Ebola virus infects many different cell types including endothelial cells, fibroblasts, hepatocytes adrenal cortical cells, and epithelial cell, causing necrosis. It attacks macrophages and dendritic cells first, and then it is carried to regional lymph nodes via lymphatics and subsequently to the liver, spleen, thymus, and other lymphoid tissues via the blood stream. Fatal disease is characterized by multifocal necrosis in tissues such as liver and spleen.

Immediately upon a person's entrance to the ED, or in advance of entry if possible, a thorough history of international travel or contact with an individual with EVD within the previous 21 days should be obtained. Patients who meet the exposure criteria should be questioned regarding the presence of signs or symptoms compatible with EVD including: fever (subjective or $\geq$ 100.4 °F or 38.0 °C), headache, fatigue, weakness, muscle pain, vomiting, diarrhea, abdominal pain, or hemorrhage (bleeding gums, blood in urine, nose bleeds, coffee ground emesis or melena). If the patient meets both exposure risk factor and clinical criteria, isolate the patient in a private room or in a separate enclosed area with private bathroom with covered bedside commode and adhere to procedures and precautions designed to prevent transmission either by direct or indirect contact. Detailed recommendation and guideline can be found at https://www.cdc.gov/vhf/ebola. If Ebola virus disease is suspected, local or state health department should be immediately contacted for consultation and to assess whether or not testing is indicated and the need for initiating identification of contacts [25].

Clinical Presentation

Patients with Ebola virus disease typically have an abrupt onset of symptoms 6–12 days after exposure (range 2–21 days). There is no evidence that infected persons who are asymptomatic are

Telegram: @medical_k

www.konkur.in

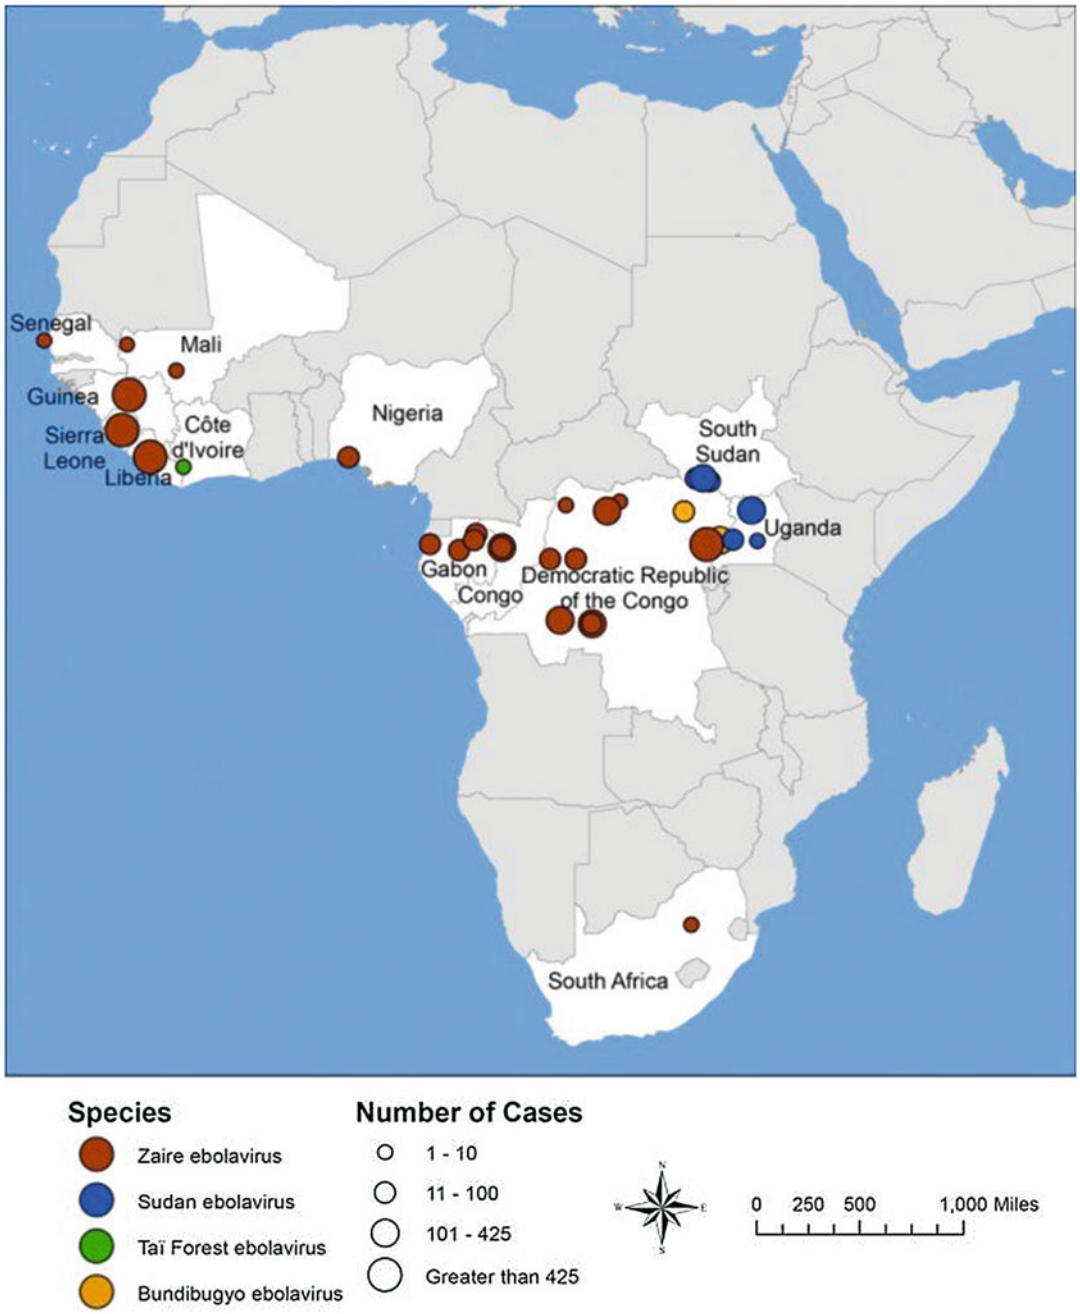

Fig. 2 Ebola virus outbreaks by species and size, Since 1976. (From CDC- Center for Disease Control and Prevention website)

infectious to others. However, all symptomatic individuals should be assumed to have virus in the blood or other body fluids, and appropriate safety precautions should be taken. Common signs and symptoms include fever (87%), fatigue (76%), vomiting (67%), and diarrhea (66%), loss of appetite (65%), abdominal pain (45%), and unexplained bleeding (18%) and also may

Telegram: @medical_k

www.konkur.in

present with cough, rhinorrhea, headache, or myalgia [26].

In the 2014 outbreak, the primary clinical presentation was gastrointestinal symptoms developing within the first few days of illness. Vomiting and diarrhea may result in severe fluid loss, leading to dehydration, hypotension, and shock. A diffuse erythematous, nonpruritic maculopapular rash may develop by day 5 to 7 of illness. The rash usually involves the face, neck, trunk, and arms. Hemorrhagic manifestations include blood in the stool, petechiae, ecchymosis, oozing from venipuncture sites and /or mucosal bleeding. Clinically significant hemorrhage may be seen in the terminal phase of illness and in pregnancy. Patients occasionally develop meningoencephalitis, with findings of altered mental status, hyperreflexia, neck stiffness, and gait instability. Other manifestations include uveitis, relative bradycardia, myocarditis, pericarditis, hypoxia, hypoventilation due to respiratory muscle fatigue contributing to respiratory failure.

Altered mental status, shock, and bleeding are poor prognostic factors. Major causes of death are due to electrolyte imbalance, shock, and multiorgan failure. Contacts are observed for 21 days and need not to be isolated before onset of symptoms. In the initial stages of presentation, Ebola virus disease is easily confused with influenza, gastroenteritis, malaria, typhoid, and other bacterial infections.

Laboratory Diagnosis

Patients with Ebola virus disease typically develop leukopenia, thrombocytopenia, transaminases elevation, renal and coagulation abnormalities [27]. Diagnosis can be made by detection of viral genome by reverse transcription polymerase chain reaction (RT-PCR). The Ebola virus is generally detectable in blood specimen by RT-PCR within 3 days after onset of symptoms. A repeat testing may be needed for patients with symptoms for fewer than 3 days [28]. According to CDC guidelines, a negative RT-PCR test that is collected >72 h after the onset of symptoms excludes Ebola virus disease [29].

Antigen capture ELISA may be also used. A rapid lateral-flow chromatographic immunoassay (ReEBOV) can detect Ebola virus antigen within 15 min, with sensitivity of 80–98% and specificity of 80–100%. A second Ebola rapid antigen finger stick test was approved by FDA in November 2018. This test uses a portable battery-operated reader that allowed to be performed at point of care outside of the laboratory.

Immunoglobulin G (IgG) and immunoglobulin M (IgM) antibodies are detected by ELISA later in the disease course or after recovery.

Treatment

The mainstay of treatment for Ebola virus disease involves supportive care in order to maintain adequate organ function (e.g., cardiovascular, respiratory, or renal) while the immune system mobilizes an adaptive response to eliminate the infection [27]. They should receive care in designated treatment centers and by clinician trained to care for such patients.

Patients may lose large amounts of fluid through vomiting and diarrhea, requiring rapid volume replacement to prevent shock; antiemetic and antidiarrheal agents may also be beneficial. Careful attention balancing intake with fluid losses will assist with fluid repletion targets. When available, patients will benefit from hemodynamic monitoring and intravenous (IV) fluid repletion. However, patients in the early phase of illness who respond to oral antiemetic and antidiarrheal therapy may be able to take in sufficient fluids by mouth to prevent or correct dehydration. Patients may develop significant electrolyte disturbances (e.g., hyponatremia, hypokalemia, hypomagnesemia, and hypocalcemia) and may require frequent repletion of electrolytes to prevent cardiac arrhythmias.

There are no approved medications for treatment of Ebola virus disease or for use as post exposure prophylaxis in persons who have been exposed to the virus but have not yet become ill. The 2014–2016 West African outbreaks focused attention on the potential anti-Ebola activity of drugs that were developed for other purposes. In

Telegram: @medical_k

www.konkur.in

addition, it accelerated the evaluation of experimental therapies that had been developed to treat or prevent Ebola or Marburg virus infection and had demonstrated efficacy in laboratory animals.

Investigational drugs include monoclonal antibodies (mAb114, REGN-EB3, and ZMapp) and nucleotide analogues (GS-5734, also known as remdesivir). The novel nucleotide analogue prodrug remdesivir was highly efficacious in macaques infected with Ebola virus, even when initiated 3 days after virus challenge. Studies of tissue distribution indicated drug penetration to the testes and central nervous system. Remdesivir, together with ZMapp, was also used to treat a newborn baby infected with Ebola virus in Guinea, near the end of the West African epidemic [30].

Prevention

Practice careful hygiene when in an epidemic area. Patient isolation and full-body protective clothing are required to prevent contact with infected body fluids. Healthcare personnel should wear appropriate personal protective equipment (PPE): disposable water-resistant coveralls, a waterproof apron or impermeable gown, an N95 mask, a disposable full face shield, two sets of gloves, and impermeable foot and leg coverings. It is recommended to use a powered air purifier respirator suit (PAPR) when performing medical procedures like intubation or airway suctioning. Avoid handling the body in burial or funeral rituals of people who have died from Ebola.

No approved vaccines are available to prevent the spread of Ebola virus. However, during the 2014–2016 epidemic in West Africa, accelerated paths were developed for vaccine testing and introduction into field use. The recombinant vesicular stomatitis virus-Zaire Ebola (VSV-Ebola) virus vaccine has been most widely used. The VSV-Ebola vaccine was the only specific countermeasure reported to have protective efficacy against Ebola virus during the 2014–2016 West African epidemic. In a large trial of ring vaccination in Guinea, the VSV-Ebola vaccine was safe and effective in inducing rapid immunity against Ebola virus [31].

In the Democratic Republic of the Congo (DRC), the VSV-Ebola vaccine was administered to nearly 4000 people during the outbreak in the Equateur Province of the DRC that occurred from May to July 2018. It has been used even more extensively in the ongoing epidemic in the eastern DRC, with more than 130,000 people vaccinated as of June 8, 2019. The vaccine is also being given to health care workers in South Sudan and Uganda, bordering on the outbreak area in the DRC. A survey of recipients in the outbreak area in the eastern DRC found that the vaccine was well tolerated and accepted by the local community.

