing, palpitations, abdominal pain • Cyclosporin coadministration increases drug levels • Lower risk for liver toxicity
Macitentan	• First-line therapy for moderate PAH (functional class II–III)	• Metabolized by CYP3A4 • Side effects include nasopharyngitis, headache, anemia • Liver function and hemoglobin testing recommended prior to therapy
L-Type Ca^{2+} Channel Blockers		
Nifedipine (long acting) Amlodipine Diltiazem	• Use only in PAH patients with positive vasodilator testing	• Oral administration • Side effects include edema, fatigue, hypotension • Diltiazem: significant negative chronotropic and inotropic effects; avoid in bradycardia

Abbreviations: IV, intravenous; SC, subcutaneous.

Chapter 36

Blood Coagulation and Anticoagulant, Fibrinolytic, and Antiplatelet Drugs

Jeffrey I. Weitz

Blood must remain fluid within the vasculature and yet clot quickly when exposed to subendothelial surfaces at sites of vascular injury. Under normal circumstances, a delicate balance between coagulation and fibrinolysis prevents both thrombosis and hemorrhage. Alteration of this balance in favor of coagulation results in thrombosis. Thrombi, composed of platelet aggregates, fibrin, and trapped red blood cells, can form in arteries or veins. Antithrombotic drugs used to treat thrombosis include antiplatelet drugs, which inhibit platelet activation or aggregation; anticoagulants, which attenuate fibrin formation; and fibrinolytic agents, which degrade fibrin. All antithrombotic drugs increase the risk of bleeding.

This chapter reviews the agents commonly used for controlling blood fluidity, including:

- The parenteral anticoagulant *heparin* and its derivatives, which activate antithrombin, a natural inhibitor of coagulant proteases
- The coumarin anticoagulants, which lower the functional levels of multiple coagulation factors
- The direct oral anticoagulants, which inhibit factor Xa or thrombin
- Fibrinolytic agents, which degrade fibrin
- Antiplatelet agents, which attenuate platelet activation (*aspirin, clopidogrel, prasugrel, ticagrelor*, and *vorapaxar*) or aggregation (glycoprotein IIb/IIIa inhibitors)
- Vitamin K, which is required for the biosynthesis of key coagulation factors

Overview of Hemostasis: Platelet Function, Blood Coagulation, and Fibrinolysis

Hemostasis is the cessation of blood loss from a damaged vessel. Platelets first adhere to macromolecules in the subendothelial regions of the injured blood vessel, where they become activated. Adherent platelets release substances that activate nearby platelets, thereby recruiting them to the site of injury. Activated platelets then aggregate to form the primary hemostatic plug.

Vessel wall injury also exposes tissue factor (TF), which initiates the coagulation system. Activated platelets enhance activation of the coagulation system by providing a surface onto which clotting factors assemble and by releasing stored clotting factors. This results in a burst of thrombin (factor IIa) generation. Thrombin converts soluble fibrinogen to fibrin, activates platelets, and feeds back to promote additional thrombin generation. The fibrin strands tie the platelet aggregates together to form a stable clot.

The processes of platelet activation and aggregation and blood coagulation are summarized in Figures 36–1 and 36–2 (see also the animation on the Goodman & Gilman site on *AccessMedicine.com*). Coagulation involves a series of zymogen activation reactions, as shown in Figure 36–2. At each stage, a precursor protein, or zymogen, is converted to an active protease by cleavage of one or more peptide bonds in the precursor molecule. The final protease generated is thrombin. Later, as wound healing occurs, the fibrin clot is degraded. The pathway of clot removal, fibrinolysis, is shown in Figure 36–3, along with sites of action of fibrinolytic agents.

Abbreviations

ACT: activated clotting time
α_2-AP: α_2-antiplasmin
aPTT: activated partial thromboplastin time
COX: cyclooxygenase
CrCL: creatinine clearance
CYP: cytochrome P450
EPCR: endothelial protein C receptor
Gla: γ-carboxyglutamic acid
Glu: glutamic acid
GP: glycoprotein
INR: international normalized ratio
LMWH: low-molecular-weight heparin
PAI: plasminogen activator inhibitor
PAR: protease-activated receptor
PT: prothrombin time
TF: tissue factor
TFPI: tissue factor pathway inhibitor
t-PA: tissue plasminogen activator
TxA_2: thromboxane A_2
u-PA: urokinase plasminogen activator
VKOR: vitamin K epoxide reductase

Conversion of Fibrinogen to Fibrin

Fibrinogen, a 340,000-Da protein, is a dimer, each half of which consists of three pairs of polypeptide chains (designated Aα, Bβ, and γ). Disulfide bonds covalently link the chains and the two halves of the molecule. Thrombin converts fibrinogen to fibrin monomers by releasing fibrinopeptide A (a 16–amino acid fragment) and fibrinopeptide B (a 14–amino acid fragment) from the amino termini of the Aα and Bβ chains, respectively. Removal of the fibrinopeptides creates new amino termini, which form knobs that fit into preformed holes on other fibrin monomers to form a fibrin gel, which is the end point of *in vitro* tests of coagulation (see Coagulation *In Vitro*). Initially, the fibrin monomers are bound to each other noncovalently. Subsequently, factor XIII, a transglutaminase that is activated by thrombin, catalyzes interchain covalent cross-links between adjacent fibrin monomers, which strengthen the clot.

Structure of Coagulation Factors

In addition to factor XIII, the coagulation factors include factors II (prothrombin), VII, IX, X, XI, XII, high-molecular-weight kininogen, and prekallikrein. A stretch of about 200 amino acid residues at the carboxyl termini of each of these zymogens exhibits homology to trypsin and contains the active site of the proteases. In addition, 9 to 12 Glu residues near the amino termini of factors II, VII, IX, and X are converted to Gla (γ-carboxyglutamic acid) residues in a vitamin K–dependent posttranslational step. The Gla residues bind Ca^{2+} and are essential for the coagulant activities of these proteins by enabling their interaction with the anionic phospholipid membrane of activated platelets.

Nonenzymatic Protein Cofactors

TF, factor V, and factor VIII are critical cofactors in coagulation. A nonenzymatic lipoprotein cofactor, TF is not normally present on blood-contacting cells. TF is constitutively expressed on the surface of subendothelial smooth muscle cells and fibroblasts, which are exposed when the vessel wall is damaged. Activated monocytes and leukocyte-derived microvesicles also express TF on their surface. TF binds factor VIIa and enhances its catalytic efficiency. The TF–factor VIIa complex initiates coagulation by activating factors IX and X.

Factor VIII and Factor V Are Procofactors

Factor VIII circulates in plasma bound to von Willebrand factor, which serves to stabilize it. Factor V circulates in plasma, is stored in platelets in a partially activated form, and is released when platelets are activated. Thrombin releases von Willebrand factor from factor VIII and activates factors V and VIII to yield factors Va and VIIIa, respectively. Once activated, the cofactors bind to the surface of activated platelets and serve as receptors; factor VIIIa serves as the receptor for factor IXa, while factor Va serves as the receptor for factor Xa. In addition to binding factors IXa and Xa, factors VIIIa and Va bind their substrates, factors X and prothrombin (factor II), respectively.

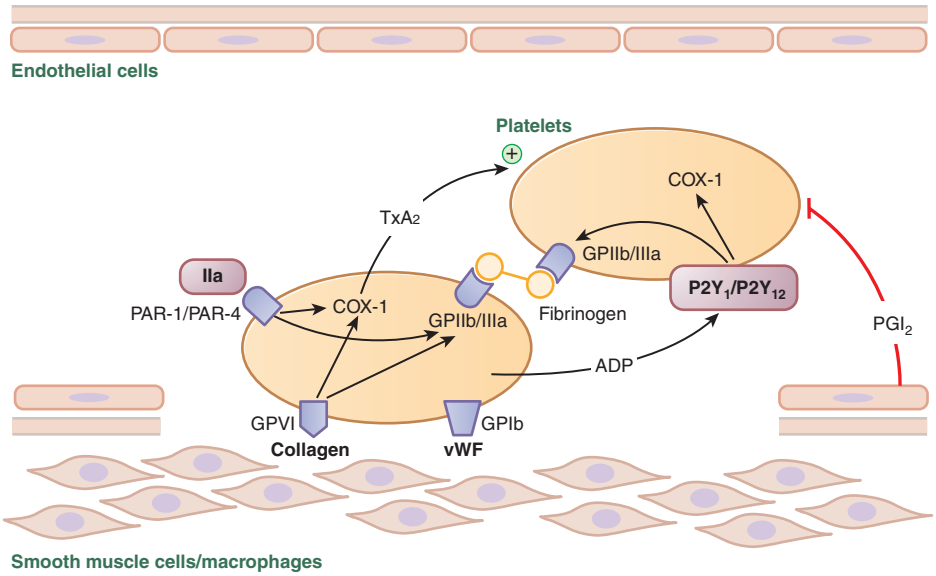

Figure 36–1 *Platelet adhesion and aggregation.* GPVI and GPIb are platelet receptors that bind to collagen and von Willebrand factor (vWF), causing platelets to adhere to the subendothelium of a damaged blood vessel. PAR-1 and PAR-4 are PARs that respond to thrombin (IIa); $P2Y_1$ and $P2Y_{12}$ are receptors for ADP; when stimulated by agonists, these receptors activate the fibrinogen-binding protein GPIIb/IIIa and COX-1 to promote platelet aggregation and secretion. TxA_2 is the major product of COX-1 involved in platelet activation. Prostacyclin (PGI_2), synthesized by endothelial cells, inhibits platelet activation.

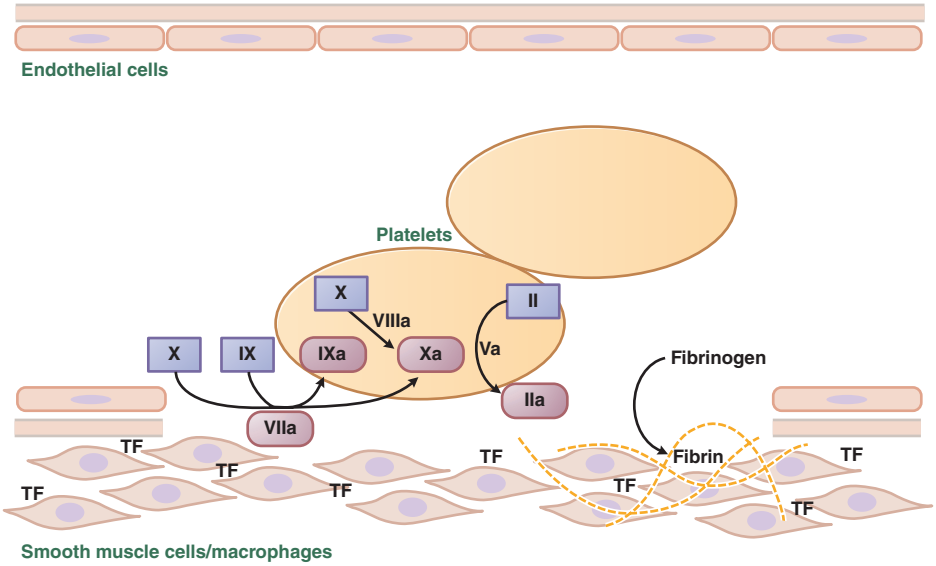

Figure 36–2 *Major reactions of blood coagulation.* Shown are interactions among proteins of the "extrinsic" (TF and factor VII), "intrinsic" (factors IX and VIII), and "common" (factors X, V, and II) coagulation pathways that are important *in vivo*. Blue rectangles enclose the coagulation factor zymogens (indicated by Roman numerals); the rounded boxes represent the active proteases. Activated coagulation factors are followed by the letter *a*: II, prothrombin; IIa, thrombin.

Activation of Prothrombin

By cleaving two peptide bonds on prothrombin, factor Xa converts it to thrombin. In the presence of factor Va, a negatively charged phospholipid surface, and Ca^{2+} (the so-called prothrombinase complex), factor Xa activates prothrombin with 10^9-fold greater efficiency than that of factor Xa alone. This maximal rate of activation only occurs when prothrombin and factor Xa contain Gla residues at their amino termini, which endows them with the capacity to bind calcium and interact with the anionic phospholipid surface.

Initiation of Coagulation

TF exposed at sites of vessel wall injury initiates coagulation via the *extrinsic pathway*. The small amount of factor VIIa circulating in plasma binds subendothelial TF, and the TF–factor VIIa complex then activates factors X and IX (see Figure 36–2). When bound to TF in the presence of anionic phospholipids and Ca^{2+} (extrinsic tenase), factor VIIa activity is increased 30,000-fold over that of factor VIIa alone.

The *intrinsic pathway* is initiated *in vitro* when factor XII, prekallikrein, and high-molecular-weight kininogen interact with kaolin, glass, or another negatively charged surface to generate small amounts of factor XIIa. Factor XII can be activated *in vivo* by contact of the blood with medical devices, such as mechanical heart valves or extracorporeal circuits, or by cell-free DNA, neutrophil extracellular traps (web-like structures composed of DNA and histones extruded from activated neutrophils), or inorganic polyphosphates released from activated platelets. Factor XIIa activates factor XI, and the resultant factor XIa then activates factor IX. Factor IXa activates factor X in a reaction accelerated by factor VIIIa, anionic phospholipids, and Ca^{2+}. Optimal thrombin generation depends on the formation of this factor IXa complex (intrinsic tenase) because it activates factor X more efficiently than the TF–factor VIIa complex.

Activation of factor XII is not essential for hemostasis, as evidenced by the fact that patients deficient in factor XII, prekallikrein, or high-molecular-weight kininogen do not have excessive bleeding. Factor XI deficiency is associated with a variable and usually mild bleeding disorder.

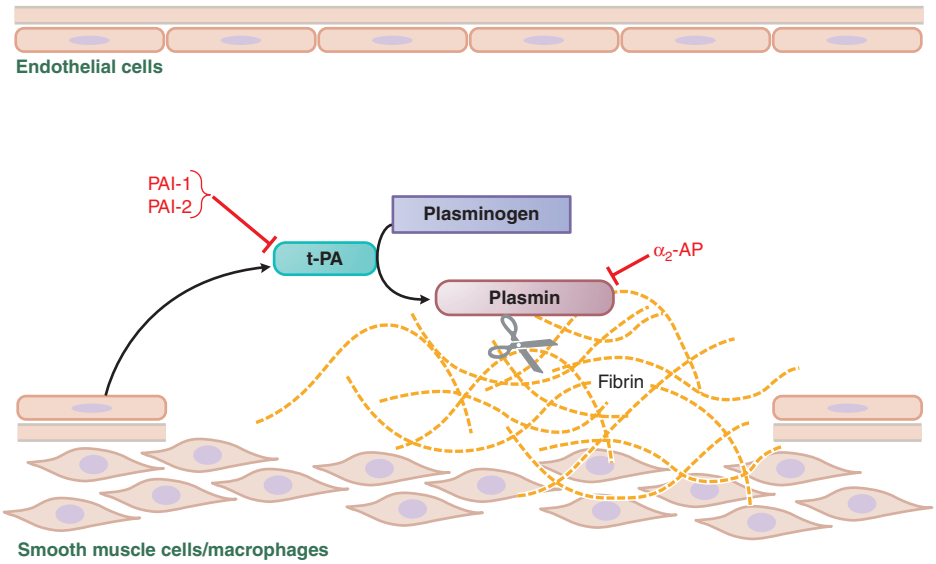

Figure 36–3 *Fibrinolysis.* Endothelial cells secrete t-PA at sites of injury. t-PA binds to fibrin and converts plasminogen to plasmin, which digests fibrin. PAI-1 and PAI-2 inactivate t-PA; α_2-AP inactivates plasmin.

In contrast, congenital deficiency of factor VIII or IX results in hemophilia A or B, respectively, and is associated with spontaneous bleeding, which can be fatal.

Fibrinolysis

The fibrinolysis pathway is summarized in Figure 36–3. The fibrinolytic system dissolves intravascular fibrin through the action of plasmin. To initiate fibrinolysis, plasminogen activators convert single-chain plasminogen, an inactive precursor, into two-chain plasmin by cleavage of a specific peptide bond. There are two distinct plasminogen activators: t-PA and u-PA, which is also known as urokinase. Although both activators are synthesized by endothelial cells, t-PA predominates under most conditions and drives intravascular fibrinolysis, while synthesis of u-PA mainly occurs in response to inflammatory stimuli and promotes extravascular fibrinolysis.

The fibrinolytic system is regulated such that unwanted fibrin thrombi are removed, while fibrin in wounds is preserved to maintain hemostasis. t-PA is released from endothelial cells in response to various stimuli. Released t-PA is rapidly cleared from blood or inhibited by plasminogen activator inhibitor (PAI) type 1 and, to a lesser extent, by PAI-2. Therefore, t-PA exerts little effect on circulating plasminogen in the absence of fibrin, and circulating α_2-antiplasmin rapidly inhibits any plasmin that is generated. The catalytic efficiency of t-PA activation of plasminogen increases more than 300-fold in the presence of fibrin, which promotes plasmin generation on its surface.

Plasminogen and plasmin bind to lysine residues on fibrin via five loop-like regions near their amino termini, which are known as kringle domains. To inactivate plasmin, α_2-antiplasmin binds to the first of these kringle domains and then blocks the active site of plasmin. Because the kringle domains are occupied when plasmin binds to fibrin, plasmin on the fibrin surface is protected from inhibition by α_2-antiplasmin and can digest the fibrin. Once the fibrin clot undergoes degradation, α_2-antiplasmin rapidly inhibits any plasmin that escapes from this local milieu. To prevent premature clot lysis, factor XIIIa mediates covalent cross-linking of small amounts of α_2-antiplasmin onto fibrin.

When thrombi occlude major arteries or veins, therapeutic doses of plasminogen activators are sometimes administered to rapidly degrade the fibrin and restore blood flow. In high doses, these plasminogen activators promote the generation of so much plasmin that the inhibitory controls are overwhelmed. Plasmin is a relatively nonspecific protease; in addition to degrading fibrin, it degrades several coagulation factors. Reduction in the levels of these coagulation proteins impairs the capacity for thrombin generation, which can contribute to bleeding. In addition, unopposed plasmin tends to dissolve fibrin in hemostatic plugs as well as that in pathological thrombi, a phenomenon that also increases the risk of bleeding. Therefore, hemorrhage is the major side effect of fibrinolytic drugs.

Coagulation *In Vitro*

Whole blood normally clots in 4 to 8 min when placed in a glass tube. Under these conditions, contact of the blood with glass activates factor XII, thereby initiating coagulation via the *intrinsic pathway*. Clotting is prevented if a chelating agent such as ethylenediaminetetraacetic acid or citrate is added to bind Ca^{2+}. Recalcified plasma normally clots in 2 to 4 min. The clotting time after recalcification is shortened to 26 to 33 sec by the addition of negatively charged phospholipids and particulate substances, such as silica (silicon dioxide), kaolin (aluminum silicate), or celite (diatomaceous earth), which activate factor XII; the measurement of this is termed the *activated partial thromboplastin time* (aPTT). Alternatively, recalcified plasma clots in 12 to 14 sec after addition of "thromboplastin" (a mixture of TF and phospholipid) and calcium; the measurement of this is termed the *prothrombin time* (PT).

Natural Anticoagulant Mechanisms

Platelet activation and coagulation do not normally occur within an intact blood vessel. Thrombosis is prevented by several regulatory mechanisms that require healthy vascular endothelium. Nitric oxide and prostacyclin synthesized by endothelial cells inhibit platelet activation, as does CD39, an ADP- and ATP-degrading enzyme expressed on the surface of endothelial cells.

Antithrombin is a plasma protein that inhibits coagulation enzymes of the extrinsic, intrinsic, and common pathways. Heparan sulfate proteoglycans synthesized by endothelial cells enhance the activity of antithrombin by about 1000-fold. Another regulatory system involves protein C, a plasma zymogen that is homologous to factors II, VII, IX, and X; its activity depends on the binding of Ca^{2+} to Gla residues within its amino terminal domain. Protein C binds to endothelial protein C receptor (EPCR), which presents it to the thrombin-thrombomodulin complex for activation. Activated protein C then dissociates from EPCR, and, in combination with protein S, its nonenzymatic Gla-containing cofactor, activated protein C degrades factors Va and VIIIa. Without these activated cofactors, the rates of activation of prothrombin and factor X are greatly diminished, and thrombin generation is attenuated. Congenital or acquired deficiency of protein C or protein S is associated with an increased risk of venous thrombosis.

Tissue factor pathway inhibitor (TFPI) is a natural anticoagulant found in the lipoprotein fraction of plasma or bound to endothelial cell surface. TFPI first binds and inhibits factor Xa, and this binary complex then inhibits factor VIIa bound to TF. By this mechanism, factor Xa regulates its own generation.

Parenteral Anticoagulants

Heparin, Low-Molecular-Weight Heparin, Fondaparinux

Heparin and Its Standardization

Heparin, a glycosaminoglycan found in the secretory granules of mast cells, is synthesized from UDP-sugar precursors as a polymer of alternating D-glucuronic acid and *N*-acetyl-D-glucosamine residues. *Heparin* is commonly extracted from porcine intestinal mucosa, which is rich in mast cells, and preparations may contain small amounts of other glycosaminoglycans. Various commercial *heparin* preparations have similar biological activity (~150 USP units/mg). A USP unit reflects the quantity of *heparin* that prevents 1 mL of citrated sheep plasma from clotting for 1 h after calcium addition. European manufacturers measure potency with an anti–factor Xa assay. To determine *heparin* potency, residual factor Xa activity in the sample is compared with that detected in controls containing known concentrations of an international *heparin* standard. When assessed this way, *heparin* potency is expressed in international units per milligram. Effective October 1, 2009, the new USP unit dose was harmonized with the international unit dose. As a result, the new USP unit dose is about 10% less potent than the old one, which results in a requirement for somewhat higher *heparin* doses to achieve the same level of anticoagulation.

Heparin Derivatives

Derivatives of *heparin* in current use include *low-molecular-weight heparin* (LMWH) and *fondaparinux* (see their comparison in Table 36–1).

Mechanism of Action. *Heparin*, LMWH, and *fondaparinux* have no intrinsic anticoagulant activity; rather, these agents bind to antithrombin and accelerate the rate at which it inhibits various coagulation proteases. Synthesized in the liver, antithrombin circulates in plasma at an approximate concentration of 2.5 μM. Antithrombin inhibits activated coagulation factors, particularly thrombin and factor Xa, by serving as a "suicide substrate." Thus, inhibition occurs when the protease attacks a specific Arg–Ser peptide bond in the reactive center loop of antithrombin and becomes trapped as a stable 1:1 complex. *Heparin* binds to antithrombin via a specific pentasaccharide sequence that contains a 3-*O*-sulfated glucosamine residue (Figure 36–4).

Pentasaccharide binding to antithrombin induces a conformational change in antithrombin that renders its reactive site more accessible to the target protease (Figure 36–5). This conformational change accelerates the rate of factor Xa inhibition by at least two orders of magnitude but

TABLE 36–1 ■ COMPARISON OF THE FEATURES OF SUBCUTANEOUS HEPARIN, LOW-MOLECULAR-WEIGHT HEPARIN, AND FONDAPARINUX

FEATURES	HEPARIN	LMWH	FONDAPARINUX
Source	Biological	Biological	Synthetic
Mean molecular weight (Da)	15,000	5000	1500
Target	Xa and IIa	Xa and IIa	Xa
Subcutaneous			
Bioavailability (%)	30 (at low doses)	90	100
$t_{1/2}$ (h)	1–8[a]	4	17
Renal excretion	No	Yes	Yes
Antidote effect	Complete	Partial	None
Thrombocytopenia	<5%	<1%	<0.1%

[a]Half-life *t* is dose dependent; half-life is 1 h with 5000 units given subcutaneously and can extend to 8 h with higher doses.

has no effect on the rate of thrombin inhibition. To enhance the rate of thrombin inhibition by antithrombin, *heparin* serves as a catalytic template to which both the inhibitor and the protease bind. Only *heparin* molecules composed of 18 or more saccharide units (molecular weight >5400) are of sufficient length to bridge antithrombin and thrombin together. Consequently, by definition, *heparin* catalyzes the rates of factor Xa and thrombin inhibition to a similar extent, as expressed by an anti–factor Xa to anti–factor IIa (thrombin) ratio of 1:1 (Figure 36–5A). In contrast, at least half of the LMWH molecules (mean molecular weight of 5000, which corresponds to about 17 saccharide units) are too short to provide this bridging function and have no effect on the rate of thrombin inhibition by antithrombin (Figure 36–5B). Because these shorter molecules still induce the conformational change in antithrombin that accelerates inhibition of factor Xa, LMWH has greater anti–factor Xa activity than anti–factor IIa activity, and the ratio ranges from 3:1 to 2:1 depending on the preparation. *Fondaparinux*, a synthetic analogue of the pentasaccharide sequence in *heparin* or LMWH that mediates their interaction with antithrombin, has only anti–factor Xa activity because it is too short to bridge antithrombin to thrombin (Figure 36–5C).

Heparin, LMWH, and *fondaparinux* act in a catalytic fashion. After binding to antithrombin and promoting the formation of covalent complexes between antithrombin and target proteases, the *heparin*, LMWH, or *fondaparinux* dissociates from the complex and can then catalyze other antithrombin molecules.

Platelet factor 4, a cationic protein released from α-granules during platelet activation, binds *heparin* and prevents it from interacting with antithrombin. This phenomenon may limit the activity of *heparin* in the vicinity of platelet-rich thrombi. Because LMWH and *fondaparinux* have a lower affinity for platelet factor 4, these agents may retain their activity in the vicinity of such thrombi to a greater extent than *heparin*.

Miscellaneous Pharmacological Effects. High doses of *heparin* can interfere with platelet aggregation and prolong the bleeding time. In contrast, LMWH and *fondaparinux* have little effect on platelets. *Heparin* "clears" lipemic plasma *in vivo* by causing the release of lipoprotein lipase into the circulation. Lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids. The clearing of lipemic plasma may occur at concentrations of *heparin* below those necessary to produce an anticoagulant effect.

Clinical Use. *Heparin*, LMWH, or *fondaparinux* can be used to initiate treatment of deep vein thrombosis and pulmonary embolism (Ortel et al., 2020). They also can be used for the initial management of patients with unstable angina or acute myocardial infarction (Larson et al., 2019). For most of these indications, LMWH or *fondaparinux* has replaced continuous *heparin* infusions because of their pharmacokinetic advantages, which permit subcutaneous administration once or twice daily in fixed or weight-adjusted doses without coagulation monitoring. Thus, LMWH or *fondaparinux* can be used for out-of-hospital management of patients with deep vein thrombosis or pulmonary embolism.

Heparin or LMWH is used during coronary balloon angioplasty with or without stent placement to prevent thrombosis. *Fondaparinux* is not used in this setting because of the risk of catheter thrombosis, a complication caused by catheter-induced activation of factor XII; longer *heparin* molecules are better than shorter ones for blocking this process. Cardiopulmonary bypass circuits also activate factor XII, which can cause clotting of the oxygenator. *Heparin* remains the agent of choice for surgery requiring cardiopulmonary bypass. *Heparin* or LMWH also is used to treat selected patients with disseminated intravascular coagulation. Subcutaneous administration of low-dose *heparin* or LMWH is often used for thromboprophylaxis in immobilized medically ill patients (Schünemann et al., 2018) or in those who have undergone major surgery (Anderson et al., 2019).

Unlike the oral anticoagulants, *heparin*, LMWH, and *fondaparinux* do not cross the placenta and have not been associated with fetal malformations, making them the drugs of choice for anticoagulation during pregnancy. *Heparin*, LMWH, and *fondaparinux* do not appear to increase fetal mortality or prematurity. If possible, the drugs should be discontinued 24 h before delivery to minimize the risk of postpartum bleeding.

ADME. *Heparin*, LMWH, and *fondaparinux* are not absorbed through the GI mucosa and must be given parenterally. *Heparin* is given by continuous intravenous infusion, intermittent infusion every 4 to 6 h, or

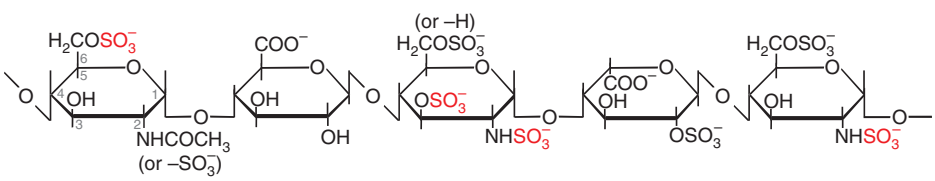

Figure 36–1 *The antithrombin-binding pentasaccharide structure of heparin.* Sulfate groups required for binding to antithrombin are indicated in red

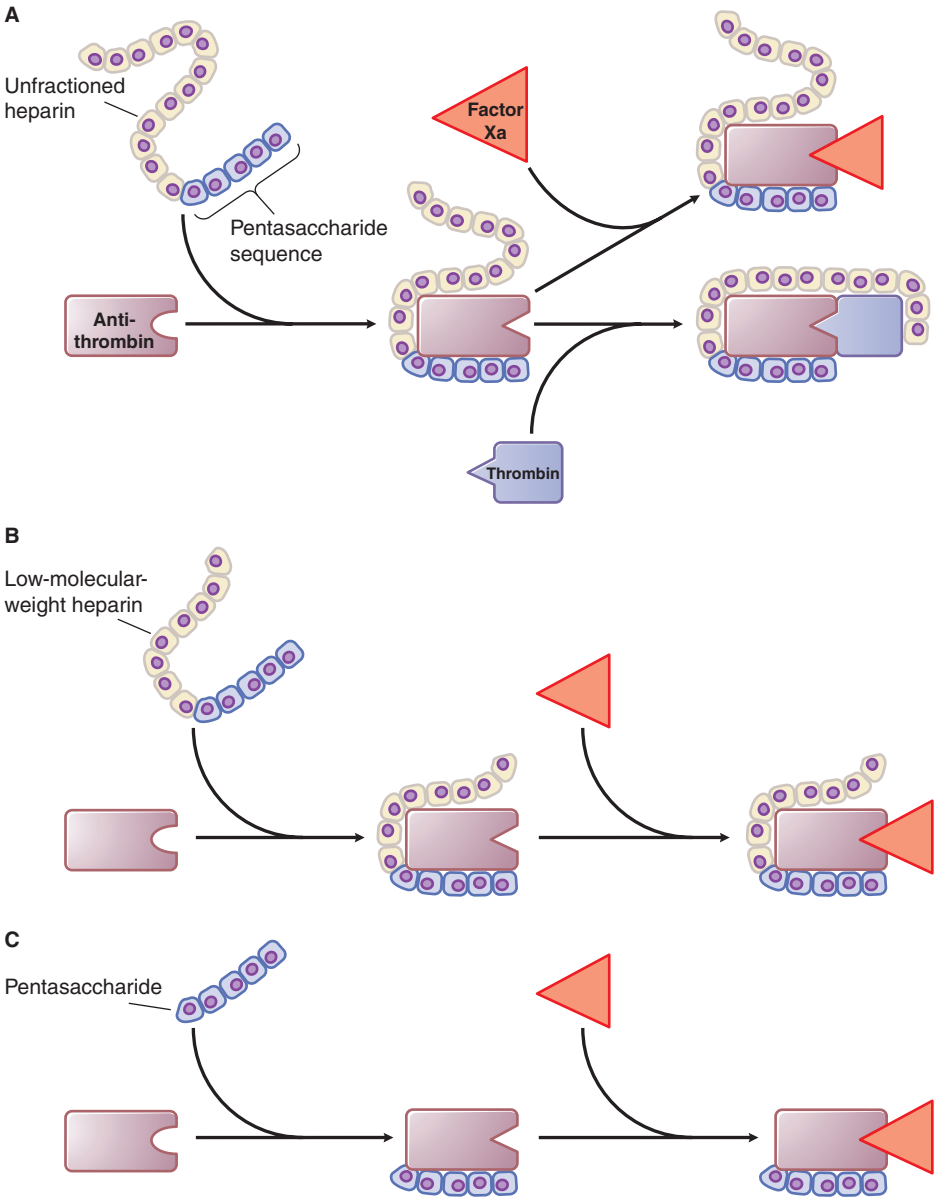

Figure 36–5 *Mechanism of action of heparin, LMWH, and fondaparinux, a synthetic pentasaccharide.* **A.** *Heparin* binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, *heparin* must simultaneously bind to antithrombin and thrombin. Only *heparin* chains composed of at least 18 saccharide units (molecular weight [MW] ~5400 Da) are of sufficient length to perform this bridging function. With a mean MW of approximately 15,000 Da, virtually all of the *heparin* chains are long enough to do this. **B.** LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because at least half of the LMWH chains (mean MW ~4500–5000 Da) are too short to bridge antithrombin to thrombin. **C.** The pentasaccharide accelerates only factor Xa inhibition by antithrombin; the pentasaccharide is too short to bridge antithrombin to thrombin.

subcutaneous injection every 8 to 12 h. *Heparin* has an immediate onset of action when given intravenously. In contrast, there is considerable variation in the bioavailability of *heparin* given subcutaneously, and the onset of action is delayed by 1 to 2 h. LMWH and *fondaparinux* are absorbed more uniformly after subcutaneous injection. The $t_{1/2}$ of *heparin* in plasma depends on the dose administered. When doses of 100, 400, or 800 units/kg of *heparin* are injected intravenously, the half-lives are about 1, 2.5, and 5 h, respectively. *Heparin* appears to be cleared and degraded primarily by the reticuloendothelial system; a small amount of intact *heparin* appears in the urine.

Both LMWH and *fondaparinux* have longer biological half-lives than *heparin*, 4-6 h and 17 h, respectively. Because these smaller *heparin* fragments are cleared almost exclusively by the kidneys, the drugs can accumulate in patients with renal impairment and lead to bleeding. Both LMWH and *fondaparinux* are contraindicated in patients with a creatinine clearance below 30 mL/min. In addition, *fondaparinux* must be used with caution for thromboprophylaxis in patients undergoing hip fracture, hip replacement, knee replacement, or abdominal surgery for who have a body weight less than 50 kg because of an increased risk for bleeding.

Administration and Monitoring. Full-dose *heparin* usually is administered by continuous intravenous infusion. Treatment of venous thromboembolism is initiated with a fixed-dose bolus injection of 5000 units or with a weight-adjusted bolus, followed by 800 to 1600 units/h delivered by an infusion pump. Therapy is monitored by measuring the aPTT. The therapeutic range for *heparin* is that which is equivalent to a plasma *heparin* level of 0.3 to 0.7 units/mL, as determined with an anti–factor Xa assay. An aPTT that is two or three times the normal mean aPTT value generally is assumed to be therapeutic. The aPTT should be measured initially and the infusion rate adjusted every 6 h. Once a steady dosage schedule has been established, daily aPTT monitoring usually is sufficient. Extremely high doses of *heparin* are required to prevent clotting in patients undergoing percutaneous coronary intervention or cardiac surgery with

cardiopulmonary bypass. The aPTT is infinitely prolonged with these high doses of *heparin*, so a less-sensitive coagulation test, the *activated clotting time* (ACT), is employed to monitor therapy in this situation.

For therapeutic purposes, *heparin* also can be administered subcutaneously on a twice-daily basis. A total daily dose of about 35,000 units administered as divided doses every 8 to 12 h usually is sufficient to achieve an aPTT of twice the control value (measured midway between doses). For low-dose *heparin* therapy (to prevent venous thromboembolism in hospitalized medical or surgical patients), a subcutaneous dose of 5000 units is given two or three times daily.

Heparin Resistance. Patients who fail to achieve a therapeutic aPTT with daily doses of *heparin* of 35,000 units or more are considered to have *heparin* resistance, which may reflect pseudo- or true resistance. Concomitant measurement of the aPTT and the anti–factor Xa level distinguishes between these two possibilities. With *heparin* pseudoresistance, the anti–factor Xa level is therapeutic despite the subtherapeutic aPTT, whereas with true *heparin* resistance, both the anti–factor Xa level and the aPTT are subtherapeutic. Pseudoresistance to *heparin* occurs if the aPTT is shorter than the control value prior to initiating *heparin* treatment because of high concentrations of factor VIII and fibrinogen. True *heparin* resistance occurs because of high plasma levels of proteins that compete with antithrombin for *heparin* binding or because of antithrombin deficiency. *Heparin* does not require dose adjustment in patients with pseudoresistance because the anti–factor Xa level is therapeutic. In contrast, with true resistance, *heparin* doses need to be increased until a therapeutic aPTT or anti–factor Xa level is achieved. Patients with severe antithrombin deficiency may require antithrombin concentrate to achieve therapeutic anticoagulation with *heparin*. Alternatively, they may be treated with a direct oral anticoagulant because these agents do not require antithrombin as a cofactor.

LMWH Preparations

Enoxaparin and *dalteparin* are the LMWH preparations marketed in the U.S.; *tinzaparin* is available in other countries. The composition of these agents differs, as do their dosing regimens. Because LMWH produces a relatively predictable anticoagulant response, monitoring is not done routinely. Patients with renal impairment may require monitoring with an anti–factor Xa assay because this condition can prolong the $t_{1/2}$ and slow the elimination of LMWH. Obese patients, pregnant women, and children given LMWH also may require monitoring. Weight-based prophylactic dosing of *enoxaparin* is preferable to fixed dosing for obese patients.

Fondaparinux

Fondaparinux, a synthetic pentasaccharide, is administered by subcutaneous injection, reaches peak plasma levels in 2 h, has a $t_{1/2}$ of 17 h, and is excreted in the urine. Because of the risk of accumulation and subsequent bleeding, *fondaparinux* should not be used in patients with a creatinine clearance less than 30 mL/min. *Fondaparinux* can be given subcutaneously once a day at a fixed or weight-adjusted dose without coagulation monitoring. *Fondaparinux* is much less likely than *heparin* or LMWH to trigger *heparin*-induced thrombocytopenia, and the drug has been used successfully to treat patients with this condition. *Fondaparinux* is approved for thromboprophylaxis in patients undergoing hip or knee surgery or surgery for hip fracture and for initial therapy of patients with deep vein thrombosis or pulmonary embolism. In some countries, but not the U.S., *fondaparinux* also is licensed as an alternative to *heparin* or LMWH in patients with acute coronary syndrome. For this indication and for thromboprophylaxis, *fondaparinux* is administered subcutaneously once daily at a dose of 2.5 mg.

Bleeding. The major untoward effect of *heparin*, LMWH, and *fondaparinux* is bleeding. Major bleeding occurs in 1% to 5% of patients treated with intravenous *heparin* for venous thromboembolism. The incidence of bleeding is somewhat less in patients treated with LMWH for this indication. Often, an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction due to concomitant administration of *aspirin* or other antiplatelet drugs.

The anticoagulant effect of *heparin* disappears within hours of discontinuation of the drug. Mild bleeding due to *heparin* usually can be controlled without administration of an antagonist. If life-threatening hemorrhage occurs, *heparin* can rapidly be reversed by the intravenous infusion of *protamine sulfate* (a mixture of basic polypeptides isolated from salmon sperm), which binds tightly to *heparin* and neutralizes its anticoagulant effect. *Protamine* also interacts with platelets, fibrinogen, and other plasma proteins and may cause an anticoagulant effect of its own. Therefore, one should give the minimal amount of *protamine* required to neutralize the *heparin* present in the plasma. This amount is 1 mg of *protamine* for every 100 units of *heparin* remaining in the patient; *protamine* is given intravenously at a slow rate (up to a maximum of 50 mg over 10 min). *Protamine* binds only long *heparin* molecules. Therefore, *protamine* only partially reverses the anticoagulant activity of LMWH and has no effect on that of *fondaparinux*. *Protamine* can cause severe hypotension, noncardiogenic pulmonary edema, and catastrophic pulmonary vasoconstriction when given rapidly and at high doses. Risk factors include previous administration of *protamine*-containing drugs (e.g., NPH insulin, protamine zinc insulin, and certain β blockers), allergy to fish, severe left ventricular dysfunction, and abnormal pulmonary hemodynamics.

Heparin-Induced Thrombocytopenia. *Heparin*-induced thrombocytopenia (platelet count <150,000/μL or a 50% decrease from the pretreatment value) occurs in about 0.5% of medical patients 5 to 10 days after initiation of therapy with *heparin*. Although the incidence is lower, thrombocytopenia also occurs with LMWH and rarely with *fondaparinux*. Life-threatening thrombotic complications that can lead to limb amputation occur in up to one-half of the affected *heparin*-treated patients and may precede the onset of thrombocytopenia. Women are twice as likely as men to develop this condition, and *heparin*-induced thrombocytopenia is more common in surgical patients than medical patients.

Venous thromboembolism occurs most commonly, but arterial thrombosis causing limb ischemia, myocardial infarction, or stroke also occurs. Bilateral adrenal hemorrhage, skin lesions at the site of subcutaneous *heparin* injection, and a variety of systemic reactions may accompany *heparin*-induced thrombocytopenia. The development of immunoglobulin G antibodies against complexes of *heparin* with platelet factor 4 (or, rarely, other chemokines) causes most of these reactions.

Heparin or LMWH should be discontinued immediately if unexplained thrombocytopenia or any of the clinical manifestations mentioned occur 5 or more days after beginning therapy, regardless of the dose or route of administration (Cuker et al., 2019). The diagnosis of *heparin*-induced thrombocytopenia can be confirmed with a *heparin*-dependent platelet activation assay or an immunoassay for antibodies that react with *heparin*–platelet factor 4 complexes. Because thrombotic complications may occur after cessation of therapy, an alternative anticoagulant such as *bivalirudin*, *argatroban*, or *rivaroxaban* (see below) should be administered to patients with *heparin*-induced thrombocytopenia. *Fondaparinux* is another alternative, although *fondaparinux*-induced thrombocytopenia has been reported in postmarketing studies. LMWH should be avoided because it cross-reacts with *heparin* antibodies. *Warfarin may precipitate venous limb gangrene or skin necrosis in patients with heparin-induced thrombocytopenia and should not be used until the platelet count returns to normal.*

Other Toxicities. Reversible abnormalities of hepatic function tests occur frequently in patients who are receiving *heparin* or LMWH. Osteoporosis occurs occasionally in patients who have received therapeutic doses of *heparin* (>20,000 units/day) for extended periods (e.g., 3–6 months). The risk of osteoporosis is lower with LMWH or *fondaparinux* than it is with *heparin*. *Heparin* can inhibit the synthesis of aldosterone by the adrenal glands and occasionally causes hyperkalemia.

Other Parenteral Anticoagulants

Desirudin and Lepirudin

Desirudin and *lepirudin* (both drugs are no longer available in the U.S.) are recombinant forms of hirudin. *Desirudin* is indicated for

thromboprophylaxis in patients undergoing elective hip replacement surgery. Both *desirudin* and *lepirudin* are also used for treating thrombosis in the setting of *heparin*-induced thrombocytopenia (Morgan et al., 2020). *Desirudin* and *lepirudin* are eliminated by the kidneys; the $t_{1/2}$ is about 2 h after subcutaneous administration and about 10 min after intravenous infusion. Both drugs should be used cautiously in patients with decreased renal function, and serum creatinine and aPTT should be monitored daily.

Bivalirudin

Bivalirudin is a synthetic 20–amino acid polypeptide that directly inhibits thrombin. *Bivalirudin* is administered intravenously and is used as an alternative to *heparin* in patients undergoing coronary angioplasty or cardiopulmonary bypass surgery (Barria Perez et al., 2016; Koster et al., 2018). Patients with *heparin*-induced thrombocytopenia or a history of this disorder also can be given *bivalirudin* instead of *heparin* during coronary angioplasty. The $t_{1/2}$ of *bivalirudin* is 25 min; dosage reductions are recommended for patients with renal impairment.

Argatroban

Argatroban, a synthetic compound based on the structure of L-arginine, binds reversibly to the active site of thrombin. *Argatroban* is administered intravenously and has a $t_{1/2}$ of 40 to 50 min. It is metabolized in the liver and excreted in the bile. Therefore, *argatroban* can be used in patients with renal impairment, but dose reduction is required for patients with hepatic insufficiency. *Argatroban* is licensed for the prophylaxis or treatment of patients with, or at risk of developing, *heparin*-induced thrombocytopenia (Morgan et al., 2020). In addition to prolonging the aPTT, *argatroban* prolongs the PT, which can complicate the transitioning of patients from *argatroban* to warfarin. A factor X assay can be used instead of the PT to monitor *warfarin* in these patients.

Vitamin K Antagonist

Warfarin

Warfarin or other vitamin K antagonists are commonly used oral anticoagulants.

Mechanism of Action

Coagulation factors II, VII, IX, and X and proteins C and S are synthesized in the liver and are biologically inactive unless 9 to 13 of the amino-terminal Glu residues are γ-carboxylated to form the Ca^{2+}-binding Gla domain. This carboxylation reaction requires CO_2, O_2, and reduced vitamin K and is catalyzed by γ-glutamyl carboxylase (Figure 36–6). Carboxylation is coupled to the oxidation of vitamin K to its corresponding epoxide form. Reduced vitamin K must be regenerated from the epoxide form for sustained carboxylation and synthesis of functional proteins. The enzyme that catalyzes this reaction, *vitamin K epoxide reductase* (VKOR), is inhibited by therapeutic doses of *warfarin*.

At therapeutic doses, *warfarin* decreases the functional amount of each vitamin K–dependent coagulation factor made by the liver by 30% to 70%. *Warfarin* has no effect on the activity of fully γ-carboxylated factors already in the circulation, and these must be cleared before it can produce an anticoagulant effect. The approximate $t_{1/2}$ values of factors VII, IX, X, and II are 6, 24, 36, and 50 h, respectively, while the $t_{1/2}$ values of protein C and protein S are 8 and 24 h, respectively. Because of the long $t_{1/2}$ of some of the coagulation factors, in particular factor II, the full antithrombotic effect of *warfarin* is not achieved for 4 to 5 days. For this reason, *warfarin* must be overlapped with a rapidly acting parenteral anticoagulant, such as *heparin*, LMWH, or *fondaparinux*, in patients with thrombosis or at high risk for thrombosis.

ADME

The bioavailability of *warfarin* is nearly complete when the drug is administered orally, intravenously, or rectally. Generic *warfarin* tablets may vary

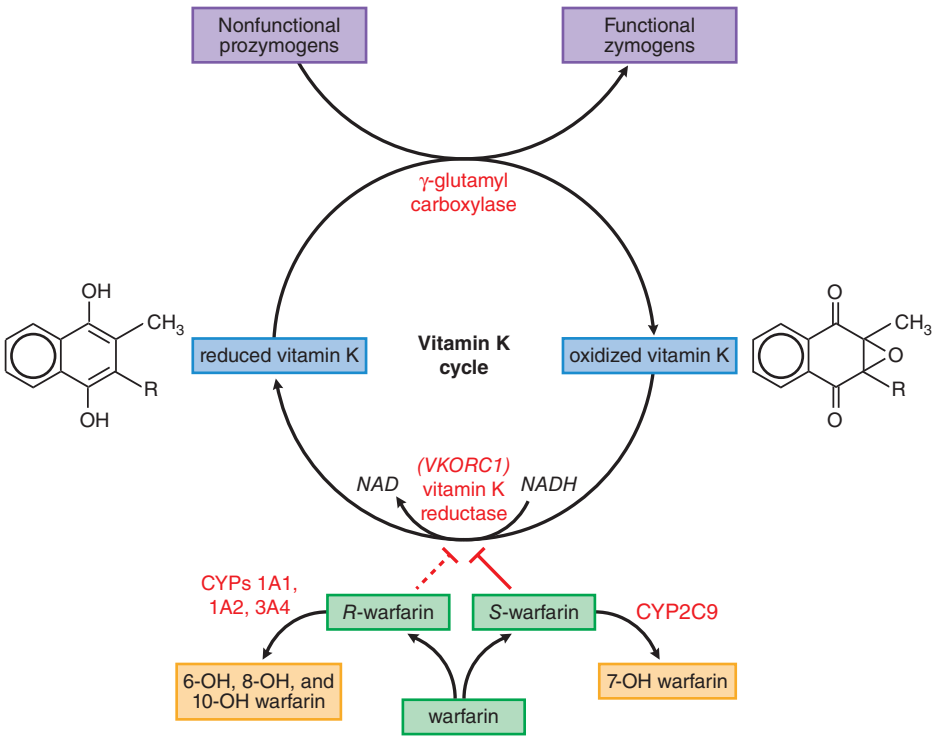

Figure 36–6 *The vitamin K cycle and mechanism of action of warfarin.* In the racemic mixture of *S*- and *R*-enantiomers, *S*-warfarin is more active. By blocking VKOR encoded by the *VKORC1* gene, *warfarin* inhibits the conversion of oxidized vitamin K epoxide to its reduced form, vitamin K hydroquinone. This inhibits vitamin K–dependent γ-carboxylation of factors II, VII, IX, and X because reduced vitamin K serves as a cofactor for a γ-glutamyl carboxylase that catalyzes the γ-carboxylation process whereby prozymogens are converted to zymogens capable of binding Ca^{2+} and interacting with anionic phospholipids. *S*-Warfarin is metabolized by *CYP2C9*; common genetic polymorphisms in this enzyme increase *warfarin* metabolism. Polymorphisms in the VKORC1 increase the susceptibility of the enzyme to *warfarin*-induced inhibition. Thus, patients expressing polymorphisms in these two enzymes require reduction of *warfarin* dosage (see Table 36–2).

TABLE 36–2 ■ EFFECT OF *CYP2C9* GENOTYPES AND *VKORC1* HAPLOTYPES ON WARFARIN DOSING

GENOTYPE or HAPLOTYPE	FREQUENCY (%)			DOSE REDUCTION COMPARED WITH WILD TYPE (%)
	CAUCASIANS	AFRICAN AMERICANS	ASIANS	
CYP2C9				
*1/*1	70	90	95	—
*1/*2	17	2	0	22
*1/*3	9	3	4	34
*2/*2	2	0	0	43
*2/*3	1	0	0	53
*3/*3	0	0	1	76
VKORC1				
Non-A/non-A	37	82	7	—
Non-A/A	45	12	30	26
A/A	18	6	63	50

Polymorphisms in two genes, *CYP2C9* and *VKORC1*, largely account for the genetic contribution to the variability in warfarin response. *CYP2C9* variants affect warfarin pharmacokinetics. *CYP2C9* metabolizes warfarin, and the non-*1/*1 variants are less active than *CYP2C9**1/*1, necessitating a reduction in dose. *VKORC1* variants affect warfarin pharmacodynamics. *VKORC1* is the target of coumarin anticoagulants such as warfarin. The non-A/A and A/A forms have decreased requirements for warfarin.
Source: Ghimire LV, Stein CM. Warfarin pharmacogenetics. Goodman and Gilman Online.

in their rate of dissolution, and this may cause some variation in the rate and extent of absorption. Food in the GI tract also can decrease the rate of absorption. Plasma *warfarin* concentrations peak in 2 to 8 h. *Warfarin* is administered as a racemic mixture of *S*- and *R*-warfarin. *S*-Warfarin is 3- to 5-fold more potent than *R*-warfarin and is mainly metabolized by cytochrome P450 (CYP) type 2C9. Inactive metabolites of *warfarin* are excreted in urine and stool. The $t_{1/2}$ varies (25–60 h), but the duration of action of *warfarin* is 2 to 5 days.

Table 36–2 summarizes the effects of known genetic factors on *warfarin* dose requirements. Polymorphisms in two genes, *CYP2C9* and *VKORC1*, account for most of the genetic contribution to variability in *warfarin* response (Johnson et al., 2017). *CYP2C9* variants affect *warfarin* pharmacokinetics, whereas *VKORC1* variants affect *warfarin* pharmacodynamics. Common variations in the *CYP2C9* gene (designated *CYP2C9*2* and **3*), encode an enzyme with decreased activity and thus are associated with higher drug concentrations and reduced *warfarin* dose requirements. *VKORC1* variants are more prevalent than those of *CYP2C9*, particularly in Asians, followed by European Americans and African Americans. The *warfarin* dose requirement is decreased in patients with these variants. Point-of-care methods for *CYP2C9* and *VKORC1* genotyping and algorithms that incorporate genotype information have been developed to facilitate precision dosing of *warfarin*. It remains uncertain, however, whether precision dosing improves clinical outcome compared with usual *warfarin* management (Li et al., 2019; Tse et al., 2018).

Clinical Use

Vitamin K antagonists are used to prevent the progression or recurrence of acute deep vein thrombosis or pulmonary embolism following an initial course of *heparin*, LMWH, or *fondaparinux*. They also are effective in preventing stroke or systemic embolization in patients with atrial fibrillation, mechanical heart valves, or ventricular assist devices.

Prior to initiation of therapy, laboratory tests are used in conjunction with the history and physical examination to uncover hemostatic defects that might make the use of warfarin more dangerous (e.g., congenital coagulation factor deficiency, thrombocytopenia, hepatic or renal insufficiency, vascular anomalies). Thereafter, the *international normalized ratio* (INR) calculated from the patient's PT is used to monitor the extent of anticoagulation and compliance. The target therapeutic INR ranges for various clinical indications have been established and reflect the extent of anticoagulation that reduces the morbidity from thromboembolic disease while minimally increasing the risk of serious hemorrhage. For most indications, an INR range of 2 to 3 is used. A higher INR range (2.5–3.5) is recommended for patients with mechanical heart valves in the mitral position or for patients with mechanical valves in another position who have concomitant atrial fibrillation or a prior history of stroke.

For treatment of acute venous thromboembolism, *heparin*, LMWH, or *fondaparinux* usually is continued for at least 5 days after *warfarin* therapy is begun. The parenteral agent is stopped when the INR is in the therapeutic range on 2 consecutive days. This overlap allows for adequate depletion of vitamin K–dependent coagulation factors with long half-lives, especially factor II. Frequent INR measurements are indicated at the onset of therapy to ensure that a therapeutic effect is obtained. Once a stable dose of *warfarin* has been identified, the INR can be monitored every 3 to 4 weeks.

Dosage

The usual adult dosage of *warfarin* is 2 to 5 mg/day for 2 to 4 days, followed by 1 to 10 mg/day as indicated by measurements of the INR (see the functional definition of INR in the section on clinical use). A lower initial dose should be given to patients with an increased risk of bleeding, including the elderly.

Interactions

Warfarin interactions can be caused by drugs, foods, or genetic factors that alter (1) uptake or metabolism of *warfarin* or vitamin K; (2) synthesis, function, or clearance of clotting factors; or (3) the integrity of any epithelial surface. Reduced *warfarin* efficacy can occur because of reduced absorption (e.g., binding to cholestyramine in the GI tract) or increased hepatic clearance from induction of hepatic enzymes (e.g., *CYP2C9* induction by barbiturates, *carbamazepine*, or *rifampin*). *Warfarin* has a decreased volume of distribution and a short $t_{1/2}$ with hypoproteinemia, such as occurs with nephrotic syndrome. Relative *warfarin* resistance can also be caused by ingestion of large amounts of vitamin K–rich foods or supplements or by increased levels of coagulation factors during pregnancy.

Drug interactions that enhance the risk of hemorrhage in patients taking *warfarin* include decreased metabolism due to *CYP2C9* inhibition by *amiodarone*, azole antifungals, *cimetidine, clopidogrel, cotrimoxazole, disulfiram, fluoxetine, isoniazid, metronidazole, sulfinpyrazone, tolcapone*, or *zafirlukast*. Relative deficiency of vitamin K may result from

inadequate diet (e.g., postoperative patients on parenteral fluids), especially when coupled with the elimination of intestinal flora by antimicrobial agents. Gut bacteria synthesize vitamin K and are an important source of this vitamin. Consequently, antibiotics can cause an increase in the INR in patients on *warfarin*. Low concentrations of coagulation factors may result from impaired hepatic function, congestive heart failure, or hypermetabolic states, such as hyperthyroidism; generally, these conditions enhance the effect of *warfarin* on the INR. Serious interactions that do not alter the INR include inhibition of platelet function by agents such as *aspirin* and gastritis or frank ulceration induced by anti-inflammatory drugs. Agents may have more than one effect (e.g., *clofibrate* increases the rate of turnover of coagulation factors and inhibits platelet function).

Hypersensitivity to Warfarin

About 10% of patients require less than 1.5 mg/day of *warfarin* to achieve an INR of 2 to 3. These patients often possess variants of *CYP2C9* or *VKORC1*; these variants affect the pharmacokinetics or pharmacodynamics of *warfarin*, respectively. Supplementation with low daily doses of vitamin K renders these patients less sensitive to *warfarin* and may result in more stable dosing.

Adverse Effects

Bleeding. The most common side effect of *warfarin* is bleeding. The risk of bleeding increases with the intensity and duration of anticoagulant therapy, the use of other medications that interfere with hemostasis, and the presence of an anatomical source of bleeding. The incidence of major bleeding episodes is generally less than 3% per year in patients treated to a target INR of 2 to 3. The risk of intracranial hemorrhage increases dramatically with an INR greater than 4, although up to two-thirds of intracranial bleeds on *warfarin* occur when the INR is therapeutic.

If the INR is above the therapeutic range and the patient is not bleeding or in need of a surgical procedure, *warfarin* can be held temporarily and restarted at a lower dose once the INR is within the therapeutic range. If the INR is 10 or greater, vitamin K_1 can be given orally at a dose of 2.5 to 5 mg. These doses of oral vitamin K_1 generally cause the INR to decrease substantially within 24 to 48 h without rendering the patient resistant to further *warfarin* therapy. Higher doses of vitamin K_1 or parenteral administration may be required if more rapid correction of the INR is necessary. The effect of vitamin K_1 is delayed for at least several hours because reversal of anticoagulation requires synthesis of fully carboxylated coagulation factors. If immediate hemostatic competence is necessary because of serious bleeding or profound *warfarin* overdosage, adequate concentrations of vitamin K–dependent coagulation factors can be restored by transfusion of four-factor prothrombin complex concentrate, supplemented with 10 mg of vitamin K_1, given by slow intravenous infusion. Vitamin K_1 administered intravenously carries the risk of anaphylactoid reactions. Patients who receive high doses of vitamin K_1 may become unresponsive to *warfarin* for several days, but *heparin* or LMWH can be given if continued anticoagulation is required.

Birth Defects. Administration of *warfarin* during pregnancy causes birth defects and abortion. CNS abnormalities have been reported following exposure during the second and third trimesters. Fetal or neonatal hemorrhage and intrauterine death may occur, even when maternal INR values are within the therapeutic range. Vitamin K antagonists should not be used during pregnancy, but *heparin* or LMWH can be used safely.

Skin Necrosis. *Warfarin*-induced skin necrosis is a rare complication characterized by the appearance of skin lesions 3 to 10 days after treatment is initiated. The lesions typically are on the extremities, but adipose tissue, the penis, and the female breast also may be involved. Skin necrosis occurs in patients with protein C or S deficiency or in those with *heparin*-induced thrombocytopenia.

Other Toxicities. A reversible, sometimes painful, blue-tinged discoloration of the plantar surfaces and sides of the toes that blanches with pressure and fades with elevation of the legs (purple toe syndrome) may develop 3 to 8 weeks after initiation of therapy with *warfarin*; cholesterol emboli released from atheromatous plaques have been implicated as the cause. *Warfarin* can cause fatal calciphylaxis (calcium accumulation in small blood vessels) or calcium uremic arteriolopathy. Other infrequent reactions include alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramps, and anorexia.

Direct Oral Anticoagulants

Direct Oral Thrombin Inhibitor

Dabigatran

Dabigatran etexilate is a synthetic prodrug with a molecular weight of 628 Da.

Mechanism of Action. *Dabigatran etexilate* is rapidly converted to *dabigatran* by plasma esterases. *Dabigatran* competitively and reversibly blocks the active site of free and clot-bound thrombin, thereby inhibiting thrombin-mediated conversion of fibrinogen to fibrin, feedback activation of coagulation, and platelet activation.

ADME. *Dabigatran* has oral bioavailability of about 6%, a peak onset of action in 2 h, and a plasma $t_{1/2}$ of 12 to 14 h. *Dabigatran* is given twice a day in capsule form. The bioavailability of the drug is altered if capsules are chewed or broken prior to ingestion. Therefore, the capsules should be swallowed whole. Circulating *dabigatran* is 35% bound to plasma proteins. Around 80% of absorbed *dabigatran* is excreted unchanged by the kidneys. A dosage reduction is required when *dabigatran* is administered to patients with severe renal impairment (creatinine clearance 15–30 mL/min). Dosage recommendations are not available for patients with a creatinine clearance below 15 mL/min.

When given in fixed doses, *dabigatran etexilate* produces such a predictable anticoagulant response that routine coagulation monitoring is unnecessary. Although *dabigatran* prolongs the aPTT, the values plateau with higher drug levels. *Dabigatran* has an unreliable effect on the INR. The thrombin time is too sensitive to use to monitor *dabigatran* therapy because the test is markedly prolonged with even low levels of drug. To circumvent this problem, a diluted thrombin time assay has been developed. By comparing the results with those obtained with *dabigatran* calibrators, this test can be used to quantify plasma *dabigatran* concentrations.

Therapeutic Uses. *Dabigatran* is licensed for treatment of acute venous thromboembolism after at least 5 days of parenteral anticoagulation with *heparin*, LMWH, or *fondaparinux* (Schulman et al., 2014), for secondary prevention of venous thromboembolism, and for stroke prevention in patients with nonvalvular atrial fibrillation (Connolly et al., 2009). It is contraindicated in patients with mechanical heart valves (Eikelboom et al., 2013). In some countries, lower-dose regimens of once-daily *dabigatran* are licensed for thromboprophylaxis after knee or hip arthroplasty.

Adverse Effects. Bleeding is the major side effect of *dabigatran*. In elderly patients with atrial fibrillation, the annual risk of major bleeding with *dabigatran* 150 mg twice daily is like that with *warfarin*, about 3.0%. However, the risk of intracranial bleeding is reduced by 70% with *dabigatran* compared with *warfarin*. In contrast, the risk of GI bleeding is higher with *dabigatran*, particularly in those over 75 years of age. Additional risk factors for bleeding with *dabigatran* include renal impairment and concurrent use of antiplatelet agents or nonsteroidal anti-inflammatory drugs. *Dabigatran* should not be used in patients with mechanical prosthetic heart valves and in patients with triple-positive antiphospholipid antibody syndrome (positive for lupus anticoagulant, anticardiolipin antibodies, and anti–β_2-glycoprotein I antibodies).

Drug Interactions. *Dabigatran* is a substrate for P-glycoprotein, so drugs that inhibit or induce P-glycoprotein have the potential to increase or decrease plasma *dabigatran* concentrations, respectively. *Verapamil, dronedarone, quinidine, ketoconazole*, and *clarithromycin* can increase *dabigatran* concentrations, while *rifampicin* may decrease the concentration.

Direct Oral Factor Xa Inhibitors

Rivaroxaban, Apixaban, Edoxaban, and Betrixaban

Mechanism of Action. *Rivaroxaban*, *apixaban*, *edoxaban*, and *betrixaban* inhibit free and clot-associated factor Xa, which results in reduced thrombin generation. In turn, platelet aggregation and fibrin formation are suppressed. Manufacturing of *betrixaban* was stopped in 2020, and the drug is no longer available.

ADME. *Rivaroxaban* has 80% oral bioavailability, a peak onset of action in 3 h, and a plasma $t_{1/2}$ of 7 to 11 h. Maximum absorption of *rivaroxaban* occurs in the stomach, and when given in therapeutic doses, the drug should be administered with a meal to enhance absorption. *Rivaroxaban* is provided in tablet form; the tablet can be crushed and delivered via nasogastric tube. *Rivaroxaban* is 95% plasma protein bound. About one-third of the drug is excreted unchanged in the urine; the remainder is metabolized by hepatic CYP3A4, and inactive metabolites are excreted equally in the urine and feces. *Rivaroxaban* exposure is increased in patients with renal impairment or severe hepatic dysfunction. The therapeutic dose of *rivaroxaban* is reduced from 20 mg once daily to 15 mg once daily if the creatinine clearance is 15 to 50 mL/min. The drug should not be used in those with a lower creatinine clearance. In patients with acute deep vein thrombosis or pulmonary embolism, *rivaroxaban* is started at a dose of 15 mg twice daily for 21 days, and the dose is then reduced to 20 mg once daily thereafter. For secondary prevention of venous thromboembolism after 6 months of treatment, the *rivaroxaban* dose can be reduced from 20 mg once daily to 10 mg once daily (Weitz et al., 2017).

The bioavailability of *apixaban* is around 50%, and peak concentrations are achieved 1 to 3 h after ingestion. Food does not affect absorption, and the drug can be administered as a whole tablet, or the tablet can be crushed in water and delivered via a nasogastric tube. *Apixaban* is 87% plasma protein bound, and about 27% of the drug is cleared unchanged via the kidneys. *Apixaban* is metabolized by hepatic CYP3A4, and metabolites are excreted in the bile, intestines, and urine. The usual dose of *apixaban* is 5 mg twice daily. The dose is reduced to 2.5 mg twice daily in patients who have two of the following three characteristics: age over 80 years, body weight of 60 kg or less, or serum creatinine concentration of 1.5 mg/dL or higher. In patients with acute venous thromboembolism, patients start *apixaban* at a dose of 10 mg twice daily for 7 days, and the dose is then decreased to 5 mg twice daily thereafter. For those requiring treatment beyond 6 to 12 months, the *apixaban* dose can be decreased to 2.5 mg twice daily.

The bioavailability of *edoxaban* is 62%, and peak drug concentrations are achieved 1 to 2 h after ingestion. Food does not affect absorption. *Edoxaban* is 55% protein bound. Of the absorbed *edoxaban*, about 50% is eliminated as unchanged drug in the urine. There is minimal hepatic metabolism, and liver disease does not affect drug pharmacodynamics. Drug exposure is increased by renal impairment, low body weight, and concomitant intake of potent P-glycoprotein inhibitors. Therefore, the dose of *edoxaban* should be reduced from 60 to 30 mg once daily in patients with a creatinine clearance between 15 and 50 mL/min, in those with a body weight of 60 kg or less, or in those taking *quinidine*, *dronedarone*, *rifampin*, *erythromycin*, *ketoconazole*, or *cyclosporine*. *Edoxaban* is contraindicated in those with a creatinine clearance below 15 mL/min. In the U.S., but not in other countries, *edoxaban* is also not recommended in patients with a creatinine clearance over 95 mL/min because subgroup analysis of the results of the trial comparing *edoxaban* with *warfarin* for stoke prevention in atrial fibrillation revealed a higher risk of ischemic stroke with *edoxaban* than with *warfarin* in such patients.

Rivaroxaban, *apixaban*, and *edoxaban* are given in fixed doses and do not require routine coagulation monitoring. The drugs affect the PT more than the aPTT, but they prolong the PT to a variable extent, and this test does not provide a reliable measure of their anticoagulant activity. Anti–factor Xa assays using specific drug calibrators can be used to measure drug levels. Renal function should be assessed at least yearly in patients taking oral factor Xa inhibitors or more frequently in patients with renal dysfunction.

Therapeutic Uses. *Rivaroxaban*, *apixaban*, and *edoxaban* are licensed for stroke prevention in patients with atrial fibrillation (Giugliano et al., 2013; Granger et al., 2011; Patel et al., 2011) and for treatment of acute deep vein thrombosis or pulmonary embolism (Beyer-Westendorf and Ageno, 2015; Gómez-Outes et al., 2015). For the last indication, *edoxaban* is started only after a minimum 5-day course of treatment with *heparin*, LMWH, or *fondaparinux* (Buller et al., 2013). In contrast, *rivaroxaban* and *apixaban* can be started immediately (EINSTEIN Investigators, 2010, 2012; Granziera et al., 2016). Studies comparing *apixaban*, *rivaroxaban,* or *edoxaban* with *dalteparin* for treatment of cancer-associated venous thromboembolism reveal that oral direct factor Xa inhibitors are at least as effective as *dalteparin* but are associated with more bleeding in patients with intact gastrointestinal cancers, particularly those of the upper gastrointestinal tract (Mulder et al., 2020).

Rivaroxaban and *apixaban* are also licensed for postoperative thromboprophylaxis in patients undergoing hip or knee arthroplasty (Anderson et al., 2019); for this indication, the drugs are given at doses of 10 mg once daily and 2.5 mg twice daily, respectively. All three drugs are contraindicated for stroke prevention in patients with mechanical heart valves. In addition, the drugs should be avoided in patients with antiphospholipid syndrome because *warfarin* appears superior to direct oral factor Xa inhibitors for prevention of recurrent thrombosis (Ghembaza and Saadoun, 2020).

Low-dose *rivaroxaban* (2.5 mg twice daily) in combination with *aspirin* (81 or 100 mg daily) is licensed for prevention of major adverse cardiac and limb events in patients with coronary or peripheral artery disease (Capodanno et al., 2020). This combination produces dual pathway inhibition because the *rivaroxaban* attenuates thrombin generation and fibrin formation, while the *aspirin* attenuates platelet activation. Inhibition of both pathways with *rivaroxaban* plus *aspirin* proved to be more effective than single-pathway inhibition with either *rivaroxaban* or *aspirin* alone in patients with coronary or peripheral artery disease (Eikelboom et al., 2017) and was more effective than *aspirin* alone after revascularization procedures for peripheral artery disease (Bonaca et al., 2020).

Adverse Effects. As with all anticoagulants, the major adverse effect is bleeding. Rates of intracranial bleeding with *rivaroxaban*, *apixaban*, and *edoxaban* are at least 50% lower than that with *warfarin*. Rates of bleeding in other sites are similar or lower than those with *warfarin*. The sole exception is the GI tract; rates of GI bleeding with *rivaroxaban* and *edoxaban*, but not *apixaban*, are higher than that with *warfarin*. The explanation for this difference is uncertain, but it may reflect the capacity of unabsorbed anticoagulant in the gut to promote bleeding from preexisting lesions. Despite the increased risk of GI bleeding, rates of life-threatening and fatal bleeding are lower with all the oral factor Xa inhibitors than with *warfarin*. Like with other anticoagulants, the risk of bleeding with *rivaroxaban, apixaban*, or *edoxaban* is increased in patients taking concomitant antiplatelet agents or nonsteroidal anti-inflammatory agents.

Drug Interactions. All the oral factor Xa inhibitors are substrates for P-glycoprotein. Consequently, potent inhibitors or inducers of P-glycoprotein will increase or decrease drug concentrations, respectively. *Rivaroxaban* and *apixaban* are metabolized by CYP3A4, whereas *edoxaban* undergoes only minimal CYP3A4-mediated metabolism. Plasma levels of *rivaroxaban* and *apixaban* are reduced by potent inducers of both P-glycoprotein and CYP3A4, such as *carbamazepine*, *phenytoin*, *rifampin*, and St. John's wort and increased by potent inhibitors, such as *dronedarone, ketoconazole, itraconazole, ritonavir, clarithromycin, erythromycin*, and *cyclosporine*.

Reversal Agents for Direct Oral Anticoagulants

Life-threatening bleeding can occur with the direct oral anticoagulants, and patients taking these drugs may require urgent surgery or interventions. Therefore, the availability of specific reversal agents streamlines the management of such patients. *Idarucizumab* is licensed for *dabigatran*

reversal in patients with serious bleeding, such as intracranial bleeding, or in those requiring urgent surgery or intervention.

Recombinant coagulation factor Xa, inactivated-zhzo, also called *andexanet alfa*, is FDA-approved for reversal of patients treated with *rivaroxaban* and *apixaban* with serious bleeding. *Andexanet alfa* has not been evaluated for reversal of *apixaban*, *rivaroxaban*, or *edoxaban* prior to urgent surgery. Because *andexanet* also reverses the anticoagulant effect of *heparin* and LMWH, it should not be used in patients undergoing procedures where *heparin* is used routinely, such as vascular or cardiac surgery.

Andexanet alfa is considerably more expensive than *idarucizumab* and is not as widely available. Because of the cost, *andexanet* is often reserved for patients with the most serious bleeds, especially intracranial hemorrhage. If *andexanet* is unavailable, the results of cohort studies suggest that four-factor prothrombin complex concentrate improves hemostasis in patients with serious bleeding. If this is ineffective, activated prothrombin complex concentrate or recombinant factor VIIa can be considered (Cuker et al., 2018).

In patients taking *dabigatran* who present with serious bleeding in the setting of acute renal failure, hemodialysis can be used to remove *dabigatran* from the circulation. Dialysis is of no value for removal of *rivaroxaban*, *apixaban*, or *edoxaban* because of their higher protein binding.

Idarucizumab

A specific reversal agent for *dabigatran*, *idarucizumab* is a humanized mouse monoclonal antibody fragment directed against *dabigatran*. The antibody binds *dabigatran* with an affinity 350-fold higher than that of *dabigatran* for thrombin, and the essentially irreversible *idarucizumab-dabigatran* complex is cleared by the kidneys. *Idarucizumab* is infused as two intravenous boluses, each of 2.5 g. It rapidly reverses the anticoagulant effects of *dabigatran*, and patients have then safely undergone major surgery (Pollack et al., 2017).

Andexanet Alfa

Andexanet alfa has been renamed by the FDA and is now referred to generically as *coagulation factor Xa (recombinant), inactivated-zhzo*. For simplicity, it is referred to as *andexanet* in this chapter. Designed as a decoy for the oral factor Xa inhibitors, *andexanet* is a recombinant analogue of factor Xa that has the active site serine residue replaced with an alanine residue to eliminate catalytic activity and the Gla domain removed to preclude its incorporation in the prothrombinase complex. *Andexanet* is administered as an intravenous bolus followed by a 2-h infusion. By sequestering circulating factor Xa inhibitors, *andexanet* rapidly reverses the anti–factor Xa activity produced by these agents and restores thrombin generation (Connolly et al., 2019). Higher doses of *andexanet* are needed to reverse *rivaroxaban* or *edoxaban* than *apixaban* (Connolly et al., 2019).

Ciraparantag

Ciraparantag is a synthetic, small cationic molecule that is reported to bind *dabigatran, rivaroxaban, apixaban*, and *edoxaban*, as well as *heparin* and LMWH. In healthy volunteers given *edoxaban*, an intravenous bolus of *ciraparantag* restored the whole-blood clotting time to normal. *Ciraparantag* is currently in phase III clinical trials.

Fibrinolytic Drugs

Fibrinolytic drugs initiate the fibrinolytic pathway, which is summarized in Figure 36–3. These agents include recombinant t-PA (*alteplase*) and its variants, *urokinase* and *streptokinase*. *Urokinase* and *streptokinase* are rarely used and no longer available in the U.S.

Tissue Plasminogen Activator

Tissue plasminogen activator is a serine protease and a poor plasminogen activator in the absence of fibrin. When bound to fibrin, t-PA activates fibrin-bound plasminogen several hundred–fold more rapidly than it activates plasminogen in the circulation. Because it has little activity except in the presence of fibrin, physiological t-PA concentrations of 5 to 10 ng/mL do not induce systemic plasmin generation. With therapeutic infusion of recombinant t-PA (*alteplase*), the concentrations rise to 300 to 3000 ng/mL, which can induce systemic fibrinogen degradation. Clearance of *alteplase* primarily occurs via hepatic metabolism, and its $t_{1/2}$ is about 5 min. *Alteplase* is effective for treatment of acute myocardial infarction (O'Gara et al., 2013), acute ischemic stroke, and life-threatening pulmonary embolism (Meyer et al., 2014).

For coronary thrombolysis, *alteplase* is given as a 15-mg intravenous bolus, followed by 0.75 mg/kg over 30 min (not to exceed 50 mg) and 0.5 mg/kg (up to 35 mg accumulated dose) over the following hour. Other recombinant variants of t-PA include *reteplase* and *tenecteplase*. They differ from *alteplase* by having longer plasma half-lives that allow convenient bolus dosing. In addition, in contrast to *alteplase*, *tenecteplase* is relatively resistant to inhibition by PAI-1. Despite these apparent advantages, these agents are like *alteplase* in terms of efficacy and toxicity.

Hemorrhagic Toxicity of Thrombolytic Therapy

The major toxicity of all thrombolytic agents is hemorrhage. It is due to (1) degradation of fibrin in hemostatic plugs at sites of vascular injury or (2) the systemic lytic state that results from the systemic generation of plasmin, which degrades fibrinogen and other coagulation factors, especially factors V and VIII. Contraindications to fibrinolytic therapy are listed in Table 36–3.

If *heparin* is used concurrently with *alteplase*, serious hemorrhage will occur in 2% to 4% of patients. Intracranial hemorrhage is the most serious problem and can occur in up to 1% of patients. For this reason, mechanical reperfusion is preferred over systemic thrombolysis in patients with acute myocardial infarction with ST-segment elevation. In patients with acute ischemic stroke, the current standard of care is mechanical thrombus extraction, which can be done with or without adjunctive *alteplase* or *tenecteplase*.

Inhibitors of Fibrinolysis

ε-Aminocaproic Acid and Tranexamic Acid

ε-Aminocaproic acid and *tranexamic acid* are lysine analogues that compete for lysine binding sites on plasminogen and plasmin, thereby blocking their interaction with fibrin. Therefore, these agents inhibit fibrinolysis and can reverse states that are associated with excessive fibrinolysis.

The main problem with their use is that thrombi that form during treatment are not degraded. For example, in patients with hematuria,

TABLE 36–3 ■ ABSOLUTE AND RELATIVE CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY

Absolute Contraindications

- Prior intracranial hemorrhage
- Known structural cerebral vascular lesion
- Known malignant intracranial neoplasm
- Ischemic stroke within 3 months
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed-head trauma or facial trauma within 3 months

Relative Contraindications

- Uncontrolled hypertension (systolic blood pressure >180 mmHg or diastolic blood pressure >110 mmHg)
- Traumatic or prolonged CPR or major surgery within 3 weeks
- Recent (within 2–4 weeks) internal bleeding
- Noncompressible vascular punctures
- For streptokinase: prior exposure (more than 5 days ago) or prior allergic reaction to streptokinase
- Pregnancy
- Active peptic ulcer
- Current use of warfarin and INR >1.7

ureteral obstruction by clots may lead to renal failure after treatment with *ε-aminocaproic acid* or *tranexamic acid*. *ε-Aminocaproic acid* has been used intravenously to reduce bleeding after prostatic surgery and orally to reduce bleeding after tooth extractions in patients with hemophilia. *ε-Aminocaproic acid* is absorbed rapidly after oral administration, and 50% is excreted unchanged in the urine within 12 h. For intravenous use, a loading dose of 4 to 5 g is given over 1 h, followed by an infusion of 1 to 1.25 g/h until bleeding is controlled. No more than 30 g should be given in a 24-h period. Rarely, the drug causes myopathy and muscle necrosis.

Tranexamic acid is given intravenously in trauma resuscitation, in patients with massive hemorrhage, and in women with postpartum hemorrhage (Franchini and Mannucci, 2020). It is also used to reduce operative bleeding in patients undergoing hip or knee arthroplasty or cardiac surgery. There appears to be little or no increased risk of thrombosis. *Tranexamic acid* is excreted in the urine; therefore, dose reduction is necessary in patients with renal impairment. Oral *tranexamic acid* is approved for treatment of heavy menstrual bleeding, usually given at a dose of 1 g four times daily for 4 days.

Antiplatelet Drugs

Platelet aggregates form the initial hemostatic plug at sites of vascular injury. Platelets also contribute to the pathological thrombi that lead to myocardial infarction, stroke, and peripheral arterial thrombosis. Potent inhibitors of platelet function have been developed in recent years. These drugs act by discrete mechanisms (Figure 36–7); thus, in combination, their effects are additive or even synergistic.

Aspirin

In platelets, the major product of metabolism by *cyclooxygenase* (COX) type1 is *thromboxane A2* (TxA_2), a labile inducer of platelet aggregation and a potent vasoconstrictor. *Aspirin* blocks production of TxA_2 by acetylating a serine residue near the active site of platelet COX-1. Because platelets do not synthesize new proteins, the action of *aspirin* on platelet COX-1 is permanent, lasting for the lifetime of the platelet (7–10 days). Thus, repeated doses of *aspirin* produce a cumulative effect on platelet function.

Complete inactivation of platelet COX-1 is achieved with a daily *aspirin* dose of 75 mg. Therefore, *aspirin* is maximally effective as an antithrombotic agent at doses much lower than those required for other actions of the drug. Numerous trials indicated that *aspirin*, when used as an antithrombotic drug, is maximally effective at doses of 50 to 325 mg/day. Higher doses do not improve efficacy and potentially are less efficacious because of inhibition of prostacyclin production, which can be largely spared by using lower doses of *aspirin*. Higher doses also increase toxicity, especially bleeding. Therefore, daily *aspirin* doses of 100 mg or less are used for most indications (Arnett et al., 2019). Nonsteroidal anti-inflammatory drugs that are reversible inhibitors of COX-1 have not been shown to have antithrombotic efficacy and, in fact, may even interfere with low-dose *aspirin* regimens (see Chapters 41 and 42).

Dipyridamole

Dipyridamole interferes with platelet function by increasing the intracellular concentration of cyclic AMP. This effect is mediated by inhibition of phosphodiesterase or by blockade of uptake of adenosine, thereby increasing the dwell time of adenosine at cell surface adenosine A_2 receptors that link to the stimulation of platelet adenylyl cyclase. *Dipyridamole* is a vasodilator that, in combination with *warfarin*, inhibits embolization from prosthetic heart valves. *Dipyridamole* is approved for secondary prevention of stroke when it is combined with low-dose *aspirin*.

$P2Y_{12}$ Receptor Antagonists

Clopidogrel

Clopidogrel is a thienopyridine prodrug that inhibits the $P2Y_{12}$ receptor. Platelets contain two purinergic receptors, $P2Y_1$ and $P2Y_{12}$; both are G

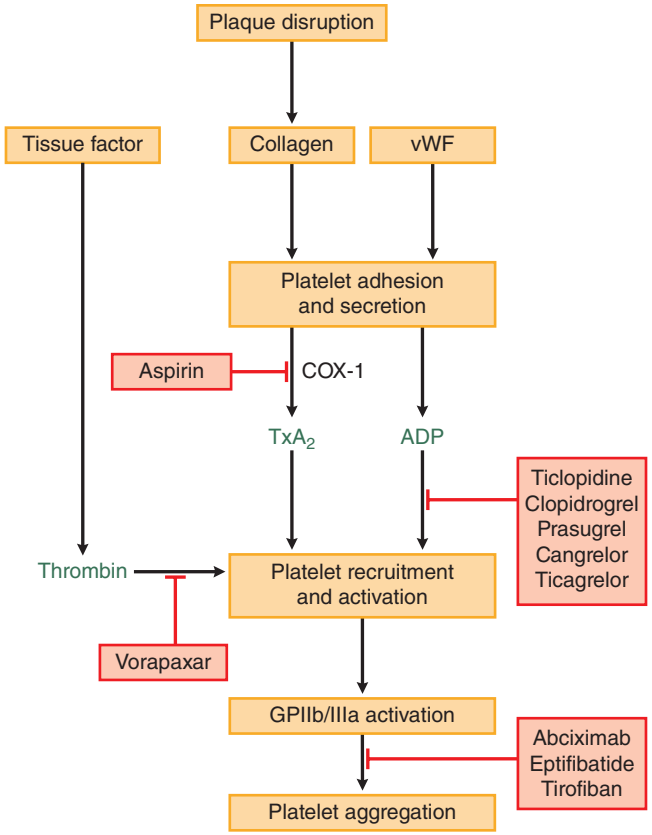

Figure 36–7 *Sites of action of antiplatelet drugs.* *Aspirin* inhibits TxA_2 synthesis by irreversibly acetylating COX-1. Reduced TxA_2 release attenuates platelet activation and recruitment to the site of vascular injury. *Ticlopidine*, *clopidogrel*, and *prasugrel* irreversibly block $P2Y_{12}$, a key ADP receptor on the platelet surface; *cangrelor* and *ticagrelor* are reversible inhibitors of $P2Y_{12}$. *Abciximab*, *eptifibatide*, and *tirofiban* inhibit the final common pathway of platelet aggregation by blocking fibrinogen and von Willebrand factor (vWF) from binding to activated GPIIb/IIIa. *Vorapaxar* inhibits thrombin-mediated platelet activation by targeting PAR-1, the major thrombin receptor on platelets.

protein-coupled receptors for ADP. The ADP-activated platelet $P2Y_1$ receptor couples to the G_q-PLC-IP_3–Ca^{2+} pathway and induces platelet shape change and aggregation. The $P2Y_{12}$ receptor couples to G_i and, when activated by ADP, inhibits adenylyl cyclase, resulting in lower levels of intracellular cyclic AMP and thereby less cyclic AMP–dependent inhibition of platelet activation. Both receptors must be stimulated to result in maximal platelet activation.

Clopidogrel is an irreversible inhibitor of $P2Y_{12}$. It has largely replaced *ticlopidine* because *clopidogrel* is more potent and less toxic, with thrombocytopenia and leukopenia occurring only rarely. *Clopidogrel* is a prodrug that requires metabolic activation in the liver. Therefore, it has a slow onset of action. It also has a slow offset of action because of its irreversible effect on $P2Y_{12}$. Metabolic activation of *clopidogrel* can be affected by polymorphisms in *CYP2C19* that result in reduced or absent CYP2C19 activity. These polymorphisms contribute to the variable effect of *clopidogrel* on ADP-induced platelet aggregation. Inhibition of platelet activation is seen 2 h after ingestion of a loading dose of *clopidogrel*, and platelets are affected for the remainder of their life span.

Therapeutic Uses. *Clopidogrel* is somewhat better than *aspirin* for secondary prevention of stroke, and the combination of *clopidogrel* plus *aspirin* is superior to *aspirin* alone for prevention of recurrent ischemia in patients with unstable angina. The FDA-approved indications for *clopidogrel* are to reduce the rate of stroke, myocardial infarction, and death in patients with recent myocardial infarction, ischemic stroke, established peripheral artery disease, or acute coronary syndrome (Rahmann et al., 2019). *Clopidogrel* is routinely used in combination with *aspirin* after coronary stent implantation.

Adverse Effects. *Clopidogrel* increases the risk of bleeding, particularly when combined with *aspirin* or an anticoagulant. Thrombotic thrombocytopenic purpura can occur but is rare.

Drug Interactions. CYP2C19 inhibition by proton pump inhibitors (e.g., *omeprazole, lansoprazole, dexlansoprazole*, and *pantoprazole*) may reduce conversion to the active metabolite of *clopidogrel*, which may contribute to the lower efficacy of *clopidogrel* when coadministered with proton pump inhibitors. Other *clopidogrel* drug interactions include CYP2C19 inducers and opioids (decrease exposure to *clopidogrel*); bleeding risk is increased with anticoagulants, nonsteroidal anti-inflammatory drugs, and antidepressant drugs such as selective serotonin reuptake inhibitors. Extra caution is advised in patients coadministered *warfarin* (a CYP2C9 substrate) because high doses of *clopidogrel* inhibit CYP2C9 and the acyl-β-glucuronide metabolite of *clopidogrel* is a strong inhibitor of CYP2C8, causing drug interactions with CYP2C8 substrates (e.g., *repaglinide*).

Prasugrel

The newest member of the thienopyridine class, *prasugrel*, is a prodrug that requires metabolic activation in the liver. However, because the activation of *prasugrel* is more efficient than that of *clopidogrel*, *prasugrel* has a more rapid onset of action, and it produces greater and more predictable inhibition of ADP-induced platelet aggregation.

Prasugrel is rapidly and completely absorbed from the gut. It is hydrolyzed in the intestine to a thiolactone, which is then converted to the active metabolite in the liver. Most of the absorbed *prasugrel* undergoes activation; by comparison, only 15% of absorbed *clopidogrel* undergoes metabolic activation. Because the active metabolites of *prasugrel* bind irreversibly to the $P2Y_{12}$ receptor, its effect lasts the lifetime of the platelets. This slow offset of action can be problematic if patients require urgent surgery. *Prasugrel* is inactivated by methylation or conjugation with cysteine. Moderate renal or hepatic impairment does not appear to change the drug pharmacodynamics.

Therapeutic Uses. *Prasugrel* is indicated to reduce the rate of thrombotic cardiovascular events (including stent thrombosis) in patients with acute coronary syndrome who are managed with percutaneous coronary intervention. The incidence of cardiovascular death, myocardial infarction, and stroke is significantly lower with *prasugrel* than with *clopidogrel*, mainly reflecting a reduction in the incidence of nonfatal myocardial infarction. The incidence of stent thrombosis is also lower with *prasugrel* than with *clopidogrel*.

Adverse Effects. *Prasugrel* is associated with higher rates of fatal and life-threatening bleeding than *clopidogrel*. Because patients with a history of a prior stroke or transient ischemic attack are at particularly high risk of intracranial bleeding, the drug is contraindicated in such patients. Patients over 75 years of age should not be prescribed *prasugrel* because of the increased bleeding risk. After a loading dose of 60 mg, *prasugrel* is given once daily at a dose of 10 mg. The daily dose should be reduced to 5 mg in patients weighing less than 60 kg. No dose adjustment is required in patients with hepatic or renal impairment. If patients present with serious bleeding, platelet transfusion may be beneficial. *Prasugrel* has been reported to cause thrombotic thrombocytopenic purpura.

Drug Interactions. Concomitant administration of *prasugrel* with anticoagulants, antidepressant drugs such as selective serotonin reuptake inhibitors, or nonsteroidal anti-inflammatory drugs increases the risk of bleeding.

Ticagrelor

Ticagrelor is an orally active, reversible inhibitor of $P2Y_{12}$. The drug is given twice daily and not only has a more rapid onset and offset of action than *clopidogrel*, but also produces greater and more predictable inhibition of ADP-induced platelet aggregation. The bioavailability of *ticagrelor* is about 36%. It can be given as a whole tablet or crushed in water and administered via a nasogastric tube. *Ticagrelor* is metabolized by hepatic CYP3A4.

Therapeutic Uses. *Ticagrelor* is FDA approved for reduction in the risk of cardiovascular death, myocardial infarction, and stroke in patients with acute coronary syndrome or a history of myocardial infarction. In contrast to *prasugrel*, which is only indicated in patients with acute coronary syndrome undergoing percutaneous intervention, *ticagrelor* is indicated both in those undergoing intervention and in those managed medically.

Adverse Effects. Dyspnea is reported in 17% of patients. This is often transient and not associated with pulmonary disease. *Ticagrelor* is associated with a higher risk of intracranial bleeding than *clopidogrel* and is contraindicated in patients with a history of prior intracranial bleeding. Platelet transfusion is ineffective in patients taking *ticagrelor* who present with serious bleeding because the drug will bind to $P2Y_{12}$ on the transfused platelets. *Bentracimab* (PB2452) was developed to overcome this problem. An antibody fragment that binds *ticagrelor* and its active metabolite with high affinity, *bentracimab* is administered as an intravenous bolus followed by an infusion for up to 24 h. In volunteers given *ticagrelor*, *bentracimab* rapidly and completely reversed its antiplatelet effects (Bhatt et al., 2019). *Bentracimab* is currently under investigation for *ticagrelor* reversal in patients with life-threatening bleeding or who require urgent surgery or intervention.

Drug Interactions. Concomitant *aspirin* at a dose greater than 100 mg daily may reduce the effectiveness of *ticagrelor*. Potent inhibitors of CYP3A (e.g., *ketoconazole, itraconazole, voriconazole, clarithromycin, nefazodone, ritonavir, saquinavir, nelfinavir, indinavir, atazanavir,* and *telithromycin*) and strong inducers of CYP3A (e.g., *rifampin, phenytoin, carbamazepine*, and *phenobarbital*) should be avoided. Opioids decrease *ticagrelor* systemic exposure. *Ticagrelor* increases serum concentrations of *simvastatin* and *lovastatin* and may affect *digoxin* metabolism.

Cangrelor

Cangrelor is a parenteral reversible inhibitor of $P2Y_{12}$. When administered intravenously as a bolus followed by an infusion, *cangrelor* inhibits ADP-induced platelet aggregation within minutes, and its effect on platelet aggregation disappears within 1 h of discontinuation of the drug. *Cangrelor* has a short half-life because it is rapidly dephosphorylated in the circulation to an inactive metabolite.

Therapeutic Use. *Cangrelor* is indicated for reduction in the risk of periprocedural myocardial infarction, repeat coronary revascularization, and stent thrombosis in patients undergoing percutaneous coronary intervention who have not been treated with an oral $P2Y_{12}$ inhibitor and are not given a glycoprotein IIb/IIIa antagonist.

Adverse Effects. The risk of bleeding with *cangrelor* is greater than that with *clopidogrel* during the coronary intervention.

Drug Interactions. When transitioning to oral $P2Y_{12}$ inhibitor therapy, *ticagrelor* can be given at a loading dose of 180 mg at any time during the *cangrelor* infusion or immediately after discontinuation. In contrast, loading doses of *prasugrel* or *clopidogrel* (60 and 600 mg, respectively) should only be given after *cangrelor* is stopped because *cangrelor* blocks the interaction of their active metabolites with $P2Y_{12}$.

Thrombin Receptor Inhibitor

There are two major thrombin receptors on the platelet surface, *protease-activated receptor* (PAR) type 1 and type 4. Thrombin binds to these G protein-coupled receptors and cleaves them at their amino termini. The newly created amino termini then serve as tethered ligands to activate the receptors. PAR-1 is activated by lower concentrations of thrombin than are required to activate PAR-4.

Vorapaxar

Vorapaxar is a competitive antagonist of PAR-1 and inhibits thrombin-induced platelet aggregation. The drug is 90% bioavailable and has a rapid onset of action and a circulating half-life of 3 to 4 days. However, because *vorapaxar* remains tightly bound to PAR-1 on platelets, its effect on thrombin-induced platelet aggregation can persist for up to 4 weeks after the drug is stopped. *Vorapaxar* is metabolized in the liver by CYP3A4.

Therapeutic Uses. *Vorapaxar* is given orally in combination with either *aspirin* or *clopidogrel*. It is indicated for the reduction of thrombotic cardiovascular events in patients with a history of myocardial infarction or peripheral artery disease.

Adverse Effects. *Vorapaxar* increases the risk of bleeding and is contraindicated in patients with a history of intracranial bleeding, stroke, or transient ischemic attack.

Drug Interactions. Potent CYP3A4 inducers, such as *rifampin*, reduce drug exposure, while strong CYP3A4 inhibitors, such as *ketoconazole*, increase drug exposure. Antacids and *pantoprazole* reduce drug exposure.

Glycoprotein IIb/IIIa Inhibitors

Glycoprotein IIb/IIIa is a platelet-surface integrin, designated $\alpha_{IIb}\beta_3$ by the integrin nomenclature. This dimeric glycoprotein undergoes a conformational transformation when platelets are activated to serve as a receptor for fibrinogen and von Willebrand factor, which anchor platelets to each other, thereby mediating aggregation (Figure 36–1). Thus, inhibitors of this receptor are potent antiplatelet agents that act by a mechanism distinct from that of *aspirin* or $P2Y_{12}$ or PAR-1 inhibitors. Three agents are approved for use at present; their features are highlighted in Table 36–4. The use of these agents has decreased with the availability of potent $P2Y_{12}$ inhibitors such as *prasugrel* and *ticagrelor*.

Abciximab

Abciximab is the Fab fragment of a humanized monoclonal antibody directed against the $\alpha_{IIb}\beta_3$ receptor. It also binds to the vitronectin receptor on platelets, vascular endothelial cells, and smooth muscle cells.

The antibody is administered to patients undergoing percutaneous coronary intervention and, when used in conjunction with *aspirin* and *heparin*, has been shown to prevent recurrent myocardial infarction and death. The $t_{1/2}$ of the circulating antibody is about 30 min, but antibody remains bound to the $\alpha_{IIb}\beta_3$ receptor and inhibits platelet aggregation as measured *in vitro* for 18 to 24 h after infusion. It is given as a 0.25-mg/kg bolus followed by an infusion of 0.125 µg/kg/min (maximum 10 µg/kg/min) for 12 to 24 h.

Adverse Effects. The major side effect of *abciximab* is bleeding, and the contraindications to its use are similar to those for the fibrinolytic agents listed in Table 36–4. The frequency of major hemorrhage in clinical trials varies from 1% to 10%, depending on the intensity of concomitant anticoagulation with *heparin*. Thrombocytopenia with a platelet count below 50,000/µL occurs in about 2% of patients and may be due to the formation of antibodies directed against neoepitopes induced by bound antibody. Because the duration of action is long, if major bleeding occurs, platelet transfusion may reverse the aggregation defect because free antibody concentrations fall rapidly after cessation of infusion. *Abciximab* re-administration may be associated with human anti-chimeric antibodies, increased incidence and severity of thrombocytopenia, and enhanced risk of hypersensitivity reactions. *Abciximab* is associated with pseudothrombocytopenia (laboratory artifact requiring blood draws be collected in three separate tubes [ethylenediaminetetraacetic acid, citrate, and heparin]).

Eptifibatide

Eptifibatide is a cyclic peptide inhibitor of the fibrinogen binding site on $\alpha_{IIb}\beta_3$. It is administered intravenously and blocks platelet aggregation. In patients undergoing percutaneous coronary intervention, *eptifibatide* is typically given as a double intravenous bolus of 180 µg/kg (spaced 10 min apart), followed by an infusion of 2 µg/kg/min for 18 to 24 h. The drug is cleared by the kidneys and has a short plasma half-life of 10 to 15 min. Like *abciximab*, *eptifibatide* is mainly used in patients undergoing primary percutaneous coronary intervention for acute ST-segment elevation myocardial infarction, although it also can be used in patients with unstable angina.

Adverse Effects. The major side effect is bleeding. Thrombocytopenia occurs in 0.5% to 1% of patients and is less frequent than with *abciximab*.

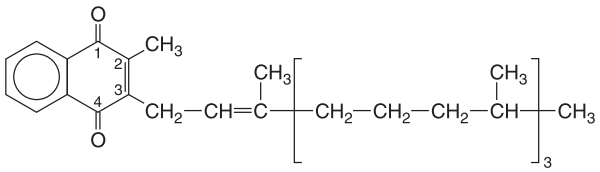
Tirofiban

Tirofiban is an intravenously administered nonpeptide, small-molecule inhibitor of $\alpha_{IIb}\beta_3$. It has a short duration of action and is used for management of patients with non–ST-segment elevation acute coronary syndrome. *Tirofiban* is administered as an intravenously bolus of 25 µg/kg followed by an infusion of 0.15 µg/kg/min for up to 18 h. The infusion dose is reduced by half in patients with a creatinine clearance below 60 mL/min. Like the other agents in this class, the major side effect of *tirofiban* is bleeding, and it may induce thrombocytopenia.

The Role of Vitamin K

Green plants are a nutritional source of vitamin K for humans, in whom vitamin K is an essential cofactor in the γ-carboxylation of multiple glutamate residues of several clotting factors and anticoagulant proteins. The vitamin K–dependent formation of Gla residues permits the appropriate interactions of clotting factors, Ca^{2+}, and membrane phospholipids and modulator proteins (see Figures 36–1, 36–2, and 36–3). Vitamin K antagonists (coumarin derivatives) block Gla formation and thereby inhibit clotting; excess vitamin K_1 can reverse the effects.

Vitamin K activity is associated with at least two distinct natural substances, designated as vitamin K_1 and vitamin K_2. Vitamin K_1, or *phytonadione* (also referred to as phylloquinone), is 2-methyl-3-phytyl-1,4-naphthoquinone; it is found in plants and is the only natural vitamin K available for therapeutic use. Vitamin K_2 is a series of compounds (the menaquinones) in which the phytyl side chain of phytonadione has been replaced by a side chain of 2 to 13 prenyl units. Synthesis of menaquinones occurs in gram-positive bacteria, and the intestinal flora synthesizes the large amounts of vitamin K contained in human and animal feces. *Menadione* (no longer available in the U.S.) is at least as active on a molar basis as *phytonadione*.



PHYTONADIONE (vitamin K_1, phylloquinone)

Physiological Functions and Pharmacological Actions

Phytonadione and menaquinones promote the biosynthesis of the factors II (prothrombin), VII, IX, and X, as well as the anticoagulant proteins C, S, and Z.

Figure 36–6 summarizes the coupling of the vitamin K cycle with glutamate carboxylation. The γ-glutamyl carboxylase and epoxide reductase are integral membrane proteins of the endoplasmic reticulum and function as a multicomponent complex. With respect to proteins affecting

TABLE 36–4 ■ FEATURES OF GPIIb/IIIa ANTAGONISTS

FEATURE	ABCIXIMAB	EPTIFIBATIDE	TIROFIBAN
Description	Fab fragment of humanized mouse mAb	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD-mimetic
Specific for GPIIb/IIIa	No	Yes	Yes
Plasma $t_{1/2}$	Short (minutes)	Long (2.5 h)	Long (2.0 h)
Platelet-bound $t_{1/2}$	Long (days)	Short (seconds)	Short (seconds)
Renal clearance	No	Yes	Yes

blood coagulation, these reactions occur in the liver, but γ-carboxylation of glutamate also occurs in lung, bone, and other cell types. Mutations in γ-glutamyl carboxylase can cause bleeding disorders.

Human Requirements

In patients rendered vitamin K deficient by a starvation diet or antibiotic therapy for 3 to 4 weeks, the minimum daily requirement is estimated to be 0.03 μg/kg of body weight and possibly as high as 1 μg/kg, which is approximately the recommended daily intake for adults (70 μg).

Symptoms of Deficiency

The major clinical manifestation of vitamin K deficiency is bleeding. Ecchymoses, epistaxis, hematuria, GI bleeding, and postoperative hemorrhage are common; intracranial hemorrhage may occur. Hemoptysis is uncommon. The presence of vitamin K–dependent proteins in bone such as osteocalcin and matrix Gla protein may explain why fetal bone abnormalities can occur with maternal *warfarin* administration in the first trimester of pregnancy. Vitamin K plays a role in adult skeletal maintenance and the prevention of osteoporosis. Low concentrations of the vitamin are associated with decreased bone mineral density and subsequent fractures; vitamin K supplementation increases the carboxylation state of osteocalcin and improves bone mineral density, but the relationship between these effects is unclear. Bone mineral density in adults does not appear to be changed with long-term *warfarin* therapy, but new bone formation may be affected.

Toxicity

Phytonadione and the menaquinones are nontoxic. *Menadione* and its derivatives (synthetic forms of vitamin K) may produce hemolytic anemia and kernicterus in neonates and should not be used as therapeutic forms of vitamin K.

ADME

The mechanism of intestinal absorption of compounds with vitamin K activity varies depending on their solubility. In the presence of bile salts, *phytonadione* and the menaquinones are adequately absorbed from the intestine, *phytonadione* by an energy-dependent, saturable process in proximal portions of the small intestine and menaquinones by diffusion in the distal small intestine and the colon. After absorption, *phytonadione* is incorporated into chylomicrons in close association with triglycerides and lipoproteins. The low *phytonadione* levels in newborns may partly reflect the low plasma lipoprotein concentrations at birth and may lead to an underestimation of vitamin K tissue stores. After absorption, *phytonadione* and menaquinones are concentrated in the liver, but the concentration of *phytonadione* declines rapidly. Menaquinones, produced in the distal bowel, are less biologically active because of their long side chain. Very little vitamin K accumulates in other tissues. There is only modest storage of vitamin K in the body. Consequently, when lack of bile interferes with absorption of vitamin K, there is progressive reduction in the levels of the vitamin K–dependent clotting factors over the course of several weeks.

Therapeutic Uses

Vitamin K is used therapeutically to correct the bleeding tendency or hemorrhage associated with its deficiency. Vitamin K deficiency can result from inadequate intake, absorption, or utilization of the vitamin or as a consequence of the action of *warfarin*.

Phytonadione is available in tablet form and in a dispersion with buffered polysorbate and propylene glycol or polyoxyethylated fatty acid derivatives and dextrose. *Phytonadione* may be given by any route; however, the subcutaneous route should be avoided in patients with a coagulopathy because of the risk of bleeding. The oral route is preferred, but if more rapid reversal is required, *phytonadione* can be given by slow intravenous infusion; it should not be given rapidly because severe reactions resembling anaphylaxis can occur.

Inadequate Intake

After infancy, hypoprothrombinemia due to dietary deficiency of vitamin K is extremely rare. The vitamin is present in many foods and is synthesized by intestinal bacteria. Occasionally, the use of a broad-spectrum antibiotic may itself produce hypoprothrombinemia that responds readily to small doses of vitamin K and reestablishment of normal bowel flora. Hypoprothrombinemia can occur in patients receiving prolonged intravenous alimentation; to prevent this, it is recommended that such patients receive 1 mg of *phytonadione* per week (the equivalent of about 150 μg/day).

Hypoprothrombinemia of the Newborn

Healthy newborn infants have decreased plasma concentrations of vitamin K–dependent clotting factors for a few days after birth, the time required for adequate dietary intake of the vitamin and for establishment of normal intestinal flora. Measurements of non-γ-carboxylated prothrombin suggest that vitamin K deficiency occurs in about 3% of live births.

Hemorrhagic disease of the newborn has been associated with breast-feeding; human milk has low concentrations of vitamin K. In addition, the microbiome of breast-fed infants may lack microorganisms that synthesize the vitamin. Commercial infant formulas are supplemented with vitamin K. In the neonate with hemorrhagic disease of the newborn, administration of vitamin K raises the concentration of these clotting factors to levels normal for newborns and controls the bleeding tendency within about 6 h. Routine administration of 1 mg *phytonadione* intramuscularly at birth is required by law in the U.S. The dose may have to be increased or repeated if the mother has received *warfarin* or anticonvulsant drug therapy or if the infant develops a bleeding diathesis. Alternatively, some clinicians treat mothers who are receiving anticonvulsants with oral vitamin K prior to delivery (20 mg/day for 2 weeks).

Inadequate Absorption

Vitamin K is poorly absorbed in the absence of bile. Thus, hypoprothrombinemia may be associated with intrahepatic or extrahepatic biliary obstruction or with defective intestinal absorption of fat from other causes.

Biliary Obstruction or Fistula

Bleeding that accompanies obstructive jaundice or a biliary fistula responds promptly to the administration of vitamin K. Oral *phytonadione* administered with bile salts is both safe and effective and should be used in the care of the jaundiced patient, both preoperatively and postoperatively. In the absence of significant hepatocellular disease, the prothrombin level rapidly returns to normal. If oral administration is not feasible, a parenteral preparation should be used. The usual daily dose of vitamin K is 10 mg.

Malabsorption Syndromes

Among the disorders that result in inadequate absorption of vitamin K from the intestinal tract are cystic fibrosis, celiac disease, Crohn's disease, ulcerative colitis, dysentery, and extensive resection of bowel. Because drugs that reduce the bacterial population of the bowel are used frequently in many of these disorders, the availability of the vitamin may be further reduced. For immediate correction of the deficiency, parenteral vitamin K should be given.

Inadequate Utilization

Hepatocellular disease or long-standing biliary obstruction may be accompanied or followed by hypoprothrombinemia. If inadequate secretion of bile salts is contributing to the syndrome, some benefit may be obtained from the parenteral administration of 10 mg of *phytonadione* daily. Paradoxically, administration of large doses of vitamin K or its analogues in an attempt to correct the hypoprothrombinemia can be associated with severe hepatitis or cirrhosis, which may contribute to a further reduction in the level of prothrombin.

Drug- and Venom-Induced Hypoprothrombinemia

Warfarin and its congeners act as competitive antagonists of vitamin K and interfere with the hepatic biosynthesis of Gla-containing clotting factors. The treatment of bleeding caused by oral anticoagulants was described previously. Vitamin K may be of help in combating the bleeding and hypoprothrombinemia that follow the bite of the tropical American pit viper or other species whose venom degrades or inactivates prothrombin.

Drug Facts for Your Personal Formulary: *Agents That Modify Blood Coagulation*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Unfractionated Heparin		
Heparin	• Prophylaxis/treatment of venous thromboembolism • Acute coronary syndrome • Percutaneous coronary intervention • Cardiopulmonary bypass surgery • Disseminated intravascular coagulation	• Administered SC 2–3 times daily for thromboprophylaxis • Administered IV for immediate onset of action with aPTT monitoring • Can be used in renal impairment • Can be used in pregnancy
Low-Molecular-Weight Heparin		
Enoxaparin Dalteparin Tinzaparin (not in the U.S.)	• Prophylaxis against venous thromboembolism • Initial treatment of venous thromboembolism • Maintenance treatment in patients with cancer-associated venous thromboembolism • Acute coronary syndrome	• Administered SC once or twice daily • Routine anti–factor Xa monitoring not required • Dosage adjustment required when CrCL <30 mL/min • Can be used in pregnancy
Fondaparinux		
Fondaparinux	• Prophylaxis against venous thromboembolism • Initial treatment of venous thromboembolism • Heparin-induced thrombocytopenia but not for other thrombocytopenias • Acute coronary syndrome in some countries	• Once-daily SC injection • Lower dose used for thromboprophylaxis and in acute coronary syndrome • Contraindicated if CrCL <30 mL/min • Use in pregnancy less established than for low-molecular-weight heparin • Routine anti–factor Xa monitoring not required
Other Anticoagulants		
Desirudin	• Thromboprophylaxis after hip arthroplasty	• Twice-daily SC injection • Dosage adjustment required with renal impairment
Bivalirudin	• Percutaneous coronary intervention • Heparin-induced thrombocytopenia	• Administered IV • ACT or aPTT monitoring • Requires dose reduction with renal impairment
Argatroban	• Heparin-induced thrombocytopenia but not for other thrombocytopenias	• Hepatic metabolism • Can be used in renal impairment • Increases INR, which can complicate transition to warfarin
Vitamin K Antagonist		
Warfarin	• Treatment of venous thromboembolism in tandem with parenteral anticoagulation • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation • Prevention of stroke in patient with mechanical heart valves or ventricular assist devices	• Oral vitamin K antagonist • Narrow therapeutic index • Requires regular INR monitoring • Multiple drug interactions • Dietary vitamin K interactions • Can be used in renal failure • Contraindicated in pregnancy (fetal risk)
Direct Oral Thrombin Inhibitor		
Dabigatran etexilate	• Treatment of acute venous thromboembolism after at least 5 days of parenteral anticoagulation • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation • Thromboprophylaxis after hip or knee arthroplasty	• Fixed twice-daily oral dosing (once daily if used for thromboprophylaxis) • Reduce the dose with CrCL 15–30 mL/min • Contraindicated if CrCL <15 mL/min • Use with caution in patients with recent bleeding, especially GI bleeding • Can be reversed with idarucizumab
Direct Oral Factor Xa Inhibitors		
Rivaroxaban	• Treatment of acute venous thromboembolism • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation • Thromboprophylaxis after hip or knee arthroplasty • Prevention of recurrent ischemia in stabilized acute coronary syndrome patients (not in North America) • Secondary prevention of major adverse cardiovascular and limb events in patients with coronary or peripheral artery disease	• Fixed oral dosing (once daily except for initial treatment of venous thromboembolism, which starts with twice-daily dosing for 21 days and once daily thereafter, or for secondary prevention after acute coronary syndrome or in patients with coronary or peripheral artery disease where the drug is given twice daily in low doses) • Avoid in patients with renal/hepatic dysfunction • Use with caution in patients with recent bleeding, especially GI bleeding
Apixaban	• Treatment of acute venous thromboembolism • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation • Thromboprophylaxis after hip or knee arthroplasty	• Fixed oral dosing (twice daily, higher dose for the first 7 days for acute venous thromboembolism) • Reduce dose for stroke prophylaxis if any two of the following are present: age >80 years, body weight <60 kg, or serum creatinine ≥1.5 mg/dL • Use with caution in patients with recent bleeding, especially GI bleeding

Drug Facts for Your Personal Formulary: *Agents That Modify Blood Coagulation (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Edoxaban	• Treatment of acute venous thromboembolism after at least 5 days of parenteral anticoagulation • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation	• Fixed once-daily dosing • Reduce the dose if any of the following is present: CrCL 15–50 mL/min, body weight <60 kg, or concomitant potent P-glycoprotein inhibitor • Not recommended for patients with CrCL <15 mL/min • Contraindicated if CrCL >95 mL/min • Use with caution in patients with recent bleeding, especially GI bleeding
Reversal Agents for Direct Oral Anticoagulants		
Idarucizumab	• Reversal of dabigatran	• Humanized Fab fragment against dabigatran • Bolus IV administration • Rapid and complete reversal
Andexanet alfa	• Reversal of rivaroxaban or apixaban • Reversal of edoxaban (off-label use)	• Recombinant analogue of factor Xa, inactivated-zhzo • Acts as a decoy for oral factor Xa inhibitors • Given as IV bolus followed by 2-h IV infusion
Ciraparantag (not available in the U.S.)	• Reversal of dabigatran, rivaroxaban, apixaban, or edoxaban	• Synthetic small molecule • Binds target drugs • In phase III evaluation
Fibrinolytic Drugs		
Alteplase	• Thrombolysis in acute ischemic stroke, massive pulmonary embolism, or myocardial infarction	• IV bolus followed by an infusion • Risk of major bleeding, including intracranial bleeding
Reteplase	• Thrombolysis in myocardial infarction	• Two IV boluses • Risk of major bleeding, including intracranial bleeding
Tenecteplase	• Thrombolysis in pulmonary embolism and myocardial infarction	• Single IV bolus • Risk of major bleeding, including intracranial bleeding
Inhibitors of Fibrinolysis		
ε-Aminocaproic acid	• Reduce intraoperative bleeding	• Inhibits plasmin-mediated degradation of fibrin • IV infusion
Tranexamic acid	• Major head injury • Major trauma resuscitation • Reduce intraoperative bleeding • Topical application for dental bleeding and epistaxis • Menorrhagia	• Inhibits plasmin-mediated degradation of fibrin • Available in oral or IV form • Given orally in patients undergoing dental procedures or in women with menorrhagia and IV in patients with major trauma or undergoing major orthopedic surgery
Antiplatelet Drugs		
Aspirin	• Acute myocardial infarction or acute ischemic stroke • Secondary prevention in patients with stroke, coronary artery disease, or peripheral artery disease	• COX-1 inhibitor (selectivity >100× over COX-2) • Antithrombotic effect achieved with low doses (<100 mg daily) • Reduced toxicity with lower doses
Dipyridamole	• Secondary prevention of stroke when combined with aspirin	• Available as a fixed-dose combined tablet with low-dose aspirin
Clopidogrel	• Acute coronary syndrome • Secondary prevention in patients with myocardial infarction, stroke, or peripheral artery disease	• Irreversible inhibitor of $P2Y_{12}$ • Given once daily • Variable response because common genetic polymorphisms attenuate metabolic activation • Proton pump inhibitors reduce conversion to active metabolite
Prasugrel	• After coronary intervention for acute coronary syndrome	• Irreversible inhibitor of $P2Y_{12}$ • Given once daily • More predictable inhibition of ADP-induced platelet activation than clopidogrel because of more efficient metabolic activation • Contraindicated in patients with cerebrovascular disease, prior intracranial bleed, or >75 years of age • Reduce dose in patients weighing <60 kg • Higher bleeding risk than clopidogrel
Ticagrelor	• Acute coronary syndrome with or without coronary intervention	• Reversible inhibitor of $P2Y_{12}$ • Given twice daily • Does not require metabolic activation • Higher bleeding risk than clopidogrel • Contraindicated in patients with a history of intracranial bleeding

Drug Facts for Your Personal Formulary: *Agents That Modify Blood Coagulation (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Cangrelor	• Percutaneous coronary intervention	• $P2Y_{12}$ inhibitor • Rapid onset and offset IV agent • Higher bleeding risk than clopidogrel • When administered with cangrelor, clopidogrel and prasugrel will have no antiplatelet effect
Vorapaxar	• Secondary prevention in patients with a history of myocardial infarction or peripheral artery disease	• PAR-1 antagonist • Contraindicated in patients with cerebrovascular disease or prior intracranial bleed
Abciximab Eptifibatide Tirofiban	• Coronary intervention for acute coronary syndrome	• Glycoprotein IIb/IIIa antagonists • Up to 10% bleeding risk • Can cause thrombocytopenia • Eptifibatide contraindicated in renal failure • Reduce tirofiban dose if CrCL ≤60 mL/min
Vitamin Supplementation		
Vitamin K	• Reversal of warfarin • Hypoproteinemia of the newborn • Biliary obstruction • Malnutrition	• Oral administration preferred • Can be given by slow IV infusion but higher risk of adverse events

Abbreviations: SC, subcutaneous; IV intravenous; CrCL, creatinine clearance.

Chapter 37

Drug Therapy for Dyslipidemias

Natalia Ruiz-Negrón and Donald K. Blumenthal

Dyslipidemia is a disorder of lipoprotein metabolism, including lipoprotein overproduction or deficiency. Dyslipidemia is a major cause of atherosclerotic cardiovascular disease (ASCVD), ischemic cerebrovascular disease, and peripheral vascular disease. Cardiovascular disease is the number one cause of death globally (World Health Organization, 2020). Genetic disorders, metabolic diseases such as diabetes mellitus, and lifestyle factors are common causes of dyslipidemias, including hypercholesterolemia and low levels of high-density lipoprotein (HDL) cholesterol.

In 2018, various professional organizations, including the American Heart Association (AHA) and the American College of Cardiology (ACC), published updated guidelines for the management of blood cholesterol (Grundy et al., 2019). Contrary to the 2014 ACC/AHA cholesterol guidelines (Stone et al., 2014), these updated guidelines recommend cholesterol percent reduction targets in certain high-risk groups for the primary prevention of cardiovascular disease. This change signaled a shift to previous approaches used for cholesterol management, like those highlighted in the 2004 Adult Treatment Panel III guidelines (Grundy et al., 2004; NCEP, 2002). However, fixed-dose statin recommendations, like those emphasized in the 2014 ACC/AHA guideline, remained in place in the 2018 AHA/ACC cholesterol guidelines, particularly when managing secondary prevention of cardiovascular disease and patients with diabetes mellitus. With these changes, the most recent guidelines appear to merge recommendations and varying schools of thought on cholesterol management from previously published guidelines (Table 37–1). Since its release, part of the 2018 AHA/ACC cholesterol guidelines have been updated and published separately as the 2019 ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease (Arnett et al., 2019). However, only updates on *aspirin* use and more specific recommendations on nonpharmacological aspects of ASCVD prevention were added.

Plasma Lipoprotein Metabolism

Lipoproteins are macromolecular assemblies that contain lipids and proteins. The lipid constituents include free and esterified cholesterol, triglycerides, and phospholipids. Lipoproteins are generally spherical particles, with a shell composed of free cholesterol and phospholipid, with fatty acids oriented toward the core of the particle. The protein components, known as *apolipoproteins* or *apoproteins*, provide structural stability to the lipoproteins and may function as ligands in lipoprotein-receptor interactions or as cofactors in enzymatic processes that regulate lipoprotein metabolism. The major classes of lipoproteins and their properties are summarized in Table 37–2. Apoproteins have well-defined roles in plasma lipoprotein metabolism (Table 37–3). Mutations in lipoproteins or their receptors can lead to familial dyslipidemias and premature death due to accelerated atherosclerosis.

In all spherical lipoproteins, the most water-insoluble lipids (cholesteryl esters and triglycerides) are core components, and the more polar, water-soluble components (apoproteins, phospholipids, and unesterified cholesterol) are located on the surface. Except for apo(a), the lipid-binding regions of all apoproteins contain amphipathic helices that interact with the polar, hydrophilic lipids (such as surface phospholipids) and with the aqueous plasma environment in which the lipoproteins circulate. Differences in the non–lipid-binding regions determine the functional specificities of the apolipoproteins.

Figure 37–1 summarizes the pathways involved in the uptake and transport of dietary fat and cholesterol from the intestines to adipose tissue, peripheral tissues, and the liver. Figure 37–2 shows the reverse cholesterol pathway that transports cholesterol from peripheral tissues back to the liver for excretion in the bile. These pathways involve the lipoprotein structures described in the next sections.

Chylomicrons

Intestinal cholesterol absorption is mediated by the Niemann-Pick C1–like 1 protein, which appears to be the target of *ezetimibe*, a cholesterol absorption inhibitor. After their uptake by epithelial cells in the small intestines, dietary lipids and endogenous lipids are transferred to the endoplasmic reticulum where newly synthesized apo B-48 is available to form chylomicrons. Apo B-48, synthesized only by intestinal epithelial cells, is unique to chylomicrons and functions primarily as a structural component of chylomicrons.

Chylomicrons are synthesized from the fatty acids of dietary triglycerides and cholesterol absorbed by epithelial cells in the small intestine. Chylomicrons are the largest and lowest-density plasma lipoproteins. In

Abbreviations

ABC: ATP-binding cassette
ACAT-2: type 2 isozyme of acyl coenzyme A:cholesterol acyltransferase
ACC: American College of Cardiology
ACL: ATP-citrate lyase
ACTH: adrenocorticotropic hormone
ADA: American Diabetes Association
AHA: American Heart Association
ALT: alanine aminotransferase
ANGPTL3: angiopoietin-like protein 3
apo(a): apolipoprotein (a)
ASCVD: atherosclerotic cardiovascular disease
CETP: cholesteryl ester transfer protein
CHD: coronary heart disease
CYPs: cytochrome P450s
DHA: docosahexaenoic acid
EL: endothelial lipase
EPA: eicosapentaenoic acid
ER: extended release
FH: familial hypercholesterolemia
GI: gastrointestinal
GWAS: genome-wide association studies
HDL: high-density lipoprotein
HDL-C: high-density lipoprotein cholesterol concentration
HeFH: heterozygous familial hypercholesterolemia
HIV: human immunodeficiency virus
HL: hepatic lipase
HMG-CoA: β-hydroxy β-methylglutaryl coenzyme A
HoFH: homozygous familial hypercholesterolemia
IDL: intermediate-density lipoprotein
IgG: immunoglobulin G
IR: immediate release
LCAT: lecithin:cholesterol acyltransferase
LDL: low-density lipoprotein
LDL-C: low-density lipoprotein cholesterol concentration
LDLR: LDL receptor gene
LP(a): lipoprotein (a)
LPL: lipoprotein lipase
LRP: LDL receptor–related protein
MTP: microsomal triglyceride transfer protein
NAD: nicotinamide adenine dinucleotide
NADP: nicotinamide adenine dinucleotide phosphate
NCEP: National Cholesterol Education Program
OTC: over-the-counter
PCE: pooled cohort equations
PCSK9: proprotein convertase subtilisin/kexin type 9
PPAR: peroxisome proliferator–activated receptor
SR: scavenger receptor
VLDL: very low-density lipoprotein

normolipidemic individuals, chylomicrons are present in plasma for 3 to 6 h after a fat-containing meal has been ingested. Dietary cholesterol is esterified by the acyl coenzyme A:cholesterol acyltransferase type 2 (ACAT-2). ACAT-2 is found in the intestine and in the liver, where cellular free cholesterol is esterified before triglyceride-rich lipoproteins (chylomicrons and very low-density lipoproteins [VLDLs]) are assembled.

Chylomicrons enter the systemic circulation via the thoracic duct. Chylomicron triglycerides are then metabolized to free fatty acids by an extracellular lipoprotein lipase (LPL) at the capillary luminal surface of tissues that synthesize LPL (see Figure 37–1), including adipose tissue, skeletal and cardiac muscle, and breast tissue of lactating women. The resulting free fatty acids are taken up and used by the adjacent tissues. The interaction of chylomicrons and LPL requires apo C-II as a cofactor.

Chylomicron Remnants

LPL-mediated removal of much of the dietary triglycerides generates the *chylomicron remnants*, which contain all of the dietary cholesterol. Chylomicron remnants detach from the capillary surface and are removed from the circulation by the liver within minutes (see Figure 37–1). First, the remnants are sequestered by the interaction of apo E with heparan sulfate proteoglycans on the surface of hepatocytes and are processed by the hepatic lipase (HL), further reducing the remnant triglyceride content. Next, apo E mediates remnant uptake by interacting with the hepatic low-density lipoprotein (LDL) receptor or the LDL receptor–related protein (LRP).

During the initial hydrolysis of chylomicron triglycerides by LPL, apo A-I and phospholipids are shed from the surface of chylomicrons and remain in the plasma. This is one mechanism by which nascent (precursor) HDL is generated (see Figure 37–2). Chylomicron remnants are not precursors of LDL, but the dietary cholesterol delivered to the liver by remnants increases plasma low-density lipoprotein cholesterol (LDL-C) levels. Increased liver cholesterol suppresses steroid receptor element binding protein–regulated expression of proprotein convertase subtilisin/kexin type 9 (PCSK9), thus reducing LDL receptor–mediated catabolism of LDL by the liver (see PCSK9 Inhibitors below for additional details).

Very Low-Density Lipoproteins

The VLDLs are produced in the liver when triglyceride production is stimulated by an increased flux of free fatty acids or by increased *de novo* synthesis of fatty acids by the liver. Apo B-100, apo E, and apo C-I, C-II, and C-III are synthesized constitutively by the liver and incorporated into VLDLs (see Table 37–3). Triglycerides are synthesized in the endoplasmic reticulum and, along with other lipid constituents, are transferred by the microsomal triglyceride transfer protein (MTP) to the site in the endoplasmic reticulum where newly synthesized apo B-100 is available to form nascent (precursor) VLDL. Small amounts of apo E and the C apoproteins are incorporated into nascent particles within the liver before secretion, but most of these apoproteins are acquired from plasma HDL after the VLDLs are secreted by the liver. Mutations of MTP that result in the inability of triglycerides to be transferred to either apo B-100 in the liver or apo B-48 in the intestine prevent VLDL and chylomicron production and cause the genetic disorder *abetalipoproteinemia*.

Plasma VLDL is catabolized by LPL in the capillary beds in a process similar to the lipolytic processing of chylomicrons (see Figure 37–1). When triglyceride hydrolysis is nearly complete, the VLDL remnants, usually termed *IDLs*, are released from the capillary endothelium and reenter the circulation. Apo B-100–containing small VLDLs and IDLs, which have a $t_{1/2}$ of less than 30 min, have two potential fates. About 40% to 60% are cleared from the plasma by the liver via apo B-100– and apo E–mediated interaction with LDL receptors and LRP. LPL and HL convert the remainder of the IDLs to LDLs by removal of additional triglycerides. The C apoproteins, apo E, and apo A-V redistribute to HDL.

Apolipoprotein E plays a major role in the metabolism of triglyceride-rich lipoproteins (chylomicrons, chylomicron remnants, VLDLs, and IDLs). About half of the apo E in the plasma of fasting subjects is associated with triglyceride-rich lipoproteins, and the other half is a constituent of HDL.

Low-Density Lipoproteins

Virtually all LDL particles in the circulation are derived from VLDL. The LDL particles have a $t_{1/2}$ of 1.5 to 2 days. In subjects without hypertriglyceridemia, two-thirds of plasma cholesterol is found in the LDL. Plasma clearance of LDL is mediated primarily by LDL receptors (apo B-100 binds LDL to its receptor); a small component is mediated by nonreceptor clearance mechanisms.

TABLE 37–1 ■ COMPARISON OF KEY CLINICAL GUIDELINES FOR THE MANAGEMENT OF CHOLESTEROL IN ADULTS

	ATPIII 2004	ACC/AHA 2014	AHA/ACC 2018	ACC/AHA 2019
Risk assessment strategy	10-year FRS; CHD risk factors	10-year PCE	10-year or lifetime PCE	10-year or lifetime PCE
Candidates for treatment	Patients above LDL-C goal	Patients in four statin benefit groups	Patients above LDL-C goal	Primary prevention in all patients
Recommended statin intensity	Titrated to achieve LDL-C goal	Moderate-to-high intensity	Moderate-to-high intensity (may be titrated to achieve a specific LDL-C percent reduction goal)	Moderate-to-high intensity (may be titrated to achieve a specific LDL-C percent reduction goal)

Recommendations	*Risk groups and LDL-C goals:*
	• High risk if CHD, risk equivalent, or FRS ≥20% (LDL-C goal <100 mg/dL; <70 mg/dL optional)
	• Moderate-high risk if ≥2 risk factors or FRS 10% to <20% (LDL-C goal <130 mg/dL; <100 mg/dL optional)
	• Moderate risk if ≥2 risk factors or FRS <10% (LDL-C goal <130 mg/dL; therapy started if LDL-C >160 mg/dL)
	• Lower risk if 0 or 1 risk factor (LDL-C goal <160 mg/dL; therapy started if LDL-C >190 mg/dL)
		Four statin benefit groups:
		• If ≥21 years old, clinical ASCVD, high-intensity statin (or moderate, if >75 years old)
		• If ≥21 years old and LDL-C ≥190 mg/dL, high-intensity statin
		• If 40–75 years old with DM and LDL-C 70–189 mg/dL, moderate-intensity statin (or high-intensity if ASCVD ≥7.5%)
		• If 40–75 years old with LDL-C 70–189 mg/dL, moderate- to high-intensity statin if ASCVD ≥7.5%
			Risk groups and LDL-C goals:
			• Primary Prevention (ages 40–75 years):
			  • If LDL-C ≥190 mg/dL, high-intensity statin recommended regardless of ASCVD risk
			  • If patient has DM, moderate-intensity statin recommended regardless of ASCVD risk
			  • High risk if ASCVD ≥20% (LDL-C goal reduction of ≥50%)
			  • Intermediate risk if ASCVD ≥7.5% to <20% + risk factors present (LDL-C goal reduction of 30%–49%)
			  • Borderline risk if ASCVD ≥5% to <7.5% + risk factors present (moderate-intensity statin might be recommended; no specific LDL-C percent reduction stated)
			  • Low risk if ASCVD <5% (lifestyle intervention only; statin therapy not recommended)
			• Secondary Prevention:
			  • Very high-risk ASCVD if major events and/or high-risk conditions present: high-intensity statin recommended
			  • Not very high-risk ASCVD: high-intensity statin recommended if age ≤75 years (LDL-C goal reduction of ≥50%); if age ≥75 years, moderate-intensity statin reasonable, depending on clinical assessment
				Same recommendations as those stated in AHA/ACC 2018 under "Primary Prevention"

Refer to Table 37–4 for discussion of ASCVD risk factors.
ATPIII, Adult Treatment Panel III; CHD, coronary heart disease; DM, diabetes mellitus; FRS, Framingham Risk Score.
Source: Data from ATPIII (Grundy et al., 2004; NCEP, 2002), ACC/AHA 2014 (Stone et al., 2014), AHA/ACC 2018 (Grundy et al., 2019), and ACC/AHA 2019 (Arnett et al., 2019).

The most common cause of autosomal dominant hypercholesterolemia involves loss-of-function mutations of the *LDL* receptor gene (*LDLR*). Defective or absent LDL receptors cause high levels of plasma LDL-C and the most common form of familial hypercholesterolemia (FH). Treatment of homozygous familial hypercholesterolemia (HoFH), which is associated with accelerated ASCVD and premature death at or before the age of 30, is treated by inhibiting cholesterol synthesis with statins or by inhibiting angiopoietin-like protein 3 with monoclonal antibodies. LDL becomes atherogenic when modified by oxidation, a required step for LDL uptake by the *scavenger receptors* (SRs) of macrophages. This process leads to foam cell formation in arterial lesions. At least two SRs are involved (SR-AI/II and CD36). SR-AI/II appears to be expressed more in early atherogenesis, and CD36 expression is greater as foam cells form during lesion progression. The liver expresses a large complement of LDL receptors and removes about 75% of all LDL from the plasma. Consequently, manipulation of hepatic LDL receptor gene expression is a most effective way to modulate plasma LDL-C level. *The most effective dietary alteration (decreased consumption of saturated fat and cholesterol) and pharmacological treatment (statins) for hypercholesterolemia act by enhancing hepatic LDL receptor expression.*

High-Density Lipoproteins

The HDLs are protective lipoproteins that decrease the risk of CHD; thus, high levels of HDLs are generally desirable. This protective effect may result from the participation of HDL in reverse cholesterol transport, the process by which excess cholesterol is acquired from cells and transferred to the liver for excretion (see Figure 37–2). HDL effects also include putative anti-inflammatory, antioxidative, platelet antiaggregatory, anticoagulant, and profibrinolytic activities. Apo A-I is the major HDL apoprotein, and its plasma concentration is a more powerful inverse predictor of CHD risk than an overall high-density lipoprotein cholesterol (HDL-C) level. Apo A-I synthesis is required for normal production of HDL.

Mutations in the apo A-I gene that cause HDL deficiency often are associated with accelerated atherogenesis. In addition, two major subclasses of mature HDL particles in the plasma can be differentiated by their

TABLE 37–2 ■ CHARACTERISTICS OF PLASMA LIPOPROTEINS

LIPOPROTEIN CLASS	DENSITY (g/mL)	MAJOR LIPID CONSTITUENT	TG:CHOL	SIGNIFICANT APOPROTEINS	SITE OF SYNTHESIS	CATABOLIC PATHWAY
Chylomicrons and remnants	<1.006	Dietary triglycerides and cholesterol	10:1	B-48, E, A-I, A-IV, C-I, C-II, C-III	Intestine	TG hydrolysis by LPL; apo E–mediated remnant uptake by liver
VLDL	<1.006	"Endogenous" or hepatic triglycerides	5:1	B-100, E, C-I, C-II, C-III	Liver	TG hydrolysis by LPL
IDL	1.006–1.019	Cholesteryl esters and "endogenous" triglycerides	1:1	B-100, E, C-II, C-III	Product of VLDL catabolism	50% converted to LDL mediated by HL; 50% apo E–mediated uptake by liver
LDL	1.019–1.063	Cholesteryl esters	NS	B-100	Product of VLDL catabolism	Apo B-100-mediated uptake by LDL receptor (~75% in liver)
HDL	1.063–1.21	Phospholipids, cholesteryl esters	NS	A-I, A-II, E, C-I, C-II, C-III	Intestine, liver, plasma	Complex: transfer of cholesteryl ester to VLDL and LDL; uptake of HDL cholesterol by hepatocytes
Lp(a)	1.05–1.09	Cholesteryl esters	NS	B-100, apo(a)	Liver	Unknown

CHOL, cholesterol; NS, not significant (TG is <5% of LDL and HDL); TG, triglyceride.

content of the major HDL apoproteins, apo A-I and apo A-II. Epidemiologic evidence in humans suggests that apo A-II may be atheroprotective.

The membrane transporter ABCA1 facilitates the transfer of free cholesterol from cells to HDL. After free cholesterol is acquired by the nascent pre-β1 HDL, it is esterified by lecithin:cholesterol acyltransferase (LCAT). The newly esterified and nonpolar cholesterol moves into the core of the particle, which becomes progressively more spherical, larger, and less dense with continued cholesterol acquisition and esterification. As the cholesteryl ester content of the particle (now called HDL_2) increases, the cholesteryl esters of these particles begin to be exchanged for triglycerides derived from any of the triglyceride-containing lipoproteins (chylomicrons, VLDLs, remnant lipoproteins, and LDLs). This exchange, mediated by cholesterol ester transfer protein (CETP), accounts for the removal of about two-thirds of the cholesterol associated with HDL in humans. The transferred cholesterol subsequently is metabolized as part of the lipoprotein into which it was transferred. Treatments that target CETP and the ATP-binding cassette (ABC) transporters have yielded equivocal results in humans. While CETP inhibitors effectively reduce LDL-C levels, they also increase the frequency of adverse cardiovascular events (angina, revascularization, myocardial infarction, heart failure, and death).

The triglyceride that is transferred into HDL_2 is hydrolyzed in the liver by HL, a process that regenerates smaller, spherical HDL_3 particles that recirculate and acquire additional free cholesterol from tissues containing excess free cholesterol. HL is sensitive to hormone regulation, and HL activity modulates HDL-C levels. Androgens increase HL gene expression/activity, which accounts for the lower HDL-C values observed in men than in women. Estrogens reduce HL activity, but their impact on HDL-C levels in women is substantially less than that of androgens on HDL-C levels in men. HL appears to have a pivotal role in regulating HDL-C levels, as HL activity is increased in many patients with low HDL-C levels.

TABLE 37–3 ■ APOLIPOPROTEINS

APOLIPOPROTEIN (MW in kDa)	AVERAGE CONCENTRATION (mg/dL)	SITES OF SYNTHESIS	FUNCTIONS
apo A-I (~29)	130	Liver, intestine	Structural in HDL; LCAT cofactor; ligand of ABCA1 receptor; reverse cholesterol transport
apo A-II (~17)	40	Liver	Forms -*S*-*S*- complex with apo E-2 and E-3, which inhibits E-2 and E-3 binding to lipoprotein receptors
apo A-V (~40)	<1	Liver	Modulates triglyceride incorporation into hepatic VLDL; activates LPL
apo B-100 (~513)	85	Liver	Structural protein of VLDL, IDL, LDL; LDL receptor ligand
apo B-48 (~241)	Fluctuates according to dietary fat intake	Intestine	Structural protein of chylomicrons
apo C-I (~6.6)	6	Liver	LCAT activator; modulates receptor binding of remnants
apo C-II (8.9)	3	Liver	LPL cofactor
apo C-III (8.8)	12	Liver	Modulates receptor binding of remnants
apo E (34)	5	Liver, brain, skin, gonads, spleen	Ligand for LDL receptor and receptors binding remnants; reverse cholesterol transport (HDL with apo E)
apo(a) (Variable)	Variable (under genetic control)	Liver	Modulator of fibrinolysis

MW, molecular weight.

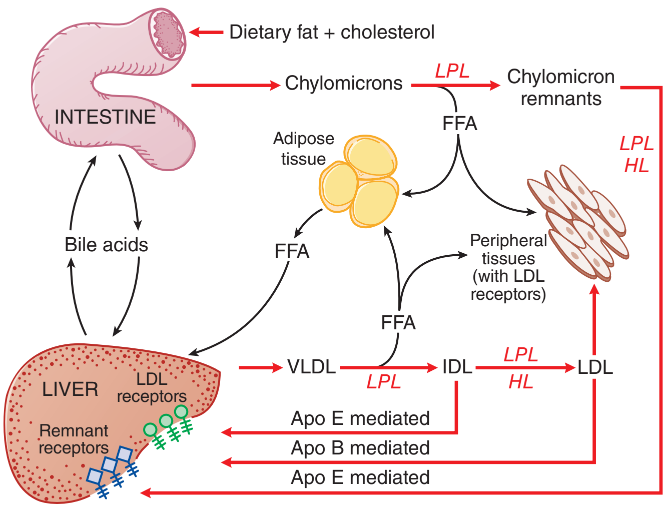

Figure 37–1 *The major pathways involved in the metabolism of chylomicrons synthesized by the intestine and VLDL synthesized by the liver.* Chylomicrons are converted to chylomicron remnants by the hydrolysis of their triglycerides by LPL. Chylomicron remnants are rapidly cleared from the plasma by the liver. "Remnant receptors" include the LRP, LDL receptors, and perhaps other receptors. Free fatty acid (FFA) released by LPL is used by muscle tissue as an energy source or taken up and stored by adipose tissue.

Lipoprotein (a)

Lipoprotein (a) [Lp(a)] is composed of an LDL particle that has a second apoprotein, apo(a), in addition to apo B-100. Apo(a) of Lp(a) is structurally related to plasminogen and appears to be atherogenic.

Atherosclerotic Cardiovascular Disease Risk Assessment

Therapy for dyslipidemias is centered around reducing the risk of fatal and nonfatal atherosclerotic cardiovascular events (ASCVD), including myocardial infarction and stroke. A flowchart that illustrates the assessment and management of ASCVD risk is shown in Figure 37–3.

The major conventional risk factors for ASCVD are elevated LDL-C, reduced HDL-C, cigarette smoking, hypertension, type 2 diabetes mellitus, advanced age, and a family history of premature CHD events (men <55 years; women <65 years) in a first-degree relative (Table 37–4). As more data have become available, ASCVD risk calculators have also begun to include race.

More recently, diagnosis and risk assessment based on genetic testing for monogenetic mutations that lead to FH (e.g., in the *LDLR*, *APOB*, *PCSK9*, and *LDLRAP1* genes) are recommended for patients suspected of having FH, as well as their at-risk relatives (Sturm et al., 2018). Early identification of individuals and their family members at risk for FH before the elevated LDL-C phenotype presents clinically could provide opportunities for interventions that reduce LDL-C before the onset of coronary artery disease. Pediatric patients identified with FH that are started on clinical interventions to reduce LDL-C have lower cumulative LDL-C burden and reduced risk of ASCVD compared to their affected parents. Screening at-risk family members (termed *cascade testing*) is considered a cost-effective means of identifying patients with FH and preventing associated morbidity and mortality but is not routinely done in the U.S. at present. In addition to monogenetic FH testing, there is significant interest in developing polygenetic risk scores based on genome-wide association studies (GWAS) to assess the aggregate contributions of many small-effect alleles on increasing LDL-C levels and consequent atherosclerotic cardiovascular risk.

Primary prevention involves management of risk factors to prevent a first-ever ASCVD event. Secondary prevention is aimed at patients who have had a prior ASCVD event (i.e., myocardial infarction, stroke, or revascularization) and whose risk factors must be reduced aggressively. In addition to cholesterol management, a comprehensive approach to ASCVD risk reduction includes smoking cessation, weight management, physical activity, healthy eating habits, appropriate use of aspirin, and management of blood glucose and blood pressure. All treatment plans to reduce ASCVD risk must include patient counseling surrounding lifestyle changes. Secondary causes of dyslipidemias (Table 37–5), including medications that affect cholesterol, should also be considered prior to initiating treatment. Patients should also be evaluated for metabolic syndrome, which affects more than one in three adults and includes insulin resistance, obesity, hypertension, low HDL-C levels, a procoagulant state, vascular inflammation, and substantially increased risk of cardiovascular disease.

The pooled cohort equation (PCE), published as part of the 2014 ACC/AHA guideline on the assessment of cardiovascular risk and still referenced in the 2018 AHA/ACC cholesterol guidelines, was developed based on data from nine cohort studies funded by the National Heart, Lung, and Blood Institute and included data from geographically and racially diverse patient populations. The PCE estimates an individual patient's 10-year or lifetime risk of ASCVD (defined as nonfatal myocardial infarction, coronary heart disease death, or fatal or nonfatal stroke) based on age, gender, total cholesterol, HDL-C, race, systolic blood pressure, smoking status, and history of diabetes and hypertension. This risk calculator is intended for primary prevention in patients between the ages of 20 and 79 years. The ASCVD Risk Estimator is

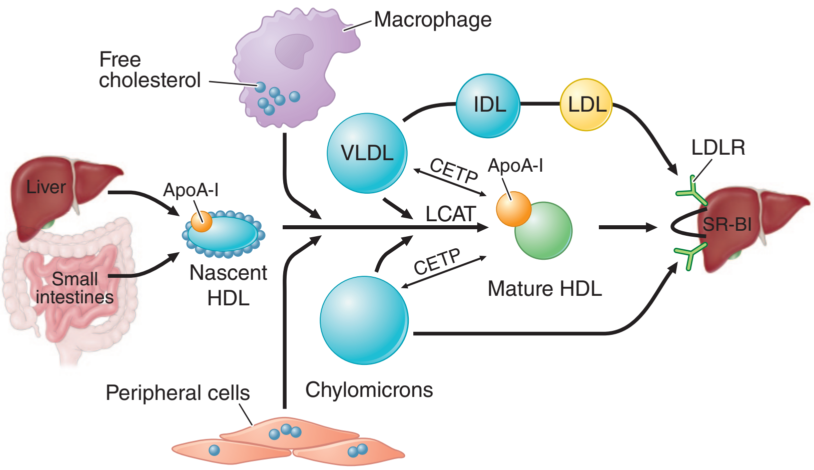

Figure 37–2 *HDL pathways and reverse cholesterol transport.* The intestines and liver generate nascent HDL, which collect free cholesterol from macrophages and peripheral tissues. The cholesterol is esterified by LCAT to cholesterol esters, leading to mature HDL particles (HDL_3 and HDL_2). Cholesterol is also acquired from cholesterol-containing lipoproteins including chylomicrons and chylomicron remnants, VLDL and VLDL remnants (IDLs), and LDL. The mature HDL particles deliver the cholesterol esters to the liver, which are then excreted into the small intestines as bile. See text for additional details. Figure 37–3 *Flowchart for assessing and managing ASCVD risk.* This chart is based on the 2018 AHA/ACC Multi-society Guideline on the Management of Blood Cholesterol and the 2019 ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease. Refer to Table 37–1 and the aforementioned guidelines for additional details.

available online (https://tools.acc.org/ldl/ascvd_risk_estimator/index.html#!/calulate/estimator/) and as a mobile device application. Cardiovascular risk assessment calculators have also been developed for lifetime risk of cardiovascular disease and projected 10-year ASCVD risk when a patient is placed on specific risk-reduction therapies.

TABLE 37–4 ■ RISK FACTORS FOR ATHEROSCLEROTIC CARDIOVASCULAR DISEASE

Age
Male >45 years of age or female >55 years of age
Family history of premature CHD[a]
A first-degree relative (male <55 years of age or female <65 years of age when the first CHD clinical event occurs)
Current cigarette smoking
Defined as smoking within the preceding 30 days
Hypertension
Systolic blood pressure ≥130 mmHg, diastolic pressure ≥90 mmHg, or use of antihypertensive medication, irrespective of blood pressure
Low HDL-C
<40 mg/dL (consider <50 mg/dL as "low" for women)
Obesity
Body mass index >25 kg/m^2 and waist circumference >40 inches (men) or >35 inches (women)
Type 2 diabetes mellitus[b]

CHD, coronary heart disease.
[a]CHD defined as myocardial infarction, coronary death, or a coronary revascularization procedure.
[b]Diabetes mellitus is considered a high- or very high-risk condition for ASCVD.

Statin Drug Therapy

Although an understanding of optimal lipoprotein levels is helpful (see ranges in Table 37–6), the 2018 AHA/ACC cholesterol guideline recommends titrating statin therapy to specific LDL-C percent decrease goals in certain patient groups, depending on their age and ASCVD risk score. Because the overwhelming body of evidence for ASCVD risk reduction with lipid-lowering therapies is from statin trials, evidence-based statin therapy of appropriate intensity is the hallmark of drug therapy of dyslipidemias. Patients aged 40 to 75 years with a known history of clinical ASCVD or diabetes mellitus and those with elevated LDL-C greater than or equal to 190 mg/dL should be offered statins regardless of their ASCVD risk score. For primary prevention in patients 40 through 79 years of age with an LDL-C between 70 and 189 mg/dL, use of the PCE is recommended to identify patients more likely to benefit from treatment. Table 37–1 summarizes 2018 AHA/ACC guideline recommendations for use of statins in adults.

Mechanism of Action

Statins exert their major effect—reduction of LDL-C levels—through a mevalonic acid-like moiety that competitively inhibits β-hydroxy β-methylglutaryl coenzyme A (HMG-CoA) reductase. By reducing the conversion of HMG-CoA to mevalonate, statins inhibit an early and rate-limiting step in cholesterol biosynthesis. Statins affect blood cholesterol levels by inhibiting hepatic cholesterol synthesis, which results in increased expression of the LDL receptor gene. Some studies suggested that statins also can reduce LDL-C levels by enhancing the removal of LDL precursors (VLDL and IDL) and by decreasing hepatic VLDL production. The reduction in hepatic VLDL production induced by statins is thought to be mediated by reduced synthesis of cholesterol, a required component of VLDLs. Higher doses of the more potent statins (e.g., *atorvastatin*, *simvastatin*, and *rosuvastatin*) also can reduce triglyceride levels caused by elevated VLDL levels. Figure 37–4 shows a representative statin structure and the reaction catalyzed by HMG-CoA reductase.

TABLE 37–6 ■ CLASSIFICATION OF PLASMA LIPID LEVELS (mg/dL)

Non–HDL-C	
<130	Desirable
130–159	Above desirable
160–189	Borderline high
190–219	High
≥220	Very high
HDL-C	
<40	Low (consider <50 mg/dL as low for women)
>60	High (desirable because of negative risk)
LDL-C	
<70	Optimal for very high-risk patients[a]
<100	Desirable
100–129	Above desirable
130–159	Borderline high
160–189	High
≥190	Very high
Triglycerides	
<150	Normal
150–199	Borderline high
200–499	High
≥500	Very high

[a]Some consider LDL-C <70 mg/dL the optimal goal for patients with coronary heart disease or risk equivalents.

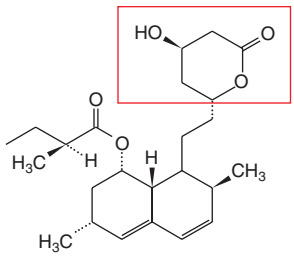
ADME

After oral administration, intestinal absorption of the statins is variable (30%–85%). All statins, except *simvastatin* and *lovastatin*, are administered in the β-hydroxy acid form, which is the form that inhibits HMG-CoA reductase. *Simvastatin* and *lovastatin* are administered as inactive lactones that must be transformed in the liver to their respective β-hydroxy acids, simvastatin acid and lovastatin acid. There is extensive first-pass hepatic uptake of all statins, mediated primarily by the organic anion transporter OATP1B1 (see Chapter 5). *Hepatic cholesterol synthesis is maximal between midnight and 2:00 AM. Thus, statins with* $t_{1/2}$ *of 4 h or less (all but* atorvastatin *and* rosuvastatin*) should be taken in the evening. Atorvastatin* and *rosuvastatin* both have longer half-lives and may be taken at other times of day to optimize adherence.

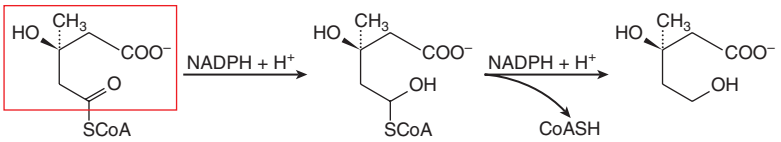
Due to extensive first-pass hepatic uptake, the systemic bioavailability of statins and their hepatic metabolites varies between 5% and 30% of administered doses. *Atorvastatin*, *lovastatin*, and *simvastatin* are primarily metabolized by CYPs 3A4 and 3A5. *Fluvastatin* is mostly (50%–80%) metabolized by CYP2C9 to inactive metabolites, but CYP3A4 and CYP2C8 also contribute to its metabolism. *Rosuvastatin* is excreted primarily unchanged in the stool, though around 10% is metabolized by CYP2C9. *Pravastatin*, however, is not metabolized to any appreciable extent by the CYP system and is excreted unchanged in the urine. The metabolites of all statins, except *fluvastatin* and *pravastatin*, have some HMG-CoA reductase inhibitory activity.

Under steady-state conditions, small amounts of the parent drug and its metabolites produced in the liver can be found in the systemic circulation. In the plasma, more than 95% of statins and their metabolites are protein bound, with the exception of *pravastatin* and its metabolites, which are only 50% bound. Peak plasma concentrations of statins are achieved in 1 to 4 h. The $t_{1/2}$ of the parent compounds are 1 to 4 h, except in the case of *atorvastatin* and *rosuvastatin*, which have $t_{1/2}$ of about 20 h, and *simvastatin* with a $t_{1/2}$ of about 12 h. The longer $t_{1/2}$ of *atorvastatin* and *rosuvastatin* may contribute to their greater cholesterol-lowering effect.



LOVASTATIN

Reaction Catalyzed by HMG-CoA Reductase



HMG-CoA intermediate MEVALONATE

Figure 37–4 *Lovastatin and the HMG-CoA reductase reaction.*

The liver biotransforms all statins, and more than 70% of statin metabolites are excreted by the liver, with subsequent elimination in the feces.

Therapeutic Effects

Effects of Statins on LDL-C Levels

Dose-response relationships for all statins demonstrate that the efficacy of LDL-C lowering is log linear; LDL-C is reduced by about 6% (from baseline) with each doubling of the dose. Maximal effects on plasma cholesterol levels are achieved within 7 to 10 days. The statins are effective in almost all patients with high LDL-C levels. The exception is patients with HoFH, who have very attenuated responses to the usual doses of statins because both alleles of the *LDLR* gene code for dysfunctional LDL receptors.

Triglyceride Reduction by Statins

Triglyceride levels greater than 250 mg/dL are reduced substantially by statins, and the percent reduction achieved is similar to the percent reduction of LDL-C.

Effect of Statins on HDL-C Levels

Most studies of patients treated with statins have systematically excluded patients with low HDL-C levels. In studies of patients with elevated LDL-C levels and gender-appropriate HDL-C levels (40–50 mg/dL for men; 50–60 mg/dL for women), an increase in HDL-C of 5% to 10% was observed, irrespective of the dose or statin employed. However, in patients with reduced HDL-C levels (<35 mg/dL), statins may differ in their effects on HDL-C levels. More studies are needed to ascertain whether the effects of statins on HDL-C in patients with low HDL-C levels are clinically significant.

Adverse Effects and Drug Interactions

Myopathy

The major adverse effect associated with statin use is myopathy. Myopathy refers to a broad spectrum of muscle complaints, ranging from mild muscle soreness or weakness (myalgia) to life-threatening rhabdomyolysis. The risk of muscle adverse effects increases in proportion to statin dose and plasma concentrations. Consequently, factors inhibiting statin catabolism are associated with increased myopathy risk, including advanced age (especially >80 years of age), hepatic or renal dysfunction, perioperative periods, small body size, and untreated hypothyroidism. Measurements of creatinine kinase are not routinely necessary, unless the patient also is taking a drug that enhances the risk of myopathy. Concomitant use of drugs that diminish statin catabolism or interfere with hepatic uptake is associated with increased risk of myopathy and rhabdomyolysis. The most common statin interactions occur with fibrates, especially *gemfibrozil* (38%), and with *cyclosporine* (4%), *digoxin* (5%), *warfarin* (4%), macrolide antibiotics (3%), and azole antifungals (1%). Other drugs that increase the risk of statin-induced myopathy include *niacin* (rare), human immunodeficiency virus (HIV) protease inhibitors, *amiodarone*, and *nefazodone*.

Hepatotoxicity

Serious hepatotoxicity is rare and unpredictable, with a rate of about 1 case per million person-years of use. However, since 2012, the FDA has no longer recommended routine monitoring of alanine aminotransferase (ALT) or other liver enzymes following the initiation of statin therapy because routine periodic monitoring does not appear to be effective in detecting or preventing serious liver injury. Liver enzymes should be evaluated in patients with clinical symptoms suggestive of liver injury following initiation or changes in statin treatment (FDA, 2012). Statin use is contraindicated in patients with active liver disease.

Additional Precautions or Contraindications

Statins should be used with caution in patients with renal impairment. *Atorvastatin* is often the statin of choice for patients with severe renal dysfunction, as it does not require dose adjustment. *Statins are contraindicated during pregnancy and should be discontinued prior to conception, if possible.* Data regarding statin use while breastfeeding are limited, and use should be discouraged.

Drug Interactions

Gemfibrozil, the drug most commonly associated with statin-induced myopathy, both inhibits uptake of the active hydroxy acid forms of statins into hepatocytes by OATP1B1 and interferes with the transformation of most statins by glucuronidases. Coadministration of *gemfibrozil* nearly doubles the plasma concentration of statin hydroxy acids. When statins are administered with *niacin*, the myopathy is likely caused by an enhanced inhibition of skeletal muscle cholesterol synthesis (a pharmacodynamic interaction). In 2016, the FDA withdrew approval for statin drug combinations containing fibrates or *niacin* (FDA, 2016).

Drugs that interfere with statin oxidation are those metabolized primarily by CYP3A4 and include certain macrolide antibiotics (e.g., *erythromycin*); azole antifungals (e.g., *itraconazole*); *cyclosporine*; *nefazodone*, a phenylpiperazine antidepressant; HIV protease inhibitors; and *amiodarone*. These pharmacokinetic interactions are associated with increased plasma concentrations of statins and their active metabolites. Because *pravastatin*, *fluvastatin*, and *rosuvastatin* are not extensively metabolized by CYP3A4, these statins may be less likely to cause myopathy when used with one of these predisposing drugs. However, the benefits of combined therapy with any statin should be carefully weighed against the risk of myopathy.

According to a 2012 FDA warning, *simvastatin* should not be used in combination with *cyclosporine*, HIV protease inhibitors, *erythromycin*, or

TABLE 37–7 ■ INTENSITY OF STATINS BY APPROXIMATE REDUCTIONS IN LDL-C WITH DAILY DOSING

HIGH-INTENSITY STATINS	MODERATE-INTENSITY STATINS	LOW-INTENSITY STATINS

Source: Data from *Table 3* in 2018 AHA/ACC guidelines (Grundy et al., 2019).

gemfibrozil. In patients taking *amlodipine* or *amiodarone*, the daily dose of *simvastatin* should not exceed 20 mg. No more than 10 mg of *simvastatin* should be used in combination with *diltiazem* or *verapamil*.

Other Considerations

The choice of statin should be patient-specific and based on factors such as cost, drug interactions, possible adverse effects, and desired intensity. Statin doses are characterized as low, moderate, or high intensity (Table 37–7), based on the degree of LDL-C lowering expected (range between 30% and 60%).

Rosuvastatin and *pravastatin* may be better tolerated than other statins and should be considered in patients with a history of myalgias with other statins. *Lovastatin* absorption is increased when taken with food, and patients should be encouraged to take *lovastatin* with their evening meal. Concerns have been raised about possible cognitive impairment with statins, although review of the published data do not suggest that statins harm cognition. In contrast, other studies suggest statins may have a role in the prevention of dementias. Statins, especially at higher doses, likely confer a small increased risk of developing diabetes. However, the beneficial effects of statins on ASCVD events and mortality outweigh any increased risk conferred by promoting the development of diabetes. Some statins have been approved for use in children with heterozygous FH (HeFH). *Atorvastatin*, *lovastatin*, and *simvastatin* are indicated for children aged 11 years and older. *Pravastatin* is approved for children 8 years and older.

Nonstatin Drug Therapies

The 2018 AHA/ACC cholesterol management guideline mainly focuses on the use of statins to reduce ASCVD risk. However, the guidelines do recommend the use of *ezetimibe* and/or PCSK9 inhibitors as add-on therapies for the management of cholesterol in patients with clinical ASCVD. Several important clinical trials have evaluated whether fibrates, *niacin*, *ezetimibe*, PCSK9 inhibitors, fish oil, and *icosapent ethyl* result in further reductions in ASCVD risk when used in addition to statins (ACCORD Study Group, 2010; AIM-HIGH Investigators, 2011; Bhatt et al., 2019; Cannon et al., 2015; HPS2-THRIVE Collaborative Group, 2014; ORIGIN Trial Investigators, 2012; Sabatine et al., 2017; Schwartz et al., 2018). In April 2016, the FDA withdrew approval for *niacin* extended release (ER) or *fenofibrate* used in addition to statins, citing studies that demonstrated no additional reduction in ASCVD events versus monotherapy with a statin (FDA, 2016). In October 2017, the ACC released an update to their expert consensus decision pathway that can aid clinicians in the use of nonstatins (i.e., bile acid sequestrants, PCSK9 inhibitors, or *ezetimibe*) in addition to statins for the management of ASCVD risk (Lloyd-Jones et al., 2017). Ultimately, the use of nonstatins in high-risk patient populations requires careful shared decision making between patients and their physician.

Elevated triglycerides are an important risk factor for pancreatitis. Treatment with agents most effective at reducing levels of triglycerides (fibrate or fish oil) is recommended in patients with very elevated triglycerides (>1000 mg/dL) to reduce the risk of pancreatitis. These therapies may be used in addition to statin treatment if the patient otherwise has risk factors for ASCVD that make the patient an appropriate candidate for statin therapy.

Cholesterol Absorption Inhibitor

Ezetimibe is the first compound approved for lowering total cholesterol and LDL-C levels that acts by inhibiting cholesterol absorption by enterocytes in the small intestine. It lowers LDL-C levels by about 20% and may be used as adjunctive therapy with statins.

Mechanism of Action

Ezetimibe inhibits luminal cholesterol uptake by jejunal enterocytes, by inhibiting Niemann-Pick C1–like 1 transport protein. In human subjects, *ezetimibe* reduces cholesterol absorption by 54%, precipitating a compensatory increase in cholesterol synthesis that can be inhibited with a cholesterol synthesis inhibitor (e.g., a statin or ATP-citrate lyase [ACL] inhibitor). The consequence of inhibiting intestinal cholesterol absorption is a reduction in the incorporation of cholesterol into chylomicrons; this diminishes the delivery of cholesterol to the liver by chylomicron remnants. The diminished remnant cholesterol content may decrease atherogenesis directly, as chylomicron remnants are very atherogenic lipoproteins. Reduced delivery of intestinal cholesterol to the liver by chylomicron remnants stimulates expression of the hepatic genes regulating LDL receptor expression and cholesterol biosynthesis. The greater expression of hepatic LDL receptors enhances LDL-C clearance from the plasma. *Ezetimibe* reduces LDL-C levels by 15% to 20%.

ADME

Ezetimibe is highly water insoluble, precluding studies of its bioavailability. After ingestion, it is absorbed and glucuronidated in the intestinal epithelium and then enters an enterohepatic recirculation. Pharmacokinetic studies indicated that about 70% is excreted in the feces and about 10% in the urine (as a glucuronide conjugate). Bile acid sequestrants inhibit absorption of *ezetimibe*, and the two classes of agents should not be administered together.

Therapeutic Effects

The role of *ezetimibe* as monotherapy of patients with elevated LDL-C levels is generally limited to the small group of statin-intolerant patients. The actions of *ezetimibe* are complementary to those of statins and the ACL inhibitor, *bempedoic acid*. Dual therapy with *ezetimibe* and either of these two classes of drugs prevents both the enhanced cholesterol synthesis induced by *ezetimibe* and the increase in cholesterol absorption induced by statins, providing additive reductions in LDL-C levels. LDL-C reduction at the highest *simvastatin* dose plus *ezetimibe* is similar to that of high-intensity statins. Reduction of LDL-C is greater with a statin plus *ezetimibe/bempedoic acid* than with a statin alone.

Preparations and Use

Ezetimibe is available as a 10-mg tablet that may be taken at any time during the day, with or without food. *Ezetimibe* may be taken in combination with other dyslipidemia medications except bile acid sequestrants, which inhibit its absorption. A combination tablet containing *ezetimibe* 10 mg and various doses of *simvastatin* (10, 20, 40, or 80 mg) has been approved. A combination of 10 mg *ezetimibe* with 180 mg *bempedoic acid* in tablet form has also been approved and can be used alone or in combination with a statin.

Adverse Effects and Drug Interactions

Other than rare allergic reactions, specific adverse effects have not been observed in patients taking *ezetimibe*. *Because all statins are contraindicated in pregnant and nursing women, combination products containing* ezetimibe *and a statin should not be used by women in childbearing years in the absence of contraception.*

Bile Acid Sequestrants

Cholestyramine, Colestipol, Colesevelam

The bile acid sequestrants *cholestyramine* and *colestipol* are among the oldest of the hypolipidemic drugs and are probably the safest because they are not absorbed from the intestine. These resins also are recommended for patients 11 to 20 years of age. Although statins are remarkably effective as monotherapy, the resins could be utilized as a second-line agent if statin therapy does not lower LDL-C levels sufficiently or in cases of statin intolerance.

Mechanism of Action

Bile acid sequestrants are highly positively charged and bind negatively charged bile acids. Because of their large size, the resins are not absorbed, and the bound bile acids are excreted in the stool. Because more than 95% of bile acids are normally reabsorbed, interruption of this process depletes the pool of bile acids, and hepatic bile acid synthesis increases. As a result, hepatic cholesterol content declines, stimulating the production of LDL receptors, an effect similar to that of statins. The increase in hepatic LDL receptors increases LDL clearance and lowers LDL-C levels, but this effect is partially offset by the enhanced cholesterol synthesis caused by upregulation of HMG-CoA reductase (see Figure 37–4). Inhibition of reductase activity by a statin substantially increases the effectiveness of the resins. The resin-induced increase in bile acid production is accompanied by an increase in hepatic triglyceride synthesis, which is of consequence in patients with significant hypertriglyceridemia (baseline triglyceride level >250 mg/dL). Use of *colesevelam* to lower LDL-C levels in patients with hypertriglyceridemia should be accompanied by frequent (every 1–2 weeks) monitoring of fasting triglyceride levels.

Therapeutic Effects

The reduction in LDL-C by resins is dose dependent. Doses of 8 to 12 g of *cholestyramine* or 10 to 15 g of *colestipol* are associated with a 12% to 18% reduction in LDL-C. *Colesevelam* lowers LDL-C by 18% at its maximum dose. Maximal doses (24 g of *cholestyramine*, 30 g of *colestipol*) may reduce LDL-C by as much as 25% but will cause GI side effects, which are often intolerable. A period of 1 to 2 weeks is sufficient to attain maximal LDL-C reduction by a given resin dose. In patients with normal triglyceride levels, triglycerides may increase transiently and then return to baseline. When used with a statin, resins are usually prescribed at submaximal doses due to poor tolerability.

Preparations and Use

The powdered forms of *cholestyramine* (4 g/dose) and *colestipol* (5 g/dose) are either mixed with a fluid (water or juice) and swallowed as a slurry or mixed with crushed ice in a blender. Ideally, patients should take the resins before breakfast and before supper, starting with 1 scoop or packet twice daily and increasing the dosage after several weeks or longer as needed and as tolerated. Patients generally will not take more than two doses (scoops or packets) twice daily. *Colesevelam hydrochloride* is available as a solid tablet containing 0.625 g of *colesevelam* and as a powder in packets of 3.75 g or 1.875 g. The starting dose is either 3 tablets taken twice daily with meals or all 6 tablets taken with a meal. The tablets should be taken with a liquid. The maximum daily dose is 7 tablets (4.375 g).

Adverse Effects and Drug Interactions

The resins are generally safe, as they are not systemically absorbed. Because they are administered as chloride salts, rare instances of hyperchloremic acidosis have been reported. Severe hypertriglyceridemia is a contraindication to the use of *cholestyramine* and *colestipol* because these resins increase triglyceride levels. At present, there are insufficient data on the effect of *colesevelam* on triglyceride levels.

Drinking a slurry of powdered *cholestyramine* or *colestipol* produces a gritty sensation that is unpleasant but generally tolerated. *Colestipol* is available in a tablet form. *Colesevelam* is available as a hard capsule that absorbs water and creates a soft, gelatinous material that allegedly minimizes the potential for GI irritation. Patients taking *cholestyramine* and *colestipol* complain of bloating and dyspepsia. These symptoms can be substantially reduced if the drug is completely suspended in liquid several hours before ingestion. Constipation may occur but sometimes can be prevented by adequate daily water intake and psyllium. *Colesevelam* may be less likely than *colestipol* to cause dyspepsia, bloating, and constipation.

The effect of *cholestyramine* and *colestipol* on the absorption of most drugs has not been studied. *Cholestyramine* and *colestipol* bind and interfere with the absorption of many drugs, including some thiazides, *furosemide*, *propranolol*, L-*thyroxine*, *digoxin*, *warfarin*, and some of the statins. *Colesevelam* does not appear to interfere with the absorption of fat-soluble vitamins or of drugs such as *digoxin*, *lovastatin*, *warfarin*, *metoprolol*, *quinidine*, and *valproic acid*. *Colesevelam* reduces the maximum concentration and the area under the curve of sustained-release *verapamil* by 31% and 11%, respectively. In the absence of information to the contrary, prudence suggests that patients take other medications 1 h before or 3 to 4 h after a dose of *colesevelam* or *colestipol*. The safety and efficacy of *colesevelam* have not been studied in pediatric patients or pregnant women.

Niacin (Nicotinic Acid)

Niacin is a water-soluble B-complex vitamin that functions as a vitamin only after conversion to nicotinamide adenine dinucleotide (NAD) or nicotinamide adenine dinucleotide phosphate (NADP). Both *niacin* and its amide may be given orally as a source of niacin for its functions as a vitamin, but only *niacin* affects lipid levels. The hypolipidemic effects of *niacin* require larger doses than are required for its vitamin effects.

Mechanism of Action

In adipose tissue, *niacin* inhibits the lipolysis of triglycerides by the hormone-sensitive lipase, thereby reducing transport of free fatty acids to the liver and decreasing hepatic triglyceride synthesis. Hormone-sensitive lipase is activated by catecholamines and adrenocorticotropic hormone (ACTH). It is inhibited by insulin. *Niacin* may exert its effects on lipolysis by stimulating a G protein-coupled receptor (GPR109A) that couples to G_i and inhibits cyclic AMP production in adipocytes. In the liver, *niacin* reduces triglyceride synthesis by inhibiting both the synthesis and the esterification of fatty acids, effects that increase apo B degradation. Reduction of triglyceride synthesis reduces hepatic VLDL production, which accounts for the reduced LDL levels. *Niacin* also enhances LPL activity, an action that promotes the clearance of chylomicrons and VLDL triglycerides. *Niacin* raises HDL-C levels by decreasing the fractional clearance of apo A-I in HDL rather than by enhancing HDL synthesis.

ADME

There are various forms of *niacin* available. Crystalline *niacin* (immediate or regular, IR) refers to *niacin* tablets that dissolve quickly after ingestion, are almost completely absorbed, and lead to peak serum concentrations within 30 to 60 min. Because the $t_{1/2}$ for nicotinic acid is about 20 to 48 min, crystalline *niacin* necessitates dosing two to three times daily. Time-release (ER) *niacin* refers to preparations that continuously release *niacin* for a variable amount of time after ingestion. For example, the time to peak serum levels for ER *niacin* is 4 to 5 h. Limited data on the pharmacokinetics of nonprescription sustained-release *niacin* exist, though these dietary supplements claim to be formulated for release over time. At lower doses, most *niacin* is taken up by the liver; only the major metabolite, nicotinuric acid, is found in the urine. At higher doses, a greater proportion of the drug is excreted in the urine as unchanged nicotinic acid.

Therapeutic Effects

Niacin is indicated for the treatment of hypertriglyceridemia and elevated LDL-C. There are only two formulations of *niacin* that are FDA-approved: ER and IR. Additional formulations are sold as dietary supplements, including two "flush-free" derivatives: inositol hexanicotinate and nicotinamide riboside. However, because they are not FDA-approved, these supplements cannot claim to treat any specific disease state; instead, they can only claim to help with overall health (e.g., labels might include "to support heart health"). The potential for severe liver damage should preclude use of nonprescription formulations of *niacin* in medically unsupervised patients.

Regular or crystalline *niacin* in doses of 2 to 6 g/day reduces triglycerides by 35% to 50% (as effectively as fibrates and statins); the maximal effect occurs within 4 to 7 days. Reductions of 25% in LDL-C levels are possible with doses of 4.5 to 6 g/day; 3 to 6 weeks are required for maximal effect. *Niacin* is the most effective agent available for increasing HDL-C (30%–40%), but the effect is less in patients with HDL-C levels less than 35 mg/dL. *Niacin* also is the only lipid-lowering drug that reduces Lp(a) levels significantly. Despite salutary effect on lipids, *niacin*'s side effects limit its use (see Adverse Effects section below).

Preparations and Use

Crystalline *niacin* tablets are available without a prescription in a variety of strengths, from 50- to 500-mg tablets, and with a prescription in 500-mg tablets. *Niacin* ER is available with a prescription as 500-, 750-, and 1000-mg ER tablets. The dose of prescription *niacin* for the treatment of dyslipidemia varies depending on the formulation. *Niacin* ER should be started at 500 mg at bedtime and increased by 500 mg every 4 weeks to a maximum of 2000 mg/day. IR *niacin* should be started at 250 mg every evening and increased every 4 to 7 days to a maximum of 1500 to 2000 mg/day. IR *niacin* may then be further titrated every 2 to 4 weeks to a maximum of 6000 mg/day in patients with marked lipid abnormalities. However, the risk of experiencing adverse effects increases with doses above 2000 mg/day. Transaminases, serum albumin, fasting glucose, and uric acid levels should be measured before treatment, every 6 to 12 weeks for the first year, and every 6 months thereafter.

Adverse Effects and Drug Interactions

Two of *niacin*'s side effects, flushing and dyspepsia, limit patient compliance. The cutaneous effects include flushing and pruritus of the face and upper trunk, skin rashes, and acanthosis nigricans. Flushing and associated pruritus are prostaglandin-mediated, so taking an *aspirin* at least 30 min before each *niacin* dose can minimize flushing in many patients. Flushing can also be minimized if therapy is initiated with low doses (250–500 mg once daily) and if the drug is taken after a meal. Flushing is worse when therapy is initiated or the dosage is increased, but it ceases in most patients after 1 to 2 weeks of a stable dose. Flushing is more likely to occur when *niacin* is consumed with hot beverages or with alcohol. Dry skin, a frequent complaint, can be dealt with by using skin moisturizers, and acanthosis nigricans can be dealt with by using lotions containing *salicylic acid*. Dyspepsia and rarer episodes of nausea, vomiting, and diarrhea are less likely to occur if the drug is taken after a meal. Patients with any history of peptic ulcer disease or liver disease should not take *niacin*. Patients who consume substantial quantities of alcohol should also not take *niacin*.

The most common, medically serious side effects are hepatotoxicity, manifested as elevated serum transaminases, and hyperglycemia. Both IR (crystalline) and ER *niacin* have been reported to cause severe liver toxicity, particularly in doses above 2 g/day. Hepatotoxicity is more likely to occur with time-release formulations of *niacin*. Affected patients experience flu-like fatigue and weakness; usually, aspartate transaminase and ALT are elevated, serum albumin levels decline, and total cholesterol and LDL-C levels decline substantially.

In patients with diabetes mellitus, *niacin* should be used cautiously because *niacin*-induced insulin resistance can cause severe hyperglycemia. If *niacin* is prescribed for patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until proven to be stable. *Niacin* also elevates uric acid levels and may reactivate gout. A history of gout is a relative contraindication for *niacin* use. Rarer reversible side effects include toxic amblyopia and toxic maculopathy. Atrial tachyarrhythmias and atrial fibrillation have been reported, more commonly in elderly patients. Niacin, *at doses used in humans, has been associated with birth defects in experimental animals and should not be taken by pregnant women*.

Concurrent use of *niacin* and a statin can cause myopathy. Two randomized trials evaluating *niacin* as add-on therapy to a statin versus statin monotherapy demonstrated no further reduction in ASCVD risk, despite improved lipoprotein parameters. Given this evidence, the FDA removed the indication for *niacin* use in addition to statin therapy and withdrew approval for statin combination formulations containing *niacin* (FDA, 2016). *Niacin* could still be considered as monotherapy in a statin-intolerant patient.

Fibric Acid Derivatives

Clofibrate is a halogenated fibric acid derivative. *Gemfibrozil* is a nonhalogenated acid that is distinct from the halogenated fibrates. Several other fibric acid analogues (e.g., *fenofibrate*, *bezafibrate, ciprofibrate*) are used in Europe and elsewhere.

Mechanism of Action

The mechanisms by which fibrates lower lipoprotein levels, or raise HDL levels, remain unclear. Many of the effects of these compounds on blood lipids are mediated by their interaction with peroxisome proliferator-activated receptors (PPARs), which regulate gene transcription. Fibrates bind to PPARα and reduce triglycerides through PPARα-mediated stimulation of fatty acid oxidation, increased LPL synthesis, and reduced expression of apo C-III. Increased LPL synthesis enhances the clearance of triglyceride-rich lipoproteins. Reduced hepatic production of apo C-III, which serves as an inhibitor of lipolysis and receptor-mediated clearance, enhances the clearance of VLDLs. Fibrate-mediated increases in HDL are due to PPARα stimulation of apo A-I and apo A-II expression, which increases HDL-C levels. *Fenofibrate* is more effective than *gemfibrozil* at increasing HDL-C levels. Most fibrates have potential antithrombotic effects, including inhibition of coagulation and enhancement of fibrinolysis.

ADME

Fibrates are absorbed rapidly and efficiently (>90%) when given with a meal but less efficiently when taken on an empty stomach. Peak plasma concentrations are attained within 1 to 4 h. More than 95% of these drugs in plasma are bound to protein, nearly exclusively to albumin. The $t_{1/2}$ of fibrates range from 1.1 h (*gemfibrozil*) to 20 h (*fenofibrate*). The drugs are widely distributed throughout the body, and concentrations in liver, kidney, and intestine exceed the plasma level. *Gemfibrozil* is transferred across the placenta. The fibrate drugs are excreted predominantly as glucuronide conjugates (60%–90%) in the urine, with smaller amounts appearing in the feces. Excretion of these drugs is impaired in renal failure.

Therapeutic Effects

Effects of fibric acid agents on lipoprotein levels differ widely, depending on the starting lipoprotein profile, the presence or absence of a genetic hyperlipoproteinemia, the associated environmental influences, and the specific fibrate used. Patients with type III hyperlipoproteinemia (*dysbetalipoproteinemia*) are among the most sensitive responders to fibrates. Elevated triglyceride and cholesterol levels are dramatically lowered, and tuberoeruptive and palmar xanthomas may regress completely. Angina and intermittent claudication also improve.

In patients with mild hypertriglyceridemia (e.g., triglycerides <400 mg/dL), fibrate treatment decreases triglyceride levels by up to 50% and increases HDL-C concentrations by about 15%; LDL-C levels may be unchanged or increase. Normotriglyceridemic patients with HeFH usually experience little change in LDL-C levels with *gemfibrozil*; with the other fibric acid agents, reductions as great as 20% may occur in some patients. Fibrates usually are the drugs of choice for treating severe hypertriglyceridemia and the chylomicronemia syndrome. While the primary therapy is to remove alcohol and lower dietary fat intake as much as possible, fibrates assist by increasing triglyceride clearance and decreasing hepatic triglyceride synthesis. In patients with chylomicronemia syndrome, fibrate maintenance therapy and a low-fat diet keep triglyceride levels well below 1000 mg/dL and thus prevent episodes of pancreatitis.

Preparations and Use

Gemfibrozil usually is administered as a 600-mg dose taken twice daily, 30 min before the morning and evening meals. *Fenofibrate* is available in tablets of 48 and 145 mg or capsules containing 67, 134, or 200 mg. The choline salt of fenofibric acid is available in capsules of 45 and 135 mg.

Equivalent doses of *fenofibrate* formulations are 135 mg of choline salt, 145 mg of *fenofibrate*, and 200 mg of micronized *fenofibrate* (available in capsule form). Fibrates are the drugs of choice for treating hyperlipidemic subjects with type III hyperlipoproteinemia, as well as subjects with severe hypertriglyceridemia (triglycerides >1000 mg/dL) who are at risk for pancreatitis. A randomized clinical trial of *fenofibrate* added on to background statin therapy resulted in no further reduction of ASCVD risk (ACCORD Study Group, 2010). In 2016, the FDA withdrew approval for use of *fenofibrate* in addition to statin therapy for ASCVD risk reduction.

Adverse Effects and Drug Interactions

Fibric acid compounds usually are well tolerated. GI side effects occur in up to 5% of patients. Infrequent side effects include rash, urticaria, hair loss, myalgias, fatigue, headache, impotence, and anemia. Minor increases in liver transaminases and alkaline phosphatase have been reported. *Clofibrate*, *bezafibrate*, and *fenofibrate* reportedly potentiate the action of *warfarin*. Careful monitoring of the prothrombin time and reduction in dosage of *warfarin* may be appropriate.

A myopathy syndrome occasionally occurs in subjects taking *clofibrate*, *gemfibrozil*, or *fenofibrate* and may occur in up to 5% of patients treated with a combination of *gemfibrozil* and higher doses of statins. *Gemfibrozil* inhibits hepatic uptake of statins by OATP1B1 and competes for the same glucuronosyl transferases that metabolize most statins. Thus, levels of both drugs may be elevated when they are coadministered. Patients taking this combination should be followed at 3-month intervals with careful history and determination of creatine kinase values until a stable pattern is established. Patients taking fibrates with *rosuvastatin* should be followed especially closely even if low doses (5–10 mg) of *rosuvastatin* are employed. *Fenofibrate* is glucuronidated by enzymes that are not involved in statin glucuronidation; thus, *fenofibrate*-statin combinations are less likely to cause myopathy than combination therapy with *gemfibrozil* and statins.

All fibrates increase the lithogenicity of bile. *Clofibrate* use has been associated with increased risk of gallstone formation. Renal failure is a relative contraindication to the use of fibric acid agents, as is hepatic dysfunction. *Fibrates should not be used by children or pregnant women.*

Omega-3 Fatty Acid Ethyl Esters

Mechanism of Action

Omega-3 fatty acids, commonly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) ethyl esters, reduce VLDL triglycerides and are used as an adjunct to diet for treatment of adult patients with severe hypertriglyceridemia. The recommended daily oral dose for patients with severe hypertriglyceridemia is 3 to 4 g/day administered with food. *Icosapent ethyl*, a highly purified ethyl ester of EPA available in 1- and 0.5-g capsules, is FDA approved as adjunctive therapy for patients with hypertriglyceridemia. Daily oral dosing for adults is 4 g/day, dosed twice daily with food.

ADME

The small intestine absorbs EPA and DHA, which are mainly oxidized in the liver, similar to fatty acids derived from dietary sources. The $t_{1/2}$ of elimination is approximately 50 to 80 h.

Therapeutic Effects

Fish oil or other products containing omega-3 fatty acids are among the most common over-the-counter (OTC) herbal, vitamin, or nutritional supplements purchased by consumers each year. Doses and formulations of OTC items vary considerably. The AHA recommends that consumers eat a variety of fish at least twice a week and that fish oil supplements should only be considered for individuals with heart disease or high triglyceride levels in consultation with a medical professional. In addition to OTC fish oil products, several prescription-only products are available, generally at higher doses than those used OTC (1–1.2 g) and containing a combination of EPA and DHA. *Icosapent ethyl* does not contain DHA. Mixtures containing both EPA and DHA have increased LDL-C in patients with severe hypertriglyceridemia, whereas studies of EPA-only products suggest they may not significantly increase LDL-C while still reducing triglycerides. Controversy exists about when to treat hypertriglyceridemia. Modifiable secondary causes of high triglycerides such as uncontrolled diabetes and excessive alcohol intake should always be addressed prior to initiating therapy. While prescription omega-3 products generally have FDA indications for triglycerides of 500 mg/dL or greater, many professional organizations advocate that such products be limited to patients with levels of 1000 mg/dL or greater who are at greatest risk for pancreatitis. The ORIGIN trial found no additional reduction in ASCVD risk associated with the use of omega-3 fatty acids versus background therapy with statins alone, calling into question the common use of fish oil supplements for "heart protection" by consumers.

However, in 2019, the REDUCE-IT trial showed that patients with hypertriglyceridemia taking 4 g/day of *icosapent ethyl* experienced a decrease in cardiovascular events, including cardiovascular death, compared to patients on placebo despite the use of statins (Bhatt et al., 2019). This has brought up specific questions regarding the place of *icosapent ethyl* in therapy. Only the ADA has provided updated recommendations regarding its use. More specifically, they recommend its use in patients with diabetes and ASCVD or other cardiovascular disease risk factors who are on a statin, have well-controlled LDL-C, but still have elevated triglyceride levels between 135 and 499 mg/dL (ADA, 2021).

Adverse Effects and Drug Interactions

Adverse effects may include arthralgia, nausea, fishy burps, dyspepsia, and increased LDL-C levels. Because omega-3 fatty acids may prolong bleeding time, patients taking anticoagulants should be monitored. *Icosapent ethyl* may also increase the risk of atrial fibrillation and flutter.

PCSK9 Inhibitors

Mechanism of Action

Proprotein convertase subtilisin/kexin type 9 (PCSK9) is a protease that binds to the LDL receptor on the surface of hepatocytes and enhances lysosomal degradation of the LDL receptor, resulting in higher plasma LDL-C concentrations. Loss-of-function mutations of PCSK9 are associated with reduced LDL-C and lowered risk of ASCVD. Conversely, mutations leading to increased PCSK9 expression result in increased LDL-C levels and higher risk of ASCVD events.

Two PCSK9 inhibitors, *alirocumab* and *evolocumab*, antibodies to PCSK9, are FDA-approved (1) to lower risk of myocardial infarction, stroke, and unstable angina requiring hospitalization in patients with established cardiovascular disease, (2) to lower LDL-C as adjunctive therapy alone or in combination with other LDL-C–lowering medication in adult patients with HeFH, and (3) to lower LDL-C as adjunctive therapy in combination with other LDL-C–lowering medications in adult patients with HoFH. *Evolocumab* and *alirocumab* are fully humanized monoclonal antibodies that bind free PCSK9, thereby interfering with its binding to the LDL receptor, leading to reduced degradation of the LDL receptor and increased liver clearance of LDL from the circulation, thereby lowering serum LDL-C levels (Figure 37–5).

In 2021, the FDA approved a novel small interfering ribonucleic acid therapeutic, *inclisiran*, that targets PCSK9 mRNA and thus blocks PCSK9 protein synthesis (Wright et al., 2021). Pooled ORION trial data from three ORION phase II trials indicate *inclisiran* may be more effective in lowering LDL-C levels than maximally tolerated statin therapy in high-risk patients. Low-volume subcutaneous injections of *inclisiran* resulted in persistent reductions in LDL-C and other atherogenic lipids for more than 180 days, indicating that a biannual subcutaneous dosing regimen may be a viable dosing regimen and that once-a-year dosing might also be effective in lowering LDL-C levels. Common adverse effects of *inclisiran* include injection site reactions (8.2% vs. 1.8% in placebo) and bronchitis (4.3% vs. 2.7% in placebo).

ADME

The PCSK9 antibody inhibitors are administered as subcutaneous injections either every 2 weeks or once monthly, depending on the dose and indication. *Evolocumab* is administered as a 140-mg injection every 2 weeks or as a 420-mg injection once a month. Similarly, *alirocumab* is administered as a 75-mg injection every 2 weeks or as a 300-mg injection once a month. For the treatment of HoFH, *evolocumab* 420 mg is administered

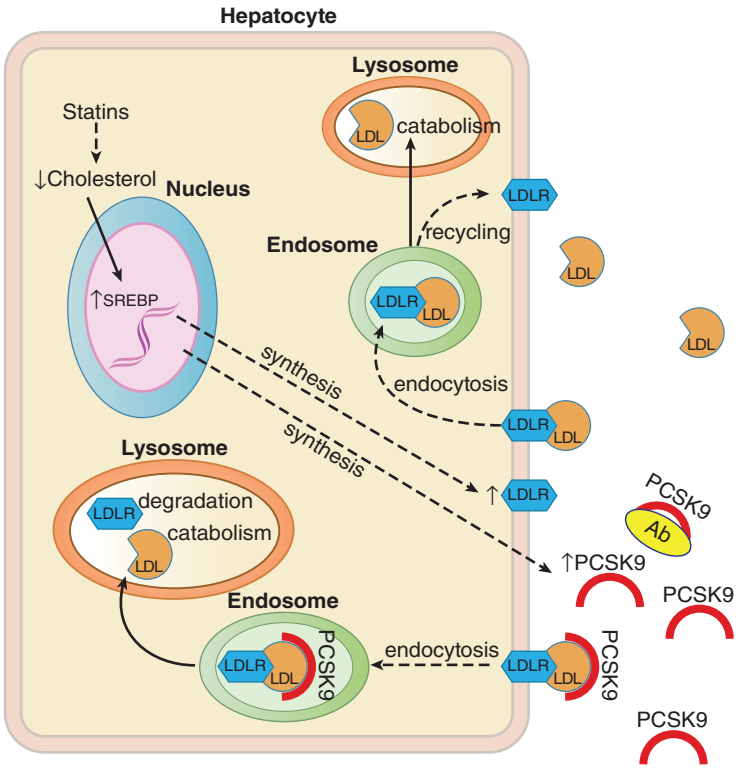

Figure 37–5 *Regulation of LDL receptor synthesis, recycling, and degradation in hepatocytes.* Statins inhibit the synthesis of cholesterol in the hepatocyte. Decreased concentrations of hepatocyte cholesterol lead to activation of sterol regulatory element–binding protein, which upregulates the transcription of hepatocyte genes including *LDLR* and *PCSK9*. This increases the synthesis of LDL receptor (LDLR) and PCSK9. Increased density of LDLR on the hepatocyte membrane increases binding of circulating LDL particles, and the LDLR-LDL complex then enters the hepatocyte by endocytosis. The LDLR-LDL complex dissociates in the endosome where LDLR is recycled to the plasma membrane and LDL enters the lysosomal pathway, leading to catabolism of the LDL particle. In the presence of circulating PCSK9, the LDLR-LDL-PCSK9 complex is removed from the plasma membrane by endocytosis and enters the lysosomal pathway for degradation. Little or no LDLR is recycled to the hepatocyte membrane, thus reducing the ability of the hepatocyte to bind LDL. There are gain-of-function mutations in *PCSK9* that enhance its activity and lead to FH (see text). Antibodies (Ab) to PCSK9 block its ability to bind the LDLR-LDL complex, thus preventing degradation of LDLR. *Inclirisan*, a small interfering RNA, acts by blocking the synthesis of PCSK9.

once monthly or every 2 weeks, whereas *alirocumab* 150 mg is administered once every 2 weeks. Administration requirements and storage of these medications are barriers when compared with the ease of oral dosage forms of other medications. *Inclisiran* is indicated as an adjunct to diet and maximally tolerated statin therapy in adults with HeFH or clinical ASCVD who require additional reduction in LDL-C. The recommended dosage is 284 mg in 1.5 mL administered as a single subcutaneous injection initially, then after 3 months, and every 6 months thereafter. *Inclisiran* can be stored at room temperature.