Hantaviruses

Etiology and Epidemiology

Hantavirus is one of the major classes of zoonotic pathogens and is a member of the *Bunyaviridae* family, which are single-stranded RNA viruses. The resulting diseases can cause significant morbidity and mortality and occur globally. Rodents of the families Muridae and Cricetidae carry medically important Hantaviruses. These pathogens are associated with two severe acute febrile illnesses: Hemorrhagic fever with renal syndrome (HFRS) and Hantavirus cardiopulmonary syndrome (HCPS), the latter is also known as Hantavirus pulmonary syndrome (HPS). The important Hanta viruses which are associated with human disease include Hantaan, Seoul, Dobrava, Puumala, Sin Nombre, Black Creek Canal, New York, Bayou, Andes, Laguna Negra, Choclo, and Rio Mamore. The first four are associated with HFRS and the rest are associated with HCPS.

Hantavirus is named after the Korean River, Hantaan, where the first outbreak was reported in 1951(Korean hemorrhagic fever). China bears the highest annual incidence by far of Hantavirus disease. More than 100,000 cases of HFRS are reported every year in China, and thousands of cases are likely to occur in Russia. Chinese cases of HFRS are most commonly caused by Seoul

Telegram: @medical_k

www.konkur.in

virus, with some cases caused by Hantaan virus. Several thousand cases of HFRS due to Puumala and Dobrava viruses occur annually throughout Europe.

In the United States, HCPS is the major clinical presentation of Hanta virus disease. As of January 2017, 728 cases of Hanta virus disease had been reported within the United States, with more cases in the western and southwestern states such as New Mexico, Arizona, California, Washington, Colorado, Montana, and Texas. There have been outbreaks in the Southwest in 1993 (Sin Nombre) and in Yosemite National Park, California, in 2012. HFRS due to Seoul virus is rarely observed in the United States, but an outbreak of Seoul virus occurred in rat breeders and pet rat in Wisconsin in 2017.

Canada reports 10 to 15% of North American cases each year. Other countries that have experienced hantavirus activity include Argentina, Bolivia, Brazil, Chile, Ecuador, French Guiana, Panama, Paraguay, Peru, Uruguay, and Venezuela. Collectively, more than 3000 cases of HCPS have been identified throughout the Americas, far less than the Eurasian total for HFRS. The case-fatality ratios are much higher for HCPS (25 to 50%) than for HFRS (about 15%).

Rodent contact is an important factor in the transmission of hantaviruses to humans. Many hantaviruses are shed in the urine, feces, or saliva of acutely infected reservoir rodents. It is suspected that transmission to humans occurs via the aerosol route. Very few patients who contract hantaviruses describe recent rodent bites. Indoor exposure may be especially important. Human-to-human transmission of hantavirus is exceedingly rare but possible. Recent findings indicate that bats, moles, shrews, and other mammals may also serve as hosts.

Clinical Presentation

Typically, a period of 2 to 3 weeks elapses between exposure to a Hantavirus and the onset of symptoms. The incubation period is 14 to 17 days (range 9–33 days) [32]. Humans can be asymptomatic from the infection or develop severe reactions, in the form of either HFRS or HCPS. Early symptoms can be nonspecific with fever, fatigue, and generalized muscle aches, especially in the legs, back, and hips. Abdominal symptoms, headache, and dizziness may also occur during this early phase. These generalized symptoms resemble other viral syndromes and make early diagnosis difficult. Symptoms in the later phase of the infection with HCPS are cough and shortness of breath, which are due to pulmonary edema and hypotensive shock. Renal dysfunction/failure with hemorrhage occurs in HFRS [33]. These two syndromes may overlap. Age, gender, genetic response, and immune status can affect the prognosis. Males tend to get more symptoms than females, but females appear to have a higher mortality rate. Interestingly, infected rodents are not affected negatively by the virus.

Laboratory Findings

Associated laboratory findings are increased hematocrit, leukocytosis, thrombocytopenia, and elevated creatinine. Serology is the main stay of diagnostic method. By the time symptoms are evident, patients already have IgM antibodies and most of them have IgG antibodies [34]. IgM and IgG antibodies can be detected by using ELISA, strip immunoblot (SIA), or immunofluorescence techniques. The polymerase chain reaction (RT-PCR) can detect hantaviruses that cause fulminant infection with high case-fatality rates (Andes, Sin Nombre, Dobrava, and possibly Hantaan viruses) in blood specimen during the early stages of pulmonary disease. However, viral RNA usually disappears from the circulation after a few days, and serologic techniques have high diagnostic accuracy.

Treatment

Treatment is generally supportive, with earlier intervention leading to better outcomes. Survival increases with early recognition, hospitalization, and adequate pulmonary and hemodynamic support. This includes intensive care unit monitoring and the initiation of mechanical ventilation as

Telegram: @medical_k

www.konkur.in

needed to treat respiratory failure. Extracorporeal membrane oxygenation (ECMO) has been used with success. Given the role of capillary leak in the development of noncardiogenic pulmonary edema and hypotension, early use of vasopressors and inotropes for management of hypotension and cautious use of intravenous fluids is needed. Early dialysis helps in acute renal failure. Antiviral treatment is generally unsatisfactory for HCPS, whereas rivabirin may be effective against HFRS due to Hantaan virus. There is no role for glucocorticoid therapy in hantavirus diseases.

Prevention

In general, rodent control is the most important preventive measure, which can be done by sealing gaps/holes in homes, setting traps, and keeping food in enclosed containers. Seldom used buildings should be opened and aired out prior to entry. If heavy infestation is present in an area where HCPS has been reported, it is recommended that the appropriate local, state, or federal health officials be consulted prior to clean-up [35].

Unfortunately, only few vaccines are available worldwide. In China and Korea, killed-virus vaccines are available for Hantaan virus and/or Seoul virus [36]. No vaccines are available for Sin Nombre virus or other agents of HCPS.

Giardia

Giardia lamblia is a parasite capable of causing epidemic or sporadic diarrheal illness from contaminated water supplies, person to person (i.e., day care, mental institutions), contaminated food, or travelers where giardiasis is endemic. There is a high prevalence in developing countries with poor hygiene and poverty is high, and has a lower prevalence in industrialized nations.

Etiology and Epidemiology

Giardiasis is one of the most common intestinal protozoan infections in the world. The etiologic agent is *Giardia lamblia* (Giardia *duodenalis*, *Giardia intestinalis*), a flagellated protozoan which infects a wide array of hosts. It is the most common cause of waterborne outbreaks of diarrhea in the USA [37]. Ingestion of even 1–10 cysts can cause clinical disease. Infection occurs when cysts are ingested with contaminated water, food, or direct fecal-oral contact. Once in the stomach, the acid pH causes cysts to excyst into trophozoites in the proximal small intestine, where they replicate and cause diarrhea and malabsorption. The transmission cycle is complete when the trophozoites are exposed to biliary acid, transforming into cysts in the jejunum, and then are passed in the feces [38].

There are eight different genotypes within *G. lamblia*, but only two types are capable of infecting humans (A and B), dogs are infected with genotypes C and D, cats with F, and livestock with type E. Previous exposure to G genotype produces partial immunity to disease and leads to a reduced risk of reinfection and to reduced development of overt symptoms in secondary infection [39].

Clinical Presentation

The great majority of patients infected with *G. lamblia* are asymptomatic. Classical presentation usually begins 1–3 weeks after ingestion of cysts and includes abdominal pain and cramps, nausea, belching, bloating, flatulence with sulfur odor, and diarrhea. Fever and vomiting are rare, as are blood or mucus tinged feces. If patient remains untreated, diarrhea may persist for several months, having flare-ups of diarrheal disease interspersed with normal stools. Chronic infection can cause disaccharidase enzyme deficiency and brush-border damage causing fat malabsorption, lactose intolerance, vitamin A and K deficiency, and failure to thrive in children [40].

Laboratory Diagnosis

The microscopic ova and parasite (O&P) evaluation is the traditional method for stool parasite testing and is the cornerstone of diagnostic testing for intestinal protozoan evaluation. However,

Telegram: @medical_k

www.konkur.in

microscopy may be cumbersome and requires an experienced laboratory technologist. The Food and Drug Administration (FDA) has approved several detection tests for *Giardia*, *Cryptosporidium*, and *Entamoeba histolytica*. These advanced molecular assays offer fast and reliable results with appropriate sensitivity and specific for detections of multiple parasites [41].

Treatment

Several agents are used to treat giardia infection and include:

Nitroimidazoles: Tinidazole [Tindamax], adults 1 g daily for 1–2 days, children >3 years: 50 mg/kg/dose daily for 1 to 2 days; most side effects include nausea, abdominal pain, anorexia, and stomatitis. This medication is not indicated for children. Metronidazole (Flagyl) (adults 250 mg/dose two to three times a day for 5–10 days) is quickly and completely absorbed after oral administration. Despite its widespread and accepted use against *Giardia*, the Food and Drug Administration (FDA) has not approved it for this indication. This medication is well tolerated; the most common side effects are gastrointestinal upset and a metallic taste.

Furazolidone: Furazolidone (Furoxone) (adults 100 mg/dose four times a day, pediatrics 1.5 mg/kg/dose) is used for a 7- to 10-day course. It is approved for use against *Giardia*. Side effects might include nausea, vomiting, and diarrhea.

Benzimidazoles (Nitazoxanide): Albendazole (Albenza) (adults 400 mg/day for 5 days, pediatric dose 15 mg/kg/day) for 5–7 days. Mebendazole (Vermox) (adults and pediatrics 200–400 mg/day) for 5–10 days. One advantage of using albendazole is its efficacy against multiple helminths and relative lack of side effects.

Paromomycin: Paromomycin (Humatin) is indicated for treatment of *Entamoeba histolytica* and *Trichomonas*. It is used in treatment of *G. lamblia* in resistant infections and pregnancy [42].

Immunocompromised individuals, IgA deficiency, drug-resistant organisms may need larger doses and longer duration in order to eradicate this organism. Patients should be advised that a transient lactase deficiency is common with Giardiasis and to consider minimizing lactose-containing food for a few weeks.

Rocky Mountain Spotted Fever (RMSF)

Rocky Mountain Spotted Fever (RMSF) is a potentially fatal tick borne illness that occurs throughout the United States (US), Canada, Central America, and South America and is the most common rickettsial infection in the in the USA. With the ease of travel patients infected by RMSF may present to family physicians in nonendemic locations. Early diagnosis is critical since it has a high mortality rate if untreated.

Epidemiology

Rickettsia rickettsii, an obligatory intracellular gram negative rod-shaped bacterium, is the causative organism of RMSF; it is a zoonotic tick-borne disease (TBD) in which humans are accidental hosts. Ticks become infected by feeding on the blood of an infected animal, then pass it through their saliva to humans, as the organism invades the endothelial and smooth muscle cells of blood vessels thus causing vascular injury, and activation of inflammatory and coagulation cascades. Ticks serve as both the vector and the reservoir of *R. rickettsii* and vary based upon geographical location: *Dermacentor variabilis* (the American dog tick) is in the south central and eastern USA, *Dermacentor andersoni* (the Rocky Mountain wood tick) is in the mountain states west of the Mississippi River, *Rhipicephalu sanguineus* (the brown dog tick) is in Arizona and Mexico [43, 44], the Cayenne tick (*Amblyomma* cajennense) is in Central and South America, and the yellow dog tick (*Amblyomma aureolatum*) is in Brazil. There is a seasonal distribution (spring and summer); therefore, the majority of cases occurs during April through September, when humans increase their recreational outdoor activity [45].

Telegram: @medical_k

www.konkur.in

Clinical Features

Infected patients typically become symptomatic within 2 days to 2 weeks, and the initial diagnosis is based on clinical signs and symptoms. The early stages are characterized by fever (95–100%), headache (80–90%), gastrointestinal symptoms (60%) nausea, vomiting, anorexia, abdominal pain (can mimic appendicitis), myalgia, edema around the eyes and on the back of hands. Rash develops in the first 2–4 days of illness (56–88%); this blanching erythematous macular or papular rash usually starts on the ankles and wrists, then spreading to the soles and palms, and then centrally to the arms, legs, and trunk. Within 48–72 h it may become petechial (a sign of severe disease) or purpuric. The later stages of RMSF (day 5 or later) the rash can lead to necrosis and gangrene (thus requiring amputation). In some cases of RMSF (up to 10%), there is no rash present at all [44]. The late stages of the disease can result in multiorgan system damage: neurological damage (altered mental status, coma, meningismus, hearing loss, and encephalitis), respiratory compromise (acute respiratory distress, pulmonary edema, and pulmonary infiltrates), cardiac involvement (pericarditis, arrhythmias, and myocarditis), acute renal failure, coagulation defects, and gastrointestinal bleeding [45].

Laboratory Diagnosis

R. rickettsii cannot be cultured in most clinical laboratories, and therefore the diagnosis is mainly clinical. Most patients with RMSF have normal white blood cell count at presentation, and thrombocytopenia can occur as the disease progresses. In advanced cases, hyponatremia is frequently noted (common with CNS symptoms), elevations in serum aminotransferases, hyperbilirubinemia, azotemia, and prolongation of the partial thromboplastin and prothrombin times (PT and PTT) is also seen. The cerebrospinal fluid (CSF) may demonstrate pleocytosis and elevated CSF protein (33%) [44].

Indirect immunofluorescence (IFA) testing is the most widely available and frequently used test with an overall sensitivity of approximately 95% and seroconversion usually occurs 14 days after the onset of symptoms. The diagnostic titer is usually greater than 1:64, or a fourfold rise in the titers collected 2 weeks apart (between paired acute and convalescent sera). Confirmation of *R. rickettsii* antigen via skin biopsy with direct immunofluorescence, or identification of rickettsial DNA in blood or tissue sample by PCR is performed when available [44, 47].

Treatment

Treatment decision for rickettsial pathogens should never be delayed while awaiting for laboratory confirmation. Following tick removal, there are two antibiotics that have proven efficacy for treating RMSF: tetracycline (doxycycline) and chloramphenicol. Doxycycline is the drug of choice in all adults and pregnant women (100 mg twice daily for 7 days) and in children (2.2 mg/kg/dose twice daily for 5–14 days). Chloramphenicol is given when tetracycline are contraindicated (adult dosage is 50–100 mg/kg IV every 6 h and the pediatric dosage is 50–75 mg/kg/dose IV every 6 h). In cases with severe nausea and vomiting, IV hydration support is necessary. Antibiotics are generally stopped 48 h after the fever subsides [46], they are most effective when given within the first 5 days, but if left untreated for 8–15 days, death may occur in up to 20% of the patients. Risk factors for severe/fatal disease include children younger than 10 years old, adults older than 60 years of age, patients with G6PD deficiency, alcohol use, and male African-American patients [47].

Prevention

The most effective prevention is to avoid areas endemic for *R. rickettsii*. Other preventive measures include: Spraying yards with pesticides, assuring that all dogs have tick collars [63]), walking on the center of paths and trails, wearing clothing treated with 0.5% permethrin, treating the skin with tick repellants (DEET), daily full

Telegram: @medical_k

www.konkur.in

body checks, and using a dryer for at least 10 min for all of the clothing worn [45]. Careful removal of the ticks with forceps or covered hands, grasping the tick nearest to the head without compressing the body, and gently pulling straight outward can also help prevent RMSF [48, 49]. No data to date support the use of prophylactic antimicrobials in individuals after a recent tick bite without clinical illness.

Introduction

Epidemics and pandemics are large-scale outbreaks of diseases that affect wide geographical areas; the former are more local, and the latter are international and potentially global. They cause significant morbidity and mortality and can have major impacts on society in a variety of ways. While noncommunicable diseases also cause pandemics (e.g., the obesity pandemic), traditionally the term is used to refer to infectious diseases, and that will be the focus of this chapter. Common usage of "outbreak" applies to the rapid emergence or spread of infectious disease; thus, the gradual emergence of disease, such as those caused by antibiotic-resistant organisms, is also outside the scope of this chapter. Table 1 lists some examples of pandemics of the past and present.

The emergence of an epidemic (and potentially, a subsequent pandemic) is the result of the convergence of four determinants: humans, pathogen, its natural host, and the environment (Fig. 1). The interplay between these determinants can alter the likelihood of the disease transmission to, and ultimately between, humans [1]. Increasing contact between the natural host and humans

Table 1 Select notable pandemics [23–27]

Pandemic	Toll	Geography	Pathogen	Era
The Black Death	50% of Europe's population died	Europe primarily	*Yersinia pestis* (plague)	1346–1353
Smallpox	Up to 50% mortality	Americas primarily	Smallpox virus	1500s–1600s
"Russian" flu	1 million deaths	Global	Influenza virus	1889–1890
"Spanish" flu	500 million cases; 30–100 million deaths	Global	Influenza virus	1918–1920
"Asian" flu	1–2 million deaths	Global	Influenza virus	1957–1958
"Hong Kong" flu	500,000–1 million deaths	Global	Influenza virus	1968–1969
AIDS	35 million deaths (to date)	Global	Human immunodeficiency virus	1960–present
SARS	8098 cases; 774 deaths	Global	SARS virus	2003
2009 H1N1	1.4 billion cases; 500,000 deaths	Global	Influenza virus	2009–2010
Ebola	28,600 cases; 11,325 deaths	Africa primarily	Zaire ebolavirus	2014–2016
Dengue	100–400 million new cases annually	Global	Dengue virus	2000–present
Zika	Most significant morbidity results from prenatal exposure. Full impact unknown	Global	Zikavirus	2007–present
COVID-19	Full impact unknown	Global	SARS-CoV-2	2019–present

increases the likelihood of transmission – this is important, because nearly all pandemics in history can be classified as zoonoses. This contact can result from human encroachment into the hosts' habitat or habitat changes that increase the hosts' (or for some diseases, the vectors') population numbers. For most zoonotic pandemics, changes beyond mere contact are necessary. Alterations of the pathogens' receptor specificity, pH tolerance, enzyme activities, and ability to evade its new hosts' defensive mechanisms are also required [2]. Many pathogens sporadically cross over to infect humans; fortunately few succeed in clearing all of the hurdles necessary to establish themselves as communicable diseases capable of human pandemic potential.

Detection

Surveillance

Following the influenza pandemic of 1918, governments and private institutions around the world began active surveillance for influenza in an effort to detect – and attempt to prematurely terminate – the next pandemic. In the USA, these efforts are based in the Centers for Disease Control and Prevention (CDC). The surveillance strategy has several components, each implemented from a different perspective. These range from a purely clinical approach, to a microbiological research perspective, to a public health and geographic tracking strategy. These surveillance categories are summarized in Table 2.

A comprehensive surveillance system is of importance for a number of reasons. Disease strains can change rapidly; when an antigenically distinct organism enters an immunologically naïve population, it has the potential to cause a pandemic. This is especially true in the case of a dramatically different strain, as in the case of recent crossover to humans of a zoonotic influenza strain. Although to date no emergence of a novel pandemic strain has been announced by detection of a closely related precursor in an animal or human prior to the outbreak [3], changes in the dynamics of the epidemiology of human influenza could be the harbinger of such an event. National responses to emerging pandemic strains are triggered by surveillance data. These responses will be presented in greater detail later in this chapter. Epidemiological data may identify subpopulations at greater risk that may require targeted interventions in an effort at mitigation of the impact of the pandemic. A unique aspect of the influenza H1N1 pandemics of both 1918 and 2009 was their predilection to cause death in different age groups than is typical for influenza. While most seasonal influenza strains are most dangerous to the young and the elderly, these two hit healthy young adults more severely, as shown in Fig. 2. At a more mundane level, but equally important, vaccines are updated based on early surveillance data that detect strains currently in circulation.

At the global level, the World Health Organization (WHO) tracks influenza activity in a similar fashion. The Global Influenza Surveillance and Response System (GISRS) tracks influenza strains in active circulation globally from a virological surveillance approach. Geographical spread that assesses both intensity of influenza activity and active strains is tracked by WHO influenza transmission zones (Fig. 3) and reported biweekly. These transmission zones are distinct from WHO Regions. The former are geographical groups of countries, areas, or territories with similar influenza transmission patterns, while the latter are based on geopolitical characteristics.

The WHO categorizes pandemics into successive phases (Table 3). The phase indicates the extent of geographical spread, and not contagiousness of the pathogen, or severity of the disease.

This infrastructure focused specifically on the detection of influenza begs the question of surveillance for noninfluenza infections with pandemic potential. All of tools that are in place for tracking influenza are also effective in identifying other sources of systemic disease outbreak, including the clinical, epidemiological, and virological surveillance components. In addition, state and national health departments and ministries of health have in place statutory notifiable conditions (reportable diseases). By law, the clinical or laboratory detection, *or suspicion*, of these diseases must be reported to governmental health officials. These include specific known contagious pathogens as well as outbreaks of clinical syndromes, such as respiratory illness, diarrheal disease,

Table 2 The CDC influenza surveillance system

Surveillance category	Report name and URL	Description
Virological	**FluView** https://gis.cdc.gov/grasp/fluview/fluportaldashboard.html	Laboratory diagnosis based; also includes detailed virological investigations US WHO Collaborating Laboratories and NREVSS[a] Laboratories report the number tested, number positive, age group, and virus subtype each week A subset of isolates go to CDC for further characterization. This includes surveillance for novel influenza, i.e., human infections that differ from currently circulating viruses Does not include an indicator of severity of disease
Outpatient illness	**ILINet** https://gis.cdc.gov/grasp/fluview/main.html	Clinical diagnosis based 2,700 outpatient providers in all 50 states, the District of Columbia and the US Virgin Islands report the total number of patients seen, and number seen with influenza-like illness, by age group. This data set includes more than 30 million patient visits annually Does not include an indicator of severity of disease
Geographic spread	**State and Territorial Epidemiologists Report** https://gis.cdc.gov/grasp/fluview/FluView8.html	Laboratory-diagnosis-based State health departments report the estimated level of geographic spread of influenza activity in their states each week Does not include an indicator of severity of disease
Hospitalization	**FluSurv-Net** https://www.cdc.gov/flu/weekly/influenza-hospitalization-surveillance.htm	Population-based, laboratory confirmed, influenza-related hospitalizations in children and adults Covers over 80 counties in the 10 Emerging Infections Program states (CA, CO, CT, GA, MD, MN, NM, NY, OR, and TN) and five additional states (IA, MI, OH, RI, and UT) An indicator of severity of disease
Mortality	**Pneumonia & Influenza Mortality Surveillance** https://gis.cdc.gov/grasp/fluview/mortality.html **Influenza-Associated Pediatric Mortality** https://gis.cdc.gov/GRASP/Fluview/PedFluDeath.html	ICD-10 diagnosis based (clinical and laboratory) The vital statistics offices of 122 cities across the US report weekly the total number of death certificates processed and the number for which pneumonia or influenza was listed as the underlying or contributing cause of death by age group. A rate of 1.645 standard deviations above the seasonal baseline is considered the "epidemic threshold" Influenza-associated death in children is a nationally notifiable condition. Demographic and clinical information are collected on each case A major indicator of severity of disease

[a]National Respiratory and Enteric Virus Surveillance System (NREVSS)

waterborne illness, and unexplained illness or death in humans or animals.

Response

Investigation

Once an unusual outbreak is detected, it is investigated and characterized. In the USA, investigation is generally initiated by local health officials and may be supplemented with federal assets. One of the primary federal assets is the Epidemiology Intelligence Service (EIS). These investigators are post-doctoral fellows and are part of a long-standing and globally recognized program. Disease detectives who investigate outbreaks, ready to deploy at a moment's notice, their field of operations covers the globe. Noteworthy past investigations are shown in Fig. 4.

Infrastructure and Organization

In the USA, national public health emergencies such as pandemics, like any other disaster, are managed under the National Response Framework (NRF): a comprehensive, national, all hazards approach to incident response, established by Homeland Security Presidential Directive 5 (HSPD-5) in 2003 and further refined in 2005 [4–6]. This plan is implemented by employing the elements of the National Incident Management System (NIMS) [7]. NIMS guides all levels of government and the private sector to work together by providing responders across the whole community with a shared vocabulary, systems, and processes. It defines an operational system that guides the ways in which personnel work together during a disaster, whatever its cause.