LDL-C plasma levels may be measured 4 to 8 weeks after initiating antibody therapy or changing doses. These antibodies inhibit PCSK9 availability for 2 to 3 weeks after administration ($t_{1/2}$ is 11–20 days), after which LDL-C levels begin to rise. Following an initial dose and 3 month dosing, inclirisan reduced serum PCSK9 levels by approximately 75% and 69% at 4 months and 6 months, respectively. After a single dose of inclirisan, reduction in LDL-C was apparent at 14 days and remained reduced by approximately 53% LDL-C at 6 months. Limited data are available in individuals with severe renal or hepatic impairment, although dose adjustments of the antibodies are not necessary in patients with mild impairment No dosage adjustments of *inclirisan* are required in patients with mild to severe renal impairment or mild to moderate liver impairment. *PCKS9 inhibitors should not be used in pregnancy because transmission across the placenta is expected. It is not known to what degree the medications will be present in breast milk, so use during lactation is also not recommended.*

Therapeutic Effects

The effects of PCSK9 inhibitors are complementary to those of statins. While statins interfere with cholesterol production and stimulate the production of LDL receptors, PCSK9 inhibitors enable the preservation of LDL receptors to be available on the surface of liver cells. PCSK9 antibody inhibitors reduce LDL-C in a dose-dependent manner by as much as 70% when used as monotherapy or by as much as 60% in patients already on statin therapy. Indications and approvals of these agents vary between countries. Currently, PCSK9 inhibitors are not FDA-approved for treatment of dyslipidemias in statin-intolerant patients without known ASCVD, although they are being used in this population elsewhere. Among patients with known ASCVD and LDL-C of 70 mg/dL or greater despite treatment with moderate- to high-intensity statins, the addition of *evolocumab* further reduced the risk of ASCVD events, but not death, in the FOURIER trial (Sabatine et al., 2017). Similar results were seen for *alirocumab* in the ODYSSEY OUTCOMES trial (Schwartz et al., 2018). Given the high cost of treatment with PCSK9 inhibitors versus relatively inexpensive statin treatment, published cost-effectiveness studies have concluded that these medications are only cost-effective in very high-risk patient populations (Fonarow et al., 2019; Grundy et al., 2019). Currently, because of these analyses, treatment with maximally tolerated doses of statins and/or *ezetimibe* is recommended prior to initiating PCSK9 inhibitors.

Adverse Effects and Drug Interactions

Several clinical trials have identified a small (<1%) risk of neurocognitive effects in patients treated with PCSK9 antibody inhibitors compared to placebo. Additional studies are under way to better understand the long-term neurocognitive effects of these medications, if any. Unlike other medications used to treat dyslipidemias, PCSK9 inhibitors do not appear to substantially increase the risk of myopathies when used as monotherapy or in combination with statins. Similar to other monoclonal antibodies, risk of infections, including nasopharyngitis, urinary tract infections, or upper respiratory infections, is slightly increased. Injection site reactions are the most frequently reported adverse effect of the antibodies and *inclisiran*,

although these occur in less than 10% of patients. There are no known drug interactions with PCSK9 inhibitors.

Inhibitor of Microsomal Triglyceride Transfer

Lomitapide

Mechanism of Action. *Lomitapide mesylate* is the first drug that acts by inhibiting MTP, which is essential for the intracellular transfer of triglycerides into triglyceride-rich lipoproteins, thus inhibiting the formation of VLDLs in hepatocytes and chylomicrons in intestinal epithelial cells.

ADME. *Lomitapide* is administered with water and without food (or at least 2 h after the evening meal) because administration with food may increase risk of GI adverse effects. The drug is metabolized by CYP3A4 and is contraindicated with inhibitors of CYP3A4.

Therapeutic Effects. *Lomitapide* is FDA-approved as an adjunct to diet for lowering LDL-C levels, total cholesterol, apo B, and non–HDL lipoproteins in patients with HoFH. *Lomitapide* reduces LDL-C by up to 50% and should be used in combination with maximally tolerated statin therapy. The recommended starting oral dose (5 mg/day) is titrated upward at 4-week intervals to a maximum dose of 60 mg daily. The long-term cardiovascular effects of *lomitapide* are currently unknown.

Adverse Effects and Drug Interactions. Reported adverse effects include significant diarrhea, vomiting, and abdominal pain in most patients. A strict low-fat diet may improve tolerability. Serious concerns also exist regarding hepatotoxicity and liver steatosis. In clinical trials, a third of patients experienced elevations in ALT or aspartate aminotransferase greater than three times the upper limit of normal. *Lomitapide* also increases hepatic fat, with or without concomitant increases in transaminases. The agent is used under an FDA Risk Evaluation and Mitigation Strategy due to its concerning side effect profile. *Lomitapide* may be embryotoxic, and women of childbearing potential should have a negative pregnancy test before starting treatment and use effective contraception during treatment.

ATP-Citrate Lyase Inhibitor

Bempedoic Acid

Bempedoic acid, a dicarboxylic acid, is a new class of cholesterol-lowering drugs approved by the FDA in 2020 that act by inhibiting *de novo* hepatocyte cholesterol biosynthesis. Its mechanism of action complements statins and other agents that lower LDL-C. The drug is approved as an adjunct to diet and maximally tolerated statin therapy to further lower LDL-C in patients with HeFH or established ASCVD. A fixed-dose combination of *bempedoic acid* and *ezetimibe* is approved for the same indication. *Bempedoic acid* also has application in patients who are statin-intolerant.

Mechanism of Action. *Bempedoic acid* acts by blocking ACL, the cytoplasmic enzyme that converts citrate to oxaloacetate and acetyl-CoA. In the *de novo* biosynthesis of cholesterol, acetyl-CoA is converted to HMG-CoA, which is the substrate for HMG-CoA reductase, the target of statins (see Figure 37–4). *Bempedoic acid* is a prodrug that is metabolized to the active drug, bempedoic acid-CoA, by a cytosolic hepatocyte enzyme, very long-chain acyl-CoA synthase-1. Bempedoic acid-CoA is a competitive inhibitor of ACL and thereby reduces *de novo* hepatic cholesterol synthesis by reducing the flow of acetyl-CoA to HMG-CoA reductase. *Bempedoic acid*'s cholesterol-lowering effects are thus additive with those of statins.

ADME. *Bempedoic acid* is administered orally once daily (180 mg), as is the combination of *bempedoic acid* and *ezetimibe* (180 mg and 10 mg, respectively). Both the prodrug and active metabolite of *bempedoic acid* are inactivated by UGT2B7 to glucuronide conjugates, which are subsequently excreted in urine (70%) by the renal transporter OAT2. OATB1B1, OAT1B3, OAT2, and OAT3 are weakly inhibited by *bempedoic acid*. The glucuronide metabolite is an OAT3 substrate and weakly inhibits OATB1B1 and OAT1B3. Elimination $t_{1/2}$ is 21 ± 11 h, and steady-state concentrations are reached after 7 days of therapy.

Therapeutic Effects. *Bempedoic acid* is FDA-approved for the treatment of adults with either HeFH or established ASCVD who need additional LDL-C lowering. As with the statins, reduced intrahepatic cholesterol synthesis results in an upregulation of LDL receptors expressed on hepatocyte membranes, which leads to increased uptake and catabolism of LDL particles and a consequent reduction in blood LDL-C concentrations. Monotherapy with *bempedoic acid* results in a 15% to 25% reduction in LDL-C, less than with statins. In combination with *ezetimibe*, the reduction in LDL-C is around 30%, and triple therapy with a statin reduces LDL-C by 65%. Reduction in HDL-C by *bempedoic acid* is typically around 5%.

Adverse Effects and Drug Interactions. Therapy with *bempedoic acid* is associated with hyperuricemia (thought to be due to competition for OAT2 in the kidney) that can increase the risk of gout. Other adverse effects include tendon ruptures and increased serum creatine kinase, creatinine, and hepatic transaminases. Due to drug interactions that may increase the risk of myopathy, *bempedoic acid* is not used with *simvastatin* doses of greater than 20 mg/day or *rosuvastatin* doses of greater than 40 mg/day. Because ACL is an enzyme essential for lipid and cholesterol synthesis, *bempedoic acid* may cause harm to the fetus.

Inhibitor of Angiopoietin-Like Protein 3

Evinacumab-dgnb

Mechanism of Action. *Evinacumab-dgnb* is a recombinant human monoclonal antibody that binds to and inhibits angiopoietin-like protein 3 (ANGPTL3). ANGPTL3 is a member of the angiopoietin-like protein family that is expressed primarily in the liver and plays a role in the regulation of lipid metabolism by inhibiting LPL and endothelial lipase (EL). *Evinacumab-dgnb* inhibition of ANGPTL3 leads to reduction in LDL-C, HDL-C, and triglycerides. *Evinacumab-dgnb* reduces LDL-C independent of the presence of LDL receptor by promoting VLDL processing and clearance upstream of LDL formation. *Evinacumab-dgnb* blockade of ANGPTL3 lowers triglycerides and HDL-C by rescuing LPL and EL activities, respectively.

ADME. The recommended dose is 15 mg/kg administered by intravenous infusion over 60 min every 4 weeks. The exact pathway through which *evinacumab-dgnb* is metabolized has not been characterized. As a human monoclonal IgG4 antibody, *evinacumab-dgnb* is expected to be degraded into small peptides and amino acids via catabolic pathways in the same manner as endogenous immunoglobulin G (IgG). The elimination $t_{1/2}$ is a function of serum *evinacumab-dgnb* concentrations and is not a constant. Based on a population pharmacokinetic analysis, the median time for serum *evinacumab-dgnb* concentrations to decrease below the lower limit of quantitation is 19 weeks after the last steady-state dose.

Therapeutic Effects. In 2021, *evinacumab* was approved by the FDA as an addition to lipid-lowering medications and diet for patients with HoFH. Its safety and effectiveness have not been established in patients with other forms of hypercholesterolemia, including HeFH. In a randomized clinical trial of 65 HoFH patients who were on a background of other lipid-lowering therapies, including maximally tolerated statins, *ezetimibe*, PCSK9 inhibitor antibodies, *lomitapide*, and lipoprotein apheresis, *evinacumab* reduced LDL-C on average by 50% after 24 weeks.

Adverse Effects and Drug Interactions. Major adverse effects include serious hypersensitivity reactions and embryo-fetal toxicity. As such, *evinacumab* is contraindicated in pregnancy and in patients with a history of allergies to *evinacumab*. Common adverse reactions (≥5%) were nasopharyngitis, influenza-like illness, dizziness, rhinorrhea, and nausea. Drug interactions have not been documented.

Future Developments in Management of Dyslipidemias

FH is the most common inherited cardiovascular disease and is associated with significant morbidity and reduction in life expectancy. It has been appreciated for many years that inherited mutations in specific

genes important for normal LDL receptor function and catabolism give rise to FH, including loss-of-function mutations in the *LDLR* gene and gain-of-function mutations in the *PCSK9* gene. An understanding of the pathophysiological sequalae of these mutations has provided valuable insights that have resulted in the invention of drugs that target key pathogenic steps and thus restore, at least in part, normal levels of LDL-C and significantly reduce the cardiovascular risk of individuals carrying these mutated genes. In addition to these monogenic causes of FH, evidence from large-scale whole-exome sequence studies has demonstrated that FH and the associated cardiovascular risks can also be caused by the aggregate effects of many small-effect alleles and that it may be possible to develop polygenic risk scores that can predict cardiovascular risk well before clinical phenotypes such as aberrant LDL-C levels are measurable. By initiating appropriate primary prevention therapy based on genetic analysis at an early age in patients with FH, there is hope that these patients could significantly reduce their risk of premature atherosclerotic disease. Moreover, the use of cascade screening to identify family members at risk of atherosclerotic disease could increase the potential benefits of genetic testing substantially. Analysis of atherosclerotic disease risk contributed by specific genes or combinations of genes in specific patient populations might identify novel drug targets that would not otherwise be discovered. Current challenges to development of polygenic risk scores based on whole-exome sequencing include wide-scale adoption by clinicians and payers, cost of whole-exome sequencing, privacy of results, development of accurate risk algorithms for genetically diverse populations, and appropriate application of risk scores by clinicians for optimal therapeutic management. Near-term benefits of polygenic risk analyses might include offset of sequencing costs by reducing inappropriate use of expensive monoclonal antibody therapies and by rapid optimization of therapy in extremely high-risk patients.

Drug Facts for Your Personal Formulary: *Therapy for Dyslipidemias*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
HMG-CoA Reductase Inhibitors (Statins)		
Atorvastatin Fluvastatin Lovastatin Pitavastatin Rosuvastatin Pravastatin Simvastatin	• The most effective and best-tolerated agents to treat dyslipidemias, especially elevated LDL-C	• Contraindicated in pregnancy • Hepatotoxicity (one case per million person-years of use); measure liver enzymes (ALT) at baseline and thereafter only when clinically indicated • Myopathy and rhabdomyolysis (one death per million prescriptions) (30-day supply); risk ↑with dose and concomitant administration of drugs that interfere with statin catabolism or hepatic uptake
Cholesterol Absorption Inhibitor		
Ezetimibe	• Monotherapy in patients with ↑ LDL-C who are statin intolerant • Combination with statin or bempedoic acid → additive reductions in LDL-C	• Bile acid sequestrants inhibit absorption of ezetimibe; avoid concurrent use • Generally, a well-tolerated agent, but rhabdomyolysis has been reported with monotherapy and with the addition of agents known to be associated with increased risk (e.g., fibrates) • Combination therapy contraindicated in pregnancy
Bile Acid–Binding Resins (Bile Acid Sequestrants)		
Cholestyramine Colestipol Colesevelam	• Probably safest lipid-lowering drugs (not absorbed systemically) • Recommended for patients 11–20 years of age	• Common GI side effects: bloating, dyspepsia, constipation • Cholestyramine and colestipol bind and interfere with absorption of many drugs; administer all other drugs either 1 h before or 3–4 h after dose of a bile acid resin • Severe hypertriglyceridemia is a contraindication to the use of cholestyramine and colestipol; they ↑ triglyceride levels
Nicotinic Acid		
Niacin	• Favorably affects all lipid parameters; most effective agent for increasing HDL-C; also lowers triglycerides and reduces LDL-C	• Contraindicated in pregnancy, peptic ulcer disease, concurrent use of statins, gout • Flushing, pruritus, and dyspepsia limit patient compliance • Rarer episodes of nausea, vomiting, and diarrhea • Hepatotoxicity, manifested as ↑ serum transaminases • Hyperglycemia and niacin-induced insulin resistance; in patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until stable • Hepatotoxicity is more likely to occur with the use of ER forms of nicotinic acid (vs. IR form)
Fibric Acid Derivatives (Fibrates)		
Gemfibrozil Fenofibrate *Not in the U.S.:* Ciprofibrate Bezafibrate	• Usual drugs of choice for treating chylomicronemia, hyperlipidemia with type III hyperlipoproteinemia, severe hypertriglyceridemia (triglycerides >1000 mg/dL)	• GI side effects occur in up to 5% of patients • Contraindicated in children and pregnancy • A myopathy syndrome may occur in patients taking clofibrate, gemfibrozil, or fenofibrate • The FDA has withdrawn approval for coadministration of fibrates with statins • Renal failure, gallbladder disease, and hepatic dysfunction are relative co[illegible]nt.aindicati[illegible]ns

Drug Facts for Your Personal Formulary: *Therapy for Dyslipidemias (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Omega-3 Fatty Acid Ethyl Esters		

Omega-3 fatty acids (EPA, DHA, and icosapent ethyl)	• Adjunct for treating severe hypertriglyceridemia (triglycerides >1000 mg/dL)
	• *Icosapent ethyl*
	  • Adjunct to maximally tolerated statin therapy to reduce risk of cardiovascular events in adults with triglyceride levels ≥150 mg/dL
	  • Adjunct to diet in adults with severe hypertriglyceridemia (triglycerides ≥500 mg/dL)
		• Adverse effects may include arthralgia, nausea, fishy burps, dyspepsia, and increased LDL
		• Since omega-3 fatty acids may prolong bleeding time, patients taking anticoagulants should be monitored

PCSK9 Inhibitors (mAbs)		
Alirocumab Evolocumab	• To ↓risk of myocardial infarction, stroke and unstable angina requiring hospitalization in patients with established cardiovascular disease • To ↓LDL-C as adjunctive therapy alone or in combination with other LDL-C-lowering medication in adults with HeFH • To ↓LDL-C as adjunctive therapy in combination with other LDL-C-lowering medications in adult with HoFH	• Hypersensitivity or injection site reactions are possible • Most effective agents at reducing LDL-C • As with other mAbs, influenza-like symptoms, nasopharyngitis, upper respiratory infections may occur • Used in addition to maximally tolerated statin doses (complementary mechanism; see Figure 37–5) • Diabetes mellitus is associated with evolocumab (9%); large LDL-C reductions (to <25 mg/dL) are associated with alirocumab
PCSK9 Inhibitor (siRNA)		
Inclisiran	• To ↓LDL-C as adjunctive therapy with diet and maximally tolerated statin therapy for treatment of adults with HeFH who require additional lowering of LDL-C • To ↓LDL-C as adjunctive therapy with diet and maximally tolerated statin therapy for treatment of adults with clinical ASCVD who require additional lowering of LDL-C	• Injection site reactions are possible • Used in addition to maximally tolerated statin doses (complementary mechanism) • Long-lasting effects on lowering PCSK9 serum levels and LDL-C (dosing every 6 months at steady-sate) • Contraindicated in pregnancy
Liver Microsomal Triglyceride Transfer Protein Inhibitor		
Lomitapide	• Used as an adjunct to diet for lowering LDL-C, total cholesterol, apo B, and non–HDL-C in patients with HoFH	• In patients with HoFH, LDL-C reduction by 40%–50% • Adverse effects include GI symptoms, elevation of serum liver enzymes, and increased liver fat • The agent is used under an FDA Risk Evaluation and Mitigation Strategy due to hepatotoxicity (i.e., elevated transaminases and hepatic steatosis) • Patients should take daily supplements containing 400 IU vitamin E, 200 mg linoleic acid, 210 mg α-linoleic acid, 110 mg EPA, and 80 mg DHA
ATP-Citrate Lyase Inhibitor		
Bempedoic acid	• Used in patients who are statin intolerant or those who do not achieve desired LDL-C levels with statins • Monotherapy in statin-intolerant patients • Combination therapy with statins and fixed-dose combination with ezetimibe	• Low rates of adverse effects in clinical trials • May increase blood uric acid levels, leading to risk of gout
Angiopoietin-Like Protein 3 Inhibitor (Monoclonal Antibody)		
Evinacumab-dgnb	• Used as an adjunct to lipid-lowering agents and diet in patients with HoFH	• In patients with HoFH on lipid-lowering agents, LDL-C reduction by 50% • Severe hypersensitive reactions possible; contraindicated in pregnancy

Chapter 38 Introduction to Immunity and Inflammation

Michael David

The introduction of pathogens and foreign proteins into the human body can stimulate immune recognition, leading to inflammatory and allergic responses. Aspects of these responses are subject to pharmacological modulation. Before describing the actions of pharmacological agents affecting allergy and immunity, this chapter describes the cellular and molecular basis of immune and allergic responses and the points of pharmacological intervention. Subsequent chapters in this section cover in detail the classes of agents that can alter allergic and immune responses, as well as the biology and pharmacology of inflammation.

Cells and Organs of the Immune System

Hematopoiesis

All blood cells, including immune cells, originate from pluripotent hematopoietic stem cells (HSCs) of the bone marrow. HSCs are a population of undifferentiated progenitor cells that are capable of self-renewal. On exposure to cytokines and contact with the surrounding stromal cells, HSCs can differentiate into megakaryocytes (the source of platelets), erythrocytes (red blood cells), and leukocytes (white blood cells). This process is known as hematopoiesis (Figure 38–1).

The HSC pool can be divided in two populations: long-term (LT) and short-term (ST) HSCs. LT-HSCs are capable of lifelong self-renewal, allowing for continuous hematopoiesis throughout life. ST-HSCs have limited self-renewing capability and differentiate into multipotent progenitors—the common *myeloid* progenitor and the common *lymphoid* progenitor. The common myeloid progenitor gives rise to the myeloid lineage of cells that includes megakaryocytes, erythrocytes; granulocytes (neutrophils, eosinophils, basophils, mast cells), monocytes, macrophages, and dendritic cells (DCs). In contrast, the common lymphoid progenitor gives rise to the lymphoid lineage of cells that includes natural killer (NK) cells, B lymphocytes (B cells), and T lymphocytes (T cells) Doula ov et al.. 2012: Eaves, 2 /15 /.

Cells of the Innate Immune System

Innate immunity refers to the host defense mechanisms that are immediately available on exposure to pathogens.

Granulocytes

Granulocytes have characteristic cytoplasmic granules containing substances that, in addition to killing invading pathogens, enhance inflammation at the site of infection or injury. Neutrophils are the most abundant of the granulocytes and are generally the first cells to arrive at the site of injury. They are specialized at engulfing and killing pathogens—a process known as phagocytosis. Like neutrophils, eosinophils are also motile phagocytic cells. These cells defend against parasitic organisms such as helminths by releasing the contents of their granules, which are thought to damage the parasite membrane. Basophils and mast cells have granules that contain histamine and other pharmacologically active substances. In addition to their protective function, these cells can become dysregulated during the generation of allergic responses, in which they play an important role (see Hypersensitivity Reactions).

Mononuclear Phagocytes

Mononuclear phagocytes consist of monocytes and macrophages. Monocytes circulate in the blood and then migrate into tissues where they differentiate into macrophages, increase 5- to 10-fold in size, and acquire enhanced phagocytic and microbicidal activity. Macrophages engulf and eliminate pathogens, dead cells, and cellular debris. Macrophages can remain motile and travel throughout the tissues by amoeboid movements, and they can also take up residence in specific tissues, becoming tissue-resident macrophages. In addition to their role as phagocytes, macrophages release proinflammatory molecules, such as cytokines and eicosanoids, that recruit other immune cells to the site of infection (see Inflammation).

Natural Killer Cells

Natural killer cells (NK cells) are cytotoxic, granular lymphocytes that target tumor and ' irus-infected cells. NK cell receptors selecti ely ' arget

Abbreviations

APC: antigen-presenting cell
BCR: B-cell receptor
C#: complement component # (e.g., C3, C5)
CAR: chimeric antigen receptor
CLL: chronic lymphocytic leukemia
CR1: complement receptor 1
CTLA-4: cytotoxic T-lymphocyte–associated protein 4
DC: dendritic cell
DN: double negative
DP: double positive
ER: endoplasmic reticulum
GI: gastrointestinal
HLA: human leukocyte antigen
HSC: hematopoietic stem cell
ICI: immune checkpoint inhibitor
IFN: interferon
Ig: immunoglobulin
IL: interleukin
iNOS: inducible nitric oxide synthase: NOS2
IRF: interferon regulatory factor
ISG: interferon-stimulated gene
ISRE: interferon-stimulated response element
LT: long term
MADCAM-1: mucosal vascular addressin cell adhesion molecule 1
MALT: mucosa-associated lymphoid tissue
MHC: major histocompatibility complex
NF-κB: nuclear factor-κB
NK cell: natural killer cell
NO: nitric oxide
PAMP: pathogen-associated molecular pattern
PD-1: programmed cell death protein 1
PRR: pattern recognition receptor
Rh: rhesus
ROS: reactive oxygen species
SARS-CoV-2: severe acute respiratory syndrome coronavirus 2
scFv: single-chain variable fragment
ST: short term
T_C: cytotoxic T cell
TCR: T-cell receptor
T_H: helper T cell
TLR: toll-like receptor
TNFα: tumor necrosis factor α
T_{Reg}: T-regulatory cells

damaged or infected host cells by recognizing abnormal expression of surface molecules seen on damaged, but not healthy, cells.

Dendritic Cells

Dendritic cells (DCs) are specialized cells that reside in tissues and stimulate adaptive immune responses. Immature DCs patrol peripheral tissues and sample their environment for infection by capturing pathogens through phagocytosis, receptor-mediated endocytosis, and pinocytosis. After maturation, DCs shift from a phenotype that promotes antigen capture to one that supports antigen presentation. Mature DCs migrate from the peripheral tissues to lymphoid organs and present antigens to activate helper and cytotoxic T cells (see Antigen Processing and Presentation).

Cells of the Adaptive Immune System

Adaptive immunity (also known as the acquired immune system) represents a branch of the immune system that is characterized by antigen specificity and immunological memory. It is mediated by B and T lymphocytes following exposure to specific antigens and is more complex than innate immunity in that it requires prior antigen processing and recognition to launch lymphocyte responses. Furthermore, in contrast to innate immune responses, which occur within hours after infection, B- and T-lymphocyte responses take days to develop.

B Cells

The B lymphocytes, also known as B cells, express cell surface pathogen receptors called immunoglobulins. When a naïve B cell (one that has not previously encountered antigen) detects a pathogen through binding of its immunoglobulin, it begins to proliferate. Its progeny can differentiate into plasma cells or memory B cells. Plasma cells are short-lived effector cells that specialize in secreting antibodies—the soluble form of immunoglobulins. Memory B cells are long-lived and persist for years following an infection. Because memory B cells express the same immunoglobulin as their parent B cell, they mount an enhanced secondary response to a pathogen on reinfection and are the basis for B cell–mediated immunity.

T Cells

The T lymphocytes, also known as T cells, express cell surface pathogen receptors called T-cell receptors (TCRs). Unlike immunoglobulins, which independently recognize antigens, TCRs only recognize antigens presented on MHC (major histocompatibility complex) molecules on the surface of DCs or other antigen-presenting cells (APCs). T cells are divided into two subpopulations—T_C (cytotoxic T) cells and T_H (helper T) cells. T_C cells or killer T cells destroy host cells that are infected with intracellular pathogens, whereas T_H cells secrete cytokines that help enhance the function of other immune cells to mediate pathogen clearance. Activated T cells can differentiate into effector cells—cells that carry out immediate functions to help clear the infection—or memory cells. Memory T cells, like memory B cells, persist for years following an infection and mount an enhanced response on re-exposure to the same pathogen (see Immunological Memory).

Organs of the Immune System

The organs of the immune system are divided into two categories based on their function: *primary lymphoid organs* and *secondary lymphoid organs*. Lymphocyte maturation and development take place in the primary lymphoid organs, whereas secondary lymphoid organs provide sites for mature lymphocytes to interact with APCs. These lymphoid organs are interconnected by blood and lymphatic vessels.

Primary Lymphoid Organs

The bone marrow and thymus make up the primary lymphoid organs. Both B-cell and T-cell precursors originate in the bone marrow from HSCs. B cells complete their maturation in the bone marrow, whereas T-cell precursors migrate to the thymus to complete their development.

The bone marrow tissue is composed of a meshwork of stromal cells (e.g., endothelial cells, adipocytes, fibroblasts, osteoclasts, osteoblasts, and macrophages). Immature B cells proliferate and differentiate within the bone marrow with direct (cell-cell contact) and indirect (cytokine release) help from stromal cells. Interleukin (IL)-1, IL-6, and IL-7 are the most important cytokines guiding the B-cell differentiation process (Hoggatt et al., 2016).

The thymus is a bilobate organ of the upper anterior mediastinum, sitting behind the sternum and in front of the heart. Each lobe is divided into smaller lobules comprising an outer compartment (cortex) and an inner compartment (medulla). Both the cortex and the medulla contain a stromal cell network of epithelial cells, DCs, and macrophages that present self-antigens to maturing T cells. This stromal cell network is responsible for the maturation process, and the cytokines IL-1, IL-2, IL-6, and IL-7 also play an important role in this process. The thymus begins to atrophy after puberty (as the thymic stroma is eventually replaced with adipose tissue), causing a decline in T-cell output. By age 35, T-cell production drops to 20% compared to that of newborn levels, and by age 65, this number further decreases to 2% (Palmer, 2013). Importantly, once the periphery is seeded with mature T cells, the host is equipped with

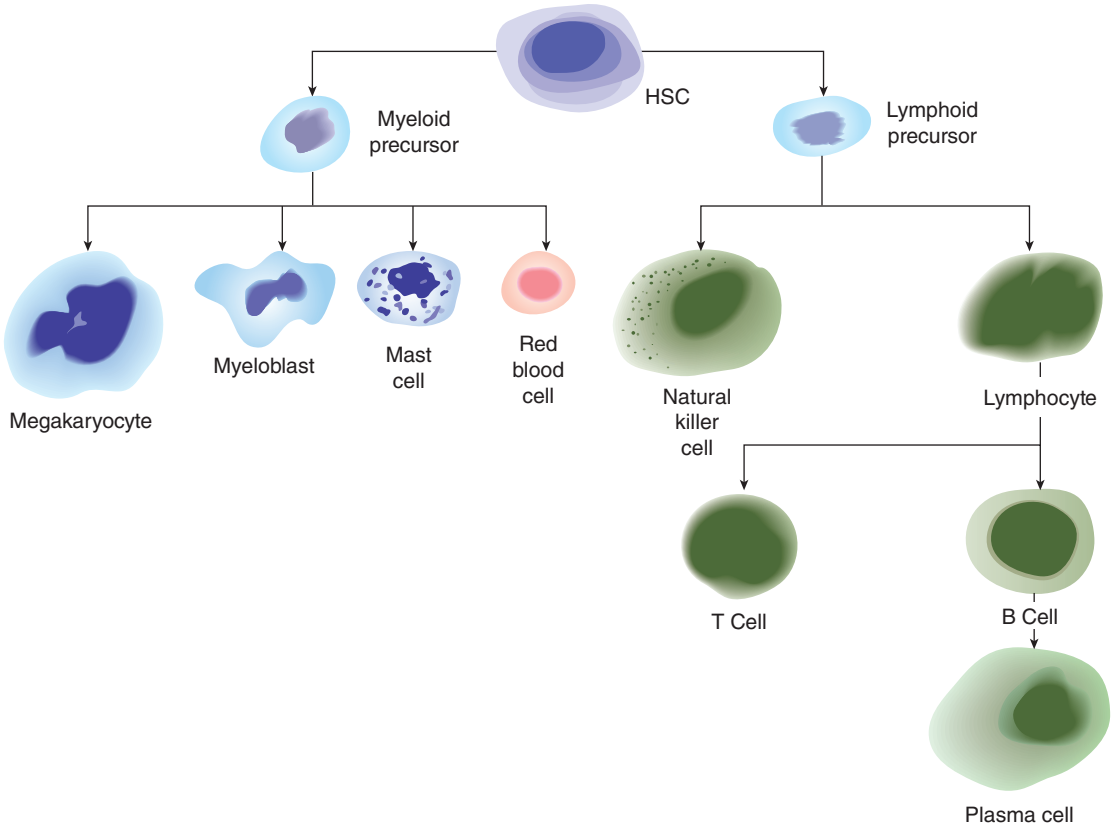

Figure 38–1 *Development of myeloid and lymphoid lineage cells from HSCs in the bone marrow.* HSCs give rise to lineage-specific precursors, which differentiate into all myeloid and lymphoid cells.

a diversity of naïve T cells that will respond to any pathogen encounter, irrespective of diminished thymic output.

Secondary Lymphoid Organs

The secondary lymphoid organs, including the spleen, lymph nodes, and mucosa-associated lymphoid tissue (MALT), are the sites where adaptive immune responses are initiated. The spleen is the largest lymphoid organ, consisting of red pulp and white pulp. The red pulp is a sponge-like tissue where old or damaged erythrocytes are recycled, whereas the white pulp region consists of lymphocytes. The spleen is the only lymphoid organ that is not connected to the lymphatic vessels. Instead, immune cells enter and exit the spleen through blood vessels.

Lymph nodes are round, specialized structures that are positioned along the lymphatic vessels like beads on a chain. They collect the lymph (containing immune cells and antigens) that drains from the skin and internal organs and provide the physical location where antigen presentation and lymphocyte activation occur. The MALTs are loosely organized lymphoid tissues located in the submucosal surfaces of the gastrointestinal (GI) tract, respiratory system, and urinary tract (Neely and Flajnik, 2016).

The Lymphatic System

The "lymphatic system" or "lymphatics" represent a network of lymphatic vessels (similar to the circulatory system's veins and capillaries) that are connected to lymph nodes. Similar to their circulatory counterparts, small lymph capillaries are made up of single endothelial cell layers, whereas in larger lymph vessels, the endothelial cells are surrounded by layers of smooth muscle cells. Additional parts of the lymphatic system are the tonsils, adenoids, spleen, and thymus. The lymphatics collect plasma continuously leaking out from blood vessels into the interstitial spaces and return this fluid, now called lymph, to the blood (after filtration in the lymph nodes) into the subclavian veins located on either side of the neck near the clavicles. Unlike blood movement, which is driven by a pump and flows throughout the body in a continuous loop, lymph flows in only one direction—upward toward the neck—and movement originates from rhythmic contractions of the smooth muscle cells, with directionality achieved via semilunar valves inside the vessels. The lymphatics therefore have an important function in regulating both immune and fluid homeostasis.

The B and T cells, unlike other blood cells, traffic through the body via both blood and lymph (hence the term *lymphocyte*). After completing their development in the primary lymphoid organs, B and T cells enter the bloodstream. When lymphocytes reach blood capillaries that empty into secondary lymphoid tissues, they enter these tissues. If a naïve lymphocyte encounters antigen, it will remain in the secondary lymphoid tissue and become activated. Otherwise, if no antigen is detected, the lymphocyte then exits through the efferent lymph and reenters the bloodstream. This pattern of movement between the blood and lymph is referred to as lymphocyte recirculation, and it allows the lymphocyte population to continuously monitor the secondary lymphoid organs for signs of infection (Masopust and Schenkel, 2013; Thomas et al., 2016).

Cytokines and Cytokine Storm

Cytokines are soluble mediators that initiate, terminate, and modulate the intensity of virtually every aspect of an organism's immune or inflammatory response. Cytokines, which are peptide based, cannot diffuse across lipid bilayers; rather, they act via cell surface receptors in an autocrine or paracrine fashion. While there is no classical definition for cytokines, the term historically encompasses interferons (IFNs), ILs, and chemokines, but does not include growth factors (which are frequently characterized by their enzymatically active receptors) and hormones (which are typically secreted into the bloodstream by cells organized into glands), in contrast to cytokines, which are released by individual, nonassembled cells of the immune system such as lymphocytes or macrophages. A feature once thought to distinguish cytokines from hormones was their differing distances of action: Whereas hormones can act over long distances

(e.g., insulin or growth hormone), cytokines were thought to function primarily in microenvironments. However, discoveries over the last few decades have indicated that cytokines, too, can elicit systemic responses, adding to the difficulty of clearly defining cytokines and distinguishing them from hormones. Today, cytokines are often defined and classified based on the structural features of their cell surface receptors, which, in contrast to growth factor receptors, do not harbor intrinsic enzymatic activities but rely on cytoplasmic enzymes to accomplish postreceptor signal transduction.

Lack of specific cytokines or their receptors can result in prominent immune deficiencies; for example, defects in the γ chain of the IL-2 receptor cause severe combined immune deficiency. Conversely, overproduction of (proinflammatory) cytokines can trigger the *cytokine storm syndrome*, which is linked to systemic inflammatory responses and multiorgan failure. Cytokine storm can occur as a consequence of a severe allergic reaction (anaphylactic shock) but is also frequently associated with the excessive tissue damage resulting from responses to various pathogens; for example, many deaths caused by the 1918 influenza pandemic of H1N1 influenza A virus and by the pandemic of SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2; the viral cause of the illness COVID-19) (2019–present) have been attributed to cytokine storms elicited by the respective pathogens.

Innate Immunity

Innate immunity refers to the defense mechanisms that are immediately available on exposure to pathogens. These mechanisms consist of anatomical barriers, soluble mediators, and cellular responses. To establish an infection, a pathogen must first penetrate a host's anatomical barriers, including the skin and mucous membranes. If a pathogen manages to breach these anatomical barriers, the cellular innate immune response initiates rapidly, within a matter of minutes, to activate further mechanisms of the immune response.

Anatomical Barriers

The skin and mucosal surfaces form the first line of defense against pathogens. The skin is made up of a thin outer layer (epidermis) of tightly packed epithelial cells and an inner layer (dermis) of connective tissue containing blood vessels, sebaceous glands, and sweat glands. The respiratory, GI, and urogenital tracts are lined by mucous membranes. Like skin, mucous membranes consist of an outer layer of epithelial cells and an underlying layer of connective tissue. These anatomical surfaces act as more than just passive barriers against pathogens. All epithelial surfaces secrete antimicrobial peptides called host defense peptides. Host defense peptides kill bacteria, fungi, and viruses by disrupting their membranes (Hancock et al., 2016). The sebum secreted by the sebaceous glands contains fatty acids and lactic acid that inhibit bacterial growth on the skin. Mucosal surfaces are continuously covered in mucus (a viscous fluid secreted by epithelial cells of mucous membranes) containing antimicrobial substances that trap foreign microorganisms and help limit the spread of infection. In the respiratory tract, this mucous is continually removed by the action of cilia on epithelial cells. In addition, all these anatomical surfaces harbor commensal microorganisms. These commensals help protect against disease by preventing colonization by harmful microorganisms. These physical, mechanical, chemical, and microbiological barriers prevent a majority of pathogens from gaining access to the cells and tissues of the body (Belkaid and Tamoutounour, 2016).

However, some pathogens manage to breach these barriers. Microbes can enter the skin through scratches, wounds, or insect bites, such as those from mosquitoes (e.g., *Plasmodium falciparum,* the protozoan species predominantly responsible for malaria); ticks (e.g., *Borrelia burgdorferi,* the bacterium responsible for Lyme disease); and fleas (e.g., *Yersinia pestis,* the bacterium responsible for bubonic plague). Many pathogens enter the body by penetrating mucous membranes. One example is the influenza virus, which expresses a surface molecule that allows it to attach to and invade cells in the mucous membranes of the respiratory tract.

Once a pathogen breaches these anatomical barriers, the innate immune system first responds by detecting the pathogen. This initiates an inflammatory response—mediated by soluble effectors such as complement, eicosanoids, and cytokines—that results in the recruitment of immune cells to the site of infection, direct lysis or phagocytosis of pathogens, and eventual activation of the adaptive immune response.

Pathogen Recognition

The first phase of an innate immune response involves pathogen detection, which is mediated by secreted and cell surface pathogen receptors. Innate immune cells recognize broad structural patterns that are conserved within microbial species but are absent from host tissues. These broad structural patterns are referred to as *PAMPs* (pathogen-associated molecular patterns) and the receptors that recognize them are called *PRRs* (pattern recognition receptors). PRRs can be divided into three broad classes: secreted, endocytic, and signaling PRRs.

Secreted PRRs and the Complement System

Secreted PRRs are opsonins (molecules that enhance phagocytosis) that bind to microbial cell walls and tag them for destruction by the complement system or by phagocytes. C-reactive protein and mannose-binding lectin are two examples of secreted PRRs; both are components of the acute-phase response (see Inflammation).

The plasma proteins known as the complement system are some of the first to act following pathogen entry into host tissues. Over 30 proteins and glycoproteins make up the complement system. These proteins circulate in blood and interstitial fluid in inactive forms that become activated in sequential cascades in response to interaction with molecular components of pathogens, leading to the activation of C3 (complement component 3), which plays the most important role in pathogen detection and clearance. Complement activation leads to the cleavage of C3 into C3b and C3a fragments. The large C3b fragment (an opsonin) attaches to pathogen surfaces in a process called complement fixation and can activate C5 and a lytic pathway that can damage the plasma membrane of adjacent cells and microorganisms. The C5a fragment attracts macrophages and neutrophils and can activate mast cells. The small C3a fragment (anaphylatoxin) also promotes inflammation. Thus, complement fixation has two functions: the formation of protein complexes that damage the pathogen's membrane and marking the pathogen for destruction by phagocytes (Morgan and Harris, 2015).

Endocytic PRRs

Endocytic PRRs are expressed on the surface of phagocytic cells. These receptors mediate the uptake and transport of microbes into lysosomes, where they are degraded. The degraded microbial peptides are processed and presented to T cells by members of the MHC family of cell surface proteins. (In humans, the MHC is also called *human leukocyte antigen* or *HLA*.) The mannose, glucan, and scavenger receptors are part of this class of receptors.

Signaling PRRs

On PAMP detection, signaling PRRs trigger intracellular signaling cascades that eventually result in the production of cytokines that orchestrate the early immune response. The most-studied group of signaling PRRs are the TLRs (toll-like receptors). TLRs are a family of PRRs that recognize a variety of microbial products. These transmembrane proteins are composed of an extracellular domain that detects pathogens and a cytoplasmic signaling domain that relays information to the nucleus. TLRs are expressed on the plasma membranes and endosomes of immune cells.

Signaling through TLRs leads to activation of two distinct signal transduction pathways (see Box 38–1: PAMPs, PRRs, and the Induction of Interferons). Most TLRs signal through a pathway that promotes the activation of the transcription factor nuclear factor-κB (NF-κB) and the production of proinflammatory cytokines such as IL-1, IL-6, IL-12, and tumor necrosis factor α (TNF-α). The exception is TLR3, which signals through a pathway that leads to the activation of the transcription factor IRF3 (interferon regulatory factor 3), and the production of IFN types I and III. TLR4 is unique in that it signals through both pathways (Cao, 2016).

BOX 38–1 ■ PAMPs, PRRs, and the Induction of Interferons

Cells of the innate immune system—predominantly dendritic cells and macrophages—recognize broad structural patterns that are conserved within microbial species but are absent from host tissues. These patterns are called *pathogen-associated molecular patterns* (PAMPs); *pattern recognition receptors* (PRRs) recognize PAMPs. There are three broad classes of PRRs: secreted, endocytic, and signaling PRRs.

Activation of signaling PRRs results in the production of cytokines that orchestrate the early immune response. The most well-studied group of signaling PRRs are the 11 Toll-like receptors (TLRs), each of which displays specificity for a distinct PAMP (e.g., TLR4 recognizes lipopolysaccharide; TLR3 binds double-stranded RNA; TLR9 interacts with foreign DNA). Another receptor group, C-type lectin-like receptors, recognizes unique carbohydrate structures on invading microorganisms. Other signaling PRRs are cytosolic, such as retinoic acid–inducible gene (RIG)-I-like receptors (RLRs) that are activated by cytoplasmic double-stranded and 5′-triphosphorylated RNA species, and the nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) that detect cytosolic endotoxins. Signaling through most PRRs leads to broad cytokine responses, mediated by NF-κB and resulting in the production of proinflammatory cytokines such as IL-1, IL-6, IL-12, and TNF-α.

In response to attack by viruses, bacteria, parasites, and tumor cells, membrane-bound and cytosolic (endosomal) signaling PRRs, including TLRs, work via several convergent pathways to stimulate the production of yet another class of cytokines, the IFNs. There are three types of IFNs: type I IFN (mainly IFN-α and IFN-β, plus other minor forms such as IFN-ε or IFN-ω); type II IFN (IFN-γ); and type III IFN (IFN-λ). IFNs are glycoproteins of about 145 amino acids, with molecular masses of approximately 19 to 24 kDa, depending on the extent of glycosylation. Viral infections are the major inducers of the transcription of genes encoding type I IFNs. Pathways leading to IFN production are complex. The contemporary model now encompasses the concept that PRRs trigger intracellular signaling cascades that involve receptor-associated adapters (e.g., TRIM, TIRAP, MyD88) and the assembly of a signalosome containing various protein kinases (e.g., TBK1, IKKε, TAK, ASK1). Activation of these kinases in response to pathogen recognition leads to the phosphorylation and activation of the latent cytoplasmic transcription factors termed interferon regulatory factors (IRFs). Activation of IRF3 and IRF7, sometimes in combination with other transcription factors, activates transcription of the genes encoding type I IFNs.

Actions of IFNs

The IFNs are unique among the cytokine superfamily in that they produce an array of pleiotropic effects when they bind to their specific receptor. IFNs convey antiviral, antiproliferative, and immunomodulatory functions onto their target cells.

The IFNs are the most crucial cytokines in the defense against invading microorganisms, particularly viruses. IFN-α, IFN-β, and the more recently discovered IFN-λ are vital elements in these defense mechanisms. Type I IFNs promote the production of interferon-stimulated genes (ISGs) in infected and neighboring cells, the products of which induce an intracellular antimicrobial program that limits the spread of infectious pathogens. Type I IFNs also augment antigen presentation, costimulation, and cytokine production by innate immune cells, leading to enhanced adaptive immune responses.

Produced by activated helper T (T_H) and natural killer (NK) cells, IFN-γ enhances the microbicidal activity of macrophages by inducing mammalian inducible nitric oxide synthase (iNOS, also called NOS2), thereby increasing their production of nitric oxide (NO) and their capacity to kill intracellular pathogens. Furthermore, $CD8^+$ T cells utilize IFN-γ to directly kill infected cells and tumors. Indeed, IFN-γ contributes significantly to the adaptive immune system, where it also influences developmental processes such as immunoglobulin (Ig) isotype switching in B cells and T_H1 cell differentiation.

Cellular Signaling in Responses to IFNs

Interferon signaling is a complex mechanism that elicits the appropriate antimicrobial program in target cells. IFNs bind to distinct heteromeric membrane receptors. Binding of the type I IFNs to their specific cell surface receptors leads to cross tyrosine phosphorylation, recruitment, and activation of the STAT (Janus kinase/signal transducer and activator of transcription) pathway. Several members of the STAT family of transcription factors and IRF9 cooperatively form the DNA binding protein complex ISGF3, which is required for expression of ISGs through activation of the interferon-stimulated response element (ISRE) in their promoters. Transcriptional induction of these immediate early response genes facilitates the establishment of an antiviral state, achieves antiproliferation in normal and tumor cells, and influences adaptive immune responses (e.g., via modulation of IL-2 production and expression of the α chain [CD25] of the IL-2R complex; see Figure 39–2).

Numerous genes contain an ISRE. Their gene products are components of the antiviral defense: 2′-5′ poly-A-synthase, double-stranded RNA activated protein kinase (PKR), cell surface proteins such as ICAM (intracellular adhesion molecule) and the major histocompatibility complex (MHC) I and II classes, chemokines (e.g., ISG15 and the IP10), and myriad genes of unknown function. More recently, numerous micro-RNAs have been added to the repertoire of IFN-induced response genes that contribute to control of pathogens.

Type I (IFN-α and IFN-β) and type III (IFN-λ) IFNs promote the production of ISGs (interferon-stimulated genes) in infected and neighboring cells, the products of which induce an intracellular antimicrobial program that limits the spread of infectious pathogens, particularly viruses. Type I IFNs also augment antigen presentation and cytokine production by innate immune cells, leading to enhanced adaptive immune responses (Gonzalez-Navajas et al., 2012).

Pathogen Clearance

Pathogens vary in the manner by which they live and replicate within their hosts. Extracellular pathogens replicate on epithelial surfaces, or within the interstitial spaces, blood, and lymph of their host. Intracellular pathogens establish infections within host cells, either in the cytoplasm or in cellular vesicles. Depending on the nature of the infection, different immune cells and effector mechanisms are involved in the control and elimination of the pathogen.

Extracellular Pathogens

Unlike pathogens that replicate within host cells, extracellular pathogens are accessible to soluble effector proteins. Pathogens that replicate within interstitial spaces, blood, and lymph are detected by secreted PRRs and complement proteins. Complement fixation triggers direct lysis of the pathogen and enhances pathogen uptake by phagocytic cells. The phagocytic cells involved in the clearance of extracellular pathogens are macrophages and neutrophils. Tissue-resident macrophages are long-lived cells that are present from the start of an infection. They engulf pathogens and release inflammatory mediators to alert host cells of an attack. Neutrophils, in contrast, are short-lived, circulating phagocytes. Inflammatory cues, such as those released by macrophages, recruit neutrophils to the site of infection, where they soon become the dominant phagocyte.

On entry into host tissues, the first immune cells a pathogen encounters are the tissue-resident macrophages. Macrophages phagocytize microorganisms in a nonspecific fashion through their phagocytic receptors. Proteins of the complement system enhance this process by binding to receptors expressed by macrophages. One such receptor is complement

receptor 1 (CR1). CR1 molecules interact with C3b fragments that have been deposited on the pathogen's surface, facilitating the engulfment and destruction of the pathogen.

In addition to engulfing invading pathogens, macrophages alert host cells of an infection. TLR4 engagement on macrophages leads to the production of proinflammatory cytokines such as IL-1, IL-6, IL-12, TNF-α, and CXCL8 (see Inflammation). These cytokines recruit immune cells, the most prominent of which are neutrophils, to the infected tissue (Lavin et al., 2015).

Circulating neutrophils have an average life span of less than 2 days. Mature neutrophils are kept in the bone marrow for up to 5 days before being released into circulation, ensuring a large reserve that can be summoned during an infection. When neutrophils sense inflammatory signals such as cytokines, chemokines, eicosanoids, ROS (reactive oxygen species), or NO (nitric oxide), they migrate to the site of infection, where they engulf and kill the invading pathogen. In addition, neutrophils can release extracellular DNA nets that trap bacterial pathogens (von Köckritz-Blickwede and Nizet, 2009). Neutrophils die within 2 h of entry into infected tissues, forming the characteristic pus that develops at sites of infection (Kruger et al., 2015).

Intracellular Pathogens

The NK cells provide an early defense against intracellular pathogens. Like neutrophils, these circulating leukocytes migrate from the blood to the site of infection in response to inflammatory cues. Once at the site of infection, NK cells target and kill infected host cells.

The NK cells express receptors that deliver either activating or inhibitory signals. The ligands for the activating NK cell receptors are typically cell surface proteins whose expression is altered during infection or trauma. Healthy cells are protected from attack by NK cells because the signals generated from the inhibitory NK cell receptors dominate those generated from the activating receptors. In contrast, interaction between NK cells and infected or damaged cells shifts the balance of inhibitory and activating signals to favor an attack. This system allows NK cells to discriminate between healthy cells that should be protected and infected cells that should be destroyed.

The NK cells are stimulated by cytokines, including type I IFNs, IL-12, and TNF-α. IFN-α and IFN-β enhance NK cell cytotoxicity and induce NK cell proliferation, whereas IL-12 enhances cytokine production. The key cytokine produced by NK cells is IFN-γ, also called type II IFN. One function of IFN-γ is to activate macrophages. Activated macrophages exhibit enhanced microbicidal activity. One mechanism of their microbicidal activity is the induction of iNOS and the production of prodigious quantities of NO (Bjorkstrom et al., 2016).

Adaptive Immunity

Adaptive immunity refers to the arm of the immune response that changes (adapts) with each new infection. The cells responsible for adaptive immunity are B cells and T cells. The effector mechanisms used by B and T cells are similar to those used by innate immune cells; however, the important distinction between innate and adaptive immunity lies in their mode of pathogen recognition. Whereas the PRRs of the innate immune response recognize broad microbial patterns, B cells and T cells express receptors that recognize highly specific molecular structures. Following pathogen exposure, B and T cells with receptors that recognize the invading pathogen proliferate robustly and differentiate into effector lymphocytes. Soon after pathogen clearance, a large number of effector B and T cells die, but a small population of memory cells survives. Those cells have the ability to mount a rapid and specific response on re-exposure to the same pathogen. This memory response, unique to adaptive immunity, is the basis for vaccination (see Chapter 40).

Initiation of the Adaptive Immune Response

The skin and mucosal surfaces prevent the majority of pathogens from entering host tissues and causing infections. Innate immune responses generally eliminate microorganisms that breach these barriers, typically within a few days. However, some pathogens establish an infection that cannot be controlled entirely by the innate immune response. In these cases, pathogen clearance requires the adaptive immune response.

Dendritic cells provide an essential link between innate and adaptive immunity. DCs engulf pathogens at the site of infection and travel to the lymphoid organs. Once there, they activate T cells by presenting them with fragments of the engulfed pathogen loaded on MHC molecules (see section on Antigen Processing and Presentation).

Pathogen Recognition

The innate immune system detects pathogens by a fixed repertoire of soluble and cell-surface receptors that recognize broad structures shared by different pathogens. The genes encoding these pathogen receptors are inherited from one generation to the next in a stable form.

The adaptive immune system uses a more focused strategy of pathogen recognition. B and T cells recognize pathogens by using their cell surface receptors: BCRs and TCRs. In contrast to the stably inherited genes encoding innate immune pathogen receptors, the genes encoding BCRs and TCRs rearrange during the course of lymphocyte development. This gene rearrangement enables the development of millions of pathogen receptors with unique binding sites, each expressed by a small subset of lymphocytes. On pathogen exposure, only those lymphocytes with receptors that recognize specific components of the invading pathogen (referred to as the receptor's *cognate antigen*) are selected to proliferate and differentiate into effector cells.

Pathogen Receptors: BCRs and TCRs

B-cell receptors (BCRs) and TCRs are structurally related molecules. The BCR, also called immunoglobulin, is composed of two identical heavy chains and two identical light chains. Each polypeptide chain expresses an amino-terminal variable region, which contains the antigen-binding site, and a carboxy-terminal constant region. Immunoglobulins are anchored in the B-cell membrane by two transmembrane regions at the end of each heavy chain. Immunoglobulins are initially surface bound but become soluble when a B cell differentiates into a plasma cell. The soluble forms of immunoglobulins are called antibodies.

The TCR is composed of an α chain (TCRα) and a β chain (TCRβ), both anchored in the T-cell membrane by a transmembrane region. The α and β chains consist of a variable region that contains the antigen-binding site and a constant region. In contrast to immunoglobulins, TCRs remain membrane bound and are not secreted.

Both BCRs and TCRs develop through gene rearrangement. This genetic recombination process (which B cells complete in the bone marrow and T cells in the thymus) is a defining feature of the adaptive immune system. The human BCR and its soluble derivative, the antibody, are composed from genes of three loci, the *IG heavy chain*, the *IGκ light chain*, and the *IGλ light chain*, yielding a repertoire of more than 10^{11} possible combinations. In close resemblance, the TCR comprises either an α and a β chain (most common) or a γ and a δ chain. Three of the key enzymes involved are RAG1 and RAG2 (RAG, recombination-activating gene; deficiencies in these enzymes result in a complete absence of mature lymphocytes) and the terminal deoxynucleotidyl transferase, albeit the full complexity of the DNA repair machinery is required to accomplish a productive rearrangement. Failure to do so will lead to the elimination of the unsuccessful B or T cells by programmed cell death (Nemazee, 2006). These events of recombination and subsequent somatic hypermutation are vital for an optimally performing adaptive immune system. They remain unutilized as pharmacological targets.

Antigen Processing and Presentation

Immunoglobulins are capable of recognizing antigens in their native form. TCRs, in contrast, only recognize processed antigen fragments presented by specialized molecules encoded by the MHC (Figure 38–2). The MHC was first identified as a genetic complex that determines an

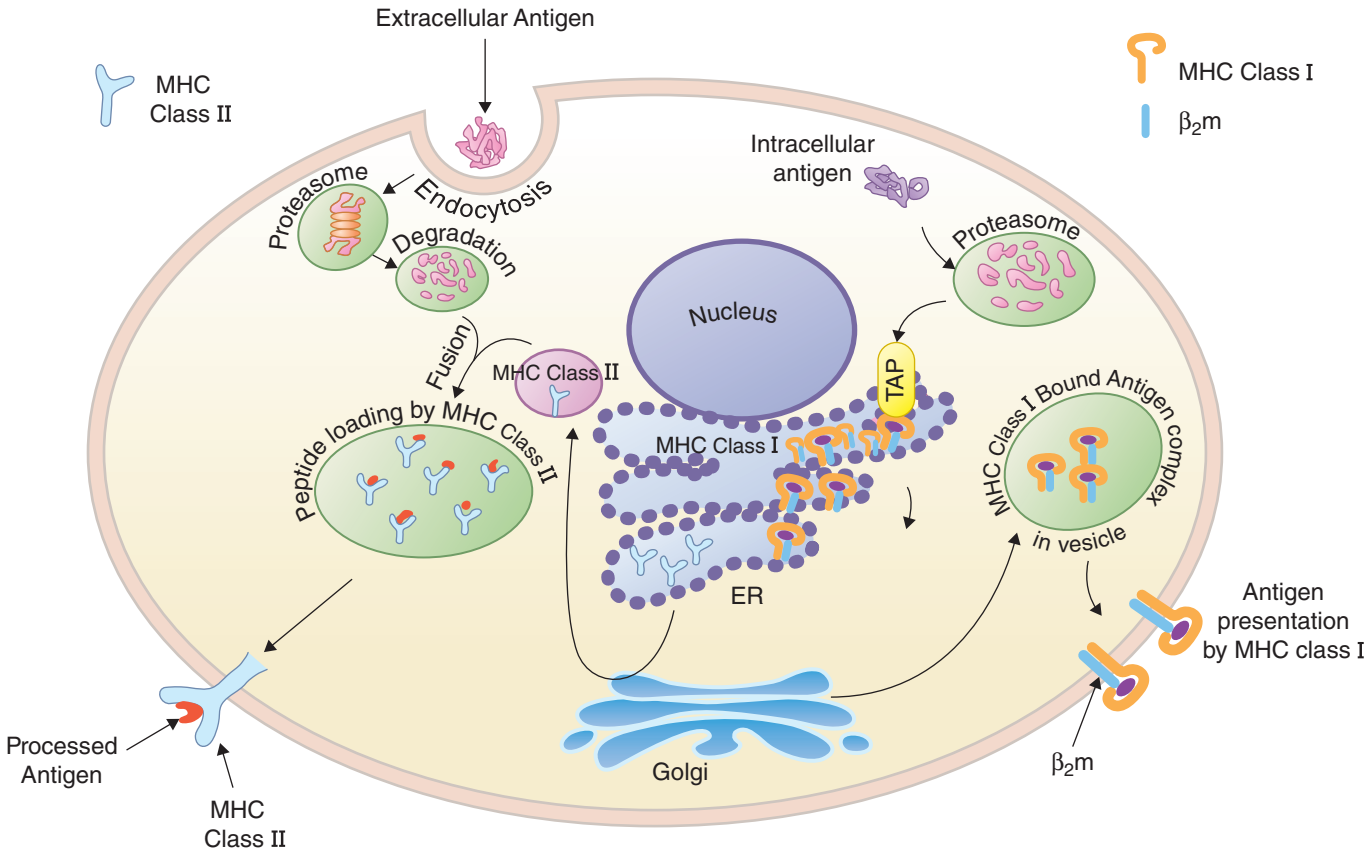

Figure 38–2 *Antigen processing and presentation via the MHC class I and II pathways.* Endogenous peptides from a variety of sources are processed by proteasomes; the resulting peptides are transported via the TAP (transporter associated with antigen processing) complex into the ER, where they encounter MHC class I–B2M (β_2-microglobulin) heterodimers. After the peptide loading of the MHC class I complex, the final peptide–MHC class I complexes migrate through the Golgi and are delivered to the cell surface to engage $CD8^+$ T cells. Exogenous antigens are endocytosed and processed by a lysosome/proteasome. The MHC class II complex is assembled in the ER, migrates through the Golgi, and subsequently fuses with the vesicle containing processed antigen fragments. These peptide cleavage products are loaded into the peptide-binding groove of the MHC class II, and the peptide–MHC class II complexes are transported to the cell surface and presented to $CD4^+$ T cells.

organism's ability to accept or reject transplanted tissue. Further studies highlighted the importance of MHC molecules in generating T_H- and T_C-cell responses.

There are two types of MHC molecules involved in antigen presentation: MHC class I and MHC class II. These structurally related molecules are expressed on different cell types but perform parallel functions in priming T-cell responses.

MHC Class I

MHC class I molecules consist of a transmembrane glycoprotein α chain noncovalently associated with a B2M (β_2-microglobulin) molecule. MHC class I molecules are expressed on the surface of nearly all nucleated cells and present peptides from endogenous antigens to CD8 T_C cells.

MHC Class II

MHC class II molecules consist of two noncovalently associated transmembrane glycoproteins, an α chain and a β chain. MHC class II molecules are primarily expressed on the surface of professional APCs (DCs, macrophages, B cells) and present peptides from exogenous antigens to CD4 T_H cells.

Antigen Processing for Presentation by MHC

Unlike immunoglobulins, which recognize a wide range of molecular structures in their native form, TCRs can only recognize antigens in the form of a peptide bound to an MHC molecule. For a pathogen to be recognized by a T cell, pathogen-derived proteins need to be degraded into peptides—an event referred to as antigen processing (see Figure 38–2). Endogenous antigens, those derived from intracellular pathogens, are processed by the cytosolic pathway for presentation by MHC class I molecules. Proteins in the cytosol are degraded into peptides by the proteosome. The resultant peptides are then transported out of the cytosol and into the endoplasmic reticulum (ER) by a protein called the TAP (transporter associated with antigen processing), which is embedded in the ER membrane. Once newly synthesized MHC class I α chains and B2M molecules are translocated into the ER membrane, the α chains and B2M molecules associate and bind peptide, forming a peptide-MHC complex. These peptide-MHC complexes make their way to the plasma membrane in membrane-enclosed vesicles of the Golgi apparatus.

Exogenous antigens, those derived from extracellular pathogens, are processed by the endocytic pathway for presentation by MHC class II molecules. In this pathway, extracellular pathogens are internalized by host cells through endocytosis or phagocytosis and are degraded by proteolytic enzymes within endocytic vesicles. Newly synthesized MHC class II α and β chains are translocated into the ER membrane, where they associate with a third chain, called the invariant chain. The invariant chain prevents MHC class II molecules from binding peptides in the ER and delivers MHC class II molecules to endocytic vesicles. Once in the endocytic vesicles, MHC class II molecules bind peptide and are carried to the cell surface by outgoing vesicles.

All T cells require peptide-MHC presentation by professional APCs for activation (see Primary Responses). If an intracellular pathogen does not infect a professional APC, CD8 T_C-cell responses can be generated through a third pathway of antigen presentation called *cross-presentation*. Cross-presentation involves the uptake of

extracellular material by professional APCs and its delivery to the MHC class I presentation pathway instead of the MHC class II presentation pathway via a mechanism that remains incompletely understood (Blum et al., 2013).

Note that protein degradation occurs continuously, even in the absence of infection. In uninfected cells, MHC molecules carry self-peptides—derived from normal cellular protein turnover—to the cell surface. While these peptide-MHC complexes do not normally provoke an immune response, recognition of these self-peptides by autoreactive T cells can result in the development of *autoimmunity* (see Autoimmunity: A Breach of Tolerance).

Lymphocyte Development and Tolerance

Innate immune PRRs are fixed receptors that recognize broad microbial structures or structures associated with damaged host cells. These receptors rarely, if ever, recognize self-antigens expressed by healthy cells. In contrast, because BCRs and TCRs develop from gene rearrangement, receptors that recognize self-antigens expressed by healthy host cells can arise. The goal of lymphocyte development is to produce cells with functional pathogen receptors but eliminate cells whose receptors recognize self-antigens. Next, we describe the processes of B-cell and T-cell development and highlight the mechanisms that maintain self-tolerance.

B-Cell Development

B-cell development takes place in the bone marrow and is driven by interaction with bone marrow stromal cells and the local cytokine environment. B-cell development can be broadly divided into pro-B-, pre-B-, immature B-, and mature B-cell stages. BCR gene rearrangement starts at the early pro-B stage and continues throughout the pre-B stage. By the immature B-cell stage, B cells express fully rearranged IgM immunoglobulins on their cell surface. At this stage, immature B cells leave the bone marrow and complete their maturation in the periphery. Mature B cells express both IgM and IgD immunoglobulins on their cell surfaces (LeBien and Tedder, 2008).

Because B-cell activation depends on help from CD4 T_H cells, negative selection of T cells whose receptors recognize self-antigens also ensures that B cells whose receptors bind to the same self-antigen will not be activated. Consequently, B cells do not undergo as rigorous of a selection process as T cells. However, B cells whose receptors recognize components of the bone marrow are negatively selected and die by apoptosis.

T-Cell Development

Unlike B cells, which develop in the bone marrow, T-cell precursors complete their development in the thymus. T-cell precursors enter the thymus as $CD4^-CD8^-$ DN (double negative) cells, not yet committed to the T-cell lineage.

The DN T cells can be divided into four subsets—DN1 to DN4—based on the expression of certain cell surface molecules. Gene rearrangement of the TCRB chain begins during the DN2 stage and continues through the DN3 stage. After β-chain rearrangement is complete, the newly synthesized β-chain combines with a protein known as the pre-Tα chain, forming the pre-TCR. DN3 cells then progress to the DN4 stage and express both the CD4 and CD8 coreceptors. These cells are now referred to as $CD4^+CD8^+$ DP (double positive) cells. DP T cells proliferate rapidly, generating clones of cells expressing the same β chain. After this period of rapid proliferation, T cells begin to rearrange their α-chain genes. Because cells within each clone can rearrange a different α chain, they generate a more diverse population than if the original cell had rearranged both the β chain and α chain before proliferating. Once a DP T cell expresses a fully rearranged TCR, it undergoes the processes of positive and negative selection.

The T cells migrate into the thymic cortex to undergo positive selection. The purpose of positive selection is to select for T cells whose TCRs can interact with an individual's own MHC molecules. In the cortex, T cells interact with cortical thymic epithelial cells, which express both MHC class I and MHC class II molecules. T cells with TCRs that do not recognize self-MHC molecules die by apoptosis. T cells with TCRs that can successfully bind to self-MHC molecules are signaled to survive and proceed to the thymic medulla. As a result of positive selection, DP thymocytes mature into single-positive T cells that express just one coreceptor (CD4 or CD8). T cells that successfully interact with MHC class I molecules develop into CD8 T cells, whereas T cells that interact with MHC class II molecules become CD4 cells.

After positive selection, T cells migrate to the thymic medulla to undergo negative selection. The purpose of negative selection is to eliminate T cells whose TCRs recognize self-antigens. This is accomplished by medullary thymic epithelial cells, which promiscuously express self-peptides on their MHC molecules. If T cells interact with self-peptides with high affinity, they are deleted by apoptosis (Shah and Zuniga-Pflucker, 2014).

The positive and negative selection processes responsible for generating self-MHC restricted and self-tolerant T cells are rigorous. It is estimated that over 98% of thymocytes die by apoptosis within the thymus, with the majority failing at the positive selection stage. The T cells that manage to successfully complete both positive and negative selection leave the thymus and take up residence in the secondary lymphoid structures.

Primary Responses

The processes of lymphocyte development and gene rearrangement generate millions of unique lymphocytes that each express pathogen receptors of a single specificity. During an infection, only a small portion of these B and T cells express receptors that can recognize the invading pathogen. To increase their numbers, each lymphocyte that recognizes the invading pathogen becomes activated and proliferates, giving rise to clones expressing identical immunoglobulins or TCRs. These processes, referred to as *clonal selection* and *clonal expansion*, are essential features of lymphocyte activation and differentiation, and facilitate the effector mechanisms that B and T cells use to combat infection.

B-Cell Activation and Antibody Production

In most primary immune responses, B-cell activation and subsequent antibody production are dependent on help from CD4 T_H cells. When circulating B cells home to secondary lymphoid tissues, they first enter at the T-cell zone. If a B cell encounters its specific antigen, cross-linking of the BCR and coreceptor induces a signal transduction cascade that mediates changes in cell surface expression of adhesion molecules and chemokine receptors, preventing the B cells from leaving the T-cell zone.

After immunoglobulins bind their cognate antigen, they internalize the antigen by receptor-mediated endocytosis and process the antigen for display by MHC class II molecules. If a CD4 T_H cell recognizes its antigen, the B and T cell form a conjugate pair. This cognate interaction facilitates the delivery of T cell–derived cytokines to B cells. The most important of these cytokines is IL-4, which is essential for B-cell proliferation and differentiation into antibody-secreting plasma cells.

The initial antibodies produced by plasma cells are of generally low affinity. They help to keep the infection under control until a stronger antibody response is generated. Antibody quality improves over the course of the infection due to two processes: somatic hypermutation and isotype switching. Somatic hypermutation introduces random single-nucleotide substitutions throughout the immunoglobulin variable regions. These changes can result in immunoglobulin molecules with increased affinity for the pathogen. B cells producing these improved immunoglobulin molecules outcompete for binding to the invading pathogen and are preferentially selected to become plasma cells. As an infection proceeds, antibodies of higher affinity are produced—a

process referred to as *affinity maturation* (Di Noia and Neuberger, 2007).

Isotype Switching. Immunoglobulin class switching (i.e., isotype switching or class-switch recombination) is a process that alters the type of immunoglobulin produced by proliferating B cells via rearrangement of the DNA in the immunoglobulin region. Only the constant region of the antibody's heavy chain is changed; thus, isotype switching impacts only how the antibody interacts with different effector molecules. The variable region of the antibody generated via V(D)J (*V*ariable, *D*iversity, and *J*oining segments) recombination at the immature B-cell state remains unaltered during the class switching process, and consequently, isotype switching does not affect antigen specificity (in this context, *variable* and *constant* refer to changes or lack thereof between antibodies that target different epitopes).

The immunoglobulin molecules emerging from the isotype switching process can be divided into five classes (isotypes): IgA, IgD, IgE, IgG, and IgM. These isotypes differ in their heavy chain constant regions and have specialized effector functions. As an infection proceeds, antibodies with additional effector functions are generated by isotype switching. This process is strongly influenced by cytokines secreted into the microenvironment by the B cell's cognate T cell (Xu et al., 2012). IgM and IgD are the first antibodies produced following activation of naïve mature B cells, and the antibodies tag pathogens for destruction by the complement system. As an infection proceeds, antibodies with additional effector functions are generated by isotype switching, which yields, in order, IgG, IgA, or IgE. IgA dominates immunoglobulin levels in association with mucosal membranes such as the gut-associated lymphoid tissue. IgE is implicated in the immune responses to various worms or protozoan parasites but is most prominently recognized for its role in hypersensitivity reactions where it mediates allergic reactions and the more severe anaphylactic reactions.

Role of Antibodies in Pathogen Clearance. Antibodies can aid in pathogen clearance in a number of ways. They can bind to a pathogen (or toxin) and prevent it from interacting with host cells. These antibodies are called neutralizing antibodies. Antibodies can also function as opsonins—coating of pathogens with antibodies can facilitate their engulfment by phagocytic cells, which often express receptors for the constant regions of antibodies. In addition, antibody deposition can activate the complement system, leading to the direct lysis of pathogens.

Antibody Production in Response to Vaccination. The development of these "natural antibodies" represents the core of adaptive immunity, and it not only represent the foundation of an organism's adaption to repeated encounters with potential pathogens in their natural environment but also forms the basis of the concept of immunization/vaccination. In the latter scenario, the immune system is primed by presentation with antigens that represent or resemble all or part of the actual pathogen. Historically, harmless microorganisms similar or related to the targeted pathogen were introduced into the body to elicit a protective immunity against the dangerous pathogen; for example, cowpox virus and vaccinia virus were used in inoculations to create protection against smallpox (see Chapter 40 and Kaynarcalidan et al., 2021). Over time, other strategies were developed that follow that same basic principle: instead of related, nonpathogenic microorganisms, the actual pathogen was administered in an attenuated or killed version (e.g., influenza vaccine). The advent of molecular biology facilitated the development of vaccines that are based on individual recombinant viral proteins rather than the entire pathogen. The latest technologies involve the delivery (sometimes with the help of replication-incompetent vector delivery systems) of part of a pathogen's genetic material (either RNA or DNA) to allow the host organism to *temporarily* produce these microbial antigens. The advantages of these systems are easy adaptability of the vaccine to mutations in the pathogen and the potential for quick, inexpensive, and scalable manufacturing due to complete *in vitro* manufacturing processes. For instance, mRNA-based vaccines have proved successful at inducing immunity against SARS-CoV-2.

Common to all vaccines is the inclusions of so-called adjuvants, which provide for the nonspecific stimulation of the initial steps in the innate immune response that are characterized by the production of the cytokines that promote lymphocyte development and switch recombination, as outlined above.

Another major advance harnessing the protective as well as therapeutic properties of antibodies came with the large-scale production of monoclonal antibodies that are characterized by limited but complete reproducible specificity since they originate in a laboratory environment rather than a (mammalian) organism (see Figure 39–4). This control over every property of these recombinant antibodies has recently been expanded with the aid of gene editing technologies such as CRISPR/Cas9, which allows for the manufacturing of chimeric monoclonal antibodies that are refractory to rejection by the patient's immune system and whose antigen specificity can be altered *in vitro* to improve their efficacy (see Chapter 40).

T-Cell Activation

Naïve T cells first encounter antigen presented by DCs in the secondary lymphoid tissues. For T cells to become fully activated, they need to receive two signals (Figure 38–3):

- A primary signal generated through ligation of the TCR
- A costimulatory signal generated through ligation of a T-cell surface protein called CD28

Both signals must be delivered by ligands on the same APC.

The primary signal is generated when the TCR engages a peptide-MHC complex. The TCR associates with an accessory molecule called CD3, forming the TCR-CD3 complex. CD3 does not influence the interaction of the TCR with its antigen but participates in the signal transduction that occurs after antigen engagement. The T-cell coreceptors CD4 and CD8 bind to the conserved regions of MHC molecules, strengthening and stabilizing the interaction between the TCR and the peptide-MHC complex. CD4 and CD8 also participate in signal transduction.

The costimulatory signal is generated when CD28 binds to its ligands, called B7-1 (CD80) and B7-2 (CD86). These costimulatory B7 molecules are expressed only on activated professional APCs, highlighting their importance in T-cell activation. Additional stimulatory and inhibitory coreceptors can modulate T cell ativaion by binding to their ligands on APCs or tumor cells. Activating and blocking monoclonal antibodies can interfere with this fine-tuning of TCR signaling, thus permitting the pharmacological modulation of the immune response (Figure 38–4).

Engagement of the TCR complex activates signal transduction cascades that induce the expression of multiple genes, including NFAT, AP-1, and NF-κB. One of the most important downstream targets of these genes is IL-2, a cytokine that is essential for T-cell proliferation and survival. The IL-2 receptor, CD25, is expressed on activated T cells. When T cells become activated, they begin to express a cell surface protein called CTLA-4 (cytotoxic T-lymphocyte–associated protein 4). This protein resembles CD28 and binds to the costimulatory B7 molecules with higher affinity than does CD28. Whereas CD28 ligation promotes T-cell activation, CTLA-4 ligation dampens T-cell activation. This inhibitory molecule serves to keep T-cell responses in check (Brownlie and Zamoyska, 2013). In addition to CTLA-4, T cells upregulate expression of other inhibitory coreceptors such as PD-1 (programmed cell death protein 1) and PSGL-1 (P-selectin glycoprotein ligand-1) that help to fine-tune the ensuing T-cell response (Attanasio and Wherry, 2016; Tinoco et al., 2016).

T-Cell Anergy. For a naïve T cell to become fully activated, it must receive a signal through the TCR and CD28. If a T cell engages a peptide-MHC

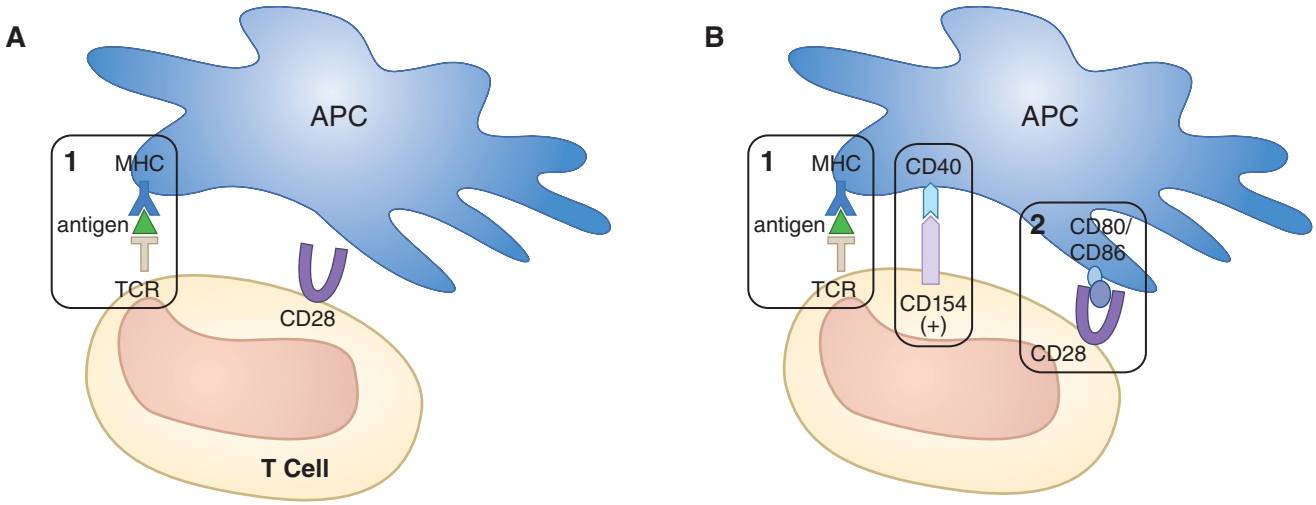

Figure 38–3 *T-cell activation: costimulation.* Two signals are required for T-cell activation: presentation of an antigen ligand to the TCR and signaling by an additional "costimulatory" pair. **A.** The primary signal, *signal 1*, is the interaction of the TCR with the MHC-antigen complex on the APC. Activation requires a second, costimulatory interaction. **B.** *Signal 2*, the costimulatory interaction between CD28 on the T cell (the costimulatory receptor) and the costimulatory ligand on the APC, CD80/CD86, leads to T-cell activation. Additional costimulatory signals, such as the interaction of CD154 with CD40 on the APC, can further enhance T-cell activation (+). In the absence of costimulation, a T cell can become anergic or unresponsive. Additional APC–T-cell interactions can occur after T-cell activation, and some can be inhibitory, providing *immune checkpoints* that are important for reducing autoimmunity and for regulating the size and extent of immune responses, See Figures 39–2 and 39–5 for details.

complex in the absence of a sufficient costimulatory signal, it enters a state of nonresponsiveness referred to as clonal anergy. Anergy is defined by the inability of T cells to proliferate after engaging a peptide-MHC complex due to a lack of IL-2 production and signaling (Figure 38–3; see also Figure 39–2).

CD4 T_H-Cell Differentiation and Effector Functions. Following activation, naïve CD4 T_H cells can differentiate into specialized T_H-cell subsets. These T_H-cell subsets display unique patterns of cytokine production and perform distinct effector functions. The initial studies on T_H-cell differentiation generated a biphasic model in which activated T_H cells differentiate into either T_H1 cells, which defend mainly against intracellular pathogens, or T_H2 cells, which aid in the clearance of extracellular pathogens. More recent models of T_H-cell differentiation have been expanded to include T_H9, T_H17, T_H22, T_{FH} (follicular helper T), and T_{Reg} (T-regulatory) cells (DuPage and Bluestone, 2016).

As their name implies, CD4 T_H cells help activate other immune cells. T_H1 cells secrete IFN-γ and TNF-α, which activate macrophages to kill pathogens located within their phagosomes. These cytokines also activate CD8 T_C cells to kill infected host cells. T_H2 cells, which produce IL-4 and IL-5, defend against extracellular pathogens by enhancing humoral immunity. IL-4 activates B cells to differentiate into antibody-secreting plasma cells. T_H2-derived cytokines also induce class switching to IgA and IgE. Another subset of CD4 T_H cells, the T_{Reg} cell, is responsible for maintaining peripheral tolerance. Through various mechanisms, these cells suppress the proliferation of effector T cells, keeping the T-cell response under control.

CD8 T_C-Cell Effector Functions. The main role of CD8 T_C cells is to induce cytolysis of infected host cells expressing peptide-MHC class I complexes. Activated CD8 T_C cells kill their target cells by two distinct pathways: the granule exocytosis pathway and the Fas-FasL pathway. The granule exocytosis pathway involves the release of perforin and granule enzymes (granzymes) A and B. Perforin molecules form pores in the target cell membrane, allowing the granzyme molecules to enter the cell. Upregulation of FasL (CD95L) on activated T_C cells induces the aggregation of Fas (CD95) on target cells. Both pathways activate the caspase cascade in the target cell, resulting in programmed cell death.

In addition to their cytolytic activity, activated CD8 T_C cells release proinflammatory cytokines, including IFN-γ and TNF-α. These cytokines further aid in pathogen clearance by enhancing the activity of macrophages and neutrophils (Harty et al., 2000).

Leukocyte Extravasation: Diapedesis

Leukocytes fulfill most of their immunological functions outside the bloodstream in the surrounding tissues. Consequently, traversing the capillary endothelial cell barrier is a crucial step in this process. Extravasation (diapedesis) refers to the movement of leukocytes out of the blood into the site of infection or physical tissue damage (Figure 38–5). In the case of blood monocytes, extravasation also occurs in the absence of pathophysiological events and facilitates their conversion into tissue macrophages. On a molecular level, diapedesis can be dissected into four mechanistic steps: *chemoattraction*, *rolling adhesion*, *tight adhesion,* and *transmigration* (Vestweber, 2015).

While initially believed to play its most important role in innate immunity, diapedesis has garnered more attention in recent years as a pharmacological target in the treatment of chronic (inflammatory) autoimmune diseases such as *multiple sclerosis* or *Crohn's disease* (see Autoimmunity). The leukocyte cell surface adhesion molecule $\alpha_4\beta_1$ integrin (VLA-4) that facilitates extravasation of $CD4^+$ T cells interacts with VCAM-1 on vascular endothelial cells. *Natalizumab* is a humanized monoclonal antibody directed against α_4 integrin; *natalizumab's* interference with the $\alpha_4\beta_1$ integrin–VCAM-1 interaction leads to a blockade of autoreactive T-cell diapedesis into the brain and thus prevents attack on the myelin composing the nerve shielding. Similarly, *natalizumab*-mediated prevention of $\alpha_4\beta_7$ integrin binding to the adhesion molecule MADCAM-1 found on endothelial cells of venules is responsible for the efficacy of the drug against Crohn's disease. Another monoclonal antibody recently approved for the treatment of Crohn's disease and ulcerative colitis is *vedolizumab*, which produces fewer side effects due to its $\alpha_4\beta_7$-restricted binding specificity. Preventing entry of effector cells to inflammatory sites through the use of neutralizing antibodies has shown high therapeutic potential in multiple disease settings.

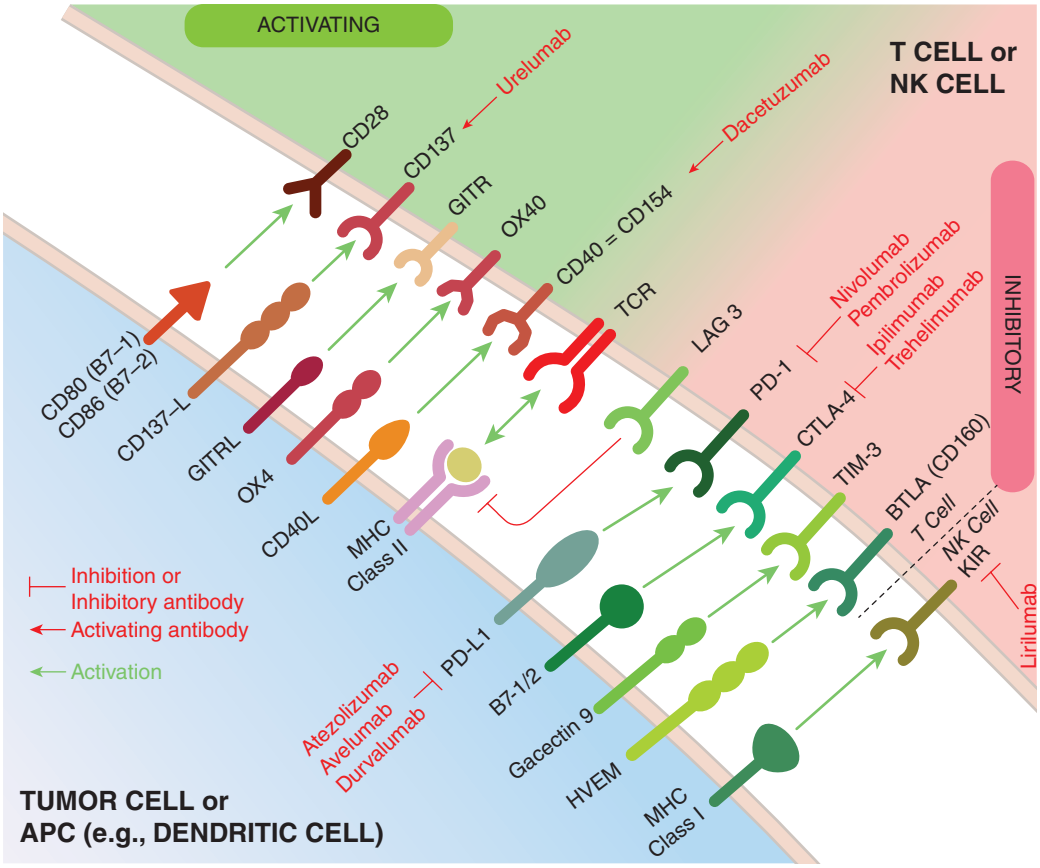

Figure 38–4 *T-cell activation and its modulation.* TCR signaling on $CD4^+$ cells after engagement with an MHC class II–peptide complex is enhanced by activating coreceptors (green-shaded area) or attenuated by inhibitory coreceptors (red-shaded area) after these bind their respective ligands on APCs or tumor cells. Numerous activating (→) or blocking (⟞) monoclonal antibodies interfere with this fine-tuning of TCR signaling, thus allowing for the pharmacological modulation of the resulting immune response.

Immunological Memory

The numbers of B and T cells decline after pathogen clearance, leaving behind a small population of memory cells. These memory cells have the ability to mount an enhanced secondary immune response upon re-exposure to the same pathogen.

Due to their expression of certain cell surface molecules, memory T cells are more sensitive to TCR-mediated activation by peptide-MHC complexes than naïve T cells. In addition, memory T cells have less-stringent requirements for costimulatory signals, allowing them to respond to peptide-MHC complexes displayed on cells that lack the costimulatory B7 molecules (Farber et al., 2014). Memory B cells produce better antibodies than naïve B cells because they express immunoglobulins that underwent somatic hypermutation and isotype switching during the first antigen encounter (Kurosaki et al., 2015). Combined, these properties allow for a faster and stronger secondary immune response, features that form the foundation of vaccination and subsequent "booster" or "refresher" inoculations (see Chapter 40).

Summary: Innate and Adaptive Immunity in Infectious Diseases

The innate and adaptive immune systems work together to keep the host healthy. The innate immune response is the body's first line of defense and eliminates the majority of pathogens on its own. In the case that the innate immune system is insufficient to eliminate the pathogen, it keeps the infection in check until the adaptive immune system is able to mount a response. Pathogens will be cleared (acute infections), or they may evade the immune response and persist (chronic infections). Chronic infections such as HIV/AIDS and hepatitis B and C lead to immune system suppression that results in susceptibility to secondary infections or cancers associated with infection.

Inflammation

What Is Inflammation, and What Purpose Does It Serve?

The inflammatory response, or inflammation, is a physiological response to tissue injury and infection, although it should be clear that *inflammation* is not a synonym for *infection*. The Romans described the characteristics of this response almost 2000 years ago: pain (*dolor*), heat (*calor*), redness (*rubor*), and swelling (*tumor*). Within minutes of tissue injury and infection, plasma proteins mediate an increase in vascular diameter (vasodilation) and vascular permeability. Vasodilation increases blood flow to the area of injury, resulting in the heating and reddening of the tissue. Increased vascular permeability allows leakage of fluid from the blood vessels into the damaged tissue, resulting in swelling (edema). Within a few hours of these vascular changes, leukocytes arrive at the site of injury. They adhere to activated endothelial cells in the inflamed region and pass through the capillary walls into the tissue (extravasation). These leukocytes phagocytize the invading pathogens and release soluble mediators—cytokines, prostaglandins, leukotrienes—that further contribute to the inflammatory response and the recruitment and activation of effector cells.

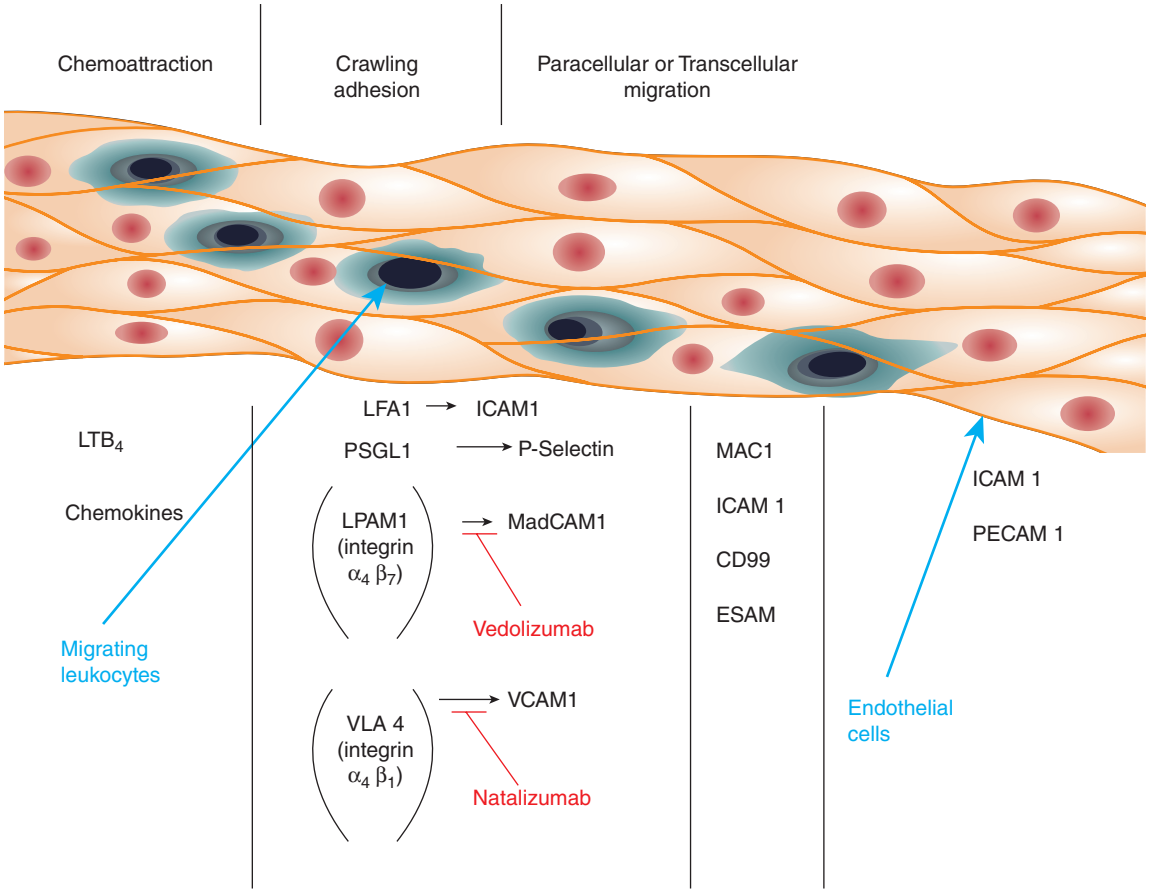

Figure 38–5 *Leukocyte diapedesis.* Leukocytes are recruited to the site of injury or infection by various chemoattractants. The expression of specific, complementary adhesion molecules on the surfaces of both the endothelial cells and the leukocytes facilitates the initial capture and subsequently the "rolling" binding of the leukocyte. After engagement of additional adhesion molecules, the leukocyte enters the subendothelial space, either by squeezing between endothelial cells (paracellular migration) or via movement through individual endothelial cells (transcellular migration). CAM, cellular adhesion molecule; CD99, cluster of differentiation 99 antigen; ESAM, endothelial CAM; ICAM, inter-CAM; MAC-1, macrophage-1 antigen; MADCAM-1, mucosal vascular addressin cell adhesion molecule 1; PSGL-1, P-selectin glycoprotein ligand 1; VCAM-1, vascular CAM 1.

Inflammation can be *acute*, as in response to tissue injury, or it may be *chronic*, leading to progressive tissue destruction, as seen in chronic infections, autoimmunity, and certain cancers. Below are details of both forms of inflammation, including their triggers, the soluble mediators and cell types involved, and the resulting tissue pathology.

The leukocyte inflammatory response is a multistep process whose individual stages can be defined based on the speed of their occurrence, which in turn depends on the availability of the factors that dominate their phases (Figure 38–6). The earliest response (phase 1) is the mobilization of Ca^{2+} that occurs within milliseconds of activation (ligand-receptor interaction). This elevation of cellular Ca^{2+} is the trigger for the release of preexisting factors and mediators stored in intracellular compartments (phase 2), factors such as histamine and proteases. Slightly delayed are phases 3 and 4, the release of mediators whose generation requires *de novo* synthesis but which is generally limited to simple, enzymatic steps that can take place within minutes of the initiating events. The synthesis and release of eicosanoids and the generation of ROS illustrate phases 3 and 4 of the inflammatory response. Phase 5, the slowest (>10 min) but most diverse and complex phase of immune and inflammatory responses, is characterized by processes that involve transcriptional and/or translational events, both stimulatory (e.g., production of cytokines) and inhibitory (e.g., transcriptional suppression by glucocorticoids). Phase 5 not only takes longer to initiate but also persists for a significantly longer period, with the consequences often still apparent days after the initiating events.

Acute Inflammatory Response

The acute inflammatory response provides protection following tissue injury and infection by restricting damage to the localized site, recruiting immune cells to eliminate the invading pathogen, and initiating the process of wound repair.

Following tissue damage, a number of plasma proteins are activated, including those of the clotting and kinin systems. The enzymatic cascade of the clotting system produces fibrin strands that accumulate to form clots, limiting the spread of infection into the blood (see Chapter 36). The enzymatic cascade of the kinin system results in the production of bradykinin—a peptide that induces vasodilation and enhanced vascular permeability (see Chapter 43). In addition, the complement products C3a and C5a bind to receptors on local mast cells, facilitating their degranulation. The resulting release of histamine, prostaglandins, and leukotrienes contributes to vascular changes by inducing vasodilation and enhancing vascular permeability. Prostaglandins and leukotrienes also serve as chemoattractants for neutrophils (see Chapter 41).

Within a few hours of these vascular changes, neutrophils bind to the endothelial cells of the inflamed region and extravasate into the tissue (see previous section, Diapedesis) where they phagocytize the invading pathogens and release soluble inflammatory mediators, including macrophage inflammatory proteins (MIPs) 1α and 1β, which are chemokines that attract macrophages to the site of inflammation. Macrophages arrive at the damaged tissue 5 to 6 h after the onset of the inflammatory response. Activated macrophages secrete three major

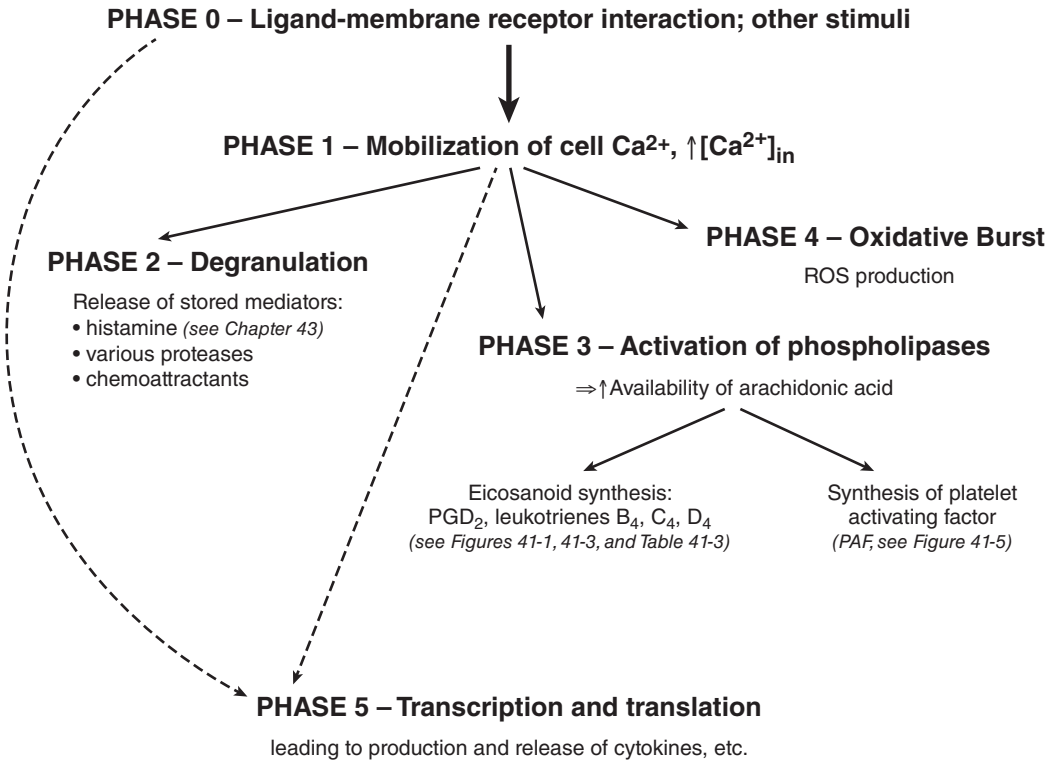

Figure 38–6 *The leukocyte inflammatory response.* Steps 1 through 4 occur immediately following ligand-receptor activation and in rapid succession. Step 5, which involves transcription and translation, results in a slower (>10 min) but more persistent response with effects that are apparent for days. See text for details.

proinflammatory cytokines: IL-1, IL-6, and TNFα. These cytokines induce coagulation, increase vascular permeability, and promote the acute-phase response. IL-1 and TNFα also induce increased expression of adhesion molecules on endothelial cells, allowing for circulating leukocytes (neutrophils, macrophages, granulocytes, and lymphocytes) to interact with the endothelium and extravasate into the inflamed tissues. Acute inflammation displays a rapid onset following tissue injury and resolves relatively quickly. The resulting tissue pathology is typically mild and localized.

Chronic Inflammation

Chronic inflammation results from continuous exposure to the offending element. This can be due to pathogen persistence, autoimmune diseases in which self-antigens continuously activate T cells, and cancers. The hallmark of chronic inflammation is the accumulation and activation of macrophages and lymphocytes, as well as fibroblasts that replace the original, damaged, or necrotic tissue. Soluble factors released by macrophages and lymphocytes play an important role in the development of chronic inflammation. Whereas non-protein–based soluble factors (e.g., eicosanoids, bioamines) dominate the landscape during acute inflammation, in chronic inflammation, cytokines, chemokines, growth factors, and secreted/released enzymes and ROS are the primary actors. For instance, cytotoxic T cells and T_H1 cells release IFN-γ, which activates macrophages and DCs. These, in turn, release a variety of soluble factors, such as IL-6 and TNFα, that ultimately result in tissue injury and cell death. Replacement of tissue lost in this manner by fibroblasts leads to fibrosis due to excessive amounts of growth factors (platelet-derived growth factor, transforming growth factor β), fibrogenic cytokines (IL-1 and TNFα), and angiogenic factors (fibroblast growth factor [FGF], vascular endothelial growth factor [VEGF]). Chronic inflammation can also lead to the formation of granulomas, cellular masses consisting of activated macrophages surrounded by activated lymphocytes.

There are myriad anti-inflammatory drugs available (see Chapter 42). The newest group of anti-inflammatory agents, whose use is limited to chronic inflammatory conditions, aims to eliminate proinflammatory cytokines through the use of monoclonal antibodies or soluble receptors (typically a truncated receptor encompassing only the ligand-binding, extracellular domain). *Infliximab*, *adalimumab*, *certolizumab*, and *golimumab* are monoclonal antibodies that bind and neutralize TNFα; *etanercept* is a TNFα receptor fusion protein with the same goal.

Immune System–Related Conditions and Immune Checkpoint Modulators

There are pathological conditions to which the immune system contributes, such as overreactions (allergy, autoimmunity, transplant rejection) or insufficient responses (immune deficiencies, cancer). The basic elements that lead to the activation of B and T cells have been identified for several decades; understanding the fine-tuning of these triggering steps has taken longer. In recent years, the area of immune checkpoints and immune system modulation has advanced rapidly to provide clinically important treatments. These basic elements can exist as soluble factors or as cell-surface receptors (co-receptors).

The components of the immune modulation fall into two categories, *those that enhance* the responses that are triggered by engagement of the antigen receptor, and *those that attenuate* immune responses; the latter play a role in terminating immune responses that are no longer necessary and in preventing excessive immune responses that have potentially fatal consequences (e.g., anaphylactic shock, septic shock). Both types of modulation primarily alter T-cell responses, affecting B-cell function only indirectly for the most part. Engagement of these modulatory co-receptors *per se* produces little if any response; co-engagement with the antigen receptor is required to produce their immunomodulatory

function. The ultimate T-cell response depends on the effects of simultaneous occupation of the TCR, of inhibitory or activating co-receptors, and of various cytokine receptors. The following sections present examples of immune system–related conditions and the utility of immunomodulatory biological agents.

Hypersensitivity Reactions

The immune system mobilizes a number of effector mechanisms to eliminate pathogens from the body. These effector mechanisms typically generate a localized inflammatory response that effectively eliminates the pathogen, with minimal collateral damage to the surrounding tissue. Besides pathogens, humans come into contact with numerous foreign antigens, such as plant pollen and food. Contact with these environmental antigens does not elicit an immune response in the majority of individuals. However, in certain predisposed individuals, the immune system can mount a response to these generally innocuous antigens, resulting in tissue damage that ranges from mild irritation to life-threatening anaphylactic shock. These immune responses are referred to as allergic reactions or hypersensitivity reactions. Hypersensitivity reactions can be divided into four categories, type I to type IV, distinguished by the cell types and effector molecules involved (Burmester et al., 2003).

Type I Hypersensitivity: Immediate Hypersensitivity Reactions

Type I hypersensitivity reactions require that an individual first produces IgE antibodies on initial encounter with an antigen, also referred to as an allergen. After the antigen is cleared, the remaining antigen-specific IgE molecules will be bound by mast cells, basophils, and eosinophils that express receptors for the IgE constant region (FcεR1). This process is referred to as sensitization. On subsequent exposure to antigen, cross-linking of the IgE molecules on sensitized cells induces their immediate degranulation. The release of inflammatory mediators such as histamine, leukotrienes, and prostaglandins causes vasodilation, bronchial smooth muscle contraction, and mucus production similar to that seen during inflammatory responses to tissue injury and infection. Type I hypersensitivity reactions can be local or systemic. Systemic reactions against peanut or bee venom antigens can result in anaphylaxis, a potentially life-threatening condition.

Allergic asthma is an example of type I hypersensitivity. On exposure to certain allergens (typically inhaled), individuals with allergic asthma experience inflammation of the airways, characterized by tissue swelling and excessive mucus production. This narrowing of the airways makes it difficult to breathe (see Chapter 44).

Type II Hypersensitivity: Antibody-Mediated Cytotoxic Reactions

Type II hypersensitivities are antibody-mediated cytotoxic reactions. One example is the immunization to erythrocyte antigens during pregnancy. In an Rh-negative mother with an Rh-positive fetus (Rh inherited from the father), the mother forms antibodies against the Rh antigen when fetal blood cells come into contact with the maternal immune system, typically during delivery. If a subsequent pregnancy with an Rh-positive fetus occurs, maternal IgG antibodies can cross the placenta and cause hemolysis of fetal Rh-positive erythrocytes. Close monitoring and adequate symptomatic treatments (e.g., plasma exchange, intrauterine infusion, Rh immunoglobulin) are prescribed, as fetal symptoms can range from mild to potential fetal death from heart failure.

Type III Hypersensitivity: Immune Complex–Mediated Reactions

Type III hypersensitivity reactions are mediated by antibody-antigen complexes that form during an immune response. When not properly cleared, these immune complexes can settle into various tissues, where they induce complement activation. These immune complexes are of particular concern in the kidney, where they can lead to glomerulonephritis and kidney failure. In the past, type III hypersensitivity reactions fell largely in the realm of autoimmune diseases (e.g., systemic lupus erythematosus); their incidence rate has significantly risen with the introduction of nonhuman or nonhumanized monoclonal antibodies as pharmacological agents (human antimouse antibodies). Murine or murine-human (mu-hu) chimeric (chim) therapeutic monoclonal antibodies are "mistaken" by the patient's immune system as potentially dangerous, foreign antigens. The resulting immune response not only "defuses" the therapeutic antibody but also promotes the formation of antibody(mu)-antibody(hu) or antibody(chim)-antibody(hu) complexes that trigger type III hypersensitivity reactions.

Type IV Hypersensitivity: Delayed Hypersensitivity Reactions

Unlike types I to III hypersensitivity reactions, which are antibody mediated, type IV reactions are mediated by T cells. However, all these hypersensitivity reactions are memory responses. Haptens are molecules that are too small to function as antigens on their own. These molecules penetrate the epidermis and bind to carrier proteins in the skin. Hapten-carrier complexes are detected by APCs in the skin (Langerhans cells), which then migrate to the lymph nodes and prime T-cell responses. When an individual is re-exposed to the hapten, antigen-specific T cells migrate to the skin, causing local inflammation and edema. Nickel in clothing and jewelry is a common trigger of type IV hypersensitivity reactions.

Autoimmunity, Immune Deficiency, and Transplant Rejection

Just as for a regular and appropriate immune response, autoimmunity is founded in either humoral (autoantibody) or cellular (T-cell) responses. As described in the section on lymphocyte development, the process of central tolerance limits the development of autoreactive B and T cells. This process is imperfect, and mechanisms of peripheral tolerance are in place to limit the activity of self-reactive lymphocytes that manage to escape thymic deletion. Peripheral tolerance is primarily mediated by two mechanisms: the action of T_{Reg} cells (see section on CD4 T_H-cell effector functions) and the induction of T-cell anergy. Naïve T cells require costimulatory signals to become activated. Consequently, autoreactive T cells typically will not become activated if they interact with an MHC molecule expressing self-antigen because most tissues do not express costimulatory molecules. Induction of anergy leaves T cells unresponsive, even on subsequent exposure to antigen with sufficient costimulation.

Autoimmunity: A Breach of Tolerance

There are several theories about the origins of individual autoimmune disorders:

- *Molecular Mimicry.* The hypothesis of molecular mimicry reasons that unique pathogen-derived antigens resemble endogenous host antigens. If an infection occurs, the immune system's defensive arsenal (antibodies, cytotoxic T lymphocytes, and NK cells) not only attack the pathogen-derived antigen but also assault the host's structurally similar antigen, thus causing autoimmunity in the form of collateral damage.
- *Relationship Between Autoimmunity and the HLA System.* Individuals with specific HLA types are more likely to develop certain autoimmune diseases (e.g., type 1 diabetes, ankylosing spondylitis, celiac disease, systemic lupus erythematosus). A reasonable explanation for this observation might be found in the fact that particular HLA proteins are more "efficient" than others in presenting antigens and consequently might erroneously activate T cells.
- *Altered Thymic Function.* Thymic T-cell selection is crucial to central tolerance; type I IFNs, which are highly induced during infectious events, also govern several steps in T-cell selection. Therefore, pathogen-induced disturbances to thymic events might negatively affect elimination of autoreactive T cells. Regardless of the mechanism, central tolerance has thus far not been exploited for pharmacological intervention.

Immune Deficiencies

Primary immunodeficiency encompasses genetic or developmental defects in the immune system that leave the individual susceptible to infections to various degrees. Severe forms (severe combined immunodeficiency) are typically diagnosed in early childhood and are associated with significantly reduced life expectancy. Presently, nine classes of primary immunodeficiency are recognized, totaling over 120 unique conditions. Unfortunately, current treatment options are limited to supportive therapy in the form of antiviral, antifungal, and antibacterial drugs.

Acquired immunodeficiency refers to the loss of immune function due to environmental exposure. These conditions encompass patients receiving immune-suppressive therapy for autoimmune disorders or to prevent transplant rejections. Acquired immunodeficiency is also commonly observed in patients suffering from hematopoietic malignancies, as tumor cells outcompete functional leukocytes for space in the bone marrow or blood. Probably the most common use for the term, however, is in connection with HIV infection, the underlying cause for AIDS (see Chapter 64).

Transplant Rejection

"Host-versus-graft disease" or "graft-versus-host disease" results from the immunological rejection of a transplanted tissue by the recipient's immune system, or in cases where bone marrow is transplanted, the "new" immune system might attack the host's tissues. The intensity of rejection is minimized with increased compatibility between donor and recipient; however, a lifelong regimen of immunosuppressive drugs is unavoidable (see Chapter 39).

Classical immunosuppressive therapy employs glucocorticoids (e.g., *prednisone*), inhibitors of T-cell activation (e.g., *cyclosporine*), T-cell proliferation inhibitors (e.g., mycophenolic acid), or mTOR inhibitors (e.g., *sirolimus*) that inhibit production of IL-2, a cytokine essential for T-cell activation and proliferation. Treatment of transplant rejection also has benefitted from advances in monoclonal antibody therapy. Antibodies directed against the IL-2 receptor (e.g., *daclizumab*) or CD20 (e.g., *rituximab*) are now available to prevent transplant rejection (see Figure 39–2).

Cancer Immunotherapy: Immune Checkpoints and Their Inhibitors

As described previously, T-cell responses are modulated by a balance between costimulatory signals, exemplified by CD28 ligation, and coinhibitory signals, such as those provided by CTLA-4 or PD-1 ligation (Figure 38–7). *Immune checkpoints* refer to inhibitory (often negative feedback) regulators that limit the amplitude and duration of an immune response. Under normal physiological conditions, immune checkpoints protect tissues from damage during an immune response and contribute to the maintenance of self-tolerance. Thus, immune checkpoints act as physiological brakes on the immune system and are essential for the maintenance of immune homeostasis and the prevention of autoimmunity.

Cancer cells express a variety of genetic and epigenetic alterations that distinguish them from healthy cells. These tumor-associated antigens can be recognized by the host antitumor T cells, which can kill the transformed tumor cells. Unfortunately, a tumor can often progress despite a high infiltration of T cells as a result of T-cell dysfunction and the development of immuno-evasive mechanisms by the tumor cells. In particular, *immune checkpoint molecules* become highly expressed on the surface of T cells in the tumor microenvironment, an expression upregulated by T-cell exhaustion. The two most widely studied immune checkpoint molecules are CTLA-4 and PD-1.

CTLA-4 and PD-1 act through different mechanisms to inhibit TCR signaling and reduce T-cell activation and function. B7 (CD80/CD86) on the tumor cell has a higher affinity for the CTLA-4 expressed on T cells than for CD28 on the T cell; thus, a coinhibitory interaction forms in preference to a costimulatory interaction (see Figure 38–7). By effectively displacing stimulatory CD28/B7 interactions, CTLA-4 can prevent costimulation, thereby dampening TCR signaling. PD-1 on T cells can bind

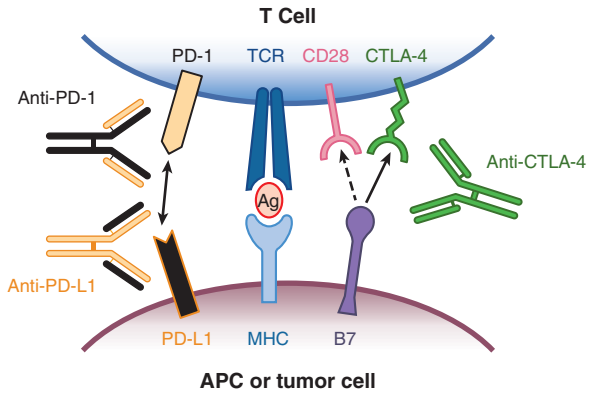

Figure 38–7 *Immune checkpoint evasion.* Via the TCR, a T cell can detect and bind an antigen (Ag) presented by the MHC of a tumor cell. If there is a satisfactory costimulatory receptor, the T cell will be activated to proliferate and mount an immune response against the tumor cell. However, in the tumor microenvironment, immune checkpoint molecules such as CTLA-4 and PD-1 may be highly expressed on the surface of the T cell, an expression upregulated by T-cell exhaustion. If the tumor cell expresses immune checkpoint ligands (B7 and PD-L1 are shown), then binding of the cognate coinhibitory ligands on the T cell can occur. The affinity of B7 for CTLA-4 exceeds its affinity for CD28, thereby replacing a costimulatory pairing with a coinhibitory one. Thus, in this example, two coinhibitory pairings can occur. The result is an inhibition of T-cell function. Monoclonal antibodies to PD-1 or PD-L1 can remove that checkpoint, and anti–CTLA-4 can remove that inhibitory checkpoint, restoring T-cell function. James Allison and Tasuku Honjo shared the 2018 Nobel Prize in Medicine/Physiology "for their discovery of cancer therapy by inhibition of negative immune regulation."

PD-L1 expressed by APCs and tumors, and this interaction dampens TCR and CD28 signaling, also reducing T-cell proliferation and immune function. Thus, these inhibitory signals induce a dysfunctional "exhausted" state in T cells that limits their ability to kill and destroy tumor cells, thereby permitting tumors to grow and metastasize.

Immune checkpoint inhibitors (ICIs) are antibodies that block CTLA-4, PD-1, or PD-L1, and their mechanism of action is to ligate these proteins to prevent their TCR inhibitory function (see Figure 38–7) (Cruz et al., 2020; Pardoll, 2012; Tang et al., 2016). ICIs have had impressive efficacy in patients with a number of cancers (e.g., melanoma) and are now the standard therapy. While subsets of cancer patients respond to ICIs, combination therapies targeting multiple immune checkpoints can increase clinical responses. ICIs have induced clinical responses and long-term progression-free survival in patients with metastatic melanoma and partial responses in patients with lung, kidney, and colon cancer. ICIs work through various mechanisms that reinvigorate antitumor T cells within the tumor and the lymph nodes draining the tumor.

In addition to these immune checkpoints, additional ICIs have been identified and are being tested in clinical trials. Figure 38–4 provides an overview of activating and inhibitory coreceptors on T cells and the drugs (monoclonal antibodies) that target these inhibitory pathways. In general, these antibodies work by releasing the "brake" on antitumor T cells, which reinvigorates these to kill tumors. It is important to be aware that some monoclonal antibodies block the immune checkpoint itself (PD-1), while others block their respective ligand (PD-L1). The clinical utility of modulating these pathways in cancer therapy is discussed in Chapter 72.

Immune checkpoint inhibitors hold great promise for treating cancer patients with advanced disease, as evidenced by the recent success of clinical trials and FDA approvals. Biologics to stimulate antitumor T cells have been approved by the FDA and are the first line of treatment of cancers such as metastatic melanoma, non–small cell lung cancer, and renal cell carcinoma. In addition, anti–PD-1, anti–PD-L1, and anti–CTLA-4

therapies are currently in clinical trials to assess their efficacy in head and neck cancers, breast cancer, small cell lung cancer, Hodgkin lymphoma, gastric cancer, hepatocellular carcinoma, bladder cancer, ovarian cancer, colon cancer, and Merkel cell carcinoma. It is important to note that only a small fraction of patients respond to ICIs; this frequency can increase when patients are given combination therapy, such as administering both anti–PD-1 and anti–CTLA-4 antibodies or combining ICIs with radiation or chemotherapy. One consequence of ICI therapy is the development of immune-related adverse events in which patients can develop toxicities including hepatitis, pneumonitis, colitis, rash, vitiligo, and endocrine pathology. Increased efficacy of ICIs will likely be achieved when additional drugs are developed to target other inhibitory pathways in combination, but caution must be used to ensure patient safety (Callahan et al., 2016).

In addition to solid tumors, liquid tumors like CLL (chronic lymphocytic leukemia) are also being targeted by immunotherapeutic approaches. Patient T cells can be engineered to express chimeric antigen receptors (CARs) comprising antibody-binding domains connected to domains that activate T cells. In the case of CLL, CAR-T cells recognize CD19 on B cells, and their chimeric receptor sustains T activation. CAR-T cells are engineered from patient blood, expanded *in vitro*; then, millions are infused into the same patient. These cells circulate in the patient and recognize and destroy all B cells expressing CD19. This cellular therapy has shown promise in patients with CLL, resulting in highly durable objective responses (Kalos et al., 2011). Complementing ICIs and CAR-T cells, many additional immunotherapies are currently being investigated in clinical trials. Examples include cancer vaccines, adaptive cell therapies using DCs and tumor-infiltrating lymphocytes, oncolytic viruses, antibody-antigen conjugates, antibody-drug conjugates, and cytokines.

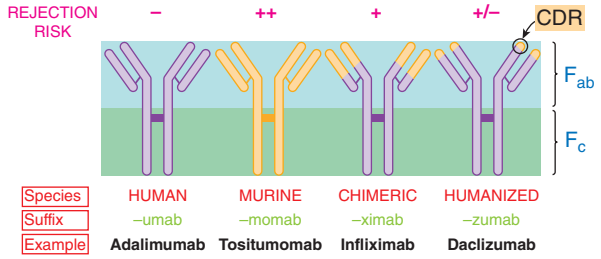

Figure 38–8 *Former nomenclature of therapeutic monoclonal antibodies.* This older nomenclature, still in use by some workers, focused primarily on the source of the antibody (murine, human, chimeric, or humanized). Current nomenclature (Table 38-1) incorporates information on the target tissue as well. Abbreviations: Fab, antigen-binding fragment; Fc, crystallizable fragment; CDR, complementarity-determining regions of the variable domains, also called hypervariable regions.

A Note on Nomenclature

The naming of monoclonal antibodies has changed over the years. The current system, shown in Table 38–1, is a four-component system, with each antibody having a unique signifying syllable followed by syllables for target tissue, source organism, and the conserved suffix, *mab*; for example, ri-tu-xi-mab. A further revision of the nomenclature is in progress.

A former system, pictured in Figure 38–8, is also still in use.

TABLE 38–1 ■ CURRENT NOMENCLATURE FOR THERAPEUTIC MONOCLONAL ANTIBODIES

UNIQUE PREFIX	TARGET TISSUE		SOURCE ORGANISM		CONSERVED SUFFIX
variable	*-o(s)-*	bone	*-u-*	human	-mab
	-vi(r)-	viral	*-o-*	mouse	
	-ba(c)-	bacterial	*-a-*	rat	
	-li(m)-	immune	*-e-*	hamster	
	-le(s)-	infectious lesions	*-i-*	primate	
	-ci(r)-	cardiovascular	*-xi-*	chimeric	
	-mu(l)-	musculoskeletal	*-zu-*	humanized	
	-ki(n)-	interleukin	*-axo-*	rat/murine hybrid	
	-co(l)-	colonic tumor			
	-me(l)-	melanoma			
	-ma(r)-	mammary tumor			
	-go(t)-	testicular tumor			
	-go(v)-	ovarian tumor			
	-pr(o)-	prostate tumor			
	-tu(m)-	miscellaneous tumor			
	-neu(r)-	nervous system			
	-tox(a)-	toxin as target			
Examples: Beva	ci		zu		mab
Ri	tu		xi		mab
Ala	ci		zu		mab
Glemba	tum		u		mab

Current nomenclature incorporates information on the source of the antibody as well as the intended target tissue. An older nomenclature, still used by some workers, focuses on the source of the antibody (see Figure 38–8).

Engineered (Recombinant) Antibodies

Most engineered antibodies are based on the use of the heavy and light chain, or fragments thereof, of the variable region of immunoglobulins. They are derived from hybridomas created through the fusion of mortal, antibody-producing primary B cells with immortal myeloma cells. The resulting immortal antibody-producing cell can be expanded into a large culture to produce unlimited quantities of antibodies of identical specificity (hence, "monoclonal"), whereby each fusion cell will give rise to a unique hybridoma with a distinct antibody product. The antigen specificity of each Ig molecule depends on the makeup of the paratope (antigen-binding site), which comprises six complementarity-determining regions. A large number of mAbs are currently used therapeutically (see Table 40–4).

F(ab) fragments represent enzymatic cleavage products derived from monoclonal antibodies (papain can cleave an immunoglobulin monomer into two monovalent F(ab) fragments and an Fc fragment). Similarly, pepsin cleaves below the hinge region, producing a bivalent $F(ab')_2$ fragment (Figure 38–9). These antibody derivatives can be produced by cell-based methods rather than molecular biological techniques. The valency of the Ig or F(ab) molecule will determine the functional properties of the product: bivalent Igs and their derivatives can either bind their target and neutralize it (e.g., blocking or competing Igs) or act as activators of cell surface receptors by forcing two of them via their two antigen-binding sites into proximity sufficient to trigger transactivation. In these cases, the antigen specificities of both F(ab) domains are identical; intact Igs or $F(ab')_2$ fragments can promote the formation only of homodimers of their antigens. F(ab) fragments of single valency can interact with only a single antigen molecule and thus can act only as neutralizing or blocking agents.

Engineered bivalent *bispecific* Ig or $F(ab')_2$ fragments create the opportunity for a single Ig or $F(ab')_2$ molecule to bind *two* cognate yet distinct antigens. This feature allows for the forced formation of various heterodimers (e.g., activation of cell surface receptors that are made up of two distinct chains).

The bivalent antibody *amivantamab* employs this engineered duality to expand treatment of EGFR-mutated non-small cell lung cancer (NSCLC). *Amivantamab* targets both EGFR and c-MET (mesenchymal-epithelial transition receptor) on the surface of the NSCLC cells. This bivalent complex provides three modes of attack:

1. Interaction of the bivalent mAB with EGFR and c-MET downregulates oncogenic signaling via these receptors and causes their heterodimerization and internalization.
2. The mAb's Fc-dependent interaction with NK cells and with the EGFR promotes NK cell-mediated cellular toxicity of the cancer cell.
3. The mAb's Fc-dependent interaction with macrophages promotes macrophage-mediated trogocytosis (Guo, et al, 2021).

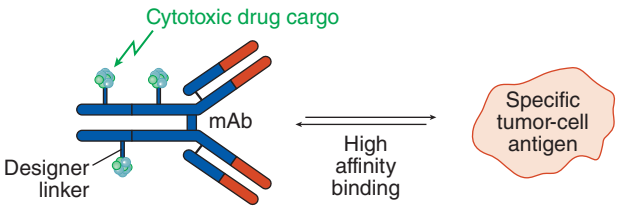

Figure 38-10 *Antibody-drug conjugates (ADCs).* The antibody of an ADC should have low immunogenicity, a long half-life, and a high affinity for the tumor antigen. The target antigen should as specific to the tumor cell as as possible, with high expression on the tumor cell and little or no expression elsewhere. The cytotoxic drug cargo, usually a small molecule, should be effective in the sub-nM range. The linker should keep the drug and mAb attached in the plasma and until the mAb has bound to the tumor antigen, when the drug-linker bonds may be severed to release active drug at the tumor site in response to local conditions (pH, proteolytic enzymes: a "cleavable" linker) or via lysosomal degradation of the ADC within the tumor cell following endocytosis (a "non-cleavable" linker). The average number of drug molecules bound per mAb molecule ranges from 2 to 8 amongst currently approved ADCs. Only a fraction of administered drug reaches the targeted cells; thus the cytotoxic drug should be potent and one must anticipate off-target effects of the drug.

Antibodies can also be designed to carry, target, and deliver small molecule drugs to discrete sites, such as to the surface of a tumor cell. Antibody-drug conjugates (ADCs) are increasingly being approved for use in cancer chemotherapy to deliver a cytotoxic cargo to specific cells expressing the target antigen. Figure 38–10 shows the basic design of an ADC. Molecules of the drug (the cargo or payload) are connected to the mAb by a bespoke linker that attaches to amino acid side chains on the antibody (usually cys or lys residues) and to the drug molecule. The linker is designed to prevent the drug's release in the plasma following injection but to permit the drug's release in conditions at the tumor site (e.g., low pH, proteolytic enzymes) or after endocytosis of the ADC into the tumor cell. Table 38–2 shows the ADCs currently FDA-approved as

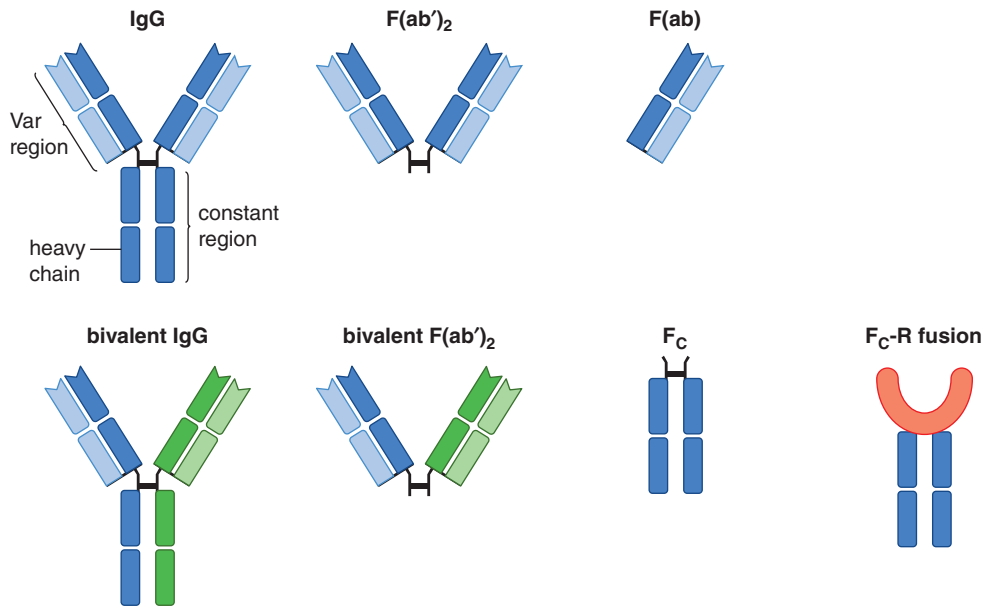

Figure 38–9 *Engineered antibodies and fragments.* See text for details.

TABLE 38–2 ■ FDA-APPROVED ANTIBODY-DRUG CONJUGATES FOR CANCER THERAPY*

mAb	mAb TARGET	CYTOTOXIC DRUG CARGO	DRUG ACTION
Belantamab[h]	BCMA	methyl auristatin F	microtubule inhibition
Brentuximab[h]	CD30	methyl auristatin E	microtubule inhibition
Enfortumab[s]	Nectin 4	methyl auristatin E	microtubule inhibition
Famtrastumab[s]	HER2	Dxd-camptothecin	topoisomerase 1 inhibition
Gemtusumab[h]	CD33	Ozogamicin-calicheamicin	DNA cleavage
Inotuzumab[h]	CD22	Ozogamicin-calicheamicin	DNA cleavage
Loncastuximab[h]	CD19	pyrrolobenzodiazepine dimer	DNA cleavage
Polatuzumab[h]	CD79b	methyl auristatin E	microtubule inhibition
Sacituzumab[s]	Trop2	SN-38/campothecin	topoisomerase 1 inhibition
Tisotumab[s]	Tissue factor	methyl auristatin E	microtubule inhibition
Trastuzumab[s]	HER2	mertansine (DM1)	microtubule inhibition

*These ADCs are designed for use in treating hemotological malignancies[h] and certain solid tumors[s]. See current FDA-approved label for approved indications and prescribing information. See also Chapter 72. Similar conjugates, known as immunotoxins, use a targeting protein coupled to a toxin. For example, *moxetumomab pasudotox-tdfk* is the Fv portion of an antibody to CD22, linked to a 38kDa fragment of Pseudomonas endotoxin A and used in treating refractory hairy cell leukemia in adults. Other examples of FDA-approved immunotoxins are *denileukin diftitox* and *tagraxofusp-erzs*.

Abbreviations: BCMA, B cell maturation antigen; HER2, human epidermal growth factor receptor 2; Trop2, tumor-associated Ca^{2+} signal transducer 2. For more detailed information, see Tong, et al. (2021), Ceci et al. (2022), and Fu, et al (2022).

cancer therapeutics, noting the molecular target of the mAb, the cargo, and that drug's action.

Molecular biology facilitates the advanced rearrangement, fusion, and editing of the antibody coding genes. These genes typically consist of heavy and light chain domains of the variable region of Ig. The simplest form of an antigen binding protein is the so-called single-chain variable fragment (scFv) in which the heavy and light chain fragments that comprise the antigen binding site are assembled as a linear fusion protein with a connecting linker region rather than being held together by disulfide bonds as in the natural Ig. Functionally, scFvs mimic F(ab) fragments. A rather unique approach is the fusion of the Ig Fc domain to the ligand binding domain of a cytokine receptor (as in *etanercept*). The resulting product binds and neutralizes the respective cytokine via its ligand binding domain, and the Fc portion extends the half-life of the recombinant fusion protein in the bloodstream.

Gene editing techniques such as CRISPR/Cas9 bring previously unimaginable opportunities in the creation of antibodies with desired specificities. Previous cloning techniques allowed for the reassembling of Ig domains into novel orders and facilitated the generation of chimeric or humanized monoclonal antibodies, but these techniques did not alter the antigen specificity of the resulting new molecule. Site-specific mutations within the complementarity-determining region created using CRISPR/Cas9 open up the possibility to introduce mutations into the antigen binding site of all of the aforementioned antibodies and their derivatives, theoretically eliminating the need for new immunizations.

As the clinically oriented chapters of this book demonstrate, combinations of these various techniques are yielding an unprecedented expansion in the availability of new antibodies against pathological conditions ranging from cancer to autoimmunity, and from immune hyperreactions and chronic inflammation to immune deficiencies.

Chapter 39

Immunosuppressants, Immunomodulation, and Tolerance

Carla V. Rothlin and J. Silvio Gutkind

This chapter reviews the components of the immune response and drugs that modulate immunity via immunosuppression, tolerance, or neutralization of cytokine signaling. Four major classes of immunosuppressive drugs are discussed: glucocorticoids, calcineurin inhibitors, antiproliferative and antimetabolic agents, and antibodies or small molecules that target cytokine signaling. While there are similarities, the approach to the use of immunosuppressant drugs in transplant rejection has evolved separately from the approaches used to treat autoimmune disease and thus is presented separately.

The Immune Response

The immune system evolved to discriminate self from non-self. *Innate immunity* (natural immunity) is primitive, based on the recognition of conserved molecular patterns of microorganisms and, as such, broadly reactive. *Adaptive immunity* (learned immunity) is antigen specific, depends on antigen exposure or priming, and can be of very high affinity. The two arms of immunity work closely together, with the innate immune system most active early in an immune response and adaptive immunity becoming progressively dominant over time.

The major effectors of *innate immunity* are complement, granulocytes, monocytes/macrophages, natural killer (NK) cells, innate lymphoid cells, mast cells, and basophils. The major effectors of *adaptive immunity* are B and T lymphocytes. B lymphocytes make antibodies; T lymphocytes function as helper, cytolytic, and regulatory (suppressor) cells. These cells not only are important in the normal immune response to infection and tumors but also mediate transplant rejection and autoimmunity.

Immunoglobulins (antibodies) produced by B lymphocytes can recognize a large variety of specific structural conformations. In contrast, T lymphocytes recognize antigens as peptide fragments in the context of major histocompatibility complex II (MHC II) proteins (called human leukocyte antigens [HLAs] in humans) on the surface of antigen-presenting cells (APCs), such as dendritic cells and macrophages, or on MHC I, which is expressed by all nucleated cells. Once activated by specific antigen recognition, both B and T lymphocytes are triggered to divide and differentiate, leading to release of soluble mediators (cytokines, chemokines) and antibodies in the case of B cells that perform as effectors and regulators of the immune response. Chapter 38 presents a more detailed view of the immune system at the levels of the molecules, cells, and organs involved in immunity.

Immunosuppression

Immunosuppressive drugs are used to dampen the immune response in organ transplantation and autoimmune disease. In transplantation, the major classes of immunosuppressive drugs used today are:

- Glucocorticoids
- Calcineurin inhibitors
- Antiproliferative/antimetabolic agents
- Biologicals (antibodies)

Table 39–1 summarizes the sites of action of representative immunosuppressants on T-cell activation. These drugs are successful in treating conditions such as acute immune rejection of organ transplants and autoimmune diseases. However, such therapies often require lifelong use and nonspecifically suppress the entire immune system, exposing patients in some instances to higher risks of infection and cancer. The calcineurin inhibitors and daily glucocorticoids, in particular, are nephrotoxic and diabetogenic, respectively, thus restricting their usefulness in a variety of clinical settings.

Monoclonal and polyclonal antibody preparations directed at both T cells and B cells or against cytokines such as tumor necrosis factor (TNF) α are important therapies providing an opportunity to more specifically target immune pathways. Biologicals designed to deplete B cells (anti-CD20) are approved for the treatment of relapsing-remitting and primary progressive multiple sclerosis (MS). Newer small molecules and antibodies have expanded the arsenal of immunosuppressives. In particular, inhibitors of the mammalian target of rapamycin (mTOR; *sirolimus, everolimus, temsirolimus*) (Budde et al., 2011; Euvrard et al., 2012) and anti-CD25 (interleukin 2 receptor [IL-2R]) and various antibodies (e.g., *basiliximab, daclizumab*) (Nashan, 2005) target growth factor pathways. *Belatacept* and others inhibit T-cell costimulation (see Figures 39–2 and 39–4). Thus, there

Abbreviations

ALG: antilymphocyte globulin
APC: antigen-presenting cell
ATG: antithymocyte globulin
AUC: area under the plasma concentration–time curve
CAPS: cryopyrin-associated periodic syndromes
CLL: chronic lymphocytic leukemia
CTLA-4: cytotoxic T-lymphocyte–associated antigen 4
CYP: cytochrome P450
GA: glatiramer acetate
GI: gastrointestinal
GM-CSF: granulocyte-macrophage colony-stimulating factor
GVHD: graft-versus-host disease
HLA: human leukocyte antigen
HSC: hematopoietic stem cell
IFN: interferon
Ig: immunoglobulin
IL: interleukin
IL-1RA: IL-1 receptor antagonist
IL-2R: interleukin 2 receptor
JAK: Janus kinase
JAKinib: Janus kinase inhibitor
JCV: John Cunningham virus
LDL: low-density lipoprotein
LFA: lymphocyte function–associated antigen
mAb: monoclonal antibody
MAO: monoamine oxidase
MHC: histocompatibility complex
MMF: mycophenolate mofetil
6-MP: 6-mercaptopurine
MPA: mycophenolic acid
MPAG: MPA glucuronide
MS: multiple sclerosis
mTOR: mammalian target of rapamycin
NFAT: nuclear factor of activated T lymphocytes
NK: natural killer
PD-1: programmed cell death protein 1
PD-L1: programmed death ligand 1
PML: progressive multifocal leukoencephalopathy
S1P: sphingosine-1-phosphate
S1PR: sphingosine-1-phosphate receptor
STAT: signal transducer and activator of transcription
TCR: T-cell receptor
TNF: tumor necrosis factor
TYK2: tyrosine kinase 2
VZV: varicella-zoster virus

are useful pharmacological tools that can substantially limit clonal expansion and potentially promote tolerance (Goldfarb-Rumyantzev et al., 2006; Halloran, 2004; Krensky et al., 1990).

General Approach to Organ Transplantation Therapy

Organ transplantation therapy is organized around five general principles.

1. Carefully prepare the patient and select the best available ABO blood type–compatible HLA match for organ donation.
2. Employ multitier immunosuppressive therapy and simultaneously use several agents, each of which is directed at a different molecular target within the allograft response. Synergistic effects permit use of the various agents at relatively low doses, thereby limiting specific toxicities while maximizing the immunosuppressive effect.
3. Employ intensive induction and lower-dose maintenance drug protocols. Greater immunosuppression is required to gain early engraftment or to treat established rejection than to maintain long-term immunosuppression. The early high risk of acute rejection is replaced over time by the increased risk of the medications' side effects, necessitating a slow reduction of immunosuppressive drugs used for maintenance.
4. Investigate each episode of transplant dysfunction, evaluating for recurrence of the disease, rejection, drug toxicity, and infection (keeping in mind that these various problems can, and often do, coexist).
5. Reduce dosage or withdraw a drug if its toxicity exceeds its benefit (Danovitch et al., 2007).

TABLE 39–1 ■ SITES OF ACTION OF SELECTED IMMUNOSUPPRESSIVE AGENTS ON T-CELL ACTIVATION

DRUG	SITE (AND MECHANISM) OF ACTION
Glucocorticoids	Glucocorticoid response elements in DNA (regulate gene transcription)
Cyclosporine	Calcineurin (inhibits phosphatase activity)
Tacrolimus	Calcineurin (inhibits phosphatase activity)
Azathioprine	DNA (false nucleotide incorporation)
Mycophenolate mofetil	Inosine monophosphate dehydrogenase (inhibits activity)
Sirolimus	mTOR, protein kinase involved in cell-cycle progression (inhibits activity)
Everolimus	mTOR, protein kinase involved in cell-cycle progression (inhibits activity)
Belatacept	Costimulatory ligands (CD80 and CD86) present on antigen presenting cells (inhibits activity)
Alemtuzumab	CD52 protein, widely expressed on B cells, T cells, macrophages, NK cells (induces lysis)
Muromonab-CD3	T-cell receptor complex (blocks antigen recognition)
Daclizumab, basiliximab	IL-2R (block IL-2–mediated T-cell activation)

Biological Induction Therapy

In many transplant centers, induction therapy with biological agents is used to delay the use of the nephrotoxic calcineurin inhibitors or to intensify the initial immunosuppressive therapy in patients at high risk of rejection (i.e., repeat transplants, broadly presensitized patients, African American patients, or pediatric patients). This strategy has been an important component of immunosuppression since the 1960s, when Starzl and colleagues demonstrated the beneficial effect of antilymphocyte globulin (ALG) in the prophylaxis of rejection. Two preparations are FDA-approved for use in transplantation: lymphocyte immune globulin (Atgam) and antithymocyte globulin (ATG; Thymoglobulin) (Brennan et al., 2006; Nashan, 2005). ATG is the most frequently used depleting agent. *Alemtuzumab*, a humanized anti-CD52 monoclonal antibody (mAb) that produces prolonged lymphocyte depletion, is approved for use in chronic lymphocytic leukemia (CLL) and MS but is increasingly used off-label as induction therapy in transplantation (Jones and Coles, 2014).

Most limitations of murine-based mAbs generally were overcome by the introduction of chimeric or humanized mAbs that lack antigenicity and have a prolonged serum $t_{1/2}$. Antibodies derived from transgenic mice carrying human antibody genes are labeled "humanized" (90%–95% human) or "fully human" (100% human); antibodies derived from human cells are labeled "human." However, all three types of antibodies are of equal efficacy and safety. Chimeric antibodies generally contain

about 33% mouse protein and 67% human protein and produce an antibody response that results in reduced efficacy and shorter $t_{1/2}$ compared to humanized antibodies.

Biological agents for induction therapy in the prophylaxis of rejection currently are used in about 70% of *de novo* transplant patients. Biological agents for induction can be divided into two groups: the *depleting agents* and the *immune modulators*. The depleting agents consist of lymphocyte immune globulin, ATG, *muromonab*-CD3 mAb (discontinued in the U.S.), and *teplizumab*-CD3 mAb (FDA-approved as breakthrough therapy in 2019). Their efficacy derives from their ability to deplete the recipient's CD3-positive cells at the time of transplantation and antigen presentation. The second group of biological agents, the anti–IL-2R mAbs, do not deplete T lymphocytes; rather, they block interleukin (IL)-2–mediated T-cell activation by binding to the α chain of IL-2R (CD25). For patients with high levels of anti-HLA antibodies and humoral rejection, more aggressive therapies include plasmapheresis, intravenous immunoglobulin, and *rituximab*, a chimeric anti-CD20 mAb (Brennan et al., 2006; Chan et al., 2011; Guerra et al., 2011; Nashan, 2005; Sureshkumar et al., 2012).

Maintenance Immunotherapy

Basic immunosuppressive therapy uses multiple drugs simultaneously, typically a calcineurin inhibitor, glucocorticoids, and *mycophenolate* (an inhibitor of purine metabolism), each directed at a discrete step in T-cell activation (Vincenti et al., 2008). Glucocorticoids, *azathioprine, cyclosporine, tacrolimus, mycophenolate, sirolimus, belatacept*, and various mAbs and polyclonal antibodies all are approved for use in transplantation.

Therapy for Established Rejection

Low doses of *prednisone*, calcineurin inhibitors, purine metabolism inhibitors, *sirolimus*, or *belatacept* are effective in preventing acute cellular rejection; they are less effective in blocking activated T lymphocytes and thus are not very effective against established, acute rejection or for the total prevention of chronic rejection. Therefore, treatment of established rejection requires the use of agents directed against activated T cells. These include glucocorticoids in high doses (pulse therapy) or polyclonal antilymphocyte antibodies.

Glucocorticoids

The introduction of glucocorticoids as immunosuppressive drugs in the 1960s played a key role in making organ transplantation possible. *Prednisone*, *prednisolone*, and other glucocorticoids are used alone and in combination with other immunosuppressive agents for treatment of transplant rejection and autoimmune disorders. The pharmacological properties of glucocorticoids are described in Chapter 50.

Mechanism of Action

Glucocorticoids have broad anti-inflammatory effects on multiple components of cellular immunity but relatively little effect on humoral immunity. Glucocorticoids bind to receptors inside cells and regulate the transcription of numerous other genes. Glucocorticoids also curtail activation of nuclear factor-κB, suppress formation of proinflammatory cytokines such as IL-1 and IL-6, inhibit T cells from making IL-2 and proliferating, and inhibit the activation of cytotoxic T lymphocytes. In addition, glucocorticoid-treated neutrophils and monocytes display poor chemotaxis and decreased release of lysosomal enzymes.

Therapeutic Uses

There are numerous therapeutic indications for glucocorticoids. They commonly are combined with other immunosuppressive agents to prevent and treat transplant rejection. Glucocorticoids also are efficacious for treatment of graft-versus-host disease (GVHD) in bone marrow transplantation. Glucocorticoids are routinely used to treat autoimmune disorders such as rheumatoid and other arthritides, systemic lupus erythematosus, systemic dermatomyositis, psoriasis and other skin conditions, asthma and other allergic disorders, inflammatory bowel disease, inflammatory ophthalmic diseases, autoimmune hematological disorders, and acute exacerbations of MS (see section on MS). In addition, glucocorticoids limit allergic reactions that occur with other immunosuppressive agents and are used in transplant recipients to block the first-dose cytokine storm caused by treatment with ATG (see Antithymocyte Globulin). Due to the long-term side effects of continuous steroid treatment, immunosuppressive protocols in transplantation include the option of early steroid withdrawal, particularly in pediatric patients (Gajardo et al., 2021). The risks of this practice continue to be evaluated, particularly in recipients of organs from deceased donors (Bae et al., 2020).

Toxicity

Extensive glucocorticoid use often results in disabling and life-threatening adverse effects. These effects include growth retardation in children, avascular necrosis of bone, osteopenia, increased risk of infection, poor wound healing, cataracts, hyperglycemia, and hypertension (see Chapter 50). The advent of combined glucocorticoid/calcineurin inhibitor regimens has allowed reduced doses or rapid withdrawal of steroids, resulting in lower steroid-induced morbidities (Vincenti et al., 2008).

Calcineurin Inhibitors

Among the most effective immunosuppressive drugs in routine use are the calcineurin inhibitors *cyclosporine* and *tacrolimus* (Figure 39–1), which target intracellular signaling pathways induced as a consequence of T-cell receptor (TCR) activation (Figure 39–2). *Cyclosporine* and *tacrolimus* bind to an immunophilin (cyclophilin for *cyclosporine* or FKBP-12 for *tacrolimus*), resulting in subsequent interaction with calcineurin to block its phosphatase activity. A *cyclosporine* analogue, *voclosporin*, with distinct binding for cyclophilin and immunosuppressive activity superior to that of *cyclosporine* was FDA-approved in 2021 for the treatment of lupus nephritis (Kuglstatter et al., 2011). Calcineurin-catalyzed dephosphorylation is required for movement of a component of the nuclear factor of activated T lymphocytes (NFAT) into the nucleus. NFAT, in turn, is required to induce a number of cytokine genes, including the gene for IL-2, a prototypic T-cell growth and differentiation factor (Verghese et al., 2014).

Tacrolimus

Tacrolimus is a macrolide antibiotic produced by *Streptomyces tsukubaensis*. Because of perceived slightly greater efficacy and ease of blood level monitoring, *tacrolimus* has become the preferred calcineurin inhibitor in most transplant centers (Ekberg et al., 2007).

Mechanism of Action. Like *cyclosporine*, *tacrolimus* inhibits T-cell activation by inhibiting calcineurin. *Tacrolimus* binds to an intracellular protein, FKBP-12, an immunophilin structurally related to cyclophilin. A complex of *tacrolimus*–FKBP-12, Ca^{2+}, calmodulin, and calcineurin then forms, and calcineurin phosphatase activity is inhibited (see Figure 39–2). Inhibition of phosphatase activity prevents dephosphorylation and nuclear translocation of NFAT and inhibits T-cell activation. Thus, although the intracellular receptors differ, *cyclosporine* and *tacrolimus* target the same pathway for immunosuppression.

ADME. *Tacrolimus* is available for oral administration as capsules and extended-release capsules (0.5, 1, and 5 mg); extended-release tablets (0.75, 1, and 4 mg); and a solution for injection (5 mg/mL). Sublingual *tacrolimus* has been used off-label for the short term in patients who are unable to receive medications orally. Because of intersubject variability in pharmacokinetics, individualized dosing is required for optimal therapy. For *tacrolimus*, whole blood is the preferred sampling compartment; the trough drug level in whole blood seems to correlate better with clinical events for *tacrolimus* than for *cyclosporine*. Target concentrations are 10 to 15 ng/mL in the early preoperative period and 6 to 8 ng/mL at 3 months posttransplantation. Target concentrations are dependent on sampling technique, product-release characteristics, and immediate- versus extended-release forms. Gastrointestinal (GI) absorption is incomplete and variable. Food decreases the rate and extent of absorption. Plasma protein binding of *tacrolimus* is 75% to 99%, involving

primarily albumin and α_1-acid glycoprotein. The $t_{1/2}$ of *tacrolimus* is about 12 h. *Tacrolimus* is extensively metabolized in the liver by hepatic CYPs 3A4 and 3A5. Some of the metabolites are active. The bulk of excretion of the parent drug and metabolites is in the feces.

Therapeutic Uses. *Tacrolimus* is indicated for the prophylaxis of solid-organ allograft rejection in a manner similar to *cyclosporine* (see Cyclosporine) and is used off-label as rescue therapy in patients with rejection episodes despite "therapeutic" levels of *cyclosporine*. Recommended initial oral doses are 0.2 mg/kg per day for adult kidney transplant patients, 0.1 to 0.15 mg/kg per day for adult liver transplant patients, 0.075 mg/kg per day for adult heart transplant patients, and 0.15 to 0.2 mg/kg per day for pediatric liver transplant patients in two divided doses 12 h apart. These dosages are intended to achieve typical blood trough levels in the 5- to 20-ng/mL range (Goring et al., 2014). Note that the oral dose of *tacrolimus* depends on product release characteristics (immediate- vs. extended-release formulation) and the specific cocktail of medications selected for prophylaxis.

Toxicity. Nephrotoxicity, neurotoxicity (e.g., tremor, headache, motor disturbances, seizures), GI complaints, hypertension, hyperkalemia, hyperglycemia, and diabetes all are associated with *tacrolimus* use. *Tacrolimus* has a negative effect on pancreatic islet β cells, and glucose intolerance and diabetes mellitus are well-recognized complications of *tacrolimus*-based immunosuppression. While combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, new-onset diabetes after transplantation incidence was significantly higher with *tacrolimus* than with *cyclosporine*, the other calcineurin inhibitor. Obese patients, African American or Hispanic transplant recipients, or those with a family history of type 2 diabetes or obesity are especially at risk. As with other immunosuppressive agents, there is an increased risk of secondary tumors and opportunistic infections. Notably,

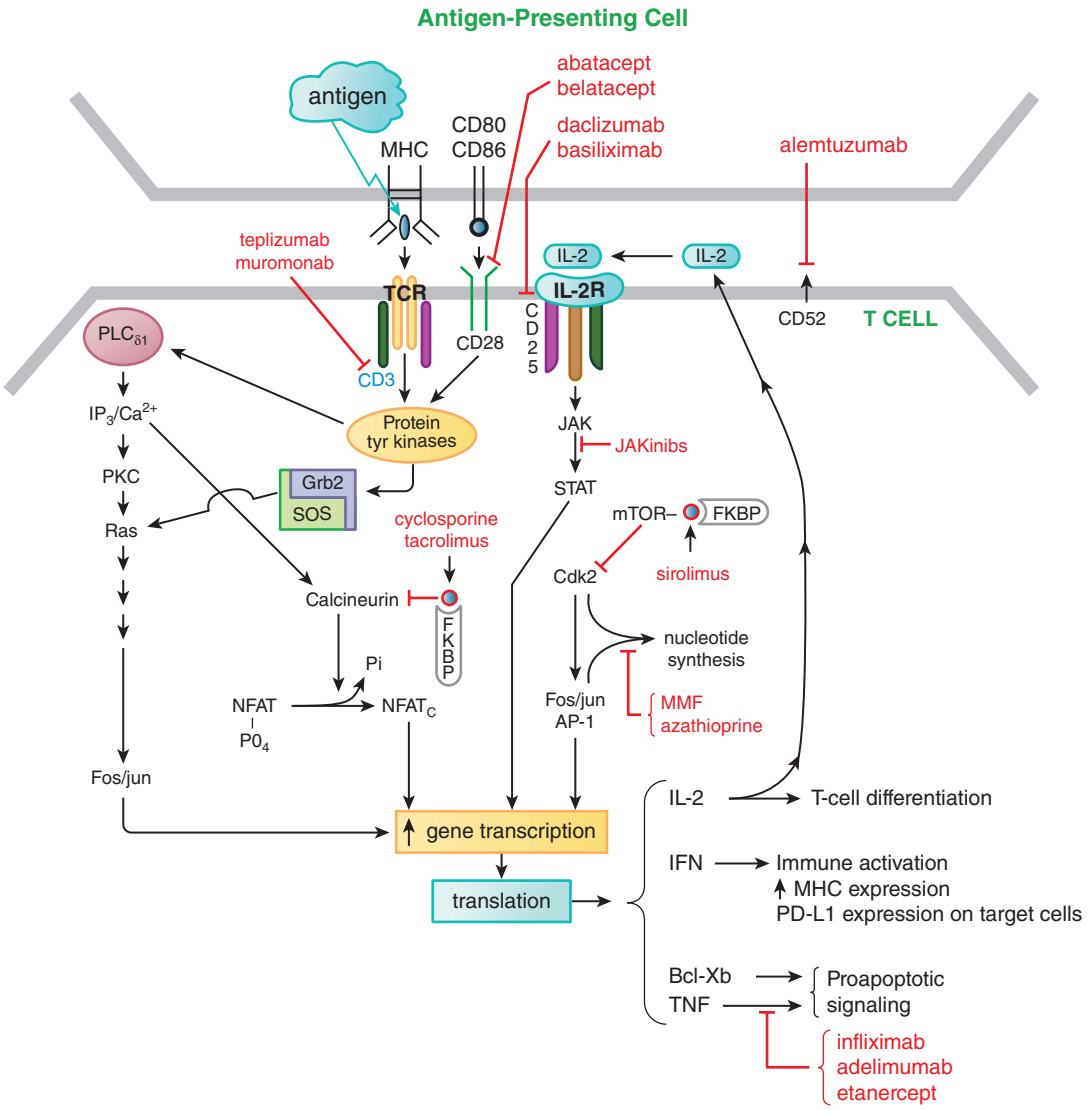

Figure 39–2 *T-cell activation and sites of action of immunosuppressive agents.* The TCR recognizes antigens bound to the MHC. A costimulatory signal is required for T-cell activation: The CD80/CD86-CD28 interaction from the APC to the T cell. Activation leads to IL-2 production (in a positive-feedback loop) and a host of other events, some of which are bracketed in the lower right-hand corner. Numerous agents are available to suppress T-cell activation. *Cyclosporine* and *tacrolimus* bind to immunophilins (cyclophilin and FKBP, respectively), forming a complex that inhibits the phosphatase calcineurin and the calcineurin-catalyzed dephosphorylation that permits translocation of NFAT into the nucleus. NFAT is required for transcription of IL-2 and other growth- and differentiation-associated cytokines (lymphokines). *Sirolimus* (rapamycin) works downstream of the IL-2R, binding to FKBP; the FKBP-*sirolimus* complex binds to and inhibits the mTOR, a kinase involved in cell cycle progression (proliferation). MMF and *azathioprine* inhibit nucleic acid synthesis, thereby inhibiting T-cell proliferation. The antibody *muromunab* inhibits TCR function via interaction with its CD3 component. *Daclizumab* and *basiliximab* block IL-2 signaling by interacting with the alpha subunit of the IL-2R complex (CD25). Several antibodies can block the systemic effects of released TNF. *Alemtuzumab*, by binding to CD52, marks the cell for destruction, thereby depleting $CD52^+$ cells. Small-molecule inhibitors ("JAKinibs") targeting members of the Janus kinase (JAK) family block the tyrosine phosphorylation of STAT transcription factors in response to IL-2 and multiple cytokines, thereby inhibiting many of their biological functions. APC, antigen-presenting cell.

tacrolimus does not adversely affect uric acid or low-density lipoprotein (LDL) cholesterol. Diarrhea and alopecia are common in patients on concomitant *mycophenolate* therapy.

Drug Interactions. Because of its potential for nephrotoxicity, *tacrolimus* blood levels and renal function should be monitored closely. Coadministration with *cyclosporine* results in additive or synergistic nephrotoxicity; therefore, a delay of at least 24 h is required when switching a patient from *cyclosporine* to *tacrolimus*. Because *tacrolimus* is metabolized mainly by CYP3A4/5, the potential interactions described in the following section for *cyclosporine* also apply for *tacrolimus*. Per the label, concomitant use of *tacrolimus* with *cyclosporine* or *sirolimus* is not recommended for prophylaxis against renal transplant rejection.

Cyclosporine

Cyclosporine (cyclosporin A), a cyclic polypeptide of 11 amino acids produced by the fungus *Beauveria nivea,* inhibits calcineurin activity (Azzi et al., 2013).

Mechanism of Action. *Cyclosporine* forms a complex with cyclophilin, a cytoplasmic-receptor protein present in target cells (see Figure 39–2). This complex binds to calcineurin, inhibiting Ca^{2+}-stimulated dephosphorylation of the cytosolic component of NFAT. When cytoplasmic NFAT is dephosphorylated, it translocates to the nucleus and complexes with nuclear components required for complete T-cell activation, including transactivation of IL-2 and other lymphokine genes. Calcineurin

phosphatase activity is inhibited after physical interaction with the *cyclosporine*/cyclophilin complex.

At the level of immune system function, *cyclosporine* suppresses some humoral immunity but is more effective against T-cell–dependent immune mechanisms such as those underlying transplant rejection and some forms of autoimmunity. It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, blunting expression of many lymphokines, including IL-2, and the expression of antiapoptotic proteins. *Cyclosporine* also increases expression of transforming growth factor-β, a potent inhibitor of IL-2–stimulated T-cell proliferation and generation of cytotoxic T lymphocytes (Colombo and Ammirati, 2011; Molnar et al., 2015).

ADME. Because *cyclosporine* is lipophilic and highly hydrophobic, it is formulated for clinical administration using castor oil or other strategies to ensure solubilization. *Cyclosporine* can be administered intravenously or orally. The intravenous preparation is provided as a solution in an ethanol–polyoxyethylated castor oil vehicle that must be further diluted in 0.9% sodium chloride solution or 5% dextrose solution before injection. The oral dosage forms include soft gelatin capsules and oral solutions. *Cyclosporine* supplied in the original soft gelatin capsule is absorbed slowly, with 20% to 50% bioavailability. A modified microemulsion formulation, NEORAL, has become the most widely used preparation. It has more uniform and slightly increased bioavailability compared to the original formulation. It is provided as 25- and 100-mg soft gelatin capsules and a 100-mg/mL oral solution. The original and microemulsion formulations are *not bioequivalent* and cannot be used interchangeably without heightened monitoring of drug concentrations and assessment of graft function. A second modified formulation, GENGRAF, is also marketed, and like NEORAL, is *not interchangeable* with nonmodified *cyclosporine* formulations. Transplant units need to educate patients that the *cyclosporine* preparation known as SANDIMMUNE and its generics are not the same as NEORAL and its generics, such that one preparation cannot be substituted for another without risk of inadequate immunosuppression or increased toxicity. The danger of unauthorized, inadvertent, unmonitored, or inappropriate substitution of nonequivalent formulations can result in graft loss and other adverse patient outcomes.

Blood levels taken 2 h after a dose administration (so-called C_2 levels) may correlate better with the AUC (area under the plasma concentration–time curve) than other single points, but no single time point can simulate the exposure better than more frequent drug sampling. In practice, if a patient has clinical signs or symptoms of toxicity or if there is unexplained rejection or renal dysfunction, a pharmacokinetic profile can be used to estimate that person's systemic exposure to the drug.

Cyclosporine absorption is incomplete following oral administration and varies with the individual patient and the formulation used. *Cyclosporine* is distributed extensively outside the vascular compartment. After intravenous dosing, the steady-state volume of distribution reportedly is as high as 3 to 5 L/kg in solid-organ transplant recipients. The elimination of *cyclosporine* from the blood generally is biphasic, with a terminal $t_{1/2}$ of 5 to 18 h. After intravenous infusion, clearance is about 5 to 7 mL/min/kg in adult recipients of renal transplants, but results differ by age and between different patient populations. For example, clearance is slower in cardiac transplant patients and more rapid in children. Thus, the intersubject variability is so large that individual monitoring is required.

After oral administration of *cyclosporine* (as NEORAL), the time to peak blood concentrations is 1.5 to 2 h. Administration with food delays and decreases absorption. High- and low-fat meals consumed within 30 min of administration decrease the AUC by about 13% and the maximum concentration by 33%. This makes it imperative to individualize dosage regimens for outpatients. *Cyclosporine* is extensively metabolized by hepatic CYP3A4 and to a lesser degree in the GI tract and kidneys. At least 25 metabolites have been identified in human bile, feces, blood, and urine. All of the metabolites have reduced biological activity and toxicity compared to the parent drug. *Cyclosporine* and its metabolites are excreted principally through the bile into the feces, with only about 6% excreted in the urine. *Cyclosporine* is also excreted in human milk. In the presence of hepatic dysfunction, dosage adjustments are required. No adjustments generally are necessary for patients on dialysis or with renal failure.

Therapeutic Uses. Clinical indications for *cyclosporine* are kidney, liver, heart, and other organ transplantation; rheumatoid arthritis; psoriasis; and xerophthalmia. Its use in dermatology is discussed in Chapter 75. *Cyclosporine* usually is combined with other agents, especially glucocorticoids and either *azathioprine* or *mycophenolate*, and, most recently, *sirolimus*. The dose of *cyclosporine* varies, depending on the organ transplanted and the other drugs used in the specific treatment protocol(s). The initial dose generally is not given before the transplant because of the concern about nephrotoxicity. For renal transplant patients, therapeutic algorithms have been developed to delay *cyclosporine* or *tacrolimus* introduction until a threshold renal function has been attained. Dosing is guided by signs of rejection (too low a dose), renal or other toxicity (too high a dose), and close monitoring of blood levels. Great care must be taken to differentiate renal toxicity from rejection in kidney transplant patients. Ultrasound-guided allograft biopsy is the best way to assess the basis for renal dysfunction. Because adverse reactions have been ascribed more frequently to the intravenous formulation, this route of administration is discontinued as soon as the patient can take the drug orally.

In rheumatoid arthritis, *cyclosporine* is used in severe cases that have not responded to *methotrexate*. *Cyclosporine* can be combined with *methotrexate*, but the levels of both drugs must be monitored closely. In psoriasis, *cyclosporine* is indicated for treatment of adult immunocompetent patients with severe and disabling disease for whom other systemic therapies are contraindicated or have failed. Because of its mechanism of action, there is a theoretical basis for the use of *cyclosporine* in a variety of other T-cell–mediated diseases. *Cyclosporine* reportedly is effective in Behçet's disease, acute ocular syndrome, endogenous uveitis, atopic dermatitis, inflammatory bowel disease, and nephrotic syndrome, even when standard therapies have failed.

Toxicity. The principal adverse reactions to *cyclosporine* therapy are renal dysfunction and hypertension. Tremor, hirsutism, hyperlipidemia, and gum hyperplasia also are frequently encountered. Hypertension occurs in about 50% of renal transplant and almost all cardiac transplant patients. Hyperuricemia may lead to worsening of gout, increased P-glycoprotein activity, and hypercholesterolemia (see Chapters 4, 37, and 42). Nephrotoxicity occurs in the majority of patients and is the major reason for cessation or modification of therapy. Combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, although this seems more problematic in patients treated with *tacrolimus* (see previous Tacrolimus section). *Cyclosporine*, as opposed to *tacrolimus*, is more likely to produce elevations in LDL cholesterol.

Drug Interactions. *Cyclosporine* interacts with a wide variety of commonly used drugs, and close attention must be paid to drug interactions. Any drug that affects CYPs, especially CYP3A4, may affect *cyclosporine* blood concentrations. Substances that inhibit this enzyme can decrease *cyclosporine* metabolism and increase blood concentrations. These include Ca^{2+} channel blockers (e.g., *verapamil, nicardipine*); antifungal agents (e.g., *fluconazole, ketoconazole*); antibiotics (e.g., *erythromycin*); glucocorticoids (e.g., *methylprednisolone*); HIV-protease inhibitors (e.g., *indinavir*); and other drugs (e.g., *allopurinol, metoclopramide*). Grapefruit juice inhibits CYP3A4 and the P-glycoprotein multidrug efflux pump and thereby can increase *cyclosporine* blood concentrations. In contrast, drugs that induce CYP3A4 activity can increase *cyclosporine* metabolism and decrease blood concentrations. Such drugs include antibiotics (e.g., *nafcillin, rifampin*); anticonvulsants (e.g., *phenobarbital, phenytoin*); and others (e.g., *octreotide, ticlopidine*).

Interactions between *cyclosporine* and *sirolimus* require that administration of the two drugs be separated by time. *Sirolimus* aggravates *cyclosporine*-induced renal dysfunction, while *cyclosporine* increases *sirolimus*-induced hyperlipidemia and myelosuppression. Additive nephrotoxicity may occur when *cyclosporine* is coadministered with nonsteroidal anti-inflammatory drugs (NSAIDs) and other drugs that cause renal dysfunction; elevation of *methotrexate* levels may occur when the

two drugs are coadministered, as can reduced clearance of other drugs, including *prednisolone*, *digoxin*, and statins (Azzi et al., 2013; Ekberg et al., 2007).

Antiproliferative and Antimetabolic Drugs

Sirolimus

Sirolimus is a macrocyclic lactone produced by *Streptomyces hygroscopicus*.

Mechanism of Action. *Sirolimus* inhibits T-lymphocyte activation and proliferation downstream of the IL-2 and other T-cell growth factor receptors (see Figure 39–2). Like *cyclosporine* and *tacrolimus*, therapeutic action of *sirolimus* requires formation of a complex with an immunophilin, in this case *FKBP-12*. The *sirolimus–FKBP-12 complex* does not affect calcineurin activity; rather, it binds to and inhibits the protein kinase mTOR, which is a key enzyme in cell cycle progression. Inhibition of mTOR blocks cell cycle progression at the $G_1 \rightarrow S$ phase transition.

In animal models, *sirolimus* not only inhibits transplant rejection, GVHD, and a variety of autoimmune diseases but also has effects for several months after discontinuation, suggesting a tolerizing effect (see Tolerance). A newer indication for *sirolimus* is to avoid the use of calcineurin inhibitors, even when patients are stable, to protect kidney function (Schena et al., 2009).

ADME. After oral administration, *sirolimus* is absorbed rapidly and reaches a peak blood concentration within about 1 h after a single dose in healthy subjects and within about 2 h after multiple oral doses in renal transplant patients. Systemic availability is about 15%, and blood concentrations are proportional to dose between 3 and 12 mg/m^2. A high-fat meal decreases peak blood concentration by 34%; *sirolimus* therefore should be taken consistently either with or without food, and blood levels should be monitored closely. About 40% of *sirolimus* in plasma is protein bound, especially to albumin. The drug partitions into formed elements of blood (blood-to-plasma ratio = 38 in renal transplant patients). *Sirolimus* is extensively metabolized by CYP3A4 and is transported by P-glycoprotein. The bulk of total excretion is via the feces. Although some of its metabolites are active, *sirolimus* itself is the major active component in whole blood and contributes more than 90% of the immunosuppressive effect. The blood $t_{1/2}$ after multiple doses in stable renal transplant patients is 62 h. A loading dose of three times the maintenance dose will provide nearly steady-state concentrations within 1 day in most patients.

Therapeutic Uses. *Sirolimus* is indicated for prophylaxis of organ transplant rejection, usually in combination with a reduced dose of calcineurin inhibitor and glucocorticoids. *Sirolimus* has been used with glucocorticoids and *mycophenolate* to avoid permanent renal damage. *Sirolimus* dosing regimens are relatively complex, with blood levels generally targeted between 5 and 15 ng/mL. It is recommended that the daily maintenance dose be reduced by approximately one-third in patients with hepatic impairment. *Sirolimus* also has been incorporated into stents to inhibit local cell proliferation and blood vessel occlusion (Moes et al., 2015).

Toxicity. The use of *sirolimus* in renal transplant patients is associated with a dose-dependent increase in serum cholesterol and triglycerides that may require treatment. Although immunotherapy with *sirolimus per se* is not considered nephrotoxic, patients treated with *cyclosporine* plus *sirolimus* have impaired renal function compared to patients treated with *cyclosporine* alone. *Sirolimus* can worsen proteinuria and should be used with caution in patients with a glomerular filtration rate below 30% or proteinuria; these conditions can worsen renal failure. Renal function and proteinuria therefore must be monitored closely in such patients. Lymphocele, a known surgical complication associated with renal transplantation, is increased in a dose-dependent fashion by *sirolimus*, requiring close postoperative follow-up.

Other adverse effects include anemia, leukopenia, thrombocytopenia, mouth ulcer, hypokalemia, and GI effects. Delayed wound healing may occur with *sirolimus* use. This mTOR inhibitor has been shown to have anticancer effects, especially on skin cancer; it is considered the immunosuppressant of choice in patients with a history of malignancy. *Temsirolimus* is specifically approved for kidney (but not skin) cancer, while *everolimus* is approved for a variety of cancers (but not skin cancer). As with other immunosuppressive agents, there is an increased risk of infections.

Drug Interactions. Because *sirolimus* is a substrate for CYP3A4 and is transported by P-glycoprotein, close attention to interactions with other drugs that are metabolized or transported by these proteins is required (see Chapters 4 and 5). Dose adjustment may be required when *sirolimus* is coadministered with CYP3A4 and P-glycoprotein inhibitors (e.g., *diltiazem*) or strong inducers (e.g., *rifampin*) (Alberú et al., 2011; Euvrard et al., 2012).

Everolimus

Everolimus [40-*O*-(2-hydroxyethyl)-rapamycin] is FDA-approved for treatment of astrocytoma, breast cancer, kidney and liver transplant rejection prophylaxis, pancreatic neuroendocrine tumor, renal angiomyolipoma, and renal cell cancer. It is chemically closely related to sirolimus but has distinct pharmacokinetics. The main difference is a shorter $t_{1/2}$ and thus a shorter time to achieve steady-state concentrations of the drug. Dosage on a milligram per kilogram basis is similar to (but not the same as) that of *sirolimus*. In kidney transplant rejection prophylaxis, the initial dose of *everolimus* is 0.75 mg twice daily, with later adjustment based on serum concentrations. As with *sirolimus*, the combination of a calcineurin inhibitor and an mTOR inhibitor produces worse renal function at 1 year than does calcineurin inhibitor therapy alone, suggesting a drug interaction between the mTOR inhibitors and the calcineurin inhibitors that reduces rejection but enhances toxicity. The toxicity of *everolimus* and the potential for drug interactions seem to be the same as with *sirolimus* (Budde et al., 2011; Moes et al., 2015). Like *sirolimus*, individualization of drug dose through therapeutic drug monitoring is required.

Azathioprine

Azathioprine is a purine antimetabolite. It is an imidazolyl derivative of 6-mercaptopurine, metabolites of which can inhibit purine synthesis.

Mechanism of Action. Following exposure to nucleophiles such as glutathione, *azathioprine* is cleaved to 6-mercaptopurine (6-MP), which in turn is converted to additional metabolites that inhibit *de novo* purine synthesis (see Chapter 70). A fraudulent nucleotide, 6-thio-IMP, is converted to 6-thio-GMP and finally to 6-thio-GTP, which is incorporated into DNA. Cell proliferation thereby is inhibited, impairing a variety of lymphocyte functions. *Azathioprine* appears to be a more potent immunosuppressive agent than 6-MP (Hardinger et al., 2013).

ADME. *Azathioprine* is well absorbed orally and reaches maximum blood levels within 1 to 2 h after administration. The $t_{1/2}$ of *azathioprine* is about 10 min, and the $t_{1/2}$ of 6-MP is about 1 h. Other metabolites have a $t_{1/2}$ of up to 5 h. Blood levels have limited predictive value because of extensive metabolism, significant activity of many different metabolites, and high tissue levels attained. *Azathioprine* and *mercaptopurine* are moderately bound to plasma proteins and are partially dialyzable. Both are rapidly removed from the blood by oxidation or methylation in the liver or erythrocytes. Renal clearance has little impact on the biological effectiveness or toxicity.

Therapeutic Uses. *Azathioprine* is indicated as an adjunct for prevention of organ transplant rejection and in severe rheumatoid arthritis. The usual starting dose of *azathioprine* is 3 to 5 mg/kg per day. Lower initial doses (1 mg/kg per day) are used in treating rheumatoid arthritis. Complete blood count and liver function tests should be monitored.

Toxicity. The major side effect of *azathioprine* is bone marrow suppression, including leukopenia (common), thrombocytopenia (less common), or anemia (uncommon). Other important adverse effects include increased susceptibility to infections (especially varicella and herpes simplex viruses), hepatotoxicity, alopecia, GI toxicity, pancreatitis, and increased risk of neoplasia.

Drug Interactions. Xanthine oxidase, an enzyme of major importance in the catabolism of *azathioprine* metabolites, is blocked by *allopurinol*. Hence, the combination of *azathioprine* with *allopurinol* should be avoided.

Adverse effects resulting from coadministration of *azathioprine* with other myelosuppressive agents or angiotensin-converting enzyme inhibitors include leukopenia, thrombocytopenia, and anemia as a result of myelosuppression.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is the 2-morpholinoethyl ester of mycophenolic acid (MPA).

Mechanism of Action. *Mycophenolate mofetil* is a prodrug that is rapidly hydrolyzed to the active drug MPA, a selective, noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase, an enzyme in the *de novo* pathway of guanine nucleotide synthesis. B and T lymphocytes are highly dependent on this pathway for cell proliferation; MPA thus selectively inhibits lymphocyte proliferation and functions, including antibody formation, cellular adhesion, and migration.

ADME. *Mycophenolate mofetil* undergoes rapid and complete metabolism to MPA after oral or intravenous administration. MPA is then metabolized to the inactive MPA glucuronide (MPAG). The parent drug is cleared from the blood within a few minutes. The $t_{1/2}$ of MPA is approximately 16 h. Most (87%) is excreted in the urine as MPAG. Plasma concentrations of MPA and MPAG are increased in patients with renal insufficiency.

Therapeutic Uses. *Mycophenolate mofetil* is indicated for prophylaxis of transplant rejection, and it typically is used in combination with glucocorticoids and a calcineurin inhibitor but not with *azathioprine*. Combined treatment with *sirolimus* is possible, although potential drug interactions necessitate careful monitoring of drug levels. The approved dose for liver transplantation rejection prophylaxis is 1 g twice daily. For renal transplants, 1 g is administered orally or intravenously (over 2 h) twice daily (2 g/day). A higher dose, 1.5 g twice daily (3 g/day), may be recommended for African American renal transplant patients and all liver and cardiac transplant patients. MMF is increasingly used off-label in systemic lupus. MMF has been used to treat a number of different inflammatory disorders, including MS and sarcoidosis. A delayed-release formulation of MPA is available; it does not release MPA under acidic conditions (pH <5), as in the stomach, but is soluble in neutral pH, as in the intestine. The enteric coating results in a delay in the time to reach maximum MPA concentrations (Darji et al., 2008).

Toxicity. The principal toxicities of MMF are GI and hematological: leukopenia, pure red cell aplasia, diarrhea, and vomiting. The MPA formulation has been introduced to reduce the frequent GI upset and has had variable results. There also is an increased incidence of some infections, especially sepsis associated with cytomegalovirus. *Tacrolimus* in combination with MMF has been associated with activation of polyoma viruses such as BK virus, which can cause interstitial nephritis. The use of MMF in pregnancy is associated with congenital anomalies and increased risk of pregnancy loss.

Drug Interactions. *Tacrolimus* delays elimination of MMF by impairing the conversion of MPA to MPAG. This may enhance GI toxicity. Coadministration with antacids containing aluminum or magnesium hydroxide leads to decreased absorption of MMF; thus, these drugs should not be administered simultaneously. MMF should not be administered with *cholestyramine* or other drugs that affect enterohepatic circulation. Such agents decrease plasma MPA concentrations, probably by binding free MPA in the intestines. *Acyclovir* and *ganciclovir* may compete with MPAG for tubular secretion, possibly resulting in increased concentrations of both MPAG and the antiviral agents in the blood, an effect that may be compounded in patients with renal insufficiency. MMF serum level monitoring is not performed routinely (Darji et al., 2008; Goldfarb-Rumyantzev et al., 2006).

Sphingosine-1-Phosphate Receptor Modulators

Sphingosine-1-phosphate (S1P) is a sphingolipid metabolite that affects inflammation and immunity, among numerous other biological functions (McGinley and Cohen, 2021; Spiegel and Milstien, 2011). The relevance of S1P to immunity derives from its role in promoting the egress of lymphocytes from lymphoid tissues.

Sphingosine-1-phosphate is produced enzymatically by phosphorylation of sphingosine derived from ceramide (Figure 39–3A). S1P acts intracellularly and, once exported from the cell, also extracellularly, where it interacts with transmembrane receptors on the cell surface. The five cell surface receptors for S1P (S1PR) are G protein-coupled receptors, $S1P_1R$ through $S1P_5R$, which couple to effectors via the G_i/G_o family (see Chapter 3). These receptors are differentially expressed in different tissues: $S1P_5Rs$ are found in the CNS; $S1P_4Rs$ seem largely confined to the immune system; $S1P_2R$ and $S1P_3R$ are widely expressed; endothelial cells and B and T lymphocytes express predominantly $S1P_1R$.

Sphingosine-1-phosphate receptor modulators are being explored as pharmacotherapy for a wide variety of conditions, including CNS degenerative diseases, chemotherapy-induced neuropathy, stroke, lupus erythematosus, psoriasis, and inflammatory bowel disease (McGinley and Cohen, 2021). The pharmacological profiles for these drugs are presented below.

Available S1P Modulators

There are currently four approved modulators of S1PRs: *fingolimod*, *siponimod*, *ozanimod*, and *ponesimod*.

Mechanism of Action and Specificities

Although the approved S1PR inhibitors differ slightly in their specificity for S1PRs, these compounds cause irreversible downregulation, internalization, and degradation of $S1P_1R$; thus, these compounds all function as irreversible agonists at $S1P_1R$. B cells and CCR7-positive T cells normally respond to a gradient of S1P and exit the lymphoid tissue. However, inhibition or blockade of the $S1P_1R$ reduces lymphocyte egress, causing sequestration of host lymphocytes in lymph nodes and Peyer patches and thus away from the circulation, thereby protecting lesions and grafts from T-cell–mediated attack and reducing allergic inflammation.

All but *fingolimod* act directly. *Fingolimod* is a prodrug. It is phosphorylated by sphingosine kinase 2 (SK2); *fingolimod phosphate* is the active form (Figure 39-3B). *Fingolimod* has broad receptor affinity, interacting with all subtypes of S1PRs except $S1P_2R$. *Siponimod* and *ozanimod* have high affinity for $S1P_1R$ and $S1P_5R$. *Ponesimod* shows the greatest specificity, interacting with high affinity only at $S1P_1R$.

ADME

Administration. These agents are effective orally with good bioavailability; see individual package inserts for required predose testing and specific regimens for initiating dosing to reduce risk of bradycardia and atrioventricular conduction delays. When switching from immunosuppressant agents with prolonged half-lives of effect, such as *natalizumab*, *teriflunomide*, or *mitoxantrone*, account for the duration and mode of action of these drugs to avoid additive immunosuppressive effects when initiating an inhibitor of S1P action. Due to the adverse effect profile of these agents, a number of precautions must be taken in advance of initiating therapy. Do not administer S1PR modulators to patients with active infections. Before initiating treatment, follow recommendations on the FDA-approved package insert with respect to complete blood count, infections, immunizations (especially against varicella-zoster virus [VZV]) and the timing of vaccinations, monitoring electrocardiogram and blood pressure, determining whether patient has conduction abnormalities or is taking any drugs that slow heart rate, and assessing serum transaminase and bilirubin levels and condition of the optic fundus.

Metabolism and Excretion, Drug Interactions, and Contraindications. *Fingolimod* is cleared by phosphorylation to its active form ($t_{1/2}$ 6–9 h) and by the action of CYP4F2, which *ketoconazole* can inhibit. Severe hepatic disease increases exposure.

Ozanimod metabolism produces a series of active metabolites with similar specificity for $S1P_1R$ and $S1P_5R$; thus, although the plasma $t_{1/2}$ of the parent drug is approximately 21 h, the $t_{1/2}$ of the effect is approximately 11 days. An active metabolite of *ozanimod* inhibits monoamine oxidase (MAO)-B, providing the potential of serious hypertensive interactions

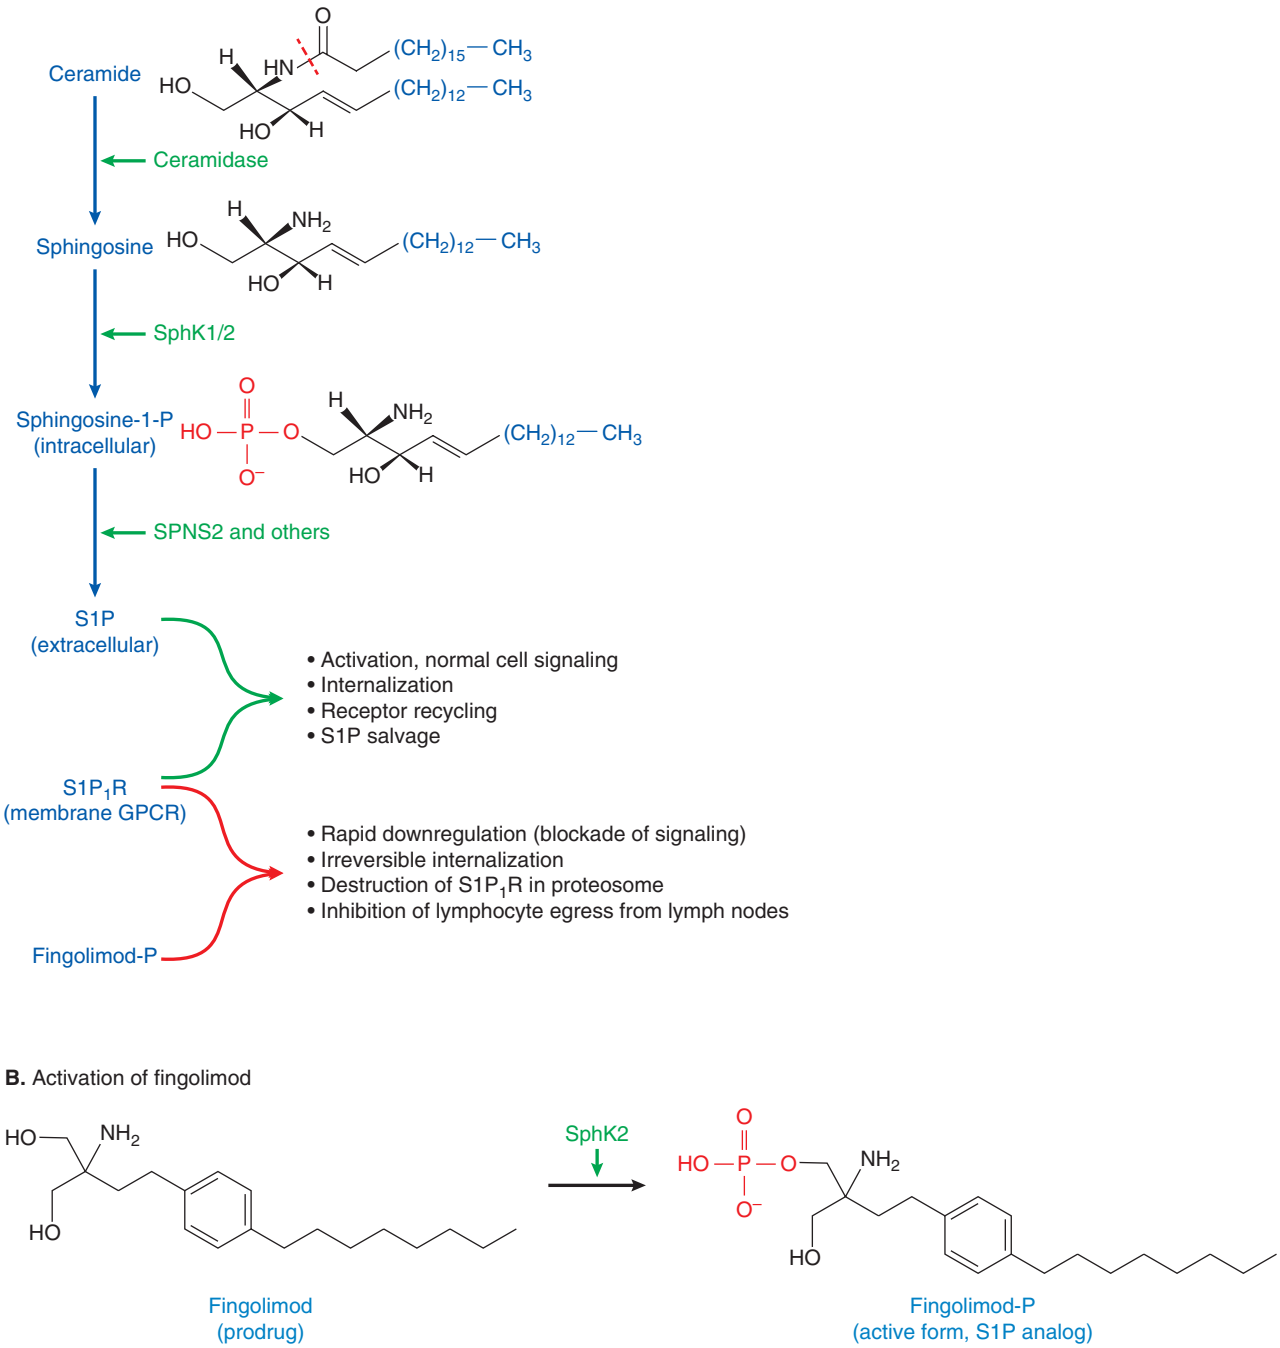

Figure 39–3 **A.** *Sphingosine-1-phosphate formation and action at S1P$_1$R.* **B.** *The prodrug fingolimod and its active metabolite.* GPCR, G protein-coupled receptor; SphK, sphingosine kinase; SPNS2, S1P transporter.

between *ozanimod* and agents that increase sympathetic tone, norepinephrine, or serotonin (opioids, selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, tricyclic antidepressants, MAO inhibitors, tyramine, and foods containing tyramine). *Siponimod* is metabolized by CYP2C9, which is highly polymorphic, and subsequently by CYP3A4. Concomitant use of moderate to strong inducers (e.g., *rifampin*, *carbamazepine*) or inhibitors (e.g., *fluconazole*) of these CYPs is not recommended. CYP2C9*3/*3 and CYP2C9*2/*2 polymorphs show decreased clearance and increased exposure; use of *siponimod* is contraindicated in patients with the homozygous CYP2C9*3/*3 genotype. Excretion is mainly via the biliary/fecal route. *Ponesimod* is metabolized by CYP3A4 and UGT1A1, with a $t_{1/2}$ of approximately 26 h. Coadministration with strong inducers of these enzymes (e.g., *rifampin*, *phenytoin*, *carbamazepine*) is not recommended. Conversely, *ponesimod* is not recommended for patients with moderate or severe hepatic impairment (Child-Pugh class B or C). Excretion is predominantly via the feces.

Adverse Effects

The shared common adverse effects include increased risk of infections (upper respiratory, urinary tract infection), bradyarrhythmias and impaired atrioventricular conduction, hypertension (monitor blood pressure), hepatic transaminase elevation (monitor), altered vision (macular edema), and dyspnea. An increased risk of cutaneous malignancies and breast cancer has been reported, as has posterior reversible encephalopathy syndrome. Lymphopenia and heart rate reduction reverse upon discontinuation of the drug. To avoid fetal harm, women of childbearing age should use effective contraception during treatment and from

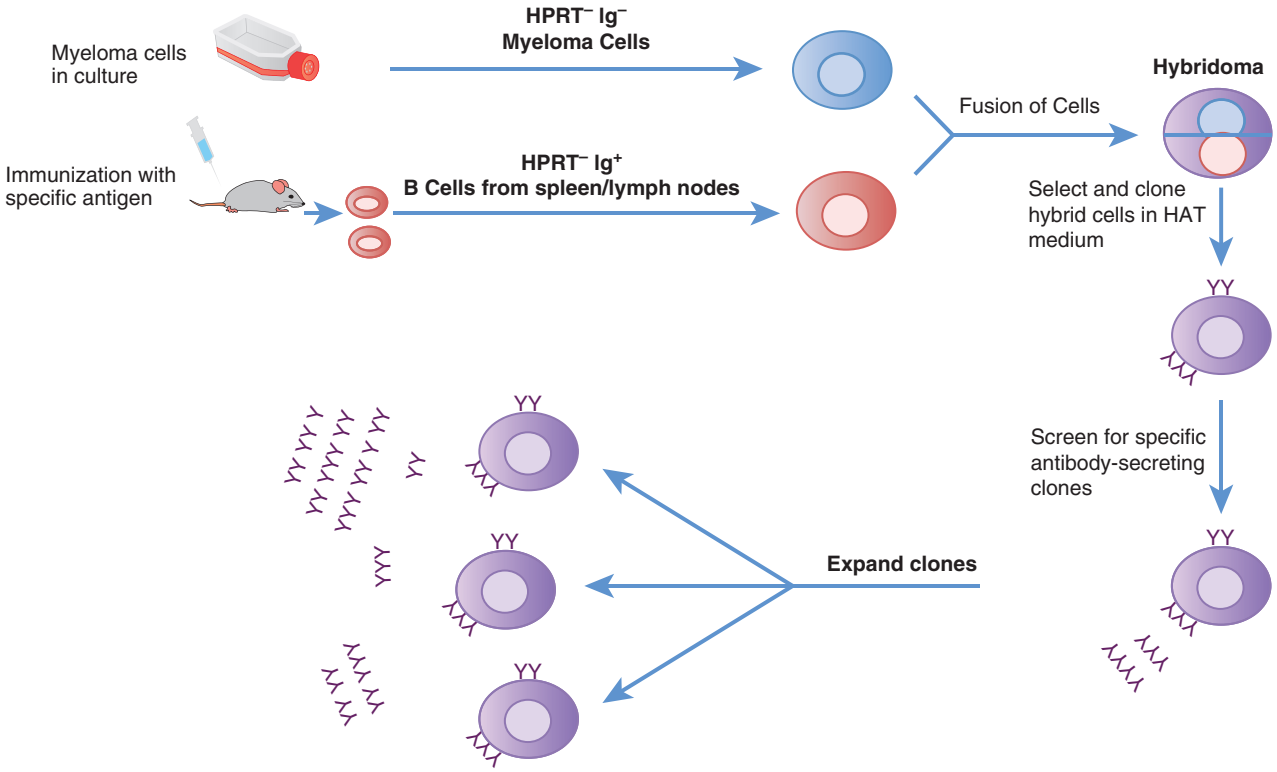

Figure 39–4 *Generation of mAbs.* Mice are immunized with the selected antigen, and the spleen or lymph node is harvested and B cells separated. These B cells are fused to a suitable B-cell myeloma selected for its ability to grow in medium supplemented with HAT (hypoxanthine, aminopterin, and thymidine). Only myeloma cells that fuse with B cells can survive in HAT-supplemented medium. The hybridomas expand in culture. Hybridomas of interest are selected based on a specific screening technique and then cloned by limiting dilution. The mAbs can be used directly as supernatants or ascites fluid for experimental use but are purified for clinical use.