An important aspect of the NRF is the assumption that disaster events are managed best at the lowest possible geographical, organizational, and jurisdictional level. This means that the primary

www.konkur.in

Table 3 WHO pandemic phases. Though specific to influenza, the general principles are applicable to pandemics due to other etiologies, such as coronavirus. Based on information from https://www.who.int/csr/disease/swineflu/phase/en/

Phase	Description
Inter-pandemic phase	
1	No viruses circulating in animals has caused disease in humans
2	An animal virus circulating among animals has caused disease in humans
Pandemic alert phase	
3	Some human-to-human transmission has occurred, but not at a level sufficient to sustain community-level outbreaks
4	Sustained human-to-human transmission leading to community-level outbreaks
5	Human-to-human spread of the virus into at least two countries in one WHO region
Pandemic phase	
6	Community level outbreaks in at least two WHO regions
Postpeak	Incidence decreasing below peak observed levels in most countries. Additional waves may occur
Postpandemic	Disease activity has returned to levels normally seen

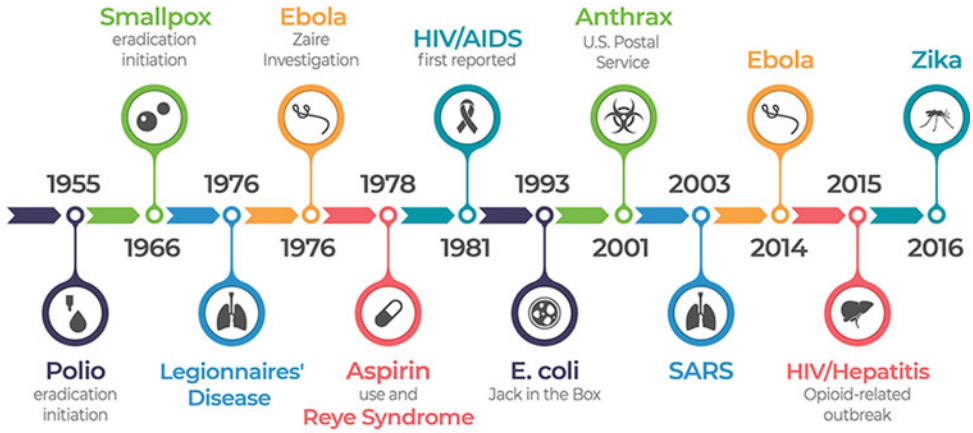

Fig. 4 Outbreaks investigated by the EIS. (Figure from CDC, public domain)

responsibility falls to local, state, and tribal governments. This is appropriate, as they are the first to respond and the last to leave – and for the local government, they *do not* leave. This level coordinates jurisdictional resources, exercises police or extraordinary powers as needed, and provides leadership of the response. They negotiate mutual aid agreements prior to the incident and request outside assistance when the local capabilities exceeded. Federal agencies advise and assist local response. In the USA, the Department of Homeland Security (DHS) is the principal agency for federal domestic incident management, coordinating federal resources when they are requested. All other federal departments may contribute, depending on the nature of the incident.

In addition to the command and control functions of NIMS, the NRF also requires tactical capabilities. These are organized as the Emergency Support Functions (ESF), listed in Table 4. An organizational structure that coordinates the resources and capabilities necessary to respond to a disaster, ESF, includes private sector capabilities of corporations and nongovernmental organizations, as well as state and federal capabilities. It is through ESF that the NRF endeavors to provide the support, resources, program implementation, and services that are most likely needed to save lives, protect property and the environment, restore essential services and critical infrastructure, and help victims and communities recover from a disaster.

Telegram: @medical_k

www.konkur.in

Table 4 Emergency support functions. Asterisks indicate those relevant in pandemic incidents

Designation	Description	Role
ESF1*	Transportation	Get what is needed to where it is needed
ESF2*	Communications	How to call for help, coordinate response
ESF3*	Public works and engineering	What about the infrastructure
ESF4	Firefighting	(self-explanatory)
ESF5*	Emergency management	Coordinating the response
ESF6*	Mass care, housing, and human services	Helping the victims
ESF7*	Resources support	The "stuff" that is needed
ESF8*	Public health and medical services	Addressing medical needs
ESF9*	Urban search and rescue	Finding the victims
ESF10*	Oil and hazardous materials response	Getting fuel; or cleaning the spill
ESF11*	Agriculture and natural resources	Food supply, materials
ESF12*	Energy	Powering the response; or dealing with a radiological incident
ESF13*	Public safety and security	Maintaining order
ESF14*	Long-term community recovery and mitigation	Rebuilding
ESF15*	External affairs	Coordinating across jurisdictions, specifically, internationally

Of special interest in pandemic incidents is ESF 8. In addition to local health professionals and health systems, there are state and federal resources that can supplement the medical response. Most states have a state emergency reserve of volunteers (SERV). These are databases of statewide health professionals who register and are credentialed in advance, in order to assist public health and healthcare systems in the event of an incident [8]. When a disaster strikes, these volunteers can be enlisted to help fill in the gaps where local healthcare systems are overwhelmed.

Table 5 lists key federal resources available to provide medical assistance in support of, and at the request of, state and local efforts. These resources include health professionals – full-time federal employees, a "reserve" force, and a volunteer force. Portable health care facilities and supplies for their operation are also part of this resource pool. Federal disaster resources *must be requested* by state officials; they are not deployed unilaterally. Not included in the table are military resources, which can augment and support the civilian resources of ESF8 (and most other ESFs).

The Strategic National Stockpile (SNS) is a collection of critical medications and supplies. While primarily designed to respond to military or terrorist attacks, when they would be rapidly dispensed through the affected state(s)'s official Points of Distribution, most of the constituent SNS parts have application to other types of disaster, including pandemics. The SNS can be used to facilitate the operation of the federal disaster personnel teams and facilities or it may be deployed to state and local responders independently of any other federal ESF8 resources. Figure 5 illustrates historical dispensing of the SNS.

Control Strategies

Stopping Versus Slowing the Spread

Following the detection of an outbreak with the potential of rapid spread, the initial goal is to prevent the spread completely. This is accomplished by quarantine of affected individuals until the disease has run its course or has been successfully treated. In addition, all precautions necessary are taken to prevent transmission of the disease to those who are providing care to the infected individual(s). When first established, the US Public Health Service was focused on identifying shipborne diseases and enforcing quarantine in order to prevent spread in the

Table 5 Key federal sources of medical assistance. Additional details are at https://www.phe.gov/Preparedness/support/medicalassistance/Pages/default.aspx

Resource	Responsible authority	Description
Personnel resources		
Commissioned Corps, US Public Health Service [full-time federal employees]	Assistant Secretary for Health, Department of Health and Human Services	**Rapid deployment force.** Multidisciplinary teams capable of deploying within 12 h of notification to provide mass care at shelters, and staff points of distribution or casualty collection points **Applied public health teams.** Experts in public health that deploy within 36 h of notification and function as a "public health department in a box" **Mental health teams.** Behavioral health experts who can deploy within 36 h of notification and assess the affected population, responder stress, and provide therapy, counseling, and crisis intervention
National Disaster Medical System [intermittent federal employees]	Assistant Secretary for Preparedness and Response, Department of Health and Human Services	**Disaster medical assistance teams.** Multidisciplinary, capable of deploying within 6 h of notification to provide primary and acute care, triage of mass casualties, initial resuscitation and stabilization, advanced life support, and preparation for evacuation. Can sustain operations for 72 h without external support **Disaster mortuary operational response team**. Multidisciplinary team to recover, identify, and process deceased victims. May employ disaster portable morgue units to establish a stand-alone morgue operation **National Veterinary Response Team** provides assistance with veterinary services following major disasters, emergencies, public health, or other events **National Medical Response Team** provides medical care following a nuclear, biological, and/or chemical incident, mass casualty decontamination, medical triage, and medical care for stabilization for transportation
Medical Reserve Corps [volunteer responders]	Assistant Secretary for Health, Department of Health and Human Services	Provides the structure necessary to deploy volunteer medical and public health personnel in response to an emergency by identifying in advance specific, trained, credentialed personnel available and ready to respond to emergencies
Facility resources		
Federal Medical Stations	Assistant Secretary for Preparedness and Response, Department of Health and Human Services	A deployable healthcare facility to provide surge beds to support local healthcare systems. These are not mobile and cannot be relocated once established. Staffing is provided by displaced local/regional clinicians or can be provided by the federal government through any of the resources listed above. Supplies are from the Strategic National Stockpile
Material resources		
Strategic National Stockpile	Centers for Disease Control and Prevention	The national repository of antibiotics, chemical antidotes, antitoxins, ACLS medications, IV and airway supplies, ventilators, and other medical/surgical items. Organized by incident-specific "push-packs" that can be delivered to Federal Medical Stations or state points of distribution within 12 h of the decision to deploy them

Telegram: @medical_k

www.konkur.in

preantibiotic era. Even today, there are 20 Quarantine Stations strategically located at the US ports of entry where most international travelers arrive [9]. The idea of this strategy is analogous to quenching the spark before the flame begins. This strategy worked well in 2003 and 2014 for SARS and Ebola, respectively.

This primary strategy of prevention is reasonable when the number of infected individuals is relatively small and geographically localized. As the outbreak develops to an epidemic, this strategy becomes more difficult to effectively implement and ultimately may fail. Separation of infected from uninfected populations can be maintained to a degree, but when boundaries are political rather than geological, they tend to leak. The speed and convenience of modern modes of transportation further undermine efforts to contain the disease.

As an epidemic progresses to a pandemic, a different strategy is needed. Rather than *preventing* its spread – the goal is to *slow* its spread. This is the "flattening the curve" phrase, which became ubiquitous during the COVID-19 pandemic. While the same number of individuals will ultimately experience infection, the goal here is to avoid overwhelming the capabilities of the health system (Fig. 6), which would result in otherwise avoidable deaths. The slowing of the spread of the infection also has the potential to buy time for the development of improved treatments, and the deployment or possibly the development of a vaccine.

Slowing the infection presents some hazards in the case of a pandemic. By prematurely terminating transmission before a critical mass of protective seropositivity is reached in the population, the population could be left vulnerable to subsequent pandemic waves by the same organism – the disaster is not averted, it is merely postponed. The degree of population immunity, needed in the population to protect it, is dependent upon the reproduction rate (R_0, i.e., the number of new people infected by each infected person) of the infection. Once the reproduction rate passes below the "herd immunity threshold," where $R_0 \leq ((R_0–1)/R_0)$, incidence of the disease declines [10].

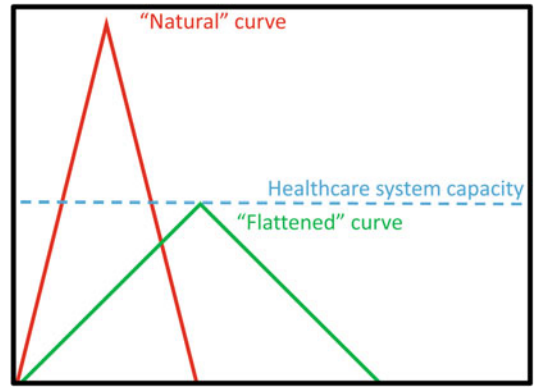

Fig. 6 Slowing transmission. The natural curve results in overwhelming healthcare systems and increase in otherwise avoidable morbidity and mortality. By "flattening the curve," while the same number of infections may occur, the healthcare system is not overwhelmed and thus is able to provide optimal care to all infected patients

There are a number of tools of use in slowing the spread of disease. Universal precautions, isolation procedures, environmental decontamination, and use of personal protective equipment such as gowns, gloves, masks, respirators, etc., by healthcare professionals while caring for infected or potentially infected individuals are important to prevent the spread of infection. Outside of the healthcare setting, the most aggressive tool to prevent contagion is quarantine, ranging from voluntary self-quarantine to legally enforced confinement. Less intrusive measures include "social distancing," which may vary from maintaining a minimum physical separation between individuals to avoiding mass gatherings to closing schools, businesses, and other enterprises. While the concept is intuitively sound, there is only limited evidence to suggest that social distancing is beneficial [11]. The implementation of barrier protection methods, such as face masks and gloves, by the general public is another strategy that has been employed, though currently evidence for patient-oriented outcomes is lacking [12].

Treatment

In spite of the best efforts at controlling the spread of a pandemic, clinical care of its victims will be

Telegram: @medical_k

www.konkur.in

needed. Perhaps the top priority is healthcare workforce protection – if this is neglected, the healthcare workforce will be rapidly rendered ineffective. Proper use of personal protective gear, isolation procedures, and environmental disinfection, although mentioned earlier, are worth repeating.

For familiar diseases without effective treatments, as well as those caused by novel pathogens, the most important care is supportive. Sepsis, shock, and respiratory (or other organ) failure, as well as other problems, need to be appropriately treated. When there are known specific treatments (e.g., antibiotics or antiviral medications with demonstrated efficacy against the pathogen), they should be used. For novel pathogens, or pandemics of familiar but untreatable diseases, there is a temptation to try a variety of unproven therapies. While the desire to "do something" is strong, it must be tempered. "Compassionate use" of unproven remedies may well be termed "compassionate harm" – every intervention has the potential to injure, and without data it is impossible to truly balance benefit against harm. This was seen in the early days of the COVID-19 pandemic, when any idea suggested was often widely adopted, usually without tracking outcomes [13]. *It is critical during pandemics that experimental interventions be monitored* for benefit and harm; properly controlled clinical trials are preferable *and possible* in these circumstances; at the very least, registries must be maintained for subsequent analysis of therapeutic effect.

In addition to pharmacotherapy, immunotherapy may be considered. Early in a pandemic, the use of convalescent serum may prove beneficial. Later, other therapeutic biologics based on protective antibodies may be developed. A protective vaccine to administer to uninfected individuals may become available, though a significant amount of time is required to demonstrate both effectiveness and safety. The first recipients of new vaccines should be those at highest risk of infection or severe disease, including healthcare workers. Sometimes, the immune response to the pathogen may be primarily responsible for the pathology, and immune system modulators may be worth considering. As with the caveat for investigational drugs, none of these interventions should be used without monitoring and tracking the results.

Perhaps, one of the most important lessons relevant to clinical care from the beginning of the COVID-19 pandemic was the importance of maintaining a broad differential diagnosis, and not overlooking the timely and appropriate care of *nonpandemic* disease. Common diseases are common, even during a pandemic, and neglect of acute and chronic diseases makes a sizeable contribution to the excess mortality that may be observed during a pandemic. While these deaths are decidedly a result of the pandemic, they are due to neglect and mismanagement, not infection!

Practice Preparedness

Key to a successful response to a pandemic, or any disaster, is preparedness. This was an important component of a Homeland Security Presidential Directive 8 which incorporated preparedness into the NSF [6]. Waiting until a disaster has arrived to prepare for it makes failure much more likely.

Caring for their regular patients is the principal professional obligation of the family physician in the event of a disaster [14]. However, without a plan for continuity, the physician's ability to aid their patients will be hampered. It is wise for the physician to ensure that a proper clinic disaster plan is in place, whether they are employed, volunteer, or in private practice. A written disaster plan is extremely valuable. The development of such a plan requires substantial thought and effort – and best done prior to a catastrophic event. It should integrate with the disaster plans of the local community, health systems, and the state/provincial governments [15–17].

One part of the disaster plan specific to pandemics addresses isolation measures. A simple example of the most basic of measures is separate waiting areas for patients with symptoms of infection and those with noninfectious illnesses. During the initial period of an outbreak, it may be necessary to temporarily postpone preventative health care, and take measures such as scheduling

Telegram: @medical_k

www.konkur.in

chronic disease management visits early in the day prior to scheduling patients with presumed infectious conditions, and other chronological isolation strategies. Many of these physical and chronological measures may be also beneficial during nondisaster periods, and during seasonal illnesses such as influenza. Following recent outbreaks and pandemics affecting the USA, there is increasing interest in incorporating negative pressure rooms into primary care clinic design.

Disaster planning should also address the requisitioning of personal protective equipment (PPE) and supplies. Healthcare professionals are much more reluctant to care for disaster victims when adequate PPE is not available [18]. Because of the potential for resupply system disruption, PPE and all other material required for clinic operation should be stockpiled in adequate quantities to continue clinic operations for an extended period. This includes adequate water, food, and even shelter space for clinic staff while at work, depending on the potential level of disruption of local infrastructure caused by the event.

During a pandemic, some clinic staff will be unable to perform their functions due to personal illness, caring for family members, disruption of the local transportation system, fear of illness, or other reasons. Cross-training staff to perform functions outside their usual job description can help compensate for staff absenteeism.

A communications plan is critical. How will the physician communicate with his or her staff following the disaster? How will patients communicate with the clinic? How will the physician communicate with public health authorities? How about with the rest of the community?

Finally, the plan needs to address one of the most ironic situations in a pandemic: *health* care professional job loss and facility closure during a public *health* crisis. Due to social distancing and other isolation strategies, as well as fear of acquiring infection in a healthcare facility, patient visits have the potential to drop precipitously. This can result in the need to lay off staff, significant loss of billing-indexed physician income, and even practice closure. While it is difficult to fully anticipate and mitigate the economic impact of a pandemic on a family medicine practice, steps can be taken to soften the blow. Potential strategies include actions such as increasing the use of telemedicine, retasking clinic staff to jobs such as quality improvement activities and chronic disease registry creation and maintenance when direct patient care duties decrease, encouraging employees to utilize their paid time off during the lulls in clinic activity, and transitioning physicians and other staff into the "surge labor pool" of the local or regional hospitals during the crisis.

Opportunities in the Broader Response

Family physicians have a uniquely comprehensive clinical skill set that is not limited by patient age or sex, organ system, or disease state. It encompasses procedural and cognitive proficiencies, flavored by a public health/community health orientation. This can be of great value outside of their local practice in times of crisis such as pandemics and other disasters. All family physicians should give serious consideration to registering with their state's SERV. For some who are looking for a higher level of involvement, volunteering through NGOs or federal avenues such as the Medical Reserve Corps, intermittent employment with National Disaster Management System, or even a career focus in the Commissioned Corps is a possibility. The key is to establish the connections *prior to* the next disaster.

Ethical Considerations

Though the final section of this chapter, the ethics of pandemics are of primary importance. The countless ethical issues involved in medical care under ordinary circumstances are relevant; there are two that warrant extra discussion here.

Outbreaks, epidemics, and pandemics are particularly dangerous times for healthcare professionals. What is the moral duty to treat patients during these times? During the 2014 Ebola outbreak, 95% of expatriate doctors left Liberia – just when they were needed the most [19]. Similarly, in the early days of the AIDS pandemic, many

Telegram: @medical_k

www.konkur.in

physicians refused to treat AIDS patients, prompting a soul-searching discussion in the medical profession [20]. Historically, many physicians fled cities during the plague, including Galen from Rome and Sydenham from London. Prominent physicians fled Philadelphia and New York during outbreaks of yellow fever and cholera in the eighteenth and nineteenth centuries. Many physicians who did not leave refused to visit patients who were acutely ill. However, most physicians treated patients who sought help [20]. The ethical principles of beneficence and justice compel one to ask, "Did we enter the profession to help those suffering? Or make a comfortable living off of the suffering (so long as risks are relatively low)?" Family physicians have a clear track record of selecting their specialty, not for financial gain, prestige and respect, or a comfortable lifestyle – indeed, often in spite of the opposite – but to make a meaningful difference in the lives of their patients and communities. When responding to this ethical call, workforce protection is critical: good isolation practices, adequate PPE, and supporting one another to avoid critical incident stress and burnout [21].

The WHO defines health as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity [22]." This clearly specifies health and disease as reaching far beyond a merely biological perspective. The social determinants of health are increasingly receiving proper attention within the US health care delivery systems. In responding to the threat of a pandemic, it is vital that this continues. Strict quarantine-like activities significantly impact education, mental health, and the economy. This impact is disproportionately felt by those most disadvantaged by social determinants of health, hurting those most vulnerable. The excess mortality seen during pandemics is the result of chronic disease neglect, domestic violence, suicide, food insecurity, etc. – not just the direct biological result of infection. An exclusively biological approach inevitably violates the principles of autonomy, justice, and nonmaleficence. The big picture of health that encompasses all its determinants is what Family Medicine is all about. Its voice must be heard advocating for patients and a balanced approach to society's pandemic response.

Box 1 Incident Command (ICS) for Health Professionals

Excerpts from "Incident Command System Primer for Public Health and Medical Professionals," US Department of Health and Human Services [28].

Traditionally, preparedness actions for public health and medical emergency or disaster response have focused on the operational (tactical) knowledge and skills required by individuals to respond. This has resulted in training programs developed primarily for such topics as victim triage or the characteristics of specific hazards (e.g., chemical or biological agents). Though this knowledge is important and has relevance, much of it is easily accessed during incident response and does little to maximize the capacities and capabilities of existing structures. In other words, teaching and training on these topics provides little in the way of strategic knowledge that improves the ability of individuals to respond as part of a cohesive system. . .

Public health and medical disciplines have focused historically on the operation functions necessary for response. Experience demonstrates that problems will arise if inadequate attention is paid to the other functional areas:

- Protection of responders: Inadequate initial consideration for personal protective equipment (PPE) could cause responders to be exposed to an infectious disease (a safety function).
- Management of strategies: Inadequate coordination of strategies and tactics for screening for a disease might promote confusion in the patient population if people receive different evaluation or treatment at various healthcare facilities (a command function).

(continued)

Telegram: @medical_k

www.konkur.in

Box 1 Incident Command (ICS) for Health Professionals (continued)

- Management of information: Inadequate information management might result in the transportation of patients to a hospital that is already overwhelmed with walk-in patients (a planning function).

Many of the most severe challenges during an incident response arise within the response system itself. Therefore, ICS devotes a large portion of its activities to supporting the response system, whether through logistics, planning, or administration/finance sections. . .

For public health and medicine to be considered equal partners and fully integrated into the response community, the concepts put forth in ICS should form the basis of their response systems. Without this foundation, it will become increasingly difficult for public health and medicine to maximize their roles in incident response.

Introduction

The evaluation and management of work-related health conditions offers the family physician a unique medical challenge that may extend far beyond the confines of a clinic or a hospital. The floors of a lumber mill, the flight deck of a 747, and the dark tunnels of a coal mine are but a few of the environments that can become the concern of the family physician caring for the worker.

From Antiquity to Nanotechnology

The practice of occupational and environmental medicine has its roots in antiquity. Concern for the health of workers has been documented as early as ancient Egypt when Imhotep, considered the grandfather of occupational medicine, described treatment for injuries sustained by pyramid workers. Similar writings are found in ancient Greece, when both Hippocrates and Pliny the Elder wrote on the maladies of miners, horsemen, and metalworkers. Throughout history, many figures have advanced the health of workers. However, it is Bernardino Ramazzini that is considered the "father" of modern occupational medicine. Through his dedication to exploring the ailments of the worker, Ramazzini expanded the breadth and depth of occupational medicine by promoting worksite visits. The toils of his studies resulted in one of the earliest textbooks of occupational medicine, De Morbis Artificum Diatriba, which was published in 1700 [1].

Since the time of Ramazzini, there have been many pioneers of the specialty. One more modern contemporary that deserves special attention is Dr. Alice Hamilton. In the early 1900s, Hamilton not only advanced our understanding of the toxicological dangers of work, such as lead, but she also championed the importance of workplace safety. Hamilton's work and accomplishments extend far beyond the care of workers; she was a prominent social activist and also the first female faculty member of Harvard University [2].

Over the last two decades, the most important change in occupational medicine has been a focus on the importance of work. In the past, there was great emphasis in ensuring people were fit for work, leading to the exclusion of disabled persons from the productive work they desired. Moreover, a large part of treating work-related injury and disease was removal from work on medical grounds. Although this may be still necessary in some cases, it is now recognized that work is crucial for health, socialization, and personal identity. Conversely, absence from work is frequently demotivating, demoralizing, and fraught with risks of depression, adverse mood changes, deleterious effects on career progression, and iatrogenically induced prolonged/permanent disability. Poor outcomes have also been demonstrated in occupational injuries compared with similar injuries sustained from sport and recreation.

Telegram: @medical_k

www.konkur.in

These considerations have led to a revised approach to work injuries. Occupational medicine is now focused on maintaining functional ability by returning injured workers to productive employment via appropriate work restrictions matching the job to the worker, [3] and case management. It is in this endeavor that occupational medicine finds itself at a frontier within the practice of medicine.

The blossoming concept of work as a potential healing entity, coupled with the development of novel compounds and industries that may represent dangers to health that have not yet been fully delineated, such as graphene and nanotechnology, presents ongoing health challenges for workers and occupational medicine providers.

This chapter will discuss the epidemiology of work-related illnesses and injuries, the history of the origins of Occupational Medicine in the United States as a well as review some common occupational diagnoses, in no particular order of importance. The diagnoses discussed are in no way exhaustive.

Practice Overview

At the level of the individual patient, occupational and environmental medicine (OEM) focuses on the care of the injured worker, the prevention of workplace injury and illness, and the improvement of worker health and productivity. A division of preventive medicine, OEM is one of the smallest medical specialties recognized by the American Board of Medical Specialties. However, the expertise OEM provides regarding worker health and population management skills renders it an increasingly important specialty.

Despite this need, there is a shortage of OEM physicians. Indeed, in 2018, only 71 physicians achieved board certification in OEM [4]. In addition, with the number of board-certified occupational medicine specialists in decline, it is anticipated that nearly 1700 OEM physicians will retire in the next 10 years. The result is that there will be a 33% reduction in specialist numbers [5]. As such, there is a burgeoning practice opportunity for family physicians that are willing to pursue additional training and education in the treatment of workers.

Epidemiology

As the number of specialist OEM physicians declines, the incidence of work-related health conditions continues to be significant. In 2018, there were approximately three million nonfatal workplace injuries and illnesses reported in private and public sectors. Alarmingly, 2018 was the first year the rate of total recordable injuries did not decline since 2012. More than half of these were injuries severe enough to require work modifications, job transfer, or time off from work [5]. For the private sector, the highest rates occurred in the manufacturing, health care, and retail industries. For state and local governments, which historically have had higher incidence rates than the private sector, nursing and residential care facilities have the highest rates of injuries and illnesses. Agriculture, forestry, and fishing experienced the highest fatality rates. In all sectors, persons 55–64 years of age had the highest incidence of injuries (113.4/10,000). The most common type of injury events were overexertion and bodily reactions, slips and falls, and contact with objects. The most common injuries were sprains/strains/tears, soreness/pain, and cuts/lacerations/punctures [6].