2 weeks to 3 months thereafter (depending on half-life of active drug; see requirements of the individual agents).

Therapeutic Uses

Ozanimod is approved for ulcerative colitis (see Chapter 55). All four agents are approved for treatment of relapsing-remitting MS. That use is discussed further in the final section of this chapter, Immunotherapy for Multiple Sclerosis.

Other Antiproliferative and Cytotoxic Agents

Many of the cytotoxic and antimetabolic agents used in cancer chemotherapy (see Chapter 70) are immunosuppressive due to their action on lymphocytes and other cells of the immune system. Other cytotoxic drugs that have been used both on- and off-label as immunosuppressive agents include *methotrexate*, *cyclophosphamide*, *thalidomide*, and *chlorambucil*. *Methotrexate* is used for prophylaxis against GVHD and treatment of rheumatoid arthritis, psoriasis, bullous pemphigoid, and some cancers. *Cyclophosphamide* and *chlorambucil* are used in leukemia and lymphomas and a variety of other malignancies. *Cyclophosphamide* also is FDA-approved for childhood nephrotic syndrome and is used widely off-label for treatment of severe systemic lupus erythematosus, MS, and vasculitides such as granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis). *Leflunomide* is a pyrimidine synthesis inhibitor indicated for the treatment of adults with rheumatoid arthritis. This drug has found increasing empirical use in the treatment of polyomavirus nephropathy seen in immunosuppressed renal transplant recipients. There are no controlled studies showing efficacy compared with control patients treated with only withdrawal or reduction of immunosuppression alone in BK virus nephropathy. The drug inhibits dihydroorotate dehydrogenase in the *de novo* pathway of pyrimidine synthesis. It is hepatotoxic and can cause fetal injury when administered to pregnant women.

Immunosuppression Antibodies and Fusion Receptor Protein

Polyclonal and monoclonal antibodies against lymphocyte cell surface antigens are widely used for prevention and treatment of organ transplant rejection. Polyclonal antisera are generated by repeated injections of human thymocytes (for ATG) or lymphocytes (for ALG) into animals and then purifying the serum immunoglobulin fraction. These preparations vary in efficacy and toxicity from batch to batch.

The capacity to produce mAbs (Figure 39–4) has overcome the problems of variability in efficacy and toxicity seen with the polyclonal products, but mAbs are more limited in their target specificity. The first-generation murine mAbs have been replaced by newer humanized or fully human mAbs that lack antigenicity, have a prolonged $t_{1/2}$, and can be mutagenized to alter their affinity to Fc receptors.

Another class of biological agents developed for both autoimmunity and transplantation are fusion receptor proteins. These agents consist of the ligand-binding domains of receptors bound to the Fc region of an immunoglobulin (usually immunoglobulin [Ig] G1) to provide a longer $t_{1/2}$ (Baldo, 2015). Examples include *abatacept* (a first-generation cytotoxic T-lymphocyte–associated antigen 4 [CTLA-4]-Ig) and *belatacept* (a second-generation CTLA-4-Ig); these agents comprise the Fc region of IgG1 fused to the extracellular domain of CTLA-4. For more information, see the section on Costimulatory Blockade.

Antithymocyte Globulin

Antithymocyte globulin is a purified gamma globulin from the serum of rabbits immunized with human thymocytes (Thiyagarajan et al., 2013). It is provided as a sterile, freeze-dried product for intravenous administration after reconstitution with sterile water. ATG is one of many immune globulin preparations used therapeutically, generally for passive immunization (see Table 39–2 and Chapter 40).

TABLE 39–2 ■ SELECTED IMMUNE GLOBULIN PREPARATIONS

GENERIC NAME	COMMON SYNONYMS	ORIGIN
Antithymocyte globulin	ATG	Rabbit
Botulism immune globulin intravenous	BIG-IV	Human
Cytomegalovirus immune globulin intravenous	CMV-IGIV	Human
Hepatitis B immune globulin	HBIG	Human
Immune globulin intramuscular	Gamma globulin, IgG, IGIM	Human
Immune globulin intravenous	IVIG	Human
Immune globulin subcutaneous	IGSC	Human
Lymphocyte immune globulin	ALG, antithymocyte globulin (equine), ATG (equine)	Equine
Rabies immune globulin	RIG	Human
Rho(D) immune globulin intramuscular	Rho[D] IGIM	Human
Rho(D) immune globulin intravenous	Rho[D] IGIV	Human
Rho(D) immune globulin microdose	Rho[D] IG microdose	Human
Tetanus immune globulin	TIG	Human
Vaccinia immune globulin intravenous	VIGIV	Human

Mechanism of Action. Antithymocyte globulin contains cytotoxic antibodies that bind to CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA class I and II molecules on the surface of human T lymphocytes. The antibodies deplete circulating lymphocytes by direct cytotoxicity (both complement and cell mediated) and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function.

Therapeutic Uses. Antithymocyte globulin is used for induction immunosuppression, although the approved indications are for the treatment and prophylaxis of acute renal transplant rejection in combination with other immunosuppressive agents and for the treatment of aplastic anemia. Antilymphocyte-depleting agents (Thymoglobulin, Atgam) are not registered for use as induction immunosuppression. A course of ATG often is given to renal transplant patients with delayed graft function to avoid early treatment with the nephrotoxic calcineurin inhibitors, thereby aiding in recovery from ischemic reperfusion injury. The recommended dose of Thymoglobulin for acute rejection of renal grafts is 1.5 mg/kg per day (over 4–6 h) for 7 to 14 days. Mean T-cell counts fall by day 2 of therapy. The recommended dose of Atgam for acute rejection of renal grafts is 10 to 15 mg/kg per day for 14 days. ATG also is used for acute rejection of other types of organ transplants and for prophylaxis of rejection.

Toxicity. Polyclonal antibodies are xenogeneic proteins that can elicit major side effects, including fever and chills with the potential for hypotension. Premedication with corticosteroids, *acetaminophen*, or an antihistamine and administration of the antiserum by slow infusion (over 4–6 h) into a large-diameter vessel minimize such reactions. Serum sickness and glomerulonephritis can occur; anaphylaxis is rare. Hematological complications include leukopenia and thrombocytopenia. As with other immunosuppressive agents, there is an increased risk of infection and malignancy, especially when multiple immunosuppressive agents are combined. No drug interactions have been described; anti-ATG antibodies develop but do not limit repeated use.

Immunomodulation

Immunosuppression refers to the overall reduction in the magnitude of the immune response. Here we define as immunomodulators those therapeutic approaches that are targeted to a specific molecular driver of the immune response (e.g., cytokines).

Immunotherapy and the Nature of Costimulation and Inhibition

Multiple costimulatory and inhibitory molecules interact to regulate T-cell responses. Immune activation requires two signals that emanate from the interaction of membrane proteins on APCs and T cells (Figures 39–5A and 39–5B). A growing number of antibodies directed at these interacting proteins permits interruption of immune activation to produce a state of immune suppression. Figures 39–2 and 39–5 point out some of these antibodies, which are especially useful in preventing rejection after organ transplantation, as summarized in the material that follows.

In what might be considered an antiparallel system to activation, inhibitory regulation of T-cell activity can also result from the interaction of paired membrane ligands of APCs and T cells (Figure 39–5C). These points of negative regulation are called *immune checkpoints*. By targeting and blocking these immune checkpoints, antibodies can permit T-cell activation to proceed, unfettered by downregulation (Figures 39–5C and 39–5D). Activating immune attacks of tumor cells by blockade of immune checkpoints is producing new therapeutic options for cancer therapy (Callahan et al., 2016; Topalian et al., 2015). Chapter 72 presents the use of immunotherapy in cancer treatment.

Anti-CD3 Monoclonal Antibodies

CD3 is a component of the TCR complex on the surface of human T lymphocytes (see Figure 39–2). Antibodies directed at the ε chain of CD3 have been used with considerable efficacy in human transplantation. The anti-CD3 antibody is monoclonal and targets the CD3 chain of the TCR, inducing its endocytosis and T-cell inactivation and removal through phagocytosis. The original mouse IgG2a antihuman CD3 mAb, *muromonab-CD3* (OKT3), is no longer marketed due to its side effects: It frequently caused cytokine release syndrome and severe pulmonary edema.

Genetically altered anti-CD3 mAbs have been developed that are "humanized" to minimize the occurrence of antiantibody responses and mutated to prevent binding to Fc receptors. In initial clinical trials, a humanized anti-CD3 mAb that does not bind to Fc receptors reversed acute renal allograft rejection without causing the first-dose cytokine release syndrome. Humanized anti-CD3 mAbs are also in clinical trials in patients with type 1 autoimmune diabetes (Mignogna et al., 2021). Interestingly, a prevention trial in nondiabetic patients at high risk for type 1 diabetes resulted in a significant extension on the median diagnosis in patients treated with *teplizumab* (an Fc receptor nonbinding anti-CD3 mAb) in comparison to placebo (Sims et al., 2021).

Anti-CD52 Monoclonal Antibody (Alemtuzumab)

Alemtuzumab is a depleting humanized anti-CD52 mAb.

Mechanism of Action. *Alemtuzumab* binds the CD52 protein that is wildly expressed on B cells and T cells, as well as macrophages, NK cells, and some granulocytes. *Alemtuzumab* binding to CD52 induces an antibody-dependent lysis of cells and a profound leukopenia that may last for more than a year (Jones and Coles, 2014).

Therapeutic Uses. *Alemtuzumab* is used mainly for induction of immunosuppressive therapy and allows the avoidance of the early high dose of steroids. For transplants, the most common regimen is a single intraoperative dose of 30 mg. *Alemtuzumab* is also used for the treatment of refractory acute cellular- and antibody-mediated rejections with the same

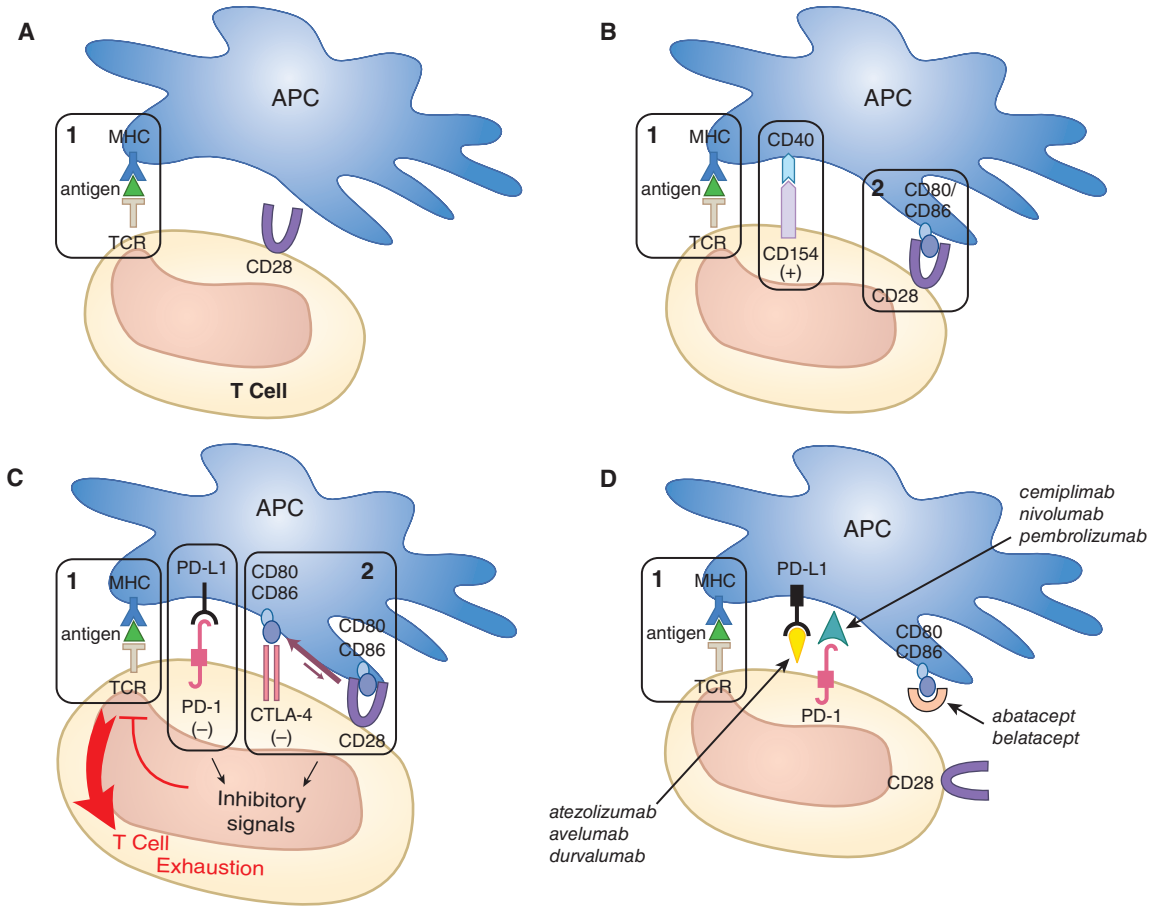

Figure 39–5 *T-cell activation: costimulation and coinhibitory checkpoints.* Numerous membrane CD proteins may be expressed on the APC and the T cell that lead to signaling interactions between ligands and receptors. These interactions can enhance or reduce the activation state of the T cell. Two signals are required for T-cell activation: presentation of an antigen ligand to the TCR and signaling by an additional "costimulatory" pair. **A.** The primary signal, *signal 1*, is the interaction of the TCR with the MHC-antigen complex on the APC. Activation requires a second, costimulatory interaction. **B**. *Signal 2*, the costimulatory interaction between CD28 on the T cell (the costimulatory receptor) and the costimulatory ligand on the APC, CD80/CD86, leads to T-cell activation. Additional costimulatory signals, such as the interaction of CD154 with CD40 on the APC, can further enhance T-cell activation (+). In the absence of costimulation, a T cell can become anergic or unresponsive. **C.** Additional APC–T-cell interactions can occur after T-cell activation, and some can be inhibitory, providing *immune checkpoints* that are important for reducing autoimmunity and for regulating the size and extent of immune responses. For example, the interaction of CTLA-4 (CD152) with CD80/86 produces inhibitory signals that attenuate T-cell activation and proliferation (–). CD28 and CTLA-4 compete for binding to CD80/CD86. As the figure suggests, the affinity of CTLA-4 for CD80/CD86 exceeds that of CD28, and the equilibrium lies toward the formation of the inhibitory signaling complex, CTLA-4-CD80/CD86. T cells may express varying amounts of another important modifier, PD-1 (programmed cell death protein 1, also called CD279). When liganded by PD-L1 (programmed death ligand 1), PD-1 produces inhibitory signals (↑ protein phosphatase activity, ↓ signaling by TCR, ↓ MAPK activity; see Figure 39–2) and reduces T-cell proliferation, leading to T-cell exhaustion, a state of hyporesponsiveness. When PD-1 is highly expressed, as during conditions of chronic viral infection and cancer, suppression of T-cell activity via this pathway can be very effective; this pathway can facilitate continued viral replication and tumor progression. **D.** These immune checkpoints are useful sites for pharmacological regulation of T-cell activation. For instance, the agents *abatacept* and *belatacept* are fusion proteins that contain the extracellular CTLA-4 domain and act as decoys. These agents block costimulation of T cells by binding CD80/CD86 (see additional examples in Figure 39–2). *Nivolumab, pembrolizumab*, and *cemiplimab* (antibodies to PD-1) and *atezolizumab, avelumab,* and *durvalumab* (antibodies to PD-L1) block interaction of PD-1 with PD-L1, thereby blocking the immune suppression that would normally ensue and producing a state of immune hyperactivity. Checkpoint inhibitors that enhance immune responses are being used in cancer therapy (see Chapter 72). Antibodies can also be designed to aid in generating a state of immune suppression that would be useful in treating autoimmune diseases. APC, antigen-presenting cell; CD, cluster of differentiation.

dose used during induction. The drug is licensed for the management of CLL and MS (CAMMS223 Investigators et al., 2008).

Toxicity. Neutropenia remains the most common adverse effect seen with *alemtuzumab.* Almost half of the patients will also experience thrombocytopenia and anemia. Another major side effect is autoimmune hemolytic anemia and other autoimmune diseases thought to be due to immune reconstitution after the profound lymphocyte depletion.

Anti–IL-2 Receptor (Anti-CD25) Antibodies

Daclizumab is a humanized murine complementarity-determining region/human IgG1 chimeric mAb. *Basiliximab* is a murine-human chimeric mAb. Both are licensed for use in conjunction with *cyclosporine* and corticosteroids for the prophylaxis of acute organ rejection in patients receiving renal transplants.

Mechanism of Action. The anti-CD25 mAbs bind with high affinity to the α subunit of the IL-2 receptor (see Figure 39–2) and act as receptor antagonists, inhibiting T-cell activation and proliferation without inducing cell lysis (see Table 39–1). *Daclizumab* has a somewhat lower affinity but a longer $t_{1/2}$ (20 days) than *basiliximab* (Brennan et al., 2006). In addition, the induction of $CD56^+$ $CD4^+$ T cells is associated with response to therapy in patients with MS (D'Amico et al., 2015).

Therapeutic Uses. Anti-CD25 mAbs are used for induction therapy in solid-organ transplantation. They are also in phase III clinical trials in patients with MS. The long $t_{1/2}$ of *daclizumab* (20 days) results in saturation of the IL-2Rα on circulating lymphocytes for up to 120 days after transplantation. *Daclizumab* is administered in five doses (1 mg/kg given intravenously over 15 min in 50–100 mL of normal saline) starting immediately preoperatively and subsequently at biweekly intervals.

The $t_{1/2}$ of *basiliximab* is 7 days. In trials, *basiliximab* was administered in a fixed dose of 20 mg preoperatively and on days 0 and 4 after transplantation. This regimen of *basiliximab*-saturated IL-2R acts on circulating lymphocytes for 25 to 35 days after transplantation. *Basiliximab* was used with a maintenance regimen consisting of *cyclosporine* and *prednisone* and was found to be safe and effective when used in a maintenance regimen consisting of *cyclosporine*, MMF, and *prednisone*.

While *daclizumab* and *basiliximab* are comparable in effectiveness, *daclizumab* has a more costly dosing regimen. The higher cost has reduced demand, and *daclizumab* is now produced only for use in treating MS.

Toxicity. *Basiliximab* and *daclizumab* seem to be relatively safe as induction agents, with most of the clinical trials reporting adverse reactions rates comparable to placebo. No cytokine release syndrome has been noted, but anaphylactic reactions, rare lymphoproliferative disorders, and opportunistic infections may occur. No drug interactions have been described.

Belatacept, a Fusion Protein

Belatacept is a fusion protein composed of a modified Fc fragment of a human immunoglobulin linked to the extracellular domain of the CTLA-4 (CD152) that is present on T cells (Figure 39–6). This second-generation CTLA-4-Ig has two amino acid substitutions, increasing its affinity for CD80 (2-fold) and CD86 (4-fold), yielding a 10-fold increase in potency *in vitro* compared to CTLA-4-Ig (Chinen et al., 2015).

Mechanism of Action. Induction of specific immune responses by T lymphocytes requires two signals: an antigen-specific signal via the TCR and a costimulatory signal provided by the interaction of molecules such as CD28 on CD4 lymphocyte with CD80 and CD86 on APCs and CD2 engagement by lymphocyte function–associated antigen-3 (LFA-3, also known as CD58) on CD8 cells (see Figure 39–5) (Riella and Sayegh, 2013). *Belatacept* is a selective T-cell costimulation blocker that potently binds the cell surface costimulatory ligands (CD80 and CD86) present on APCs, interrupting their interaction with CD28 on T cells (signal 2). The inhibition of signal 2 inhibits T-cell activation, promoting anergy and apoptosis.

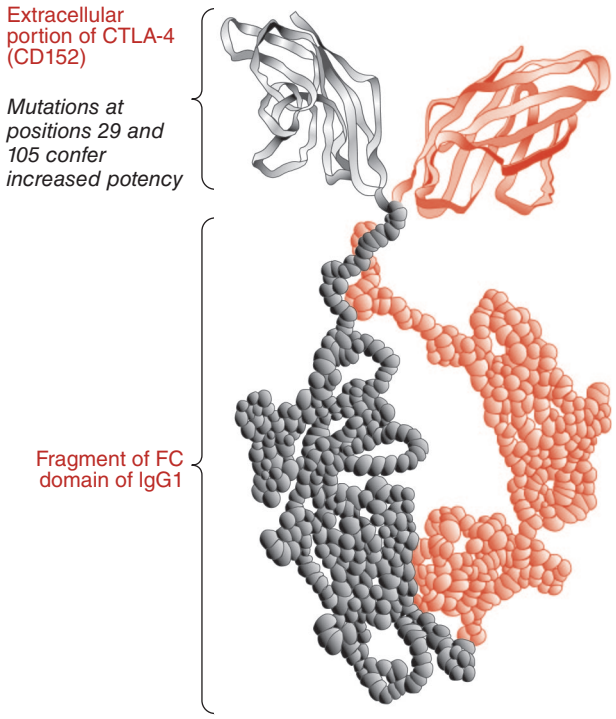

Figure 39–6 *Structure of belatacept, a CLTA-4-Ig congener.* For details, see the ext and Fi ure 39–4.

Disposition and Pharmacokinetics. *Belatacept* is the first intravenous maintenance therapy in solid-organ transplantation. *Belatacept*'s pharmacokinetics were determined to be linear, with zero-order intravenous infusion and first-order elimination within the standard dose range of 5 to 10 mg/kg. The $t_{1/2}$ of *belatacept* is about 11 days.

Therapeutic Uses. Preclinical renal transplant studies showed that *belatacept* did not induce tolerance but did prolong graft survival. *Belatacept* is FDA-approved as an alternative to calcineurin inhibitors as a strategy to prevent long-term calcineurin inhibitor toxicity (Satyananda and Shapiro, 2014; Talawila and Pengel, 2015). *Belatacept* has been approved specifically for prophylaxis of organ rejection in adult patients receiving a kidney transplant in combination with *basiliximab* induction, MMF, and corticosteroids.

The BENEFIT trial compared two *belatacept*-based regimens to *cyclosporine* and showed better kidney function and metabolic profile with *belatacept*-treated patients compared to *cyclosporine*. Patients were induced with *basiliximab* and maintained on MMF and a *prednisone* taper. While infusions of *belatacept* are required relatively frequently early after transplantation, it becomes once per month by the end of the first or third month, depending on the dosage regimen chosen (Masson et al., 2014).

Toxicity. An increased risk of posttransplant lymphoproliferative disorder in Epstein-Barr virus–seronegative patients has been observed with *belatacept* treatment. Hence, its use is restricted to Epstein-Barr virus–seropositive patients. Infusion-related reactions occur infrequently, and the drug is generally well tolerated (Masson et al., 2014).

Drug Interactions. No specific pharmacokinetic drug-drug interactions have been reported with *belatacept* (Pestana et al., 2012).

Interleukin Antagonists

Antibodies to the IL-2 Receptor (CD25)

Anti–IL-2R mAbs discussed previously have been FDA-approved as a second-line drugs for patients with MS.

Anti-CD52

Mature lymphocytes express CD52 (CAMPATH-1 antigen), a negatively charged membrane dodecapeptide. *Alemtuzumab,* discussed previously, is a humanized mAb that binds to CD52 and targets the lymphocyte for destruction. In addition to the uses mentioned, *alemtuzumab* is approved for use in CLL and MS.

Anti-TNF Reagents

Tumor necrosis factor α is a proinflammatory cytokine that has been implicated in the pathogenesis of several immune-mediated intestinal, skin, and joint diseases. Several diseases (rheumatoid arthritis, Crohn's disease) are associated with elevated levels of TNFα. As a result, a number of anti-TNF agents have been developed as treatments.

Infliximab is a chimeric IgG1 mAb containing a human constant (Fc) region and a murine variable region. It binds with high affinity to TNFα and prevents the cytokine from binding to its receptors. *Infliximab* is approved in the U.S. for treating the symptoms of rheumatoid arthritis and is typically used in combination with *methotrexate* in patients who do not respond to *methotrexate* alone. *Infliximab* also is approved for treatment of moderate-to-severe Crohn's disease in patients who have failed to respond to conventional therapy (see Chapter 55). Other FDA-approved indications include ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis. About one in six patients receiving *infliximab* experiences an infusion reaction characterized by fever, urticaria, hypotension, and ıyspnea witnin 1 to 2 h after antibody admiı istr .tion.

The development of antinuclear antibodies and, rarely, a lupus-like syndrome have been reported after treatment with *infliximab* (Meroni et al., 2015).

Etanercept is a fusion protein that targets TNFα. *Etanercept*, with the ligand-binding portion of a human TNFα receptor fused to the Fc portion of human IgG1, binds to TNFα and prevents it from interacting with its receptors. It is approved for treatment of the symptoms of rheumatoid arthritis, ankylosing spondylitis, plaque psoriasis, polyarticular juvenile idiopathic arthritis, and psoriatic arthritis. *Etanercept* can be used in combination with *methotrexate* in patients who have not responded adequately to *methotrexate* alone. Injection-site reactions (i.e., erythema, itching, pain, or swelling) have occurred in more than one-third of *etanercept*-treated patients.

Adalimumab is another anti-TNF product for subcutaneous use. This recombinant human IgG1 mAb is approved for use in rheumatoid arthritis, ankylosing spondylitis, Crohn's disease, juvenile idiopathic arthritis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis.

Golimumab is a human IgG1 (anti-TNFα) monoclonal antibody. *Golimumab* alone or in combination with *methotrexate* is approved for treatment of moderately to severely active rheumatoid arthritis and active psoriatic arthritis. It is also approved for treatment of patients with ankylosing spondylitis and moderately to severely active ulcerative colitis. *Golimumab* is administered by subcutaneous injections and is available in 50- and 100-mg doses.

Certolizumab pegol is a humanized pegylated antibody specific to TNFα. Pegylation of the Fab' fragment provides sustained activity. This agent is approved for the treatment of adults with Crohn's disease and rheumatoid arthritis, active psoriatic arthritis, and active ankylosing spondylitis. It is available as 200-mg lyophilized powder or 200-mg/mL prefilled sterile injections for subcutaneous administration.

Toxicity. All anti-TNF agents (i.e., *infliximab, etanercept, adalimumab, golimumab, certolizumab*) carry an FDA black-box warning concerning increase in the risk of serious infections, lymphomas, and other malignancies. For example, fatal hepatosplenic T-cell lymphomas have been reported in adolescent and young adult patients with Crohn's disease treated with *infliximab* in conjunction with *azathioprine* or *6-MP*.

IL-1 Inhibition

Plasma IL-1 levels are increased in patients with active inflammation (see Chapter 38). In addition to the naturally occurring IL-1 receptor antagonist (IL-1RA), several IL-1RAs are in development, and a few have been approved for clinical use.

Anakinra is an FDA-approved recombinant, nonglycosylated form of human IL-1RA for the management of joint disease in rheumatoid arthritis. *Anakinra* is also approved for cryopyrin-associated periodic syndromes (CAPS), a group of rare inherited inflammatory diseases associated with overproduction of IL-1 that includes familial cold autoinflammatory and Muckle-Wells syndromes, and for treatment of neonatal-onset multisystem inflammatory disease. It can be used alone or in combination with anti-TNF agents such as *etanercept*, *infliximab*, or *adalimumab*.

Canakinumab is an IL-1β mAb that is FDA-approved for CAPS and active systemic juvenile idiopathic arthritis. *Canakinumab* is being evaluated for use in chronic obstructive pulmonary disease.

Rilonacept, a fusion protein that binds IL-1, is being evaluated for gout. IL-1 is an inflammatory mediator of joint pain associated with elevated uric acid crystals.

Other Interleukin Antagonists

Tocilizumab, an IL-6 receptor antagonist, is FDA-approved for treatment of rheumatoid arthritis and systemic juvenile idiopathic arthritis, giant cell arteritis, polyarticular juvenile idiopathic arthritis, and cytokine release syndrome. Two other biologicals targeting the IL-6 receptor have been developed: *sarilumab* and *satralizumab*. *Satralizumab* is approved for the treatment of neuromyelitis optica spectrum disorder in adult patients who are positive for anti–aquaporin-4 antibody. *Siltuximab* is an IL-6 antagonist approved for treatment of multicentric Castleman disease if the patient is HIV and human herpesvirus 8 negative. A series of biologicals target the IL-12 and IL-23 pathways. *Ustekinumab* is directed against the IL-12 β subunit, which is a common subunit of IL-12 and IL-23, and is indicated for the treatment of plaque psoriasis and psoriatic arthritis. Selective targeting of the IL-23 pathway was achieved with the development of mAbs that target the IL-23 p19 subunit (*guselkumab*, *risankizumab*, *tildrakizumab*). *Tildrakizumab* and *risankizumab* have significantly longer half-lives than *guselkumab* and are administered in a maintenance regimen every 12 weeks versus 8 weeks, respectively. *Secukinumab* is a human anti–IL-17A antagonist and *ixekizumab* is a humanized anti–IL-17A antagonist that are indicated for treatment of plaque psoriasis, psoriatic arthritis and ankylosing spondylitis. *Brodalumab* also inhibits the IL-17 pathway, although by targeting IL-17 receptor A. The IL-17 receptor A is a coreceptor for multiple IL-17 cytokines, including IL-17A, IL-17A/F, IL-17F, IL-17E, and IL-17C. *Brodalumab* is also indicated for the treatment of plaque psoriasis but has been reported to lead in some patients to suicidal ideation and behavior.

A decoy-resistant variant of IL-18 (ST-067) is in a phase I clinical trial in a broad array of solid tumors. This variant was engineered to be resistant to IL-18 binding protein, which is frequently upregulated in tumors.

Therapeutic approaches targeting cytokine pathways associated with type II immune responses such as those triggered by IL-4 and IL-5 have been approved for asthma and moderate-to-severe atopic dermatitis. They are discussed in more detail in Chapters 44 and 75 along with biologicals directed to IL-13, IL-33, and thymic stromal lymphopoietin, which are in clinical development.

Inhibition of Cytokine Signaling: JAK Inhibitors

The use of "biologicals" such as antibodies and proteins targeting a diversity of immune cell functions and immune modulating cytokines and their receptors has revolutionized the treatment of most autoimmune diseases. However, not all patients respond fully to these biological agents, and there is a potential cross talk among the multiple cytokines that accumulate in the inflammatory microenvironment. The latter may render ineffective some of the single targeting agents, including some of the widely used mAbs. A recently developed strategy instead targets a shared repertoire of intracellular molecules that transduce the signals generated by multiple cytokine receptors, thereby inhibiting their function concomitantly. Among them, a growing family of cytokine signaling inhibitors represents an active area of drug development, with multiple small-molecule inhibitors recently approved (see Table 39–2), primarily inhibitors of the Janus kinase (JAK) family.

JAK Inhibitors

Mechanism of Action. Janus kinases are protein tyrosine kinases that are stimulated by agonist-occupied cytokine receptors; in turn, JAKs initiate intracellular signaling cascades mediating most biological functions regulated by these cytokines (Aaronson and Horvath, 2002; Stark and Darnel, 2012). These include the direct tyrosine phosphorylation of signal transducer and activator of transcription (STAT) transcription factors, such as STAT2, STAT3, and STAT5, which initiate the expression of growth-promoting and inflammatory gene programs (Aaronson and Horvath, 2002; Stark and Darnel, 2012) (see Figure 39–2). The available JAK inhibitors, known as JAKis or JAKinibs, have varying specificities for the JAK isoforms, which include JAK1, JAK2, JAK3, and tyrosine kinase 2 (TYK2). Most JAKinibs target the ATP binding site of the JAK tyrosine kinase domain, while some of the most recently developed JAKinibs act as allosteric inhibitors targeting specific JAKs (Alexander et al., 2021; Gadina et al., 2020).

Therapeutic Uses. In the past few years, 10 JAKinibs have been approved for use in humans (two JAK1 and JAK2 inhibitors: *ruxolitinib* and *baricitinib*; three JAK1 inhibitors: *upadacitinib*, *filgotinib*, and *abrocitinib*; two JAK2 inhibitors: *fedratinib* and *pacritinib*; a JAK1, JAK2, and JAK3 inhibitor: *tofacitinib*; and two pan-JAK [JAK1/JAK2/JAK3/TYK2] inhibitors, *peficitinib* and *delgocitinib*) for multiple indications, including rheumatoid arthritis, psoriatic arthritis, ulcerative colitis, polycythemia vera, GVHD, myelofibrosis, ankylosing spondyloarthritis, and allergic dermatitis and atopic dermatitis. Among these, *abrocitinib*, *baricitinib*,

fedratinib, *ruxolitinib*, *tofacitinib*, and *upadacitinib* are FDA-approved; *filgotinib* is approved by the European Medicines Agency; *peficitinib* is approved in South Korea and Japan only; and *delgocitinib* is approved by the Japanese Pharmaceutical and Medical Devices Agency.

Many clinical trials are ongoing using these JAKinibs for multiple autoimmune and inflammatory conditions, including alopecia areata, lupus, Sjögren's syndrome, and inflammatory eye disease (Alexander et al., 2021). Numerous new JAKinibs are under current development, including TYK2-specific inhibitors, JAK3-specific inhibitors, and multitarget agents inhibiting JAKs and other kinases. Development includes nonabsorbable JAKinibs aimed at achieving local responses while limiting systemic exposures. JAKinibs represent an attractive area for future drug development, building on the well-established therapeutic activity of the approved agents and the opportunities to identify new indications and develop next-generation JAKinibs with distinct kinase selectivity. See Chapter 75 for additional information on JAKinibs and their clinical use.

ADME.

Administration. JAKinibs are delivered by oral administration and are readily absorbed, reaching peak plasma concentrations shortly after administration.

Ruxolitinib is metabolized primarily by hepatic CYP3A4. Hence, CYP3A4 inhibitors such as *ketoconazole* can reduce the clearance rate and increase *ruxolitinib* half-life. Conversely, *rifampin*, which induces CYP3A4, decreases the exposure and half-life of *ruxolitinib*.

Tofacitinib is also primarily metabolized by hepatic CYPs and is affected as expected by CYP inhibitors and inducers. Unmetabolized *tofacitinib* is eliminated by the kidneys, and dose adjustment is necessary in patients with liver and renal impairment.

Baricitinib is a substrate for the organic anion transporter OAT3, the multidrug and toxin extrusion protein (MATE) 2-K, P-glycoprotein, and breast cancer resistance protein (BCRP); *baricitinib* is actively secreted in the kidney, and probenecid, an OAT3 inhibitor, decreases renal clearance and increases the AUC of *baricitinib* (Posada et al., 2017).

Drug Interactions. Most JAKinibs exhibit drug interactions with potent inhibitors of CYP3A4, such as *ketoconazole*, or moderate inhibitors of CYP3A4 and potent inhibitors of CYP2C19 such as *fluconazole*. The combination of JAKinibs with other strong systemic immunosuppressants is generally not recommended. All age-appropriate vaccinations (see Chapter 40) should be completed prior to therapy, including prophylactic herpes zoster vaccinations. Immunizations with live vaccines should be avoided.

Toxicities. As with most immunosuppressive agents, JAKinibs are associated with a risk for infection. Most frequent side effects are anemia, thrombocytopenia, leukopenia, lymphopenia, and neutropenia, as well as hyperlipidemia diarrhea, and in some cases, headache and high blood pressure. *Baricitinib*, *tofacitinib*, and *upadacitinib* increase the risk of venous thromboembolism, deep venous thromboembolism, and pulmonary embolism. The FDA has recently issued a boxed warning for oral JAKinibs used chronically. The black-box warning for these agents includes the following:

- Increased risk of serious bacterial, fungal, viral, and opportunistic infections leading to hospitalization or death
- Higher rate of all-cause mortality, including sudden cardiovascular death
- Higher rate of certain cancers
- Higher rate of cardiovascular death, myocardial infarction, and stroke
- Thrombosis

JAK inhibitors should be used with awareness of the latest information from the FDA on initiating therapy and patient monitoring and with knowledge of the recommended usages and potential adverse reactions.

Inhibition of Lymphocyte Function–Associated Antigen

Alefacept is a human LFA-3–IgG1 fusion protein. The LFA-3 portion of *alefacept* binds to CD2 on T lymphocytes, blocking the interaction between LFA-3 and CD2 and interfering with T-cell activation. *Alefacept* is approved for use in psoriasis. Treatment with *alefacept* has been shown to produce a dose-dependent reduction in T-effector memory cells (CD45, RO^+) but not in naïve cells (CD45, RA^+) (Vincenti and Kirk, 2008). This effect has been related to its efficacy in psoriatic disease and is of significant interest in transplantation because T-effector memory cells are associated with costimulation blockade-resistant and depletional induction-resistant rejection. *Alefacept* delays rejection in cardiac transplantation in nonhuman primates and has synergistic potential when used with costimulation blockade or *sirolimus*-based regimens in nonhuman primates (Vincenti and Kirk, 2008). A phase II multicenter study to assess the safety and efficacy of maintenance therapy with *alefacept* in kidney transplant recipients showed no difference from placebo controls (Rostaing et al., 2013).

Biologicals Targeting Integrins

Mechanism of Action

Leukocyte migration through the endothelium is a critical step in the inflammatory response that depends, in part, on the interaction between integrins and their ligands. Binding of integrins expressed on leukocytes and their corresponding ligands—cell adhesion molecules expressed on endothelial cells—allows for leukocyte arrest and subsequent transmigration (Dustin, 2019; Luo et al., 2007). Integrins are heterodimeric receptors, composed of α and β subunits, and biologicals targeting integrins, such as *natalizumab* and *vedolizumab*, have been developed to inhibit leukocyte migration to inflamed tissues. While *natalizumab* targets α4, a shared subunit between the α4β1 and α4β7 integrins, *vedolizumab* selectively blocks the α4β7 integrin. Interestingly, the expression of cell adhesion molecules can be tissue specific. Such is the case of MAdCAM-1 (mucosal addressin cell adhesion molecule 1), the ligand for the α4β7 integrin, which is expressed on endothelial cells at mucosal sites. Thus, neutralization of α4β7-MAdCAM-1 interaction reduces leukocytes homing to the inflamed intestine. By contrast, interaction of α4β1 integrin with VCAM-1 (vascular cell adhesion molecule 1) is critical for T-cell trafficking across the blood-brain barrier; blocking this interaction has been highly effective in inhibiting T-cell infiltration in the CNS.

Therapeutic Uses

Natalizumab is indicated for the treatment of adult patients with relapsing-remitting MS as well as active, secondary progressive disease. *Natalizumab* is also indicated for the treatment of moderate to severe Crohn's disease that does not adequately respond to conventional therapies or TNFα inhibitors. *Vedolizumab*, a selective α4β7 integrin antagonist, is indicated for moderately to severely active Crohn's disease and ulcerative colitis.

Toxicities

A significant increase the risk of progressive multifocal leukoencephalopathy (PML) has been observed after *natalizumab* administration. PML is a rare, opportunistic viral infection of the brain caused by the human polyomavirus 2, also known as John Cunningham virus (JCV). PML can lead to death or severe disability. A series of factors are known to increase the risk of PML in patients treated with *natalizumab*. These include the presence of anti-JCV antibodies, prolonged treatment with *natalizumab*, or prior treatment with immunosuppressants such as *mitoxantrone*, *azathioprine*, *methotrexate*, *cyclophosphamide*, or MMF. While only one case of PML has been reported with the use of *vedolizumab*, monitoring of patients for new or worsening neurological signs or symptoms is recommended in patients receiving this biological. Both *natalizumab* and *vedolizumab* increase the risk of infections. Given the selective ability of *natalizumab* to inhibit T-cell trafficking to the CNS, this drug is associated with an increased risk of herpes encephalitis and meningitis.

Cytokine Therapy

Interferon

For a description of interferon (IFN) induction and signaling and the major actions of IFN, see Chapter 38. IFN-β was among the first cytokines

used for the treatment of autoimmune diseases, particularly MS. IFNs are endogenous regulatory cytokines that increase or decrease transcriptional initiation of hundreds of genes in a cell-dependent fashion with multiple mechanisms of action, including induction of IL-10. The different IFN-β formulations have modest therapeutic efficacy, decreasing the exacerbation rate in MS by approximately 30%. They are relatively safe; fatigue is the major side effect. There are multiple preparations of IFN-β in the market that are administered either by the intramuscular or subcutaneous routes. IFN-β preparations are usually used for MS, and IFN-α/γ preparations are used for infections. There are no significant differences between these IFN preparations, and as more efficacious drugs are now available, they should no longer be considered first-line drugs for the treatment of MS (see below).

Granulocyte-Macrophage Colony-Stimulating Factor

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is a cytokine that functions as a growth factor that stimulates the differentiation of hematopoietic stem cells (HSCs) into granulocytes such as neutrophils, eosinophils, and basophils. It also promotes the differentiation of HSCs into monocytes. A recombinant form of GM-CSF, *sargramostim*, is approved for the acceleration of myeloid reconstitution following autologous bone marrow or peripheral blood progenitor cell transplantation. *Sargramostim* is also indicated for the induction of neutrophil production following chemotherapy and in patients who have been acutely exposed to myelosuppressive doses of radiation.

Targeting B Cells

Most of the advances in transplantation can be attributed to drugs designed to inhibit T-cell responses. As a result, T-cell–mediated acute rejection has been become much less of a problem, while B-cell–mediated responses such as antibody-mediated rejection and other effects of donor-specific antibodies have become more evident. Both biologicals and small molecules with B-cell–specific effects now are in development for transplantation, including humanized mAbs to CD20 and inhibitors of the two B-cell–activation factors, BLYS and APRIL, and their respective receptors. *Belimumab*, an mAb that targets BLYS, is approved for use in patients with systemic lupus erythematosus.

The CD20 antibodies *rituximab* and *ocrelizumab* deplete circulating mature B lymphocytes (though they may remain to some degree in lymph nodes), and positive results from clinical trials in patients with rheumatoid arthritis and MS strongly suggest that B cells play a critical part in disease pathogenesis. Genetic fine mapping studies demonstrated a potentially pathogenic role of B cells in MS and rheumatoid arthritis that were not limited to antibody production. In particular, a definitive genetic modeling study pointed to the crucial role of B cells as APCs (Farh et al., 2015).

Tolerance

Immunosuppression has concomitant risks of opportunistic infections and secondary tumors. Therefore, the ultimate goal of research on organ transplantation and autoimmune diseases is to induce and maintain immunological tolerance, the active state of antigen-specific nonresponsiveness (Krensky and Clayberger, 1994). Tolerance, if attainable, would represent a true cure for conditions discussed previously in this section without the side effects of the various immunosuppressive therapies. The calcineurin inhibitors prevent tolerance induction in some, but not all, preclinical models. In these same model systems, *sirolimus* does not prevent tolerance and may even promote tolerance (Kawai et al., 2014; Krensky and Clayberger, 1994). In experimental animals, *sirolimus* promotes regulatory T cells, a subtype of T cells shown to suppress all immunity and promotes tolerance. Studies in kidney transplant recipients showed that *sirolimus* spared regulatory T cells in the periphery, unlike calcineurin inhibitors, which reduced their percentage (Segundo et al., 2006).

Costimulatory Blockade

Inhibition of the costimulatory signal has been shown to induce tolerance (Figure 39–5).

Abatacept is a fusion protein (see previous discussion) that contains the binding region of CTLA-4 (CD152), which is a CD28 homolog, and the Fc region of the human IgG1. CTLA-4-Ig competitively inhibits CD28 binding to CD80 and CD86 and thus inhibits the activation of T cells. CTLA-4-Ig is effective in the treatment of rheumatoid arthritis in patients resistant to other drugs.

A second costimulatory pathway involves the interaction of CD40 on activated T cells with CD40 ligand (CD154) on B cells, endothelium, or APCs (see Figure 39–5). Among the purported activities of anti-CD154 antibody treatment is the blockade of B7 expression induced by immune activation. Two humanized anti-CD154 mAbs have been used in clinical trials in renal transplantation and autoimmune diseases. The development of these antibodies, however, was discontinued due to associated thromboembolic events. Alternative approaches to block CD154 with improved safety profile, including modified antibodies, recombinant proteins, and biologicals that target CD40 are under clinical trial.

Donor Cell Chimerism

A promising approach is induction of chimerism (coexistence of cells from two genetic lineages in a single individual) by first dampening or eliminating immune function in the recipient with ionizing radiation, drugs such as *cyclophosphamide*, or antibody treatment, and then providing a new source of immune function by adoptive transfer (transfusion) of bone marrow or hematopoietic stem cells. On reconstitution of immune function, the recipient no longer recognizes new antigens provided during a critical period as "nonself." Such tolerance is long lived and less likely to be complicated by the use of calcineurin inhibitors.

Antigens

Specific antigens induce immunological tolerance in preclinical models of diabetes mellitus, arthritis, and MS. *In vitro* and preclinical *in vivo* studies demonstrated that one can selectively inhibit immune responses to specific antigens without the associated toxicity of immunosuppressive therapies. With these insights comes the promise of specific immune therapies to treat an array of immune disorders from autoimmunity to transplant rejection (Riedhammer and Weissert, 2015). To date, this approach has worked only in animal models of autoimmune disease.

Soluble HLA

In the precyclosporine era, blood transfusions were shown to be associated with improved outcomes in renal transplant patients. These findings gave rise to donor-specific transfusion protocols that improved outcomes. After the introduction of *cyclosporine*, however, these effects of blood transfusions disappeared, presumably due to the efficacy of this drug in blocking T-cell activation. Nevertheless, the existence of tolerance-promoting effects of transfusions is irrefutable. It is possible that this effect is due to HLA molecules on the surface of cells or in soluble forms. Soluble HLA and peptides corresponding to linear sequences of HLA molecules can induce immunological tolerance in animal models via a variety of mechanisms (Murphy and Krensky, 1999).

Immunotherapy for Multiple Sclerosis

Clinical Features and Pathology

Multiple sclerosis is a genetically mediated demyelinating inflammatory disease of the CNS white matter that includes a loss of immune tolerance and the development of apparent autoimmunity toward components of the CNS. The detailed etiology of MS remains unknown. The disease occurs with prevalence increasing from late adolescence to 35 years of age and then declining. MS is 2- to 3-fold more common in females than in males and occurs mainly in higher latitudes of the temperate climates. Epidemiological studies suggest a role for environmental factors in the pathogenesis of MS, including low vitamin D, smoking, increases in body mass index, and high salt intake (Ransohoff et al., 2015).

Genome-wide association studies have identified 200 genetic variants associated with MS susceptibility (International Multiple Sclerosis Genetics Consortium et al., 2007). Many of these variants fall within specific signaling cascades, which suggests that alterations in pathways—rather than individual genes—may be useful in predicting response to therapy. Over half of genetic variants associated with MS risk are also found in other putative autoimmune diseases, and risk alleles are primarily associated with genes that regulate immune function. Single-nucleotide variants were strongly enriched within binding sites for immune-related transcription factors (Farh et al., 2015). In patients with MS, there are activated T cells that are reactive to different myelin antigens, including myelin basic protein, and these T cells secrete proinflammatory cytokines, whereas in healthy controls, T cells secrete the anti-inflammatory IL-10 cytokine (Cao et al., 2015). IL-2–IL-2R signaling features prominently in current considerations of understanding the progression of MS (Peerlings et al., 2021).

Attacks are classified by type and severity and likely correspond to specific degrees of CNS damage and pathological processes. Thus, physicians refer to relapsing-remitting MS (the form in 85% of younger patients), secondary progressive MS (progressive neurological deterioration following a long period of relapsing-remitting disease), and primary progressive MS (~15% of patients, wherein deterioration with relatively little inflammation is apparent at onset).

Pharmacotherapy

There are no pharmacological cures for MS. Specific therapies are aimed at resolving acute attacks, reducing recurrences and exacerbations, and slowing the progression of disability. There are now both parenteral and oral immunomodulatory agents for the treatment of MS that are classified as "disease-modifying" agents. Disease-modifying agents for the various stages of MS are summarized below. See Table 39–3 for the efficacy ranking of approved therapies; pharmacological profiles for most of them are presented earlier in this chapter. The high annual cost of these newer disease-modifying agents is an issue (Medical Letter, 2021a, 2021b).

Acute exacerbations of MS can be treated with a short course of *methylprednisolone* (3–5 days of 500–1000 mg/day, administered orally or intravenously) (Comi and Radaelli, 2015). To varying degrees, the agents listed reduce relapse rates in relapsing-remitting MS and secondary progressive MS. Relapsing-remitting MS is often treated initially with an antibody to CD20 (i.e., *ocrelizumab* or *ofatumumab*) or with *natalizumab*. The American Academy of Neurology's guidelines for using disease-modifying therapies for adults with MS (Rae-Grant et al., 2018) suggest *alemtuzumab*, *natalizumab*, or an S1PR modulator for MS patients with highly active disease. In general, the disease-modifying immunomodulatory agents for MS should not be coadministered with other immunosuppressive drugs. In administering any of these immunomodulatory agents, it is essential to follow the FDA-approved instructions for initiation and maintenance of treatment and monitoring during the process, with awareness of potential adverse effects, drug interactions, and risks of fetal harm. Earlier rather than later use of these drugs in the course of MS is more effective in preventing disease relapses. The reductions in annual relapse rates achieved by these disease-modifying agents in clinical trials has varied from 34% to 68% (Goldschmidt and McGinley, 2021; Medical Letter, 2021a).

Parenteral Agents

First-Generation Agents. The so-called first-generation (but not necessarily "first-line") drugs include IFN-β (discussed above in Cytokine Therapy) and random polymers that contain amino acids commonly used as MHC anchors. *Glatiramer acetate* (GA), a random-sequence polypeptide consisting of four amino acids (alanine [A], lysine [K], glutamate [E], and tyrosine [Y]) with an average length of 40 to 100 amino acids, binds efficiently to MHC class II DR molecules *in vitro*. In

TABLE 39–3 ■ EFFICACY RANKING OF APPROVED THERAPIES FOR MULTIPLE SCLEROSIS[a]

DRUG	ERA OF DEVELOPMENT	MECHANISM OF ACTION	KEY CONSIDERATIONS
Most effective			
Natalizumab	Second	Monoclonal antibody against integrin α4	Risk of PML must be assessed via presence of JCV antibodies.
Ocrelizumab	Third	mAb against CD20 (B cells)	Low risk of PML, slight increase in infections
Alemtuzumab	Third	mAb against CD52	High risk of second-degree thyroiditis and other autoimmune disease
Highly effective			
Fingolimod	Second	Sphingosine S1P-R modulator	Cardiac complications preclude use in individuals over the age of 50 and those with history of cardiac disease. VZV antibody testing must be conducted to mitigate risk of disseminated herpes zoster.
Dimethyl fumarate	Third	Immunomodulator	Necessary to monitor lymphocyte count as risk mitigation against PML. Gastrointestinal complications may limit use.
Moderately effective			
IFN-β	First	Immunomodulator	Well-characterized long-term safety and efficacy profiles. Patients should not be required to "fail" before receiving alternative treatments.
Glatiramer acetate	First	Immunomodulator	Best safety profile for pregnant women with mild disease. Patients should not be required to "fail" before receiving alternative treatments.
Teriflunomide	Third	Pyrimidine-synthesis inhibitor	Risk of teratogenicity precludes use in women who are, or intend to become, pregnant.

[a]Rankings are estimated on the basis of clinical trials, postapproval studies, and a few head-to-head comparisons. The factors that determine drug efficacy in any individual patient are largely undefined, and good clinical judgment is essential for treatment selection. For details, see Ransohoff et al., 2015. Reproduced with permission from Ransohoff RM, et al. Multiple sclerosis—a quiet revolution. *Nat Rev Neurol*, **2015**, 11:134–142. Copyright © 2015 Nature Publishing Group.

clinical trials, GA, administered subcutaneously to patients with relapsing-remitting MS, decreased the rate of exacerbations by about 30%, similar to the efficacy of IFN-β. *In vivo* administration of GA induces highly cross-reactive $CD4^+$ T cells that are immune-deviated to secrete anti-inflammatory T_H2 cytokines such as IL-4 and IL-13. Administration of GA also prevents the appearance of new lesions detectable by magnetic resonance imaging (Duda et al., 2000). GA provided an early illustration of the potential of an agent that ameliorates autoimmune disease by altering signals through the TCR complex. However, the long-term treatment of patients with MS has moved from the use of IFN-β and GA to more effective and directed treatments, and there is no rationale for the use of step therapy with IFN-β and GA before using the more effective drugs such as *ocrelizumab* and *natalizumab*.

Antibodies to α4 Integrin. *Natalizumab* is a recombinant humanized antibody to the adhesion molecule α4 integrin. An interaction of α4β1 integrin with vascular cell adhesion molecule 1 (VCAM1) is critical for T-cell trafficking from the periphery into the CNS; blocking this interaction has been highly effective in inhibiting exacerbations of MS. *Natalizumab* is administered via a 60-min IV infusion every 4 weeks. Its use is associated with the development of PML; consequently, the availability of *natalizumab* is restricted by a Risk Evaluation and Mitigation Strategy program that dictates measurement of JCV antibodies. Patients negative for JCV are often recommended to begin *natalizumab*, while JCV-positive persons are tested for VZV to evaluate for treatment with an S1PR modulator.

Antibodies to CD20. B-cell depletion therapy with *ocrelizumab*, a humanized antibody to CD20, and with *ofatumumab*, a recombinant human antibody to CD20, is an efficacious treatment (Hauser et al., 2017). *Ocrelizumab* must be administered by IV infusion at 6-month intervals; *ofatumumab* is administered subcutaneously on a monthly basis. Both antibodies are approved for relapsing-remitting MS and secondary progressive MS. *Ocrelizumab* is also approved for primary progressive MS. *Rituximab,* a chimeric antibody to CD20 (see Chapter 72), has been used off-label for the treatment of MS.

Antibodies to CD52. *Alemtuzumab* is a humanized mAb directed against CD52 that depletes $CD52^+$ B and T cells. It is approved for relapsing-remitting MS. *Alemtuzumab* has a long-lasting effect, but due to adverse infusion responses, serious autoimmune reactions, and association with malignancies, it is recommended for patients who have had suboptimal response to two other disease-modifying agents. The antibody is administered by a daily intravenous infusion for 5 consecutive days, then again 12 months later for 3 consecutive days. *Alemtuzumab* is more effective than IFN-β1a in preventing relapses. Due to the risk of fetal harm, women of childbearing potential should use effective contraception while taking *alemtuzumab* and for 4 months thereafter.

Anthracenediones. *Mitoxantrone*, an inhibitor of DNA replication, has shown effect in reducing relapse rates and slowing progression of MS. The drug is given by a short intravenous infusion every 3 months. Long-term cumulative risks (cardiotoxicity, chronic myeloid leukemia) are significant, reducing its safety profile.

Oral Agents

S1PR Modulators. The pharmacology of S1PR modulators has been described earlier in the chapter. The relevance of S1P to immunity derives from the role of S1P in promoting the egress of lymphocytes from lymphoid tissues and their infiltration into the CNS. The efficacy of S1PR modulators in MS resides in their capacity to act as irreversible activators of S1PRs and cause irreversible downregulation of S1P signaling (see Figure 39–3), thereby reducing the egress of lymphocytes from lymphoid tissue and disrupting the targeting of circulating lymphocytes to the CNS. There are four FDA-approved S1PR modulators: *ponesimod, siponimod, ozanimod,* and *fingolimod.* All but *fingolimod* act directly; *fingolimod* is phosphorylated to its active form (see Figure 39–3). The individual agents differ in their specificity for the five S1PRs and thus in the breadth of their effects and side effects. *Fingolimod* interacts with all subtypes of S1PRs except $S1P_2R$. *Siponimod* and *ozanimod* have high affinity for $S1P_1R$ and $S1P_5R$. *Ponesimod* shows the greatest specificity, interacting with high affinity only at $S1P_1R$, the S1PR found on lymphocytes and endothelial cells. All four S1PR modulators are approved for use in treating relapsing-remitting MS. *Ponesimod* is approved for secondary progressive MS as well. S1PR modulators are FDA-approved as a first-line therapy in MS, decreasing the exacerbation rate by about 50%. MS may worsen when S1PR modulators are withdrawn.

Fumarates. *Monomethyl fumarate, dimethyl fumarate*, and *diroximel fumarate* appear to have multiple immunomodulatory effects and are used for relapsing-remitting and secondary progressive MS in adults. A detailed mechanism of action is unknown. *Dimethyl fumarate* and *diroximel fumarate* are metabolized to *monomethyl fumarate*, the active form, which is an activator of *nrf2* that mediates an antioxidative stress response. *Monomethyl fumarate* also is a nicotinic acid receptor agonist, an action that may contribute to the cutaneous flushing associated with the initiation of fumarates. The fumarates reduce annualized relapse rates by about 50% as compared with placebo. These agents appear to be safe, although GI side effects can occasionally cause difficulties. Fumarates have been associated with lymphopenia, PML, and opportunistic infections (viral [e.g., herpes zoster virus], fungal, bacterial). The different preparations have different dosing, but all begin with a 7-day twice-daily initiation dosage followed by a double-dose twice-daily maintenance regimen. Prior to initiation, patient blood count, serum aminotransferase, alkaline phosphatase, and bilirubin should be assessed and then monitored throughout the drug's use for signs of lymphopenia and liver injury.

Teriflunomide. *Teriflunomide* reduces pyrimidine synthesis by reversibly inhibiting dihydro-orotate dehydrogenase, thereby causing a reduction in proliferation of activated B and T cells (Bar-Or et al., 2014). The drug carries an FDA boxed warning about risks of hepatotoxicity and teratogenicity, and a complete blood count before treatment and assessments and monitoring of serum enzymes and bilirubin before and during the treatment period are required. Physicians should be aware of drug interactions due to effects of *teriflunomide* on CYPs 2C8 and 1A2; administration of *teriflunomide* with *warfarin* may reduce *warfarin*'s effect. *Teriflunomide* is approved for treating relapsing-remitting MS; in clinical trials, it has reduced annual relapse rates by approximately 34%.

Cladribine. The purine antimetabolite *cladribine* (chloro-2′-deoxy-β -D-adenosine) is FDA-approved for treatment of relapsing-remitting MS and secondary progressive MS in adults. The drug selectively depletes B cells. *Cladribine* carries an FDA boxed warning about risks of malignancies and teratogenicity and requires cancer screening and other assessments prior to initiation. Patients taking *cladribine* are at increased risk for opportunistic infections and hepatic damage. The drug is administered in four doses at prescribed times over the course of a year, followed by a 2-year hiatus. In clinical trials, *cladribine* has reduced annual relapse rates by approximately 50%.

	Therapeutic Uses	Clinical Pharmacology and Tips
Glucocorticoids		
Prednisone (prednisone → prednisolone in liver)	• Prevent and treat transplant rejection; treat GVHD in bone marrow transplant, autoimmune disease, rheumatoid arthritis, ulcerative colitis, MS, systemic lupus erythematosus	• Broad effects on cellular immunity • Affects transcription of many genes; ↓ nuclear factor-κB activation, ↓ proinflammatory cytokines IL-1 and IL-6 • ↓ T-cell proliferation, cytotoxic T-lymphocyte activation and neutrophil and monocyte function • Can cause ↑ blood glucose, hypertension, cushingoid habitus, ↑ weight, ↑ risk of infection, osteoporosis, glaucoma, cataracts, depression, anxiety, psychosis • Long-term treatment → adrenal suppression; withdraw slowly on alternate days
Prednisolone	• Rheumatoid arthritis, uveitis, ulcerative colitis, vasculitis, sarcoidosis, systemic lupus erythematosus	• As above
Methylprednisolone	• Systemic lupus erythematosus, MS	• As above
Dexamethasone	• Rheumatoid arthritis, idiopathic thrombocytopenic purpura	• As above
Calcineurin Inhibitors		
Cyclosporine	• Transplant rejection prophylaxis, transplant rejection rescue therapy, rheumatoid arthritis, psoriasis and other skin diseases, xerophthalmia	• Use algorithms to delay dosing until renal function okay in kidney transplant patients • Monitor C_0 to avoid side effects • Side effects: tremor, hallucinations, drowsiness, coma, nephrotoxicity, hypertension, hirsutism, hyperlipidemia, gum hyperplasia • Metabolized by CYP3A → drug interactions • Severe interactions with antiarrhythmics
Tacrolimus	• Transplant rejection prophylaxis, transplant rejection rescue therapy	• GI absorption is incomplete and variable • Side effects include nephrotoxicity, neurotoxicity, GI complaints, and hypertension • Glucose intolerance and diabetes mellitus • Metabolized by CYP3A → drug interactions • Monitor blood levels to avoid nephrotoxicity
Voclosporin	• Lupus nephritis	• Side effects include nephrotoxicity, high blood pressure, neurotoxicity • Metabolized by CYP3A4 → drug interactions • ↑ risk of skin cancers and lymphomas • ↑ risk of infections
Antiproliferative and Antimetabolic Agents		
Azathioprine (inhibits purine synthesis and DNA replication)	• Adjunct for prevention of organ transplant rejection, rheumatoid arthritis	• Renal clearance has little effect on efficacy or toxicity • Side effects include bone marrow suppression (leukopenia > thrombocytopenia > anemia) • Susceptibility to infections, hepatotoxicity, alopecia, GI toxicity • Avoid allopurinol
Mycophenolate mofetil (inhibits GMP synthesis → selective inhibition of DNA synthesis in B and T cells)	• Prophylaxis of transplant rejection, used off-label for systemic lupus erythematosus, MS, sarcoidosis	• Side effects include GI (diarrhea and vomiting) and hematological (leukopenia, pure red cell aplasia) problems • Contraindicated in pregnancy
Sirolimus (mTOR inhibitor)	• Prophylaxis of organ transplant rejection, incorporated into stents to inhibit occlusion	• Monitor blood levels • Hyperlipidemia • Anemia, leukopenia, thrombocytopenia • GI effects, mouth ulcers, hyperkalemia • Anticancer effects • Metabolized by CYP3A → possible drug interactions
Everolimus (mTOR inhibitor)	• Astrocytoma, breast cancer, kidney and liver transplant reception prophylaxis, pancreatic neuroendocrine tumor, renal angiomyolipoma, renal cell cancer	• Pharmacokinetics distinct from sirolimus • Toxicity similar to that of sirolimus
Temsirolimus (mTOR inhibitor)	• Advanced renal cell carcinoma	• Weekly intravenous administration • Pharmacokinetics distinct from sirolimus and everolimus • Toxicity similar to that of sirolimus

Drug Facts for Your Personal Formulary: *Immunosuppressants, Immunomodulators, and tolerogens (continued)*

	Therapeutic Uses	Clinical Pharmacology and Tips
T-Cell Costimulatory Blocker		
Belatacept (binds to CD80/CD86, blocking CD28 costimulation)	• Prevention of renal transplant rejection	• ↑ Risk of posttransplant lymphoproliferative disorder involving the CNS, PML, and serious CNS infections → administration of higher or more frequent dosing than the recommended doses is *not* recommended
Antibodies Against Cell Surface Molecules		
Antilymphocyte globulin/antithymocyte globulin Atgam Thymoglobulin	• Prevention and treatment of organ transplant rejection, aplastic anemia	• Contains antibodies against numerous T-cell surface molecules • Can elicit fever, chills, hypotension; use premedication (steroid/acetaminophen/antihistamine) • Watch for leukopenia, thrombocytopenia
Abetacept Belatacept	• Prophylaxis of organ transplant rejection, autoimmunity trials	• CTLA-4-Ig fusion protein • Risk for posttransplant lymphoproliferative disorder
Anti-CD52 Alemtuzumab	• Chronic lymphocytic leukemia, MS, prevention and treatment of transplant rejection	• Prolonged lymphocyte depletion (neutropenia, thrombocytopenia as side effects) • Secondary autoimmunity
Anti-CD20 Rituximab Ocrelizumab	• Rheumatoid arthritis, MS	• Deplete circulating mature B lymphocytes
Anti-CD2 Alefacept	• Psoriasis	
Anti-BLyS Belimumab	• Systemic lupus erythematosus, lupus nephritis	• ↑ risk of infections • Cases of PML have been reported • Depression
Biologicals Targeting Cytokines and Their Receptors		
Anti–IL-1 Anakinra (recombinant IL-1 receptor antagonist) Canakinumab (IL-1β antibody) Rilonacept (fusion protein: IL-binding domains of IL-$1R_1$ and IL-RAcP linked to Fc region of IgG1)	• Rheumatoid arthritis, cryopyrin-associated syndromes	• IL-1 can be neutralized by endogenous IL-1R antagonist (IL-1Ra); levels of IL-1Ra are insufficient to neutralize the increased amounts of IL-1 produced in disease • IL-1 blockade can ↑ risk of serious opportunistic infections; discontinue anti–IL-1 therapy in patients with infections • ↑ in serious infections in patients with rheumatoid arthritis treated with anakinra and etanercept → this combination is not recommended • Live vaccines should not be administered in patients treated with anti–IL-1 therapies
Anti–IL-2 Basiliximab (antibody to IL-2R α chain/CD25) Daclizumab (antibody to IL-2R α chain)	• Prophylaxis of acute organ transplant rejection	• β Adrenergic blocking effects (worsening of heart failure and bronchospasm) • Block T-cell activation • Do not deplete • Good safety profile
Anti–IL-4 Dupilumab (mAb to IL-4Rα)	• Moderate-to-severe atopic dermatitis, maintenance treatment of moderate-to-severe asthma with eosinophilic phenotype or glucocorticoid-dependent asthma, maintenance treatment of chronic rhinosinusitis with nasal polyposis	• Associated with a reduction of oral glucocorticoid use for severe asthma; however, reduction of glucocorticoid dose, if deemed appropriate, should be gradual
Anti–IL-5 Benralizumab (blocking antibody to IL-5Rα) Mepolizumab (antibody to IL-5) Reslizumab (antibody to IL-5)	• Maintenance treatment of severe asthma (eosinophilic phenotype) • Mepolizumab is also indicated for eosinophilic granulomatosis with polyangiitis and hypereosinophilic syndrome	• Reslizumab is an intravenous infusion only • Benralizumab is a cytolytic mAb that induces efficient depletion of eosinophils in circulation

Drug Facts for Your Personal Formulary: *Immunosuppressants, Immunomodulators, and tolerogens (continued)*

	Therapeutic Uses	Clinical Pharmacology and Tips
Biologicals Targeting Cytokines and Their Receptors (cont.)		
Anti–IL-6 Sarilumab (antibody to IL-6R) Satralizumab (antibody to IL-6R) Tocilizumab (antibody to IL-6R) Siltuximab (chimeric mAb to IL-6)	• Tocilizumab and sarilumab: approved for the treatment of rheumatoid arthritis in patients who do not adequately respond to one or more disease-modifying agents • Tocilizumab: also approved for the treatment of giant cell arteritis, polyarticular juvenile idiopathic arthritis, systemic juvenile idiopathic arthritis, and cytokine release syndrome • Satralizumab: approved for the treatment of neuromyelitis optica spectrum disorder in adult patients who are positive for anti–aquaporin-4 antibody • Siltuximab: approved for treatment of multicentric Castleman disease if patient is negative for HIV and human herpesvirua-8	• IL-6 blockade can ↑ the risk of serious infections • Serious cases of hepatoxicity have been reported • Avoid use of live vaccines in patients treated with tocilizumab
Anti–IL-12/IL-23 Ustekinumab (antibody to IL-12β subunit, aka p40; IL-12β is a common subunit of IL-12 and IL-23)	• Moderate-to-severe plaque psoriasis, active psoriatic arthritis, moderately to severely active Crohn's disease, and moderately to severely active ulcerative colitis	• IL-12 and IL-23 blockade can ↑ the risk of serious infections • Consider discontinuation if patients develop serious infections
Anti–IL-17 Brodalumab (antibody to IL-17RA) Ixekizumab (antibody to IL-17A antibody) Secukinumab (antibody to IL-17A antibody)	• Patients aged 6 years or older with moderate-to-severe plaque psoriasis who are candidates for systemic therapy or phototherapy • Adults with active psoriatic arthritis, active ankylosing spondylitis, or active nonradiographic axial spondyloarthritis with objective signs of inflammation	• IL-17 blockade can ↑ the risk of serious infections; discontinue therapy in patients who develop serious infections • ↑ risk of inflammatory bowel disease (IBD), including Crohn's disease and ulcerative colitis; monitor for onset or exacerbation of IBD; if IBD is diagnosed, discontinue anti–IL-17 treatment • Suicidal ideation and behavior have occurred in patients treated with brodalumab
Anti–IL-23 Guselkumab Risankizumab Tildrakizumab (antibodies to IL-23 p19 subunit)	• Moderate-to-severe plaque psoriasis • Guselkumab is also approved for active psoriatic arthritis	• May ↑ risk of infections • Guselkumab is administered by subcutaneous injection on weeks 0 and 4 and every 8 weeks thereafter • Tildrakizumab and risankizumab: administered subcutaneously on weeks 0 and 4 and every 12 weeks thereafter
Anti-TNFα Adalimumab (human mAb to TNFα) Certolizumab (anti-TNFα, humanized Fab fragment) Golimumab (human mAb to TNFα) Infliximab (chimeric antibody to TNFα) Etanercept (decoy receptor)	• Rheumatoid arthritis, Crohn's disease, ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, ulcerative colitis	• TNFα blockade can ↑ risk of serious infections; administration of anti-TNFα therapies should be discontinued in patients who develop serious infections • ↑ risk of lymphoma and other malignancies
GM-CSF Sargramostim (recombinant GM-CSF)	• Acceleration of myeloid reconstitution following autologous bone marrow or peripheral blood progenitor cell transplantation • Promotion of neutrophil recovery following chemotherapy • Mobilization of hematopoietic progenitor cells into peripheral blood for collection by leukapheresis and autologous transplantation in adult patients • Acute exposure to myelosuppressive doses of radiation	• Can cause infusion-related reactions, characterized by respiratory distress, hypoxia, flushing, hypotension, syncope, and/or tachycardia

Drug Facts for Your Personal Formulary: *Immunosuppressants, Immunomodulators, and tolerogens* (*continued*)

	Therapeutic Uses	Clinical Pharmacology and Tips
Small-Molecule Inhibitors of Cytokine Receptor Signaling		
JAK inhibitors		• *Clinical tips for all JAK inhibitors:* Note FDA boxed warning and instructions for baseline testing, initiating therapy, and subsequent monitoring. Side effects: thrombocytopenia, anemia, and neutropenia; ↑ risk of infections (upper respiratory, sinus, common cold; also hepatitis C virus, etc.). Risk of fetal harm; nonuse during breastfeeding. Avoid concurrent use of live vaccines. Be aware of drug-drug interactions for each agent. JAKinibs have an FDA boxed warning for: • Increased risk of serious bacterial, fungal, viral, and opportunistic infections leading to hospitalization or death • Higher rate of all-cause mortality, including sudden cardiovascular death • Higher rate of certain cancers • Higher rate of thrombosis, cardiovascular death, myocardial infarction, and stroke
JAK1/JAK2 inhibitors Ruxolitinib Baricitinib	• Rheumatoid arthritis, graft-versus-host disease, myelofibrosis, polycythemia vera	
JAK1 inhibitors Upadacitinib Abrocitinib	• Rheumatoid arthritis, psoriatic arthritis, atopic dermatitis	
JAK2 inhibitors Fedratinib Pacritinib	• Myelofibrosis	• Avoid in patients at high risk of pulmonary embolism • Drug interactions via CYPs 3A4 and 2C19
JAK1/JAK3 inhibitor Tofacitinib	• Rheumatoid arthritis, psoriasis, ulcerative colitis, polyarticular course juvenile idiopathic arthritis	
Pan-JAK inhibitor Peficitinib (inhibits JAK1, JAK2, JAK3, and TYK2; modest selectivity for JAK3)	• Peficitinib (approved in Japan and Korea): rheumatoid arthritis	• In trials, well tolerated over 6-year period • ↑ risk of infections (herpes zoster virus, others) • Disease-modifying antirheumatic drug therapy: concurrent methotrexate does not affect pharmacokinetics of either drug • Drug interactions via P-glycoprotein, OATP1B1, and CYP3A4
Biologicals Targeting LFA		
Alefacept (anti-CD2)	Psoriasis	
Biologicals Targeting Integrins		
Natalizumab (targets α4, blocking both α4β1 and α4β7 integrin)	• MS (relapsing forms of and active secondary progressive disease), Crohn's disease (moderate-to-severe active disease that does not adequately respond to conventional therapies or anti-TNFα)	• Targets α4 integrin, blocking T-cell trafficking • ↑ risk of infection • Contraindicated in patients who have or have had PML • ↑ risk of developing herpes encephalitis and meningitis • ↑ risk of infections • Hepatotoxicity
Vedolizumab (blocks α4β7 but not α4β1 integrin)	• Ulcerative colitis and Crohn's disease (moderate-to-severe active disease)	• ↑ risk of PML; monitor patients for new or worsening of neurological signs and symptoms • ↑ risk of infections • Hepatotoxicity
S1PR Modulators		
Ponesimod ($S1P_1R$) Siponimod ($S1P_{1,5}R$) Ozanimod ($S1P_{1,5}R$) Fingolimod ($S1P_{1,3,4,5}R$)	• Relapsing-remitting MS (all), secondary progressive MS (siponimod, ponesimod), ulcerative colitis (ozanimod)	• These agents ↓ lymphocyte egress and homing • ↑ risk of infection • Follow FDA guidelines for administration and monitoring • First dose effects: bradycardia, ↓ atrioventricular conduction, ↑ QTc interval; monitor before and during initiation of therapy • Risk of macular edema; evaluate and monitor • Fetal risk • Monitor for cutaneous malignancies • Siponimod: contraindicated in patients with the homozygous CYP2C9*3/*3 genotype • Ozanimod: active metabolite inhibits MAO-B ⇒ potential for hypertensive crisis with agents that ↑ sympathetic tone
Additional Drugs for MS (see Table 39–3 and text for further information)		
Oral Agents: Fumarates, teriflunomide, cladribine *Parental Agents:* Glatiramer acetate, interferon β

Chapter 40 Immune Globulins and Vaccines

Roberto Tinoco and James E. Crowe, Jr.

Historical Perspective

The historical impact of infectious diseases is evident in the high mortality rates in young children and adults and the disruption that these diseases have caused in emerging societies. The rise of civilization in conjunction with the domestication of plants and animals permitted people to live in denser communities with each other and with their animals. Such proximity provided ideal breeding grounds for infectious pathogens, and their spread resulted in epidemics throughout the world. As people began to question the underlying causes of disease and the apparent protection to reinfection afforded to some survivors of a disease, ideas of immunity and disease prevention were born, apparently as early as the 5th century.

The concept of immunity goes back at least to the 17th century when emperor K'ang of China documented his practice of variolation, or inoculation, of his troops and his own children with smallpox to confer protection from the disease (Hopkins, 2002). Variolation involved taking liquid from a smallpox pustule of an infected patient, cutting the skin of an uninfected person, and then introducing the inoculum. Records from the 18th century note that enslaved Africans brought to the U.S. bore scars from smallpox variolation and were thought to be immune to the disease. Variolation against smallpox was also reported by Lady Mary Montagu during her time in Constantinople (1716–1718). Lady Montagu, herself a survivor of smallpox, reported that certain Turkish women would open a wound in healthy individuals and introduce the contents of a smallpox vesicle with a large needle, thereby providing a level of protection against smallpox. About 2% to 3% died after variolation, whereas 20% to 30% died from natural infection. Lady Montagu had herself and a son variolated and later had a daughter successfully variolated in London under the auspices of physicians of the Royal Society. Positive outcomes notwithstanding, fear of the procedure persisted.

Around the same time, in Boston, Cotton Mather and Dr. Zabdiel Boylston began a program of variolation against smallpox. The program met with general success but was opposed by many physicians, fearful that inoculation spread the disease and worried by deaths after inoculation (~2% of those inoculated). One Puritan religious leader, Edmund Massey, preached against inoculation, quoting from the book of Job (Job 2:7: "So Satan went forth from the presence of the Lord and smote Job with sore boils.") and arguing that Satan was the prime practitioner of inoculation and that such diseases as smallpox were a necessary trial of

Abbreviations

ACIP: Advisory Committee on Immunization Practices
AID: activation-induced cytidine deaminase
APC: antigen-presenting cell
ASD: autism spectrum disorder
BCG: bacille Calmette-Guérin
BCR: B-cell receptor
CDC: Centers for Disease Control and Prevention
CoP: correlate of protection
COVID-19: coronavirus disease 2019
CRM: cross-reactive material
DTaP: diphtheria and tetanus toxoids and acellular pertussis
EBOV: *Zaire ebolavirus*, Ebola virus
EMA: European Medicines Agency
EUA: Emergency Use Authorization
Fab: fragment, antigen-binding
Fc: fragment crystallizable
GBS: Guillain-Barré syndrome
GPCR: G protein-coupled receptor
H1N1: hemagglutinin subtype 1 and neuraminidase subtype 1
H3N2: hemagglutinin subtype 3 and neuraminidase subtype 2
HA: hemagglutinin
Hib: *Haemophilus influenzae* type b
HIV: human immunodeficiency virus
HPV: human papillomavirus
Ig: immunoglobulin
IIV: inactivated influenza vaccine
IOM: Institute of Medicine (now National Academy of Medicine)
IPV: inactivated poliovirus (vaccine)
JE: Japanese encephalitis
mCoP: mechanistic correlate of protection
MeV: measles virus
MMR: measles-mumps-rubella
MMRV: measles-mumps-rubella-varicella
mAbs: monoclonal antibodies
mRNA: messenger RNA
nCoP: nonmechanistic correlate of protection
PCV: pneumococcal conjugate vaccine
PRP: polyribosylribitol phosphate
RBD: receptor binding domain
RSV: respiratory syncytial virus
SAE: serious adverse event
SARS-CoV-2: severe acute respiratory syndrome coronavirus 2
SIDS: sudden infant death syndrome
TB: *Mycobacterium tuberculosis*
Td: tetanus toxoid and reduced diphtheria toxoid
Tdap: tetanus toxoid, reduced diphtheria toxoid, acellular pertussis
VZV: varicella-zoster virus

faith or punishment for sins, the fear of which "is a happy restraint upon many people" (Gross and Sepkowitz, 1998). Medical practice in Boston has come a long way since that time.

In 1796, Edward Jenner, who coined the term *vaccination*, from *vacca*, Latin for "cow," helped to advance vaccine safety. He tested the hypothesis that smallpox protection could be achieved by using cowpox, a nonfatal, self-limited disease in humans caused by a virus of the Poxviridae family that includes monkeypox and smallpox and that can spread from cows to humans. Jenner infected a boy with cowpox pus from an infected milkmaid; the boy got mildly ill from cowpox, recovered, and when challenged with smallpox collected from scabs of a smallpox patient, was unaffected, showed no symptoms, and was fully protected against the disease. Thus, it was possible to inoculate against a disease using material from a related but less-harmful disease.

By the early to mid-19th century, vaccination was accepted widely, and governments in the U.S. and Europe began to require vaccination of children. As in our own era, there was organized resistance from antivaccination groups. There was also a sense that immunity waned with time, and revaccinations were introduced, producing a sustained diminution of smallpox.

The work of Pasteur and Koch established a link between microorganisms and disease and provided the scientific understanding to develop more specific vaccines. Preservatives (glycerol was an early additive) and refrigeration increased shelf life of vaccines and permitted their wider distribution. The cells of the immune system began to be identified around 1890, followed by the discovery of antibodies and hyperimmune serum and the demonstration of the efficacy of adjuvants (aluminum was the first) to increase immunogenicity (Marrack et al., 2009). In the 1950s, freeze-drying became standard, permitting worldwide distribution of purified vaccines. Through the coordinating efforts of the World Health Organization (WHO), smallpox was declared "eliminated" in 1979.

Other scourges were attacked by vaccination in the mid-20th century. One was polio, an incurable neurological disease causing muscle wasting, paralysis, and death if the diaphragm is affected. In 1955, Jonas Salk released a vaccine against poliovirus. The Salk vaccine, an inactivated virus preparation administered by injection, was followed in 1961 by the Sabin oral vaccine, which employs an attenuated poliovirus that provides immunity to all three types of poliovirus. As a result of the polio vaccines, the annual number of cases in the U.S. fell to 161 in 1961 from 35,000 in 1955 (Hinman, 1984). Eradication of polio depends on interruption of person-to-person transmission, which requires that a high percentage of the susceptible population be inoculated. Most adults in developed countries are immune, but when a significant fraction of children are unvaccinated, there is the potential for an outbreak because wild polioviruses circulate.

These fundamental observations and experiments paved the way for the modern vaccines that have reduced mortality and morbidity rates from infectious pathogens across the globe. Modern laboratory technologies have rendered vaccines safe and highly effective against infectious pathogens and virus-transforming cancers and against neoantigens on cancerous cells. Vaccination strategies are a public health success, as shown by the complete worldwide eradication of smallpox and the elimination of polio in the Americas in 1994, Europe in 2002, and Southeast Asia in 2014, with remaining endemic cases only in Pakistan, Afghanistan, and Nigeria in 2016, according to WHO. In 2016, WHO and the Pan American Health Organization declared the Americas free of endemic measles, credited to immunization campaigns.

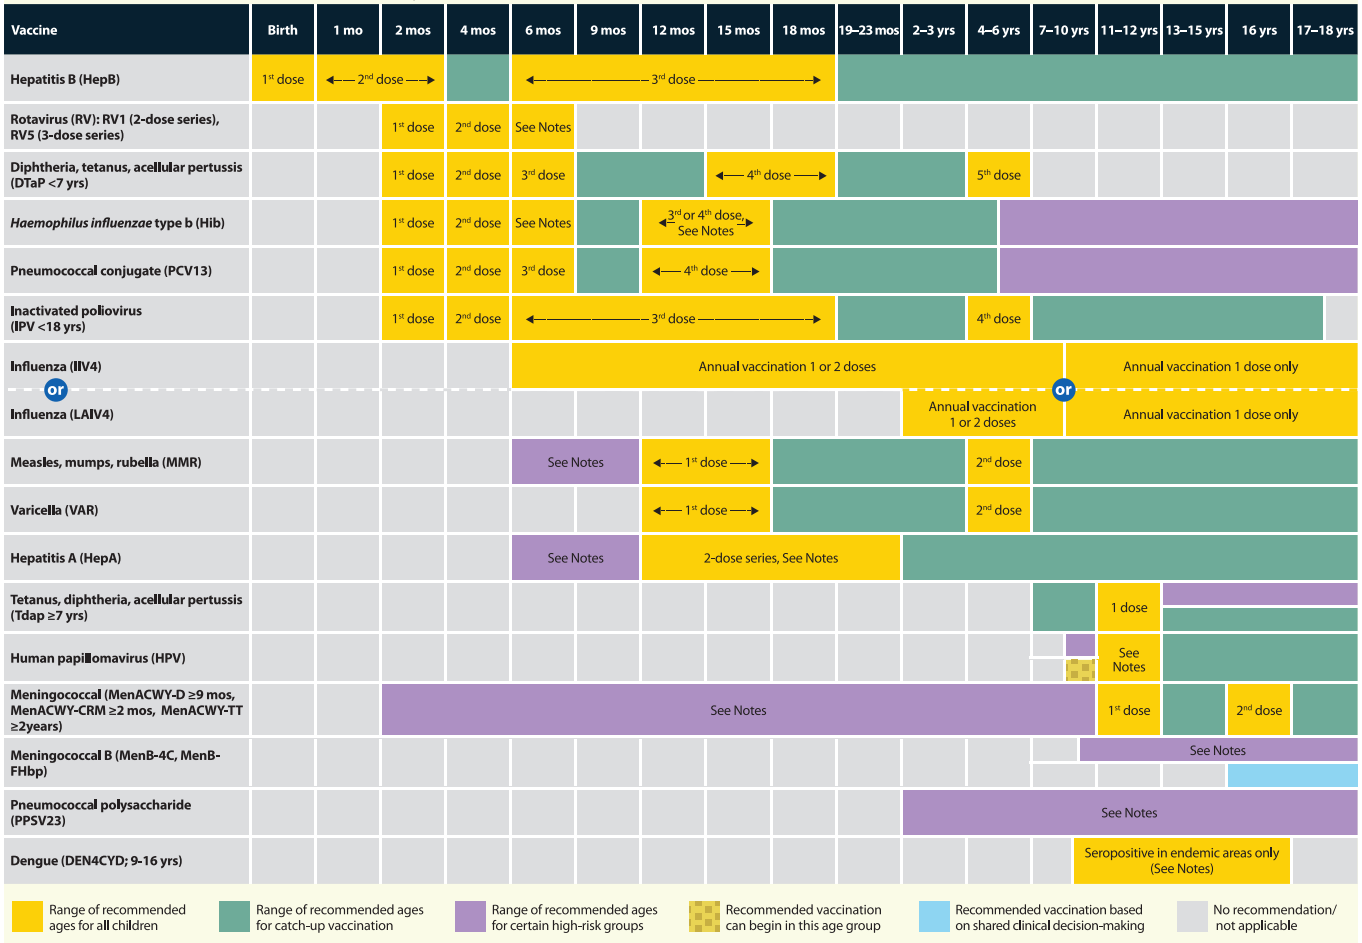
Table 40–1 summarizes the current recommendations for childhood vaccinations. A later section of the chapter discusses the issue of nonvaccinators.

Vaccination Induces Development of Immunological Memory

The hallmarks of an immune response to pathogens are the recognition and activation of the innate immune response that limits pathogen spread when microbes breach the host's natural protective barriers, such as the skin, the respiratory epithelium, or the gastrointestinal epithelium. If the pathogen is not controlled, the innate immune system then recruits the humoral (antibody-secreting B cell) and cellular (T cell) arms of the adaptive immune response to specifically target and destroy the invading pathogen. Once the microbe is eliminated during this primary response, small numbers of pathogen-specific B and T cells survive long term, sometimes for the entire life of the host, as *memory B and T cells*. These memory cells confer host protection against reinfection with the same pathogen. During a second response, memory cells use their specific

TABLE 40–1 ■ RECOMMENDED IMMUNIZATION SCHEDULE FOR CHILDREN AND ADOLESCENTS AGED 18 YEARS OR YOUNGER, U.S., 2022*

These recommendations must be read with the notes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars.
To determine minimum intervals between doses, see the catch-up schedule.*



*These recommendations are reprinted from the website of the Centers for Disease Control and Prevention (CDC) and should be read with Tables 2 and 3 and the notes provided on the CDC website: https://www.cdc.gov/vaccines/schedules/downloads/child/0-18yrs-child-combined-schedule.pdf. **For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity during the time periods indicated by the green bars. To determine minimum intervals between doses, see the catch-up schedule (Table 2) on the CDC website.**

antigen receptors to recognize the invading pathogen. This results in their activation and expansion to directly kill infected cells (via T cells) or generate antibodies (via B cells) that will neutralize the pathogen.

Vaccination technology takes advantage of this paradigm. As a means of generating immunological memory, uninfected individuals are given a controlled infection or exposed to antigen that elicits an immune response. When these vaccinated individuals are subsequently infected with these pathogens in their environment, the responses of their memory T and B cells outpace the invading microbes to neutralize and prevent their spread in a much more rapid secondary response of greater magnitude.

B-cell clonal expansion results in the differentiation of long-lived memory B cells and emergence of shorter-lived plasma cells that produce antibodies. During the primary response, following the vaccination, B cells will undergo this differentiation process and will initially secrete immunoglobulin (Ig) M antibodies. IgM antibodies are large and provide some protection. Days after the response is initiated, B cells will undergo clonal selection and will produce IgG, which is a higher-affinity antibody with enhanced pathogen neutralization capacity.

Differentiated plasma cells can also produce other antibody classes, such as IgA, IgD, and IgE, that have unique functions. IgD can be expressed on the surface of B cells; its function continues to be investigated. IgA antibodies are concentrated in mucous secretions, breast milk, and tears. IgE antibodies are important in the elimination of parasitic infections. *Because IgG antibodies have undergone a selection process that increases their affinity, these antibody types are the goals of vaccine design*. Secondary responses after vaccination therefore elicit a faster and larger B-cell response, and these B cells primarily make IgG antibodies (Clem, 2011).

Cellular immunity involving both $CD4^+$ and $CD8^+$ T cells is also a goal of vaccine design. Unlike B cells, T cells target intracellular pathogens that have infected host cells. $CD4^+$ T cells (helper T cells) stimulate B cells to produce antibody. $CD8^+$ T cells kill infected cells. Like B cells, antigen-memory T cells survive long term and provide protection for future encounters with their specific antigen.

Immunization Strategies

Immunity can be achieved from either passive or active methods involving exposure to natural infection or through artificial human-made antigens. Individuals can develop antibodies from natural infection or after vaccination.

Passive

Passive immunity involves the transfer of preformed antibodies from an immune individual to a nonimmune individual to confer temporary immunity. An example of passive natural immunity is the transfer of antibodies from mother to fetus during pregnancy and through breast milk and colostrum consumed by an infant. These antibodies enter the body

Botulism antitoxin bivalent (equine) types A and B
Botulism antitoxin heptavalent (A, B, C, D, E, F, G) (equine)
Antivenin (*Micrurus fulvius*) (equine origin) [i.e., North American coral snake antiven]
Crotalidae polyvalent immune Fab (ovine)
Digoxin immune Fab (ovine)
Antithymocyte globulin (rabbit)

and provide a first line of defense to the fetus or infant, who otherwise has no immunity to any pathogen.

An example of *artificial passive immunization* is the injection of antivenom antibodies. Animals are immunized with venom antigen, and their hyperimmunized serum is transfused into the patient. Antivenom can be monovalent, effective against one type of venom, or polyvalent and effective against venom from multiple species. An antivenom binds and neutralizes a toxin. Early administration after injury is critical because antivenom can halt but not reverse venom damage. Even though antivenom is purified, trace proteins remain, and these can trigger anaphylaxis or serum sickness in patients. Most antivenoms are administered intravenously but can also be injected intramuscularly against the venoms of stonefish and redback spiders. Antivenoms have been developed against venomous spiders, acarids, insects, scorpions, marine animals, and snakes. Passive immunization is used for a variety of toxins and infections; a list of available immunoglobulins is shown in Table 40–2.

Active

A natural infection that stimulates the immune response in uninfected individuals may lead to development of immunological memory and protection from reinfection, as in the case of infection with the measles virus (MeV). This induction of immunity occurs only if the individual survives the primary infection, which is not always the case for viruses like MeV, influenza virus, or Ebola virus (EBOV). Active immunization through injection of artificial antigens elicits a controlled immune response leading to the generation of immunological memory. This type of immunization, compared to natural infection, does not cause infectious disease or compromise the life of the individual. Thus, vaccine technologies through active stimulation of the immune system ensure that the individual survives and has protection against the pathogen in the natural environment.

Vaccine Types

Advanced technologies are currently used to generate vaccines to prevent many infectious diseases and to deter infectious pathogens that cause cancer, such as hepatitis viruses that can lead to hepatocellular carcinoma, and human papillomaviruses (HPVs) that can cause cervical, anal, vaginal, and penile cancers. Effective vaccines activate both the innate and the adaptive immune systems. There are many different types of vaccines, each with advantages and disadvantages. Vaccine design involves an understanding of the nature of the microbe, the tropism of the pathogen, and the practical need in certain regions of the world. The following section summarizes current methods used in vaccine design. For a list of vaccines approved by the FDA, see Table 40–3.

Live Attenuated

Live attenuated vaccines use a weakened form of a virus that contains antigens that appropriately stimulate an immune response. Such viruses have been passaged to reduce their virulence but retain immunogenic antigens that elicit strong humoral and cellular responses and the development of memory cells after one or two doses. A virus, for example, can be isolated from humans and then used to infect monkey cells. After several passages, the virus can no longer infect human cells but retains immunogenic capacity. These attenuated viruses can elicit a robust immune response because they are similar in many respects to the natural pathogen.

Several drawbacks exist with these vaccines. Because these are live viruses, they generally must be refrigerated to retain their activity. In remote areas of the world where refrigeration is not available, obtaining and storing this type of vaccine can be limiting. Because viruses can mutate and change in the host, it may be possible that viruses can become virulent again and cause disease, although the frequency of adverse reactions using these vaccines is very low. Furthermore, attenuated vaccines cannot be used in immune-compromised individuals (e.g., patients with HIV [human immunodeficiency virus] or cancer). In addition, these vaccines are usually not given during pregnancy. MeV, polio, rotavirus, yellow fever, and varicella viruses are examples of pathogens from which live attenuated vaccines have been generated. Attenuated vaccines for bacteria are more challenging to generate than for viruses because bacteria have more complex genomes; however, recombinant DNA technology can be utilized to remove virulence but retain immunogenicity. A vaccine against *Vibrio cholerae* has been generated this way. A live attenuated vaccine for tuberculosis also has been developed.

Inactivated

Polio, influenza, and rabies viruses and typhoid and plague bacteria have been utilized to generate inactivated vaccines. Killing pathogens by heat, radiation, or chemicals to inactivate them generates the antigenic starting materials. The dead pathogens can no longer replicate or mutate to their disease-causing state and thus are safe. These types of vaccines are useful because they can be freeze-dried and transported without refrigeration, an important consideration in reaching developing countries. A drawback with inactivated vaccines is that they induce an immune response that may be weaker than that induced by the natural infection; thus, patients often require multiple doses of inactivated vaccines or periodic booster vaccinations to sustain immunity to the pathogen. In areas where people have limited access to healthcare, ensuring that these multiple doses are delivered on time can be problematic and may result in reduced immunity to the pathogen, as in the case of poliovirus endemic disease.

Subunit Vaccines

As with inactivated vaccines, subunit vaccines do not contain live pathogens; rather, subunit vaccines use a component of the microorganism as a vaccine antigen to mimic exposure to the organism itself. Subunit vaccines typically contain *polysaccharides* or proteins (*surface proteins* or *toxoids*). Compared to live attenuated vaccines, subunit vaccines induce a less-robust immune response. The selection of antigenic subunit and the design and development of the vaccine can be lengthy and costly because the pathogen's subunit antigens and their combination must be thoroughly tested to ensure they elicit an effective immune response. Scientists can identify the more immunogenic antigens in the laboratory and manufacture these antigen molecules via recombinant DNA technology,

Zoster vaccine, live (Oka/Merck)
Rotavirus vaccine, live, oral
Rotavirus vaccine, live, oral, pentavalent
Influenza vaccine, live, intranasal (quadrivalent, types A and types B)
Adenovirus type 4 and type 7 vaccine, live, oral
Yellow fever vaccine
Smallpox (vaccinia) vaccine, live
Smallpox and monkeypox vaccine, live, nonreplicating
Dengue tetravalent vaccine, live
Inactivated or subunit viral
Poliovirus vaccine inactivated (human diploid cell)
Poliovirus vaccine inactivated (monkey kidney cell)
Hepatitis A vaccine, inactivated
Hepatitis B (recombinant) vaccine
Hepatitis A vaccine, inactivated, and hepatitis B (recombinant) vaccine
Influenza A (H1N1) 2009 monovalent vaccine
Influenza virus vaccine, H5N1 (for national stockpile)
Influenza A (H5N1) virus monovalent vaccine, adjuvanted
Influenza virus vaccine (trivalent, types A and B)
Influenza virus vaccine (quadrivalent, types A and B)
Human papillomavirus bivalent (types 16, 18) vaccine, recombinant
Human papillomavirus quadrivalent (types 6, 11, 16, 18) vaccine, recombinant
Human papillomavirus 9-valent vaccine, recombinant
Japanese encephalitis virus vaccine, inactivated
Japanese encephalitis virus vaccine, inactivated, adsorbed
Rabies vaccine
Rabies vaccine adsorbed
Zoster vaccine recombinant, adjuvanted
Vectored viral
[illegible] vaccine, live

producing *recombinant subunit vaccines*. For example, the hepatitis B vaccine is generated by the insertion into yeast of hepatitis B genes coding for selected antigens. The yeast cells express these antigens, which are then purified and used in making a vaccine. A drawback to these vaccines is that even though they elicit an immune response, immunity is not guaranteed. Subunit vaccines usually are considered safe because they have no live replicating pathogen present.

Polysaccharides

Polysaccharide subunit vaccines utilize polysaccharide (sugar) antigens to induce an immune response. Bacterial cell walls are composed of peptidoglycan polysaccharides that help pathogens evade the immune system. This evasion mechanism is highly effective in infants and young children, making them more susceptible to infection. Unfortunately, these polysaccharides are not very immunogenic. Furthermore, the vaccines produced using polysaccharide antigens often induce suboptimal immune responses that result in only short-term immunity. Meningococcal infection caused by *Neisseria meningitidis* (groups A, C, W-135, and Y) and *pneumococcal* disease are polysaccharide subunit vaccines against bacterial pathogens. Conjugate subunit vaccines use a technology to bind polysaccharide from the bacterial capsule to a carrier protein, often diphtheria or tetanus toxoid. This sort of antigen combination can induce long-term protection in infants and adults. These vaccines provide protection against pathogens where plain polysaccharide vaccines fail to work in infants and provide more long-term protection in young children and adults. The *Haemophilus influenzae* type b (Hib) and *pneumococcal* (pneumococcal conjugate vaccine [PCV] 7 valent, PCV10 valent, PCV13 valent) vaccines are conjugate subunit vaccines recommended for children (see Table 40–1). The *meningococcal A* vaccine used in Africa is also an example of a conjugate subunit vaccine.

Surface Protein Subunit Vaccines

Protein-based subunit vaccines use purified proteins from the pathogen or recombinant proteins based on pathogen sequences to induce an immune response. Because these proteins may not be presented in fully native conformations (i.e., as in the live pathogen), some of the antibodies generated against these antigens may not bind efficiently to the live pathogen. Acellular pertussis and hepatitis B vaccines are examples of protein-based subunit vaccines. The hepatitis B vaccine contains the hepatitis B virus envelope protein made as an antigen produced in yeast cell culture.

Toxoids

Pathogenic bacteria such as *Clostridium tetani* and *Corynebacterium diphtheriae* induce disease (tetanus or diphtheria, respectively) through production of their toxins. Vaccines against these toxins, known as toxoid vaccines, are effective because they elicit an immune response that results in the production of toxin-specific neutralizing antibodies, preventing cell damage in the patient. Inactivated toxins (*toxoids*) are used as the immunogen; however, because these proteins often are not highly immunogenic, they must be adsorbed to adjuvants (aluminum or calcium salts) to increase their capacity to stimulate the immune response. Toxoid vaccines generally are safe because they do not contain live pathogens. In addition, these proteins usually are stable over a wide range of temperatures and humidities (Baxter, 2007).

DNA Vaccines

Sequencing the genome of a pathogen provides information that enables the production of a DNA vaccine against selected genetic material. A microbe's antigenic genes are selected and incorporated in synthetic DNA. Intramuscular or intradermal injection delivers this engineered DNA to antigen-presenting cells (APCs), which uptake the DNA and transcribe and translate it to produce antigenic proteins. These APCs present these antigens to both humoral and cellular immune system components to generate immunity. This type of vaccine poses no risk of infection, can easily be developed and produced, is cost-effective, is stable, and may provide long-term protection (Robinson et al., 2000). Disadvantages include its limit to protein antigens and the possibility of generating tolerance to that antigen because of low immunogenicity, thereby rendering [illegible] immunity

Many DNA vaccines are currently in experimental phases, but none has been licensed in the U.S. DNA vaccines for influenza virus, herpesvirus, flaviviruses like Zika virus, and others are in the early stages of development. A DNA vaccine against West Nile virus has been approved for veterinary use. Delivery platforms for enhancing efficacy of DNA vaccines (e.g., electroporation) are being developed.

mRNA Vaccines

One of the barriers to effectiveness of DNA vaccines is that the nucleic acids must not only be delivered into the cytoplasm of cells but also achieve nuclear import to localize with host cell DNA polymerases to produce messenger RNA (mRNA). Delivering mRNA instead leaps over this problem, but historically, RNA was difficult to use for several reasons. RNA is inherently unstable as it is susceptible to degradation by enzymes that are ubiquitous in biological settings, is difficult to deliver into cells, and can trigger cell programs inhibiting translation following recognition by Toll-like receptors and other host cell sensing mechanisms. Decades of research have overcome these obstacles, with recent successes. The cytoplasmic delivery and stability issues were surmounted by development of novel lipid nanoparticle formulations that protect the RNA and facilitate delivery to cells. The use of engineered RNAs, such as incorporation of modified nucleosides, allowed evasion of rapid host cell detection. As a result, several major successes occurred with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) vaccines in 2020 (discussed below), and these technologies are being investigated for novel vaccines for influenza, HIV-1, and other major pathogens.

Recombinant Vectors

A vector is a virus or bacterium that is used to deliver heterologous microbial genes to cells for expression in the vaccinee to elicit an immune response. Once the vector infects or transduces host cells, the selected antigens will be presented during the immune response to generate immunity. Both viruses and bacteria are being investigated as recombinant vectors for candidate vaccines. Virus vectors that have been used in candidate vaccines include many poxviruses (vaccinia virus, modified vaccinia Ankara, avian poxviruses, and others), many adenoviruses (of both human and primate origin), and other families of viruses.

Immunoglobulins

Structure

Vaccination results in the expansion and differentiation of B cells into long-lived memory cells, which provide long-term protection to secondary challenge, and plasma cells, which are immunoglobulin (antibody)-generating cells that produce large quantities of these proteins. Antibodies in the body are found in two forms, either membrane bound on B cells as B-cell receptors (BCRs) that can deliver signals to activate and induce B-cell differentiation after antigen ligation or as soluble effector molecules that neutralize antigens throughout the body. Antibodies are heterodimeric proteins composed of two chains, the light and heavy chains. Both light and heavy chains contain variable regions in the N-terminal region of the protein that engage antigens. Naïve B cells express BCRs with low affinity to antigen. These BCRs can be selected through VDJ (variable, diversity, joining) recombination via the activity of RAG (recombination-activating gene) enzymes. Antibody diversity is achieved through antigen-binding site region variation, combinatorial diversity of gene segments, and combination of light and heavy regions, an overall diversity program that can result in an antibody repertoire of potentially 10^{16} to 10^{18} different molecules, ensuring that a unique B cell in the body will exist to recognize any foreign antigen. In addition to this diversity, antibodies also can undergo class-switch recombination in which the constant region of the heavy chain can be switched, based on cytokine signals by T cells, to tailor antibody specificity and function. It is this portion of the antibody that determines the five main isotypes: IgM, IgD, IgG, IgA, and IgE. These isotypes differ in size, Fc (fragment crystallizable) receptor binding, ability to fix complement, and appropriate isotypes for specific pathogens (Schroeder and Cavacini, 2010).

Antibody diversity can be further enhanced following antigen recognition by memory B cells and help from $CD4^+$ T cells. B cells can further strengthen their antibody affinity by mutating their variable regions, and with repetitive antigen stimulation, the affinity of the B-cell clones selected for expansion by binding to antigen can increase further. This mechanism explains why some vaccines, like the one for hepatitis B, are most immunogenic when delivered in three doses. This repeated antigen stimulation induces somatic hypermutation of antibody variable genes to increase antibody potency. Activation-induced cytidine deaminase (AID) is a key enzyme that mediates class-switch recombination and somatic hypermutation. Human patients with defective AID suffer from hyper-IgM syndrome and are unable to class-switch their antibodies, which makes them more susceptible to certain infections.

Manufactured antibodies can be used for passive immunization; for a list of available antibodies, see Table 40–4. Such monoclonal antibodies (mAbs) are biologicals that have become some of the most important drug classes of our era. To date, mAbs have been implemented most effectively for use in cancer immunotherapy and management of autoimmune diseases. Several mAbs have been advanced for infectious diseases, including for respiratory syncytial virus (RSV), EBOV, SARS-CoV-2, and *Clostridium difficile* toxin. As the cost of production of mAbs continues to fall, more of these biologicals will likely be used for prophylaxis or treatment of infectious diseases.

Antibody Classes and Functions

Immunoglobulin M

The first antibody class expressed by B cells is IgM. IgM molecules are membrane-bound monomers found on circulating mature B cells. When mature B cells are antigen stimulated, they generate IgM pentamers that are secreted. IgM antibodies, also called natural antibodies, have low affinity as monomers, but their avidity can increase in their pentameric structure, which improves epitope binding to repeating antigens on pathogens. These antibodies are associated with a primary immune response; they are found at mucosal surfaces and constitute 10% of the antibody content of serum. IgM molecules function by coating their specific antigen to target the pathogen for destruction via phagocytosis or to induce complement fixation to kill the pathogen (Schroeder and Cavacini, 2010).

Immunoglobulin D

Like IgM molecules, IgD molecules are also expressed on naïve B cells that have not been activated by their specific antigen and thus have not undergone somatic hypermutation. They are expressed as monomers on the surface of B cells and can also be secreted; they represent less than 0.5% of the antibody in the serum (Schroeder and Cavacini, 2010). The exact function of IgD antibody is not fully known, but it can bind bacterial proteins through its constant region (Riesbeck and Nordstrom, 2006).

Immunoglobulin G

The IgG antibodies exist as monomers, represent about 70% of the antibody in circulation, and have been the most studied. Among immunoglobulins, IgGs have the longest $t_{1/2}$ in serum and are generated with high affinity after affinity maturation. The constant region of the heavy chain can further lead to diversity in the structure of these antibodies to generate four subclasses: IgG1, IgG2, IgG3, and IgG4. These subclasses are named based on their concentrations in serum, with IgG1 the most abundant and IgG4 the least. IgG1, IgG2, and IgG3 subclasses can activate complement to opsonize pathogens, but IgG4 cannot. These antibodies can also differ in their ability and affinity to engage Fc receptors, which further enhances their effector functions. All IgG subclasses cross the placenta to provide passive immunity to the fetus. Allotypes for IgG exist, conferring differences between individuals, especially for IgG3 in which the exact length of the antibody hinge region varies between allotypes.

TABLE 40–4 ■ THERAPEUTIC MONOCLONAL ANTIBODIES APPROVED IN THE EUROPEAN UNION AND THE U.S., JULY 2021

ANTIBODY	TARGET; *ANTIBODY TYPE*	THERAPEUTIC USE
Abciximab	GPIIb/IIIa; *chimeric IgG1 Fab*	Prevention of blood clots in angioplasty
Adalimumab	TNF; *human IgG1*	Rheumatoid arthritis
Ado-trastuzumab emtansine	HER2; *humanized IgG1; immunoconjugate*	Breast cancer
Aducanumab	Amyloid beta; *human IgG1*	Alzheimer's disease
Alemtuzumab	CD52; *humanized IgG1*	Multiple sclerosis
Alirocumab	PCSK9; *human IgG1*	Lowering cholesterol
Amivantamab, amivantamab-vmjw	EGFR, cMET; *human bispecific IgG1*	Non–small cell lung cancer with EGFR exon 20 insertion mutations
Ansuvimab-zykl	Ebola virus glycoprotein; *human IgG1*	Ebola virus infection
Atezolizumab[a]	PD-L1; *humanized IgG1*	Bladder cancer
Atoltivimab, maftivimab, and odesivimab-ebgn	Ebola virus; *cocktail of 3 human IgG1*	Ebola virus infection
Avelumab	PD-L1; *human IgG1*	Merkel cell carcinoma
Basiliximab	IL-2R; *chimeric IgG1*	Prevention of kidney transplant rejection
Belantamab mafodotin, belantamab mafodotin-blmf	B-cell maturation antigen; *humanized IgG1 ADC*	Multiple myeloma
Belimumab	BLyS; *human IgG1*	Systemic lupus erythematosus
Benralizumab	IL-5Rα; *humanized IgG1*	Asthma
Bevacizumab	VEGF; *humanized IgG1*	Colorectal cancer
Bezlotoxumab	*Clostridium difficile* toxin B; *human IgG1*	*C. difficile* infections
Blinatumomab	CD19, CD3; *murine bispecific tandem scFv*	Acute lymphoblastic leukemia
Brentuximab vedotin	CD30; *chimeric IgG1; immunoconjugate*	Hodgkin lymphoma, systemic anaplastic large cell lymphoma
Brodalumab	IL-17RA; *human IgG2*	Plaque psoriasis
Brolucizumab, brolucizumab-dbll	VEGF-A; *humanized scFv*	Neovascular age-related macular degeneration
Burosumab, burosumab-twza	FGF23; *human IgG1*	X-linked hypophosphatemia
Canakinumab	IL-1β; *human IgG1*	Muckle-Wells syndrome
Caplacizumab, caplacizumab-yhdp	von Willebrand factor; *humanized nanobody*	Acquired thrombotic thrombocytopenic purpura
Catumaxomab[b]	EPCAM/CD3; *rat/mouse bispecific mAb*	Malignant ascites
Cemiplimab, cemiplimab-rwlc	PD-1; *human mAb IgG4*	Cutaneous squamous cell carcinoma
Certolizumab pegol	TNF; *humanized Fab, pegylated*	Crohn disease
Cetuximab	EGFR; *chimeric IgG1*	Colorectal cancer
Crizanlizumab; crizanlizumab-tmca	CD62 (aka P-selectin); *humanized IgG2*	Sickle cell disease
Daclizumab	IL-2R; *humanized IgG1*	Multiple sclerosis
Daratumumab	CD38; *human IgG1*	Multiple myeloma
Denosumab	RANK-L; *human IgG2*	Bone loss
Dinutuximab	GD2; *chimeric IgG1*	Neuroblastoma
Dostarlimab, dostarlimab-gxly	PD-1; *humanized IgG4*	Endometrial cancer
Dupilumab	IL-4Rα/*human IgG4*	Eczema
Durvalumab	PD-L1/*human IgG1*	Urothelial carcinoma
Eculizumab	C5; *humanized IgG2/4*	Paroxysmal nocturnal hemoglobinuria
Efalizumab	CD11a; *humanized IgG1*	Psoriasis
Elotuzumab	SLAMF7; *humanized IgG1*	Multiple myeloma
Emapalumab, emapalumab-lzsg	IFNγ; *human IgG1*	Primary hemophagocytic lymphohistiocytosis

Eptinezumab, eptinezumab-jjmr	CGRP; *humanized IgG1*	Migraine prevention
Erenumab, erenumab-aooe	CGRP receptor; *human IgG2*	Migraine prevention
Evinacumab	Angiopoietin-like 3; *human IgG4*	Homozygous familial hypercholesterolemia
Evolocumab	PCSK9; *human IgG2*	Lowering cholesterol
Fremanezumab, fremanezumab-vfrm	CGRP; *humanized IgG2*	Migraine prevention
Galcanezumab, galcanezumab-gnlm	CGRP; *humanized IgG4*	Migraine prevention
Gemtuzumab ozogamicin[a]	CD33; *humanized IgG4*	Acute myeloid leukemia
Golimumab	TNF; *human IgG1*	Rheumatoid and psoriatic arthritis, ankylosing spondylitis
Ibalizumab, ibalizumab-uiyk	CD4; *humanized IgG4*	HIV infection
Ibritumomab tiuxetan	CD20; *murine IgG1*	Non-Hodgkin lymphoma
Idarucizumab	Dabigatran; *humanized Fab*	Dabigatran excess (reversing anticoagulation)
Inebilizumab, inebilizumab-cdon	CD19; *humanized IgG1*	Neuromyelitis optica spectrum disorders
Infliximab	TNF; *chimeric IgG1*	Crohn disease
Inotuzumab ozogamicin	CD22; *humanized IgG4; ADC*	Acute lymphoblastic leukemia
Isatuximab, isatuximab-irfc	CD38; *chimeric IgG1*	Multiple myeloma
Guselkumab	IL-23 p19; *human IgG1*	Plaque psoriasis
Ipilimumab	CTLA-4; *human IgG1*	Metastatic melanoma
Ixekizumab	IL-17A; *humanized IgG4*	Psoriasis
Lanadelumab, lanadelumab-flyo	Plasma kallikrein; *human IgG1*	Hereditary angioedema attacks
Loncastuximab tesirine, loncastuximab tesirine-lpyl	CD19; *humanized IgG1 ADC*	Diffuse large B-cell lymphoma
Margetuximab-cmkb	HER2; *chimeric IgG1*	HER2-positive metastatic breast cancer
Mepolizumab	IL-5; *hIgG1*	Severe eosinophilic asthma
Mogamulizumab, mogamulizumab-kpkc	CCR4; *humanized IgG1*	Mycosis fungoides or Sézary syndrome
Moxetumomab pasudotox, moxetumomab pasudotox-tdfk	CD22; *murine IgG1 dsFv immunotoxin*	Hairy cell leukemia
Muromonab-CD3	CD3; *murine IgG2a*	Reversal of kidney transplant rejection
Natalizumab	α4 integrin; *humanized IgG4*	Multiple sclerosis
Naxitamab-gqgk	GD2; *humanized IgG1*	High-risk neuroblastoma and refractory osteomedullary disease
Necitumumab	EGFR; *human IgG1*	Non–small cell lung cancer
Nivolumab	PD1; *human IgG4*	Melanoma, non–small cell lung cancer, renal cell carcinoma
Obiltoxaximab[a]	Protective antigen *of Bacillus anthracis* exotoxin[c]; *chimeric IgG1*	Prevention of inhalational anthrax
Obinutuzumab	CD20; *humanized IgG1; glycoengineered*	Chronic lymphocytic leukemia
Ocrelizumab	CD20; *human IgG1*	Multiple sclerosis
Ofatumumab	CD20; *human IgG1*	Chronic lymphocytic leukemia
Olaratumab	PDGFR; *human IgG1*	Soft-tissue sarcoma
Omalizumab	IgE; *humanized IgG1*	Asthma
Palivizumab	RSV; *humanized IgG1*	Prevention of respiratory syncytial virus infection
Panitumumab	EGFR; *human IgG2*	Colorectal cancer

(*Continued*)

TABLE 40–4 ■ THERAPEUTIC MONOCLONAL ANTIBODIES APPROVED IN THE EUROPEAN UNION AND THE U.S., JULY 2021 (*CONTINUED*)

ANTIBODY	TARGET; *ANTIBODY TYPE*	THERAPEUTIC USE
Pembrolizumab	PD1; *humanized IgG4*	Melanoma, non–small cell carcinoma
Pertuzumab	HER2; *humanized IgG1*	Breast cancer
Polatuzumab vedotin, polatuzumab vedotin-piiq	CD79b; *humanized IgG1 ADC*	Diffuse large B-cell lymphoma
Ramucirumab	VEGFR2; *human IgG1*	Gastric cancer
Ranibizumab	VEGF; *humanized IgG1 Fab*	Macular degeneration
Ravulizumab, ravulizumab-cwvz	C5; *humanized IgG2/4*	Paroxysmal nocturnal hemoglobinuria
Raxibacumab[a]	*B. anthracis* protective antigen[c]; *human IgG1*	Prevention of inhalational anthrax
Reslizumab	IL-5; *humanized IgG4*	Asthma
Risankizumab, risankizumab-rzaa	IL-23 p19; *humanized IgG1*	Plaque psoriasis
Rituximab	CD20; *chimeric IgG1*	Non-Hodgkin lymphoma
Romosozumab, romosozumab-aqqg	Sclerostin; *humanized IgG2*	Osteoporosis in postmenopausal women at increased risk of fracture
Sacituzumab govitecan; sacituzumab govitecan-hziy	TROP-2; *humanized IgG1 ADC*	Triple-negative breast cancer
Sarilumab	IL-6R; *human IgG1*	Rheumatoid arthritis
Satralizumab, satralizumab-mwge	IL-6R; *humanized IgG2*	Neuromyelitis optica spectrum disorder
Secukinumab	IL-17A; *human IgG1*	Psoriasis
Siltuximab	IL-6; *chimeric IgG1*	Castleman disease
Tafasitamab, tafasitamab-cxix	CD19; *humanized IgG1*	Diffuse large B-cell lymphoma
Teprotumumab, teprotumumab-trbw	IGF-1R; *human IgG1*	Thyroid eye disease
Tildrakizumab; tildrakizumab-asmn	IL-23 p19; *humanized IgG1*	Plaque psoriasis
Tocilizumab	IL-6R; *humanized IgG1*	Rheumatoid arthritis
Tositumomab-I^{131}[a]	CD20; *murine IgG2a*	Non-Hodgkin lymphoma
Trastuzumab	HER2; *hIgG1*	Breast cancer
[fam-]trastuzumab deruxtecan, fam-trastuzumab deruxtecan-nxki	HER2; *humanized IgG1 ADC*	HER2-positive metastatic breast cancer
Ustekinumab	IL-12/23; *human IgG1*	Psoriasis
Vedolizumab	α4β7 integrin; *humanized IgG1*	Ulcerative colitis, Crohn disease

[a]Not approved in the European Union.
[b]Not approved in the U.S.
[c]Inhibits the binding of the protective antigen to its membrane receptors, thereby preventing the intracellular entry of the anthrax lethal factor and edema factor, the enzymatic toxin components responsible for the pathogenic effects of anthrax toxin.

Vaccines predominantly induce these antibody types, which become important during the secondary immune response to inactivate pathogens. Different subclasses are selected during the secondary antibody response. In designing vaccines, scientists must determine which antibody subclass will provide the optimal response. In addition to complement and opsonization, IgG antibodies can directly neutralize toxins and viruses (Schroeder and Cavacini, 2010).

Immunoglobulin A

The IgA antibody class is expressed as monomers or dimers and represents about 15% of the antibodies in serum, slightly higher than IgM antibodies. IgA antibodies are found at the highest concentrations at mucosal surfaces and in saliva and breast milk (Woof and Mestecky, 2005). In late pregnancy and the early postnatal period, female mammary glands produce colostrum; more than half of the protein content of colostrum that breastfeeding neonates consume is IgA antibodies. IgA is primarily a monomer in the serum but a dimer at mucosal sites.

IgA antibodies have two subclasses, IgA1 and IgA2, that differ only slightly in their structures. IgA1 antibodies are longer than IgA2 antibodies and are therefore more sensitive to degradation. IgA2 is more stable and is found primarily in mucosal secretions, in contrast to IgA1, which predominates in serum. IgA antibodies work via direct neutralization of viruses, bacteria, and toxins to protect mucosal tissues and to prevent antigen binding to host cells that damage or infect mucosal tissues. IgA

antibodies within cells may also prevent pathogen tropism. Even though IgA antibodies do not lead to complement fixation, neutrophils can uptake them to mediate antibody-dependent cell-mediated cytotoxicity (Schroeder and Cavacini, 2010).

Immunoglobulin E

The IgE antibody class is present at the lowest serum concentration, less than 0.01% of circulating antibodies, and has the shortest $t_{1/2}$. IgE binds with very high affinity to Fcγ receptors, receptors that Langerhans and mast cells, basophils, and eosinophils express. Fc receptor engagement also results in FcγR upregulation on bound cells. These antibodies recognize antigens on parasitic worms when they are cross-linked on granulocytes; the cells degranulate to release inflammatory mediators to destroy the parasite. IgE antibodies are also relevant in mediating allergic reactions by recognizing innocuous antigens, such as bee venom and peanut antigen.

Patients who develop allergic reactions generate memory B cells that produce IgE antibodies to specific antigens. The granulocytes become coated with IgE antibodies and on antigen reexposure (e.g., a bee's sting or peanuts), the antigen cross-links IgEs, leading to granulocyte degranulation, which can result in anaphylactic shock. Therapies are in development to generate and use antibodies against soluble IgE molecules to prevent their uptake by granulocytes. For a list of approved mAbs, see Table 40–4.

Monoclonal Antibodies for RSV

Palivizumab is a humanized murine mAb that is licensed for use in high-risk infants to prevent hospitalization due to RSV. The drug was first approved in 1998, but the recommendations for use have evolved over time. The following recommendations are provided by the American Academy of Pediatrics as a policy statement in the organization's publication *Red Book*, with the policy last reaffirmed in February 2019.

In the first year of life, *palivizumab* prophylaxis is recommended for infants born before 29 weeks, 0 days' gestation. Prophylaxis is not recommended for otherwise healthy infants born at or after 29 weeks, 0 days' gestation. Prophylaxis in the first year of life is recommended for preterm infants with chronic lung disease of prematurity, defined as birth at less than 32 weeks, 0 days' gestation and a requirement for greater than 21% oxygen for at least 28 days after birth. Clinicians may administer prophylaxis in the first year of life to certain infants with hemodynamically significant heart disease. Clinicians may administer up to a maximum of 5 monthly doses of *palivizumab* (15 mg/kg per dose) during the RSV season to infants who qualify for prophylaxis in the first year of life. Qualifying infants born during the RSV season may require fewer doses. For example, infants born in January would receive their last dose in March. Prophylaxis is *not* recommended in the second year of life except for children who required at least 28 days of supplemental oxygen after birth and who continue to require medical intervention (supplemental oxygen, chronic corticosteroid, or diuretic therapy). Monthly prophylaxis should be discontinued in any child who experiences a breakthrough RSV hospitalization. Children with pulmonary abnormality or neuromuscular disease that impairs the ability to clear secretions from the upper airways may be considered for prophylaxis in the first year of life. Children younger than 24 months who will be profoundly immunocompromised during the RSV season may be considered for prophylaxis. Insufficient data are available to recommend *palivizumab* prophylaxis for children with cystic fibrosis or Down syndrome. The burden of RSV disease and costs associated with transport from remote locations may result in a broader use of *palivizumab* for RSV prevention in Alaska Native populations and possibly in selected other American Indian populations. *Palivizumab* prophylaxis is not recommended for prevention of healthcare-associated RSV disease.

Monoclonal Antibodies for EBOV

Atoltivimab/maftivimab/odesivimab (developed as REGN-EB3; brand name Inmazeb) is a cocktail of three mAbs for the treatment of EBOV. In the PALM clinical trial and as part of an expanded access program conducted in the Democratic Republic of the Congo during an EBOV outbreak in 2018 to 2019, of participants who received the cocktail, 33.8% died after 28 days, compared to 51% of the participants who received a control. This combination was the first FDA-approved treatment for EBOV, approved for use in the U.S. in October 2020 with orphan drug and breakthrough therapy designations. The cocktail also was given an orphan drug designation by the European Medicines Agency (EMA).

Ebanga (*ansuvimab*; originally mAb114) is a single human mAb for treating EBOV infection in adults and children. Ebanga halved the mortality rate of EBOV infection (from ~70% to ~34%). The FDA issued authorization for Ebanga in late 2020.

Monoclonal Antibodies for SARS-CoV-2

Human mAbs against SARS-CoV-2 are a rapidly evolving group of agents. Many were developed rapidly during the SARS-CoV-2 outbreak and tested in the clinic. Several anti–SARS-CoV-2 mAbs have received Emergency Use Authorization (EUA) from the FDA.

Bamlanivimab (also known as LY-CoV555 and LY3819253) is a neutralizing mAb that targets the receptor binding domain (RBD) of the S protein of SARS-CoV-2. *Etesevimab* (also known as LY-CoV016 and LY3832479) is a second mAb that binds to a different but overlapping epitope in the RBD of the SARS-CoV-2 spike protein. *Casirivimab* (also designated REGN10933) and *imdevimab* (REGN10987) are recombinant human mAbs that bind to nonoverlapping epitopes of the spike protein RBD. Two combinations (*bamlanivimab* plus *etesevimab* and *casirivimab* plus *imdevimab*) obtained EUA for the treatment of mild to moderate coronavirus disease 2019 (COVID-19) in nonhospitalized patients with laboratory-confirmed SARS-CoV-2 infection who are at high risk for progressing to severe disease and/or hospitalization. Because SARS-CoV-2 antigenic variants of concern emerged in circulation that evaded the action of *bamlanivimab*, the *bamlanivimab* plus *etesevimab* combination, and the *casirivimab* plus *imdevimab* combination, the FDA subsequently revoked the EUA for those drugs. In May 2021, the FDA granted an EUA for *sotrovimab* (VIR-7831), an investigational single-dose mAb, for the treatment of mild-to-moderate COVID-19 in adults and pediatric patients (≥12 years of age weighing ≥40 kg) with positive results of direct SARS-CoV-2 viral testing and who are at high risk for progression to severe COVID-19, including hospitalization or death. A combination of two long-acting human mAbs (AZD7442) that were modified in an Fc format for long-half life (long-acting antibody) obtained FDA EUA in December 2021 for prevention of disease in high-risk individuals and obtained a marketing authorization from the European Marketing Agency in March 2022 for any individual 12 years or older. Many other mAbs for SARS-CoV-2 are in earlier stages of clinical development.

Specific Conventional Vaccines Recommended in the U.S.

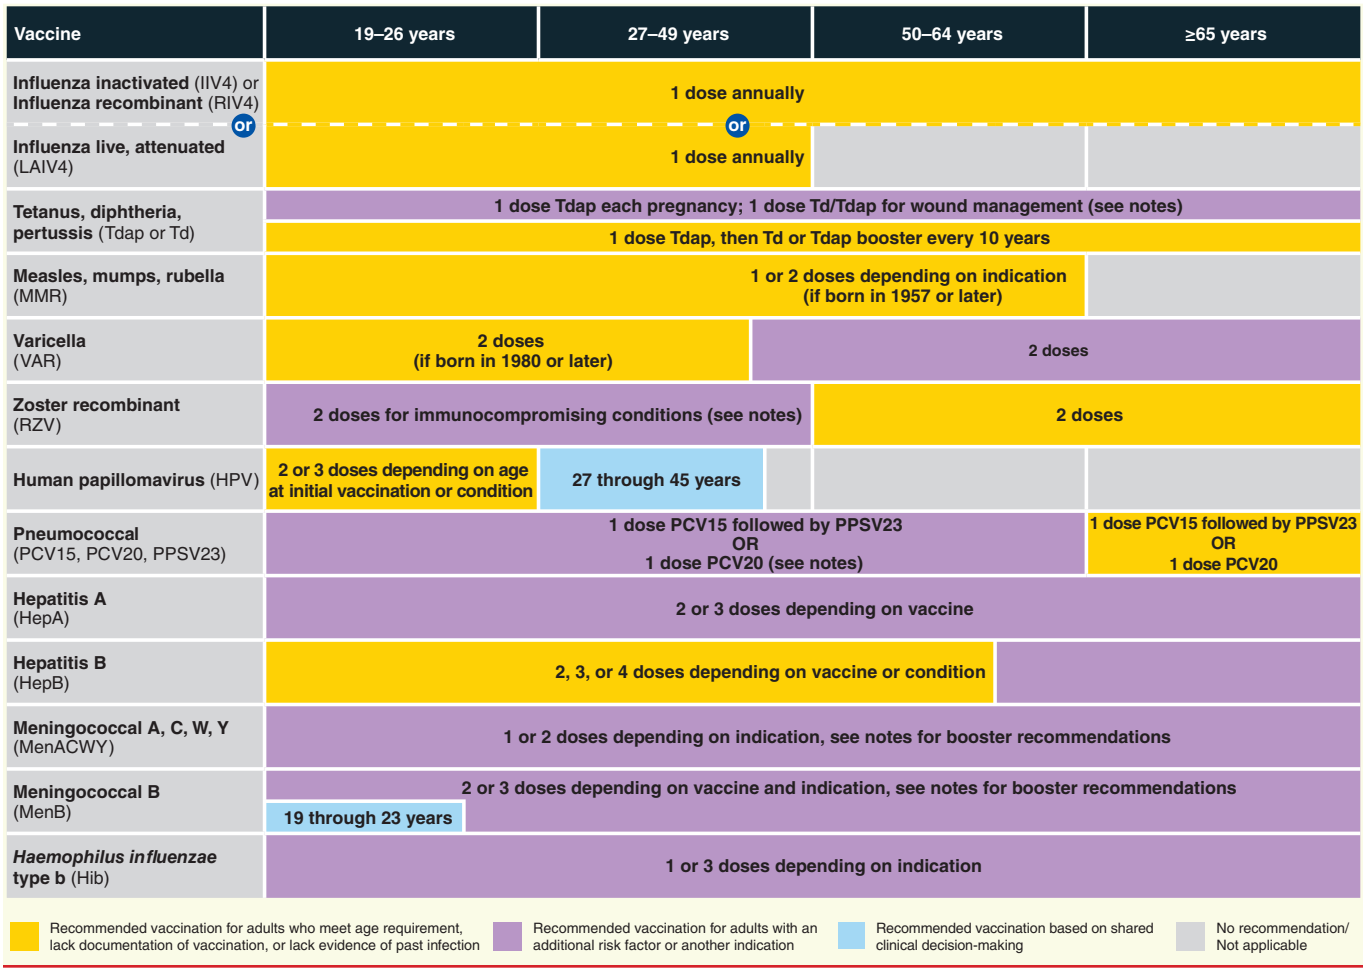
The Centers for Disease Control and Prevention (CDC) maintains tables listing currently recommended vaccinations for various susceptibilities throughout life. Next is a discussion of the properties and schedule of administration for the vaccinations recommended from birth to elder adulthood. The vaccines are grouped by the target type (bacterium, virus, etc.) and then by vaccine type, as discussed in the previous section. See Table 40–1 for infant and childhood vaccination schedules. For a complete list of the adult recommended immunizations and immunization schedule, see Tables 40–5 and 40–6.

Vaccines for Bacteria

Bacterial Toxoid Vaccines: Diphtheria and Tetanus

Tetanus Toxoid Vaccine. Tetanus is a disease characterized by prolonged spasms and tetany caused by the toxin secreted by the bacterium *C. tetani*, which enters from environmental sources through wounds. Tetanus toxin enters the nervous system and by retrograde transport reaches the inhibitory interneurons of the spinal cord, where the active fragment cleaves synaptobrevin (see Figures 10–3 to 10–6), thereby inhibiting exocytosis of neurotransmitter from these nerve cells and resulting in

TABLE 40–5 ■ RECOMMENDED IMMUNIZATION SCHEDULE FOR ADULTS AGED 19 YEARS OR OLDER BY AGE GROUP, U.S., 2022



NOTE: The above recommendations are reprinted from the website of the Centers for Disease Control and Prevention (CDC) and should be read along with the footnotes of this schedule, available on the CDC website: https://cdc.gov/vaccines/schedules/.

uninhibited skeletal muscle contraction. The toxoid is produced by deactivating toxin isolated from the bacterium using formaldehyde. Immunization usually begins at about age 2 months, as a component of the combination vaccine DTaP (diphtheria and tetanus toxoids and acellular pertussis) that is given to infants. Tetanus toxoid is included in several combination vaccine formulations. DTaP is the vaccine used in children younger than age 7; Tdap (tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis) and Td (tetanus toxoid and reduced diphtheria toxoid), given at later ages, are booster immunizations that offer continued protection from those diseases for adolescents and adults. In these designations, upper- and lowercase letters represent the comparative quantity of antigen present. Thus, the shared uppercase *T* indicates there is about the same amount of tetanus toxoid in DTaP, Tdap, and Td. The uppercase *D* and *P* in the childhood formulation indicate that there is more diphtheria and pertussis antigen in DTaP than in Tdap or Td.

Diphtheria Toxoid Vaccines. Diphtheria is a disease caused by a secreted toxin of the aerobic gram-positive bacterium *C. diphtheriae*; toxin production is under control of the bacterial systems, but the structural gene for toxin production is contributed by a β phage that infects all pathogenic strains of *C. diphtheriae*. The A subunit of the toxin is an ADP-ribosylase; following its entry into a cell, this subunit ADP-ribosylates eukaryotic elongation factor 2 (eEF-2) and thereby inhibits protein translation in human cells (Gill et al., 1973). The throat of the victim becomes swollen and sore during infection, and the toxin causes damage to myelin sheaths in the nervous system, leading to loss of sensation or motor control. The vaccine, which has been used for nearly 80 years, is a toxoid that is produced by treating toxin with formalin. The toxoid is used to immunize infants beginning at about 2 months, typically as part of the combination DTaP vaccine. The diphtheria toxin also has been detoxified genetically by introduction of point mutations that abrogate enzymatic activity but allow retention of binding activity; for instance, the mutant diphtheria toxin protein CRM_{197} (cross-reactive material) is the protein carrier for a licensed Hib vaccine.

Pertussis Vaccines. Pertussis, or whooping cough, is a respiratory tract disease characterized by prolonged paroxysmal coughing and sometimes respiratory failure; it is caused by the gram-negative coccobacillus *Bordetella pertussis*. The secreted pertussis toxin has an A subunit that, once in the cell cytosol, ADP-ribosylates the α subunit of the G_i protein that couples inhibitory G protein-coupled receptor (GPCR) signaling to adenylyl cyclase to reduce cyclic AMP production. After ADP-ribosylation, $G_{i\alpha}$ becomes inactive, and GPCR-mediated reduction of cyclic AMP production is abolished. The physiological sequelae of this action of pertussis toxin are thought to contribute to the constellation of symptoms of whooping cough. Routine vaccination typically begins as part of the childhood combination DTaP vaccine series. It is also appropriate to immunize healthy adults, adolescents, and pregnant mothers as pertussis does occur throughout life due to waning immunity. There are two licensed pertussis vaccines, the historical inactivated organism "whole-cell" vaccine used in the past in the U.S. and still in many other countries and a second "acellular" formulation that incorporates antigen fragments derived from the organism. Both vaccines are immunogenic and protective. The whole-cell vaccine appears to induce more durable

TABLE 40–6 ■ RECOMMENDED IMMUNIZATION SCHEDULE FOR ADULTS AGED 19 YEARS OR OLDER BY MEDICAL CONDITION AND OTHER INDICATIONS, U.S., 2022

Vaccine	Pregnancy	Immuno-compromised (excluding HIV infection)	HIV infection CD4 percentage and count		Asplenia, complement deficiencies	End-stage renal disease, or on hemodialysis	Heart or lung disease; alcoholism[1]	Chronic liver disease	Diabetes	Health care personnel[2]	Men who have sex with men
			<15% or <200 mm^3	≥15% and ≥200 mm^3							
IIV4 or RIV4	1 dose annually										
or										or	
LAIV4	Contraindicated					Precaution				1 dose annually	
Tdap or Td	1 dose Tdap each pregnancy	1 dose Tdap, then Td or Tdap booster every 10 years									
MMR	Contraindicated*	Contraindicated	1 or 2 doses depending on indication								
VAR	Contraindicated*	Contraindicated		2 doses							
RZV		2 doses at age ≥19 years		2 doses at age ≥50 years							
HPV	Not Recommended*	3 doses through age 26 years	2 or 3 doses through age 26 years depending on age at initial vaccination or condition								
Pneumococcal (PCV15, PCV20, PPSV23)		1 dose PCV15 followed by PPSV23 OR 1 dose PCV20 (see notes)									
HepA	2 or 3 doses depending on vaccine										
HepB	3 doses (see notes)	2, 3, or 4 doses depending on vaccine or condition									
MenACWY	1 or 2 doses depending on indication, see notes for booster recommendations										
MenB	Precaution	2 or 3 doses depending on vaccine and indication, see notes for booster recommendations									
Hib		3 doses HSCT[3] recipients only			1 dose						

Recommended vaccination for adults who meet age requirement, lack documentation of vaccination, or lack evidence of past infection

Recommended vaccination for adults with an additional risk factor or another indication

Recommended vaccination based on shared clinical decision-making

Precaution—vaccination might be indicated if benefit of protection outweighs risk of adverse reaction

Contraindicated or not recommended—vaccine should not be administered.

*Vaccinate after pregnancy.

No recommendation/ Not applicable

1. Precaution for LAIV4 does not apply to alcoholism. **2.** See notes for influenza; hepatitis B; measles, mumps, and rubella; and varicella vaccinations. **3.** Hematopoietic stem cell transplant.

NOTE: The above recommendations are reprinted from the website of the Centers for Disease Control and Prevention (CDC) and should be read along with the footnotes of this schedule available on the CDC website: https://cdc.gov/vaccines/schedules/.

immunity, but the acellular vaccine causes about one-tenth the rate of side effects (e.g., fever, injection site pain, erythema). Most developed countries now use acellular pertussis vaccine to reduce the reactivity profile, but many other countries continue to use the whole-cell vaccine successfully because the response is equally efficacious and more durable and the vaccine is economical.

Conjugated Bacterial Polysaccharide Vaccines

Haemophilus influenzae *Type B Vaccine.* *Haemophilus influenzae* is a major cause of life-threatening childhood bacterial diseases, including buccal, preseptal, and orbital cellulitis, epiglottitis, bacteremia with sepsis, and meningitis. Universal vaccination with the Hib vaccine has nearly eliminated these diseases in the U.S. The Hib vaccine is a polysaccharide-protein conjugate that confers immunity to the disease by inducing antibodies to the capsular polysaccharide polyribosylribitol phosphate (PRP). The Hib polysaccharide has been conjugated to diverse proteins, including the mutant diphtheria protein CRM_{197} (a vaccine termed HbOC [Hib oligosaccharide conjugate]); the meningococcal group B outer membrane protein C (a vaccine termed PRP-OMPC [PRP outer membrane protein conjugate]); and tetanospasmin, which is a toxoid of the *C. tetani* neurotoxin (a vaccine termed PRP-T [PRP tetanus]). The vaccines all exhibit a high level of safety and immunogenicity. Interestingly, widespread immunization not only reduces disease in those vaccinated but also reduces nasal carriage of the bacterium, resulting in reduced transmission to even those not vaccinated and providing evidence of herd immunity.

Streptococcus pneumoniae *Vaccines.* The gram-positive encapsulated bacterium *S. pneumoniae* causes invasive diseases in infants and young children, including meningitis, bacteremia and sepsis, and pneumonia. There are myriad *S. pneumoniae* types, based on the capsular polysaccharide; thus, polyvalent vaccines are needed. Vaccines confer immunity by inducing type-specific antipolysaccharide antibodies. Two types of vaccines are available, *polysaccharide* and *conjugate* vaccines. The 23-valent polysaccharide vaccine contains long chains of capsular polysaccharides that are collected from inactivated bacteria. Polysaccharide vaccine is used in children older than 2 years and in at-risk adults. PCVs have been developed, and increasing numbers of serotypes have been incorporated over time. The combined 13 serotypes in PCV13 protect against most invasive disease in the U.S. Infants are given a primary series of PCV13 at ages 2, 4, and 6 months, with a booster at 12 to 15 months.

Neisseria meningitidis *Vaccines.* *Neisseria meningitidis* is a significant cause of invasive bacterial disease in childhood, causing sepsis and meningitis. As with *S. pneumoniae*, there are diverse types of polysaccharide; thus, type-specific anticapsular polysaccharide antibodies mediate protection against invasive disease. Therefore, multivalent vaccines are required for coverage against diverse strains. A licensed quadrivalent polysaccharide vaccine protects against four subtypes of meningococcus—designated A, C, Y, and W-135. The polysaccharide vaccine works only in children older than 2 years. A tetravalent meningococcal conjugate vaccine, also containing the A, C, Y, and W-135 subtypes, is available.

Four-component, protein-based meningococcal B vaccines (incorporating fHbp, NadA, NHBA, and PorA P1.4 proteins) have been developed to prevent septicemia and meningitis caused by serogroup B meningococcal strains. In the U.S., 11- to 12-year-old individuals should get a meningococcal conjugate vaccine, with a booster dose at 16 years old. Teens and young adults (16–23 years old) also may get a serogroup B meningococcal vaccine. The CDC also recommends meningococcal vaccination for other children and adults who are at increased risk for meningococcal disease.

Vaccines for Viruses

Poliovirus Vaccines

Polio is characterized by acute flaccid paralysis, against which the WHO and others are conducting a worldwide eradication campaign. There are two types of poliovirus vaccines in use. The first is a *live attenuated oral vaccine* in use since the early 1960s (the "Sabin vaccine"), containing attenuated poliovirus types I, II, and III, produced in monkey kidney cell tissue culture. The vaccine replicates in the intestine and induces systemic and mucosal immunity, but also is shed in the stool, sometimes transmitting to close contacts. Infection of most close contacts contributes to herd immunity in the human population. Rarely (about one case per million doses), partial revertant viruses occur that cause vaccine-associated paralytic poliomyelitis in contacts. In many parts of the world, live poliovirus vaccine is still used. The last known case of naturally acquired poliovirus disease acquired in the U.S. occurred in 1979; the U.S. discontinued use of the live vaccine in 2000. Live poliovirus vaccine is contraindicated in subjects with primary immunodeficiency. Pregnant women and children with symptomatic HIV infection should receive inactivated poliovirus vaccine (IPV).

The second type of vaccine is a *killed virus* preparation called *IPV* (the "Salk vaccine"). Killed vaccine induces mainly humoral immunity but still exhibits excellent efficacy against disease. IPV does not transmit virus to contacts and does not cause vaccine-associated paralysis. An enhanced-potency IPV vaccine has been available since 1998, and this IPV preparation is now a component of some combination vaccines.

Measles Virus Vaccines

The current measles vaccine is a live attenuated strain given subcutaneously. A live, "more attenuated" preparation of the Enders-Edmonston virus strain (designated the Moraten strain) is the MeV vaccine currently used in the U.S. Vaccination is initiated at 12 to 15 months of age in the U.S. because transplacentally acquired maternal antibodies inhibit immunogenicity of vaccine in the first year of life.

Mumps Virus Vaccine

Mumps virus causes a febrile illness most commonly associated with inflammation of the parotids and sometimes with more severe conditions, including aseptic meningitis. A live attenuated virus vaccine has been used exclusively since the 1970s. The Jeryl-Lynn vaccine (from a mixture of two strains) was isolated from the throat of the daughter of Maurice Hilleman, a noted vaccine developer. The vaccine is typically given as a component of the combination MMR (measles-mumps-rubella) or MMRV (measles-mumps-rubella-varicella) vaccine at 12 to 15 months of age and a second dose of MMR at 4 through 6 years of age. Although mumps outbreaks still occur even in vaccinated people in close-contact settings in the U.S., such as college dorms or close-knit religious communities, high vaccination coverage reduces the size and duration of those outbreaks.

Rubella Virus Vaccine

Rubella virus, the single member of the genus *Rubivirus* in the family *Togaviridae*, is spread by respiratory droplets and causes a mild infection with viremia. Rubella is harmful only to fetuses, and the effects can be devastating. A rubella infection during pregnancy can cause miscarriage, preterm birth, stillbirth, or various birth defects. The risks decrease as pregnancy progresses. The main goal of rubella immunization is to prevent congenital rubella syndrome. The live attenuated rubella virus vaccine is given subcutaneously, now usually as a component of MMR or MMRV vaccine, beginning between 12 and 15 months of age, and a second dose of MMR is given at 4 through 6 years of age. The live rubella virus vaccine strain RA 27/3 is grown in human diploid cell culture. In the U.S., universal immunization (both boys and girls) is used to reduce infection of pregnant women. As a result, rubella and congenital rubella syndrome have been eliminated in the U.S. Rubella vaccine is part of MMR or MMRV combination vaccines for universal immunization starting at 12 to 15 months, followed by a booster dose at school entry.

Varicella-Zoster Virus Vaccine

Varicella-zoster virus (VZV) is one of the most infectious agents that affect humans. It is spread by the respiratory route by small aerosol particles (cough, sneeze, etc.). Infection causes a febrile syndrome with vesicular rash, sometimes complicated by pneumonia or invasive bacterial skin disease. Congenital varicella syndrome can occur if varicella infection occurs during pregnancy. The vaccine used is the Oka strain of live attenuated VZV attenuated by sequential passage in cell monolayer cultures; it was licensed for universal immunization in the U.S. in 1995. The virus in the Oka/Merck vaccine in current use in the U.S. was further passaged in MRC-5 human diploid-cell cultures. The vaccine is often given as a part of the combination MMRV vaccine.

In 2017, the adjuvanted recombinant zoster vaccine (RZV or Shingrix), which is a two-dose, subunit vaccine containing recombinant VZV glycoprotein E in combination with a novel adjuvant (AS01B), was FDA approved for the prevention of herpes zoster in adults aged 50 years or older. The vaccine is given as two intramuscular doses, administered 2 to 6 months apart. The Advisory Committee on Immunization Practices (ACIP) recommends the recombinant zoster vaccine to prevent shingles in immunocompetent adults aged 50 years and older.

Hepatitis A Virus Vaccines

Hepatitis A virus infection causes acute liver disease after transmission by the fecal-oral route. An inactivated vaccine is recommended for all children, starting at 1 year of age. Two hepatitis A vaccines and one hepatitis A/hepatitis B combination vaccine are licensed in the U.S. The vaccine is given as a two-dose series.

Hepatitis B Virus Vaccines

Hepatitis B virus is transmitted between people by contact with blood or other bodily fluids, including by sexual contact and maternal transfer to fetus or infant. Hepatitis B virus can cause a life-threatening and sometimes chronic liver disease. All infants receive the hepatitis B vaccine. When the mother has active infection, the neonate is treated with both the vaccine and hepatitis B immune globulin. The vaccine is a recombinant protein produced in yeast that is the protective antigen, hepatitis B surface antigen. Chapter 63 covers the treatment of hepatitis B virus with nucleoside analogues and other agents.

Rotavirus Vaccines

Throughout the world, rotavirus is the most common cause of dehydrating diarrhea in infants. Four or five types (based on the surface proteins) cause severe disease. An early live attenuated vaccine (Rotashield) was withdrawn after association with intussusception (a segmental telescoping collapse of the intestine). Two similar vaccines are now used that are safe and immunogenic. One is an oral pentavalent human-bovine reassortant rotavirus vaccine (containing five reassortant rotaviruses developed from human and the Wistar Calf 3 bovine parent rotaviral strains) first licensed in the U.S. in 2006 (RotaTeq). This vaccine is administered in a three-dose schedule, at 2, 4, and 6 months of age. Another oral live attenuated rotavirus vaccine licensed in the U.S. is based on a single attenuated human strain (Rotarix) using a two-dose schedule beginning at 2 months of age. Rotavirus vaccines are used for universal immunization during infancy, with care to keep the initiation of the two- or three-dose series at a young age, as the rare rotavirus-associated intussusception risk with infection appears slightly higher at older ages.

Influenza Virus Vaccines

The orthomyxovirus influenza virus is a respiratory virus spread person-to-person by large-particle aerosols and fomites. The virus circulates

in humans in two major serotypes (types A and B); two distinct A subtypes, designated H1N1 (hemagglutinin type 1 and neuraminidase type 1) and H3N2 (hemagglutinin type 3 and neuraminidase type 2), currently cause disease ("the flu") in humans. Current seasonal influenza vaccines are trivalent, including A/H1N1, A/H3N2, and B antigens, or quadrivalent with a second type B antigen. Experimental vaccines are being tested for some avian influenza viruses (e.g., A/H5N1 and A/H7N9) that have infected humans and have pandemic potential. During each annual seasonal epidemic, point mutations occur in genes encoding the hemagglutinin and neuraminidase proteins, which are the principal targets for protective antibodies. This antigenic drift in circulating influenza strains has led to a process in which regulatory officials and manufacturers adjust the virus antigens in influenza vaccines every year. Occasionally, the segmented virus genome reasserts during coinfection of an animal with a human and an avian virus, a new virus arises (antigenic shift), and a pandemic occurs. Major worldwide pandemics occurred in 1918 (H1N1), 1957 (H2N2 [hemagglutinin type 2 and neuraminidase type 2]), 1968 (H3N2), and 2009 (a novel H1N1). Major adjustments of vaccines must be made in such instances.

Three principal types of influenza vaccines are licensed at present: inactivated vaccine, recombinant protein vaccine, and live attenuated virus vaccine. The inactivated vaccine is prepared by treating wild-type viruses prepared in eggs or cell culture with an inactivating agent. Inactivated vaccine often prevents more than half of serious influenza-related disease when the viruses chosen for the seasonal vaccine antigenically match the eventual epidemic virus well. The vaccine is most effective at preventing severe respiratory disease and influenza-related hospitalizations.

All persons aged 6 months and older should be vaccinated. Those at most risk of severe disease and in most need of vaccine are infants, young children, people older than 65 years, pregnant women, and those with chronic health conditions or immunodeficiency. This vaccine is contraindicated in those who have had a life-threatening allergic reaction after a dose of influenza vaccine or have a severe allergy to any component of the vaccine, some of which contain a small amount of egg protein. Some people with a history of Guillain-Barré syndrome should not receive this vaccine. The vaccine is usually given as a single dose each year, although children 6 months through 8 years of age may need two doses during a single influenza season. Some inactivated influenza vaccines (IIVs) contain a small amount of the preservative thimerosal (see Preservatives, Including Thimerosal). Although any association with developmental disorders has been disproven, public concern about this topic has led to the development of thimerosal-free IIVs.

The second type of nonreplicating influenza vaccine is a purified recombinant hemagglutinin (HA) protein vaccine. A complementary DNA encoding the HA antigen of choice is used to make a recombinant baculovirus (a virus that infects invertebrates). The recombinant baculovirus is used to deliver the HA gene to an FDA-qualified insect cell line to produce large amounts of the HA antigen.

The third principal type of influenza vaccine is a trivalent or quadrivalent live attenuated virus vaccine that is administered topically by nasal spray. New vaccines are prepared each year to address antigenic drift by reasserting genes encoding the current HA and neuraminidase antigens with a virus genetic background containing internal viral genes with well-defined attenuating mutations. The vaccine is licensed in the U.S. for persons 2 to 49 years of age. In some pediatric studies, the live attenuated vaccine appeared to provide a higher level of protection than inactivated vaccine; however, CDC vaccine effectiveness data from the influenza seasons in 2013 to 2016 in the U.S. indicated that the quadrivalent live attenuated vaccine did not demonstrate statistically significant effectiveness in children 2 to 17 years of age. Therefore, the CDC provided an interim recommendation that the vaccine should not be used in any setting in the U.S. for the 2016 to 2017 influenza season. Live attenuated influenza vaccine was recommended again by the CDC in the 2018 to 2019 influenza season; due to the limited use of this vaccine in the U.S. since that time, there have been no recent estimates of effectiveness. Practitioners should check regularly for updated guidelines from the CDC on this point.

Human Papillomavirus Vaccines

Human papillomaviruses cause nearly all cases of cervical and anal cancer and most oropharyngeal cancers. Most such cancers are caused by just two of the many HPV serotypes, types 16 and 18. Remarkably, even though the virus cannot be grown efficiently in culture, effective HPV vaccines were developed using virus-like particles that are formed by HPV surface components. All licensed HPV vaccines protect against at least these two types and some protect against four or nine types of HPV, with effectiveness against vaginal and vulvar cancers in women, as well as most cases of anal cancer and genital warts in both females and males. HPV vaccines are recommended for all 11- and 12-year-olds to protect against HPV infection and for everyone through age 26 years, if not vaccinated already. The CDC recommends that some adults age 27 through 45 years, who are not already vaccinated, should receive the HPV vaccine depending on their risk for new HPV infections. HPV vaccination is also recommended for any man who has sex with a man. The vaccines are given in a three-dose regimen on a schedule of 0, 1 to 2, and 6 months.

Maternal Immunization

Maternal immunization during pregnancy can enhance newborn protection after birth by providing passive immunity to the neonate. Immunizing pregnant mothers is safe and protects the child from deadly infectious pathogens early in life when the immune system is not fully developed. One of the most successful maternal immunization protocols involves injection of tetanus toxoid to stimulate the production of IgG antibodies that have high neutralizing capacity and can cross the placenta. Vaccines for group B *Streptococcus*, Hib, RSV, *Streptococcus pneumoniae*, *Bordetella pertussis*, and trivalent IIVs have been tested in pregnant women. For a complete list of vaccines that may be used and those that are contraindicated, visit the CDC website on this topic: https://www.cdc.gov/vaccines/.

Vaccines for Travel

International travelers should ensure that their vaccination status is current for conventional vaccines, including diphtheria, tetanus, pertussis, hepatitis A and B, and poliovirus; exposures to these agents may be more common in some international settings. Listed below are additional vaccines that may be of benefit as preventive vaccines.

Japanese Encephalitis Virus Vaccine

Japanese encephalitis (JE) is a serious mosquito-borne flavivirus infection (not spread person to person) that can cause mild infections with fever and headache, serious neurological sequelae, and even death. Travelers who spend a month or longer in some rural parts of Korea, Japan, China, and eastern areas of Russia should consider vaccination. Two JE vaccines are licensed in the U.S.: an inactivated mouse brain–derived JE vaccine (JE-MB) for use in travelers aged 1 year or older and an inactivated Vero cell culture–derived JE vaccine (JE-VC) for persons aged 17 years or older.

Yellow Fever Virus Vaccine

Yellow fever is a mosquito-borne flaviviral disease with a wide range of systemic symptoms. In severe cases, the disease causes hepatitis, hemorrhagic fever, and death. The CDC recommends this vaccine for children older than 9 months and adults who will be traveling to high-risk areas. There is generally a requirement for documentation of vaccination for travel to and from infected areas. The vaccine is a live attenuated virus vaccine that has been used successfully for many decades. For international travel, yellow fever virus vaccine must be approved by WHO and must be administered by an approved yellow fever vaccination center that can provide both vaccination and a validated International Certificate of Vaccination. The vaccine should be given at least 10 days before travel to an endemic area. Generally, a single dose suffices. Major shortages of

yellow fever vaccine have occurred in recent years due to manufacturing problems. To meet yellow fever vaccination needs, the FDA authorized the distribution of the yellow fever vaccine Stamaril (Sanofi Pasteur) through an expanded access program forecast to be effective through mid-2021 during the vaccine shortage. This vaccine is registered and distributed in over 70 countries but remains unlicensed in the U.S.

Typhoid Vaccine

Typhoid fever is an acute illness caused by the bacterium *Salmonella typhi*, which is transmitted by ingestion of contaminated water or food. Typhoid vaccination is recommended for international travelers who will visit rural areas or villages that have inadequate sanitation. Symptoms include fever, headache, anorexia, and abdominal discomfort; the disease can be fatal. Treatment is challenging, and there has been an increase in the number of drug-resistant strains of *S. typhi* over the last several decades. There are two vaccines available to prevent infection: a single-dose, injectable, inactivated typhoid vaccine and an oral live typhoid vaccine that is taken in a four-dose course.

Rabies Virus Vaccine

Rabies is caused by a lyssavirus transmitted to humans from the bite of infected mammals; the untreated infection is nearly always fatal in humans. Rabies vaccination is used in two ways, first as a preventive vaccine prior to exposure and second as a postexposure intervention to prevent progression to fatal disease. Candidates for preexposure vaccination are people at high risk of exposure to natural rabies (e.g., veterinarians, animal handlers, spelunkers) or to laboratory strains or tissues (e.g., those involved in production of rabies biologicals). Preventive vaccination should be offered to international travelers who are likely to encounter animals in parts of the world where rabies is common (see CDC website). The vaccine is given in a three-dose series on days 0, 7, and 28. For those who may be repeatedly exposed to rabies virus, periodic testing for immunity is recommended, and booster doses can be administered as needed to maintain immunity. Postexposure vaccination is used in emergency settings following a bite or close exposure to an animal that may be rabid. In this setting, the vaccine is given in a four-dose series on days 0, 3, 7, and 14, concomitant with two injections of rabies immune globulin on day 0, one locally into the bite site and a second in an intramuscular injection for systemic administration of antibodies. A bite victim who has been previously vaccinated should receive two doses of rabies vaccine on days 0 and 3 but does not need rabies immune globulin.

Specialty Vaccines

There are limited-use vaccines that are offered in special circumstances to at-risk persons.

Anthrax Vaccine

Anthrax vaccine is offered to certain at-risk adults 18 to 65 years of age, including some members of the U.S. military, laboratory workers who work with anthrax, and some veterinarians or other individuals who handle animals or animal products. Anthrax is a serious disease in animals and human caused by *Bacillus anthracis*. People can contract anthrax from contact with infected animals or animal products. Usually, the cutaneous infection causes ulcers on the skin and systemic symptoms, including fever and malaise; up to 20% of untreated cases are fatal. Inhaled spores of *B. anthracis* usually cause fatal infection. Anthrax vaccine adsorbed (AVA), given as multiple booster injections, protects against cutaneous and inhalation anthrax acquired by exposure on skin or by inhalation. The CDC recommends anthrax intramuscular booster shots at 1, 6, 12, and 18 months, and then annually.

Cholera Vaccines

In 2016, the FDA approved a live attenuated vaccine (Vaxchora) for the prevention of cholera caused by serogroup O1 for adults 18 through 64 years of age traveling to cholera-affected areas. The vaccine is taken as a single, oral liquid dose of approximately 3 fl oz at least 10 days before travel to a cholera-affected area. Efficacy was demonstrated in a randomized, placebo-controlled human challenge study of U.S. volunteers; efficacy was 90% among those challenged 10 days after vaccination and 80% among those challenged 3 months after vaccination. In late 2020, however, the manufacturer temporarily stopped making and selling the vaccine, which may therefore be in limited supply or unavailable. Three other oral inactivated or nonlive cholera vaccines are available: Dukoral, ShanChol, and Euvichol-Plus/Euvichol. These cholera vaccines are WHO prequalified but are not available in the U.S.

Vaccinia Virus (Smallpox Vaccine)

Vaccinia vaccine is a live attenuated *Orthopoxvirus* vaccine developed by multiple passages in cell culture to isolate viral variants that cause only limited infection in humans. The virus is produced as purified calf lymph and given percutaneously with a bifurcated needle. This vaccine was used in the first successful worldwide efforts to eradicate a human virus, variola or smallpox. Routine universal vaccinia immunization was discontinued around 1980, following the declaration by WHO that variola (smallpox) was eradicated, but the vaccine is still available. The nonemergency use of vaccinia vaccine includes vaccination of laboratory and healthcare workers exposed occupationally to vaccinia virus, to recombinant vaccinia viruses, or other orthopoxviruses that can infect humans, such as monkeypox virus and cowpox virus. Because there are still laboratory stocks of variola in research use in several countries, including the U.S., the U.S. ACIP has developed recommendations for the use of vaccinia vaccine if variola virus were used as an agent of biological terrorism or if a smallpox outbreak occurred accidentally. Large-scale use in the military and consideration of use in medical first responders in the U.S. has been implemented in recent decades. A derivative of conventional vaccinia virus vaccine has been developed that has desirable properties. Modified vaccinia Ankara (MVA) virus is a highly attenuated strain of vaccinia virus isolated after more than 500 passages in chicken embryo fibroblasts, during which the virus lost about 10% of the vaccinia genome and the ability to replicate productively in human and other primate cells.

Other Vaccines for Biodefense and Special Pathogens

There are several limited-use vaccines, such as those for workers in high-containment facilities conducting research on highly pathogenic agents that are emerging infectious diseases or potential agents for use in bioterrorism or biowarfare. Typically, these vaccines are used only under Investigational New Drug status. Examples include vaccines for Eastern equine encephalitis virus, Venezuelan equine encephalitis virus, Rift Valley fever virus, botulinum toxin, and others.

International Vaccines

There are additional vaccines pertinent to exposures in other countries that are licensed in some areas but not yet in the U.S.

Dengue Virus Vaccine

Dengue fever is another mosquito-borne flaviviral disease caused by four different viral serotypes and annually affecting about 400 million people worldwide. The disease can be a mild systemic febrile illness during primary infection but can cause severe dengue disease and death during a second infection with virus of a different serotype. It is thought that cross-reactive nonneutralizing antibodies induced by one infection enhance the disease caused by subsequent infection with a heterologous serotype virus. This antibody-dependent enhancement concern has been a significant barrier to vaccine development efforts. Nevertheless, much progress has been made recently in dengue vaccine development.

CYD-TDV developed by Sanofi Pasteur is a recombinant tetravalent (four-serotype) live attenuated virus vaccine that was first licensed in Mexico in December 2015 for use in individuals 9 to 45 years of age living in endemic areas. It is given as a three-dose series on a 0-, 6-, and 12-month schedule. The WHO recommends that the vaccine be given

only to persons with confirmed previous dengue virus infection; the vaccine manufacturer announced in 2017 that people who receive the vaccine and have not been previously infected with a dengue virus may be at risk of developing severe dengue if they get dengue after being vaccinated. In May 2019, the vaccine was FDA-approved for use in children aged 9 to 16 years with laboratory-confirmed previous dengue virus infection and living in an area where dengue is endemic; in June 2021, the ACIP also recommended this use. Such areas in the U.S. include the territories of American Samoa, Puerto Rico, the U.S. Virgin Islands, and freely associated states, including the Federated States of Micronesia, the Republic of Marshall Islands, and the Republic of Palau. It should be noted that the vaccine is *not* approved for use in U.S. travelers who are visiting but not living in an area where dengue is endemic. Additional dengue vaccine candidates are in clinical development.

Malaria Vaccine

The RTS, S vaccine is a recombinant protein-based malaria vaccine with AS01 adjuvant against *Plasmodium falciparum* that was developed by a large international public-private consortium and is the first malaria vaccine to complete efficacy trial testing with a positive review of the outcome. It is relevant for *P. falciparum*, which is common in sub-Saharan Africa, but does not protect against *Plasmodium vivax* malaria, which is more common in many countries outside Africa. In July 2015, the EMA issued a "European Scientific Opinion" on the vaccine, and WHO and its Strategic Advisory Group of Experts have advocated its use in large-scale implementation pilot tests in Africa. Another candidate malaria vaccine is designated PfSPZ (*P. falciparum* and sporozoites). Sporozoites, the sexual form of the parasite extracted from mosquito salivary glands, are made noninfectious through irradiation and then injected or infused to immunize. Clinical trials have been promising, and phase III trials are underway in Africa. Chapter 66 covers the life cycle of malaria parasites and the pharmacotherapy of the disease.

BCG Vaccine

Bacille Calmette-Guérin (BCG) vaccine is used to prevent severe disease due to *Mycobacterium tuberculosis* (TB). BCG vaccine is produced using a live attenuated bovine bacillus strain, *Mycobacterium bovis*, that has lost its ability to cause severe disease in humans. The vaccine typically is given as a single intradermal dose, often to infants near the time of birth. The efficacy of BCG vaccine against TB is uncertain in many settings, but the consensus is that the vaccine does protect against the most severe forms of disseminated TB, such as miliary disease and TB meningitis. The vaccine is a WHO essential medicine for endemic areas but is not used for universal vaccination in the U.S. Chapter 65 covers agents used in the chemotherapy of tuberculosis.

SARS-CoV-2 and COVID-19

Coronavirus disease 2019 is caused by SARS-CoV-2, a new viral strain that has caused a global pandemic from 2019 to present. This novel coronavirus has led to widespread morbidity and mortality throughout the world. The SARS-CoV-2 virus infects through attachment to several host factors, especially the angiotensin-converting enzyme 2 (ACE-2) entry receptor that is expressed on the surface of airway epithelial cells. Infection can result in the upper and lower respiratory tracts, but multiple other organs also can be affected including the lung, pharynx, heart, liver, brain, gastrointestinal tract, and kidneys. A coordinated innate and adaptive immune response is necessary for effective clearance of the virus and development of memory B and T cells that protect the host from reinfection. SARS-CoV-2 subverts the immune response, and defects in the innate immune response can permit viral replication to proceed uninterrupted while delaying the adaptive immune response.

The adaptive immune response is critical in the resolution of SARS-CoV-2 infection. The presence of SARS-CoV-2–specific $CD4^+$ T cells is associated with mild COVID-19, while a delay or absence of these cells correlates with severe or fatal COVID-19 disease. The presence of virus-specific $CD8^+$ T cells is also associated with better COVID-19 patient outcomes. Antibodies are generated to most of the proteins of the virus, with protective neutralizing antibodies focused on the spike protein that mediates attachment and fusion to host cells. Antibodies alone cannot clear SARS-CoV-2 infection; T cells are required to achieve viral clearance.

Several risk factors for severe or fatal COVID-19 disease have been identified, with age being a major risk factor. In the U.S., when compared to a 18–29-year-old, a 65-year-old has about a 97-fold higher risk of death from COVID-19 (CDC, 2020). Additional risk factors for severe or fatal COVID-19 disease include obesity, diabetes, kidney disease, and thoracic malignancies, among others. Men have an increased risk of severe disease compared to women. While pediatric SARS-CoV-2 infection is not yet fully understood, young children usually have mild disease, although in rare cases, severe disease associated with multisystem inflammatory syndrome in children occurs. Socioeconomic risk factors increase the risk of COVID-19, principally due to close-contact settings at work or home. Inequality in access to healthcare and reduced quality of healthcare have contributed to increased COVID-19 prevalence in poorer communities, disproportionally impacting Black and Hispanic communities in the U.S. Some patients who have recovered from COVID-19 have persisting effects. These postinfection sequelae, termed "long COVID," include fatigue, decreased lung capacity, and inability to fully work or exercise. Other symptoms may include vision and cognitive problems.

SARS-CoV-2 Vaccines

Data from studies of a previous coronavirus outbreak caused by SARS-CoV indicated that B and T cells persist for years against that virus. SARS-CoV-2 infection elicits B- and T-cell memory; studies of durability of natural immunity for those previously infected with SARS-CoV-2 are ongoing. Studies suggest that SARS-CoV-2 infection can elicit B- and T-cell memory with estimated half-lives of 3 to 5 months.

The development of multiple vaccines with high efficacy against severe or fatal COVID-19 in record time has been an impressive achievement. The immunity from these vaccines has tended to fade with time, necessitating an additional "booster" dose at roughly 5 to 8 months after the initial dose(s). Current vaccines are delivered by injection; nasal spray formulations are forthcoming.

The panels of Figure 40–1 show some salient features of SARS-CoV-2 , its interaction with host cells, and the points of attack by antibodies produced in response to several available vaccines.

Several types of vaccines against SARS-CoV-2 are now available.

mRNA Vaccines

Three major mRNA-based SARS-CoV-2 vaccines have been tested at scale, and two, the Pfizer/BioNTech and Moderna vaccines, were remarkably efficacious and widely approved for use.

The Pfizer/BioNTech vaccine (BNT162b2) contains an mRNA encoding full-length SARS-CoV-2 spike protein, delivered in a lipid nanoparticle. Once injected, the nanoparticles are taken up by APCs that subsequently express spike protein, resulting in an immune response. The vaccine is safe and has a 95% efficacy in preventing severe or fatal COVID-19. It is injected in two doses, 21 days apart. The vaccine can be stored for 6 months at –70°C and 5 days at +2 to +8°C. The Moderna SARS-CoV-2 vaccine (mRNA-1273) is also a nanoparticle encapsulated mRNA that encodes a full-length SARS-CoV-2 spike protein that elicits 94% protective immunity against severe or fatal COVID-19. This vaccine also requires two doses, 28 days apart. The vaccine can be stored for 6 months at –20°C and 30 days at +2 to +8°C. A third two-dose mRNA SARS-CoV-2 vaccine (CVnCoV) was produced by CureVac, but the results of a 40,000-person efficacy trial announced in June 2021 showed that this vaccine was only 47% effective at preventing disease. The reason for reduced efficacy is under investigation. One plausible difference is that the BioNTech and Moderna vaccines use chemically modified nucleosides to avoid recognition by Toll-like receptors, while the CVnCoV candidate used unmodified nucleosides to produce mRNA.

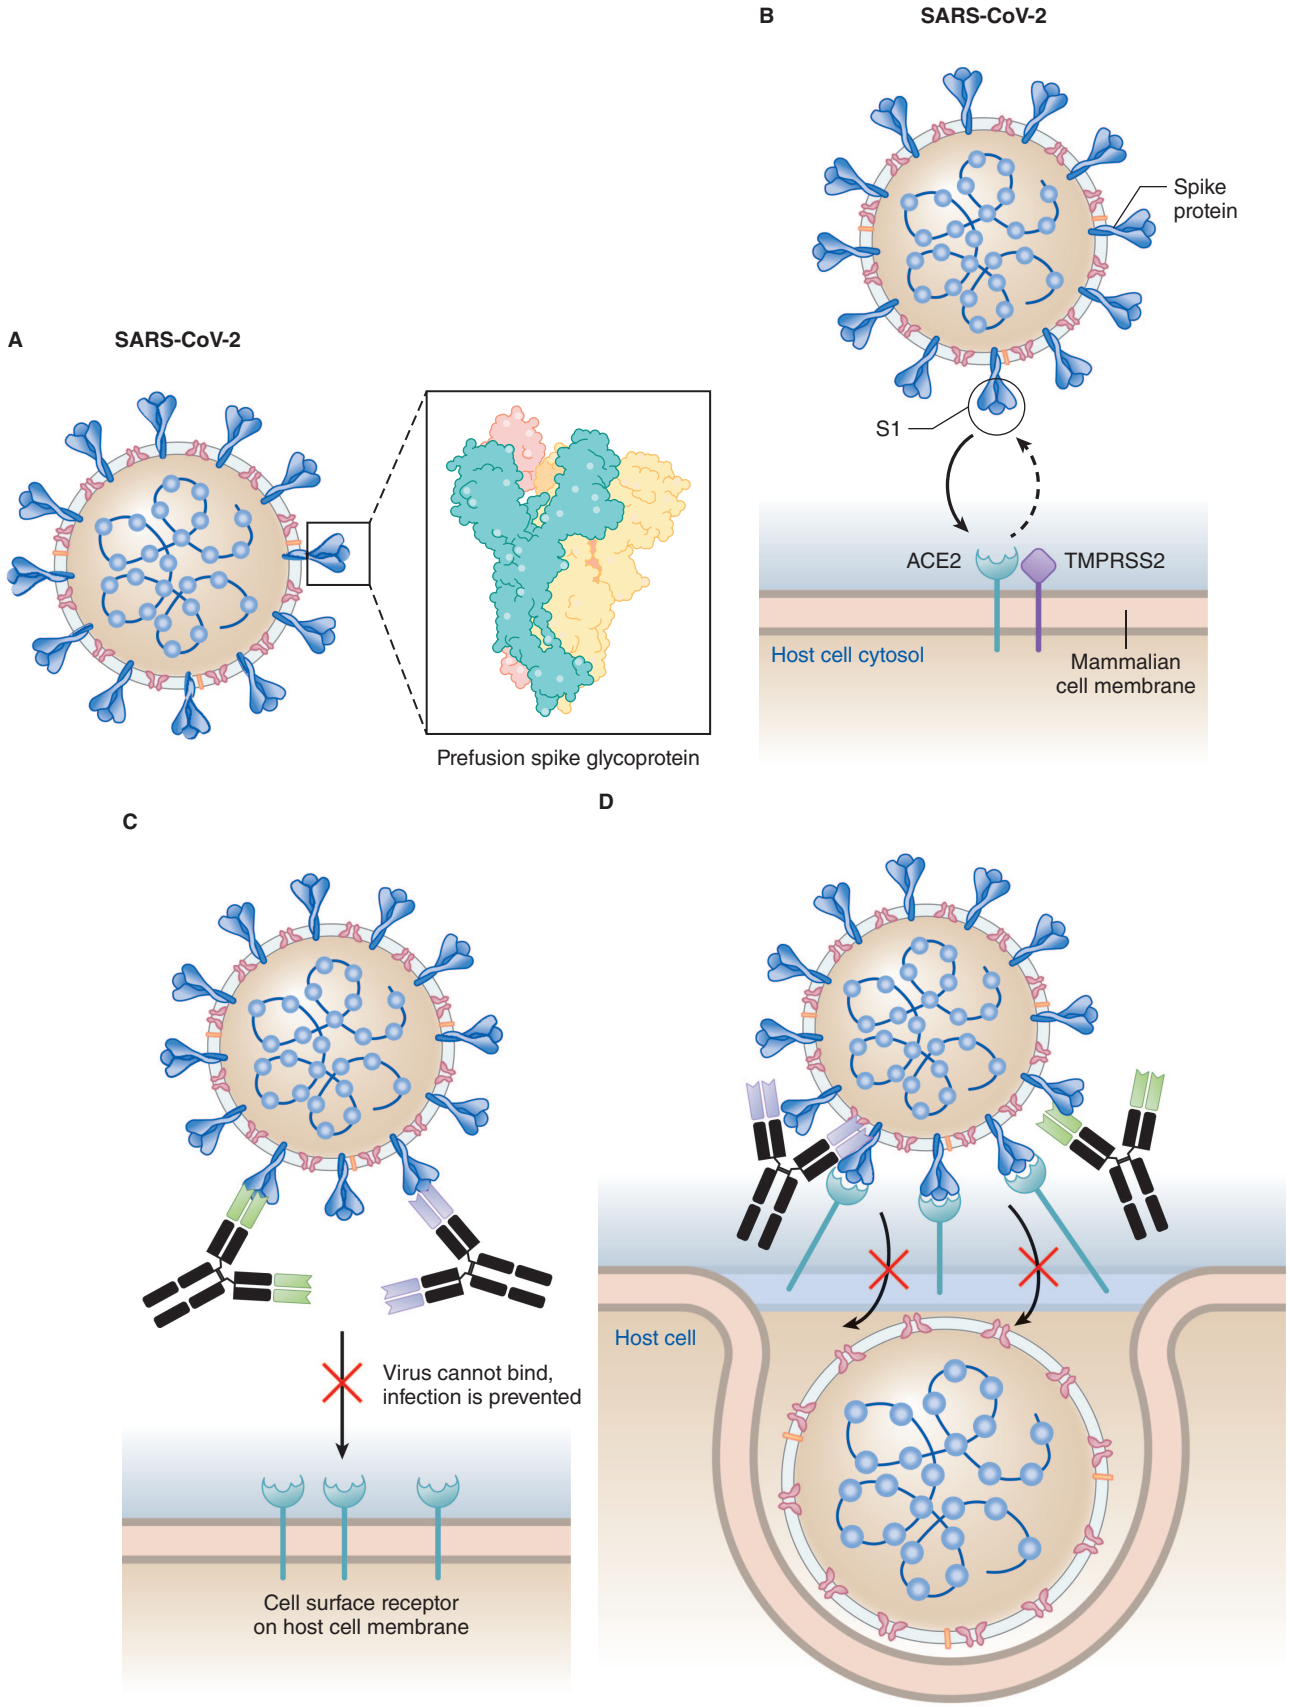


Figure 40–1 **A.** *SARS-CoV-2 virus particles are decorated on the surface with trimeric spike (or "S") glycoproteins in a prefusion conformation.* **B.** The S1 segment of the spike protein of SARS-CoV-2 interacts with cell surface factors of mammalian host cells to facilitate attachment of virus to cells. These host attachment points include ACE2 (angiotensin-converting enzyme 2), a single-pass, transmembrane protease, and TMPRSS2 (transmembrane protease serine 2), a type II transmembrane-bound serine protease. **C.** Some spike protein–specific antibodies can block attachment of virus particles to host cell surface receptors, preventing infection. **D.** Other protein-specific antibodies can block fusion of virus and host cell membranes, even after the virus attaches to host cell surface factors. **E.** Some spike protein–specific antibodies that are bound to virus particles or to S protein on the surface of virus-infected cells activate Fc-receptor–bearing cells to promote virus clearance. (Figure made with BioRender.com.)

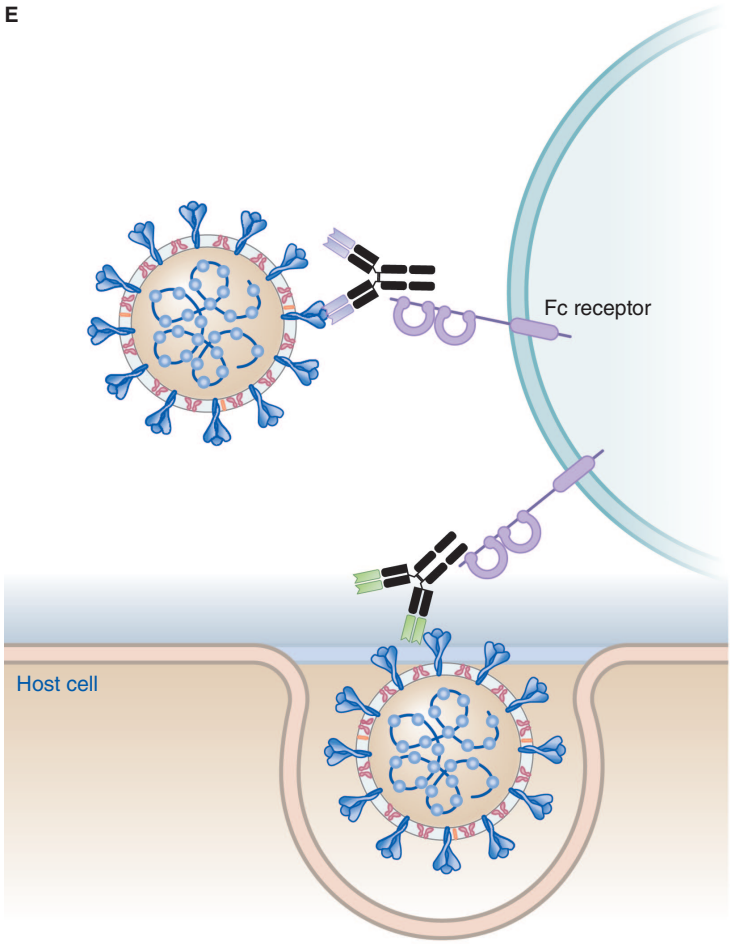

Figure 40–1 (*Continued*)

Adenovirus Vaccines

The Oxford/AstraZeneca vaccine (ChAdOx1/AZD1222) contains a safe adenovirus vector containing dsDNA encoding SARS-CoV-2 spike protein. Once injected, the adenovirus delivers dsDNA to antigen-presenting cells that then express spike proteins, resulting in an immune response. The vaccine, injected in two doses 12 weeks apart, is safe and has an 82% efficacy in preventing severe or fatal COVID-19. The vaccine can be stored for 6 months at +2 to +8°C. It has been authorized for use in Europe and other countries.

The Johnson & Johnson vaccine (JNJ-78436735/Ad26.COV2.S) contains a safe adenovirus vector containing dsDNA encoding SARS-CoV-2 spike protein. The vaccine, injected as a single dose, is safe and has a 72% efficacy in preventing severe or fatal COVID-19. The vaccine can be stored for 3 months at +2 to +8°C and for 2 years at –20°C. It has been authorized for use in the U.S., Europe, and other countries.

The Gamelaya vaccine (Sputnik V/Gam-Covid-Vac) contains a safe adenovirus vector containing dsDNA encoding SARS-CoV-2 spike protein. The vaccine, injected in two doses 21 days apart, is safe and has a 91% efficacy in preventing severe or fatal COVID-19. The vaccine can be stored for 6 months at +2 to +8°C and for 2 years at –20°C. It has been authorized for use in Russia and other countries.

Nanoparticle Vaccines

The Novavax vaccine (NVX-CoV2373) contains nanoparticles coated with synthetic spike proteins. Once injected with adjuvant, the particles are taken up by APCs that present spike proteins, resulting in an immune response. The vaccine, injected in two doses 21 days apart, is safe and has a 95% efficacy in preventing severe or fatal COVID-19. This vaccine can be stored for 6 months at +2 to +8°C and for 2 years at –20°C. The Novavax vaccine has been approved by the EMA and Drugs Controller General of India and has been granted emergency use status by the WHO.

Inactivated Virus Vaccine

The Sinopharm vaccine (BBIBP-CorV) contains inactivated coronavirus. The coronavirus is inactivated with β-propiolactone, which prevents the virus from replicating but allows all the proteins to remain intact. Once injected, the inactivated viral particles are taken up by APCs that present coronavirus proteins, resulting in an immune response. The vaccine, injected in two doses 21 days apart, has a 79% efficacy in preventing severe or fatal COVID-19. It can be stored at +2 to +8°C. This vaccine has been used in China.

The SinoVac vaccine (CoronaVac) also contains coronavirus inactivated with β-propiolactone. The vaccine, injected in two doses 14 days apart, has a 50% efficacy in preventing severe or fatal COVID-19. The vaccine can be stored at +2 to +8°C. It has been used in China.

The Bharat Biotech vaccine (BBV152/Covaxin) also contains coronavirus inactivated with β-propiolactone. This vaccine, injected in two doses 2 days apart, has an 81% efficacy in preventing severe or fatal COVID-19; it can be stored at +2 to +8°C; it has been used in India and other countries.

The Future of Vaccine Technology

Vaccination technology and improved methods to generate vaccines have led to the prevention of many infectious diseases. People no longer die at the high rates that prevailed before vaccines were developed. In the developing world, however, according to WHO reports, over 40% of deaths

are due to infectious diseases, highlighting a continued need to improve existing vaccines, develop new vaccines, and improve delivery methods to increase efficacy. Viruses, bacteria, parasites, and antigens on cancerous cells are all future vaccine targets. New vaccines for pregnant mothers will be available to prevent diseases that can become chronic if the fetus becomes infected *in utero*, as is the case with malaria. Furthermore, an increasing elderly population will need access to better vaccines that can stimulate their aging immune systems, which are susceptible to infections like influenza and varicella viruses. Delivery methods are being explored to utilize nanoparticles and alternative adjuvants to improve vaccine immunogenicity so people will only need one vaccine dose rather than several. Needleless delivery is already possible, as in the cases of oral polio vaccine and nasal sprays for influenza. Investigation continues for developing new edible vaccines using plants, microneedles, and needle-free dermal patches.

Most vaccines work through preventing disease due to acute infections; the challenge remains to develop vaccines against chronic viral infections where the host is immunosuppressed. These pathogens evade the immune system and persist in the host's own cells. To overcome these chronic pathogens, vaccines need to elicit both antibody and T-cell responses, where B cells can neutralize the pathogen and T cells can actively kill and destroy infected cells. Vaccines against HPV and hepatitis B viruses protect not only from viral infection but also from developing infection-associated cancers.

There is a need for new vaccines for other viral pathogens that can cause further complications. For example, infection with group A *Streptococcus* can lead to rheumatic fever, *Helicobacter pylori* may result in stomach cancer, and chlamydia infection can cause blindness and infertility. Vaccines provide effective prophylaxis; however, the frontier in vaccine technology will involve vaccines as therapies for already-established disease. Vaccines can be used against pathogens that become chronic, as in shingles, and in conditions of autoimmunity and cancer, where the immune response is dysregulated. In the case of cancer, vaccines can be used to augment immunity to tumors to prevent their growth and metastasis. In the case of autoimmunity, the goal of this "negative vaccination" is to use vaccines to dampen immune function to prevent self-tissue destruction (Nossal, 2011).

Vaccine Safety: Myths, Truths, and Consequences

Vaccine Adjuvants and Safety

Adjuvants are substances added to vaccines to enhance the magnitude, quality, and duration of the protective immune response. Adjuvants are useful in vaccines because they stimulate the innate immune system that subsequently activates a strong adaptive immune response to ensure immune protection. Because many modern vaccines do not contain live pathogens, they must include adjuvants to ensure vaccine efficacy. Adjuvants are particularly useful in subunit protein vaccines, which often are inadequately immunogenic without enhancement.

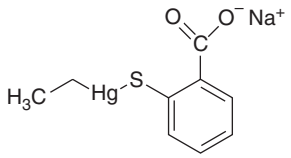
There is extensive experience in human vaccines with two adjuvants, aluminum and monophosphoryl lipid A. Aluminum, in the form of alum, has been used for nearly 90 years in vaccines; aluminum hydroxide [$Al(OH)_3$] and aluminum phosphate ($AlPO_4$) are currently used. Aluminum is used in many childhood vaccines in the U.S. targeted to diphtheria-tetanus-pertussis, Hib and pneumococcus, hepatitis A and B, and HPV. Monophosphoryl lipid A (isolated from bacteria) has been used in the HPV vaccine Cervarix since 2009. An influenza vaccine licensed for the 2016 to 2017 season included the adjuvant MF59, an oil-in-water emulsion of squalene oil. An influenza vaccine that is targeted to influenza H5N1 contains a new adjuvant termed AS03 (an "adjuvant system" containing α-tocopherol and squalene in an oil-in-water emulsion) and was licensed for inclusion in the U.S. pandemic influenza vaccine stockpile. Live attenuated virus vaccines do not contain adjuvants; thus, *adjuvant-free vaccines* include those directed against measles, mumps, rubella, chicken pox, rotavirus, polio, and live attenuated seasonal influenza virus.

Vaccines Do Not Cause Autism

Autism spectrum disorder (ASD) rates have increased in the U.S. and other parts of the world in parallel with expansion in the diagnostic criteria of autism that now include spectrum disorders with a broader array of symptoms (Hansen et al., 2015). The CDC found that 1 of 68 children in the U.S. has ASD. Patients with this disorder have developmental impairments that affect their communication, behavior, and social interactions. Even though some people have been concerned about a causal link between vaccines and autism, many large scientific studies have failed to detect any such link (Hviid et al., 2003; Madsen et al., 2002; Schechter and Grether, 2008; Taylor et al., 2014). The Institute of Medicine (IOM; now termed the National Academy of Medicine) conducted thorough reviews and concluded that current childhood and adult vaccines are very safe. In 2014, a CDC study added to reports around the world that vaccines do not cause ASD. They concluded that the total amount of antigen received from vaccines did not differ between children with ASD and those without the disorder. Vaccination with the MMR vaccine also is not associated with development of ASD in children.

Preservatives, Including Thimerosal

Preservatives added to vaccine preparations are designed to kill or inhibit the growth of bacteria and fungi that could contaminate a vaccine vial. There are historical reports of severe adverse events or death due to bacterial contamination of multidose vials lacking preservative. The highest risk of contamination is probably due to repetitive puncture of a multidose vaccine vial that is stored over time. Therefore, the U.S. *Code of Federal Regulations* requires the addition of a preservative to multidose vials of vaccines. Preservatives eliminate or reduce contamination in this setting. Several preservatives have been incorporated into licensed vaccines, including 2-phenoxyethanol, benzethonium chloride, phenol, and thimerosal.



thimerosal-Na⁺

Thimerosal, known to many by the trade name Merthiolate, has been one of the most used preservatives; it is an organomercurial, an organic compound containing mercury. Thimerosal has been used safely since the early 20th century as a preservative in biologics, including many vaccines, and has a long history of use. Over time, concerns were raised about its safety because some organomercurials were increasingly associated with neurotoxicity, and children began receiving increasing numbers of licensed vaccines. The FDA chose to work with manufacturers toward reduction or elimination of thimerosal from childhood vaccines because of these *theoretical concerns*. As a result, *thiomersal has been eliminated or reduced to trace amounts in nearly all childhood vaccines except some IIVs.*

In terms of toxicity from mercury, most of the data in the field pertain to methylmercury, whereas thimerosal is a derivative of ethylmercury, which is cleared more rapidly. Thimerosal does not have significant toxic effects at the concentrations used in vaccine formulations. However, questions were raised about the potential association of thimerosal-containing vaccines in children and the occurrence of neurodevelopmental disorders, especially autism. A rather sordid history of fraud, conflict of interest, and other irregularities has been revealed pertaining to the now-debunked association studies of thimerosal and autism; decades of studies have been conducted in safety reviews around this matter.

The National Vaccine Advisory Committee, ACIP of the CDC, and the IOM's Immunization Safety Review Committee have all conducted extensive reviews of association studies, and the conclusion is that autism is not associated with the amount of thimerosal in childhood vaccines. In

any event, recognizing public concern, between 2001 and 2003, thimerosal was eliminated from or reduced in childhood vaccines (except for influenza) for children under 6 years old in hopes of encouraging childhood vaccination. The CDC has compiled a thorough review and list of articles relating to this issue (CDC, 2015).

Adverse Events With Vaccines

For injectable vaccines, common adverse effects include minor *local reactions* to vaccines at the injection site (pain, swelling, and redness). More widespread effects, termed *systemic reactions*, may include fever, rash, irritability, drowsiness, and other symptoms, depending on the vaccine. The profile of reactions seen in large-scale trials is carefully documented in package inserts. During vaccine candidate testing, any occurrence of serious adverse events (SAEs) is examined carefully. SAEs are events following vaccination that involve hospitalization, life-threatening events, death, disability, permanent damage, congenital anomaly/birth defect, or other conditions requiring medical intervention. Vaccines with clear association with SAEs are typically not licensed. In some cases, to increase the likelihood of detecting rare SAEs, the FDA requires phase IV studies (postmarketing surveillance) to follow the performance of vaccines as use expands beyond the size of the trials leading to licensure. The government also collects data after licensure through the vaccine adverse event reporting system. Vaccines can be withdrawn from market if concerns arise. For example, licensure for use of the live oral rotavirus vaccine Rotashield, which was recommended for routine immunization of the U.S. infants in 1998, was withdrawn in 1999 when reports in the vaccine adverse event reporting system suggested an association between the vaccine and intussusception, a form of bowel obstruction.

Allergic Reactions

Allergy to components of vaccine formulations also can cause reactions. Trace amounts of antibiotics like *neomycin*, used to ensure sterility in some vaccines (e.g., MMR, trivalent IPV, and varicella vaccine), may cause adverse reactions. A history of anaphylactic reaction (but not local reaction) to *neomycin* is a contraindication to future immunization with those vaccines. Persons with a history of egg allergy should not be given an influenza vaccine prepared in eggs. Gelatin, which is used as a stabilizer in some virus vaccines like varicella and MMR vaccines, may cause allergic reaction in some.

Fainting

Fainting, or syncope, also has been reported in people after vaccination. Fainting is more common in adolescents than in children or adults and thus is more common after vaccination with HPV, meningococcal vaccine 4 (MCV4), and Tdap. Immediate fainting episodes following vaccination procedures are triggered by pain or anxiety, rather than the contents of the vaccines. While fainting is not serious, falling while fainting can cause injury, with head injuries the most serious. Clinicians can give patients drinks and snacks to prevent some fainting and can prevent falls by having patients lie down or sit during the procedure. Patients who faint after vaccination will recover after a few minutes, and clinicians should observe patients for at least 15 min after vaccination (a recommendation of the CDC).

Febrile Seizure

Fevers of 102°F (38.9°C) or higher can cause children to experience febrile seizures, which are characterized by body spasms and jerky movements that may last for up to 2 min. About 5% of children will experience a febrile seizure in their lifetime, with most occurring at 14 to 18 months of age. Children experiencing simple febrile seizures recover quickly without long-term harm. These common seizures also are caused by febrile illnesses associated with viral infections, especially roseola, ear infections, and other common childhood illnesses. Current vaccines sometimes induce fevers, usually low grade in nature, but rarely result in febrile seizures. Although fever following vaccination with most vaccines rarely causes febrile seizure, there is a small increase in risk after MMR and MMRV vaccines. The CDC also has reported a small increase in febrile seizures after a child receives the IIV together with PCV13 vaccine or in combination with diphtheria, tetanus, or DTaP vaccines. The increase of febrile seizures when combining these vaccines is small, and the CDC does not recommend delivering them on separate days. Importantly, vaccine usage can help prevent febrile seizures by providing vaccinated children protection against measles, mumps, rubella, chickenpox, influenza, and pneumococcal infectious pathogens that may result in febrile seizures.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is a rare disease that affects the nervous system. Patients with GBS display muscle weakness and sometimes paralysis that results when their own immune system injures their neurons. GBS often occurs after an infection with bacteria or virus; most patients with GBS recover fully. However, some subjects can have permanent nerve damage. The incidence of GBS in the U.S. currently is about 3000 to 6000 cases per year; thus, it is rare in a population of about 350 million. GBS is more common in older adults, with people older than 50 years at greater risk. GBS may have several underlying causes, but scientists report that two-thirds of GBS cases occurred after patients were ill with gastroenteritis or respiratory tract infections. Infection with *Campylobacter jejuni* is the most common risk factor for the disease, but GBS also has been reported commonly after influenza virus, cytomegalovirus, or Epstein-Barr viral infection. GBS after vaccination is reported but rare.

An IOM study reported that widespread use of the 1976 swine influenza virus vaccine was associated with a small increase in risk for GBS, with an additional case of GBS per 100,000 people who were vaccinated, although later statistical review called this association into question. Current assessments are that there is no significant risk of GBS after obtaining a seasonal influenza vaccine, or if there is an association, the risk is approximately one case per million vaccinated individuals, a low rate that is difficult to detect with certainty. Studies have shown that a person is more likely to get GBS after influenza infection than after a vaccination. Importantly, severe morbidity and mortality are significant risks after influenza infection, and vaccination prevents complications and death.

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) peaks when babies are between 2 and 4 months old, and infants are also given many vaccines during this period. The temporal overlap of peak SIDS incidence and the period of initiation of childhood vaccination series led to questions about any causal relationship between vaccines and SIDS. Numerous studies have failed to detect a causative association for vaccines and SIDS (Silvers et al., 2001). The IOM 2003 report reviewed the relationship of SIDS and vaccines and concluded that vaccines do not cause SIDS. Infant death by SIDS has decreased dramatically due to the 1992 American Academy of Pediatrics recommendations to place infants on their backs to sleep and the 1994 National Institute of Child Health and Human Development campaign efforts.

Safety of Multiple Vaccinations

Children are exposed to many bacteria and viruses in their environment through food, teething of objects, and exposure to pets and to other humans. The typical viral infection results in exposure of the immune system to a dozen or more antigens; some bacteria express hundreds of antigens during infection. Each recommended childhood vaccine protects against 1 to 69 antigens. When a child is given the full recommended vaccines on the 2014 schedule, they are exposed to up to 315 antigens by age 2, which provides them critical protection against pathogens in the environment (CDC, 2016). Vaccinating patients against multiple antigens has been shown to be safe when they are delivered in combination at the same time. This strategy is advantageous for patients, especially children, because they lack immunity to most vaccine-preventable diseases, so receiving this protection during the relatively vulnerable period of early development is important. The patient also has fewer doctor visits with combination or multiple vaccinations, reducing cost in terms of money and time for parents and disruption for children. Numerous studies have shown that giving various vaccine combinations does not cause chronic disease. Furthermore, each time a combination vaccine or multiple vaccination schedule is licensed, that intervention already has been tested

for safety and efficacy in combination with the vaccines previously recommended for that age group. The ACIP and the Academy of Pediatrics recommend receiving multiple vaccines at the same time (CDC, 2016).

Vaccine Myths and Their Public Health Consequences

The decreased rates of mortality and morbidity due to infectious diseases contracted in childhood and adulthood substantiate the success of vaccines. A dramatic example of success is the worldwide eradication of smallpox, a pathogen responsible for epidemics that killed 300 to 500 million people in the 20th century and disfigured many survivors. In the 20th century, poliovirus and MeV also incapacitated and killed infected individuals, especially young children. These scourges have been largely eliminated thanks to decades of successful public health vaccination strategies. Until the SARS-CoV-2 pandemic of 2020, younger generations had never seen the debilitating effects and mortality caused by such diseases. Infectious diseases, however, continue to affect the lives of many people in the developing world who have less access to healthcare or are affected by wars or famine. Recently, preventable diseases are arising again in the developed world because of vaccine myths that have reduced vaccination rates in these countries.

One of these myths concerns autism. A study that has been retracted and discredited claimed there was a link between vaccination in children and autism (Wakefield et al., 1998). Despite major shortcomings and incorrect interpretations, this study changed public perceptions regarding vaccine safety; the influence of this faulty article persists. Experimental studies in different parts of the world with large cohorts, statistical power, and rigor have found no evidence that vaccines cause autism (American Academy of Pediatrics, 2017; Madsen et al., 2002). Researchers have found that autism occurs in families, may have a genetic component, and may be affected by environmental triggers such as insecticides, certain drugs, and rubella virus. The exact causes of ASDs are unknown and continue to be investigated (Landrigan, 2010).

Nonetheless, the antivaccination movement has gained momentum, with celebrities, politicians, and social media continuing to propagate erroneous vaccine information and conspiracy theories. According to the CDC, vaccination rates have fallen in many parts of the U.S. In nine U.S. states, fewer than two-thirds of children ages 19 to 35 months have been vaccinated with the recommended seven-vaccination regimen. This dismissal of scientific evidence on vaccines can have deadly consequences. Infectious epidemics due to preventable agents like poliovirus and MeV can reemerge. Unvaccinated children will be more susceptible to infection, and many of them will not survive. Furthermore, unvaccinated subjects contribute to reducing the benefits of herd immunity that protects people who cannot be vaccinated for medical reasons, such as cancer, HIV infection, and other types of immunodeficiency.

Diseases due to pertussis, polio, measles, *H. influenzae*, and rubella virus once affected hundreds of thousands of people and killed thousands. Following the introduction of universal vaccinations, the rates of these diseases decreased to near-zero levels in the U.S. Some believe that because these diseases have been nearly eliminated in the U.S., vaccination is no longer needed. This thinking is incorrect. Vaccine-preventable diseases are communicable diseases, spreading from person to person, and the causative viruses and bacteria survive in nature. People, especially the unvaccinated, can be infected, and infected individuals will spread the disease to unvaccinated individuals. A greater fraction of vaccinated individuals in a population leads to fewer opportunities for the disease to spread (herd immunity).

Parental vaccine concerns should be taken seriously, and misconceptions should be thoroughly discussed by providers to ensure that patients have scientific information and are informed about the risks associated with failure to vaccinate. By providing parental education, pediatricians and other primary care medical providers can help reduce vaccine hesitancy.

In a similar vein, misinformation about the safety of SARS-CoV-2 vaccines has slowed vaccination efforts in the U.S. during the COVID-19 pander ıic

Licensure and Monitoring of Vaccines

Immune Correlates and Mechanisms

During the process of vaccine development and testing, manufacturers seek to define laboratory tests and parameters that are associated with efficacy, which have been designated immune correlates of protection (CoPs). First, it is important theoretically to understand some features of the biological mechanism of protection to optimize development and use of vaccines. At a practical level, identification of a correlate allows monitoring of the reproducibility of vaccines during repetitive manufacture, monitoring the expected impact of new combinations of vaccine antigens on immunogenicity of existing vaccines, and other critical issues.

Plotkin and others have developed terminology for principal types of correlates (Plotkin and Gilbert, 2012). A *CoP* is a marker of immune function that statistically correlates with protection. Such markers can be simply associated with protection (termed nCoP) or alternatively may be known to directly measure the immune effectors that mediate protection (mCoP). From a practical standpoint, either an nCoP or an mCoP can enable monitoring and prediction of effective vaccination.

The ideal CoP is one that is quantitative and derives from a reproducible laboratory test that has been validated under good laboratory practice conditions. The type of protection suggested for a particular correlate may vary because vaccines may be designed to prevent differing classes of infection, such as local versus systemic infection or severe disease versus any disease. Examples of quantitative CoPs in use include a threshold of 10 mIU/mL in serum of hepatitis B antibodies detected in a standardized enzyme-linked immunosorbent assay, serum diphtheria toxin neutralization concentration of 0.01 to 0.1 IU/mL, a serum virus neutralization dilution titer of 1/5 for yellow fever virus, or a 1/40 dilution of serum in influenza hemagglutination inhibition titer.

Regulatory and Advisory Bodies

The Center for Biologics Evaluation and Research of the FDA regulates vaccine products in the U.S., with recommendations from its Vaccines and Related Biological Products Advisory Committee. The EMA regulates in Europe. Manufacturers conduct phase I studies (safety and immunogenicity studies) in a small number of closely monitored subjects; phase II studies (dose-ranging studies) typically in several hundred subjects; and then phase III trials (efficacy studies) typically in thousands of subjects. If the studies are successful, the sponsor submits a Biologics License Application to the FDA, which may lead to licensure. Licensure allows use, but decisions on whether vaccines are recommended for specific populations or for universal use are made by additional advisory bodies. The CDC hosts the ACIP, a committee of public health and medical experts that makes recommendations for use of vaccines in the U.S. Various professional medical societies also publish recommendations, for instance, the American Academy of Pediatrics publishes the *AAP Red Book*, or "Report of the Committee on Infectious Diseases of the American Academy of Pediatrics," which contains vaccine recommendations. Finally, third-party payers, such as insurance companies, affect usage through reimbursement policies; thus, issues of cost, benefit, and profitability become considerations, as examined in Chapter 1.

Chapter 41

Lipid-Derived Autacoids: Eicosanoids and Platelet-Activating Factor

Emanuela Ricciotti, Tilo Grosser, and Garret A. FitzGerald

Membrane lipids supply the substrate for the synthesis of *eicosanoids* and *platelet-activating factor* (PAF). Arachidonic acid (AA) metabolites, including *PGs* (prostaglandins), *PGI_2* (prostacyclin), *TxA_2* (thromboxane A_2), *LTs* (leukotrienes), and *epoxygenase products* of cytochromes P450 (CYP)s, collectively the eicosanoids, are not stored but are produced by most cells when a variety of physical, chemical, and hormonal stimuli activate acyl hydrolases that make arachidonate available for further metabolism. *Membrane glycerophosphocholine* derivatives can be modified enzymatically to produce PAF. PAF is formed by a smaller number of cell types, principally leukocytes, platelets, and endothelial cells. Eicosanoids and PAF lipids function as signaling molecules in many biological processes, including the regulation of vascular tone, renal function, hemostasis, parturition, gastrointestinal (GI) mucosal integrity, and stem cell function. They are also important mediators of innate immunity and inflammation. Several classes of drugs, most notably NSAIDs (nonsteroidal anti-inflammatory drugs) (see Chapter 42), including *aspirin*, owe their principal therapeutic effects—relief of inflammatory pain and antipyresis—to blockade of PG formation.

Eicosanoids

Eicosanoids, from the Greek *eikosi* ("twenty"), are formed from precursor essential fatty acids that contain 20 carbons and 3, 4, or 5 double bonds: 8,11,14-eicosatrienoic acid (dihomo-γ-linolenic acid), 5,8,11,14-eicosatetraenoic acid (AA; Figure 41–1), and 5,8,11,14,17-eicosapentaenoic acid (EPA). AA is the most abundant precursor, derived from the dietary omega-6 fatty acid, linoleic acid (9,12-octadecadienoic acid), or ingested directly as a dietary constituent. EPA is a major constituent of oils from fatty fish such as salmon.

HISTORY

In 1930, American gynecologists Kurzrok and Lieb observed that strips of uterine myometrium relax or contract when exposed to semen. Subsequently, Goldblatt in England and von Euler in Sweden reported independently on smooth muscle contracting and vasodepressor activities in seminal fluid and accessory reproductive glands. In 1935, von Euler identified the active material as a lipid-soluble acid, which he named *prostaglandin*. Samuelsson, Bergström, and their colleagues elucidated the structures of PGE_1 and $PGF_{1\alpha}$ in 1962. In 1964, Bergström and coworkers and van Dorp and associates independently achieved biosynthesis of PGE_2 from AA. Discovery of TxA_2, PGI_2, and the LTs followed. Vane, Smith, and Willis in 1971 reported that *aspirin* and NSAIDs act by inhibiting PG biosynthesis. This remarkable period of discovery linked the Nobel Prize of von Euler in 1970 to that of Bergström, Samuelsson, and Vane in 1982.

Biosynthesis

Biosynthesis of eicosanoids is limited by the availability of AA and depends primarily on the release of esterified AA from membrane phospholipids or other complex lipids by acyl hydrolases, notably phospholipase A_2 (PLA_2). Once liberated, AA is metabolized rapidly to oxygenated products by cyclooxygenases (COXs), lipoxygenases (LOXs), and CYPs (see Figure 41–1).

Chemical and physical stimuli activate the Ca^{2+}-dependent translocation of group IV_A cytosolic phospholipase A_2 ($cPLA_2$) to the membrane, where it hydrolyzes the *sn*-2 ester bond of membrane phosphatidylcholine and phosphatidylethanolamine, releasing AA. Multiple additional PLA_2 isoforms (secretory [s] and Ca^{2+}-independent [i] forms) have been characterized. Under basal conditions, AA liberated by $iPLA_2$ (Ca^{2+}-independent PLA_2) is reincorporated into cell membranes by the action of arachidonoyl-CoA synthetase and lysophospholipid acyltransferases (Pérez-Chacón et al., 2009). During stimulation, $cPLA_2$ dominates the acute release of AA, while an inducible $sPLA_2$ contributes to AA release under conditions of sustained or intense stimulation. $sPLA_2$ contributes to platelet microparticle generation of eicosanoids that then direct microparticle internalization by neutrophils driving inflammation (Duchez et al., 2015).

Products of Cyclooxygenases (Prostaglandin G/H Synthases)

Prostaglandin endoperoxide G/H synthase is called *cyclooxygenase* or *COX* colloquially. Products of this pathway are PGs, PGI_2, and TxA_2, collectively termed *prostanoids*. The pathway is described by Figure 41–1 and its legend.

Prostanoids are distinguished by substitutions on their cyclopentane rings and the number of double bonds in their side chains, as indicated by numerical subscripts (dihomo-γ-linolenic acid is the precursor of *$series_1$*, AA for *$series_2$*, and EPA for *$series_3$*). Prostanoids derived from AA carry the subscript 2 and are the major series in mammals.

There are two distinct functional COX isoforms in humans, COX-1 and COX-2 (Rouzer and Marnett, 2009; Smith et al., 2011). COX-1, expressed constitutively in most cells, is the dominant source of prostanoids for housekeeping functions, such as cytoprotection of the gastric epithelium (see Chapter 53). COX-2, in contrast, is upregulated by cytokines, shear stress, and growth factors and is the principal source of prostanoid formation in inflammation and cancer. However, this distinction is

Abbreviations

15-PGDH: 15-hydroxyprostaglandin dehydrogenase
AA: arachidonic acid
ACTH: corticotropin (formerly adrenocorticotrophic hormone)
AERD: *aspirin*-exacerbated respiratory disease
AGEPC: acetyl glyceryl ether phosphorylcholine
APRL: antihypertensive polar renal lipid
BLT: leukotriene B_4 receptor
COX: cyclooxygenase
CYP: cytochrome P450
CysLT: cysteinyl leukotriene
CysLTr: cysteinyl leukotriene receptor
DPr: prostaglandin D_2 receptor
EDHF: endothelium-derived hyperpolarizing factor
EET: epoxyeicosatrienoic acid
EPA: 5,8,11,14,17-eicosapentaenoic acid
EPr: prostaglandin E_2 receptor
FLAP: 5-lipoxygenase-activating protein
fMLP: formyl-methionyl-leucyl-phenylalanine
FPr: prostaglandin $F_{2\alpha}$ receptor
GI: gastrointestinal
GPCR: G protein-coupled receptor
HETE: hydroxyeicosatetraenoic acid
H-PGDS: hematopoietic prostaglandin D synthase
HPETE: hydroperoxyeicosatetraenoic acid
IL: interleukin
IPr: prostacyclin receptor
LOX: lipoxygenase
LT: leukotriene
LX_: lipoxin, e.g., LXA, LXB
mPGES-1: microsomal prostaglandin E synthase-1
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
PAF: platelet-activating factor
PAF-AH: platelet-activating factor acetylhydrolase
PAH: pulmonary arterial hypertension
PD-1: programmed cell death 1
PD-L1: programmed cell death 1 ligand
PG: prostaglandin
PGI_2: prostaglandin I_2 (prostacyclin)
PGT: prostaglandin transporter
PL: phospholipase, e.g., PLA, PLC
PMN: polymorphonuclear leukocyte
POX: peroxidase
oxPL: oxidized phospholipid
SARS-CoV-2: severe acute respiratory syndrome coronavirus 2
TNF: tumor necrosis factor
TPr: thromboxane A_2 receptor
TxA_2: thromboxane A_2

not absolute; both enzymes may contribute to the generation of autoregulatory and homeostatic prostanoids during physiological and pathophysiological processes.

With 61% amino acid identity, COX-1 and COX-2 have remarkably similar crystal structures. Both COXs are glycosylated on asparagine in all organisms and the *N*-glycosylation appears to be necessary for proper protein folding. Both isoforms are expressed as dimers, homotypically inserted into the endoplasmic reticular membrane. Each monomer exhibits half of the site's activity and binds a distinct ligand that may influence the catalytic activity of the other monomer (Smith and Malkowski, 2019). COX-2 is also found in the Golgi apparatus and associated with lipid droplets (Smith and Malkowski, 2019). Although the enzymatic proprieties of COX-1 and COX-2 are very similar, COX-2 is more catalytically effective in the presence of lower AA concentrations, because COX-1 exhibits negative allosterism in this setting, and peroxide concentrations. Through sequential COX and POX (peroxidase) activity, both COXs convert AA to two unstable intermediates that are then converted to the prostanoids by synthases, each expressed in a relatively cell-specific fashion. For example, COX-1–derived TxA_2 is the dominant product in platelets, whereas COX-2–derived PGE_2 and TxA_2 dominate in activated macrophages. Prostanoids are released from cells by diffusion, although transport may be facilitated through the multidrug resistance-associated protein transporter (Schuster, 2002). The prostaglandin transporter (PGT) transports extracellular PGs into the cytoplasm for degradation (Lu et al., 1996). Despite the structural similarities between the two COX isozymes, COX-2 has a broader substrate preference and is able also to oxygenate neutral derivatives of AA and other fatty acids (Smith and Malkowski, 2019). Moreover, there are variable levels of functional complementarity between COX-1 and COX-2 in cells and tissues. In the kidney, COX-1 cannot compensate for loss of COX-2 in renal development, while COX-2 can compensate for the loss of COX-1, independently from its prostaglandin-synthetic capacity under basal conditions (Li et al., 2018a). Similarly, in the female reproductive system, COX-1 function may be replaced by COX-2, but not vice versa (Li et al., 2018b).

Lipoxygenase Products

Major products of the LOX pathways are hydroxy fatty acid derivatives known as HETEs (hydroxyeicosatetraenoic acids), LTs, and LXs (lipoxins) (Figure 41–2) (Haeggström and Funk, 2011; Powell and Rokach, 2015). LTs play a major role in the development and persistence of the inflammatory response.

The LOXs are a family of enzymes containing nonheme iron; LOXs catalyze the oxygenation of polyenic fatty acids to corresponding lipid hydroperoxides. The enzymes require a fatty acid substrate with two cis double bonds separated by a methylene group. AA, which contains several double bonds in this configuration, is metabolized to hydroperoxyeicosatetraenoic acids (HPETEs), which vary in the site of insertion of the hydroperoxy group. HPETEs are converted to their corresponding HETEs either nonenzymatically or by a POX.

There are five active human LOXs—5(*S*)-LOX, 12(*S*)-LOX, 12(*R*)-LOX, 15(*S*)-LOX-1, and 15(*S*)-LOX-2—classified according to the site of hydroperoxy group insertion. Their expression is frequently cell specific; platelets have only 12(*S*)-LOX, whereas leukocytes contain both 5(*S*)- and 12(*S*)-LOX (see Figure 41–2). 12(*R*)-LOX is restricted in expression mostly to the skin. The epidermal LOXs, which constitute a distinct LOX subgroup, also include 15-LOX-2 and eLOX-3, the most recently identified family member. eLOX-3 has been reported to metabolize further 12(*R*)-HETE, the product of 12(*R*)-LOX, to a specific epoxyalcohol product.

The 5-LOX pathway leads to the synthesis of the LTs. When eosinophils, mast cells, polymorphonuclear leukocytes (PMNs), or monocytes are activated, 5-LOX translocates to the nuclear membrane and associates with 5-LOX–activating protein (FLAP), an integral membrane protein that facilitates AA to 5-LOX interaction (Evans et al., 2008). Drugs that inhibit FLAP block LT production. A two-step reaction is catalyzed by 5-LOX: oxygenation of AA to form 5-HPETE followed by dehydration to an unstable epoxide, LTA_4. LTA_4 is transformed by distinct enzymes to LTB_4 or LTC_4. Extracellular metabolism of the peptide moiety of LTC_4 generates LTD_4 and LTE_4 (Peters-Golden and Henderson, 2007). Collectively, LTC_4, LTD_4, and LTE_4 are cysteinyl leukotrienes (CysLT). LTB_4 and LTC_4 are actively transported out of the cell. LTA_4, the primary product of the 5-LOX pathway, is metabolized by 12-LOX to form LXA_4 and LXB_4. These mediators also can arise through 5-LOX metabolism of 15-HETE.

Products of CYPs

The CYP epoxygenases, primarily CYP2C and CYP2J, metabolize AA to EETs (epoxyeicosatrienoic acids) (Fleming, 2014). Initially described in endothelial cells as endothelial-derived hyperpolarizing factors (EDHFs) that promote vasodilation, particularly in the coronary circulation, EETs

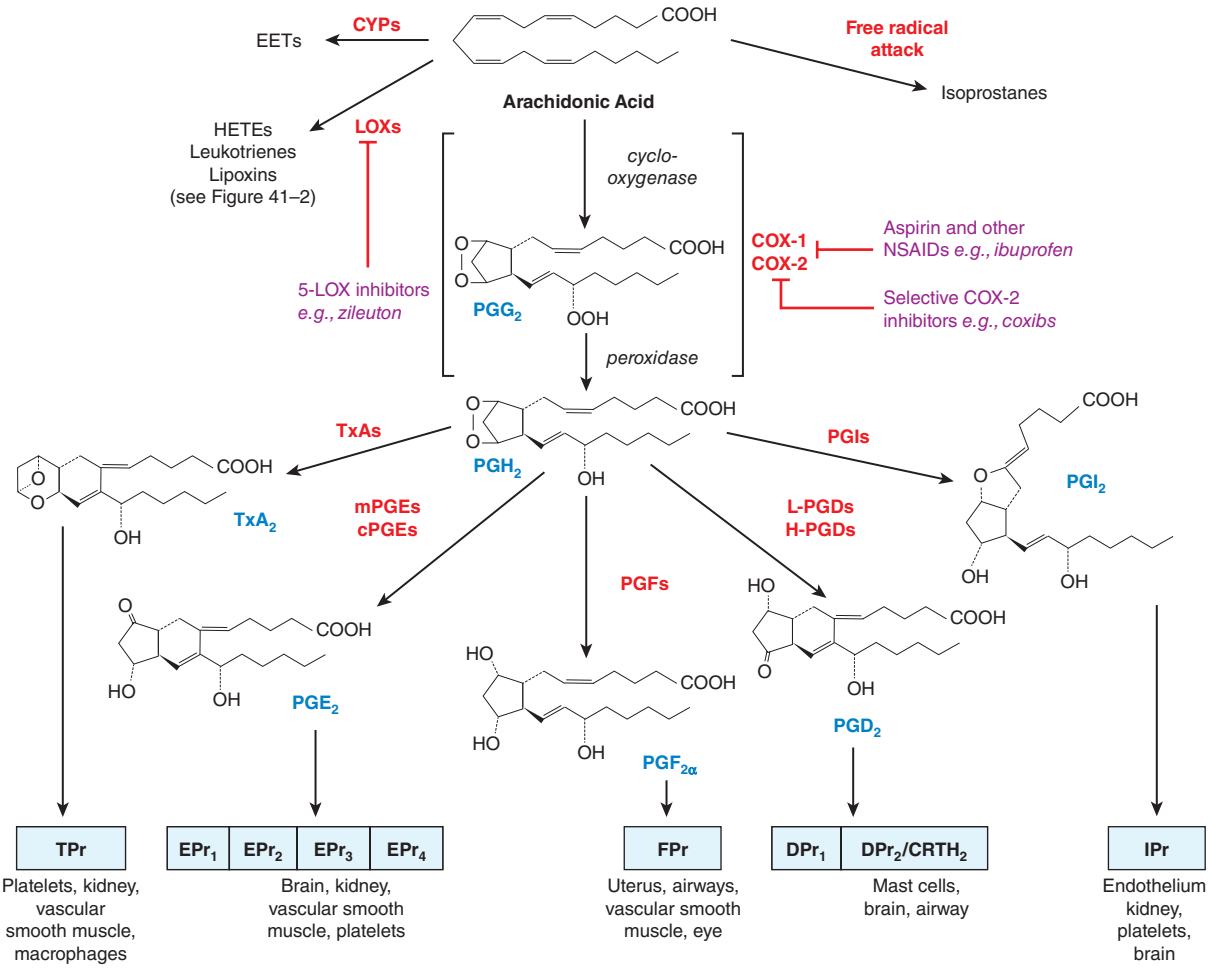

Figure 41–1 *Metabolism of AA.* Cyclic endoperoxides (PGG_2 and PGH_2) arise from the sequential COX and hydroperoxidase actions of COX-1 or COX-2 on AA released from membrane phospholipids. Subsequent products are generated by tissue-specific synthases and transduce their effects via membrane-bound receptors (blue boxes). EETs and isoprostanes are generated via CYP activity and nonenzymatic free radical attack, respectively. *Aspirin* and nonselective NSAIDs are nonselective inhibitors of COX-1 and COX-2 but do not affect LOX activity. See the text and the Abbreviations list for further definitions.

can be produced by any cell that expresses CYP epoxygenase, including astrocytes, and may play a protective role in cerebral ischemia (Wan et al., 2020; Zhang et al., 2017). EET biosynthesis can be altered by pharmacological, nutritional, and genetic factors that affect CYP expression.

Other Pathways

The isoeicosanoids, a family of eicosanoid isomers, are generated by nonenzymatic free radical catalyzed oxidation of AA. Unlike PGs, these compounds are initially formed esterified in phospholipids and released by PLs; the isoeicosanoids then circulate and are metabolized and excreted into urine. Their production is not inhibited *in vivo* by inhibitors of COX-1 or COX-2, but their formation is suppressed by antioxidants. Isoprostanes correlate with cardiovascular risk factors, and increased levels are found in many clinical conditions (Milne et al., 2015). Their relevance as biologically active mediators remains speculative. A series of compounds, *LXs, maresins,* and *resolvins*, when synthesized and administered to certain models of inflammation, hasten its resolution. It remains to be established whether the endogenous compounds are formed in quantities sufficient to exert this effect *in vivo* (Skarke et al., 2015).

Since COX, LOX, and CYP products are all formed from AA, the biosynthesis of these metabolites should be considered as part of the same metabolic network and should be assessed using broad-spectrum eicosanoid assays to uncover the interconnectivity between the different pathways and capture potential substrate rediversion in response to perturbations (Mazaleuskaya et al., 2016).

Inhibitors of Eicosanoid Biosynthesis

Inhibition of PLA_2 decreases the release of the precursor fatty acid and the synthesis of all its metabolites. PLA_2 may be inhibited by drugs that reduce the availability of Ca^{2+}. *Glucocorticoids* inhibit PLA_2 indirectly by inducing the synthesis of a group of proteins termed *annexins* that modulate PLA_2 activity. Glucocorticoids also downregulate induced expression of COX-2 but not of COX-1 (see Chapter 50). *Aspirin* and NSAIDs inhibit the COX, but not the POX, moiety of both COX enzymes and thus the formation of downstream prostanoids. These drugs do not inhibit LOXs and may cause increased formation of LTs by shunting of substrate to the LOX pathway. LTs may contribute to the adverse GI effects associated with NSAIDs (Janusz et al., 1998; Xu et al., 2009). Dual inhibitors of COX and 5-LOX have proven effective in some models of inflammation and tissue injury and may lessen the degree of adverse GI effects compared to traditional COX inhibitors (Minutoli et al., 2015; Oak et al., 2014; Shaaban et al., 2020).

Differences in the sensitivity of COX-1 and COX-2 to inhibition by anti-inflammatory drugs led to the development of selective inhibitors of COX-2, including the coxibs (Grosser et al., 2010) (see Chapter 42). These drugs were hypothesized to offer therapeutic advantages over older NSAIDs (many of which are nonselective COX inhibitors) because COX-2 was thought to be the predominant source of PGs in inflammation, whereas COX-1 is the major source of cytoprotective PGs in the GI tract and platelet TxA_2. Randomized trials of selective COX-2

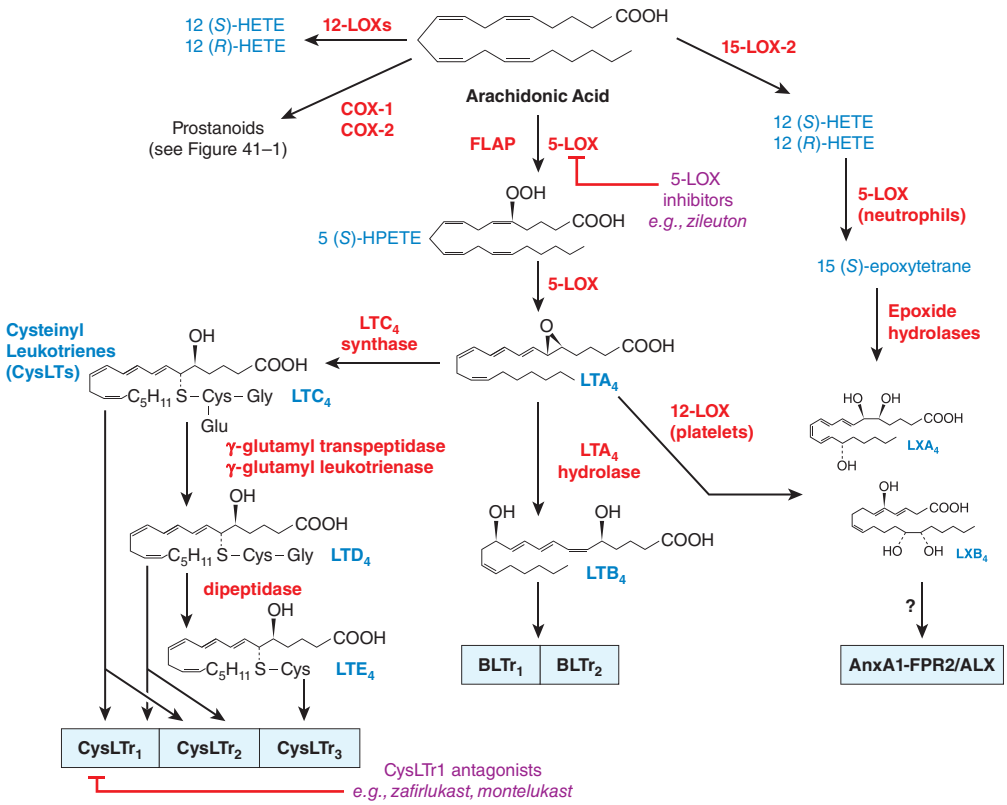

Figure 41–2 *Lipoxygenase pathways of AA metabolism.* FLAP presents AA to 5-LOX, leading to the generation of the LTs. LXs are products of cellular interaction via a 5-LOX–12-LOX pathway or via a 15-LOX–5-LOX pathway. Biological effects are transduced via membrane-bound receptors (blue boxes). The biological relevance of LXs in vivo remains controversial (Schebb NH et al., 2022). LXA_4 can activate a GPCR also activated by annexin A1 and by the formyl peptide. This GPCR is termed the AnxA1-formyl peptide receptor 2/ALX receptor (AnxA1-FPR2/ALX) to reflect the range of its putative ligands. The existence of endogenous ligands for AnxA1-FPR2/ALX is disputable (Merlin J et al., 2022). LXB2 receptor has yet to be identified. *Zileuton* inhibits 5-LOX but not the COX pathways (expanded in Figure 41–1). CysLT antagonists prevent activation of $CysLTr_1$. See the text and the Abbreviations list for further definitions.

inhibitors reported their superiority in GI safety over nonselective NSAID comparators.

However, there now is compelling evidence that COX-2 inhibitors confer a spectrum of cardiovascular hazards (myocardial infarction, stroke, systemic and pulmonary hypertension, congestive heart failure, and sudden cardiac death) (Grosser et al., 2010). The hazards can be explained sufficiently by suppression of cardioprotective COX-2–derived PGs, especially PGI_2, and the unrestrained effects of endogenous stimuli, such as platelet COX-1–derived TxA_2, on platelet activation, vascular proliferation and remodeling, hypertension, and atherogenesis.

Because LTs mediate inflammation, efforts have focused on development of LT receptor antagonists and selective inhibitors of the LOXs. *Zileuton*, an inhibitor of 5-LOX, and selective $CysLTr_1$ antagonists (*zafirlukast, pranlukast*, and *montelukast*) have established efficacy in the treatment of mild-to-moderate asthma (see Chapter 44). However, these treatments remain less effective than inhaled corticosteroids. A common polymorphism in the gene for LTC_4 synthase that correlates with increased LTC_4 generation may be associated with higher asthma risk in some populations and with the efficacy of anti-LT therapy. Small studies have reported that polymorphisms in the genes encoding 5-LOX or FLAP may be linked to asthma and lung function (Bai et al., 2012; Holloway et al., 2008), in addition to myocardial infarction, stroke, and atherosclerosis (Peters-Golden and Henderson, 2007); thus, inhibition of LT biosynthesis may eventually prove to be useful in the prevention of cardiovascular disease.

Eicosanoid Degradation

Most eicosanoids are efficiently and rapidly inactivated (Figure 41–3). The enzymatic catabolic reactions are of two types:

- A rapid initial step, catalyzed by widely distributed PG-specific enzymes, wherein PGs lose most of their biological activity
- A second step in which these metabolites are oxidized, probably by enzymes identical to those responsible for the β and ω oxidation of fatty acids

The lung, kidney, and liver play prominent roles in the enzymatically catalyzed reactions. Metabolic clearance requires an energy-dependent cellular uptake by the PG transporter and possibly other transporters (Schuster, 2002). The initial step is the oxidation of the 15-OH group to the corresponding ketone by 15-hydroxyprostaglandin dehydrogenase (15-PGDH). PGI_2 and TxA_2, however, undergo spontaneous hydrolysis as a first degradative step. LTC_4 degradation occurs in the lungs, kidney, and liver but may also occur in myeloid tisuue via CYP4F enzymes. Inactivation of 15-PGDH, which elevates the capacity of tissues to form PGE_2, enhances tissue regeneration after hematopoietic stem cell transplantation and after hemihepatectomy (Zhang et al., 2015). Its enhanced expression with advancing age has been speculated to contribute to sarcopenia.

Pharmacological Properties

The eicosanoids function through activation of specific G protein-coupled receptors (GPCRs) (Table 41–1) that couple to intracellular second-messenger systems to modulate cellular activity (Figure 41–4).

Prostaglandin Receptors

The PGs activate membrane receptors locally near their sites of formation. Eicosanoid receptors interact with G_s, G_i, and G_q to modulate the activities of adenylyl cyclase and PLC (see Chapter 3). Single-gene products have been identified for the receptors for PGI_2 (the IPr), $PGF_{2\alpha}$ (the FPr), and TxA_2 (the TPr). Four distinct PGE_2 receptors (EPr_{1-4}) and two PGD_2 receptors (DPr_1 and DPr_2—also known as $CRTH_2$) have been cloned. Additional isoforms of the TPr (α and β), FPr (A and B), and EPr_3 (I–VI, e, f) receptors can arise through differential messenger RNA splicing (Smyth et al., 2009; Woodward et al., 2011). The prostanoid receptors

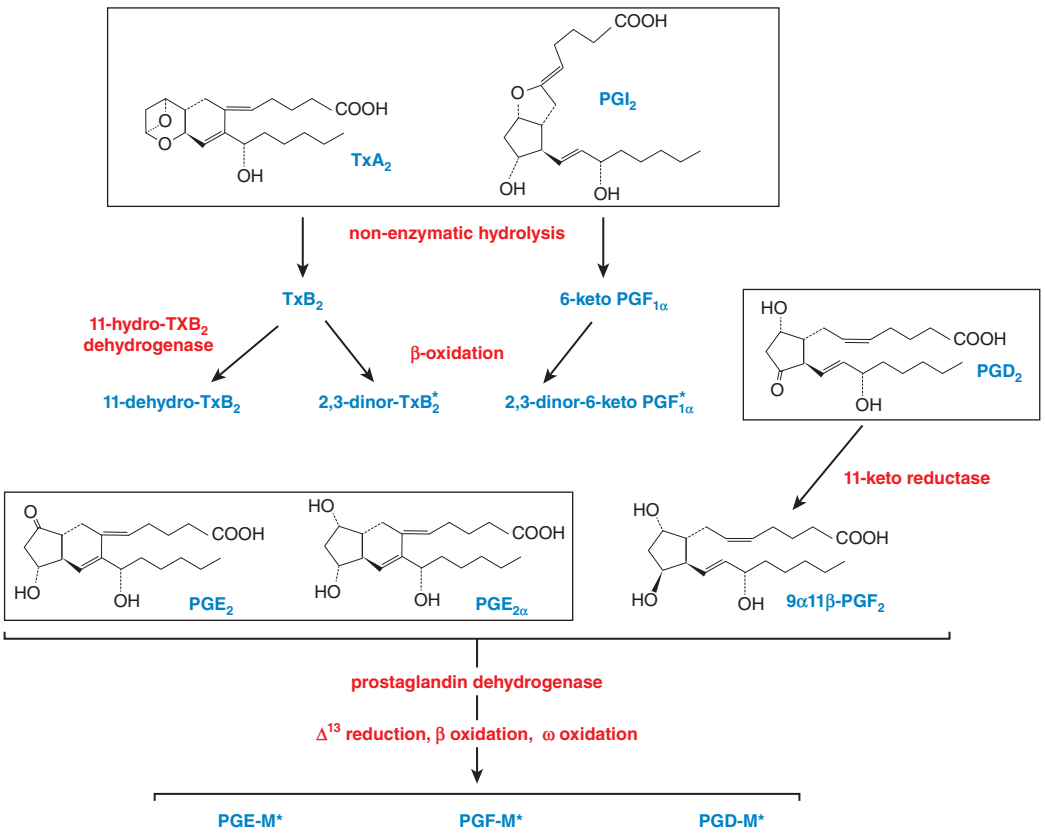

Figure 41–3 *Major pathways of prostanoid degradation.* Active metabolites are boxed. *Major urinary metabolites (M). See the text and the Abbreviations list for further definitions.

appear to derive from an ancestral EPr and share high homology. Phylogenetic comparison of this receptor family reveals three subclusters (see Figure 41–4):

- The relaxant receptors EPr_2, EPr_4, IPr, and DPr_1, which increase cellular cyclic AMP generation
- The contractile receptors EPr_1, FPr, and TPr, which increase cytosolic levels of Ca^{2+}
- EPr_3, which can couple to both elevation of cytosolic [Ca^{2+}] and inhibition of adenylyl cyclase

The DPr_2 receptor is an exception and is unrelated to the other prostanoid receptors; rather, it is a member of the fMLP (formyl-methionyl-leucyl-phenylalanine) receptor superfamily.

The structures of the active and inactive states of various human PG receptors, including DPr_2, EPr_3, EPr_4, and TPr, were recently resolved.

Leukotriene Receptors

Two receptors exist for LTB_4 (BLT_1 and BLT_2) and three for CysLTs ($CysLTr_1$ $CysLTr_2$ and $CysLTr_3$; Bäck et al., 2011, 2014; Kanaoka et al., 2013). The fMLP-2 receptor also binds LXA_4, but the functional importance of this ligand *in vivo* remains controversial. All are GPCRs and couple with G_q and other G proteins, depending on the cellular context. BLT_1 is expressed predominantly in leukocytes, thymus, and spleen, whereas BLT_2, the low-affinity receptor for LTB_4, is found in spleen, leukocytes, ovary, liver, and intestine.

$CysLTr_1$ binds LTD_4 with higher affinity than LTC_4, while $CysLTr_2$ shows equal affinity for both LTs. Both receptors bind LTE_4 with low affinity. $CysLTr_3$ (also known as OXGR1 or GPR99) appears to have high affinity only for LTE_4 (Kanaoka et al., 2013). Activation of G_q, leading to mobilization of intracellular Ca^{2+}, is the primary signaling pathway reported. Studies also have placed G_i downstream of $CysLTr_2$. $CysLTr_1$ is expressed in lung and intestinal smooth muscle, spleen, and peripheral blood leukocytes, whereas $CysLTr_2$ is found in heart, spleen, peripheral blood leukocytes, adrenal medulla, and brain. $CysLTr_3$ is expressed in kidney, trachea, lung, salivary glands, airway epithelial cells, and mast cells.

The crystal structures of $CysLTr_1$, $CysLTr_2$, and BLT_1 were recently resolved, advances that could facilitate development of therapeutic agents acting at these receptors.

Other Agents

Other AA-derived products (e.g., isoprostanes, EETs) have potent biological activities, and there is evidence for distinct receptors for some of these substances. An orphan receptor, GPR31, has been identified as a receptor for 12(S)-HETE (Powell and Rokach, 2015). Specific receptors for the HETEs and EETs have been proposed, and evidence that the orphan receptor GPR75 functions as a receptor for 20-HETE has been provided (Garcia et al., 2017).

Physiological Actions and Pharmacological Effects

The widespread biosynthesis and myriad pharmacological actions of eicosanoids are reflected in their complex physiology and pathophysiology. Knowledge of the distribution of the major eicosanoid receptors helps to put the complexity into perspective (see Figure 41–1). The development of mice with targeted disruptions of genes regulating eicosanoid biosynthesis and eicosanoid receptors has revealed unexpected roles for these autacoids and has clarified hypotheses about their functions (see Table 41–1).

Cardiovascular System

Because of their short $t_{1/2}$—seconds to minutes at physiological pH—the activities on vascular tone of endogenous prostanoids occur primarily locally at their sites of biosynthesis. Systemic effects of prostanoids on blood pressure involve renal and hormonal processes. PGI_2, the major arachidonate metabolite released from the vascular endothelium, is derived primarily from COX-2 in humans and is considered to be

TABLE 41–1 ■ HUMAN EICOSANOID RECEPTORS

RECEPTOR	LIGANDS 1° (2°)	PRIMARY COUPLING	MAJOR PHENOTYPE IN KNOCKOUT MICE
DPr_1	PGD_2	G_s	↓ Allergic asthma
DPr_2/$CHRT_2$	PGD_2 ($15d\text{-}PGJ_2$)	G_i	↑ or ↓ Allergic airway inflammation
EPr_1	PGE_2 (PGI_2)	G_q	↓ Response of colon to carcinogens
EPr_2	PGE_2	G_s	Impaired ovulation and fertilization Salt-sensitive hypertension
EPr_3 I–VI, e, f	PGE_2	G_i; G_s; G_q	Resistance to pyrogens ↓ Acute cutaneous inflammation
EPr_4	PGE_2	G_s	Patent ductus arteriosus ↓ Bone mass/density in aged mice ↑ Bowel inflammatory response ↓ Colon carcinogenesis
$FPr_{A,B}$	$PGF_{2\alpha}$ (IsoPs)	G_q	Failure of parturition
IPr	PGI_2 (PGE_2)	G_s	↑ Thrombotic response ↓ Response to vascular injury ↑ Atherosclerosis ↑ Cardiac fibrosis Salt-sensitive hypertension ↓ Joint inflammation
$TPr_{\alpha,\beta}$	TxA_2 (IsoPs)	G_q; G_i; $G_{12/13}$; G_{16}	↑ Bleeding time ↓ Response to vascular injury ↓ Atherosclerosis ↑ Survival after cardiac allograft
$BLTr_1$	LTB_4	G_{16}; G_i	Some suppression of inflammatory response
$BLTr_2$	LTB_4 [12(*S*)-HETE, 12(*R*)-HETE]	G_q-like; G_i-like; G_z-like	? (Reports of altered inflammatory processes)
$CysLTr_1$	LTD_4 (LTC_4/LTE_4)	G_q	↓ Innate and adaptive immune vascular permeability response ↑ Pulmonary inflammatory and fibrotic response
$CysLTr_2$	LTC_4/LTD_4 (LTE_4)	G_q	↓ Pulmonary inflammatory and fibrotic response

This table lists the major classes of eicosanoid receptors and their signaling characteristics. Splice variants for EPr_3, TPr, and FPr are indicated.

"atheroprotective." PGI_2 generation and release is regulated by shear stress and by both vasoconstrictor and vasodilator autacoids. In most vascular beds, PGE_2, PGI_2, and PGD_2 elicit vasodilation, and systemic infusion of high concentrations results in a drop in blood pressure; as mentioned above, physiologically, these responses are quite local because endogenous prostanoids are paracrine mediators that do not circulate (Smyth et al., 2009). $PGF_{2\alpha}$ is a potent constrictor of both pulmonary arteries and veins. TxA_2 is a potent vasoconstrictor and a mitogen in smooth muscle cells.

PGE_2 can also cause vasoconstriction through activation of EP_1 and EP_3. Infusion of PGD_2 in humans results in flushing, nasal congestion, and hypotension. Local subcutaneous release of PGD_2 contributes to dilation of the vasculature in the skin, which causes facial flushing associated with niacin treatment in humans. Subsequent formation of F-ring metabolites from PGD_2 may result in hypertension. PGI_2 relaxes vascular smooth muscle, causing hypotension and reflex tachycardia on intravenous administration. PGI_2 limits pulmonary hypertension induced by hypoxia and systemic hypertension induced by AngII and lowers pulmonary resistance in patients with pulmonary hypertension.

Cyclooxygenase 2–derived PGE_2, acting via the EPr_4, maintains the ductus arteriosus patent until birth, when reduced PGE_2 levels (a consequence of increased PGE_2 metabolism) permit closure. The traditional NSAIDs induce closure of a patent ductus in neonates (see Chapter 42). Contrary to expectation, animals lacking the EPr_4 during development die with a patent ductus during the perinatal period (see Table 41–1) because the mechanism for control of the ductus *in utero*, and its remodeling at birth, is absent.

Infusion of PGs of the E and F series generally increases cardiac output. Weak, direct inotropic effects have been noted in various isolated preparations. In the intact animal, however, increased force of contraction and increased heart rate are, in large measure, a reflex consequence of a fall in total peripheral resistance. PGI_2 and PGE_2, acting on the IPr or the EPr_3, respectively, protect against oxidative injury in cardiac tissue.

Studies suggest a role for COX-2 in cardiac function. PGI_2 and PGE_2, acting on the IPr or the EP_3, respectively, protect against oxidative injury in cardiac tissue. IPr deletion augments myocardial ischemia/reperfusion injury, and both microsomal PGE synthase-1 (mPGES-1) deletion and cardiomyocyte-specific deletion of the EPr_4 exacerbate the decline in cardiac function after experimental myocardial infarction. COX-2–derived TxA_2 contributed to oxidant stress, isoprostane generation, and activation of the TPr, and also possibly the FPr, to increase cardiomyocyte apoptosis and fibrosis in a model of heart failure. Selective deletion of COX-2 in cardiomyocytes results in mild heart failure and a predisposition to arrhythmogenesis in mice (Wang et al., 2009).

LTC_4 and LTD_4 can constrict or relax isolated vascular smooth muscle preparations, depending on the concentrations used and the vascular bed in question (Bäck et al., 2011). Although LTC_4 and LTD_4 have little effect on most large arteries or veins, nanomolar concentrations of these

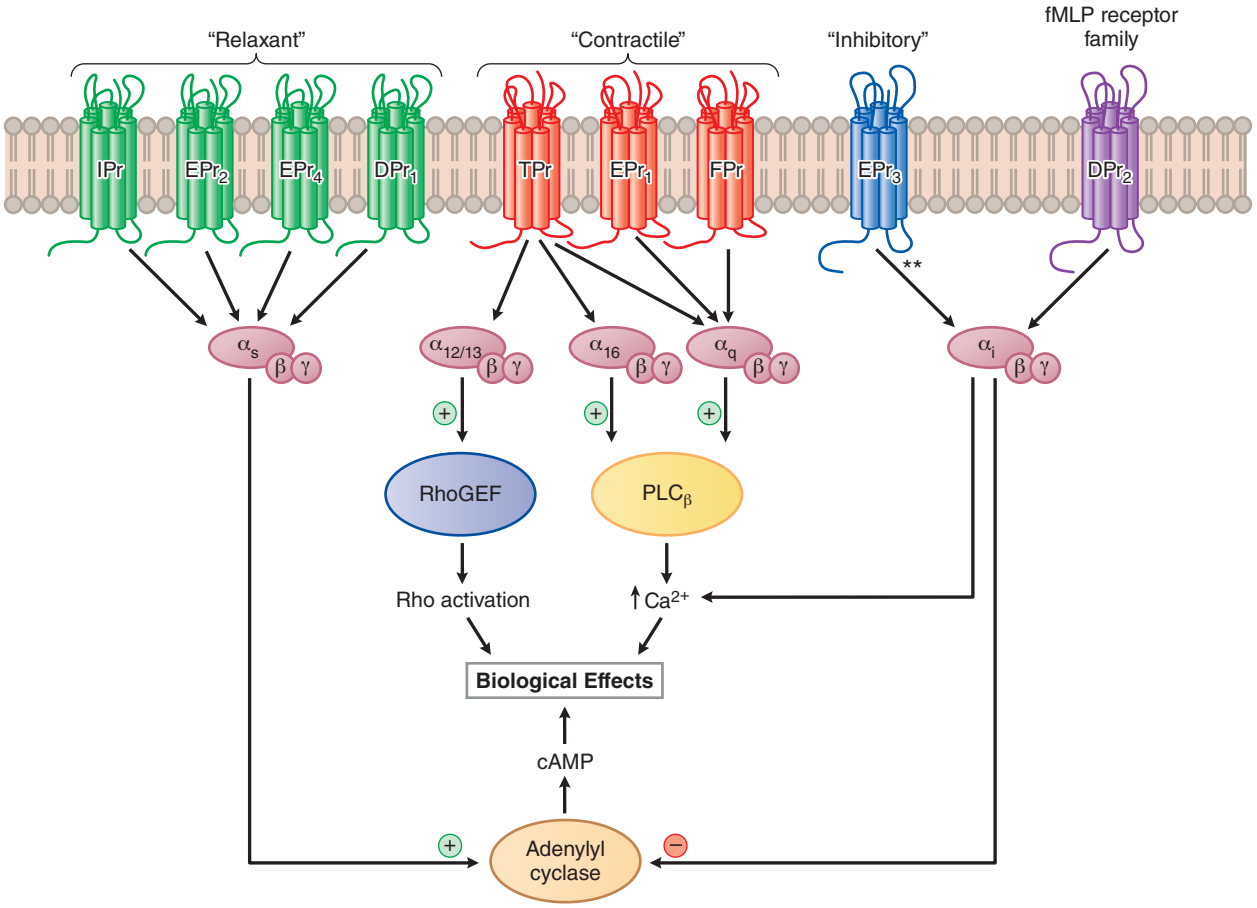

Figure 41–4 *Prostanoid receptors and their primary signaling pathways.* Prostanoid receptors are heptaspanning GPCRs. The terms *relaxant*, *contractile*, and *inhibitory* refer to the phylogenetic characterization of their primary effects. All EPr_3 isoforms couple through G_i; some can also activate G_s or $G_{12/13}$ pathways. RhoGEF, rho guanine nucleotide exchange factor.

agents contract coronary arteries and distal segments of the pulmonary artery. The renal vasculature is resistant to this constrictor action, but the mesenteric vasculature is not. LTC_4 and LTD_4 act in the microvasculature to increase permeability of postcapillary venules; they are about 1000-fold more potent than histamine in this regard. At higher concentrations, LTC_4 and LTD_4 can constrict arterioles and reduce exudation of plasma. There is evidence for a role of the LTs in cardiovascular disease (Peters-Golden and Henderson, 2007). Human genetic studies have indicated a link between cardiovascular disease and polymorphisms in the LT biosynthetic enzymes and FLAP.

The EETs cause vasodilation in several vascular beds by activating the large conductance Ca^{2+}-activated K^+ channels of smooth muscle cells, thereby hyperpolarizing the smooth muscle and causing relaxation. EETs also function as EDHFs, particularly in the coronary circulation. Endogenous biosynthesis of EETs is increased in human syndromes of hypertension.

Platelets

Platelet aggregation leads to activation of membrane phospholipases, with the release of AA and consequent eicosanoid biosynthesis. In human platelets, TxA_2 and 12-HETE are the two major eicosanoids formed, although eicosanoids from other sources (e.g., PGI_2 derived from vascular endothelium) also affect platelet function. Mature platelets express only COX-1. TxA_2, the major product of COX-1 in platelets, induces platelet aggregation and amplifies the signal for other more potent platelet agonists such as thrombin and ADP. The importance of the TxA_2 pathway is evident from the efficacy of platelet COX-1 inhibition with low-dose *aspirin* in the secondary prevention of myocardial infarction and ischemic stroke. The total biosynthesis of TxA_2, as determined by excretion of its urinary metabolites, is augmented in clinical syndromes of platelet activation, including unstable angina, myocardial infarction, and stroke. Deletion of the TPr in the mouse prolongs bleeding time, renders platelets unresponsive to TPr agonists, and blunts the response to vasopressors and the proliferative response to vascular injury (Smyth et al., 2009). TxA_2 induces platelet shape change, through G_{12}/G_{13}-mediated Rho/Rho kinase–dependent regulation of myosin light-chain phosphorylation, and aggregation through G_q-dependent activation of PKC. The actions of TxA_2 on platelets are restrained by its short $t_{1/2}$ (~30 sec), by rapid TPr desensitization, and by endogenous inhibitors of platelet function, including nitric oxide (NO) and PGI_2.

Low concentrations of PGE_2, via the EPr_3, enhance platelet aggregation. In contrast, higher concentrations of PGE_2, acting via the IPr or possibly EPr_2 or EPr_4, inhibit platelet aggregation. Both PGI_2 and PGD_2 inhibit the aggregation of platelets. PGI_2 limits platelet activation by TxA_2 and disaggregates preformed platelet clumps. The increased incidence of myocardial infarction and stroke in patients receiving selective inhibitors of COX-2, explained by inhibition of COX-2–dependent PGI_2 formation, supports this concept (Grosser et al., 2010).

Inflammation and Immunity

Eicosanoids play a major role in inflammatory and immune responses. LTs generally are proinflammatory and interact with PGs to promote and sustain inflammation (Ricciotti and FitzGerald, 2011), although there are some exceptions, such as the inhibitory actions of PGE_2 on mast cell activation. PGs and LXs and related compounds may also contribute to the resolution of inflammation (Buckley et al., 2014). COX-2 is the major source of prostanoids formed during and after an inflammatory response. Moreover, eicosanoids may modulate virus infection by regulating virus-host interactions and the host immune and inflammatory responses activated by viral pathogens. For example, eicosanoids may be

involved in different stages of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection and in the development of COVID-19. Eicosanoids may directly influence SARS-CoV-2 entry, replication, and clearance (Theken and FitzGerald, 2021). The nonstructural SARS-CoV-2 protein, Nsp7, may interact with microsomal prostaglandin E synthase-2 (Gordon et al., 2020). Infection caused by different viruses may impact the expression of genes for proteins in the arachidonic acid pathway and the biosynthesis of bioactive lipids. PGE_2, through its effects on type I interferon signaling, cytotoxic T-cell and Th17 responses, macrophage polarization, natural killer cell functions, neutrophil extracellular trap formation, inflammasome activation, and nuclear factor-κB activation, may contribute to the cytokine storm and hyperinflammation response observed in COVID-19 patients. CysLTs may regulate the immune and inflammatory response to SARS-CoV-2 infection by having a chemoattractant effect on neutrophils and lymphocytes and by causing macrophage activation and proinflammatory cytokine secretion. PGE_2 and PGI_2 are the predominant proinflammatory prostanoids that contribute to increased vascular permeability and blood flow in the inflamed region. TxA_2 can increase platelet-leukocyte interactions. PGD_2 may contribute to the resolution of inflammation. Lymphocytes have a minimal capacity to form PGs, yet they are a primary target of their action. PGs generally inhibit lymphocyte function and proliferation, suppressing the immune response. PGE_2 plays a complex role in the inflammatory process and depresses the humoral antibody response by inhibiting the differentiation of B lymphocytes into antibody-secreting plasma cells. PGE_2 can induce immunoglobulin class switching, resulting in increased IgE production (see Chapter 38). PGE_2 acts on T lymphocytes to inhibit mitogen-stimulated proliferation and lymphokine release by sensitized cells. PGE_2 and TxA_2 also may play a role in T-lymphocyte development by regulating apoptosis of immature thymocytes. PGE_2, acting via EPr_2 and EPr_4, can interact with the programmed cell death protein 1 (PD-1) (see Figure 38–7) to restrain cytotoxic T-cell function and survival during chronic infection in mice (Chen et al., 2015). The COX-2/mPGES-1/PGE_2 pathway can regulate PD ligand 1 (PD-L1) expression in tumor-infiltrating myeloid cells (Prima et al., 2017). Given the efficacy of blockade of this pathway in a range of cancers, the possibility that blockade of PGE_2 synthesis or action might augment this effect has been suggested.

The synthesis, release, and subsequent effects of eicosanoids are prominent components of the inflammatory response (see Figure 38–6). PGD_2 is a potent leukocyte chemoattractant, primarily through the DPr_2. The LTs are potent mediators of inflammation. Deletion of either 5-LOX or FLAP reduces inflammatory responses in model systems. LTB_4, a potent proinflammatory eicosanoid, acts as a chemotactic agent for neutrophils, T lymphocytes, eosinophils, monocytes, dendritic cells, and possibly also mast cells, recruiting them to sites of injury or inflammation (Bäck et al., 2011). LTB_4 stimulates the aggregation of eosinophils and promotes degranulation and generation of superoxide. It also promotes adhesion of neutrophils to vascular endothelial cells and their transendothelial migration and stimulates synthesis of proinflammatory cytokines from macrophages and lymphocytes.

The CysLTs are chemotaxins for eosinophils and monocytes. They also induce cytokine generation in eosinophils, mast cells, and dendritic cells. At higher concentrations, these LTs also promote eosinophil adherence, degranulation, cytokine or chemokine release, and oxygen radical formation. In addition, CysLTs contribute to inflammation by increasing endothelial permeability, thus promoting migration of inflammatory cells to the site of inflammation.

Bronchial and Tracheal Muscle

A complex mixture of autacoids is released when sensitized lung tissue is challenged by the appropriate antigen, including COX-derived bronchodilator and bronchoconstrictor substances. Among these, TxA_2, $PGF_{2\alpha}$, and PGD_2 contract, and PGE_2 and PGI_2 relax, bronchial and tracheal muscle. PGI_2 causes bronchodilation in most species; human bronchial tissue is particularly sensitive. PGI_2 antagonizes bronchoconstriction induced by other agents. PGI_2 suppresses allergic airway inflammation by promoting regulatory T-cell signaling and reprogramming (Norlander et al., 2021). PGD_2 appears to be the primary bronchoconstrictor prostanoid of relevance in humans. Polymorphisms in the genes for hematopoietic PGD_2 synthase (H-PGDS) and the TPr have been associated with asthma in humans.

Roughly 10% of people who take *aspirin* or NSAIDs develop bronchospasm, termed *aspirin*-exacerbated respiratory disease (AERD). This immune dysfunction involves a shift in AA metabolism to LT formation. This substrate diversion appears to involve COX-1, not COX-2. CysLTs are bronchoconstrictors that act principally on smooth muscle in the airways and are a thousand times more potent than histamine. They also stimulate bronchial mucus secretion and cause mucosal edema.

The CysLTs probably dominate during allergic constriction of the airway. Deficiency of 5-LOX leads to reduced influx of eosinophils in airways and attenuates bronchoconstriction. Furthermore, unlike COX inhibitors and histaminergic antagonists, CysLTr antagonists and 5-LOX inhibitors are effective in the treatment of human asthma (see Inhibitors of Eicosanoid Biosynthesis). The relatively slow LT metabolism in lung contributes to the long-lasting bronchoconstriction that follows challenge with antigen and may be a factor in the high bronchial tone that is observed in asthmatic patients in periods between acute attacks (see Chapter 44).

GI Smooth Muscle

PGE_2 and $PGF_{2\alpha}$ stimulate contraction of the main longitudinal muscle from stomach to colon. PG endoperoxides, TxA_2, and PGI_2 also produce contraction but are less active. Circular muscle generally relaxes in response to PGE_2 and contracts in response to $PGF_{2\alpha}$. The LTs have potent contractile effects. PGs reduce transit time in the small intestine and colon. Diarrhea, cramps, and reflux of bile have been noted in response to oral PGE analogues. PGE_2 and $PGF_{2\alpha}$ stimulate the movement of water and electrolytes into the intestinal lumen. Such effects may underlie the watery diarrhea that follows their oral or parenteral administration. PGE_2 appears to contribute to the water and electrolyte loss in cholera, a disease that is somewhat responsive to therapy with NSAIDs.

GI Secretion

In the stomach, PGE_2 and PGI_2 contribute to increased mucus secretion (*cytoprotection*), reduced acid secretion, and reduced pepsin content. PGE_2 and its analogues also inhibit gastric damage caused by a variety of ulcerogenic agents and promote healing of duodenal and gastric ulcers (see Chapter 53). While COX-1 may be the dominant source of such cytoprotective PGs under physiological conditions, both COX-1 and COX-2 may be contributing to ulcer healing through the regulation of angiogenesis (Jones et al., 1999). PGE_2 promotes healing of GI ulcers through the stimulation of angiogenesis via the upregulation of vascular endothelial growth factor (VEGF) expression mediated by EPr_4. Selective inhibitors of COX-2 and deletion of the enzyme delay ulcer healing in rodents, but the impact of COX-2 inhibitors in humans is unclear. CysLTs, by constricting gastric blood vessels and enhancing production of proinflammatory cytokines, may contribute to the gastric damage.

Uterus

Strips of nonpregnant human uterus are contracted by $PGF_{2\alpha}$ and TxA_2 but are relaxed by PGE_2. Sensitivity to the contractile response is most prominent before menstruation, whereas relaxation is greatest at midcycle. PGE_2, together with oxytocin, is essential for the onset of parturition. PGI_2 and high concentrations of PGE_2 produce uterine relaxation. The intravenous infusion of low concentrations of PGE_2 or $PGF_{2\alpha}$ to pregnant women produces a dose-dependent increase in uterine tone and in the frequency and intensity of rhythmic uterine contractions. PGE_2 and $PGF_{2\alpha}$ can be administered to terminate pregnancy. Uterine responsiveness to PGs increases as pregnancy progresses but remains smaller than the response to oxytocin.

Kidney

COX-1– and COX-2–derived eicosanoids regulate kidney blood flow and glomerular filtration rate. COX-2–derived PGE_2 and PGI_2 increase medullary blood flow, resulting in pressure diuresis, and inhibit tubular Na^+ reabsorption (Hao and Breyer, 2007). Expression of medullary COX-2 is

increased during high salt intake. COX-1–derived products promote salt excretion in the collecting ducts. Cortical COX-2–derived PGE_2 and PGI_2 increase renal blood flow and glomerular filtration through their local vasodilating effects and as part of the tubuloglomerular feedback mechanism that controls renin release. Expression of COX-2 in macula densa cells increases in conditions of low distal tubular flow during low dietary salt intake or volume depletion. COX-2–derived PGE_2 and possibly PGI_2 result in increased renin release, leading to sodium retention and elevated blood pressure.

TxA_2, generated at low levels in the normal kidney, has potent vasoconstrictor effects that reduce renal blood flow and glomerular filtration rate. Infusion of $PGF_{2\alpha}$ causes both natriuresis and diuresis. Conversely, $PGF_{2\alpha}$ may activate the renin-angiotensin system, contributing to elevated blood pressure. CYP epoxygenase products may regulate renal function. Both 20-HETE and the EETs are generated in renal tissue; 20-HETE constricts the renal arteries, while EETs mediate vasodilation and natriuresis.

Bartter syndrome is an autosomal recessive trait that manifests as hypokalemic metabolic alkalosis. The antenatal variant of Bartter syndrome is due to dysfunctional ROMK2 (Kir1.1), the K^+ channel that recycles K^+ into the tubular fluid. This syndrome also is known as *hyper-PGE syndrome*. The relationship between dysfunctional ROMK2 and elevated PGE_2 synthesis is not clear; however, in patients with antenatal Bartter syndrome, inhibition of COX-2 ameliorates many of the clinical symptoms.

Eye

$PGF_{2\alpha}$ induces constriction of the iris sphincter muscle, but its overall effect in the eye is to decrease intraocular pressure by increasing the aqueous humor outflow. A variety of FPr agonists have proven effective in the treatment of open-angle glaucoma, a condition associated with the loss of COX-2 expression in the pigmented epithelium of the ciliary body (see Chapter 74). An EPr2 agonist, with a nonprostaglandin structure, has been recently approved for the treatment of glaucoma and ocular hypertension.

Central Nervous System

PGE_2 induces fever. The hypothalamus regulates the body temperature set point, which is elevated by endogenous pyrogens such as interleukin (IL)-1β, IL-6, TNFα (tumor necrosis factor α), and interferons (Morrison and Nakamura, 2011). The response is mediated by coordinate induction of COX-2 and mPGES-1 in the endothelium of blood vessels in the preoptic hypothalamic area to form PGE_2. PGE_2 can cross the blood-brain barrier and act on the EPr_3 (and perhaps EPr_1) on thermosensitive neurons, triggering the hypothalamus to elevate body temperature. Exogenous $PGF_{2\alpha}$ and PGI_2 induce fever but do not contribute to the endogenous pyretic response. PGE_2 can mediate age-associated maladaptive inflammation and cognitive decline through its myeloid EPr_2 by inducing an energy-deficient state in macrophages and microglia. EPr_2 blockade reduces the inflammatory response, restores the cell bioenergetics, and reverses cognitive aging (Minhas et al., 2021). PGD_2 appears to act on arachnoid trabecular cells in the basal forebrain to mediate an increase in extracellular adenosine that, in turn, facilitates induction of sleep. COX-2–derived prostanoids also have been implicated in the pathogenesis of several CNS degenerative disorders (e.g., Alzheimer's disease, Parkinson's disease; see Chapter 21).

Pain

Inflammatory mediators, including LTs and PGs, increase the sensitivity of nociceptors and potentiate pain perception. Centrally, both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli. Both PGE_2 (through EPr_1 and EPr_4) and PGI_2 (via IPr) reduce the threshold to stimulation of nociceptors, causing "peripheral sensitization." PGE_2, and perhaps PGD_2, PGI_2, and $PGF_{2\alpha}$, can increase excitability in neuronal pain transmission pathways in the spinal cord, causing hyperalgesia and allodynia. LTB_4 also produces hyperalgesia. The release of these eicosanoids during the inflammatory process thus serves as an amplification system for the pain mechanism. The role of PGE_2 and PGI_2 in inflammatory pain is discussed in more detail in Chapter 42.

Endocrine System

The systemic administration of PGE_2 increases circulating concentrations of ACTH (corticotropin), growth hormone, prolactin, and gonadotropins. Other effects include stimulation of steroid production by the adrenals, stimulation of insulin release, and thyrotropin-like effects on the thyroid. PGE_2 works as part of a positive-feedback loop to induce oocyte maturation required for fertilization during and after ovulation. PGE_2-dependent critical events for ovulation are regulated by the activity of the PGT, which modulates the extracellular levels of PGE_2 in granulosa cells (Yerushalmi et al., 2016). The critical role of $PGF_{2\alpha}$ in parturition relies on its capacity to induce an oxytocin-dependent decline in progesterone levels. LOX metabolites also have endocrine effects. 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates a portion of the aldosterone release stimulated by AngII, but not that which occurs in response to ACTH.

Bone

PGs are strong modulators of bone metabolism. COX-1 is expressed in normal bone, while COX-2 is upregulated in settings such as inflammation and during mechanical stress. PGE_2 stimulates bone formation by increasing osteoblastogenesis and bone resorption via activation of osteoclasts. Osteoblast-derived PGE_2 activates EPr_4 in sensory nerves to control bone homeostasis and regeneration (Chen et al., 2019).

Skeletal Muscle

PGs play an essential role in skeletal muscle biology. PGE_2 is the main PG produced in resting skeletal muscle. PGE_2 contributes to regeneration of damaged muscles and maintains mature muscle myofiber homeostasis. PGE_2, acting via EPr_4, drives muscle repair after injury by accelerating muscle stem cell expansion (Ho et al., 2017). COX-2 deletion or inhibition may impair skeletal muscle healing (Ho et al., 2017). In aging skeletal muscle, inactivation of 15-PGDH, which increases its expression with aging, restores PGE_2 and PGD_2 and increases muscle mass, strength, and exercise performance by impacting mitochondrial function, autophagy, and proteostasis (Palla et al., 2021). H-PGDS-derived PGD_2 is implicated in muscle necrosis and muscle tissue damage (Mohri et al., 2009). H-PGDS inhibition ameliorates myonecrosis in mouse models of Duchenne muscular dystrophy (Mohri et al., 2009), and urinary excretion of PGD_2 metabolites reflects the severity of this disease (Takeshita et al., 2018).

Cancer

Pharmacological inhibition or genetic deletion of COX-2 restrains tumor formation in models of colon, breast, lung, and other cancers. Large human epidemiological studies have reported that incidental use of NSAIDs is associated with significant reductions in relative risk for developing these and other cancers. PGE_2 has been implicated as the primary pro-oncogenic prostanoid in multiple studies. PGE_2, produced by the tumor cell, stromal cells, or cells in the tumor microenvironment, can promote cancer initiation and progression by controlling multiple biological processes. Fibroblast-derived PGE_2 may induce early tumor initiation by driving the proliferation of epithelial stem cells through EPr_4. Deletion or inhibition of EPr_4 reduces tumor formation in mouse models of colon cancer (Roulis et al., 2020). PGE_2-derived COX-2 can promote tumor progression by shaping the tumor microenvironment and favoring tumor escape. COX-2 deletion reduces tumor growth by restoring effector $CD8^+$ T-cell infiltration and reducing myeloid-derived suppressor cells, and COX-2 inhibition reverses tumor resistance to immunotherapy in mouse models of pancreatic adenocarcinoma (Markosyan et al., 2019). PGE_2 induces cytotoxic T-lymphocyte exhaustion by modulating inhibitory T-cell receptor function. PGE_2 can upregulate PD-1 expression on effector $CD8^+$ T-cells (Miao et al., 2017) and PD-L1 expression in tumor-associated macrophages and myeloid-derived suppressor cells (Prima et al., 2017). PGE_2 controls the suppressive activity of polymorphonuclear myeloid-derived suppressor cells, which dampen the antitumoral activity of T cells and other immune cells (Veglia et al., 2019). PGE_2 reduces the viability of natural killer cells, chemokine production, and chemokine receptor expression in conventional type 1 dendritic cells (Böttcher et al., 2018).

Therapeutic Uses

Inhibitors and Antagonists

The NSAIDs are used widely for their anti-inflammatory effects, whereas low-dose *aspirin* is used for cardioprotection (see Chapter 42). LT antagonists are useful clinically in the treatment of asthma, and FPr agonists are used in the treatment of open-angle glaucoma (see Chapter 74). EPr agonists are used to induce labor and to ameliorate gastric irritation owing to NSAIDs. DPr_1 antagonists have been explored for offsetting the facial flushing associated with niacin. Orally active antagonists of LTC_4 and LTD_4, which block $CysLTr_1$, are used in the treatment of asthma that is mild to moderately severe (see Chapter 44). They are also the mainstay of treatment for AERD, given the underlying dysregulation of LT production in that adverse response.

Prostanoids and Their Analogues

Prostanoids have a short $t_{1/2}$ in the circulation, and their systemic administration produces significant adverse effects (e.g., pain, flushing, and diarrhea). Nonetheless, several prostanoids are of clinical utility in the following situations.

Labor and Therapeutic Abortion. PGE_2, $PGF_{2\alpha}$, and their analogues are used to induce labor at term and terminate pregnancy by promoting uterine contractions. These agents facilitate labor by promoting ripening and dilation of the cervix. *Dinoprostone* or *misoprostol*, synthetic analogues of PGE_2 and PGE_1, are used for cervical ripening and induction of labor and as abortifacients in the second trimester of pregnancy. *Misoprostol*, in combination with the antiprogesterone *mifepristone* (RU486), is highly effective in the termination of pregnancy. An analogue of $PGF_{2\alpha}$, *carboprost tromethamine*, is used to induce second-trimester abortions and to control postpartum hemorrhage that does not respond to conventional methods.

Maintenance of Patent Ductus Arteriosus. The ductus arteriosus in neonates is highly sensitive to vasodilation by PGE_1. Maintenance of a patent ductus may be important hemodynamically in some neonates with congenital heart disease. PGE_1 (*alprostadil*) is highly effective for palliative therapy to maintain temporary patency until surgery can be performed. Apnea is observed in about 10% of neonates treated, particularly those who weigh less than 2 kg at birth.

Gastric Cytoprotection. Several PG analogues are used to suppress gastric ulceration. *Misoprostol*, a PGE_1 analogue, is approved for prevention of NSAID-induced gastric ulcers and is about as effective as the proton pump inhibitor *omeprazole* (see Chapter 53).

Impotence. PGE_1 (*alprostadil*), given as an intracavernous injection or urethral suppository, is a second-line treatment of erectile dysfunction. Phosphodiesterase 5 inhibitors (e.g., *sildenafil*, *tadalafil*, *vardenafil*, and *avanafil*; see Chapter 49) have superseded PGE_1 as the preferred treatment of this condition.

Pulmonary Arterial Hypertension. Long-term therapy with PGI_2 (*epoprostenol*), via continuous intravenous infusion, improves symptoms and hemodynamics and can delay or preclude the need for lung or heart-lung transplantation in a number of patients with pulmonary arterial hypertension (PAH). Several orally available PGI_2 analogues have also been used clinically for PAH. *Iloprost* specifically targets lung vasculature and can be inhaled or delivered by intravenous administration (injectable form is not available in the U.S.). *Treprostinil* ($t_{1/2}$ ~4 h) may be delivered by continuous subcutaneous infusion, intravenous infusion, or orally. *Selexipag* ($t_{1/2}$ ~0.8–2.5 h; $t_{1/2}$ active metabolite ~6.2–13.5 h) is the first approved PGI_2 analogue with a nonprostanoid structure. Chapter 35 presents a comprehensive picture of the treatment of PAH.

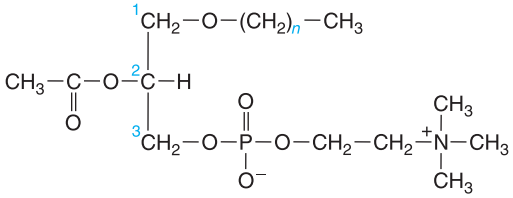
Glaucoma. *Latanoprost*, a stable, long-acting $PGF_{2\alpha}$ derivative, was the first prostanoid used for glaucoma. Similar prostanoids with ocular hypotensive effects include *bimatoprost*, *tafluprost*, and *travoprost*. These drugs act as agonists at the FPr and are administered as ophthalmic drops. Recently, *latanoprost* has been combined with other moieties to treat glaucoma: *Latanoprostene bunod* is metabolized into *latanoprost* and *butanediol mononitrate* (a source of NO); *latanoprost* has also been combined with Rho kinase inhibitors (Tanna and Johnson, 2018). Chapter 74 covers the clinical pharmacology of these drugs in the treatment of glaucoma.

Platelet-Activating Factor

In 1971, Henson demonstrated that a soluble factor released from leukocytes caused platelets to aggregate. Benveniste and his coworkers characterized the factor as a polar lipid and named it PAF. During this period, Muirhead described an antihypertensive polar renal lipid (APRL) produced by interstitial cells of the renal medulla that proved to be identical to PAF. Hanahan and coworkers then synthesized acetyl glyceryl ether phosphorylcholine (AGEPC) and determined that this phospholipid had chemical and biological properties identical to those of PAF. Independent determination of the structures of PAF and APRL showed them to be structurally identical to AGEPC. The commonly accepted name for this substance is PAF; however, its actions extend far beyond platelets.

Chemistry and Biosynthesis

PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) represents a family of phospholipids because the alkyl group at position 1 can vary in length from 12 to 18 carbon atoms (Prescott et al., 2000). In human neutrophils, PAF consists predominantly of a mixture of the 16- and 18-carbon ethers, but its composition may change when cells are stimulated.



PLATELET-ACTIVATING FACTOR (n = 11 to 17)

Biosynthesis of eicosanoids and PAF depends on PLA_2 activity. The major biosynthetic pathway for PAF, the remodeling pathway, involves the precursor 1-*O*-alkyl-2-acyl-glycerophosphocholine, a membrane lipid; the 2-acyl substituents include AA. PAF is synthesized from this substrate in two steps (Figure 41–5). The rate-limiting step is the second

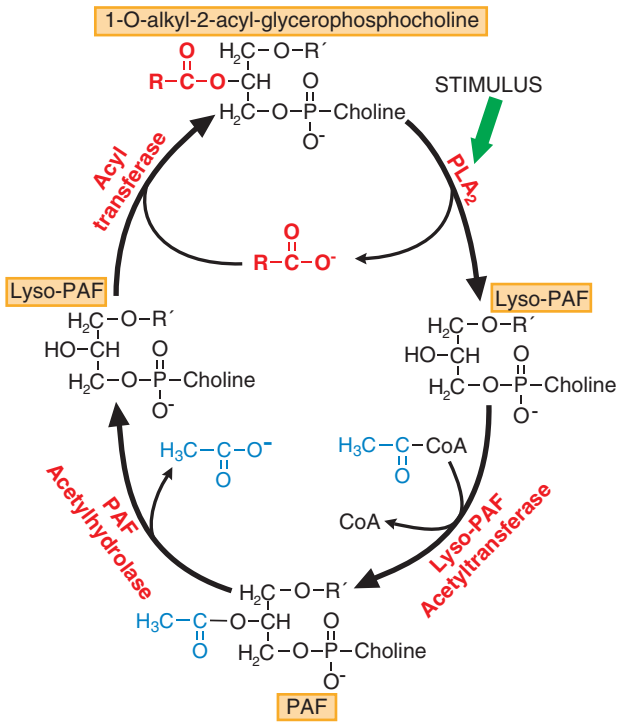


Figure 41–5 *Synthesis and degradation of PAF.* $RCOO^-$ is a mixture of fatty acids but is enriched in AA that may be metabolized to eicosanoids.

one, acetyl-coenzyme-A-lyso-PAF acetyltransferase. The synthesis of PAF may be stimulated during antigen-antibody reactions or by a variety of agents, including chemotactic peptides, thrombin, collagen, and other autacoids; PAF also can stimulate its own formation. Both the PL and acetyltransferase are Ca^{2+}-dependent enzymes; thus, PAF synthesis is regulated by the availability of Ca^{2+}. PAF-AHs (AHs, acetylhydrolases) inactivate PAH by catalyzing the hydrolysis of the acetyl group, generating Lyso-PAF, which is then converted to a 1-*O*-alkyl-2-acyl-glycerophosphocholine by an acyltransferase (McIntyre et al., 2009; Stafforini et al., 2003).

Synthesis of PAF also can occur *de novo* by transfer of a phosphocholine substituent to alkyl acetyl glycerol by a lyso-glycerophosphate acetyl–coenzyme A transferase. This pathway may contribute to physiological levels of PAF for normal cellular functions. PAF-like molecules can be formed from oxidized phospholipids (oxPLs) (Stafforini et al., 2003). These compounds are increased in settings of oxidant stress, such as cigarette smoking, and differ structurally from PAF in that they contain a fatty acid at the *sn*-1 position of glycerol joined through an ester bond and various short-chain acyl groups at the *sn*-2 position. oxPLs mimic the structure of PAF, bind to its receptor, and elicit the same responses. Unlike the highly controlled synthesis of PAF, oxPL production is unregulated. Degradation of oxPLs by PAF-AH is necessary to suppress toxicity. Increased levels of plasma PAF-AH have been reported in colon cancer, cardiovascular disease, and stroke.

Sites of PAF Synthesis

PAF is not stored in cells but is synthesized in response to stimulation. PAF is synthesized by platelets, neutrophils, monocytes, mast cells, eosinophils, renal mesangial cells, renal medullary cells, and vascular endothelial cells. Depending on cell type, PAF can either remain cell-associated or be secreted. For example, PAF is released from monocytes but retained by leukocytes and endothelial cells. In endothelial cells, PAF is displayed on the surface for juxtacrine signaling and stimulates adherent leukocytes.

Mechanism of Action of PAF

Extracellular PAF exerts its actions by stimulating a specific GPCR (Honda et al., 2002). The PAF receptor couples to G_q (to activate the phospholipase/inositol 1,4,5-trisphosphate/Ca^{2+} pathway) and to G_i (to inhibit adenylyl cyclase). Consequent activation of PLA_2, PLC, and PLD gives rise to second messengers, including AA-derived PGs, TxA_2, or LTs, which may function as mediators of the effects of PAF.

In addition, p38 mitogen-activated protein kinase is activated downstream of the PAF receptor–G_q interaction, while extracellular signal–regulated kinase activation can occur via interaction of activated PAF receptor with G_q, G_o, or their βγ subunits, or via transactivation of the epidermal growth factor receptor, leading to nuclear factor-κB activation. The crystal structure of the PAF receptor was recently resolved (Cao et al., 2018). PAF exerts many of its important proinflammatory actions without leaving its cell of origin. For example, PAF is synthesized in a regulated fashion by endothelial cells stimulated by inflammatory mediators. This PAF is presented on the surface of the endothelium, where it activates the PAF receptor on juxtaposed cells, including platelets, PMNs, and monocytes, and acts cooperatively with P-selectin to promote adhesion. This proadhesive function of PAF is important for orchestrating the interaction of platelets and circulating inflammatory cells with the inflamed endothelium.

Physiological and Pathological Functions of PAF

PAF is a potent lipid mediator of pathological events and has been implicated in allergic asthma, endotoxic shock, acute pancreatitis, certain cancers, dermal inflammation, and inflammatory cardiovascular diseases such as atherosclerosis.

Inflammatory and Allergic Responses

Experimental administration of PAF reproduces many of the signs and symptoms in anaphylactic shock. However, the effects of PAF antagonists in the treatment of inflammatory and allergic disorders have been disappointing. In patients with asthma, PAF antagonists partially inhibit the bronchoconstriction induced by antigen challenge but not by challenges by methacholine, exercise, or inhalation of cold air. These results may reflect the complexity of these pathological conditions and the likelihood that other mediators contribute to the inflammation associated with these disorders.

Cardiovascular System

PAF is a potent vasodilator in most vascular beds; when administered intravenously, it causes hypotension. PAF-induced vasodilation is independent of effects on sympathetic innervation, the renin-angiotensin system, or AA metabolism and likely results from a combination of direct and indirect actions. PAF may, alternatively, induce vasoconstriction depending on the concentration, vascular bed, and involvement of platelets or leukocytes. For example, the intracoronary administration of very low concentrations of PAF increases coronary blood flow by a mechanism that involves the release of a platelet-derived vasodilator. Coronary blood flow is decreased at higher doses by the formation of intravascular aggregates of platelets or the formation of TxA_2. The pulmonary vasculature also is constricted by PAF, and a similar mechanism is thought to be involved.

Intradermal injection of PAF causes an initial vasoconstriction followed by a typical wheal and flare. PAF increases vascular permeability and edema by causing contraction of venular endothelial cells. In this respect, the actions of PAF resemble those of histamine and bradykinin, but PAF is more potent than histamine or bradykinin by three orders of magnitude.

Platelets

The PAF receptor is constitutively expressed on the surface of platelets. PAF potently stimulates platelet aggregation. The intravenous injection of PAF causes formation of intravascular platelet aggregates and thrombocytopenia. Although this is accompanied by the release of TxA_2 and the granular contents of the platelet, PAF does not require the presence of TxA_2 or other aggregating agents to produce this effect. PAF antagonists fail to block thrombin-induced aggregation, even though they prolong bleeding time and prevent thrombus formation in some experimental models. Thus, PAF may contribute to thrombus formation, but it does not function as an independent mediator of platelet aggregation.

Leukocytes

Platelet-activating factor is a potent and common activator of inflammatory cells and stimulates a variety of responses in PMNs (eosinophils, neutrophils, and basophils). PAF stimulates PMNs to aggregate, degranulate, and generate free radicals and LTs. PAF is also a potent chemotactic factor for eosinophils, neutrophils, and monocytes and promotes PMN-endothelial adhesion, contributing, along with other adhesion molecular systems, to leukocyte rolling, tight adhesion, and migration through the endothelial monolayer. PAF also stimulates basophils to release histamine, activates mast cells, and induces cytokine release from monocytes. In addition, PAF promotes aggregation of monocytes and degranulation of eosinophils.

Smooth Muscle

PAF contracts GI, uterine, and pulmonary smooth muscle. PAF enhances the amplitude of spontaneous uterine contractions; these contractions are inhibited by inhibitors of PG synthesis. PAF does not affect tracheal smooth muscle but contracts airway smooth muscle. When given by aerosol, PAF increases airway resistance as well as the responsiveness to other bronchoconstrictors. PAF also increases mucus secretion and the permeability of pulmonary microvessels.

Stomach

In addition to contracting the fundus of the stomach, PAF is the most potent known ulcerogen. When given intravenously, it causes hemorrhagic erosions of the gastric mucosa that extend into the submucosa.

Kidney

PAF decreases renal blood flow, glomerular filtration rate, urine volume, and excretion of Na^+ without changes in systemic hemodynamics. PAF

exerts a receptor-mediated biphasic effect on afferent arterioles, dilating them at low concentrations and constricting them at higher concentrations. The vasoconstrictor effect appears to be mediated, at least in part, by COX products, whereas vasodilation is a consequence of the stimulation of NO production by endothelium.

Other

PAF, a potent mediator of angiogenesis, has been implicated in many cancers such as breast, prostate, esophageal, lung, pancreatic, and skin. Cigarette smoke exposure has been found to upregulate PAF signaling (Kispert et al., 2019). Lordan and colleagues (2019) have recently reviewed the breadth of actions ascribed to PAF. PAF-AH deficiency has been associated with small increases in a range of cardiovascular and thrombotic diseases in some human populations.

PAF Receptor Antagonists

Several experimental PAF receptor antagonists exist that selectively inhibit the actions of PAF *in vivo* and *in vitro*. None has proven clinically useful. Inhibition of PAF-AH, which also functions as a lipoprotein-associated PLA_2, was studied as a maneuver that might elevate endogenous levels of PAF. Trials of an inhibitor *darapladib* failed to establish either clinical efficacy attributable to eicosanoid suppression or an adverse effect profile attributable to increased levels of PAF (O'Donoghue et al., 2014).

Drug Facts for Your Personal Formulary: *Eicosanoids*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Prostanoids and Prostanoid Analogues: PGE_1/PGE_2		
Alprostadil (PGE_1)	• Erectile dysfunction • Temporary maintenance of patent ductus arteriosus in neonates	• Rapidly metabolized • Prolonged erection (4–6 h) in 4% of patients • Apnea in 10%–12% of neonates with congenital heart defects; ventilator assistance should be available during treatment
Misoprostol (PGE_1 analogue)	• Protection from NSAID-induced gastric toxicity	• Contraindicated for use in pregnant women; women who may become pregnant must use birth control when taking misoprostol • Combined with mifepristone to terminate early pregnancy
Dinoprostone (PGE_2)	• Labor induction	• Rapidly metabolized
Prostanoids and Prostanoid Analogues: PGI_2 (Prostacyclin)		
Epoprostenol (PGI_2)	• Pulmonary arterial hypertension	• Rapidly metabolized • Administered by intravenous infusion • Most common dose-limiting adverse effects are nausea, vomiting, headache, hypotension, and flushing
Iloprost (PGI_2 analogue)	• Pulmonary arterial hypertension	• Administered by inhalation • Synthetic PGI_2 analogue with longer $t_{1/2}$ • May increase risk of bleeding when used with anticoagulants or platelet inhibitors
Treprostinil (PGI_2 analogue)	• Pulmonary arterial hypertension	• May be administered by subcutaneous/intravenous infusion or by inhalation or orally • Adverse events similar to iloprost
Selexipag (PGI_2 analogue)	• Pulmonary arterial hypertension	• Oral selective IPr agonist • Active metabolite $t_{1/2}$ 6.2–13.5 h • Adverse effects similar to epoprostenol • Contraindicated with strong CYP2C8 inhibitors
Prostanoids and Prostanoid Analogues: $PGF_{2\alpha}$		
Carboprost tromethamine	• Abortifacient (second trimester) • Postpartum hemorrhage	• Common adverse effects are vomiting, diarrhea, nausea, fever, flushing
Bimatoprost	• Ocular hypertension • Open-angle glaucoma • Hypotrichosis of the eyelashes	• Upper respiratory tract infections in about 10% of patients • May cause changes in pigmentation and hair growth
Latanoprost	• Ocular hypertension • Open-angle glaucoma	• Increased iris pigmentation with time
Tafluprost	• Ocular hypertension • Open-angle glaucoma	• Metabolized to active drug in the eye • May cause increased iris pigmentation
Travoprost	• Ocular hypertension • Open-angle glaucoma	• May cause increased iris pigmentation
Nonsteroidal Anti-Inflammatory Drugs		
Listed in Chapter 42		
Cysteinyl Leukotriene Receptor Antagonists/5-Lipoxygenase Inhibitors		
Listed in Chapter 44

Chapter 42

Pharmacotherapy of Inflammation, Fever, Pain, and Gout

Tilo Grosser, Emanuela Ricciotti, and Garret A. FitzGerald

This chapter describes the nonsteroidal anti-inflammatory drugs (NSAIDs) used to treat inflammation, pain, and fever and the drugs used for hyperuricemia and gout. The NSAIDs are first considered by class, then by groups of chemically similar agents described in more detail. Many of the basic properties of these drugs are summarized in Tables 42–1, 42–2, and 42–3.

The NSAIDs act by inhibiting the prostaglandin (PG) G/H synthase enzymes, colloquially known as the cyclooxygenases (COXs) (see Chapter 41). There are two forms, COX-1 and COX-2. The inhibition of COX-2 is thought to mediate, in large part, the antipyretic, analgesic, and anti-inflammatory actions of NSAIDs. Adverse reactions are largely caused by the inhibition of COX-1 and COX-2 in tissues in which they fulfill physiological functions, such as the GI tract, the kidney, and the cardiovascular system. *Aspirin* is the only irreversible inhibitor of the COX enzymes in clinical use. All other NSAIDs bind the COXs reversibly and act either by competing directly with arachidonic acid (AA) at the active site of COX-1 and COX-2 or by changing their steric conformation in a way that alters their ability to bind arachidonic acid. *Acetaminophen* (*paracetamol*) is effective as an antipyretic and analgesic agent at typical doses that partly inhibit COXs and has only weak anti-inflammatory activity. Purposefully designed selective inhibitors of COX-2 (*celecoxib*, *etoricoxib*) are a subclass of NSAIDs; several of the older traditional NSAIDs, such as *diclofenac* and *meloxicam* (Figure 42–1) also selectively inhibit COX-2 at therapeutic doses.

Inflammation, Pain, and Fever

Inflammation

The inflammatory process is the immune system's protective response to an injurious stimulus. It can be evoked by noxious agents, infections, and physical injuries, which release damage- and pathogen-associated molecules that are recognized by cells charged with immune surveillance (Tang et al., 2012). The ability to mount an inflammatory response is essential for survival in the face of environmental pathogens and injury. Sometimes, inflammation may be exaggerated and sustained without apparent benefit and even with severe adverse consequences

HISTORICAL PERSPECTIVE

The history of *aspirin* provides an interesting example of the translation of a compound from the realm of herbal folklore to contemporary therapeutics. The use of willow bark and leaves to relieve fever has been attributed to Hippocrates but was most clearly documented by Edmund Stone in a 1763 letter to the president of the Royal Society. Similar properties were attributed to potions from meadowsweet (*Spiraea ulmaria*), from which the name *aspirin* is derived. Salicin was crystallized in 1829 by Leroux, and Pina isolated salicylic acid in 1836. In 1859, Kolbe synthesized salicylic acid, and by 1874 it was being produced industrially. It soon was being used for rheumatic fever and gout and as a general antipyretic. However, its unpleasant taste and adverse GI effects made it difficult to tolerate for more than short periods. In 1899, Hoffmann, a chemist at Bayer Laboratories, sought to improve the adverse effect profile of salicylic acid (which his father was taking with difficulty for arthritis). Hoffmann came across the earlier work of the French chemist Gerhardt, who had acetylated salicylic acid in 1853, apparently ameliorating its adverse effect profile, but without improving its efficacy, and therefore abandoned the project. Hoffmann resumed the quest, and Bayer began testing acetylsalicylic acid (ASA) in animals by 1899 and proceeded soon thereafter to human studies and the marketing of *aspirin*.

Acetaminophen was first used in medicine by von Mering in 1893. However, it gained popularity only after 1949, when it was recognized as the major active metabolite of both *acetanilide* and *phenacetin*. *Acetanilide* is the parent member of this group of drugs. It was introduced into medicine in 1886 under the name *antifebrin* by Cahn and Hepp, who had discovered its antipyretic action accidentally. However, *acetanilide* proved to be excessively toxic. A number of chemical derivatives were developed and tested. One of the more satisfactory of these was *phenacetin*. It was introduced into therapy in 1887 and was extensively employed in analgesic mixtures until it was implicated in analgesic abuse nephropathy, hemolytic anemia, and bladder cancer; it was withdrawn in the 1980s.

Abbreviations

AA: arachidonic acid
Ab: antibody
ABCG2: ATP Binding Cassette Subfamily G Member 2
ACE: angiotensin-converting enzyme
ASA: acetylsalicylic acid/aspirin
AUC: area under the curve
CABG: coronary artery bypass graft
CNS: central nervous system
COX: cyclooxygenase
CSF: cerebrospinal fluid
DMARD: disease-modifying antirheumatic drug
G6PD: glucose-6-phosphate dehydrogenase
GI: gastrointestinal
GLUT: glucose transporter
GSH: glutathione
FAP: familial adenomatous polyposis
FDA: U.S. Food and Drug Administration
15(*R*)-HETE: 15(*R*)-hydroxyeicosatetraenoic acid
5-HIAA: 5-hydroxyindoleacetic acid
5HT: 5-hydroxytryptamine/serotonin
Ig: immunoglobulin
IL: interleukin
IM: intramuscular
IV: intravenous
LOX: lipoxygenase
LT: leukotriene
MI: myocardial infarction
MRP: multidrug resistance-associated protein
NAC: *N*-acetylcysteine
NAPQI: *N*-acetyl-*p*-benzoquinone imine
NERD: NSAID-exacerbated respiratory disease
NPT: sodium-dependent phosphate transporter
NSAID: nonsteroidal anti-inflammatory drug
OAT: organic anion transporter
OTC: over the counter
PAF: platelet-activating factor
PG: prostaglandin
PGI_2: prostacyclin
PPI: proton pump inhibitor
r: receptor
TNF: tumor necrosis factor
Tx: thromboxane
SLC5A8: Solute Carrier Family 5 Member 8
SLC5A12: Solute Carrier Family 5 Member 12
UGT: uridine diphosphate glucuronosyltransferase
URAT: urate transporter
XO: xanthine oxidase

(e.g., hypersensitivity, autoimmune diseases, chronic inflammation). The inflammatory response is characterized mechanistically by:

- Transient local vasodilation and increased capillary permeability
- Infiltration of leukocytes and phagocytic cells
- Resolution with or without tissue degeneration and fibrosis

Many molecules are involved in the promotion and resolution of the inflammatory process. Histamine, bradykinin, 5HT, prostanoids, LTs, PAF, and an array of cytokines are important mediators (see Chapters 38, 41, and 43). Prostanoid biosynthesis is significantly increased in inflamed tissue. PGE_2 and prostacyclin (PGI_2) are the primary prostanoids that mediate inflammation. They increase local blood flow, vascular permeability, and leukocyte infiltration through activation of their respective receptors, EPr and IPr. PGD_2, a major product of mast cells, contributes to inflammation in allergic responses, particularly in the lung.

Activation of endothelial cells plays a key role in recruiting circulating cells to inflammatory sites (Muller, 2011). Endothelial activation results in leukocyte rolling and adhesion as the leukocytes recognize newly expressed selectins, integrins, and adhesion molecules. PGE_2 and TxA_2 enhance leukocyte chemoattraction and endothelial adhesion.

The recruitment of inflammatory cells to sites of injury also involves the concerted interactions of the complement factors, PAF, and eicosanoids such as LTB_4 (see Chapter 41). All can act as chemotactic agonists. Cytokines play essential roles in orchestrating the inflammatory process, especially TNF and IL-1. Several biological anti-inflammatory therapeutics target these cytokines or their signaling pathways (see Chapter 39). Other cytokines and growth factors (e.g., IL-2, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor) contribute to manifestations of the inflammatory response. The concentrations of many of these factors are increased in the synovia of patients with inflammatory arthritis. Glucocorticoids interfere with the synthesis and actions of cytokines, such as IL-1 or TNF-α (see Chapter 39). Although some of the actions of these cytokines are accompanied by the release of PGs and TxA_2, COX inhibitors appear to block primarily their pyrogenic effects.

Pain

Nociceptors, peripheral terminals of primary afferent fibers that sense pain, can be activated by various stimuli, such as heat, acids, or pressure. Inflammatory mediators released from nonneuronal cells during tissue injury increase the sensitivity of nociceptors and potentiate pain perception. Among these mediators are bradykinin, H^+, 5HT, ATP, neurotrophins (nerve growth factor), LTs, and PGs. PGE_2 and PGI_2 reduce the threshold to stimulation of nociceptors, causing *peripheral sensitization*. Reversal of peripheral sensitization is thought to represent the mechanistic basis for the peripheral component of the analgesic activity of NSAIDs. NSAIDs may also have important central actions in the spinal cord and brain. Both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli.

Centrally active PGE_2 and perhaps also PGD_2, PGI_2, and $PGF_{2\alpha}$ contribute to *central sensitization*, an increase in excitability of spinal dorsal horn neurons that causes hyperalgesia and allodynia in part by disinhibition of glycinergic pathways (Grosser et al., 2017a). Central sensitization reflects the plasticity of the nociceptive system that is invoked by injury. This usually is reversible within hours to days following adequate responses of the nociceptive system (e.g., in postoperative pain). However, chronic inflammatory diseases may cause persistent modification of the architecture of the nociceptive system, which may lead to long-lasting changes in its responsiveness. These mechanisms contribute to chronic pain.

Fever

The hypothalamus regulates the set point at which body temperature is maintained. This set point is elevated in fever, reflecting an infection, or resulting from tissue damage, inflammation, graft rejection, or malignancy. These conditions all enhance formation of cytokines such as IL-1β, IL-6, TNF-α, and interferons, which act as endogenous pyrogens. The initial phase of the thermoregulatory response to such pyrogens may be mediated by ceramide release in neurons of the preoptic area in the anterior hypothalamus (Sanchez-Alavez et al., 2006). The second phase is mediated by coordinate induction of COX-2 and formation of PGE_2 (Engblom et al., 2003). PGE_2 can cross the blood-brain barrier and act on EPr_3 and perhaps EPr_1 receptors on thermosensitive neurons. This triggers the hypothalamus to elevate body temperature by promoting an increase in heat generation and a decrease in heat loss. NSAIDs suppress this response by inhibiting COX-2–dependent PGE_2 synthesis.

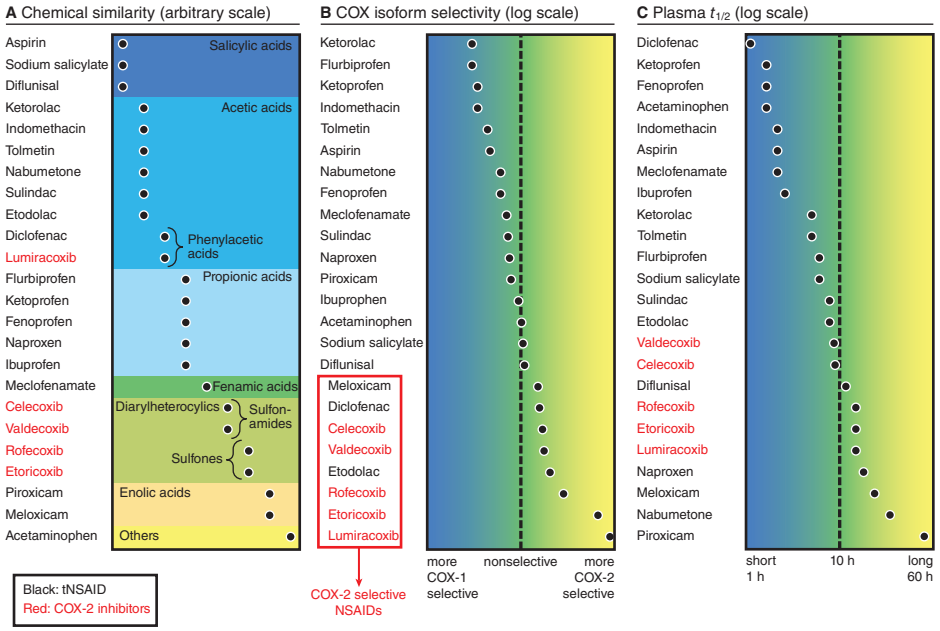

Figure 42–1 *Classification of NSAIDs by chemical similarity* (**A**), *COX isoform selectivity* (**B**), *and plasma* $t_{1/2}$ (**C**). The COX selectivity chart is plotted from data published in Warner T., et al. Nonsteroid drug selectivities for cyclooxygenase-1 rather than cyclooxygenase-2 are associated with human gastrointestinal toxicity: a full in vitro analysis. *Proc Natl Acad Sci USA*, **1999**, *96*:7563–7568; and FitzGerald GA, Patrono C. The coxibs, selective inhibitors of cyclooxygenase-2. *N Engl J Med*, **2001**, *345*:433–442.

Nonsteroidal Anti-inflammatory Drugs

The NSAIDs are mechanistically classified as *isoform nonselective NSAIDs*, which inhibit both COX-1 and COX-2, and *COX-2–selective NSAIDs* (FitzGerald and Patrono, 2001). Most NSAIDs are competitive, noncompetitive, or mixed reversible inhibitors of the COX enzymes. *Aspirin* (ASA) is a noncompetitive, irreversible inhibitor because it acetylates the isozymes in the hydrophobic AA-binding channel by which the lipid substrate gains access to the COX catalytic site deep within the enzyme. *Acetaminophen*, which is antipyretic and analgesic but largely devoid of anti-inflammatory activity at commonly used doses, acts as a noncompetitive reversible inhibitor by reducing the peroxide site of the enzymes.

The majority of NSAIDs are organic acids with relatively low pK_a values. As organic acids, the compounds generally are well absorbed orally, highly bound to plasma proteins, and excreted either by glomerular filtration or by tubular secretion. They also accumulate in sites of inflammation, where the pH is lower, potentially confounding the relationship between plasma concentrations and duration of drug effect. Most COX-2–selective NSAIDs have a relatively bulky side group, which aligns with a large side pocket in the AA-binding channel of COX-2 but hinders its optimal orientation in the smaller binding channel of COX-1 (Smith et al., 2011). Both isoform nonselective NSAIDs and the COX-2–selective NSAIDs generally are hydrophobic drugs, a feature that allows them to access the AA-binding channel and results in shared pharmacokinetic characteristics. Again, *aspirin* and *acetaminophen* are exceptions to this rule.

Mechanism of Action

Cyclooxygenase Inhibition

The principal therapeutic effects of NSAIDs derive from their ability to inhibit PG production. The first enzyme in the PG synthetic pathway is COX, also known as PG G/H synthase. This enzyme converts AA to the unstable intermediates PGG_2 and PGH_2 and leads to the production of the prostanoids, TxA_2, and a variety of PGs (see Chapter 41). COX-1, expressed constitutively in most cells, is the dominant source of prostanoids for housekeeping functions, such as hemostasis. Conversely, COX-2, induced by cytokines, shear stress, and tumor promoters, is the more important source of prostanoid formation in inflammation and perhaps in cancer (see Chapter 41). However, both enzymes contribute to the generation of autoregulatory and homeostatic prostanoids with important functions in normal physiology (see Chapter 41). The indiscriminate inhibition of both inflammatory and homeostatic prostanoids by NSAIDs explains mechanistically most adverse reactions to this drug class. For example, inhibition of COX-1 accounts largely for the gastric adverse events and bleeding that complicate therapy because COX-1 is the dominant cytoprotective isoform in gastric epithelial cells and forms TxA_2 in platelets, which amplifies platelet activation and constricts blood vessels at the site of injury. Similarly, COX-2–derived products play important roles in blood pressure regulation and act as endogenous inhibitors of hemostasis. Inhibition of COX-2 can cause or exacerbate hypertension and increase the likelihood of thrombotic events.

While the functional COX enzymes are sequence homodimers, they are configured as conformational heterodimers in which one of the monomers functions as the catalytic subunit with heme bound and the other, without heme, serves as the allosteric subunit. Most NSAIDs inhibit the catalytic subunits of COX-1 and COX-2. However, COX-2 inhibition by *naproxen* and *flurbiprofen* occurs primarily on the allosteric subunit (Dong et al., 2011; Zou et al., 2012).

Irreversible Cyclooxygenase Inhibition by Aspirin

Aspirin covalently acetylates the catalytic subunits of the COX-1 and COX-2 dimers, irreversibly inhibiting COX activity. This is an important distinction from all the other NSAIDs because the duration of *aspirin*'s effects is related to the turnover rate of the COXs in different target tissues.

The importance of enzyme turnover in recovery from *aspirin* action is most notable in platelets, which, being anucleate, have a markedly limited capacity for protein synthesis. Thus, the consequences of inhibition of platelet COX-1 last for the lifetime of the platelet. Inhibition of platelet COX-1–dependent TxA_2 formation therefore is cumulative with repeated doses of *aspirin* (at least as low as 30 mg/day) and takes 8 to 12 days (the platelet turnover time) to recover fully once therapy has been stopped. Importantly, even a partially recovered platelet pool—just a few days after the last *aspirin* dose—may afford recovery of sufficient hemostatic integrity for some types of elective surgery to be performed.

However, such a partial platelet function also may predispose non-adherent patients on low-dose *aspirin* for antiplatelet therapy to thrombotic events. The unique sensitivity of platelets to inhibition by low doses of *aspirin* is related to their presystemic inhibition in the portal circulation before *aspirin* is deacetylated to salicylate on first pass through the liver (Pedersen and FitzGerald, 1984). In contrast to *aspirin*, salicylic acid has no acetylating capacity. It is a relatively weak, reversible inhibitor of COX. Salicylic acid derivates, rather than the acid, are available for clinical use.

The COXs are configured such that the active site is accessed by the AA substrate via a hydrophobic channel. *Aspirin* acetylates serine 529 of COX-1, located high up in the hydrophobic channel. Interposition of the bulky acetyl residue prevents the binding of AA to the active site of the enzyme and thus impedes the ability of the enzyme to make PGs. *Aspirin* acetylates a homologous serine at position 516 in COX-2. Although covalent modification of COX-2 by *aspirin* also blocks the COX activity of this isoform, an interesting property not shared by COX-1 is that acetylated COX-2 synthesizes 15(*R*)-HETE. This may be metabolized, at least *in vitro*, by 5-LOX to yield 15-epi-lipoxin A_4, which has anti-inflammatory properties in model systems (see Chapter 41).

Selective Inhibition of Cyclooxygenase 2

The chronic use of the NSAIDs is limited by their poor GI tolerability. Selective inhibitors of COX-2 were developed to afford efficacy like traditional NSAIDs with better GI tolerability (FitzGerald and Patrono, 2001). Six such COX-2 inhibitors, the coxibs, were approved for clinical use: *celecoxib, rofecoxib, valdecoxib* (initially approved in the U.S.) and its prodrug *parecoxib*, *etoricoxib*, and *lumiracoxib*. Most coxibs (including *valdecoxib*) have been either restricted in their use or withdrawn from the market in view of their adverse cardiovascular risk profile (Grosser et al., 2010). *Celecoxib* currently is the only COX-2 inhibitor licensed for use in the U.S. Some older NSAID compounds—*diclofenac*, *etodolac*, *meloxicam*, and *nimesulide* (not available in the U.S.)—exhibit selectivity for COX-2 similar to *celecoxib* (see Figure 42–1).

ADME

Absorption. The NSAIDs are rapidly absorbed following oral ingestion, and peak plasma concentrations are reached within 2 to 3 h. The poor aqueous solubility of most NSAIDs often is reflected by a less-than-proportional increase in the AUC of plasma concentration–time curves, due to incomplete dissolution, when the dose is increased. Food intake may delay absorption and systemic availability (i.e., *fenoprofen*, *sulindac*). Antacids, commonly prescribed to patients on NSAID therapy, variably delay absorption. Some compounds (e.g., *diclofenac*, *nabumetone*) undergo first-pass or presystemic elimination. *Aspirin* begins to acetylate platelets within minutes of reaching the presystemic circulation (Pedersen and FitzGerald, 1984).

Distribution. Most NSAIDs are extensively bound (95%–99%) to plasma proteins, usually albumin. Conditions that alter plasma protein concentration may result in an increased free drug fraction with potential toxic effects. Highly protein bound NSAIDs have the potential to displace other drugs if they compete for the same binding sites. Most NSAIDs are distributed widely throughout the body and readily penetrate arthritic joints, yielding synovial fluid concentrations in the range of half the plasma concentration (i.e., *ibuprofen, naproxen, piroxicam*) (Day et al., 1999). Most NSAIDs achieve sufficient concentrations in the CNS to have a central analgesic effect. *Celecoxib* is particularly lipophilic and moves readily into the CNS. Multiple NSAIDs are marketed in formulations for topical application on inflamed or injured joints. However, direct transport of topically applied NSAIDs into inflamed tissues and joints appears to be minimal, and detectable concentrations in synovial fluid of some agents (i.e., *diclofenac*) following topical use are primarily attained via dermal absorption and systemic circulation. Methods designed to enhance transdermal delivery into inflamed joints, such as iontophoresis, electroporation, or chemical penetration enhancers and nanoparticulate formulations, are under investigation. Other targeted applications (e.g., to macrophages) are also being explored as a delivery route for NSAIDs (Mazaleuskaya et al., 2021).

Metabolism and Excretion. Hepatic biotransformation, often via cytochrome P450 isoforms (CYPs) 2C9, 1A2, and 3A4, and renal excretion are the principal routes of metabolism and elimination of the majority of NSAIDs. Plasma $t_{1/2}$ varies considerably among NSAIDs. *Ibuprofen*, *diclofenac*, and *acetaminophen* have a $t_{1/2}$ of 1 to 4 h, while *piroxicam* has a $t_{1/2}$ of about 50 h at steady state. *Naproxen* has a comparatively long but highly variable $t_{1/2}$ ranging from 9 to 25 h. Elimination pathways frequently involve oxidation or hydroxylation. *Acetaminophen*, at therapeutic doses, is oxidized only to a small degree to form traces of the highly reactive metabolite NAPQI. Following overdose, however, the principal metabolic pathways are saturated, and hepatotoxic NAPQI concentrations can be formed (see Figure 9–4).

Several NSAIDs or their metabolites are glucuronidated or otherwise conjugated. In some cases, such as the propionic acid derivatives *naproxen* and *ketoprofen*, the glucuronide metabolites can hydrolyze back to form the active parent drug; this may prolong elimination of the NSAID significantly. In general, NSAIDs are not recommended in the setting of advanced hepatic or renal disease due to their adverse pharmacodynamic effects. NSAIDs usually are not removed by hemodialysis due to their extensive plasma protein binding; salicylic acid is an exception to this rule. The activity of the major metabolizing enzymes is influenced by genetic variation, age, sex, circadian variation, disease, social behavior such as smoking or drinking, and interacting drugs that are CYP substrates, inhibitors, or inducers. Variation in the composition of intestinal microbiota may also contribute to variability in metabolism and elimination (Liang et al., 2015). Clinical evidence linking genetic variation in metabolizing enzymes to an increased rate of adverse events with NSAIDs use is limited. However, an association between *CYP2C9* alleles that decrease enzymatic function and elevated NSAID plasma concentrations has been established. Carriers of these variants should consider reductions in the starting NSAID dose or selection of NSAIDs with shorter half-lives to reduce the likelihood of adverse effects (Theken et al., 2020).

Therapeutic Uses

The NSAIDs are antipyretic, analgesic, and anti-inflammatory, with the exception of *acetaminophen*, which is antipyretic and analgesic but is largely devoid of anti-inflammatory activity at therapeutic doses.

Inflammation

The NSAIDs provide mostly symptomatic relief from pain and inflammation associated with musculoskeletal disorders, such as rheumatoid arthritis and osteoarthritis. Some NSAIDs are approved for the treatment of ankylosing spondylitis and gout. Patients with more debilitating disease may not respond adequately to full therapeutic doses of NSAIDs and may require aggressive therapy with second-line agents.

Pain

The NSAIDs are effective against inflammatory pain of low to moderate intensity. Although their maximal efficacy is generally less than that of opioids, NSAIDs lack the unwanted adverse effects of opiates in the CNS, including respiratory depression and the potential for development of physical dependence. Coadministration of NSAIDs can reduce the opioid dose needed for sufficient pain control with the objective of reducing the adverse effects of opioids. NSAIDs, unlike opioids, are devoid of addictive potential. NSAIDs do not change the perception of sensory modalities other than pain. NSAIDs are particularly effective when inflammation has caused sensitization of pain perception (see other discussion in this section on inflammation, pain, and fever). Thus, postoperative pain or pain arising from inflammation, such as arthritic pain, is controlled well by NSAIDs, whereas pain arising from the hollow viscera usually is not relieved. An exception to this is menstrual pain. Treatment of menstrual pain with NSAIDs has been met with considerable success because cramps and other symptoms of primary dysmenorrhea are caused by the release of PGs by the endometrium during menstruation. NSAIDs are commonly used to treat migraine attacks and can be combined with

drugs such as the triptans or antiemetics to aid relief from the associated nausea. NSAIDs generally lack efficacy in neuropathic pain.

Fever

Antipyretic therapy is reserved for patients in whom fever may be deleterious and for those who experience considerable relief when fever is lowered. NSAIDs reduce fever in most situations, but not the circadian variation in temperature or the rise in response to exercise or increased ambient temperature.

Fetal Circulatory System

The PGs are implicated in the maintenance of patency of the ductus arteriosus; *indomethacin*, *ibuprofen*, and other NSAIDs have been used in neonates to close an inappropriately patent ductus. Conversely, infusion of prostanoid analogues maintains ductal patency after birth in settings of ductus arteriosus–dependent congenital heart disease as a bridge to definitive repair (see Chapter 41).

Cardioprotection

Ingestion of *aspirin* prolongs bleeding time. This effect is due to irreversible acetylation of platelet COX and the consequent inhibition of platelet function. It is the permanent suppression of platelet TxA_2 formation that is thought to underlie the cardioprotective effect of *aspirin*.

Aspirin reduces the risk of serious vascular events in high-risk patients (e.g., those with previous myocardial infarction) by 20% to 25%. The reduction of subsequent thrombotic strokes is somewhat less, roughly 10% to 15% (Antithrombotic Trialists' Collaboration et al., 2009). Low-dose *aspirin* (≤100 mg/day) is associated with a lower risk for GI adverse events than higher doses (e.g., 325 mg/day) and is often used following percutaneous coronary intervention (Xian et al., 2015). Low doses of *aspirin* are associated with a small (roughly 2-fold) but detectable increase in the incidence of serious GI bleeds and intracranial bleeds in placebo-controlled trials. The benefit from *aspirin*, however, outweighs these risks in the case of secondary prevention of cardiovascular disease. The issue is much more nuanced in patients who have never had a serious atherothrombotic event (primary prevention); here, prevention of myocardial infarction by *aspirin* is numerically balanced by the serious GI bleeds it precipitates (Patrono, 2015). Recent randomized clinical trials of *aspirin* in primary cardioprevention failed to detect a beneficial effect, perhaps obscured by other cardioprotective treatments, while the GI bleeding risk remains apparent (Ricciotti and FitzGerald, 2021). Given their relatively short $t_{1/2}$ and reversible COX inhibition, most other NSAIDs are not thought likely to afford cardioprotection. Cardioprotection is lost when combining low-dose *aspirin* with other short acting NSAIDs like *ibuprofen* through a drug-drug interaction at the *aspirin* target site in platelet COX-1 (Catella-Lawson et al., 2001; Farkouh et al., 2004; Li et al., 2014). COX-2–selective NSAIDs are devoid of antiplatelet activity, as mature platelets do not express COX-2.

Other Clinical Uses

Systemic Mastocytosis. Systemic mastocytosis is a condition in which there are excessive mast cells in the bone marrow, reticuloendothelial system, GI system, bones, and skin (Theoharides et al., 2015). In patients with systemic mastocytosis, PGD_2, released from mast cells, is the major mediator of severe episodes of flushing, vasodilation, and hypotension; this effect of PGD_2 is resistant to antihistamines. The addition of *aspirin* or *ketoprofen* (off-label use) may be beneficial in patients with high levels of urinary PGD metabolites who have flushing and angioedema. However, NSAIDs can cause degranulation of mast cells, so blockade with histamine receptor antagonists should be established before NSAIDs are initiated.

Niacin Tolerability. Large doses of niacin (nicotinic acid) effectively lower serum cholesterol levels, reduce low-density lipoprotein, and raise high-density lipoprotein (see Chapter 37). However, niacin induces intense facial flushing mediated largely by release of PGD_2 from the skin, which can be inhibited by treatment with *aspirin* (Song et al., 2012).

Bartter Syndrome. Bartter syndrome includes a series of rare disorders (frequency ≤1/100,000 persons) characterized by hypokalemic, hypochloremic metabolic alkalosis with normal blood pressure, and hyperplasia of the juxtaglomerular complex. Fatigue, muscle weakness, diarrhea, and dehydration are the main symptoms. Distinct variants are caused by mutations in a Na^+-K^+-$2Cl^-$ cotransporter, an apical ATP-regulated K^+ channel, a basolateral Cl^- channel, a protein (barttin) involved in cotransporter trafficking, and the extracellular Ca^{2+}-sensing receptor. Renal COX-2 is induced, and biosynthesis of PGE_2 is increased. Treatment with *indomethacin*, combined with potassium repletion and *spironolactone*, is associated with improvement in the biochemical derangements and symptoms. Selective COX-2 inhibitors also have been used (Nusing et al., 2001).

Preeclampsia. A syndrome characterized by hypertension and proteinuria during pregnancy, preeclampsia is a leading cause of maternal and perinatal morbidity and mortality. Low-dose *aspirin* (81 or 100 mg) reduces the incidence of preterm preeclampsia effectively when administered early to women at increased risk (Rolnik et al., 2020). Platelet activation through endothelial inflammation and renal dysregulation of blood pressure are proposed targets of low-dose *aspirin* in preeclampsia (Burton et al., 2019). The antihypertensive and antiplatelet effects of *aspirin* may be most pronounced when dosed in the evening (Bonten et al., 2015; Chen et al., 2018; Hermida et al., 2003).

Cancer Chemoprevention. Epidemiological studies suggested that daily use of *aspirin* is associated with a 24% decrease in the incidence of and a 35% decrease in mortality from sporadic colon cancer (Rothwell et al., 2010). Randomized controlled trials provide direct evidence for a beneficial effect of *aspirin* in the primary prevention of colorectal cancer in patients at high risk due to the Lynch syndrome, but only weak evidence in patients with familial adenomatous polyposis (FAP; Ricciotti and FitzGerald, 2021). COX-2–selective NSAIDs have shown efficacy in patients with FAP but are no longer approved for this indication due to cardiovascular safety concerns.

Adverse Effects of NSAID Therapy

Adverse events common to *aspirin* and NSAIDs are outlined in Table 42–1. To minimize potential adverse events of NSAIDs, the lowest effective dose should be used for the shortest feasible length of time. Age generally is correlated with an increased probability of developing serious adverse reactions to NSAIDs, and caution is warranted in choosing a lower starting dose for elderly patients. NSAIDs are labeled with a black-box warning related to cardiovascular risks and are specifically contraindicated following coronary artery bypass graft (CABG) surgery.

Gastrointestinal

The most common symptoms associated with these drugs are GI (~40% of patients), including dyspepsia, abdominal pain, anorexia, nausea, and diarrhea. However, these symptoms are not predictive of gastric or intestinal lesions such as subepithelial hemorrhages, erosions, and ulcers, which can be endoscopically detected in about 30% to 50% of NSAID users but are often asymptomatic and tend to heal spontaneously. Serious complications—bleeding, perforation, or obstruction—occur at an annual rate of 1% to 2% in regular NSAID users. Many patients who develop a serious upper GI adverse event while receiving NSAID therapy are asymptomatic prior to diagnosis. The risk is particularly high in those with *Helicobacter pylori* infection, heavy alcohol consumption, or other risk factors for mucosal injury, including the concurrent use of glucocorticoids. All selective COX-2 inhibitors are less prone to induce gastric ulcers than equally efficacious doses of isoform nonselective NSAIDs (Sostres et al., 2013).

Several mechanisms contribute to NSAID-induced GI complications (see Chapter 41). Inhibition of COX-1 in gastric and intestinal epithelial cells depresses mucosal cytoprotective PGs, especially PGI_2 and PGE_2. These eicosanoids inhibit acid secretion by the stomach, enhance mucosal blood flow, and promote the secretion of cytoprotective mucus in the intestine. COX-2 also contributes to constitutive formation of these PGs by human gastric epithelium, and products of COX-2 may contribute to ulcer healing. Another factor that may play a part in the formation of ulcers is the local irritation from contact of orally

TABLE 42–1 ■ SOME SHARED ADVERSE EFFECTS OF NSAIDs[a]

SYSTEM	MANIFESTATIONS
Gastrointestinal	Abdominal pain, bleeding, constipation, diarrhea, dyspepsia, dysphagia, eructation,[b] esophageal stricture/ulceration, esophagitis, flatulence, gastritis, hematemesis,[b] melena,[b] nausea, odynophagia, perforation, pyrosis, stomatitis, ulcers, vomiting, xerostomia[b]
Platelets	Inhibited platelet activation,[b] propensity for bruising,[b] increased risk of hemorrhage,[b] platelet dysfunction,[b] thrombocytopenia[b]
Renal	Azotemia,[b] cystitis,[b] dysuria,[b] hematuria, hyponatremia, interstitial nephritis, nephrotic syndrome,[b] oliguria,[b] polyuria,[b] renal failure, renal papillary necrosis, proteinuria, salt and water retention, hypertension, worsening of renal function in renal/cardiac/cirrhotic patients, effectiveness of antihypertensives and diuretics, hyperkalemia,[b] ↓ urate excretion (especially with aspirin)
Cardiovascular	Edema,[b] heart failure,[c] hypertension, MI,[c] palpitations,[b] premature closure of ductus arteriosus, sinus tachycardia,[b] stroke,[c] thrombosis,[c] vasculitis[b]
Neurologic	Anorexia,[b] anxiety,[b] aseptic meningitis, confusion,[b] depression, dizziness, drowsiness,[b] headache, insomnia,[b] malaise,[b] paresthesias, tinnitus, seizures,[b] syncope,[b] vertigo[b]
Reproductive	Prolongation of gestation, inhibition of labor, delayed ovulation
Hypersensitivity	Anaphylactoid reactions, angioedema, severe bronchospasm, urticaria, flushing, hypotension, shock
Hematologic	Anemia, agranulocytosis, aplastic anemia,[b] hemolytic anemia,[b] leukopenia[b]
Hepatic	Elevated enzymes, hepatitis, hepatic failure,[b] jaundice
Dermatologic	Diaphoresis,[b] exfoliative dermatitis, photosensitivity,[b] pruritus, purpura,[b] rash, Stevens-Johnson syndrome, toxic epidermal necrolysis, urticaria
Respiratory	Dyspnea,[b] hyperventilation (salicylates)
Other	Alopecia,[b] blurred vision,[b] conjunctivitis,[b] epistaxis,[b] fever,[b] hearing loss,[b] pancreatitis,[b] paresthesias, visual disturbance,[b] weight gain[b]

[b]Reported for most, but not all, NSAIDs.
[c]With the exception of low-dose aspirin.

administered NSAIDs—most of which are organic acids—with the cell surface phospholipid bilayer of the gastric and intestinal mucosa. Such irritation may compromise the hydrophobic lining of the gastroduodenal mucosa, making it vulnerable to subsequent damage from gastric acid. NSAIDs may also cause mitochondrial and endoplasmic reticulum damage in epithelial cells (Bjarnason et al., 2018). However, the incidence of serious GI adverse events is not significantly reduced by formulations devised to limit drug contact with the gastric mucosa, such as enteric coating or efferent solutions, suggesting that the contribution of direct irritation to the overall risk is temporary. Platelet inhibition by NSAIDs increases the likelihood of bleeds when mucosal damage has occurred. In the small intestine, NSAIDs can change the composition and activity of the gut microbiota. These changes may alter the disposition and the pharmacokinetic proprieties of the NSAIDs and their efficacy and toxicity profiles (Liang et al., 2015). NSAID-gut microbiota interactions may contribute to the development of NSAID-induced enteropathy and, to lesser extent, to NSAID exacerbation of *Clostridium difficile* infection. There is less evidence that the gut microbiota modulates *aspirin*'s antiplatelet and anticancer effects (Bjarnason et al., 2018).

Coadministration of proton pump inhibitors or H_2 antagonists in conjunction with NSAIDs reduces the rate of duodenal and gastric ulceration (see Chapter 53, Figure 53–1). However, proton pump inhibitors, which are also metabolized by CYP2C9 and liable to interact with NSAIDs, may increase the risk of damage in the small intestine by inducing dysbiosis (Washio et al., 2016). Approaches to preventing or mitigating NSAID-induced small intestinal damage, for example by administration of poorly absorbable antibiotics, mucosal protective agents, or supplementation with probiotics, are under investigation.

Cardiovascular

The COX-2–selective NSAIDs were developed to improve GI safety. However, COX-2 inhibitors depress formation of PGI_2 but do not inhibit the COX-1–catalyzed formation of platelet TxA_2. PGI_2 inhibits platelet aggregation and constrains the effect of prothrombotic and atherogenic stimuli by TxA_2 (Grosser et al., 2006, 2010, 2017a), and renal PGI_2 and PGE_2 formed by COX-2 contribute to arterial pressure homeostasis (see Chapter 41). Genetic deletion of the PGI_2 receptor (IPr) in mice augments the thrombotic response to endothelial injury, accelerates experimental atherogenesis, increases vascular proliferation, and adds to the effect of hypertensive stimuli (Cheng et al., 2002, 2006; Egan et al., 2004; Kobayashi et al., 2004). Tissue-specific genetic deletion of COX-2 in the vasculature accelerates the response to thrombotic stimuli and raises blood pressure (Yu et al., 2012). Together, these mechanisms would be expected to increase the cardiovascular risk of humans by shifting to a prothrombotic environment on endothelial surfaces, as COX-2 inhibition in humans depresses PGI_2 synthesis (Catella-Lawson et al., 1999; McAdam et al., 1999). Indeed, a human mutation of the IPr that disrupts its signaling may be associated with increased cardiovascular risk (Arehart et al., 2008).

Clinical trials—with *celecoxib*, *valdecoxib* (withdrawn), and *rofecoxib* (withdrawn)—revealed an increase in the incidence of myocardial infarction, stroke, and vascular death by approximately 1.4-fold (Coxib and Traditional NSAID Trialists' Collaboration et al., 2013). The risk extends to *diclofenac*, which is almost as COX-2 selective as *celecoxib*, and to some of the other older NSAIDs. An exception in some individuals may be *naproxen*. There is considerable between-person variation in the $t_{1/2}$ of *naproxen*, and platelet inhibition might be anticipated throughout the dosing interval in some, but not all, individuals on *naproxen* (Capone et al., 2005; Grosser et al., 2017b). While this is supported by randomized controlled trials (Coxib and Traditional NSAID Trialists' Collaboration et al., 2013), identifying individuals who fall into the long-acting group is currently not practical in clinical routine. The FDA has determined that the data differentiating the risk between distinct NSAIDs is not sufficient to distinguish between drugs on the regulatory level; thus, a cardiovascular risk warning is included on the label of all NSAIDs (FDA, 2015). The Standard Care versus Celecoxib Outcome Trial (SCOT) (MacDonald et al., 2017) and the Prospective Randomized Evaluation of Celecoxib Integrated Safety versus Ibuprofen or Naproxen (PRECISION; Nissen et al., 2016) trial, mandated by the European Medicines Agency and the FDA, respectively, to compare the cardiovascular profile of *celecoxib* to traditional NSAIDs, failed to resolve this issue due to the limitations in their study designs (FitzGerald, 2017; Grosser et al., 2017b). Similarly, all prescription NSAIDs share a black-box warning contraindicating their use for the treatment of perioperative pain in the setting of CABG surgery.

The NSAIDs with selectivity for COX-2 should be reserved for patients at high risk for GI complications. The cardiovascular risk appears to be conditioned by factors influencing drug exposure, such as dose, $t_{1/2}$, degree of COX-2 selectivity, potency, and treatment duration. Thus, the lowest possible dose should be prescribed for the shortest possible period.

NSAIDs increase the risk of heart failure and may exacerbate preexisting heart failure, particularly at high doses (Arfé et al., 2016). Mechanisms may involve fluid retention and blood pressure increases caused by renal effects of NSAIDs and potentially direct effects on the myocardium and vasculature.

Blood Pressure and Renal Adverse Events

All NSAIDs have been associated with renal and renovascular adverse events including renal failure. Up to 5% of regular NSAID users can be expected to develop hypertension. Hypertensive complications may occur more commonly in patients treated with COX-2–selective than with nonselective NSAIDs. Heart failure risk is roughly doubled.

The NSAIDs have little effect on renal function or blood pressure in healthy human subjects because of the redundancy of systems that regulate renal function. In situations that challenge the regulatory systems, such as dehydration, hypovolemia, volume depletion from diuretics, congestive heart failure, hepatic cirrhosis, chronic kidney disease, and other states of activation of the sympathoadrenal or renin-angiotensin systems, regulation of renal function by PG formation becomes crucial (see Chapter 41). NSAIDs impair the PG-induced inhibition of both the reabsorption of Cl^- and the action of antidiuretic hormone, which may result in the retention of salt and water resulting in edema. Inhibition of COX-2–derived PGs that contribute to the regulation of renal medullary blood flow may lead to a rise in blood pressure, increasing the risk of cardiovascular thrombotic events and heart failure. NSAIDs promote reabsorption of K^+ because of decreased availability of Na^+ at distal tubular sites and suppression of the PG-induced secretion of renin. While the last effect may account in part for the usefulness of NSAIDs in the treatment of Bartter syndrome (see Bartter Syndrome section, above), hyperkalemia is a potential complication of NSAIDs, particularly with concurrent use of other drugs that raise potassium levels.

Renal Failure. Depression of afferent and medullary renal blood flow by inhibition of vasodilator PGs can lead to ischemic episodes and acute kidney injury including acute tubular necrosis. NSAID-induced acute kidney injury can occur during chronic use, but it is typically characterized by an increase in plasma creatinine in the absence of major proteinuria following initiation of therapy (Zhang et al., 2017). This has proven a particular risk in older individuals and professional athletes. If recognized early, discontinuation of NSAIDs permits recovery of renal function. A form of more subacute nephrotoxicity induced by NSAID-triggered immune mechanisms is acute interstitial nephritis. Analgesic nephropathy is a condition of slowly progressive renal failure characterized by papillary necrosis and chronic interstitial nephritis. It has become rare since *phenacetin* was removed from the market.

Pregnancy

Myometrial COX-2 expression and levels of PGE_2 and $PGF_{2\alpha}$ increase markedly in the myometrium during labor. Prolongation of gestation by NSAIDs has been demonstrated in humans. Some NSAIDs, particularly *indomethacin*, have been used off label to stop preterm labor. However, this use is associated with closure of the ductus arteriosus and impaired fetal circulation *in utero*, particularly in fetuses older than 32 weeks of gestation. COX-2–selective inhibitors have been used off label as tocolytic agents; this use has been associated with stenosis of the ductus arteriosus and oligohydramnios.

Hypersensitivity

Pseudo-allergic and allergic reactions to NSAIDs are among the most frequent hypersensitivity drug reactions observed in clinical practice. Pseudo-allergic reactions are thought to involve inhibition of PGE_2 formation and diversion of eicosanoid precursors to alternative biosynthetic pathways—particularly the 5-lipoxygenase pathway resulting in the formation of cysteinyl leukotrienes—when COX-1 is inhibited (Cahill and Boyce, 2017). Ensuing mast cell and eosinophil activation underlie various phenotypes in susceptible individuals (Blanca-Lopez et al., 2019). NSAID-exacerbated respiratory disease (NERD) is characterized by symptoms ranging from vasomotor rhinitis and bronchial constriction to angioedema and generalized urticaria. Patients with asthma and chronic rhinosinusitis often including nasal polyps are predisposed to developing NERD shortly after initiation of NSAID treatment. Urticaria and angioedema are the major symptoms in NSAID-exacerbated cutaneous disease in patients with underlying chronic urticaria and NSAID-induced urticaria/angioedema in patients without chronic urticaria. Pseudo-allergic hypersensitivity is a contraindication to therapy with any other NSAID because of a high probability of cross sensitivity. Allergic hypersensitivity reactions to NSAIDs are induced by specific IgE- or T-cell–dependent immunologic mechanisms and are more restricted to individual or chemically similar NSAIDs. They may present with cutaneous and respiratory symptoms, hypotension, and anaphylaxis. Although less common in children, hypersensitivity reactions to NSAIDs may occur in 10% to 25% of patients with asthma, nasal polyps, or chronic urticaria and in 1% of apparently healthy individuals. Hypersensitivity can be provoked by even low doses (<80 mg) of *aspirin*. Treatment is like that of other hypersensitivity reactions, including support of vital organ function and administration of *epinephrine* in severe cases.

Aspirin Resistance

All forms of treatment failure with *aspirin* have been collectively called *aspirin resistance*, but pharmacological resistance to *aspirin* is rare. Pseudo-resistance, reflecting delayed and reduced drug absorption, complicates enteric-coated but not immediate-release *aspirin* administration (Grosser et al., 2013).

Hepatotoxicity

Liver injury occurs in 17% of adults with unintentional *acetaminophen* overdose (Blieden et al., 2014). Liver toxicity from therapeutic doses of *acetaminophen* is extremely rare (see Acetaminophen section). By contrast, therapeutic dosing of *diclofenac* (or *lumiracoxib*, a *diclofenac* analogue) may be complicated by hepatotoxicity. While the entire class of NSAIDs has a rate of less than 1 liver injury per 100,000 patients on average, chronic consumption of *diclofenac* is associated with a risk of 6 to 11 liver injuries per 100,000 users (Bjornsson et al., 2013; de Abajo et al., 2004) (see Diclofenac section). Mechanisms of hepatotoxicity include hypersensitivity reactions and metabolic aberrations, which are likely influenced by genetic susceptibility. NSAIDs are not recommended in advanced hepatic or renal disease.

Reye Syndrome

Due to the possible association with Reye syndrome, *aspirin* and other salicylates are contraindicated in children and young adults less than 20 years of age with viral illness–associated fever (Schrör, 2007). Reye syndrome, a severe and often fatal disease, is characterized by the acute onset of encephalopathy, liver dysfunction, and fatty infiltration of the liver and other viscera. Although a mechanistic understanding is lacking, the epidemiologic association between *aspirin* use and Reye syndrome is sufficiently strong that *aspirin* and *bismuth subsalicylate* labels indicate the risk. As the use of *aspirin* in children has declined dramatically, so has the incidence of Reye syndrome. *Acetaminophen* and *ibuprofen* have not been implicated in Reye syndrome and are the agents of choice for antipyresis in children and youths.

Vaccination

NSAIDs may be taken to prevent or treat local or systemic vaccine reactions including pain or fever, headache, myalgia, or malaise associated with immunization. However, contrasting data have been reported on a potential interference with the desired vaccination-induced immune response (Saleh et al., 2016). Currently, the World Health Organization advises against the prophylactic use of NSAIDs at the time of vaccination due to lack of evidence about their impact on the vaccine response (World Health Organization, 2016).

Drug Interactions

Refer to the individual product labels for a comprehensive listing of NSAID drug-drug interactions.

Concomitant NSAIDs and Low-Dose Aspirin

Many patients consume both an NSAID for chronic pain and low-dose *aspirin* for cardioprevention. Epidemiological studies suggest that this combination therapy increases significantly the likelihood of GI adverse events over either class of NSAID alone. In addition, prior occupancy of platelet COX-1 by the NSAID can impede access of *aspirin* to its acetylation target Ser^{529} and prevents irreversible inhibition of platelet function (Catella-Lawson et al., 2001). This occurs with *ibuprofen* and *naproxen* and may also affect other isoform nonselective NSAIDs (Li et al., 2014). This drug-drug interaction may undermine the cardioprotective effect of *aspirin*. *Celecoxib* is unlikely to cause this drug-drug interaction *in vivo* but confers a direct cardiovascular hazard (Grosser et al., 2017a). Thus, pain management in patients with preexisting cardiovascular disease remains a particular challenge because of the cardiovascular adverse effects of NSAIDs and the risk of drug-drug interactions that might undermine the antiplatelet effects of *aspirin*.

Other Drug-Drug Interactions

ACE Inhibitors. ACE inhibitors act, at least partly, by preventing the breakdown of kinins that stimulate PG production (see Figure 43–4). Thus, NSAIDs may attenuate the effectiveness of ACE inhibitors by blocking the production of vasodilator and natriuretic PGs. The combination of NSAIDs and ACE inhibitors also can produce marked hyperkalemia, leading to cardiac arrhythmia, especially in the elderly and in patients with hypertension, diabetes mellitus, or ischemic heart disease. Corticosteroids and selective serotonin reuptake inhibitors may increase the frequency or severity of GI complications when combined with NSAIDs.

Warfarin. The NSAIDs may augment the risk of bleeding in patients receiving *warfarin* because almost all NSAIDs suppress normal platelet function temporarily during the dosing interval and because some NSAIDs also increase *warfarin* levels by interfering with its metabolism. Thus, concurrent administration should be avoided.

Miscellaneous. Many NSAIDs are highly bound to plasma proteins, so they may displace other drugs from their binding sites. Such interactions can occur in patients given salicylates or other NSAIDs together with *warfarin*, sulfonylurea hypoglycemic agents, or *methotrexate*; the dosage of such agents may require adjustment to prevent toxicity. Patients taking *lithium* should be monitored because NSAIDs, including *aspirin*, reduce the renal excretion of this drug and can lead to toxicity.

Pediatric and Geriatric Use

Therapeutic Uses in Children

Therapeutic uses for NSAIDs in children include fever (*acetaminophen, ibuprofen*); pain (*acetaminophen, ibuprofen*); postoperative pain (*ketorolac* injection [single-dose only]); inflammatory disorders, such as juvenile arthritis (*celecoxib, etodolac, meloxicam, naproxen, oxaprozin, tolmetin*) and Kawasaki disease (off-label high-dose *aspirin*); and relief of ocular itching due to seasonal allergic rhinitis and postoperative inflammation after cataract extraction (*ketorolac* ophthalmic solution).

Kawasaki Disease. *Aspirin* generally is avoided in pediatric populations due to its potential association with Reye syndrome. However, in Kawasaki disease, children are treated with high doses of *aspirin* (30–100 mg/kg per day) during the acute phase, followed by low-dose antiplatelet therapy in the subacute phase until normalization of inflammatory markers.

Pharmacokinetics in Children

NSAID dosing recommendations frequently are based on extrapolation of pharmacokinetic data from adults or children older than 2 years, and there are often insufficient data for dose selection in younger infants. For example, the pharmacokinetics of the most used NSAID in children, *acetaminophen*, differ substantially between the neonatal period and older children or adults. The systemic bioavailability of rectal *acetaminophen* formulations in neonates and preterm babies is higher than in older patients. *Acetaminophen* clearance is reduced in preterm neonates, probably due to their immature glucuronide conjugation system (sulfation is the principal route of biotransformation at this age). Therefore, *acetaminophen* dosing intervals need to be extended (8–12 h) or daily doses reduced to avoid accumulation and liver toxicity.

Aspirin elimination also is delayed in neonates and young infants compared to adults, raising the risk of accumulation. Disease also may affect NSAID disposition in children. For example, *ibuprofen* plasma concentrations are reduced, and clearance is increased (~80%) in children with cystic fibrosis. This is probably related to the GI and hepatic pathologies associated with this disease. *Aspirin*'s kinetics are markedly altered during the febrile phase of rheumatic fever or Kawasaki vasculitis. The reduction in serum albumin associated with these conditions causes an elevation of the free salicylate concentration, which may saturate renal excretion and result in salicylate accumulation to toxic levels. In addition to dose reduction, monitoring of the free drug may be warranted in these situations.

Pharmacokinetics in the Elderly

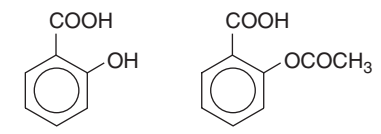
The clearance of many NSAIDs is reduced in the elderly due to changes in hepatic metabolism and creatine clearance. NSAIDs with a long $t_{1/2}$ and primarily oxidative metabolism (i.e., *piroxicam, tenoxicam, celecoxib*) have elevated plasma concentrations in elderly patients. For example, plasma concentrations after the same dose of *celecoxib* may rise 2-fold in patients older than 65 years compared to patients younger than 50 years of age, warranting dose adjustment. The capacity of plasma albumin to bind drugs is diminished in older patients and may result in higher concentrations of unbound NSAIDs. For example, free *naproxen* concentrations are markedly increased in older patients, and the higher susceptibility of older patients to GI complications may be due in part to elevated total or free NSAID concentrations. Generally, it is advisable to start most NSAIDs at a low dosage in the elderly and increase the dosage only if the therapeutic efficacy is insufficient.

Specific Properties of Individual NSAIDs

In this section, important characteristics of individual substances are discussed. NSAIDs are grouped by their chemical similarity, as in Figure 42–1.

Aspirin and Other Salicylates

The salicylates include *aspirin, salicylic acid, methyl salicylate, diflunisal, salsalate* (an unapproved marketed drug in the U.S.), *olsalazine, sulfasalazine, balsalazide, choline magnesium trisalicylate* (an unapproved marketed drug in the U.S.), *magnesium salicylate, mesalamine*, and *salicylamide* (a carboxamide derivative of *salicylic acid* contained as an ingredient in some OTC combination pain relievers). Salicylic acid is so irritating to the GI tract that it can only be used externally; therefore, the various derivatives of this acid have been synthesized for systemic use. For example, *aspirin* is the acetate ester of salicylic acid. *Aspirin* is widely consumed most often at low doses for cardioprotection and at higher doses as an analgesic, antipyretic, and anti-inflammatory agent. Its possibility of misuse and serious toxicity is underappreciated, and it remains a cause of fatal poisoning in children.



SALICYLIC ACID ASPIRIN

Table 42–2 summarizes the clinical pharmacokinetic properties of two salicylates, *aspirin* and *diflunisal*.

TABLE 42–2 ■ NSAIDs: SALICYLATES, ACETAMINOPHEN, AND ACETIC ACID DERIVATIVES

CLASS/DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Salicylates				
Aspirin	Peak C_p, 1 h Protein binding, 80%–90% Metabolite, salicyluric acid $t_{1/2}$, therapeutic, 2–3 h $t_{1/2}$, toxic dose, 15–30 h	Antiplatelet, 40–80 mg/day Pain/fever, 325–650 mg every 4–6 h Rheumatic fever, children 1 g every 4–6 h or 10 mg/kg every 4–6 h	Permanent platelet COX-1 inhibition Adverse effects: GI, ↑clotting time hypersensitivity Avoid in children with acute febrile illness (Reye syndrome)	
Diflunisal	Peak C_p, 2–3 h Protein binding, 99% Metabolite, glucuronide $t_{1/2}$, 8–12 h	250–500 mg every 8–12 h (maximum = 1 g/dose and 4 g/day); children <12 y: 10–15 mg/kg every 4 h (maximum 5 doses/24 h) IV (>50 kg): 1000 mg every 6 h or 650 mg every 4 h; (<50 kg): 15 mg/kg every 6 h or 12.5 mg/kg every 4 h	Not metabolized to salicylate, competitive COX inhibitor, excreted into breast milk. Not marketed for IV administration in the U.S.	Analgesic and anti-inflammatory, 4–5× more potent Antipyretic, weaker Fewer platelet and GI side effects
Para-aminophenol derivative				
Acetaminophen	Peak C_p, 30–60 min Protein binding, 20%–50% Metabolites, glucuronides (60%); sulfates (35%) $t_{1/2}$, 2 h	650 mg or less every 4 h (maximum of 4000 mg/24 h)	Weak nonspecific COX inhibitor at common doses Potency may be modulated by peroxidase Overdose → toxic metabolite, (NAPQI) liver necrosis	Analgesic/antipyretic, equivalent Anti-inflammatory, GI, and platelet effects < aspirin at 1000 mg/day
Acetic acid derivatives				
Indomethacin	Peak C_p, 1–2 h Protein binding, 99% Metabolites, *O*-demethyl (50%); unchanged (20%) $t_{1/2}$, 2 h	25 mg 2–3 times/day; 75–100 mg at night	Side effects (3%–50%); frontal headache, neutropenia, thrombocytopenia; 20% discontinue	10–40× more potent; intolerance typically limits dose
Sulindac (sulfoxide prodrug)	Peak C_p 1–2 h; active metabolite 8 h, extensive enterohepatic circulation Metabolites, sulfone/conjugates (30%); sulindac/conjugate (25%) $t_{1/2}$, 7 h; 18 h for active sulfone metabolite	150–200 mg twice/day orally	20% GI side effects; 10% CNS side effects (headache, dizziness, rash)	Efficacy comparable
Etodolac	Peak C_p, 1 h Protein binding, 99% Metabolism, hepatic $t_{1/2}$, 7 h	200–400 mg 3–4 times/day, max: 1200 mg/day or 1000 mg/day (extended release) >6 years (extended release): 400 mg/day (20–30 kg); add 200 mg/15 kg more weight	Some COX-2 selectivity *in vitro* Adverse effects similar to sulindac, but ~ half as frequent	100 mg etodolac efficacy ≈ 650 mg of aspirin; may be better tolerated
Tolmetin	Peak C_p, 20–60 min Protein binding, 99% Metabolites, carboxylate conjugates $t_{1/2}$, 5 h	Adults: 400–600 mg 3 times/day Children >2 y: 20 mg/kg/day in 3–4 divided doses	Food delays and decreases peak absorption May persist in synovial fluid ⇒ biological efficacy > plasma $t_{1/2}$	Efficacy similar; 25%–40% develop side effects; 5%–10% discontinue drug
Ketorolac	Peak C_p, 30–60 min Protein binding, 99% Metabolite, glucuronide (90%) $t_{1/2}$, 4–6 h	See FDA package insert	Parenterally (60 mg IM, then 30 mg every 6 h, or 30 mg IV every 6 h) Available as ocular prep	Potent analgesic, poor anti-inflammatory

TABLE 42–2 ■ NSAIDs: SALICYLATES, ACETAMINOPHEN, AND ACETIC ACID DERIVATIVES (*CONTINUED*)

CLASS/DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Diclofenac	Peak C_p, 1 h; extended release, 5 h Protein binding, 99% Metabolites, glucuronide and sulfide (renal 65%, bile 35%) $t_{1/2}$, 1.2–2 h (immediate-release tabs); 12 h (topical epolamine patch)	50 mg 3 times/day or 75 mg twice/day	As topical gel, ocular solution, oral tablets combined with misoprostol First-pass effect; oral bioavailability, 50%	More potent; 20%, side effects; 2%, discontinue; 15%, elevated liver enzymes Substrate for CYPs 2C9 and 3A4
Nabumetone (6-methoxy-2-napthylacetic acid prodrug)	Peak C_p, ~3 h Protein binding, 99% Metabolites, conjugates $t_{1/2}$, 19–26 h; 22–38 h (elderly)	500–1000 mg 1–2 times/day (maximum 2000 mg/day) Patients <50 kg less likely to require >1000 mg/day	First-pass effects, 35% conversion of prodrug to active metabolite; preferential COX-2 inhibition at low doses; adverse effects (13%): GI upset, abdominal pain	Less fecal blood loss during short-term therapy

Time to peak plasma drug concentration (C_p) is after a single dose. In general, food delays absorption but does not decrease peak concentration. The majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. Typical $t_{1/2}$ is listed for therapeutic doses; if $t_{1/2}$ is much different with the toxic dose, this is also given. Typical adult oral doses are listed unless otherwise noted. Refer to the current product labeling for complete prescribing information, including current labeled pediatric indications.

GI, gastrointestinal.

Mechanism of Action

The effects of *aspirin* are largely caused by its capacity to acetylate proteins and inhibit cyclooxygenase irreversibly. Other salicylates generally act by virtue of their content of salicylic acid, which is a relatively weak inhibitor of the purified COX enzymes. Salicylic acid may also suppress inflammatory upregulation of COX-2 by interfering with transcription factor binding to the COX-2 promoter.

ADME

Absorption. Orally ingested salicylates are absorbed rapidly, partly from the stomach, but mostly from the upper small intestine. The peak plasma level is reached in about 1 h. The rate of absorption is determined by disintegration and dissolution rates of the tablets administered, the pH at the mucosal surface, and gastric emptying time. Even though salicylate is more ionized as the pH is increased, a rise in pH also increases the solubility of salicylate and thus dissolution of the tablets. The overall effect is to enhance absorption. The presence of food delays absorption of salicylates. Rectal absorption of salicylate usually is slower than oral absorption and is incomplete and inconsistent.

Salicylic acid is absorbed rapidly from the intact skin, especially when applied in oily liniments or ointments, and systemic poisoning has occurred from its application to large areas of skin. Methyl salicylate likewise is speedily absorbed when applied cutaneously; however, its GI absorption may be delayed many hours, making gastric lavage effective for removal even in poisonings that present late after oral ingestion.

Enteric coating delays and reduces the bioavailability of *aspirin* by roughly half and renders absorption more variable in the presence of food (Bogentoft et al., 1978), which is likely the cause of "pseudo-resistance" to *aspirin* (see Aspirin Resistance).

Distribution. After absorption, salicylates are distributed throughout most body tissues and transcellular fluids, primarily by pH-dependent processes. Salicylates are transported actively out of the CSF across the choroid plexus. The drugs readily cross the placental barrier. Roughly 80% to 90% of the salicylate in plasma is bound to proteins, especially albumin; the proportion of the total that is bound declines as plasma concentrations increase. Hypoalbuminemia is associated with a proportionately higher level of free salicylate in the plasma. Salicylate competes with a variety of compounds for plasma protein-binding sites; these include thyroxine, triiodothyronine, *penicillin*, *phenytoin*, *sulfinpyrazone*, bilirubin, uric acid, and other NSAIDs, such as *naproxen*. *Aspirin* is plasma protein bound to a more limited extent; however, it acetylates albumin *in vivo* by reaction with the ε-amino group of lysine and may change the binding of other drugs to albumin. *Aspirin* also acetylates other plasma and tissue proteins, but there is no evidence that this contributes to clinical efficacy or adverse events.

Metabolism and Excretion. *Aspirin* is rapidly deacetylated to form salicylic acid by spontaneous hydrolysis or esterases located in the intestinal wall, red blood cells, and liver. The three chief metabolic products are salicyluric acid (the glycine conjugate), the ether or phenolic glucuronide, and the ester or acyl glucuronide. Salicylates and their metabolites are excreted in the urine. The excretion of free salicylates is variable and depends on the dose and the urinary pH. For example, the clearance of salicylate is about four times as great at pH 8 as at pH 6, and it is well above the glomerular filtration rate at pH 8. High rates of urine flow decrease tubular reabsorption, whereas the opposite is true in oliguria. The plasma $t_{1/2}$ for *aspirin* is about 20 min, and for salicylate, it is 2 to 3 h at antiplatelet doses, rising to 12 h at usual anti-inflammatory doses. The $t_{1/2}$ of salicylate may rise to 15 to 30 h at high therapeutic doses or when there is intoxication. This dose-dependent elimination is the result of the limited capacity of the liver to form salicyluric acid and the phenolic glucuronide, resulting in a larger proportion of unchanged drug being excreted in the urine at higher doses. Salicylate metabolism shows high intersubject variability due to the variable contribution of different metabolic pathways. Women frequently exhibit higher plasma concentrations, perhaps due to lower intrinsic esterase activity and gender differences in hepatic metabolism. In the elderly, salicylate clearance is reduced and salicylate exposure is significantly increased. The plasma concentration of salicylate is increased by conditions that decrease the glomerular filtration rate or reduce proximal tubule secretion, such as renal disease, or the presence of inhibitors that compete for the transport system (e.g., *probenecid*). In case of an overdose, hemodialysis and hemofiltration techniques remove salicylic acid effectively from the circulation.

Monitoring of Plasma Salicylate Concentrations. *Aspirin* is one of the NSAIDs for which plasma salicylate can provide a means to monitor therapy and toxicity. Intermittent analgesic-antipyretic doses of *aspirin* typically produce plasma *aspirin* levels of less than 20 μg/mL and plasma salicylate levels of less than 60 μg/mL. The *daily* ingestion of anti-inflammatory doses of 4 to 5 g of *aspirin* produces plasma salicylate levels in the range of 120 to 350 μg/mL. Optimal anti-inflammatory effects for patients with rheumatic diseases require plasma salicylate concentrations of 150 to 300 μg/mL. Significant adverse effects can be seen at levels greater than 300 μg/mL. At lower concentrations, the drug

clearance is nearly constant (despite saturation of metabolic capacity being approached) because the fraction of drug that is free, and thus available for metabolism or excretion, increases as binding sites on plasma proteins are saturated. The total concentration of salicylate in plasma is therefore a relatively linear function of dose at lower concentrations. At higher concentrations, however, as metabolic pathways of disposition become saturated, small increments in dose can disproportionately increase plasma salicylate concentration. Failure to anticipate this phenomenon can lead to toxicity.

Therapeutic Uses

Systemic Uses. The *analgesic-antipyretic* dose of *aspirin* for adults is 325 to 1000 mg orally every 4 to 6 h. It is only rarely used for inflammatory diseases such as *arthritis, spondyloarthropathies*, and *systemic lupus erythematosus*; NSAIDs with an assumed better GI safety profile (though weakly supported by evidence from comparisons in controlled trials) are preferred. The anti-inflammatory doses of *aspirin*, as might be given in rheumatic fever, range from 4 to 8 g/day in divided doses. The maximum recommended daily dose of *aspirin* for adults and children 12 years or older is 4 g. The rectal administration of *aspirin* suppositories may be preferred in infants or when the oral route is unavailable. *Aspirin* suppresses clinical signs and improves tissue inflammation in acute rheumatic fever. Other salicylates available for systemic use include *salsalate* (salicylsalicylic acid), *magnesium salicylate*, *diflunisal*, and a combination of choline salicylate and magnesium salicylate (*choline magnesium trisalicylate*).

Diflunisal is a difluorophenyl derivative of salicylic acid that is not converted to salicylic acid *in vivo*. It is a competitive inhibitor of COX and a potent anti-inflammatory drug but is largely devoid of antipyretic effects, perhaps because of poor penetration into the CNS. The drug has been used primarily as an analgesic in the treatment of osteoarthritis and musculoskeletal strains or sprains; in these circumstances, it is about three to four times more potent than *aspirin*. *Diflunisal* may produce fewer auditory side effects (see Ototoxic Effects) and appears to cause fewer and less-intense GI and antiplatelet effects than does *aspirin*.

Local Uses. *Mesalamine* (5-aminosalicylic acid) is a salicylate that is used for its local effects in the treatment of *inflammatory bowel disease* (see Figure 55–4). Oral formulations that deliver drug to the lower intestine are efficacious in the treatment of inflammatory bowel disease (in particular, ulcerative colitis). These preparations rely on pH-sensitive coatings and other delayed-release mechanisms such as linkage to another moiety to create a poorly absorbed parent compound that must be cleaved by bacteria in the colon to form the active drug. *Mesalamine* is available as a rectal enema for treatment of mild-to-moderate ulcerative colitis, proctitis, and proctosigmoiditis and as a rectal suppository for the treatment of active ulcerative proctitis. *Mesalamine* derivatives in clinical use include *balasalazide*, *sulfasalazine*, and *olsalazine*. *Sulfasalazine* (salicylazosulfapyridine) contains *mesalamine* linked covalently to *sulfapyridine*, and *balsalazide* contains *mesalamine* linked to the carrier molecule 4-aminobenzoyl-β-alanine (see Figure 55-3). *Sulfasalazine* and *olsalazine* have been used in the treatment of rheumatoid arthritis and ankylosing spondylitis. Some OTC medications to relieve indigestion and some diarrhea agents contain bismuth subsalicylate and have the potential to cause salicylate intoxication, particularly in children.

The keratolytic action of free salicylic acid is employed for the local treatment of warts, corns, fungal infections, and certain types of eczematous dermatitis. After treatment with salicylic acid, cells swell, soften, and desquamate. *Methyl salicylate* (oil of wintergreen) is a common ingredient of ointments and deep-heating liniments used in the management of musculoskeletal pain; it also is available in herbal medicines and as a flavoring agent. The cutaneous application of *methyl salicylate* can result in pharmacologically active, and even toxic, systemic salicylate concentrations and has been reported to increase prothrombin time in patients receiving *warfarin*.

Adverse Effects and Toxicity

Respiration. Salicylates increase O_2 consumption and CO_2 production especially in skeletal muscle at anti-inflammatory doses, a result of uncoupling oxidative phosphorylation. The increased production of CO_2 stimulates respiration. Salicylates also stimulate the respiratory center directly in the medulla. Respiratory rate and depth increase, the P_{CO_2} falls, and respiratory alkalosis ensues.

Acid-Base and Electrolyte Balance and Renal Effects. Therapeutic doses of salicylate produce definite changes in the acid-base balance and electrolyte pattern. Compensation for the initial event, respiratory alkalosis, is achieved by increased renal excretion of bicarbonate, which is accompanied by increased Na^+ and K^+ excretion; plasma bicarbonate is thus lowered, and blood pH returns toward normal. This stage of compensatory renal acidosis was often seen in adults given intensive salicylate therapy before the development of safer alternatives. Today, it is an indicator of ensuing intoxication (see Salicylate Intoxication). Salicylates can cause retention of salt and water, as well as acute reduction of renal function in patients with congestive heart failure, renal disease, or hypovolemia. Although long-term use of salicylates alone rarely is associated with nephrotoxicity, the prolonged and excessive ingestion of analgesic mixtures containing salicylates in combination with other NSAIDs can produce papillary necrosis and interstitial nephritis (see Analgesic Nephropathy).

Cardiovascular Effects. Low-dose *aspirin* (≤100 mg daily) lowers cardiovascular risk and is recommended for the prevention of myocardial infarction and stroke in patients at elevated risk (see Cardioprotection section) (Patrono, 2015). At high therapeutic doses (≥3 g daily), salt and water retention can lead to an increase (≤20%) in circulating plasma volume and decreased hematocrit (via a dilutional effect). There is a tendency for the peripheral vessels to dilate because of a direct effect on vascular smooth muscle. Cardiac output and work are increased. Those with carditis or compromised cardiac function may not have sufficient cardiac reserve to meet the increased demands, and congestive cardiac failure and pulmonary edema can occur. High doses of salicylates can produce noncardiogenic pulmonary edema, particularly in older patients who ingest salicylates regularly over a prolonged period.

GI Effects. Ingestion of salicylates may result in epigastric distress, heartburn, dyspepsia, nausea, and vomiting. Salicylates also may cause erosive and reactive gastropathies, GI ulceration, and hemorrhage.

Aspirin-induced gastric bleeding sometimes is painless and, if unrecognized, may lead to iron-deficiency anemia. The daily ingestion of anti-inflammatory doses of *aspirin* (3–4 g) results in an average fecal blood loss of between 3 and 8 mL/day, as compared with about 0.6 mL/day in untreated subjects. Gastroscopic examination of *aspirin*-treated subjects often reveals discrete ulcerative and hemorrhagic lesions of the gastric mucosa.

Hepatic Effects. Salicylates can cause hepatic injury, usually after high doses that result in plasma salicylate concentrations greater than 150 μg/mL. The injury is not an acute effect; rather, the onset characteristically occurs after several months of high-dose treatment. The majority of cases occur in patients with connective tissue disorders. There usually are no symptoms, simply an increase in serum levels of hepatic transaminases, but some patients note right upper quadrant abdominal discomfort and tenderness. Overt jaundice is uncommon. The injury usually is reversible on discontinuation of salicylates. However, the use of salicylates is contraindicated in patients with chronic liver disease. Large doses of salicylates may cause hyperglycemia, glycosuria, and depletion of liver and muscle glycogen.

Uricosuric Effects. The effects of salicylates on uric acid excretion are markedly dependent on dose. Low doses (1 or 2 g/day) may decrease urate excretion and elevate plasma urate concentrations; intermediate doses (2 or 3 g/day) usually do not alter urate excretion. Larger-than-recommended doses (>5 g/day) induce uricosuria and lower plasma urate levels; however, such large doses are tolerated poorly. Even small doses of salicylate can block the effects of *probenecid* and other uricosuric agents that decrease tubular reabsorption of uric acid.

Hematologic Effects. Irreversible inhibition of platelet function underlies the cardioprotective effect of *aspirin*. If possible, *aspirin* therapy

should be stopped at least 1 week before surgery; however, preoperative *aspirin* often is recommended prior to cardiovascular surgery and percutaneous interventions. Patients with severe hepatic damage, hypoprothrombinemia, vitamin K deficiency, or hemophilia should avoid *aspirin* because the inhibition of platelet hemostasis can result in hemorrhage. Salicylates ordinarily do not alter the leukocyte or platelet count, the hematocrit, or the hemoglobin content. However, doses of 3 to 4 g/day markedly decrease plasma iron concentration and shorten erythrocyte survival time. *Aspirin* can cause a mild degree of hemolysis in individuals with a deficiency of G6PD.

Endocrine Effects. Long-term administration of salicylates decreases thyroidal uptake and clearance of iodine but increases O_2 consumption and the rate of disappearance of thyroxine and triiodothyronine from the circulation. These effects probably are caused by the competitive displacement by salicylate of thyroxine and triiodothyronine from transthyretin and the thyroxine-binding globulin in plasma (see Chapter 47).

Ototoxic Effects. Hearing impairment, alterations of perceived sounds, and tinnitus commonly occur during high-dose salicylate therapy and are sometimes observed at low doses. Ototoxic symptoms are caused by increased labyrinthine pressure or an effect on the hair cells of the cochlea, perhaps secondary to vasoconstriction in the auditory microvasculature. Symptoms usually resolve within 2 or 3 days after withdrawal of the drug. As most competitive COX inhibitors are not associated with hearing loss or tinnitus, a direct effect of salicylic acid rather than suppression of PG synthesis is likely.

Salicylates and Pregnancy. Infants born to women who ingest salicylates for long periods may have significantly reduced birth weights. When administered during the third trimester, there also is an increase in perinatal mortality, anemia, antepartum and postpartum hemorrhage, prolonged gestation, and complicated deliveries; thus, its use during this period should be avoided. NSAIDs during the third trimester of pregnancy also can cause premature closure of the ductus arteriosus and should be avoided.

Local Irritant Effects. Salicylic acid is irritating to skin and mucosa and destroys epithelial cells.

Salicylate Intoxication. Salicylate poisoning or serious intoxication most often occurs in children and sometimes is fatal. CNS effects, intense hyperpnea, and hyperpyrexia are prominent symptoms. Death has followed use of 10 to 30 g of *sodium salicylate* or *aspirin* in adults, but much larger amounts (130 g of *aspirin* in one case) have been ingested without a fatal outcome. The lethal dose of *methyl salicylate* (also known as oil of wintergreen, sweet birch oil, gaultheria oil, or betula oil) is considerably less than that of sodium salicylate. As little as a 4 mL (4.7 g) of *methyl salicylate* may cause severe systemic toxicity in children. Mild chronic salicylate intoxication is called *salicylism*. When fully developed, the syndrome includes headache, dizziness, tinnitus, difficulty hearing, dimness of vision, mental confusion, lassitude, drowsiness, sweating, thirst, hyperventilation, nausea, vomiting, and occasionally diarrhea.

Neurological Effects. In high doses, salicylates have toxic effects on the CNS, consisting of stimulation (including convulsions) followed by depression. Confusion, dizziness, tinnitus, high-tone deafness, delirium, psychosis, stupor, and coma may occur. Salicylates induce nausea and vomiting, which result from stimulation of sites that are accessible from the CSF, probably in the medullary chemoreceptor trigger zone.

Respiration. The respiratory effects of salicylates contribute to the serious acid-base balance disturbances that characterize poisoning by this class of compounds. Salicylates stimulate respiration indirectly by uncoupling of oxidative phosphorylation and directly by stimulation of the respiratory center in the medulla. Uncoupling of oxidative phosphorylation also leads to excessive heat production, and salicylate toxicity is associated with hyperthermia, particularly in children. Prolonged exposure to high doses of salicylates leads to depression of the medulla, with central respiratory depression and circulatory collapse, secondary to vasomotor depression. Because enhanced CO_2 production continues, respiratory acidosis ensues. Respiratory failure is the usual cause of death in fatal cases of salicylate poisoning. Elderly patients with chronic salicylate intoxication often develop noncardiogenic pulmonary edema, which is considered an indication for hemodialysis.

Acid-Base Balance and Electrolytes. High therapeutic doses of salicylate are associated with a primary respiratory alkalosis and compensatory metabolic acidosis. The phase of primary respiratory alkalosis rarely is recognized in children with salicylate toxicity. They usually present in a state of mixed respiratory and metabolic acidosis, characterized by a decrease in blood pH, a low plasma bicarbonate concentration, and normal or nearly normal plasma P_{CO_2}. Direct salicylate-induced depression of respiration prevents adequate respiratory hyperventilation to match the increased peripheral production of CO_2. Consequently, plasma P_{CO_2} increases and blood pH decreases. Because the concentration of bicarbonate in plasma already is low due to increased renal bicarbonate excretion, the acid-base status at this stage essentially is an uncompensated respiratory acidosis.

Superimposed, however, is a true metabolic acidosis caused by accumulation of acids because of three processes. First, toxic concentrations of salicylates displace plasma bicarbonate. Second, vasomotor depression caused by toxic doses of salicylates impairs renal function, with consequent accumulation of sulfuric and phosphoric acids; renal failure can ensue. Third, salicylates in toxic doses may decrease aerobic metabolism because of inhibition of various enzymes. This derangement of carbohydrate metabolism leads to the accumulation of organic acids, especially pyruvic, lactic, and acetoacetic acids.

The same series of events also causes alterations of water and electrolyte balance. The low plasma P_{CO_2} leads to decreased renal tubular reabsorption of bicarbonate and increased renal excretion of Na^+, K^+, and water. Water also is lost by salicylate-induced sweating (especially in the presence of hyperthermia) and hyperventilation. Dehydration, which can be profound, particularly in children, rapidly occurs. Because more water than electrolyte is lost through the lungs and by sweating, the dehydration is associated with hypernatremia.

Cardiovascular Effects. Toxic doses of salicylates lead to an exaggeration of the unfavorable cardiovascular responses seen at high therapeutic doses, and central vasomotor paralysis occurs. Petechiae may be seen due to defective platelet function.

Metabolic Effects. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen; these effects are partly explained by the release of epinephrine. Such doses also reduce aerobic metabolism of glucose, increase glucose-6-phosphatase activity, and promote the secretion of glucocorticoids. There is a greater risk of hypoglycemia and subsequent permanent brain injury in children. Salicylates in toxic doses cause a significant negative nitrogen balance, characterized by an aminoaciduria. Adrenocortical activation may contribute to the negative nitrogen balance by enhancing protein catabolism. Salicylates reduce lipogenesis by partially blocking incorporation of acetate into fatty acids; they also inhibit epinephrine-stimulated lipolysis in fat cells and displace long-chain fatty acids from binding sites on human plasma proteins. The combination of these effects leads to increased entry and enhanced oxidation of fatty acids in muscle, liver, and other tissues and to decreased plasma concentrations of free fatty acids, phospholipid, and cholesterol; the oxidation of ketone bodies also is increased.

Management of Salicylate Overdose. Salicylate poisoning represents an acute medical emergency, and death may result despite maximal therapy. Monitoring of salicylate levels is a useful guide to therapy but must occur in conjunction with an assessment of the patient's overall clinical condition, acid-base balance, formulation of salicylate ingested, timing, and dose. There is no specific antidote for salicylate poisoning. Treatment is supportive and may include alkalinization with intravenous sodium bicarbonate or hemodialysis.

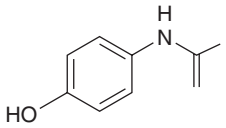
Drug Interactions

The plasma concentration of salicylates generally is little affected by other drugs, but concurrent administration of *aspirin* lowers the concentrations of *indomethacin*, *naproxen*, *ketoprofen*, and *fenoprofen*, at least

in part by displacement from plasma proteins. Important adverse interactions of *aspirin* with *warfarin*, sulfonylureas, and *methotrexate* were mentioned previously (in Drug Interactions). Other interactions of *aspirin* include the antagonism of *spironolactone*-induced natriuresis and the blockade of the active transport of *penicillin* from CSF to blood. Magnesium-aluminum hydroxide antacids can alkalize the urine enough to increase salicylic acid clearance significantly and reduce steady-state concentrations. Conversely, discontinuation of antacid therapy can increase plasma concentrations to toxic levels.

Acetaminophen

Acetaminophen (paracetamol; *N*-acetyl-*p*-aminophenol) is the active metabolite of phenacetin.



ACETAMINOPHEN

Acetaminophen raises the threshold to painful stimuli, thus exerting an analgesic effect against pain due to a variety of etiologies. *Acetaminophen* is available without a prescription and is used as a common household analgesic by children and adults. It also is available in fixed-dose combinations containing narcotic and nonnarcotic analgesics (including *aspirin* and other salicylates), barbiturates, caffeine, vascular headache remedies, sleep aids, toothache remedies, antihistamines, antitussives, decongestants, expectorants, cold and flu preparations, and sore throat treatments. *Acetaminophen* is well tolerated; however, overdosage—two-thirds of which are intentionally induced—can cause severe hepatic damage (see Figure 9–4); it leads to nearly 80,000 emergency department visits and 30,000 hospitalizations annually in the U.S. (Blieden et al., 2014). The maximum FDA-recommended dose of *acetaminophen* is 4 g/day.

Mechanism of Action

Acetaminophen has analgesic and antipyretic effects like those of *aspirin*, but only weak anti-inflammatory effects at commonly used doses (1000 mg/day). It is a nonselective COX inhibitor (Catella-Lawson et al., 2001), which acts at the peroxide site of the enzyme and is thus distinct among NSAIDs. The presence of high concentrations of peroxides, as occur at sites of inflammation, reduces its COX-inhibitory activity.

ADME

Oral *acetaminophen* has excellent bioavailability. Peak plasma concentrations occur within 30 to 60 min, and the $t_{1/2}$ in plasma is about 2 h. *Acetaminophen* is relatively uniformly distributed throughout most body fluids. Binding of the drug to plasma proteins is variable, but less than with other NSAIDs. Some 90% to 100% of drug may be recovered in the urine within the first day at therapeutic dosing, primarily after hepatic conjugation with glucuronic acid (~60%), sulfuric acid (~35%), or cysteine (~3%); small amounts of hydroxylated and deacetylated metabolites also have been detected (see Table 42–2). Children have less capacity for glucuronidation of the drug than do adults. A small proportion of *acetaminophen* undergoes CYP-mediated *N*-hydroxylation to form NAPQI, a highly reactive intermediate. This metabolite normally reacts with sulfhydryl groups in GSH and thereby is rendered harmless. However, after ingestion of large doses of *acetaminophen*, the metabolite is formed in amounts sufficient to deplete hepatic GSH and contributes significantly to the toxic effects of overdose (see Management of Acetaminophen Intoxication).

Therapeutic Uses

Acetaminophen is suitable for analgesic or antipyretic uses; it is particularly valuable for patients in whom *aspirin* is contraindicated (e.g., those with aspirin hypersensitivity, children with a febrile illness, patients with bleeding disorders). The conventional oral dose of *acetaminophen* is 325 to 650 mg every 4 to 6 h; total daily doses should not exceed 4 g/day (2 g/day for persons with a history of heavy alcohol use). Single doses for children 2 to 11 years old depend on age and weight (~10–15 mg/kg); no more than five doses should be administered in 24 h. An injectable preparation is typically used in combination with narcotic analgesics for its opioid-sparing effect. Particular attention is warranted due to the availability of a wide variety of prescription and nonprescription multi-ingredient medications that represent potentially toxic overlapping sources of *acetaminophen*.

Adverse Effects and Toxicity

Acetaminophen usually is well tolerated. Therapeutic doses of *acetaminophen* have no clinically relevant effects on the cardiovascular and respiratory systems, platelets, or coagulation. The GI adverse effects are less common than with therapeutic doses of NSAIDs at 1000 mg, the most commonly used daily dose. This corresponds to approximately 50% inhibition of COXs at time of peak drug action. Common therapeutic doses of other NSAIDs (e.g., *ibuprofen*) achieve 100% inhibition. Doses of 3000 to 4000 mg/day *acetaminophen* have been associated with GI and hypertensive adverse effects seen at therapeutic doses of other NSAIDs (García-Rodríguez and Hernández-Díaz, 2001; Sudano et al., 2010). Rash and other allergic reactions occur occasionally, but sometimes these are more serious and may be accompanied by drug fever and mucosal lesions. Patients who show hypersensitivity reactions to the salicylates only rarely exhibit sensitivity to *acetaminophen*. The most serious acute adverse effect of overdosage of *acetaminophen* is a potentially fatal hepatic necrosis. Hepatic injury with *acetaminophen* involves its conversion to the toxic metabolite NAPQI (see Figure 9–4). The glucuronide and sulfate conjugation pathways become saturated, and increasing amounts undergo CYP-mediated *N*-hydroxylation to form NAPQI. This is eliminated rapidly by conjugation with GSH and then further metabolized to a mercapturic acid and excreted into the urine. In the setting of *acetaminophen* overdose, hepatocellular levels of GSH become depleted. The highly reactive NAPQI metabolite binds covalently to cell macromolecules, leading to dysfunction of enzymatic systems and structural and metabolic disarray. Furthermore, depletion of intracellular GSH renders the hepatocytes highly susceptible to oxidative stress and apoptosis. Renal tubular necrosis and hypoglycemic coma also may occur.

In adults, hepatotoxicity may occur after ingestion of a single dose of 10 to 15 g (150–250 mg/kg) of *acetaminophen* in adults and greater than 150 mg/kg in children; doses of 20 to 25 g or more are potentially fatal. Conditions of CYP induction (e.g., chronic heavy alcohol consumption) or GSH depletion (e.g., fasting or malnutrition) increase the susceptibility to hepatic injury, which has been documented, albeit uncommonly, with doses in the therapeutic range. Plasma transaminases become elevated, sometimes markedly so, beginning about 12 to 36 h after ingestion. Symptoms that occur during the first 2 days of acute poisoning by *acetaminophen* reflect gastric distress (e.g., nausea, abdominal pain, anorexia) and belie the potential seriousness of the intoxication. Clinical indications of hepatic damage manifest within 2 to 4 days of ingestion of toxic doses, with right subcostal pain, tender hepatomegaly, jaundice, and coagulopathy. Renal impairment or frank renal failure may occur. Liver enzyme abnormalities typically peak 72 to 96 h after ingestion and may be accompanied by hepatic encephalopathy. Biopsy of the liver reveals centrilobular necrosis with sparing of the periportal area. In nonfatal cases, the hepatic lesions are reversible over a period of weeks or months. The hepatotoxicity of *acetaminophen* has led to the promotion of much lower doses for clinical use, resulting in lower maximal inhibition of COXs than other NSAIDs.

Management of Acetaminophen Intoxication. Severe liver damage occurs in 90% of patients with plasma concentrations of *acetaminophen* greater than 300 μg/mL at 4 h or 45 μg/mL at 15 h after the ingestion of the drug. Activated charcoal, if given within 4 h of ingestion, decreases *acetaminophen* absorption by 50% to 90% and should be administered if the ingested dose is suspected to exceed 7.5 g. *N*-acetylcysteine (NAC) is the accepted antidote for *acetaminophen* overdose and is indicated for those at risk of hepatic injury. NAC functions by detoxifying NAPQI. It both repletes GSH stores and may conjugate directly with NAPQI by serving as a GSH substitute. If given within 8 to 16 h of *acetaminophen* overdose,

the otherwise high mortality plummets to less than 1%. In addition to NAC therapy, aggressive supportive care is warranted. This includes management of hepatic and renal failure, if they occur, and intubation if the patient becomes obtunded. Hypoglycemia can result from liver failure, and plasma glucose should be monitored closely. Fulminant hepatic failure is an indication for liver transplantation.

Acetic Acid Derivatives

Diclofenac

Diclofenac, a phenylacetic acid derivative, is the most frequently used NSAID in Europe. *Diclofenac* has analgesic, antipyretic, and anti-inflammatory activities. Its potency is substantially greater than that of other NSAIDs. Although it was not developed to be a COX-2–selective drug, the selectivity of *diclofenac* for COX-2 resembles that of *celecoxib* (see Figure 42–1).

ADME. *Diclofenac* displays rapid absorption, extensive protein binding, and a $t_{1/2}$ of 1 to 2 h (see Table 42–2). The short $t_{1/2}$ makes it necessary to give doses of *diclofenac* considerably higher than would be required to inhibit COX-2 fully at peak plasma concentrations to afford sustained COX inhibition throughout the dosing interval. Thus, both COX isoforms are inhibited for the first phase of the dosing interval. However, as plasma levels decrease, *diclofenac* behaves like a COX-2 inhibitor in the later phase of the dosing interval. There is a substantial first-pass effect, such that only about 50% of *diclofenac* is available systemically. The drug accumulates in synovial fluid after oral administration, which may explain why its duration of therapeutic effect is considerably longer than its plasma $t_{1/2}$. *Diclofenac* is metabolized in the liver by a member of the CYP2C subfamily to 4-hydroxydiclofenac, the principal metabolite, and other hydroxylated forms; after glucuronidation and sulfation, the metabolites are excreted in the urine (65%) and bile (35%).

Therapeutic Uses. *Diclofenac* is approved in the U.S. for the long-term symptomatic treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, and acute migraine. Multiple oral formulations are available, providing a range of release times; the usual daily oral dosage is 50 to 150 mg, given in several divided doses. For acute pain such as migraine, a powdered form for dissolution in water and a solution for intravenous injection are available. *Diclofenac* also is available in combination with *misoprostol*, a PGE_1 analogue. This combination retains the efficacy of *diclofenac* while reducing the frequency of GI ulcers and erosions. A 1% topical gel, a topical solution, and a transdermal patch are available for short-term treatment of pain due to minor strains, sprains, and bruises. A 3% gel formulation is indicated for topical treatment of actinic keratosis. In addition, an ophthalmic solution of *diclofenac* is available for treatment of postoperative inflammation following cataract extraction and for the temporary relief of pain and photophobia in patients undergoing corneal refractive surgery.

Adverse Effects. *Diclofenac* produces side effects (particularly GI) in about 20% of patients. The incidence of serious GI adverse effects, hypertension, and myocardial infarction is similar to the COX-2–selective inhibitors (Cannon et al., 2006). Hypersensitivity reactions have occurred following topical application and systemic administration. Severe liver injury occurs in 6 to 11 per 100,000 regular users annually (Bjornsson et al., 2013; de Abajo et al., 2004). Elevation of hepatic transaminases in plasma by more than three times the upper normal limit, indicating significant liver damage, occurs in about 4% of patients (Rostom et al., 2005). Transaminases should be monitored during the first 8 weeks of therapy with *diclofenac*. Other untoward responses to *diclofenac* include CNS effects, rashes, fluid retention, edema, and renal function impairment. The drug is not recommended for children, nursing mothers, or pregnant women.

Diclofenac is extensively metabolized. One metabolite, 4′-hydroxy diclofenac, can form reactive benzoquinone imines (similar to *acetaminophen*'s metabolite NAPQI) that deplete hepatic GSH. UGT2B7 is the primary catalyst in the formation of another highly reactive metabolite, diclofenac acyl glucuronide (King et al., 2001). Genetic variation that causes higher catalytic activity of UGT2B7 is associated with an increased risk of hepatotoxicity among patients taking *diclofenac* (Daly et al., 2007).

Indomethacin

Indomethacin is a methylated indole derivative indicated for the treatment of moderate-to-severe rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis; acute gouty arthritis; and acute painful shoulder. Although *indomethacin* is still used clinically, mainly as a steroid-sparing agent, toxicity and the availability of safer alternatives have limited its use.

Indomethacin is a potent nonselective inhibitor of the COXs. It also inhibits the motility of polymorphonuclear leukocytes, depresses the biosynthesis of mucopolysaccharides, and may have a direct, COX-independent vasoconstrictor effect. *Indomethacin* has prominent anti-inflammatory and analgesic-antipyretic properties like those of the salicylates.

ADME. Oral *indomethacin* has excellent bioavailability. Peak concentrations occur 1 to 2 h after dosing (see Table 42–2). The concentration of the drug in the CSF is low, but its concentration in synovial fluid is equal to that in plasma within 5 h of administration. There is enterohepatic cycling of the *indomethacin* metabolites and probably of *indomethacin* itself. The $t_{1/2}$ in plasma is variable, perhaps because of enterohepatic cycling, but averages about 2.5 h.

Therapeutic Uses. While *indomethacin* is estimated to be about 20 times more potent than *aspirin*, a high rate of intolerance limits its use. An intravenous formulation of *indomethacin* is approved for closure of persistent patent ductus arteriosus in premature infants. The regimen involves intravenous administration of 0.1 to 0.25 mg/kg every 12 h for three doses, with the course repeated one time if necessary. Successful closure can be expected in more than 70% of neonates treated. The principal limitation of treating neonates is renal toxicity, and therapy is interrupted if the output of urine falls significantly (<0.6 mL/kg/h). An injectable formulation of *ibuprofen* is an alternative for the treatment of patent ductus arteriosus.

Adverse Effects. A very high percentage (35%–50%) of patients receiving *indomethacin* experience adverse drug reactions. GI adverse events are common and can be fatal; elderly patients are at significantly greater risk. Diarrhea may occur and sometimes is associated with ulcerative lesions of the bowel. Acute pancreatitis has been reported, as have rare, but potentially fatal, cases of hepatitis. The most frequent CNS effect is severe frontal headache. Dizziness, vertigo, light-headedness, and mental confusion may occur. Seizures have been reported, as have severe depression, psychosis, hallucinations, and suicide. Caution is advised when administering *indomethacin* to elderly patients or to those with underlying epilepsy, psychiatric disorders, or Parkinson's disease because they are at greater risk for the development of serious CNS adverse effects. Hematopoietic reactions include neutropenia, thrombocytopenia, and, rarely, aplastic anemia.

Concurrent administration of *probenecid* increases the total plasma concentration of *indomethacin* and its inactive metabolites. *Indomethacin* antagonizes the natriuretic and antihypertensive effects of *furosemide* and thiazide diuretics and blunts the antihypertensive effect of β receptor antagonists, AT_1 receptor antagonists, and ACE inhibitors.

Sulindac

Sulindac is a congener of *indomethacin*. *Sulindac* is a prodrug whose anti-inflammatory activity resides in its sulfide metabolite, which is more than 500 times more potent than *sulindac* as an inhibitor of COX but less than half as potent as *indomethacin* (see Figure 42–1). ADME data are summarized in Table 42–2. *Sulindac* is used for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, painful shoulder, and gouty arthritis. Its analgesic and anti-inflammatory effects are comparable to those achieved with *aspirin*. The most common dosage for adults is 150 to 200 mg twice a day. Although the incidence of toxicity is lower than with *indomethacin*, adverse reactions to *sulindac* are common. The typical NSAID GI side effects are seen in nearly 20% of patients. CNS side effects as described for *indomethacin* are seen in 10% or fewer of patients. Rash occurs in 3% to 9% of patients, and pruritus occurs in 1% to 3% of patients. Transient elevations of hepatic transaminases in plasma are less

common. The same precautions that apply to other NSAIDs regarding patients at risk for GI toxicity, cardiovascular risk, and renal impairment also apply to *sulindac*.

Etodolac

Etodolac is an acetic acid derivative with some degree of COX-2 selectivity (see Table 42–2, Figure 42–1). A single oral dose (200–400 mg) of *etodolac* provides postoperative analgesia that lasts for 6 to 8 h. *Etodolac* also is effective in the treatment of osteoarthritis, rheumatoid arthritis, and mild-to-moderate pain, and the drug appears to be uricosuric. Sustained-release preparations are available. *Etodolac* is relatively well tolerated. About 5% of patients who have taken the drug for 1 year or less discontinue treatment because of GI side effects, rashes, and CNS effects.

Tolmetin

Tolmetin is approved for the treatment of osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis and has been used in the treatment of ankylosing spondylitis. ADME and comparison to *aspirin* are provided in Table 42–2. Recommended doses of *tolmetin* for adults (200–600 mg three times/day) are typically given with meals, milk, or antacids to lessen abdominal discomfort. However, peak plasma concentrations and bioavailability are reduced when the drug is taken with food. Side effects occur in 25% to 40% of patients who take tolmetin. GI side effects are the most common (~15%), and gastric ulceration has been observed. CNS side effects similar to those seen with *indomethacin* and *aspirin* occur, but they are less common and less severe.

Ketorolac

Ketorolac is a potent analgesic but only a moderately effective anti-inflammatory drug. The use of *ketorolac* is limited to 5 days or less for acute pain; the drug can be administered orally, intravenously, intramuscularly, or intranasally. Typical doses are 30 to 60 mg (intramuscular), 15 to 30 mg (intravenous), 10 to 20 mg (oral), and 31.5 mg (intranasal). Pediatric patients aged between 2 and 16 years may receive a single intramuscular (1 mg/kg up to 30 mg) or intravenous (0.5 mg/kg up to 15 mg) dose of *ketorolac* for severe acute pain. *Ketorolac* has a rapid onset of action and a short duration of action (see Table 42–2).