While rarely considered during national debates over the financing of medicine, the direct cost associated with work-related health care is tremendous. In 2018, the cost of worker's compensation-related health care was approximately 170.8 billion dollars [7] split nearly evenly between medical and indemnity costs [7]. In addition, injuries in 2018 resulted in roughly 70 million lost workdays. These costs are staggering, especially when compared to the 2015 cost (in millions) for heart disease (113), trauma (102), and mental disorders (98) [8]. Moreover, the true costs of occupational injuries and disease are much larger when indirect costs of lost productivity are included. The loss of productivity exceeds the direct costs of diagnosis, treatment, and indemnity payments (wage replacement while off work) for injured workers.

Telegram: @medical_k

www.konkur.in

While these data increasingly provide incentives for employers to prevent work-related injury and disease, much of society remains unaware of the cost of injured workers.

Legal Underpinnings and Entities

Given that work is an integral part of the lives many of the patients that family physicians will see and work may affect their presentation of illness or injury, a basic understanding of the key regulatory bodies and systems is necessary for successful practice and delivery of care.

Worker's Compensation (WC)

WC is the oldest form of social insurance in the United States and the third largest source of support for disabled workers after Social Security and Medicare. Workers' compensation allows for the provision of monetary compensation for medical and rehabilitation costs and lost wages to certain workers with work-related injuries or disabilities. Prior to the establishment of WC, litigation was usually necessary for full compensation. Workers rendered injured or ill due to a work-related injury or illness bore the full brunt of medical care and lost wages unless employers voluntarily offered compensation. Founded on the principle of providing a compulsory "no-fault" form of insurance for workers injured in the course of employment, employers are held responsible for compensation for work-related injuries and illnesses, regardless of findings of cause, through an insurance mechanism. In this no-fault system, in exchange for certain and prompt compensation, the worker accepts compensation limited to the standard amount specified by each state, whether the payment fully covers lost wages, pain, and/or suffering. As such, WC is the exclusive remedy for injured workers.

The first workers' compensation laws were passed in 1911 by nine states, with Hawaii being the last state to do so in 1963. A similar system had already existed in Europe with Germany being the first to pass these laws in 1884. While WC laws are similar overall, differences can exist between states and federal and private entities. It is important for the family physician to be aware of this and familiar with the nuances of their local jurisdictions [1].

Occupational Health and Safety Administration

At the turn of the twentieth century, industrial accidents in the workplace became more publicized, causing public outrage. In the wake of disasters such as the Triangle Shirtwaist Factory fire, regulatory agencies and acts, such as the Safety Appliance Act and the United States Bureau of Mines were formed. With further increases in industrialization that followed World War II, the incidence of workplace injuries increased dramatically. The dangers of industrialization were compounded by the increasing use of industrial chemicals, many of which had unknown health effects. It is estimated that in 1970, there were 14,000 work-related fatalities in the United States [9].

In 1970, the US government passed the bipartisan Occupational Safety and Health Act (OSH Act), the purpose of which was to create and maintain the safety and health of workers in the United States through training, education, and assistance. Perhaps, the most powerful component of the act is its general duty clause, which states each employer:

> shall furnish to each of his employees employment and a place of employment which are free from recognized hazards that are causing or are likely to cause death or serious physical harm to his employees.

The clause enables the broad protection of workers and workplace safety, even in the absence of specific applicable regulations or standards.

The act led to the establishment of the most recognized government agency pertaining to work safety, the Occupational Health and Safety Administration (OSHA). OSHA, a component of the Department of Labor, is the government's regulatory agency for work safety. Some of the

Telegram: @medical_k

www.konkur.in

agency's many services include regulatory inspections and enforcement of standards, such as those pertaining to lead and blood-borne pathogens [10].

National Institute of Occupational Safety and Health

The OSH Act also created the National Institute for Occupational Safety and Health (NIOSH) as part of the Centers for Disease Control and Prevention. The purpose of NIOSH is to conduct research on worker injury/illness and to make recommendations on workplace safety issues. Examples of NIOSH's research areas include such subjects as the danger of antineoplastic medications to health-care workers and hazards in offshore gas/oil extraction. In addition, NIOSH also funds education, research, and training in occupational health. The roles of NIOSH and OSHA are distinct, with OSHA being the regulatory aspect of work safety [11].

Americans with Disabilities Act (ADA)

The purpose of the ADA, promoted in 1990 by Senator Tom Harkin of Indiana, is to prevent discrimination against individuals with disabilities in transportation, public accommodations, communications, governmental activities, and employment [12]. The ADA was one of the most important pieces of social legislation in the United States and represented a major change in thinking. An impetus to the act was the ongoing exclusion from employment of many Americans with disabilities or a history of disabilities, even when such individuals had improved medically and/or wished to work. The act was amended in 2008 by the Americans with Disabilities Act Amendment Act (ADAAA).

A complete understanding of the nuances of this complicated piece of legislation is beyond the scope of this chapter. However, a basic understanding of ADAAA by the family physician is important as they may be called upon to opine on the physical capabilities of workers.

First, private employers with greater than 15 employees, state/local governments, employment agencies, and labor unions must provide accommodations for applicants and workers with disabilities if such accommodations would not impose undue hardships on the employer. Examples of accommodations include alteration of work schedules and the use of modified equipment. Undue hardship is defined generally as "an action requiring significant difficulty or expense," when considering the applicable covered employer's situation.

Second, the act prevents pre-hire inquiries, such as physical examinations, into an applicant's medical status. However, an employer may require a physical examination to determine if an individual can perform the essential functions of a job after an offer of hire has been made and before employment commences. Such examinations must be required of all employees and not on an individual basis. Pertinent records must be kept confidential and separate from employee human resources files [13].

Family and Medical Leave Act (FMLA)

FMLA was passed into law in 1993. The purpose of this law is to provide employees 12 weeks of unpaid, job-protected leave for qualified medical conditions. In addition, health insurance benefits as part of employment must be continued during such leave. FMLA is applicable to all public agencies, public and private elementary/secondary schools, and employers with greater than 50 employees. To qualify for FMLA, employees must have worked for an employer for 12 months, worked 1250 hours in those 12 months, and worked in a location where the company has greater than 50 employees within a 75-mile radius. Qualifying reasons for leave include the birth/care of a newborn, the initiation of foster care/adoption by the employee, the care of a family member with serious medical conditions, or a serious medical condition of the employee that prevents work [14].

Many family physicians encounter this piece of legislation as a multipage form with a request

Telegram: @medical_k

www.konkur.in

from patients for physician certification. Satisfactory completion of this documentation will allow appropriate protections for both the patient and employer and efficient execution of this law.

General Approach to the Evaluation of the Worker

The evaluation of the worker requires considerations and elements that extend beyond normal history and physical examination.

The Standard for Documentation

The provision of occupational health services occurs in a legal framework. The family physician should assume that any records pertaining to a work-related health condition will be scrutinized by numerous stakeholders, including insurance adjusters, employers, and legal representatives. For example, claims adjusters require detailed information in order to appropriately manage a worker's compensation claim. A failure to provide precise documentation can lead to a loss of appropriate medical treatment covered by workers compensation, costly delays in care, and erroneous assignment of financial/legal responsibilities [15]. As such, attention to detail and accuracy is required throughout occupational health care. It would not be overdramatic to state that if scalpels are the tools of the surgeon, the instruments of the successful occupational health provider are words.

The Systematic Injury History

The majority of occupational health-related treatment by the family physician involves the care of an acutely injured worker. Among the most common work-related injuries seen in primary care clinics involves low back pain, and this complaint can be used to demonstrate the proper documentation of a potentially injurious work event.

Certainly, it would not be sufficient to simply document a "patient injured while lifting at work." Legal needs aside, such a vague description sheds little insight into neither the diagnosis nor avenues for preventing recurrences. Similar to a forensic investigation, any report of a potentially work-related injury should include the mechanism of injury, the location, the time of the event, and the employees involved in the event. A useful paradigm for recalling these crucial elements is the "4 Ws": what, when, where, and who.

Medications and Substances

Outside of the obvious dangers of alcohol and illicit drug use at work, several legal medications can be hazardous. For example, in 2018, there were roughly 67,000 deaths from drug overdose. Seventy percent of these deaths were due to prescription opioids [16]. Both prescription and over the counter medications can potentially cause serious and dangerous impairment of workers on the job. Because of this, a detailed description of a worker's medication regimen is required for those who have suffered an acute injury. Special attention should be paid to dosing schedules. For example, a potentially sedating medication, such as cyclobenzaprine (Amrix, Fexmid, Flexeril), may not pose a work safety issue if the employee only works day shifts and the medication is taken in the evening.

An Objective Physical Examination

The physical examination of the worker differs from general primary care in one crucial way: an emphasis on objective evidence. Insurers are conscious of the possibility of fraud, and thus, there is a strong desire to limit liability for non-work-related conditions. Consequently, insurers place an emphasis on objective indications of pathology. The family physician should note as many objective indications of pathology, such as straight-leg tests and reflexes, as possible during

Telegram: @medical_k

www.konkur.in

the examination. Indications of nonorganic etiologies should also be noted. It is important to note that the pursuit of objective evidence does not discount the report of subjective symptoms by patients. Some legitimate and serious medical conditions, such as migraine headaches, have no objective signs on examination.

The Occupational History

Understanding the nature of a patient's work is vital for the treatment and management of work-related medical conditions. US physicians rarely inquire about work activities during routine clinical encounters [17]. This finding is unfortunate as family physicians are frequently the first physicians to evaluate work-related diseases.

The occupational history need not be an overly tedious and lengthy task [18]. In the case of a simple injury, only a brief history of pertinent facts may suffice. For more complicated diagnoses, such as an occupational infection or chemical injury, more detail may be required. Obtaining the occupational history can be expedited by having patients complete an occupational history questionnaire prior to the clinical visit.

An occupational history begins with obtaining basic information such as job title, employer, work schedule, and general work activities, in particular the activities surrounding the presenting injury or illness in some cases. Special attention should be given to any recent changes at work, such as new equipment/chemicals or alterations in work schedule. It should be noted that a simple description of the current job and tasks is may be insufficient when evaluating workers with ailments. Some exposures, such as asbestos, can take several decades to produce health effects. Thus, a review of a patient's entire work history may be necessary in some instances. The establishment of whether the injury or illness is work-related is important in that removing the exposure may potentially help the condition at hand. Additionally, this ascertainment will help determine the payor [19].

Psychosocial Factors

The complicated interplay between work, health, legal entanglements, and worker's compensation demands a careful assessment of psychosocial factors when caring for workers. For example, psychiatric conditions are associated with maladaptive coping mechanisms and delayed recovery from work-related low back pain [20]. The family physician should assess for psychosocial factors, such as work monotony, relationship with supervisors, and job satisfaction. The purpose of inquiring about such stressors is not to discredit the patient or to imply malingering. Rather, identifying such complications can provide additional treatment options, such as pain counseling or depression treatment, and help to identify and remove otherwise seemingly insurmountable barriers for recovery and return to work [21].

General Approach to the Treatment of the Worker

Communication

Occupational health care can be a challenging endeavor for the family physician. Such emotions are compounded for the patient, many of whom have significant home, work, and financial stressors in addition to the medical condition. Uncertainty, such as with diagnosis and return to work, has been linked to poor recovery and outcomes with work-related care [22]. Unchecked catastrophizing by the worker has been shown to impede improvement [23]. Thus, thorough and clear communication, with a plan for improving function and symptoms, by the physician is of paramount importance. For example, setting return to work dates and educating workers on how to prevent reinjury and recurrence can promote early RTW [24]. Catastrophizing can be mitigated by giving proper context to injuries and diagnostic findings and by positive reinforcement regarding the ability of the worker to perform their job duties. Using modified duty/light

Telegram: @medical_k

www.konkur.in

duty titration to progress the worker toward full duty by allowing them to remain in the workplace, surrounded by the culture of work, can help toward successful maintaining of work status and return to work.