Topical (ophthalmic) *ketorolac* is approved for the treatment of seasonal allergic conjunctivitis and postoperative ocular inflammation. *Ketorolac* in a fixed-dose combination with *phenylephrine* is indicated as an irrigation during cataract or intraocular lens replacement surgery to maintain pupil size, prevent miosis, and reduce postoperative pain. Side effects of systemic *ketorolac* include somnolence (6%), dizziness (7%), headache (17%), GI pain (13%), dyspepsia (12%), nausea (12%), and pain at the site of injection (2%). Serious adverse GI, renal, bleeding, and hypersensitivity reactions to *ketorolac* may occur. Patients receiving greater than recommended doses or concomitant NSAID therapy and the elderly appear to be particularly at risk. Although *ketorolac* is widely used in postoperative patients, it should not be used for routine obstetric analgesia, in patients with severe kidney disease, for perioperative pain after CABG, or in combination with *probenecid* (*probenecid* triples AUC and doubles $t_{1/2}$ of *ketorolac*, thereby promoting adverse effects).

Nabumetone

Nabumetone is the prodrug of 6-methoxy-2-naphthylacetic acid. *Nabumetone* is approved for the treatment of rheumatoid arthritis and osteoarthritis. Its comparative pharmacokinetic properties are summarized in Table 42–2. *Nabumetone* is associated with crampy lower abdominal pain (12%) and diarrhea (14%). Other side effects include rash (3%–9%); headache (3%–9%); dizziness (3%–9%); and heartburn, tinnitus, and pruritus (3%–9%).

Propionic Acid Derivatives

The propionic acid derivatives *ibuprofen, naproxen, flurbiprofen, fenoprofen, ketoprofen*, and *oxaprozin* are available in the U.S. (see Table 42–3). *Ibuprofen* is the most used NSAID in the U.S. and is available with or without a prescription. *Naproxen*, also available with or without a prescription, has a longer but variable $t_{1/2}$. *Oxaprozin* also has a long $t_{1/2}$ and may be given once daily.

Mechanism of Action

Propionic acid derivatives are nonselective COX inhibitors with the effects and side effects common to other NSAIDs. Some of the propionic acid derivatives, particularly *naproxen*, have inhibitory effects on leukocyte function, and some evidence suggests that *naproxen* may have slightly better efficacy regarding analgesia and relief of morning stiffness. This suggestion of benefit accords with the longer $t_{1/2}$ of *naproxen* in comparison to other propionic acid derivatives.

Therapeutic Uses

Propionic acid derivatives are approved for use in the symptomatic treatment of rheumatoid arthritis, juvenile arthritis, and osteoarthritis. Some also are approved for pain, ankylosing spondylitis, acute gouty arthritis, tendinitis, bursitis, headache, postoperative dental pain and swelling, and primary dysmenorrhea. These agents may be comparable in efficacy to *aspirin* for the control of the signs and symptoms of rheumatoid arthritis and osteoarthritis.

Drug Interactions

Ibuprofen and *naproxen* have been shown to interfere with the antiplatelet effects of *aspirin* (Catella-Lawson et al., 2001; Li et al., 2014). Propionic acid derivatives have not been shown to alter the pharmacokinetics of the oral hypoglycemic drugs or *warfarin*. Refer to the full product labeling for a comprehensive listing of other drug interactions.

Ibuprofen

ADME. Table 42–3 summarizes the comparative pharmacokinetics of *ibuprofen*. *Ibuprofen* is absorbed rapidly, bound avidly to protein, and undergoes hepatic metabolism (90% is metabolized to hydroxylate or carboxylate derivatives) and renal excretion of metabolites. The $t_{1/2}$ is about 2 h. Slow equilibration with the synovial space means that its antiarthritic effects may persist after plasma levels decline. In experimental animals, *ibuprofen* and its metabolites readily cross the placenta.

Therapeutic Uses. *Ibuprofen* is supplied as tablets, chewable tablets, capsules, caplets, and gelcaps containing 50 to 600 mg; as oral drops; and as an oral suspension. An injectable formulation of *ibuprofen* is approved to close patent ductus arteriosus in premature infants. Solid oral dosage forms containing 200 mg or less are available without a prescription. *Ibuprofen* is licensed for marketing alone and in fixed-dose combinations with antihistamines, decongestants, *famotidine*, *oxycodone*, and *hydrocodone*. It is short acting, with a $t_{1/2}$ of about 2 h. The usual dose for mild-to-moderate pain is 400 mg every 4 to 6 h as needed.

Adverse Effects. *Ibuprofen* is better tolerated than *aspirin* and *indomethacin* and has been used in patients with a history of GI intolerance to other NSAIDs. Nevertheless, 5% to 15% of patients experience GI side effects. Less-frequent adverse effects of *ibuprofen* include rashes (3%–9%), thrombocytopenia (<1%), headache (1%–3%), dizziness (3%–9%), blurred vision (<1%), and, in a few cases, toxic amblyopia (<1%), fluid retention (1%–3%), and edema (1%–3%). Patients who develop ocular disturbances should discontinue the use of *ibuprofen* and have an ophthalmic evaluation. *Ibuprofen* can be used occasionally by pregnant women; however, the concerns apply regarding third-trimester effects, including delay of parturition. Excretion into breast milk is thought to be minimal, so *ibuprofen* also can be used with caution by women who are breastfeeding.

Naproxen

Naproxen is supplied as tablets, delayed-release tablets, extended-release tablets, gelcaps, and caplets containing 200 to 500 mg of *naproxen* or *naproxen sodium* and as oral suspensions and suppositories. Solid oral dosage forms containing 200 mg or less are available without a prescription. *Naproxen* is licensed for marketing alone and in fixed-dose combinations with *pseudoephedrine*, *diphenhydramine*, *esomeprazole*, and *sumatriptan*; it is packaged with *lansoprazole*. *Naproxen* is indicated for juvenile and rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, tendonitis, bursitis, and acute gout.

TABLE 42–3 ■ COMPARISON OF REPRESENTATIVE NSAIDs: FENAMATES AND PROPIONIC ACID DERIVATIVES

CLASS/DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Fenamates				
Mefenamic acid	Peak C_p, 2–4 h Protein binding, >90% Metabolism, CYP2C9 oxidation; glucuronidation of parent drug and metabolites $t_{1/2}$, 2–4 h	500 mg load, then 250 mg every 6 h	Therapy usually should not exceed 7 days or 2–3 days (dysmenorrhea); 15% elevated liver enzymes; excreted in breast milk	Efficacy similar
Meclofenamate	Peak C_p, 0.5–2 h; 3–4 h (with food) Protein binding, 99% Metabolism, oxidation to 3-OH (~20% activity of parent) $t_{1/2}$, 0.8–2.1 h (parent); 0.5–4 h (active metabolite)	50–100 mg 4–6 times/day (maximum 400 mg/day)	Side effects: CNS, GI, and rash (all >10%); administration with food ↓ rate/extent of absorption	Efficacy similar
Propionic acid derivatives				
Ibuprofen	Peak C_p, 2 h (tablets), 1 h (chewable tablets), 0.75 h (liquid) Protein binding, 99% Metabolites, CYP2C9 oxidation to 2- and 3-hydroxylates; conjugation to acyl glucuronides $t_{1/2}$, 2–4 h (adults); 23–75 h (premature infants); 0.9–2.3 h (children)	200–800 mg 3–6 times/day with food (maximum 3.2 g/day); Canadian and U.S. pediatric max, 2.4 g/day Children: 4–10 mg/kg/dose, 3–4 times/day	10%–15% discontinue; may increase risk of aseptic meningitis; excreted in breast milk Racemate: 60% of R-enantiomer converts to S-ibuprofen	Equipotent
Naproxen	Peak C_p, 2–4 h (base tabs); 1–4 h (liquid); 1–2 h (sodium salt); 4–12 h (delayed-release tabs) Protein binding, 99% (↑ free fraction in elderly) Metabolism, CYPs 2C9, 1A2, 2C8 oxidation to 6-O-desmethyl and other metabolites $t_{1/2}$, 9–25 h	250 mg 3–4 times/day; 250–550 mg 2 times/day; 750–1000 mg daily (extended release) Children: 5 mg/kg 2 times/day (max 15 mg/kg/day)	Peak anti-inflammatory effects after 2–4 weeks; ↑ free fraction and ↓ excretion ⇒ ↑ risk of toxicity in elderly; may increase risk of aseptic meningitis; excreted in breast milk; variably prolonged $t_{1/2}$ may afford cardioprotection in some individuals	Usually better tolerated
Fenoprofen	Peak C_p, 2 h Protein binding, 99% Metabolites, 4-OH metabolite; glucuronide conjugates $t_{1/2}$, 2.5–3 h	200 mg 4–6 times/day or 300–600 mg 3–4 times/day (max 3.2 g/day)	Peak anti-inflammatory effects after 2–3 weeks; 15% experience side effects; few discontinue use; excreted in breast milk	Generally better tolerated
Ketoprofen	Peak C_p, 1.2 h; 6.8 h (extended release) Protein binding, 99% Metabolites, glucuronide conjugates; enterohepatic recirculation? $t_{1/2}$, 0.9–3.3 h	25–50 mg 3–4 times/day; 75 mg 3 times/day; 200 mg daily (extended release); max 300 mg/day Anti-inflammatory, 50–75 mg 3–4 times/day	30% develop side effects (usually GI, usually mild); ~13% liver function abnormalities; unbound fraction, systemic exposure, and $t_{1/2}$ ↑ with age in elderly; excreted in breast milk	Generally better tolerated; biological efficacy > plasma $t_{1/2}$
Flurbiprofen	Peak C_p, ~2 h Protein binding, 99% Metabolism, CYP2C9 oxidation, UGTB7 glucuronidation of parent and 4′-OH metabolite $t_{1/2}$, 7.5 h	200–300 mg/day in 2–4 divided doses (maximum 100 mg/dose)	Racemate; excreted in breast milk; available for ophthalmic use	Generally better tolerated

(*Continued*)

TABLE 42–3 ■ COMPARISON OF REPRESENTATIVE NSAIDs: FENAMATES AND PROPIONIC ACID DERIVATIVES (*CONTINUED*)

CLASS/DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Oxaprozin	Peak C_p, 2.4–3 h Protein binding, 99% Metabolism, 65% oxidates, 35% glucuronides $t_{1/2}$, 41–55 h	600–1200 mg daily (maximum 1800 mg); children >21 kg: 600–1200 mg daily based on weight (maximum 1200 mg)	Slow onset, not indicated for fever or acute pain; dose in elderly adjusted on the basis of weight; expected to be excreted in breast milk	Generally better tolerated

Time to peak plasma drug concentration (C_p) is after a single dose. In general, food delays absorption but does not decrease peak concentration. The majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. Typical $t_{1/2}$ is listed for therapeutic doses; if $t_{1/2}$ is much different with the toxic dose, this is also given. Typical adult oral doses are listed unless otherwise noted. Refer to the current product labeling for complete prescribing information, including current labeled pediatric indications.

ADME. Naproxen is absorbed fully after oral administration. *Naproxen* also is absorbed rectally but more slowly than after oral administration. *Naproxen* is almost completely (99%) bound to plasma proteins after normal therapeutic doses. The $t_{1/2}$ of naproxen in plasma is variable, 9 to 25 h. Age plays a role in the variability of the $t_{1/2}$ because of the age-related decline in renal function (and consequently longer $t_{1/2}$) (see Table 42–3). Low doses should be prescribed in the elderly. *Naproxen* is extensively metabolized in the liver. About 30% of the drug undergoes 6-desmethylation, and most of this metabolite and *naproxen*, itself, are excreted in the urine as the glucuronide or other conjugates. *Naproxen* crosses the placenta and appears in the milk of lactating women at about 1% of the maternal plasma concentration.

Adverse Effects. Although the best available data were consistent with the suggestion that *naproxen* is an NSAID that is not associated with an increase in myocardial infarction (Coxib and Traditional NSAID Trialists' Collaboration et al., 2013), in 2015, based on the advisory committee recommendations, the FDA issued a warning that NSAIDs can cause heart attacks and strokes and that there is inconclusive evidence regarding whether the particular risk of any NSAID is definitively higher or lower than another NSAID (https://www.fda.gov/Drugs/DrugSafety/ucm451800.htm).

About 1% to 10% of patients taking *naproxen* experience GI adverse effects that include heartburn, abdominal pain, constipation, diarrhea, nausea, dyspepsia, and stomatitis. Adverse effects with *naproxen* occur at approximately the same frequency as with *indomethacin* and other NSAIDs (see Table 42–1). CNS side effects include drowsiness (3%–9%), headache (3%–9%), dizziness (≤9%), vertigo (<3%), and depression (<1%). Other common reactions include pruritus (3%–9%) and diaphoresis (<3%). Rare instances of jaundice, impairment of renal function, angioedema, thrombocytopenia, and agranulocytosis have been reported.

Fenamates

The fenamates (anthranilic acids) include *mefenamic acid*, *meclofenamate*, and *flufenamic acid*. The pharmacological properties of the fenamates are those of typical NSAIDs, and therapeutically, they have no advantages over others in the class (see Table 42–3). *Mefenamic acid* and *meclofenamate sodium* are used in the short-term treatment of pain in soft-tissue injuries, dysmenorrhea, and rheumatoid arthritis and osteoarthritis. These drugs are not recommended for use in children or pregnant women. Roughly 5% of patients develop a reversible elevation of hepatic transaminases. Diarrhea, which may be severe and associated with steatorrhea and inflammation of the bowel, also is relatively common. Autoimmune hemolytic anemia is a potentially serious but rare side effect.

Enolic Acids (Oxicams)

The oxicam derivative *piroxicam* is the nonselective COX inhibitor with the longest $t_{1/2}$. *Meloxicam* shows COX-2 selectivity comparable to celecoxib (see Figure 42–1) and was approved as a COX-2–selective NSAID in some countries. These agents are similar in efficacy to *aspirin*, *indomethacin*, or *naproxen* for the long-term treatment of rheumatoid arthritis or osteoarthritis. The main advantage suggested for these compounds is their long $t_{1/2}$, which permits once-a-day dosing (see comparative pharmacokinetic and dosing data in Table 42–4).

Piroxicam

Piroxicam may inhibit activation and aggregation of neutrophils, apparently independently of its ability to inhibit COX; hence, additional modes of anti-inflammatory action have been proposed, including inhibition of proteoglycanase and collagenase in cartilage and decreasing proinflammatory cytokine levels.

Piroxicam is approved for the treatment of rheumatoid arthritis and osteoarthritis. Due to its slow onset of action and delayed attainment of steady state, it is less suited for acute analgesia but has been used to treat acute gout.

ADME. The pharmacokinetics of *piroxicam* are described in Table 42–4. The usual daily dose is 20 mg. *Piroxicam* is absorbed completely after oral administration and undergoes enterohepatic recirculation. Estimates of the $t_{1/2}$ in plasma have been variable; the average is about 50 h in adults. Steady-state blood levels are reached in 7 to 12 days. Less than 5% of the drug is excreted into the urine unchanged. The major metabolic transformation in humans is hydroxylation of the pyridyl ring (predominantly by an isozyme of the CYP2C subfamily), and this inactive metabolite and its glucuronide conjugate account for about 60% of the drug excreted in the urine and feces.

Adverse Effects. Approximately 20% of patients experience side effects with *piroxicam*, and about 5% of patients discontinue use because of these effects. *Piroxicam* may be associated with more GI and serious skin reactions than other nonselective NSAIDs. In 2007, the European Medicines Agency reviewed the safety of orally administered *piroxicam* and concluded that its benefits outweigh its risks but advised that it should no longer be considered a first-line agent or used for the treatment of acute (short-term) pain and inflammation.

Meloxicam

Meloxicam is approved for use in osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis. The recommended adult dose of *meloxicam* is 7.5 to 15 mg once daily. *Meloxicam* demonstrates some COX-2 selectivity (see Figure 42–1). There is significantly less gastric injury compared to *piroxicam* (20 mg/day) in subjects treated with 7.5 mg/day of *meloxicam*, but the advantage is lost with a dosage of 15 mg/day (Patoia et al., 1996).

Purpose-Developed COX-2–Selective NSAIDs

Selective inhibitors of COX-2 are molecules with side chains that fit within its hydrophobic pocket but are too large to block COX-1 with equally high affinity. *Celecoxib* is the only purposefully developed COX-2 inhibitor still approved in the U.S. (see its clinical pharmacokinetic properties and precautions in Table 42–4). As mentioned, other, older compounds (*diclofenac*, *etodolac*, *meloxicam*, *nimesulide*) have been retrospectively found to have similar selectivity for COX-2 (see Figure 42–1). *Etoricoxib* is approved in several countries but restricted in its indications; *rofecoxib*, *valdecoxib*, and *lumiracoxib* were withdrawn worldwide because of the

TABLE 42–4 ■ REPRESENTATIVE NSAIDs: ENOLIC ACID DERIVATIVES AND COXIBS

CLASS/DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Enolic acid derivatives				
Piroxicam	Peak C_p, 3–5 h Protein binding, 99% Metabolism, CYP2C9 hydroxylation, conjugation, *N*-demethylation $t_{1/2}$, ~50 h	20 mg daily	20% side effects; 5% discontinue; slow onset, not indicated for fever or acute pain; excreted in breast milk	Equipotent with lower incidence of minor GI effects
Meloxicam	Peak C_p, 4–5 h (and 12–14 h due to biliary recycling) Protein binding, 99% Metabolism, hydroxylation $t_{1/2}$, 15–20 h	7.5 mg daily (maximum 15 mg/day); children ≥2: lowest effective dose, 0.125 mg/kg daily (maximum 7.5 mg daily)	Some COX-2 selectivity, especially at lower doses; elderly females have higher systemic exposure and peak plasma concentrations than men and young women; excretion in breast milk unknown	—
Diaryl heterocyclic NSAIDs (COX-2 selective)				
			Evidence for cardiovascular adverse events	Decrease in GI side effects and in platelet effects
Celecoxib	Peak C_p, ~3 h Protein binding, 97% Metabolism, CYPs 2C9 (major) and 3A4 (minor), glucuronidation $t_{1/2}$, 11.2 h	100–200 mg 1–2 times/day; 400 mg followed by 200 mg if needed on first day (acute pain); maximum, 800 mg/day. Children >2 y: 50 mg (10–25 kg) or 100 mg (>25 kg) 2 times/day	CYP2D6 and CYP2D8 inhibitor; adverse effects: GI complaints (5%); aseptic meningitis and methemoglobinemia have been reported; disseminated intravascular coagulation risk in pediatric patients; 40% higher systemic exposure in blacks and elderly females; excreted in breast milk	Usually better tolerated; does not usually prolong bleeding time

Time to peak plasma drug concentration C_p is after a single dose. In general, food delays absorption but does not decrease peak concentration. The majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. Typical $t_{1/2}$ is listed for therapeutic doses; if $t_{1/2}$ is much different with the toxic dose, this is also given. Typical adult oral doses are listed unless otherwise noted. Refer to the current product labeling for complete prescribing information, including current labeled pediatric indications.

cardiovascular complications caused by suppression of cardioprotective COX-2–derived PGs, especially PGI_2, and the unrestrained effects of endogenous stimuli, such as platelet COX-1–derived TxA_2, on platelet activation, vascular proliferation and remodeling, hypertension, and atherogenesis. COX-2–selective NSAIDs should be avoided in patients prone to cardiovascular or cerebrovascular disease. While the purposefully developed COX-2 inhibitors have generally been shown to reduce severe GI complications when compared to isoform nonselective compounds, none of the COX-2–selective NSAIDs has established superior efficacy.

Celecoxib

ADME. The bioavailability of oral *celecoxib* is not known; peak plasma levels occur at 2 to 4 h after administration. The elderly (≥65 years of age) may have up to 2-fold higher peak concentrations and AUC values than younger patients (≤55 years of age). *Celecoxib* is bound extensively to plasma proteins. Most is excreted as carboxylic acid and glucuronide metabolites in the urine and feces. The elimination $t_{1/2}$ is approximately 11 h. The drug commonly is given once or twice daily during chronic treatment. Plasma concentrations are increased in patients with mild and moderate hepatic impairment, requiring reduction in dose. *Celecoxib* is metabolized predominantly by CYP2C9 and inhibits CYP2D6. Thus, vigilance is necessary during coadministration of drugs that are known to inhibit CYP2C9 and drugs that are metabolized by CYP2D6.

Therapeutic Uses. *Celecoxib* is used for the management of acute pain for the treatment of osteoarthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, and primary dysmenorrhea. The recommended dose for treating osteoarthritis is 200 mg/day as a single dose or divided as two doses. In the treatment of rheumatoid arthritis, the recommended dose is 100 to 200 mg twice daily. Due to cardiovascular hazard, physicians should use the lowest possible dose for the shortest possible duration.

Adverse Effects. *Celecoxib* confers a risk of myocardial infarction and stroke, and this appears to relate to dose and the underlying risk of cardiovascular disease. Effects attributed to inhibition of PG production in the kidney—hypertension and edema—occur with nonselective COX inhibitors and also with *celecoxib*. Selective COX-2 inhibitors lose their GI advantage over other NSAIDs alone when used in conjunction with aspirin. Chronic use of *celecoxib* may decrease bone mineral density, particularly in older male patients. There is some suggestion that *celecoxib* may slow fracture healing and tendon-to-bone healing.

Etoricoxib

Etoricoxib is a COX-2–selective inhibitor with selectivity second only to that of *lumiracoxib* (see Figure 42–1). *Etoricoxib* is incompletely (~80%) absorbed and has a $t_{1/2}$ of 20 to 26 h. It is extensively metabolized before excretion. Patients with hepatic impairment are prone to drug accumulation. Renal insufficiency does not affect drug clearance. *Etoricoxib* is used for symptomatic relief in the treatment of osteoarthritis, rheumatoid arthritis, and acute gouty arthritis, as well as for the short-term treatment of musculoskeletal pain, postoperative pain, and primary dysmenorrhea. The drug is associated with the increased risk of heart attack and stroke. *Etoricoxib* is not available in the U.S.

Disease-Modifying Antirheumatic Drugs

Rheumatoid arthritis is an autoimmune disease that affects about 1% of the population. The pharmacological management of rheumatoid arthritis includes symptomatic relief through the use of NSAIDs. However, although they have anti-inflammatory effects, NSAIDs have minimal, if any, effect on progression of joint deformity. Disease-modifying

TABLE 42–5 ■ DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

DRUG	CLASS OR ACTION	CHAPTER NUMBER
Small molecules		
Methotrexate	Antifolate	70
Leflunomide	Pyrimidine synthase inhibitor	70
Hydroxychloroquine	Antimalarial	66
Minocycline	5-Lipoxygenase inhibitor, tetracycline antibiotic	41, 60
Sulfasalazine	Salicylate	42, 55
Azathioprine	Purine synthase inhibitor	70
Cyclosporine	Calcineurin inhibitor	39
Cyclophosphamide	Alkylating agent	70
Penicillamine	Chelating agent	76
Auranofin	Gold compound	76
Biologicals		
Adalimumab Golimumab Etanercept Infliximab Certolizumab	Ab, TNF-α antagonist Ab, TNF-α antagonist Ab, TNF-α antagonist IgG-TNF receptor fusion protein (anti-TNF) Fab fragment toward TNF-α	38, 39
Abatacept	T-cell costimulation inhibitor (binds B7 protein on antigen-presenting cell)	38, 39
Rituximab	Ab toward CD20 (cytotoxic toward B cells)	72
Anakinra	IL-1 receptor antagonist	39, 72
Tocilizumab	IL-6 receptor antagonist	39, 72
Tofacitinib	Janus kinase inhibitor	39, 71

antirheumatic drugs (DMARDs), on the other hand, reduce the disease activity of rheumatoid arthritis and retard the progression of arthritic tissue destruction. DMARDs include a diverse group of small-molecule nonbiological and biological agents (mainly antibodies or binding proteins), as summarized in Table 42–5.

Biological DMARDs remain reserved for patients with persistent moderate or high disease activity and indicators of poor prognosis. Therapy is tailored to the individual patient, and the use of these agents must be weighed against their potentially serious adverse effects. The combination of NSAIDs with these agents is common.

Pharmacotherapy of Gout

Gout results from the precipitation of urate crystals in the tissues and the subsequent inflammatory response. Acute gout usually causes painful distal monoarthritis and can cause joint destruction, subcutaneous deposits (tophi), and renal calculi and damage. Gout affects 3% of the adult population of Western countries. Risk factors include male sex, diuretic use, alcohol intake, obesity, hypertension, and consumption of sweetened beverages, red meat, and certain types of seafood (Hainer et al., 2014).

The pathophysiology of gout is incompletely understood. Hyperuricemia, while a prerequisite, does not inevitably lead to gout. Uric acid, the end product of purine metabolism, is relatively insoluble compared to its hypoxanthine and xanthine precursors, and normal serum urate levels (~5 mg/dL, or 0.3 mM) approach the limit of solubility. In most patients with gout, hyperuricemia arises from underexcretion rather than overproduction of urate. Mutations of one of the renal URATs, URAT-1, are associated with hypouricemia. Urate tends to crystallize as monosodium urate in colder or more acidic conditions. Monosodium urate crystals activate monocytes/macrophages via the toll-like receptor pathway, mounting an innate immune response. This results in the activation of the NLRP3 inflammasome; the secretion of cytokines, including IL-1β and TNF-α; endothelial activation; and attraction of neutrophils to the site of inflammation. Neutrophils secrete inflammatory mediators that lower the local pH and lead to further urate precipitation. The aims of treatment are to:

- Decrease the symptoms of an acute attack
- Decrease the risk of recurrent attacks
- Lower serum urate levels

The following therapeutic strategies are available for these purposes:

- Drugs that relieve inflammation and pain (NSAIDs, *colchicine*, glucocorticoids)
- Drugs that prevent inflammatory responses to crystals (*colchicine* and NSAIDs)
- Drugs that act by inhibition of urate formation (e.g., *allopurinol*, *febuxostat*) or augmentation of urate excretion (*probenecid*)

The NSAIDs have been discussed previously. Glucocorticoids are discussed in Chapter 50. This section focuses on *colchicine, allopurinol, febuxostat, pegloticase, rasburicase*, and the uricosuric agents *probenecid* and *benzbromarone*. Some other drugs used off label to reduce uric acid levels or treat gout include *losartan*, *fenofibrate*, and *canakinumab*. *Canakinumab*, a recombinant human monoclonal antibody to the proinflammatory cytokine IL-1β, is approved by the European Medicines Agency for the treatment of gout when management with *colchicine*, corticosteroids, or NSAIDs is ineffective or when a patient experiences frequent attacks. In the U.S., the agent is not FDA-approved for gout but is approved for use in treating several autoinflammatory syndromes and systemic idiopathic juvenile arthritis.

Colchicine

Colchicine is one of the oldest available therapies for acute gout. The botanical source of *colchicine*, the autumn crocus, *Colchicum autumnale*, was known to the Greeks and Egyptians as a purgative and antiarthritic agent by 1500 BCE and described as a treatment for gout in the 1st century CE (Škubnik et al., 2020). Extracts and corms containing *colchicine* were being used for gout and joint pain around 550 CE. *Colchicine* is considered second-line therapy because it has a narrow therapeutic window and a high rate of side effects, particularly at higher doses.

Mechanism of Action

Colchicine exerts a variety of pharmacological effects; how these relate to its activity in gout is partially understood (Leung et al., 2015). *Colchicine* has antimitotic effects, arresting cell division in G_1 by interfering with microtubule and spindle formation (an effect shared with vinca alkaloids). This effect is greatest on cells with rapid turnover (e.g., neutrophils, GI epithelium). Depolymerization of microtubules by *colchicine* reduces neutrophil recruitment to inflamed tissue and neutrophil adhesion. *Colchicine* may alter neutrophil motility and decreases the secretion of chemotactic factors and superoxide anions by activated neutrophils. *Colchicine* limits monosodium urate crystal–induced NLRP3 inflammasome activation and subsequent formation of IL-1β and IL-18. This mechanism may explain its therapeutic activity in familial Mediterranean fever and other inflammatory diseases. *Colchicine* inhibits the release of histamine-containing granules from mast cells, the secretion of insulin from pancreatic β cells, and the movement of melanin granules in melanophores.

Colchicine also exhibits a variety of other pharmacological effects. It lowers body temperature, increases the sensitivity to central depressants, depresses the respiratory center, enhances the response to sympathomimetic agents, constricts blood vessels, and induces hypertension by central vasomotor stimulation. It enhances GI activity by neurogenic stimulation but depresses it by a direct effect and alters neuromuscular function.

ADME

Absorption of oral *colchicine* is rapid but variable. Peak plasma concentrations occur 0.5 to 2 h after dosing. Food does not affect the rate or extent of *colchicine* absorption. In plasma, 39% of *colchicine* is protein bound, primarily to albumin. The formation of *colchicine*-tubulin complexes in many tissues contributes to its large volume of distribution. There is significant enterohepatic circulation. The exact metabolism of *colchicine* in humans is unknown; *in vitro* studies indicate that it may undergo oxidative demethylation by CYP3A4 and possibly glucuronidation. In healthy volunteers, 40% to 65% of the total absorbed oral dose of *colchicine* is recovered unchanged in the urine. The kidney, liver, and spleen also contain high concentrations of *colchicine*, but it apparently is largely excluded from heart, skeletal muscle, and brain. *Colchicine* is a substrate of the P-glycoprotein exporter (see Chapter 4). The plasma $t_{1/2}$ of *colchicine* is approximately 31 h. The drug is contraindicated in patients with hepatic or renal impairment requiring concomitant therapy with CYP3A4 or P-glycoprotein inhibitors. *Colchicine* is not removed by hemodialysis.

Therapeutic Uses

The dosing regimen for *colchicine* must be individualized based on age, renal and hepatic function, concomitant use of other medications, and disease severity. A minimum of 3 days, but preferably 7 to 14 days, should elapse between courses of gout treatment with *colchicine* to avoid cumulative toxicity. Patients with hepatic or renal disease and dialysis patients should receive reduced doses or less-frequent therapy. For elderly patients, adjust the dose for renal function. For those with cardiac, renal, hepatic, or GI disease, NSAIDs or glucocorticoids may be preferred.

Acute Gout. *Colchicine* dramatically relieves acute attacks of gout. It is effective in roughly two-thirds of patients if given within 24 h of attack onset. Pain, swelling, and redness abate within 12 h and are completely gone within 48 to 72 h. The regimen approved for adults recommends a total of two doses taken 1 h apart: 1.2 mg (2 tablets) at the first sign of a gout flare followed by 0.6 mg (1 tablet) 1 h later. Patients with severe renal or hepatic dysfunction and patients receiving dialysis should not receive repeat courses of therapy more frequently than every 2 weeks.

Prevention of Acute Gout. *Colchicine* is used in the prevention of recurrent gout, particularly in the early stages of antihyperuricemic therapy. The typical dose for prophylaxis in patients with normal renal and hepatic function is 0.6 mg taken orally 3 or 4 days/week for patients who have less than one attack per year, 0.6 mg daily for patients who have more than one attack per year, and 0.6 mg up to two times daily for patients who have severe attacks.

Adverse Effects

Exposure of the GI tract to large amounts of *colchicine* and its metabolites via enterohepatic circulation and the rapid rate of turnover of the GI mucosa may explain why the GI tract is particularly susceptible to *colchicine* toxicity. Nausea, vomiting, diarrhea, and abdominal pain are the most common untoward effects and the earliest signs of impending *colchicine* toxicity. Drug administration should be discontinued as soon as these symptoms occur. There is a latent period, which is not altered by dose, of several hours or more between the administration of the drug and the onset of symptoms. A dosing study demonstrated that one dose initially and a single additional dose after 1 h was much less toxic than the traditional hourly dosing regimen for acute gout flares. Acute intoxication causes hemorrhagic gastropathy.

Other serious side effects of *colchicine* therapy include myelosuppression, leukopenia, granulocytopenia, thrombopenia, aplastic anemia, and rhabdomyolysis. Rarely, it can cause reversible axonal neuromyopathy.

Life-threatening toxicities are associated with administration of concomitant therapy with P-glycoprotein or CYP3A4 inhibitors. The FDA suspended the U.S. marketing of all injectable dosage forms of *colchicine* in 2008. *Colchicine* is marketed in a fixed-dose combination with *probenecid* for the management of frequent recurrent gout attacks.

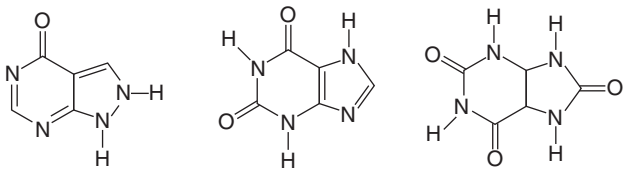
Allopurinol

History

Allopurinol initially was synthesized as a candidate antineoplastic agent but was found to lack antineoplastic activity. Subsequent testing showed it to be an inhibitor of xanthine oxidase (XO) that was useful clinically for the treatment of gout.

Allopurinol inhibits XO and prevents the synthesis of urate from hypoxanthine and xanthine. *Allopurinol* is used for treating hyperuricemia in patients with gout and for prevention in those with hematological malignancies about to undergo chemotherapy (acute tumor lysis syndrome). Even though underexcretion rather than overproduction of urate is the underlying defect in most gout patients, *allopurinol* remains effective therapy.

Allopurinol is an analogue of hypoxanthine. Its active metabolite, oxypurinol, is an analogue of xanthine.



Mechanism of Action

Both *allopurinol* and its primary metabolite, oxypurinol (alloxanthine), reduce urate production by inhibiting XO, the enzyme that converts xanthine to uric acid. *Allopurinol* competitively inhibits XO at low concentrations and is a noncompetitive inhibitor at high concentrations. *Allopurinol* also is a substrate for XO; the product of this reaction, oxypurinol, also is a noncompetitive inhibitor of the enzyme. The formation of oxypurinol, together with its long persistence in tissues, is responsible for much of the pharmacological activity of *allopurinol*.

In the absence of *allopurinol*, the dominant urinary purine is uric acid. During *allopurinol* treatment, the urinary purines include hypoxanthine, xanthine, and uric acid. Because each has its independent solubility, the concentration of uric acid in plasma is reduced and purine excretion is increased, without exposing the urinary tract to an excessive load of uric acid. Despite their increased concentrations during *allopurinol* therapy, hypoxanthine and xanthine are efficiently excreted, and tissue deposition does not occur. There is a small risk of xanthine stones in patients whose urate load before *allopurinol* therapy is very high; this risk can be minimized by liberal fluid intake and urinary alkalization.

Allopurinol facilitates the dissolution of tophi and prevents the development or progression of chronic gouty arthritis by lowering the uric acid concentration in plasma below the limit of its solubility. The formation of uric acid stones virtually disappears with therapy, which prevents the development of nephropathy. Once significant renal injury has occurred, *allopurinol* cannot restore renal function but may delay disease progression. The incidence of acute attacks of gouty arthritis may increase during the early months of *allopurinol* therapy because of mobilization of tissue stores of uric acid. Coadministration of *colchicine* helps suppress such acute attacks. In some patients, the *allopurinol*-induced increase in excretion of oxypurines is less than the reduction in uric acid excretion; this disparity primarily is a result of reutilization of oxypurines and feedback inhibition of *de novo* purine biosynthesis.

ADME

Allopurinol is absorbed relatively rapidly after oral ingestion, and peak plasma concentrations are reached within 60 to 90 min. About 20% is excreted in the feces in 48 to 72 h, presumably as unabsorbed drug, and 10% to 30% is excreted unchanged in the urine. The remainder undergoes metabolism, mostly to oxypurinol, an active metabolite. Oxypurinol is excreted slowly in the urine by glomerular filtration, counterbalanced by some tubular reabsorption. The plasma $t_{1/2}$ of *allopurinol* is approximately 1 to 2 h, and that of oxypurinol is approximately 18 to 30 h (longer in individuals with renal impairment). This allows for once-daily dosing and makes *allopurinol* the most commonly used antihyperuricemic agent. *Allopurinol* and its active metabolite oxypurinol are distributed in total tissue water, with the exception of brain, where their concentrations are about one-third of those in other tissues. Neither compound is bound to plasma proteins. The plasma concentrations of the two compounds do not correlate well with therapeutic or toxic effects.

Therapeutic Uses

Allopurinol is available for oral and intravenous use. Oral therapy provides effective therapy for primary and secondary gout, hyperuricemia secondary to malignancies, and calcium oxalate calculi. The goal of therapy is to reduce the plasma uric acid concentration to less than 6 mg/dL (<360 μmol/L) and typically less than 5 mg/dL (<297 μmol/L) in patients with tophi to accelerate the clearance of monosodium urate. Historically, it was customary to antecede *allopurinol* therapy with *colchicine* as it was thought *allopurinol* could worsen acute attacks. It is now considered safe and routine to initiate *allopurinol* during acute attacks as long as NSAIDs and *colchicine* are given concomitantly. Fluid intake should be sufficient to maintain daily urinary volume greater than 2 L; slightly alkaline urine is preferred. An initial daily dose of 100 mg in patients with estimated glomerular filtration rates greater than 40 mg/min is increased by 100-mg increments at weekly intervals. Most patients can be maintained on 300 mg/day. Patients with reduced glomerular filtration require a lower dose to achieve the targeted uric acid concentration. With frequent monitoring for adverse effects, daily doses may exceed 300 mg, even in renal impairment. Those with hematological malignancies may need up to 800 mg/day beginning 2 to 3 days before the start of chemotherapy.

The usual dose in children with secondary hyperuricemia associated with malignancies is 150 to 300 mg/day, depending on age. *Allopurinol* also is useful in lowering the high plasma concentrations of uric acid in patients with Lesch-Nyhan syndrome, thereby preventing the complications resulting from hyperuricemia; however, there is no evidence that it alters the progressive neurological and behavioral abnormalities that are characteristic of the disease. Other orphan uses for *allopurinol* include Chagas disease and the *ex vivo* preservation of cadaveric kidneys prior to transplantation.

Adverse Effects

Allopurinol generally is well tolerated. The most common adverse effects are hypersensitivity reactions that may manifest after months or years of therapy. If indicated, desensitization to *allopurinol* can be carried out starting at 10 to 25 μg/day, with the drug diluted in oral suspension and doubled every 3 to 14 days until the desired dose is reached; the success rate is approximately 50%.

Serious hypersensitivity reactions preclude further use of the drug. The cutaneous reaction caused by *allopurinol* is predominantly a pruritic, erythematous, or maculopapular eruption, but occasionally, the lesion is urticarial or purpuric. Rarely, toxic epidermal necrolysis or Stevens-Johnson syndrome occurs, which can be fatal. The risk for Stevens-Johnson syndrome is limited primarily to the first 2 months of treatment. Because the rash may precede severe hypersensitivity reactions, patients who develop a rash should discontinue *allopurinol*. Among polymorphic genetic factors that appear to contribute to such delayed hypersensitivity reactions is the human leucocyte antigen B*5801 allele (HLA-B*5801) (Li et al., 2021). Its presence may help to identify those at risk among susceptible populations (e.g., Korean, Thai, Sardinian Italian, and Han Chinese) (Yu et al., 2017).

Oxypurinol has orphan drug status and is available for compassionate use in the U.S. for patients who are intolerant of *allopurinol*. Fever, malaise, and myalgias also may occur in about 3% of patients, more frequently in those with renal impairment. Transient leukopenia or leukocytosis and eosinophilia are rare reactions that may require cessation of therapy. Hepatomegaly and elevated levels of transaminases in plasma and progressive renal insufficiency also may occur.

Allopurinol is contraindicated in patients who have exhibited serious adverse effects or hypersensitivity reactions to the medication and in nursing mothers and children, except those with malignancy or certain inborn errors of purine metabolism (e.g., Lesch-Nyhan syndrome). *Allopurinol* generally is used in patients with hyperuricemia posttransplantation. It can be used in conjunction with a uricosuric agent.

Drug Interactions

Allopurinol increases the $t_{1/2}$ of *probenecid* and enhances its uricosuric effect, while *probenecid* increases the clearance of oxypurinol, thereby increasing dose requirements of *allopurinol*. *Allopurinol* inhibits the enzymatic inactivation of *mercaptopurine* and its derivative *azathioprine* by XO. Thus, when *allopurinol* is used concomitantly with oral *mercaptopurine* or *azathioprine*, dosage of the antineoplastic agent must be reduced to 25% to 33% of the usual dose (see Chapters 39 and 70). This is important when treating gout in a transplant recipient. The risk of bone marrow suppression also is increased when *allopurinol* is administered with cytotoxic agents that are not metabolized by XO, particularly *cyclophosphamide*. *Allopurinol* may interfere with the hepatic inactivation of other drugs, including *warfarin*. Although the effect is variable, increased monitoring of prothrombin activity is recommended in patients receiving these medications concomitantly.

Whether the increased incidence of rash in patients receiving concurrent *allopurinol* and *ampicillin* can be ascribed to *allopurinol* or to hyperuricemia is not known. Hypersensitivity reactions have been reported in patients with compromised renal function, especially those who are receiving a combination of *allopurinol* and a thiazide diuretic. The concomitant administration of *allopurinol* and *theophylline* leads to increased accumulation of an active metabolite of *theophylline*, 1-methylxanthine; the concentration of *theophylline* in plasma also may be increased (see Chapter 44).

Febuxostat

Febuxostat is an XO inhibitor approved for treatment of hyperuricemia in patients with gout.

Mechanism of Action

Febuxostat is a nonpurine inhibitor of XO. Unlike oxypurinol, the active metabolite of *allopurinol* that inhibits the reduced form of XO,

febuxostat forms a stable complex with both the reduced and oxidized enzymes and inhibits catalytic function in both states.

ADME

Febuxostat is rapidly absorbed, reaching C_{Pmax} at 1 to 1.5 h after dose. The absolute bioavailability is unknown. Magnesium hydroxide and aluminum hydroxide delay absorption by about 1 h; food reduces absorption slightly. *Febuxostat* ($t_{1/2}$ of 5–8 h) is extensively metabolized by both conjugation via UGT enzymes, including UGTs 1A1, 1A3, 1A9, and 2B7, and oxidation by CYPs 1A2, 2C8, and 2C9 and non-CYP enzymes; elimination occurs via hepatic and renal pathways. Mild-to-moderate renal or hepatic impairment does not produce relevant effects on its elimination kinetics.

Therapeutic Use

Febuxostat is approved for hyperuric patients with gout attacks but is not recommended for treatment of asymptomatic hyperuricemia. It is available in 40- and 80-mg oral tablets. A dose of 40 mg/day *febuxostat* lowers serum uric acid to similar *levels* as 300 mg/day *allopurinol*. More patients reach the target urate concentration of 6.0 mg/dL (360 μmol/L) on 80 mg/day *febuxostat* than on 300 mg/day *allopurinol*. Thus, therapy should be initiated with 40 mg/day and the dose increased if the target serum uric acid concentration is not reached within 2 weeks.

Adverse Events

In clinical studies, the most common adverse reactions noted were liver function abnormalities, nausea, joint pain, and rash. Liver function should be monitored periodically. An increase in gout flares was frequently observed after initiation of therapy, due to reduction in serum uric acid levels resulting in mobilization of urate from tissue deposits. Concurrent prophylactic treatment with an NSAID or *colchicine* is usually required. There was a higher rate of myocardial infarction and stroke in patients taking *febuxostat* compared to *allopurinol*. Although a causal relationship between the cardiovascular events and *febuxostat* therapy is not clear, *febuxostat* carries a boxed warning about possible increased risk of cardiovascular death. Patients should be monitored for cardiovascular complications.

Drug Interactions

Plasma levels of drugs metabolized by XO (e.g., *mercaptopurine*, *azathioprine*) will increase when administered concurrently with *febuxostat*. Thus, *febuxostat* is contraindicated in patients on *azathioprine* or *mercaptopurine*. *Febuxostat* does inhibit the XO-catalyzed hydroxylation of 1-methylxanthine, the metabolite of *theophylline*, to 1-methylurate. While this elevates the urinary excretion of 1-methylxanthine by 400-fold, *febuxostat* (80 mg/day) does not significantly alter the C_{Pmax} and AUC for *theophylline* (Tsai et al., 2012).

Uricase

Pegloticase is a pegylated uricase (urate oxidase) that catalyzes the enzymatic oxidation of uric acid into allantoin, a more soluble and inactive metabolite. The recombinant enzyme, based on the porcine uricase, is administered by infusion every 2 weeks. *Pegloticase* is used for the treatment of severe, treatment-refractory, chronic gout or when use of other urate-lowering therapies is contraindicated.

The drug's efficacy may be hampered by the production of antibodies against the drug. *Pegloticase* antibodies develop in nearly 90% of people, and high titers are associated with loss of the urate-lowering effect and with an elevated risk for infusion reactions. Anaphylactic reactions and hemolysis in G6PD-deficient patients have been associated with the use of *pegloticase*. Other frequently observed adverse reactions include vomiting, nausea, chest pain, constipation, diarrhea, and erythema, pruritus, and urticaria.

Rasburicase is a recombinant uricase that has been shown to lower urate levels more effectively than *allopurinol*. It is indicated for the initial management of elevated plasma uric acid levels in pediatric and adult patients with leukemia, lymphoma, and solid tumor malignancies who are receiving anticancer therapy expected to result in tumor lysis and significant hyperuricemia. The experience with *rasburicase* for treatment of gout is limited because of the formation of activity-limiting antibodies against the drug. Hemolysis in G6PD-deficient patients, methemoglobinemia, acute renal failure, and anaphylaxis have been associated with the use of *rasburicase*. Other frequently observed adverse reactions include vomiting, fever, nausea, headache, abdominal pain, constipation, diarrhea, and mucositis. *Rasburicase* causes enzymatic degradation of the uric acid in blood samples, and special handling is required to prevent spuriously low values for plasma uric acid in patients receiving the drug.

Uricosuric Agents

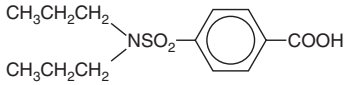
Uricosuric agents increase the excretion of uric acid. These agents are typically reserved for patients who underexcrete uric acid relative to their plasma levels. In humans, urate is filtered, secreted, and reabsorbed by the kidneys. Reabsorption is robust, such that the net amount excreted usually is about 10% of that filtered. Reabsorption is mediated by an OAT family member, URAT-1, encoded by the *SLC22A12* gene, which is expressed at the apical brush border of the proximal nephron.

Urate is exchanged by URAT-1 for either an organic anion such as lactate or nicotinate or less potently for an inorganic anion such as chloride. Uricosuric drugs such as *probenecid*, *benzbromarone* (not available in the U.S.), and *losartan* compete with urate for the transporter from the apical side of tubular epithelial cells, thereby inhibiting its reabsorption via the urate–anion exchanger system. Increased levels of antiuricosuric metabolites such as nicotinate (a metabolite of niacin), pyrazinoate (a metabolite of *pyrazinamide*), hydroxybutyrate and acetoacetate (e.g., in diabetic ketoacidosis), and lactate (e.g., in alcohol intoxication) enhance reabsorption of urate by stimulating URAT-1–dependent anion exchange. Depending on dosage, substrates of URAT-1 may, via competition, decrease transport of urate into the tubular cell or, via promotion of anion exchange, increase the excretion of urate out of the cell. Transport of urate through tubular cells is bidirectional, resulting in the secretion of urate, although the quantitative relevance of the efflux mechanism remains unclear. Therefore, there are two mechanisms by which a drug may nullify the uricosuric action of another. First, the drug may inhibit the secretion of the uricosuric agent, thereby denying it access to its site of action, the luminal aspect of the brush border. Second, the inhibition of urate secretion by one drug may counterbalance the inhibition of urate reabsorption by the other.

Urate homeostasis and the characteristics of the multiple renal transporters participating in urate secretion and reabsorption (see Figure 42–2) and their modulation by pharmacological agents have recently been reviewed (Tátrai et al., 2021).

Probenecid

Probenecid is a highly lipid-soluble benzoic acid derivative (pK_a = 3.4).



PROBENECID

Mechanism of Action. ***Inhibition of Organic Acid Transport.*** The actions of *probenecid* are confined largely to inhibition of the transport of organic acids across epithelial barriers. *Probenecid* inhibits the reabsorption of uric acid by OATs, principally URAT-1. Uric acid is the only important endogenous compound whose excretion is known to be increased by *probenecid*. The uricosuric action of *probenecid* is blunted by the coadministration of salicylates.

Inhibition of Transport of Miscellaneous Substances. *Probenecid* decreases the tubular secretion of several drugs by inhibition of OAT-1 and -3, which are expressed at the basolateral surface of proximal tubular cells. OAT-1/3 inhibition reduces renal secretion and increases plasma levels of drugs such as *methotrexate* and the active metabolite of *clofibrate*. It inhibits renal secretion of the inactive glucuronide metabolites of NSAIDs such as *naproxen*, *ketoprofen*, and *indomethacin* and thereby can increase their plasma concentrations. *Probenecid* inhibits the transport of

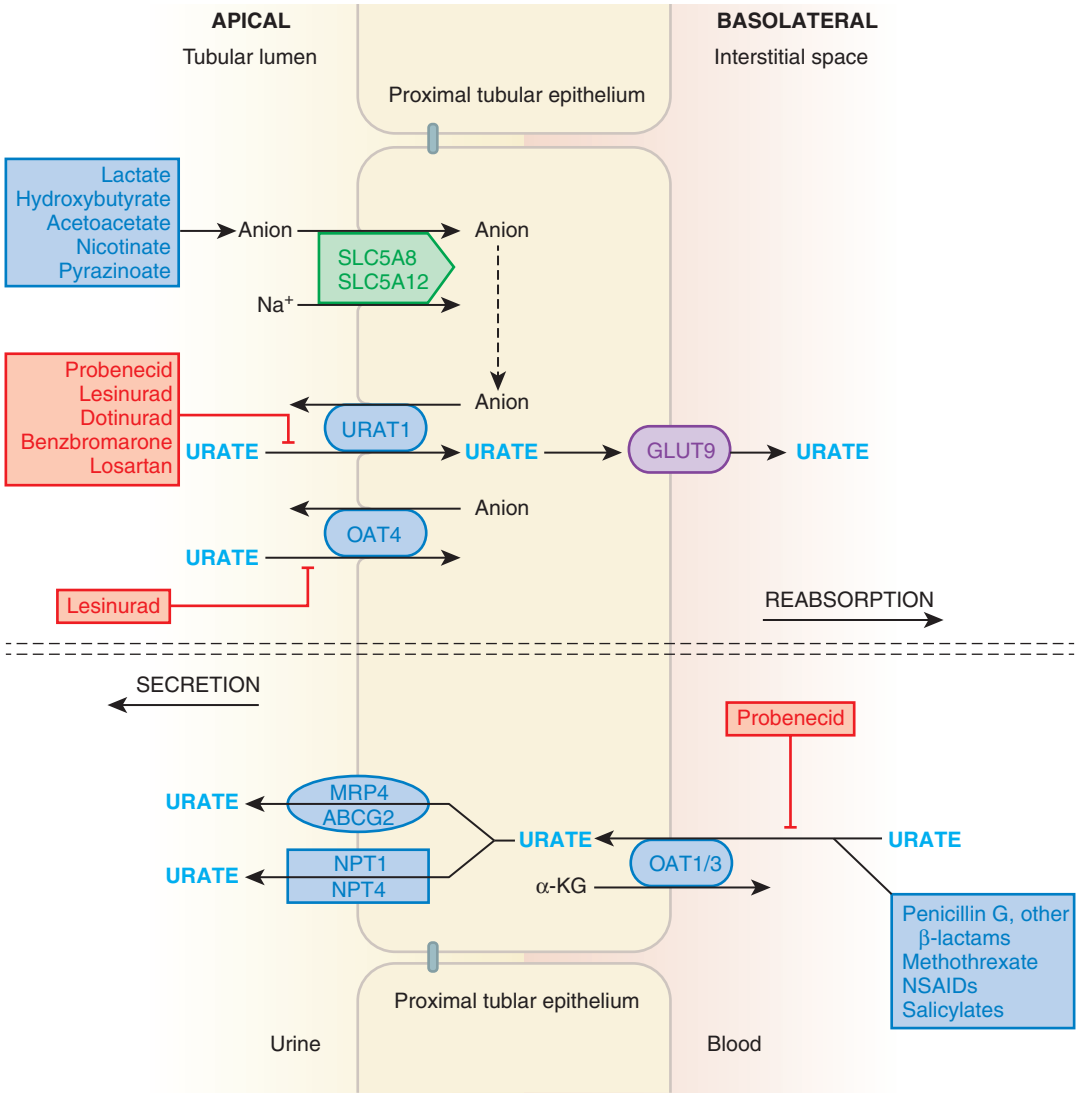


Figure 42–2 *A pharmacologist's view of urate transport in the proximal tubule and its inhibition by drugs.* URAT1 is the primary anion exchange transporter for urate from the tubular lumen into the proximal tubular epithelial cell. OAT4 does likewise but to a much lesser degree. Na^+-coupled anion transport by SLC5A8 and SLC5A12 provides intracellular anions to URAT. High luminal concentrations of these organic anions support URAT1 activity. GLUT9 is a major contributor to basolateral transport of urate (reabsorption). Several polymorphisms of GLUT9 are associated with altered risk for gout. The basolateral urate transporters OAT1 and OAT3 play a role in the secretion of urate into the tubular lumen, which involves MRP4, ABCG2, NTP1, and NTP4 at the apical cell membrane. In gout, *probenecid* generally leads to a net increase in urate excretion. Drug-drug interactions occur when drugs compete for transport via OAT3 and OAT4, leading to increase in plasma levels. *Probenecid*'s inhibition of the secretion of *penicillin* and other β-lactam antibiotics is therapeutically exploited to prolong the dwell time of these drugs in the body. α-KG, α-ketoglutarate.

5-HIAA and other acidic metabolites of cerebral monoamines from the CSF to the plasma. The transport of drugs such as *penicillin G* also may be affected, and *probenecid* is used therapeutically to elevate and prolong plasma β-lactam levels. *Probenecid* depresses the biliary secretion of certain compounds, including the diagnostic agents indocyanine green and bromosulfophthalein. It also decreases the biliary secretion of *rifampin*, leading to higher plasma concentrations.

ADME. *Probenecid* is absorbed completely after oral administration. Peak plasma concentrations are reached in 2 to 4 h. The $t_{1/2}$ of the drug in plasma is dose dependent and varies from less than 5 to more than 8 h. Between 85% and 95% of the drug is bound to plasma albumin; the 5% to 15% of unbound drug is cleared by glomerular filtration and active secretion by the proximal tubule. A small amount of probenecid glucuronide appears in the urine. It also is hydroxylated to metabolites that retain their carboxyl function and have uricosuric activity.

Therapeutic Uses. *Probenecid* is marketed for oral administration, alone and in combination with *colchicine*. The starting dose is 250 mg twice daily, increasing over 1 to 2 weeks to 500 to 1000 mg twice daily. *Probenecid* increases urinary urate levels. Liberal fluid intake therefore should be maintained throughout therapy to minimize the risk of renal stones. *Probenecid* should not be used in gouty patients with nephrolithiasis or with overproduction of uric acid. Concomitant *colchicine* or NSAIDs are indicated early during therapy to avoid precipitating an attack of gout, which may occur in 20% or fewer of gouty patients treated with *probenecid* alone. After 6 months, if serum uric acid levels are within normal limits and there have been no gout attacks, the dose of *probenecid* may be tapered off by 500 mg every 6 months.

Combination with Penicillin. Higher doses of *probenecid* (1–2 g/day) are used as an adjuvant to prolong the dwell time of *penicillin* and other β-lactam antibiotics in the body (see Chapter 58).

Adverse Effects. *Probenecid* is well tolerated. Approximately 2% of patients develop mild GI irritation. The risk is increased at higher doses. It is ineffective in patients with renal insufficiency and should be avoided in those with creatinine clearance of less than 50 mL/min. Hypersensitivity

reactions usually are mild and occur in 2% to 4% of patients. Substantial overdosage with *probenecid* results in CNS stimulation, convulsions, and death from respiratory failure.

Dotinurad

Dotinurad is a novel inhibitor of renal uric acid reabsorption currently approved in Japan (Kuriyama, 2020).

Mechanism of Action. *Dotinurad*, which is structurally derived from benzbromarone, is a potent inhibitor of URAT-1 (Uda et al., 2020) localized in the brush-border membrane of the renal proximal tubules. Like other uricosuric agents, the drug is thought to inhibit the transporter from the luminal side in the renal tubules.

ADME. Mass balance calculations suggest that more than 90% of an orally administered *dotinurad* dose is absorbed (Omura et al., 2020). C_{Pmax} is reached after approximately 3 h. *Dotinurad* is highly plasma bound (>99%) and eliminated with a $t_{1/2}$ of approximately 10 h (clearance ~1 L/h). Glucuronidation and sulfation are the major routes of metabolism.

Therapeutic Uses. Clinical trials demonstrated effective reduction in uric acid levels at doses of 1, 2, and 4 mg/day.

Adverse Effects. *Dotinurad* was well tolerated in clinical trials. Adverse reactions reported in an open-label study of 8 to 12 months of treatment with daily administration of 2 to 4 mg *dotinurad* included nasopharyngitis (17.9%) and gouty arthritis (13.0%). Renal calculi were reported in 1.5% of patients, suggesting that, as with *lesinurad*, a potential impact on renal function needs to be considered during chronic treatment.

Lesinurad

Lesinurad was FDA-approved for combination therapy with an XO inhibitor in treating hyperuricemia. However, the drug has recently been discontinued in the U.S. and withdrawn in the European Union.

Mechanism of Action. *Lesinurad* inhibits the URAT-1 and OAT-4 transporters, thereby reducing renal uric acid reabsorption.

ADME. *Lesinurad* is rapidly absorbed after oral administration and has bioavailability of about 100%. *Lesinurad* is largely bound to plasma albumin and other plasma proteins (<98%). The elimination $t_{1/2}$ is about 5 h (clearance ~6 L/h). CYP2C9 is the major metabolizing enzyme. *Lesinurad* (30% unchanged) and its metabolites are excreted in the urine (>60% of dose) and feces. Renal impairment increases exposure, and *lesinurad* should not be used when renal function is severely reduced (estimated creatinine clearance <45 mL/min).

Therapeutic Uses. *Lesinurad* (200 mg/day) is marketed for the treatment of gout in patients who have not achieved the target serum uric acid levels with an XO inhibitor alone. It should not be used for the treatment of asymptomatic hyperuricemia or as monotherapy.

Adverse Effects. *Lesinurad* has been labeled with a boxed warning because of a risk of acute renal failure that is more common when it is used without an XO inhibitor. Increases in blood creatinine levels (1.5- to 2-fold) were observed with a frequency of approximately 4% during combination therapy and 8% during monotherapy. Renal failure occurred in less than 1% of patients during combination therapy but approximately 9% during monotherapy. Similarly, the risk of nephrolithiasis is increased when *lesinurad* is given alone. Thus, if treatment with the XO inhibitor is interrupted, *lesinurad* dosing should also be interrupted. Other adverse reactions reported by patients during clinical trials include headache (~5%), influenza-like symptoms (~5%), and gastroesophageal reflux (~3%).

Benzbromarone

Benzbromarone, a potent uricosuric agent, is a reversible inhibitor of the urate-anion exchanger, URAT-1, in the proximal tubule. Hepatotoxicity reported in conjunction with its use has limited its availability, and it is not approved for use in the U.S. or the European Union. The drug is absorbed readily after oral ingestion; peak plasma levels are achieved in about 4 h. It is metabolized to monobrominated and dehalogenated derivatives, both of which have uricosuric activity, and is excreted primarily in the bile. *Benzbromarone* metabolism involves predominantly CYP2C9, with contributions by CYP3A4 and CYP1A1. The drug's potent inhibition of CYP2C9 predisposes to drug-drug interactions, and patients homozygous for the CYP2C9*3/*3 polymorphism metabolize the drug more slowly to 6-OH-benzbromarone (Uchida et al., 2010); the clinical significance of this finding is unclear. In addition to the formation of hepatotoxic metabolites, inhibition of mitochondrial function may play a role in the development of a fulminant hepatitis in some patients.

As the micronized powder, it is effective in a single daily dose ranging from 25 to 100 mg. It is effective in patients with renal insufficiency and is prescribed to patients who are either allergic to or refractory to other drugs used for the treatment of gout. Preparations that combine *allopurinol* and *benzbromarone* are more effective than either drug alone in lowering serum uric acid levels, despite the fact that *benzbromarone* lowers plasma levels of oxypurinol, the active metabolite of *allopurinol*. The uricosuric action is blunted by *aspirin* or *sulfinpyrazone*.

Drug Facts for Your Personal Formulary: *NSAIDs* (see also Tables 42–1, 42–2, and 42–3)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Salicylates • Used to treat pain, fever, inflammation • Adverse Effects: Primarily GI and cardiovascular, salicylate intoxication		
Aspirin	• Vascular indications • Pain/fever • Rheumatoid disease/rheumatic fever	• Irreversible COX inhibitor ⇒ long-acting inhibition of platelet function at low doses • At higher concentrations, small increments in dose disproportionately ↑ C_p and toxicity • Use in children: limited due to Reye syndrome association • Reduces the risk of recurrent adenomas in persons with a history of colorectal cancer or adenomas • Prolongs bleeding time for ~36 h after a dose
Salsalate	• Arthritis • Rheumatic disorders	• Prodrug of salicylic acid • Marketed but not approved in the U.S.
Diflunisal	• Mild to moderate pain • Osteoarthritis/rheumatoid arthritis	• Salicylic acid derivative • Largely devoid of antipyretic effects • $t_{1/2}$ prolonged with renal impairment

Drug Facts for Your Personal Formulary: *NSAIDs* (see also Tables 42–1, 42–2, and 42–3) (*continued*)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Mesalamine (5-aminosalicylic acid)	• Inflammatory bowel disease (see Chapter 55)	• Oral formulation delivers 5-aminosalicylic acid to lower GI tract; relative bowel specificity reduces side effects • May cause an acute intolerance syndrome (difficult to discern from an exacerbation)
Sulfasalazine	• Rheumatoid arthritis • Inflammatory bowel disease (see Chapter 55)	• Active metabolite, 5-aminosalicylic acid (see mesalamine), is released by colonic bacteria • With G6PD deficiency: susceptibility to hemolytic anemia • Urine and skin discolorations • Incidence of side effects increased in slow acetylators
Olsalazine	• Inflammatory bowel disease (see Chapter 55)	• Active metabolite, 5-aminosalicylic acid (see mesalamine), is released by colonic bacteria • Photosensitivity
Balsalazide	• Inflammatory bowel disease (see Chapter 55)	• Active metabolite, 5-aminosalicylic acid (see mesalamine), is released by colonic bacteria
Para-Aminophenol Derivative • Only acetaminophen remains on the market		
Acetaminophen	• Pain • Fever	• Weak nonspecific COX inhibitor at common doses • Low anti-inflammatory activity • Little effect on platelets • Overdose results in formation of hepatotoxic metabolite (NAPQI) • Toxicity risk ↑ with liver impairment, ethanol consumption ≥3 drinks/day, or malnutrition
Acetic Acid Derivatives		
Indomethacin	• Acute pain • Arthritis, inflammatory conditions • Patent ductus arteriosus	• Potent anti-inflammatory with frequent adverse events (20% discontinue) • High-risk medication in patients ≥65 years
Sulindac	• Inflammatory diseases including osteoarthritis, rheumatoid arthritis, acute gouty arthritis, ankylosing spondylitis, acute painful shoulder	• Sulfoxide prodrug
Etodolac	• Pain, osteoarthritis, rheumatoid arthritis, juvenile arthritis	• Some COX-2 selectivity
Tolmetin	• Osteoarthritis, rheumatoid arthritis, juvenile arthritis	• ~33% of patients experience side effects
Ketorolac	• Moderate-to-severe acute pain • Off label: pericarditis, migraine • Ocular pain, seasonal allergic conjunctivitis	• Potent analgesic, poor anti-inflammatory • Limit systemic therapy to 5 days (risk of GI bleeding) • Do not use postoperatively for pain from CABG or in advanced renal disease • Avoid administration with other NSAIDs or probenecid (probenecid increases ketorolac AUC [3×] and $t_{1/2}$ [2×])
Diclofenac	• Pain • Dysmenorrhea • Migraine (oral solution) • Osteoarthritis, rheumatoid arthritis • Ankylosing spondylitis	• Some COX-2 selectivity • Short $t_{1/2}$ requires relatively high doses to extend dosing interval • Rate of cardiovascular toxicity similar to that of COX-2 inhibitors • Liver toxicity (4%); severe liver injury in ~8 per 100,000 regular users annually
Nabumetone	• Osteoarthritis, rheumatoid arthritis	• Some COX-2 selectivity • 6-Methoxy-2-napthylacetic acid prodrug
Fenamates • Anthranilic acids; Nonselective COX inhibitors with effects similar to other NSAIDs		
Mefenamic acid	• Pain • Dysmenorrhea	• For patients ≥14 years and ≤7 days of treatment • ↑ Hepatic enzymes in 5%
Meclofenamate	• Pain/fever, dysmenorrhea • Osteoarthritis, rheumatoid arthritis, juvenile arthritis • Ankylosing spondylitis, acute gouty arthritis, acute painful shoulder	• For patients ≥14 years • ↑ Hepatic enzymes in 5%
Propionic Acid Derivatives • Nonselective COX inhibitors with the effects and side effects common to other NSAIDs		
Ibuprofen	• Pain/fever, dysmenorrhea • Osteoarthritis, rheumatoid arthritis • Inflammatory diseases • Patent ductus arteriosus	• Over-the-counter NSAID and by prescription • Injectable solution available • $t_{1/2}$: 2–4 h (adults); 23–75 h (premature infants); 0.9–2.3 h (children) • Interacts with aspirin's antiplatelet effect
Naproxen	• Pain, dysmenorrhea • Osteoarthritis, rheumatoid arthritis, ankylosing spondylitis; gout; juvenile arthritis, inflammatory diseases • Patent ductus arteriosus	• Over-the-counter NSAID and by prescription • $t_{1/2}$ variable (9–25 h), age-related • FDA warning: naproxen may not have a lower risk of cardiovascular side effects compared to other NSAIDs • Interacts with aspirin's antiplatelet effect
Fenoprofen	• Pain • Osteoarthritis, rheumatoid arthritis	

Drug Facts for Your Personal Formulary: *NSAIDs* (see also Tables 42–1, 42–2, and 42–3) (*continued*)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Ketoprofen	• Pain, dysmenorrhea • Osteoarthritis, rheumatoid arthritis	• 30% develop side effects (usually GI, usually mild) • ↑ Hepatic enzymes ~1%
Flurbiprofen	• Osteoarthritis, rheumatoid arthritis	• ↑ Hepatic enzymes >1%
Oxaprozin	• Osteoarthritis, rheumatoid arthritis, juvenile arthritis	• $t_{1/2}$: 41–55 h • Slow onset, not indicated for fever or acute pain
Enolic Acid Derivatives		
Piroxicam	• Osteoarthritis, rheumatoid arthritis	• Nonselective COX inhibitor with the longest $t_{1/2}$ (~50 h) • Slow onset, not indicated for fever or acute pain • Adverse effects, 20%; 5% of patients discontinue; more GI and serious skin reactions than other NSAIDs
Meloxicam	• Osteoarthritis, rheumatoid arthritis, juvenile arthritis	• Some COX-2 selectivity • $t_{1/2}$: 15–20 h
Diaryl Heterocyclic NSAIDs		
Celecoxib	• Pain • Dysmenorrhea • Osteoarthritis, rheumatoid arthritis, juvenile arthritis • Ankylosing spondylitis • Off-label use: gout	• COX-2 selective • Sulfonamide • Risk of myocardial infarction observed in randomized placebo-controlled trials
Drugs That Relieve Inflammation and Pain		
NSAIDs	• *See* NSAIDs, above	• *See* NSAIDs, above
Glucocorticoids	• *See* Chapter 50	• *See* Chapter 50
Colchicine	• Prophylaxis and the treatment of acute gout flares	• Depolymerizes microtubules ⇒ ↓ neutrophil migration into inflamed area • Narrow therapeutic index; toxic effects related to antimitotic activity • $t_{1/2}$: 31 h (21–50 h) • Individualize dose on the basis of age and hepatic and renal function • Contraindicated in patients with GI, renal, hepatic, or cardiac disorders • Adverse effects: primarily GI • Drug interactions with P-glycoprotein and CYP3A4 inhibitors
Xanthine Oxidase (XO) Inhibitors • Inhibit urate synthesis		
Allopurinol	• Hyperuricemia in patients with gout • Calcium oxalate calculi • Hyperuricemia associated with cancer treatment	• Reduce dose in renal impairment • Rash, diarrhea, nausea frequent; discontinue if rash develops • Beware of Stevens-Johnson syndrome/toxic epidermal necrosis (high risk of mortality); test for genetic factors (e.g., HLA-B*5801) in susceptible populations (see text) • N.B.: Risk of gout attacks in early months of therapy (tissue urate mobilization)
Febuxostat	• Hyperuricemia	• Nonpurine • More selective for XO than allopurinol • Liver function abnormalities (5%–7%)
Uricase • Oxidizes uric acid to allantoin (more soluble and inactive metabolite)		
Pegloticase	• Chronic gout refractory to conventional therapy	• ↓ Blood urate within hours of initial administration • Antibody development against drug may limit efficacy, cause hypersensitivity reactions • Adverse effects: bruising (11%), urticaria (11%), nausea (11%), gout flare during early therapy (74%), chest pain (6%)
Rasburicase	• Hyperuricemia associated with malignancy (pediatric and adult patients)	• ↓ Uric acid levels within hours of initial administration • Not suitable for chronic gout; activity-limiting antibodies form against the drug
Uricosuric Drugs • Inhibit of reabsorption of uric acid by organic anion transporters, thereby increasing excretion of uric acid		
Probenecid	• Hyperuricemia associated with gout (but not for acute attacks) • Prolongation and elevation of β-lactam plasma levels	• Promotes net tubular secretion of urate; alters tubular handling of organic acids (Figure 42–2) • Risk of gout attacks during the early months of therapy (tissue urate mobilization) • Ineffective in patients with renal insufficiency
Lesinurad	• Gout in patients who have not achieved the target serum uric acid levels with XO inhibitor alone	• Discontinued in the U.S., withdrawn in European Union • Substrate of the highly polymorphic CYP2C9; caution needed in CYP2C9 poor metabolizers • Must be used together with XO inhibitor due to renal failure risk

Chapter 43

Histamine, Bradykinin, and Their Antagonists

Bruce L. Zuraw and Sandra C. Christiansen

Histamine is an endogenous biogenic amine that plays a role in the immediate allergic response and is an important regulator of gastric acid secretion. More recently, a role for histamine as a modulator of neurotransmitter release in the central and peripheral nervous systems has emerged. The cloning of four receptors for histamine and the development of subtype-specific receptor antagonists have enhanced our understanding of the physiological and pathophysiological roles of histamine. Competitive antagonists of H_1 receptors are used therapeutically in treating allergies, urticaria, anaphylactic reactions, nausea, motion sickness, and insomnia. Antagonists of the H_2 receptor are effective in reducing gastric acid secretion.

The peptides bradykinin and kallidin, released after activation of the kallikrein-kinin system, have cardiovascular effects similar to those of histamine and play prominent roles in inflammation and nociception. *Icatibant*, a competitive antagonist of the bradykinin B_2 receptor, and *ecallantide*, a specific plasma kallikrein inhibitor, are approved for the treatment of acute episodes of edema in patients with hereditary angioedema.

Histamine

Histamine is a hydrophilic molecule consisting of an imidazole ring and an amino group connected by an ethylene group; histamine is biosynthesized from histidine by decarboxylation (Figure 43–1). Histamine acts through four classes of receptors, designated H_1 through H_4. The four histamine receptors, all G protein-coupled receptors (GPCRs), can be differentially activated by analogues of histamine (Figure 43–2) and inhibited by specific antagonists (Table 43–1).

Distribution and Biosynthesis

Distribution

Almost all mammalian tissues contain histamine in amounts ranging from less than 1 to more than 100 μg/g. Concentrations in plasma and other body fluids are generally very low, but they are significant in human CSF (cerebrospinal fluid). The concentration of histamine is particularly high in tissues that contain large numbers of mast cells, such as skin, bronchial mucosa, and intestinal mucosa.

EARLY HISTORY OF HISTAMINE

Histamine was first prepared synthetically in 1907 and isolated from ergot extracts in 1910. It was identified as a natural constituent of mammalian tissues in 1927 by Best and colleagues and named *histamine* after the Greek word for tissue, *histos*. Dale and Laidlaw made the crucial observation that histamine injection into mammals caused a shock-like reaction and proposed its role in mediating symptoms of anaphylaxis (Emanuel, 1999).

Synthesis, Storage, and Metabolism

Histamine is formed by the decarboxylation of histidine by the enzyme *L-histidine decarboxylase* (Figure 43–1). Mast cells and basophils synthesize histamine and store it in secretory granules. At the secretory granule pH of about 5.5, histamine is positively charged and ionically complexed with negatively charged acidic groups on other granule constituents, primarily proteases and heparin or chondroitin sulfate proteoglycans. The turnover rate of histamine in secretory granules is slow (days to weeks). Non–mast cell sites of histamine formation include the epidermis, enterochromaffin-like cells of the gastric mucosa, neurons within the central nervous system (CNS), and cells in regenerating or rapidly growing tissues. Turnover is rapid at these non–mast cell sites because the histamine is released continuously rather than stored. Non–mast cell sites of histamine production contribute significantly to the daily excretion of histamine metabolites in the urine. Because L-histidine decarboxylase is an inducible enzyme, the histamine-forming capacity at such sites is subject to regulation. Histamine that is released or ingested is rapidly metabolized by either ring methylation catalyzed by *histamine*-N-*methyltransferase* or oxidative deamination catalyzed by *diamine oxidase* (Figure 43–1), and the metabolites are eliminated in the urine.

Release and Functions of Endogenous Histamine

Histamine is released from storage granules as a result of the interaction of antigen with immunoglobulin E (IgE) antibodies on the mast cell surface. Histamine plays a central role in immediate hypersensitivity and allergic responses. The actions of histamine on bronchial smooth muscle and

Abbreviations

ACE: angiotensin I–converting enzyme
ADHD: attention-deficit/hyperactivity disorder
Ang: angiotensin
ARNI: angiotensin receptor–neprilysin inhibitor
AT: angiotensin receptor (e.g., AT_1 and AT_2 receptors)
AV: atrioventricular
C1: the C1 esterase of the complement system
C1-INH: inhibitor of the activated C1 component of complement
CSF: cerebrospinal fluid
EET: epoxyeicosatrienoic acid
eNOS: endothelial nitric oxide synthase
GABA: γ-aminobutyric acid
GI: gastrointestinal
GPCR: G protein-coupled receptor
HMW: high molecular weight
5HT: serotonin (5-hydroxytryptamine)
IgE: immunoglobulin E
IL-1: interleukin-1
iNOS: inducible nitric oxide synthase
IP_3: inositol trisphosphate
LMW: low molecular weight
NO: nitric oxide
PKC: protein kinase C
TNFα: tumor necrosis factor α

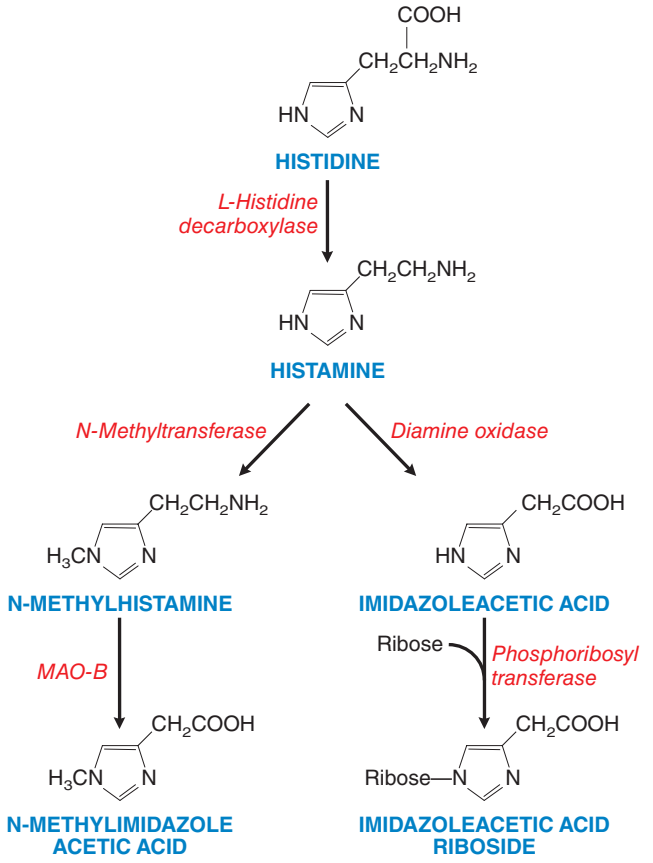

Figure 43–1 *Pathways of histamine synthesis and metabolism in humans.* Histamine is synthesized from histidine by decarboxylation. Histamine is metabolized via two pathways, predominantly by methylation of the ring followed by oxidative deamination (left side of figure) and secondarily by oxidative deamination and then conjugation with ribose.

blood vessels account for many of the symptoms of the allergic response. Histamine is a leukocyte chemoattractant, plays a major role in regulating gastric acid secretion, and modulates neurotransmitter release. In addition, some drugs act directly on mast cells to release histamine, causing untoward effects (see below).

Role in Allergic Responses

The principal target cells of immediate hypersensitivity reactions are mast cells and basophils. As part of the allergic response to an antigen, IgE antibodies are generated and bind to the surfaces of mast cells and basophils via specific high-affinity Fc receptors. This receptor, FcεRI, consists of α, β, and two γ chains (see Chapter 38). Antigen bridges the IgE molecules and via FcεRI activates signaling pathways in mast cells or basophils involving tyrosine kinases and subsequent phosphorylation of multiple protein substrates within 5 to 15 sec of contact with antigen. These events trigger the exocytosis of the contents of secretory granules that, in addition to histamine, includes serotonin, proteases, lysosomal enzymes, cytokines, and proteoglycans.

Release of Other Autacoids

Stimulation of IgE receptors also activates PLA_2 (phospholipase A_2), leading to the production of a host of mediators, including PAF (platelet-activating factor) and metabolites of arachidonic acid such as leukotrienes C_4 and D_4, which contract bronchial smooth muscle (see Chapters 41 and 44). Kinins also are generated during some allergic responses. Thus, the mast cell secretes a variety of inflammatory mediators in addition to histamine, each contributing to aspects of the allergic response (see discussion that follows).

Histamine Release by Drugs, Peptides, Venoms, and Other Agents

Mechanical injury and many compounds, including a large number of therapeutic agents, stimulate the release of histamine from mast cells directly and without prior sensitization (McNeil, 2021a). Responses of this sort are most likely to occur following intravenous injections of certain categories of substances, particularly organic bases. *Tubocurarine*, *succinylcholine*, *morphine*, some antibiotics, radiocontrast media, and certain carbohydrate plasma expanders also may elicit the response. The phenomenon is one of clinical concern and may account for unexpected anaphylactoid reactions. Basic polypeptides often are effective histamine releasers, and over a limited range, their potency generally increases with the number of basic groups. For example, bradykinin is a poor histamine releaser, whereas kallidin (Lys-bradykinin) and substance P, with more positively charged amino acids, are more active (Johnson and Erdos, 1973). Some venoms, such as that of the wasp, contain potent histamine-releasing peptides. Basic polypeptides released on tissue injury constitute pathophysiological stimuli for secretion from mast cells and basophils.

The mechanism by which basic secretagogues release histamine likely involves their direct interaction with MRGPRX2, a mast cell–specific member of the Mas-related G protein-coupled receptor (MRGPR) superfamily of eight proteins. Two of these proteins in the X family, MRGPRX1 and MRGPRX2, interact with a variety of positively charged compounds, transducing signals that result in itch and pain. Activation of MRGPRX2 on mast cells appears to provide a route for histamine release that is independent of the traditional IgE pathway and likely contribute to some adverse drug reactions (McNeil, 2021b). Inhibitors of MRGPRX2 may have therapeutic potential for the treatment of pseudoallergic and inflammatory diseases.

Within seconds of the intravenous injection of a histamine liberator, human subjects experience a burning, itching sensation. This effect, which is most marked in the palms of the hand and in the face, scalp, and ears, is soon followed by a feeling of intense warmth. The skin reddens, and the color rapidly spreads over the trunk. Blood pressure falls, the heart rate accelerates, and the subject usually complains of headache. After a few minutes, blood pressure recovers, and crops of hives usually appear on the skin. Colic, nausea, hypersecretion of acid, and moderate

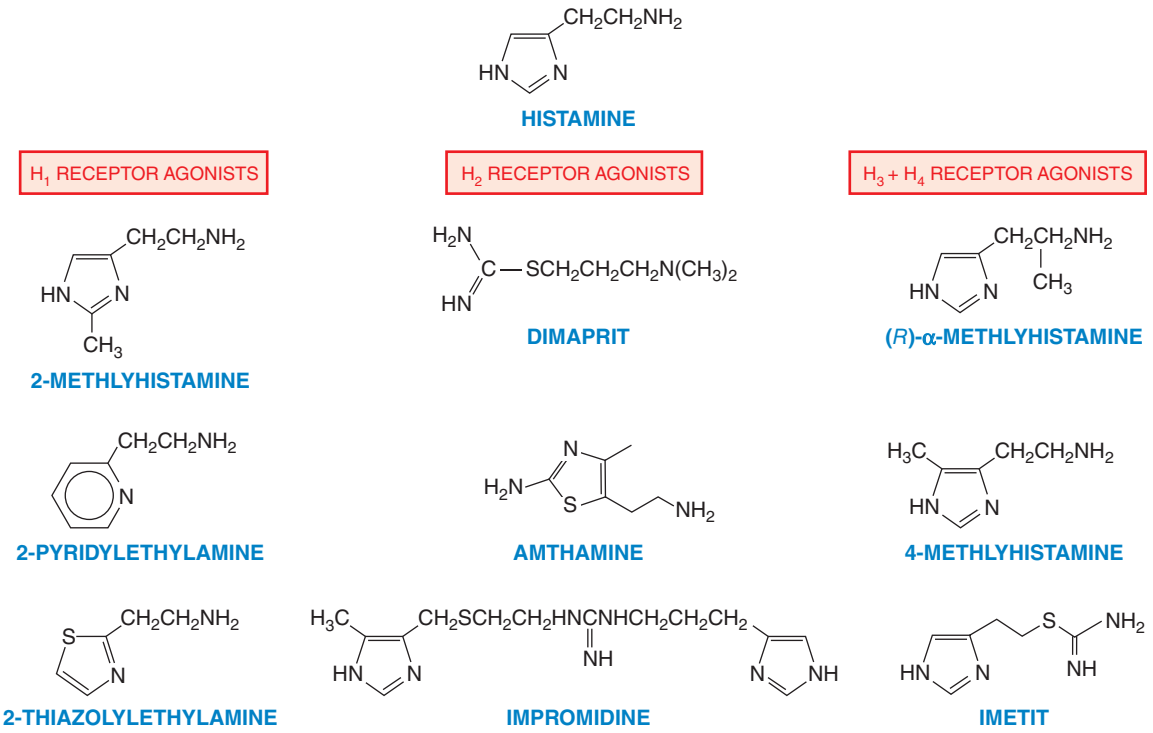

Figure 43–2 *Structure of histamine and some H_1, H_2, H_3, and H_4 agonists.* *Dimaprit* and *4-methylhistamine*, originally identified as specific H_2 agonists, have a much higher affinity for the H_4 receptor; *4-methylhistamine* is the most specific available H_4 agonist, with about 10-fold higher affinity than *dimaprit*, a partial H_4 agonist. *Impromidine* not only is among the most potent H_2 agonists but also is an antagonist at H_1 and H_3 receptors and a partial agonist at H_4 receptors. (*R*)-*α-Methylhistamine* and *imetit* are high-affinity agonists of H_3 receptors and lower-affinity full agonists at H_4 receptors.

bronchospasm also frequently occur. The effect becomes less intense with successive administration of the secretagogue as mast cell stores of histamine are depleted. Histamine liberators do not deplete histamine from non–mast cell sites.

Increased Proliferation of Mast Cells and Basophils; Gastric Carcinoid Tumors

In urticaria pigmentosa (cutaneous mastocytosis), mast cells aggregate in the upper corium and give rise to pigmented cutaneous lesions that sting when stroked. In systemic mastocytosis, overproliferation of mast cells is also found in other organs. Patients with these syndromes suffer a constellation of signs and symptoms attributable to excessive histamine release, including urticaria, dermographism, pruritus, headache, weakness, hypotension, flushing of the face, and a variety of gastrointestinal (GI) effects, such as diarrhea or peptic ulceration. A variety of stimuli, including exertion, insect stings, exposure to heat, and allergens (including drugs to which a patient is allergic), can activate mast cells and cause histamine release, as can organic bases (many drugs) that cause histamine release directly. In myelogenous leukemia, elevation of blood basophils can result in histamine content high enough to cause flushing, pruritus, and hypotension. Patients with a history of anaphylaxis to venoms often have elevated baseline tryptase levels, suggesting either an increase in the mast cell burden or hereditary alpha tryptasemia. Management of these patients can be complicated by a large release of histamine after cytolysis, causing shock. Gastric carcinoid tumors secrete histamine, which is responsible for episodes of vasodilation as part of the patchy "geographical" flush.

Gastric Acid Secretion

Histamine acting at H_2 receptors is a powerful gastric secretagogue, evoking copious secretion of acid from parietal cells (see Figure 53–1); it also increases the output of pepsin and intrinsic factor. The secretion of gastric acid from parietal cells also is caused by stimulation of the vagus nerve and by the enteric hormone gastrin. However, histamine is the dominant

[a]At least 20 alternately spliced H_3 isoforms have been detected at the mRNA level. Eight of these isoforms, ranging in size from 329 to 445 residues, were found to be functionally competent by binding or signaling assays (see Esbenshade et al., 2008).

physiological mediator of acid secretion; blockade of H_2 receptors not only antagonizes acid secretion in response to histamine but also inhibits responses to gastrin and vagal stimulation (see Chapter 53).

CNS

Histamine-containing neurons affect both homeostatic and higher brain functions, including regulation of the sleep-wake cycle, circadian and feeding rhythms, immunity, learning, memory, drinking, and body temperature. However, no human disease has yet been directly linked to dysfunction of the brain histamine system. Histamine, histidine decarboxylase, enzymes that metabolize histamine, and H_1, H_2, and H_3 receptors are distributed widely but nonuniformly in the CNS. H_1 receptors are associated with both neuronal and nonneuronal cells and are concentrated in regions that control neuroendocrine function, behavior, and nutritional state. Distribution of H_2 receptors is more consistent with histaminergic projections than that of H_1 receptors, suggesting that they mediate many of the postsynaptic actions of histamine. H_3 receptors are concentrated in areas known to receive histaminergic projections, consistent with their function as presynaptic autoreceptors. Histamine inhibits appetite and increases wakefulness via H_1 receptors.

Physiological and Pharmacological Effects

Receptor-Effector Coupling and Mechanisms of Action

Histamine receptors are GPCRs, coupling to second-messenger systems and producing effects (Simons, 2004) as noted in Table 43–1. H_1 receptors couple to $G_{q/11}$ and activate the PLC-IP_3-Ca^{2+} pathway and its myriad sequelae, including activation of PKC (protein kinase C), PLA_2, eNOS (endothelial nitric oxide synthase), and other Ca^{2+}-calmodulin–dependent enzymes. H_2 receptors link to G_s to activate the adenylyl cyclase–cyclic AMP–PKA pathway; H_3 and H_4 receptors couple to $G_{i/o}$ to inhibit adenylyl cyclase and decrease cellular cyclic AMP. Activation of H_3 receptors also can activate MAP kinase and inhibit the Na^+/H^+ exchanger; activation of H_4 receptors can mobilize stored Ca^{2+} (Simons and Simons, 2011). H_3 and H_4 receptors have about 1000-fold higher affinity for histamine (low nanomolar range) than do H_1 and H_2 receptors (low micromolar range). Activation of H_1 receptors on vascular endothelium stimulates eNOS to produce nitric oxide (NO), which diffuses to nearby smooth muscle cells to increase cyclic GMP and cause relaxation. Stimulation of H_1 receptors on smooth muscle will mobilize Ca^{2+} and cause contraction, whereas activation of H_2 receptors on the same smooth muscle cell will link via G_s to enhanced cyclic AMP accumulation, activation of PKA, and then to relaxation.

Pharmacological definition of H_1, H_2, and H_3 receptors was possible through the use of relatively specific agonists and antagonists. Because the H_4 receptor exhibits 35% to 40% homology to isoforms of the H_3 receptor, the two were initially harder to distinguish pharmacologically, but this has been resolved by the development of several H_3- and H_4-selective antagonists (Sander et al., 2008; Thurmond, 2015). *4-Methylhistamine* and *dimaprit*, previously identified as specific H_2 agonists, are actually more potent H_4 agonists.

H_1 and H_2 Receptors

H_1 and H_2 receptors are distributed widely in the periphery and in the CNS, and their activation by histamine can exert local or widespread effects (Simons and Simons, 2011). For example, histamine causes itching and stimulates secretion from nasal mucosa. It contracts many smooth muscles, such as those of the bronchi and gut, but markedly relaxes others, including those in small blood vessels. H_2-receptor–mediated cyclic AMP signaling is a crucial step in acid secretion by gastric parietal cells. Other, less-prominent effects include formation of edema and stimulation of sensory nerve endings. Bronchoconstriction and contraction of the gut are mediated, in part, by H_1 receptors. In the CNS, H_1 activation inhibits appetite and increases wakefulness. Gastric secretion results from the activation of H_2 receptors. Some responses, such as vascular dilation, are mediated by both H_1 and H_2 receptor stimulation.

H_3 and H_4 Receptors

The H_3 receptors are expressed mainly in the CNS, especially in the basal ganglia, hippocampus, and cortex (Haas et al., 2008). Presynaptic H_3 receptors function as autoreceptors on histaminergic neurons, inhibiting histamine release, and as heteroreceptors on nonhistaminergic neurons (i.e., for serotoninergic, noradrenergic, dopaminergic, γ-aminobutyric acid [GABA]-ergic, glutamatergic, and cholinergic neurons), modulating the release of other neurotransmitters. H_3 receptors are also found postsynaptically, especially in the basal ganglia, but their function is still being unraveled (Ellenbroek and Ghiabi, 2014). H_3 agonists promote sleep, and H_3 antagonists promote wakefulness. The H_4 receptors primarily are found in eosinophils, dendritic cells, mast cells, monocytes, basophils, and T cells but have also been detected in the GI tract, dermal fibroblasts, CNS, and primary sensory afferent neurons (Thurmond, 2015). H_4 gene and/or protein expression is reduced in some human tumor cell types including breast, colorectal, oral squamous cell, bladder, and gastric cancer and melanoma (Massari et al., 2020).

Feedback Regulation of Release

Stimulation of H_2 receptor increases cyclic AMP and leads to feedback inhibition of histamine release from mast cells and basophils, whereas activation of H_3 and H_4 receptors has the opposite effect by decreasing cellular cyclic AMP. Activation of presynaptic H_3 receptors inhibits histamine release from histaminergic neurons. Because H_3 receptors have high constitutive activity, histamine release is tonically inhibited. H_3 inverse agonists thus reduce receptor activation and increase histamine release from histaminergic neurons.

Cardiovascular System

Histamine dilates resistance vessels, increases capillary permeability, and lowers systemic blood pressure. In some vascular beds, histamine constricts veins, contributing to the extravasation of fluid and edema formation upstream in capillaries and postcapillary venules.

Vasodilation. Vasodilation is the most important vascular effect of histamine in humans and can result from activation of either the H_1 or H_2 receptor. H_1 receptors have a higher affinity for histamine and cause Ca^{2+}-dependent activation of eNOS in endothelial cells; NO diffuses to vascular smooth muscle, increasing cyclic GMP (see Table 43–1) and causing rapid and short-lived vasodilation. By contrast, activation of H_2 receptors on vascular smooth muscle stimulates the cyclic AMP–PKA pathway, causing dilation that develops more slowly and is more sustained. As a result, H_1 antagonists effectively counter small dilator responses to low concentrations of histamine but blunt only the initial phase of larger responses to higher concentrations of the amine.

Increased Capillary Permeability. Histamine's effect on small vessels results in efflux of plasma protein and fluid into the extracellular spaces and an increase in lymph flow, causing edema. H_1 receptor activation on endothelial cells is the major mediator of this response, leading to G_q-mediated activation of RhoA and ROCK, which stimulates the contractile machinery of the cells and disrupts interendothelial junctions (Mikelis et al., 2015). The gaps between endothelial cells also may permit passage of circulating cells recruited to tissues during the mast cell response. Recruitment of circulating leukocytes is enhanced by H_1 receptor–mediated expression of adhesion molecules (e.g., P-selectin) on endothelial cells.

Triple Response of Lewis. If histamine is injected intradermally, it elicits a characteristic phenomenon known as the *triple response*. This consists of the following:

- A localized "reddening" around the injection site, appearing within a few seconds and maximal at about 1 min
- A "flare" or red flush extending about 1 cm beyond the original red spot and developing more slowly
- A "wheal" or swelling that is discernible in 1–2 min at the injection site

The initial red spot (a few millimeters) results from the direct vasodilating effect of histamine (H_1 receptor–mediated NO production).

The flare is due to histamine-induced stimulation of axonal reflexes that cause vasodilation indirectly, and the wheal reflects histamine's capacity to increase capillary permeability (edema formation).

Heart. Histamine affects both cardiac contractility and electrical events directly. It increases the force of contraction of both atrial and ventricular muscle by promoting the influx of Ca^{2+}, and it speeds heart rate by hastening diastolic depolarization in the sinoatrial node. It also directly slows atrioventricular (AV) conduction to increase automaticity and, in high doses, can elicit arrhythmias. The slowed AV conduction involves mainly H_1 receptors, while the other effects are largely attributable to H_2 receptors and cyclic AMP accumulation. The direct cardiac effects of histamine given intravenously are overshadowed by baroreceptor reflexes stimulated by reduced blood pressure.

Histamine Shock. Histamine given in large doses or released during systemic anaphylaxis causes a profound and progressive fall in blood pressure. As the small blood vessels dilate, they trap large amounts of blood, their permeability increases, and plasma escapes from the circulation. These effects, resembling surgical or traumatic shock, diminish effective blood volume, reduce venous return, and greatly lower cardiac output.

Extravascular Smooth Muscle

Histamine directly contracts or, more rarely, relaxes various extravascular smooth muscles. Contraction is due to activation of H_1 receptors on smooth muscle to increase intracellular Ca^{2+}, and relaxation is mainly due to activation of H_2 receptors. Although the spasmogenic influence of H_1 receptors is dominant in human bronchial muscle, H_2 receptors with dilator function also are present. Thus, histamine-induced bronchospasm *in vitro* is potentiated slightly by H_2 blockade. Patients with bronchial asthma and certain other pulmonary diseases are much more sensitive to the bronchoconstrictor effects of histamine.

Peripheral Nerve Endings

Histamine stimulates various nerve endings, causing sensory effects. In the epidermis, it causes itch; in the dermis, it evokes pain, sometimes accompanied by itching. Stimulant actions on nerve endings, including autonomic afferents and efferents, contribute to the "flare" component of the triple response and to indirect effects of histamine on the bronchi and other organs.

Central Nervous System

Histaminergic neurons originate in the tuberomammillary nucleus of the posterior hypothalamus, projecting to virtually all regions of the brain. Neuronal histamine has both stimulatory and inhibitory functions in the CNS. Stimulatory functions promote wakefulness, cognition, locomotion, energy metabolism, and nociception. Inhibitory functions suppress appetite, convulsions, stress-induced excitation, and denervation-induced super sensitivity.

Immune System

Activation of H_4 receptors has been associated with induction of cellular shape change, chemotaxis, secretion of cytokines, and upregulation of adhesion molecules (Thurmond, 2015). Because of the unique localization and function of H_4 receptors, H_4 antagonists are promising candidates to treat inflammatory conditions such as allergic rhinitis, asthma, rheumatoid arthritis, atopic dermatitis, and possibly pruritus and neuropathic pain. None has yet been FDA approved.

Histamine Shock

Histamine given in large doses or released during systemic anaphylaxis causes a profound and progressive fall in blood pressure. As the small blood vessels dilate, they trap large amounts of blood, their permeability increases, and plasma escapes from the circulation. These effects, resembling surgical or traumatic shock, diminish effective blood volume, reduce venous return, and greatly lower cardiac output.

Histamine Toxicity From Ingestion

Histamine is the toxin in food poisoning from spoiled scombroid fish such as tuna. Symptoms include severe nausea, vomiting, headache, flushing, and sweating. Histamine toxicity also can follow red wine consumption in persons with a diminished ability to degrade histamine. The symptoms of histamine poisoning can be suppressed by H_1 antagonists.

HISTORY

Antihistamine activity was first demonstrated by Bovet and Staub in 1937 with one of a series of amines with a phenolic ether moiety. The substance, 2-isopropyl-5-methylphenoxy-ethyldiethyl-amine, protected guinea pigs against several lethal doses of histamine but was too toxic for clinical use. By 1944, Bovet and his colleagues had described *pyrilamine maleate*, an effective histamine antagonist of this category. The discovery of highly effective *diphenhydramine* and *tripelennamine* soon followed. In the 1980s, nonsedating H_1 histamine receptor antagonists were developed for treatment of allergic diseases. Despite success in blocking allergic responses to histamine, the H_1 antihistamines failed to inhibit a number of other responses, notably gastric acid secretion. The discovery of H_2 receptors and H_2 antagonists by James Black and colleagues provided a new class of agents that antagonized histamine-induced acid secretion (Black et al., 1972); the pharmacology of these drugs (e.g., *cimetidine, famotidine*) is described in Chapter 53. Black shared the 1988 Nobel Prize in Medicine/Physiology with Gertrude Elion and George Hitchings, awarded to the trio "for their discoveries of important principles for drug treatment."

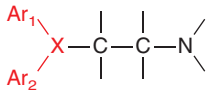
Histamine Receptor Antagonists

H_1 Receptor Antagonists

Pharmacological Properties

All the available H_1 receptor "antagonists" are actually inverse agonists (see Chapter 3) that reduce constitutive activity of the receptor and compete with histamine binding to the receptor (Simons, 2004). The pharmacological actions and therapeutic applications of these antagonists can be largely predicted from knowledge of the location and mode of signaling of the histamine receptors.

Chemistry. Like histamine, many H_1 antagonists contain a substituted ethylamine moiety (the black portion on the figure that follows). Unlike histamine, which has a primary amino group and a single aromatic ring, most H_1 antagonists have a tertiary amino group linked by a two- or three-atom chain to two aromatic substituents (in red) and conform to the general formula:

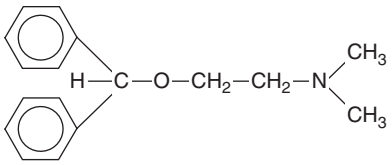


where Ar is aryl and X is a nitrogen or carbon atom or a —C—O— ether linkage to the β-aminoethyl side chain. Sometimes, the two aromatic rings are bridged, as in the tricyclic derivatives, or the ethylamine may be part of a ring structure. Figure 43–3 shows the varied structures of representative H_1 antagonists built around this framework and that constitute the several generations of compounds.

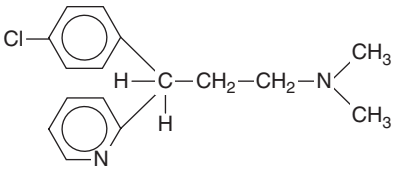
Effects on Physiological Systems

Smooth Muscle. The H_1 antagonists inhibit most of the effects of histamine on smooth muscles, especially the constriction of respiratory smooth muscle. H_1 antagonists inhibit the more rapid vasodilator effects mediated by activation of H_1 receptors on endothelial cells (synthesis/release of NO and other mediators) at lower doses of histamine. They also inhibit venous constriction seen in some vascular beds.

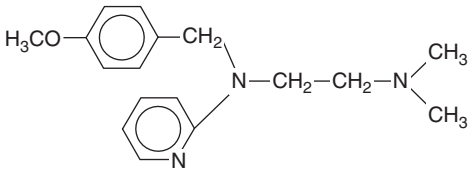
Capillary Permeability. H_1 antagonists strongly block the increased capillary permeability and formation of edema and wheal caused by histamine.



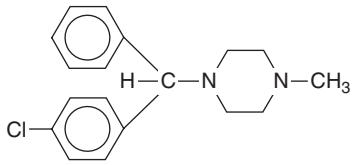
DIPHENHYDRAMINE (an ethanolamine)



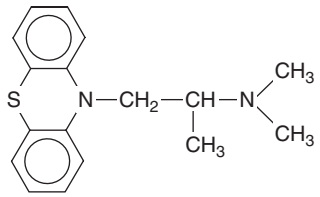
CHLORPHENIRAMINE (an alkylamine)



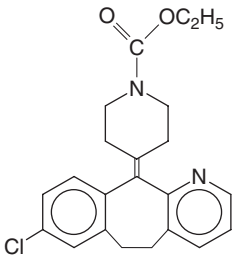
PYRILAMINE (an ethylenediamine)



CHLORCYCLIZINE (a piperazine)



PROMETHAZINE (a phenothiazine)



LORATADINE (a tricyclic piperidine)

Figure 43–3 *Representative H_1 antagonists.*

Flare and Itch. H_1 antagonists suppress the action of histamine on nerve endings, including the flare component of the triple response and the itching caused by intradermal injection.

Exocrine Glands. H_1 antagonists do not suppress gastric secretion. However, the antimuscarinic properties of many H_1 antagonists may contribute to lessened secretion in cholinergically innervated glands and reduce ongoing secretion in, for example, the respiratory tree.

Immediate Hypersensitivity Reactions: Anaphylaxis and Allergy. During hypersensitivity reactions, histamine is one of the many potent autacoids released, and its relative contribution to the ensuing symptoms varies widely with species and tissue. The protection afforded by H_1 antagonists varies accordingly. In humans, edema formation and itch are effectively suppressed. Other effects, such as hypotension, are less well antagonized. H_1 antagonists are ineffective in blocking bronchoconstriction due to asthma.

Mast Cell–Stabilizing and Anti-inflammatory Properties. Many second-generation H_1 antagonists (e.g., *cetirizine*, *desloratadine*, *fexofenadine*, *olopatadine*, *ketotifen*, *alcaftadine*, and others) exhibit mast cell–stabilizing effects, resulting in reduced release of mast cell mediators during an allergic response (Levi-Schaffer and Eliashar, 2009). These agents also have anti-inflammatory properties, which can include reduced cytokine secretion, decreased adhesion molecule expression, and inhibition of eosinophil infiltration. These effects can be both H_1 receptor dependent and independent, but precise mechanisms are still unclear, and it is unknown what role they play at normal therapeutic doses of these drugs. There is some evidence that H_1 antagonists with these additional properties may be more effective in the topical treatment of allergic conjunctivitis (Abelson et al., 2015).

CNS. The first-generation H_1 antagonists can both stimulate and depress the CNS (Simons and Simons, 2011). Stimulation is occasionally encountered in patients given conventional doses; the patients become restless, nervous, and unable to sleep. Central excitation also is a striking feature of overdose, which commonly results in convulsions, particularly in infants. Central depression, on the other hand, usually accompanies therapeutic doses of the older H_1 antagonists. Diminished alertness, slowed reaction times, and somnolence are common manifestations. Patients vary in their susceptibility and responses to individual drugs. The ethanolamines (e.g., *diphenhydramine*) are particularly prone to causing sedation. Because of the sedation that occurs with first-generation antihistamines, these drugs cannot be tolerated or used safely by many patients except at bedtime. Even then, patients may experience an antihistamine "hangover" in the morning, resulting in sedation with or without psychomotor impairment. Second-generation H_1 antagonists are termed *nonsedating* because they do not cross the blood-brain barrier appreciably. This is due to their decreased lipophilicity and because they are substrates of P-glycoprotein, which pumps them out of the blood-brain barrier capillary endothelial cells and back into the capillary lumen (see Chapter 4 and Simons and Simons, 2011).

Many antipsychotic agents are H_1 and H_2 receptor antagonists, but it is unclear whether this property plays a role in the antipsychotic effects of these agents. In test systems, the atypical antipsychotic agent *clozapine* is an effective H_1 antagonist, a weak H_3 antagonist, and an H_4 receptor agonist. The H_1 antagonist activity of typical and atypical antipsychotic drugs is responsible for the propensity of these agents to cause weight gain.

Anticholinergic Effects. Many of the first-generation H_1 antagonists tend to inhibit muscarinic cholinergic responses and may be manifest during clinical use (Simons and Simons, 2011). Some H_1 antagonists also can be used to treat motion sickness (see Chapters 11 and 54), probably as a result of their anticholinergic properties. Indeed, *promethazine* has perhaps the strongest muscarinic-blocking activity among these agents and is the most effective H_1 antagonist in combating motion sickness. The second-generation H_1 antagonists have no effect on muscarinic receptors (Simons and Simons, 2011).

Local Anesthetic Effect. Some H_1 antagonists have local anesthetic activity, and a few are more potent than *procaine*. *Promethazine* is especially active. However, the concentrations required for this effect are much higher than those that antagonize histamine's interactions with its receptors.

ADME. The H_1 antagonists are well absorbed from the GI tract. Following oral administration, peak plasma concentrations are achieved in 1 to

3 h, and effects usually last 4 to 6 h for first-generation agents; however, some of the drugs are much longer acting, as are most second-generation H_1 antagonists (del Cuvillo et al., 2006; Simons, 2004) (Table 43–2). These agents are distributed widely throughout the body, including the CNS for the first-generation agents. Peak concentrations of these drugs in the skin may persist long after plasma levels have declined. Thus, inhibition of "wheal-and-flare" responses to the intradermal injection of histamine or allergen can persist for 36 h or more after initial treatment and up to 7 days after discontinuation of treatment in patients who regularly use an H_1 antagonist for 1 week or more (del Cuvillo et al., 2006).

All first-generation and most second-generation H_1 antagonists are metabolized by CYPs, and little, if any, is excreted unchanged in the urine; most appears there as metabolites (Bartra et al., 2006; Simons, 2004). Exceptions are *cetirizine* and *acrivastine* (<40% metabolized) and *fexofenadine*, *levocetirizine*, and *epinastine* (<10% metabolized). *Cetirizine*, *levocetirizine*, and *acrivastine* are excreted primarily into the urine; *fexofenadine* is mainly excreted in the feces; and *epinastine* is excreted in both urine (55%) and feces (30%).

The H_1 antagonists that are metabolized are eliminated more rapidly by children than by adults and more slowly in those with severe liver disease. These antagonists also have higher potential for drug interactions. For example, plasma levels of H_1 antagonists may be reduced when coadministered with drugs that induce CYP synthesis (e.g., benzodiazepines) or elevated when taken with drugs that compete with or inhibit the same CYP isoform (e.g., *erythromycin*, *ketoconazole*, antidepressants) (Bartra et al., 2006; Simons, 2004). Clinically relevant interactions are more likely with first-generation than second-generation drugs, which have a higher therapeutic index. However, two second-generation H_1 antagonists marketed previously, *terfenadine* and *astemizole*, were found in rare cases to prolong the QTc interval and induce torsade de pointes, a potentially fatal arrhythmia, due to their capacity to inhibit a cardiac K^+ channel, I_{Kr}, when their metabolism was impaired and their plasma concentrations rose too high, due, for instance, to liver disease or to drugs that inhibited the CYP3A family (Bartra et al., 2006; Simons, 2004) (see Chapter 30). This led to the withdrawal of *terfenadine* and *astemizole* from the market. *Astemizole* and an active hydroxylated metabolite naturally have very long half-lives. *Terfenadine* is a prodrug, metabolized by hepatic CYP3A4 to fexofenadine, which is its replacement and lacks noticeable cardiotoxicity. *In vitro* testing for a new drug's capacity to inhibit I_{Kr} is now available.

Therapeutic Uses

The H_1 antagonists are used for treatment of various immediate hypersensitivity reactions. The central properties of some of the drugs also are of therapeutic value for suppressing motion sickness or for sedation.

Allergic Diseases. H_1 antagonists are useful in acute types of allergy that present with symptoms of rhinitis, urticaria, and conjunctivitis (Simons and Simons, 2011). Their effect is confined to the suppression of symptoms attributable to the histamine released by the antigen-antibody reaction. In bronchial asthma, histamine antagonists have limited efficacy and are not used as sole therapy (see Chapters 42 and 44). In the treatment of systemic anaphylaxis, where autacoids other than histamine are important, the mainstay of therapy is *epinephrine*; histamine antagonists have only a subordinate and adjuvant role. The same is true for severe angioedema, in which laryngeal swelling constitutes a threat to life (see Chapter 14).

Certain allergic dermatoses respond favorably to H_1 antagonists. The benefit is most striking in acute urticaria. H_1 antagonists are also first-line therapy for chronic urticaria but may require doses up to four times higher than that approved for treating rhinitis; patients refractory to high-dose H_1 antagonists should be switched to drugs targeting the immune response (Viegas et al., 2014). H_1 antagonists have a place in the treatment of pruritus. Some relief may be obtained in many patients with atopic and contact dermatitis (although topical corticosteroids are more effective) and in such diverse conditions as insect bites and poison ivy. The urticarial and edematous lesions of serum sickness respond to H_1 antagonists, but fever and arthralgia often do not.

Common Cold. H_1 antagonists are without value in combating the common cold. The weak anticholinergic effects of the older agents may tend to lessen rhinorrhea, but this drying effect may do more harm than good, as may their tendency to induce somnolence.

Motion Sickness, Vertigo, and Sedation. *Scopolamine*, the muscarinic antagonist, given orally, parenterally, or transdermally, is the most effective drug for the prophylaxis and treatment of motion sickness. Some H_1 antagonists are useful for milder cases and have fewer adverse effects. These drugs include *dimenhydrinate* and the piperazines (e.g., *cyclizine*, *meclizine*). *Promethazine*, a phenothiazine, is more potent and more effective, and its additional antiemetic properties may be of value in reducing vomiting; however, its pronounced sedative action usually is disadvantageous. Whenever possible, the various drugs should be administered about 1 h before the anticipated motion. Treatment after the onset of nausea and vomiting rarely is beneficial. Some H_1 antagonists, notably *dimenhydrinate* and *meclizine*, often are of benefit in vestibular disturbances such as Ménière disease and other types of true vertigo. Only *promethazine* is useful in treating the nausea and vomiting subsequent to chemotherapy or radiation therapy for malignancies; however, other, more effective, antiemetic drugs (e.g., serotonin $5HT_3$ antagonists) are available (see Chapter 54). *Diphenhydramine* can reverse the extrapyramidal side effects caused by antipsychotics (see Chapter 19). The tendency of some H_1 receptor antagonists to produce somnolence has led to their use as hypnotics. H_1 antagonists, principally *diphenhydramine*, often are present in various proprietary over-the-counter remedies for insomnia. The sedative and mild antianxiety activities of *hydroxyzine* contribute to its use as an anxiolytic.

Adverse Effects

The most frequent side effect of first-generation H_1 antagonists is sedation. Concurrent ingestion of alcohol or other CNS depressants produces an additive effect that impairs motor skills. Other untoward central actions include dizziness, tinnitus, lassitude, incoordination, fatigue, blurred vision, diplopia, euphoria, nervousness, insomnia, and tremors. Additional potential side effects, including loss of appetite, nausea, vomiting, epigastric distress, and constipation or diarrhea, may be reduced by taking the drug with meals. H_1 antagonists such as *cyproheptadine* may increase appetite and cause weight gain. Other side effects, owing to the antimuscarinic actions of some first-generation H_1 antagonists, include dryness of the mouth and respiratory passages (sometimes inducing cough), urinary retention or frequency, and dysuria. These effects are not observed with second-generation H_1 antagonists. Allergic dermatitis is not uncommon; other hypersensitivity reactions include drug fever and photosensitization. Hematological complications, such as leukopenia, agranulocytosis, and hemolytic anemia, are very rare.

Because H_1 antihistamines cross the placenta, caution is advised for women who are or may become pregnant (Simons and Simons, 2011). Several antihistamines (e.g., *azelastine*, *hydroxyzine*, *fexofenadine*) had teratogenic effects in animal studies, whereas others (e.g., *chlorpheniramine*, *diphenhydramine*, *cetirizine*, *loratadine*) did not. A recent systematic review concluded that antihistamines are unlikely to be strong risk factors for major birth defects (Gilboa et al., 2014). A combination drug consisting of the H_1 antagonist *doxylamine* and vitamin B_6 (*pyridoxine*) was approved in 1956 for treating the nausea and vomiting of pregnancy and then voluntarily removed in 1983 due to concerns over birth defects. Subsequent analyses showed the drug caused no increased risk of birth defects, and in 2013, it was reapproved for the same indication in a fixed-dose, delayed-release formulation. Antihistamines can be excreted in small amounts in breast milk, and first-generation antihistamines taken by lactating mothers may cause symptoms such as irritability, drowsiness, or respiratory depression in the nursing infant.

In acute poisoning with first-generation H_1 antagonists, their central excitatory effects constitute the greatest danger. The syndrome includes hallucinations, excitement, ataxia, incoordination, athetosis, convulsions, and fixed, dilated pupils with a flushed face, together with sinus tachycardia, urinary retention, dry mouth, and fever. The syndrome exhibits a remarkable similarity to that of *atropine* poisoning. Terminally, there is

TABLE 43–2 ■ PREPARATIONS AND DOSAGE OF REPRESENTATIVE H_1 RECEPTOR ANTAGONISTS[a]

CLASS *Generic Name*	DURATION OF ACTION (h)[b]	PREPARATIONS[c]	SINGLE DOSE (adult)
First-generation agents			
Tricyclic dibenzoxepins			
Doxepin HCl	6–24	O, L, T	10–150 mg; insomnia: 6 mg (O) Pruritus: thin film 4 times/day (T)
Ethanolamines			
Carbinoxamine maleate	3–6	O, L	4–8 mg; 6–16 mg (SR)
Clemastine fumarate	12	O, L	1.34–2.68 mg
Diphenhydramine HCl	12	O, L, I, T	25–50 mg (O/L/I)
Dimenhydrinate[d]	4–6	O, I	50–100 mg
Ethylenediamines			
Pyrilamine maleate (only in combination products)	4–6	O, L	7.5–30 mg
Alkylamines			
Chlorpheniramine maleate	24	O, L, I, SR	4 mg, 12 mg (SR)
Brompheniramine maleate	4–6	O, L, I, SR	2 mg
Piperazines			
Hydroxyzine HCl	6–24	O, L, I	25–100 mg
Hydroxyzine pamoate	6–24	O, L (not in the U.S.)	25–100 mg
Cyclizine HCl	4–6	O	50 mg
Cyclizine lactate (not in the U.S.)	4–6	I	50 mg
Meclizine HCl	12–24	O	25–50 mg
Phenothiazines			
Promethazine HCl	4–6	O, L, I, S	12.5–50 mg
Piperidines			
Cyproheptadine HCl[e]	4–6	O, L	1–6.5 mg
Second-generation agents			
Tricyclic dibenzoxepins			
Olopatadine HCl	6–12	T	2 sprays/nostril; 1 drop/eye
Alkylamines			
Acrivastine[f]	6–8	O	8 mg
Piperazines			
Cetirizine HCl[f]	12–24	O, L	5–10 mg
Levocetirizine HCl	12–24	O, L	2.5–5 mg
Piperidines			
Alcaftadine	16–24	T	1 drop/eye
Bepotastine besilate	8	T	1 drop/eye
Desloratadine	24	O, L	5 mg
Fexofenadine HCl	12–24	O, L	60–180 mg
Ketotifen fumarate	8–12	T	1 drop/eye
Loratadine	24	O, L	10 mg
Other second-generation drugs			
Azelastine HCl[f]	12–24	T	2 sprays/nostril; 1 drop/eye
Emedastine	8–12	T	1 drop/eye
Epinastine	8–12	T	1 drop/eye

[a]For a discussion of phenothiazines, see Chapter 19.
[b]Duration of action of H_1 antihistamines by objective assessment of suppression of histamine- or allergen-induced symptoms is longer than expected from measurement of plasma concentrations or terminal elimination $t_{1/2}$ values.
[c]Preparations are designated as follows: O, oral solids; L, oral liquids; I, injection; S, suppository; SR, sustained release; T, topical. Many H_1 receptor antagonists also are available in preparations that contain multiple drugs. SR forms dissuade pseudoephedrine extraction for methamphetamine production.
[d]Dimenhydrinate is a combination of diphenhydramine and 8-chlorotheophylline in equal molecular proportions.
[e]Also has antiserotonin properties.
[f]Has mild sedating effects.

deepening coma with cardiorespiratory collapse and death usually within 2 to 18 h. Treatment is along general symptomatic and supportive lines. Overdoses of second-generation H_1 antagonists have not been associated with significant toxicity (Simons and Simons, 2011).

Pediatric and Geriatric Indications and Problems. Although little clinical testing has been done, second-generation antihistamines are preferred for elderly patients (>65 years of age), especially those with impaired cognitive function, because they lack the sedative and anticholinergic effects of first-generation drugs (Simons, 2004). In addition, a recent prospective study in participants 65 years old and older without dementia showed a significant 10-year cumulative dose-response relationship between use of anticholinergics (first-generation H_1 antagonists among the most common) and risk of dementia, primarily Alzheimer's disease (Gray et al., 2015).

First-generation antihistamines are not recommended for use in children because their sedative effects can impair learning and school performance. The second-generation drugs have been approved by the FDA for use in children and are available in appropriate lower-dose formulations (e.g., chewable or rapidly dissolving tablets, syrup). Use of over-the-counter cough and cold medicines (containing mixtures of antihistamines, decongestants, antitussives, and expectorants) in young children has been associated with serious side effects and deaths. In 2008, the FDA recommended that they should not be used in children less than 2 years of age, and drug manufacturers affiliated with the Consumer Healthcare Products Association voluntarily relabeled products "do not use" for children less than 4 years of age.

Available H_1 Antagonists

Summarized next are notable properties of a number of H_1 antagonists, grouped by their chemical structures. Representative preparations are listed in Table 43–2. Second-generation H_1 antagonists cause fewer adverse effects and are superior in safety compared to older first-generation H_1 antagonists (Fein et al., 2019).

First-Generation Dibenzoxepin Tricyclic (Doxepin). *Doxepin* is marketed as a tricyclic antidepressant (see Chapter 18). It also is one of the most potent H_1 antagonists and has significant H_2 antagonist activity, but this does not translate into greater clinical effectiveness. It can cause drowsiness and is associated with anticholinergic effects. *Doxepin* is better tolerated by patients with depression than by those who are not depressed, for whom even small doses may cause disorientation and confusion.

Second-Generation Dibenzoxepin Tricyclic (Olopatadine). Olopatadine is a topical H_1 antagonist with additional mast cell–stabilizing and anti-inflammatory properties. In drop form, it is an effective treatment of allergic conjunctivitis and as a spray helps reduce the nasal symptoms of allergic rhinitis.

Ethanolamines (Prototype: Diphenhydramine). The ethanolamines possess significant antimuscarinic activity and have a pronounced tendency to induce sedation. About half of those treated acutely with conventional doses experience somnolence. The incidence of GI side effects, however, is low with this group.

Ethylenediamine (Prototype: Pyrilamine). *Pyrilamine* is among the most specific H_1 antagonists. Although its central effects are relatively feeble, somnolence occurs in a fair proportion of patients. GI side effects are common.

First-Generation Alkylamines (Prototype: Chlorpheniramine). The first-generation alkylamines are among the most potent H_1 antagonists. The drugs are less prone to produce drowsiness and are more suitable for daytime use, but a significant proportion of patients still experience sedation. Side effects involving CNS stimulation are more common than with other groups.

Second-Generation Alkylamine (Acrivastine). The second-generation alkylamine is a derivative of the first-generation alkylamine *triprolidine* and may exhibit a somewhat higher incidence of mild sedation than other second-generation H_1 antagonists.

First-Generation Piperazines. *Hydroxyzine* is a long-acting compound that is used widely for skin allergies; its considerable CNS-depressant activity may contribute to its prominent antipruritic action, and it is also used as a sedative and antianxiety agent. *Cyclizine* and *meclizine* have been used primarily to counter motion sickness, although *promethazine* and *diphenhydramine* are more effective (as is the antimuscarinic *scopolamine*).

Second-Generation Piperazines (Cetirizine). *Cetirizine* has minimal anticholinergic effects. It also has negligible penetration into the brain but is associated with a somewhat higher incidence of drowsiness than most other second-generation H_1 antagonists. The active enantiomer *levocetirizine* has slightly greater potency and may be used at half the dose with less resultant sedation. *Cetirizine* and *levocetirizine* have additional mast cell–stabilizing and anti-inflammatory properties.

Phenothiazines (Prototype: Promethazine). *Promethazine*, which has prominent sedative and considerable anticholinergic effects, and its many congeners are used primarily for their antiemetic effects (see Chapter 54).

First-Generation Piperidine (Cyproheptadine). *Cyproheptadine* uniquely has both antihistamine and antiserotonin activity by antagonizing the $5HT_{2A}$ receptor. *Cyproheptadine* causes drowsiness; it also has significant anticholinergic effects and can increase appetite.

Second-Generation Piperidines (Prototype: Loratadine). *Terfenadine* and *astemizole*, early second-generation drugs, are no longer marketed because of their potential for causing a rare, but potentially fatal, arrhythmia, torsade de pointes (see previous discussion). *Terfenadine* was replaced by *fexofenadine*, an active metabolite that lacks the toxic side effects of *terfenadine*, is not sedating, and retains the antiallergic properties of the parent compound. Another antihistamine of this class developed using this strategy is *desloratadine*, an active metabolite of *loratadine*. These agents lack significant anticholinergic actions and penetrate poorly into the CNS. Taken together, these properties appear to account for the low incidence of side effects of piperidine antihistamines. All members of this class have mast cell–stabilizing and anti-inflammatory properties. Although the therapeutic significance of these additional effects is unclear for the drugs administered orally, they appear to provide additional benefit when used in topical formulations to treat allergic conjunctivitis. *Alcaftadine* has additional antagonist activity on H_4 receptors, which likely explains its superiority to other topical H_1 antagonists in reducing the ocular itch of allergic conjunctivitis (Thurmond, 2015).

Other Second-Generation H_1 Antagonists. Drugs in this group (*azelastine*, *emedastine*, and *epinastine*) have divergent structures with therapeutic efficacy and side effects similar to other second-generation H_1 antagonists. They all are marketed as topical eye drops for the treatment of allergic conjunctivitis; *azelastine* is also available as a nasal spray for treating symptoms of allergic or vasomotor rhinitis. *Epinastine* has both H_1 and H_2 antagonist activity, which may help reduce eyelid edema. *Epinastine* and *azelastine* exhibit mast cell–stabilizing and anti-inflammatory properties. *Emedastine* is a highly selective H_1 antagonist without these additional actions.

H_2 Receptor Antagonists

The pharmacology and clinical utility of H_2 antagonists (e.g., *cimetidine*, *ranitidine*) for inhibiting gastric acid secretion in the treatment of GI disorders are described in Chapter 53.

H_3 Receptor Antagonists

The H_3 receptors are presynaptic autoreceptors on histaminergic neurons that originate in the tuberomammillary nucleus in the hypothalamus and project throughout the CNS, most prominently to the hippocampus, amygdala, nucleus accumbens, globus pallidus, striatum, hypothalamus, and cortex (Haas et al., 2008; Sander et al., 2008). The activated H_3 receptor depresses neuronal firing at the level of cell bodies/dendrites and decreases histamine release from depolarized terminals. Thus, H_3 agonists decrease histaminergic transmission, and antagonists increase it.

The H_3 receptors also are presynaptic heteroreceptors on a variety of neurons in brain and peripheral tissues, and their activation inhibits

transmitter release from noradrenergic, serotoninergic, GABAergic, cholinergic, and glutamatergic neurons, as well as pain-sensitive C fibers. H_3 receptors in the brain have significant constitutive activity in the absence of agonist; consequently, inverse agonists reduce this constitutive activity, withdraw inhibition of transmitter release, and thereby promote transmitter release (activation of these neurons).

The H_3 antagonists/inverse agonists have a wide range of central effects; for example, they promote wakefulness, improve cognitive function (e.g., enhance memory, learning, and attention), and reduce food intake. As a result, there is considerable interest in developing H_3 antagonists for possible treatment of sleeping disorders, ADHD (attention-deficit/hyperactivity disorder), epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer's disease (Haas et al., 2008; Sander et al., 2008).

Thioperamide was the first "specific" H_3 antagonist/inverse agonist available experimentally, but it was equally effective at the H_4 receptor. A number of other imidazole derivatives have been developed as H_3 antagonists, including *clobenpropit*, *ciproxifan*, and *proxyfan*, but the imidazole ring enhances binding to the H_4 receptor and CYPs. Because of this, more selective nonimidazole H_3 antagonists/inverse agonists (*thioperamide*, *ciproxifan*, *pitolisant*) were developed (Haas et al., 2008; Sander et al., 2008).

Based on the functions of H_3 receptors in the CNS, H_3 antagonists have potential in the treatment of sleeping disorders, ADHD, epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer's disease. The selective H_3 receptor antagonist/inverse agonist *pitolisant* demonstrated efficacy in the treatment of excessive daytime sleepiness or cataplexy in adults with narcolepsy (Wang, 2021) and is now FDA-approved. *Pitolisant* was also shown to be effective for the treatment of daytime sleepiness in patients with obstructive sleep apnea. *Pitolisant* binds with high affinity to H_3 receptors (K_i = 1 nM), without appreciable affinity for H_1, H_2, or H_4 receptors (K_i > 10 μM).

H_4 Receptor Antagonists

The H_4 receptors are expressed on cells with inflammatory or immune functions and can mediate histamine-induced chemotaxis, induction of cell shape change, secretion of cytokines, and upregulation of adhesion molecules (Thurmond et al., 2008). The H_4 receptors also have a role in pruritus and neuropathic pain. Because of the unique localization and function of H_4 receptors, H_4 antagonists are promising candidates to treat inflammatory conditions and possibly pruritus and neuropathic pain (Thurmond, 2015).

The H_4 receptor has the highest homology with the H_3 receptor and binds many H_3 ligands, especially those with imidazole rings, although sometimes with different effects (Thurmond et al., 2008). For example, *thioperamide* is an effective inverse agonist at both H_3 and H_4 receptors, whereas the H_3 inverse agonist *clobenpropit* is a partial agonist of the H_4 receptor; *impentamine* (an H_3 agonist) and *iodophenpropit* (an H_3 inverse agonist) are both neutral H_4 antagonists.

H_4-specific antagonists have been tested in phase I and II clinical trials for treatment of persistent asthma, pruritis, dermatitis, and rheumatoid arthritis. JNJ39758979 showed benefit for the treatment of eosinophilic asthma but did not meet the study primary endpoint. Another H_4 receptor antagonist, ZPL-3893787, effected significant improvement in atopic dermatitis scores in patients with moderate-to-severe disease. No H_4 receptor antagonist has yet been FDA-approved.

Bradykinin, Kallidin, and Their Antagonists

In the 1920s and 1930s, Frey, Kraut, and Werle characterized a hypotensive substance in urine, which was also found in other fluids and tissues, and named this material *kallikrein* after a Greek synonym for the pancreas, an especially rich source (Werle, 1970). It was established that kallikrein generates a pharmacologically active substance from an inactive precursor present in plasma; the active substance, *kallidin*, proved to be a polypeptide cleaved from a plasma globulin (Werle, 1970). Rocha e Silva, Beraldo, and associates later reported that trypsin and certain snake venoms acted on plasma globulin to produce a substance that lowered blood pressure and caused a slowly developing contraction of the gut (Rocha e Silva et al., 1949); they named it *bradykinin*, derived from the Greek words *bradys*, meaning "slow," and *kinein*, meaning "to move." In 1960, bradykinin, a nine amino acid peptide, was isolated and synthesized; shortly thereafter, kallidin was identified as bradykinin with an additional N-terminal Lys residue. The kinins have short half-lives because they are destroyed by plasma and tissue peptidases (Erdös and Skidgel, 1997). Two types of kinin receptors, B_1 and B_2, were identified based on the rank order of potency of kinin analogues and later validated by cloning (Leeb-Lundberg et al., 2005). The development of receptor-specific antagonists and receptor knockout mice has furthered our understanding of the role of kinins in the regulation of cardiovascular homeostasis and inflammatory processes (Leeb-Lundberg et al., 2005).

Tissue damage, allergic reactions, viral infections, and other inflammatory events activate a series of proteolytic reactions that generate bradykinin and kallidin in tissues. These peptides contribute to inflammatory responses as autacoids that act locally to produce pain, vasodilation, and increased vascular permeability but can also have beneficial effects, for example, in the heart, kidney, and circulation (Bhoola et al., 1992). Much of their activity is due to stimulation of the release of potent mediators such as prostaglandins, NO, or EDHF (endothelial-derived hyperpolarizing factor).

The Endogenous Kallikrein-Kininogen-Kinin Systems

The nonapeptide bradykinin and decapeptide kallidin (*lysyl-bradykinin*) (Table 43–3) are cleaved from α_2 globulins termed *kininogens* (Figure 43–4). There are two kininogens: high molecular weight (HMW) kininogen and low molecular weight (LMW) kininogen. A number of serine proteases will generate kinins, but the two highly specific proteases that release bradykinin and kallidin from the kininogens are termed *kallikreins*. Bradykinin and kallidin are the natural ligands for the bradykinin B_2 receptor (BDKRB2), while the carboxypeptidase-cleaved

TABLE 43–3 ■ STRUCTURE OF KININ AGONISTS AND ANTAGONISTS

NAME	STRUCTURE	FUNCTION
Bradykinin	Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg	Agonist, B_2
Kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg	Agonist, B_2
[des-Arg^9]-Bradykinin	Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe	Agonist, B_1
[des-Arg^{10}]-Kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe	Agonist, B_1

Hyp, trans-4-hydroxy-Pro; Thi, β-(2-thienyl)-Ala; Tic, [D]-1,2,3,4-tetrahydroisoquinolin-3-yl-carbonyl; Oic, (3aS, 7aS)-octahydroindol-2-yl-carbonyl.

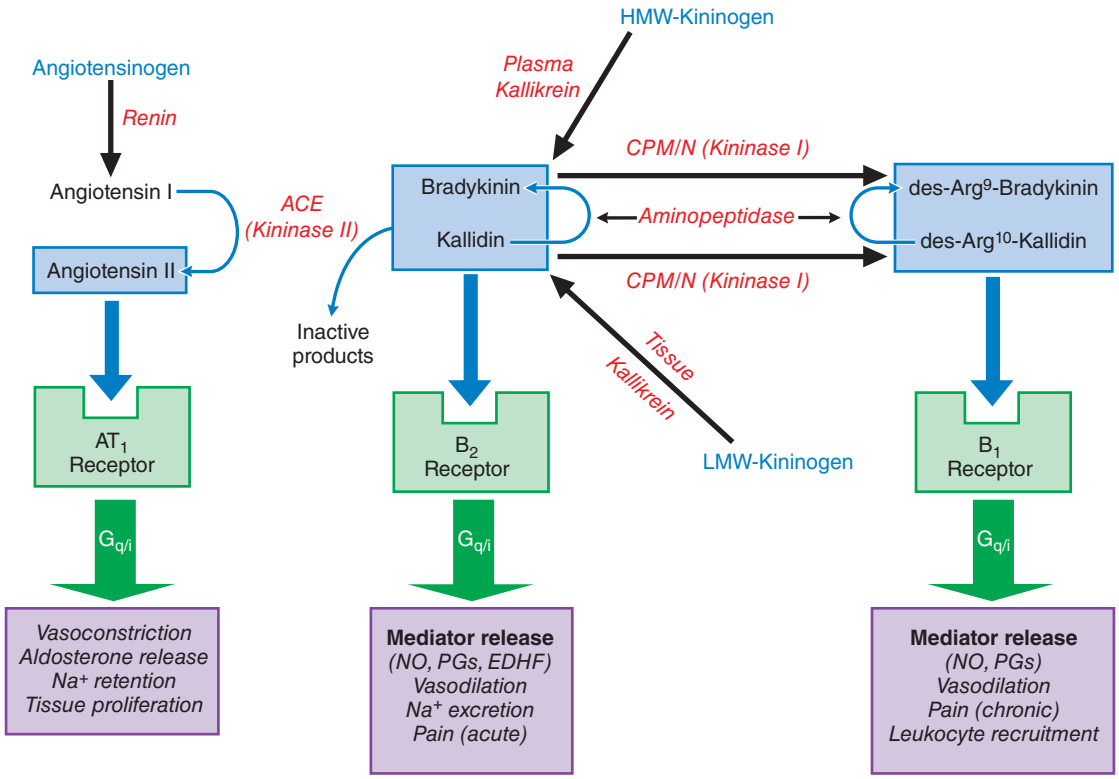

Figure 43–4 *Synthesis and receptor interactions of active peptides generated by the kallikrein-kinin and renin-angiotensin systems.* Bradykinin is generated by the action of plasma kallikrein on HMW kininogen, whereas kallidin (Lys1-bradykinin) is released by the hydrolysis of LMW kininogen by tissue kallikrein. Kallidin and bradykinin are the natural ligands of the B_2 receptor but can be converted to corresponding agonists of the B_1 receptor by removal of the C-terminal Arg by kininase I–type enzymes: the plasma membrane–bound CPM or soluble plasma CPN. Kallidin or [des-Arg^{10}]-kallidin can be converted to the active peptides bradykinin or to [des-Arg^9]-bradykinin by aminopeptidase cleavage of the N-terminal Lys residue. In a parallel fashion, the inactive decapeptide AngI is generated by the action of renin on the plasma substrate angiotensinogen. By removal of the C-terminal His-Leu dipeptide, ACE generates the active peptide AngII. These two systems have opposing effects. AngII is a potent vasoconstrictor that also causes aldosterone release and Na^+ retention via activation of the AT_1 receptor; bradykinin is a vasodilator that stimulates Na^+ excretion by activating the B_2 receptor. ACE generates active AngII and, at the same time, inactivates bradykinin and kallidin; thus, its effects are prohypertensive, and ACE inhibitors are effective antihypertensive agents. The B_2 receptor mediates most of bradykinin's effects under normal circumstances, whereas synthesis of the B_1 receptor is induced by inflammatory mediators in inflammatory conditions. Both B_1 and B_2 receptors couple through G_q to activate PLC and increase intracellular Ca^{2+}; the physiological response depends on receptor distribution on particular cell types and occupancy by agonist peptides. For instance, on endothelial cells, activation of B_2 receptors results in Ca^{2+}-calmodulin–dependent activation of eNOS and generation of NO, which causes cyclic GMP accumulation and relaxation in neighboring smooth muscle cells. However, in endothelial cells under inflammatory conditions, B_1 receptor stimulation results in prolonged NO production via G_i and an acute MAP kinase–dependent activation of iNOS. On smooth muscle cells, activation of kinin receptors coupling through G_q results in an increased $[Ca^{2+}]_i$ and contraction. B_1 and B_2 receptors also can couple through G_i to activate PLA_2, causing the release of arachidonic acid and the local generation of prostanoids and other metabolites such as EDHF. Kallikrein also plays a role in the intrinsic blood coagulation pathway (see Chapter 36). CPM, carboxypeptidase M; CPN, carboxypeptidase N; EDHF, endothelial-derived hyperpolarizing factor.

des-Arg products of these peptides are the natural ligands for the bradykinin B_1 receptor (BDKB1R).

Kallikreins

Bradykinin and kallidin are cleaved from HMW or LMW kininogens by plasma or tissue kallikrein, respectively (see Figure 43–4). Plasma kallikrein and tissue kallikrein are distinct enzymes that are activated by different mechanisms (Bhoola et al., 1992). Plasma prekallikrein is an inactive protein of about 88 kDa that complexes with its substrate, HMW kininogen. The ensuing proteolytic cascade is normally restrained by the protease inhibitors present in plasma, most importantly C1-INH (the inhibitor of the activated first component of complement) and α_2 macroglobulin. Under experimental conditions, the plasma kallikrein-kinin system (also called the plasma contact system) is activated by the binding of factor XII (*Hageman factor*) to negatively charged surfaces. Bound factor XII, a protease that is common to both the kinin and the intrinsic coagulation cascades (see Chapter 36), slowly undergoes autoactivation and, in turn, activates prekallikrein. Importantly, kallikrein rapidly further activates factor XII, thereby exerting a positive feedback on the system. *In vivo*, the order of this process can be reversed. The binding of the HMW kininogen–prekallikrein complex to endothelial cells leads to activation of the prekallikrein–HMW kininogen complex by either heat shock protein 90 (Hsp90) or prolylcarboxypeptidase to generate kallikrein, which can then activate factor XII to start the positive-feedback loop and cleave HMW kininogen to generate bradykinin (Kaplan and Joseph, 2014). This process may contribute to the symptoms of hereditary angioedema in patients who are deficient in C1-INH.

Human tissue kallikreins compose a 15-member gene family with high sequence identity that are clustered at chromosome 19q13.4 (Prassas et al., 2015). However, the classical "tissue kallikrein," hK1, is the only family member to readily generate kallidin from LMW kininogen. Tissue kallikrein is synthesized as a 29-kDa preproprotein in the epithelial cells or secretory cells in several tissues, including salivary glands, pancreas, prostate, and renal distal nephron (Bhoola et al., 1992). Tissue kallikrein also is expressed in human neutrophils; it acts locally near its sites of origin. The synthesis of tissue preprokallikrein is controlled by a number of factors, including aldosterone in the kidney and salivary gland and androgens in certain other glands. Preprokallikrein is cleaved to the zymogen prokallikrein when secreted. The activation of prokallikrein to active tissue kallikrein requires proteolytic cleavage to remove a seven–amino acid propeptide, which can be accomplished *in vitro* by plasma

kallikrein and by some serine and metalloproteases. However, the activating enzyme(s) *in vivo* is unknown.

Kininogens

The two substrates for the kallikreins, HMW kininogen (120 kDa) and LMW kininogen (66 kDa), are derived from a single gene by alternative splicing. The first 401 amino acids are identical (through the bradykinin sequence and 12 additional residues) and then the sequences diverge, with HMW kininogen containing a 56-kDa C-terminal light chain and LMW kininogen a 4-kDa light chain (Bhoola et al., 1992). HMW kininogen is cleaved by both plasma and tissue kallikrein to yield bradykinin and kallidin, respectively, whereas LMW kininogen is cleaved only by tissue kallikrein to produce kallidin. In addition to being substrates for kallikreins, kininogens are also cysteine protease inhibitors.

Metabolism of Kinins

The decapeptide kallidin is about as active as the nonapeptide bradykinin, even without conversion to bradykinin, which occurs when the N-terminal lysine residue is removed by an aminopeptidase (see Figure 43–4). The $t_{1/2}$ of kinins in plasma is only about 15 sec; 80% to 90% of the kinins may be destroyed in a single passage through the pulmonary vascular bed by enzymes present on the large endothelial surface area of the lung (Erdös and Skidgel, 1997). Plasma concentrations of bradykinin are difficult to measure because inadequate inhibition of kininogenases or kininases in the blood can lead to artifactual formation or degradation of bradykinin during blood collection. When care is taken to inhibit these processes, the reported physiological concentrations of bradykinin in blood are in the picomolar range.

The principal catabolizing enzyme in the lung and other vascular beds is kininase II, or ACE (angiotensin I–converting enzyme), a membrane-anchored peptidase on the surface of endothelial cells (see Chapter 30). Removal of the C-terminal dipeptide by ACE or neutral endopeptidase 24.11 (neprilysin) inactivates kinins (Figure 43–5) (Erdös and Skidgel, 1997). A slower-acting plasma enzyme, carboxypeptidase N (lysine carboxypeptidase, kininase I), releases the C-terminal arginine residue, producing [desArg^9]-bradykinin or [des-Arg^{10}]-kallidin (see Table 43–3 and Figures 43–4 and 43–5) (Skidgel and Erdös, 2007), both of which no longer activate B_2 receptors but are B_1 receptor agonists. Carboxypeptidase N is expressed in the liver and constitutively secreted into the blood. A rare familial carboxypeptidase N deficiency was associated with angioedema or urticaria, possibly due to increased bradykinin (Skidgel and Erdös, 2007). Carboxypeptidase M, which cleaves the C-terminal Arg of bradykinin about 3-fold faster than carboxypeptidase N, is a widely distributed plasma membrane–bound enzyme that is also found on lung microvascular endothelial cells (Zhang et al., 2013a). Finally, aminopeptidase P is a membrane enzyme on epithelial and endothelial cells that can cleave the N-terminal arginine of bradykinin, rendering it inactive and susceptible to further cleavage by dipeptidyl peptidase IV (Erdös and Skidgel, 1997) (see Figure 43–5).

Kinin Receptors and Their Signaling Pathways

The B_1 and B_2 kinin receptors are GPCRs whose signaling mediates most of the biological effects of the kallikrein-kinin system (Leeb-Lundberg et al., 2005). The B_2 receptor is constitutively expressed in most normal tissues, where it selectively binds intact bradykinin and kallidin (see Table 43–3 and Figure 43–4). The B_2 receptor mediates the effects of bradykinin and kallidin under normal circumstances, whereas synthesis of the B_1 receptor is induced by inflammatory conditions. The B_1 receptor is activated by the C-terminal des-Arg metabolites of bradykinin and kallidin produced by the actions of carboxypeptidases N and M. While [des-Arg^{10}]-kallidin is a potent B_1 receptor agonist, [desArg^9]-bradykinin is a relatively weak B_1 receptor agonist in humans as opposed to rodents where it is a potent agonist. Interestingly, carboxypeptidase M and the B_1 receptor interact on the cell surface to form an efficient signaling complex that enhances B_1 receptor agonist affinity and can lead to allosteric activation of B_1 receptor signaling by substrate binding to carboxypeptidase M (Zhang et al., 2013a, 2013b). B_1 receptors are normally absent or expressed at low levels in most tissues. B_1 receptor expression is upregulated by tissue injury and inflammation and by cytokines, endotoxins, and growth factors. Carboxypeptidase M expression also is increased by cytokines, to such a degree that B_1 receptor effects may predominate over B_2 effects (Zhang et al., 2013a).

Both B_1 and B_2 receptors couple through G_q to activate PLC and increase intracellular Ca^{2+}; the physiological response depends on receptor distribution on particular cell types, the cell environment, and mediators generated (Leeb-Lundberg et al., 2005). For example, on normal endothelial cells, activation of B_2 receptors results in G_q and Ca^{2+}-calmodulin–dependent activation of eNOS and short-term generation of NO, which causes cyclic GMP accumulation and relaxation in neighboring smooth muscle cells. However, direct activation of B_1 or B_2 receptors on smooth muscle cells leads to coupling through G_q and increased $[Ca^{2+}]_i$, resulting in contraction.

Inflammatory conditions alter receptor signaling in endothelial cells, such that B_2 receptor stimulation leads to prolonged eNOS-derived NO that depends on G_i-mediated activation of MEK1/2 and JNK1/2, whereas B_1 receptor activation couples through G_i and MAP kinase activation to cause ERK1/2-mediated phosphorylation and activation of iNOS (inducible nitric oxide synthase), which generates prolonged, high-output NO (Kuhr et al., 2010; Lowry et al., 2013). Both B_1 and B_2 receptor stimulation activate the proinflammatory transcription factor NF-κB (nuclear factor-κB) coupled through $G\alpha_q$ and βγ subunits and also activate the MAP kinase pathway (Leeb-Lundberg et al., 2005). B_1 and B_2 receptors also can couple through G_i to activate PLA_2, causing the release of arachidonic acid and the local generation of metabolites such as prostaglandins and vasodilator epoxyeicosatrienoic acids (EETs) (Campbell and Falck, 2007).

The B_1 and B_2 receptors differ in their time courses of downregulation after agonist stimulation; the B_2 receptor response is rapidly desensitized, whereas the B_1 response is not (Leeb-Lundberg et al., 2005). This likely is

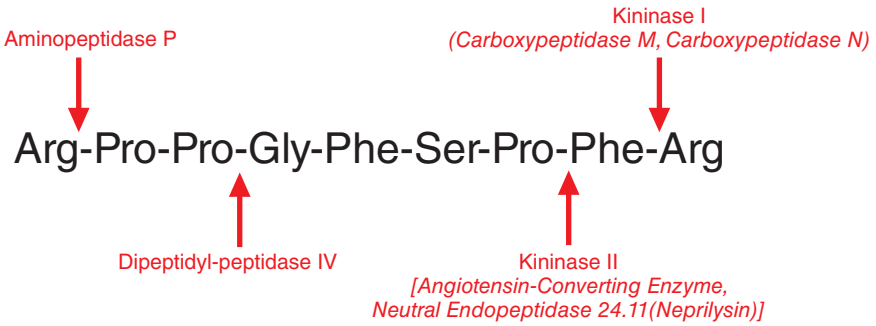

Figure 43–5 *Schematic diagram of the degradation of bradykinin.* Arrows denote the primary cleavage sites in bradykinin. Bradykinin and kallidin are inactivated *in vivo* primarily by kininase II (ACE). Neutral endopeptidase 24.11 (neprilysin) cleaves bradykinin and kallidin at the same Pro-Phe bond as ACE and also is classified as a kininase II–type enzyme. In addition, aminopeptidase P can inactivate bradykinin by hydrolyzing the N-terminal Arg1-Pro2 bond, leaving bradykinin susceptible to further degradation by dipeptidyl peptidase IV. Bradykinin and kallidin are converted to their respective des-Arg^9 or des-Arg^{10} metabolites by kininase I–type carboxypeptidases M and N. Unlike the parent peptides, these kinin metabolites are potent ligands for B_1 kinin receptors but not B_2 kinin receptors.

due to modification at a Ser/Thr-rich cluster present in the C-terminal tail of the B_2 receptor that is not conserved in the B_1 receptor sequence. However, the B_1 receptor can heterodimerize with the B_2 receptor and in this form can be cross-desensitized by activation of the B_2 receptor with agonist (Zhang et al., 2015). Another difference between B_1 and B_2 receptors is that the B_1 receptor shows high constitutive activity when expressed.

Physiological and Pharmacological Effects of Kallikrein-Kinin Pathways

Kinins play important physiological and pathophysiological roles. Our understanding of the precise roles of kinins has been hampered by the difficulty in measuring activation of the pathways due to the short half-lives of kinins as well as the difficulties in preventing *ex vivo* activation of the pathways.

Physiological Effects of Kinins

Cardiovascular

Infusion of bradykinin causes vasodilation and lowers blood pressure. Bradykinin causes vasodilation by activating its B_2 receptor on endothelial cells, resulting in the generation of NO, prostacyclin, and a hyperpolarizing EET that is a CYP-derived metabolite of arachidonate (Campbell and Falck, 2007). Animals deficient in tissue kallikrein display arterial function abnormalities with impaired flow-dependent vasodilation and endothelial dysfunction. The endogenous kallikrein-kinin system plays a minor role in the regulation of normal blood pressure, but it may be important in hypertensive states. Urinary kallikrein concentrations are decreased in individuals with high blood pressure.

The kallikrein-kinin system is cardioprotective. Many of the beneficial effects of ACE inhibitors on cardiac function are attributable to enhancement of bradykinin effects, such as their antiproliferative activity or ability to increase tissue glucose uptake (Heitsch, 2003; Madeddu et al., 2007). Bradykinin contributes to the beneficial effect of preconditioning to protect the heart against ischemia and reperfusion injury. Bradykinin also stimulates tissue plasminogen activator release from the vascular endothelium and may contribute to the endogenous defense against some cardiovascular events, such as myocardial infarction and stroke (Heitsch, 2003; Madeddu et al., 2007).

As a substrate of the endopeptidase neprilysin, bradykinin is theorized to be involved in the cardioprotective mechanism of *sacubitril/valsartan*, a novel angiotensin receptor–neprilysin inhibitor (ARNI) combination drug that is used to decrease mortality in heart failure. The cardioprotective, natriuretic, and blood pressure–lowering effects of this drug are under investigation.

Kidney

Renal kinins act in a paracrine manner to regulate urine volume and composition. Kallikrein is synthesized and secreted by the connecting cells of the distal nephron. Tissue kininogen and kinin receptors are present in the cells of the collecting duct. Like other vasodilators, kinins increase renal blood flow. Bradykinin also causes natriuresis by inhibiting Na^+ reabsorption at the cortical collecting duct. Treatment with mineralocorticoids, ACE inhibitors, and inhibitors of neutral endopeptidase (neprilysin) increases renal kallikrein. Kinins have been shown to protect against diabetic nephropathy, thereby protecting against renal insufficiency.

Pathological Effects of Kinins

Angioedema

Plasma kinins increase permeability in the microcirculation, acting on the small venules to cause disruption of the interendothelial junctions. This, together with an increased hydrostatic pressure gradient, causes edema. The major mechanism of angioedema in patients with C1 inhibitor deficiency (hereditary angioedema due to C1 inhibitor deficiency and acquired C1 inhibitor deficiency) is increased generation of bradykinin due to dysregulation of the plasma kallikrein-kinin system (Busse and Christiansen, 2020). There is also evidence that some forms of hereditary angioedema with normal C1 inhibitor are due to bradykinin. Finally, angioedema associated with use of ACE inhibitors may be caused by the prolonged half-life of bradykinin when ACE is inhibited.

Respiratory Disease

Kinins have been implicated in allergic airway disorders such as asthma and rhinitis (Abraham et al., 2006). Inhalation of kinins causes bronchospasm mimicking an asthma attack in asthmatic patients but not in normal individuals. This bradykinin-induced bronchoconstriction is blocked by anticholinergic agents but not by antihistamines or cyclooxygenase inhibitors. Similarly, nasal challenge with bradykinin is followed by sneezing and glandular secretions in patients with allergic rhinitis, but not in normal individuals or those with nonallergic, noninfectious perennial rhinitis.

Anaphylaxis

Release of oversulfated proteoglycans from mast cells can activate the plasma kallikrein-kinin system in patients undergoing an anaphylactic reaction. In murine models of anaphylaxis, inhibition of bradykinin generation prevents complications such as hypothermia and death.

Pain

The kinins are powerful algesic agents that cause an intense burning pain when applied to the exposed base of a blister. Bradykinin excites primary sensory neurons and provokes the release of neuropeptides such as substance P, neurokinin A, and calcitonin gene–related peptide. Although there is overlap, B_2 receptors generally mediate acute bradykinin algesia, whereas the pain of chronic inflammation appears to involve increased numbers and activation of B_1 receptors.

Inflammation

Kinins participate in a variety of inflammatory conditions (Bhoola et al., 1992; Leeb-Lundberg et al., 2005). The B_1 receptors on inflammatory cells (e.g., macrophages) can elicit production of the inflammatory mediators IL-1 (interleukin-1) and TNFα (tissue necrosis factor α). Kinin levels are increased in a number of chronic inflammatory diseases and may be significant in gout, disseminated intravascular coagulation, inflammatory bowel disease, rheumatoid arthritis, and asthma. In addition, kinins and their receptors are associated with a variety of neuroinflammatory disorders, including neuropathic pain in diabetes, autoimmune encephalomyelitis, and Alzheimer's disease. Kinins may contribute to the skeletal changes seen in chronic inflammatory states; kinins stimulate bone resorption through B_1 and possibly B_2 receptors, perhaps by osteoblast-mediated osteoclast activation (see Chapter 52).

Diabetic Macular Edema

Diabetic macular edema is characterized in part by enhanced microvascular permeability with edema. Increased kallikrein activity has been found in the eyes of diabetic rats showing evidence of increased angiogenesis. Patients with diabetic retinopathy and diabetic macular degeneration have also been shown to have significantly increased plasma kallikrein activity in vitreous fluid. Early clinical studies are looking at the beneficial effect of kallikrein inhibitors for the treatment of diabetic macular edema.

Other Effects

Kinins promote dilation of the fetal pulmonary artery, closure of the ductus arteriosus, and constriction of the umbilical vessels, all of which occur in the transition from fetal to neonatal circulation. Kinins also affect the CNS, disrupting the blood-brain barrier and allowing increased CNS penetration. Kinins and kinin receptor signaling have been associated with neuroinflammatory disorders, such as neuropathic pain in diabetes, autoimmune encephalomyelitis, and Alzheimer's disease.

Drugs Acting on the Kallikrein-Kinin System

An imbalance between plasma kallikrein activity and its naturally-occuring inhibitors can contribute to disease, such as hereditary angioedema. Several classes of drugs can usefully modulate the activity of the kallikrein-kinin system, including inhibitors of plasma kallikrein, C1

TABLE 43–4 ■ PREPARATIONS AND DOSAGE OF KALLIKREIN-KININ ACTING DRUGS

DRUG	INDICATION	ADMINISTRATION[a]	DOSE (adult)
Plasma Kallikrein Inhibitors			
Recombinant plasma kallikrein inhibitor			
Ecallantide	On-demand	SC	30 mg
Monoclonal antibody to plasma kallikrein			
Lanadelumab	Prophylactic	SC	300 mg q2-4 weeks
Oral plasma kallikrein inhibitor			
Berotralstat	Prophylactic	O	150 mg qDay
C1 Inhibitors			
Plasma-derived concentrates			
Berinert	On-demand	IV	20 IU/kg
Cinryze	Prophylactic	IV	1,000 IU q3-4 days
Haegarda	Prophylactic	SC	60 IU/kg q3-4 days
Recombinant C1 inhibitor			
Ruconest	On-demand	IV	50 IU/kg
Bradykinin B2 receptor antagonist			
Icatibant	On-demand	SC	30 mg

[a]O, oral; SC, subcutaneous; IV, intravenous.

esterase inhibitors, and bradykinin receptor antagonists. Table 43–4 and the text below describe the currently available agents.

Kallikrein Inhibitors

Ecallantide

Ecallantide is a synthetic plasma kallikrein inhibitor approved for the treatment of acute attacks of hereditary angioedema in patients 12 years and older. It is administered by a healthcare professional (with appropriate medical support to manage possible anaphylaxis) subcutaneously at a total dose of 30 mg, divided into three 10-mg injections of 1 mL each. An additional dose of 30 mg may be administered within a 24-h period if the attack persists. The most common side effects (~3%–8% of patients) include headache, nausea, diarrhea, fever, injection site reactions, and nasopharyngitis. Safety has not been tested in pregnant or nursing women. Anaphylaxis has been reported in about 4% of treated patients, occurring within 1 h after dosing. Approximately 20% of patients treated with *ecallantide* develop antibodies to the drug and may be at a higher risk of hypersensitivity reactions on subsequent exposure. *Ecallantide* has been investigated as a potential treatment of angioedema caused by ACE inhibitors (Zuraw et al., 2013); however, studies conflict in demonstrating benefit (Bernstein et al., 2015; Lewis et al., 2015).

C1 Inhibitor

Concentrates of *C1 inhibitor* have been approved for the on-demand and prophylactic treatment of hereditary angioedema. C1 inhibitor acts on both of the proteases in the plasma kallikrein-kinin system (plasma kallikrein and active factor [F] XII), decreasing the production of bradykinin. *Cinryze* and *Berinert* are plasma-derived C1 inhibitor concentrates that are administered by intravenous infusion. *Berinert* is approved in the U.S. for on-demand treatment of hereditary angioedema attacks in adults and children. It is administered at a dose of 20 IU/kg by slow injection. *Cinryze* is approved for prophylactic use with a starting dose of 1000 IU twice weekly. *Ruconest* is a recombinant human C1 inhibitor that is approved for on-demand use at a dose of 50 IU/kg by slow intravenous injection in adults and adolescents. *Haegarda* is a more concentrated form of *Berinert* that is administered for long-term prophylaxis by subcutaneous injection at a dose of 60 IU/kg twice weekly in adults and children. All of the C1 inhibitor preparations are safe and generally well tolerated. At very high doses, C1 inhibitor may be thrombogenic, but this has not been an issue at normal doses. Extremely rare instances of allergic reactions to C1 inhibitor have been reported.

Lanadelumab

Lanadelumab is a fully human IgG1/kappa light chain monoclonal antibody produced in Chinese hamster ovary cells. *Lanadelumab* rapidly inhibits active plasma kallikrein, preventing HMW kininogen cleavage and generation of bradykinin. It is approved for the long-term prophylaxis of hereditary angioedema in patients 12 years and older. The starting dose of *lanadelumab* is 300 mg twice monthly, which can be reduced to 300 mg monthly if the patient does well after 6 months. *Lanadelumab* is well tolerated, with rare hypersensitivity reactions described.

Berotralstat

Berotralstat is an orally available small-molecule plasma kallikrein inhibitor. *Berotralstat* inhibits plasma kallikrein, preventing HMW kininogen cleavage and generation of bradykinin. It is approved for the long-term prophylaxis of hereditary angioedema in patients 12 years and older. The starting dose of *berotralstat* is 150 mg daily with food. The most common adverse reactions to *berotralstat* have been abdominal pain, vomiting, diarrhea, back pain, and gastroesophageal reflux disease, which are typically transient. In patients with chronic administration of agents that inhibit P-glycoprotein or BCRP (breast cancer resistance protein) (i.e., *cyclosporine*), the recommended dosage of *berotralstat* is one 110-mg capsule orally daily with food. *Berotralstat* can prolong the QT interval at doses above the recommended 150 mg daily.

Other Kallikrein Inhibitors

With the success of kallikrein inhibitors in treating hereditary angioedema due to C1 inhibitor deficiency, a number of other kallikrein inhibition strategies are being pursued in ongoing clinical trials for hereditary angioedema. These include other orally available small-molecule inhibitors, an antisense oligonucleotide directed at plasma kallikrein, and CRISPR-Cas9–mediated knockdown of plasma kallikrein. The efficacy of kallikrein inhibitors for diabetic macular edema is also being studied in clinical trials.

Aprotinin is a natural proteinase inhibitor that inhibits mediators of the inflammatory response, fibrinolysis, and thrombin generation, including kallikrein and plasmin. *Aprotinin* was employed clinically to reduce blood loss in patients undergoing coronary artery bypass surgery, but unfavorable survival statistics in retrospective and prospective studies resulted in its discontinuation.

Kinin Receptor Antagonists

The utility of specific kinin receptor antagonists currently is being investigated in diverse areas such as pain, inflammation, chronic inflammatory diseases, and cardiovascular diseases (Campos et al., 2006). The beneficial effects of ACE inhibitor therapy rest in part on enhancing bradykinin activity (e.g., on the heart, kidney, blood pressure; see Chapter 30); this has led to the suggestion that kinin agonists could be therapeutically beneficial (Heitsch, 2003; Rhaleb et al., 2011).

Icatibant

The selective B_2 receptor antagonist *icatibant* has been approved in the E.U. and U.S. for treatment of acute episodes of swelling in patients more than 18 years of age with hereditary angioedema. It is administered by a healthcare professional, or self-administered by the patient after training, at a dose of 30 mg in 3 mL of solution by subcutaneous injection in the abdomen. Additional doses may be administered at intervals of at least 6 h if the response is inadequate or symptoms recur, not to exceed three doses in any 24-h period. A common side effect experienced by most patients is a local reaction at the injection site (e.g., redness, bruising, swelling, burning, itching). A small percentage of patients have experienced fever, elevated transaminase, dizziness, nausea, headache, or rash.

Safety has not been tested in pregnant or nursing women. *Icatibant* was investigated in randomized, placebo-controlled trials for treatment of ACE inhibitor–associated angioedema but was shown to lack clinical utility (Sinert et al., 2017; Straka et al., 2017).

Other Kinin Receptor Antagonists

Orally available B_2 and B_1 bradykinin receptor antagonists have been developed. An oral potent B_2 receptor is currently in early-phase clinical trials for hereditary angioedema due to C1 inhibitor deficiency. Despite several phase I studies being started, no B_1 receptor antagonists are currently undergoing clinical testing.

FXII Inhibitors

Garadacimab is a fully human monoclonal IgG4 antibody directed against the active site of FXIIa, the activated protease form of coagulation factor XII. A phase II clinical trial using three doses of subcutaneous *garadacimab* given every 4 weeks demonstrated significant efficacy in patients with hereditary angioedema due to C1 inhibitor deficiency. A pivotal phase III study is currently in progress.

FXIIa inhibitors are also being considered for additional indications, including prevention of clotting/thrombosis, sepsis, multiple sclerosis, and Alzheimer's disease. Orally available FXIIa inhibitors are in development.

ACE Inhibitors

The ACE inhibitors, widely used in the treatment of hypertension, congestive heart failure, and diabetic nephropathy, block the conversion of angiotensin (Ang) I to AngII and also block the degradation of bradykinin by ACE (see Figure 43–4 and Chapter 30). Numerous studies demonstrated that bradykinin contributes to many of the protective effects of ACE inhibitors (Heitsch, 2003; Madeddu et al., 2007). The search is on to find a suitable stable B_2 agonist for clinical evaluation that provides cardiovascular benefit without proinflammatory effects.

A rare side effect of ACE inhibitors is angioedema, which is likely due to the inhibition of kinin metabolism by ACE (Zuraw et al., 2013). A common side effect of ACE inhibitors that may be related to enhanced kinin levels is a chronic, nonproductive cough that dissipates when the drug is stopped. Bradykinin may also contribute to the therapeutic effects of the AT_1 receptor antagonists. During AT_1 receptor blockade, AngII signaling through the unopposed AT_2 subtype receptor is enhanced, causing an increase in bradykinin concentrations, which has beneficial effects on cardiovascular and renal function (Padia and Carey, 2013). However, the increase in bradykinin levels is likely more modest than that achieved by ACE inhibitors, as reflected by the lower incidence of angioedema in patients taking AT_1 receptor antagonists (Zuraw et al., 2013).

Drug Facts for Your Personal Formulary: H_1 Antagonists

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
First-Generation Antihistamines: H_1 receptor inverse agonists • Most have central and anticholinergic effects • Use with caution in children and in adults >65 years of age		
Doxepin	• Tricyclic antidepressant • Insomnia • Pruritis (topical cream) • Pruritis (atopic dermatitis, eczema, lichen simplex) (cream)	• Causes significant sedation/drowsiness • Anticholinergic effects • Increased risk of suicidal thoughts (children, adolescents, and young adults)
Carbinoxamine Clemastine Diphenhydramine Dimenhydrinate	• Symptoms of allergic response • Mild urticaria • Insomnia (diphenhydramine) • Motion sickness (dimenhydrinate, diphenhydramine)	• Pronounced tendency to cause sedation • Significant anticholinergic effects • GI side effects are low • Carbinoxamine and diphenhydramine: adjunct to epinephrine for anaphylaxis
Pyrilamine (only available as an ingredient in over-the-counter combination preparations)	• Symptoms of allergic response	• Anticholinergic effects • Central effects < other first-generation drugs • GI side effects are quite common
Chlorpheniramine Dexchlorpheniramine Brompheniramine Dexbrompheniramine (component of cold medicine)	• Allergic conjunctivitis • Allergic rhinitis • Anaphylaxis (adjunct), histamine-mediated angioedema, dermatographism, pruritus, sneezing, urticaria (brompheniramine) • Symptoms of allergic response	• Less drowsiness than other first-generation drugs; CNS stimulation side effects more common
Hydroxyzine	• Pruritis • Sedation • Antianxiety • Atopic dermatitis • Antiemetic • Urticaria	• CNS depressant action may contribute to antipruritic effects
Cyclizine (discontinued in the U.S.) Meclizine (not for use in children)	• Motion sickness • Nausea/vomiting • Vertigo	• Antinausea properties due to prominent anticholinergic effects • Less likely to cause drowsiness than other first-generation drugs • Meclizine, most used, long effect (≥8 h)
Promethazine	• Antiemetic • Motion sickness • Pruritus • Sedation • Symptoms of allergic response (off-label use)	• Risk of fatal respiratory depression in children, especially <2 years • May lower seizure threshold • Has local anesthetic activity • Most potent antihistamine antiemetic

Drug Facts for Your Personal Formulary: *H_1 Antagonists (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Cyproheptadine	• Allergic conjunctivitis • Allergic rhinitis • Anaphylaxis • Histamine-mediated angioedema • Pruritus, allergy • Vasomotor rhinitis • Urticaria • Dermatographism	• May increase appetite, cause weight gain • Has significant anticholinergic activity • Also blocks serotonin effects by antagonizing the $5HT_{2A}$ receptor
Second-Generation Antihistamines: H_1 receptor inverse agonists • Lack significant central and anticholinergic effects		
Olopatadine (nasal and ophthalmic only)	• Allergic conjunctivitis • Allergic rhinitis • Ocular pruritus • Rhinorrhea • Sneezing	• Approved for once-daily dosing • Eye drops may cause headaches in some • Nasal spray can cause epistaxis and nasal ulceration or septal perforation • Some increase in risk of somnolence with nasal spray • Nasal spray minor side effects include bitter taste and headache
Acrivastine (only marketed in combination with pseudoephedrine)	• Allergic rhinitis • Nasal congestion • Allergic symptoms	• ~40% metabolized by CYPs, reducing potential for drug interactions • Somewhat higher risk of mild sedation than other second-generation drugs
Cetirizine Levocetirizine	• Allergic rhinitis • Atopic dermatitis (cetirizine) • Urticaria (chronic idiopathic)	• Somewhat higher risk of mild sedation than other second-generation drugs; more potent levocetirizine can be used at lower dose with less risk of sedation • Only ~30% (cetirizine) or ~1% (levocetirizine) metabolized by CYPs, reducing potential for drug interactions
Loratadine Desloratadine	• Allergic rhinitis • Chronic idiopathic urticaria • Exercise-induced bronchospasm prophylaxis (loratadine) • Pruritus (desloratadine)	• Desloratadine is the active metabolite of loratadine • 24-h duration of activity so only once-a-day dosing is required
Fexofenadine	• Allergic rhinitis • Chronic idiopathic urticaria	• Is the active metabolite of terfenadine (withdrawn from the market due to risk of torsades de pointes) • Only ~8% metabolized by CYPs, reducing potential for drug interactions
Alcaftadine (ophthalmic only)	• Allergic conjunctivitis • Ocular pruritus	• In addition to mast cell–stabilizing and anti-inflammatory properties, its H_4 antagonist activity may give superior relief from ocular itching • Approved for once-daily dosing • Most common adverse reactions (<4%) are eye irritation, redness, and pruritis
Bepotastine (ophthalmic only)	• Allergic conjunctivitis • Ocular pruritus	• Has mast cell–stabilizing and anti-inflammatory properties • Most common (~25%) adverse reaction is mild taste • Other minor (2%–5%) reactions are eye irritation, headache, and nasopharyngitis
Ketotifen (ophthalmic only)	• Allergic conjunctivitis • Ocular pruritus	• Has mast cell–stabilizing and anti-inflammatory properties • Most common (~10%–25%) adverse reactions are red eyes and mild headache or rhinitis
Azelastine (nasal and ophthalmic only)	• Allergic conjunctivitis • Allergic rhinitis (alone and combined with fluticasone) • Ocular pruritus • Vasomotor rhinitis	• Has mast cell–stabilizing and anti-inflammatory properties • Eye drops may cause transient eye burning/stinging • Some increase in risk of somnolence with nasal spray • Minor side effects with eye drops and nasal spray include bitter taste and headache
Emedastine (ophthalmic only)	• Allergic conjunctivitis • Ocular pruritus	• Lacks mast cell–stabilizing and anti-inflammatory properties • Common side effect: headache (~11%) • Minor reactions (<5%): abnormal dreams, bad taste, eye irritation
Epinastine (ophthalmic only)	• Allergic conjunctivitis • Ocular pruritus	• In addition to mast cell–stabilizing and anti-inflammatory properties, its H_2 antagonist activity may reduce eyelid edema • Common side effect (~10%): symptoms of upper respiratory infection • Minor ocular reactions: burning sensation, folliculosis, hyperemia, and pruritis

Drug Facts for Your Personal Formulary: H_1 Antagonists (continued)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Drugs Acting on the Kallikrein-Kinin System		
Recombinant Kallikrein Inhibitor Ecallantide	• Acute attacks of hereditary angioedema	• Approved for patients ≥12 years old • Patients may develop antibodies to the drug • Risk of hypersensitivity on subsequent exposure • Must be administered by healthcare professional
C1 Inhibitors Various plasma-derived concentrates	• On-demand and prophylactic treatment of hereditary angioedema	• Approved for adult and pediatric patients • Inhibit plasma kallikrein and active FXII
Antibody to plasma kallikrein Lanadelumab	• Prophylactic treatment of hereditary angioedema	• Approved for patients ≥12 years old • Fully human monoclonal antibody to plasma kallikrein
Kinin receptor antagonists Icatibant	• Acute attacks of hereditary angioedema	• Approved for patients ≥18 years old • B_2 kinin receptor antagonist • Commonly produces local reaction at injection site
Small molecule plasma inhibitor Berotralstat	• Prophylactic treatment of hereditary angioedema	• Approved for patients ≥12 years old • May interact with P-gp or BCRP inhibitors

Chapter 44

Pulmonary Pharmacology

Peter J. Barnes

Pulmonary pharmacology concerns understanding how drugs act on the lung and the pharmacological therapy of pulmonary diseases. Much of pulmonary pharmacology is concerned with the effects of drugs on the airways and the therapy of airway obstruction, particularly asthma and chronic obstructive pulmonary disease (COPD), which are among the most common diseases of the airways, although there are marked differences in inflammatory mechanisms and response to therapy between these diseases. This chapter discusses the pharmacotherapy of obstructive airways disease, particularly therapy with bronchodilators, which act mainly by reversing airway smooth muscle contraction, and anti-inflammatory drugs, which suppress the inflammatory response in the airways. This chapter focuses on the pulmonary pharmacology of β_2 adrenergic agonists and corticosteroids; the basic pharmacology of these classes of agents is presented elsewhere (see Chapters 14 and 50).

This chapter also discusses other drugs used to treat obstructive airway diseases, such as mucolytics and respiratory stimulants, and covers the drug therapy of cough, the most common respiratory symptom. Drugs used in the treatment of pulmonary hypertension (see Chapter 35) or lung infections, including tuberculosis (see Chapter 65), are covered elsewhere.

Mechanisms of Asthma

Asthma is a chronic inflammatory disease of the airways that is characterized by activation of *mast cells*, infiltration of *eosinophils*, *T helper 2 (T_H2) lymphocytes, and innate type 2 lymphocytes (ILC2)* (Figure 44–1) (Papi et al., 2018). Mast cell activation by allergens and physical stimuli releases *bronchoconstrictor mediators*, such as *histamine, leukotriene (LT) D_4*, and *prostaglandin (PG) D_2*, which cause airway smooth muscle contraction, vasodilation, microvascular leakage, and plasma exudation.

Many of the symptoms of asthma are due to airway smooth muscle contraction, and therefore, bronchodilators are important as symptom relievers. Whether airway smooth muscle is intrinsically abnormal in asthma is not clear, but increased contractility of airway smooth muscle may contribute to airway hyperresponsiveness, the physiological hallmark of asthma.

Chronic inflammation in allergic asthma may initially be driven by allergen exposure, but it appears to become autonomous so that asthma is essentially incurable. The inflammation may be orchestrated by dendritic cells that regulate T_H2 cells that drive eosinophilic inflammation and by IgE formation by B lymphocytes. Nonallergic asthma is also eosinophilic, orchestrated by T_H2 and ILC2 cells.

Abbreviations

ACh: acetylcholine
AUC: area under the curve
BDP: beclomethasone dipropionate
cAMP: 3′-5′ cyclic adenosine monophosphate, cyclic AMP
CCR: C-C chemokine receptor
COMT: catechol-*O*-methyl transferase
COPD: chronic obstructive pulmonary disease
CRTh2: chemokine receptor homologous molecule expressed on Th2 lymphocytes
cys-LT: cysteinyl-leukotriene
DPI: dry powder inhaler
F_{eNO}: fractional exhaled nitric oxide
FEV_1: forced expiratory volume in 1 sec
GI: gastrointestinal
GPCR: G protein-coupled receptor
GR: glucocorticoid receptor
HDAC: histone deacetylase
HFA: hydrofluoroalkane
HPA: hypothalamic-pituitary-adrenal
ICS: inhaled corticosteroid
Ig: immunoglobulin
IL: interleukin
ILC2: innate type 2 lymphocyte
IP_3: inositol 1,4,5-trisphosphate
LABA: long-acting β_2 agonist
LAMA: long-acting muscarinic antagonist
LTRA: leukotriene cys-LT_1-receptor antagonist
5-LO: 5′-lipoxygenase
LT: leukotriene
MAO: monoamine oxidase
MAP: mitogen-activated protein
MDI: metered-dose inhaler
MMAD: mass median aerodynamic diameter
MMP: matrix metalloproteinase
NF-κB: nuclear factor kappa B
PDE: cyclic nucleotide phosphodiesterase
PG: prostaglandin
PKA: protein kinase A
pMDI: pressurized metered-dose inhaler
SABA: short-acting β_2 agonists
SAMA: short-acting muscarinic antagonist
TAS2R: taste 2 receptor
Tc1 cell: cytotoxic T lymphocyte
T_H17: T helper 17 cell
T_H2: T helper 2 lymphocyte
TNF: tumor necrosis factor
TRP: transient receptor potential
TSLP: thymic stromal lymphopoietin
VIP: vasoactive intestinal polypeptide

Airway epithelium plays an important role through the release of multiple inflammatory mediators and through the release of growth factors in an attempt to repair the damage caused by inflammation. The inflammatory process in asthma is mediated through the release of more than 100 inflammatory mediators, including lipid mediators, cytokines, chemokines, and growth factors.

Chronic inflammation may lead to structural changes (remodeling) in the airways, including an increase in the number (hyperplasia) and size (hypertrophy) of airway smooth muscle cells, blood vessels (angiogenesis), and mucus-secreting cells (goblet cell hyperplasia). A characteristic histological feature of asthma is collagen deposition (fibrosis) below the basement membrane of the airway epithelium (termed subepithelial cell fibrosis) (see Figure 44–1). This appears to be the result of eosinophilic inflammation and is found even at the onset of asthmatic symptoms. The complex inflammation of asthma is suppressed by corticosteroids in most patients, but even if asthma is well controlled, the inflammation and symptoms return if corticosteroids are discontinued. Asthma usually starts in early childhood, then may disappear during adolescence and reappear in adulthood. It is characterized by variable airflow obstruction and typically shows a good therapeutic response to bronchodilators and corticosteroids. Asthma severity usually does not change, so that patients with mild asthma rarely progress to severe asthma and patients with severe asthma usually have this from the onset, although some patients, particularly with late-onset asthma, show a progressive loss of lung function like patients with COPD. Patients with severe asthma may have a pattern of inflammation more similar to COPD and are characterized by reduced responsiveness to corticosteroids (Ray et al., 2016).

Mechanisms of COPD

COPD involves inflammation of the respiratory tract with a pattern that differs from that of asthma. In COPD, there is a *predominance of neutrophils, macrophages, cytotoxic T lymphocytes (Tc1 cells), and T helper 17 (T_H17) cells*. The inflammation *predominantly affects small airways*, resulting in progressive small-airway narrowing and fibrosis (chronic obstructive bronchiolitis) and inflammation in the lung parenchyma, resulting in alveolar wall destruction (emphysema) (Figure 44–2) (Agustí and Hogg, 2019; Barnes et al., 2015). These pathological changes result in airway closure on expiration, leading to air trapping and hyperinflation, particularly on exercise (dynamic hyperinflation). This accounts for shortness of breath on exertion and exercise limitation that are characteristic symptoms of COPD.

Bronchodilators reduce air trapping by dilating peripheral airways and are the mainstay of treatment in COPD. In contrast to asthma, the airflow obstruction of COPD tends to be progressive. The inflammation in the peripheral lung of patients with COPD is also mediated by multiple inflammatory mediators and cytokines, but the pattern of mediators differs from that of asthma. In contrast to asthma, the inflammation in patients with COPD is largely corticosteroid resistant, and there are currently no safe and effective anti-inflammatory treatments. Many patients with COPD have comorbidities, including ischemic heart disease, hypertension, congestive heart failure, diabetes, osteoporosis, skeletal muscle wasting, depression, chronic renal disease, and anemia (Divo and Celli, 2020). These diseases may occur together as part of multimorbidity, as diseases of accelerated aging with common pathogenetic mechanisms (Barnes et al., 2019).

Routes of Drug Delivery to the Lungs

Drugs may be delivered to the lungs by oral or parenteral routes and also by inhalation. The choice depends on the drug and on the respiratory disease.

Inhaled Route

Inhalation (Figure 44–3) is the preferred mode of delivery of many drugs with a direct effect on airways, particularly for asthma and COPD (Lavorini et al., 2019). It is the only way to deliver some drugs, such as cromolyn sodium and anticholinergic drugs, and is the preferred route of delivery for β_2 agonists and corticosteroids to reduce systemic side effects. Antibiotics may be delivered by inhalation in patients with chronic respiratory sepsis (e.g., in cystic fibrosis). The major advantage of inhalation is the delivery of drug to the airways in doses that are effective with a much lower risk of systemic side effects. This is particularly important with the use of inhaled corticosteroids (ICS), which largely avoids systemic side effects. In addition, inhaled bronchodilators have a more rapid onset of action than when taken orally.

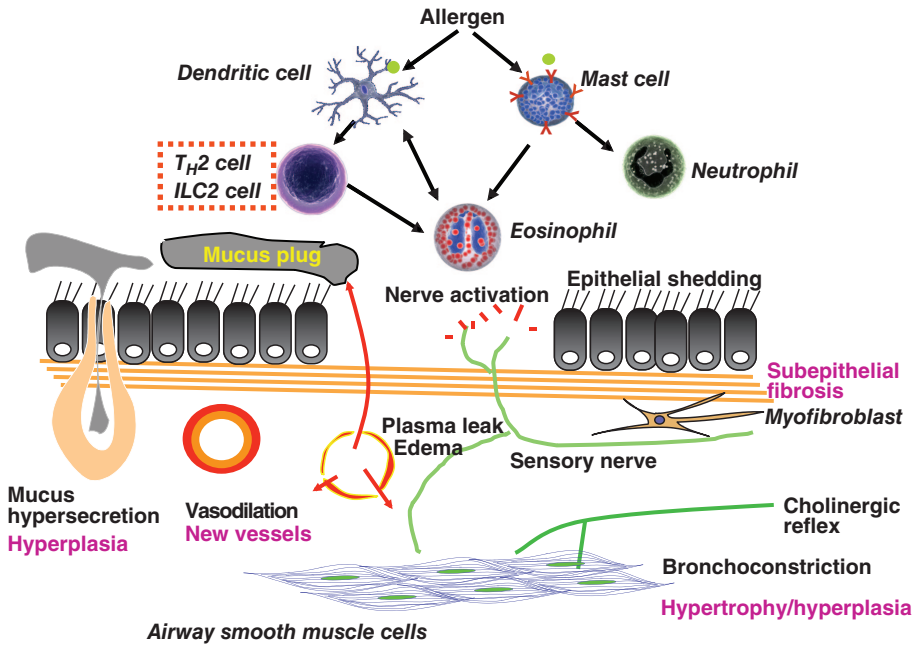

Figure 44–1 *Cellular mechanisms of asthma.* Myriad inflammatory cells are recruited and activated in the airways, where they release multiple inflammatory mediators, which can also arise from structural cells. These mediators lead to bronchoconstriction, plasma exudation and edema, vasodilation, mucus hypersecretion, and activation of sensory nerves. Chronic inflammation leads to structural changes, including subepithelial fibrosis (basement membrane thickening), airway smooth muscle hypertrophy and hyperplasia, angiogenesis, and hyperplasia of mucus-secreting cells.

Particle Size

The size of particles for inhalation is of critical importance in determining the site of deposition in the respiratory tract. The optimum size for particles to settle in the airways is 2- to 5-μm MMAD (mass median aerodynamic diameter). Larger particles settle out in the upper airways, whereas smaller particles remain suspended and are therefore exhaled. There is increasing interest in delivering drugs to small airways, particularly in COPD and severe asthma (Usmani and Barnes, 2012). This involves delivering drug particles of about 1-μm MMAD, which is now possible using drugs formulated in hydrofluoroalkane (HFA) propellant.

Pharmacokinetics

Of the total drug delivered, only 10% to 20% enters the lower airways with a conventional pressurized metered-dose inhaler (pMDI). Drugs are absorbed from the airway lumen and have direct effects on target cells of the airway. Drugs may also be absorbed into the bronchial circulation and

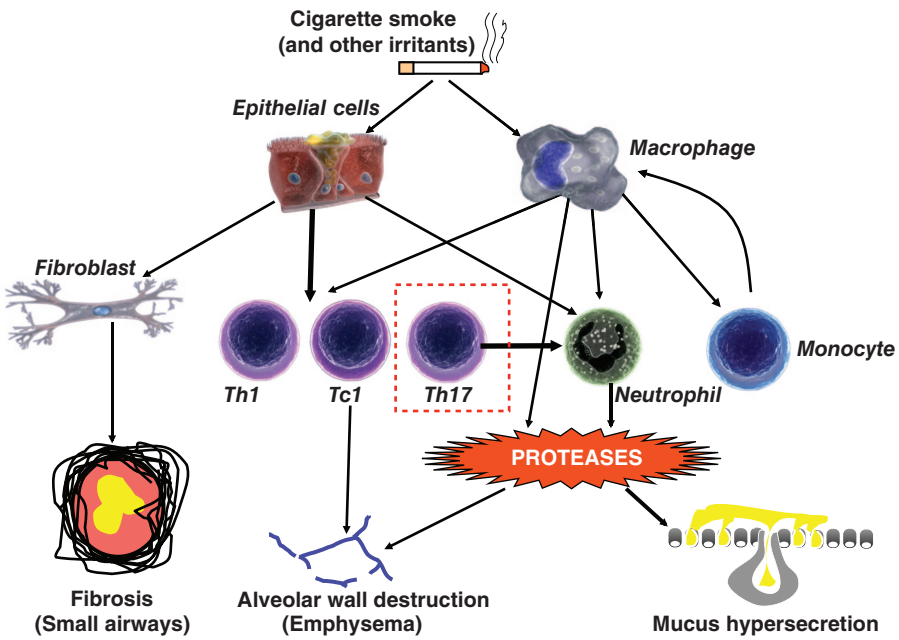

Figure 44–2 *Cellular mechanisms in COPD.* Cigarette smoke and other irritants activate epithelial cells and macrophages in the lung to release mediators that attract circulating inflammatory cells, including monocytes (which differentiate to macrophages within the lung), neutrophils, and T lymphocytes (T_H1, Tc1, and T_H17 cells). Fibrogenic factors released from epithelial cells and macrophages lead to fibrosis of small airways. Release of proteases results in alveolar wall destruction (emphysema) and mucus hypersecretion (chronic bronchitis).

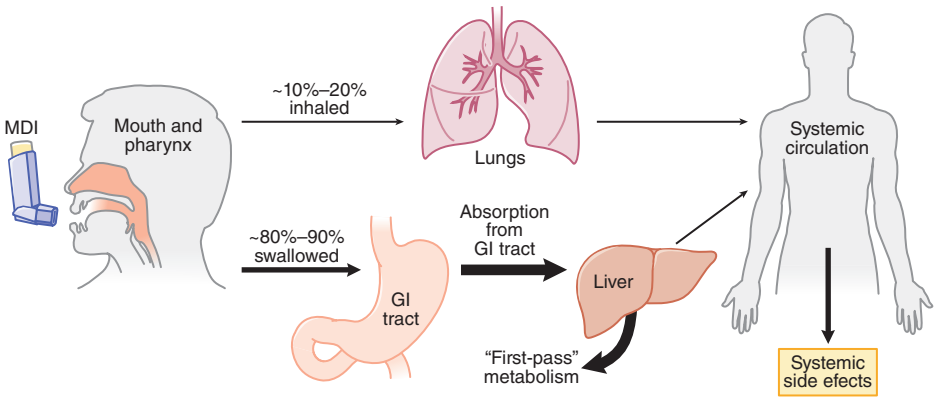

Figure 44–3 *Schematic representation of the deposition of inhaled drugs (e.g., corticosteroids, β_2 agonists).* Inhalation therapy deposits drugs directly, but not exclusively, in the lungs. Distribution between lungs and oropharynx depends mostly on the particle size and the efficiency of the delivery method. Most material will be swallowed and absorbed, entering systemic circulation after undergoing the first-pass effect in the liver. Some drug will also be absorbed into the systemic circulation from the lungs. Use of a large-volume spacer will reduce the amount of drug deposited on the oropharynx, thereby reducing the amount swallowed and absorbed from the GI tract and thus limiting systemic effects.

then distributed to more peripheral airways. Drugs with higher molecular weights tend to be retained to a greater extent in the airways. Nevertheless, several drugs have greater therapeutic efficacy when given by the inhaled route. The ICS *ciclesonide* is a prodrug activated by esterases in the respiratory tract to the active principle *des-ciclesonide*. More extensive pulmonary distribution of a drug with a smaller MMAD increases alveolar deposition and thus is likely to increase absorption from the lungs into the general circulation, resulting in more systemic side effects. Thus, although HFA pMDIs deliver more ICS to smaller airways, there is also increased systemic absorption, so that the therapeutic ratio may not be changed.

Delivery Devices

Pressurized Metered-Dose Inhalers. Drugs are propelled from a canister in the pMDI with the aid of a propellant, previously with a chlorofluorocarbon (Freon) but now replaced by an HFA that is more ozone friendly, that is, does not contribute to ozone depletion in Earth's upper atmosphere. These devices are convenient, portable, and typically deliver 50 to 200 doses of drug.

Spacer Chambers. Large-volume spacer devices between the pMDI and the patient reduce the velocity of particles entering the upper airways and the size of the particles by allowing evaporation of liquid propellant. This reduces the amount of drug that impinges on the oropharynx and increases the proportion of drug inhaled into the lower airways. Application of spacer chambers is useful in the reduction of the oropharyngeal deposition of ICS and the consequent reduction in the local side effects of these drugs. Spacer devices are also useful in delivering inhaled drugs to small children who are not able to use a pMDI. Children as young as 3 years of age can use a spacer device fitted with a face mask.

Dry Powder Inhalers. Drugs may also be delivered as a micronized dry powder, using devices that deliver a fine powder dispersed by air turbulence on inhalation, which requires a minimum inspiratory flow. Children younger than 7 years of age find it difficult to use a dry powder inhaler (DPI). DPIs have been developed for systemic delivery of peptides and proteins, such as insulin, but have proved to be problematic because of consistency of dosing.

Nebulizers. Two types of nebulizer are available. *Jet nebulizers* are driven by a stream of gas (air or oxygen), whereas *ultrasonic nebulizers* use a rapidly vibrating piezoelectric crystal and thus do not require a source of compressed gas. The nebulized drug may be inspired during tidal breathing, and it is possible to deliver much higher doses of drug compared with a pMDI. Nebulizers are therefore useful in treating acute exacerbations of asthma and COPD, for delivering drugs when airway obstruction is extreme, for delivering inhaled drugs to infants and small children who cannot use the other inhalation devices, and for giving drugs such as antibiotics when relatively high doses must be delivered.

Oral Route

Drugs for treatment of pulmonary diseases may also be given orally. The oral dose is much higher than the inhaled dose required to achieve the same effect (typically by a ratio of about 20:1), so that systemic side effects are more common. *When there is a choice of inhaled or oral route for a drug (e.g., β_2 agonist or corticosteroid), the inhaled route is always preferable*, and the oral route should be reserved for the few patients unable to use inhalers (e.g., small children, patients with physical problems such as severe arthritis of the hands). *Theophylline* is ineffective by the inhaled route and therefore must be given systemically. Corticosteroids may have to be given orally for parenchymal lung diseases (e.g., in interstitial lung diseases).

Parenteral Route

The intravenous route should be reserved for delivery of drugs in the severely ill patient who is unable to absorb drugs from the gastrointestinal (GI) tract. Side effects are generally frequent due to the high plasma concentrations. Biologics are usually given by subcutaneous injection.

Bronchodilators

Bronchodilator drugs relax constricted airway smooth muscle *in vitro* and cause immediate reversal of airway obstruction in asthma *in vivo* (Cazzola et al., 2012). They also prevent bronchoconstriction (and thereby provide bronchoprotection). Three main classes of bronchodilator are in current clinical use:

- β_2 Adrenergic agonists (sympathomimetics)
- *Theophylline* (a methylxanthine)
- Anticholinergic agents (muscarinic receptor antagonists)

Bronchodilators may directly relax airway smooth muscle or may cause bronchodilation indirectly by blocking the effects of bronchoconstrictor mediators or neurotransmitters. For example, *anti-LTs* (LT receptor antagonists and 5′-lipoxygenase inhibitors) have a small bronchodilator effect in some asthmatic patients and appear to prevent bronchoconstriction. *Corticosteroids*, although they gradually improve airway obstruction, have no direct effect on contraction of airway smooth muscle and therefore are not considered to be bronchodilators.

β_2 Adrenergic Agonists

Inhaled β_2 agonists are the bronchodilator treatment of choice in asthma because they are the most effective bronchodilators and have minimal side effects when used correctly. Systemic, short-acting, and nonselective

β agonists, such as *isoproterenol* (*isoprenaline*) or *metaproterenol*, should only be used as a last resort.

Chemistry

The development of β_2 agonists is based on substitutions in the catecholamine structure of norepinephrine and epinephrine (see Chapters 10 and 14). The catechol ring consists of hydroxyl groups in the 3 and 4 positions of the benzene ring. Norepinephrine differs from epinephrine only in the terminal amine group; in general, further modification at this site confers β receptor selectivity. Many inhaled β_2-selective agonists are approved, and although there may be differences in potency, there are no clinically significant differences in selectivity. Inhaled β_2-selective drugs in current clinical use have a similar duration of action (3–6 h).

Administration of long-acting β_2 agonists (LABAs) by inhalation provides a much longer duration of effect (Cazzola et al., 2019b). *Salmeterol* and *formoterol* provide bronchodilation and bronchoprotection for more than 12 h and are usually given twice daily. *Formoterol* has a bulky substitution in the aliphatic chain and has moderate lipophilicity, which appears to keep the drug in the membrane close to the receptor, so it behaves as a slow-release drug; however, when diluted in plasma, *formoterol* loses this property, thereby avoiding long-term side effects, and can be used as a reliever. *Salmeterol* has a long aliphatic chain that may aid in anchoring the drug within the receptor binding cleft ("exosite") and that may thus contribute to *salmeterol*'s long duration. Once-daily β_2 agonists (sometimes called ultra-LABAs), such as *indacaterol*, *vilanterol*, and *olodaterol*, have a duration of action that exceeds 24 h; these agents are suitable for once-daily dosing.

Mode of Action

Occupation of β_2 receptors by agonists results in the activation of the G_s–adenylyl cyclase–3′-5′ cyclic adenosine monophosphate (cAMP)–protein kinase A (PKA) pathway, resulting in phosphorylative events leading to bronchial smooth muscle relaxation (Figure 44–4). β_2 Agonists act as functional antagonists of constriction, relaxing airway smooth muscle irrespective of the constrictor stimuli. β_2 Receptors are localized to several different airway cells in addition to smooth muscle, where they may have additional effects. β_2 Agonists also may cause bronchodilation *indirectly* by inhibiting the release of bronchoconstrictor mediators from inflammatory cells and of bronchoconstrictor neurotransmitters from airway nerves. These mechanisms include the following:

- Prevention of mediator release from isolated human lung mast cells (via β_2 receptors)
- Prevention of microvascular leakage and thus the development of bronchial mucosal edema after exposure to mediators (e.g., histamine, LTD_4, and PGD_2)
- Increase in *mucus secretion* from submucosal glands and *ion transport* across airway epithelium (may enhance mucociliary clearance, reversing defective clearance found in asthma and COPD)
- *Reduction in neurotransmission* in human airway *cholinergic nerves* by an action at presynaptic β_2 receptors to inhibit acetylcholine (ACh) release

Although these additional effects of β_2 agonists may be relevant to the prophylactic use of these drugs against various challenges, their rapid bronchodilator action is probably attributable to their direct effect on smooth muscle of all airways.

Anti-inflammatory Effects

Whether β_2 agonists have anti-inflammatory effects in asthma is controversial. The inhibitory effects of β_2 agonists on mast cell mediator release and microvascular leakage are clearly anti-inflammatory, suggesting that β_2 agonists may modify *acute* inflammation. However, β_2 agonists do not appear to have a significant inhibitory effect on the *chronic* inflammation of asthmatic airways, which is suppressed by corticosteroids. This has now been confirmed by several biopsy and bronchoalveolar lavage studies in patients with asthma who are taking regular β_2 agonists (including LABAs), that demonstrated no significant reduction in the number or activation in inflammatory cells in the airways, in contrast to resolution of the inflammation that occurs with ICS. This may be related to the fact that effects of β_2 agonists on macrophages, eosinophils, and lymphocytes are rapidly desensitized.

Clinical Use

Short-Acting β_2 Agonists. Inhaled short-acting β_2 agonists (SABAs) are the most widely used and effective bronchodilators in the treatment of asthma. When inhaled from pMDIs or DPIs, they are convenient, easy to use, rapid in onset, and without significant systemic side effects. These agents are effective in protecting against various asthma triggers, such as exercise, cold air, and allergens. SABAs are the bronchodilators of choice in treating acute severe asthma. The nebulized route of administration is easier and safer than intravenous administration and just as effective. Inhalation is preferable to oral administration because systemic side effects are less. *SABAs, such as albuterol (salbutamol), should be used "as required" by symptoms and not on a regular basis in the treatment of mild asthma; increased use indicates the need for more anti-inflammatory therapy.*

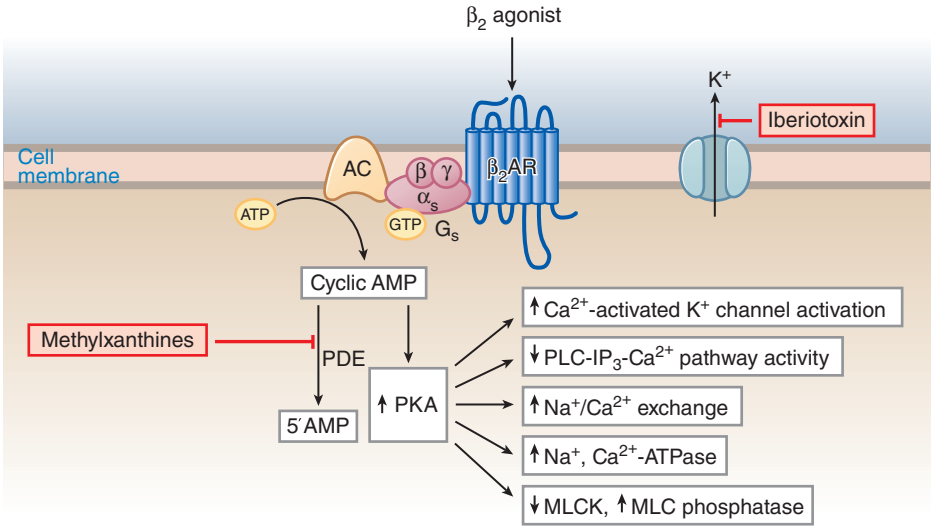

Figure 44–4 *Molecular actions of β_2 agonists to induce relaxation of airway smooth muscle cells.* Activation of β_2 receptors (β_2AR) results in activation of adenylyl cyclase (AC) via G_s, leading to an increase in intracellular cAMP and activation of PKA. PKA phosphorylates a variety of target substrates, resulting in opening of Ca^{2+}-activated K^+ channels (K_{Ca}), thereby facilitating hyperpolarization, decreased phosphoinositide (PI) hydrolysis, increased Na^+/Ca^{2+} exchange, increased Na^+, Ca^{2+}-ATPase activity, and decreased myosin light chain kinase (MLCK) activity and increased myosin light chain (MLC) phosphatase. β_2 Receptors may also couple to K_{Ca} via G_s. IP_3, inositol 1,4,5-trisphosphate; PDE, cyclic nucleotide phosphodiesterase; PLC, phospholipase C.

Oral β_2 agonists are occasionally indicated as an additional bronchodilator. Slow-release preparations (e.g., slow-release *albuterol* and *bambuterol* [not available in the U.S.]) may be indicated in nocturnal asthma; however, these agents have an increased risk of side effects. Several SABAs are available; they are resistant to uptake and enzymatic degradation by COMT (catechol-*O*-methyl transferase) and monoamine oxide (MAO); all are usable by inhalation and orally, have a similar duration of action (~3–4 h; less in severe asthma), and similar side effects. Differences in β_2 receptor selectivity have been claimed but are not clinically important. Drugs in clinical use include *albuterol, levalbuterol, metaproterenol, terbutaline,* and *pirbuterol*, as well as several drugs not available in the U.S. (*fenoterol, tulobuterol,* and *rimiterol*).

Long-Acting Inhaled β_2 Agonists. The LABAs *salmeterol and formoterol* (and *arformoterol,* the active enantiomer of *formoterol*) have proved to be a significant advance in asthma and COPD therapy. These drugs have a bronchodilator action of more than 12 h and protect against bronchoconstriction for a similar period (Cazzola et al., 2019b). They improve asthma control (when given twice daily) compared with regular treatment with SABAs (four to six times daily). Once-daily LABAs, such as *indacaterol, vilanterol*, and *olodaterol*, with a duration of over 24 h, are more effective in patients with COPD than twice-daily LABAs and more frequent SABAs (Cazzola et al., 2019b).

Tolerance to the bronchodilator effect of *formoterol* and the bronchoprotective effects of *formoterol* and *salmeterol* has been demonstrated but is of doubtful clinical significance. Although both *formoterol* and *salmeterol* have a similar duration of effect in clinical studies, there are differences. *Formoterol* has a more rapid onset of action and is an almost-full agonist, whereas *salmeterol* is a partial agonist with a slower onset of action. These differences might confer a theoretical advantage for *formoterol* in more severe asthma, whereas it may also make it more likely to induce tolerance. However, no significant clinical differences between *salmeterol* and *formoterol* have been found in the treatment of patients with severe asthma. More importantly, *formoterol* does not have long-lasting side effects, unlike *salmeterol* and other ultra-LABAs and is the only LABA that can be used as rescue therapy.

In COPD, LABAs are effective bronchodilators that may be used alone or in combination with LAMAs or ICSs. LABAs improve symptoms and exercise tolerance by reducing both air trapping and exacerbations. *In patients with asthma, LABAs should never be used alone because they do not treat the underlying chronic inflammation, and this may increase the risk of life-threatening and fatal asthma exacerbations; rather, LABAs should always be used in combination with an ICS in a fixed-dose combination inhaler.* LABAs are an effective add-on therapy to ICSs and are more effective than increasing the dose of an ICS when asthma is not controlled at low doses.

Combination Inhalers. Combination inhalers that contain a LABA and a corticosteroid (e.g., *fluticasone propionate/salmeterol, budesonide/formoterol, fluticasone furoate/vilanterol*) are now widely used in the treatment of asthma and COPD. In asthma, combining a LABA with a corticosteroid offers complementary synergistic actions (Barnes, 2002). The combination inhaler is more convenient for patients, simplifies therapy, and improves adherence with the ICS. Also, delivering the two drugs in the same inhaler ensures they are delivered simultaneously to the same cells in the airways, allowing the beneficial molecular interactions between LABAs and corticosteroids to occur. Combination inhalers are now the preferred therapy for patients with persistent asthma. These combination inhalers are also more effective in patients with COPD than a LABA and an ICS alone, but the mechanisms accounting for this beneficial interaction are less well understood than in patients with asthma.

Stereoselective β_2 Agonists. *Albuterol* is a racemic mixture of active *R*- and inactive *S*-isomers. Although *R-albuterol* (*levalbuterol*) was more potent than racemic *R/S-albuterol* in some studies, careful dose responses showed no advantage in terms of efficacy and no evidence that the *S-albuterol* is detrimental in asthmatic patients. Because *levalbuterol* is usually more expensive than normally used racemic *albuterol*, this therapy has no clear clinical advantage. Stereoselective *formoterol* (*R,R-formoterol*, *arformoterol*) has now been developed as a nebulized solution but also appears to offer no clinical advantage over racemic *formoterol* in patients with COPD (Loh et al., 2015).

β_2 Receptor Polymorphisms. Several single-nucleotide polymorphisms and haplotypes of the human *ADRβ2*, which affect the structure of β_2 receptors, have been described. The common variants are $Gly^{16}Arg$ and $Gln^{27}Glu$, which have *in vitro* effects on receptor desensitization, but clinical studies have shown inconsistent effects on the bronchodilator responses to SABAs and LABAs (Hikino et al., 2019). Some studies have shown that patients with the common homozygous $Arg^{16}Arg$ variant have more frequent adverse effects and a poorer response to SABAs than heterozygotes or $Gly^{16}Gly$ homozygotes, but overall, these differences are small, and there appears to be no clinical value in measuring *ADRβ2* genotype. Bleecker and colleagues (2007) found no differences in responses to LABAs between these genotypes. A recent study suggested that the Gly^{16} to Arg substitution may be clinically relevant in treating childhood asthma (Turner et al., 2016).

Side Effects. Unwanted effects are dose-related and due to stimulation of extrapulmonary β receptors (Table 44–1 and Chapter 14). Side effects are not common with inhaled therapy but quite common with oral or intravenous administration.

- *Muscle tremor* due to stimulation of β_2 receptors in skeletal muscle is the most common side effect. It may be more troublesome with elderly patients and thus is frequently encountered in patients with COPD.
- *Tachycardia* and *palpitations* are due to reflex cardiac stimulation secondary to peripheral vasodilation, from direct stimulation of atrial β_2 receptors (human heart has a relatively high proportion of β_2 receptors; see Chapter 14), and possibly also from stimulation of myocardial β_1 receptors as the doses of β_2 agonist are increased.
- *Hypokalemia* is a potentially serious side effect. This is due to β_2 receptor stimulation of potassium entry into skeletal muscle, which may be secondary to a rise in insulin secretion. Hypokalemia might be serious in the presence of hypoxia, as in acute asthma, when there may be a predisposition to cardiac arrhythmias (Chapter 34). In practice, however, significant arrhythmias after nebulized β_2 agonists are rarely observed in acute asthma or patients with COPD.
- *Ventilation-perfusion (V/Q) mismatch* due to pulmonary vasodilation in blood vessels previously constricted by hypoxia results in the shunting of blood to poorly ventilated areas and a fall in arterial oxygen tension. Although in practice the effect of β_2 agonists on Pao_2 is usually very small (<5 mmHg fall), occasionally in severe COPD it can be large, although it may be prevented by giving additional inspired oxygen.
- *Metabolic* effects (increase in free fatty acid, insulin, glucose, pyruvate, and lactate) are usually seen only after large systemic doses.

Tolerance. Continuous treatment with an agonist often leads to tolerance, which may be due to downregulation of the receptor (see Chapter 14). Tolerance of nonairway β_2 receptor–mediated responses, such as tremor and cardiovascular and metabolic responses, is readily induced in normal and asthmatic subjects. In asthmatic patients, tolerance to the bronchodilator effects of β_2 agonists has not usually been found. However, tolerance develops to the bronchoprotective effects of β_2 agonists, and this is more marked with indirect bronchoconstrictors that activate mast cells (e.g., adenosine, allergen, and exercise) than with direct bronchoconstrictors,

TABLE 44–1 ■ SIDE EFFECTS OF β_2 AGONISTS

- Muscle tremor (direct effect on skeletal muscle β_2 receptors)
- Tachycardia (direct effect on atrial β_2 receptors, reflex effect from increased peripheral vasodilation via β_2 receptors)
- Hypokalemia (direct β_2 effect on skeletal muscle uptake of K^+)
- Restlessness
- Hypoxemia (↑ ventilation/perfusion mismatch due to reversal of hypoxic pulmonary vasoconstriction)
- Metabolic effects (↑ FFA, glucose, lactate, pyruvate, insulin)

such as histamine and methacholine. The reason for the relative resistance of airway smooth muscle β_2 responses to desensitization remains uncertain but may reflect the large receptor reserve: More than 90% of β_2 receptors may be lost without any reduction in the relaxation response. The high level of *ADRβ2 expression* in airway smooth muscle compared with peripheral lung may also contribute to the resistance to tolerance and reflect a high rate of β receptor synthesis. In addition, the expression of GRK2, which phosphorylates and inactivates occupied β_2 receptors, is very low in airway smooth muscle. By contrast, there is no receptor reserve in inflammatory cells, GRK2 expression is high, and tolerance to β_2 agonists rapidly develops at these sites.

Experimental studies have shown that corticosteroids prevent the development of tolerance in airway smooth muscle and prevent and reverse the fall in pulmonary β receptor density. However, ICSs fail to prevent the tolerance to the bronchoprotective effect of inhaled β_2 agonists, possibly because they do not reach airway smooth muscle in a high enough concentration.

Long-Term Safety. Because of a possible relationship between adrenergic drug therapy and the rise in asthma deaths in several countries during the early 1960s, doubts were cast on the long-term safety of β agonists. An epidemiological study examining the links between drugs prescribed for asthma and death or near death from asthma attacks found a marked increase in the risk of death with high doses of all inhaled β_2 agonists. The risk was greater with *fenoterol*, but when the dose is adjusted to the equivalent dose for *albuterol*, there is no significant difference in the risk for these two drugs.

The link between high β_2 agonist usage and increased asthma mortality does not prove a causal association: patients with more severe and poorly controlled asthma, who are more likely to have an increased risk of fatal attacks, are more likely to be using higher doses of β_2 agonist inhalers and less likely to be using effective anti-inflammatory treatment. Indeed, in the patients who used regular inhaled steroids, there was a significant reduction in risk of death. Studies in the literature support the following:

SABAs should be used only on demand for symptom control, and if they are required frequently (more than three times weekly), an ICS is needed.

The safety of LABAs in asthma remains controversial. LABA treatment has been associated with increased near-fatal exacerbations and death, but concomitant treatment with an ICS appears to obviate this risk, so it is *recommended that LABAs should be used only when ICSs are also prescribed (preferably in the form of a combination inhaler so that the LABAs can never be taken without the ICSs)* (Busse et al., 2018). All LABAs approved in the U.S. carry a black-box warning cautioning against overuse. There are fewer safety concerns with LABA use in COPD. No major adverse effects and no evidence of cardiovascular problems were reported in several large and prolonged studies (Kew et al., 2013).

Future Developments

The β agonists will continue to be the bronchodilators of choice for asthma because they are effective in all patients and have few or no side effects when used in low doses. When used as required for symptom control, inhaled β_2 agonists appear safe. Use of large doses of inhaled β_2 agonists indicates poor asthma control; such patients should be assessed and appropriate controller medication used. LABAs are a useful option for long-term control in asthma and COPD. In patients with asthma, LABAs should probably only be used in a fixed combination with an ICS to prevent the potential danger associated with LABAs alone. There is little advantage to be gained by improving β_2 receptor selectivity because most of the side effects of these agents are due to β_2 receptor stimulation (muscle tremor, tachycardia, hypokalemia). Once-daily inhaled β_2 agonists are useful in patients with COPD and may have additive effects with long-acting muscarinic antagonists (LAMAs). *Formoterol* combined with an ICS is now recommended as the rescue bronchodilator of choice; this combination is more effective and avoids the potential dangers of overuse of short-acting β_2 agonists (Bateman et al., 2018; O'Byrne et al., 2018).

Muscarinic Cholinergic Antagonists

The basic pharmacology of the antimuscarinic agents is presented in Chapter 11.

HISTORY

Datura stramonium (jimson weed) and related species of the nightshade family contain a mixture of muscarinic antagonists (*atropine, hyoscyamine, scopolamine*) and were smoked for relief of asthma two centuries ago. Subsequently, the purified plant alkaloid *atropine* was introduced for treating asthma. Due to the significant side effects of *atropine*, particularly drying of secretions, less-soluble quaternary compounds, such as *atropine methylnitrate* and *ipratropium bromide*, have been developed. These compounds are topically active and are not significantly absorbed from the respiratory or GI tracts.

Mode of Action

As competitive antagonists of endogenous ACh at muscarinic receptors, these agents inhibit the direct constrictor effect on bronchial smooth muscle mediated via the M_3-G_q-PLC-IP_3-Ca^{2+} pathway (see Chapters 3 and 11). The efficacy stems from the role played by the parasympathetic nervous system in regulating bronchomotor tone. The effects of ACh on the respiratory system include bronchoconstriction and tracheobronchial mucus secretion. Thus, antimuscarinic drugs antagonize these effects of ACh, resulting in bronchodilation and reduced mucus secretion. ACh may also result in structural changes such as airway fibrosis and an increase in neutrophilic inflammation (Kistemaker and Gosens, 2015).

Acetylcholine may be released from airway cells other than neurons, including epithelial cells (Kummer and Krasteva-Christ, 2014). The synthesis of ACh in epithelial cells is increased by inflammatory stimuli (such as tumor necrosis factor [TNF] α), which increase the expression of choline acetyltransferase, which could contribute to cholinergic effects in airway diseases. Muscarinic receptors are expressed in airway smooth muscle of small airways that do not appear to be significantly innervated by cholinergic nerves; these receptors may be a mechanism of cholinergic narrowing in peripheral airways that could be relevant in COPD, responding to locally synthesized, nonneuronal ACh.

Myriad mechanical, chemical, and immunological stimuli elicit reflex bronchoconstriction via vagal pathways, and cholinergic pathways may play an important role in regulating acute bronchomotor responses in animals. Anticholinergic drugs will inhibit only ACh-mediated bronchoconstriction and will have no blocking effect on the *direct* effects of inflammatory mediators, such as histamine and LTs. Furthermore, cholinergic antagonists probably have little or no effect on mast cells, microvascular leak, or the chronic inflammatory response.

Clinical Use

In asthmatic patients, anticholinergic drugs are less effective as bronchodilators than β_2 agonists and offer less-efficient protection against bronchial challenges. LAMAs are currently used as an additional bronchodilator in asthmatic patients not controlled on maximal doses of LABA. Nebulized anticholinergic drugs are effective in acute severe asthma but less effective than β_2 agonists. In the acute and chronic treatment of asthma, anticholinergic drugs may have an additive effect with β_2 agonists and should therefore be considered when control of asthma is not adequate with nebulized β_2 agonists. A muscarinic antagonist should be considered when there are problems with *theophylline* or when inhaled β_2 agonists cause a troublesome tremor in elderly patients.

In COPD, anticholinergic drugs may be as effective as or even superior to β_2 agonists. Their relatively greater effect in COPD than in asthma may be explained by an inhibitory effect on vagal tone, which, although not necessarily increased in COPD, may be the only reversible element of airway obstruction and one that is exaggerated by geometric factors in the narrowed airways of patients with COPD (Figure 44–5). Anticholinergic drugs reduce air trapping and improve exercise tolerance in patients with COPD.

Therapeutic Choices

The short-acting muscarinic antagonist (SAMA) *ipratropium bromide* is available as a pMDI and nebulized preparation. The onset of

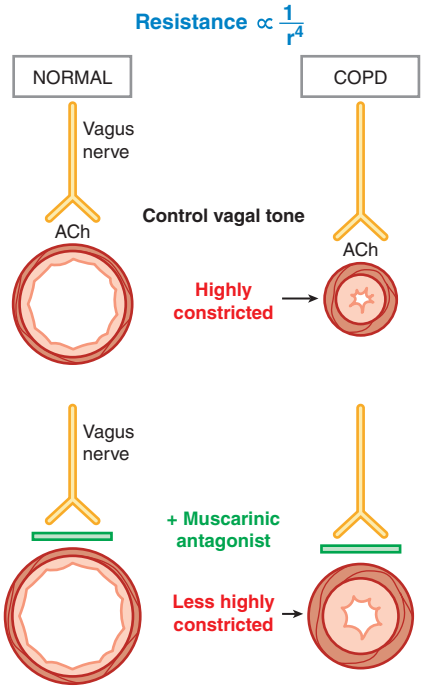

Figure 44–5 *Anticholinergic drugs inhibit vagally mediated airway tone, thereby producing bronchodilation.* This effect is small in normal airways but is greater in airways of patients with COPD, which are structurally narrowed and have higher resistance to airflow because airway resistance is inversely related to the fourth power of the radius r.

bronchodilation is relatively slow and is usually maximal 30 to 60 min after inhalation but may persist for 6 to 8 h. It is usually given by MDI three or four times daily on a regular basis, rather than intermittently for symptom relief, in view of its slow onset of action, but has now been replaced by LAMAs, such as *tiotropium bromide*.

Long-Acting Muscarinic Antagonists

Several LAMAs have now been developed for the treatment of COPD and, more recently, severe asthma. *Tiotropium bromide* is a long-acting anticholinergic drug that is suitable for once-daily dosing as a DPI or via a soft mist inhaler device and is more effective than *ipratropium* four times daily according to several studies; it also significantly reduces exacerbations. *Tiotropium* binds to all muscarinic receptor subtypes but dissociates slowly from M_3 and M_1 receptors, giving it a degree of kinetic receptor selectivity for these receptors compared with M_2 receptors, from which it dissociates more rapidly. Thus, compared with *ipratropium*, *tiotropium* is less likely to antagonize M_2-mediated inhibition of ACh release (the resulting increase in ACh could counteract the blockade of M_3 receptor–mediated bronchoconstriction) (see Chapter 11). Over a 4-year period, *tiotropium* improved lung function and health status and reduced exacerbations and all-cause mortality (Tashkin et al., 2008). Although there was no effect on disease progression overall, there was a small effect in the patients with moderate COPD (Global Initiative for Chronic Obstructive Lung Disease [GOLD] stage 2; GOLD, 2021) (Decramer et al., 2009).

Glycopyrrolate bromide and *umeclidinium bromide* are also once-daily LAMAs with very similar clinical effects to *tiotropium*, whereas *aclidinium bromide* is given twice daily (Cazzola et al., 2013). LAMAs are now the bronchodilators of choice for patients with COPD in preference to LABAs alone (Cho et al., 2018). LAMAs are also effective as additional bronchodilators in patient with asthma not adequately controlled with maximal ICS/LABA therapy, although not all patients respond and there is little effect on symptoms and only a small additional protection against exacerbations (Kerstjens et al., 2015).

Combination Inhalers

There are additive bronchodilator effects between anticholinergics and β_2 agonists in patients with COPD, which has led to the development of fixed-dose combinations. SABA/SAMA combinations, such as *albuterol/ipratropium*, are popular as a reliever. Several studies have demonstrated additive effects of these two drugs, thus providing an advantage over increasing the dose of β_2 agonist in patients who experience side effects.

LABA/LAMA dual combination inhalers have also been developed, including *indacaterol/glycopyrrolate, vilanterol/umeclidinium,* and *olodaterol/tiotropium* (all once daily), and *formoterol/glycopyrrolate* and *formoterol/aclidinium* (twice daily), which all show beneficial effects on lung function compared with either LABA or LAMA alone, although they may not be clearly beneficial in terms of reducing exacerbations (Mammen et al., 2020).

Adverse Effects

Inhaled anticholinergic drugs are generally well tolerated. On stopping inhaled anticholinergics, a small rebound increase in airway responsiveness has been described. Systemic side effects after SAMA or LAMA are uncommon during normal clinical use because there is little systemic absorption. Because cholinergic agonists can stimulate *mucus secretion*, there has been concern that anticholinergics may reduce secretion and lead to more viscous mucus. However, *ipratropium bromide* and *tiotropium bromide*, even in high doses, have no detectable effect on mucociliary clearance in either normal subjects or in patients with airway disease. A significant unwanted effect is the unpleasant *bitter taste* of inhaled *ipratropium*, which may contribute to poor compliance. Nebulized *ipratropium bromide* may precipitate *glaucoma* in elderly patients due to a direct effect of the nebulized drug on the eye. This may be prevented by nebulization with a mouthpiece rather than a face mask.

Reports of *paradoxical bronchoconstriction* with *ipratropium bromide*, particularly when given by nebulizer, were largely explained as effects of the hypotonic nebulizer solution and by antibacterial additives, such as benzalkonium chloride and EDTA. This problem has not been described with *tiotropium bromide* or other LAMAs. Occasionally, bronchoconstriction may occur with *ipratropium bromide* given by metered-dose inhaler (MDI). It is possible that this is due to blockade of prejunctional M_2 receptors on airway cholinergic nerves that normally inhibit ACh release.

LAMAs cause dryness of the mouth in 10% to 15% of patients, but this usually disappears during continued therapy. Urinary retention is occasionally seen in elderly patients.

Future Developments

The LABA/LAMA fixed-combination inhalers are likely to become the bronchodilators of choice in patients with COPD, and LAMAs are added to ICS/LABA combinations in severe asthma.

Triple inhalers that have the ICS/LABA/LAMA combination are now available and include *fluticasone furoate/vilanterol/umeclidinium* once daily and *budesonide/formoterol/glycopyrrolate* and *beclomethasone propionate/formoterol/glycopyrrolate* given twice daily (Ritondo et al., 2021). Triple inhalers are more effective than LABA/LAMA or ICS/LABA combinations in reducing exacerbations in COPD patients and may reduce cardiovascular mortality (Lipson et al., 2018; Rabe et al., 2020). Triple inhalers may also be the treatment of choice for patients with asthma-COPD overlap (Park et al., 2021).

Dual-action drugs that are both muscarinic antagonists and β_2 agonists (known as MABAs) are also in clinical development, but it has proved difficult to balance the β agonist and anticholinergic activities (Hughes et al., 2012).

Phosphodiesterase Inhibitors

The phosphodiesterase (PDE) inhibitors relax smooth muscle and inhibit inflammatory cells through an increase in cellular cAMP and its sequelae. PDE4 is the predominant PDE isoform in inflammatory cells, including mast cells, eosinophils, neutrophils, T lymphocytes, macrophages, and structural cells such as sensory nerves and epithelial cells, suggesting that PDE4 inhibitors could be useful as an anti-inflammatory treatment in both asthma and COPD (Spina and Page, 2017). In animal models of asthma, PDE4 inhibitors reduce eosinophil infiltration and responses to

allergen; in COPD, they are effective against smoke-induced inflammation and emphysema.

Of the four subfamilies of PDE4, PDE4D is the major form whose inhibition is associated with vomiting, a limiting side effect. Inhibition of PDE4B is important for anti-inflammatory effects.

To overcome the problems of dose-limiting side effects, compounds selective for PDE4B have been developed but have not shown any clinical advantage (Goto et al., 2014). Several inhaled PDE4 inhibitors have been developed that avoid side effects seen with oral administration, but most lack efficacy (Phillips, 2020). One potent inhaled PDE4 inhibitor, CHF6001, reduces the late response to allergen in patients with mild asthma but provides no significant improvement in COPD patients (Singh et al., 2020). A dual PDE3/4 inhibitor provides bronchodilation in patients with COPD when given by nebulization but its anti-inflammatory effects are uncertain (Franciosi et al., 2013).

Roflumilast

Roflumilast is an oral nonselective PDE4 inhibitor that is converted to its more active and long-acting metabolite, roflumilast *N*-oxide.

ADME. The drug is well absorbed after oral administration (bioavailability ~80%). It is extensively metabolized to its *N*-oxide active metabolite by CYPs 3A4 and 1A2. Thus, agents that inhibit these CYPs (e.g., *erythromycin*, *ketoconazole*, *fluvoxamine*, *enoxacin*, *cimetidine*) will increase the area under the curve (AUC) for *roflumilast*. Conversely, *rifampicin*, an inducer of CY3A4, will decrease *roflumilast*'s C_{max} and AUC; thus, a strong CYP inducer could reduce the effectiveness of *roflumilast*. The drug and its active metabolite are largely excreted as conjugates in the urine.

Therapeutic Use. *Roflumilast* is currently used as an additional therapy in patients with severe COPD with chronic bronchitis who continue to have exacerbations despite treatment with triple inhaled therapy (ICS + LABA + LAMA). *Roflumilast* is approved for patients with COPD with severe disease (force expiratory volume in 1 sec [FEV_1] <50% predicted, frequent exacerbations, and chronic bronchitis). Given once daily by mouth (500-mg tablet), it reduces exacerbations by approximately 20% but has little effect on symptoms and lung function (Calverley et al., 2009); it is effective on top of long-acting bronchodilators and ICSs (Martinez et al., 2016).

In patients with mild asthma, *roflumilast* provides improvement in FEV_1 similar to an ICS; its has similar positive effects when added to *montelukast* in moderate to severe asthma (Bateman et al., 2016). Thus, it may be suitable for treating patients with predominantly neutrophilic inflammation. It should not be used for acute bronchospasm.

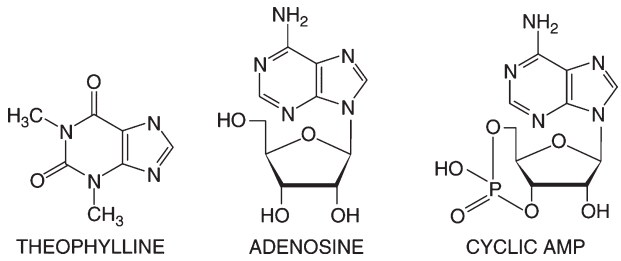
Untoward Effects; Drug Interactions. The relatively weak efficacy of *roflumilast* is due to dose limitations as a result of side effects, particularly diarrhea, headaches, and nausea, which are also due to PDE4 inhibition. *Roflumilast* is contraindicated in severe liver impairment (Child-Pugh B or C). There are insufficient data on the safety of *roflumilast* during pregnancy; the drug should be used with caution and only if the benefits outweigh the risk to the fetus.

Ensifentrine

Ensifentrine (RPL554) is an inhaled PDE3/4 inhibitor with 3.5 orders of magnitude selectivity for PDE3 over PDE4 (Cazzola et al., 2019a). Inhaled *ensifentrine* induces bronchodilatation in asthmatic and COPD patients, which is likely to be due to PDE3 inhibition. Anti-inflammatory effects have not been convincingly demonstrated, likely explained by its low PDE4 inhibitory activity. While *ensifentrine* produces an additional bronchodilator response in COPD when added to an inhaled LAMA, it has not been demonstrated to have further bronchodilatation in COPD patients on a LABA-LAMA combination inhaler, so its clinical value is questionable. *Ensifentrine* can reduce symptoms in COPD patients (Watz et al., 2020). Although most of the clinical studies have been performed using a nebulized formulation, dry powder and pMDI formulations have now been developed. The drug is in phase III studies in COPD patients.

Methylxanthines

Methylxanthines, such as *theophylline*, which are related to caffeine, have been used in the treatment of asthma since 1930, and *theophylline* is still widely used in developing countries because it is inexpensive. *Theophylline* became more useful with the introduction of reliable slow-release preparations. However, inhaled β_2 agonists are far more effective as bronchodilators, and ICSs have a greater anti-inflammatory effect. In patients with severe asthma and COPD, it still remains a useful drug as an add-on therapy (Barnes, 2013b).



Chemistry

Theophylline is a methylxanthine similar in structure to the common dietary xanthines caffeine and theobromine. Several substituted derivatives have been synthesized, but only two appear to have any advantage over *theophylline*: *Enprofylline* is a more potent bronchodilator and may have fewer toxic effects because it does not antagonize adenosine receptors; *doxofylline*, a methylxanthine available in some countries, inhibits PDEs similarly to *theophylline* but is less active as an adenosine antagonist and has a more favorable side effect profile (Cazzola and Matera, 2020). Many salts of *theophylline* have also been marketed; the most common is *aminophylline*. Other salts do not have any advantage. *Theophylline* remains the major methylxanthine in clinical use.

Mechanism of Action

In addition to its bronchodilator action, *theophylline* has many nonbronchodilator effects that may be relevant to its effects in asthma and COPD (Figure 44–6). Several molecular mechanisms of action have been proposed:

- *Inhibition of PDEs*. *Theophylline* is a nonselective PDE inhibitor, but the degree of inhibition is relatively modest at concentrations of *theophylline* that are within the therapeutic range. PDE inhibition and the concomitant elevation of cellular cAMP and cyclic GMP likely account for the bronchodilator action of *theophylline*. Several isoenzyme families of PDE have now been recognized, and those important in smooth muscle relaxation include PDE3, PDE4, and PDE5, but inhibition of PDE3 is likely to be a main mechanism of bronchodilation,
- *Adenosine receptor antagonism*. *Theophylline* antagonizes adenosine receptors at therapeutic concentrations. Adenosine causes bronchoconstriction in airways from asthmatic patients by releasing histamine and LTs. Antagonism of adenosine A_1 receptors may be responsible for serious side effects, including cardiac arrhythmias and seizures.
- *Interleukin (IL)-10 release*. IL-10 has a broad spectrum of anti-inflammatory effects, and its secretion is reduced in asthma and COPD. IL-10 release is increased by *theophylline*, and this effect may be mediated via PDE inhibition, although this has not been seen at the low doses that are effective in asthma.
- *Effects on gene transcription*. *Theophylline* prevents the translocation of the proinflammatory transcription factor nuclear factor-κB (NF-κB) into the nucleus, potentially reducing the expression of inflammatory genes in asthma and COPD (Ichiyama et al., 2001). However, these effects are seen at high concentrations and may be mediated by inhibition of PDE.
- *Effects on apoptosis*. Prolonged survival of granulocytes due to a reduction in apoptosis may be important in perpetuating chronic inflammation in asthma (eosinophils) and COPD (neutrophils). *Theophylline* promotes apoptosis in eosinophils and neutrophils *in vitro*, an effect mediated by antagonism of adenosine A_{2a} receptors

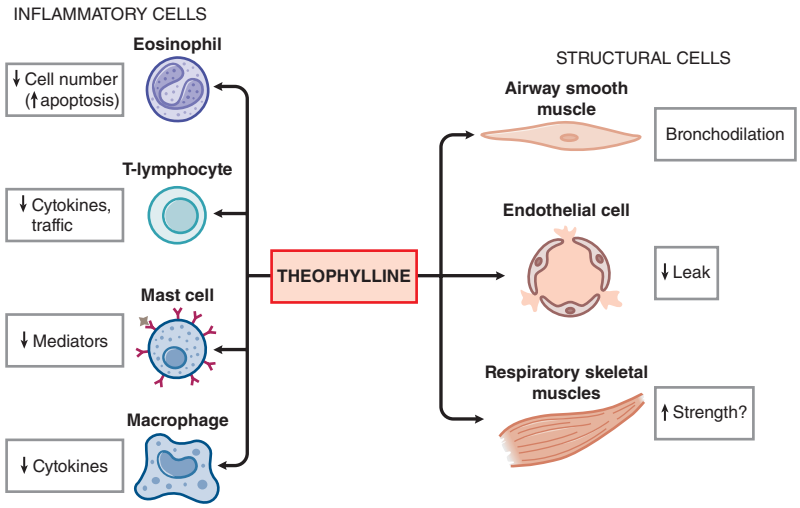


Figure 44–6 *Theophylline affects multiple cell types in the airway.*

(Yasui et al., 2000). *Theophylline* also induces apoptosis in T lymphocytes via PDE inhibition.

- *Histone deacetylase (HDAC) activation.* Recruitment of HDAC2 by glucocorticoid receptors (GRs) switches off activated inflammatory genes. Therapeutic concentrations of *theophylline* activate HDAC, thereby enhancing the anti-inflammatory effects of corticosteroids (Cosio et al., 2004). This mechanism is independent of PDE inhibition or adenosine antagonism and is mediated by inhibition of phosphoinositide-3-kinase-δ, which is activated by oxidative stress (To et al., 2010). Low concentrations of *theophylline* (1–5 mg/L) increase HDAC activity assessed in bronchial biopsies of asthmatic patients and correlate with the reduction in eosinophil numbers in the biopsy.

Nonbronchodilator Effects

Theophylline has clinical benefit in asthma and COPD at plasma concentrations less than 10 mg/L, sufficiently low that such effects are unlikely to be fully explained by its PDE3 inhibition. *Theophylline* has anti-inflammatory effects in asthma; chronic oral treatment with *theophylline* inhibits the late response to inhaled allergen, reduces infiltration of eosinophils and $CD4^+$ lymphocytes into the airways after allergen challenge, and reduces eosinophils in bronchial walls and sputum (Lim et al., 2001). In patients with COPD, *theophylline* reduces the total number and proportion of neutrophils in induced sputum, the concentration of CXCL8, and neutrophil chemotactic responses (Culpitt et al., 2002). *Theophylline* withdrawal in patients with COPD results in worsening of disease. In vitro, *theophylline* increases responsiveness to corticosteroids and reverses steroid resistance in cells from COPD patients (Ito et al., 2002) via activastion of HDAC2 (Ito et al., 2002).

Pharmacokinetics and Metabolism

Theophylline has antiasthmic effects other than bronchodilation below 10 mg/L, so the therapeutic range is now considered as 5 to 15 mg/L (28–83 μM). The dose of *theophylline* required to give these therapeutic concentrations varies among subjects, largely because of differences in plasma clearance of the drug. *Theophylline* is rapidly and completely absorbed, but there are large interindividual variations in clearance due to differences in hepatic metabolism. *Theophylline* is metabolized in the liver, mainly by CYP1A2; many factors influence hepatic metabolism and clearance of *theophylline* (Table 44–2).

Because of these variations in clearance, individualization of *theophylline* dosage is required, and plasma concentrations should be measured 4 h after the last dose with slow-release preparations when steady state has been achieved. There is no significant circadian variation in *theophylline* metabolism, although there may be delayed absorption at night related to supine posture.

Preparations and Routes of Administration

Intravenous aminophylline, an ethylene diamine ester of *theophylline* that is water soluble, has been used for many years in the treatment of acute severe asthma. The recommended dose is 6 mg/kg given intravenously over 20 to 30 min, followed by a maintenance dose of 0.5 mg/kg per hour. If the patient is already taking *theophylline* or there are any factors that decrease clearance, these doses should be halved, and the plasma level checked more frequently. Nebulized β_2 agonists are now preferred over intravenous *aminophylline* for acute exacerbations of asthma and COPD.

Oral immediate-release *theophylline* tablets or elixirs, which are rapidly absorbed, give wide fluctuations in plasma levels and are not recommended. Several sustained-release preparations are now available that are absorbed at a constant rate and provide steady plasma concentrations over a 12- to 24-h period. Both slow-release *aminophylline* and *theophylline* are available and are equally effective (although the ethylene diamine component of *aminophylline* has been implicated in allergic reactions). For continuous treatment, twice-daily therapy (~8 mg/kg twice daily) is needed. For nocturnal asthma, a single dose of slow-release *theophylline* at night is often effective. Once optimal doses have been determined, routine monitoring of plasma concentrations is usually not necessary unless a change in clearance is suspected or evidence of toxicity emerges.

TABLE 44–2 ■ FACTORS AFFECTING CLEARANCE OF THEOPHYLLINE

Increased clearance

- Enzyme induction (mainly CYP1A2) by coadministered drugs (e.g., rifampicin, barbiturates, ethanol)
- Smoking (tobacco, marijuana) via CYP1A2 induction
- High-protein, low-carbohydrate diet
- Barbecued meat
- Childhood

Decreased clearance

- CYP inhibition (cimetidine, erythromycin, ciprofloxacin, allopurinol, fluvoxamine, zileuton, zafirlukast)
- Congestive heart failure
- Liver disease
- Pneumonia
- Viral infection and vaccination
- High-carbohydrate diet
- Old age

Clinical Use

In patients with acute asthma, intravenous *aminophylline* is less effective than nebulized β_2 agonists and should therefore be reserved for those patients who fail to respond to, or are intolerant of, β agonists. *Theophylline* should not be added routinely to nebulized β_2 agonists because it does not increase the bronchodilator response and may increase their side effects. *Theophylline* has been used as a controller in the management of mild persistent asthma, although it is usually found to be less effective than low doses of ICSs. Addition of low-dose *theophylline* to an ICS in patients who are not adequately controlled provides better symptom control and lung function than doubling the dose of ICS (Lim et al., 2000). LABAs are more effective as an add-on therapy, but *theophylline* is considerably less expensive and may be the only affordable add-on treatment when the costs of medication are limiting.

Theophylline is still used as a bronchodilator in COPD, but inhaled anticholinergics and β_2 agonists are preferred. *Theophylline* tends to be added to these inhaled bronchodilators in patients with more severe disease and can give additional clinical improvement when added to a LABA (Ram et al., 2005). However, low-dose *theophylline* does not reduce exacerbations when added to ICS in patients with severe COPD (Devereux et al., 2018) or reduce exacerbations with or without a low dose of oral corticosteroids (Jenkins et al., 2020b).

Side Effects

Unwanted effects of *theophylline* are usually related to plasma concentration and tend to occur at C_p greater than 15 mg/L. The most common side effects are headache, nausea, and vomiting (due to inhibition of PDE4), abdominal discomfort, and restlessness (Table 44–3). There may also be increased acid secretion (PDE inhibition) and diuresis (antagonism of adenosine A_1 receptors). *Theophylline* may lead to behavioral disturbance and learning difficulties in schoolchildren. At high concentrations, cardiac arrhythmias may occur due to inhibition of cardiac PDE3 and antagonism of cardiac A_1 receptors. At very high concentrations, seizures may occur due to central A_1 receptor antagonism. Use of low doses of *theophylline*, targeting plasma concentrations of 5 to 10 mg/L, largely avoids side effects and drug interactions.

Summary and Future Developments

Theophylline use has been declining, partly because of the problems with side effects, but mainly because more effective therapy with β_2 agonists and ICSs has been introduced. Oral *theophylline* remains a useful add-on treatment in some patients with difficult asthma and appears to have effects beyond those provided by steroids. Rapid-release *theophylline* preparations are the only affordable antiasthma medication in some developing countries. There is increasing evidence that *theophylline* has some antiasthmic effect at doses that are lower than those needed for bronchodilation, and plasma levels of 5 to 15 mg/L are recommended.

Novel Classes of Bronchodilator

Currently, the most effective bronchodilators are LABAs for asthma and a LAMA for COPD. Inventing new classes of bronchodilator has been difficult; several agents have had problems with vasodilator side effects because they relax vascular smooth muscle to a greater extent than airway smooth muscle.

TABLE 44–3 ■ SIDE EFFECTS OF THEOPHYLLINE AND MECHANISMS

SIDE EFFECT	PROPOSED MECHANISM
Nausea and vomiting	PDE4 inhibition
Headaches	PDE4 inhibition
Gastric discomfort	PDE4 inhibition
Diuresis	A_1 receptor antagonism
Behavioral disturbance (?)	?
Cardiac arrhythmias	PDE3 inhibition, A_1 receptor antagonism
Epileptic seizures	A_1 receptor antagonism

Magnesium Sulfate

Magnesium sulfate ($MgSO_4$) is useful as an additional bronchodilator in children and adults with acute severe asthma. Intravenous or nebulized $MgSO_4$ benefits adults and children with severe exacerbations (FEV_1 <30% of predicted value), giving improvement in lung function when added to nebulized β_2 agonist and a reduction in hospital admissions (Knightly et al., 2017). The treatment is cheap and well tolerated, although the clinical benefit appears small. Side effects include flushing and nausea but are usually minor. $MgSO_4$ appears to act as a bronchodilator and may reduce cytosolic Ca^{2+} concentrations in airway smooth muscle cells. The concentration of *magnesium* is lower in serum and erythrocytes of asthmatic patients than in normal controls and correlates with airway hyperresponsiveness, although the improvement in acute severe asthma after *magnesium* does not correlate with plasma concentrations. The effects of intravenous $MgSO_4$ in COPD are minimal, and there are too few studies to make any firm recommendation (Vafadar Moradi et al., 2021).

Potassium Channel Openers

The K^+ channel openers such as *cromakalim* or *levcromakalim* (the *levo*-isomer of *cromakalim*) open ATP-dependent K^+ channels in smooth muscle, leading to membrane hyperpolarization and relaxation of airway smooth muscle (Pelaia et al., 2002). Clinical studies in asthma have been disappointing, with no bronchodilation or protection against bronchoconstrictor challenges. These agents are dose-limited by cardiovascular side effects so their development has been stopped. Ca^{2+}-activated large conductance K^+ channels (maxi-K channels) are also opened by β_2 agonists; so maxi-K activators are being considered as bronchodilators.

Vasoactive Intestinal Polypeptide Analogues

Vasoactive intestinal polypeptide (VIP) is a 28-amino acid peptide. It binds to two G protein-coupled receptors (GPCRs), $VPAC_1$ and $VPAC_2$, both of which couple primarily to G_s to stimulate the adenylyl cyclase–cAMP–PKA pathway leading to relaxation of smooth muscle. VIP is a potent dilator of human airway smooth muscle *in vitro* but is not effective in patients because it is rapidly metabolized (plasma $t_{1/2}$ ~2 min); in addition, VIP causes vasodilator side effects. More stable analogues of VIP, such as Ro 25-1533, which selectively stimulates VIP receptors in airway smooth muscle (via $VPAC_2$), have been synthesized. Inhaled Ro 25-1533 has a rapid bronchodilator effect in asthmatic patients, but it is not as prolonged as *formoterol* (Linden et al., 2003).

Bitter Taste Receptor Agonists

Bitter taste receptors (TAS2R) are GPCRs that are expressed in airway smooth muscle and mediate bronchodilation in response to agonists, such as *quinine* and *chloroquine*, even after β_2 receptor desensitization (Nayak et al., 2019). However, current agonists are weak, so more potent drugs are needed.

Other Inhibitors of Smooth Muscle Contraction

Agents that inhibit the contractile machinery of airway smooth muscle, including rho kinase inhibitors, inhibitors of myosin light chain kinase, and allosteric modulators of smooth muscle myosin (Sirigu et al., 2016), are also in development. Because such agents would also cause vasodilation, it would be necessary to administer them by inhalation.

Corticosteroids

The introduction of *ICSs*, as a way of reducing the requirement and side effects of oral glucocorticosteroids, has revolutionized the treatment of chronic asthma (Barnes, 2017). Because asthma is a chronic inflammatory disease, ICSs are considered first-line therapy in all but patients with the mildest disease. In marked contrast, ICSs are much less effective in COPD and should be used only in patients with severe disease who have

frequent exacerbations and increased blood eosinophils. Oral corticosteroids remain the mainstay of treatment of several other pulmonary diseases, such as sarcoidosis and pulmonary eosinophilic syndromes. The general pharmacology of corticosteroids is presented in Chapter 50.

Mechanism of Action

Corticosteroids enter target cells and bind to GRs in the cytoplasm (see Figure 50–7. There is only one type of GR that binds corticosteroids and no evidence for the existence of subtypes that might mediate different aspects of corticosteroid action (Barnes, 2011). The steroid-GR complex moves into the nucleus, where it binds to specific sequences on the upstream regulatory elements of certain target genes, resulting in increased (or, rarely, decreased) transcription of the gene, with subsequent increased (or decreased) synthesis of the gene products.

The GRs may also interact with protein transcription factors and coactivator molecules in the nucleus and thereby influence the synthesis of certain proteins independently of any direct interaction with DNA. The repression of transcription factors, such as AP-1 and NF-κB, is likely to account for many of the anti-inflammatory effects of steroids in asthma. Corticosteroids reverse the activating effect of these proinflammatory transcription factors on histone acetylation by recruiting HDAC2 to inflammatory genes that have been activated through acetylation of associated histones (Figure 44–7). GRs are acetylated when corticosteroids are bound and bind to DNA in this acetylated state as dimers, whereas the acetylated GR has to be deacetylated by HDAC2 to interact with inflammatory genes and NF-κB (Ito et al., 2006).

There may be additional mechanisms that are also important in the anti-inflammatory actions of corticosteroids. Corticosteroids have potent inhibitory effects on MAP kinase signaling pathways through the induction of MAP kinase phosphatase 1, which may inhibit the expression of multiple inflammatory genes.

Anti-inflammatory Effects in Asthma

Corticosteroids have widespread effects on gene transcription, increasing the transcription of several anti-inflammatory genes and suppressing transcription of many inflammatory genes. Steroids have inhibitory effects on many inflammatory and structural cells that are activated in asthma and prevent the recruitment of inflammatory cells into the airways (Figure 44–8). In patients with mild asthma, the inflammation may be completely resolved after inhaled steroids.

Steroids potently inhibit the formation of multiple inflammatory cytokines, particularly cytokines released from T_H2 cells. Corticosteroids also decrease eosinophil survival by inducing apoptosis. Corticosteroids inhibit the expression of multiple inflammatory genes in airway epithelial cells, probably the most important action of ICSs in suppressing asthmatic inflammation. Corticosteroids also prevent and reverse the increase in vascular permeability due to inflammatory mediators and may therefore lead to resolution of airway edema. Steroids have a direct inhibitory effect on mucus glycoprotein secretion from airway submucosal glands, as well as indirect inhibitory effects by downregulation of inflammatory stimuli that stimulate mucus secretion.

Corticosteroids have no direct effect on contractile responses of airway smooth muscle; improvement in lung function after ICSs is presumably due to an effect on the chronic airway inflammation, edema, and airway hyperresponsiveness. A single dose of an ICS has no effect on the early response to allergen (reflecting the ICS's lack of effect on mast cell mediator release) but inhibits the late response (which may be due to an effect on macrophages, eosinophils, and airway wall edema) and also inhibits the increase in airway hyperresponsiveness.

The ICSs have rapid anti-inflammatory effects, reducing airway hyperresponsiveness and inflammatory mediator concentrations in sputum within a few hours (Erin et al., 2008). However, it may take several weeks or months to achieve maximal effects on airway hyperresponsiveness,

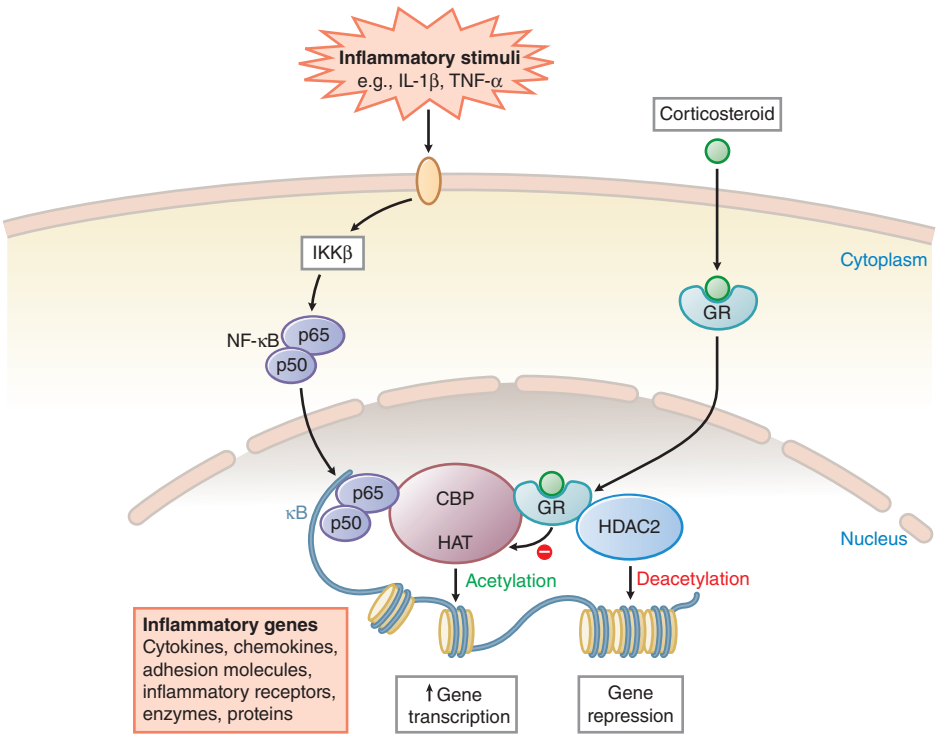

Figure 44–7 *Mechanism of anti-inflammatory action of corticosteroids in asthma.* Inflammatory stimuli (IL-1β, TNF-α, etc.) activate IKKβ, leading to activation of the transcription factor NF-κB. A dimer of p50 and p65 NF-κB proteins translocates to the nucleus and binds to specific κB recognition sites and to coactivators, such as the CREB-binding protein (CBP), which have intrinsic histone acetyltransferase (HAT) activity. This results in acetylation of core histones and consequent increased expression of genes encoding multiple inflammatory proteins. Cytosolic GRs bind corticosteroids; the receptor-ligand complexes translocate to the nucleus and bind to coactivators to inhibit HAT activity in two ways: directly and, more importantly, by recruiting HDAC2, which reverses histone acetylation, leading to the suppression of activated inflammatory genes.

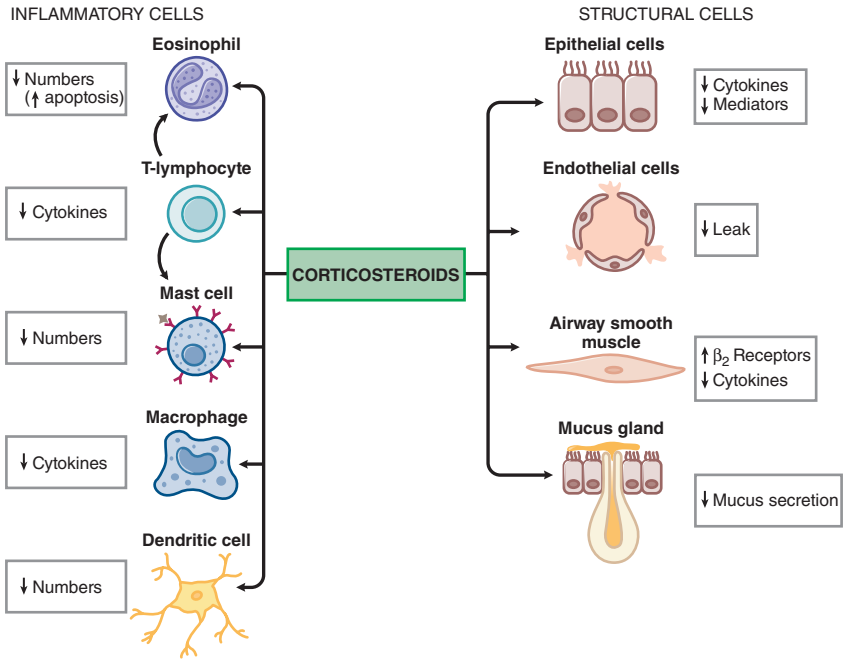

Figure 44–8 *Effect of corticosteroids on inflammatory and structural cells in the airways.*

presumably reflecting the slow healing of the damaged inflamed airway. It is important to recognize that corticosteroids *suppress* inflammation in the airways but do not cure the underlying disease. When steroids are withdrawn, there is a recurrence of the same degree of airway hyperresponsiveness, although in patients with mild asthma, it may take several months to return.

Interaction with β_2 Adrenergic Receptors

Steroids potentiate the effects of β agonists on bronchial smooth muscle and prevent and reverse β receptor desensitization in airways *in vitro* and *in vivo* (Newton and Giembycz, 2016). At a molecular level, corticosteroids increase the transcription of the β_2 receptor gene in human lung *in vitro* and in the respiratory mucosa *in vivo* and also increase the stability of its messenger RNA. They also prevent or reverse uncoupling of β_2 receptors to G_s. In experimental systems, corticosteroids prevent downregulation of β_2 receptors.

β_2 Agonists also enhance the action of GRs, resulting in increased nuclear translocation of liganded GR receptors and enhancing the binding of GRs to DNA. This effect has been demonstrated in sputum macrophages of asthmatic patients after an ICS and inhaled LABA (Barnes, 2017). This suggests that β_2 agonists and corticosteroids enhance each other's beneficial effects in asthma therapy.

Pharmacokinetics

The pharmacokinetics of oral corticosteroids are described in Chapter 50. The pharmacokinetics of ICSs are important in relation to systemic effects (Barnes, 2017). The fraction of steroid that is inhaled into the lungs acts locally on the airway mucosa but may be absorbed from the airway and alveolar surface. Thus, a portion of an inhaled dose reaches the systemic circulation. Furthermore, the fraction of inhaled steroid that is deposited in the oropharynx is swallowed and absorbed from the gut. The absorbed fraction may be metabolized in the liver (first-pass metabolism) before reaching the systemic circulation (see Figure 44–3). The use of a spacer chamber reduces oropharyngeal deposition and therefore reduces systemic absorption of ICSs, although this effect is minimal in corticosteroids with a high first-pass metabolism. Mouth rinsing and discarding the rinse have a similar effect, and this procedure should be used with high-dose dry powder steroid inhalers when spacer chambers cannot be used.

Beclomethasone dipropionate (BDP) and *ciclesonide* are prodrugs that release the active corticosteroid after the ester group is cleaved by esterases in the lung. *Ciclesonide* is available as an MDI for asthma and as a nasal spray for allergic rhinitis. *Budesonide, fluticasone propionate*, and *mometasone furoate* have a greater first-pass metabolism than BDP and are therefore less likely to produce systemic effects at high inhaled doses.

Routes of Administration and Dosing

Inhaled Corticosteroids in Asthma

Inhaled corticosteroids are recommended as first-line therapy for patients with persistent asthma. They should be started in any patient who needs to use a β_2 agonist inhaler for symptom control more than twice weekly. They are effective in mild, moderate, and severe asthma and in children as well as adults (Barnes, 2017).

Most of the benefit may be obtained from doses of less than 400 µg BDP or equivalent. However, some patients (with relative corticosteroid resistance) may benefit from higher doses (up to 2000 µg/day). For most patients, ICSs should be used twice daily, a regimen that improves adherence once control of asthma has been achieved (which may require four-time daily dosing initially or a course of oral steroids if symptoms are severe). Administration once daily of some steroids (e.g., *budesonide*, *mometasone*, and *ciclesonide* in mild asthma and *fluticasone furoate* in all patients) is effective when doses of 400 µg or less are needed. If a dose greater than 800 µg daily via pMDI is used, a spacer device should be employed to reduce the risk of oropharyngeal side effects. ICSs may be used in children in the same way as in adults; at doses of 400 µg/day or less, there is no evidence of significant growth suppression (Agertoft and Pedersen, 2000; Pedersen, 2001). The dose of ICS should be the minimal dose that controls asthma; once control is achieved, the dose should be slowly reduced. Nebulized corticosteroids (e.g., *budesonide*) are useful in the treatment of small children who are not able to use other inhaler devices.

ICSs may also be used in combination with a rapidly acting β_2 agonist such as *formoterol* or *albuterol* (anti-inflammatory reliever) as a reliever in patients with mild asthma. The combination gives better control of asthma and exacerbations with lower overall doses of ICS than with regular low-dose ICS (Bateman et al., 2018; O'Byrne et al., 2018). The ICS-*formoterol* inhaler as twice-daily maintenance (single inhaler maintenance and reliever therapy [SMART]) is not yet approved in the U.S. (Global Initiative for Asthma, 2021; Jenkins et al., 2020a).

Inhaled Corticosteroids in COPD

ICSs are far less effective in the treatment of COPD than asthma (Ernst et al., 2015), and their major effect is reducing exacerbations in selected patients who have frequent exacerbations (≥2 severe exacerbations/year) and have increased blood eosinophils (>300 cells/μL). Corticosteroids do not appear to have any significant anti-inflammatory effect in COPD; there appears to be an active resistance mechanism, which may be explained by impaired activity of HDAC2 as a result of oxidative stress (Barnes, 2013a). ICSs have no effect on the progression of COPD, even when given to patients with presymptomatic disease; in addition, ICSs have no effect on mortality (Vestbo et al., 2016). Many patients are treated unnecessarily with high doses of ICS, and because these doses may cause long-term systemic side effects, ICSs can be safely withdrawn in the absence of frequent exacerbations with a high blood eosinophil count (Calverley et al., 2017). For COPD patients who benefit from ICS, it is convenient to administer the agent via a triple fixed-dose inhaler in combination with a LABA and a LAMA (Ritondo et al., 2021).

Patients with cystic fibrosis and bronchiectasis, which involve chronic neutrophilic inflammation of the airways, are also resistant to high doses of ICS.

Systemic Steroids

Intravenous steroids are indicated in acute asthma if lung function is less than 30% predicted and in patients who show no significant improvement with nebulized β_2 agonist. *Hydrocortisone* is the steroid of choice because it has the most rapid onset (5–6 h after administration), compared with 8 h with *prednisolone*. It is common to give *hydrocortisone* 4 mg/kg initially, followed by a maintenance dose of 3 mg/kg every 6 h. *Methylprednisolone* is also available for intravenous use. Intravenous therapy is usually given until a satisfactory response is obtained, and then oral *prednisolone* may be substituted. *Oral prednisone* or *prednisolone* (40–60 mg) has a similar effect to intravenous *hydrocortisone* and is easier to administer. A high dose of *inhaled fluticasone propionate* (2000 μg daily) is as effective as a course of oral *prednisolone* in controlling acute exacerbations of asthma in a family practice setting and in children in an emergency department setting, although this route of delivery is more expensive (Manjra et al., 2000).

Prednisone and *prednisolone* are the most commonly used oral steroids. Maximal beneficial effect is usually achieved with 30 to 40 mg *prednisone* daily, although a few patients may need 60 to 80 mg daily to achieve control of symptoms. The usual maintenance dose is about 10 to 15 mg/day. Short courses of oral steroids (30–40 mg *prednisolone* daily for 1–2 weeks) are indicated for exacerbations of asthma; the dose may be tapered over 1 week after the exacerbation is resolved (the taper is not strictly necessary after a short course of therapy, but patients find it reassuring). Oral steroids are usually given as a single dose in the morning because this coincides with the normal diurnal increase in plasma cortisol and produces less adrenal suppression than if given in divided doses or at night. Oral corticosteroids are used to treat acute exacerbations of COPD, but the effect is small (Walters et al., 2018).

Adverse Effects

Corticosteroids inhibit corticotropin and cortisol secretion by a negative-feedback effect on the pituitary gland (see Chapter 46). Hypothalamic-pituitary-adrenal (HPA) axis suppression depends on dose and usually only occurs with doses of *prednisone* greater than 7.5 to 10 mg/day. Significant suppression after short courses of corticosteroid therapy is not usually a problem, but prolonged suppression may occur after several months or years. *Steroid doses after prolonged oral therapy must be reduced slowly*. Symptoms of "steroid withdrawal syndrome" include lassitude, musculoskeletal pains, and, occasionally, fever. HPA suppression with inhaled steroids is usually seen only when the daily inhaled dose exceeds 2000 μg BDP or its equivalent daily.

Side effects of long-term oral corticosteroid therapy include fluid retention, increased appetite, weight gain, osteoporosis, capillary fragility, hypertension, peptic ulceration, diabetes, cataracts, and psychosis. Their frequency tends to increase with age. Very occasionally, adverse reactions (such as anaphylaxis) to intravenous *hydrocortisone* have been described, particularly in *aspirin*-sensitive asthmatic patients.

TABLE 44–4 ■ SIDE EFFECTS OF INHALED CORTICOSTEROIDS

Local side effects
Dysphonia
Oropharyngeal candidiasis
Cough
Systemic side effects
Adrenal suppression and insufficiency
Growth suppression
Bruising
Osteoporosis
Cataracts
Glaucoma
Metabolic abnormalities (glucose, insulin, triglycerides)
Psychiatric disturbances (euphoria, depression)
Pneumonia

The incidence of systemic side effects after ICSs is an important consideration, particularly in children (Table 44–4). Initial studies suggested that adrenal suppression occurred only with inhaled doses greater than 1500 to 2000 μg/day (Patel et al., 2020). More sensitive measurements of systemic effects include indices of bone metabolism, such as serum osteocalcin and urinary pyridinium cross-links, and in children, knemometry, which may be increased with inhaled doses as low as 400 μg/day BDP in some patients (Agertoft and Pedersen, 2000). The clinical relevance of these measurements is not yet clear. Nevertheless, it is important to reduce the likelihood of systemic effects by using the lowest dose of ICS needed to control the asthma and by use of a large-volume spacer to reduce oropharyngeal deposition.

Several systemic effects of inhaled steroids have been described and include dermal thinning and skin capillary fragility (relatively common in elderly patients after high-dose inhaled steroids). Other side effects, such as cataract formation and osteoporosis, are reported but often in patients who are also receiving courses of oral steroids (Patel et al., 2020). There is some evidence that use of high-dose ICSs is associated with cataract and glaucoma, but it is difficult to dissociate the effects of ICS from the effects of courses of oral steroids that these patients usually require. There has been particular concern about the use of inhaled steroids in children because of growth suppression (Agertoft and Pedersen, 2000).

The ICSs may have *local side effects* due to the deposition of inhaled steroid in the oropharynx. The most common problem is hoarseness and weakness of the voice (dysphonia) due to atrophy of the vocal cords following laryngeal deposition of steroid; it may occur in up to 40% of patients and is noticed particularly by patients who need to use their voices during their work (lecturers, teachers, and singers). Throat irritation and coughing after inhalation are common with MDIs and appear to be due to additives because these problems are not usually seen if the patient switches to a DPI. There is no evidence for atrophy of the lining of the airway. Oropharyngeal candidiasis occurs in about 5% of patients. There is no evidence for increased lung infections, including tuberculosis, in patients with asthma. High doses of ICSs increase the risk of pneumonia in patients with COPD; the risk appears to be higher with *fluticasone propionate* than *budesonide* (Lodise et al., 2020). In COPD patients, ICSs may also cause osteoporosis, fractures, and an increase in diabetes, conditions for which these patients already have an increased risk (Suissa et al., 2010).

Corticosteroid MDIs with HFA propellants produce smaller aerosol particles and may have a more peripheral deposition, making them useful in treating patients with more severe asthma.

Therapeutic Choices

Numerous ICSs are now available, including BDP, *triamcinolone*, *flunisolide*, *budesonide*, *hemihydrate, fluticasone propionate, mometasone furoate*, *ciclesonide*, and *fluticasone furoate*. All are equally effective as antiasthma drugs, but there are differences in their pharmacokinetics: *Budesonide*, *fluticasone*, *mometasone*, and *ciclesonide* have a lower oral bioavailability than BDP because they are subject to greater first-pass hepatic metabolism; this results in reduced systemic absorption from the fraction of the inhaled drug that is swallowed (Derendorf et al., 2006) and thus reduced adverse effects. At high doses (>1000 μg), *budesonide* and *fluticasone propionate* have fewer systemic effects than BDP and *triamcinolone* (not marketed in the U.S.), and they are preferred in patients who need high doses of ICSs and in children. *Ciclesonide* is a prodrug that is converted to the active metabolite by esterases in the lung, giving it low oral bioavailability and a high therapeutic index (Mukker et al., 2016). *Fluticasone furoate* has the longest duration of action, is suitable for once-daily dosing, and is usually combined with the ultra-LABA *vilanterol* (Syed, 2015).

When doses of ICS exceed 800 μg BDP or equivalent daily, a large-volume spacer is recommended to reduce oropharyngeal deposition and systemic absorption in the case of BDP. All currently available ICSs are absorbed from the lung into the systemic circulation, so that some systemic absorption is inevitable. However, the amount of drug absorbed does not appear to have clinical effects in doses of less than 800 μg BDP equivalent. Although there are potency differences among corticosteroids, there are relatively few comparative studies, partly because dose comparison of corticosteroids is difficult due to their long time course of action and the relative flatness of their dose-response curves.

Future Developments

Early treatment with ICSs in both adults and children may give a greater improvement in lung function than if treatment is delayed, likely reflecting the fact that corticosteroids are able to modify the underlying inflammatory process and prevent structural changes (fibrosis, smooth muscle hyperplasia, etc.). ICSs are currently recommended for patients with persistent asthmatic symptoms (e.g., need for an inhaled β_2 agonist more than twice a week). A major change in the use of ICS is in combination with a rapid-acting β_2 agonist as a safer and more effective rescue therapy. The combination is now the preferred treatment for all asthmatic patients.

Developing new corticosteroids with fewer systemic effects is desirable. It has been possible to develop corticosteroids that dissociate the DNA-binding effect of corticosteroids (which mediates most of the adverse effects) from the inhibitory effect on transcription factors such as NF-κB (which mediates much of the anti-inflammatory effect). Such "dissociated steroids" or selective GR agonists should, theoretically, retain anti-inflammatory activity but have a reduced risk of adverse effects; achieving this separation of desired and adverse effects is proving difficult *in vivo* (Zhang et al., 2020). Several nonsteroidal selective GR agonists are now in development for asthma (Rogliani et al., 2020).

Corticosteroid resistance is a major barrier to effective therapy in patients with severe asthma, in asthmatic patients who smoke, and in patients with COPD and cystic fibrosis (Barnes, 2013a). "Steroid-resistant" asthma is thought to be due to reduced anti-inflammatory actions of corticosteroids. In patients with COPD and some patients with severe asthma, there is a reduction in HDAC2 expression that reduces corticosteroid responsiveness; this is potentially reversible by theophylline.

Mediator Antagonists

Over 100 different inflammatory mediators have been implicated in both asthma and COPD, suggesting that inhibition of synthesis or antagonists of receptors for these mediators may be beneficial (Barnes, 2004). However, specific inhibitors have been largely disappointing in both diseases, indicating the redundancy of inflammatory mediators. The variability n pati nt esponse to antileuko rie ne agent in asthma suggests hat there may be biomarkers that select good responders, for example, those patients with increased leukotriene production, such as increased urinary LTE_4.

Antihistamines

Histamine mimics many of the features of asthma and is released from mast cells in acute asthmatic responses, suggesting that antihistamines may be useful in asthma therapy. There is, however, little evidence that histamine H_1 receptor antagonists provide any useful clinical benefit. Newer antihistamines, such as *cetirizine* and *azelastine*, have some beneficial effects, but this may be unrelated to H_1 receptor antagonism. Antihistamines are not recommended in the routine management of asthma.

Antileukotrienes

There is considerable evidence that cys-LTs (cysteinyl-leukotrienes) are produced in asthma and that they have potent effects on airway function, inducing bronchoconstriction, airway hyperresponsiveness, plasma exudation, mucus secretion, and eosinophilic inflammation (Figure 44–9; also see Chapter 41). These findings led to the development of 5′-lipoxygenase (5-LO) enzyme inhibitors (of which *zileuton* is the only drug marketed) and leukotriene cys-LT_1-receptor antagonists (LTRAs), including *montelukast*, *zafirlukast*, and *pranlukast* (not available in the U.S.) (Yokomizo et al., 2018).

Clinical Studies

Leukotriene cys-LT_1-receptor antagonists are widely used in the management of asthma; they can be administered orally and are relatively well tolerated. They effectively inhibit the effects of inhaled cys-LTs, but they are less effective than ICS in controlling asthma and preventing exacerbations, reflecting the fact that many other mediators are likely to contribute to clinical asthma. Even in *aspirin*-sensitive asthma, in which increased production of cys-LTs is thought to play an important role, LTRAs are less effective than ICS. When added to ICS, they provide little further control of asthma and are less effective than LABAs as add-on treatments for asthma (Chauhan et al., 2017). In patients with severe asthma who are not controlled on high doses of ICS and LABA, LTRAs do not provide any additional benefit (Robinson et al., 2001).

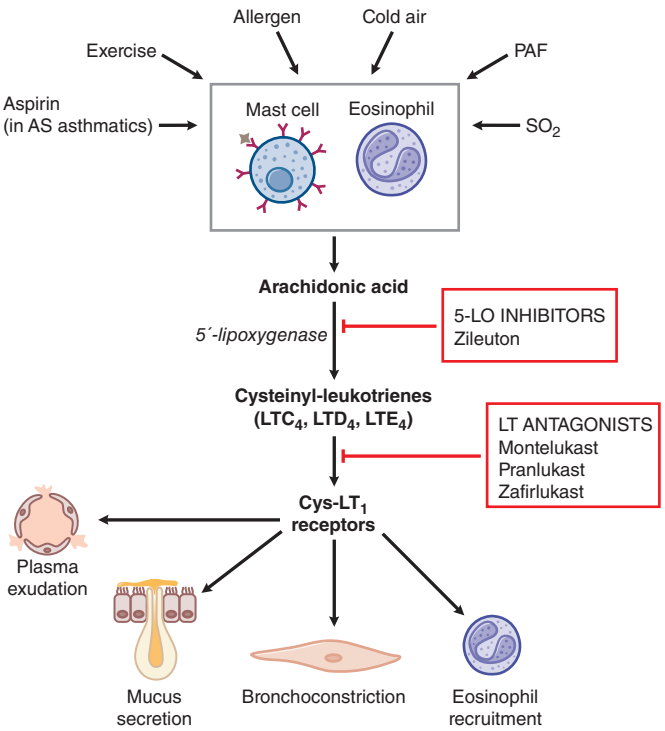

Figure 44–9 *Effects of cysteinyl-LTs on the airways and their inhibition by anti-LTs.* AS, *aspiri* sensitive; PAF, platelet-activating factor.

The 5-LO inhibitor *zileuton* appears to be more effective than LTRAs in asthma control and treating *aspirin*-sensitive asthma, which may be explained by inhibition of other mediators, such as LTB_4, which is chemoattractant to neutrophils, and 5-oxo-eicosatetraenoic acid (5-Oxo-ETE), which is chemotactic for eosinophils. However, *zileuton* is not available in most countries, and there have been concerns about frequent side effects, particularly hepatic dysfunction, and the need for frequent dosing (four times daily).

In COPD, cys-LTs are not elevated in exhaled breath condensate, and LTRAs have no role in the therapy of COPD. By contrast, LTB_4 is elevated in COPD, suggesting that 5-LO inhibitors that reduce LTB_4 synthesis could have some potential benefit by reducing neutrophil inflammation. However, a pilot study failed to indicate any clear benefit of a 5-LO inhibitor in COPD patients (Gompertz and Stockley, 2002).

Adverse Effects

Leukotriene cys-LT_1-receptor antagonists are usually well tolerated but are associated with headaches and eosinophilic granulosis with polyangiitis. *Montelukast* has been associated with an increase in serious neuropsychiatric events in children and adults, including suicidal thoughts, and now has a black-box warning by the FDA (Glockler-Lauf et al., 2019).

Immunomodulatory Therapies

Immunosuppressive Therapy

Immunosuppressive therapy (e.g., *methotrexate, cyclosporine A, gold, intravenous immunoglobulin*) has been considered in asthma when other treatments have been unsuccessful or to reduce the dose of maintenance oral steroids required. However, immunosuppressive treatments are less effective and have a greater propensity for side effects than oral corticosteroids and therefore cannot be routinely recommended.

Biologic Therapies

Several antibodies that block cytokines or antibodies are now available for the treatment of severe asthma, although not yet recommended for COPD (Barnes, 2018).

Anti-IgE

Increased immunoglobulin E (IgE) is a fundamental feature of allergic asthma. *Omalizumab* is a humanized monoclonal antibody that blocks the binding of IgE to high-affinity IgE receptors (FcεR1) on mast cells and thus prevents their activation by allergens (Figure 44–10). It blocks binding on IgE to low-affinity IgE receptors (FcεRII, CD23) on other inflammatory cells, including T and B lymphocytes, macrophages, and possibly eosinophils, to inhibit chronic inflammation. *Omalizumab* also reduces levels of circulating IgE. In addition, *omalizumab* enhances the secretion of type 1 interferons after exposure to rhinovirus and reduces FcεRI expression on dendritic cells, resulting in enhanced protection against viral infection (Gill et al., 2018). This may account for the effect of *omalizumab* to reduce virally induced exacerbations (see below).

Clinical Use. *Omalizumab* is used for the treatment of patients with severe allergic asthma. The antibody is administered subcutaneously every 2 to 4 weeks, and the dose is determined by the titer of circulating total IgE. *Omalizumab* reduces the requirement for oral corticosteroids and ICSs and markedly reduces asthma exacerbations. Not all patients respond, and there are no clear clinical predictors of clinical response, necessitating a trial of therapy (usually over 4 months); high blood eosinophils and fractional exhaled nitric oxide (F_{eNO}) may be associated with a better response (Casale et al., 2019). *Omalizumab* has greater than 50% excellent clinical effectiveness in adults and children with severe asthma (Humbert et al., 2018). *Omalizumab* also has some efficacy in nonatopic asthma with normal circulating IgE levels, a result presumed to reflect reduced local IgE responses (Pillai et al., 2016). Because of its high cost, this treatment is generally used only in patients with very severe allergic asthma who are poorly controlled even on oral corticosteroids and in patients with very severe concomitant allergic rhinitis. It may also be of value in protecting against anaphylaxis during specific immunotherapy. *Omalizumab* is effective in preventing asthma exacerbations if administered prior to the exacerbation season (Teach et al., 2015). The major side effect of *omalizumab* is an anaphylactic response, which is uncommon (<0.1%).

Anti–IL-5

Interleukin-5 plays a pivotal role in eosinophilic inflammation and is also involved in eosinophil survival and priming through activation of the specific receptor, IL-5Rα, which is mainly expressed on eosinophils.

Anti–IL-5 and anti–IL-5 receptor (IL-5Rα) blocking antibodies inhibit eosinophilic inflammation in asthmatic patients (Figure 44–11). Three antibodies are approved for use in severe eosinophilic (type 2 immunity) asthma. The anti–IL-5 antibodies *mepolizumab* (given subcutaneously every 4 weeks) and *reslizumab* (given IV every 4 weeks) block circulating IL-5. *Benralizumab* (given subcutaneously every 8 weeks) blocks IL-5Rα (Menzella et al., 2020). *Benralizumab*, by binding to eosinophil IL-5Rα,

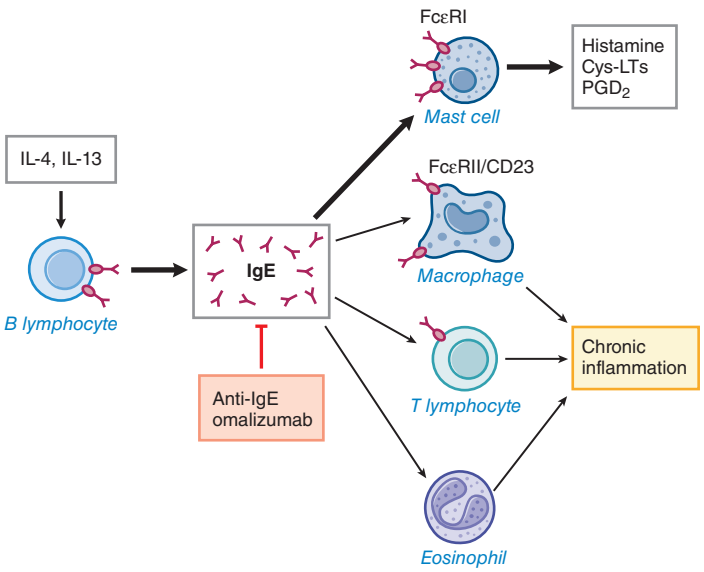

Figure 44–10 *Immunoglobulin E plays a central role in allergic diseases.* Blocking IgE using an antibody, such as *omalizumab*, is a rational therapeutic approach. IgE may activate high-affinity receptors (FcεRI) on mast cells as well as low-affinity receptors (FcεRII, CD23) on other inflammatory cells. *Omalizumab* prevents these interactions and the resulting inflammation.

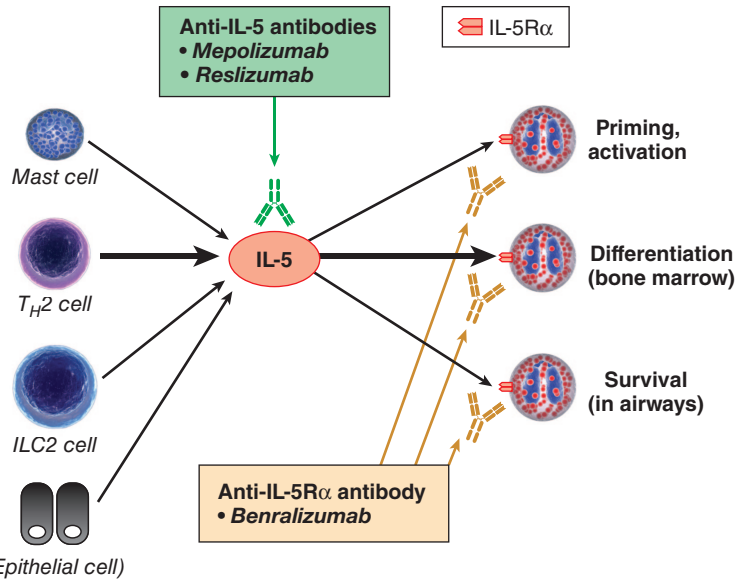

Figure 44–11 *Anti–IL-5 therapies.* IL-5, released predominantly from T_H2 and ILC2 lymphocytes, stimulates eosinophilic inflammation. IL-5 action can be inhibited by the antibodies *mepolizumab* and *reslizumab*. The IL-5 receptor (IL-5Rα) can be blocked and rendered unresponsive to IL-5 by the antibody *benralizumab*.

causes apoptosis and a more rapid resolution of eosinophilic inflammation in the airways. These therapies all reduce exacerbations by around 50%, with small improvements in symptoms, quality of life, and lung function in severe asthma patients (blood eosinophil count of >300 cells/μL). They also reduce the maintenance dose of oral corticosteroids by at least 50%, permitting many steroid-dependent asthmatics to come off steroid treatments completely. Anti–IL-5 treatments have not been effective in reducing exacerbations in COPD patients, even when there is an increase in blood eosinophils (Criner et al., 2019; Pavord et al., 2017).

Anti–IL-5 therapy is well tolerated, with only occasional anaphylaxis. There is no evidence for any increase in worm or parasitic infections, although these treatments are not yet used much in countries where these infectious diseases are prevalent.

Anti–IL-4/13

Interleukin-4 helps to direct IgE synthesis and eosinophilic inflammation; blocking IL-4 has been ineffective in clinical studies. Similarly, blocking IL-13 has also proved to be ineffective in clinical studies of severe eosinophilic asthma. However, blocking IL-4Rα, the common receptor for these cytokines, with *dupilumab* appears to be very effective in these patients. *Dupilumab* (given subcutaneously every 2 weeks) reduces exacerbations, improves symptoms and lung function in patients with moderate to severe asthma (Castro et al., 2018), and reduces the requirement for oral corticosteroids in steroid-dependent patients (Rabe et al., 2018). *Dupilumab* reduces F_{eNO}, which is regulated by IL-4α stimulation of inducible nitric oxide synthase, but has no effect on blood eosinophils. The drug is well tolerated. An important clinical advantage is that *dupilumab* is effective in treating atopic dermatitis and rhinosinusitis, which are common comorbidities in severe asthma (Muñoz-Bellido et al., 2022).

Anti-TNF

Tumor necrosis factor-α (TNFα) plays an amplifying role in inflammation. TNFα is increased in sputum, bronchoalveolar lavage, and plasma of patients with severe asthma and COPD. These findings suggest that anti-TNF therapies, which are clinically effective in other chronic inflammatory diseases (e.g., rheumatoid arthritis and inflammatory bowel disease), would be useful therapies in severe asthma and COPD. A large, controlled trial of an anti-TNF blocking antibody (*golimumab*) showed no effect on exacerbations or asthma control in patients with severe asthma. Side effects included increased incidence of pneumonia (Wenzel et al., 2009). Similarly, the anti-TNF blocking antibody *infliximab* provided no clinical benefits in COPD patients, but side effects were common, including pneumonia and increased incidence of lung cancer (Rennard et al., 2007).

Specific Immunotherapy: Desensitization to Allergens

Theoretically, specific immunotherapy against common allergens should be effective in preventing asthma. Although this treatment is effective in allergic rhinitis due to single allergens such as grass pollen, there is little evidence that desensitizing injections to common allergens are effective in controlling chronic asthma (Rolland et al., 2009).

Sublingual immunotherapy is safer, and several studies have shown its clinical benefit in asthma, although it is uncertain whether this treatment reduces exacerbations and improves the quality of life (Calderón and Bacharier, 2021; Fortescue et al., 2020).

Specific immunotherapy induces the secretion of the anti-inflammatory cytokine IL-10 from regulatory helper T lymphocytes, and this blocks costimulatory signal transduction in T cells (via CD28) so that they are unable to react to allergens presented by antigen-presenting cells (see Figures 38–3 and 38–4). Applying an understanding of the cellular processes involved might lead to safer and more effective approaches in the future. More specific immunotherapies may be developed with recombinant allergens, cloned allergen epitopes, T-cell peptide fragments of allergens, CpG oligonucleotides, and vaccines of conjugates of allergen and TLR-9 (toll-like receptor-9) to stimulate T_H1 immunity and suppress T_H2 immunity (Shamji and Durham, 2017).

Cromones

Cromolyn sodium (*disodium cromoglycate*) is a derivative of *khellin*, an Egyptian herbal remedy, and was found to protect against allergen challenge without any bronchodilator effect. A structurally related drug, *nedocromil sodium*, which has a similar pharmacological profile to *cromolyn*, was subsequently developed. Although *cromolyn* was popular in the past because of its good safety profile, its use has sharply declined with the more widespread use of the more effective ICSs, particularly in children. Cromones are no longer recommended for asthma therapy. Interest continues in these compound as downregulators of mast cell activity (Paivandy and Pejler, 2021).

New Drugs in Development for Airway Disease

Several new classes of drug are in development for asthma and COPD, but clinical development has been slow, and many treatments have either proved to be ineffective or are limited by toxicology and side effect profiles (Gross and Barnes, 2017).

Novel Mediator Antagonists

Many mediators have been implicated in asthma and COPD, many of which have redundant functions, so it is not surprising that inhibiting single mediators, such as bradykinin and platelet-activating factor, has been ineffective in asthma. However, blocking a mediator that is upstream in an inflammatory cascade might be more effective, particularly with cytokines that play a pivotal role in a cytokine network (Barnes, 2018).

DP_2 Antagonists

Prostaglandin D_2 is predominantly released from mast cells in asthmatic patients and mediates bronchoconstriction via thromboxane receptors and vasodilatation via DP_1 receptors (DPr_1). PGD_2 is a chemoattractant for T_H2 lymphocytes, ILC2, and eosinophils via the DP_2 receptor (DPr_2, previously known as CRTh2). Several small-molecule DPr_2 antagonists have been developed for the treatment of asthma. After promising initial results, one such agent, *fevipiprant*, failed to meet the primary endpoint of reduced exacerbations in patients with moderate to severe eosinophilic asthma, and development has now stopped (Brightling et al., 2021). Other DP_2 antagonists are also in clinical development, but this class of drug appears to be far less effective than anti–IL-5 antibodies in eosinophilic asthma.

Antioxidants

Oxidative stress is important in severe asthma and COPD and may contribute to corticosteroid resistance. Existing antioxidants include vitamins C and E and *N*-acetyl-cysteine. These drugs have weak effects, but more potent antioxidants are in development, including activators of the transcription factor Nrf2. Although several new antioxidants are in development for the treatment of airway disease, none is currently approved (Barnes, 2020).

Cytokine Modifiers

In addition to blocking antibodies against T2 cytokines mentioned above, antibodies against other critical cytokines have been tested in asthma and COPD.

Interleukin-1, released from the NLRP3 inflammasome, is thought to play an important role in asthma associated with obesity (Wood et al., 2019). In COPD, anti–IL-1 antibodies, such as *canakinumab*, have proved to be disappointing. NLRP3 inflammasome inhibitors are in development.

Interleukin-17 is important in orchestrating chronic neutrophilic inflammation and is secreted mainly from T_H17 and ILC3 cells. It may play a role in severe neutrophilic asthma. An IL-17 receptor antibody, *brodalumab*, was ineffective in severe asthma (Busse et al., 2013). An anti–IL-17 antibody was also reported to be ineffective in COPD patients (Eich et al., 2017).

Thymic stromal lymphopoietin (TSLP) is an upstream cytokine or alarmin that shows increased expression in airway epithelial cells in asthmatic patients, particularly in severe disease. TSLP activates T2 immunity in the airway, with the recruitment of T_H2 and ILC2 cells to drive eosinophilic inflammation (Porsbjerg et al., 2020). *Tezepelumab* is an antibody that blocks TSLP and inhibits both IL-5 (with reduced blood eosinophils) and IL-4/13 (with reduced F_{eNO}). In severe eosinophilic asthma, *tezepelumab* induces a 70% reduction in exacerbations as well as improvement in symptoms and lung function. *Tezepelumab* also has effects in non-type 2 asthma, reflecting its effects on other types of immunity. Tezepelumab-ekko is FDA-approved as add-on maintenence treatment of severe asthma in patients 12 years and older.

Interleukin-33 is another alarmin that regulates T2 immunity with a profile similar to that of TSLP. Antibodies that block IL-33 and its receptor ST2 are currently in clinical trials for asthma and COPD (Porsbjerg et al., 2020).

Chemokine Receptor Antagonists

Many chemokines are involved in asthma and COPD and play a key role in recruitment into the lungs of inflammatory cells, such as eosinophils, neutrophils, macrophages, and lymphocytes. Chemokine receptors are attractive targets because they are GPCRs with defined binding pockets (Taylor et al., 2019); small-molecule inhibitors are now in development. Antagonists of the various C-C motif chemokine receptors (CCRs) could block recruitment of eosinophils, neutrophils, and monocytes in the airways of patients with asthma; to date, the compounds tested have not proven clinically useful. A promising CCR4 antagonist attenuated allergic lung inflammation in an animal model of asthma (Zhang et al., 2017).

Protease Inhibitors

Several proteolytic enzymes are involved in the chronic inflammation of airway diseases. Mast cell tryptase has several effects on airways, including increasing responsiveness of airway smooth muscle to constrictors, increasing plasma exudation, potentiating eosinophil recruitment, and stimulating fibroblast proliferation. Tryptase inhibitors have so far proved to be disappointing in clinical studies.

In COPD, proteases are involved in the degradation of connective tissue, particularly the breakdown of elastin fibers in the development of emphysema. Matrix metalloproteinase 9 (MMP9) appears to be the predominant elastolytic enzyme in emphysema, and several selective MMP9 inhibitors are now in development.

New Anti-inflammatory Drugs

Mitogen-Activated Protein Kinase Inhibitors

Mitogen-activated protein (MAP) kinase pathways are involved in chronic inflammation in asthma and COPD (Barnes, 2016). *Losmapimod* and related compounds block the p38 MAP kinase pathway. These drugs inhibit the synthesis of many inflammatory cytokines, chemokines, and inflammatory enzymes. To date, the clinical use of inhibitors of p38 MAP kinase for COPD and asthma has been disappointing or dose-limited by side effects.

Mucoregulators

Mucus hypersecretion occurs in chronic bronchitis, COPD, cystic fibrosis, and asthma (Fahy and Dickey, 2010). In chronic bronchitis, mucus hypersecretion is related to chronic irritation by cigarette smoke and may involve neural mechanisms and the activation of neutrophils to release enzymes such as neutrophil elastase and proteinase 3 that have powerful stimulatory effects on mucus secretion. Mast cell–derived chymase is also a potent mucus secretagogue. This suggests that several classes of drugs may be developed to control mucus hypersecretion. Mucus secretion is regulated by epidermal growth factor receptors (EGFRs), but a nebulized EGFR inhibitor has been ineffective in COPD (Woodruff et al., 2010).

Systemic anticholinergic drugs appear to reduce mucociliary clearance, but this is not observed with either *ipratropium bromide* or *tiotropium bromide*, presumably reflecting their poor absorption from the respiratory tract. β_2 Agonists increase mucus production and mucociliary clearance and increase ciliary beat frequency *in vitro*. Because inflammation leads to mucus hypersecretion, anti-inflammatory treatments should reduce mucus hypersecretion; ICSs are very effective in reducing increased mucus production in asthma.

Mucolytics

Several agents reduce the viscosity of sputum *in vitro*. One group consists of derivatives of cysteine that reduce the disulfide bridges that bind glycoproteins to other proteins, such as albumin and secretory IgA. These drugs also act as antioxidants and may therefore reduce airway inflammation. Only *N-acetylcysteine* is available in the U.S.; *carbocysteine, methylcysteine, erdosteine*, and *bromhexine* are available elsewhere. Orally administered, these agents are relatively well tolerated, but clinical studies in chronic bronchitis, asthma, and bronchiectasis have been disappointing. *N-Acetylcysteine* is not currently recommended for COPD management.

DNAse (*dornase alfa*) reduces mucus viscosity in sputum of patients with cystic fibrosis and is indicated if there is significant symptomatic and lung function improvement after a trial of therapy (Yang and Montgomery, 2018). There is no evidence that *dornase alfa* is effective in COPD or asthma, however.

Osmotic agents, such as nebulized hypertonic saline and *mannitol* given by DPI, give marginal clinical benefit in cystic fibrosis but have demonstrated efficacy in chronic bronchitis and COPD (Nevitt et al., 2020).

Expectorants

Expectorants are oral drugs that are supposed to enhance the clearance of mucus. Although expectorants were once commonly prescribed, there is little or no objective evidence for their efficacy (Albrecht et al., 2017). Lacking evidence for their efficacy, the FDA has removed most expectorants from the market in a review of over-the-counter drugs. With the exception of *guaifenesin*, no agents are approved as expectorants in the U.S. For patients who find it difficult to clear mucus, adequate hydration and inhalation of steam may be of some benefit.

Antitussives

Although cough is a common symptom of airway disease, its mechanisms are poorly understood, and current treatment is unsatisfactory (Song and Chung, 2020). Viral infections of the upper respiratory tract are the most common cause of cough; postviral cough is usually self-limiting and commonly patient medicated. Their wide use notwithstanding, over-the-counter cough medications are largely ineffective. Because cough is a defensive reflex, its suppression may be inappropriate in bacterial lung infection. Before treatment with antitussives, it is important to identify underlying causal mechanisms that may require therapy.

Whenever possible, treat the underlying cause, not the cough. Asthma commonly presents as cough, and the cough will usually respond to ICSs. A syndrome characterized by cough in association with sputum eosinophilia but no airway hyperresponsiveness, termed *eosinophilic bronchitis*, also responds to ICSs (Diver et al., 2019). Nonasthmatic cough does not respond to ICSs but sometimes responds to anticholinergic therapy. The cough associated with postnasal drip of sinusitis responds to antibiotics (if warranted), nasal decongestants, and intranasal steroids. The cough associated with angiotensin-converting enzyme inhibitors (in ~15% of patients treated) responds to lowering the dose or withdrawal of the drug and substitution of an AT_1 receptor antagonist (see Chapter 30).

Gastroesophageal reflux is a common cause of cough through a reflex mechanism and occasionally as a result of acid aspiration into the lungs. This cough may respond to suppression of gastric acid with an H_2 receptor antagonist or a proton pump inhibitor (see Chapter 53). Several treatments that have been assessed in the treatment of refractory cough (Song and Chung, 2020).

Opiates

Opiates have a central mechanism of action on μ opioid receptors in the medullary cough center. There is some evidence that they may have additional peripheral action on cough receptors in the proximal airways. *Codeine* and *pholcodine* (not available in the U.S.) are commonly used, but there is little evidence that they are clinically effective, particularly on postviral cough; in addition, they are associated with sedation and constipation. *Morphine* and *methadone* are effective but indicated only for intractable cough associated with bronchial carcinoma.

Dextromethorphan

Dextromethorphan is a centrally active *N*-methyl-D-aspartate receptor antagonist. It may also antagonize opioid receptors. Despite the fact that it is in numerous over-the-counter cough suppressants and used commonly to treat cough, it is poorly effective. In children with acute nocturnal cough, it is not significantly different from placebo in reducing cough (Dicpinigaitis et al., 2014). It can cause hallucinations at higher doses and has significant abuse potential.

Local Anesthetics

Benzonatate, a local anesthetic, acts peripherally by anesthetizing the stretch receptors located in the respiratory passages, lungs, and pleura. By dampening the activity of these receptors, *benzonatate* may reduce the cough reflex. The recommended dose is 100 mg, three times per day, and up to 600 mg/day, if needed. Severe allergic reactions have been reported in patients allergic to *para-aminobenzoic acid*, a metabolite of *benzonatate*.

Neuromodulators

Gabapentin and *pregabalin* are γ-aminobutyric acid analogues that inhibit neurotransmission and have been used in neuropathic pain syndromes. They have been shown to benefit chronic idiopathic cough (Gibson and Vertigan, 2015). Side effects of somnolence and dizziness are common at higher doses, so it is usual to initiate therapy at lower doses.

Other Drugs

Several other drugs reportedly have small benefits in protecting against cough challenges or in reducing cough in pulmonary diseases. These drugs include *moguisteine* (not available in the U.S.), which acts peripherally and appears to open ATP-sensitive K^+ channels. *Theobromine*, a naturally occurring methylxanthine, reduces cough induced by tussive agents. Although the expectorant *guaifenesin* is not typically known as a cough suppressant, it is significantly better than placebo in reducing acute viral cough and inhibits cough-reflex sensitivity in patients with upper respiratory tract infections (Dicpinigaitis et al., 2014).

Novel Antitussives

There is a need to develop new, more effective therapies for cough, particularly drugs that act peripherally to avoid sedation. There are close analogies between chronic cough and sensory hyperesthesia, so new therapies with novel antitussives are likely to arise from pain research.

Transient Receptor Potential Antagonists

Several types of transient receptor potential (TRP) ion channels have been described on airway sensory nerves and may be activated by various mediators and physical factors, resulting in cough. TRPV1 (previously called the *vanilloid receptor*) is activated by capsaicin, H^+, and bradykinin, all of which are potent tussive agents. *TRPV1 inhibitors* block cough induced by capsaicin and bradykinin and are effective in some models of cough. In a clinical study of an oral TRPV1 inhibitor, there was protection against capsaicin-induced cough but no clinical improvement in chronic idiopathic cough after long-term treatment (Belvisi et al., 2017). Side effects of these drugs are loss of temperature regulation and hyperthermia, which has prevented clinical development.

Transient receptor potential A1 is emerging as a more promising novel target for antitussives. This channel is activated by oxidative stress and many irritants and may be sensitized by inflammatory cytokines. Several selective TRPA1 antagonists are now in development. TRPV4 may also activate cough and may be activated by ATP (Bonvini et al., 2015).

ATP Receptor Antagonists

Adenosine triphosphate is a potent tussive agent and stimulates cough in patients with asthma and COPD via activation of $P2X_3$ receptors on afferent nerves (see Table 16–7). A *$P2X_3$ antagonist* (*gefapixant*) is effective in reducing chronic idiopathic cough, although abnormal taste (dysgeusia) is a frequent side effect (Dicpinigaitis et al., 2020). *Gefapixant* is named after the late Geof Burnstock, a pioneer of purinergic signaling.

Drugs for Dyspnea and Ventilatory Control

Drugs for Dyspnea

Bronchodilators should reduce breathlessness in patients with airway obstruction. Chronic oxygen use may have a beneficial effect, but in a few patients, dyspnea may be extreme. Drugs that reduce breathlessness may also depress ventilation in parallel and may be dangerous in severe asthma and COPD. Some patients show a beneficial response to *dihydrocodeine* and *diazepam*; however, these drugs must be used with caution because of the risk of ventilatory depression (Currow et al., 2014). *Slow-release morphine tablets* may also be helpful in patients with COPD with extreme dyspnea. Nebulized *morphine* may reduce breathlessness in COPD and act on pulmonary opioid receptors. Nebulized *furosemide* has some efficacy in treating dyspnea a variety of causes, but the evidence

is not yet sufficiently convincing to recommend this as routine therapy (Barbetta et al., 2017).

Ventilatory Stimulants

Selective respiratory stimulants are indicated if ventilation is impaired as a result of overdose with sedatives, in postanesthetic respiratory depression, and in idiopathic hypoventilation. Respiratory stimulants are rarely indicated in COPD because respiratory drive is already maximal, and further stimulation of ventilation may be counterproductive because of the increase in energy expenditure caused by the drugs.

Doxapram

At low doses (0.5 mg/kg IV), *doxapram* stimulates carotid chemoreceptors; at higher doses, it stimulates medullary respiratory centers. Its effect is transient; thus, intravenous infusion (0.3–3 mg/kg per min) is needed for sustained effect. Unwanted effects include nausea, sweating, anxiety, and hallucinations, and at higher doses, increased pulmonary and systemic pressure. Both the kidney and the liver participate in the clearance of *doxapram*; thus, use caution if hepatic or renal function is impaired. In COPD, the infusion of *doxapram* is restricted to 2 h. The use of *doxapram* to treat ventilatory failure in COPD has now largely been replaced by noninvasive ventilation.

Almitrine

Almitrine bismesylate is a piperazine derivative that appears to selectively stimulate peripheral chemoreceptors and is without central actions. *Almitrine* stimulates ventilation only when there is hypoxia. Long-term use of *almitrine* is associated with peripheral neuropathy, limiting its availability in most countries, including the U.S.

Acetazolamide

The carbonic anhydrase inhibitor *acetazolamide* (see Chapter 29) induces metabolic acidosis and thereby stimulates ventilation; it is not widely used because the metabolic imbalance it produces may be detrimental in the face of respiratory acidosis. It has a small beneficial effect in respiratory failure in patients with COPD. The drug has proved useful in prevention of high-altitude (mountain) sickness (Faisy et al., 2016).

Naloxone

Naloxone is a competitive opioid antagonist that is indicated only if ventilatory depression is due to overdose of opioids.

Flumazenil

Flumazenil, a benzodiazepine antagonist, can reverse respiratory depression due to benzodiazepine overdose (Chapter 22).

Drug Facts for Your Personal Formulary: *Asthma and COPD Therapeutics*

Drug	Therapeutic Uses	Clinical Tips
Short-Acting β_2 Agonists: Inhaled bronchodilators for symptom relief and acute bronchodilation		
Albuterol (salbutamol)	• Asthma, COPD, and exercise-induced bronchospasm • Inhaled: 180 µg (2 puffs) every 4–6 h as needed • Nebulized: 2.5 mg via oral inhalation every 6–8 h as needed over 5–15 min • Oral: 2–4 mg by mouth every 6–8 h	• Also available nebulized and inhaled as levalbuterol (active isomer, so half the dose) • May need to be nebulized with oxygen in severe exacerbation • Adverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Levalbuterol (L-albuterol)	• Bronchodilator • Inhaled (MDI nebulizer)	• Half of doses of racemic albuterol • No advantage over racemic albuterol • Adverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Pirbuterol	• 400 µg (2 puffs) every 4–6 h as needed • Inhaled (MDI nebulizer)	• Similar to albuterol • Adverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Long-Acting β_2 Agonists: Add-on therapy to ICSs in asthma; can be used alone in COPD		
Formoterol	• Asthma as add-on to ICS • Maintenance and treatment of severe COPD • Inhaled: 12 µg (contents of 1 capsule) every 12 h • Nebulized 20 µg in 2 mL, twice per day	• Used as maintenance, usually in a combination with an ICS • Can also be used as a reliever of bronchospasm • Adverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Arformoterol Salmeterol Indacaterol Olodaterol	• Arformoterol for severe COPD • Maintenance treatment for COPD • Arformoterol, inhaled (nebulized), 15 µg in 2 mL twice daily • Salmeterol, inhaled 50 µg twice daily • Indacaterol, inhaled (DPI) 75 µg once daily • Olodaterol, inhaled 2.5 µg once daily	• Cannot be used as a reliever, only for maintenance treatment for COPD • Adverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Anticholinergics: Muscarinic receptor antagonists inhaled as bronchodilators		
Ipratropium bromide Albuterol/ipratropium combination	• Inhaled, 2 puffs (17 µg/puff) 3–4 times/day • Combination albuterol 103 µg/ipratropium 18 µg/puff; 2 puffs 4 times daily	• Largely replaced by LAMAs • Avoid spraying in eyes • Adverse effects include dry mouth, tachycardia, urinary retention, glaucoma • Combination with albuterol may be used as a reliever
Tiotropium bromide	• 2.5 µg via oral inhalation (2 puffs of 1.25 µg/actuation) once daily	• Caution in patients with urinary retention or glaucoma history
Umeclidinium bromide	• Inhaled (DPI) 62.5 µg (1 puff) once daily	
Aclidinium bromide	• Inhaled (DPI) 400 µg (1 puff) twice daily	
Glycopyrrolate	• Inhaled (DPI) 1 capsule (15.6 µg) inhaled twice daily	

Drug Facts for Your Personal Formulary: *Asthma and COPD Therapeutics (continued)*

Drug	Therapeutic Uses	Clinical Tips
LAMA-LABA Combination Inhalers: Maintenance treatment for COPD		
Glycopyrrolate/ indacaterol	• Inhaled (DPI) 1 inhalation (glycopyrrolate 15.6 µg/ indacaterol 27.5 µg) twice daily	• Side effects of anticholinergics and β_2 agonists as above • Maintenance treatment for COPD
Umeclidinium/ vilanterol	• Inhaled (DPI) 1 inhalation (umeclidinium 62.5 µg/25 µg vilanterol) once daily	
Tiotropium/olodaterol	• Inhaled (mist inhaler), 2 inhalations (containing 2.5 µg tiotropium/2.5 µg of olodaterol per inhalation) once daily	
Inhaled Corticosteroids: Maintenance treatment for asthma		
Beclomethasone dipropionate (BDP)	• Inhaled (MDI, DPI); 88 µg (1 spray = 44 µg) twice daily • Not to exceed 440 µg twice daily	• More systemic effects than other ICSs: orally bioavailable BDP is converted to an active metabolite, beclomethasone monopropionate, following absorption • Local effects: hoarse voice, candidiasis • Systemic effects: growth suppression, bruising, adrenal suppression
Fluticasone propionate	• Inhaled (MDI, DPI); 50, 100, 250 µg 2 puffs, twice daily • Do not exceed 1000 µg daily	• Fewer systemic effects than BDP • Local effects: hoarse voice, candidiasis
Budesonide	• Inhaled via jet nebulizer either once daily or divided into 2 doses (maximum daily dose 0.5 mg/day)	• Fewer systemic effects than BDP • Used in children less than 8 who cannot use DPI • Local effects: hoarse voice, candidiasis
Ciclesonide	• Inhaled (MDI) 80 µg twice daily	• Least-systemic effects of all ICSs; may be effective once daily • Local effects: hoarse voice, candidiasis
ICS/LABA Combination Inhalers: Maintenance treatment in asthma and COPD		
Fluticasone propionate/ salmeterol	• Inhaled (DPI) • Starting dosage based on asthma severity	• Use lowest dose that maintains asthma control • Use only in severe COPD or asthma-COPD overlap • Adverse effects as for ICSs and LABAs
Budesonide/formoterol	• Inhaled (MDI) (80 µg budesonide and 4.5 µg formoterol per inhalation) twice daily	
Fluticasone furoate/ vilanterol	• Inhaled (DPI) 1 inhalation (fluticasone furoate 100 µg/ vilanterol 25 µg) once daily	
Systemic Corticosteroids: Short course or oral maintenance for asthma (and COPD)		
Prednisone Prednisolone	• Oral: 40–80 mg once daily or divided dose for 3–10 days for acute exacerbation • Minimal dose for maintenance	• Prednisone converted to prednisolone in the liver • Bruising, weight gain, edema, osteoporosis, diabetes, cataracts, adrenal suppression (see Chapter 46)
Hydrocortisone succinate	• IM/IV: 100–500 mg every 12 h for acute severe asthma	• Only if patient not able to take oral steroids
Methylprednisolone	• IV: 100–1000 mg for acute severe asthma	• Rarely indicated because of steroid side effects
Antileukotrienes (Leukotriene Modifiers) for Asthma Maintenance		
Montelukast Zafirlukast Zileuton	• Oral: montelukast (10 mg once/day); zafirlukast (20 mg twice/day); zileuton (600 mg four times/day or 1200 mg twice/day)	• Less effective than ICS in asthma • Headache, Churg-Strauss syndrome • Zileuton may cause hepatic dysfunction (do not use if alanine aminotransferase increased)
Methylxanthines: Add-on maintenance treatment of severe asthma and COPD		
Theophylline (oral) Aminophylline (IV)	• Aminophylline (IV) is indicated for severe exacerbation that does not respond to nebulized β agonists; shorter action than theophylline	• Interaction with drugs that affect CYP1A2; see Table 44–2 • Nausea, headaches, diuresis, arrhythmias, seizures
Phosphodiesterase Inhibitor		
Roflumilast	• COPD • Mild asthma with mainly neutrophilic inflammation	• PDE4 inhibitor • Do not use for bronchospasm • Contraindicated in severe liver disease • Subject to interaction with inhibitors and inducers of CYP4A3

Drug Facts for Your Personal Formulary: *Asthma and COPD Therapeutics (continued)*

Drug	Therapeutic Uses	Clinical Tips
Immunomodulators (consult FDA package insert prior to use)		
Omalizumab	• Severe allergic asthma • Non-atopic asthma	• Anti-IgE • Prevents IgE activation of mast cells
Reslizumab, Mepolizumab	• ↓ severe eosinic inflammation in asthma	• mAbs; bind circulating IL-5 • Can ↓ oral corticosteroid need
Benralizumab (antibody to IL-5 receptor)	• ↓ severe eosinic inflammation in asthma	• Antibody blocks IL-5 receptor • Causes apoptosis of eosinophils
Dupilumab (antibody to IL-4/13 receptor)	• Moderate-to-severe asthma to improve lung function and reduce exacerbations	• IL-4Rα blocker • Improves co-morbidities of asthma (atopic dermatitis, rhinosinusitis)
Tezepelumab-ekko (human mAb to TSLP)	• Add-on therapy for patients 12 years and older with severe asthma; 210 mg subcutaneously every 4 weeks	• Treat any helminth infections prior to use • As treatment progresses, decrease steroids *gradually*, if appropriate • Avoid concomitatnt use of live attenuated vaccines

Chapter 45 Hematopoietic Agents: Growth Factors, Minerals, and Vitamins

Michael Choi and Thomas J. Kipps

Hematopoiesis

The finite life span of most mature blood cells requires their continuous replacement, a process termed *hematopoiesis*. New cell production must respond to basal needs and states of increased demand. Erythrocyte production can increase more than 20-fold in response to anemia or hypoxemia, leukocyte production increases dramatically in response to systemic infections, and platelet production can increase 10- to 20-fold when platelet consumption results in thrombocytopenia.

The regulation of blood cell production is complex. Hematopoietic stem cells are rare marrow cells that manifest self-renewal and lineage commitment, resulting in cells destined to differentiate into the 10 or more distinct blood cell lineages. For the most part, this process occurs in the marrow cavities of the skull, vertebral bodies, pelvis, and proximal long bones; it involves interactions among hematopoietic stem and progenitor cells and the cells and complex macromolecules of the marrow stroma and is influenced by a number of soluble and membrane-bound hematopoietic growth factors. Several hormones and cytokines have been identified and cloned that affect hematopoiesis, permitting their production in quantities sufficient for research and, in some cases, therapeutic use. Clinical applications range from the treatment of primary hematological diseases (e.g., aplastic anemia, congenital neutropenia) to use as adjuncts in the treatment of severe infections and in the management of patients with kidney failure or those undergoing cancer chemotherapy or marrow transplantation.

Hematopoiesis also requires an adequate supply of minerals (e.g., iron, cobalt, and copper) and vitamins (e.g., folic acid, vitamin B_{12}, pyridoxine, ascorbic acid, and riboflavin); deficiencies generally result in characteristic anemias or, less frequently, a general failure of hematopoiesis (Rojas-Hernandez and Oo, 2018). Therapeutic correction of a specific deficiency state depends on the accurate diagnosis of the basis for the anemia and on knowledge about the correct dose, formulation, and route of administration of the deficient mineral(s) or vitamin(s).

Growth Factor Physiology

Steady-state hematopoiesis encompasses the tightly regulated production of more than 400 billion blood cells each day. The hematopoietic organ also is unique in adult physiology in that several mature cell types are derived from a much smaller number of multipotent progenitors, which develop from a more limited number of pluripotent hematopoietic stem cells. Such cells are capable of maintaining their own number and differentiating under the influence of cellular and humoral factors to produce the large and diverse number of mature blood cells.

Our understanding of stem cell differentiation owes much to the *in vitro* culture of marrow cells. Using the results from clonal cultures in semisolid medium, stem cell differentiation can be described as a series of developmental steps that produce mixed blood cell lineage colonies, which give rise to large, immature and small, mature single-lineage burst-forming units (BFUs) and colony-forming units (CFUs), respectively, for each of the major blood cell types. These early progenitors (BFUs and CFUs) are capable of further proliferation and differentiation, increasing their number by some 30-fold. It is at this most mature stage of development that the lineage-committed growth factors (colony-stimulating factors [CSFs] for monocytes [M-CSFs] and granulocytes [G-CSFs], erythropoietin, and thrombopoietin) exert their primary proliferative and differentiative effects. Overall, proliferation and maturation of the CFU for each cell line can amplify the resulting mature cell product by another 30-fold or more, generating more than 1000 mature cells from each committed stem cell.

Hematopoietic and lymphopoietic growth factors are glycoproteins produced by a number of marrow cells and peripheral tissues. They are active at very low concentrations and typically affect more than one committed cell lineage. Most interact synergistically with other factors and stimulate production of additional growth factors, a process termed *networking*. Growth factors generally exert actions at several points in the processes of cell proliferation and differentiation and in mature cell function. However, the network of growth factors that contributes to any given cell lineage depends absolutely on a nonredundant, lineage-specific

Abbreviations

BFU: burst-forming units
CFU: colony-forming units
CFU-E: CFU erythrocyte
CFU-GM: CFU granulocyte and macrophage
CFU-Meg: CFU megakaryocyte
$CH_3H_4PteGlu_1$: methyltetrahydrofolate
CKD: chronic kidney disease
CoA: coenzyme A
CSF: colony-stimulating factor
dTMP: deoxythymidine monophosphate
dUMP: deoxyuridine monophosphate
ESA: erythropoiesis-stimulating agent
FIGLU: formiminoglutamic acid
G-CSF: granulocyte colony-stimulating factor
GI: gastrointestinal
GM-CSF: granulocyte-macrophage colony-stimulating factor
HFE: high Fe, hereditary hemochromatosis protein, hemeostatic iron regulator
HIF: hypoxia-inducible factor
HIV: human immunodeficiency virus
IL: interleukin
IRE: iron-regulating element
IRP: iron-regulating protein
ITP: immune thrombocytopenia
M-CSF: monocyte-/macrophage-stimulating factor
MDS: myelodysplastic syndromes
PBSC: peripheral blood stem cell
PteGlu: pteroylglutamic acid, folic acid
rHuMGDF: recombinant human megakaryocyte growth and development factor
SAM: *S*-adenosylmethionine
TPO: thrombopoietin
TRA: thrombopoietin receptor agonist
TGFβ: transforming growth factor β
VHL: von Hippel-Lindau

factor, such that absence of factors that stimulate developmentally early progenitors is compensated for by redundant cytokines, but loss of the lineage-specific factor leads to a specific cytopenia.

Some of the overlapping and nonredundant effects of the more important hematopoietic growth factors are illustrated in Figure 45–1 and Table 45–1.

Erythropoiesis-Stimulating Agents

Erythropoiesis-stimulating agent (ESA) is the term given to a pharmacological substance that stimulates red blood cell production.

Erythropoietin

Erythropoietin is the most important regulator of the proliferation of committed erythroid progenitors (CFU-E, colony forming units, erythrocyte) and their immediate progeny. In its absence, severe anemia is invariably present, commonly seen in patients with renal failure. Erythropoiesis is controlled by a feedback system in which a sensor in the kidney detects changes in oxygen delivery to modulate the erythropoietin secretion. The sensor mechanism is now understood at the molecular level (Haase, 2010).

Hypoxia-inducible factor (HIF), a heterodimeric (HIF-1α and HIF-1β) transcription factor, enhances expression of multiple hypoxia-inducible genes, such as vascular endothelial growth factor and erythropoietin.

HISTORICAL PERSPECTIVE

Modern concepts of hematopoietic cell growth and differentiation derive from experiments done in the 1950s. Till and McCulloch demonstrated that individual hematopoietic cells could form macroscopic hematopoietic colonies in the spleens of irradiated mice, thereby establishing the concept of discrete hematopoietic stem cells (i.e., the presence of a multilineage clonal splenic colony appearing 11 days after transplantation implied that a single cell lodged and expanded into several cell lineages). This concept now has been expanded to include normal human marrow cells. Moreover, such cells now can be prospectively identified.

The basis for identifying soluble growth factors was provided by Sachs and independently by Metcalf, who developed clonal, *in vitro* assays for hematopoietic progenitor cells. Such hematopoietic colonies first developed only in the presence of conditioned culture medium from leukocytes or tumor cell lines. Individual growth factors then were isolated based on their activities in clonal *in vitro* assays, assays that were instrumental in purifying a hierarchy of progenitor cells committed to individual and combinations of mature blood cells (Kondo et al., 2003).

In 1906, Paul Carnot postulated the existence of a circulating growth factor that controls red blood cell development. He observed an increase in the red cell count in rabbits injected with serum obtained from anemic animals and postulated the existence of a factor that he called hemopoietin. Only in the 1950s did Reissmann, Erslev, and Jacobsen and coworkers define the origin and actions of the hormone, now called erythropoietin. Subsequently, extensive studies of erythropoietin were carried out in patients with anemia and polycythemia, leading to the purification of erythropoietin from urine and the subsequent cloning of the erythropoietin gene. The high-level expression of erythropoietin in cell lines has allowed for its purification and use in humans with anemia.

Similarly, the existence of specific leukocyte growth factors was suggested by the capacity of different conditioned culture media to induce the *in vitro* growth of colonies containing different combinations of granulocytes and monocytes. An activity that stimulated the production of both granulocytes and monocytes was purified from murine lung-conditioned medium, leading to cloning of granulocyte-macrophage colony-stimulating factor (GM-CSF), first from mice (Gough et al., 1984) and subsequently from humans (Wong et al., 1985). Finding an activity that stimulated the exclusive production of neutrophils permitted the cloning of granulocyte colony-stimulating factor (G-CSF) (Welte et al., 1985). Subsequently, a megakaryocyte colony-stimulating factor termed thrombopoietin was purified and cloned (Kaushansky, 1998).

Growth factors that support lymphocyte growth were identified using assays that measured the capacity of the cytokine to promote lymphocyte proliferation *in vitro*. This permitted the identification of the growth-promoting properties of IL-7, IL-4, or IL-15 for all lymphocytes, B cells, or NK (natural killer) cells, respectively (Goodwin et al., 1989; Grabstein et al., 1994). Recombinant expression of these complementary DNAs permitted production of sufficient quantities of biologically active growth factors for clinical investigations, allowing for the demonstration of the potential clinical utility of such factors.

HIF-1α is labile due to its prolyl hydroxylation and subsequent polyubiquitination and degradation, aided by the von Hippel-Lindau (VHL) protein. During states of hypoxia, the prolyl hydroxylase is inactive, allowing the accumulation of HIF-1α and activating erythropoietin expression, which in turn stimulates rapid expansion of erythroid progenitors. Specific alteration of VHL leads to an oxygen-sensing defect, characterized by constitutively elevated levels of HIF-1α and erythropoietin, with resultant polycythemia (Gordeuk et al., 2004). A second isoform of HIF, HIF-2α, is

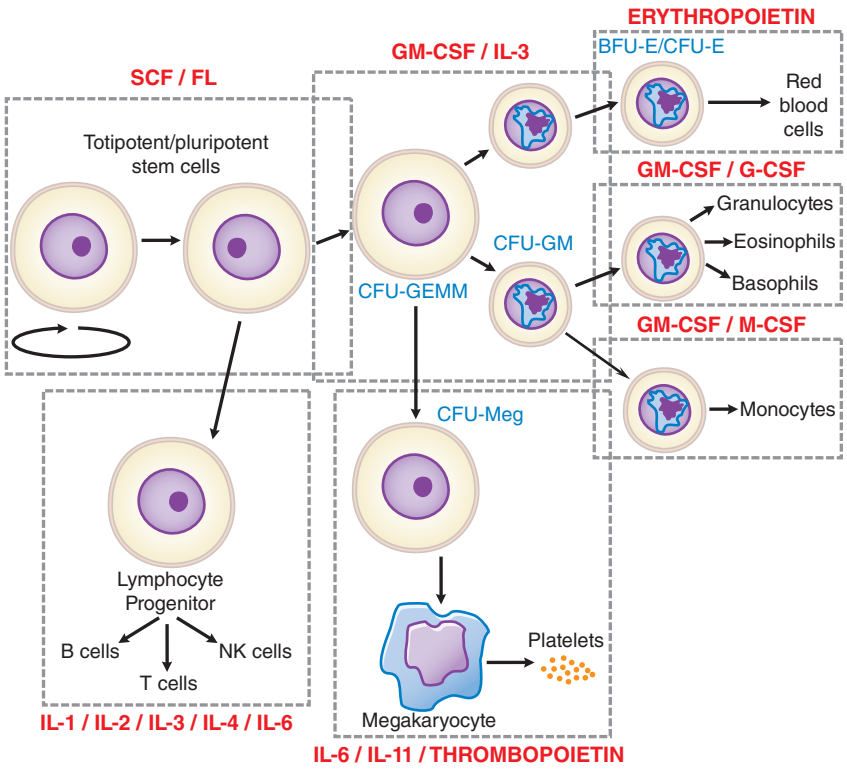

Figure 45–1 *Sites of action of hematopoietic growth factors in the differentiation and maturation of marrow cell lines.* A self-sustaining pool of marrow stem cells differentiates under the influence of specific hematopoietic growth factors to form a variety of hematopoietic and lymphopoietic cells. SCF, FL, IL-3, and GM-CSF, together with cell-cell interactions in the marrow, stimulate stem cells to form a series of BFUs and CFUs: CFU-GEMM, CFU-GM, CFU-Meg, BFU-E, and CFU-E. After considerable proliferation, further differentiation is stimulated by synergistic interactions with growth factors for each of the major cell lines—G-CSF, M-CSF, thrombopoietin, and erythropoietin. Each of these factors also influences the proliferation, maturation, and in some cases the function of the derivative cell line (Table 45–1). BFU-E, burst forming unit, erythrocyte; CFU-GEMM, colony-forming unit, granulocyte, erythrocyte, monocyte, and megakaryocyte; FL, FLT3 (FMS tyr kinase 3) ligand; SCF, stem cell factor.

an important regulator of the expression of genes that contribute to iron absorption (Mastrogiannaki et al., 2013); a genetic gain-of-function mutation in HIF-2α also induces erythrocytosis in patients (Percy et al., 2008).

Erythropoietin is expressed primarily in peritubular interstitial cells of the kidney. Erythropoietin contains 193 amino acids, of which the first 27 are cleaved during secretion. The final hormone is heavily glycosylated and has a molecular mass of about 30 kDa. After secretion, erythropoietin binds to a receptor on the surface of committed erythroid progenitors in the marrow and is internalized. With anemia or hypoxemia, synthesis rapidly increases by 100-fold or more, serum erythropoietin levels rise, and marrow progenitor cell survival, proliferation, and maturation are dramatically stimulated. This finely tuned feedback loop can be disrupted by kidney disease, marrow damage, or a deficiency in iron or an essential vitamin. With an infection or an inflammatory state, erythropoietin secretion, iron delivery, and progenitor proliferation all are suppressed by inflammatory cytokines, but this accounts for only part of the resultant anemia; interference with iron metabolism also is a result of inflammatory mediator actions on the hepatic protein hepcidin (Drakesmith and Prentice, 2012). Loss of hepcidin-producing liver mass or genetic or acquired conditions that repress hepcidin production by the liver may lead to iron overload (Pietrangelo, 2016).

Preparations

Preparations of recombinant human erythropoietin include *epoetin alfa, epoetin beta, epoetin omega*, and *epoetin zeta*, which differ almost exclusively in carbohydrate modifications due to manufacturing differences and are supplied in single-use vials or syringes containing 500 to 40,000 units for intravenous or subcutaneous administration. When injected intravenously, epoetin alfas are cleared from plasma with a $t_{1/2}$ of 4 to 8 h. However, the effect on marrow progenitors lasts much longer, and once-weekly dosing can be sufficient to achieve an adequate response. An engineered epoetin alfa, *darbepoetin*, which displays a longer circulatory half-life, is also available for use in patients with indications similar to those for other epoetins. Based on phage display technology, small peptide agonists of the erythropoietin receptor were identified and developed into clinical agents by coupling to polyethylene glycol. One such erythropoiesis-stimulating peptide, *peginesatide*, was approved for the treatment of anemia due to chronic kidney disease (CKD); postmarketing reports of serious hypersensitivity reactions and anaphylaxis necessitated its removal from the market.

Recombinant human erythropoietin (*epoetin alfa*) is nearly identical to the endogenous hormone. The carbohydrate modification pattern of *epoetin alfa* differs slightly from the native protein, but this difference apparently does not alter kinetics, potency, or immunoreactivity of the drug. Modern assays can detect these differences and thereby identify athletes who use the recombinant product for "blood doping."

Therapeutic Uses, Monitoring, and Adverse Effects

Recombinant erythropoietin therapy, in conjunction with adequate iron intake, can be highly effective in a number of anemias, especially those associated with poor erythropoietic response. *Epoetin alfa* is effective in the treatment of anemias associated with surgery, AIDS, cancer chemotherapy, prematurity, and certain chronic inflammatory conditions. *Darbepoetin alfa* also has been approved for use in patients with anemia associated with CKD. A Cochrane analysis could not demonstrate the superiority of one form of ESA over any another.

During erythropoietin therapy, absolute or functional iron deficiency may develop. Functional iron deficiency (i.e., normal ferritin levels but low transferrin saturation) presumably results from the inability to mobilize iron stores rapidly enough to support the increased erythropoiesis. Supplemental iron therapy is recommended for all patients whose serum ferritin is less than 100 μg/L or whose serum transferrin saturation

TABLE 45–1 ■ HEMATOPOIETIC GROWTH FACTORS

Erythropoietin (EPO)

- Stimulates proliferation and maturation of committed erythroid progenitors to increase red cell production

Stem cell factor (SCF, c-kit ligand, Steel factor) and FLT 3 ligand (FL)

- Act synergistically with a wide range of other colony-stimulating factors and interleukins to stimulate pluripotent and committed stem cells
- FL also stimulates both dendritic and natural killer (NK) cells (antitumor response)
- SCF also stimulates mast cells and melanocytes

Interleukins

IL-1, IL-3, IL-5, IL-6, IL-9, and IL-11

- Act synergistically with each other and SCF, GM-CSF, G-CSF, and EPO to stimulate BFU erythrocytes (BFU-E), CFU-GEMM, CFU-GM, CFU-E, and CFU-Meg growth
- Numerous immunological roles, including stimulation of B-cell and T-cell growth

IL-5

- Controls eosinophil survival and differentiation

IL-6; IL-6 and *IL-11*

- IL-6 stimulates human myeloma cells to proliferate
- IL-6 and IL-11 stimulate BFU megakaryocytes to increase platelet production

IL-1, IL-2, IL-4, IL-7, and IL-12

- Stimulate growth and function of T cells, B cells, NK cells, and monocytes
- Co-stimulate B, T, and lymphokine-activated killer (LAK) cells

IL-8 and IL-10

- Numerous immunological activities involving B- and T-cell functions
- IL-8 acts as a chemotactic factor for basophils and neutrophils

Granulocyte-macrophage colony-stimulating factor (GM-CSF)

- Acts synergistically with SCF, IL-1, IL-3, and IL-6 to stimulate CFU-GM and CFU-Meg to increase neutrophil and monocyte production
- With EPO may promote BFU-E formation
- Enhances migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils
- Prevents alveolar proteinosis

Granulocyte colony-stimulating factor (G-CSF)

- Stimulates CFU granulocytes to increase neutrophil production
- Enhances phagocytic and cytotoxic activities of neutrophils

Monocyte/macrophage colony-stimulating factor (M-CSF, CSF-1)

- Stimulates CFU macrophages (CFU-Ms) to increase monocyte precursors
- Activates and enhances function of monocyte/macrophages

Macrophage colony-stimulating factor (M-CSF)

- Stimulates CFU-M to increase monocyte/macrophage precursors
- Acts in concert with tissues and other growth factors to determine the proliferation, differentiation, and survival of a range of cells of the mononuclear phagocyte system

Thrombopoietin (TPO, *Mpl* ligand)

- Stimulates the self-renewal and expansion of hematopoietic stem cells
- Stimulates stem cell differentiation into megakaryocyte progenitors
- Selectively stimulates megakaryocytopoiesis to increase platelet production
- Acts synergistically with other growth factors, especially IL-6 and IL-11

is below 20%. During initial therapy and after any dosage adjustment, the hematocrit is determined once a week (patients infected with HIV [human immunodeficiency virus] and those with cancer) or twice a week (patients with renal failure) until it has stabilized in the target range and the maintenance dose has been established; the hematocrit then is monitored at regular intervals. If the hematocrit increases by more than 4 points in any 2-week period, the dose should be decreased. Due to the time required for erythropoiesis and the erythrocyte half-life, hematocrit changes lag behind dosage adjustments by 2 to 6 weeks. The dose of *darbepoetin* should be decreased if the hemoglobin increase exceeds 1 g/dL in any 2-week period because of the association of excessive rate of rise of hemoglobin with adverse cardiovascular events.

The use of ESAs is associated with an increased risk of thrombosis. During hemodialysis, patients receiving *epoetin alfa* or *darbepoetin* may require increased anticoagulation. The risk of thrombotic events is higher in adults with ischemic heart disease or congestive heart failure receiving *epoetin alfa* therapy with the goal of reaching a normal hematocrit (42%) than in those with a lower target hematocrit of 30% (Bennett et al., 2008). ESA use is associated with increased rates of cancer recurrence and decreased on-study survival in patients in whom the drugs are administered for cancer-induced or for chemotherapy-induced anemia (Bohlius et al., 2009). Due to those concerns, the FDA issued "black-box" warnings regarding increased risk of death, serious adverse cardiovascular reactions, and stroke when ESAs were administered to target a final hemoglobin concentrations near normal physiological levels. In June 2011, the FDA specified that ESAs should not be used to increase hemoglobin to concentrations above 11 g/dL.

The most common side effect of *epoetin alfa* therapy is aggravation of hypertension, which occurs in 20% to 30% of patients and most often is associated with a rapid rise in hematocrit levels. Hypertensive encephalopathy and seizures have occurred in patients with chronic renal failure treated with *epoetin alfa*. For this reason, ESAs should not be used in patients with pre-existing uncontrolled hypertension. Patients may require initiation of, or increases in, antihypertensive therapy. Headache, tachycardia, edema, shortness of breath, nausea, vomiting, diarrhea, injection site stinging, and flu-like symptoms (e.g., arthralgias and myalgias) also have been reported in conjunction with *epoetin alfa* therapy.

Anemia of Chronic Renal Failure

Patients with anemia secondary to CKD are ideal candidates for *epoetin alfa* therapy as the disease represents a true hormone deficiency state. ESA use for patients with CKD can reduce the need for red cell transfusions. Dosing is individualized to the lowest dose necessary to reduce the need for transfusions. The response in predialysis, peritoneal dialysis, and hemodialysis patients depends on the severity of the renal failure, the erythropoietin dose and route of administration, and iron availability (Besarab et al., 1999; Kaufman et al., 1998). The subcutaneous route of administration is preferred over the intravenous route because absorption is slower and the amount of drug required is reduced by 20% to 40%, although the intravenous route is typically used for patients who already are on hemodialysis.

Patients with a hemoglobin of less than 10 g/dL are started on doses of 50 to 100 units/kg of *epoetin alfa*, given subcutaneously, three times a week. Patients who are not on dialysis can receive 10,000 to 20,000 units every other week. The dose of *epoetin alfa* should be adjusted to obtain a gradual rise in the hematocrit over a 2- to 4-month period to a final hemoglobin of less than 11 g/dL. Treatment to hemoglobin levels greater than 11 g/dL is not recommended. The final maintenance dose of *epoetin alfa* can vary from 10 units/kg to more than 300 units/kg, with an average dose of 75 units/kg, three times a week. Children less than 5 years of age generally require a higher dose. Resistance to therapy is common in patients who develop an inflammatory illness or become iron deficient, so close monitoring of general health, iron status, or other causes of anemia is essential. Less-common causes of resistance include occult blood loss, folic acid deficiency, carnitine deficiency, inadequate dialysis, aluminum toxicity, or osteitis fibrosa cystica secondary to hyperparathyroidism. ESA therapy is typically discontinued if a patient does respond over

a 12-week escalation period, as further increases in dose may increase the risks without improving the benefit of therapy.

Darbepoetin alfa is approved for use in patients who are anemic secondary to CKD. The recommended starting dose is 0.45 μg/kg administered intravenously or subcutaneously once weekly or 0.75 μg/kg administered every 2 weeks, with dose adjustments depending on the response. As with *epoetin alfa*, side effects tend to occur when patients experience a rapid rise in hemoglobin concentration; a rise of less than 1 g/dL every 2 weeks generally is considered safe.

Anemia in Patients With AIDS

Epoetin alfa therapy has been approved for the treatment of HIV-infected patients with anemia due to *zidovudine* therapy (Fischl et al., 1990). Excellent responses to doses of 100 to 300 units/kg, given subcutaneously three times a week, generally are seen in patients with *zidovudine*-induced anemia. However, a more recent analysis of erythropoietin therapy in patients with HIV infection failed to support its routine use (Martí-Carvajal et al., 2011). The reason for the difference between 1990 and 2011 may reflect the more effective therapy for HIV in the highly active antiretroviral therapy era, such that the origin of anemia in HIV-infected individuals today is different from what it was at the onset of the AIDS epidemic. Accordingly, ESAs are not commonly used in HIV-infected individuals, except for those who have therapy indications similar to those without HIV infection, such as anemia associated with renal failure.

Anemia Associated With Hematological Malignancy

Guidelines support the use of recombinant erythropoietin in patients with low-grade myelodysplastic syndrome. In this setting, neutropenia often dictates the use of G-CSF, which frequently augments the erythroid response to erythropoietin. In responding patients, the response duration is usually 2 to 3 years. A baseline serum erythropoietin level may help to predict the response; most patients with blood levels greater than 500 IU/L are unlikely to respond to any dose of the drug. Most patients treated with *epoetin alfa* experience an improvement in their anemia and their sense of well-being (Littlewood et al., 2001).

Anemia in Patients With Cancer Undergoing Chemotherapy

Epoetin alfa therapy, 150 units/kg three times a week or 450 to 600 units/kg once a week, can reduce the transfusion requirement in patients with cancer undergoing chemotherapy as well as lead to reduced anemia-related symptoms. Previous therapeutic guidelines (Rizzo et al., 2002) recommended the use of *epoetin alfa* in patients with chemotherapy-associated anemia when hemoglobin levels fall below 10 g/dL, basing the decision to treat less-severe anemia (hemoglobin 10–12 g/dL) on clinical circumstances. Following these recommendations, case reports suggested a direct effect of both *epoetin alfa* and *darbepoetin alfa* in stimulation of tumor cells. A meta-analysis of a large number of patients and clinical trials estimated the risk of death at about 10% higher than for cancer patients who were not treated with these agents (Bohlius et al., 2009). Based on these results, new guidelines were issued (Rizzo et al., 2010) and subsequently updated (Bohlius et al., 2019). ESAs may be offered to patients with symptomatic chemotherapy-associated anemia with hemoglobin values of less than 10 g/dL who cannot tolerate or refuse red blood cell transfusion and whose cancer treatment is palliative. Again, the goal of ESA treatment should not be to normalize the hemoglobin values, but to mitigate symptoms of anemia that typically associate with hemoglobin values of less than or equal to 10 g/dL. Treatment with iron may be necessary to improve the response to ESAs for patients with low serum ferritin.

Use in Perioperative Patients

Epoetin alfa has been used perioperatively to treat anemia (hematocrit 30%–36%) and reduce the need for allogeneic erythrocyte transfusion in nonanemic patients during and following surgery in patients with moderate or large anticipated blood loss. Patients undergoing elective orthopedic and cardiac procedures have been treated with 150 to 300 units/kg of *epoetin alfa* once daily for the 10 days preceding surgery, on the day of surgery, and for 4 days after surgery. As an alternative, 600 units/kg can be given on days 21, 14, and 7 before surgery, with an additional dose on the day of surgery. ESAs are used in this manner to correct anemia in patients who cannot receive transfusions. Most Jehovah's Witnesses who refuse red blood cell transfusions find it acceptable to receive recombinant *epoetin alfa*.

Other Uses

Epoetin alfa has been evaluated for the treatment of the anemia of prematurity, in which impaired erythropoietin production is central to the pathogenesis. However, *epoetin alfa* appears to have limited efficacy in decreasing the number of blood donors to which the infant is exposed; a more effective approach is to limit the amount of blood drawn from the infant and to use satellite packs that divide one unit of blood into smaller aliquots that can be given at successive intervals. This approach mitigates the risk of therapy. In this regard, it should be noted that administration of *epoetin alfa* to premature infants was associated with an increased incidence of retinopathy of prematurity in one retrospective study (Ohlsson and Aher, 2020).

Competitive athletes have used *epoetin alfa* to increase their hemoglobin levels ("blood doping") in an attempt to improve their athletic performance. Unfortunately, this misuse of the drug has been implicated in the deaths of several athletes and is strongly discouraged.

Sequestration of Transforming Growth Factor β Superfamily Ligands

Transforming growth factor β (TGFβ) superfamily ligands are soluble growth factors that regulate hematopoiesis. Canonical signaling by TGFβ family ligand-receptor complexes is transduced by SMAD proteins, which inhibit hematopoietic stem cell proliferation. Under physiological conditions, erythroid progenitor cells produce ligands such as activins and growth differentiation factors (GDFs), which inhibit terminal erythroid differentiation by induction of apoptosis and cell-cycle arrest in erythroblasts, in a tightly regulated feedback loop. However, in disorders of ineffective erythropoiesis, such as thalassemia and myelodysplastic syndrome, there is a constitutive increase of SMAD2 and SMAD3 signaling, which inhibits red cell maturation (Figure 45–2).

Luspatercept is a recombinant fusion protein that consists of a human IgG1 Fc domain linked with a modified extracellular domain of the activin receptor 2B (ActRIIB), which binds and traps select TGFβ family ligands. *Luspatercept* binds GDF8, GDF11, and activin B; has lower affinity for activin A; and does not bind TGFβ1, TGFβ2, or TGFβ3. This pattern of ligand trapping decreases SMAD2 and SMAD3 signaling, enabling erythroblast differentiation and erythroid maturation, with fewer nonhematological effects (Kubasch et al., 2021).

Therapeutic Uses, Monitoring, and Adverse Effects

Beta Thalassemia. *Luspatercept* is indicated for adult patients with beta thalassemia who require regular red cell transfusions (Capellini et al., 2020; Piga et al., 2019). Approximately 20% of patients had at least a 33% reduction in transfusion burden during weeks 13 to 24 of treatment (the primary endpoint of the phase III clinical trial), compared to 4.5% of patients randomized to placebo. Eleven percent of patients achieved transfusion independence or at least an 8-week interval. Of patients initially randomized to *luspatercept*, approximately 70% were still receiving treatment and experiencing a reduction in transfusion burden at the end of a 2-year period (prior to planned unmasking and crossover).

Thromboembolic events occurred in 3.6% of patients treated with *luspatercept* (compared to 0.9% of patients in the placebo group). All events were in patients who had undergone splenectomy and had other risk factors for thromboembolic disease (e.g., prior venous thrombosis). It is recommended to consider thromboprophylaxis in patients at increased risk and to monitor all patients for signs and symptoms of thromboembolic disease. Other adverse events include transient bone pain, arthralgias, dizziness, hypertension, and hyperuricemia.

The starting dose of *luspatercept* is 1 mg/kg once every 3 weeks by subcutaneous injection by a healthcare professional. It is recommended to delay dosing for hemoglobin levels of 11.5 g/dL or greater (if not influenced

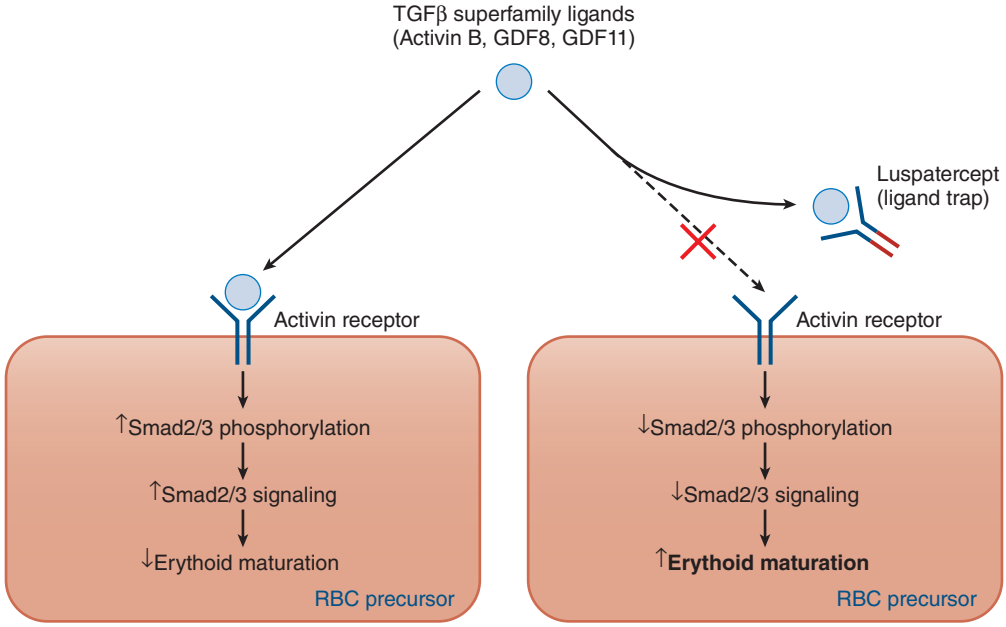

Figure 45–2 *Mechanism of action of luspatercept.* Erythroid development is regulated by opposing inhibitory and stimulatory influences of growth factors, transduced by various members of the SMAD family. Several ligands of the TGFβ superfamily can bind to and activate activin receptors, resulting in the phosphorylation of SMAD2/3. Phospho-SMAD2/3 is an inhibitory signal for erythroid maturation. In myelodysplastic syndromes, there is an imbalance of the usual regulation: The SMAD2/3 signaling pathway in erythroid cells is overactive, impairing erythroid maturation and resulting in anemia (**left panel**). *Luspatercept* is a fusion protein consisting of a modified activin receptor and the Fc domain of human IgG1. *Luspatercept* sequesters activin B, GDF8, and GDF11 (members of the TGFβ superfamily), preventing their interaction with the activin receptor, thereby reducing SMAD2/3 signaling and dis-inhibiting and promoting erythroid maturation (**right panel**). GDF, growth differentiation factor; RBC, red blood cell.

by recent transfusion). Patients who do not achieve a reduction in red blood cell transfusion burden after at least 6 weeks may increase the dose to 1.25 mg/kg, which is the maximum dose. Patients should discontinue use of *luspatercept* if they do not have a decrease in transfusion burden after 9 weeks of treatment at this maximum dose or if there is unacceptable toxicity.

Myelodysplastic Syndromes. The FDA has approved use of *luspatercept* for the treatment of adult patients with myelodysplastic syndromes (MDS), specifically those with very low- to intermediate-risk MDS with ring sideroblasts or myelodysplastic/myeloproliferative neoplasms with ring sideroblasts and thrombocytosis, with anemia despite ESA and requiring 2 or more red blood units over an 8-week period. In a phase III trial, the primary response rate (defined as transfusion independence for 8 weeks or longer) was 38%. Approximately 70% of patients had an increase in hemoglobin of at least 1.5 g/dL (Fenaux et al., 2020).

The most common side effects of *luspatercept* reported by patients with MDS include mild fatigue, diarrhea, asthenia, nausea, dizziness, and back pain. Thromboembolism has not been associated with *luspatercept* in patients with MDS. To date, the use of *luspatercept* has not been associated with an increased risk of progression to acute myeloid leukemia. However, long-term follow-up is ongoing, as patients within this subgroup of MDS typically have only a low risk of progression to acute myeloid leukemia.

The recommended starting dose for patients with MDS is 1 mg/kg once every 3 weeks by subcutaneous injection. The dose may be increased up to 1.75 mg/kg if patients are not red blood cell transfusion–free. Specific dose modification for response is provided in the prescribing information.

Myeloid Growth Factors

The myeloid growth factors are glycoproteins that stimulate the proliferation and differentiation of one or more myeloid cell types. Recombinant forms of several growth factors have been produced, including GM-CSF, G-CSF, interleukin-3 (IL-3), M-CSF or CSF-1, and stem cell factor (see Table 45–1), although only G-CSF and GM-CSF have found meaningful clinical applications.

Myeloid growth factors are produced naturally by a number of different cells, including fibroblasts, endothelial cells, macrophages, and T cells (Figure 45–3). These factors are active at extremely low concentrations and act via membrane receptors of the cytokine receptor superfamily to activate the Jak/STAT signal transduction pathway. GM-CSF can stimulate proliferation, differentiation, and function of a number of the myeloid cell lineages (see Figure 45–1). It acts synergistically with other growth factors, including erythropoietin, at the level of the BFU. GM-CSF stimulates CFU-GM (CFU granulocyte and macrophage), CFU-M (CFU macrophage), CFU-E, and CFU-Meg (CFU megakaryocyte) to increase cell production. GM-CSF also enhances the migration, phagocytosis,

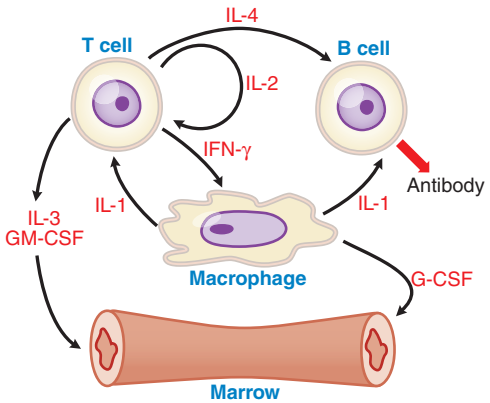

Figure 45–3 *Cytokine-cell interactions.* Macrophages, T cells, B cells, and marrow stem cells interact via several cytokines (IL-1, IL-2, IL-3, IL-4, interferon [IFN] γ, GM-CSF, and G-CSF) in response to a bacterial or a foreign antigen challenge. See Table 45–1 for the functional activities of these various cytokines.

superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils (Weisbart et al., 1987).

The activity of G-CSF is restricted to neutrophils and their progenitors, stimulating their proliferation, differentiation, and function. It acts primarily on CFU-G (CFU granulocyte), although it also can play a synergistic role with IL-3 and GM-CSF in stimulating other cell lines. G-CSF enhances phagocytic and cytotoxic activities of neutrophils. G-CSF reduces inflammation by inhibiting IL-1, tumor necrosis factor, and interferon γ. G-CSF also mobilizes primitive hematopoietic cells, including hematopoietic stem cells, from the marrow into the peripheral blood (Sheridan et al., 1992). This observation has virtually transformed the practice of stem cell transplantation, such that more than 90% of all such procedures today use G-CSF–mobilized peripheral blood cells as the donor stem cell product.

Granulocyte-Macrophage Colony-Stimulating Factor

Recombinant human GM-CSF (*sargramostim*) is a glycoprotein with 127 amino acids. The primary therapeutic effect of *sargramostim* is the stimulation of myelopoiesis.

The initial clinical application of *sargramostim* was in patients undergoing autologous marrow transplantation. By shortening the duration of neutropenia, transplant morbidity was significantly reduced without a change in long-term survival or risk of inducing an early relapse of the malignant process (Brandt et al., 1988).

The role of GM-CSF therapy in allogeneic transplantation is less clear. Its effect on neutrophil recovery is less pronounced in patients receiving prophylactic treatment of graft-versus-host disease. However, it may improve survival in transplant patients who exhibit early graft failure (Nemunaitis et al., 1990).

It also has been used to mobilize CD34-positive progenitor cells for peripheral blood stem cell (PBSC) collection for transplantation after myeloablative chemotherapy (Haas et al., 1990). *Sargramostim* has been used to shorten the period of neutropenia and reduce morbidity in patients receiving intensive cancer chemotherapy (Gerhartz et al., 1993). It also stimulates myelopoiesis in some patients with cyclic neutropenia, myelodysplasia, aplastic anemia, or AIDS-associated neutropenia.

Sargramostim is administered by subcutaneous injection or slow intravenous infusion at doses of 125 to 500 μg/m^2 per day. Plasma levels of GM-CSF rise rapidly after subcutaneous injection and then decline with a $t_{1/2}$ of 2 to 3 h. When given intravenously, infusions should be maintained over 3 to 6 h. With the initiation of therapy, there is a transient decrease in the absolute leukocyte count secondary to cell margination and pulmonary vascular sequestration. This is followed by a dose-dependent, biphasic increase in leukocyte counts over the next 7 to 10 days. Once the drug is discontinued, the leukocyte count returns to baseline within 2 to 10 days. When GM-CSF is given in lower doses, the response is primarily neutrophilic, whereas monocytosis and eosinophilia are observed at larger doses. After hematopoietic stem cell transplantation or intensive chemotherapy, *sargramostim* is given daily during the period of maximum neutropenia until a sustained rise in the granulocyte count is observed. Frequent blood counts are essential to avoid an excessive rise in the granulocyte count. Higher doses are associated with more pronounced side effects, including bone pain, malaise, flu-like symptoms, fever, diarrhea, dyspnea, and rash. An acute reaction to the first dose, characterized by flushing, hypotension, nausea, vomiting, and dyspnea, with a fall in arterial oxygen saturation due to granulocyte sequestration in the pulmonary circulation, occurs in sensitive patients. With prolonged administration, a few patients may develop a capillary leak syndrome, with peripheral edema and pleural and pericardial effusions. Other serious side effects include transient supraventricular arrhythmia, dyspnea, and elevation of serum creatinine, bilirubin, and hepatic enzymes.

Granulocyte Colony-Stimulating Factor

Recombinant human G-CSF, *filgrastim*, is a glycoprotein with 175 amino acids. The principal action of *filgrastim* is the stimulation of CFU-G to increase neutrophil production (see Figure 45–1). Several forms of G-CSF are now available, including two longer-acting pegylated forms (*pegfilgrastim* and *lipegfilgrastim*), *tbo-filgrastim,* and biosimilar *filgrastim-sndz*. The biosimilar approval pathway had not been established at the time of *tbo-filgrastim*'s Biologics License Application, but its pharmacokinetic parameters, safety, and efficacy do not differ substantially from those of *filgrastim*.

Filgrastim is effective in the treatment of severe neutropenia after autologous hematopoietic stem cell transplantation and high-dose cancer chemotherapy (Lieschke and Burgess, 1992). Like GM-CSF, *filgrastim* shortens the period of severe neutropenia and reduces morbidity secondary to bacterial and fungal infections (Hammond et al., 1989). G-CSF also is effective in the treatment of severe congenital neutropenias. *Filgrastim* therapy can improve neutrophil counts in some patients with myelodysplasia or marrow damage (moderately severe aplastic anemia or tumor infiltration of the marrow). The neutropenia of patients with AIDS receiving *zidovudine* also can be partially or completely reversed.

Filgrastim is routinely used in patients undergoing PBSC collection for stem cell transplantation. It promotes the release of CD34$^+$ progenitor cells from the marrow, reducing the number of collections necessary for transplant. G-CSF–induced mobilization of stem cells into the circulation also has the potential to enhance repair of other damaged organs in which PBSCs might play a role. PBSC grafts have a higher cell dose and somewhat more committed progenitor cells than steady-state marrow grafts, resulting in faster engraftment and faster immunological reconstitution.

Filgrastim is administered by subcutaneous injection or intravenous infusion (over at least 30 min) at doses of 1 to 20 μg/kg per day. The usual starting dose in a patient receiving myelosuppressive chemotherapy is 5 μg/kg per day, rounded to the nearest vial size, for example 300 or 480 μg daily. The distribution and clearance rate from plasma ($t_{1/2}$ of 3.5 h) are similar for both routes of administration. As with GM-CSF therapy, G-CSF administered after hematopoietic stem cell transplantation or intensive cancer chemotherapy will increase granulocyte production and shorten the period of severe neutropenia. Frequent blood cell counts should be obtained to determine the effectiveness of the treatment and guide dosage adjustment. In patients who received intensive myelosuppressive cancer chemotherapy, daily administration of G-CSF for 14 to 21 days or more may be necessary to correct the neutropenia.

A prolonged half-life allows for single dose administration of *pegfilgrastim*, rather than daily administration. The recommended dose for *pegfilgrastim* is fixed at 6 mg for patients weighing more than 20 kg, administered subcutaneously once per chemotherapy cycle. Due to potential sensitivity of dividing myeloid cells to cytotoxic chemotherapy, *pegfilgrastim* is typically administered 24 h after chemotherapy and at least 14 days prior to the next planned chemotherapy dose (Lyman et al., 2017).

Adverse Reactions

Adverse reactions to *filgrastim* include mild-to-moderate bone pain in patients receiving high doses over a protracted period, local skin reactions following subcutaneous injection, and rare cutaneous necrotizing vasculitis. Patients with a history of hypersensitivity to proteins produced by *Escherichia coli* should not receive the drug; the same holds for patients with sickle cell anemia, as it has been known to precipitate severe crises and even death. Mild-to-moderate splenomegaly has been observed in patients on long-term therapy.

In 2004 and 2006, two papers were published suggesting that previously healthy stem cell donors receiving human G-CSF for mobilization displayed marrow cell changes concerning for the development of future malignancy. Previous studies have shown an increase in myeloid leukemia in patients with breast cancer receiving G-CSF for neutropenia. However, careful follow-up has failed to reveal any meaningful increase in myeloid leukemia in normal stem cell donors administered G-CSF.

Selecting From Available Preparations

There are limited comparative data from randomized controlled trial and insufficient data to recommend one CSF over others for primary prevention of febrile neutropenia. In practice, most institutions use G-CSF rather than GM-CSF. Guidelines from the American Society of Clinical Oncology support the use of all G-CSF preparations, including biosimilars (Smith et al., 2015).

Thrombopoietic Growth Factors

Interleukin-11

Interleukin-11 (IL-11) is a cytokine that stimulates hematopoiesis, intestinal epithelial cell growth, and osteoclastogenesis and inhibits adipogenesis. IL-11 also enhances megakaryocyte maturation *in vitro*. Recombinant human IL-11, *oprelvekin* ($t_{1/2}$ ~7 h), leads to a thrombopoietic response in 5 to 9 days when administered daily to normal subjects.

The drug is administered to patients at 25 to 50 μg/kg per day subcutaneously. *Oprelvekin* is approved for use in patients undergoing chemotherapy for nonmyeloid malignancies with severe thrombocytopenia (platelet count $<20 \times 10^9$/L), and it is administered until the platelet count returns to more than 100×10^9/L. The major complications of therapy are fluid retention and associated cardiac symptoms, such as tachycardia, palpitation, edema, and shortness of breath; this is a significant concern in elderly patients and often requires concomitant therapy with diuretics. Also reported are blurred vision, injection site rash or erythema, and paresthesias.

Thrombopoietin

Thrombopoietin (TPO), a glycoprotein produced by the liver, marrow stromal cells, and other organs, is the primary regulator of platelet production. Two forms of recombinant TPO have been tested for clinical use. One is a truncated version of the native protein, termed recombinant human megakaryocyte growth and development factor (rHuMGDF), that is covalently modified with polyethylene glycol to increase the circulatory $t_{1/2}$. The second is the full-length polypeptide termed recombinant human thrombopoietin (rHuTPO). While use in thrombocytopenic clinical trial subjects was found to be safe, the use of rHuMGDF in a clinical trial of normal platelet donors, designed to boost the quantity of donated platelets, led to donor thrombocytopenia in several subjects due to the immunogenicity of this agent (Li et al., 2001). This experience led to both agents being abandoned for clinical use and to the development of small molecular mimics of recombinant TPO, termed thrombopoietin receptor agonists (TPO-RA or TRA), also called TPO mimetics.

Thrombopoietin Receptor Agonists

Thrombopoietin receptor agonists (TRAs) stimulate production of megakaryocytes and platelets in the marrow by activating the TPO receptor. TRAs are FDA-approved for use in patients with immune thrombocytopenia (ITP), and several are approved for patients with liver disease scheduled to undergo surgery. *Romiplostim* contains four copies of a small peptide that binds with high affinity to the TPO receptor, grafted onto an immunoglobulin scaffold. *Romiplostim* is safe and efficacious in patients with ITP (Kuter et al., 2008). The drug is administered weekly by subcutaneous injection, starting with a dose of 1 μg/kg, titrated to a maximum of 10 μg/kg, until the platelet count increases above 50×10^9/L.

The other approved agents are considered nonpeptide TRAs, derived from small-molecule screens for chemicals that bind to and activate the TPO receptor. *Eltrombopag* is a small organic TRA that is administered orally; the recommended starting dose is 50 mg/day, titrated to 75 mg depending on platelet response. A lower dose (25 mg/day) is used in patients of Asian descent or with impaired liver function. *Avatrombopag* is another oral nonpeptide that is more potent than *eltrombopag* and has less stringent dietary restrictions or need for liver function test monitoring than *eltrombopag*. *Avatrombopag* is approved for treatment of patients with chronic ITP who have insufficient response to prior treatment (Bussel et al., 2014), as well as for adults with chronic liver disease and thrombocytopenia scheduled for surgery. For the latter, *avatrombopag* is started 10 to 13 days prior to the scheduled procedure and dosed for 5 consecutive days, such that the surgery is 5 to 8 days after the last dose (Terrault et al., 2014). *Lusutrombopag*, another oral nonpeptide TRA, is also approved to increase platelet counts in patients with thrombocytopenia in the setting of liver disease who are scheduled for elective surgery (Peck-Radosavljevic et al., 2019).

Clinical uses of TRAs include treatment of patients with chronic ITP, chronic hepatitis C–associated thrombocytopenia, severe aplastic anemia, and chronic liver disease–associated thrombocytopenia (preprocedure as outlined above). TRAs are under investigation for use in raising the platelet counts of patients with MDS, congenital thrombocytopenia due to muscle heavy-chain myosin-9 (MYH9) mutation, HIV-associated thrombocytopenia, radiation injury, or chemotherapy-induced thrombocytopenia.

Risks of TRAs include thrombosis. *Eltrombopag* was associated with risk of portal vein thrombosis in patients with advanced liver disease, although many cases had platelet counts greater than 200,000/μL and there could have been other causes of thrombosis. The risk of thrombosis was not noted in trials of preprocedural *avatrombopag* or *lusutrombopag*, perhaps due to the limited duration of the trials. The risk of thrombosis was not increased in patients with chronic ITP treated with TRAs compared to placebo. Patients on TRAs have been noted to develop marrow fibrosis that generally is reversible and not associated with development of other cytopenias (Janssens et al., 2016). Given the short life span of platelets, especially in patients with ITP, platelet counts may drop precipitously after abrupt discontinuation of TRA, even below the prior baseline. This rebound thrombocytopenia was seen in the clinical trials, which mandated complete treatment hold for platelet counts above 400,000/μL. While the product labeling adopted this dosing scheme, patients should be closely monitored for large fluctuations in platelet counts.

Iron Deficiency and Other Hypochromic Anemias

The Bioavailability of Iron

Iron exists in the environment largely as ferric oxide, ferric hydroxide, and polymers. In this state, its biological availability is limited unless solubilized by acid or chelating agents. For example, bacteria and some plants produce high-affinity chelating agents that extract iron from the surrounding

HISTORICAL PERSPECTIVE

The modern understanding of iron metabolism began in 1937 with the work of McCance and Widdowson on iron absorption and excretion and Heilmeyer and Plotner's measurement of iron in plasma (Beutler, 2002). In 1947, Laurell described a plasma iron transport protein that he called *transferrin* (Laurell, 1951). Around the same time, Hahn and coworkers used radioisotopes to measure iron absorption and define the role of the intestinal mucosa to regulate this function (Hahn, 1948). In the next decade, Huff and associates initiated isotopic studies of internal iron metabolism. The subsequent development of practical clinical measurements of serum iron, transferrin saturation, plasma ferritin, and red cell protoporphyrin permitted the definition and detection of the body's iron store status and iron-deficient erythropoiesis. In 1994, Feder and colleagues identified the *HFE* (High Fe, Hereditary Hemochromatosis Protein, or Homeostatic Iron Regulator) gene, which is mutated in type 1 hemochromatosis (Feder et al., 1996). Subsequently, Ganz and colleagues discovered a peptide produced by the liver, which was termed *hepcidin* (Park et al., 2001), now known to be the master regulator of iron homeostasis and to play a role in anemia of chronic disease (Ganz and Nemeth, 2011).

environment. Most mammals have little difficulty in acquiring iron; this is explained by ample iron intake and perhaps also by a greater efficiency in absorbing iron. Humans, however, appear to be an exception. Although total dietary intake of elemental iron in humans usually exceeds requirements, the bioavailability of the iron in the diet is limited.

Iron deficiency is the most common nutritional cause of anemia in humans. It can result from inadequate iron intake, malabsorption, blood loss, or an increased requirement, as with pregnancy. When severe, it results in a characteristic microcytic, hypochromic anemia. In addition to its role in hemoglobin, iron is an essential component of myoglobin, heme enzymes (e.g., cytochromes, catalase, and peroxidase), and the metalloflavoprotein enzymes (e.g., xanthine oxidase and α-glycerophosphate oxidase). Iron deficiency can affect metabolism in muscle independently of the effect of anemia on O_2 delivery. This may reflect a reduction in the activity of iron-dependent mitochondrial enzymes. Iron deficiency also has been associated with behavioral and learning problems in children, abnormalities in catecholamine metabolism, and possibly impaired heat production.

Metabolism of Iron

The body store of iron is divided between essential iron-containing compounds and excess iron, which is held in storage (Table 45–2). *Hemoglobin* dominates the essential fraction. Each hemoglobin molecule contains four atoms of iron, amounting to 1.1 mg (20 μmol) of iron/mL of red blood cells. Other forms of essential iron include *myoglobin* and a variety of heme and nonheme iron-dependent enzymes. *Ferritin* is a protein-iron storage complex that exists as individual molecules or as aggregates. *Apoferritin* (molecular weight ~450 kDa) is composed of 24 polypeptide subunits that form an outer shell around a storage cavity for polynuclear hydrous ferric oxide phosphate. More than 30% of the weight of ferritin may be iron (4000 atoms of iron per ferritin molecule). Ferritin aggregates, referred to as *hemosiderin* and visible by light microscopy, constitute about one-third of normal stores. The two predominant sites of iron storage are the reticuloendothelial system and the hepatocytes.

Internal exchange of iron is accomplished by the plasma protein *transferrin*, a 76-kDa glycoprotein that has two binding sites for ferric iron. Iron is delivered from transferrin to intracellular sites by means of specific transferrin receptors in the plasma membrane. The iron-transferrin complex binds to the receptor, and the ternary complex is internalized through clathrin-coated pits by receptor-mediated endocytosis. A proton-pumping ATPase lowers the pH of the intracellular vesicular compartment (the endosomes) to about 5.5. Iron subsequently dissociates, and the receptor returns the apotransferrin to the cell surface, where it is released into the extracellular environment. Cells regulate their expression of transferrin receptors and intracellular ferritin in response to the iron supply (De Domenico et al., 2008). The synthesis of apoferritin and transferrin receptors is regulated posttranscriptionally by two iron-regulating proteins, IRP1 and IRP2. These IRPs are cytosolic RNA-binding proteins that bind to iron-regulating elements (IREs) present in the 5′ or 3′ untranslated regions of mRNA encoding apoferritin or the transferrin receptors, respectively. Binding of these IRPs to the 5′ IRE of apoferritin mRNA represses translation, whereas binding to the 3′ IRE of mRNA encoding the transferrin receptors enhances transcript stability, thereby increasing protein production.

The flow of iron through the plasma amounts to a total of 30 to 40 mg/day in the adult (~0.46 mg/kg of body weight). The major internal circulation of iron involves the erythron and reticuloendothelial cells (Figure 45–4). About 80% of the iron in plasma goes to the erythroid marrow to be packaged into new erythrocytes; these normally circulate for about 120 days before being catabolized by the reticuloendothelial system. At that time, a portion of the iron is immediately returned to the plasma bound to transferrin, while another portion is incorporated into the ferritin stores of reticuloendothelial cells and returned to the circulation more gradually. With abnormalities in erythrocyte

Estimated iron amounts for pregnancy, based on a 120-lb woman.
Source: Iron requirements and iron balance during pregnancy have recently been reviewed (Fisher AL, Nemeth E. Iron homeostasis during pregnancy. *Am J Clin Nutr*, **2017**, *106*(suppl 6):1567S–1574S; Georgieff MK. Iron deficiency in pregnancy. *Am J Obstet Gynecol*, **2020**, *223*:516–524).

maturation, the predominant portion of iron assimilated by the erythroid marrow may be rapidly localized in the reticuloendothelial cells as defective red cell precursors are broken down; this is termed *ineffective erythropoiesis*. The rate of iron turnover in plasma may be reduced by half or more with red cell aplasia, with all the iron directed to the hepatocytes for storage.

The human body conserves its iron stores to a remarkable degree. Only 10% of the total is lost per year by normal men (i.e., ~1 mg/day). Two-thirds of this iron is excreted from the gastrointestinal (GI) tract as extravasated red cells, iron in bile, and iron in exfoliated mucosal cells. The other third is accounted for by small amounts of iron in desquamated skin and in the urine. Additional losses of iron occur in women due to menstruation. Although the average loss in menstruating women is about 0.5 mg per day, 10% of menstruating women lose more than 2 mg per day. Pregnancy and lactation impose an even greater requirement for iron (Table 45–3). Other causes of iron loss include blood donation, the use of anti-inflammatory drugs that cause bleeding from the gastric mucosa, and GI disease with associated bleeding.

The limited physiological losses of iron point to the primary importance of absorption in determining the body's iron content (Garrick and Garrick, 2009). After acidification and partial digestion of food in the stomach, iron is presented to the intestinal mucosa as either inorganic iron or heme iron. A ferrireductase, duodenal cytochrome B, located on the luminal surface of absorptive cells of the duodenum and upper small intestine, reduces the iron to the ferrous state, which is the substrate for divalent metal (ion) transporter 1 (DMT1, SLC11A2). DMT1 transports the iron to the basolateral membrane, where it is taken up by another transporter, *ferroportin* (Fpn; SLC40A1), and subsequently reoxidized to Fe^{3+}, primarily by hephaestin (Hp; *HEPH*), a transmembrane copper-dependent ferroxidase. Apotransferrin binds the resultant oxidized Fe^{3+}. The hepatic protein, hepcidin, binds to ferroportin, inducing its internalization and degradation, thus limiting the amount of iron released into the blood (Camaschella, 2013). Conditions that enhance the levels of hepcidin, such as inflammation, can result in decreased gut iron absorption, reduced serum iron, and inadequate iron available for developing red blood cells. Conversely, when hepcidin levels are low, such as in hemochromatosis, iron overload occurs due to excessive ferroportin-mediated iron influx.

Genetic polymorphism and consequent dysfunction in hepcidin or in proteins regulating its expression can result in inadequate levels of hepcidin and cause hereditary hemochromatosis (Pietrangelo, 2016). This can be due to polymorphism in *HFE*, resulting in a Cys→Tyr change at position 282 (C282Y) in the HFE protein, or pathogenic mutations in hepcidin (*HAMP*), ferroportin (*FPN*), hemojuvelin (*HJV*), or transferrin receptor 2 (*TfR2*). The phenotype may vary, ranging from severe, as in *HJV*– or *HAMP*–juvenile-onset hemochromatosis, to relatively milder forms of adult-onset hemochromatosis, resulting from defects in *FPN* or *TfR2*. Acquired hemochromatosis can result from excessive amounts of parenteral iron, such as may occur in multiple transfusions for hereditary anemia or acquired aplastic anemia, from loss of hepcidin-producing liver mass, or with disease factors such as hepatitis C or chronic alcoholism that impair the production of hepcidin.

Iron Requirements; Availability of Dietary Iron

Adult men must absorb only 13 μg of iron/kg of body weight/d (~1 mg/day), whereas menstruating women require about 21 μg/kg (~1.4 mg) per day. In the last two trimesters of pregnancy, requirements increase to about 80 μg/kg (5–6 mg) per day; infants have similar requirements due to their rapid growth (Table 45–4).

The difference between dietary supply and requirements is reflected in the size of iron stores, which are low or absent when iron balance is precarious and high when iron balance is favorable. In infants after the third month of life and in pregnant women after the first trimester, stores of iron are negligible. Menstruating women have approximately one-third the stored iron found in adult men (see Table 45–2).

Although the iron content of the diet obviously is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed (Conrad and Umbreit, 2000). The nonheme fraction represents the larger amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the

TABLE 45–4 ■ DAILY IRON ABSORPTION REQUIREMENT

SUBJECT	IRON REQUIREMENT (μg/kg)	AVAILABLE IRON IN POOR DIET–GOOD DIET (μg/kg)	SAFETY FACTOR: AVAILABLE/REQUIREMENT
Infant	67	33–66	0.5–1
Child	22	48–96	2–4
Adolescent (male)	21	30–60	1.5–3
Adolescent (female)	20	30–60	1.5–3
Adult (male)	13	26–52	2–4
Adult (female)	21	18–36	1–2
Mid-to-late pregnancy	80	18–36	0.22–0.45

The numbers in columns 2 and 3 refer to iron absorption via the GI tract in micrograms per kilogram body weight. As noted in Figure 45–4, of 14.4 mg of dietary iron presented to the GI tract each day, only about 1 mg is absorbed. See text concerning factors influencing iron absorption and differential absorption of heme versus nonheme iron.

absorption of nonheme iron. In developed countries, the normal adult diet contains about 6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer's yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most nongreen vegetables. Iron also may be added from cooking in iron pots. In assessing dietary iron intake, it is important to consider not only the amount of iron ingested but also its bioavailability.

Iron Deficiency

The prevalence of iron deficiency anemia in the U.S. is on the order of 1% to 4% and depends on the economic status of the population (McLean et al., 2009). In developing countries, up to 20% to 40% of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption (Camaschella, 2015). More severe iron deficiency is usually the result of blood loss, either from the GI tract or, in women, from the uterus. Finally, treatment of patients with *erythropoietin* can result in a functional iron deficiency. Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, which may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birthweight infants are at greatest risk for developing iron deficiency, especially if they are not breast fed or do not receive iron-fortified formula (Finch, 2015). After the age of 2 to 3 years, the requirement for iron declines until adolescence, when rapid growth combined with irregular dietary habits again increase the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11 to 18 is insufficient to meet their requirements.

Treatment of Iron Deficiency

General Therapeutic Principles

The response of iron deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb oral iron, and the presence of other complicating illnesses, such as those resulting in chronic blood loss or anatomic or physiological defects that interfere with oral iron absorption. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.

Clinically, the effectiveness of iron therapy is best evaluated by tracking the reticulocyte response and the rise in the hemoglobin or the hematocrit. An increase in the reticulocyte count is not observed for at least 4 to 7 days after beginning therapy. A measurable increase in the hemoglobin level takes even longer. A decision regarding the effectiveness of treatment should not be made for 4 weeks after the start of treatment. An increase of 2 g/dL or more in the concentration of hemoglobin by that time should be considered a positive response, assuming that no other change in the patient's clinical status can account for the improvement and that the patient has not been transfused.

If the response to iron treatment is inadequate, the diagnosis must be reconsidered. A full laboratory evaluation should be conducted, and poor compliance by the patient or the presence of a concurrent inflammatory disease should be explored. A source of continued bleeding obviously should be sought. If no other explanation can be found, an evaluation of the patient's ability to absorb oral iron should be considered. There is no justification for merely continuing oral iron therapy beyond 3 to 4 weeks if a favorable response has not occurred.

For patients treated with oral iron, once a response is demonstrated, therapy may be extended beyond normalization of the hemoglobin if it is desirable to replenish iron stores. This may require a considerable period of oral therapy because the rate of absorption of iron by the intestine will decrease markedly as iron stores are reconstituted. The prophylactic use of oral iron should be reserved for patients at high risk, including pregnant women, women with excessive menstrual blood loss, and infants. Iron supplements also may be of value for rapidly growing infants who are consuming substandard diets and for adults with a recognized cause of chronic blood loss. Except for infants, in whom the use of supplemented formulas is routine, the use of over-the-counter mixtures of vitamins and minerals to prevent iron deficiency should be discouraged.

Parenteral iron treatment may be necessary for patients with excessive chronic blood loss that exceeds the capacity for oral iron absorption or patients with anatomic or physiological conditions that preclude sufficient absorption. Several formulations allow for rapid repletion of iron stores with much lower risk of anaphylaxis than previous high-molecular-weight iron dextran products.

Therapy With Oral Iron

Orally administered ferrous sulfate is often the treatment of choice for iron deficiency due to cost-effectiveness, especially in resource-poor settings. The patient's ability to tolerate and absorb medicinal iron is a key factor in determining the rate of response to oral iron therapy. The small intestine regulates absorption and, with increasing doses of oral iron, limits the entry of iron into the bloodstream. This provides a natural ceiling on how much iron can be supplied by oral therapy. In the patient with moderately severe iron deficiency anemia, tolerable doses of oral iron will deliver, at most, 40 to 60 mg of iron per day to the erythroid marrow. This is an amount sufficient for production rates of two to three times normal.

Ferrous salts are absorbed about three times as well as ferric salts. Variations in the particular ferrous salt have relatively little effect on bioavailability; the sulfate, fumarate, succinate, gluconate, aspartate, other ferrous salts, and polysaccharide-ferrihydrite complex are absorbed to approximately the same extent. The effective dose of all these preparations is based on iron content.

Other iron compounds have utility in fortification of foods. Reduced iron (metallic iron, elemental iron) is as effective as ferrous sulfate, provided that the material employed has a small particle size. Large-particle ferrum reductum and iron phosphate salts have much lower bioavailability. Ferric edetate has been shown to have good bioavailability and to have advantages for maintenance of the normal appearance and taste of food.

The amount of iron in iron tablets is important. It also is essential that the coating of the tablet dissolves rapidly in the stomach. Delayed-release preparations are available, but absorption from such preparations varies. Ascorbic acid (≥200 mg) increases the absorption of medicinal iron by at least 30%. However, the increased uptake is associated with an increase in the incidence of side effects. Preparations that contain other compounds with therapeutic action, such as vitamin B_{12}, folate, or cobalt, are not recommended because the patient's response to the combination cannot easily be interpreted.

Untoward Effects of Oral Preparations of Iron. Side effects of oral iron preparations include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate therapy at a small dosage and then gradually to increase the dosage to that desired. Only individuals with underlying disorders that augment the absorption of iron run the hazard of developing iron overload (hemochromatosis).

Dosing. Traditionally, the treatment of adults with iron deficiency has been 150 to 200 mg of elemental iron in up to three divided dose (e.g., ferrous sulfate 325 mg three times daily, equaling 195 mg of elemental iron per day), of which 25 mg is absorbed and utilized. However, this convention has been challenged by data demonstrating that dosing more than once a day may be counterproductive by decreasing iron absorption (due to increased hepcidin levels) and increasing the risk of side

TABLE 45–5 AVERAGE RESPONSE TO ORAL IRON

TOTAL DOSE OF IRON (mg/day)	ESTIMATED ABSORPTION		INCREASE IN BLOOD HEMOGLOBIN (g/L/day)
	%	mg	
35	40	14	0.7
105	24	25	1.4
195	18	35	1.9
390	12	45	2.2

effects (Moretti et al., 2015). Therefore, once-daily administration of ferrous sulfate 325 mg on an empty stomach is a typical dosage that maximizes absorption while maintaining high tolerance (Düzen Oflas et al., 2020).

Children weighing 15 to 30 kg can take half the average adult dose; small children and infants can tolerate relatively large doses of iron (e.g., 5 mg/kg). When the object is the prevention of iron deficiency in pregnant women, for example, doses of 15 to 30 mg of iron per day are adequate. Bioavailability of iron is reduced with food and by concurrent antacids. For a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered four times a day.

The duration of treatment is governed by the rate of recovery of hemoglobin (Table 45–5) and the desire to create iron stores. The former depends on the severity of the anemia. With a daily rate of repair of 2 g of hemoglobin per liter of whole blood, the red cell mass usually is reconstituted within 1 to 2 months. Thus, an individual with a hemoglobin of 50 g/L may achieve a normal complement of 150 g/L in about 50 days, whereas an individual with a hemoglobin of 100 g/L may take only half that time. The creation of stores of iron requires many months of oral iron administration. The rate of absorption decreases rapidly after recovery from anemia, and after 3 to 4 months of treatment, stores may increase at a rate of not much more than 100 mg/month. Much of the strategy of continued therapy depends on the estimated future iron balance. Patients with an inadequate diet may require continued therapy with low doses of iron. If the bleeding has stopped, no further therapy is required after the hemoglobin has returned to normal. With continued bleeding, long-term, high-dose therapy clearly is indicated.

Iron Poisoning. Large amounts of ferrous salts are toxic, but fatalities are rare in adults. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1 to 2 g of iron may cause death, but 2 to 10 g usually are ingested in fatal cases. All iron preparations should be kept in childproof bottles. Signs and symptoms of severe poisoning may occur within 30 min after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. If death does not occur within 6 h, there may be a transient period of apparent recovery, followed by death in 12 to 24 h. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring.

In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and determination of the concentration of iron in plasma can be performed. If the latter is less than 63 μmol (3.5 mg/L), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an X-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol; 3.5 mg/L), *deferoxamine* should be administered (see Chapter 76). The speed of diagnosis and therapy is important. With early treatment, the mortality from iron poisoning can be reduced from 45% to about 1%. *Deferiprone* and *deferasirox* are oral iron chelators that are FDA approved for treatment of patients with thalassemia who have iron overload.

Therapy With Parenteral Iron

Parenteral iron (IV iron) administration may be an effective alternative to oral iron. Previously, parenteral iron formulations carried a higher risk of anaphylactic and anaphylactoid reactions. However, this concern has been addressed by evidence of safety and efficacy of newer IV iron formulations. Thus, IV iron may be considered sooner in the treatment paradigm of iron-deficient patients. Common indications are iron malabsorption (e.g., sprue, short-bowel syndrome), oral iron intolerance, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin. Parenteral iron can be given to iron-deficient patients to create iron stores within one or two sessions, something that would take months to achieve by the oral route.

Several iron formulations are available in the U.S. (Larson and Coyne, 2014). These include *ferumoxytol*, *iron dextran*, *sodium ferric gluconate*, *iron sucrose*, *ferric carboxymaltose*, and *iron isomaltoside* (Table 45–6).

Ferumoxytol. *Ferumoxytol* is a semisynthetic carbohydrate-coated superparamagnetic iron oxide nanoparticle approved for treatment of iron deficiency anemia in patients with CKD; the *ferumoxytol* must be administered as a 1.02-g infusion over a relatively short infusion time of 15 min (Auerbach et al., 2013). Indications for *ferric gluconate* and *iron sucrose* are limited to patients with CKD and documented iron deficiency, although broader applications are being advocated (Larson and Coyne, 2014).

Iron Dextran. *Iron dextran* injection is a colloidal solution of *ferric oxyhydroxide* complexed with polymerized dextran (molecular weight ~180 kDa) that contains 50 mg/mL of elemental iron. The use of low-molecular-weight *iron dextran* has reduced the incidence of toxicity relative to that observed with high-molecular-weight preparations. *Iron dextran* can be administered by intravenous (preferred) or intramuscular injection. Injection of a therapeutic dose should be initiated only after a test dose of 0.5 mL (25 mg of iron). Given intravenously in a dose less than 500 mg, the *iron dextran* complex is cleared with a plasma $t_{1/2}$ of 6 h. When 1 g or more is administered intravenously as total-dose therapy, reticuloendothelial cell clearance is constant at 10 to 20 mg/h.

Intramuscular injection of *iron dextran* should be initiated only after a test dose of 0.5 mL (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 mL (25 mg of iron) for infants weighing less than 4.5 kg,

TABLE 45–6 INTRAVENOUS IRON FORMULATIONS

DRUG	DOSING
Ferumoxytol	Single dose of 1020 mg; or 2 doses of 510 mg, given 3–8 days apart
Iron dextran, low molecular weight	Single dose of 1000 mg, or multiple doses of 100 mg
Ferric gluconate	Multiple doses of 125–250 mg
Iron sucrose	Multiple doses of 100–300 mg
Ferric carboxymaltose	If weight ≥50 mg: 2 doses of 750 mg, given 7 or more days apart. If weight <50 kg: 2 doses of 15 mg/kg, given 7 or more days apart
Iron isomaltoside (ferric derisomaltose)	If weight ≥50 mg: single dose of 1000 mg If weight <50 kg: single dose of 20 mg/kg Or up to 3 doses of 500 mg given over 7 days

Product labeling is available on the FDA website: https://www.accessdata.fda.gov/scripts/cder/daf/.

1 mL (50 mg of iron) for children weighing less than 9 kg, and 2 mL (100 mg of iron) for other patients. However, local reactions and the concern about malignant change at the site of injection make intramuscular administration inappropriate except when the intravenous route is inaccessible. The patient should be observed for signs of immediate anaphylaxis and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Use *iron dextran* with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, *iron dextran* therapy must be abandoned.

With multiple total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss, accumulations of slowly metabolized *iron dextran* stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. It seems prudent, however, to withhold the drug whenever the plasma ferritin rises above 800 μg/L.

Sodium Ferric Gluconate. *Sodium ferric gluconate* is an intravenous iron preparation with a molecular size of about 295 kDa and an osmolality of 990 mOsm/L. Administration of *ferric gluconate* at doses ranging from 62.5 to 125 mg during hemodialysis is associated with transferrin saturation exceeding 100%. Unlike *iron dextran*, which requires processing by macrophages that may require several weeks, about 80% of *sodium ferric gluconate* is delivered to transferrin within 24 h. *Sodium ferric gluconate* also has a lower risk of inducing serious anaphylactic reactions than *iron dextran* (Sengolge et al., 2005).

Iron Sucrose. *Iron sucrose* is a complex of polynuclear iron (III)–hydroxide in sucrose (Beguin and Jaspers, 2014). Following intravenous injection, the complex is taken up by the reticuloendothelial system, where it dissociates into iron and sucrose. *Iron sucrose* is generally administered in daily amounts of 100 to 200 mg within a 14-day period to a total cumulative dose of 1000 mg. Like *sodium ferric gluconate*, *iron sucrose* appears to be better tolerated and to cause fewer adverse events than *iron dextran* (Hayat, 2008). This agent is FDA-approved for the treatment of iron deficiency in patients with CKD. Chronic use has the potential to cause renal tubulointerstitial damage (Agarwal, 2006).

Ferric Carboxymaltose. *Ferric carboxymaltose* is an iron complex consisting of a ferric hydroxide core and a carbohydrate shell (Keating, 2015). With this preparation, a replenishment dose of up to 1000 mg of iron can be administered in 15 min. Intravenous administration results in transient elevations in serum iron, serum ferritin, and transferrin saturation, with subsequent correction in hemoglobin levels and replenishment of depleted iron stores. *Ferric carboxymaltose* is rapidly cleared from the circulation, becoming distributed (~80%) in the marrow, as well as the liver and spleen. Common reported drug-related adverse effects include headache, dizziness, nausea, abdominal pain, constipation, diarrhea, rash, and injection site reactions. However, the incidence of drug-related adverse events appears similar to that of patients treated with oral *ferrous sulfate*. *Ferric carboxymaltose* is FDA-approved for therapy of iron deficiency anemia.

Iron Isomaltoside. *Iron isomaltoside* (also called ferric derisomaltose) consists of iron strongly bound to a chemically modified isomaltooligosaccharides (Auerbach et al., 2019). Unlike the branched dextran polysaccharides in *iron dextran*, the isomaltoside carbohydrate moiety is linear and unbranched, which is theorized to lower its potential immunogenicity. The strength of iron binding enables a controlled slow release of bioavailable iron, mitigating the risk of toxicity from labile free iron. *Iron isomaltoside* was introduced in Europe in 2010. The FDA approved its use in the U.S. in 2020 as an infusion of up to 1 g (or 20 mg/kg if weight is less than 50 kg) for adult patients with an intolerance to oral iron or an unsatisfactory response to oral iron therapy or for patients with CKD not requiring hemodialysis. Conveniently, *iron isomaltoside* can provide full correction of an iron deficit with a single infusion.

Copper, Pyridoxine, and Riboflavin

Copper

Copper has redox properties similar to those of iron, which simultaneously are essential and potentially toxic to the cell. Cells have virtually no free copper. Instead, copper is stored by metallothioneins and distributed by specialized chaperones to sites that make use of its redox properties. Transfer of copper to nascent cuproenzymes is performed by individual or collective activities of P-type ATPases, ATP7A and ATP7B, which are expressed in all tissues (Nevitt et al., 2012). In mammals, the liver is the organ most responsible for the storage, distribution, and excretion of copper. Mutations in ATP7A or ATP7B that interfere with this function have been found responsible for Wilson disease or Menkes syndrome (steely hair syndrome) (de Bie et al., 2007), respectively, which can result in life-threatening hepatic failure.

Copper deficiency is extremely rare; the amount present in food is more than adequate to provide the needed body complement of slightly more than 100 mg. Even in clinical states associated with hypocupremia (sprue, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery, in those who are receiving parenteral nutrition, in malnourished infants, and in patients ingesting excessive amounts of zinc (Willis et al., 2005). Copper deficiency interferes with the absorption of iron and its release from reticuloendothelial cells. In humans, the prominent findings have been leukopenia, particularly granulocytopenia, and anemia. Concentrations of iron in plasma are variable, and the anemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leukopenia and anemia, a therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of *cupric sulfate* have been given by mouth, or 1 to 2 mg per day may be added to the solution of nutrients for parenteral administration.

Pyridoxine

Patients with either hereditary or acquired sideroblastic anemia characteristically have impaired hemoglobin synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Hereditary sideroblastic anemia is an X-linked recessive trait with variable penetrance and expression that results from mutations in the erythrocyte form of δ-aminolevulinate synthase.