Medications

In occupational injuries, the physician is also repeatedly tasked with managing pain. Unfortunately, the increasing use of opioids for the treatment of non-cancer-related pain has led to a greater potential for injured workers to be using impairing medications while at work. In the interest of the worker and the public, the family physician treating work-related pain should minimize the use of impairing medications, such as opioids and muscle relaxers. This is especially true for what are called "safety-sensitive" work positions. A systematic review of nearly 22,000 studies by ACOEM found a positive association between opioid use and motor vehicle crashes. Based on this, ACOEM now recommends that workers performing safety sensitive work, such as commercial driving or crane operations, should not use opioids acutely or chronically [25]. Early use of opioids for the treatment of acute, work-related low back pain has been shown to be associated with prolonged disability, higher medical costs, and prolonged opioid use. Much pain from occupational injuries can be effectively managed with acetaminophen and nonsteroidal anti-inflammatories [26].

Return to Work

One of the most important ways the family physician can serve the best interest of the worker is with appropriate management of return to work. Many physicians inappropriately assign time off from work for injured patients. One of the primary reasons for this is a perceived duty to be a patient advocate. Family physicians, like other medical providers, are motivated by a desire to minimize suffering and pain. Thus, when a worker complains of pain at work, removal from work appears to be in the patient's best interest. However, it is the converse that is usually true. It has been showed repeatedly that work, in safe environments and with proper guidance, is of paramount importance to health. Removal from work is associated not just with financial loss but also increased mortality from cardiovascular-, respiratory-, violence-, alcohol-, and accident-related etiologies [27]. Likewise, continued work maintains physical and mental conditioning. Thus, it is the return to work as safely and as soon as possible that is almost always in the worker's best interest. This endeavor should be the goal of the family physician's advocacy.

Appropriate return to work can also be adversely affected by the time constraints of the busy family physician's schedule. Time limitations are in turn compounded by a lack of training in return to work by most medical providers outside of occupational medicine. To improve the efficiency of return to work discussions, ACOEM and the American Medical Association (AMA) have created guidance documents for return to work recommendations by primary care physicians [28]. One of the unifying features of the guidelines is the use of a step-based algorithm [29].

The proper use of the algorithms is dependent on having a sound understanding of the definitions of restrictions, limitations, and tolerance [30]. Restrictions are activities that a worker should not perform due to personal risk or risk of hurting others. Limitations are needed when there is a task the worker cannot perform due to their medical condition. Tolerance is the ability of the worker to endure symptoms. It is important to remember that tolerance cannot be determined reliably by medical science. Ultimately, it is the worker that decides to tolerate symptoms that do not cause worse injury or pose a danger to self/others [29].

Removing a worker from work without considering activities the worker can perform within the context of work or even working full duty with the presenting injury is a disservice to the worker and to society. The family physician should try to gain an understanding of the job tasks and direct the worker/patient accordingly.

Representative Occupational Medicine Challenges

Conditions: Musculoskeletal Injuries

Musculoskeletal injuries represent the bulk of work-related medical conditions encountered by most physicians. In a survey of family physicians between 1997 and 2000, 56% of work-related care by family physicians involved acute problems, and 48% involved musculoskeletal chief complaints [31]. In 2018, the incidence of musculoskeletal disorders was 27.2 per 10,000 workers. Sprains, strains, and tears were most common types of injuries by far.

The treatment of many common industrial injuries is covered elsewhere in this text. Table 1 summarizes a few of the work-related injuries most frequently seen by family physicians and lists their potential risk factors.

Conditions: Infectious Exposures

Exposure to infectious agents at work is a risk faced by many industries. This risk is especially robust in health-care-related fields, and the family physician can expect to encounter work-related infectious exposures, even if the provider is not actively providing occupational health-care services. An estimated 5.6 million workers are at risk from blood-borne pathogens. Between 1995 and 2007, there were 30,945 exposure events in the National Healthcare Safety Network. Eighty-two percent involved percutaneous injuries and 79% percent involved blood products. Nurses and providers were the most frequently injured, involved in 72% of cases [36, 39].

By far, the most concerning health-care-work-related infections are HIV, hepatitis B, and hepatitis C. The potential impact of these infections in the health-care workforce is so great; the subject is addressed specifically by the OSHA Bloodborne Pathogen Standard (29 CFR 1910.1030). To prevent unnecessary transmission of blood-borne pathogens, the CDC provides in-depth and updated postexposure management protocols on their website. Management options can include rapid initiation of antiretrovirals for confirmed HIV exposures and the use of the hepatitis B immunoglobulin/hepatitis B vaccine for hepatitis B exposures. Unfortunately, there is no post-exposure treatment for hepatitis C other than monitoring.

While these viruses have remained the primary blood-borne pathogen concerns for health-care workers, there are several other infectious agents not involving blood exposures that can be encountered in the workplace. There is perhaps no better example of the havoc that infectious diseases can

Table 1 Common work-related musculoskeletal injuries/conditions seen by family physicians and relevant risk factors

Condition	Potential occupational risk factors	Nonoccupational risk factors
Low back injury [32, 33, 34]	Repetitive loading of spine Inadequate rest time at work Awkward lifting Lack of decision control High job demand/stress	Psychiatric disorders Age Smoking
Carpal tunnel syndrome [34–36]	High hand force Prolonged hand force Vibration Repetitive motion	Diabetes Pregnancy Hypothyroidism genetic predisposition
Rotator cuff tear [34, 37]	Prolonged shoulder flexion Forceful pinching Work above at or above shoulder height Work stress	Age Overhead sports
Slips and falls [38]	Weather Poor lighting Slippery surfaces	Inappropriate footwear Age Fatigue

www.konkur.in

create in the workplace than the 2020 COVID-19 pandemic. After the initiation of social distancing during the pandemic, the task of managing workplace and community exposures to the novel coronavirus, work restrictions, and the development of testing algorithms fell squarely on the shoulders of occupational health. The scale of the social isolation and quarantine efforts was unparalleled in modern times and management required the cooperation between occupational medicine and virtually every other field of medicine. Although COVID-19 is an extreme example, infections such as tuberculosis, pediculosis, scabies, and pertussis represent more typical challenges. The management of each of these conditions is outside the scope of this chapter, and the family physician interested in managing community exposures is encouraged to review materials from the CDC and to interact with local occupational medicine providers and emergency management systems.

Finally, zoonotic infections can also pose serious risks for some workers. Table 2 summarizes some of the zoonotic illness and their associated occupations and settings.

Conditions: Chemical and Environmental Exposures

The EPA's catalog of chemicals used at one time or another in industry exceeds 80,000. Most recently, the EPA estimates that 7500 chemicals were used by industry in 2012 [40]. Many such chemicals can result in serious health effects, including cancer and death. Similarly, both indoor and outdoor environments can produce symptoms and illness, even in the absence of harmful chemicals or chemical concentrations. Table 3 summarizes some of the most well established chemically and environmentally induced health conditions.

The chemical and environmental exposures most commonly encountered by the family physician are limited to a few conditions. The most prevalent are occupational skin diseases, building-related illness, and occupational respiratory conditions.

Latex Allergy

To meet compliance with the Bloodborne Pathogen Standard, which required barrier methods during health-care delivery, the use of latex gloves increased dramatically. This resulted in an increase in immediate hypersensitivity reactions associated with an IgE type I response to naturally occurring rubber from the *Hevea brasiliensis* tree. Those at risk include health-care workers food handlers, security personnel, and emergency service personnel (i.e., paramedics) [41]. Atopy is an independent risk factor. Rates of latex allergy have decreased in recent years with changes in latex processing and the increased use of latex free gloves [42, 43].

Symptoms from latex allergy can range from simple urticaria to life-threatening anaphylaxis. Symptoms typically begin within a few minutes to an hour of contact. Inhaled exposure can occur in the presence of powdered latex. The diagnosis is confirmed by skin prick testing or RAST testing for specific IgE. The primary strategy for management is avoidance.

Building-Related Illness

With increased focus on the safety of work environments in recent years, concerns and symptoms related to indoor air quality are becoming more common. There are several terms that describe conditions secondary to indoor air quality, such as "sick building syndrome" (SBS), more recently referred to as building-associated illness (BAI), and multiple chemical sensitivity [44]. It may also be referred to as idiopathic environmental intolerance (IEI). All of these conditions can lead to a vague constellation of symptoms, such as headache, upper respiratory symptoms, and fatigue. While abnormalities in specific components of indoor air quality (IAQ) can be the cause of such complaints, symptoms are often reported in environments where IAQ is within normal limit, often other than increased carbon dioxide levels, indicative of a mismatch between airflow and human occupancy. Although some consider many instances to be psychogenic, indoor air contaminants below the irritation threshold concentration can cause symptoms, especially those with low odor thresholds.

Several factors can contribute to poor indoor air quality. Environmental elements to consider are building ventilation rates, temperature and

Table 2 Unique occupational infections, symptoms, and associated work and environments

Condition	At risk occupations/environments	History/pearls
Brucellosis	Veterinarians Exposure to fluids and aborted products of conception from infected livestock consumption of products from infected livestock, such as unpasteurized cheese/milk Laboratory personnel, via aerosolization Slaughterhouse workers Recent international travel	Undulant fever with sweats and malaise Systemic involvement Can be detected via antibodies and treated with antibiotics
Rabies	Animal bites, especially bats Biologists, veterinarians Greenhouse workers	Postexposure treatment can consist of rabies immunoglobulin and active vaccine Consider preexposure prophylaxis in those working with animals, especially in endemic areas abroad
Q fever	Veterinarians Animal caretakers Farm workers, especially those working with sheep, cattle, and goats Living downwind from contaminated farms or farm products (i.e., manure, dust) Laboratory personnel	Caused by Coxiella burnetii Exposure is typically through products of conception, fluids, or dust Extremely resistant to environment Widely variant clinic presentation, including flu-like illness, hepatitis, pyrexia of unknown origin, and pneumonia Liver function tests may be elevated in many patients
Scabies	Health-care workers Spread via direct skin to skin contact with Infected individuals Higher risk in crowded environments, such as nursing homes or correctional facilities	Caused by human itch mite, *Sarcoptes scabiei* Intense itching and rash Can be spread from an asymptomatic carrier Usually no symptoms for 2–6 weeks
Leptospirosis	Farmers, ranchers, veterinarians, sewer workers, rice farms, laboratory personnel, and loggers Spread in urine of farm animals Higher incidence in tropical regions Exposure occurs via contaminated soils or Animal tissue/urine Subsistence farming and urban slums Flooding associated with disease outbreaks	Caused by spirochetes from the genus *Leptospira* Varying clinical presentation, from subclinical to death Usually fever, myalgias, headaches, cough, nausea, and vomiting Look for conjunctival suffusion
Tularemia	Laboratory personnel Farmers Veterinarians Hunters Landscapers Meat handlers Animal or insect bites, especially ticks	Caused by *Francisella tularensis* Ocular and aerosolized exposure also possible Can survive long term in adverse water conditions Nonspecific symptoms, usually a combination of Fever, malaise, and anorexia fever may be intermittent
Rat-bite fever	Laboratory personnel Pet shop workers	Caused mostly by *Streptobacillus moniliformis* Exposure via bites/scratches or fecal contaminated food Clinical course varies depending on infectious agent

References [34, 45, 46]

temperature fluctuations, humidity, chemicals (i.e., formaldehyde and ozone), and odors. Personal factors, such as atopy and contact lens use, and psychosocial factors should also be considered.

As building-related illnesses can involve significant anxiety, clear and open communication is important to effective management. Initial evaluation begins with an interview of affected

Table 3 Chemicals/elements and associated health conditions

Chemical/ elements	At-risk occupations/environments	History/pearls
Asbestos	Construction Shipbuilding Insulators Environmental contamination	Lung cancer Mesothelioma Pathology can develop many years after exposure Malignancy risk significantly increased with smoking
Silica	Sandblasters Concrete/masonry workers Mining	Chronic obstructive pulmonary disorder Scleroderma Increases risk of tuberculosis Unlike coal, causes calcification of hilar lymph nodes
Coal	Coal miners, especially those at the drilling face or with other heavy dust exposures	Lung fibrosis Unlike silicosis, no increase in TB or fungal infections in simple cases
Vinyl chloride	Used to make polyvinyl chloride, Which is in turn used to make many Plastic products Production of automobile upholstery/parts and housewares	Acutely, causes CNS effects such as dizziness, drowsiness, and headaches Chronic exposure can damage GI system and result in liver cancer
Benzene	Rubber manufacturing Chemical and petroleum production Shoemakers printers Steel workers gas station employees	Acutely, can cause dizziness, unconsciousness, and death Chronic exposure can lead to leukemia
Carbon monoxide	Forklift operators Foundry workers Miners Garage attendants Mechanics firefighters	Headache Tachypnea Cyanosis Syncope Binds strongly to heme O_2-carrying sites, decreasing available O_2 for the body
Hydrogen sulfide	Sanitation workers Farmers Natural gas drilling and refining workers in confined spaces, especially low-lying, marshy areas with hot weather and little wind	Health effects on concentration (ppm) Symptoms can vary from the smell of rotten eggs, to conjunctivitis and respiratory tract irritation, to immediate collapse with 1–2 breaths at levels of 700–1000 ppm
Pesticides	Agricultural workers Greenhouse workers Pesticide handlers (i.e., crop dusters, chemical manufacturers)	Wide variety of health effects, depending on type of pesticide involved Must consider pesticide toxicity, exposure, and absorption together when evaluating cases Workers covered by the agricultural worker Protection standard
Lead	Inhalation of lead fumes during burning and sintering Lead reclamation (i.e., battery recycling) Glassmakers, pottery workers military and law enforcement Munition workers welders	Lassitude Malnutrition Gingival lead line Encephalopathy Paralysis of wrist and ankles Renal failure
Cadmium	Smelting/refining Manufacturing/construction Plating processes Battery production Dietary intake: Shellfish, meat by products, liver, food stored in cadmium-glazed containers	Renal failure Chemical pneumonitis Lung cancer Osteomalacia Japanese rice paddies irrigated with cadmium-contaminated water resulted in an epidemic of osteoporosis in the 1940s Tobacco leaves concentrate cadmium, leading to chronic exposure in smokers

www.konkur.in

employees and a work site walk-through. Following the initial investigation, management options can include improvement of ventilation rates, temporary removal from work environments, measures of environmental parameters by an industrial hygienist, cleaning of ventilation systems, and reengineering.