Oral therapy with *pyridoxine* is of proven benefit in correcting the sideroblastic anemias associated with the antituberculosis drugs *isoniazid* and *pyrazinamide*, which act as vitamin B_6 antagonists. A daily dose of 50 mg of *pyridoxine* completely corrects the defect without interfering with treatment, and routine supplementation of *pyridoxine* often is recommended (see Chapter 65). In contrast, if pyridoxine is given to counteract the sideroblastic abnormality associated with administration of *levodopa*, the effectiveness of *levodopa* in controlling Parkinson's disease is decreased. *Pyridoxine* therapy does not correct the sideroblastic abnormalities produced by *chloramphenicol* or lead. Patients with idiopathic acquired sideroblastic anemia generally fail to respond to oral *pyridoxine*, and those individuals who appear to have a *pyridoxine*-responsive anemia require prolonged therapy with large doses of the vitamin, 50 to 500 mg/day. The occasional patient who is refractory to oral *pyridoxine* may respond to parenteral administration of *pyridoxal phosphate*. However, oral *pyridoxine* in doses of 200 to 300 mg/day produces intracellular concentrations of *pyridoxal phosphate* equal to or greater than those generated by therapy with the phosphorylated vitamin.

Riboflavin

The spontaneous appearance in humans of red cell aplasia due to riboflavin deficiency undoubtedly is rare, if it occurs at all. Riboflavin deficiency has been described in combination with infection and protein deficiency, both of which are capable of producing hypoproliferative anemia. However, it seems reasonable to include riboflavin in the nutritional management of patients with gross, generalized malnutrition.

Vitamin B_{12}, Folic Acid, and the Treatment of Megaloblastic Anemias

Vitamin B_{12} and folic acid are dietary essentials. A deficiency of either vitamin impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Because tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins.

Cellular Roles of Vitamin B_{12} and Folic Acid

The major roles of vitamin B_{12} and folic acid in intracellular metabolism are summarized in Figure 45–5. Intracellular vitamin B_{12} is maintained as two active coenzymes: methylcobalamin and deoxyadenosylcobalamin.

Methylcobalamin (CH_3B_{12}) supports the *methionine synthetase* reaction, which is essential for normal metabolism of folate (Weissbach, 2008). Methyl groups contributed by methyltetrahydrofolate ($CH_3H_4PteGlu_1$) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate-cobalamin interaction is pivotal for normal synthesis of purines and pyrimidines and, therefore, of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of folylpolyglutamates; and, through the synthesis of methionine and its product *S*-adenosylmethionine (SAM), the maintenance of a number of methylation reactions.

HISTORY

The discovery of vitamin B_{12} and folic acid is a dramatic story that began almost 200 years ago and includes two Nobel Prize–winning discoveries. Beginning in 1824, Combe and Addison wrote a series of case reports describing what must have been megaloblastic anemias (still known as Addisonian pernicious anemia). Austin Flint in 1860 first described a severe gastric atrophy and called attention to its possible relationship to the anemia. After Whipple's observation in 1925 that liver is a source of a potent hematopoietic substance for iron-deficient dogs, Minot and Murphy carried out Nobel Prize–winning experiments that demonstrated the effectiveness of the feeding of liver to reverse pernicious anemia. Soon thereafter, Castle defined the need for both intrinsic factor, a substance secreted by the parietal cells of the gastric mucosa, and extrinsic factor, the vitamin-like material provided by crude liver extracts. Nearly 20 years passed before Rickes and coworkers and Smith and Parker isolated and crystallized vitamin B_{12}; Dorothy Crowfoot Hodgkin received the 1964 Nobel Prize in Chemistry "for her determinations by X-ray techniques of the structures of important biochemical substances," including the crystal structure of vitamin B_{12}.

As attempts were being made to purify extrinsic factor, Wills and her associates described a macrocytic anemia in women in India that responded to a factor present in crude liver extracts but not in the purified fractions known to be effective in pernicious anemia. This factor, first called Wills' factor and later vitamin M, is now known to be folic acid. The term *folic acid* was coined by Mitchell and coworkers in 1941, after its isolation from leafy vegetables. From more recent work, we know that neither vitamin B_{12} nor folic acid as purified from foodstuffs is the active coenzyme in humans. During extraction, active labile forms are converted to stable congeners of vitamin B_{12} and folic acid, cyanocobalamin and PteGlu (pteroylglutamic acid), respectively. These congeners must be modified *in vivo* to be effective. Despite our knowledge of the intracellular metabolic pathways in which these vitamins function as required cofactors, many questions remain, such as: What is the relationship of vitamin B_{12} deficiency to the neurological abnormalities that occur in megaloblastic anemia?

Deoxyadenosylcobalamin (deoxyadenosyl B_{12}) is a cofactor for the *mitochondrial mutase* enzyme that catalyzes the isomerization of l-methylmalonyl coenzyme A (CoA) to succinyl CoA, an important reaction in carbohydrate and lipid metabolism. This reaction has no direct relationship to the metabolic pathways that involve folate.

Because methyltetrahydrofolate is the principal folate congener supplied to cells, the transfer of the methyl group to cobalamin is essential for the adequate supply of tetrahydrofolate ($H_4PteGlu_1$). Tetrahydrofolate is a precursor for the formation of intracellular folylpolyglutamates; it also acts as the acceptor of a one-carbon unit in the conversion of serine to glycine, with the resultant formation of 5,10-methylenetetrahydrofolate (5,10-$CH_2H_4PteGlu$). The last derivative donates the methylene group to deoxythymidine monophosphate (dUMP) for the synthesis of deoxyuridine monophosphate (dTMP)—an extremely important reaction in DNA synthesis. In the process, the 5,10-$CH_2H_4PteGlu$ is converted to dihydrofolate ($H_2PteGlu$). The cycle then is completed by the reduction of the $H_2PteGlu$ to $H_4PteGlu$ by dihydrofolate reductase, the step that is blocked by folate antagonists such as methotrexate (see Chapter 70). As shown in Figure 45–5, other pathways also lead to the synthesis of 5,10-methylenetetrahydrofolate. These pathways are important in the metabolism of formiminoglutamic acid (FIGLU) and purines and pyrimidines.

Deficiency of either vitamin B_{12} or folate decreases the synthesis of methionine and SAM and consequently interferes with protein biosynthesis, a number of methylation reactions, and the synthesis of polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate; this tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin B_{12} deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methyltetrahydrofolate pool (not shown in Figure 45–5). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin B_{12} to accept and transfer methyl groups, and subsequent steps in folate metabolism that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin B_{12} or folic acid.

The mechanisms responsible for the neurological lesions of vitamin B_{12} deficiency are less well understood (Solomon, 2007). Damage to the myelin sheath is the most obvious lesion in this neuropathy. This observation led to the early suggestion that the deoxyadenosyl B_{12}–dependent methylmalonyl CoA mutase reaction, a step in propionate metabolism, is related to the abnormality. However, other evidence suggests that the deficiency of methionine synthetase and the block of the conversion of methionine to SAM are more likely to be responsible.

Vitamin B_{12} and Human Health

Humans depend on exogenous sources of vitamin B_{12} (see structure in Figure 45–6). In nature, the primary sources are certain microorganisms that grow in soil or the intestinal lumen of animals that synthesize the vitamin. The daily nutritional requirement of 3 to 5 μg must generally be obtained from animal by-products in the diet. However, some vitamin B_{12} is available from legumes, which are contaminated with bacteria that can synthesize vitamin B_{12}, and vegetarians often fortify their diets with a wide range of vitamins and minerals; thus, strict vegetarians rarely develop vitamin B_{12} deficiency. The terms *vitamin B_{12}* and *cyanocobalamin* are used interchangeably as generic terms for all of the cobamides active in humans. Preparations of vitamin B_{12} for therapeutic use contain either cyanocobalamin or hydroxocobalamin because only these derivatives remain active after storage.

Metabolic Functions

The active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin are essential for cell growth and replication. Methylcobalamin is required for the conversion of homocysteine to methionine and its derivative SAM. In addition, when concentrations of vitamin B_{12} are inadequate, folate becomes "trapped" as methyltetrahydrofolate to cause a functional deficiency of other required intracellular forms of folic acid. The hematological abnormalities in vitamin B_{12}–deficient patients result from this

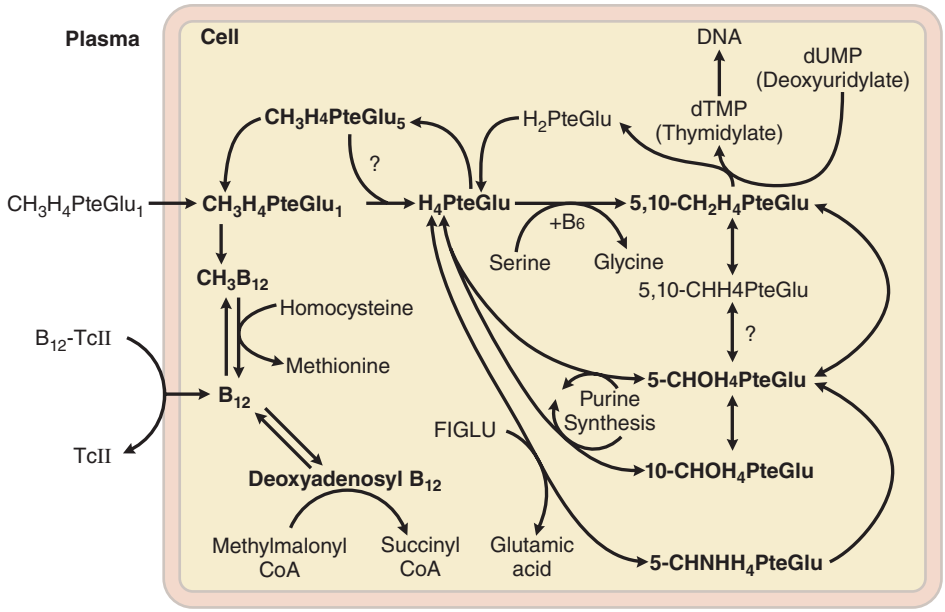

Figure 45–5 *Interrelationships and metabolic roles of vitamin B_{12} and folic acid.* See text for explanation. See Figure 45–6 for structures of vitamin B_{12} congeners and Figure 45–8 for structures of the various folate congeners. FIGLU, formiminoglutamic acid, which arises from the catabolism of histidine; TcII, transcobalamin II.

process. Deoxyadenosylcobalamin (deoxyadenosyl B_{12}) is required for the rearrangement of methylmalonyl CoA to succinyl CoA.

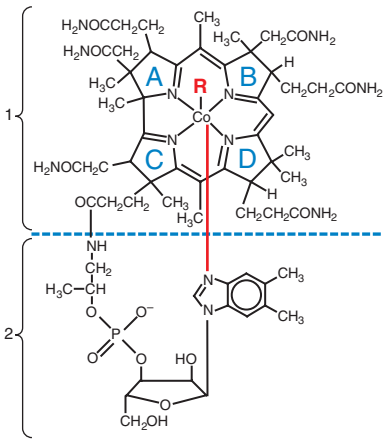
ADME and Daily Requirements

In the presence of gastric acid and pancreatic proteases, dietary vitamin B_{12} is released from food and salivary-binding protein and bound to gastric intrinsic factor. When the vitamin B_{12}–intrinsic factor complex reaches the ileum, it interacts with a receptor on the mucosal cell surface and is actively transported into circulation. Vitamin B_{12} deficiency in adults is rarely the result of a deficient diet per se; rather, it usually reflects a defect in one or another aspect of this complex sequence of absorption (Figure 45–7). Antibodies to parietal cells or intrinsic factor complex also can play a prominent role in producing a deficiency. Several intestinal conditions can interfere with absorption, including pancreatic disorders (loss of pancreatic protease secretion), bacterial overgrowth, intestinal parasites, sprue, and localized damage to ileal mucosal cells by disease or as a result of surgery.

Absorbed vitamin B_{12} binds to transcobalamin II, a plasma β globulin, for transport to tissues. The supply of vitamin B_{12} available for tissues is directly related to the size of the hepatic storage pool and the amount of vitamin B_{12} bound to transcobalamin II (see Figure 45–7). Vitamin B_{12} bound to transcobalamin II is rapidly cleared from plasma and preferentially distributed to hepatic parenchymal cells. As much as 90% of the body's stores of vitamin B_{12}, from 1 to 10 mg, is in the liver. Vitamin B_{12} is stored as the active coenzyme with a turnover rate of 0.5 to 8 μg per day. The recommended daily intake of the vitamin in adults is 2.4 μg. Approximately 3 μg of cobalamins are secreted into bile each day, 50% to 60% of which is not destined for reabsorption. Interference with reabsorption by intestinal disease can progressively deplete hepatic stores of the vitamin.

Vitamin B_{12} Deficiency

The plasma concentration of vitamin B_{12} is the best routine measure of B_{12} deficiency and normally ranges from 150 to 660 pM (~200 to 900 pg/mL). Deficiency should be suspected whenever the concentration falls below 150 pM. The correlation is excellent except when the plasma concentrations of transcobalamin I and III are increased, as occurs with hepatic disease or a myeloproliferative disorder. Inasmuch as the vitamin B_{12} bound to these transport proteins is relatively unavailable to cells,



Vitamin B_{12} Congeners

Permissive Name	*R Group*
Cyanocobalamin (Vitamin B_{12})	–CN
Hydroxocobalamin	–OH
Methylcobalamin	$–CH_3$
5'-Deoxyadenosylcobalamin	–5'-Deoxyadenosyl

Figure 45–6 *The structures and nomenclature of vitamin B_{12} congeners.* The vitamin B_{12} molecule has three major portions: (1) a planar group porphyrin-like ring structure with four reduced pyrrole rings (A–D) linked to a central cobalt atom and extensively substituted with methyl, acetamide, and propionamide residues; (2) a 5,6-dimethylbenzimidazolyl nucleotide, which links almost at right angles to the planar nucleus with bonds to the cobalt atom and to the propionate side chain of the C pyrrole ring; and (3) a variable R group—the most important of which are found in the stable compounds cyanocobalamin and hydroxocobalamin and the active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin.

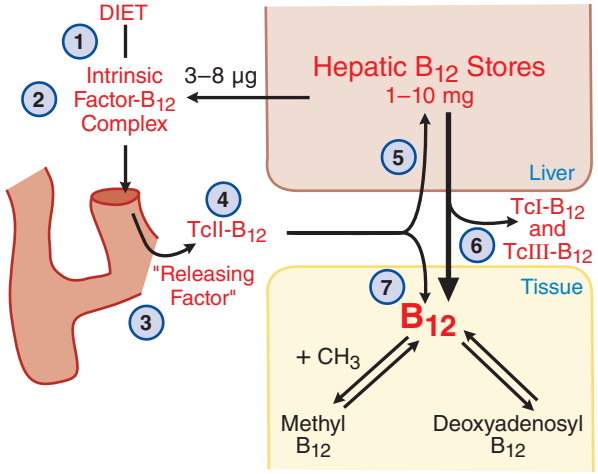


Figure 45–7 *Absorption and distribution of vitamin B_{12}.* Deficiency of vitamin B_{12} can result from a congenital or acquired defect in (1) inadequate dietary supply; (2) inadequate secretion of intrinsic factor (classical pernicious anemia); (3) ileal disease; (4) congenital absence of TcII; or (5) rapid depletion of hepatic stores by interference with reabsorption of vitamin B_{12} excreted in bile. The utility of measurements of the concentration of vitamin B_{12} in plasma to estimate supply available to tissues can be compromised by liver disease and (6) the appearance of abnormal amounts of TcI and TcIII in plasma. The formation of methylcobalamin requires (7) normal transport into cells and an adequate supply of folic acid as $CH_3H_4PteGlu_1$. TcI, TcII, transcobalamins I and II.

tissues can become deficient when the concentration of vitamin B_{12} in plasma is normal or even high. In subjects with congenital absence of transcobalamin II, megaloblastic anemia occurs despite relatively normal plasma concentrations of vitamin B_{12}; the anemia will respond to parenteral doses of vitamin B_{12} that exceed the renal clearance.

Vitamin B_{12} deficiency is recognized clinically by its impact on the hematopoietic and nervous systems. The sensitivity of the hematopoietic system relates to its high rate of cell turnover. Other tissues with high rates of cell turnover (e.g., mucosa and cervical epithelium) also have high requirements for the vitamin. As a result of an inadequate supply of vitamin B_{12}, DNA replication becomes highly abnormal. Once a hematopoietic stem cell is committed to enter a programmed series of cell divisions, the defect in chromosomal replication results in an inability of maturing cells to complete nuclear divisions while cytoplasmic maturation continues at a relatively normal rate. This results in the production of morphologically abnormal cells and death of cells during maturation, a phenomenon referred to as *ineffective hematopoiesis*. Severe deficiency affects all cell lines; pronounced pancytopenia results.

The diagnosis of a vitamin B_{12} deficiency usually can be made using measurements of the serum vitamin B_{12} or serum methylmalonate (which is somewhat more sensitive and useful in identifying metabolic deficiency in patients with normal serum vitamin B_{12} levels). In managing a patient with severe megaloblastic anemia, a therapeutic trial using very small doses of the vitamin can be used to confirm the diagnosis. Serial measurements of the reticulocyte count, serum iron, and hematocrit are performed to define the characteristic recovery of normal red cell production. The Schilling test can be used to measure the absorption of the vitamin and delineate the mechanism of the disease. By performing the Schilling test with and without added intrinsic factor, it is possible to discriminate between intrinsic factor deficiency by itself and primary ileal cell disease. *Vitamin B_{12} deficiency can irreversibly damage the nervous system.* Because the neurological damage can be dissociated from the changes in the hematopoietic system, vitamin B_{12} deficiency must be considered in elderly patients with dementia or psychiatric disorders, even if they are not anemic (Spence, 2016).

Vitamin B_{12} Therapy

Vitamin B_{12} has an undeserved reputation as a health tonic and has been used for a number of disease states. Numerous multivitamin preparations are marketed either as nutritional supplements or for the treatment of anemia; many are supplemented with intrinsic factor. Although the combination of oral vitamin B_{12} and intrinsic factor would appear to be ideal for patients with an intrinsic factor deficiency, such preparations are not reliable.

Vitamin B_{12} is available for injection or oral administration; combinations with other vitamins and minerals also can be given orally or parenterally. The choice of a preparation always depends on the cause of the deficiency. Oral administration cannot be relied on for effective therapy in the patient with a marked deficiency of vitamin B_{12} and abnormal hematopoiesis or neurological deficits. The treatment of choice for vitamin B_{12} deficiency is cyanocobalamin administered by intramuscular or subcutaneous injection, never intravenously. Cyanocobalamin is administered in doses of 1 to 1000 µg. Tissue uptake, storage, and utilization depend on the availability of transcobalamin II. Doses greater than 100 µg are cleared rapidly from plasma into the urine, and administration of larger amounts of vitamin B_{12} will not result in greater retention of the vitamin. Administration of 1000 µg is of value in the performance of the Schilling test. After isotopically labeled vitamin B_{12} is administered orally, the compound that is absorbed can be quantitatively recovered in the urine if 1000 µg of *cyanocobalamin* is administered intramuscularly. This unlabeled material saturates the transport system and tissue binding sites, so more than 90% of the labeled and unlabeled vitamin is excreted during the next 24 h.

Effective use of the vitamin B_{12} depends on accurate diagnosis and an understanding of the following general principles of therapy:

- Vitamin B_{12} should be given prophylactically only when there is a reasonable probability that a deficiency exists or will exist (i.e., dietary deficiency in the strict vegetarian, the predictable malabsorption of vitamin B_{12} in patients who have had a gastrectomy, and certain diseases of the small intestine) (Del Villar Madrigal et al., 2015). When GI function is normal, an oral prophylactic supplement of vitamins and minerals, including vitamin B_{12}, may be indicated. Otherwise, the patient should receive monthly injections of cyanocobalamin.
- The relative ease of treatment with vitamin B_{12} should not prevent a full investigation of the etiology of the deficiency. The initial diagnosis usually is suggested by macrocytic anemia or an unexplained neuropsychiatric disorder.
- Therapy always should be as specific as possible. Although a large number of multivitamin preparations are available, the use of shotgun vitamin therapy in the treatment of vitamin B_{12} deficiency can be dangerous: Sufficient folic acid may be given to result in a hematological recovery that can mask continued vitamin B_{12} deficiency and permit neurological damage to develop or progress.
- Although a classical therapeutic trial with small amounts of vitamin B_{12} can help confirm the diagnosis, acutely ill elderly patients may not be able to tolerate the delay in the correction of a severe anemia. Such patients require supplemental blood transfusions and immediate therapy with folic acid and vitamin B_{12} to guarantee rapid recovery.
- Long-term therapy with vitamin B_{12} must be evaluated at intervals of 6 to 12 months in patients who are otherwise well. If there is an additional illness or a condition that may increase the requirement for the vitamin (e.g., pregnancy), reassessment should be performed more frequently.

Treatment of the Acutely Ill Patient. The therapeutic approach depends on the severity of the illness. In uncomplicated pernicious anemia, in which the abnormality is restricted to a mild or moderate anemia without leukopenia, thrombocytopenia, or neurological signs or symptoms, the administration of vitamin B_{12} alone will suffice. Moreover, therapy may be delayed until other causes of megaloblastic anemia have been excluded and sufficient studies of GI function have been performed to reveal the underlying cause of the disease. In this situation, a therapeutic trial with small amounts of parenteral vitamin B_{12} (1–10 µg/day) can confirm the presence of an uncomplicated vitamin B_{12} deficiency.

In contrast, patients with neurological changes or severe leukopenia or thrombocytopenia associated with infection or bleeding require emergency treatment. Effective therapy must not wait for detailed diagnostic tests. Once the megaloblastic erythropoiesis has been confirmed and sufficient blood collected for later measurements of vitamin B_{12} and folic acid, the patient should receive intramuscular injections of 100 µg of cyanocobalamin and 1 to 5 mg of folic acid. For the next 1 to 2 weeks, the patient should receive daily intramuscular injections of 100 µg of cyanocobalamin, together with a daily oral supplement of 1 to 2 mg of folic acid. Because an effective increase in red cell mass will not occur for 10 to 20 days, the patient with a markedly depressed hematocrit and tissue hypoxia also should receive a transfusion of 2 to 3 units of packed red blood cells. If congestive heart failure is present, diuretics can be administered to prevent volume overload.

The first objective hematological change is the disappearance of the megaloblastic morphology of the marrow. As the ineffective erythropoiesis is corrected, the concentration of iron in plasma falls dramatically as the metal is used in the formation of hemoglobin, usually within the first 48 h. Full correction of precursor maturation in marrow with production of an increased number of reticulocytes begins about the second or third day and peaks 3 to 5 days later. Patients with complicating iron deficiency, an infection or other inflammatory state, or renal disease may be unable to correct their anemia. Therefore, it is important to monitor the reticulocyte index over the first several weeks. If it does not continue at elevated levels while the hematocrit is below 35%, plasma concentrations of iron and folic acid should again be determined and the patient reevaluated for an illness that could inhibit the response of the marrow. The degree and rate of improvement of neurological signs and symptoms depend on the severity and the duration of the abnormalities. Those that have been present for only a few months usually disappear relatively rapidly. When a defect has been present for many months or years, full return to normal function may never occur.

Long-Term Therapy With Vitamin B_{12}. Once begun, vitamin B_{12} therapy must be maintained for life. This fact must be impressed on the patient and family, and a system must be established to guarantee continued monthly injections of cyanocobalamin.

Intramuscular injection of 100 µg of cyanocobalamin every 4 weeks is usually sufficient. Patients with severe neurological symptoms and signs may be treated with larger doses of vitamin B_{12} in the period immediately after the diagnosis. Doses of 100 µg per day or several times per week may be given for several months with the hope of encouraging faster and more complete recovery. It is important to monitor vitamin B_{12} concentrations in plasma and to obtain peripheral blood counts at intervals of 3 to 6 months to confirm the adequacy of therapy. Because refractoriness to therapy can develop at any time, evaluation must continue throughout the patient's life. Intranasal preparations are available for maintenance following normalization of vitamin B_{12}–deficient patients without nervous system involvement.

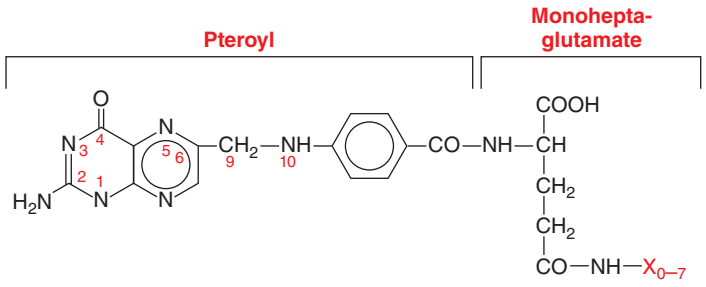
Folic Acid and Human Health

Biochemical Roles of Folate

Pteroylglutamic acid (Figure 45–8) is the common pharmaceutical form of folic acid. It is not the principal folate congener in food or the active coenzyme for intracellular metabolism. After absorption, PteGlu is rapidly reduced at the 5, 6, 7, and 8 positions to *tetrahydrofolic acid* (H_4PteGlu), which then acts as an acceptor of a number of one-carbon units. These are attached at either the 5 or the 10 position of the pteridine ring or may bridge these atoms to form a new five-membered ring. The most important forms of the coenzyme are synthesized by the reactions depicted in Figure 45–5, and each plays a specific role in intracellular metabolism:

- *Conversion of homocysteine to methionine*. This reaction requires CH_3H_4PteGlu as a methyl donor and uses vitamin B_{12} as a cofactor.
- *Conversion of serine to glycine*. This reaction requires tetrahydrofolate as an acceptor of a methylene group from serine and uses pyridoxal phosphate as a cofactor. It results in the formation of 5,10-CH_2H_4PteGlu, an essential coenzyme for the synthesis of dTMP.
- *Synthesis of thymidylate*. 5,10-CH_2H_4PteGlu donates a methylene group and reducing equivalents to dUMP for the synthesis of dTMP—a rate-limiting step in DNA synthesis.
- *Histidine metabolism*. H_4PteGlu also acts as an acceptor of a formimino group in the conversion of FIGLU to glutamic acid.
- *Synthesis of purines*. Two steps in the synthesis of purine nucleotides require the participation of 10-$CHOH_4$PteGlu as a formyl donor in reactions catalyzed by ribotide transformylases: the formylation of glycinamide ribonucleotide and the formylation of 5-aminoimidazole-4-carboxamide ribonucleotide. By these reactions, carbon atoms at positions 8 and 2, respectively, are incorporated into the growing purine ring.
- *Utilization or generation of formate*. This reversible reaction uses H_4PteGlu and 10-$CHOH_4$PteGlu.

Daily Requirements. Many food sources are rich in folates, especially fresh green vegetables, liver, yeast, and some fruits. However, lengthy cooking can destroy up to 90% of the folate content of such food. Generally, a standard U.S. diet provides 50 to 500 µg of absorbable folate per



Position	Radical	Congener	
N^5	—CH_3	CH_3H_4PteGlu	Methyltetrahydrofolate
N^5	—CHO	5-$CHOH_4$PteGlu	Folinic acid (citrovorum factor)
N^{10}	—CHO	10-$CHOH_4$PteGlu	10-Formyltetrahydrofolate
$N^{5,10}$	=CH—	5,10-CHH_4PteGlu	5,10-Methenyltetrahydrofolate
$N^{5,10}$	—CH_2—	5,10-CH_2H_4PteGlu	5,10-Methylenetetrahydrofolate
N^5	—CHNH	$CHNHH_4$PteGlu	Formiminotetrahydrofolate
N^{10}	—CH_2OH	CH_2OHH_4PteGlu	Hydroxymethyltetrahydrofolate

Figure 45–8 *The structures and nomenclature of PteGlu (folic acid) and its congeners.* X represents additional residues of glutamate; polyglutamates are the storage and active forms of the vitamin. The number of residues of glutamate is variable.

day, although individuals with high intakes of fresh vegetables and meats will ingest as much as 2 mg/day. In the normal adult, the recommended daily intake is 400 µg; pregnant or lactating women and patients with high rates of cell turnover (such as patients with a hemolytic anemia) may require 500 to 600 µg or more per day. For the prevention of neural tube defects, a daily intake of at least 400 µg of folate in food or in supplements beginning a month before pregnancy and continued for at least the first trimester is recommended. Folate supplementation also is being considered in patients with elevated levels of plasma homocysteine.

ADME. As with vitamin B_{12}, the diagnosis and management of deficiencies of folic acid depend on an understanding of the transport pathways and intracellular metabolism of the vitamin (Figure 45–9). Folates present in food are largely in the form of reduced polyglutamates, and absorption requires transport and the action of a *pteroylglutamyl carboxypeptidase* associated with mucosal cell membranes. The mucosae of the duodenum and upper part of the jejunum are rich in dihydrofolate reductase and can methylate most of or all the reduced folate that is absorbed. Because most absorption occurs in the proximal portion of the small intestine, it is not unusual for folate deficiency to occur when the jejunum is diseased. Both nontropical and tropical sprues are common causes of folate deficiency and megaloblastic anemia.

Once absorbed, folate is transported rapidly to tissues as $CH_3H_4PteGlu$. Although certain plasma proteins do bind folate derivatives, they have a greater affinity for nonmethylated analogues. The role of such binding proteins in folate homeostasis is not well understood. An increase in binding capacity is detectable in folate deficiency and in certain disease states, such as uremia, cancer, and alcoholism. A constant supply of $CH_3H_4PteGlu$ is maintained by food and by an enterohepatic cycle of the vitamin. The liver actively reduces and methylates PteGlu (and H_2 or $H_4PteGlu$) and then transports the $CH_3H_4PteGlu$ into bile for reabsorption by the gut and subsequent delivery to tissues. This pathway may provide 200 µg or more of folate each day for recirculation to tissues. The importance of the enterohepatic cycle was suggested by animal studies that showed a rapid reduction of the plasma folate concentration after either drainage of bile or ingestion of alcohol, which apparently blocks the release of $CH_3H_4PteGlu$ from hepatic parenchymal cells.

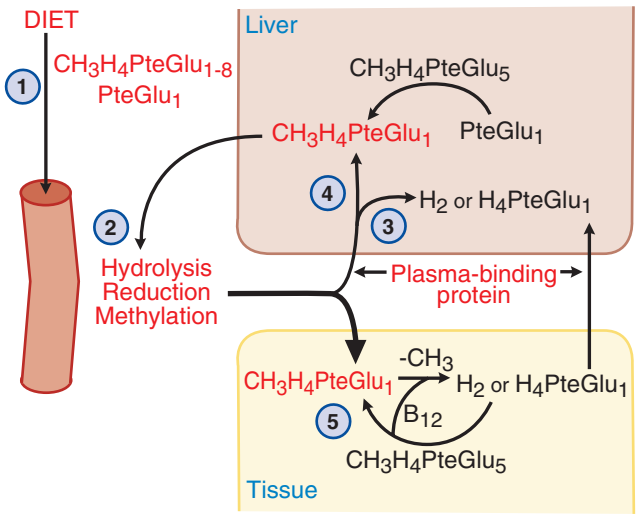


Figure 45–9 *Absorption and distribution of folate derivatives.* Dietary sources of folate polyglutamates are hydrolyzed to the monoglutamate, reduced, and methylated to $CH_3H_4PteGlu_1$ during GI transport. Folate deficiency commonly results from (1) inadequate dietary supply and (2) small intestinal disease. In patients with uremia, alcoholism, or hepatic disease, there may be defects in (3) the concentration of folate-binding proteins in plasma and (4) the flow of $CH_3H_4PteGlu_1$ into bile for reabsorption and transport to tissue (the folate enterohepatic cycle). Finally, vitamin B_{12} deficiency will (5) "trap" folate as $CH_3H_4PteGlu$, thereby reducing the availability of $H_4PteGlu_1$ for its essential roles in purine and pyrimidine synthesis.

Folate Deficiency. Folate deficiency is a common complication of diseases of the small intestine that interfere with the absorption of folate from food and the recirculation of folate through the enterohepatic cycle. The prevalence of folate deficiency in persons over age 65 is relatively high due to reduced dietary intake or intestinal malabsorption (Araujo et al., 2015). In acute or chronic alcoholism, daily intake of folate in food may be severely restricted, and the enterohepatic cycle of the vitamin may be impaired by toxic effects of alcohol on hepatic parenchymal cells; this is the most common cause of folate-deficient megaloblastic erythropoiesis and the most amenable to therapy, via reinstitution of a normal diet. Disease states characterized by a high rate of cell turnover, such as hemolytic anemias, also may be complicated by folate deficiency. In addition, drugs that inhibit dihydrofolate reductase (e.g., *methotrexate* and *trimethoprim*) or that interfere with the absorption and storage of folate in tissues (e.g., certain anticonvulsants and oral contraceptives) can lower the concentration of folate in plasma and may cause a megaloblastic anemia (Hesdorffer and Longo, 2015).

Folate deficiency is recognized by its impact on the hematopoietic system. As with vitamin B_{12}, this fact reflects the increased requirement associated with high rates of cell turnover. The megaloblastic anemia that results from folate deficiency cannot be distinguished from that caused by vitamin B_{12} deficiency. In contrast to vitamin B_{12} deficiency, folate deficiency is rarely, if ever, associated with neurological abnormalities. After deprivation of folate, megaloblastic anemia develops much more rapidly than it does following interruption of vitamin B_{12} absorption (e.g., gastric surgery). This observation reflects the fact that body stores of folate are limited. Although the rate of induction of megaloblastic erythropoiesis may vary, a folate-deficiency state may appear in 1 to 4 weeks, depending on the individual's dietary habits and stores of the vitamin.

Folate deficiency is implicated in the incidence of neural tube defects (Wallingford et al., 2013). An inadequate intake of folate also can result in elevations in plasma homocysteine. Because even moderate hyperhomocysteinemia is considered an independent risk factor for coronary artery and peripheral vascular disease and for venous thrombosis, the role of folate as a methyl donor in the homocysteine-to-methionine conversion is receiving increased attention (Stanger and Wonisch, 2012).

General Principles of Therapy. The therapeutic use of folic acid is limited to the prevention and treatment of deficiencies of the vitamin. As with vitamin B_{12} therapy, effective use of the vitamin depends on accurate diagnosis and an understanding of the mechanisms that are operative in a specific disease state. The following general principles of therapy should be respected:

- Dietary supplementation is necessary when there is a requirement that may not be met by a "normal" diet. The daily ingestion of a multivitamin preparation containing 400 to 500 µg of folic acid has become standard practice before and during pregnancy to reduce the incidence of neural tube defects and for as long as a woman is breastfeeding. In women with a history of a pregnancy complicated by a neural tube defect, an even larger dose of 4 mg/day has been recommended. Patients on total parenteral nutrition should receive folic acid supplements as part of their fluid regimen because liver folate stores are limited. Adult patients with a disease state characterized by high cell turnover (e.g., hemolytic anemia) generally require 1 mg of folic acid given once or twice a day. The 1-mg dose also has been used in the treatment of patients with elevated levels of homocysteine.
- Any patient with folate deficiency and a megaloblastic anemia should be evaluated carefully to determine the underlying cause of the deficiency state. This should include evaluation of the effects of medications, the amount of alcohol intake, the patient's history of travel, and the function of the GI tract.
- Therapy always should be as specific as possible. Multivitamin preparations should be avoided unless there is good reason to suspect deficiency of several vitamins.
- The potential danger of mistreating a patient who has vitamin B_{12} deficiency with folic acid must be kept in mind. The administration of large doses of folic acid can result in an apparent improvement of the megaloblastic anemia because PteGlu is converted by dihydrofolate

reductase to H_4PteGlu; this circumvents the methylfolate "trap." However, folate therapy does not prevent or alleviate the neurological defects of vitamin B_{12} deficiency, and these may progress and become irreversible.

Therapeutic Use of Folate. Folic acid is marketed as oral tablets containing PteGlu or l-methylfolate, as an aqueous solution for injection (5 mg/mL), and in combination with other vitamins and minerals. Folinic acid (leucovorin calcium, citrovorum factor) is the 5-formyl derivative of tetrahydrofolic acid. The principal therapeutic uses of folinic acid are to circumvent the inhibition of dihydrofolate reductase as a part of high-dose *methotrexate* therapy and to potentiate *fluorouracil* in the treatment of colorectal cancer (see Chapter 70). It also has been used as an antidote to counteract the toxicity of folate antagonists such as *pyrimethamine* or *trimethoprim*. Folinic acid provides no advantage over folic acid, is more expensive, and therefore is not recommended. A single exception is the megaloblastic anemia associated with congenital dihydrofolate reductase deficiency.

Evaluation of the serum folate level can help exclude folate deficiency, but only in patients whose serum folate levels exceed 5.0 ng/mL; 2% to 5% of healthy adults can have serum folate levels that are below this level. Red cell folate levels (reference range >140 ng/mL) reflect chronic folate levels, are less affected by acute ingestion of folate than are serum levels, but are more time consuming and costly to measure. Serum folate concentrations more frequently show a higher correlation with serum homocysteine, which is a sensitive marker of deficiency (Farrell et al., 2013). In any case, a patient with a low serum or red cell folate level should have follow-up tests that include serum homocysteine (reference range, 5–16 mM), which is elevated in B_{12} and folate deficiency, and serum methylmalonic acid (reference range, 70–270 mM), which is elevated only in B_{12} deficiency.

Untoward Effects. There have been rare reports of reactions to parenteral injections of folic acid and *leucovorin*. Oral folic acid usually is not toxic. Folic acid in large amounts may counteract the antiepileptic effect of *phenobarbital*, *phenytoin*, and *primidone* and increase the frequency of seizures in susceptible children. The FDA recommends that oral tablets of folic acid be limited to strengths of 1 mg or less.

Drug Facts for Your Personal Formulary: *Hematopoietic Agents: Growth Factors, Minerals, and Vitamins*

Drug	Therapeutic Use (Principle Labeled Indications)	Clinical Pharmacology and Tips
Erythropoietin-Stimulating Agents (ESAs): Stimulate red blood cell production; bind to erythropoietin (EPO) receptor on erythroid progenitor cells		
Epoetin alfa	• Anemia due to CKD • Anemia due to chemotherapy in patients with cancer	• Use the lowest dose sufficient to reduce the need for transfusions • ↑ risk of death, cardiovascular event, or stroke if administered to a target hemoblobin >11 g/dL • Not indicated in patients receiving chemotherapy when expected outcome is curative or when the anemia can be managed by transfusion • Darbepoetin alfa may be dosed less frequently, but the two ESAs have similar efficacy
Darbepoetin alfa	• Anemia due to CKD • Anemia due to chemotherapy in patients with cancer	
Granulocyte Colony-Stimulating Factors (GCSFs): Stimulate production, maturation, and activation of neutrophils		
Filgrastim	• Chemotherapy-induced myelosuppression in nonmyeloid malignancies • Acute myeloid leukemia following induction or consolidation chemotherapy • After bone marrow transplantation • Severe chronic neutropenia	• Indicated for prophylactic use to ↓ risk of neutropenic fever when risk is anticipated to be ~20% or greater • Not intended as routine treatment of established neutropenic fever
Pegfilgrastim	• Prevention of chemotherapy-induced neutropenia	• Compared to filgrastim: prolonged duration of effect and reduced renal clearance • Typically administered 24 h after chemotherapy and at least 14 days prior to the next chemotherapy dose
Thrombopoietin Receptor Agonists (TRAs): Stimulate production of megakaryocytes and platelets in the marrow		
Romiplostim	• Immune thrombocytopenia (ITP) with insufficient response to corticosteroids, immune globulin, or splenectomy	• Use only when degree of thrombocytopenia and clinical condition ↑ risk of bleeding; not intended to completely normalize platelet count
Eltrombopag	• Severe aplastic anemia (first-line in combination with immune suppression) • Chronic hepatitis C virus (HCV)–associated thrombocytopenia • ITP with insufficient response to corticosteroids, immune globulin, or splenectomy	• As above, not intended to completely normalize platelet count • In patients with chronic HCV, with interferon and ribavirin may ↑ risk of hepatic decompensation
Avatrombopag	• Chronic ITP with insufficient response to a previous treatment • Chronic liver disease–associated thrombocytopenia who are scheduled to undergo a procedure	• In chronic ITP, use lowest dose necessary to achieve platelet counts >50,000/μL • For preprocedural use: 5-day course beginning avatrombopag 10 days prior to scheduled procedure; conduct procedure 5–8 days after the last dose
Lusutrombopag	• Chronic liver disease–associated thrombocytopenia with a scheduled procedure	• 3 mg once daily for 7 days, beginning 8–14 days prior to scheduled procedure; conduct procedure 2–8 days after the last lusutrombopag dose

Drug	Therapeutic Use (Principle Labeled Indications)	Clinical Pharmacology and Tips
TFGβ Inhibitor: Stimulates red blood cell productions by promoting erythroid maturation in conditions with ineffective erythropoiesis		
Luspatercept	• Anemia due to beta thalassemia • Anemia due to myelodysplastic syndrome (MDS) with ring sideroblasts (RS) or MDS/myeloproliferative neoplasm with RS and thrombocytosis	• Monitor blood pressure • Monitor for signs/symptoms of thromboembolism
Oral Iron: Corrects iron deficiency and builds iron stores necessary for hemoglobin synthesis		
Ferrous sulfate and other iron salts	• Iron deficiency anemia	• 65 mg of elemental iron (e.g., ferrous sulfate 325-mg tablet) every other day, maximizing relative absorption • Daily dosing ⇒ ↓ absorption, but may be reasonable to improve adherence • Ferrous salts have equivalent efficacy • Enteric-coated and slow-/sustained-release forms not preferred (poor absorption)
Parenteral Iron: Corrects iron deficiency in clinical situations when there is a need for rapid repletion, or poor absorption or lack of response to oral iron		
Iron dextran	• Iron deficiency in patients with intolerance to oral iron or unsatisfactory response to oral iron	• Administer 25-mg test dose first • 1 g can be given as a single dose • Administered as a slow infusion
Sodium ferric gluconate	• Iron deficiency in patients with CKD undergoing hemodialysis in conjunction with supplemental EPO therapy	• Multiple doses of 125–250 mg • 125-mg dose is administered over 1 h • Avoided in pregnancy due to benzyl alcohol preservative (potential fetal risk)
Iron sucrose	• Iron deficiency in patients with CKD	• Multiple doses of 100–300 mg • Administered as a slow IV injection or infusion • Less preferred in pregnancy due to the need for multiple infusions rather than single replacement dose
Ferumoxytol	• Iron deficiency anemia in adults with an intolerance or unsatisfactory response to oral iron or who have CKD	• Single dose of 1020 mg or two doses of 510 mg, given 3–8 days apart • Administered over at least 15 min (30 min for 1020-mg dose) • Monitor for signs of hypersensitivity for ≥30 min after infusion
Ferric carboxymaltose	• Iron deficiency anemia in patients with intolerance to oral iron or unsatisfactory response to oral iron or who have non–dialysis-dependent CKD	• Two doses of 750 mg (or 15 mg/kg if weight <50 kg), given 7 or more days apart • Administer as a slow IV push over 15 min
Ferric derisomaltose	• Iron deficiency anemia in patients with intolerance to oral iron or unsatisfactory response to oral iron or who have non–dialysis-dependent CKD	• Single dose of 100 mg (20 mg/kg if weight <50 kg) • Administer doses up to 1 g over at least 20 min • Administer doses >1 g over at least 30 min • 500 mg can be administered as slow IV bolus injection (250 mg/min) • Use in pregnancy not prospectively studied, but retrospective review notes safety/efficacy profile similar to that typically observed with other formulations
Agents for Megaloblastic Anemias: Folic acid and vitamin B_{12} are necessary for purine and pyrimidine synthesis		
Cyanocobalamin (vitamin B_{12})	• Treatment of pernicious anemia or vitamin B_{12} deficiency due to dietary deficiencies or malabsorption • Prevention of vitamin B_{12} deficiency in patients with increased requirements	• Oral: 1000–2000 µg daily • Intramuscular (IM) or deep subcutaneous (SQ): 1000 µg • Initial therapy for severe/symptomatic disease is IM or deep SQ 1000 µg daily three times per week for 1 week, then once weekly for 4–8 weeks; maintenance doses: 1000 µg IM/SQ monthly, or 1000–2000 µg orally daily when symptoms have resolved • For mild/asymptomatic deficiency: 1000 µg weekly for 4–8 weeks, then monthly maintenance; or 1000–2000 µg orally daily in patients without impaired GI absorption • Continue indefinitely unless a reversible cause of deficiency has been addressed
Folic acid	• Treatment of megaloblastic and macrocytic anemias due to folate deficiency	• 1–5 mg orally once daily
Leucovorin calcium (folinic acid)	• Rescue agent after high-dose methotrexate (MTX) • Treatment of advanced colorectal cancer • Treatment of megaloblastic anemias due to folic acid deficiency when oral therapy is not feasible	• 5-Formyl derivative of tetrahydrofolic acid • Colon cancer: potentiates the effect of 5-fluorouracil by binding and stabilizing 5-dUMP and thymidylate synthetase • Starting 24 h after MTX treatment to replenish active folate stores

Chapter 46 Introduction to Endocrinology: The Hypothalamic-Pituitary Axis

Dequina A. Nicholas and Mark A. Lawson

Endocrinology and Hormones: General Concepts

Endocrinology analyzes the biosynthesis of hormones, their sites of production, and the sites and mechanisms of their action and interaction. The term *hormone* is of Greek origin and classically refers to a chemical messenger that circulates in body fluids and produces specific effects on cells distant from the hormone's point of origin. The major functions of hormones include the regulation of energy storage, production, and utilization; the adaptation to new environments or conditions of stress; the facilitation of growth and development; and the maturation and function of the reproductive system. Although hormones were originally defined as products of ductless glands, we now appreciate that many tissues and cell types not classically considered as "endocrine" (e.g., the heart, kidneys, GI tract, adipocytes, stem cells, and neurons) synthesize and secrete hormones that play key physiological roles. The current understanding of hormones emphasizes their cellular origin and action. Broadly, the field of endocrinology also includes the consideration of substances that act by means of autocrine and paracrine mechanisms, the influence of neurons—particularly those in the hypothalamus—that regulate endocrine function through synaptic or peptide hormone action, and the reciprocal interactions of cytokines and other components of the immune system with the endocrine system.

Conceptually, hormones may be divided into two classes based on mechanism of action:

- Hormones that act predominantly via *nuclear receptors* to modulate transcription in target cells (e.g., steroid hormones, retinoids, thyroid hormone, and vitamin D)
- Hormones that typically act via *membrane receptors* to exert rapid effects on signal transduction pathways (e.g., peptide and amino acid hormones)

Notably, the steroid hormones operate through both mechanisms, and their effect on cells is determined by the receptor complement in an individual cell. The receptors for both classes of hormones provide tractable targets for a diverse group of compounds that are among the most widely used drugs in clinical medicine.

The Hypothalamic-Pituitary-Endocrine Axis

Many of the classic endocrine hormones (e.g., cortisol, thyroid hormone, sex steroids, GH) are regulated by complex reciprocal interactions among the hypothalamus, anterior pituitary, and target organs or tissues (Table 46–1). The basic organization of the hypothalamic-pituitary-endocrine axis is summarized in Figure 46–1.

Discrete sets of hypothalamic neurons produce different releasing and inhibiting hormones, which are axonally transported to the median eminence. On stimulation, either synaptic or by other intrahypothalamic hormones, these neurons secrete their respective hypothalamic hormones into the hypothalamic-adenohypophyseal portal veins, which connect to the *anterior pituitary* gland. The *hypothalamic hormones* bind to membrane receptors on specific subsets of pituitary cells and regulate the secretion of the corresponding *pituitary hormones*. The pituitary hormones circulate to the target tissues where they activate cognate receptors to exert cell-specific effects or stimulate the synthesis and secretion of the target endocrine hormones. These interactions follow *feed-forward regulation* in which the originating hypothalamic signal is amplified by the anterior pituitary, then elicits a regulated response from target tissues and stimulates the production of hormones by the endocrine targets. In contrast, the *posterior pituitary* contains the endings of nerve axons arising from the hypothalamus, forming the neurohypophysis, which has direct

Abbreviations

AC: adenylyl cyclase
ACTH: corticotropin, formerly adrenocorticotrophic hormone
ADH: antidiuretic hormone
CG: chorionic gonadotropin
COX: cyclooxygenase
CRH: corticotropin-releasing hormone
DA: dopamine
ELISA: enzyme-linked immunosorbent assay
FP: prostaglandin F receptor
FSH: follicle-stimulating hormone, follitropin
GH: growth hormone
GHR: GH receptor
GHRH: growth hormone–releasing hormone
GI: gastrointestinal
GnRH: gonadotropin-releasing hormone
GPCR: G protein-coupled receptor
hCG: human chorionic gonadotropin
5HT: 5-hydroxytryptamin serotonin
IGF-1: insulin-like growth factor 1
IGFBP: IGF-binding protein
IRS: insulin receptor substrate
LH: luteinizing hormone; lutropin
MRI: magnetic resonance imaging
α-MSH: α-melanocyte–stimulating hormone
NO: nitric oxide
NPY: neuropeptide Y
OXTR: oxytocin receptor
POMC: pro-opiomelanocortin
PRL: prolactin
SC: subcutaneous
SHC: Src homology-containing protein
SHP2: Src-homology-2-domain-containing protein tyrosine phosphatase 2
SST: somatostatin
SSTR: SST receptor
TRH: thyrotropin-releasing hormone
TSH: thyroid-stimulating hormone, thyrotropin
VIP: vasoactive intestinal peptide

access to the circulation and does not rely on intermediate action of the pituitary (see Figure 46–1).

Typically, feed-forward signals are controlled by *negative feedback*, which permits precise regulation of hormone levels and reestablishment of homeostasis after activation of a secretory event (Figure 46–2). The endocrine target hormone circulates to both the hypothalamus and pituitary, where it acts via specific receptors to inhibit the production and secretion of both its hypothalamic-releasing hormone and the regulatory pituitary hormone. In addition, other brain regions have inputs to the hypothalamic hormone–producing neurons, and hormones produced independently by other tissues target both the hypothalamus and anterior pituitary, further integrating the regulation of hormone levels in response to diverse stimuli.

Pituitary Hormones and Their Hypothalamic-Releasing Factors

The anterior pituitary hormones can be classified into three different groups based on their structural features (Table 46–2):

- Pro-opiomelanocortin (POMC)-derived hormones include *corticotropin* (ACTH) and *α-melanocyte–stimulating hormone* (α-MSH). These are derived from POMC by proteolytic processing (see Figures 23–3 and 50–1).
- Somatotropic hormones include *growth hormone* (GH) and prolactin (PRL). In humans, the somatotropic family also includes placental lactogen.

TABLE 46–1 ■ HORMONES THAT INTEGRATE THE HYPOTHALAMIC-PITUITARY-ENDOCRINE AXIS

HYPOTHALAMIC HORMONE	EFFECT ON PITUITARY TROPHIC (SIGNAL) HORMONE	TARGET HORMONE(S)
Growth hormone–releasing hormone	↑↑ Growth hormone	IGF-1
Somatostatin	↓ Growth hormone ↓ Thyroid-stimulating hormone	
Dopamine	↓ Prolactin	—
Corticotropin-releasing hormone	↑ Corticotropin	Cortisol
Thyrotropin-releasing hormone	↑ Thyroid-stimulating hormone ↑ Prolactin	Thyroid hormone
Gonadotropin-releasing hormone	↑ Follicle-stimulating hormone ↑ Luteinizing hormone	Estrogen (f) Progesterone/estrogen (f) Testosterone (m)

f, female; m, male; ↑, increased production; ↓, decreased production.

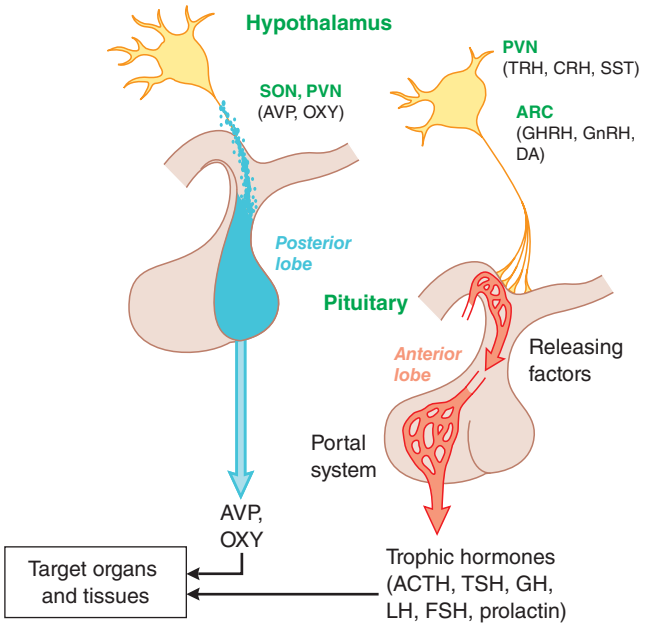

Figure 46–1 *Organization of the anterior and posterior pituitary gland.* Hypothalamic neurons in the supraoptic (SON) and paraventricular (PVN) nuclei synthesize arginine vasopressin (AVP) or oxytocin (OXY). Most of their axons project directly to the posterior pituitary, from which AVP and OXY are secreted into the systemic circulation to regulate their target tissues. Neurons that regulate the anterior lobe cluster in the mediobasal hypothalamus, including the PVN and the arcuate (ARC) nuclei. They secrete hypothalamic releasing hormones, which reach the anterior pituitary via the hypothalamic-adenohypophyseal portal system and stimulate distinct populations of pituitary cells. These cells, in turn, secrete the trophic (signal) hormones, which regulate endocrine organs and other tissues. ARC, arcuate; AVP, arginine vasopressin; OXY, oxytocin; PVN, paraventricular nuclei; SON, supraoptic nuclei; see Abbreviations list for other abbreviations.

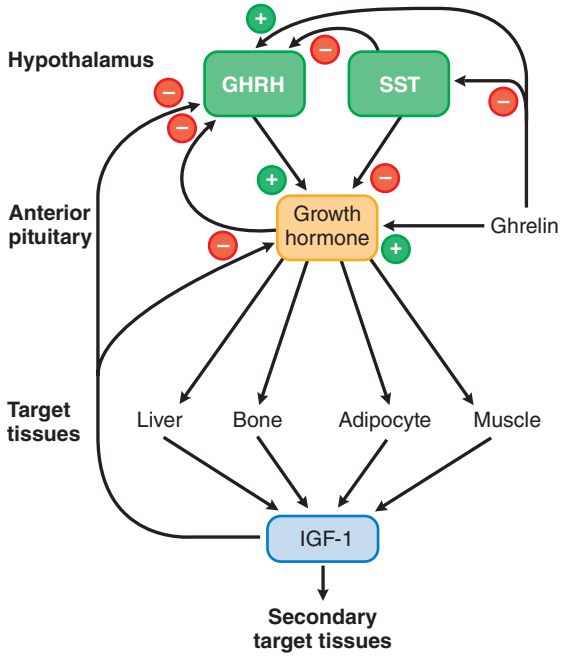

Figure 46–2 *Growth hormone secretion and actions.* Two hypothalamic factors, GHRH and SST, stimulate or inhibit the release of GH from the pituitary, respectively. Insulin-like growth factor-1 (IGF-1), a product of GH action on peripheral tissues, causes negative-feedback inhibition of GH release by acting at the hypothalamus and the pituitary. The actions of GH can be direct or indirect (mediated by IGF-1). See text for discussion of the other agents that modulate GH secretion and of the effects of locally produced IGF-1. Inhibition, –; stimulation, +.

- The glycoprotein hormones include *thyroid-stimulating hormone* (TSH, also called thyrotropin), *luteinizing hormone* (LH, also called lutropin), and *follicle-stimulating hormone* (FSH, also called follitropin). In humans, the glycoprotein hormone family also includes placental *human chorionic gonadotropin* (hCG).

The synthesis and release of *anterior pituitary hormones* are influenced by the CNS. Their secretion is positively regulated by a group of peptides referred to as *hypothalamic-releasing hormones* (see Figure 46–1). These include *corticotropin-releasing hormone* (CRH), *growth hormone–releasing hormone* (GHRH), *gonadotropin-releasing hormone* (GnRH), and *thyrotropin-releasing hormone* (TRH). *Somatostatin* (SST), another hypothalamic peptide, negatively regulates secretion of pituitary GH and TSH. The neurotransmitter *dopamine* (DA) inhibits the secretion of PRL by lactotropes.

Posterior pituitary hormones, which are synthesized by hypothalamic neurons and secreted from the neurohypophysis, include *oxytocin* and *arginine vasopressin* (also called antidiuretic hormone [ADH]). Arginine vasopressin plays an important role in water homeostasis (see Chapter 29); oxytocin plays important roles in labor and parturition and in milk letdown as discussed in the sections that follow. In contrast to other anterior pituitary hormone regulatory models, oxytocin is not regulated by feedback control. Rather, only the feed-forward component of the axis exists, and secretion is reduced by cessation of the stimulatory input.

Growth Hormone and Prolactin

Growth hormone and PRL are structurally related members of the somatotropic hormone family and share many biological features. The somatotropes and lactotropes, the pituitary cells that produce and secrete GH and PRL, respectively, are subject to strong inhibitory input from hypothalamic neurons. For PRL, dopaminergic input is the dominant negative regulator of secretion. GH and PRL act via membrane receptors that belong to the class 1 cytokine receptor family and modulate target cell function via very similar signal transduction pathways (see Chapter 3).

Structures of Growth Hormone and Prolactin

Table 46–2 presents some features of the somatotropic family of hormones. GH is secreted by somatotropes as a heterogeneous mixture of peptides. The principal form is a single unglycosylated polypeptide chain of 22 kDa that has two disulfide bonds. Alternative splicing produces a smaller form (~20 kDa) with equal bioactivity that makes up 5% to 10% of circulating GH. Recombinant human GH consists entirely of the 22 kDa form, which allows detection of GH abuse. In the circulation, a 55 kDa protein, which is derived from the extracellular domain of the proteolytically cleaved GHRH receptor, binds approximately 45% of the 22 kDa and 25% of the 20 kDa forms. A second protein unrelated to the GHR also binds approximately 5% to 10% of circulating GH with lower affinity. Bound GH is cleared more slowly and has a biological $t_{1/2}$ about 10 times that of unbound GH, suggesting that the bound hormone may provide a GH reservoir that dampens acute fluctuations in GH levels associated with its pulsatile secretion.

Human PRL is synthesized by lactotropes. A portion of the secreted hormone is glycosylated at a single Asn residue. In the circulation, multimeric forms of PRL occur, as do degradation products of 16 kDa and 18 kDa. As with GH, the biological significance of these polymeric and degraded forms is not known.

TABLE 46–2 ■ PROPERTIES OF THE PROTEIN HORMONES OF THE HUMAN ADENOHYPOPHYSIS AND PLACENTA

CLASS AND HORMONE	MASS (daltons)	PEPTIDE CHAINS	AMINO ACID RESIDUES AND COMMENTS	
POMC-derived hormones[a]				
Corticotropin	4500	1	39	These peptides are derived by proteolytic processing of the common precursor, POMC.
α-Melanocyte–stimulating hormone	1650		13	
Somatotropic family of hormones				
Growth hormone	22,000	1	191	Receptors for these hormones belong to the cytokine superfamily.
Prolactin	23,000		199	
Placental lactogen	22,125		190	
Glycoprotein hormones				
Luteinizing hormone	29,400	2	β-121	These are heterodimeric glycoproteins with a common α subunit of 92 amino acids and unique β subunits that determine biological specificity and $t_{1/2}$.
Follicle-stimulating hormone	32,600		β-111	
Human chorionic gonadotropin	38,600		β-145	
Thyroid-stimulating hormone	28,000		β-118	

[a]See Figure 23–3 and 50–1 and associated text for further discussion of POMC-derived peptides, including ACTH and α-melanocyte–stimulating hormone.

Human placental lactogen, structurally similar to GH and PRL, is synthesized in pregnant females, with maximal levels near term. Human placental lactogen alters the mother's metabolism mainly by reducing maternal insulin sensitivity to favor fetal nutrition (Cattini et al., 2020).

Regulation of Growth Hormone Secretion

Daily GH secretion varies throughout life. GH secretion is high in children, peaks during puberty, and then decreases with age in adulthood. GH is secreted in discrete but irregular pulses, and the amplitude of secretory pulses is greatest at night. GH secretion is stimulated by GHRH and ghrelin and is subject to feedback inhibition by GH itself, SST, and *insulin-like growth factor 1* (IGF-1; see Figure 46–2).

Growth Hormone–Releasing Hormone

GHRH, a peptide with 44 amino acids produced by hypothalamic neurons, stimulates GH secretion (see Figure 46–2) by binding to a specific GPCR on somatotropes in the anterior pituitary. The stimulated GHRH receptor couples to G_s to raise intracellular levels of cAMP and Ca^{2+}, thereby stimulating GH synthesis and secretion. Loss-of-function mutations of the GHRH receptor cause a rare form of short stature in humans.

Ghrelin

Ghrelin, a 28-amino-acid peptide, stimulates GH secretion through actions on a GPCR called the GH secretagogue receptor. Ghrelin is synthesized predominantly in endocrine cells in the fundus of the stomach but also is produced at lower levels at several other sites, including the pituitary and hypothalamus. Hypothalamic ghrelin is thought to be a stimulus for GH release through actions on pituitary somatotropes and hypothalamic GHRH-secreting neurons.

Both fasting and hypoglycemia increase circulating stomach-derived ghrelin levels, and this, in turn, stimulates appetite and increases food intake, apparently by central actions on NPY and agouti-related peptide neurons in the hypothalamus. The physiologic role of stomach-derived ghrelin in GH secretion is unclear due to a lack of phenotype in ghrelin and GH secretagogue receptor knockout models and conflicting results of clinical studies attempting to correlate circulating levels of ghrelin with GH secretion (Nass et al., 2011).

Other Stimuli

Several neurotransmitters, drugs, metabolites, and other stimuli modulate the release of GHRH or SST and thereby affect GH secretion. DA, 5HT, and α_2 adrenergic receptor agonists stimulate GH release, as do hypoglycemia, exercise, stress, emotional excitement, sex steroids, and ingestion of protein-rich meals. In contrast, β adrenergic receptor agonists, free fatty acids, glucose, IGF-1, and GH itself inhibit release.

Feedback Control of GH Secretion

Growth hormone secretion is regulated by negative-feedback loops. The negative-feedback action of GH is mediated through GH itself, in part by SST, which is synthesized in widely distributed neurons (Ergun-Longmire and Wajnrajch, 2013) and via its major peripheral effector *IGF-1* (see Figure 46–2).

Insulin-like Growth Factor 1. The inhibitory effect of IGF-1 on GH secretion is predominantly through direct effects on the anterior pituitary gland but also at the hypothalamus via stimulation of SST secretion. After its synthesis and release, IGF-1 interacts with receptors on the cell surface that mediate its biological activities. This receptor is present in essentially all tissues and binds IGF-1 and the related growth factor, IGF-2, with high affinity. The type 1 IGF receptor is closely related to the insulin receptor and consists of a heterotetramer with intrinsic tyrosine kinase activity. The signal transduction pathway for the insulin receptor is described in detail in Chapter 51.

Somatostatin. SST is synthesized as a 92-amino-acid precursor and processed by proteolytic cleavage to generate two peptides: SST-28 and SST-14 (Figure 46–3). SST exerts its effects by binding to and activating a family of five related GPCRs that signal through G_i to inhibit cAMP formation and to activate K^+ channels and protein phosphotyrosine phosphatases.

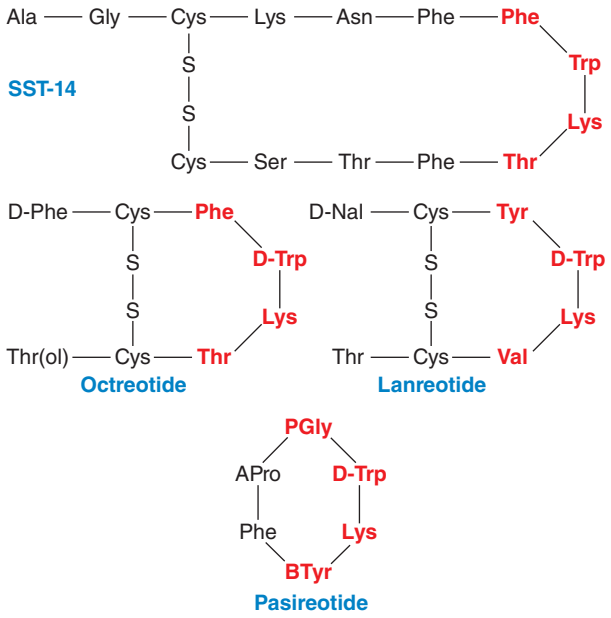

Figure 46–3 *Structures of SST-14 and selected synthetic analogues.* Residues that play key roles in binding to SST receptors are shown in red. *Octreotide*, *lanreotide*, and *pasireotide* are clinically available synthetic analogues of SST. APro, [(2-aminoethyl) aminocarboxyl oxy]-L-proline; D-Nal, 3-(2-napthyl)-D-alanyl; PGly, phenylglycine; BTyr, benzyltyrosine.

There are five SSTR subtypes. $SSTR_{1-4}$ bind the two forms of SST with approximately equal affinity. $SSTR_5$ has a 10- to 15-fold greater affinity for SST-28. $SSTR_2$ and $SSTR_5$ are the most important for regulation of GH secretion, and studies suggested that these two SSTRs form functional heterodimers with distinctive signaling behavior (Grant et al., 2008). SST exerts direct effects on somatotropes in the pituitary and indirect effects mediated via GHRH neurons in the arcuate nucleus.

Regulation of Prolactin Secretion

Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation of its secretion is predominantly inhibitory. The major regulator of PRL secretion is DA, which interacts with the D_2 receptor, a GPCR on lactotropes, to inhibit PRL secretion (Figure 46–4). TRH and hypothalamic VIP have PRL-releasing properties, but their physiologic significance is uncertain. Many of the physiological factors that influence GH secretion also affect PRL secretion. Thus, sleep, stress, hypoglycemia, exercise, and sex steroids increase the secretion of both hormones.

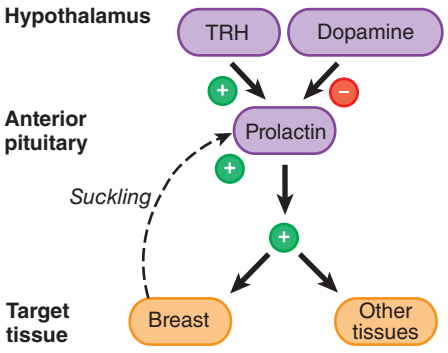

Figure 46–4 *Prolactin secretion and actions.* PRL is the only anterior pituitary hormone for which a unique stimulatory releasing factor has not been identified. TRH and VIP, however, can stimulate PRL release; DA inhibits it. Suckling induces PRL secretion, and PRL not only affects lactation and reproductive functions but also has effects on many other tissues. PRL is not under feedback control by peripheral hormones.

PRL acts predominantly in women, both during pregnancy and in the postpartum period while breastfeeding. During pregnancy, the maternal serum PRL level starts to increase at 8 weeks of gestation, peaks to 150 to 250 ng/mL at term, and declines thereafter to prepregnancy levels unless the mother breastfeeds the infant. Suckling or breast manipulation in nursing mothers transmits signals from the breast to the hypothalamus via the spinal cord and the median forebrain bundle, causing elevation of circulating PRL levels. PRL levels can rise 10-fold within 30 min of stimulation. This response is distinct from milk letdown, which is mediated by oxytocin release from the posterior pituitary gland. The suckling response becomes less pronounced after several months of breastfeeding, and PRL concentrations eventually decline to prepregnancy levels. PRL also is synthesized by decidual cells early in pregnancy (accounting for the high levels of PRL in amniotic fluid during the first trimester of human pregnancy).

Molecular and Cellular Basis of Growth Hormone and Prolactin Action

All effects of GH and PRL result from their interactions with specific membrane receptors on target tissues (Figure 46–5). Receptors for GH and PRL belong to the class 1 cytokine receptor family and thus have sequence homology with the receptors for leptin, erythropoietin, granulocyte-macrophage colony-stimulating factor, and several of the interleukins. Within this receptor family (except for GHR), a Trp-Ser-X-Trp-Ser motif is conserved in the extracellular ligand-binding domain. In addition to this domain, these receptors also have a single membrane-spanning region and an intracellular domain that mediates signal transduction in response to ligand-induced conformational changes.

Growth hormone receptor is activated by the binding of a single GH to two receptor monomers to form a GH-$[GHR]_2$ ternary complex. GH first binds one monomer of the GHR dimer at the high-affinity GH site 1, followed by a second, lower-affinity interaction of GH with the other GHR at GH site 2. The ligand-occupied GHR dimer lacks inherent tyrosine kinase activity but provides docking sites for two molecules of JAK2, a cytoplasmic tyrosine kinase of the Janus kinase family. Instead, GH binding induces a conformational change that juxtaposes the JAK2 molecules and leads to *trans*-phosphorylation and autoactivation of JAK2, with consequent tyrosine phosphorylation of docking sites on the cytoplasmic segments of the GHR and of proteins that mediate downstream signaling events (see Figure 46–5; Chia, 2014). These include STAT proteins, SHC (an adapter protein that regulates the Ras/MAPK signaling pathway), and IRS-1 and IRS-2 (insulin receptor substrates 1 and 2, proteins that activate the PI3K pathway). One critical target of STAT5 is the gene encoding IGF-1, a mediator of many of the effects of GH (see Figure 46–2). The fine control of GH action also involves feedback regulatory events that subsequently turn off the GH signal. As part of its action, GH induces the expression of a family of suppressor of cytokine signaling (SOC) proteins and a group of protein tyrosine phosphatases (including SHP2) that, by different mechanisms, disrupt the communication of the activated GHR with JAK2 (Flores-Morales et al., 2006).

The effects of PRL on target cells also result from interactions with a cytokine family receptor that is widely distributed and signals through many of the same pathways as the GHR (Bernard et al., 2015). Alternative splicing of the PRL receptor gene on chromosome 5 gives rise to multiple forms of the receptor that are identical in the extracellular domain but differ in their cytoplasmic domains. In addition, soluble forms that correspond to the extracellular domain of the receptor are found in circulation. Unlike human GH and placental lactogen, which also bind to the PRL receptor and thus are lactogenic, PRL binds specifically to the PRL receptor and has no somatotropic (GH-like) activity.

Physiology of Growth Hormone and Prolactin

The most striking physiological effect of GH is the stimulation of the longitudinal growth of bones. GH also increases bone mineral density after the epiphyses have closed, increases muscle mass, increases the glomerular filtration rate, and stimulates preadipocyte differentiation into adipocytes. GH has potent anti-insulin actions in both the liver and peripheral tissues (e.g., adipocytes and muscle) that decrease glucose utilization and increase lipolysis, but most of its anabolic and growth-promoting effects are mediated indirectly through the induction of IGF-1. IGF-1 interacts

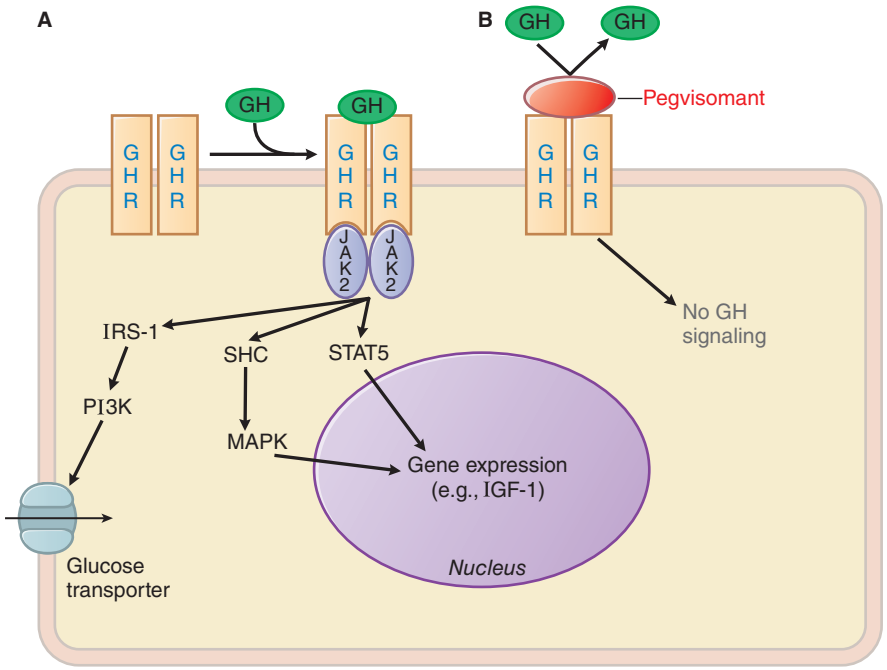

Figure 46–5 *Mechanisms of GH and PRL action and of GHR antagonism.* **A.** GH and two GHRs form a ternary complex that induces association and Tyr autophosphorylation of JAK2 and of docking sites on the cytoplasmic tail of GHRs. JAK2 phosphorylates cytoplasmic proteins that activate downstream signaling pathways, including STAT5 and mediators upstream of MAPK, which ultimately modulate gene expression. The structurally related PRL receptor also is a ligand-activated homodimer that recruits the JAK-STAT signaling pathway. GHR also activates IRS-1, which may mediate the increased expression of glucose transporters on the plasma membrane. **B.** *Pegvisomant*, a recombinant pegylated variant of human GH, is a high-affinity GH antagonist that interferes with GH binding

with receptors on the cell surface that mediate its biological activities. Circulating IGF-1 is associated with a family of IGF-binding proteins (IGFBP) that serve as transport proteins and may mediate certain aspects of IGF-1 signaling. Most IGF-1 in circulation is bound to IGFBP-3 and another protein called the acid-labile subunit.

The essential role of IGF-1 in growth is evidenced by patients with loss-of-function mutations in both alleles of the *IGF1* gene. These patients have severe intrauterine and postnatal growth retardation that is unresponsive to GH but responsive to recombinant human IGF-1 (Walenkamp and Wit, 2008).

The PRL effects are limited primarily to the mammary gland, where PRL plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelia and is essential for lactation. Target genes by which PRL induces mammary development include those encoding milk proteins (e.g., caseins and whey acidic protein), genes important for intracellular structure (e.g., keratins), and genes important for cell-cell communication (e.g., amphiregulin). PRL receptors are present in many other sites, including the hypothalamus, liver, adrenal glands, testes, ovaries, prostate, and immune system, suggesting that PRL may play multiple roles outside the breast. The physiological effects of PRL at these sites remain poorly characterized.

Pathophysiology of Growth Hormone and Prolactin

Distinct endocrine disorders result from either excessive or deficient GH production. In contrast, PRL predominantly affects endocrine function when produced in excess.

Excess Production

Syndromes of excess secretion of GH and PRL typically are caused by somatotrope or lactotrope adenomas that oversecrete the respective hormones. These adenomas often retain some features of the normal regulation described previously, thus permitting pharmacological modulation of secretion—an important modality in therapy.

Clinical Manifestations of Excess Growth Hormone. GH excess causes distinct clinical syndromes depending on the age of the patient. If the epiphyses are unfused, GH excess causes increased longitudinal growth, resulting in *gigantism*. In adults, GH excess causes *acromegaly*. The symptoms and signs of acromegaly (e.g., arthropathy, carpal tunnel syndrome, generalized visceromegaly, macroglossia, hypertension, glucose intolerance, headache, lethargy, excess perspiration, and sleep apnea) progress slowly, and diagnosis is often delayed. Mortality is increased at least 2-fold relative to age-matched controls, predominantly due to increased death from cardiovascular disease. Treatments that normalize GH and IGF-1 levels reverse this increased risk of mortality and ameliorate most of the other symptoms and signs.

Clinical Manifestations of Excess Prolactin. *Hyperprolactinemia* is a relatively common endocrine abnormality that can result from hypothalamic or pituitary diseases that interfere with the delivery of inhibitory dopaminergic signals, from renal failure, from primary hypothyroidism associated with increased TRH levels, or from treatment with DA receptor antagonists. Most often, hyperprolactinemia is caused by PRL-secreting pituitary adenomas. Manifestations of PRL excess in women include galactorrhea, amenorrhea, and infertility. In men, hyperprolactinemia causes loss of libido, erectile dysfunction, and infertility.

Diagnosis of Growth Hormone and Prolactin Excess. Although acromegaly should be suspected in patients with the appropriate symptoms and signs, diagnostic confirmation requires the demonstration of increased circulating GH or IGF-1. The definitive diagnostic test for acromegaly is the oral glucose tolerance test. Whereas normal subjects suppress their GH level to less than 1 ng/mL in response to an oral glucose challenge, patients with acromegaly either fail to suppress or show a paradoxical increase in GH level.

In patients with hyperprolactinemia, the major question is whether conditions other than a PRL-producing adenoma are responsible for the elevated PRL level. Medications that inhibit DA signaling can cause moderate elevations in PRL (e.g., antipsychotics, *metoclopramide*), as can primary hypothyroidism, pituitary mass lesions that interfere with DA delivery to the lactotropes, and pregnancy. Thus, thyroid function and pregnancy tests are indicated, as is MRI to look for a pituitary adenoma or other defect that might elevate serum PRL.

Impaired Production

Clinical Manifestations of Growth Hormone Deficiency. Children with GH deficiency present with short stature, delayed bone age, and a low age-adjusted growth velocity. GH deficiency in adults is associated with decreased muscle mass and exercise capacity, decreased bone density, impaired psychosocial function, and increased mortality from cardiovascular causes. The diagnosis of GH deficiency should be considered in children with height more than 2 to 2.5 standard deviations below normal, delayed bone age, a decreased growth velocity, and a predicted adult height substantially below the mean parental height. In adults, overt GH deficiency usually results from pituitary lesions caused by a functioning or nonfunctioning pituitary adenoma, secondary to trauma, or related to surgery or radiotherapy for a pituitary or suprasellar mass (Ergun-Longmire and Wajnrajch, 2013). Almost all patients with multiple deficits in other pituitary hormones also have deficient GH secretion.

Clinical Manifestations of Prolactin Deficiency. PRL deficiency may result from conditions that damage the pituitary gland. Inasmuch as the sole clinical manifestation of PRL deficiency is failure of postpartum lactation, PRL is not given as part of endocrine replacement therapy.

Pharmacotherapy of Growth Hormone and Prolactin Disorders

Treatment of Growth Hormone Excess

The initial treatment modality in gigantism/acromegaly is selective removal of the adenoma by transsphenoidal surgery. Radiation and drugs that inhibit GH secretion or action are given if surgery does not result in cure (Katznelson et al., 2014). Pituitary irradiation may be associated with significant long-term complications, including visual deterioration and pituitary dysfunction. Thus, increased attention has been given to the pharmacological management of acromegaly.

Somatostatin Analogues

The development of synthetic analogues of SST has revolutionized the medical treatment of acromegaly. The goal of treatment is to decrease GH levels to less than 2.5 ng/mL after an oral glucose tolerance test and to bring IGF-1 levels to within the normal range for age and sex. The two SST analogues used widely are *octreotide* and *lanreotide*, synthetic derivatives that have longer half-lives than SST and bind preferentially to SST_2 and SST_5 receptors (see Figure 46–3).

Octreotide. *Octreotide* exerts pharmacological actions similar to those of SST. *Octreotide* (100 μg) administered subcutaneously three times daily is 100% bioactive. Peak effects are seen within 30 min, serum $t_{1/2}$ is about 90 min, and duration of action is about 12 h. An equally effective, long-acting, slow-release form, *octreotide LAR*, is administered intramuscularly in a dose of 10, 20, or 30 mg once every 4 weeks. In addition to its effect on GH secretion, *octreotide* can decrease tumor size, although tumor growth generally resumes after *octreotide* treatment is stopped.

Lanreotide. *Lanreotide* autogel is a long-acting octapeptide SST analogue that causes prolonged suppression of GH secretion when administered by deep subcutaneous injection of 60, 90, or 120 mg every 4 weeks. Its efficacy appears comparable to that of the long-acting formulation of *octreotide*.

Pasireotide. *Pasireotide* is a long-acting cyclohexapeptide SST analogue that is approved for the treatment of Cushing disease (excessive cortisol production triggered by increases in ACTH release due to a pituitary adenoma; see Chapter 50) in patients who are ineligible for pituitary surgery or in whom surgery has failed. *Pasireotide* binds to multiple SST receptors

(1, 2, 3, and 5) but has its highest affinity for the SST_5 receptor. In a head-to-head study, a greater percentage of subjects administered *pasireotide LAR* reached treatment goals compared to those given *octreotide LAR*. *Pasireotide LAR* also is approved for treatment of acromegaly.

Adverse Effects. Gastrointestinal side effects—including diarrhea, nausea, and abdominal pain—occur in up to 50% of patients receiving all three SST analogues. The incidence and severity of these side effects are similar for the three analogues. The symptoms usually diminish over time and do not require cessation of therapy. Approximately 25% of patients receiving these drugs develop multiple tiny gallstones, presumably due to decreased gallbladder contraction and bile secretion. Bradycardia and QT prolongation may occur in patients with underlying cardiac disease. Inhibitory effects on TSH secretion rarely lead to hypothyroidism, but thyroid function should be evaluated periodically. *Pasireotide* suppresses ACTH secretion in Cushing disease and may lead to a decrease in cortisol secretion and to hypocortisolism. All SST analogues decrease insulin secretion, but the simultaneous reduction in GH levels results in a reduction in insulin resistance. For *octreotide* and *lanreotide*, most patients will experience no change in glucose tolerance; however, depending on the relative effects on insulin secretion versus resistance, some patients may experience a worsening and others an improvement in glucose tolerance. *Pasireotide*, in addition, decreases the secretion of glucagon-like peptide 1 and glucose insulinotropic peptide, two incretins that facilitate insulin secretion and inhibit glucagon secretion. As a result, glucose tolerance usually worsens significantly and antihyperglycemic therapy is often needed.

Other Therapeutic Uses. SST blocks not only GH secretion but also the secretion of other hormones, growth factors, and cytokines. Thus, the slow-release formulations of SST analogues have been used to treat symptoms associated with metastatic carcinoid tumors (e.g., flushing and diarrhea) and adenomas secreting VIP (e.g., watery diarrhea). *Octreotide* and *lanreotide* can also be used to treat patients with thyrotrope adenomas that oversecrete TSH who have failed surgery. *Octreotide* is used for treatment of acute variceal bleeding and for perioperative prophylaxis in pancreatic surgery. Modified forms of *octreotide* labeled with indium or technetium have been used for diagnostic imaging of neuroendocrine tumors, such as pituitary adenomas and carcinoids; modified forms labeled with β emitters such as ^{90}Y have been used in selective destruction of SST_2 receptor–positive tumors.

Growth Hormone Receptor Antagonist

Pegvisomant. *Pegvisomant* is approved for the treatment of acromegaly. It is a GH analogue with amino acid substitutions that disrupt the interaction at GH site 2, effectively functioning as a GHR antagonist. *Pegvisomant* binds to the receptor and causes its internalization but cannot trigger the conformational change that stimulates JAK-STAT signaling or IGF-1 secretion (see Figure 46–5).

The drug is administered subcutaneously as a 40-mg loading dose, followed by administration of 10 mg/day. Based on serum IGF-1 levels, the dose is titrated at 4- to 6-week intervals to a maximum of 30 mg/day. *Pegvisomant* should not be used in patients with an unexplained elevation of hepatic transaminases, and liver function tests should be monitored in all patients. In addition, lipohypertrophy has occurred at injection sites, sometimes requiring cessation of therapy; this is believed to reflect the inhibition of direct actions of GH on adipocytes. Because of concerns that loss of negative feedback by GH and IGF-1 may increase the growth of GH-secreting adenomas, careful follow-up by pituitary MRI is strongly recommended.

Pegvisomant can also be given weekly, in addition to SST analogues, when IGF-1 levels are not fully controlled by the latter drugs (Lim and Fleseriu, 2017). *Pegvisomant* differs structurally from native GH and induces the formation of specific antibodies in about 15% of patients. Nevertheless, the development of tachyphylaxis due to these antibodies has not been reported.

Treatment of Prolactin Excess

The therapeutic options for patients with prolactinomas include transphenoidal surgery, radiation, and treatment with DA receptor agonists that suppress PRL production via activation of D_2 receptors. Because of the very high efficacy of DA receptor agonists, they are generally regarded as the initial treatment of choice, with surgery and radiation reserved for patients who either do not respond or are intolerant of DA receptor agonists (Melmed et al., 2011).

Dopamine Receptor Agonists

Bromocriptine, *cabergoline*, and *quinagolide* effectively reduce PRL levels, thereby relieving the inhibitory effect of hyperprolactinemia on ovulation and permitting most patients with prolactinomas to become pregnant. *Quinagolide* should not be used when pregnancy is intended. These agents generally decrease both PRL secretion and the size of the adenoma. Over time, especially with *cabergoline*, the prolactinoma may decrease in size to the extent that the drug can be discontinued without recurrence of the hyperprolactinemia.

Bromocriptine. *Bromocriptine* is the DA receptor agonist against which newer agents are compared. *Bromocriptine* is a semisynthetic ergot alkaloid (see Chapter 15) that interacts with D_2 receptors to inhibit release of PRL; to a lesser extent, it also activates D_1 dopamine receptors. The oral dose of *bromocriptine* is well absorbed; however, only 7% of the dose reaches the systemic circulation because of extensive first-pass metabolism in the liver. *Bromocriptine* has a short elimination $t_{1/2}$ (between 2 and 8 h) and thus is usually administered in divided doses. To avoid the need for frequent dosing, a slow-release oral form is available outside the U.S. *Bromocriptine* may be administered vaginally (2.5 mg once daily), with fewer GI side effects.

Bromocriptine normalizes serum PRL levels in 70% to 80% and decreases tumor size in more than 50% of patients with prolactinomas. Hyperprolactinemia and tumor growth recur on cessation of therapy in most patients. At higher concentrations, *bromocriptine* is used in the management of Parkinson disease (see Chapter 21). *Bromocriptine mesylate* (1.6–4.8 mg/day) is approved as an adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus.

Adverse Effects. Frequent side effects include nausea and vomiting, headache, and postural hypotension, particularly on initial use. Less frequently, nasal congestion, digital vasospasm, and CNS effects such as psychosis, hallucinations, nightmares, or insomnia are observed. These adverse effects can be diminished by starting at a low dose (1.25 mg) administered at bedtime with a snack and then slowly increasing the dose as needed by monitoring PRL levels. Patients often develop tolerance to the adverse effects.

Cabergoline. *Cabergoline* is an ergot derivative with a longer $t_{1/2}$ (~65 h), higher affinity, and greater selectivity for the DA D_2 receptor compared to *bromocriptine*. *Cabergoline* undergoes significant first-pass metabolism in the liver.

Cabergoline is the preferred drug for the treatment of hyperprolactinemia because of greater efficacy and lower adverse effects. Therapy is initiated at a dose of 0.25 mg twice a week or 0.5 mg once a week. The dose can be increased to 1.5 to 2 mg two or three times a week as tolerated; the dose should be increased only once every 4 weeks. Doses of 2 mg/week or less normalize PRL levels in 80% of patients. *Cabergoline* induces remission in a significant number of patients with prolactinomas. At higher doses, *cabergoline* is used in some patients with acromegaly alone or in conjunction with SST analogues.

Adverse Effects. Compared to *bromocriptine*, *cabergoline* has a much lower tendency to induce nausea, although it still may cause hypotension and dizziness. *Cabergoline* has been linked to valvular heart disease, an effect proposed to reflect agonist activity at the serotonin $5HT_{2B}$ receptor. However, this effect is seen primarily at the high doses used in patients being treated for Parkinson disease and is not seen in the conventionally used doses (≤2 mg/week) for patients with prolactinomas.

Quinagolide. *Quinagolide* is a nonergot D_2 receptor agonist with a $t_{1/2}$ of about 22 h. *Quinagolide* is administered once daily at doses of 0.1 to 0.5 mg/day. It is not approved for use in the U.S. but has been used in the European Union and Canada.

Treatment of Growth Hormone Deficiency

Somatropin

Replacement therapy is well established in GH-deficient children (Richmond and Rogol, 2016) and is gaining wider acceptance for GH-deficient adults (He and Barkan, 2020). Humans do not respond to GH from nonprimate species. In the past, when GH for therapeutic use was purified from human cadaver pituitaries, GH availability was limited and ultimately linked to the transmission of Creutzfeldt-Jakob disease. Currently, human GH is produced by recombinant DNA technology. *Somatropin* refers to the many GH preparations whose sequences match that of native GH.

Pharmacokinetics. As a peptide hormone, GH is administered subcutaneously with a bioavailability of 70%. Although the circulating $t_{1/2}$ of GH is only 20 min, its biological $t_{1/2}$ is considerably longer, and once-daily administration is sufficient.

Indications for Treatment. Deficiency in children is a well-accepted cause of short stature. With the advent of essentially unlimited supplies of recombinant GH, therapy has been extended to children with other conditions associated with short stature despite adequate GH production, including Turner syndrome, Noonan syndrome, Prader-Willi syndrome, chronic renal insufficiency, children born small for gestational age, and children with idiopathic short stature (i.e., >2.25 standard deviations below mean height for age and sex but with normal laboratory indices of GH levels). Severely affected GH-deficient adults may benefit from GH replacement therapy. The FDA also has approved GH therapy for AIDS-associated wasting and for malabsorption associated with the short-bowel syndrome (based on the finding that GH stimulates the adaptation of GI epithelial cells). Adults considered for GH treatment should have organic etiologies for the GH deficiency and must demonstrate low GH production in response to standardized stimulation tests or have at least three other pituitary hormone deficiencies.

Contraindications. GH is contraindicated for promotion of growth in pediatric patients with closed epiphyses. GH should not be used in patients with acute critical illness due to complications after open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure. GH also should not be used in patients who have any evidence of active malignancy. Other contraindications include proliferative retinopathy or severe nonproliferative diabetic retinopathy. GH therapy for Prader-Willi syndrome with a diagnosis of GH deficiency must be carefully supervised. Sudden death has been observed when GH was given to children with Prader-Willi syndrome who were severely obese or who had severe respiratory impairment. GH treatment should be avoided in patients with known hypersensitivity.

Therapeutic Uses. In GH-deficient children, *somatropin* typically is administered in a dose of 25 to 50 μg/kg per day subcutaneously in the evening; higher daily doses (e.g., 50–67 μg/kg) are employed for patients with Noonan syndrome or Turner syndrome, who have partial GH resistance. In children with overt GH deficiency, measurement of serum IGF-1 levels sometimes is used to monitor initial response and compliance. Long-term response is monitored by close evaluation of height, sometimes in conjunction with measurements of serum IGF-1 levels. GH is continued until the epiphyses are fused and may be extended into the transition period from childhood to adulthood. Children with idiopathic rather than organic GH deficiency need retesting after growth has ceased before continuing GH treatment as adults; many with this diagnosis will have normal GH levels on stimulation testing as adults.

Benefits of GH treatment in GH-deficient adults include a decrease in fat mass and increases in muscle mass, exercise capacity, energy, bone mineral density, and quality of life. For adults, a typical starting dose is 150 to 300 μg/day (these doses may vary depending on brand product), with higher doses used in younger patients transitioning from pediatric therapy. Either an elevated serum IGF-1 level or persistent side effects mandates a decrease in dose; conversely, the dose can be increased (typically by 100–200 μg/day) if serum IGF-1 has not reached the normal range after 2 months of GH therapy. Because estrogen inhibits GH action, women taking oral, but not transdermal, estrogen may require larger GH doses to achieve the target IGF-1 level.

Adverse Effects. In children, GH therapy is associated with remarkably few side effects. Rarely, patients develop intracranial hypertension with papilledema, visual changes, headache, nausea, or vomiting. Because of this, funduscopic examination is recommended at the initiation of therapy and at periodic intervals thereafter. The consensus is that GH should not be administered in the first year after treatment of pediatric tumors, including leukemia, or during the first 2 years after therapy for medulloblastomas or ependymomas. Because an increased incidence of type 2 diabetes mellitus has been reported, fasting glucose levels should be followed periodically during therapy. Finally, too-rapid growth may be associated with slipped epiphyses or scoliosis.

Side effects associated with the initiation of GH therapy in adults (peripheral edema, carpal tunnel syndrome, arthralgias, and myalgias) occur most frequently in older or obese patients and generally respond to a decrease in dose. Estrogens (e.g., birth control medications and estrogen supplements) inhibit GH action so that a larger dose is needed to maintain the same IGF-1 level. GH therapy can increase the metabolic inactivation of cortisol in the liver.

Drug Interactions. The effects of estrogen on GH therapy were noted above. This effect is much less marked with transdermal estrogen preparations. Recent studies suggested that GH therapy can increase the metabolic inactivation of glucocorticoids in the liver. Thus, GH may precipitate adrenal insufficiency in patients with occult secondary adrenal insufficiency or in patients receiving replacement doses of glucocorticoids. This has been attributed to the inhibition of the type 1 isozyme of steroid 11β-hydroxysteroid dehydrogenase, which normally converts inactive cortisone into the active 11-hydroxy derivative cortisol (see Figure 50–6). GH treatment may decrease insulin sensitivity. Therefore, the dose of insulin and/or other hypoglycemic agents may need to be adjusted when GH therapy is initiated.

Somapacitan

Somapacitan, approved by the FDA in 2020, is a human GH analogue designed with a 1.2-kDa albumin-binding moiety. This moiety extends the half-life and reduces the clearance of *somapacitan* by allowing reversible binding to endogenous albumin. This modification makes possible once-weekly administration instead of the standard daily injection.

Pharmacokinetics. As a modified form of GH, greater than 99% of *somapacitan* is bound to plasma proteins. A maximum concentration after initial subcutaneous injection is reached in 4 to 24 h, with steady-state concentrations achieved within 2 weeks of administration. The plasma $t_{1/2}$ is 2 to 3 days. The improved pharmacokinetics of *somapacitan* over GH make *somapacitan* the first human GH therapy that is administered to patients only once a week.

Therapeutic Uses. *Somapacitan* is approved in the U.S. only for adults with GH deficiency with similar outcomes to native GH. Administration follows the same indications and contraindications for GH in adults. The typical starting dose is 1.5 mg weekly. This dose is increased in increments of 0.5 to 1.5 mg (weekly dose no higher than 8 mg) until the desired clinical response and serum IGF-1 concentrations are achieved.

Adverse Effects. Side effects from *somapacitan* were reported in less than 2% of treated patients. The most common adverse effects of *somapacitan* include back and joint pain, indigestion, sleep disorder, dizziness, tonsillitis, peripheral edema, vomiting, adrenal insufficiency, hypertension, increase in blood creatine phosphokinase, weight gain, and anemia. Less common adverse effects reported are arthralgia and dyspepsia.

Insulin-like Growth Factor 1

Based on the hypothesis that GH predominantly acts via increases in IGF-1 (see Figure 46–2), IGF-1 has been developed for therapeutic use (Cohen et al., 2014). Recombinant human IGF-1 (*mecasermin*) and a combination of recombinant human IGF-1 with its binding protein, IGFBP-3 (*mecasermin rinfabate*), are FDA-approved. The latter formulation was subsequently discontinued for use in short stature due to patent

issues, although it remains available for other conditions, such as severe insulin resistance, muscular dystrophy, and HIV-related adipose redistribution syndrome.

Mecasermin is administered by subcutaneous injection, and absorption is virtually complete. IGF-1 is bound by six proteins: a ternary complex that includes IGFBP-3 and the acid labile subunit. This ternary complex accounts for more than 80% of the circulating IGF-1 and prolongs the $t_{1/2}$ of IGF-1 to about 6 h. Both the liver and kidney metabolize IGF-1.

Therapeutic Uses. *Mecasermin* is FDA-approved for patients with impaired growth secondary to mutations in the GHR or postreceptor signaling pathway, patients who develop antibodies against GH that interfere with its action, and patients with IGF-1 gene defects that lead to primary IGF-1 deficiency. Typically, the starting dose is 40 to 80 μg/kg twice daily by subcutaneous injection, with a maximum of 120 μg/kg per dose twice daily. In patients with impaired growth secondary to GH deficiency or with idiopathic short stature, *mecasermin* stimulates linear growth but is less effective than conventional therapy using recombinant GH.

Adverse Effects. Side effects of *mecasermin* include hypoglycemia and lipohypertrophy. To diminish the frequency of hypoglycemia, *mecasermin* should be administered shortly before or after a meal or snack. Lymphoid tissue hypertrophy, including enlarged tonsils, also is seen and may require surgical intervention. Other adverse effects are similar to those associated with GH therapy.

Contraindications. *Mecasermin* should not be used for growth promotion in patients with closed epiphyses. It should not be given to patients with active or suspected neoplasia and should be stopped if evidence of neoplasia develops.

Growth Hormone–Releasing Hormone

Tesamorelin. *Tesamorelin* is a synthetic N-terminally modified form of human GHRH that is resistant to degradation by dipeptidyl peptidase 4 and therefore has a prolonged duration of action. Although *tesamorelin* increases the levels of GH and IGF-1, its clinical effects are primarily to reduce visceral fat accumulation, with minimal effects on insulin resistance. *Tesamorelin* is FDA-approved for treatment of HIV-associated lipodystrophy but not for GH deficiency (Spooner and Olin, 2012).

Macimorelin. *Macimorelin* is a synthetic GH secretagogue receptor agonist or ghrelin mimetic that is FDA-approved for the diagnosis of GH deficiency. After oral administration of *macimorelin*, maximum serum GH levels of less than 2.8 ng/mL have been established by clinical studies to confirm the presence of adult GH deficiency.

Pituitary Glycoprotein Hormones: TSH and Gonadotropins

The pituitary glycoprotein hormones include *LH*, *FSH*, and *CG*. They are referred to as the gonadotropins because of their actions on the gonads. Together with TSH, they constitute the glycoprotein family of pituitary hormones (see Table 46–2). LH and FSH were named initially based on their actions on the ovary. Appreciation of their roles in male reproductive function came later. LH and FSH are synthesized and secreted by gonadotropes, which make up about 10% of the hormone-secreting cells in the anterior pituitary. CG is produced by the placenta only in primates and horses. GnRH released by a small population of hypothalamic neurons stimulates pituitary gonadotropin production, which is further regulated by feedback effects of the gonadal hormones (Figure 46–6; see Chapters 48 and 49 for details). TSH is discussed in detail in Chapter 47. TSH is measured to establish the diagnosis of thyroid disorders, and recombinant TSH (thyrotropin alfa) is used in the evaluation and treatment of well-differentiated thyroid cancer.

Structure and Function of the Gonadotropins

Each gonadotropic hormone is a glycosylated heterodimer containing a common α subunit and a distinct β subunit that confers receptor

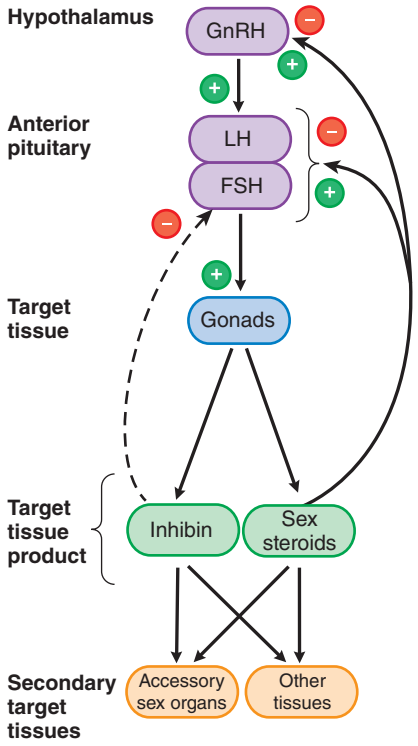

Figure 46–6 *The hypothalamic-pituitary-gonadal axis.* A single hypothalamic-releasing factor, GnRH, controls the synthesis and release of both gonadotropins (LH and FSH) in males and females. Gonadal steroid hormones (androgens, estrogens, and progesterone) exert feedback inhibition at the level of the pituitary and the hypothalamus. However, these feedback effects are dependent on sex, concentration, and time; the preovulatory surge of estrogen also can exert a stimulatory effect at the level of the pituitary and the hypothalamus. Inhibins, a family of polypeptide hormones produced by the gonads, specifically inhibit FSH secretion by the pituitary.

specificity (see Table 46–2). The heterogeneity of glycosylation on the subunits produces myriad isoforms of these hormones and may affect receptor binding and signal transduction. Terminal sialate residues seem to increase plasma half-lives of these gonadotropins (Mullen et al., 2013). Among the gonadotropin β subunits, that of CG is most divergent because it contains a carboxy-terminal extension of 30 amino acids and extra carbohydrate residues that prolong its $t_{1/2}$. The longer $t_{1/2}$ of hCG has some clinical relevance for its use in assisted reproductive technology.

Physiology of the Gonadotropins

In women, FSH stimulates the growth of developing ovarian follicles and induces the expression of LH receptors on theca and granulosa cells. FSH also regulates the expression of aromatase in granulosa cells, thereby stimulating the production of *estradiol*. LH acts on the theca cells to stimulate the *de novo* synthesis of *androstenedione*, the major precursor of ovarian estrogens in premenopausal women (see Figure 48–1). LH also is required for the rupture of the dominant follicle during ovulation and for the synthesis of progesterone by the corpus luteum. *In men*, the actions of FSH and LH are less complex. FSH acts on the Sertoli cells to stimulate the production of proteins and nutrients required for sperm maturation. LH acts on testicular Leydig cells to stimulate the *de novo* synthesis of androgens, primarily *testosterone*, from cholesterol.

Regulation of Gonadotropin Synthesis and Secretion

The predominant regulator of gonadotropin synthesis and secretion is the hypothalamic peptide GnRH, a decapeptide with blocked amino and carboxyl termini derived by proteolytic cleavage of a precursor peptide with 92 amino acids. GnRH is produced by a small population of neurons in the medial preoptic area of the hypothalamus. These neurons are unique in their developmental origin, arising from the olfactory placode

mid-gestation and migrating to their final location prior to formation of the cribriform plate.

Regulation of Pulsatile Secretion. Gonadotropin-releasing hormone secretion is pulsatile and varies in amplitude and frequency across mammalian species. Secretion is dynamically modulated by sex steroid feedback. Although some evidence indicates that GnRH neurons themselves are inherently pulsatile, developmental regulation of GnRH release through the onset of puberty and the modulation of GnRH secretion throughout the ovulatory cycle is largely governed by neurons in the arcuate nucleus, preoptic area, and periventricular area of the third ventricle that co-express kisspeptin, neurokinin B, and dynorphin. Expression of these hormones exhibits strong sex differences and is sensitive to sex steroid feedback. GnRH neurons express GPR54, the kisspeptin receptor, and ultimately, kisspeptin action governs GnRH secretion. At birth, the reproductive hypothalamic-pituitary-gonadal axis is active but becomes quiescent postpartum. The axis remains so until shortly before puberty. At that time, CNS inhibition decreases and the amplitude and frequency of GnRH pulses increase, particularly during sleep. As puberty progresses, the GnRH pulses increase further in amplitude and frequency until the normal adult pattern is established. The precise mediator gating the advancement to puberty is not well understood, but multiple lines of evidence suggest endocrine and metabolic mediators of body mass, adiposity, and energy balance may cumulatively promote reawakening of the axis and establish the rhythmicity of the ovulatory cycle in females and advancement of gonadal maturation in both sexes.

The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins; the continuous administration of GnRH leads to desensitization and downregulation of GnRH receptors on pituitary gonadotropes. LH synthesis and secretion are acutely sensitive to GnRH pulses, whereas FSH, which is secreted through regulated and unregulated pathways, is less so.

Molecular and Cellular Basis of GnRH Action. GnRH signals through a unique GPCR on gonadotropes that lacks the typical caroboxyl-terminal intracellular tail that mediates β-arrestin desensitization of signaling. Activation of the receptor leads to a signaling response that is characterized by robust activation of the $G_{q/11}$-PLC-IP_3-Ca^{2+}, $G_{q/11}$-PLC-PKC-MAP kinase, and NADPH/dual oxidase–reactive oxygen species signaling pathways that are rapidly quenched through dual specificity phosphatase and antioxidant negative feedback (see Chapter 3). Activation results in increased LH and FSH secretion, activation of cap-dependent protein synthesis, and increased expression of glycoprotein hormone subunit genes. The magnitude of the cellular responses to GnRH stimulation is proportional to the amplitude and/or frequency of stimulation, and the gonadotrope is capable of interpreting GnRH pulse patterns, which is essential for proper timing of the female ovulatory cycle. Rapid GnRH pulses generally favor elevated LH secretion and ovulation, whereas slow pulses favor FSH secretion and promote follicular development. The GnRH receptors also are present in the ovary, testis, prostate, and breast, where their physiological significance remains to be determined.

Sex Steroid Regulation of Gonadotropin Production. Gonadal steroids regulate gonadotropin production at the level of the pituitary and the hypothalamus, but effects on the hypothalamus predominate (see Figure 46–6). The feedback effects of gonadal steroids are dependent on sex, concentration, and time. In females, granulosa cell proliferation in the maturing follicle results in increased conversion of steroid precursors to estradiol, which exerts negative feedback on the hypothalamus and pituitary, promoting reduced pulsatile LH secretion. This negative feedback action restrains the neural GnRH pulse generator through upstream inhibition of kisspeptin neurons of the hypothalamic infundibular nucleus (arcuate nucleus in rodents), and this may contribute to the postovulatory decrease in GnRH and LH pulse activity during the luteal phase (estrus in rodents). However, sustained elevated estradiol near the end of the follicular phase (proestrus in rodents) exerts positive feedback effects on a different kisspeptin population in the hypothalamic preoptic area. This estradiol-induced activation of preoptic kisspeptin neurons results in high stimulation of GnRH secretion, thereby stimulating a surge in LH release that triggers ovulation. In men, testosterone inhibits gonadotropin production via actions in the hypothalamus and pituitary, in part through direct actions and in part via its conversion by aromatase to estradiol.

Other Regulators of Gonadotropin Production. Gonadotropin production is also regulated by *inhibins* and *activin.* Inhibins are members of the bone morphogenetic protein family of secreted signaling proteins. *Inhibin A* and *B* are made by granulosa cells in the ovary and Sertoli cells in the testis in response to the gonadotropins and local growth factors. They act directly in the pituitary to inhibit FSH secretion without affecting that of LH. Inhibin A exhibits variation during the menstrual cycle, suggesting that it acts as a dynamic regulator of FSH secretion. Independent of GnRH, activin is a positive regulator of FSH synthesis and secretion. Activin is produced in the placenta, pituitary, and gonads, the latter being the main source of circulating activin. The physiological role of circulating activin is unclear due to its being mostly bound by follistatin, a negative regulator of activin. Activin acts primarily as autocrine/paracrine factors at or near sites of expression, suggesting that the pituitary is the source of bioavailable activin that regulates FSH secretion. In women, activin increases FSH binding and FSH-induced aromatization in the ovarian follicle and enhances LH action in the ovary. In men, activin augments LH action in the testis, increasing androgen production and spermatogenesis.

Molecular and Cellular Basis of Gonadotropin Action

The actions of LH and hCG on target tissues are mediated by the LH receptor; those of FSH are mediated by the FSH receptor. The FSH and LH receptors couple to G_s to activate the adenylyl cyclase–cAMP pathway. At higher ligand concentrations, the agonist-occupied gonadotropin receptors also activate PKC and Ca^{2+} signaling pathways via G_q-mediated effects on PLC_β. Most actions of the gonadotropins can be mimicked by cAMP analogues.

Clinical Disorders of the Hypothalamic-Pituitary-Gonadal Axis

Clinical disorders of the hypothalamic-pituitary-gonadal axis can manifest either as alterations in levels and effects of sex steroids (hyper- or hypogonadism) or as impaired reproduction. This section focuses on those conditions that specifically affect the hypothalamic-pituitary components of the axis and those for which gonadotropins are used diagnostically or therapeutically.

Deficient sex steroid production resulting from hypothalamic or pituitary defects is termed *hypogonadotropic hypogonadism* because circulating levels of gonadotropins are either low or undetectable. Hypogonadotropic hypogonadism in some patients results from GnRH receptor mutations. Some of these mutations impair targeting of the GnRH receptor to the plasma membrane of gonadotropes, prompting efforts to develop pharmacological strategies to correct receptor trafficking and restore function (Conn et al., 2007). Many other disorders can impair gonadotropin secretion, including pituitary tumors, genetic disorders such as Kallmann syndrome, infiltrative processes such as sarcoidosis, and functional disorders such as exercise-induced amenorrhea.

In contrast, reproductive disorders caused by processes that directly impair gonadal function are termed *hypergonadotropic* because the impaired production of sex steroids leads to a loss of negative-feedback inhibition, thereby increasing the synthesis and secretion of gonadotropins.

- **Precocious Puberty.** Puberty normally is a sequential process requiring several years over which the GnRH neurons escape CNS inhibition and initiate pulsatile secretion of GnRH. This stimulates the secretion of gonadotropins and gonadal steroids, thus directing the development of secondary sexual characteristics. Normally, the initial signs of

puberty (breast development in girls and testes enlargement in boys) do not occur before age 8 in girls or age 9 in boys. The initiation of sexual maturation before this time is termed "precocious." GnRH-dependent excessive secretion of gonadotropins is rare and causes precocious puberty in children. This condition may be due to GnRH-producing hamartomas or other CNS abnormalities, but often no specific abnormality is found. This central precocious puberty must be differentiated from that due to hormone-producing tumors of the gonads, in which case, gonadotropin levels will be low. GnRH-independent precocious puberty results from peripheral production of sex steroids in a manner not driven by pituitary gonadotropins. Etiologies include adrenal or gonadal tumors, activating mutations of the LH receptor in boys, and congenital adrenal hyperplasia. Synthetic GnRH analogues play important roles in the diagnosis and treatment of GnRH-dependent precocious puberty (see further discussion). In contrast, drugs that interfere with the production of sex steroids, including *ketoconazole* and aromatase inhibitors, are used in patients with GnRH-independent precocious puberty (Shulman et al., 2008), with varying success.

- **Sexual Infantilism.** The converse of precocious puberty is a failure to initiate the processes of pubertal development at the normal time. This can reflect defects in the GnRH neurons or gonadotropes (secondary hypogonadism) or primary dysfunction in the gonads. In either case, induction of sexual maturation using sex steroids (estrogen followed by estrogen/progesterone in females, testosterone in males) is standard therapy. This suffices to direct sex differentiation in the normal manner. If fertility is the goal, then therapy with either GnRH or gonadotropins is needed to stimulate appropriate germ cell maturation.
- **Infertility.** Infertility, or a failure to conceive after 12 months of unprotected intercourse, is seen in up to 10% to 15% of couples and is increasing in frequency as women choose to delay childbearing. When the infertility is due to impaired synthesis or secretion of gonadotropins (hypogonadotropic hypogonadism), various pharmacological approaches are employed. In contrast, when infertility results from intrinsic processes affecting the gonads, pharmacotherapy generally is less effective. Therapeutic approaches to male infertility are described further in this chapter; strategies for female infertility are described in Chapter 48.

Treatment and Diagnosis of Gonadal Disorders

GnRH and Its Synthetic Agonist Analogues

A synthetic peptide comprising the native sequence of GnRH has been used both diagnostically and therapeutically in human reproductive disorders. In addition, several GnRH analogues with structural modifications have been synthesized and brought to market (Table 46–3).

GnRH Congeners

Synthetic agonist congeners of GnRH have longer half-lives than native GnRH. After a transient stimulation of gonadotropin secretion, they downregulate the GnRH receptor and inhibit gonadotropin secretion. The available GnRH agonists contain substitutions of the native sequence at position 6 that protect against proteolysis and substitutions at the carboxyl terminus that improve receptor-binding affinity. Compared to GnRH, these analogues exhibit enhanced potency and prolonged duration of action (see Table 46–3).

Pharmacokinetics. The myriad formulations of GnRH agonists provide for diverse applications, including relatively short-term effects (e.g., assisted reproduction technology) and more prolonged action (e.g., depot forms that inhibit gonadotropin secretion in GnRH-dependent precocious puberty). The rates and extents of absorption vary considerably. The intranasal formulations have bioavailability (~4%) that is considerably lower than that of the parenteral formulations, which include products for implantation and injection (subcutaneous and intramuscular).

Clinical Uses. The depot form of the GnRH agonist *leuprolide* has been used diagnostically to differentiate between GnRH-dependent and GnRH-independent precocious puberty. *Leuprolide depot* (3.75 mg) is injected subcutaneously, and serum LH is measured 2 h later. A plasma LH level of more than 6.6 mIU/mL is diagnostic of GnRH-dependent (central) disease. Clinically, the various GnRH agonists are used to achieve pharmacological castration in disorders that respond to reduction in gonadal steroids (Fuqua, 2013). A clear indication is in children with GnRH-dependent precocious puberty, whose premature sexual maturation can be arrested with minimal side effects by chronic administration of a depot form of a GnRH agonist (Li et al., 2014).

TABLE 46–3 ■ STRUCTURES OF GONADOTROPIN-RELEASING HORMONE AND GNRH ANALOGUES

GNRH CONGENER	AMINO ACID RESIDUE										DOSAGE FORMS

Ac, acetyl; Aph, aminophenyl alanine; Bzl, benzyl; AzGly, azaglycyl; Cbm, carbamoyl; Cpa, chlorophenylalanyl; D-Nal, 3-(2-naphthyl)-D-alanyl; $EtNH_2$, *N*-ethylamide; hArg$(Et)_2$, ethyl homoarginine; Hor, hydroorotyl; Lys(iPr), isopropyl-lysyl; Pal, 3-pyridylalanyl; tBu, t butyl. A dash (—) denotes amino acid identity with GnRH. IM, intramuscular; IN, intranasal; IV, intravenous; SC, subcutaneous.

[a]Not av ıila' le in the U.S.

Long-acting GnRH agonists are used for palliative therapy of hormone-responsive tumors (e.g., prostate or breast cancer), generally in conjunction with agents that block steroid biosynthesis or action to avoid transient increases in hormone levels (see Chapters 50 and 73). The GnRH agonists also are used to suppress steroid-responsive conditions such as endometriosis, uterine fibroids, acute intermittent porphyria, and priapism. They also have been evaluated off label for their potential to preserve follicles in women undergoing therapy with cytotoxic drugs for cancer treatment, although efficacy in this setting has not been established. Depot preparations can be administered subcutaneously or intramuscularly monthly or every 3 months. The long-lasting GnRH agonists have been used to avoid a premature LH surge, and thus ovulation, in various ovarian stimulation protocols for *in vitro* fertilization.

Adverse Effects. The long-acting agonists generally are well tolerated, and side effects are those that would be predicted to occur when gonadal steroidogenesis is inhibited (e.g., hot flashes and decreased bone density in both sexes, vaginal dryness and atrophy in women, and erectile dysfunction in men). Because of these effects, therapy in non–life-threatening diseases such as endometriosis or uterine fibroids generally is limited to 6 months. GnRH agonists are contraindicated in pregnant women.

Formulations and Indications.

Leuprolide. *Leuprolide* is formulated in multiple doses for injection: subcutaneous (1 mg/day), subcutaneous depot (7.5 mg/month; 22.5 mg/3 months; 30 mg/4 months; 45 mg/6 months), and intramuscular depot (3.75 mg/month; 11.25 mg/3 months). It is approved for endometriosis, uterine fibroids, advanced prostate cancer, and precocious puberty. For endometriosis, *leuprolide* once-monthly injections (3.75 mg) or 3-month injections (11.25 mg) are also copackaged in combination with once-daily *norethindrone* (a steroidal progestin) 5-mg tablets for oral administration. Pediatric formulations of *leuprolide* also are approved for central precocious puberty.

Goserelin. *Goserelin* is formulated as a subcutaneous implant (3.6 mg/month; 10.8 mg/12 weeks). It is approved for endometriosis, for use as an endometrial-thinning agent prior to endometrial ablation for dysfunctional uterine bleeding, and for advanced prostate and breast cancer.

Histrelin. *Histrelin* is formulated as a subcutaneous implant (50 mg/12 months). It is approved for central precocious puberty and advanced prostate cancer.

Nafarelin. *Nafarelin* is formulated as a nasal spray (200 μg/spray). It is approved for endometriosis (400 μg/d) and central precocious puberty (1600 μg/d).

Triptorelin. *Triptorelin* is formulated for depot intramuscular injection (3.75 mg/month; 11.25 mg/12 weeks; 22.5 mg/24 weeks) and approved for advanced prostate cancer. *Buserelin* and *deslorelin* are not available in the U.S.

GnRH Antagonist Analogues

Ganirelix and Cetrorelix. *Ganirelix acetate* and *cetrorelix acetate* are FDA-approved to suppress the LH surge and thus prevent premature ovulation in ovarian-stimulation protocols as part of assisted reproduction technology (see Chapter 48).

Both GnRH antagonists are formulated for subcutaneous administration. Bioavailability exceeds 90% within 1 to 2 h, and the $t_{1/2}$ varies depending on the dose. Once-daily administration suffices for therapeutic effect. Hypersensitivity reactions, including anaphylaxis, have been noted in postmarketing surveillance, some with the initial dose. When used in conjunction with gonadotropin injections for assisted reproduction, the effects of estrogen withdrawal (e.g., hot flashes) are not seen. GnRH antagonists are contraindicated in pregnant women.

Cetrorelix is also used off label for endometriosis and uterine fibroids, both of which are estrogen dependent. As antagonists rather than agonists, these drugs do not transiently increase gonadotropin secretion and sex steroid biosynthesis.

Degarelix. *Degarelix acetate* is FDA-approved for treatment of advanced prostate cancer. *Degarelix* suppresses testosterone levels to 50 ng/dL or less (i.e., medical castration) and lowers prostate-specific antigen more rapidly than GnRH agonists without an initial testosterone surge (Shore, 2013).

Degarelix forms a depot gel at the site of injection and is released in a biphasic pattern with a median plasma $t_{1/2}$ of 42 days for the starting dose and 28 days for the maintenance dose. *Degarelix* is distributed throughout total body water, is 90% protein bound, and is degraded by proteolysis via the hepatobiliary system. Degraded protein fragments are eliminated in the feces, and unmetabolized drug is eliminated via the kidneys.

Adverse Effects. Adverse effects include injection site reactions, hot flashes, weight gain, increases in transaminase and γ-glutamyltransaminase levels, prolonged QT interval, and decreased bone mineral density.

Dosage and Route of Administration. *Degarelix* is administered subcutaneously in the abdomen, with the site of injection varied on a regular basis. The starting dose is 240 mg administered as two injections of 120 mg on each side of the abdomen, followed by a maintenance dose of 80 mg every 28 days.

Natural and Recombinant Gonadotropins

The gonadotropins are used for both diagnosis and therapy in reproductive endocrinology. For further discussion of the uses of gonadotropins in female reproduction, see Chapter 48.

The original gonadotropin preparations for clinical therapy were prepared from human urine and included *chorionic gonadotropin*, obtained from the urine of pregnant women, and *menotropins*, obtained from the urine of postmenopausal women. Because of their relatively low purity, these gonadotropins were administered intramuscularly to decrease the incidence of hypersensitivity reactions. Subsequently, urine-derived preparations were developed with sufficient purity to be administered subcutaneously. Highly purified preparations of human gonadotropins now are prepared using recombinant DNA technology and exhibit less batch-to-batch variation. This technology is being used to produce forms of gonadotropins with increased half-lives or higher clinical efficacy. One such "designer" gonadotropin, FSH-CTP, contains the β subunit of FSH fused to the carboxy-terminal extension of hCG, thereby considerably increasing the $t_{1/2}$ of the recombinant protein. In clinical trials, FSH-CTP has been shown to stimulate follicle maturation *in vivo* when injected weekly (Macklin et al., 2006).

Preparations

Follicle-Stimulating Hormone

Follicle-stimulating hormone has long been a mainstay of regimens for either ovarian stimulation or *in vitro* fertilization. The original *menotropins* formulations contained roughly equal amounts of FSH and LH, as well as a number of other urinary proteins, and were administered intramuscularly to diminish local reactions. *Urofollitropin*, prepared by immunoconcentration of FSH with monoclonal antibodies, is pure enough to be administered subcutaneously. The amount of LH contained in such preparations is diminished considerably.

Recombinant FSH is prepared by expressing cDNAs encoding the α and β subunits of human FSH in mammalian cell lines, yielding products whose glycosylation pattern mimics that of FSH produced by gonadotropes. The two available recombinant FSH preparations, *follitropin alfa* and *follitropin beta*, differ slightly in their carbohydrate structures: Both are more pure and exhibit less interbatch variability than do preparations purified from urine; thus, they can be administered subcutaneously. The relative advantages (i.e., efficacy, lower frequency of side effects such as ovarian hyperstimulation) of recombinant FSH versus urine-derived gonadotropins have not been definitively established (van Wely et al., 2011).

Human Chorionic Gonadotropin

The hCG used clinically originally came from the urine of pregnant women. Several urine-derived preparations are available; all of them are administered intramuscularly due to local reactions. Recombinant hCG (*choriogonadotropin alfa*) is the predominant preparation used clinically.

Recombinant Human LH

Menotropins contain considerable LH activity, thereby providing any LH activity that is needed to promote follicle maturation. Traditionally, LH was not used for ovulation induction because hCG produced identical effects via the LH receptor and had a longer $t_{1/2}$. Human LH produced using recombinant DNA technology and designated *lutropin alfa* has been discontinued from the U.S. market but is available elsewhere.

Diagnostic Uses

Pregnancy Testing

During pregnancy, the placenta produces significant amounts of hCG, which can be detected in maternal urine. Over-the-counter pregnancy kits containing antibodies specific for the unique β subunit of hCG qualitatively assay for the presence of hCG and can detect pregnancy within a few days after a woman's first missed menstrual period. Quantitative measurements of plasma hCG concentration by radioimmunoassay can indicate whether pregnancy is proceeding normally and can help to detect the presence of an ectopic pregnancy, hydatidiform mole, or choriocarcinoma. Such assays also are used to follow the therapeutic response of malignancies that secrete hCG, such as germ cell tumors.

Timing of Ovulation

Ovulation occurs about 36 h after the onset of the LH surge. Therefore, urinary concentrations of LH, as measured with an over-the-counter ELISA kit, can be used to predict the time of ovulation. Urine LH levels are measured every 12 to 24 h, beginning on day 10 to 12 of the menstrual cycle (assuming a 28-day cycle), to detect the rise in LH and estimate the time of ovulation. This estimate facilitates the timing of sexual intercourse to optimize the chance of achieving pregnancy.

Localization of Endocrine Disease

Measurements of plasma LH and FSH levels with β-subunit–specific ELISA kits are useful in the diagnosis of several reproductive disorders. Low or undetectable levels of LH and FSH are indicative of hypogonadotropic hypogonadism and suggest hypothalamic or pituitary disease, whereas high levels of gonadotropins suggest primary gonadal diseases. A plasma FSH level of 10 to 12 mIU/mL or greater on day 3 of the menstrual cycle is associated with reduced fertility. Elevated FSH levels also are diagnostic of menopause in women with amenorrhea in the appropriate age range.

Human CG can be used to stimulate testosterone production and thus to assess Leydig cell function in males suspected of having primary hypogonadism (e.g., in delayed puberty). A diminished response to multiple injections of hCG indicates Leydig cell failure; a normal response suggests a hypothalamic-pituitary disorder and normal Leydig cells.

Therapeutic Uses

Male Infertility

In men with impaired fertility secondary to gonadotropin deficiency (hypogonadotropic hypogonadism), gonadotropins can establish or restore fertility (Farhat et al., 2010). Treatment typically is initiated with hCG (1500–2000 IU intramuscularly or subcutaneously) three times per week until the plasma testosterone levels indicate full induction of steroidogenesis. Thereafter, the dose of hCG is reduced to 2000 IU twice a week or 1000 IU three times a week. If spermatogenesis does not occur with hCG alone, then recombinant FSH (typical dose of 150 IU) is added to fully induce spermatogenesis.

The most common side effect of gonadotropin therapy in males is gynecomastia, which occurs in up to a third of patients and presumably reflects increased production of estrogens due to the induction of aromatase. Maturation of the prepubertal testes typically requires treatment for more than 6 months, and optimal spermatogenesis in some patients may require treatment for up to 2 years. Once spermatogenesis has been initiated, ongoing treatment with hCG alone usually is sufficient to support sperm production.

Cryptorchidism

Cryptorchidism, the failure of one or both testes to descend into the scrotum, affects up to 3% of full-term male infants and becomes less prevalent with advancing postnatal age. Cryptorchid testes have defective spermatogenesis and are at increased risk for developing germ cell tumors. Hence, the current approach is to reposition the testes as early as possible, typically at 1 year of age but definitely before 2 years of age. The local actions of androgens stimulate descent of the testes; thus, hCG has been used by some to induce testicular descent if the cryptorchidism is not secondary to anatomical blockage. Therapy usually consists of injections of hCG (3000 IU/m^2 body surface area) intramuscularly every other day for six doses.

Posterior Pituitary Hormones: Oxytocin and Vasopressin

The neurohypophyseal hormones oxytocin and arginine vasopressin are cyclic nonapeptides that differ by only two amino acids (Figure 46–7). The physiology and pharmacology of vasopressin are presented in Chapter 29.

Physiology of Oxytocin

Oxytocin is best known for its female roles in parturition and breastfeeding but is also implicated in regulation of the autonomic nervous system. In males, oxytocin seems incidental and modulates sperm motility and testosterone production. It is synthesized as a larger precursor peptide in magnocellular neurons whose cell bodies reside in the paraventricular nucleus and, to a lesser extent, the supraoptic nucleus in the hypothalamus. The precursor peptide is rapidly cleaved to active oxytocin and neurophysin I, packaged into secretory granules as an oxytocin-neurophysin complex, and secreted from nerve endings that terminate primarily in the posterior pituitary gland (neurohypophysis). In addition, oxytocinergic neurons project to regions of the hypothalamus, olfactory nucleus, cortex, limbic system, brainstem, cerebellum, and spinal cord. Other sites of oxytocin synthesis include the luteal cells of the ovary, the endometrium, the placenta, Leydig cells of the testis, and nonreproductive tissues; however, the physiologic significance of extraneuronal oxytocin is not known (Jurek and Neumann, 2018).

Oxytocin acts via a specific GPCR (OXTR) closely related to the V_{1a} and V_2 vasopressin receptors. In the human myometrium, oxytocin binds OXTR on uterine myocytes resulting in the coupling of $G_{q/11}$, activation of the PLC_β-IP_3-Ca^{2+} pathway, and enhanced activation of voltage-sensitive Ca^{2+} channels to stimulate uterine muscle contraction (Figure 46–8). Oxytocin also increases uterine prostaglandin production, which further stimulates contraction. In human mammary tissue, oxytocin stimulates contraction of myoepithelial cells through OTXR to eject milk, known as the letdown reflex.

Regulation of Oxytocin Secretion

Stimuli for oxytocin secretion include sensory input arising from cervical dilation, vaginal stretch, suckling at the breast, and infant crying.

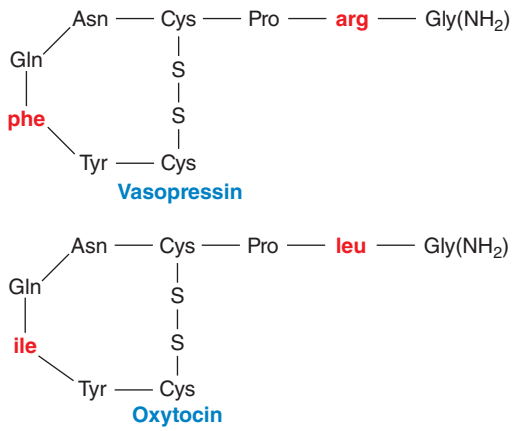

Figure 46–7 *The structures of vasopressin and oxytocin.* Vasopressin and oxytocin are cyclic nonapeptides that differ from each other by two amino acids (red).

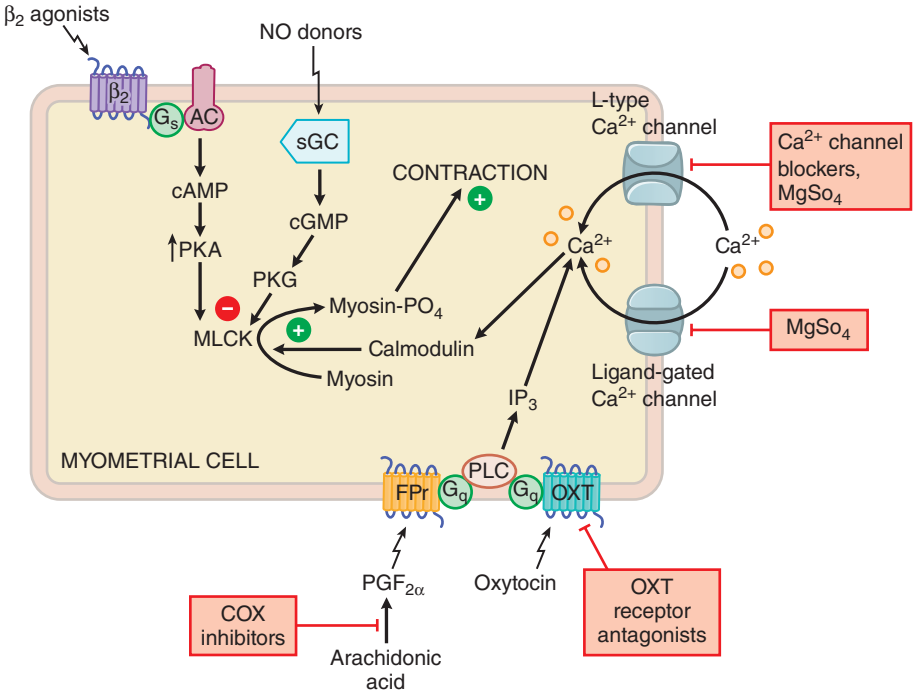

Figure 46–8 *Sites of action of oxytocin and tocolytic drugs in the uterine myometrium.* The elevation of cellular Ca^{2+} promotes contraction via the Ca^{2+}/calmodulin–dependent activation of myosin light chain kinase (MLCK). Relaxation is promoted by the elevation of cyclic nucleotides (cAMP and cGMP) and their activation of protein kinases, which cause phosphorylation/inactivation of MLCK. Pharmacological manipulations to reduce myometrial contraction include the following: (1) inhibiting Ca^{2+} entry (Ca^{2+} channel blockers, Mg_2 SO_4); (2) reducing mobilization of intracellular Ca^{2+} by antagonizing GPCR-mediated activation of the G_q-PLC-IP_3-Ca^{2+} pathway (with antagonists of the FPr and OXT receptors) or reducing production of the FPr agonist $PGF_{2\alpha}$ (with COX inhibitors); and (3) enhancing relaxation by elevating cellular cAMP (with β_2 adrenergic agonists that activate G_s-AC) and cGMP (with NO donors that stimulate soluble guanylyl cyclase).

Increases in circulating oxytocin in women in labor are difficult to detect, partly because of the pulsatile nature of oxytocin secretion and partly because of the activity of circulating oxytocinase. Nevertheless, increased oxytocin in maternal circulation is detected in the second stage of labor, likely triggered by sustained distension of the cervix and vagina.

Estradiol stimulates oxytocin secretion, whereas the ovarian polypeptide *relaxin* inhibits its release. The inhibitory effect of relaxin appears to be the net result of a direct effect on oxytocin-producing cells and indirect action mediated by endogenous opiates. Other factors that primarily affect vasopressin secretion also have some impact on oxytocin release: Pain, dehydration, hemorrhage, and hypovolemia stimulate release, whereas ethanol inhibits release. Although peripheral actions of oxytocin appear to play no significant role in the response to dehydration, hemorrhage, or hypovolemia, oxytocin may participate in the central regulation of blood pressure. Pharmacological doses of oxytocin can inhibit free water clearance by the kidney through arginine vasopressin–like activity at vasopressin V_2 receptors. As judged by the effects of intravenously administered oxytocin during labor induction, the plasma $t_{1/2}$ of oxytocin is about 13 min.

Unlike the *negative-feedback* regulation of the other pituitary hormones, oxytocin release is augmented by *positive-feedback* regulation. This positive feedback is most evident in parturition with oxytocin-induced contractions activating mechanoreceptors that signal for more oxytocin release. For this reason, uterine hyperstimulation is an adverse effect of intravenous administration of oxytocin to augment labor that should be avoided.

Sites of Oxytocin Action

Uterus

During the third trimester of pregnancy, spontaneous uterine contractions increase progressively until the sharp rise in frequency that constitutes the initiation of labor. Oxytocin regulates the frequency and force of uterine contractions. Uterine responsiveness to oxytocin roughly parallels the increase in spontaneous activity and is highly dependent on estrogen, which increases the expression of the OXTRs.

Because of difficulties associated with the measurement of oxytocin levels and because loss of pituitary oxytocin apparently does not compromise labor and delivery, the physiological role of oxytocin in pregnancy is debated. Exogenous oxytocin can enhance rhythmic contractions at any time, but an 8-fold increase in uterine sensitivity to oxytocin occurs in the last half of pregnancy and is accompanied by a 30-fold increase in OXTR numbers. Progesterone antagonizes the stimulatory effect of oxytocin *in vitro*, and refractoriness to progesterone in late pregnancy may contribute to the normal initiation of human parturition.

Breast

Oxytocin plays an important physiological role in milk ejection. Stimulation of the breast through suckling or mechanical manipulation induces oxytocin secretion, causing contraction of the myoepithelium that surrounds alveolar channels in the mammary gland. This action forces milk from the alveolar channels into large collecting sinuses, where it is available to the suckling infant.

Brain

Studies in rodents have implicated oxytocin as an important CNS regulator of social behavior and affiliation, a central role of oxytocin that remains to be established in humans. Research on the impact of oxytocin in humans has generated the Social Salience Hypothesis (Shamay-Tsoory and Abu-Akel, 2016). The Social Salience Hypothesis reconciles multiple effects of oxytocin on the CNS including enhancement of affiliative prosocial behaviors such as trust and bonding, attenuation of stress, and the regulation of cooperation and conflict among humans in a group social setting such as recognition, fear, or anxiety. In this framework, oxytocin is thought to modulate the response to social cues through interaction with dopaminergic neurons.

Brain regions innervated by oxytocinergic neurons include the amygdala, hypothalamus, hippocampus, and midbrain. Oxytocin treatment showed decreased activation of the amygdala, midbrain, and striatum in

response to stressful stimuli, implicating oxytocin as a potential intervention for mental conditions regulated by the hormone (Baumgartner et al., 2008; Huber et al., 2005). The possible therapeutic benefit of drugs that manipulate CNS oxytocin on mental conditions with perturbations in oxytocin signaling, such as social phobia, addiction, and autism, is an exciting area of ongoing investigation (Bowen and Neumann, 2017; Romano et al., 2016).

Clinical Use of Oxytocin

Despite heightened interest in using oxytocin nasal spray to treat social disorders, oxytocin is used therapeutically only to induce or augment labor and to treat or prevent postpartum hemorrhage. In 2007, oxytocin was added to a list of drugs "bearing a heightened risk of harm," although it is widely used. In the U.S., the FDA-approved label contains this notice:

> *Elective induction of labor is defined as the initiation of labor in a pregnant individual who has no medical indications for induction. Since the available data are inadequate to evaluate the benefits-to-risks considerations, Pitocin is not indicated for elective induction of labor.*

Induction of Labor

Induction of labor is indicated when the perceived risk of continued pregnancy to the mother or fetus exceeds the risks of pharmacological induction. Oxytocin is the drug of choice for induction of labor for women with a suitably ripened cervix (see Chapter 41 for a discussion of the role of prostaglandins in cervical ripening). It is administered by intravenous infusion of a diluted solution, has a $t_{1/2}$ of 12 to 15 min, and achieves a steady-state uterine response after about 30 min. Both a high-dose protocol (starting with an infusion of 6 mU/min) and low-dose protocols (starting with an infusion dose of 0.5–2 mU/min) have been used (American College of Obstetricians and Gynecologists, 2009). Oxytocin at high doses activates the vasopressin V_2 receptor and has antidiuretic effects. Vasodilating actions of oxytocin also have been noted that may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

Augmentation of Dysfunctional Labor

Oxytocin also is used when spontaneous labor is not progressing at an acceptable rate. To augment hypotonic contractions, an infusion rate of 10 mU/min typically is sufficient. As with labor induction, potential complications of uterine overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion.

Prevention and Treatment of Postpartum Hemorrhage

Oxytocin (10 units IM) is given immediately after delivery to help maintain uterine contractions and tone. Alternatively, oxytocin (20 units) is diluted in 1 L of intravenous solution (yielding a concentration of 20 mU/mL) and infused at a rate of 10 mU/min until the uterus is contracted. The infusion rate then is reduced to 1 to 2 mU/min until the mother is ready for transfer to the postpartum unit.

Tocolytic Therapy for Established Preterm Labor

Inhibition of uterine contractions of preterm labor, or *tocolysis*, has been a focus of therapy (see Figure 46–8). Although tocolytic agents delay delivery in approximately 80% of women, they neither prevent premature births nor improve adverse fetal outcomes, such as respiratory distress syndrome. Specific tocolytic agents include β adrenergic receptor agonists, $MgSO_4$, Ca^{2+} channel blockers, COX inhibitors, NO donors, and the oxytocin receptor antagonist *atosiban*. *Atosiban* is widely used in Europe but is not FDA-approved in the U.S. Chapter 48 presents additional information on tocolytic therapy.

Drug Facts for Your Personal Formulary: *Pituitary-Related Drugs*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Pituitary Hormones (Recombinant)		
Growth hormone • Somatropin • Somapacitan (GH analogue, adult only)	• Stimulating growth in childhood • GH replacement in GH-deficient adults	• Given by daily (somatropin) or weekly (somapacitan) SC injection to stimulate body growth, primarily through stimulation of IGF-1. As growth ceases, test for GH deficiency to determine if GH should be continued into adulthood. • Given only to adults with GH deficiency proven by GH stimulation tests or known organic childhood GH deficiency and low IGF-1 levels on testing of GH treatment. • Treatment in adults decreases fat mass, increases muscle mass, increases bone mass, and improves quality of life.
Oxytocin	• Augmentation of labor • Management of postpartum hemorrhage	• Administered by intravenous infusion. • Hyperstimulating the uterus should be avoided during augmentation of labor. • May provoke hypotension and reflex tachycardia.
Other Peptide Hormones		
Human chorionic gonadotropin	• Testing of Leydig cell function • Female/male infertility • Cryptorchidism in children	• Stimulates LH receptor, stimulating ovulation in female and causing increased testicular testosterone production in male. • Induces testicular descent in children with cryptorchidism.
Tesamorelin	• Treatment of HIV-associated lipodystrophy	• N-terminally modified version of human GHRH with primary effect of reducing visceral and other body fat in patients with HIV lipodystrophy.
Macimorelin	• Diagnosis of adult GH deficiency	• Orally available synthetic mimetic of ghrelin that stimulates GH secretion.
Insulin-like growth factor 1 (mecasermin)	• Treatment of children with mutations in the GH receptor or transduction mechanisms mediating GH action or IGF-1 gene defects	• Adverse effects include hypoglycemia and lipohypertrophy.
Gonadotropin-releasing hormone agonist analogues • Goserelin • Histrelin • Leuprolide • Nafarelin • Triptorelin	• Endometriosis • Diagnosis and treatment of precocious puberty • Palliative treatment of hormone-responsive tumors (prostate and breast cancer)	• Prolonged stimulation of the GnRH receptor by analogues results in downregulation of those receptors with decreased gonadotropin secretion.

Drug Facts for Your Personal Formulary: *Pituitary-Related Drugs (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Gonadotropin-releasing hormone antagonist analogues • Ganirelix • Cetrorelix • Degarelix	• Suppression of gonadotropin secretion and used in conjunction with exogenous gonadotropins for assisted reproduction • Palliative treatment of advanced prostate cancer (degarelix)	• Antagonism at the GnRH receptor results in decreased gonadotropin secretion without initial LH surge as seen with agonist analogues.
Somatostatin Analogues: Act on somatostatin receptors to reduce hormone secretion		
Octreotide	• Acromegaly	• Long-acting release form is the standard type; given monthly.
Lanreotide	• Acromegaly	• Long-acting release form is the only available standard type; given monthly.
Pasireotide	• Acromegaly • Cushing disease	• Short-acting subcutaneous form is the only version FDA-approved for Cushing disease. • LAR form given monthly is the only version FDA-approved for acromegaly. • Additional adverse effects include significant hyperglycemia in many patients.
Dopamine Agonists: Act on dopamine receptors (D_2) to decrease prolactin secretion and prolactinoma size		
Bromocriptine	• Treatment of hyperprolactinemia • Reduction in size of prolactinomas • Treatment of Parkinson disease	• An ergot derivative that must be given 1–2 times daily. • Common adverse effects include nausea, vomiting, headache, and postural hypotension.
Cabergoline	• Treatment of hyperprolactinemia • Reduction in size of prolactinomas • Parkinson disease • Acromegaly	• A long-acting ergot derivative given once or twice weekly. • Has greater efficacy and tolerability than bromocriptine and may be active in patients who do not respond to bromocriptine. • At high doses used in patients with Parkinson disease; it cross-reacts at the $5HT_{2B}$ receptor, causing cardiac valve abnormalities (not seen when used for patients with prolactinomas).
Quinagolide	• Treatment of hyperprolactinemia • Reduction in size of prolactinomas	• Not available in the U.S.
Hormone Receptor Blockers		
Pegvisomant	• Treatment of acromegaly	• Blocks GH receptor and thus the activity of high GH levels and the generation of IGF-1 in acromegaly. Given by subcutaneous injections daily alone or weekly in combination with somatostatin analogues.

Chapter 47

Thyroid and Antithyroid Drugs

Ronald J. Koenig and Gregory A. Brent

Thyroid hormone is essential for normal development, especially of the CNS. In the adult, thyroid hormone maintains metabolic homeostasis and influences the functions of virtually all organ systems. Thyroid hormone contains iodine, which must be supplied by nutritional intake. The thyroid gland contains large stores of thyroid hormone in the form of *thyroglobulin*. These stores maintain adequate systemic concentrations of thyroid hormone despite significant variations in iodine availability and nutritional intake. The thyroidal secretion is predominantly the prohormone T_4, which is converted in the liver and other tissues to supply the plasma with the active form, T_3. Local activation of T_4 also occurs in target tissues (e.g., brain and pituitary) and is increasingly recognized as an important regulatory step in thyroid hormone action. Similarly, local deactivation of T_3 is an important regulatory step. Serum concentrations of thyroid hormones are precisely regulated by the pituitary hormone *TSH* in a negative-feedback system. The predominant actions of thyroid hormone are mediated via nuclear TRs that modulate the transcription of specific genes.

Overt *hyperthyroidism* and *hypothyroidism*, thyroid hormone excess and deficiency, respectively, are associated with numerous clinical manifestations. Milder disease often has a subtler clinical presentation and may be identified based solely on abnormal biochemical tests of thyroid function. Maternal and neonatal hypothyroidism, due to iodine deficiency, remains a major preventable cause of intellectual disability worldwide (Zimmermann, 2009). Treatment of the hypothyroid patient consists of thyroid hormone replacement (Biondi and Wartofsky, 2014). Treatments for hyperthyroidism include antithyroid drugs to decrease hormone synthesis and secretion, destruction of the gland by the administration of radioactive iodine, and surgical removal (Brent, 2008). In most patients, disorders of thyroid function can be either cured or controlled.

Likewise, thyroid malignancies are most often localized and resectable (Haugen et al., 2016; Haugen and Sherman, 2013). Metastatic disease often responds to *radioiodine* treatment but may become highly aggressive. *Radioiodine*-refractory, progressive thyroid cancers may respond to targeted chemotherapies, such as tyrosine kinase inhibitors.

Thyroid Hormones

The thyroid gland produces two fundamentally different types of hormones. The thyroid follicle produces the iodothyronine hormones T_4 and T_3. The thyroid's parafollicular cells produce *calcitonin*, a peptide with 32 amino acids, which is not an important endogenous hormone but can be useful as a therapeutic agent in hypercalcemia and osteoporosis (see Chapter 52). Figures 47–1 and 47–2 show the structures of the thyroid hormones and their pathways of synthesis, storage, and release.

Chemistry of Thyroid Hormones

The principal hormones of the thyroid gland are the iodine-containing amino acid derivatives of thyronine (see Figure 47–1). Following the isolation and the chemical identification of T_4, it was generally thought that all the hormonal activity of thyroid tissue could be accounted for by its content of T_4. However, careful studies revealed that crude thyroid preparations possessed greater calorigenic activity than could be accounted for by their T_4 content. The presence of a "second" thyroid hormone was debated, but T_3 was finally detected, isolated, and synthesized by Gross and Pitt-Rivers in 1952. T_3 has a much higher affinity for the nuclear thyroid hormone receptor (TR) compared with T_4 and is much more potent biologically on a molar basis. The subsequent demonstration of T_3 production from T_4 in athyreotic humans led to the practice of effective replacement in hypothyroidism with *levothyroxine* only.

Abbreviations

CYP: cytochrome P450
Dio1, Dio2, and Dio3: deiodinase types 1, 2, and 3
DIT: diiodotyrosine
ERK: extracellular signal-regulated kinase
GPCR: G protein-coupled receptor
HOI: hypoiodous acid
IGF-1: insulin-like growth factor 1
IP_3: inositol 1,4,5-trisphosphate
KISS: potassium iodide (KI) saturated solution
LDL: low-density lipoprotein
MAP kinase: mitogen-activated protein kinase
MCT: monocarboxylic acid transporter
MEK: MAP kinase kinase
MHC: myosin heavy chain, isoform α or β
MIT: monoiodotyrosine
MTC: medullary thyroid carcinoma
NIS: sodium iodide symporter
NO: nitric oxide
NTRK: gene family coding for neutrophic tyrosine receptor kinases (TRKs)
OATP1C1: solute carrier organic anion transporter family, member 1C1
PLC: phospholipase C
RAIU: radioactive iodine uptake
RET: *rearranged during transfection* tyrosine protein kinase
rT_3: reverse T_3
T_3: 3,5,3′-triiodothyronine
T_4: thyroxine
TBG: thyroxine-binding globulin
TR: thyroid hormone receptor
TRH: thyrotropin-releasing hormone
Triac: 3,5,3′-triiodothyroacetic acid, tiratricol
TRKs: tropomyosin receptor kinases, a family of tyrosine protein kinases encoded by NTRK genes
TSH: thyroid-stimulating hormone, thyrotropin

B	Iodination	PTU, MMI
C	Coupling	PTU, MMI
D	Colloid Resorption	Colchicine, Li^+, I^-
E	Deiodination of DIT + MIT	Dinitrotyrosine
F	Deodination of T_4	PTU
G	Secretion	I^-

Figure 47–2 *Major pathways of thyroid hormone biosynthesis, storage as colloid, and release* MMI, methimazole; PTU, propylthiouracil; SCN, thiocyanate; TPO, thyroid peroxidase; D#, deiodinase 1, 2, or 3; DIT, diiodotyrosine; MIT, monoiodotyrosine; NIS, sodium iodide symporter; HOI, hypoiodous acid, and EOI, the enzyme-linked species; Tg; thyroglobulin.

Biosynthesis of Thyroid Hormones

The thyroid hormones are synthesized and stored as amino acid residues of *thyroglobulin*, a complex glycoprotein made up of two apparently identical subunits and constituting the vast majority of the thyroid follicular colloid. The thyroid gland is unique in storing great quantities of hormone precursor in this way, and extracellular thyroglobulin is proportional to the thyroid mass. The major steps in the synthesis, storage, release, and interconversion of thyroid hormones are summarized in Figure 47–2 and described next.

HISTORICAL PERSPECTIVE

The thyroid is named for the Greek word for "shield shaped," from the shape of the nearby tracheal cartilage. The gland was first recognized as an organ of importance when thyroid enlargement was observed to be associated with changes in the eyes and heart in the condition we now call *hyperthyroidism.* Parry saw his first patient in 1786 but did not publish his findings until 1825. Graves reported the disorder in 1835, Basedow in 1840. Hypothyroidism was described later, in 1874, when Gull associated atrophy of the gland with the symptoms characteristic of *hypothyroidism.* The term *myxedema* was applied to the clinical syndrome in 1878 by Ord, in the belief that the characteristic thickening of the subcutaneous tissues was due to excessive formation of mucus. In 1891, Murray first treated a case of hypothyroidism by injecting an extract of sheep thyroid gland, later shown to be fully effective when given by mouth. The successful treatment of thyroid deficiency by administering thyroid extract was an important step toward modern endocrinology.

Extirpation experiments to elucidate the function of the thyroid were at first misinterpreted because of the simultaneous removal of the parathyroids. However, Gley's research on the parathyroid glands in the late 19th century allowed the functional differentiation of these two endocrine glands. The structure of parathyroid hormone, however, was not reported until the early 1970s. Calcitonin was discovered in 1961, demonstrating that the thyroid gland produced a second hormone.

Uptake of Iodide

Iodine ingested in the diet reaches the circulation in the form of iodide ion (I^-). Normally, the I^- concentration in the blood is very low (0.2–0.4 µg/dL; ~15–30 nM). The thyroid actively transports the ion via a specific membrane-bound protein, termed sodium iodide symporter (NIS) (Kogai and Brent, 2012; Portulano et al., 2014). As a result, the ratio of $[I^-]_{thyroid}$ to $[I^-]_{plasma}$ is usually between 20 and 50 and can exceed 100 when the gland is stimulated. Iodide transport is inhibited by a number of ions, such as thiocyanate and perchlorate. TSH stimulates NIS gene expression and promotes insertion of NIS protein into the membrane in a functional configuration. Thus, decreased stores of thyroid iodine enhance iodide uptake by increasing TSH, and the administration of iodide can reverse this situation by decreasing NIS protein expression. Iodine is accumulated by other tissues, including the salivary glands, gut, and lactating breast, and it is all mediated by a single NIS gene. Individuals with congenital NIS gene mutations have absent or defective iodine concentration in all tissues known to concentrate iodine.

Oxidation and Iodination

Transport of iodine from the thyroid follicular cell to the colloid is facilitated by the apical transporter *pendrin*. The oxidation of iodide to its active form is accomplished by *thyroid peroxidase*. The reaction results in the formation of monoiodotyrosine (MIT) and diiodotyrosine (DIT) residues in thyroglobulin, a process referred to as *organification of iodine*, just prior to its extracellular storage in the lumen of the thyroid follicle.

Formation of Thyroxine and Triiodothyronine From Iodotyrosines

The remaining synthetic step is the coupling of two DIT residues to form T_4 or of an MIT and a DIT residue to form T_3. These oxidative reactions also are catalyzed by *thyroid peroxidase*. Intrathyroidal and secreted T_3 are also generated by the 5′-deiodination of T_4.

Synthesis and Secretion of Thyroid Hormones

Because T_4 and T_3 are synthesized and stored within thyroglobulin, proteolysis is an important part of the secretory process. This process is initiated by endocytosis of colloid from the follicular lumen at the apical surface of the cell, with the participation of a thyroglobulin receptor, *megalin*. This "ingested" thyroglobulin appears as intracellular colloid droplets, which apparently fuse with lysosomes containing the requisite proteolytic enzymes. TSH enhances the degradation of thyroglobulin by increasing the activity of lysosomal *thiol endopeptidases*, which selectively cleave thyroglobulin, yielding hormone-containing intermediates that subsequently are processed by exopeptidases. The liberated hormones then exit the cell primarily as T_4 along with some T_3. The T_3 secreted by the thyroid derives partly from T_3 within mature thyroglobulin and partly from deiodination of T_4 (Figure 47–3), which also occurs peripherally (Figure 47–4).

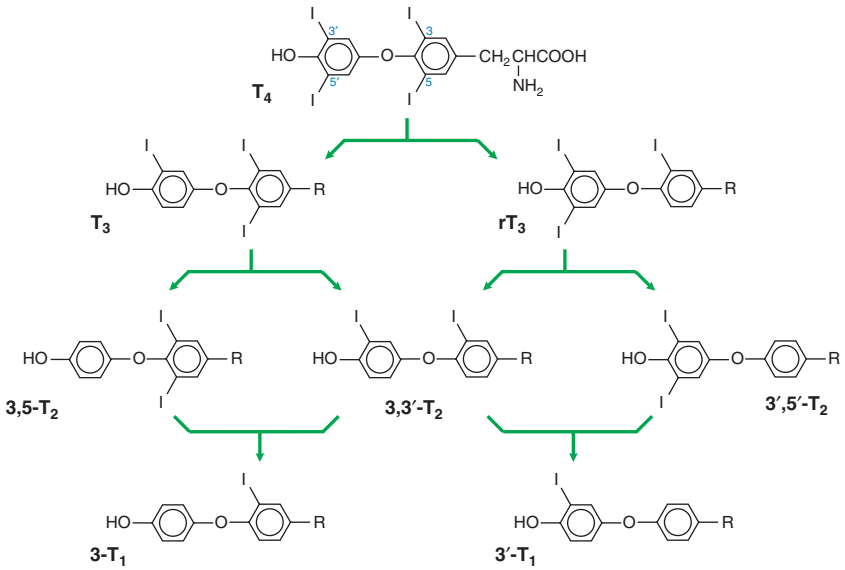

Figure 47–3 Formation of iodotyrosines and thyroid hormones.

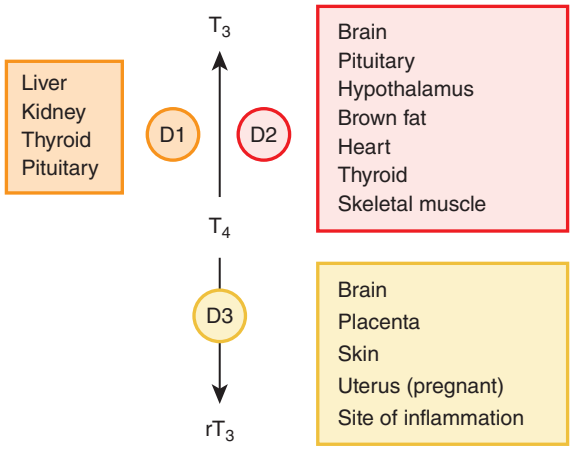

Figure 47–4 *Peripheral T_4 to T_3 conversion by different deiodinase enzymes (D1, D2, D3).*

Quantitative Aspects of Thyroid Hormone Metabolism

Selected quantitative aspects of thyroid hormone metabolism are provided in Table 47–1. The non–protein-bound (free) fraction of T_4 is much smaller than that of T_3 primarily because thyroxine-binding globulin (TBG) has a 20-fold lower dissociation constant for T_4, discussed below.

Activation and Inactivation of Thyroid Hormone by Deiodination in Peripheral Tissues

Although T_3 is secreted by the thyroid, metabolism of T_4 by 5′-deiodination of the outer ring in the peripheral tissues accounts for approximately 80% of circulating T_3; in contrast, 5′-deiodination of the inner ring produces the metabolically inactive 3,3′,5′-triiodothyronine (reverse T_3 [rT_3]; see Figure 47–3). Under normal conditions, approximately 40% of T_4 is converted to each of T_3 and rT_3, and approximately 20% is metabolized via other pathways, such as glucuronidation in the liver and excretion in the bile. T_3 has a much higher affinity for the nuclear TR compared with T_4 and is much more potent biologically on a molar basis.

There are three *iodothyronine deiodinases*, produced by the genes *DIO1*, *DIO2*, and *DIO3* (Marsili et al., 2011). Dio1 and Dio2 convert T_4 to T_3. Dio1 is a plasma membrane protein expressed primarily in the liver and kidney and also in the thyroid and pituitary (see Figure 47–4). It is upregulated in hyperthyroidism, downregulated in hypothyroidism, and inhibited by the antithyroid drug *propylthiouracil*. Dio2 is expressed primarily in the CNS (including the pituitary and hypothalamus) and brown adipose tissue, also in the thyroid, and at low levels in skeletal muscle, heart, and other tissues. The activity of Dio2 is unaffected by *propylthiouracil*. Dio2 localizes to the endoplasmic reticulum, which facilitates access of Dio2-generated T_3 to the nucleus. Organs that express Dio2 use the locally generated T_3 in addition to plasma T_3 and therefore may have a relatively high fractional occupancy of TRs by T_3. T_4 induces ubiquitination and degradation of the Dio2 enzyme. This results in suppressed levels of Dio2 in hyperthyroidism and elevated levels in hypothyroidism, thus helping to maintain T_3 homeostasis. In addition, T_3 mildly represses Dio2 expression at the transcriptional level. It has been difficult to determine the relative contributions of Dio1 and Dio2 to the plasma T_3 in humans, but current best estimates are that Dio1 accounts for approximately one-third and Dio2 for approximately two-thirds of the circulating T_3 in euthyroid individuals. Due to the positive regulation of Dio1 by T_3 and negative regulation of Dio2 by T_4 and T_3, it is thought that Dio2 accounts for more than two-thirds of the plasma T_3 in hypothyroid individuals and that Dio1 accounts for the majority of the plasma T_3 in hyperthyroid individuals.

The Dio2 polymorphism Thr92Ala is associated with reduced enzyme activity, primarily by inducing endoplasmic reticulum stress and accumulation of inactive enzyme in the trans-Golgi. In several small studies, the Dio2 Thr92Ala polymorphism has been associated with biochemical or clinical consequences (Jonklaas et al., 2021). For example, it has been associated with increased body mass index and insulin resistance. It also has been associated with lower circulating free T_3 levels in hypothyroid patients taking *levothyroxine* and with decreased psychological well-being and greater improvement in well-being following therapy with T_4/T_3 combination compared with T_4 alone. However, other studies have not confirmed these findings. The significance of Dio2 polymorphisms in human health and disease remains to be clarified.

Dio3 catalyzes inner ring or 5-deiodination, the main inactivating pathway of T_3 metabolism; Dio1 performs this function to some extent. Dio3 is found at highest levels in the CNS and placenta and also is expressed in skin and pregnant uterus. Dio3 can be induced locally by inflammation and hypoxia and is highly expressed in certain tumors. Both Dio2 and Dio3 are expressed in time- and spatially restricted patterns during development, in which they play important roles by regulating local levels of T_3.

The three deiodinases contain the rare amino acid *selenocysteine* in their active sites. Incorporation of selenocysteine into the growing peptide chain is a complex process involving multiple proteins. Mutations in one such protein, SECIS binding protein 2, are associated with abnormal circulating thyroid hormone levels.

TABLE 47–1 ■ SELECTED QUANTITATIVE ASPECTS OF THYROID HORMONE METABOLISM

	T_4	T_3
Daily production	~80–100 μg (~100–130 nmol)	~30–40 μg (~45–60 nmol)
Plasma concentration, total hormone	~5–12 μg/dL (~60–150 nmol/L)	~80–175 ng/dL (~1.2–2.7 nmol/L)
Plasma concentration, free hormone	~0.8–2.0 ng/dL (~10–25 pmol/L)	~2–4 pg/mL (~3–6 pmol/L)
Plasma free fraction (non–protein bound)	~0.02%	~0.3%
Intracellular fraction (excluding thyroid gland)	~15%	~65%
Volume of distribution	10 L	40 L
Plasma $t_{1/2}$	~7 days	~20 h
Fractional turnover	~10%/day	~56%/day

Transport of Thyroid Hormones in the Blood

Iodine in the circulation is normally present in several forms, with 95% as organic iodine and about 5% as iodide. Most (90%–95%) organic iodine is T_4; T_3 represents a relatively minor fraction (~5%). The thyroid hormones are transported in the blood in strong but noncovalent association with several plasma proteins.

Thyroxine-binding globulin is the major carrier of thyroid hormones. It is a glycoprotein (mass of ~63,000 Da) that binds one molecule of T_4 per molecule of protein with a very high affinity (K_d is ~10^{-10} M); T_3 is bound less avidly. T_4, but not T_3, also is bound by *transthyretin* (thyroxine-binding prealbumin), a retinol-binding protein. This protein is present in higher concentration than is TBG and binds T_4 with a K_d about 10^{-7} M. Albumin can also bind T_4 when the more avid carriers are saturated, but its physiological importance is unclear. Binding of thyroid hormones to plasma proteins protects the hormones from metabolism and excretion, resulting in their long half-lives in the circulation. The free (unbound) hormone is a small percentage (~0.02% of T_4 and ~0.3% of T_3) of the total hormone in plasma. The differential binding affinities for serum proteins also contribute to establishing the 10- to 100-fold differences in circulating hormone concentrations and half-lives of T_4 and T_3.

Essential to understanding the regulation of thyroid function is the "free hormone" concept: Only the unbound hormone has metabolic

TABLE 47–2 ■ IMPORTANT FACTORS THAT ALTER BINDING OF THYROXINE TO THYROXINE-BINDING GLOBULIN

INCREASE BINDING	DECREASE BINDING

activity. Because of the high degree of binding of thyroid hormones to plasma proteins, changes in either the concentrations of these proteins or the affinities of the hormone-protein interactions have major effects on the total serum hormone levels. Certain drugs and a variety of pathological and physiological conditions can alter both the binding of thyroid hormones to plasma proteins and the amounts of these proteins (Table 47–2).

Degradation and Excretion of Thyroid Hormones

T_3 and T_4 not only can be deiodinated but also can be metabolized by ether cleavage, conjugation, and oxidative decarboxylation (Figure 47–5). T_4 is eliminated slowly from the body, with a $t_{1/2}$ of 6 to 8 days. In hyperthyroidism, the $t_{1/2}$ is shortened to 3 to 4 days, whereas in hypothyroidism, it may be 9 to 10 days. In conditions associated with increased binding to TBG, such as pregnancy, clearance is retarded. The opposite effect is observed when binding to protein is inhibited by certain drugs (see Table 47–2). T_3, which is less avidly bound to protein, has a $t_{1/2}$ of about 18 to 24 h.

The liver is the major site of nondeiodinative degradation of thyroid hormones; T_4 and T_3 are conjugated with glucuronic and sulfuric acids and excreted in the bile. Some thyroid hormone is liberated by hydrolysis of the conjugates in the intestine and reabsorbed. A portion of the conjugated material reaches the colon unchanged, where it is hydrolyzed and eliminated in feces as the free compounds.

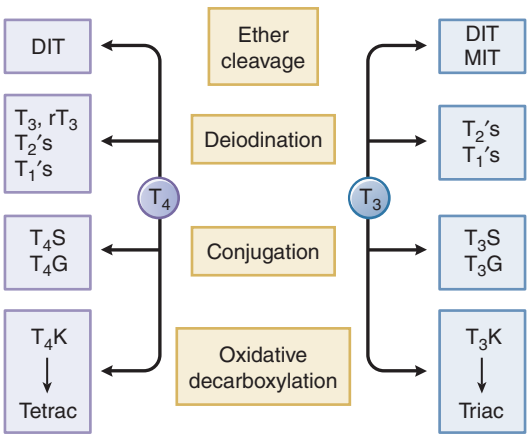

Figure 47–5 *Pathways of metabolism of T_4 and T_3.* rT_3, reverse T_3; T_3G, T_3 glucuronide; T_4G, T_4 glucuronide; T_3K, T_3 pyruvic acid; T_4K, T_4 pyruvic acid; Tetrac, tetraiodothyroacetic acid; Triac, 3,5,3′-triiodothyroacetic acid; T_3S, T_3 ulfate; T_4S T_3 sulfate.

Factors Regulating Thyroid Hormone Secretion

Thyrotropin is a glycoprotein hormone that consists of an α subunit, common to pituitary glycoproteins such as gonadotropins, and a unique β subunit. TSH is secreted in a pulsatile manner and in a circadian pattern (levels are slightly higher during sleep at night) that is the inverse of the cortisol circadian pattern, reflecting the fact that cortisol reduces TSH secretion. TSH secretion is controlled by the hypothalamic peptide *TRH* and by the concentration of free thyroid hormones in the circulation. Increased thyroid hormone inhibits transcription of both the TRH gene and the genes encoding the α and β subunits of TSH, which suppresses the secretion of TSH and causes the thyroid to become inactive and regress. Any decrease in the normal rate of thyroid hormone secretion by the thyroid evokes an enhanced secretion of TSH. Additional mechanisms mediating the effect of thyroid hormone on TSH secretion appear to be a reduction in TRH secretion by the hypothalamus and a reduction in the number of TRH receptors on pituitary cells (Figure 47–6).

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone stimulates the release of preformed TSH from secretory granules and also stimulates the subsequent synthesis of both α and β subunits of TSH. TRH is a tripeptide (L-pyroglutamyl-L-histidyl-L-proline amide) synthesized by the hypothalamus and released into the hypophyseal-portal circulation, where it interacts with TRH receptors on thyrotropes in the anterior pituitary. The binding of TRH to its receptor, a GPCR, stimulates the G_q-PLC-IP_3-Ca^{2+} pathway and activates protein kinase C, ultimately stimulating the synthesis and release of TSH. Two TRH receptors have now been identified, TRH-R1 and TRH-R2, and there are receptor-selective TRH analogues. Somatostatin, dopamine, and glucocorticoids inhibit TRH-stimulated TSH secretion.

Actions of TSH on the Thyroid

TSH increases the synthesis and secretion of thyroid hormone. These effects follow the binding of TSH to its receptor (a GPCR) on the plasma membrane of thyroid cells. Binding of TSH to its receptor stimulates the

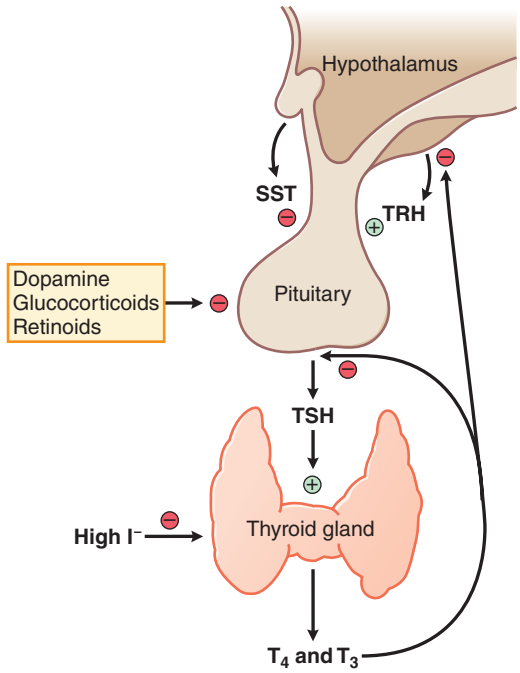

Figure 47–6 *Regulation of thyroid hormone secretion.* Myriad neural inputs influence hypothalamic secretion of thyrotropin-releasing hormone (TRH). TRH stimulates release of TSH from the anterior pituitary; TSH stimulates the synthesis and release of the thyroid hormones T_3 and T_4. T_3 and T_4 feed back to inhibit the synthesis and release of TRH and TSH. Somatostatin (SST) can inhibit TRH action, as can dopamine and high concentrations of glucocorticoids. Low levels of I^- are required for T_4 synthesis, but high levels inhibit T_4 synthesis and releas ɔ.

G_s-adenylyl cyclase–cyclic AMP pathway. Higher concentrations of TSH activate the G_q-PLC pathway. Inactivating and activating mutations of the TSH receptor have been described and can result in thyroid dysfunction.

Iodine and Thyroid Function

Adequate iodine intake is essential for normal thyroid hormone production. When iodine intake is low, thyroid hormone production is reduced, TSH is secreted in excess, and the thyroid becomes hyperplastic and hypertrophic. The enlarged and stimulated thyroid becomes remarkably efficient at extracting the residual traces of iodide from the blood, developing an iodine gradient that may be 10 times normal; in mild-to-moderate iodine deficiency, the thyroid usually succeeds in producing sufficient hormone and preferentially secreting T_3. In more severe iodine deficiency, adult hypothyroidism or congenital iodine deficiency syndrome may occur. High levels of iodine inhibit T_4 synthesis and release. In some areas of the world, simple or nontoxic goiter is prevalent because of insufficient dietary iodine. The addition of iodate to table salt (NaCl) provides a convenient iodine supplement. In the U.S., iodized salt provides 100 μg of iodine per gram. The recommended daily allowances for iodine are from 90 to 120 μg for children, 150 μg for adults, 220 μg for pregnancy, and 290 μg for lactation (Public Health Committee of the American Thyroid Association et al., 2006). Vegetables, meat, and poultry contain minimal amounts of iodine, whereas dairy products and fish are relatively high in iodine.

Iodized Salt

Iodine has been used empirically for the treatment of iodine-deficiency goiter for 150 years; however, its modern use evolved from extensive studies using iodine to prevent goiter in schoolchildren in Akron, Ohio, where endemic iodine-deficiency goiter was prevalent. The success of these experiments led to the adoption of iodine prophylaxis and therapy in many regions throughout the world where iodine-deficiency goiter was endemic. The most practical method for providing small supplements of iodine for large segments of the population is the addition of iodide or iodate to table salt; iodate is now preferred. The use of iodized salt is required by law in some countries, but in others, such as the U.S., the use is optional.

Transport of Thyroid Hormones Into and Out of Cells

The passage of thyroid hormones across the cell membrane is mediated by specific transporters (Groeneweg et al., 2020), the most well-documented of which are MCT8 and MCT10, OATP1C1, and SLC17A4. MCT8 is widely expressed, including in multiple cell types and regions of the brain. MCT8 mutations cause Allan-Herndon-Dudley syndrome, characterized by severe neurodevelopmental defects that are likely due to impaired entry of T_4 and T_3 into the brain. Individuals with this syndrome also tend to have low circulating free T_4 and elevated free T_3 levels, with some clinical evidence of thyrotoxicosis. The T_3 metabolite triac is a biologically active thyroid hormone that does not require MCT8 for cell entry (it is present naturally in serum at very low levels). In a phase II trial of patients with MCT8 deficiency, therapy with triac (*tiratricol*) improved signs of hyperthyroidism, although the patients were beyond the age where improvement in neurodevelopment might be feasible.

OATP1C1 preferentially transports T_4 over T_3 and is highly expressed in the brain. In mice, OATP1C1 plays an important role in the transport of T_4 across the blood-brain barrier. A single patient with a homozygous OATP1C1 mutation and a severe neurodevelopmental phenotype has been described. This patient showed clinical improvement when treated with triac, which does not require OATP1C1 for cell entry.

MCT10 transports T_3 more effectively than T_4 and is widely expressed. SLC17A4 transports T_3 and T_4 and is expressed in liver, kidney, intestine, and pancreas. However, the importance of MCT10 and SLC17A4 in thyroid hormone transport into or out of cells in humans remains to be determined, and mutations causing abnormal patient phenotypes have not been described.

Mediation of Effects by Nuclear Receptors

Thyroid hormone action is mediated largely by the binding of T_3 to TRs, which are members of the nuclear receptor superfamily of transcription factors (Brent, 2012). This superfamily includes the receptors for steroid hormones, vitamin D, retinoic acid, and a variety of small-molecule metabolites such as certain fatty acids and bile acids, as well as a number of "orphan receptors" (see Chapter 3).

The TRs have the classic nuclear receptor structure: an amino terminal domain, a centrally located zinc finger DNA-binding domain, and a ligand-binding domain that occupies the carboxyl terminal half of the protein. T_3 binds to TRs with about 10-fold greater affinity than does T_4, and T_4 is not thought to be biologically active in normal physiology. TRs bind to specific DNA sequences (thyroid hormone response elements) in the promoter/regulatory regions of target genes. The transcription of most target genes is repressed by unliganded TRs and induced in response to the binding of T_3. In the unliganded state, the TR ligand-binding domain interacts with a corepressor complex that includes *histone deacetylases* and other proteins. The binding of T_3 causes replacement of the corepressor complex by a coactivator complex that includes *histone acetyltransferases*, *methyltransferases*. Other thyroid hormone target genes, such as those encoding TRH and the TSH subunits, are negatively regulated by T_3. The mechanism is not well defined, but these genes tend to be induced by the unliganded TR in addition to being repressed by T_3.

Two genes encode TRs: *THRA* and *THRB*. *THRA* encodes the receptor TRα1. TRα1 is expressed in most cell types, but its major activities are in the regulation of heart rate, body temperature, skeletal muscle function, and the development of bone and small intestine. Patients with *THRA* mutations have been described with short stature, bony abnormalities, and chronic constipation, along with normal circulating TSH and low-normal T_4 levels, a syndrome termed *resistance to thyroid hormone alpha* (Onigata and Szinnai, 2014).

The *THRB* gene has two promoters that lead to the production of TRβ1 and TRβ2. These receptors have unique amino terminal domains but otherwise are identical. TRβ1 is ubiquitous; TRβ2 has a highly restricted pattern of expression, including the pituitary and hypothalamus. TRβ1 mediates specific effects in liver metabolism (including the hypocholesterolemic effect of T_3); TRβ2 has roles in the negative feedback by T_3 on hypothalamic TRH and pituitary TSH and in the development of retinal cones and the inner ear. Mutations in *THRB* cause the syndrome of *resistance to thyroid hormone beta*. This syndrome is associated with goiter, tachycardia, impaired hearing, attention-deficit/hyperactivity disorder, and other abnormalities. Laboratory evaluation typically shows elevated levels of T_4 and T_3 with TSH in the mid to upper portion of the reference range or frankly elevated (Onigata and Szinnai, 2014).

Nongenomic Effects of Thyroid Hormone

Although nuclear receptors are generally thought of as DNA-binding transcription factors, nuclear receptors, such as TRs, also are found outside the nucleus where they can exert biological effects via rapid nongenomic mechanisms (Hones et al., 2017). A truncated form of TRα1 is palmitoylated and localizes to the plasma membrane, where it causes rapid T_3-dependent NO production as well as activation of ERK and Akt signaling. Full-length TRα1 and TRβ1 reportedly associate in a T_3-dependent manner with the p85α subunit of PI3K (phosphoinositide 3-kinase), resulting in activation of Akt (protein kinase B). It is interesting to note that T_3 administration causes rapid vasodilation, which might be explained by the aforementioned generation of NO. Perhaps the strongest *in vivo* evidence for the relevance of noncanonical actions of T_3 comes from studies in mice in which the endogenous *Thra* and *Thrb* genes were mutated to yield TR proteins incapable of binding DNA (Hones et al., 2017). In these mice, T_3 could still regulate heart rate, body temperature, and blood glucose and triglyceride concentrations. There also is some evidence for nongenomic actions of thyroid hormone via a plasma membrane receptor within integrin αVβ3. This putative receptor binds extracellular T_4 in preference to T_3, resulting in activation of MAP kinase. The importance of this putative receptor in thyroid hormone physiology and pathophysiology remains uncertain.

Major Clinical Effects of Thyroid Hormones

Most cells and organs are responsive to thyroid hormone. As such, thyroid hormone regulates many physiological processes, only a few of which will be mentioned here.

Growth and Development

Perhaps the most dramatic example of thyroid hormone action is amphibian metamorphosis, in which the tadpole transforms into a frog. The development of limbs, lungs, and other features required for terrestrial life, as well as regression of the tail, are driven by T_3.

Thyroid hormone plays a critical role in brain development by mechanisms that are incompletely understood (Abduljabbar and Afifi, 2012). The absence of thyroid hormone during the period of active neurogenesis (up to 6 months postpartum) leads to irreversible intellectual disability and is accompanied by multiple morphological alterations in the brain. These severe morphological alterations result from disturbed neuronal migration, deranged axonal projections, and decreased synaptogenesis. Thyroid hormone supplementation begun during the first 2 weeks of postnatal life can prevent the development of these morphological changes. The extensive defects in growth and development in untreated congenital hypothyroidism vividly illustrate the pervasive effects of thyroid hormones in normal individuals.

Severe hypothyroidism in infancy (congenital iodine deficiency syndrome) can be *endemic* (caused by extreme environmental iodine deficiency) or *sporadic* (a consequence of abnormal thyroid development or a defect in the synthesis of thyroid hormone). The affected child usually appears normal at birth but subsequently manifests decreased growth with short extremities, intellectual disability, and listlessness. Other manifestations include puffy face, enlarged tongue, dry and doughy skin, slow heart rate, constipation, and decreased body temperature. For treatment to be fully effective, the diagnosis must be made shortly after birth and T_4 treatment initiated long before these clinical manifestations are apparent. In regions of endemic iodine deficiency, iodine replacement is best instituted before pregnancy. Screening of newborn infants for deficient thyroid function is carried out in the U.S. and in most industrialized countries.

Skeleton

Childhood hypothyroidism results in decreased linear growth, delayed bone age, and epiphyseal dysgenesis (Wojcicka et al., 2013). That these effects are mediated through TRα1 is demonstrated by the similar short stature, delayed ossification, and skeletal dysplasia that characterize subjects with *THRA* gene mutations. Childhood thyrotoxicosis also can cause decreased final height, but this is due to rapid bone maturation with premature fusion of the epiphyseal growth plates. In the adult, thyrotoxicosis accelerates bone turnover and can increase the risk of osteoporosis, especially in concert with postmenopausal estrogen deficiency.

Thermogenesis

Thyroid hormone is necessary for both obligatory thermogenesis (the heat resulting from vital processes) and facultative or adaptive thermogenesis (Mullur et al., 2014). Only a few organs, including the brain, gonads, and spleen, are unresponsive to the thermogenic effects of T_3. Obligatory thermogenesis is the result of T_3 making most biological processes thermodynamically less efficient for the sake of producing heat. It is likely that multiple mechanisms contribute to this effect, such as the induction of futile cycling, changes in mitochondrial energetics, stimulation of the Na^+/K^+ gradient across the cell membrane, and stimulation of the Ca^{2+} gradient between the cytoplasm and the sarcoplasmic reticulum. Thermogenesis is highly sensitive to thyroid hormone around the physiological range: Small changes in *levothyroxine* replacement doses may significantly alter resting energy expenditure in the hypothyroid patient. The capacity of T_3 to stimulate thermogenesis has evolved along with ancillary effects to support this action, such as the stimulation of appetite and lipogenesis

Cardiovascular System

Hyperthyroid patients have tachycardia, increased stroke volume, increased cardiac index, cardiac hypertrophy, decreased peripheral vascular resistance, and increased pulse pressure (Grais and Sowers, 2014). Hyperthyroidism is a relatively common cause of atrial fibrillation. Hypothyroid patients have bradycardia, decreased cardiac index, pericardial effusion, increased peripheral vascular resistance, decreased pulse pressure, and elevation of mean arterial pressure.

T_3 regulates myocardial gene expression primarily through TRα1, which is expressed at a higher level in cardiomyocytes than TRβ. T_3 increases the speed of diastolic relaxation (lusitropic effect) by inducing expression of the sarcoplasmic reticulum ATPase SERCA2 and decreasing phospholamban, a SERCA2 inhibitor. T_3 increases the force of myocardial contraction (inotropic effect) in part by inducing expression of the ryanodine receptor-channel (RyR2), the calcium channel of the sarcoplasmic reticulum. T_3 induces the gene encoding the α isoform of myosin heavy chain (MHC) and decreases expression of MHCβ. Because MHCα endows the myosin holoenzyme with greater ATPase activity, this is one mechanism by which T_3 enhances the velocity of contraction. The chronotropic effect of T_3 is mediated at least in part by increases in the pacemaker ion current I_f in the sinoatrial node. Several proteins that comprise the I_f channel are induced by T_3, including the hyperpolarization-activated, cyclic nucleotide–gated cation channels HCN2 and HCN4. T_3 also has a vasodilating effect on vascular smooth muscle. The mechanism is multifactorial and appears to include rapid nongenomic stimulation of endothelial cell NO production, which contributes to the decreased systemic vascular resistance and increased cardiac output of hyperthyroidism.

Lipid Metabolism

Thyroid hormone stimulates the expression of hepatic LDL receptors and reduces apolipoprotein B levels through non-LDL receptor pathways (Mullur et al., 2014), such that hypercholesterolemia is a characteristic feature of hypothyroidism.

Disorders of Thyroid Function

Thyroid Hypofunction

Hypothyroidism, known as *myxedema* when severe, is the most common disorder of thyroid function. Worldwide, hypothyroidism resulting from iodine deficiency remains a common problem. In nonendemic areas where iodine is sufficient, chronic autoimmune thyroiditis (Hashimoto thyroiditis) accounts for most cases. This disorder is characterized by circulating antibodies directed against thyroid peroxidase and, sometimes, against thyroglobulin. These conditions are examples of *primary hypothyroidism,* failure of the thyroid gland itself. *Central hypothyroidism* occurs much less often and results from diminished stimulation of the thyroid by TSH because of pituitary failure (*secondary hypothyroidism*) or hypothalamic failure (*tertiary hypothyroidism*). Hypothyroidism present at birth (*congenital hypothyroidism*) is an important preventable cause of intellectual disability in the world.

Common symptoms of hypothyroidism include fatigue, lethargy, cold intolerance, mental slowness, depression, dry skin, constipation, mild weight gain, fluid retention, muscle aches and stiffness, irregular menses, and infertility. Common signs include goiter (primary hypothyroidism only), bradycardia, delayed relaxation phase of the deep tendon reflexes, cool and dry skin, hypertension, nonpitting edema, and facial puffiness. Deficiency of thyroid hormone during the first few months of life causes feeding problems, failure to thrive, constipation, and sleepiness. Impairment of mental development is irreversible if not treated promptly. Childhood hypothyroidism impairs linear growth and bone maturation. Because the signs and symptoms of hypothyroidism are nonspecific, diagnosis requires the finding of an elevated serum TSH level and reduced or low-normal serum free T_4 or, in cases of central hypothyroidism, only a decreased serum free T_4.

Thyroid Hyperfunction

Thyrotoxicosis is a condition caused by elevated concentrations of circulating free thyroid hormones. Increased thyroid hormone production is the most common cause, with the common link of TSH receptor stimulation and increased iodine uptake by the thyroid gland, as established by the measurement of the percentage uptake of ^{123}I in a 24-h radioactive iodine uptake (RAIU) test.

TSH receptor stimulation is either the result of TSH receptor stimulating antibodies in Graves disease or somatic activating TSH receptor mutations in autonomously functioning nodules or a toxic goiter. In contrast, thyroid inflammation or destruction resulting in excess "leak" of thyroid hormones or excess exogenous thyroid hormone intake results in a low 24-h RAIU test. The term *subclinical hyperthyroidism* is defined as those with a subnormal serum TSH and normal concentrations of free T_4 and T_3. Atrial arrhythmias, excess cardiac mortality, and excessive bone loss have been associated with this profile of thyroid function tests.

Graves disease is the most common cause of high RAIU thyrotoxicosis, accounting for 60% to 90% of cases, depending on age and geographic region. Graves disease is an autoimmune disorder characterized by increased thyroid hormone production, diffuse goiter, and IgG antibodies that bind to and activate the TSH receptor. As with most types of thyroid dysfunction, women are affected more than men, with a ratio ranging from 5:1 to 7:1. While Graves disease may occur at any age, it is more common between the ages of 20 and 50. Graves disease is commonly associated with other autoimmune diseases. The characteristic exophthalmos associated with Graves disease is an infiltrative ophthalmopathy and is considered an autoimmune-mediated inflammation of the periorbital connective tissue and extraocular muscles. Toxic uninodular/multinodular goiter accounts for 10% to 40% of cases of hyperthyroidism and is more common in older patients. A low RAIU value is seen in the destructive thyroiditides and in thyrotoxicosis in patients taking excessive doses of thyroid hormone.

Most of the signs and symptoms of thyrotoxicosis stem from the excessive production of heat, increased motor activity, and increased sensitivity to catecholamines produced by the sympathetic nervous system. The skin is flushed, warm, and moist; the muscles are weak and tremulous; the heart rate is rapid, the heartbeat is forceful, and the arterial pulses are prominent and bounding. Increased expenditure of energy gives rise to increased appetite and, if intake is insufficient, to loss of weight. There also may be insomnia, difficulty in remaining still, anxiety and apprehension, intolerance to heat, and increased frequency of bowel movements. Angina, arrhythmias, and heart failure may be present in older patients. Older patients may experience lessened manifestations of sympathetic nervous system stimulation and reduced symptoms compared to younger individuals, sometimes referred to as "apathetic hyperthyroidism." Some individuals may show extensive muscular wasting as a result of thyroid myopathy. The most severe form of hyperthyroidism is thyroid storm (see section that follows on therapeutic uses of antithyroid drugs).

Thyroid Function Tests

Measurement of the total hormone concentration in plasma may not give an accurate picture of the activity of the thyroid gland; total hormone concentration changes with alterations in amount and affinity of TBG in plasma. Although equilibrium dialysis of undiluted serum and radioimmunoassay for free T_4 in the dialysate represent the gold standard for determining free T_4 concentrations, this assay is costly and typically unavailable in routine clinical laboratories. The most common assays used for estimating the free T_4 and free T_3 concentrations employ labeled analogues of these iodothyronines in chemiluminescence and enzyme-linked immunoassays. These assays are subject to influences of altered serum-binding proteins, nonthyroid disease states, acute illnesses, and other drugs. In individuals with normal pituitary function, serum measurement of TSH is the thyroid function test of choice because pituitary secretion of TSH is sensitively regulated in response to circulating concentrations of thyroid hormones. TSH is suppressed in patients with thyrotoxicosis and elevated in those with primary hypothyroidism, and these changes generally precede abnormalities in free T_4 and free T_3.

Thyroid Hormone Preparations

Synthetic preparations of the sodium salts of the natural isomers of T_4 and T_3 are used for thyroid hormone therapy (Biondi and Wartofsky, 2014).

Levothyroxine

Chemistry and Mechanism of Action

The chemistry and mechanism of action are identical to those of endogenous T_4 and have been presented above.

ADME

Levothyroxine sodium is available in tablets and liquid-filled capsules for oral administration and as a lyophilized powder for injection. Absorption of *levothyroxine* occurs in the stomach and small intestine and is incomplete (~80% of the tablet dose is absorbed). Absorption is slightly increased when the hormone is taken on an empty stomach, and it is associated with less variability in TSH levels when taken this way regularly. Patients with gastrointestinal problems that result in poor absorption of tablet formulations may achieve better absorption with liquid-filled capsules. Serum T_4 peaks 2 to 4 h after oral ingestion, but changes are barely discernible with once-daily dosing due to the plasma $t_{1/2}$ of about 7 days. Given this long $t_{1/2}$, omission of one day's dose has only marginal effects on the serum TSH and free T_4, but to maintain consistent dosing, the patient should be instructed to take a double dose the next day. Additional ADME data for *levothyroxine* are the same as for endogenous T_4 and have been presented above. If patients cannot take oral medications or intestinal absorption is in question, *levothyroxine* may be given intravenously once daily at a dose of about 80% of the patient's daily oral requirement. For any given serum TSH, the serum T_4/T_3 ratio is slightly higher in patients taking *levothyroxine* than in patients with endogenous thyroid function due to the fact that about 20% of circulating T_3 normally is supplied by direct thyroidal secretion (Gullo et al., 2011).

Liothyronine

Chemistry and Mechanism of Action

The chemistry and mechanism of action are identical to those of endogenous T_3 and have been presented above.

ADME

Liothyronine sodium is the salt of T_3 and is available in tablets and in an injectable form. *Liothyronine* absorption is nearly 100%, with peak serum levels 2 to 4 h following oral ingestion. Additional ADME data for *liothyronine* are the same as for endogenous T_3 and have been presented above. On a weight basis, the required daily dose of *liothyronine* (given three times a day to achieve steady serum T_3 levels) is about one-third that of *levothyroxine* to achieve an equivalent TSH level in hypothyroid patients (Celi et al., 2011). However, normalization of circulating TSH requires an almost 2-fold higher serum T_3 compared with *levothyroxine* therapy because negative feedback on TSH normally relies in part on the local generation of T_3 from circulating T_4.

Liothyronine may be used occasionally for thyroid hormone replacement when a rapid onset of action is desired, such as in the rare presentation of myxedema coma, or if rapid termination of action is desired, such as when preparing a patient with thyroid cancer for ^{131}I therapy. *Liothyronine* is less desirable than *levothyroxine* for chronic replacement therapy due to the requirement for more-frequent dosing (plasma $t_{1/2}$ is ~20 h), higher cost, and transient elevations of serum T_3 concentrations above the normal range. Also, organs that express Dio2 use the locally generated T_3 in addition to plasma T_3; hence, there is theoretical concern that these organs will not maintain physiological intracellular T_3 levels in the absence of plasma T_4.

T_4/T_3 Combination Preparations

A mixture of *levothyroxine* and *liothyronine* around 4:1 by weight, and desiccated thyroid preparations with a similar T_4:T_3 ratio, also are available. A 60-mg (1-grain) desiccated thyroid tablet is approximately equivalent to 65 μg of *levothyroxine* in TSH-lowering capacity.

Therapeutic Uses of Thyroid Hormone

The major indications for the therapeutic use of thyroid hormone are for hormone replacement therapy in patients with hypothyroidism and for TSH suppression therapy in patients with thyroid cancer.

Thyroid Hormone Replacement Therapy in Hypothyroidism

Levothyroxine is the hormone of choice for thyroid hormone replacement therapy due to its consistent potency and prolonged duration of action (Jonklaas et al., 2014). This therapy relies on Dio1 and Dio2 to convert T_4 to T_3 to maintain a steady serum level of free T_3.

The average daily adult full replacement dose of *levothyroxine* is 1.7 μg/kg body weight (0.8 μg/lb). Dosing should generally be based on lean body mass. The goal of therapy is to normalize the serum TSH (in primary hypothyroidism) or free T_4 (in secondary or tertiary hypothyroidism) and to relieve symptoms of hypothyroidism. In primary hypothyroidism, generally it is sufficient to follow TSH without free T_4. A patient with mild primary hypothyroidism will achieve a normal TSH with substantially less than a full replacement dose, but as the endogenous thyroid function declines, the dose will need to be increased. In individuals older than 60 years and those with known or suspected cardiac disease or with areas of autonomous thyroid function, institution of therapy at a subreplacement dose of *levothyroxine* (12.5–50 μg/day) is appropriate. The dose can be increased by 25 μg/day every 6 weeks until the TSH is normalized. Follow-up blood tests typically are done about 6 weeks after any dosage change due to the 1-week plasma $t_{1/2}$ of T_4. The vast majority of controlled trials do not support the hypothesis that combination therapy with T_4 plus T_3 provides a better therapeutic response than does T_4 alone (Jonklaas et al., 2021), although for unclear reasons, occasionally patients say they feel better when taking combination therapies, such as desiccated thyroid. A double-blind crossover study of hypothyroid patients comparing *levothyroxine* and desiccated thyroid, maintaining the same reference range TSH, found that those who preferred desiccated thyroid had lost weight on this preparation. Monotherapy with *levothyroxine* most closely mimics normal physiology and generally is recommended (Jonklaas et al., 2014).

Although *levothyroxine* monotherapy is the recommended therapy in hypothyroidism, it is worth noting that this does not precisely replicate thyroid gland secretion because 20% of circulating T_3 normally derives directly from the thyroid. The published studies comparing T_4/T_3 combination therapy with T_4 alone have significant limitations, and it remains possible that there exists a currently undefined subgroup of individuals for whom combination therapy would result in an improved clinical outcome (Jonklaas et al., 2021). For example, the published comparison trials have not focused on hypothyroid patients who feel unwell while taking *levothyroxine* despite clearly euthyroid TSH and free T_4 levels, nor have there been large trials focused on individuals with the Dio2 Thr92Ala polymorphism, which was discussed earlier. An ideally designed test of T_4/T_3 combination therapy would be difficult to conduct at this time because there are no long-acting preparations of *liothyronine* and there are no T_4/T_3 combination preparations that match the approximately 11:1 T_4:T_3 ratio of thyroid gland secretion. Nevertheless, it should be emphasized that the vast majority of hypothyroid patients feel well on *levothyroxine* monotherapy and the published outcomes from trials of T_4/T_3 combination therapy provide little evidence for benefit of combination therapy over T_4 alone.

Hypothyroidism During Pregnancy

Due to the increased serum concentration of TBG induced by estrogen, the expression of Dio3 by the placenta, and the small amount of transplacental passage of T_4 from mother to fetus, a higher dose of *levothyroxine* is usually required in pregnant patients. Overt hypothyroidism during pregnancy is associated with increased risk of miscarriage, fetal distress, preterm delivery, and impaired psychoneural and motor development in the progeny. Even mild maternal hypothyroidism may have subtle adverse effects. As part of prepregnancy planning, the dose of *levothyroxine* should be adjusted to maintain the TSH in the lower portion of the reference range. Women should increase their *levothyroxine* dose by about 30% as soon as pregnancy is confirmed, thus anticipating the increased need (Jonklaas et al., 2014). Being proactive instead of reactive is recommended since avoiding maternal hypothyroidism is important, and the approximate 7-day plasma T_4 $t_{1/2}$ means that it takes many weeks for free T_4 and TSH to reach new steady states after a *levothyroxine* dosage change. In patients taking a single *levothyroxine* tablet daily, the 30% dosage increase can be achieved by taking two extra tablets per week. The serum TSH is measured 4 to 6 weeks later, and the *levothyroxine* dose is further adjusted with the goal of maintaining the TSH in the lower portion of the reference range. Subsequent dosage adjustments are based on serum TSH, measured 4 to 6 weeks after each adjustment. TSH should be monitored frequently through the first 20 weeks' gestation when the dose adjustment is usually maximal and then less often. The *levothyroxine* dosage should revert to the prepregnancy level the day after delivery, with a follow-up TSH checked about 6 weeks later.

Isolated *hypothyroxinemia* during pregnancy, defined by a low serum free T_4 concentration and normal serum TSH concentration, has been associated in a few studies with adverse neurocognitive development in the offspring. There are currently insufficient studies to recommend routine treatment of isolated hypothyroxinemia in pregnancy. Evaluation and treatment are further complicated by the influence of the elevated serum-binding proteins in pregnancy and lower values obtained for free T_4 by the analogue method, especially in the second and third trimesters. There is some debate as to whether standard laboratory analogue free T_4 assays or total T_4 combined with an assessment of protein binding, such as T_3 uptake, more accurately reflects the true free T_4 during pregnancy. TSH remains the best test during pregnancy to evaluate thyroid status and response to treatment.

Myxedema Coma

Myxedema coma is a rare syndrome that represents the extreme expression of severe, long-standing hypothyroidism. Common precipitating factors include infection, congestive heart failure, and medical noncompliance. Myxedema coma occurs most often in elderly patients during the winter months. Cardinal features of myxedema coma are *hypothermia*, *respiratory depression*, and *decreased consciousness*.

Intravenous administration of thyroid hormone is advised (Jonklaas et al., 2014). Therapy with *levothyroxine* is begun with a loading dose of 200 to 400 μg followed by a daily full replacement dose or slightly less in the very elderly or in patients with cardiac disease (typically 50–100 μg/day intravenously). Some clinicians recommend adding *liothyronine* (10 μg intravenously followed by 2.5–10 μg every 8 h) until the patient is stable and conscious. Other important aspects of therapy include ventilatory support, passive warming with blankets, correction of hyponatremia, and treatment of the precipitating cause. Treatment with intravenous glucocorticoids is recommended until coexisting adrenal insufficiency is excluded.

Congenital Hypothyroidism

Success in the treatment of congenital hypothyroidism depends on the age at which therapy is started and the speed with which hypothyroidism is corrected. If therapy is instituted within the first 2 weeks of life, normal physical and intellectual development can be achieved (Cherella and Wassner, 2020).

To rapidly normalize the serum T_4 concentration in the congenitally hypothyroid infant, an initial daily dose of *levothyroxine* of 10 to 15 μg/kg is recommended (Cherella and Wassner, 2020; Jonklaas et al., 2014). The *levothyroxine* is administered orally as crushed tablets mixed with breast milk or water. Because rapid normalization is even more important in infants with severe hypothyroidism, doses on the higher side of the above range are preferred in those infants. There are mixed reports as to whether brand name and generic *levothyroxine* are bioequivalent in infants with severe congenital hypothyroidism, which has led some experts to recommend against generic *levothyroxine* in this situation. The biochemical goal is to achieve a free T_4 in the upper half of the reference range and a TSH in the lower half, although some infants maintain a high

TSH that seems to reflect mis-set feedback regulation. Laboratory evaluations of TSH and free T_4 are performed approximately every 2 weeks until the laboratory goals have been achieved, then every 1 to 3 months for the first year of life, every 2 to 4 months until 3 years of age, and every 3 to 12 months from age 3 years until the end of growth. Monitoring should be more frequent if the results are abnormal or compliance is in doubt. Soy formula may impair *levothyroxine* absorption, necessitating a dosage increase.

Thyroid Hormone Replacement in Thyroid Cancer

The mainstays of therapy for well-differentiated thyroid cancer (papillary, follicular) are surgical thyroidectomy, *radioiodine* (discussed in material that follows), and *levothyroxine* to maintain a low TSH (Haugen et al., 2016). The rationale for TSH suppression is that TSH is a growth factor for thyroid cancer, but there are no randomized controlled trials that addressed the optimal TSH target range. A reasonable approach is to adjust the *levothyroxine* dose to maintain a low-normal TSH value in patients without persistent disease and at low risk for recurrence, a mildly subnormal TSH value (~0.1 mU/L) in patients at high risk for recurrence, and a more subnormal TSH level (<0.1 mU/L) for patients with persistent disease. The benefits of TSH suppression need to be weighed against the risks, including osteoporosis and atrial fibrillation.

Thyroid Nodules

Nodular thyroid disease is the most common endocrinopathy. Thyroid nodules usually are asymptomatic, although they can cause neck discomfort, dysphagia, and a choking sensation. As with other forms of thyroid disease, nodules are more frequent in women. Exposure to ionizing radiation, especially in childhood, increases the rate of nodule development. Approximately 5% of thyroid nodules that come to medical attention are malignant. Most patients with thyroid nodules are euthyroid, which should be confirmed by TSH measurement. The most useful diagnostic procedures generally are ultrasound imaging and a fine-needle aspiration biopsy. The use of *levothyroxine* to suppress TSH in euthyroid individuals with thyroid nodules cannot be recommended as a general practice. However, if the TSH is elevated, it is appropriate to administer *levothyroxine* to bring the TSH into the lower portion of the reference range.

Adverse Effects of Thyroid Hormone

Adverse effects of thyroid hormone generally occur only on overtreatment and are similar to the consequences of hyperthyroidism. An excess of thyroid hormone can increase the risk of atrial fibrillation, especially in the elderly, and can increase the risk of osteoporosis, especially in postmenopausal women.

Drug Interactions

Table 47–3 lists drugs and other factors that may influence *levothyroxine* dosage requirements.

Investigational Uses of Thyroid Hormone Analogues

Thyroid hormone analogues that bind TRβ in preference to TRα1 could in principle regulate thyroid hormone–dependent processes in liver or other TRβ-dependent organs without causing cardiac side effects. Several relatively TRβ-specific agonists have been developed with this goal in mind (Zucchi, 2020). TRβ-specific agonists were tested but are not currently being pursued as therapies for hypercholesterolemia. However, the TRβ-specific agonist *resmetirom* is under investigation as therapy for nonalcoholic fatty liver disease.

The T_3 metabolite triac does not depend on the thyroid hormone transporters MCT8 and OATP1C1 for entry into cells. As described above, triac is being studied as a potential therapy for Allan-Herndon-Dudley syndrome, which is caused by MCT8 deficiency, and has been used to treat one patient with an OATP1C1 mutation.

TABLE 47–3 ■ IMPORTANT FACTORS INFLUENCING ORAL LEVOTHYROXINE THERAPY

Drugs and other factors that may increase levothyroxine dosage requirements
Impaired levothyroxine absorption
Aluminum-containing antacids, proton pump inhibitors, sucralfate
Bile acid sequestrants (cholestyramine, colestipol, colesevelam)
Calcium carbonate (effect generally small), phosphate binders (lanthanum carbonate, sevelamer)
Chromium picolinate, raloxifene, iron salts
Orlistat, kayexalate, simethicone
Food, soy products (effect generally very small), lactose intolerance (single case report)
Increased thyroxine metabolism, CYP3A4 induction
Rifampin, carbamazepine, phenytoin, sertraline, phenobarbital
Impaired $T_4 \rightarrow T_3$ conversion
Amiodarone, glucocorticoids, beta blockers
Mechanisms uncertain or multifactorial
Estrogen, pregnancy, lovastatin, simvastatin, ethionamide, Tyr kinase inhibitors
Drugs and other factors that may decrease levothyroxine dosage requirements
Advancing age (>65 years), androgen therapy in women
Drugs that may decrease TSH without changing free T_4 in levothyroxine-treated patients
Metformin

Antithyroid Drugs and Other Thyroid Inhibitors

Myriad compounds are capable of interfering, directly or indirectly, with the synthesis, release, or action of thyroid hormones (Tables 47–3 and 47–4). Several types are clinically useful:

- Antithyroid drugs, which interfere directly with the synthesis of thyroid hormones
- Ionic inhibitors, which block the iodide transport mechanism
- High concentrations of iodine, which decrease release of thyroid hormones from the gland and also may decrease hormone synthesis
- Radioactive iodine, which damages the thyroid gland with ionizing radiation

TABLE 47–4 ■ SOME AGENTS THAT DISRUPT THYROID HORMONE SYNTHESIS, RELEASE, AND METABOLISM

MECHANISM	AGENT
Iodide uptake	Perchlorate, fluoroborate, thiocyanate, nitrate
Organification of iodine	Thionamides (propylthiouracil, methimazole, carbimazole), thiocyanate, sulfonamides
Coupling reaction	Sulfonamides, thionamides
Hormone release	Li^+ salts, iodide
Peripheral iodothyronine deiodination	Propylthiouracil, amiodarone, oral cholecystographic agents
Accelerated hepatic metabolism	Phenobarbital, rifampin, carbamazepine, phenytoin, sertraline, bexarotene

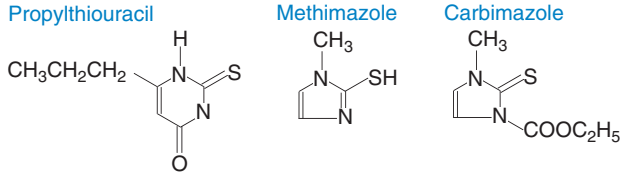

Figure 47–7 *Structures of antithyroid drugs of the thioamide type.*

Adjuvant therapy with drugs that have no specific effects on thyroid hormone synthesis is useful in controlling the peripheral manifestations of thyrotoxicosis, including inhibitors of the peripheral deiodination of T_4 to T_3, β adrenergic receptor antagonists, and Ca^{2+} channel blockers.

Antithyroid Drugs

The antithyroid drugs with clinical utility are the *thioureylenes*, which belong to the family of thioamides. *Propylthiouracil* is the prototype (Figure 47–7).

HISTORICAL PERSPECTIVE

Studies on the mechanism of the development of goiter began with the observation that rabbits fed a diet composed largely of cabbage often developed goiters. This result was probably due to the presence of precursors of the thiocyanate ion in cabbage leaves. Later, two pure compounds were shown to produce goiter: *sulfaguanidine*, a sulfanilamide antimicrobial used to treat enteric infections, and *phenylthiourea*. Investigation of the effects of thiourea derivatives revealed that rats became hypothyroid despite hyperplastic changes in their thyroid glands that were characteristic of intense thyrotropic stimulation. After treatment was begun, no new hormone was made, and the goitrogen had no visible effect on the thyroid gland following hypophysectomy or the administration of thyroid hormone. This suggested that the goiter was a compensatory change resulting from the induced state of hypothyroidism and that the primary action of the compounds was to inhibit the formation of thyroid hormone. The therapeutic possibilities of such agents in hyperthyroidism were evident, and the substances so used became known as *antithyroid drugs*.

Mechanism of Action

Antithyroid drugs inhibit the formation of thyroid hormones by interfering with the incorporation of iodine into tyrosyl residues of thyroglobulin; they also inhibit the coupling of these iodotyrosyl residues to form iodothyronines (see Figure 47–2). These drugs are thought to inhibit the peroxidase enzyme. Inhibition of hormone synthesis results in the depletion of stores of iodinated thyroglobulin as the protein is hydrolyzed and the hormones are released into the circulation. In addition to blocking hormone synthesis, *propylthiouracil* partially inhibits the peripheral deiodination of T_4 to T_3. *Methimazole* does not have this effect; this provides a rationale for the choice of *propylthiouracil* over other antithyroid drugs in the treatment of severe hyperthyroid states or of thyroid storm (Angell et al., 2015).

ADME

The antithyroid compounds currently used in the U.S. are *methimazole* (1-methyl-2-mercaptoimidazole) and, for limited indications, *propylthiouracil* (6-*n*-propylthiouracil). In Europe, *carbimazole*, a carbethoxy derivative of *methimazole*, is available, and its antithyroid action is due to its conversion to *methimazole* after absorption (see Figure 47–7). Pharmacological properties of *methimazole* and *propylthiouracil* are shown in Table 47–5.

A small dose of *methimazole*, 0.5 mg, decreases the organification of iodine in the thyroid gland, but a single dose of 10 to 25 mg is needed to extend the inhibition to 24 h. Absorption of effective amounts of *propylthiouracil* occurs within 20 to 30 min of an oral dose; the duration of action is brief. The effect of a dose of 100 mg of *propylthiouracil* begins to wane in 2 to 3 h; even a 500-mg dose is completely inhibitory for only 6 to 8 h.

The plasma $t_{1/2}$ of *methimazole* is 4 to 6 h; the $t_{1/2}$ of *propylthiouracil* is about 75 min. The drugs are concentrated in the thyroid, and *methimazole*, derived from the metabolism of *carbimazole*, accumulates after *carbimazole* is administered. Drugs and metabolites appear largely in the urine.

TABLE 47–5 ■ PHARMACOKINETIC FEATURES OF ANTITHYROID DRUGS

	PROPYLTHIOURACIL	METHIMAZOLE
Plasma protein binding	~75%	Nil
Plasma $t_{1/2}$	75 min	~4–6 h
Volume of distribution	~0.4 L/kg	~0.7 L/kg
Concentrated in thyroid	Yes	Yes
Metabolism of drug during illness		
Severe liver disease	Normal	Decreased
Severe kidney disease	Normal	Normal
Dosing frequency	1–4 times daily	Once or twice daily
Transplacental passage	Low	Low
Levels in breast milk	Low	Low

Therapeutic Uses

The antithyroid drugs are used in the treatment of hyperthyroidism in the following ways:

- As definitive treatment to control the disorder in anticipation of a spontaneous remission in Graves disease, or as long-term therapy in patients who do not undergo spontaneous remission and prefer medication rather than *radioiodine* treatment or surgery
- In conjunction with radioactive iodine, to hasten recovery while awaiting the effects of radiation
- To control the disorder in preparation for surgical treatment

Methimazole is the drug of choice for Graves disease; it is effective when given as a single daily dose, has improved adherence, and is less toxic than *propylthiouracil*, especially having a reduced risk of the very rare but devastating complication of liver failure. *Methimazole* has a relatively long plasma and intrathyroidal $t_{1/2}$, as well as a long duration of action. The usual starting dose for *methimazole* is 15 to 40 mg/day. The usual starting dose of *propylthiouracil* is 100 mg every 8 h. When doses greater than 300 mg daily are needed, further subdivision of the time of administration to every 4 to 6 h is occasionally helpful. Once euthyroidism is achieved, usually within 12 weeks, the dose of antithyroid drug can be reduced, but not stopped, lest an exacerbation of Graves disease occur.

Response to Treatment

The thyrotoxic state usually improves within 3 to 6 weeks after the initiation of antithyroid drugs. The clinical response is related to the dose of antithyroid drug, the size of the goiter, and pretreatment serum T_3 concentration. The rate of response is determined by the quantity of stored hormone, the rate of turnover of hormone in the thyroid, the $t_{1/2}$ of the hormone in the periphery, and the completeness of the block in synthesis imposed by the dosage given. Hypothyroidism may develop as a result of overtreatment. After treatment is initiated, patients should be examined and thyroid function tests (serum free T_4 and total or free T_3 concentrations) measured every 2 to 4 months. Once euthyroidism is established, follow-up every 4 to 6 months is reasonable. Control of the hyperthyroidism is usually associated with a decrease in goiter size and normalization of serum TSH concentration. When this occurs, the dose of the antithyroid drug should be significantly decreased to avoid hypothyroidism.

Untoward Reactions

The incidence of side effects from *propylthiouracil* and *methimazole* as currently used is relatively low. Fulminant hepatic necrosis is an exceedingly rare but potentially devastating complication of therapy with *propylthiouracil* that can result in death or the need for liver transplantation. It is estimated to occur in 1 in 10,000 adults or 1 in 2000 children taking this drug. Agranulocytosis is a serious reaction that occurs in 0.1% to 0.5% of patients taking either *propylthiouracil* or *methimazole*, usually in the first few weeks or months of therapy but sometimes later. Because agranulocytosis usually occurs rapidly and is not associated with a gradual reduction in granulocyte count, periodic prospective monitoring of granulocyte count is not generally helpful. Patients should be instructed to immediately report the development of sore throat or fever and should discontinue their antithyroid drug and obtain a granulocyte count. Agranulocytosis is reversible on discontinuation of the offending drug, and the administration of recombinant human granulocyte colony-stimulating factor may hasten recovery. Mild granulocytopenia, if noted, may be due to thyrotoxicosis or may be the first sign of this dangerous drug reaction; frequent leukocyte counts are then required.

The most common reaction is a mild urticarial papular rash that often subsides spontaneously without interrupting treatment but sometimes requires administration of an antihistamine and corticosteroids and changing to another antithyroid drug. Other less frequent complications are pain and stiffness in the joints, paresthesias, headache, nausea, skin pigmentation, and loss of hair. Drug fever, hepatitis, and nephritis are rare, although abnormal liver function tests are not infrequent with higher doses of *propylthiouracil*. Although vasculitis was previously thought to be a rare complication, antineutrophilic cytoplasmic antibodies have been reported to occur in about 50% of patients receiving *propylthiouracil* and rarely with *methimazole*. Hypoprothrombinemia and bleeding have also been reported with *methimazole* treatment.

Thyrotoxicosis in Pregnancy

Thyrotoxicosis occurs in about 0.2% of pregnancies and is caused most frequently by Graves disease. Antithyroid drugs are the treatment of choice; radioactive iodine is clearly contraindicated. Both *propylthiouracil* and *methimazole* cross the placenta equally, and both have been used safely in the pregnant patient. *Methimazole* is usually avoided in the first trimester in favor of *propylthiouracil* due to *methimazole*-associated embryopathy, and then *methimazole* is used for the remainder of the pregnancy due to the concern for *propylthiouracil*-associated liver failure in pregnancy. The more recent recognition of *propylthiouracil*-associated embryopathy from exposure in the first trimester, especially those defects that are not apparent at birth and detected later, such as in the urinary collecting system, has challenged this approach. Guidelines now recommend limiting use of antithyroid drugs as much as possible in the first trimester (Alexander et al., 2017). The antithyroid drug dosage should be minimized to keep the serum free T_4 index in the upper half of the normal range or slightly elevated. As pregnancy progresses, Graves disease often improves. Relapse or worsening of Graves disease is common after delivery, and patients should be monitored closely. *Methimazole* in nursing mothers, up to 20 mg daily, reportedly has no effect on thyroid function in the infant; *propylthiouracil* is thought to partition into breast milk even less than *methimazole*.

Adjuvant Therapy

Several drugs that have no intrinsic antithyroid activity are useful in the symptomatic treatment of thyrotoxicosis.

The *β adrenergic receptor antagonists* (see Chapter 14) are effective in antagonizing the sympathetic/adrenergic effects of thyrotoxicosis—thereby reducing the tachycardia, tremor, and stare—and relieving palpitations, anxiety, and tension. Either *propranolol*, 20 to 40 mg four times daily, or *atenolol*, 50 to 100 mg daily, is usually given initially.

The *Ca^{2+} channel blockers* (*diltiazem*, 60–120 mg four times daily) can be used to control tachycardia and decrease the incidence of supraventricular tachyarrhythmias. Usually, only short-term treatment with β adrenergic receptor antagonists or Ca^{2+} channel blockers is required (2–6 weeks), and it should be discontinued once the patient is euthyroid.

Immunotherapy has been used for Graves hyperthyroidism and ophthalmopathy. The B-lymphocyte–depleting agent *rituximab*, when used with *methimazole*, prolongs remission of Graves disease. The IGF-1 receptor blocker *teprotumumab* has shown remarkable effects in patients with advanced ophthalmopathy, with almost 80% of treated patients showing improvement (see Chapter 74).

Thyroid Storm

Thyroid storm is an uncommon but life-threatening complication of thyrotoxicosis in which a severe form of the disease is usually precipitated by an intercurrent medical problem. It occurs in untreated or partially treated thyrotoxic patients. Precipitating factors associated with thyrotoxic crisis include infections, stress, trauma, thyroidal or nonthyroidal surgery, diabetic ketoacidosis, labor, heart disease, and, rarely, radioactive iodine treatment.

Clinical features are similar to those of thyrotoxicosis but more exaggerated. Cardinal features include fever (temperature usually >38.5°C) and tachycardia out of proportion to the fever. Nausea, vomiting, diarrhea, agitation, and confusion are frequent presentations. Coma and death may ensue in up to 20% of patients. Thyroid function abnormalities are similar to those found in uncomplicated hyperthyroidism. Therefore, thyroid storm is primarily a clinical diagnosis.

Treatment includes supportive measures such as intravenous fluids, antipyretics, cooling blankets, and sedation. Antithyroid drugs are given in large doses. *Propylthiouracil* is preferred over *methimazole* because it also inhibits Dio1, thus impairing peripheral conversion of T_4 to T_3. Oral iodides are used after the first dose of an antithyroid drug has been administered. Treatment of the underlying precipitating illness is essential.

Ionic Inhibitors

The *ionic inhibitors* are substances that interfere with the concentration of iodide by the thyroid gland. These agents are anions that resemble iodide: *thiocyanate*, *perchlorate*, and *fluoroborate*, all monovalent hydrated anions of a size similar to that of iodide.

Thiocyanate differs from the rest qualitatively; it is not concentrated by the thyroid gland but in large amounts may inhibit the organification of iodine. *Perchlorate* is 10 times as active as *thiocyanate*. *Perchlorate* (ClO_4^-) blocks the entrance of iodide into the thyroid by competitively inhibiting the NIS and itself can be transported by NIS into the thyroid gland. The various NIS inhibitors (*perchlorate*, *thiocyanate*, and *nitrate*) are additive in inhibiting iodine uptake. *Perchlorate* can be used to control hyperthyroidism; however, when given in excessive amounts (2–3 g daily), it has caused fatal aplastic anemia. *Perchlorate* in doses of 750 mg daily has been used in the treatment of Graves disease, although it is not available in North America.

Perchlorate can be used to "discharge" inorganic *iodide* from the thyroid gland in a diagnostic test of iodide organification. Other ions, selected on the basis of their size, also have been found to be active; *fluoroborate* (BF_4^-) is as effective as *perchlorate*.

Lithium decreases secretion of T_4 and T_3, which can cause overt hypothyroidism in some patients taking Li^+ for the treatment of mania (see Chapter 19).

Iodine

Iodide is the oldest remedy for disorders of the thyroid gland. In high concentration, *iodide* can influence several of the important functions of the thyroid gland. *Iodide* limits its own transport and acutely and transiently inhibits the synthesis of iodotyrosines and iodothyronines (the *Wolff-Chaikoff effect*) (Pramyothin et al., 2011). An important clinical effect of high $[I^-]_{plasma}$ is inhibition of the release of thyroid hormone. This action is rapid and efficacious in severe thyrotoxicosis. The effect is exerted directly on the thyroid gland and can be demonstrated in the euthyroid subject as well as in the hyperthyroid patient.

Response to Iodine in Hyperthyroidism

The response to iodine in patients with hyperthyroidism is often striking and rapid: Release of thyroid hormone into the circulation is rapidly blocked, and its synthesis is mildly decreased. In the thyroid gland, vascularity is reduced, the gland becomes much firmer, the cells become

smaller, and colloid reaccumulates in the follicles as iodine concentration increases. The maximal effect occurs after 10 to 15 days of continuous therapy. *Iodide* therapy usually does not completely control the manifestations of hyperthyroidism, and the beneficial effect disappears. The uses of *iodide* in the treatment of hyperthyroidism are in the preoperative period in preparation for thyroidectomy and, in conjunction with antithyroid drugs and *propranolol*, in the treatment of thyrotoxic crisis.

Another use of *iodide* is to protect the thyroid from radioactive iodine fallout following a nuclear accident or military exposure. Because the uptake of radioactive iodine is inversely proportional to the serum concentration of stable iodine, the administration of 30 to 100 mg of iodine daily will markedly decrease the thyroid uptake of radioisotopes. Strong iodine solution (Lugol solution) consists of 5% iodine and 10% potassium iodide, yielding a dose of about 8 mg of iodine per drop. *Potassium iodide saturated solution (KISS)* also is available, containing 50 mg per drop. Typical doses include 16 to 36 mg (2–6 drops) of Lugol solution or 50 to 100 mg (1–2 drops) of KISS three times a day. Potassium iodide products (Thyroshield, various generics) are available over the counter to take in the event of a radiation emergency and block the uptake of *radioiodine* into the thyroid gland. The adult dose is 2 mL (130 mg) every 24 h, as directed by public health officials.

Euthyroid patients with a history of a wide variety of underlying thyroid disorders may develop iodine-induced hypothyroidism when exposed to large amounts of iodine present in many commonly prescribed drugs (Table 47–6), and these patients do not escape from the acute Wolff-Chaikoff effect (Pramyothin et al., 2011).

Untoward Reactions

Occasional individuals show a marked sensitivity to iodine. Angioedema is the prominent symptom, and laryngeal edema may lead to suffocation. Multiple cutaneous hemorrhages may be present; manifestations of the serum sickness type of hypersensitivity (e.g., fever, arthralgia, lymph node enlargement, and eosinophilia) may appear. Thrombotic thrombocytopenic purpura and fatal periarteritis nodosa attributed to hypersensitivity to *iodide* also have been described.

The severity of symptoms of chronic intoxication with *iodide* (*iodism*) is related to the dose. The symptoms start with an unpleasant brassy taste and burning in the mouth and throat as well as soreness of the teeth and gums. Increased salivation, coryza, sneezing, and irritation of the eyes with swelling of the eyelids commonly occur. Mild iodism simulates a "head cold." Excess transudation into the bronchial tree may lead to pulmonary edema. In addition, the parotid and submaxillary glands may become enlarged and tender, and the syndrome may be mistaken for mumps parotitis. Skin lesions are common and vary in type and intensity. Rarely, severe and sometimes fatal eruptions (ioderma) may occur after the prolonged use of *iodides*. The lesions are bizarre; they resemble those caused by bromism and generally involute quickly when *iodide* is withdrawn. Symptoms of gastric irritation are common, and diarrhea, which is sometimes bloody, may occur. Fever, anorexia, and depression may be present. The symptoms of iodism disappear within a few days after stopping the administration of *iodide*. Renal excretion of I^- can be increased by procedures that promote Cl^- excretion (e.g., osmotic diuresis, chloruretic diuretics, and salt loading). These procedures may be useful when the symptoms of iodism are severe.

TABLE 47–6 ■ IODIDE CONTENT OF COMMONLY USED DRUGS AND COMPOUNDS

DRUGS	IODINE CONTENT
Oral or local	
Amiodarone	75 mg/200 mg tablet
Iodoquinol (diiodohydroxyquin)	134 mg/tablet
Echothiophate iodide ophthalmic solution	5–41 μg/drop
Iodoquinol	134 mg/tablet
Idoxuridine ophthalmic solution	18 μg/drop
Lugol solution	5–6 mg/drop
KI, saturated solution (KISS)	38 mg/drop
Topical antiseptics	
Clioquinol cream	12 mg/g
Povidone-iodine	10 mg/mL
Radiographic contrast agents	
Diatrizoate meglumine sodium	370 mg/mL
Iothalamate	320 mg/mL
Ioxaglate	370 mg/mL
Iopamidol	370 mg/mL
Iohexol	350 mg/mL
Io[illegible]ila[illegible]	37[illegible] m[illegible]/mL

Radioactive Iodine

The primary isotopes used for the diagnosis and treatment of thyroid disease are ^{123}I and ^{131}I. ^{123}I is primarily a short-lived γ-emitter with a $t_{1/2}$ of 13 h and is used in diagnostic studies. ^{124}I has been used successfully with positron emission tomographic/computed tomographic scanning for more precise dosimetry in high-risk thyroid cancer (Jentzen et al., 2014). ^{131}I has a $t_{1/2}$ of 8 days and emits both γ rays and β particles. More than 99% of its radiation is expended within 56 days. ^{131}I is used therapeutically for thyroid destruction of an overactive or enlarged thyroid and in thyroid cancer for thyroid ablation and treatment of metastatic disease.

The chemical behavior of the radioactive isotopes of iodine is identical to that of the stable isotope, ^{127}I. ^{131}I is rapidly and efficiently trapped by the thyroid, incorporated into the iodoamino acids, and deposited in the colloid of the follicles, from which it is slowly liberated. Thus, the destructive β particles originate within the follicle and act almost exclusively on the parenchymal cells of the thyroid, with little or no damage to surrounding tissue. The γ radiation passes through the tissue and can be quantified by external detection. The effects of the radiation depend on the dosage. With properly selected doses of ^{131}I, it is possible to destroy the thyroid gland completely without detectable injury to adjacent tissues.

Therapeutic Uses

Radioactive iodine finds its widest use in the treatment of hyperthyroidism and in the diagnosis of disorders of thyroid function. The clearest indication for radioactive iodine treatment is hyperthyroidism in older patients and in those with heart disease. Radioactive iodine also is an effective treatment when Graves disease has persisted or recurred after subtotal thyroidectomy and when prolonged treatment with antithyroid drugs has not led to remission. Finally, radioactive iodine is effective in patients with toxic nodular goiter. Sodium iodide ^{131}I is provided as capsules containing carrier-free ^{131}I suitable for oral administration. Sodium iodide ^{123}I is available for scanning procedures.

Hyperthyroidism

Radioactive iodine is a valuable alternative or adjunctive treatment of hyperthyroidism (Ross, 2011). Stable *iodide* (nonradioactive) may preclude treatment and imaging with radioactive iodine for weeks after the stable *iodide* has been discontinued. In patients exposed to stable *iodide*, a 24-h *radioiodine* measurement of a tracer dose of ^{123}I should be performed before ^{131}I administration to ensure there is sufficient uptake to accomplish the desired ablation. The optimal dose of ^{131}I, expressed as the amount taken up, varies in different laboratories from 80 to 150 μCi per gram of thyroid tissue. The usual total dose is 4 to 15 mCi with a recommended target of delivering 8 mCi to the thyroid gland based on the 24-h *radioiodine* uptake (Alexander and Larsen, 2002; Brent, 2008).

Beginning a few weeks after treatment, the symptoms of hyperthyroidism gradually abate over a period of 2 to 3 months. If therapy has been inadequate, the necessity for further treatment is apparent within 6 to 1[illegible] months. [illegible] not uncommon, however, for the serum TSH to remain low

for several months after ^{131}I therapy. Thus, assessing radioactive iodine failure based on TSH concentrations alone may be misleading and should always be accompanied by determination of free T_4 and usually serum T_3 concentrations. Depending to some extent on the dosage schedule adopted, 80% of patients are cured by a single dose, about 20% require two doses, and a very small fraction require three or more doses before the disorder is controlled. β Adrenergic antagonists, antithyroid drugs, or both can be used to hasten the control of hyperthyroidism.

Advantages

With radioactive iodine treatment, the patient is spared the risks and discomfort of surgery. The cost is low, hospitalization is not required in the U.S., and patients can participate in their customary activities during the entire procedure, although there are recommendations to limit exposure in young children.

Disadvantages

The chief consequence of the use of radioactive iodine is the high incidence of delayed hypothyroidism. Although cancer death rate is not increased after *radioiodine* therapy, some studies suggest a small but significant increase in specific types of cancer, including stomach, kidney, and breast. This finding is especially significant because these tissues all express the iodine transporter NIS and may thus be especially susceptible to effects of radioactive iodine. Radioactive iodine treatment can induce a radiation thyroiditis, with release of preformed T_4 and T_3 into the circulation. In most patients, this is asymptomatic, but in some, there can be worsening of symptoms of hyperthyroidism; rarely, cardiac manifestations (e.g., atrial fibrillation or ischemic heart disease); and very rarely, thyroid storm. Pretreatment with antithyroid drugs should reduce or eliminate this complication.

The main contraindication for the use of ^{131}I therapy is pregnancy. After the first trimester, the fetal thyroid will concentrate the isotope and thus suffer damage; even during the first trimester, radioactive iodine is best avoided because there may be adverse effects of radiation on fetal tissues. In addition, the use of *radioiodine* to treat hyperthyroidism in children is controversial due to theoretical concern about causing neoplastic changes in the thyroid gland or other organs. Data are insufficient to resolve this issue, as the number of children who have been treated with *radioiodine* is relatively small. Many clinics decline to treat younger patients and reserve radioactive iodine for patients older than 25 to 30 years.

Thyroid Carcinoma

Because most well-differentiated thyroid carcinomas accumulate very little iodine, stimulation of iodine uptake with TSH is required to treat metastases effectively (Haugen et al., 2016; Haugen and Sherman, 2013). Endogenous TSH stimulation is promoted by withdrawal of thyroid hormone replacement therapy in patients previously treated with near-total or total thyroidectomy. A typical protocol, due to the *levothyroxine* $t_{1/2}$ of approximately 7 days, is to withhold therapy for about 4 weeks to achieve sufficient stimulation of endogenous TSH, usually greater than 30 mIU/L. *Liothyronine*, which has a much shorter $t_{1/2}$, can be prescribed during the first half of *levothyroxine* withdrawal to minimize symptoms of hypothyroidism. An ablative dose of ^{131}I ranging from 30 to 150 mCi or more is administered, and a repeat total-body scan is obtained several days to 1 week later.

Recombinant thyrotropin alpha (recombinant human TSH) can be used instead of thyroid hormone withdrawal to prepare a patient for *radioiodine* ablation of thyroid remnant tissue or to test the capacity of thyroid tissue, both normal and malignant, to take up radioactive iodine and to secrete thyroglobulin.

Chemotherapy of Thyroid Cancer

This field is rapidly evolving as new therapies directed at thyroid cancer driver genes are developed and as increased experience helps refine best practices for the use of these agents (Cabanillas et al., 2019). The current thyroid cancer chemotherapies are kinase inhibitors, which are discussed in greater detail in Chapter 71. It is important to note that *levothyroxine* dosage requirements often increase in patients taking protein tyrosine kinase inhibitors; therefore, TSH levels should be monitored carefully.

Papillary and Follicular Carcinomas

The majority of thyroid cancers derive from the thyroid follicular cells and are classified histologically as papillary or follicular carcinomas. Most of these carcinomas are adequately treated by surgery, *radioiodine*, and *levothyroxine* to suppress TSH. However, a small fraction progress despite these therapies, in which case systemic therapy with kinase inhibitors may be appropriate.

The choice of systemic therapies ideally is guided by somatic mutation testing of the primary tumor or a metastasis. Patients with tumors that contain *NTRK* or *RET* driver mutations (fusion genes with a variety of partners) can be treated with specific small-molecule inhibitors such as *larotrectinib* or *entrectinib* for *NTRK* fusions or *selpercatinib* or *pralsetinib* for *RET* fusions. However, these driver mutations are relatively uncommon in thyroid cancer.

In the absence of *NTRK* or *RET* driver mutations, therapy can be given with a multikinase inhibitor such as *lenvatinib* or *sorafenib*. Although these drugs are relatively promiscuous, vascular endothelial growth factor receptors are an important target. These antiangiogenic multikinase inhibitors can prolong progression-free survival, but complete responses are rare. There are no head-to-head trials comparing various multikinase inhibitors, but *lenvatinib* is commonly considered first line due to the relative strength of its randomized trial outcomes data.

The most frequent driver mutation in papillary thyroid cancer is *BRAF* V600E. *Vemurafenib* and *dabrafenib* specifically inhibit this kinase and have efficacy in *BRAF*-mutated papillary thyroid cancer, but available data do not suggest a clear benefit over *lenvatinib*. Several papillary and follicular cancer driver mutations (including *BRAF* V600E, *NTRK* and *RET* fusions, and *RAS* mutations) activate the MAP kinase pathway. Treatment of these cancers for several weeks with *dabrafenib* or *vemurafenib* (if *BRAF* V600E is present) and/or a MEK inhibitor such as *trametinib* or *selumetinib* has the potential to restore *radioiodine* uptake and facilitate *radioiodine* therapy in some of these tumors (redifferentiation therapy). The situations in which this therapy is most likely to be of benefit have yet to be defined.

Anaplastic Thyroid Cancer

Anaplastic thyroid carcinomas are undifferentiated tumors derived from thyroid follicular cells. This disease is highly aggressive with an average life expectancy of only approximately 6 months from the time of diagnosis. If feasible, local disease may be treated with surgery and external beam radiotherapy. Ideally, the approach to chemotherapy should be informed by tumor mutation profiling. The combination of *dabrafenib* plus *trametinib* is FDA-approved for anaplastic carcinomas that harbor *BRAF* V600E.

Medullary Thyroid Carcinoma

A minor fraction of thyroid cancers originates from the parafollicular cells that produce calcitonin. These tumors, denoted MTCs, can occur sporadically or as part of the autosomal dominant multiple endocrine neoplasia type 2 syndrome. Germline mutations in *RET* underlie nearly all inherited medullary carcinomas, and somatic *RET* mutations are common in sporadic MTCs. Because they derive from parafollicular cells, MTCs are not responsive to *radioiodine* or TSH suppression. The first-line therapy for MTC is surgery. RET-driven MTCs that progress despite surgery can be treated with a selective RET kinase inhibitor (*selpercatinib* or *pralsetinib*). These agents appear to have better safety profiles than multikinase inhibitors and may be more efficacious. However, the multikinase inhibitors *vandetanib* and *cabozantinib* also have efficacy and can be prescribed without regard for *RET* gene mutational status.

Drug Facts for Your Personal Formulary: *Thyroid and Antithyroid Drugs*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Thyroid Hormone Preparations: Replace T_4 or T_3 normally produced by the thyroid		
Levothyroxine (T_4)	• Hypothyroidism • TSH suppression in thyroid cancer	• Plasma $t_{1/2}$ ~1 week • Deiodinases convert circulating T_4 to the bioactive hormone T_3 • Dosage generally needs to increase during pregnancy • Congenital hypothyroidism requires rapid diagnosis and correction to allow normal physical and mental development • Overtreatment can lead to osteoporosis and atrial fibrillation
Liothyronine (T_3)	• When rapid onset of action is desired (sometimes for myxedema coma) • When rapid termination of action is desired (preparing patients with thyroid cancer for radioiodine therapy)	• Plasma $t_{1/2}$ ~18–24 h • Multiple daily doses needed to achieve needed C_{Pss} • Levothyroxine generally preferred over liothyronine for the long-term therapy of hypothyroidism
Desiccated thyroid and T_4–T_3 mixtures	• Generally not a preferred therapy, although occasional hypothyroid patients say they feel better than when taking levothyroxine	• Mixture of levothyroxine and liothyronine (~4:1 by weight) • Supplies a relative excess of T_3 compared to normal thyroidal secretion, which is ~11:1 T_4 to T_3 by weight • No convincing evidence of greater efficacy than levothyroxine alone
Antithyroid Drugs: Thionamides: Interfere with incorporation of iodine into tyrosyl residues and inhibit iodotyrosyl-coupling reactions		
Methimazole	• Reduce thyroid hormone production	• Carbimazole (available in Europe) converted to methimazole after absorption • Long intrathyroidal $t_{1/2}$ allows once-daily dosing for most patients • Preferred antithyroid drug • Do not use in first trimester of pregnancy due to embryopathy
Propylthiouracil	• Reduce thyroid hormone production • At high doses, reduces T_4 to T_3 conversion	• Major concern is liver toxicity; rare but more commonly seen in children and pregnancy • Main indications are for thyroid storm due to action on reducing T_4 to T_3 conversion and in the first trimester of pregnancy, although it has been associated with congenital defects that are not initially detected at birth
Antithyroid Drugs: Ionic Inhibitors: Inhibit iodine uptake by antagonizing the NIS		
Perchlorate	• Primarily used to enhance the response to thioamides in refractory Graves disease (e.g., that associated with amiodarone)	• Not available commercially; must be specialty compounded
Antithyroid Drugs: Iodide: Acute reduction in thyroid hormone		
Lugol solution	• Acutely reduces the secretion and synthesis of thyroid hormone	• "Escape" from thyroid inhibition after 7–10 days • Strictly contraindicated in pregnancy
KISS: potassium iodide saturated solution (or SSKI)	• Acutely reduces the secretion and synthesis of thyroid hormone	• "Escape" from thyroid inhibition after 7–10 days • Strictly contraindicated in pregnancy
Antithyroid Drugs: Radioactive Iodine: Used to destroy hyperfunctioning thyroid tissue		
^{131}I	• Effective for permanent treatment of Graves disease and toxic nodule or toxic goiter • Destruction of iodide-avid thyroid cancer	• Highly effective for permanent cure to hyperthyroidism • Effective treatment of hyperthyroidism usually results in permanent hypothyroidism and lifelong requirement for levothyroxine replacement • Absolutely contraindicated in pregnancy • Treatment of thyroid cancer requires TSH stimulation (endogenous or exogenous)
Recombinant Human TSH Agonist for the TSH Receptor		
Thyrotropin alpha	• Stimulates radioiodine uptake and thyroglobulin release in patients with thyroid cancer after thyroidectomy • Prepares patients for radioiodine ablation of thyroid remnants after thyroidectomy for thyroid cancer	• Allows assessment of residual or recurrent thyroid cancer without stopping levothyroxine and becoming clinically hypothyroid • Allows radioiodine therapy of thyroid remnants without stopping levothyroxine and becoming clinically hypothyroid
Thyroid Cancer Chemotherapeutics: TRK Inhibitors: Used when surgery, ^{131}I, TSH suppression, and external beam radiotherapy are inadequate		
Larotrectinib Entrectinib	• Systemic therapy of follicular cell–derived thyroid cancers with *NTRK* fusion gene driver mutations	• *NTRK* fusion genes are uncommon in thyroid cancer • Limited data suggest better tolerated and more efficacious than multikinase inhibitors when an *NTRK* fusion gene is present • See Chapter 71 for a more general discussion of these drugs

Drug Facts for Your Personal Formulary: *Thyroid and Antithyroid Drugs (continued)*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Thyroid Cancer Chemotherapeutics: RET Inhibitors: Used when surgery, ^{131}I, TSH suppression, and external beam radiotherapy are inadequate		
Selpercatinib Pralsetinib	• Systemic therapy of thyroid cancers with *RET* driver mutations (papillary cancers with *RET* fusion genes and medullary cancers with *RET* point mutations)	• *RET* driver mutations (fusion genes) are uncommon in papillary thyroid cancer • *RET* driver mutations (point mutations) are common in sporadic medullary cancer and nearly universal in inherited medullary cancers (multiple endocrine neoplasia type 2) • Since medullary cancers are not derived from follicular cells, ^{131}I and TSH suppression are ineffective • Limited data suggest better tolerated and more efficacious than multikinase inhibitors when a *RET* driver mutation is present • See Chapter 71 for a more general discussion of these drugs
Thyroid Cancer Chemotherapeutics: *BRAF* V600E Inhibitors: Used when surgery, ^{131}I, TSH suppression, and external beam radiotherapy are inadequate		
Vemurafenib Dabrafenib	• Systemic therapy of thyroid cancers with *BRAF* V600E driver mutation • May be useful as redifferentiation therapy to induce radioiodine uptake in non–iodine-avid thyroid cancers with *BRAF* V600E	• Although *BRAF* V600E is the most common driver mutation in papillary cancer, BRAF inhibitors have not been shown to be clearly superior to multikinase inhibitors • The role of redifferentiation therapy is uncertain • See Chapter 71 for a more general discussion of these drugs
Thyroid Cancer Chemotherapeutics: Multikinase Inhibitors: Used when surgery, ^{131}I, TSH suppression, and external beam radiotherapy are inadequate		
Lenvatinib Sorafenib	• Systemic therapy of follicular cell–derived thyroid cancers without regard to driver mutation status	• Inhibit multiple kinases including vascular endothelial growth factor receptors • Although there are no head-to-head trials, existing data suggest lenvatinib is more efficacious • Toxicities are common and can limit drug dosage or usage • See Chapter 71 for a more general discussion of these drugs
Vandetanib Cabozantinib	• Systemic therapy of medullary thyroid cancer without regard to driver mutation status	• Inhibit multiple kinases including vascular endothelial growth factor receptors and RET • Since medullary cancers are not derived from follicular cells, ^{131}I and TSH suppression are ineffective • See Chapter 71 for a more general discussion of these drugs
Thyroid Cancer Chemotherapeutics: MEK Inhibitors		
Trametinib Selumetinib	• Trametinib is FDA-approved in combination with dabrafenib to treat anaplastic cancers containing *BRAF* V600E • May be useful as redifferentiation therapy (with or without BRAF inhibition) to induce radioiodine uptake in non–iodine-avid thyroid cancers	• The role of redifferentiation therapy and the effectiveness of MEK inhibitors are uncertain • See Chapter 71 for a more general discussion of these drugs

Chapter 48

Estrogens, Progestins, and the Female Reproductive Tract

Ellis R. Levin, Wendy S. Vitek, and Stephen R. Hammes

Estrogens and *progestins* are endogenous hormones that produce numerous physiological actions. In women, these include developmental effects, neuroendocrine actions involved in the control of ovulation, the cyclical preparation of the reproductive tract for fertilization and implantation, and major actions on mineral, carbohydrate, protein, and lipid metabolism. Estrogens also have important actions in males, including effects on bone, spermatogenesis, and behavior. Well-characterized receptors for each hormone mediate biological actions in both the unliganded and the liganded states.

The most common uses of estrogens and progestins are for contraception and menopausal hormone therapy (MHT) in women, but the specific compounds and dosages used in these two settings differ substantially. Antiestrogens are used in the treatment of hormone-responsive breast cancer and infertility. Selective estrogen receptor modulators (SERMs) that display tissue-selective agonist or antagonist activities are useful to prevent breast cancer and osteoporosis. The main use of antiprogestins has been for medical abortion.

Several naturally occurring and synthetic environmental chemicals mimic, antagonize, or otherwise affect the actions of estrogens in experimental test systems. The precise effect of these agents on humans is unknown but is an area of active investigation.

Estrogens

Chemistry and Synthesis

Chemistry

Many steroidal and nonsteroidal compounds, some of which are shown in Table 48–1 and Figure 48–1, possess estrogenic activity. Estrogens nterac' w'th two receptors of .he nuclear ·eceptor superfamil ; termed ERα and ERβ. The most potent naturally occurring estrogen in humans, for both ERα- and ERβ-mediated actions, is *17β-estradiol*, followed by *estrone* and *estriol*. Each contains a phenolic A ring with a hydroxyl group at carbon 3 and a β-OH or ketone in position 17 of ring D.

The phenolic A ring is the principal structural feature responsible for selective high-affinity binding to both receptors. Most alkyl substitutions on the A ring impair binding, but substitutions on ring C or D may be tolerated. Ethinyl substitutions at the C17 position greatly increase oral potency by inhibiting first-pass hepatic metabolism. Models for the ligand-binding sites of both ERs have been determined from structure-activity relationships and structural analysis (Pike et al., 2000). Selective ligands for ERα and ERβ are available for experimental studies but are not yet used therapeutically (Harrington et al., 2003).

Biosynthesis

Steroidal estrogens arise from androstenedione or testosterone (Figure 48–1) by aromatization of the A ring. The reaction is catalyzed by aromatase (CYP19), which uses NADPH and molecular oxygen as cosubstrates. A ubiquitous flavoprotein, NADPH–cytochrome P450 reductase, also is essential. Both proteins are localized in the endoplasmic reticulum of ovarian granulosa cells, testicular Sertoli and Leydig cells, adipose stroma, placental syncytiotrophoblasts, preimplantation blastocysts, bone, various brain regions, and many other tissues (Simpson et al., 2002).

The ovaries are the principal source of circulating estrogen in premenopausal women, with estradiol the main secretory product. Ovarian estradiol production is traditionally thought to require two cell types: theca cells and granulosa cells. The gonadotropin luteinizing hormone (LH) acts via recep ors that couple to the G -adenylyl cyclase–cy clic AMP

Abbreviations

AF: activation function
CEE: conjugated equine estrogens
CHD: coronary heart disease
ER: estrogen receptor
ERα: estrogen receptor α
ERβ: estrogen receptor β
ERE: estrogen response element
FP: $PGF_{2\alpha}$ receptor
FSH: follicle-stimulating hormone
GABA: γ-aminobutyric acid
GnRH: gonadotropin-releasing hormone
hCG: human chorionic gonadotropin
HDL: high-density lipoprotein
HERS: Heart and Estrogen/Progestin Replacement Study
HRT: hormone replacement therapy
HSDD: hypoactive sexual desire disorder
HSP: heat shock protein
IGF: insulin-like growth factor
IUD: intrauterine device
IUS: intrauterine system
IVF: *in vitro* fertilization
LDL: low-density lipoprotein
LH: luteinizing hormone
LNg: levonorgestrel, as in LNg-IUS
LNg14 or 20: LNg, 14 or 20 μg/24 h
LPA: lipoprotein A
MHT: menopausal hormone therapy
MPA: medroxyprogesterone acetate
NE: norepinephrine
OHSS: ovarian hyperstimulation syndrome
OPG: osteoprotegrin
PCOS: polycystic ovary syndrome
PG: prostaglandin
PR: progesterone receptor
PRE: progesterone response element
PRM: progesterone receptor modulators
SERM: selective estrogen receptor modulator
SHBG: sex hormone–binding globulin
WHI: Women's Health Initiative

pathway to increase cholesterol (the precursors of all steroids) transport into the mitochondria of cells, where androgen precursors are produced. Follicle-stimulating hormone (FSH) then stimulates CYP19 production and activity in the granulosa cells, which converts the androgen precursors to estrogens. Notably, theca cells of the ovary contain a form of 17β-hydroxysteroid dehydrogenase (type I) that favors the production of testosterone and estradiol from androstenedione and estrone, respectively. However, in the liver, another form of this enzyme (type II) favors oxidation of circulating estradiol to estrone (Peltoketo et al., 1999), and both of these steroids are then converted to estriol (Figure 48–1). All three of these estrogens are excreted in the urine along with their glucuronide and sulfate conjugates.

In postmenopausal women, the principal source of circulating estrogen is adipose tissue stroma, where estrone is synthesized from dehydroepiandrosterone secreted by the adrenals. In men, estrogens are produced by the testes, but extragonadal production by aromatization of circulating C19 steroids (e.g., androstenedione and dehydroepiandrosterone) accounts for most circulating estrogens (Simpson, 2003).

HISTORY **Hormones in the Female Reproductive System**

The hormonal nature of the ovarian control of the female reproductive system was firmly established in 1900 by Knauer, when he found that ovarian transplants prevented the symptoms of gonadectomy, and by Halban, who showed that normal sexual development and function occurred when glands were transplanted. In 1923, Allen and Doisy devised a bioassay for ovarian extracts based on the vaginal smear of the rat. Frank and associates in 1925 detected an active sex principle in the blood of sows in estrus, and Loewe and Lange discovered in 1926 that a female sex hormone varied in the urine of women throughout the menstrual cycle. The excretion of estrogen in the urine during pregnancy also was reported by Zondek in 1928 and enabled Butenandt and Doisy in 1929 to crystallize an active substance.

Early investigations indicated that the ovary secretes two substances. Beard had postulated in 1897 that the corpus luteum serves a necessary function during pregnancy, and Fraenkel showed in 1903 that destruction of the corpora lutea in pregnant rabbits caused abortion. Several groups then isolated progesterone from mammalian corpora lutea in the 1930s.

In the early 1960s, pioneering studies by Jensen and colleagues suggested the presence of intracellular receptors for estrogens in target tissues. This was the first demonstration of receptors of the steroid/thyroid superfamily and provided techniques to identify receptors for the other steroid hormones. A second estrogen receptor (ER) was identified in 1996 and was termed ERβ to distinguish it from the receptor identified earlier, termed ERα. Two protein isoforms, A and B, of the progesterone receptor (PR) arise from a single gene by transcription initiation from different promoters.

Estrogens may be locally produced from androgens by the actions of aromatase or from estrogen conjugates by hydrolysis. Such local production of estrogens could play a causal or promotional role in the development of certain diseases, such as breast cancer, because mammary tumors contain both aromatase and hydrolytic enzymes. Estrogens also may be produced from androgens via aromatase in the CNS and other tissues and exert local effects near their production site (e.g., in bone, they affect bone mineral density).

The placenta uses fetal dehydroepiandrosterone and its 16α-hydroxyl derivative to produce large amounts of estrone and estriol. Human urine during pregnancy is thus an abundant source of natural estrogens. Pregnant mare's urine is the source of *conjugated equine estrogens*, which have been widely used therapeutically for many years.

Physiological Actions

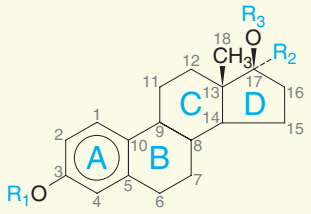
Developmental Actions

Estrogens are largely responsible for pubertal changes in girls and secondary sexual characteristics. Estrogens cause growth and development of the vagina, uterus, and fallopian tubes and contribute to breast enlargement. They also contribute to molding the body contours, shaping the skeleton, and causing the pubertal growth spurt of the long bones and epiphyseal closure. Growth of axillary and pubic hair, pigmentation of the genital region, and the regional pigmentation of the nipples and areolae that occur after the first trimester of pregnancy are also estrogenic actions. Androgens may also play a secondary role in female sexual development (see Chapter 49).

Estrogens appear to play important developmental roles in males. In boys, estrogen deficiency diminishes the pubertal growth spurt and delays skeletal maturation and epiphyseal closure so that linear growth continues into adulthood. Estrogen deficiency in men leads to macroorchidism and elevated gonadotropins and testosterone levels and may

TABLE 48–1 ■ STRUCTURAL FORMULAS OF SELECTED ESTROGENS

STEROIDAL ESTROGENS



Derivative	R_1	R_2	R_3

also affect carbohydrate and lipid metabolism and fertility in some individuals (Grumbach and Auchus, 1999).

Neuroendocrine Control of the Menstrual Cycle

A neuroendocrine cascade involving the hypothalamus, pituitary, and ovaries controls the menstrual cycle (Figure 48–2). A neuronal oscillator, or "clock," in the hypothalamus fires at intervals that coincide with bursts of gonadotropin-releasing hormone (GnRH) release into the hypothalamic-pituitary portal vasculature (see Chapter 46). GnRH interacts with its cognate receptor on pituitary gonadotropes to cause release of LH and FSH. The frequency of the GnRH pulses, which varies in the different phases of the menstrual cycle, controls the relative synthesis of the unique β subunits of FSH and LH.

The gonadotropins (LH and FSH) regulate the growth and maturation of the graafian follicle in the ovary and the ovarian production of estrogen and progesterone, which exert feedback regulation on the pituitary and hypothalamus. Because the release of GnRH is intermittent, LH and FSH secretion is pulsatile. The pulse *frequency* is determined by the neural clock (Figure 48–2), termed the *hypothalamic GnRH pulse generator* (Knobil, 1981), but the amount of gonadotropin released in each pulse (i.e., the pulse *amplitude*) is largely controlled by the actions of estrogens and progesterone on the pituitary. The intermittent, *pulsatile* nature of hormone release is essential for the maintenance of normal ovulatory menstrual cycles because constant infusion of GnRH results in cessation of gonadotropin release and ovarian steroid production (see Chapter 46). The neuropeptide kisspeptin 1, which is released from kisspeptin neurons located in the arcuate nucleus and elsewhere in the hypothalamus, regulates GnRH pulsatility through its G protein-coupled receptor, GPR54, expressed in GnRH neurons (Figure 48–2). Estrogen reduces kisspeptin production in kisspeptin neurons within the acuate nucleus, while neurokinin B through the neurokinin 3 receptor stimulates kisspeptin secretion from the same kisspeptin neurons. Inactivating mutations in GPR54 have been associated with hypogonadotropic hypogonadism (Seminara, 2006), as have inactivating mutations in the kisspeptin gene (Topaloglu et al., 2012). In contrast, activating mutations of the kisspeptin gene can lead to central precocious puberty (Silveira et al., 2010). Finally, mutations in neurokinin B or its receptor have also been associated with pubertal failure (Topaloglu et al., 2009).

Although the precise mechanism that regulates the timing of GnRH release (i.e., pulse frequency) is unclear, hypothalamic cells appear to

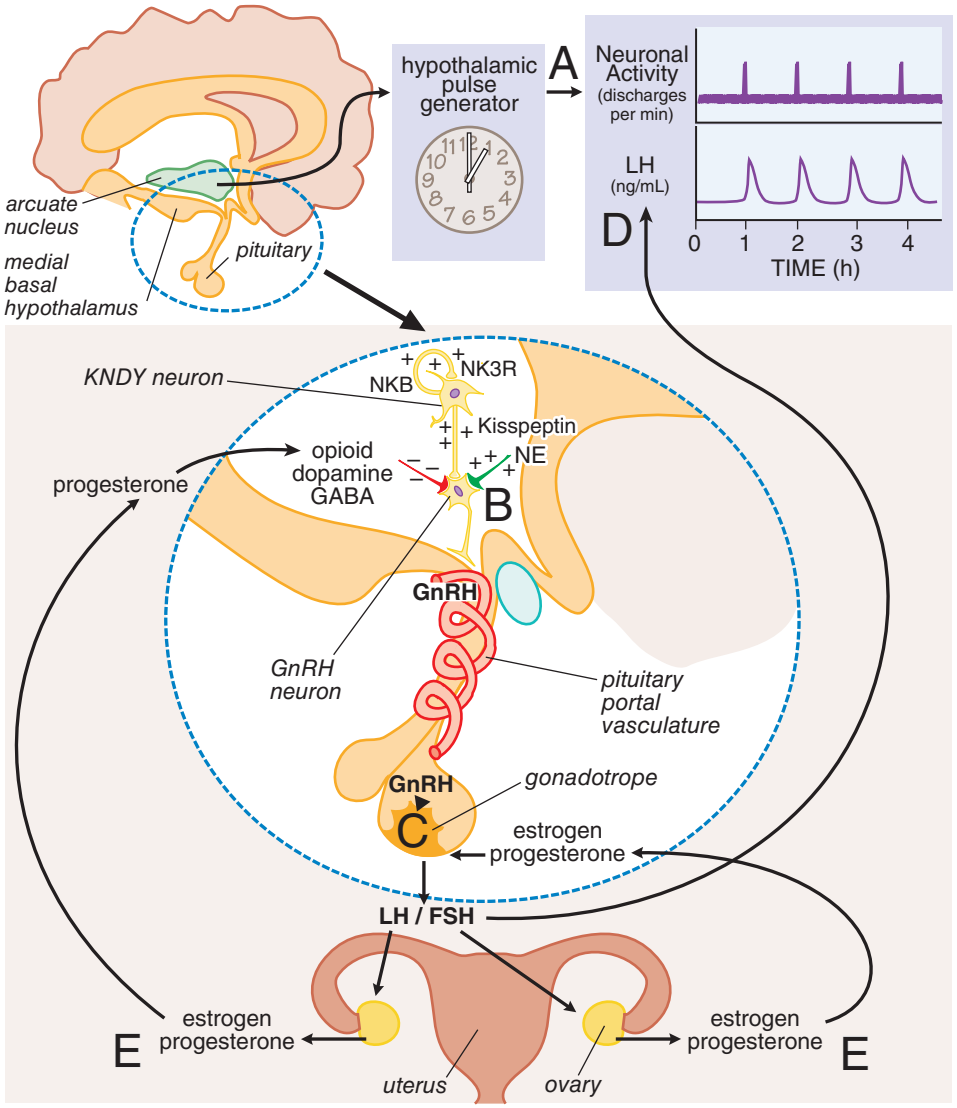

Figure 48–2 *Neuroendocrine control of gonadotropin secretion in females.* The hypothalamic pulse generator located in the arcuate nucleus of the hypothalamus functions as a neuronal "clock" that fires at regular hourly intervals (**A**). This results in the periodic release of GnRH from GnRH-containing neurons into the hypothalamic-pituitary portal vasculature (**B**). GnRH neurons (**B**) receive inhibitory input from opioid, dopamine, and γ-aminobutyric acid (GABA) neurons and stimulatory input from noradrenergic neurons. The pulses of GnRH trigger the intermittent release of LH and FSH from pituitary gonadotropes (**C**), resulting in the pulsatile plasma profile (**D**). FSH and LH regulate ovarian production of estrogen and progesterone, which exert feedback controls (**E**). (See text and Figure 48–3 for additional details.)

have an intrinsic ability to release GnRH episodically. The overall pattern of GnRH release likely is regulated by the interplay of intrinsic mechanism(s) and extrinsic synaptic inputs from opioid, catecholamine, GABAergic, and kisspeptin neurons (Figure 48–2). Ovarian steroids, primarily progesterone, regulate the frequency of GnRH release, but the cellular and molecular mechanisms of this regulation are not well established.

At puberty, the pulse generator is activated and establishes cyclic profiles of pituitary and ovarian hormones. Although the mechanism of activation is not entirely established, it may involve increases in circulating insulin-like growth factor (IGF)-1 and leptin levels, the latter acting to inhibit neuropeptide Y in the arcuate nucleus to relieve an inhibitory effect on GnRH neurons.

Figure 48–3 provides a schematic diagram of the profiles of gonadotropin and gonadal steroid levels in the menstrual cycle. The "average" plasma levels of LH throughout the cycle are shown in panel A of Figure 48–3; insets illustrate the pulsatile patterns of LH during the proliferative and secretory phases in more detail. The average LH levels are similar throughout the early (follicular) and late (luteal) phases of the cycle, but the frequency and amplitude of the LH pulses are quite different in the two phases. This characteristic pattern of hormone secretions results from complex positive- and negative-feedback mechanisms (Hotchkiss and Knobil, 1994).

In the early follicular phase of the cycle, (1) the pulse generator produces bursts of neuronal activity with a frequency of about one per hour that correspond with pulses of GnRH secretion; (2) these cause a corresponding pulsatile release of LH and FSH from pituitary gonadotropes; and (3) FSH in particular causes the graafian follicle to mature and secrete estrogen. The effects of estrogens on the pituitary are inhibitory at this time and cause the amount of LH and FSH released from the pituitary to

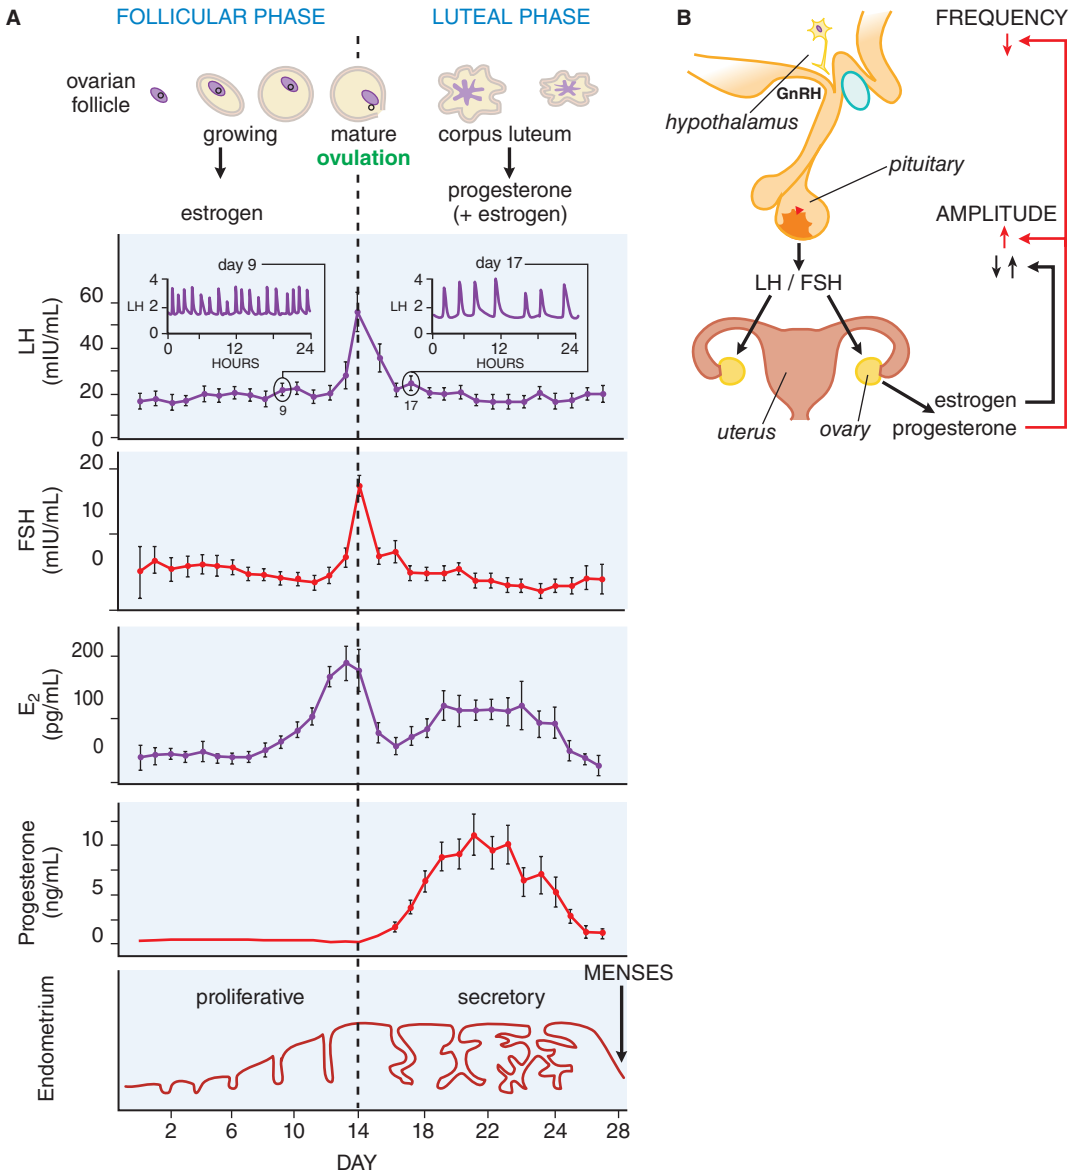

Figure 48–3 *Hormonal relationships of the human menstrual cycle.* **A.** Average daily values of LH, FSH, estradiol (E_2), and progesterone in plasma samples from women exhibiting normal 28-day menstrual cycles. Changes in the ovarian follicle (top) and endometrium (bottom) also are illustrated schematically. Frequent plasma sampling reveals pulsatile patterns of gonadotropin release. Characteristic profiles are illustrated schematically for the follicular phase (day 9, inset on left) and luteal phase (day 17, inset on right). Both the frequency (number of pulses per hour) and amplitude (extent of change of hormone release) of pulses vary throughout the cycle. (Modified from and reproduced with permission from Thorneycroft IH, et al. *Am J Obstet Gynecol,* **1971**, *111*:947–951. Copyright © Elsevier.) **B.** Major regulatory effects of ovarian steroids on hypothalamic-pituitary function. Estrogen decreases the amount of FSH and LH released (i.e., gonadotropin pulse amplitude) during most of the cycle and triggers a surge of LH release only at midcycle. Progesterone decreases the frequency of GnRH release from the hypothalamus and thus decreases the frequency of plasma gonadotropin pulses. Progesterone also increases the amount of LH released (i.e., the pulse amplitude) during the luteal phase of the cycle.

decline (i.e., the amplitude of the LH pulse decreases), so gonadotropin levels gradually fall (Figure 48–3). *Inhibin,* produced by the ovary, exerts negative feedback to selectively decrease serum FSH (see Chapter 46). Activin and follistatin, two other peptides released from the ovary, may also regulate FSH production and secretion to a lesser extent, although their levels do not vary appreciably during the menstrual cycle.

At midcycle, serum estradiol rises above a threshold level of 150 to 200 pg/mL for about 36 h. This sustained elevation of estrogen no longer inhibits gonadotropin release but exerts a brief positive-feedback effect on the pituitary to trigger the preovulatory surge of LH and FSH. This effect involves both a yet uncharacterized estrogen-induced rise in kisspeptin and a change in pituitary responsiveness to GnRH.

The midcycle surge in gonadotropins stimulates follicular rupture and ovulation within 1 to 2 days. The ruptured follicle then develops into the corpus luteum, which produces large amounts of progesterone and lesser amounts of estrogen under the influence of LH during the second half of the cycle. In the absence of pregnancy, the corpus luteum ceases to function, steroid levels drop, and menstruation occurs. When steroid levels drop, the pulse generator reverts to a firing pattern characteristic of the follicular phase, the entire system then resets, and a new ovarian cycle occurs.

Regulation of the frequency and amplitude of gonadotropin secretions by steroids may be summarized as follows: Estrogens act primarily on the pituitary to control the amplitude of gonadotropin pulses, and they may also contribute to the amplitude of GnRH pulses secreted by the hypothalamus.

In the follicular phase of the cycle, estrogens inhibit gonadotropin release but then have a brief midcycle stimulatory action that increases the amount released and causes the LH surge. Progesterone, acting on the hypothalamus, exerts the predominant control of the frequency of LH release. It decreases the firing rate of the hypothalamic pulse generator, an action thought to be mediated largely via inhibitory opioid neurons (containing PRs) that synapse with GnRH neurons. Progesterone also exerts a direct effect on the pituitary to oppose the inhibitory actions of estrogens and thus enhance the amount of LH released (i.e., to increase the amplitude of the LH pulses). These steroid feedback effects, coupled with the intrinsic activity of the hypothalamic GnRH pulse generator, lead to relatively frequent LH pulses of small amplitude in the follicular phase of the cycle and less-frequent pulses of larger amplitude in the luteal phase. Studies in knockout mice indicated that ERα (Hewitt and Korach, 2003) and PR-A (Conneely et al., 2002) mediate the major actions of estrogens and progestins, respectively, on the hypothalamic-pituitary axis.

When the ovaries are removed or cease to function, there is overproduction of FSH and LH, which are excreted in the urine. Measurement of urinary or plasma LH is valuable to assess pituitary function and the effectiveness of therapeutic doses of estrogen.

Effects of Cyclical Gonadal Steroids on the Reproductive Tract

The cyclical changes in estrogen and progesterone production by the ovaries regulate corresponding events in the fallopian tubes, uterus, cervix, and vagina. Physiologically, these changes prepare the uterus for implantation, and the proper timing of events in these tissues is essential for pregnancy. If pregnancy does not occur, the endometrium is shed as the menstrual discharge.

The uterus is composed of an *endometrium* and a *myometrium*. The endometrium contains an epithelium lining the uterine cavity and an underlying stroma; the myometrium is the smooth muscle component responsible for uterine contractions. These cell layers and the fallopian tubes, cervix, and vagina display a characteristic set of responses to both estrogens and progestins. The changes typically associated with menstruation occur largely in the endometrium (Figure 48–3).

The *luminal surface* of the endometrium is a layer of simple columnar epithelial secretory and ciliated cells that is continuous with the openings of numerous glands that extend through the underlying stroma to the myometrial border. Fertilization normally occurs in the fallopian tubes, so ovulation, transport of the fertilized ovum through the fallopian tube, and preparation of the endometrial surface must be temporally coordinated for successful implantation.

The *endometrial stroma* is a highly cellular connective tissue layer containing a variety of blood vessels that undergo cyclic changes associated with menstruation. The predominant cells are fibroblasts, but macrophages, lymphocytes, and other resident and migratory cell types also are present.

Menstruation marks the start of the menstrual cycle. During the follicular (or proliferative) phase of the cycle, estrogen begins the rebuilding of the endometrium by stimulating proliferation and differentiation. An important response to estrogen in the endometrium and other tissues is induction of the PR, which enables cells to respond to this hormone during the second half of the cycle.

In the luteal (or secretory) phase of the cycle, elevated progesterone limits the proliferative effect of estrogens on the endometrium by stimulating differentiation. Major effects include stimulation of epithelial secretions important for implantation of the blastocyst and the characteristic growth of the endometrial blood vessels seen at this time. These effects are mediated by PR-A in animal models (Conneely et al., 2002). Progesterone is thus important in preparation for implantation and for the changes that take place in the uterus at the implantation site (i.e., the decidual response). There is a narrow "window of implantation," spanning days 19 to 24 of the endometrial cycle, when the epithelial cells of the endometrium are receptive to blastocyst implantation. If implantation occurs, human chorionic gonadotropin (hCG) (see Chapter 46), produced initially by the trophoblast and later by the placenta, interacts with the LH receptor of the corpus luteum to maintain steroid hormone synthesis during the early stages of pregnancy. Later, the placenta becomes the major site of estrogen and progesterone synthesis.

Estrogens and progesterone have important effects on the fallopian tube, myometrium, and cervix. In the fallopian tube, estrogens stimulate proliferation and differentiation, whereas progesterone inhibits these processes. Also, estrogens increase and progesterone decreases tubal muscular contractility, which affects transit time of the ovum to the uterus. Estrogens increase the amount of cervical mucus and its water content to facilitate sperm penetration of the cervix, whereas progesterone generally has opposite effects. Estrogens favor rhythmic contractions of the uterine myometrium, and progesterone diminishes contractions. These effects are physiologically important and may also play a role in the action of some contraceptives.

Notably, during implantation of a fertilized ovum into the uterus, there is a strong increase in uteroplacental blood flow. In part, this is caused by spiral arteries invading into the placenta and main uterine artery. This is initially driven by the strong increase in maternal serum estrogen that stimulates nitric oxide formation and subsequent vasodilation. Estrogen stimulates vascular endothelial growth factor and placental growth factor impacting endothelial cell proliferation. Estrogens binding to the estrogen receptors that are expressed in cytotrophoblast cells and in the uterine artery wall stimulate uterine vasculature remodeling. When not present, as occurs in preeclampsia, lower estrogen levels result in altered uterine arterial remodeling, limiting blood flow increases and restricting the growth of the fetus (Mandala, 2020).

Metabolic Effects

Estrogens affect many tissues and have many metabolic actions in humans and animals. Many nonreproductive tissues, including bone, vascular endothelium, liver, CNS, immune system, GI tract, and heart, express low levels of both ERs, and the ratio of ERα to ERβ varies in a cell-specific manner. The effects of estrogens on selected aspects of mineral, lipid, carbohydrate, and protein metabolism are particularly important for understanding their pharmacological actions.

Estrogens have positive effects on bone mass (Riggs et al., 2002). Bone is continuously remodeled at sites called *bone-remodeling units* by the resorptive action of osteoclasts and the bone-forming action of osteoblasts (see Chapter 52). Estrogens directly regulate osteoblasts and increase osteocyte survival by inhibiting apoptosis (Kousteni et al., 2002; Levin, 2008). However, a major effect of estrogens is to decrease the number and activity of osteoclasts. Much of the action of estrogens on osteoclasts appears to be mediated by altering cytokine (both paracrine and autocrine) signals from osteoblasts. Estrogens also increase

osteoblast production of the cytokine osteoprotegerin (OPG), a soluble, non–membrane-bound member of the tumor necrosis factor superfamily. OPG acts as a "decoy" receptor that antagonizes the binding of OPG-ligand (OPG-L) to its receptor (termed *RANK*, or *receptor activator of NF-κB*) and prevents the differentiation of osteoclast precursors to mature osteoclasts. Estrogens increase osteoclast apoptosis, either directly or by increasing OPG. Estrogens affect bone growth and epiphyseal closure in both sexes. The importance of estrogen in the male skeleton is illustrated by a man with a completely defective ER who had osteoporosis, unfused epiphyses, increased bone turnover, and delayed bone age (Smith et al., 1994).

Estrogens slightly elevate serum triglycerides and slightly reduce total serum cholesterol levels. They increase high-density lipoprotein (HDL) levels and decrease the levels of low-density lipoprotein (LDL) and lipoprotein A (see Chapter 37). This beneficial alteration of the ratio of HDL to LDL is an attractive but unproven effect of estrogen therapy in postmenopausal women. At relatively high concentrations, estrogens have antioxidant activity and may inhibit the oxidation of LDL by affecting superoxide dismutase. Estrogen actions on the vascular wall include increased production of NO, which occurs within minutes via a mechanism involving activation of Akt (protein kinase B) and induction of NO synthase (Simoncini et al., 2000). All of these changes promote vasodilation and retard atherogenesis. Estrogens also promote endothelial cell growth while inhibiting the proliferation of vascular smooth muscle cells.

The presence of ERs in the liver suggests that the beneficial effects of estrogen on lipoprotein metabolism are due partly to direct hepatic actions. Estrogens also alter bile composition by increasing cholesterol secretion and decreasing bile acid secretion. This leads to increased saturation of bile with cholesterol and appears to be the basis for increased gallstone formation in some women receiving estrogens. In general, estrogens increase plasma levels of cortisol-binding globulin, thyroxine-binding globulin, and sex hormone–binding globulin (SHBG), which binds both androgens and estrogens.

Estrogens alter a number of metabolic pathways that affect the clotting cascade (Mendelsohn and Karas, 1999). Systemic effects include changes in hepatic production of plasma proteins. Estrogens cause a small increase in coagulation factors II, VII, IX, X, and XII, and they decrease the anticoagulation factors protein C, protein S, and antithrombin III (see Chapter 36). Fibrinolytic pathways also are affected, and several studies of women treated with estrogen alone or estrogen with a progestin have demonstrated decreased levels of plasminogen activator inhibitor 1 (PAI-1) protein with a concomitant increase in fibrinolysis (Koh et al., 1997). Thus, estrogens increase both coagulation and fibrinolytic pathways, and imbalance in these two opposing activities may cause adverse effects.

Estrogen Receptors

Estrogens exert their effects by interaction with receptors that are members of the superfamily of nuclear receptors. The two ER genes are located on separate chromosomes: *ESR1* encodes ERα, and *ESR2* encodes ERβ. Both ERs are estrogen-dependent nuclear transcription factors that have different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to differential promoter use and alternative splicing (reviewed by Kos et al., 2001; Lewandowski et al., 2002). The two human ERs are 44% identical in overall amino acid sequence and share the domain structure common to members of this family. There are significant differences between the two receptor isoforms in the ligand-binding domains and in both transactivation domains. Human ERβ does not appear to contain a functional activation function (AF)-1 domain. The receptors appear to have different biological functions and respond differently to various estrogenic compounds (Kuiper et al., 1997). However, their high homology in the DNA-binding domains suggests that both receptors recognize similar DNA sequences and hence regulate many of the same target genes.

Estrogen receptor (ER) α is expressed most abundantly in the female reproductive tract—especially the uterus, vagina, and ovaries—as well as in the mammary gland, the hypothalamus, endothelial cells, and vascular smooth muscle. *ERβ* is expressed most highly in the prostate and ovaries, with lower expression in lung, brain, bone, and vascular tissue. Many cells express both ERα and ERβ, which can form either homo- or heterodimers. Both forms of ER are expressed on breast cancers, although ERα is believed to be the predominant form responsible for growth regulation (see Chapter 73). When coexpressed with ERα, ERβ can inhibit ERα-mediated transcriptional activation in many cases (Hall and McDonnell, 1999). Polymorphic variants of ER have been identified, but attempts to correlate specific polymorphisms with the frequency of breast cancer (Han et al., 2003), bone mass (Kurabayashi et al., 2004), endometrial cancer (Weiderpass et al., 2000), or cardiovascular disease (Herrington and Howard, 2003) have led to contradictory results.

A cloned G protein-coupled estrogen receptor, GPER (originally called GPR30), also appears to interact with estrogens in some cell systems (Filardo et al., 2021), and its participation in the rapid effects of estrogen is an attractive idea. There may be interaction/crosstalk between membrane-associated ERα and membrane-localized GPER; GPER has also been reported to exist in intracellular compartments. Whether GPER plays a physiological role in estrogen signaling *in vivo* remains an unsettled question (Levin, 2008; Leeb-Lundberg, 2009; Luo and Liu, 2020; Barton et al., 2018). GPER knock-out mice do not display reproductive dysfunction but have a variety of altered physiological functions consistent with the mediation by GPER of some modulatory effects of estrogens (Prossnitz and Hathaway, 2015). A variety of GPER-selective agonists and antagonists have been characterized (Prossnitz and Arterburn, 2015). A GPER-selective agonist is in early clinical trials for anti-tumor effects ± pembrolizumab (Filardo et al, 2021).

Mechanism of Action

Both ERs are ligand-activated transcription factors that increase or decrease the transcription of target genes (Figure 48–4). After entering the cell by passive diffusion through the plasma membrane, the hormone binds to an ER in the nucleus. In the nucleus, the ER is present as an inactive monomer bound to heat shock protein (HSP) 90, and on binding estrogen, a change in ER conformation dissociates the HSPs and causes receptor dimerization, which increases the affinity and the rate of receptor binding to DNA (Cheskis et al., 1997). Homodimers of ERα or ERβ and ERα/ERβ heterodimers can be produced depending on the receptor complement in a given cell. The concept of ligand-mediated changes in ER conformation is central to understanding the mechanism of action of estrogen agonists and antagonists. The ER dimer binds to estrogen receptor elements (EREs), typically located in the promoter region of target genes. The ER/DNA complex recruits a cascade of coactivator and other proteins to the promoter region of target genes (Figure 48–4B) and allows the proteins that make up the general transcription apparatus to assemble and initiate transcription.

Besides coactivators and corepressors, both ERα and ERβ can interact physically with other transcription factors, such as Sp1 (Saville et al., 2000) or AP-1 (Paech et al., 1997), and these protein-protein interactions provide an alternate mechanism of action. In these circumstances, ER-ligand complexes interact with Sp1 or AP-1 that is already bound to its specific regulatory element, such that the ER complex does not interact directly with an ERE. This may explain how estrogens are able to regulate genes that lack a consensus ERE. Responses to agonists and antagonists mediated by these protein-protein interactions also are ER isoform and promoter specific. For example, 17β-estradiol induces transcription of a target gene controlled by an AP-1 site in the presence of an ERα/AP-1 complex but inhibits transcription in the presence of an ERβ/AP-1 complex. Conversely, antiestrogens are potent activators of ERβ/AP-1 but not of ERα/AP-1 complexes.

Other signaling systems may activate nuclear ER by ligand-independent mechanisms. Phosphorylation of ERα at serine 118 by MAPK activates the receptor (Kato et al., 1995). Similarly, PI3K-activated Akt directly phosphorylates ERα, causing ligand-independent activation of estrogen target genes (Simoncini et al., 2000). This provides a means of crosstalk between membrane-bound receptor pathways (i.e., EGF/IGF-1) that activate MAPK and the nuclear ER.

Some ERs are located on the plasma membrane of cells. These ERs are encoded by the same genes that encode ERα and ERβ but are transported to the plasma membrane and reside mainly in caveolae

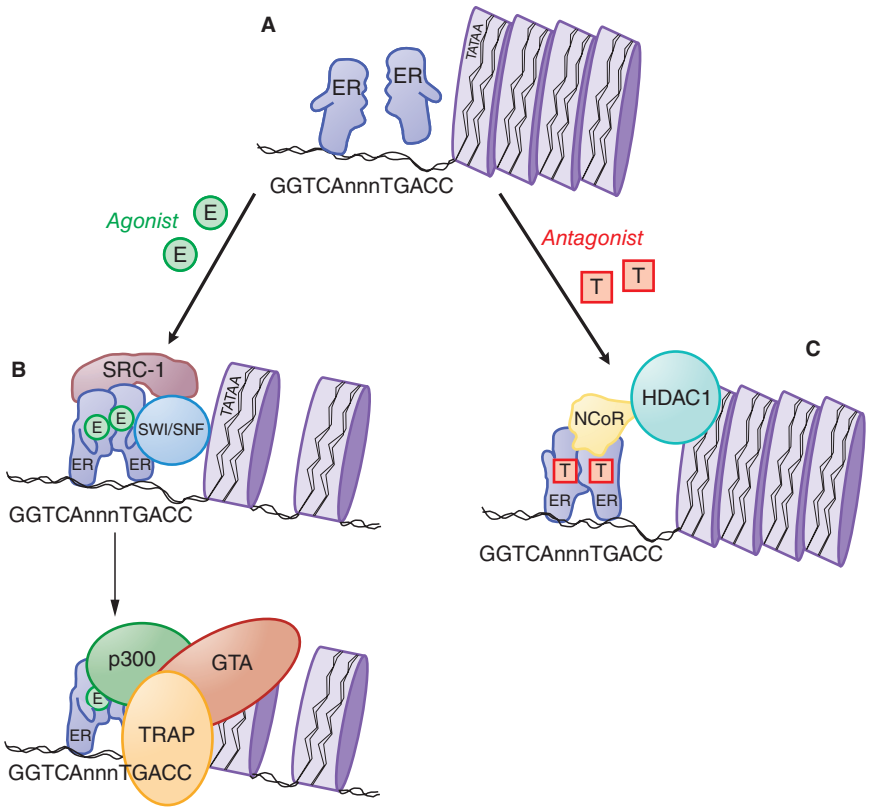

Figure 48–4 *Molecular mechanism of action of nuclear ER.* **A.** Unliganded ER exists as a monomer within the nucleus. **B.** Agonists such as 17β-estradiol (E) bind to the ER and cause a ligand-directed change in conformation that facilitates dimerization and interaction with specific ERE sequences in DNA. The ER-DNA complex recruits coactivators such as SWI/SNF that modify chromatin structure and coactivators such as SRC-1, which has histone acetyltransferase activity that further alters chromatin structure. This remodeling facilitates the exchange of the recruited proteins such that other coactivators (e.g., p300 and the TRAP complex) associate on the target gene promoter and proteins that comprise the general transcription apparatus (GTA) are recruited, with subsequent synthesis of mRNA. **C.** Antagonists such as tamoxifen (T) also bind to the ER but produce a different receptor conformation. The antagonist-induced conformation also facilitates dimerization and interaction with DNA, but a different set of proteins called corepressors, such as nuclear hormone receptor corepressor (NcoR), are recruited to the complex. NcoR further recruits proteins such as histone deacetylase I (HDAC1) that act on histones to stabilize nucleosome structure and prevent interaction with the GTA.

(Pedram et al., 2006). Translocation to the membrane by all sex steroid receptors is mediated by palmitoylation of a 9–amino acid motif in the respective E domains of the receptors (Levin, 2008). Membrane-localized ERs mediate the rapid activation of some proteins such as MAPK (phosphorylated in several cell types) and the rapid increase in cyclic AMP caused by the hormone. The finding that MAPK is activated by estradiol provides an additional level of crosstalk and complexity in estrogen signaling.

Pharmacology

ADME

Various estrogens are available for oral, parenteral, transdermal, or topical administration. Given the lipophilic nature of estrogens, absorption generally is good with the appropriate preparation. Aqueous or oil-based esters of estradiol are available for intramuscular injection, ranging in frequency from every week to once per month. Conjugated estrogens are available for intravenous or intramuscular administration. Transdermal patches that are changed once or twice weekly deliver estradiol continuously through the skin. Preparations are available for topical use in the vagina or for application to the skin. For many therapeutic uses, estrogen preparations are available in combination with a progestin. All estrogens are labeled with precautionary statements urging the prescribing of the lowest effective dose and for the shortest duration consistent with the treatment goals and risks for each individual patient.

Oral administration is common and may use estradiol, conjugated estrogens, esters of estrone and other estrogens, and *ethinyl estradiol* (*in combination with a progestin*). Estradiol is available in nonmicronized and micronized preparations. The micronized formulations yield a large surface for rapid absorption to partially overcome low absolute oral bioavailability due to first-pass metabolism (Fotherby, 1996). Addition of the ethinyl substituent at C17 (ethinyl estradiol) inhibits first-pass hepatic metabolism. Other common oral preparations contain conjugated equine estrogens, which are primarily the sulfate esters of estrone, equilin, and other naturally occurring compounds; *esterified esters*; or mixtures of synthetic conjugated estrogens prepared from plant-derived sources. These are hydrolyzed by enzymes present in the lower gut that remove the charged sulfate groups and allow absorption of estrogen across the intestinal epithelium. In another oral preparation, *estropipate*, estrone is solubilized as the sulfate and stabilized with *piperazine*. Due largely to differences in metabolism, the potencies of various oral preparations differ widely; ethinyl estradiol, for example, is much more potent than conjugated estrogens.

A number of foodstuffs and plant-derived products, largely from soy and wild yams, are available as unapproved marketed nonprescription items and often are touted as providing benefits similar to those from compounds with established estrogenic activity. These products may contain flavonoids such as genistein (Table 48–1) that display estrogenic activity in laboratory tests, albeit generally much less than that of estradiol. In theory, these preparations could produce appreciable estrogenic effects, but their efficacy at relevant doses has not been established in human trials (Fitzpatrick, 2003).

Administration of estradiol via transdermal patches provides slow, sustained release of the hormone, systemic distribution, and more constant blood levels than oral dosing. Estradiol is also available as a topical emulsion applied to the upper thigh and calf or as a gel applied once daily to the arm. The transdermal route does not lead to the high levels of the drug that occur in the portal circulation after oral administration, and it is thus expected to minimize hepatic effects of estrogens

(e.g., effects on hepatic protein synthesis, lipoprotein profiles, and triglyceride levels).

When dissolved in oil and injected, esters of estradiol are well absorbed. Preparations available for intramuscular injection include *estradiol valerate* or *estradiol cypionate* and may be absorbed over several weeks following a single intramuscular injection.

Preparations of estradiol or conjugated estrogen creams are available for topical administration to the vagina. These are effective locally, but systemic effects also are possible due to significant absorption. A 3-month vaginal ring may be used for slow release of estradiol, and tablets are also available for vaginal use (*Vagifem* and generics).

Estradiol, ethinyl estradiol, and other estrogens are extensively bound to plasma proteins. Estradiol and other naturally occurring estrogens are bound mainly to SHBG and to a lesser degree to serum albumin. In contrast, ethinyl estradiol is bound extensively to serum albumin but not SHBG. Due to their size and lipophilic nature, unbound estrogens distribute rapidly and extensively.

Variations in estradiol metabolism occur and depend on the stage of the menstrual cycle, menopausal status, and several genetic polymorphisms (Herrington and Klein, 2001). In general, the hormone undergoes rapid hepatic biotransformation, with a plasma $t_{1/2}$ measured in minutes. Estradiol is converted primarily by 17β-hydroxysteroid dehydrogenase to estrone, which undergoes conversion by 16α-hydroxylation and 17-keto reduction to estriol, the major urinary metabolite. A variety of sulfate and glucuronide conjugates also are excreted in the urine. Lesser amounts of estrone or estradiol are oxidized to the 2-hydroxycatechols by CYP3A4 in the liver and by CYP1A in extrahepatic tissues or to 4-hydroxycatechols by CYP1B1 in extrahepatic sites, with the 2-hydroxycatechol formed to a greater extent. The 2- and 4-hydroxycatechols are largely inactivated by catechol-*O*-methyl transferases. However, smaller amounts may be converted by CYP- or peroxidase-catalyzed reactions to yield semiquinones or quinones that are capable of forming DNA adducts or of generating (via redox cycling) reactive oxygen species (ROSs) that could oxidize DNA bases (Yue et al., 2003).

Estrogens also undergo enterohepatic recirculation via (1) sulfate and glucuronide conjugation in the liver, (2) biliary secretion of the conjugates into the intestine, and (3) hydrolysis in the gut (largely by bacterial enzymes) followed by reabsorption.

Many other drugs and environmental agents (e.g., cigarette smoke) act as inducers or inhibitors of the various enzymes that metabolize estrogens and thus have the potential to alter their clearance. Consideration of the impact of these factors on efficacy and untoward effects is increasingly important with the decreased doses of estrogens currently employed for both menopausal hormone therapy (MHT) and contraception.

Ethinyl estradiol is cleared much more slowly than estradiol due to decreased hepatic metabolism, and the elimination-phase $t_{1/2}$ in various studies ranges from 13 to 27 h. Unlike estradiol, the primary route of biotransformation of ethinyl estradiol is via 2-hydroxylation and subsequent formation of the corresponding 2- and 3-methyl ethers. *Mestranol*, another semisynthetic estrogen and a component of some combination oral contraceptives, is the 3-methyl ether of ethinyl estradiol. In the body, it undergoes rapid hepatic demethylation to ethinyl estradiol, which is its active form (Fotherby, 1996).

Selective Estrogen Receptor Modulators and Antiestrogens

By altering the conformation of the two different ERs and thereby changing interactions with coactivators and corepressors in cell-specific and promoter-specific contexts, ligands may have a broad spectrum of activities from purely antiestrogenic in all tissues, to partially estrogenic in some tissues with antiestrogenic or no activities in others, to purely estrogenic activities in all tissues. The elucidation of these concepts has been a major breakthrough in estrogen pharmacology and should permit the rational design of drugs with selective patterns of estrogenic activity (Smith and McManus, 2004).

Selective Estrogen Receptor Modulators: Tamoxifen, Raloxifene, and Toremifene

Selective estrogen receptor modulators, or SERMs, are compounds with tissue-selective actions. The pharmacological goal of these drugs is to produce beneficial estrogenic actions in certain tissues (e.g., bone, brain, and liver) during post-MHT but antagonist activity in tissues such as breast and endometrium, where estrogenic actions (e.g., carcinogenesis) might be deleterious. Currently approved drugs in the U.S. in this class are *tamoxifen citrate*, *raloxifene hydrochloride*, and *toremifene*, which is chemically related and has similar actions to *tamoxifen*. *Tamoxifen* and *toremifene* are used for the treatment of breast cancer, and *raloxifene* is used primarily for the prevention and treatment of osteoporosis and to reduce the risk of invasive breast cancer in high-risk postmenopausal women. They are considered in detail in Chapter 73.

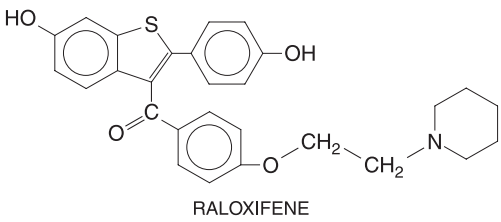
Antiestrogens: Clomiphene and Fulvestrant

The antiestrogen compounds are distinguished from the SERMs in that they are pure antagonists in all tissues studied. *Clomiphene* is approved for the treatment of infertility in anovulatory women, and *fulvestrant* is used for the treatment of breast cancer in women with disease progression after *tamoxifen*.

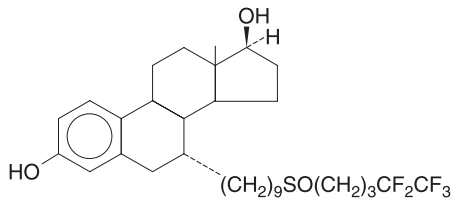
Chemistry

The structures of the *trans*-isomer of *tamoxifen*, and of *raloxifene*, *trans*-clomiphene (enclomiphene), and *fulvestrant* are as follows:

	ENCLOMIPHENE	TAMOXIFEN
R_1:	$-CH_2CH_3$	$-CH_3$
R_2:	$-Cl$	$-CH_2CH_3$



RALOXIFENE



FULVESTRANT (ICI 182, 780)

Tamoxifen is a triphenylethylene with the same stilbene nucleus as *diethylstilbestrol*; compounds of this class display a variety of estrogenic and antiestrogenic activities. In general, the *trans* conformations have antiestrogenic activity, whereas the *cis* conformations display estrogenic activity. However, the pharmacological activity of the *trans* compound depends on the species, target tissue, and gene. Hepatic metabolism produces primarily *N*-desmethyltamoxifen, which has affinity for ER comparable to that of *tamoxifen*, and lesser amounts of the highly active 4-hydroxy metabolite, which has 25- to 50-times higher affinity for both

ERα and ERβ than does *tamoxifen* (Kuiper et al., 1997). *Tamoxifen* is marketed as the pure *trans*-isomer. *Toremifene* is a triphenylethylene with a chlorine substitution at the R2 position.

Raloxifene is a polyhydroxylated nonsteroidal compound with a benzothiophene core. *Raloxifene* binds with high affinity for both ERα and ERβ (Kuiper et al., 1997).

Clomiphene citrate is a triphenylethylene; its two isomers, zuclomiphene (*cis* clomiphene) and enclomiphene (*trans* clomiphene), are a weak estrogen agonist and a potent antagonist, respectively. *Clomiphene* binds to both ERα and ERβ, but the individual isomers have not been examined (Kuiper et al., 1997).

Fulvestrant is a 7α-alkylamide derivative of estradiol that interacts with both ERα and ERβ (Van Den Bemd et al., 1999).

Pharmacological Effects

All of these agents bind to the ligand-binding pocket of both ERα and ERβ and competitively block estradiol binding. However, the conformation of the ligand-bound ERs is different with different ligands (Smith and O'Malley, 2004), and this has two important mechanistic consequences. The distinct ER-ligand conformations recruit different coactivators and corepressors onto the promoter of a target gene by differential protein-protein interactions at the receptor surface. The tissue-specific actions of SERMs thus can be explained in part by the distinct conformation of the ER when occupied by different ligands, in combination with different coactivator and corepressor levels in different cell types that together affect the nature of ER complexes formed in a tissue-selective fashion.

Tamoxifen. *Tamoxifen* exhibits antiestrogenic, estrogenic, or mixed activity depending on the species and target gene measured. In clinical tests or laboratory studies with human cells, the drug's activity depends on the tissue and end point measured. For example, *tamoxifen* inhibits the proliferation of cultured human breast cancer cells and reduces tumor size and number in women (Jaiyesimi et al., 1995), and yet it stimulates proliferation of endometrial cells and causes endometrial thickening (Lahti et al., 1993). The drug has an antiresorptive effect on bone, and in humans, it decreases total cholesterol, LDL, and lipoprotein A but does not increase HDL and triglycerides (Love et al., 1994). *Tamoxifen* treatment causes a 2- to 3-fold increase in the relative risk of deep vein thrombosis and pulmonary embolism and a roughly 2-fold increase in endometrial carcinoma (Smith, 2003). *Tamoxifen* produces hot flashes and other adverse effects, including cataracts and nausea. Due to its agonist activity in bone, it does not increase the incidence of fractures when used in this setting.

The conformation of ERs, especially in the AF-2 domain, determines whether a coactivator or a corepressor will be recruited to the ER-DNA complex (Smith and O'Malley, 2004). *Tamoxifen* induces a conformation that permits the recruitment of the corepressor to both ERα and ERβ, in contrast to 17α-estradiol, which induces a conformation that recruits coactivators to the receptor. The agonist activity of *tamoxifen* seen in tissues such as the endometrium is mediated by the ligand-independent AF-1 transactivation domain of ERα; because ERβ does not contain a functional AF-1 domain, *tamoxifen* does not activate ERβ (McInerney et al., 1998).

Raloxifene. *Raloxifene* is an estrogen agonist in bone, where it exerts an antiresorptive effect. The drug also acts as an estrogen agonist in reducing total cholesterol and LDL, but it does not increase HDL or normalize PAI-1 in postmenopausal women (Walsh et al., 1998). Studies indicated that *raloxifene* has an antiproliferative effect on ER-positive breast tumors and significantly reduces the risk of ER-positive but not ER-negative breast cancer (Cummings et al., 1999). *Raloxifene* does not alleviate the vasomotor symptoms associated with menopause. Adverse effects include hot flashes and leg cramps and a 3-fold increase in deep vein thrombosis and pulmonary embolism (Cummings et al., 1999).

Raloxifene acts as a partial agonist in bone but does not stimulate endometrial proliferation in postmenopausal women. Presumably this is due to some combination of differential expression of transcription factors in the two tissues and the effects of this SERM on ER conformation. *Raloxifene* induces a configuration in ERα that is distinct from that of *tamoxifen*-ERβ (Tamrazi et al., 2003), suggesting that a different set of coactivators/corepressors may interact with ER-*raloxifene* compared with ER-*tamoxifen*.

Fulvestrant. *Fulvestrant* is antiestrogenic. In clinical trials, it is efficacious in treating *tamoxifen*-resistant breast cancers (Robertson et al., 2003). *Fulvestrant* binds to ERα and ERβ with high affinity comparable to estradiol but represses transactivation. It also increases dramatically the intracellular proteolytic degradation of ERα while apparently protecting ERβ from degradation (Van Den Bemd et al., 1999). This effect on ERα protein levels may explain *fulvestrant*'s efficacy in *tamoxifen*-resistant breast cancer.

Clomiphene. *Clomiphene* increases gonadotropin secretion and stimulates ovulation. It increases the amplitude of LH and FSH pulses without changing pulse frequency (Kettel et al., 1993). This suggests that the drug is acting largely at the pituitary level to block inhibitory actions of estrogen on gonadotropin release from the gland or is somehow causing the hypothalamus to release larger amounts of GnRH per pulse.

The most prominent effect of *clomiphene* in women was enlargement of the ovaries and the drug-induced ovulation in many patients with amenorrhea, polycystic ovary syndrome (PCOS), and dysfunctional bleeding with anovulatory cycles. Thus, *clomiphene*'s major pharmacological use is to induce ovulation in women with a functional hypothalamic-hypophyseal-ovarian system and adequate endogenous estrogen production. In some cases, *clomiphene* is used in conjunction with human gonadotropins (see Chapter 46) to induce ovulation.

ADME

Tamoxifen is given orally, and peak plasma levels are reached within 4 to 7 h. It has two elimination phases with $t_{1/2}$ of 7 to 14 h and 4 to 11 days. Due to the prolonged $t_{1/2}$, 3 to 4 weeks of treatment are required to reach steady-state plasma levels. *Tamoxifen* is metabolized in humans by multiple hepatic CYPs, some of which it also induces (Sridar et al., 2002). In humans and other species, 4-hydroxytamoxifen is produced via hepatic metabolism, and this compound is considerably more potent than the parent drug as an antiestrogen. The major route of elimination from the body involves *N*-demethylation and deamination. The drug undergoes enterohepatic circulation, and excretion is primarily in the feces as conjugates of the deaminated metabolite. Polymorphisms affect the rate of *tamoxifen* metabolism to its more potent 4-hydroxy metabolite and may affect its therapeutic activity in breast cancer (see Chapter 73).

Raloxifene is absorbed rapidly after oral administration and has an absolute bioavailability of about 2%. The drug has a $t_{1/2}$ of about 28 h and is eliminated primarily in the feces after hepatic glucuronidation.

Clomiphene is well absorbed following oral administration, and the drug and its metabolites are eliminated primarily in the feces and to a lesser extent in the urine. The long plasma $t_{1/2}$ (5–7 days) is due largely to plasma-protein binding, enterohepatic circulation, and accumulation in fatty tissues.

Fulvestrant is administered monthly by intramuscular depot injections. Plasma concentrations reach maximal levels in 7 days and are maintained for a month. Numerous metabolites are formed *in vivo*, possibly by pathways similar to endogenous estrogen metabolism, but the drug is eliminated primarily (90%) via the feces in humans.

Therapeutic Uses

Breast Cancer. *Tamoxifen* is highly efficacious in the treatment of breast cancer. It is used alone for palliation of advanced breast cancer in women with ER-positive tumors, and it is now indicated as the hormonal treatment of choice for both early and advanced breast cancer in women of all ages (Jaiyesimi et al., 1995). Response rates are about 50% in women with ER-positive tumors. *Tamoxifen* increases disease-free survival and overall survival; treatment for 5 years reduces cancer recurrence by 50% and death by 27% and is more efficacious than shorter 1- to 2-year treatment periods. *Tamoxifen* reduces the risk of developing contralateral breast cancer and is approved for primary prevention of breast cancer in women at high risk, in whom it causes a 50% decrease in the development of new tumors. Prophylactic treatment should be limited to 5 years because effectiveness decreases thereafter. The most frequent side effect

is hot flashes. *Tamoxifen* has estrogenic activity in the uterus, increases the risk of endometrial cancer by 2- to 3-fold, and also causes a comparable increase in the risk of thromboembolic disease that leads to serious risks for women receiving anticoagulant therapy (Smith, 2003) and women with a history of deep vein thrombosis or stroke.

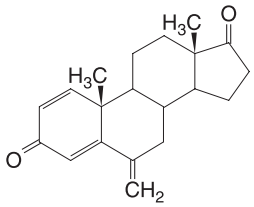
Toremifene has therapeutic actions similar to *tamoxifen*, and *fulvestrant* may be efficacious in women who become resistant to *tamoxifen*. Untoward effects of *fulvestrant* include hot flashes, GI symptoms, headache, back pain, and pharyngitis.

Osteoporosis. *Raloxifene* reduces the rate of bone loss and may increase bone mass at certain sites. In a large clinical trial, *raloxifene* increased spinal bone mineral density by more than 2% and reduced the rate of vertebral fractures by 30% to 50% but did not significantly reduce nonvertebral fractures (Delmas et al., 2002; Ettinger et al., 1999). *Raloxifene* does not appear to increase the risk of developing endometrial cancer. The drug has beneficial actions on lipoprotein metabolism, reducing both total cholesterol and LDL; however, HDL is not increased. Adverse effects include hot flashes, deep vein thrombosis, and leg cramps.

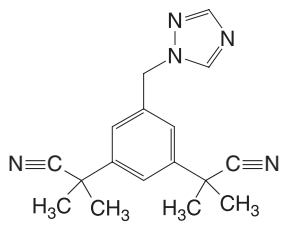
Infertility. *Clomiphene citrate* is a potent antiestrogen that primarily is used for treatment of anovulation in the setting of an intact hypothalamic-pituitary axis and adequate estrogen production (e.g., PCOS) or to induce superovulation in women with unexplained infertility. By inhibiting the negative-feedback effects of estrogen at hypothalamic and pituitary levels, *clomiphene* increases FSH levels and thereby enhances follicular maturation. The drug is relatively inexpensive, is orally active, and requires less-extensive monitoring than do other fertility protocols. However, the drug may exhibit untoward effects, including ovarian hyperstimulation, increased incidence of multiple births, ovarian cysts, hot flashes, and blurred vision. Prolonged use (e.g., ≥12 cycles) may increase the risk of ovarian cancer. The drug should not be administered to pregnant women due to reports of teratogenicity in animals, but there is no evidence of this when the drug has been used to induce ovulation.

Experimental SERM-Estrogen Combinations. There is considerable interest in MHT using combinations of a pure estrogen agonist (e.g., estradiol) with a SERM that has predominantly antagonist activity in the breast and endometrium but does not distribute to the CNS. The strategy is to obtain the beneficial actions of the agonist (e.g., prevention of hot flashes and bone loss) while the SERM blocks unwanted agonist action at peripheral sites (e.g., proliferative effects in breast and endometrium) but does not enter the brain to cause hot flashes. Animal studies have been encouraging (Labrie et al., 2003), but clinical efficacy and safety of this approach remain to be established.

Estrogen Synthesis Inhibitors



EXEMESTANE



ANASTROZOLE

Continual administration of GnRH agonists prevents ovarian synthesis of estrogens but not their peripheral synthesis from adrenal androgens (see Chapter 46). *Aminoglutethimide* inhibits aromatase activity, but its use is limited by its lack of selectivity and its side effects (sedation). It was discontinued in the U.S. in 2008.

The recognition that locally produced as well as circulating estrogens may play a significant role in breast cancer has greatly stimulated interest in the use of aromatase inhibitors to selectively block production of estrogens (see Figure 73–3). Both steroidal (e.g., *exemestane*) and nonsteroidal (e.g., *anastrozole*, *letrozole*, and *vorozole*) agents are available. Steroidal, or type I, agents are substrate analogues that act as suicide inhibitors to irreversibly inactivate aromatase, whereas the nonsteroidal, or type II, agents interact reversibly with the heme groups of CYPs (Haynes et al., 2003). *Exemestane*, *letrozole*, and *anastrozole* are currently approved in the U.S. for the treatment of breast cancer.

As discussed in Chapter 73, these agents may be used as first-line treatment of breast cancer or as second-line drugs after *tamoxifen*. They are highly efficacious and actually superior to *tamoxifen* in adjuvant use for postmenopausal women (Coombes et al., 2004), and they are indicated either following *tamoxifen* for 2 to 5 years or as initial agents. They have the added advantage of not increasing the risk of uterine cancer or venous thromboembolism. Because they dramatically reduce circulating as well as local levels of estrogens, they produce hot flashes. They lack the beneficial effect of *tamoxifen* to maintain bone density and thus are often administered with bisphosphonates. Their effects on plasma lipids remain to be established.

Progestins

HISTORY **Progestins**

Corner and Allen originally isolated a hormone in 1933 from the corpora lutea of sows and named it *progestin.* The next year, several European groups independently isolated the crystalline compound and called it *luteo-sterone*, unaware of the previous name. This difference in nomenclature was resolved in 1935 at a garden party in London given by Sir Henry Dale, who helped persuade all parties that the name *progesterone* was a suitable compromise.

Two major advances overcame the early difficulties and expense of obtaining progesterone from animal sources. The first was the synthesis of progesterone by Russel Marker from the plant product diosgenin in the 1940s, which provided a relatively inexpensive and highly pure product. The second was the synthesis of 19-nor compounds, the first orally active progestins, in the early 1950s by Carl Djerassi, who synthesized *norethindrone* at Syntex, and Frank Colton, who synthesized the isomer *norethynodrel* at Searle. These advances led to the development of effective oral contraceptives.

Chemistry

Compounds with biological activities similar to those of progesterone are referred to as progestins, progestational agents, progestagens, progestogens, gestagens, or gestogens. The progestins (Figure 48–5) include the naturally occurring hormone progesterone, 17α-acetoxyprogesterone derivatives in the pregnane series, 19-nortestosterone derivatives in the estrane series, and norgestrel and related compounds in the gonane series. *Medroxyprogesterone acetate* (MPA) and *megestrol acetate* are C21 steroids in the pregnane family with selective activity very similar to that of progesterone itself. MPA and oral micronized progesterone are widely used with estrogens for MHT and other situations in which a selective progestational effect is desired. Furthermore, depot MPA is used as a long-acting injectable contraceptive. The 19-nortestosterone derivatives (estranes) were developed for use as progestins in oral contraceptives, and although their predominant activity is progestational, they exhibit androgenic and other activities. The gonanes are another family of "19-nor" compounds, containing an ethyl rather than a methyl substituent in the 13 position. They have diminished androgenic activity relative to the estranes. These two classes of 19-nortestosterone derivatives are the

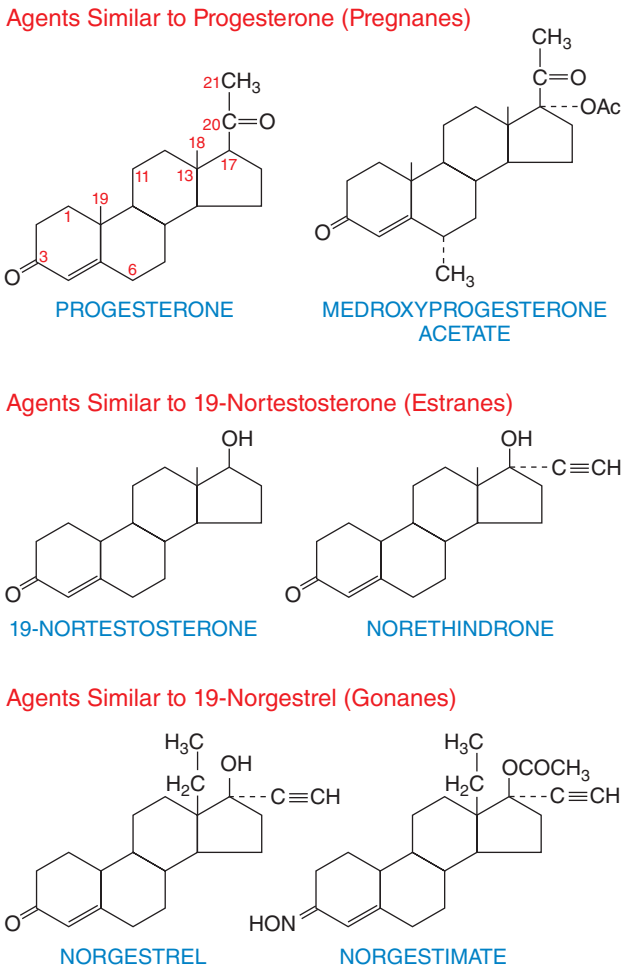


Figure 48–5 *Structural features of various progestins.*

progestational components of most oral and some long-acting injectable contraceptives. The remaining oral contraceptives contain a class of progestins derived from *spironolactone* (e.g., *drospirenone*) that have antimineralocorticoid and antiandrogenic properties.

The structural features of several progestins are shown in Figure 48–5. Unlike the ER, which requires a phenolic A ring for high-affinity binding, the PR favors a Δ^4–3-one A-ring structure in an inverted 1β,2α-conformation. Other steroid hormone receptors also bind this nonphenolic A-ring structure, although the optimal conformation differs from that for the PR. Thus, some synthetic progestins (especially the 19-nor compounds) display limited binding to glucocorticoid, androgen, and mineralocorticoid receptors, a property that probably accounts for some of their nonprogestational activities. The spectrum of activities of these compounds is highly dependent on specific substituent groups, especially the nature of the C17 substituent in the D ring, the presence of a C19 methyl group, and the presence of an ethyl group at position C13.

Biosynthesis and Secretion

Progesterone is secreted by the ovary, mainly from the corpus luteum, during the second half of the menstrual cycle (Figure 48–3). LH, acting via its G protein-coupled receptor, stimulates progesterone secretion during the normal cycle.

After fertilization, the trophoblast secretes hCG into the maternal circulation, which then stimulates the LH receptor to sustain the corpus luteum and maintain progesterone production. During the second or third month of pregnancy, the developing placenta begins to secrete estrogen and progesterone in collaboration with the fetal adrenal glands, and thereafter, the corpus luteum is not essential to continued gestation. Estrogen and progesterone continue to be secreted in large amounts by the placenta up to the time of delivery.

Physiological Actions

Neuroendocrine Actions

Progesterone produced in the luteal phase of the cycle has several physiological effects, including decreasing the frequency of GnRH pulses. This progesterone-mediated decrease in GnRH pulse frequency is critical for suppressing gonadotropin release and resetting the hypothalamic-pituitary-gonadal axis to transition from the luteal back to the follicular phase. Furthermore, GnRH suppression is the major mechanism of action of progestin-containing contraceptives.

Reproductive Tract. Progesterone decreases estrogen-driven endometrial proliferation and leads to the development of a secretory endometrium (Figure 48–3), and the abrupt decline in progesterone at the end of the cycle is the main determinant of the onset of menstruation. If the duration of the luteal phase is artificially lengthened, either by sustaining luteal function or by treatment with progesterone, decidual changes in the endometrial stroma similar to those seen in early pregnancy can be induced. Under normal circumstances, estrogen antecedes and accompanies progesterone in its action on the endometrium and is essential to the development of the normal menstrual pattern.

Progesterone also influences the endocervical glands, and the abundant watery secretion of the estrogen-stimulated structures is changed to a scant viscid material. As noted previously, these and other effects of progestins decrease penetration of the cervix by sperm.

The estrogen-induced maturation of the human vaginal epithelium is modified toward the condition of pregnancy by the action of progesterone, a change that can be detected in cytological alterations in the vaginal smear. If the quantity of estrogen concurrently acting is known to be adequate, or if it is ensured by giving estrogen, the cytological response to a progestin can be used to evaluate its progestational potency.

Progesterone is important for the maintenance of pregnancy. Progesterone suppresses menstruation and uterine contractility.

Mammary Gland. Development of the mammary gland requires both estrogen and progesterone. During pregnancy and to a minor degree during the luteal phase of the cycle, progesterone, acting with estrogen, brings about a proliferation of the acini of the mammary gland. Toward the end of pregnancy, the acini fill with secretions, and the vasculature of the gland notably increases; however, only after the levels of estrogen and progesterone decrease at parturition does lactation begin.

During the normal menstrual cycle, mitotic activity in the breast epithelium is very low in the follicular phase and then peaks in the luteal phase. This pattern is due to progesterone, which triggers a *single* round of mitotic activity in the mammary epithelium. This effect is transient because continued exposure to the hormone is rapidly followed by arrest of growth of the epithelial cells. Importantly, progesterone may be responsible for the increased risk of breast cancer associated with estrogen-progestin use in postmenopausal women, although controlled studies with only progestin have not been performed (Anderson et al., 2004; Rossouw et al., 2002).

CNS. During a normal menstrual cycle, an increase in basal body temperature of about 0.6°C (1°F) may be noted at midcycle; this correlates with ovulation. This increase is due to progesterone, but the exact mechanism of this effect is unknown. Progesterone also increases the ventilatory response of the respiratory centers to carbon dioxide and leads to reduced arterial and alveolar P_{CO_2} in the luteal phase of the menstrual cycle and during pregnancy. Progesterone also may have depressant and hypnotic actions in the CNS, possibly accounting for reports of drowsiness after hormone administration. This potential untoward effect may be abrogated by giving progesterone preparations at bedtime, which may even help some patients sleep.

Metabolic Effects. Progestins have numerous metabolic actions. Progesterone itself increases basal insulin levels and the rise in insulin after carbohydrate ingestion, but it does not normally alter glucose tolerance.

However, long-term administration of more potent progestins, such as *norgestrel*, may decrease glucose tolerance. Progesterone stimulates lipoprotein lipase activity and seems to enhance fat deposition. Progesterone and analogues such as MPA have been reported to increase LDL and cause either no effects or modest reductions in serum HDL levels. The 19-norprogestins may have more pronounced effects on plasma lipids because of their androgenic activity.

Medroxyprogesterone acetate decreases the favorable HDL increase caused by conjugated estrogens during postmenopausal hormone replacement, but it does not significantly affect the beneficial effect of estrogens to lower LDL. In contrast, micronized progesterone does not significantly alter beneficial estrogen effects on either HDL or LDL profiles (Writing Group for the PEPI Trial, 1995); the *spironolactone* derivative *drospirenone* may have advantageous effects on the cardiovascular system due to its antiandrogenic and antimineralocorticoid activities. Progesterone also may diminish the effects of aldosterone in the renal tubule and cause a decrease in sodium reabsorption that may increase mineralocorticoid secretion from the adrenal cortex.

Pharmacology

Mechanism of Action

A single gene encodes two isoforms of the progesterone receptor (PR), PR-A and PR-B. The first 164 N-terminal amino acids of PR-B are missing from PR-A; this occurs by use of two distinct estrogen-dependent promoters in the PR gene (Giangrande and McDonnell, 1999). The ratios of the individual isoforms vary in reproductive tissues as a consequence of tissue type, developmental status, and hormone levels. Both PR-A and PR-B have AF-1 and AF-2 transactivation domains, but the longer PR-B also contains an additional AF-3 that contributes to its cell- and promoter-specific activity. Because the ligand-binding domains of the two PR isoforms are identical, there is no difference in ligand binding. In the absence of ligand, PR is present primarily in the nucleus in an inactive monomeric state bound to HSP90, HSP70, and p59. When receptors bind progesterone, the HSPs dissociate, and the receptors are phosphorylated and subsequently form dimers (homo- and heterodimers) that bind with high selectivity to PREs located on target genes (Giangrande and McDonnell, 1999). Transcriptional activation by PR occurs primarily via recruitment of coactivators such as steroid-receptor coactivator 1 (SRC-1), NcoA-1, or NcoA-2 (Collingwood et al., 1999). The receptor-coactivator complex then favors further interactions with additional proteins, such as CBP and p300, which mediate other processes, including histone acetylase activity. Histone acetylation causes remodeling of chromatin that increases the accessibility of general transcriptional proteins, including RNA polymerase II, to the target promoter.

The biological activities of PR-A and PR-B are distinct and depend on the target gene. In most cells, PR-B mediates the stimulatory activities of progesterone; PR-A strongly inhibits this action of PR-B and is also a transcriptional inhibitor of other steroid receptors (McDonnell and Goldman, 1994). Current data suggest that coactivators and corepressors interact differentially with PR-A and PR-B (e.g., the corepressor SMRT binds much more tightly to PR-A than to PR-B) (Giangrande et al., 2000), and this may account, at least in part, for the differential activities of the two isoforms. Female PR-A knockout mice are infertile, with impaired ovulation and defective decidualization and implantation. Several uterine genes appear to be regulated exclusively by PR-A, including calcitonin and amphiregulin (Mulac-Jericevic et al., 2000), and the antiproliferative effect of progesterone on the estrogen-stimulated endometrium is lost in PR-A knockout mice. In contrast, knockout studies suggested that PR-B is largely responsible for mediating hormone effects in the mammary gland (Mulac-Jericevic et al., 2003).

Certain effects of progesterone, such as increased Ca^{2+} mobilization in sperm, can be seen in as little as 3 min (Blackmore, 1999) and are therefore considered transcription independent. Similarly, progesterone can promote oocyte maturation (meiotic resumption) independent of transcription (Hammes, 2004).

ADME

Progesterone undergoes rapid first-pass metabolism, but high-dose (e.g., 100–200 mg) preparations of micronized progesterone are available for oral use. Although the absolute bioavailability of these preparations is low (Fotherby, 1996), efficacious plasma levels nevertheless may be obtained. Progesterone also is available in oil solution for injection, as a vaginal gel, and as a vaginal insert for assisted reproductive technology.

Esters such as MPA are available for intramuscular or subcutaneous administration, and MPA and *megestrol acetate* may be used orally. The 19-nor steroids have good oral activity because the ethinyl substituent at C17 significantly slows hepatic metabolism. Implants and depot preparations of synthetic progestins are available in many countries for release over very long periods of time (see section on contraceptives).

In the plasma, progesterone is bound by albumin and corticosteroid-binding globulin but is not appreciably bound to SHBG. 19-Nor compounds, such as *norethindrone*, *norgestrel*, and *desogestrel*, bind to SHBG and albumin, and esters such as MPA bind primarily to albumin. Total binding of all these synthetic compounds to plasma proteins is extensive, 90% or less, but the proteins involved are compound specific.

The elimination $t_{1/2}$ of progesterone is about 5 min, and the hormone is metabolized primarily in the liver to hydroxylated metabolites and their sulfate and glucuronide conjugates, which are eliminated in the urine. A major metabolite specific for progesterone is pregnane-3α,20α-diol; its measurement in urine and plasma is used as an index of endogenous progesterone secretion. The synthetic progestins have much longer $t_{1/2}$ (e.g., ~ 7 h for *norethindrone*, 16 h for *norgestrel*, 12 h for *gestodene*, and 24 h for MPA). The metabolism of synthetic progestins is thought to be primarily hepatic, and elimination is generally via the urine as conjugates and various polar metabolites.

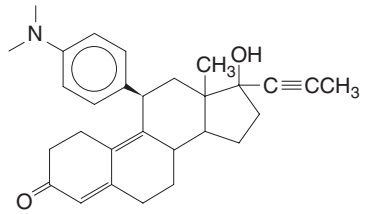
Antiprogestins and Progesterone Receptor Modulators

The first report of an antiprogestin, RU 38486 (often referred to as RU-486) or *mifepristone*, appeared in 1981; this drug is available for the termination of pregnancy (Christin-Maitre et al., 2000). In 2010, the FDA approved *ulipristal acetate*, a partial agonist at the progesterone receptor, for emergency contraception. Antiprogestins also have several other potential applications, including to prevent conception, to induce labor, and to treat uterine leiomyomas, endometriosis, meningiomas, and breast cancer (Spitz and Chwalisz, 2000).

Mifepristone

Chemistry

Mifepristone is a derivative of the 19-norprogestin *norethindrone* containing a dimethyl-aminophenol substituent at the 11β position. It effectively competes with both progesterone and glucocorticoids for binding to their respective receptors. *Mifepristone* is considered a progesterone receptor modulator (PRM) due to its context-dependent activity. Another widely studied antiprogestin is *onapristone* (or ZK 98299), which is similar in structure to *mifepristone* but contains a methyl substituent in the 13α rather than 13β orientation. More selective PRMs, such as *asoprisnil*, are being studied experimentally (DeManno et al., 2003).



MIFEPRISTONE

Pharmacological Effects

Mifepristone acts primarily as a competitive receptor antagonist for both PRs, although it may have some agonist activity in certain contexts. In contrast, *onapristone* appears to be a pure progesterone antagonist. PR complexes of both compounds antagonize the actions of progesterone-PR complexes and appear to preferentially recruit corepressors (Leonhardt and Edwards, 2002).

When administered in the early stages of pregnancy, *mifepristone* causes decidual breakdown by blockade of uterine PRs. This leads to detachment of the blastocyst, which decreases hCG production. This in turn causes a decrease in progesterone secretion from the corpus luteum, which further accentuates decidual breakdown. Decreased endogenous progesterone coupled with blockade of PRs in the uterus increases uterine prostaglandin (PG) levels and sensitizes the myometrium to their contractile actions. *Mifepristone* also causes cervical softening, which facilitates expulsion of the detached blastocyst.

Mifepristone can delay or prevent ovulation depending on the timing and manner of administration. These effects are due largely to actions on the hypothalamus and pituitary rather than the ovary, although the mechanisms are unclear.

If administered for one or several days in the mid- to late-luteal phase, *mifepristone* impairs the development of a secretory endometrium and produces menses. PR blockade at this time is the pharmacological equivalent of progesterone withdrawal, and bleeding normally ensues within several days and lasts for 1 to 2 weeks after antiprogestin treatment.

Mifepristone also binds to glucocorticoid and androgen receptors and exerts antiglucocorticoid and antiandrogenic actions. A predominant effect in humans is blockade of the feedback inhibition by cortisol of adenocorticotropic hormone secretion from the pituitary, thus increasing both corticotropin and adrenal steroid levels in the plasma.

ADME

Mifepristone is orally active with good bioavailability. Peak plasma levels occur within several hours, and the drug is slowly cleared, with a plasma $t_{1/2}$ of 20 to 40 h. In plasma, it is bound by α_1-acid glycoprotein, which contributes to the drug's long $t_{1/2}$. Metabolites are primarily the mono- and didemethylated products (thought to have pharmacological activity) formed via CYP3A4. The drug undergoes hepatic metabolism and enterohepatic circulation; metabolic products are found predominantly in the feces (Jang and Benet, 1997).

Therapeutic Uses

Mifepristone, in combination with *misoprostol* or other PGs, is available for the termination of early pregnancy. When *mifepristone* is used to produce a medical abortion, a PG is given 48 h after the antiprogestin to further increase myometrial contractions and ensure expulsion of the detached blastocyst. Intramuscular *sulprostone*, intravaginal *gemeprost*, and oral *misoprostol* have been used. The success rate with such regimens is greater than 90% among women with pregnancies of 49 days' duration or less. The most severe untoward effect is vaginal bleeding, which most often lasts 8 to 17 days but is only rarely (0.1% of patients) severe enough to require blood transfusions. High percentages of women also have experienced abdominal pain and uterine cramps, nausea, vomiting, and diarrhea due to the PG. Women receiving chronic glucocorticoid therapy should not be given *mifepristone* because of its antiglucocorticoid activity. In fact, due to its high affinity for the glucocorticoid receptor, high doses of *mifepristone* can result in adrenal insufficiency, and *mifepristone* is FDA-approved for the management of the excess glucocorticoid production seen in Cushing syndrome.

Ulipristal

Chemistry

Ulipristal, a derivative of 19-norprogesterone, functions as a selective progesterone receptor modulator, acting as a partial agonist at PRs. Unlike *mifepristone*, *ulipristal* appears to be a relatively weak glucocorticoid antagonist.

Pharmacological Effects

In high doses, *ulipristal* has antiproliferative effects in the uterus; however, its most relevant actions to date involve its capacity to inhibit ovulation. *Ulipristal*'s antiovulatory actions likely occur due to progesterone regulation at many levels, including inhibition of LH release through the hypothalamus and pituitary and inhibition of LH-induced follicular rupture within the ovary.

A 30-mg dose of *ulipristal* can inhibit ovulation when taken up to 5 days after intercourse. *Ulipristal* can block ovarian rupture at or even just after the time of the LH surge, confirming that at least some of its effects are directly in the ovary.

Therapeutic Uses

Ulipristal acetate is licensed in the E.U. and the U.S. as an emergency contraceptive. Studies comparing *ulipristal* to *levonorgestrel* (progesterone-only emergency contraception) demonstrate that *ulipristal* is at least as effective when taken up to 72 h after unprotected sexual intercourse. In addition, *ulipristal* remains effective up to 120 h (5 days) after intercourse, making *ulipristal* a more versatile emergency contraceptive than *levonorgestrel*, which does not work well beyond 72 h after unprotected intercourse. The most severe side effect in clinical trials using *ulipristal* has been a self-limited headache and some abdominal pain.

Perspective: Too Many People?

The incredible growth of the earth's human population stands out as one of the fundamental events of the last two centuries. The Old Testament dictum "be fruitful and multiply" (Genesis 9:1) has been followed too religiously by readers and nonreaders of the Bible alike. In 1798, Malthus started a great controversy by opposing the prevailing view of unlimited progress for humankind by making two postulates and a conclusion. Malthus postulated "that food is necessary for the existence of man" and that sexual attraction between female and male is necessary and likely to persist because "toward the extinction of the passion between the sexes, no progress whatever has hitherto been made," barring "individual exceptions." Malthus concluded that "the power of populations is infinitely greater than the power of the earth to produce subsistence for man," producing a "natural inequality" that would someday loom "insurmountable in the way to perfectibility of society."

Malthus was right: Passion between the sexes persists, and the power of populations is very great indeed, so much so that our sheer numbers have increased to the point that they are straining Earth's capacity to supply food, energy, and raw materials and to absorb the detritus of its human burden. Marine fisheries are being depleted, forests and aquifers are disappearing, and the atmosphere is accumulating greenhouse gases from combustion of the fossil fuels that provide the energy needs of 7 billion people, up from 1 billion in Malthus's day. Perhaps some of the blame can be laid at the feet of medical science: Advances in public health and medicine have led to a significant decline in mortality and an increased life expectancy. However, medical science has also begun to assume a portion of the responsibility for overpopulation and its adverse effects. To this end, drugs in the form of hormones and their analogues have been developed to control human fertility.

Therapeutic Uses of Estrogens and Progestins

Hormonal Contraception

Types of Hormonal Contraceptives

Combination Oral Contraceptives. The most frequently used agents in the U.S. are combination oral contraceptives containing both an estrogen and a progestin. These agents come in a variety of formulations and strengths (Table 48–2). Their theoretical efficacy generally is considered

TABLE 48–2 ■ FORMULATIONS OF REPRESENTATIVE ORAL CONTRACEPTIVES

PRODUCT	FORMULATION	
COMBINATION[a] MONOPHASIC	**ESTROGEN (μg)**	**PROGESTIN (mg)**

	20	1 (24 tabs)
Estetrol/drospirenone (FDA-approved April 15, 2021)	14.2 mg	3 (24 tabs)
PROGESTIN ONLY	**ESTROGEN (μg)**	**PROGESTIN (mg)**
Drospirenone (SLYND)	—	4 (24 tabs packaged with 4 inactive tabs)

Unless otherwise indicated, the products are packaged with 21 active (hormone-containing) pills and 7 placebo tablets. For formulations that differ from this standard (e.g., multiphasic pills, extended-cycle formulations), the number of tablets of each pill strength are indicated. Some formulations also contain iron to diminish the risk of iron deficiency anemia; these are not listed separately here.

[a]Combination formulations contain both an estrogen and a progestin.

[b]Packaged with and without seven tablets containing 75 mg ferrous fumarate.

[c]Available as a chewable tablet.

to be 99.9%. In practice, the 1-year failure rates of oral contraceptives are somewhat greater than 0.1% (Table 48–3). Combination oral contraceptives are available in many formulations. Almost all contain ethinyl estradiol as the estrogen and a 17α-alkyl-19-nortestosterone derivative as the progestin. Monophasic, biphasic, or triphasic pills are generally provided in 28-day packs, with the pills for the last 7 days containing only inert ingredients. For the monophasic agents, fixed amounts of the estrogen and progestin are present in each pill, which is taken daily for 21 days, followed by a 7-day "pill-free" period. The biphasic and triphasic preparations provide two or three different pills containing varying amounts of active ingredients, to be taken at different times during the 21-day cycle. This reduces the total amount of steroids administered and more closely approximates the estrogen-to-progestin ratios that occur during the menstrual cycle. With these preparations, predictable menstrual bleeding generally occurs during the 7-day "off" period each month. However, several oral contraceptives are now available whereby progestin withdrawal is only induced every 3 months or not at all.

TABLE 48–3 ■ ONE-YEAR FAILURE RATE WITH VARIOUS FORMS OF CONTRACEPTION

BIRTH CONTROL METHOD	FAILURE (*Perfect Use*)	RATE (%) (*Typical Use*)
Combination oral contraceptive pills	0.3	8
Progestin-only minipill	0.5	8
Depo-Provera	0.3	3
Copper intrauterine device	0.6	0.8
Progestin intrauterine device	0.2	0.2
Implanon	0.05	0.05
Ortho Evra	0.3	8
NuvaRing	0.3	8
Condoms/diaphragms	2	15
Spermicides	18	9
Tubal ligation	0.5	0.5
Vasectomy	0.1	0.15
None	85	85

The estrogen content of current preparations ranges from 20 to 35 μg. The dose of progestin is more variable because of differences in potency of the compounds used.

A transdermal preparation of *levonorgestrel* and *ethinyl estradiol* is marketed for reproductive-age women with a body mass index less than 30 kg/m^2 as a weekly application to the buttock, abdomen, or upper torso for the first 3 consecutive weeks followed by a patch-free week for each 28-day cycle. A similar 3-week-on/1-week-off cycle is employed for a disposable intravaginal ring containing *ethinyl estradiol* and *etonogestrel* and a 1-year durable intravaginal ring containing *ethinyl estradiol* and *segesterone acetate*.

Progestin-Only Contraceptives.

Several agents are available for progestin-only contraception, with theoretical efficacies of 99%. Specific preparations include the "minipill"; low doses of progestins (e.g., 350 μg of *norethindrone*) taken daily without interruption; subdermal implants of 68 mg of *etonogestrel* for contraception lasting 3 years; and crystalline suspensions of MPA for injection of 104 mg (SC) or 150 mg (IM) of drug.

Intrauterine Devices. Three doses of *levonorgestrel*-releasing intrauterine systems (IUSs) are available in the U.S. The LNg20 contains 52 mg of *levonorgestrel* (LNg), which is initially released at a rate of 20 μg/day and declines gradually to 10 to 14 μg/day after 5 years. A smaller LNg IUS is available for women with a small uterine cavity or cervical stenosis and may result in less pain with insertion. The LNg14 contains 13.5 mg of *levonorgestrel*, which is initially released at a rate of 14 μg/day and declines to 5 μg/day after 3 years. A third device, also smaller, contains 19.5 mg of

levonorgestrel and similarly last 3 years. A copper IUD, TCu380A, is also available in the U.S. It contains 380 mm^2 of copper and is approved for 10-year use. The TCu380A may be preferred over an LNg IUS in women who desire long-term contraception and wish to avoid exogenous hormones and hormonal side effects and can also be used as an emergency contraceptive.

Mechanism of Action

Combination Oral Contraceptives. Combination oral contraceptives act by preventing ovulation. Direct measurements of plasma hormone levels indicate that LH and FSH levels are suppressed, a midcycle surge of LH is absent, endogenous steroid levels are diminished, and ovulation does not occur. Although either component alone can be shown to exert these effects in certain situations, the combination synergistically decreases plasma gonadotropin levels and suppresses ovulation more consistently than either alone.

Given the multiple actions of estrogens and progestins on the hypothalamic-pituitary-ovarian axis during the menstrual cycle, several effects probably contribute to the blockade of ovulation.

Hypothalamic actions of steroids play a major role in the mechanism of oral contraceptive action. Progesterone diminishes the frequency of GnRH pulses. Because the proper frequency of LH pulses is essential for ovulation, this effect of progesterone likely plays a major role in the contraceptive action of these agents.

Multiple pituitary effects of both estrogen and progestin components are thus likely to contribute to oral contraceptive action. Oral contraceptives seem likely to decrease pituitary responsiveness to GnRH. Estrogens also suppress FSH release from the pituitary during the follicular phase of the menstrual cycle, and this effect seems likely to contribute to the lack of follicular development in oral contraceptive users. The progestin component may also inhibit the estrogen-induced LH surge at midcycle. Other effects may contribute to a minor extent to the extraordinary efficacy of oral contraceptives. Transit of sperm, the egg, and fertilized ovum are important to establish pregnancy, and steroids are likely to affect transport in the fallopian tube. In the cervix, progestin effects also are likely to produce a thick, viscous mucus to reduce sperm penetration and in the endometrium to produce a state that is not receptive to implantation. However, it is difficult to assess quantitatively the contributions of these effects because the drugs block ovulation.

Progestin-Only Contraceptives. Progestin-only pills and *levonorgestrel* implants are highly efficacious but block ovulation in only 60% to 80% of cycles. Their effectiveness is thought to be due largely to a thickening of cervical mucus, which decreases sperm penetration, and to endometrial alterations that impair implantation; such local effects account for the efficacy of IUDs that release progestins. Depot injections of MPA are thought to exert similar effects, but they also yield plasma levels of drug high enough to prevent ovulation in virtually all patients, presumably by decreasing the frequency of GnRH pulses.

Intrauterine Devices. While the contraceptive benefit of the LNg IUS is attributed to the progestin-mediated effects of thickening of cervical mucous and endometrial alterations, the contraceptive mechanism of the copper IUD is related to an inflammatory reaction within the endometrium that impairs sperm viability, motility, and fertilization.

Untoward Effects

Combination Oral Contraceptives. Untoward effects of early hormonal contraceptives fell into several major categories: adverse cardiovascular effects, including hypertension, myocardial infarction, hemorrhagic or ischemic stroke, and venous thrombosis and embolism; breast, hepatocellular, and cervical cancers; and several endocrine and metabolic effects. The current consensus is that low-dose preparations pose minimal health risks in women who have no predisposing risk factors, and these drugs also provide many beneficial health effects (Burkman et al., 2004).

Cardiovascular Effects. The question of cardiovascular side effects has been reexamined for low-dose oral contraceptives (Burkman et al., 2004). For nonsmokers without other risk factors such as hypertension or diabetes, there is no significant increase in the risk of myocardial infarction or stroke. There is a 28% increase in relative risk for venous thromboembolism, but the estimated absolute increase is very small because the incidence of these events in women without other predisposing factors is low (e.g., roughly half that associated with the risk of venous thromboembolism in pregnancy). The risk is significantly increased in women who smoke or have other factors that predispose to thrombosis or thromboembolism (Castelli, 1999). Postmarketing epidemiological studies indicated that women using transdermal contraceptives have a higher-than-expected exposure to estrogen and are at increased risk for the development of venous thromboembolism. Early high-dose combination oral contraceptives caused hypertension in 4% to 5% of normotensive women and increased blood pressure in 10% to 15% of those

Hormonal Contraception: A Brief History

Around the beginning of the 20th century, a number of European scientists, including Beard, Prenant, and Loeb, developed the concept that secretions of the corpus luteum suppressed ovulation during pregnancy. The Austrian physiologist Haberlandt then produced temporary sterility in rodents in 1927 by feeding them ovarian and placental extracts—a clear example of an oral contraceptive. In 1937, Makepeace and colleagues demonstrated that pure progesterone blocked ovulation in rabbits, and Astwood and Fevold found a similar effect in rats in 1939.

In the 1950s, Pincus, Garcia, and Rock found that progesterone and 19-norprogestins prevented ovulation in women. Ironically, this finding grew out of their attempts to treat infertility with estrogen-progestin combinations. The initial findings were that these treatments effectively blocked ovulation in most women. However, concern about cancer and other possible side effects of the estrogen they used (i.e., *diethylstilbestrol*) led to the use of a progestin alone in their studies. One of the compounds used was *norethynodrel*, and early batches of this compound were contaminated with a small amount of *mestranol*. When *mestranol* was removed, it was noted that treatment with pure *norethynodrel* led to increased breakthrough bleeding and less-consistent inhibition of ovulation. *Mestranol* was thus reincorporated into the preparation, and this combination was employed in the first large-scale clinical trial of combination oral contraceptives.

Clinical studies in the 1950s in Puerto Rico and Haiti established the virtually complete contraceptive success of the *norethynodrel/mestranol* combination. In early 1961, Enovid (*norethynodrel* plus *mestranol*; no longer marketed in the U.S.) was the first "Pill" approved by the FDA for use as a contraceptive agent in the U.S.; this was followed in 1962 by approval for Ortho-Novum (*norethindrone* plus *mestranol*). By 1966, numerous preparations using either *mestranol* or *ethinyl estradiol* with a 19-norprogestin were available. In the 1960s, the progestin-only minipill and long-acting injectable preparations were developed and introduced.

Millions of women began using oral contraceptives, and frequent reports of untoward effects began appearing in the 1970s. The recognition that these side effects were dose dependent and the realization that estrogens and progestins synergistically inhibited ovulation led to the reduction of doses and the development of low-dose or second-generation contraceptives. The increasing use of biphasic and triphasic preparations throughout the 1980s further reduced steroid dosages; it may be that currently used doses are the lowest that will provide reliable contraception. In the 1990s, the "third-generation" oral contraceptives, containing progestins with reduced androgenic activity (e.g., *norgestimate* and *desogestrel*), became available in the U.S. after being used in Europe. A variety of contraceptive formulations are currently available, including pills, injections, skin patches, subdermal implants, vaginal rings, and intrauterine devices (IUDs) that release hormones.

with preexisting hypertension. This incidence is much lower with newer low-dose preparations, and most reported changes in blood pressure are not significant. Estrogens increase serum HDL and decrease LDL levels, and progestins tend to have the opposite effect. Recent studies of several low-dose preparations have not found significant changes in total serum cholesterol or lipoprotein profiles, although slight increases in triglycerides have been reported.

Cancer. Given the growth-promoting effects of estrogens, there has been a long-standing concern that oral contraceptives might increase the incidence of endometrial, cervical, ovarian, breast, and other cancers. These concerns were further heightened in the late 1960s by reports of endometrial changes caused by sequential oral contraceptives, which have since been removed from the market in the U.S. However, it is now clear that there is *not* a widespread association between oral contraceptive use and cancer (Burkman et al., 2004; Westhoff, 1999).

Epidemiological evidence suggests that combined oral contraceptive use may increase the risk of cervical cancer by about 2-fold but only in long-term (>5 years) users with persistent human papillomavirus infection (Moodley, 2004).

There have been reports of increases in the incidence of hepatic adenoma and hepatocellular carcinoma in oral contraceptive users. Current estimates indicate there is about a doubling in the risk of liver cancer after 4 to 8 years of use. However, these are rare cancers, and the absolute increases are small.

The major present concern about the carcinogenic effects of oral contraceptives is focused on breast cancer. The risk of breast cancer in women of childbearing age is very low, and current oral contraceptive users in this group have only a very small increase in relative risk of 1.1 to 1.2, depending on other variables. This small increase is not substantially affected by duration of use, dose or type of component, age at first use, or parity. Importantly, 10 years after discontinuation of oral contraceptive use, there is no difference in breast cancer incidence between past users and never users. In addition, breast cancers diagnosed in women who have ever used oral contraceptives are more likely to be localized to the breast and thus easier to treat (Westhoff, 1999).

Combination oral contraceptives decrease the incidence of endometrial cancer by 50%, an effect that lasts 15 years after the pills are stopped. This is thought to be due to the inclusion of a progestin, which opposes estrogen-induced proliferation, throughout the entire 21-day cycle of administration. These agents also decrease the incidence of ovarian cancer. There are accumulating data that oral contraceptive use decreases the risk of colorectal cancer (Fernandez et al., 2001).

Metabolic and Endocrine Effects. The effects of sex steroids on glucose metabolism and insulin sensitivity are complex (Godsland, 1996) and may differ among agents in the same class (e.g., the 19-norprogestins). Early studies with high-dose oral contraceptives generally reported impaired glucose tolerance; these effects have decreased as steroid dosages have been lowered, and current low-dose combination contraceptives may even improve insulin sensitivity. Similarly, the high-dose progestins in early oral contraceptives did raise LDL and reduce HDL levels, but modern low-dose preparations do not produce unfavorable lipid profiles (Sherif, 1999). There also have been periodic reports that oral contraceptives increase the incidence of gallbladder disease, but any such effect appears to be weak and limited to current or very long-term users (Burkman et al., 2004).

The estrogenic component of oral contraceptives may increase hepatic synthesis of a number of serum proteins, including those that bind thyroid hormones, glucocorticoids, and sex steroids. Although physiological feedback mechanisms generally adjust hormone synthesis to maintain normal "free" hormone levels, these changes can affect the interpretation of endocrine function tests that measure *total* plasma hormone levels and may necessitate dose adjustment in patients receiving thyroid hormone replacement.

The *ethinyl estradiol* present in oral contraceptives appears to cause a dose-dependent increase in several serum factors known to increase coagulation. However, in healthy women who do not smoke, there also is an increase in fibrinolytic activity, which exerts a countereffect so that overall there is a minimal effect on hemostatic balance. This compensatory effect is diminished in smokers (Fruzzetti, 1999).

Miscellaneous Effects. Nausea, edema, and mild headache occur in some individuals, and more severe migraine headaches may be precipitated by oral contraceptive use in a smaller fraction of women. Some patients may experience breakthrough bleeding during the 21-day cycle when the active pills are being taken. Withdrawal bleeding may fail to occur in a small fraction of women during the 7-day off period, thus causing confusion about a possible pregnancy. Acne and hirsutism are thought to be mediated by the androgenic activity of the 19-norprogestins.

Progestin-Only Contraceptives. Episodes of irregular, unpredictable spotting and breakthrough bleeding are the most frequently encountered untoward effect and the major reason women discontinue use of all three types of progestin-only contraceptives. With time, the incidence of these bleeding episodes decreases.

No evidence indicates that the progestin-only minipill preparations increase thromboembolic events, which are thought to be related to the estrogenic component of combination preparations. Acne may be a problem because of the androgenic activity of *norethindrone*-containing preparations. These preparations may be attractive for nursing mothers because they do not decrease lactation as do products containing estrogens.

Headache is the most reported untoward effect of depot MPA. Mood changes and weight gain also have been reported, but controlled clinical studies of these effects are not available. Many studies have found decreases in HDL levels and increases in LDL levels, and there have been several reports of decreased bone density. These effects may be due to reduced endogenous estrogens because depot MPA is particularly effective in lowering gonadotropin levels. Because of the time required to completely eliminate the drug, the contraceptive effect of this agent may remain for 6 to 12 months after the last injection.

Progesterone-only medications have been associated with decreased bone mineral density, as noted by a black-box warning in the product label. Teenagers and younger women who have not achieved maximal bone density may be particularly at risk, although the data suggest that bone density returns to pretreatment levels quickly after drug cessation.

Implants of *etonogestrel*, one of the most effective contraceptives available, may be associated with implant site reactions and changes in menstrual bleeding pattern but do not induce significant bone loss.

Intrauterine Devices. Intrauterine devices are generally well tolerated, although complications related to the device and side effects related to the progestin can occur. Expulsion of the device is greatest in the first year and has been reported in 3% to 6% of women with an LNg20 and in 3.2% of women with an LNg14. Malposition of the device, extending into the myometrium or the endocervical canal, occurs in 10% of women and is associated with difficult placement, uterine distortion, and obesity. For malposition that is symptomatic (e.g., pain or postinsertion bleeding extending beyond 3 months), displaced through the uterine serosa, or visible in the cervical canal, the device should be removed or replaced. Not all malpositioned devices need to be removed, as this condition is often asymptomatic and does not compromise the contraceptive efficacy of the device.

Uterine perforation at the time of IUD insertion complicates approximately 1 in 1000 insertions. Symptoms of perforation may include pelvic pain and bleeding, although perforations are often asymptomatic. Surgical removal of the perforated IUD is preferred to minimize serious complications related to adhesions or perforation into the bowel, bladder, or blood vessels.

Pelvic inflammatory disease is infrequent at the time of insertion (1–10 per 1000 women undergoing insertion) and after insertion (1.4 women per 1000 women after insertion). Infections at the time of insertion or 1 month after insertion are generally related to new sexually transmitted infections. The LNg20 is associated with less risk of pelvic inflammatory disease due to thickening of the cervical mucus. Oral

antibiotic therapy may be attempted, and worsening infections should be treated with intravenous antibiotics and IUD removal.

Ectopic and intrauterine pregnancies rarely occur with an IUD *in situ*. Intrauterine pregnancies with an IUD *in situ* are at increased risk for adverse pregnancy outcomes if the IUD is left in place or removed. The decision to leave the IUD in place or remove it in pregnancy should be individualized based on the women's obstetrical history, the trimester when it is diagnosed, and the anticipated difficulty of removing the IUD.

While device-related complications are infrequent, side effects related to the progestin are common. Irregular bleeding in the first 3 to 6 months after insertion and amenorrhea at 1 year after insertion are common. Complaints of side effects such as hirsutism, acne, weight change, nausea, headache, mood change, and breast tenderness are related to systemic effects of *levonorgestrel* and are the most common reason for discontinuation (~12% of women with the LNg20). The copper IUD may be an alternative for women who discontinue the LNg IUS due to hormonal side effects, but it is associated with intermenstrual bleeding and increased volume of bleeding.

Contraindications

Modern oral contraceptives are considered generally safe in most healthy women; *however, these agents can contribute to the incidence and severity of cardiovascular, thromboembolic, or malignant disease, particularly if other risk factors are present.* Contraindications for combination oral contraceptive use are the following: the presence or history of thromboembolic disease, cerebrovascular disease, myocardial infarction, coronary artery disease, or congenital hyperlipidemia; known or suspected carcinoma of the breast or carcinoma of the female reproductive tract; abnormal undiagnosed vaginal bleeding; known or suspected pregnancy; and past or present liver tumors or impaired liver function. *The risk of serious cardiovascular side effects is particularly marked in women more than 35 years of age who smoke heavily*; even low-dose oral contraceptives are contraindicated in such patients.

Other relative contraindications include migraine headaches, hypertension, diabetes mellitus, obstructive jaundice of pregnancy or prior oral contraceptive use, and gallbladder disease. If elective surgery is planned, many physicians recommend discontinuation of oral contraceptives for several weeks to a month to minimize the possibility of thromboembolism after surgery.

Progestin-only contraceptives are contraindicated in the presence of undiagnosed vaginal bleeding, benign or malignant liver disease, and known or suspected breast cancer.

The Centers for Disease Control and Prevention U.S. medical eligibility criteria list all progestin-containing IUDs as category 2 for history of venous thromboembolism, which means a condition for which the advantages of using the method generally outweigh risks. The contraindications to IUDs are severe uterine distortion, active pelvic infection, and unexplained abnormal uterine bleeding. The copper IUD should be avoided in women with Wilson disease or a copper allergy.

Noncontraceptive Health Benefits

Oral contraceptives significantly reduce the incidence of ovarian and endometrial cancer within 6 months of use, and the incidence is decreased 50% after 2 years of use. Depot MPA injections also reduce very substantially the incidence of uterine cancer. This protective effect persists for up to 15 years after oral contraceptive use is discontinued. These agents also decrease the incidence of ovarian cysts and benign fibrocystic breast disease.

Oral contraceptives have major benefits related to menstruation in many women. These include more regular menstruation, reduced menstrual blood loss and less iron-deficiency anemia, and decreased frequency of dysmenorrhea. There also is a decreased incidence of pelvic inflammatory disease and ectopic pregnancies, and endometriosis may be ameliorated. Some women also may obtain these benefits with progestin-only contraceptives. There are suggestions that MPA may improve hematological parameters in women with sickle cell disease (Cullins, 1996).

IUDs such as the LNg20 reduce dysmenorrhea and menstrual blood loss. One year after insertion, 30% to 40% of women experience amenorrhea. The LNg20 can also be used to prevent and treat endometrial hyperplasia, although close monitoring is necessary, as endometrial adenocarcinoma has occurred in LNg20 users. While LNg14 is effective at preventing pregnancy, less is known regarding the noncontraceptive benefits of the LNg14. Even without considering the additional health benefits of these agents, fertility regulation by contraceptives is substantially safer than pregnancy or childbirth for most women.

Postcoital Contraception

Postcoital (or emergency) contraception is indicated for use in cases of mechanical failure of barrier devices or in circumstances of unprotected intercourse (Cheng et al., 2008). Because it is less effective than standard oral contraceptive regimens, it is not intended as a routine method of contraception. The mechanisms of action of the postcoital contraceptives are not fully understood, but their efficacy clearly cannot be accounted for solely by the inhibition of ovulation. Other potential mechanisms of action include effects on gamete function and survival and on implantation. These agents do not affect established pregnancies.

Both the copper IUD and the *levonorgestrel* 52-mg IUD are more effective than oral emergency contraceptive agents and can provide ongoing pregnancy prevention (Turok et al., 2021). The copper IUD or *levonorgestrel* 52-mg IUD can be inserted within 5 days after an unprotected act of sexual intercourse after a negative pregnancy test.

Selective PRMs such as *ulipristal* are approved as an emergency contraceptive, effective up to 120 h after unprotected intercourse. *Mifepristone* in oral doses ranging from 10 to 50 mg when taken within 5 days after unprotected intercourse can also be used but is not FDA-approved.

Plan B ONE STEP, which contains a single 1.5-mg tablet of *levonorgestrel*, can be taken as emergency contraception within 72 h after unprotected sex. Plan B ONE STEP and similar generic forms are available over the counter and without a prescription.

Termination of Pregnancy

If contraception is not used or fails, either *mifepristone* (RU-486) or *methotrexate* (50 mg/m^2 intramuscularly or orally) can be used to terminate an unwanted pregnancy in settings outside surgical centers. A PG then is administered to stimulate uterine contractions and expel the detached conceptus; in the U.S., PGs used include *dinoprostone* (PGE_2) administered vaginally or the PGE_1 analogue *misoprostol* given orally or vaginally. PGs used in other countries include the PGE_2 analogue *sulprostone* and the PGE_1 analogue *gemeprost*.

Mifepristone (600 mg) is FDA-approved for pregnancy termination within 49 days after the start of a woman's last menstrual period. The synthetic PGE_1 analogue *misoprostol* (400 μg) is administered orally 48 h later; vaginal administration is at least as effective but is not FDA-approved. Complete abortion using this procedure exceeds 90%; when termination of pregnancy fails or is incomplete, surgical intervention is required. Other published regimens include lower doses of *mifepristone* (200 or 400 mg) and different time intervals between the mifepristone and *misoprostol*. Finally, repeated doses of *misoprostol* alone (e.g., 800 μg vaginally or sublingually every 3 h or every 12 h for three doses) also have been effective in settings where *mifepristone* is unavailable. Vaginal bleeding follows pregnancy termination and typically lasts from 1 to 2 weeks but rarely (in 0.1% of patients) is severe enough to require blood transfusion. A high percentage of women also experience abdominal pain and uterine cramps, nausea and vomiting, and diarrhea secondary to the PG. Myocardial ischemia and infarction have been reported in association with *sulprostone* and *gemeprost*.

Because *mifepristone* carries a risk of serious, and sometimes fatal, infections and bleeding following its use for medical abortion, a black-box warning has been added to the product labeling. Fulminant septic shock associated with *Clostridium sordellii* infections may result and is attributable to the combined effects of uterine infection and inhibition of

glucocorticoid action by *mifepristone* (Cohen et al., 2007). Patients who develop symptoms and signs of infection, especially marked leukocytosis even without fever, should be treated aggressively with antibiotics effective against anaerobic organisms such as *C. sordellii* (e.g., *penicillin*, *ampicillin*, a macrolide, *clindamycin*, a tetracycline, or *metronidazole*).

Induction of Sexual Maturation

Estrogen Treatment in the Failure of Ovarian Development

In several conditions (e.g., Turner syndrome), the ovaries do not develop, and puberty does not occur. Therapy with estrogen at the appropriate time replicates the events of puberty, and androgens (see Chapter 49) or growth hormone (see Chapter 46) may be used concomitantly to promote normal growth. Although estrogens and androgens promote bone growth, they also accelerate epiphyseal fusion, and their premature use can thus result in shorter ultimate height.

Types of estrogens used and the treatment regimens may vary by country or individual preference. Examples include conjugated estrogens, 0.3 to 1.25 mg; micronized 17β-estradiol, 0.5 to 2.0 mg; ethinyl estradiol, 5 to 20 μg; and transdermal 17β-estradiol, 25 to 50 μg. To achieve optimal breast development, treatment typically is initiated with a low dose of estrogen (e.g., conjugated estrogens at a starting dosage of 0.3 mg/day or *ethinyl estradiol* at 5 μg/day) starting in patients between ages 10 and 12 years or immediately if the diagnosis is made after this age. After 3 to 6 months, the dosage is increased (e.g., 0.9–1.25 mg/day of conjugated estrogens or 20 μg/day of *ethinyl estradiol*). Once this is achieved, a progestin (e.g., *medroxyprogesterone*, 10 mg/day, or micronized progesterone, 200–400 μg/day) for 12 days each cycle is added to the regimen to optimize breast development and permit cyclical menses, thereby avoiding endometrial hyperplasia and its consequent risk of uterine cancer. Once menses are established, many clinicians will switch to a standard low-dose oral contraceptive pill or even may use an extended-cycle formulation.

Short stature, a universal feature of nonmosaic Turner syndrome, usually is treated with human growth hormone, often together with an androgen such as *oxandrolone* (see Chapter 49). Initiating treatment with human growth hormone and an androgen and delaying the onset of estrogen therapy generally produces better growth response. Doses for growth hormone treatment in this context are higher than those in growth hormone–deficient children (e.g., 67 μg/kg per day; see Chapter 46 for further discussion of growth hormone replacement therapy).

Induction of Ovulation

Infertility (i.e., the failure to conceive after 1 year of unprotected sex) affects about 10% to 15% of couples in developed nations and is increasing in incidence as more women choose to delay childbearing until later in life. The cause of infertility is attributed primarily to the woman in approximately one-third of cases, to the man in approximately one-third, and to both in approximately one-third.

Anovulation accounts for about 50% of female infertility and is a major focus of pharmacological interventions used to achieve conception. Although a history of regular cyclic bleeding is strong presumptive evidence for ovulation, assessment of urine LH levels with an ovulation predictor kit or measurement of the serum progesterone levels during the luteal phase provides more definitive information. Evaluation of anovulation may uncover PCOS, thyroid disorders, hyperprolactinemia, or hypogonadism, but the cause is often idiopathic.

A number of approaches have been used to stimulate ovulation in anovulatory women. Often, a stepwise approach is taken, initially using simpler and less expensive treatments, followed by more complex and expensive regimens if initial therapy is unsuccessful.

Clomiphene

Clomiphene citrate was reviewed previously in this chapter. A typical regimen is 50 mg/day orally for 5 consecutive days starting between days 2 and 5 of the cycle in women who have spontaneous uterine bleeding or following a bleed induced by progesterone withdrawal in women who do not. If this regimen fails to induce ovulation, the dose of *clomiphene* is increased, first to the FDA-approved maximum of 100 mg/day and possibly to higher levels of 150 or 200 mg/day. Although *clomiphene* is effective in inducing ovulation in perhaps 75% of women, successful pregnancy ensues in only 40% to 50% of those who ovulate. This has been attributed to *clomiphene*'s inhibition of estrogen action on the endometrium, resulting in an environment that is not optimal for fertilization or implantation.

Aromatase Inhibitors

Aromatase inhibitors (e.g., *letrozole*, 2.5–7.5 mg/day for 5 days, typically starting on day 3 of the cycle) induce follicle development by inhibiting estrogen biosynthesis, thus decreasing estrogen negative feedback and increasing FSH levels and follicle development. In comparing *letrozole* and *clomiphene* for ovulation induction in women with PCOS and infertility, *letrozole* was associated with a higher pregnancy and live birth rate (Legro et al., 2014). *Letrozole* is associated with fewer estrogen deprivation side effects (hot flashes, mood change) and possibly fewer multifetal gestations than *clomiphene*.

Gonadotropins

The preparations of gonadotropins available for clinical use are detailed in Chapter 46. Gonadotropins are indicated for ovulation induction in anovulatory women with hypogonadotropic hypogonadism secondary to hypothalamic or pituitary dysfunction. Gonadotropins also are used to induce ovulation in women with polycystic ovary syndrome (PCOS) who do not respond to *clomiphene*.

Given the marked increases in maternal and fetal complications associated with multifetal gestation, the goal of ovulation induction in anovulatory women is to induce the formation and ovulation of a single dominant follicle. Generally, the increased risks of twin gestation will be accepted if two follicles are present.

As shown in Figure 48–6, a typical regimen for ovulation induction is to administer 75 IU of FSH daily in a "low-dose, step-up protocol." The dose is titrated based on the rise in estradiol and the growth rate of follicles as determined by estradiol levels and transvaginal ultrasonography. If three or more mature follicles are induced, gonadotropin therapy can be canceled, and barrier contraception can be used to prevent pregnancy, thereby avoiding multifetal pregnancy.

To complete follicular maturation and induce ovulation, chorionic gonadotropin (5000–10,000 IU) or choriogonadotropin alfa is given 1 day after the last dose of gonadotropin. Fertilization of the oocyte(s) at 36 h after choriogonadotropin administration then is attempted, by either intercourse or intrauterine insemination.

Gonadotropin induction also is used for ovarian stimulation in conjunction with *in vitro* fertilization (IVF) (Figure 48–6). In this setting, larger doses of FSH (typically 225–300 IU/day) are administered to induce the maturation of multiple (ideally at least 5 and up to 20) oocytes that can be retrieved for IVF. To prevent the LH surge and subsequent premature luteinization of the ovarian follicles, gonadotropins typically are administered in conjunction with a GnRH agonist or a GnRH antagonist. The length of the IVF protocol is predicated by the initial flare of gonadotropin secretion that occurs in response to the GnRH agonists. In the long protocol, the agonist is started in the luteal phase of the previous cycle (generally on cycle day 21) and then maintained until the time of choriogonadotropin injection to induce ovulation. Alternatively, in the "flare" protocol, the GnRH agonist is started on cycle day 2 (immediately after the start of menses), and gonadotropin injections are added 1 day later. In the GnRH antagonist "short protocol," the antagonist can be used to inhibit endogenous LH secretion and is typically started after follicular recruitment is initiated. Current regimens include daily injection in a dose of 0.25 mg (*ganirelix* or *cetrorelix*) starting on the fifth or sixth day of gonadotropin stimulation or a single dose of 3 mg of *cetrorelix* administered on day 8 or 9 of the late follicular phase. Adequate follicle maturation typically takes 8 to 12 days after gonadotropin therapy is initiated.

Using either the long or short protocols, choriogonadotropin (at typical doses of 5000–10,000 IU of urine-derived product or 250 μg of choriogonadotropin alfa) is given to induce final oocyte development, and the mature eggs are retrieved from the preovulatory follicles at 36 h thereafter. The ova are retrieved by transvaginal ultrasound-guided aspiration and

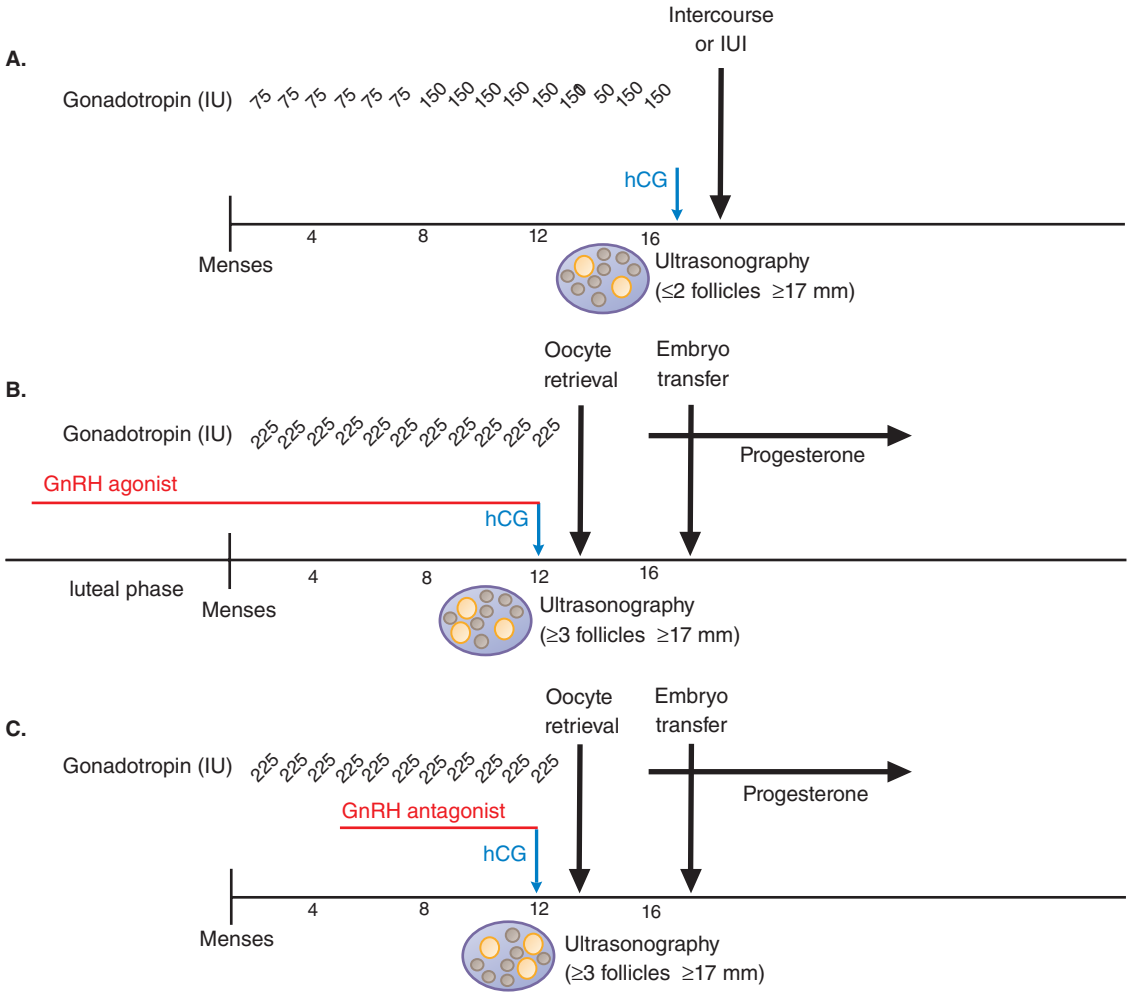

Figure 48–6 *Idealized regimens using exogenous gonadotropins for induction of fertility.* **A.** Step-up regimen for ovulation induction. After menses, daily injections of gonadotropin (75 IU) are started. Follicle maturation is assessed by serial measurement of plasma estradiol and follicle size, as discussed in the text. If an inadequate response is seen, the dose of gonadotropin is increased to 112 or 150 IU/day. When one or two follicles have achieved a diameter of 17 mm or greater, final follicle maturation and ovulation are induced by injection of choriogonadotropin. Fertilization then is achieved at 36 h after choriogonadotropin injection by intercourse or intrauterine insemination. If more than two mature follicles are seen, the cycle is terminated, and barrier contraception is used to avoid triplets or higher degrees of multifetal gestation. **B.** Long protocol for ovarian hyperstimulation using a gonadotropin-releasing hormone (GnRH) agonist to inhibit premature ovulation, followed by *in vitro* fertilization (IVF). After the GnRH agonist has inhibited endogenous secretion of gonadotropins, therapy with exogenous gonadotropins is initiated. Follicle maturation is assessed by serial measurements of plasma estradiol and follicle size by ultrasonography. When three or more follicles are 17 mm or larger in diameter, then ovulation is induced by injection of choriogonadotropin. At 32 to 36 h after the choriogonadotropin injection, the eggs are retrieved and used for IVF. Exogenous progesterone is provided to promote a receptive endometrium, followed by embryo transfer at 3 to 5 days after fertilization. **C.** Protocol for ovarian hyperstimulation in an IVF protocol using a GnRH antagonist. The cycle duration is shorter because the GnRH antagonist does not induce a transient flare of gonadotropin secretion that might disrupt the timing of the cycle, but many other elements of the cycle are analogous to those in **B**.

fertilized *in vitro* with sperm (IVF) or by intracytoplasmic sperm injection; one or two embryos then are transferred to the uterus 3 to 5 days after fertilization or are cryopreserved for a frozen embryo transfer.

Because of the inhibitory effects of GnRH agonists or antagonists on pituitary gonadotropes, the secretion of LH that normally sustains the corpus luteum after ovulation does not occur. Repeated injections of choriogonadotropin, while sustaining the corpus luteum, may increase the risk of ovarian hyperstimulation syndrome (OHSS). Thus, standard IVF regimens typically provide exogenous progesterone replacement to support the fetus until the placenta acquires the biosynthetic capacity to take over this function; regimens include progesterone in oil (50–100 mg/day intramuscularly) or micronized progesterone (180–300 mg twice daily vaginally). Vaginal preparations containing 100 or 90 mg of micronized progesterone are approved for administration two or three times daily as part of IVF.

Aside from the attendant complications of multifetal gestation, the major side effect of gonadotropin treatment is OHSS. This potentially life-threatening event is believed to result from increased ovarian secretion of substances that increase vascular permeability and is characterized by rapid accumulation of fluid in the peritoneal cavity, thorax, and even the pericardium. Symptoms and signs include abdominal pain or distention, nausea and vomiting, diarrhea, dyspnea, oliguria, and marked ovarian enlargement on ultrasonography. OHSS can lead to hypovolemia, electrolyte abnormalities, acute respiratory distress syndrome, thromboembolic events, and hepatic dysfunction.

In an effort to minimize OHSS in at-risk patients, the FSH can be withheld for a day or two ("coasting"). The rationale for this approach is that larger follicles become relatively gonadotropin independent and thus will continue to mature, while the smaller follicles undergo atresia in response to gonadotropin deprivation. Alternatively, an endogenous LH surge can be induced with a GnRH agonist during a GnRH antagonist short protocol, which nearly eliminates the incidence of OHSS by avoiding the use of choriogonadotropin to trigger oocyte maturation.

The potential deleterious effects of gonadotropins are debated. Some studies have suggested that gonadotropins are associated with an increased risk of ovarian cancer, but this conclusion is controversial (Brinton et al., 20(5)

Insulin Sensitizers

Polycystic ovary syndrome affects 4% to 7% of women of reproductive age and is the most frequent cause of anovulatory infertility. Inasmuch as patients with PCOS often exhibit hyperinsulinemia and insulin resistance, insulin sensitizers such as *metformin* have been evaluated for their effects on ovulation and fertility. Although several small trials suggested that *metformin* increased ovulation relative to placebo in patients with PCOS, a trial failed to demonstrate a significant effect of *metformin* on fertility (Legro et al., 2007); *metformin* was less effective than *clomiphene* in inducing ovulation, promoting conception, or improving live birth rates, and there was no benefit of combining *metformin* with *clomiphene* on live births, except possibly in women resistant to *clomiphene*. Thus, except in women who exhibit glucose intolerance, the consensus is that *metformin* generally should not be used for fertility induction in women with PCOS (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008).

Thiazolidinediones also have been evaluated for their ability to induce ovulation in patients with PCOS but are not used for this indication given an increased risk of congestive heart failure and myocardial ischemia.

Drug Therapy in Obstetrics

Pregnancy-Induced Hypertension/Preeclampsia

Hypertension affects up to 10% of pregnant women in the U.S. Hypertension that precedes pregnancy or manifests before 20 weeks of gestation is believed to overlap considerably in pathogenesis with essential hypertension. These patients appear to be at increased risk for gestational diabetes and need careful monitoring. In contrast, pregnancy-induced hypertension, or preeclampsia, generally presents after 20 weeks of gestation as a new-onset hypertension with proteinuria (>300 mg of urinary protein/24 h); preeclampsia is thought to involve placenta-derived factors that affect vascular integrity and endothelial function in the mother, thus causing peripheral edema, renal and hepatic dysfunction, and in severe cases, seizures. Chronic hypertension is an established risk factor for preeclampsia. The consensus panel recommended initiation of drug therapy in women with a diastolic blood pressure greater than 105 mmHg or a systolic blood pressure greater than 160 mmHg. If severe preeclampsia ensues, with marked hypertension and evidence of end-organ damage, then termination of the pregnancy by delivery of the baby is the treatment of choice, provided that the fetus is sufficiently mature to survive outside the uterus. If the baby is very preterm, then hospitalization and pharmacotherapy may be employed in an effort to permit further fetal maturation *in utero*.

Several drugs commonly used for hypertension in nonpregnant patients (e.g., angiotensin-converting enzyme inhibitors, angiotensin receptor antagonists) should not be used in pregnant women due to unequivocal evidence of adverse fetal effects. Many experts will convert the patient to the centrally acting α adrenergic agonist *α-methyldopa* (250 mg twice daily) (former FDA category B: no evidence of fetal risk in animal studies; no well-controlled studies in pregnant women), which rarely is used for hypertension in nonpregnant patients. Other drugs with reasonable evidence of safety also may be used, including the combination α_1-selective, β-nonselective adrenergic antagonist *labetalol* (100 mg twice daily) and the Ca^{2+} channel blocker *nifedipine* (30 mg once daily).

If severe preeclampsia or impending labor requires hospitalization, blood pressure can be controlled acutely with *hydralazine* (5 or 10 mg IV or IM, with repeated dosing at 20-min intervals depending on blood pressure response) or *labetalol* (20 mg IV, with dose escalation to 40 mg at 10 min if blood pressure control is inadequate). In addition to receiving drugs for blood pressure control, women with severe preeclampsia or who have CNS manifestations (e.g., headache, visual disturbance, or altered mental status) are treated as inpatients with *magnesium sulfate*, based on its documented efficacy in seizure prevention and lack of adverse effects on the mother or baby. Such treatment also should be considered for postpartum women with CNS manifestations: Approximately 20% of episodes of eclampsia occur in women more than 48 h after delivery.

Prevention or Arrest of Preterm Labor

Scope of the Problem and Etiology

Preterm birth, defined as delivery before 37 weeks of gestation, occurs in more than 10% of pregnancies in the U.S. and is increasing in frequency; it is associated with significant complications, such as neonatal respiratory distress syndrome, pulmonary hypertension, and intracranial hemorrhage.

Although incompletely understood, risk factors for preterm labor include multifetal gestation, premature rupture of the membranes, intrauterine infection, and placental insufficiency. The more premature the baby, the greater the risk of complications, prompting efforts to prevent or interrupt preterm labor.

The therapeutic objective in preterm labor is to delay delivery so that the mother can be transported to a regional facility specializing in the care of premature babies and supportive agents can be administered; such supportive treatments include glucocorticoids to stimulate fetal lung maturation (see Chapter 50) and antibiotics (e.g., *erythromycin*, *ampicillin*) to diminish the frequency of neonatal infection with group B β-hemolytic *Streptococcus* (see Chapters 58 and 60). Based on concerns over deleterious effects of antibiotic therapy, it is essential that antibiotics are not administered indiscriminately to all women thought to have preterm labor, but rather be reserved for those with premature rupture of the membranes and evidence of infection.

Prevention of Preterm Labor: Progesterone Therapy

Progesterone levels in some species diminish considerably in association with labor, whereas administration of progesterone inhibits the secretion of proinflammatory cytokines and delays cervical ripening. Thus, progesterone and its derivatives have long been advocated to diminish the onset of preterm labor in women at increased risk due to previous preterm delivery. Despite considerable controversy, recent randomized trials have revived interest in this approach. While *hydroxyprogesterone caproate* at a dose of 250 mg administered weekly by intramuscular injection has been shown to reduce preterm birth by about one-third in women with a prior preterm singleton birth, the Progestin's Role in Optimizing Neonatal Gestation trial showed no difference in the rate of preterm birth with this therapy when compared to inert oil placebo among women with a prior spontaneous preterm birth in a singleton pregnancy, possibly due to differences in the study populations (Blackwell et al., 2020; Meis et al., 2003). Vaginal administration of progesterone (200 mg each night) has been shown to reduce preterm birth in women with midtrimester cervical shortening by ultrasound examination. The role of progesterone for prevention of preterm birth in multiple gestations is controversial.

Tocolytic Therapy for Established Preterm Labor

Inhibition of uterine contractions of preterm labor, or *tocolysis*, has been a focus of therapy (Simhan and Caritis, 2007). Although tocolytic agents delay delivery in about 80% of women, they neither prevent premature births nor improve adverse fetal outcomes such as respiratory distress syndrome.

Specific tocolytic agents include β adrenergic receptor agonists, $MgSO_4$, Ca^{2+} channel blockers, COX inhibitors, oxytocin receptor antagonists, and NO donors. The mechanisms of action of these agents are illustrated in Figure 48–7.

The β adrenergic receptor agonists relax the myometrium by activating the cyclic AMP-PKA signaling cascade that phosphorylates and inactivates MLCK, a key enzyme in uterine contraction. *Ritodrine*, a selective β_2 agonist, was specifically developed as a uterine relaxant and remains the only tocolytic drug to have gained FDA approval; it was voluntarily withdrawn from the U.S. market. *Terbutaline*, which is FDA-approved for asthma, has been used off label for this purpose and can be administered orally, subcutaneously, or intravenously. *Terbutaline* may delay births, but only during the first 48 h of treatment, and is associated with a number of adverse maternal effects, including tachycardia, hypotension, and pulmonary edema.

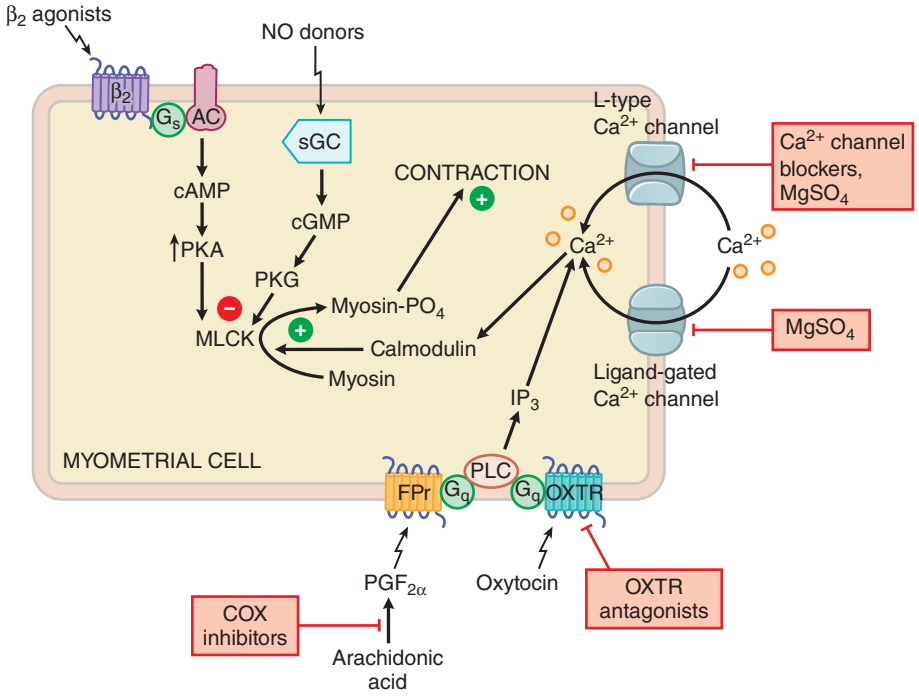

Figure 48–7 *Sites of action of tocolytic drugs in the uterine myometrium.* The elevation of cellular Ca^{2+} promotes contraction via the Ca^{2+}/calmodulin-dependent activation of MLCK. Relaxation is promoted by the elevation of cyclic nucleotides (cAMP and cGMP) and their activation of protein kinases, which cause phosphorylation/inactivation of MLCK. Pharmacological manipulations to reduce myometrial contraction include the following: (1) inhibiting Ca^{2+} entry (Ca^{2+} channel blockers, Mg_2SO_4); (2) reducing mobilization of intracellular Ca^{2+} by antagonizing G protein-coupled receptor-mediated activation of the G_q-PLC-IP_3-Ca^{2+} pathway (with antagonists of the $PGF_{2\alpha}$ and oxytocin receptors, FPr and OXTR) or reducing production of the FPr agonist, $PGF_{2\alpha}$ (with COX inhibitors); and (3) enhancing relaxation by elevating cellular cAMP (with β_2 adrenergic agonists that activate G_s-AC) and cellular cGMP (with NO donors that stimulate sGC). Note that pharmacological activators of sGC (e.g., *riociguat*) are contraindicated in pregnancy (see Chapter 35). AC, adenylyl cyclase; COX, cyclooxygenase; FPr, the PGF_2 receptor; OXTR, the oxytocin receptor; PLC, phospholipase C; sGC, soluble guanylyl cyclase.

Similarly, Ca^{2+} channel blockers inhibit the influx of Ca^{2+} through depolarization-activated, voltage-sensitive Ca^{2+} channels in the plasma membrane, thereby preventing the activation of MLCK and the stimulation of uterine contraction. *Nifedipine*, the Ca^{2+} channel blocker used most commonly for this purpose, can be administered parenterally or orally. Relative to β_2 adrenergic agonists, *nifedipine* is more likely to improve fetal outcomes and less likely to cause maternal side effects.

Based on the role of PGs in uterine contraction, COX inhibitors (e.g., *indomethacin*) have been used to inhibit preterm labor, and some data suggest that they may reduce the number of preterm births. Because they also can inhibit platelet function and induce closure *in utero* of the ductus arteriosus, these inhibitors should not be employed in term pregnancies (or in pregnancies beyond 32 weeks of gestation, when the risk of severe complications of prematurity is relatively lower). Short courses of treatment (<72 h) pose less risk for impaired circulation in the fetus.

Despite numerous clinical trials, the superiority of any one therapy has not been established, and none of the drugs has been shown definitively to improve fetal outcome.

Initiation of Labor

Labor induction is indicated when the perceived risk of continued pregnancy to the mother or fetus exceeds the risks of delivery or pharmacological induction.

Prostaglandins and Cervical Ripening

Prostaglandins play key roles in parturition (see Chapter 41). Thus, PGE_1, PGE_2, and $PGF_{2\alpha}$ are used to facilitate labor by promoting ripening and dilation of the cervix. They can be administered either orally or via local administration (either vaginally or intracervically). The ability of certain PGs to stimulate uterine contractions also makes them valuable agents in the therapy of postpartum hemorrhage.

Available preparations include *dinoprostone* (PGE_2), which is FDA-approved to facilitate cervical ripening. *Dinoprostone* is formulated as a gel for intracervical administration via syringe in a dose of 0.5 mg or as a vaginal insert (pessary) in a dose of 10 mg; the latter is designed to release active PGE_2 at a rate of 0.3 mg/h for up to 12 h and should be removed at the onset of labor or 12 h after insertion. No more than three doses should be used in a 24-h period. *Dinoprostone* should not be used in women with a history of asthma, glaucoma, or myocardial infarction. The major adverse effect is uterine hyperstimulation, which may be reversed more rapidly using the vaginal insert by removing it with the attached tape.

Misoprostol, a synthetic derivative of PGE_1 (see Chapter 41), is used off label either orally or vaginally to induce cervical ripening; typical doses are 100 μg (orally) or 25 μg (vaginally). An advantage of *misoprostol* in this setting is its considerably lower cost. Adverse effects include uterine hyperstimulation and, rarely, uterine rupture. *Misoprostol* should be discontinued for at least 3 h before initiating *oxytocin* therapy.

Oxytocin

The structure and physiology of *oxytocin* are discussed in Chapter 46. This section presents therapeutic uses of *oxytocin* in obstetrics, which include the induction of labor, the augmentation of labor that is not progressing, and the prophylaxis or treatment of postpartum hemorrhage. Although widely used, *oxytocin* recently was added to a list of drugs "bearing a heightened risk of harm" (Clark et al., 2009), and its role and specific application to most deliveries in the U.S. remain open to debate. Thus, careful review of the appropriate indications for *oxytocin* administration and attention to the dose and progress of labor during induction are essential.

Labor Induction. *Oxytocin* is the drug of choice for labor induction; for this purpose, it is administered by intravenous infusion of a diluted solution, preferably via an infusion pump. Current protocols start with an *oxytocin* dose of 6 mIU/min, followed by advancement of dose as needed, up to 40 mIU/min. Uterine hyperstimulation should be avoided; however, if it occurs, as evidenced by too-frequent contractions (more than five contractions in a 10-min interval) or the development of uterine tetany, the

oxytocin infusion should be discontinued immediately. Because the $t_{1/2}$ of intravenous *oxytocin* is relatively short (12–15 min), the hyperstimulatory effects of *oxytocin* will dissipate rapidly after the infusion is discontinued. Thereafter, the infusion can be reinitiated at a dose of half that at which hyperstimulation occurred and increased cautiously as tolerated.

Because of its structural similarity to vasopressin, *oxytocin* at higher doses activates the vasopressin V_2 receptor and has antidiuretic effects. Particularly if hypotonic fluids (e.g., dextrose in water) are infused too liberally, water intoxication may result in convulsions, coma, and even death. Vasodilating actions of *oxytocin* also have been noted, particularly at high doses, which may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of *oxytocin* by preventing the reflex tachycardia.

Augmentation of Dysfunctional Labor. *Oxytocin* also is used when spontaneous labor is not progressing at an acceptable rate. To augment hypotonic contractions in dysfunctional labor, an infusion rate of 10 mIU/min typically is sufficient; doses in excess of 40 mIU/min rarely are effective when lower concentrations fail. As with labor induction, potential complications of uterine overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion.

Menopause and Hormone Therapy