Mold

Of all the naturally occurring environmental contaminants, none seems to invoke as much fear as mold. Mold spores are omnipresent in the environment and reproduce in the presence of moisture. The most common types include Penicillium, Aspergillus, Cladosporium, and Alternaria. Molds can cause specific conditions including allergic asthma, but there is little evidence to support fears that airborne mycotoxins produce specific illnesses [47]. Similar to building-related illnesses, the evaluation of potential mold-related health conditions begins with an interview of the worker and an evaluation of the work environment that focuses on abnormal indoor moisture.

Remediation of mold and dampness in buildings may improve symptoms and consists primarily of removing the source of moisture and visible mold contamination [48]. Such cleaning could require intermittent, temporary relocation of employees. In all circumstances, clear communication with patients and the workforce is of paramount importance.

Specific Types of Occupational Examinations

As a branch of preventive medicine, one of the goals of occupational medicine is the prevention of injury and illness in the workplace. To fulfill this objective, the family physician may be asked to perform a variety of preventative and regulatory examinations for workers.

Post-hire, Preplacement Examinations

ADA prevents employers from discriminating against applicants based on disabilities. However, this protection from discrimination must be balanced with ensuring optimum safety of employees and the public. Typically performed at the request of an employer, the purpose of the post-hire, preplacement examination is to ensure that an employee can perform the essential functions of a job safely.

To ensure proper screening, it is important that the family physician have an adequate description of the employee's job duties and requirements. While this information could be obtained from the employee, a more reliable source would be a full job analysis document provided by the employer. Job analyses describe the duties and physical requirements of a work position.

Fit for Duty, Return to Work Examinations

Fit for duty (FFD) examinations are sometimes necessary when an employee has been off work for an extended period of time. Like preplacement examinations, the purpose of the FFD examination is to ensure an employee can still perform the essential functions of their job. An example where such an examination would be necessary is in the case of an employee who recently underwent a knee replacement and is hoping to return to work as a carpet layer.

Again, it is important that the family physician acquire adequate information to assess the employee's current medical status and work requirements when performing such assessments. In particular, the family physician must ensure that the patient does not pose a safety risk due to changes in medications.

Some family physicians are uncomfortable in providing fitness for duty assessments, especially when the outcome may be at odds with the wishes of the patient. In difficult scenarios, rather than putting the patient, other workers, or the public, at risk we suggest that family physicians might seek assistance of their occupational medicine colleagues.

Commercial Driver Examinations

Commercial driver 5250 fatal occupational injuries [6]. Forty percent of these fatalities were transportation-related events. Of the 2080 transportation-

Telegram: @medical_k

www.konkur.in

related fatalities, 3 out of 5 involved motorized land vehicles. With the high stakes involved, ensuring the safety of commercial drivers and public roads is one of the most important concerns of occupational medicine. Additionally, evaluation of commercial drivers is one of the most common avenues by which family physicians deliver occupational health care.

To obtain a commercial driver (CD) license, the driver must successfully meet the medical and physical requirements described by 29 CFR Part 391.41. This federal regulation provides in-depth information on medical requirements, such as blood pressure limits, and disqualifying medical conditions, such as epilepsy. Until recently, commercial driver medical certification examinations could be performed by a variety of medical providers. Unfortunately, due to a lack of standardized training for examiners, there was varying adherence to federal regulations and guidelines. To remedy this, the Federal Motor Carrier Association has required that after May 2014 that all commercial driver examinations be performed by certified commercial driver examiners [49]. Certified commercial driver medical examiners receive standardized training and must pass a certification examination. This move has reduced the number of available examiners and potentially provides family physicians with an important and lucrative occupational health opportunity.

Basic Med FAA Examinations

Another area of occupational medicine concern is aviation safety. For decades, Aviation Medical Examiners have monitored and assessed pilots for the Federal Aviation Administration. Traditionally, in-depth training was required before a physician could become an Aviation Medical Examiner. However, in 2016, the FAA launched the Basic Med program. This program allows some pilots the ability to be cleared for flying by any state licensed physician.

In order to qualify for Basic Med, a pilot must have held a medical certificate after July 14, 2006, must have a driver's license, must be examined by a state-licensed physician using the official Comprehensive Medical Examination Checklist, and complete online education.

While seemingly straightforward for healthy individuals, there are many important nuances and limitations that must be considered when performing the Basic Med examination. For example, pilots with a Basic Med certificate are limited to flying an aircraft with 6 occupants or fewer and a maximum certified takeoff weight of less than 6000 pounds, under 18,000 feet mean sea level, and at less than 250 knots. In addition, there are many medical conditions, such as depression, that require a special medical certificate from the FAA, called a Special Issuance, before a pilot may use Basic Med. The interested family physician is encouraged to review materials on the FAA website for further information on this path into aerospace medicine [50].

Comprehensive Occupational Health Programs

Many corporations and public sector organizations offer multifaceted programs designed to protect and improve the health of their employees. These programs include components such as health promotion, disability management, international health and travel medicine, benefit design, and workforce data analysis. These programs offer fascinating opportunities to improve health and medical outcomes for defined populations. With additional training, the family physician can assist with such programs.

Heat

Definitions

Heat-related injury involves a spectrum of syndromes seen in individuals exposed to environmental heat. These injuries range from mild to life-threatening, and they include heat edema, cramps, heat exhaustion, and both non-exertional and exertional heat stroke. Heat stroke is a medical emergency characterized by a core body temperature >40 °C and altered mental status. Signs of organ failure may be present [1, 4].

Epidemiology

Nonathletic heat injuries and associated complications occur more often in the elderly due to impaired physiologic ability to respond to environmental heat. Athletes, military recruits, and outdoor laborers represent high-risk groups for exertional heat injury. The number of sports-related cases of exertional heat stroke (EHS), which is the most serious form of exertional heat-related injury (EHRI), has been increasing in the United States. In fact, between 1990 and 2010, heat illness was the third most common cause of sports-related fatalities in US high school and college football players [2].

Additional risk factors for heat injury include poor heat acclimatization, improper clothing/equipment, underlying cardiovascular, neurologic or psychiatric disease, diabetes, obesity, social isolation, use of alcohol and recreational drugs, and certain prescription medications such as those with anti-cholinergic or sedative effects [1].

Diagnosis

Clinical findings include elevated core body temperature as well as tachycardia, hypotension, flushing, and confusion. Since the elderly have impaired physiologic ability to respond to heat, their clinical presentation may be less obvious. Consequently, those above age 60 are particularly susceptible to heat injury and death [3].

Treatment

The management of mild and moderate heat injury involves moving to a cooler area, rest, and hydration. Medical attention is rarely required [1]. However, heat stroke is a medical emergency and requires establishing and supporting airway, breathing, and circulation (ABC's), rapid cooling (within 30 min), and management of complications. The initial target temperature should be 38.5 °C to 38.0 °C [4]. Various methods exist for rapid cooling. The most commonly used for non-exertional heat stroke involves spraying the patient with water while fans are directed toward the patient to stimulate evaporation and convection [5]. Submersion in cold or ice water is preferred for exertional heat stroke [4, 5]. Unless malignant hyperthermia is suspected, pharmacologic agents such as dantrolene, acetaminophen, and aspirin are not generally recommended as they are not effective and may exacerbate or potentiate complications such as hepatic injury [4]. The family physician should be cognizant of potential complications including cardiopulmonary dysfunction, neurologic injury, acute kidney injury, rhabdomyolysis, hepatic injury, and disseminated intravascular coagulation.

Telegram: @medical_k

www.konkur.in

Patient Education

Exertional heat injuries can be prevented through gradual acclimatization to the heat, physical conditioning, maintaining hydration, proper sideline preparation, and improving awareness and education of staff [2]. The National Athletic Trainers Association publishes guidelines for a heat acclimatization process [6]. Hallmarks include awareness, acclimatization, wearing loose-fitting clothing, mandatory breaks, and avoiding activities in extreme temperatures [1, 6].

Cold

Hypothermia

Background

Between 2006 and 2010, there were 10,649 deaths attributed to weather-related injury, with cold exposure and hypothermia approximating 63% of these deaths [7]. The cold-related death rate was lowest for children aged 5–14 but increased thereafter with increasing age, with the highest death rate among persons aged older than 75 [7]. Medical conditions such as heart disease, malnutrition, diabetes, and dementia can predispose individuals to cold injuries. Besides age and medical conditions, other risk factors include homelessness, intoxication, being an adventure traveler, and being a military recruit [8].

Definition

Hypothermia is defined as a core temperature to <35 °C. Mild hypothermia ranges from 35 °C to 32 °C, moderate from 32 °C to 28 °C, and severe at <28 °C. As the core temperature drops, compensatory shivering and consciousness decrease, while the risk of arrhythmia increases [9]. Measuring the core temperature may not always be feasible. In these cases, the "Swiss" hypothermia classification system, which incorporates clinical signs such as vital signs, level of consciousness, and presence or absence of shivering, is used to determine the probable core temperature [9]. The Swiss classification system has four stages, which are as follows: stage I – conscious and shivering; stage II – altered mental status and not shivering; stage III – unconscious, not shivering, vital signs present; and stage IV – unconscious, no vital signs detectable.

Treatment

A conscious, shivering patient likely does not need additional medical management besides seeking shelter; however, close observation is needed to ensure clinical deterioration does not occur. The initial management can be accomplished by passive rewarming. This includes carefully transferring the patient to a warm environment, removing wet clothing, and applying insulating clothing [8]. Active external rewarming involves application of heat packs, blankets, and hot water bottles ideally to the axilla, chest, and back, which can be used for both shivering and non-shivering patients. A warm shower or bath and active exercise should not be used for initial rewarming due to increased risk for an "afterdrop effect" (movement of cold blood from the peripheries to the central circulation) triggered by increasing peripheral blood flow [9].

If at stage II or a greater degree of hypothermia is suspected, infusion of warm IV fluids (38–42 °C) in addition to passive and active external rewarming is warranted if available. Efforts should be made for evacuation, and advanced cardiac life support may also be warranted. Individuals with profound hypothermia (<28 °C) or cardiac arrest should be transported to centers with extracorporeal life support (ECLS) capability. During transport, patients should remain horizontal to decrease risk of precipitating afterdrop and arrhythmias. Those with significant trauma should be transported to dedicated trauma centers [9]. A general rule is that hypothermic patients should be warmed to a core temperature of 37 °C prior to pronouncing death. However, patients with a lethal injury, significant airway obstruction, snow burial for more than 35 min, or serum potassium level greater than 12.0 mEq/L (12.0 mmol/L) can often be pronounced dead without an initial period of rewarming [8].

Telegram: @medical_k

www.konkur.in

Patient Education

Cold weather injuries are largely preventable with proper planning, protective equipment, and avoidance of prolonged exposure. Protective clothing and equipment include layering with a base layer made of moisture-wicking material such as polyester, middle layer with wool or fleece, and an outer layer made of a wind and moisture resistant material. Clothing and shoes should be loose to promote circulation [8].

Nonfreezing Cold Injury (NFCI) and Frostbite

Background

Nonfreezing cold injuries (NFCI) and frostbite are increasingly common. As with hypothermia, risk factors include age, skiers, and other practitioners of cold-weather activities, alcohol intoxication, homelessness, and inadequate clothing/protection [10, 12].

Definitions

NFCI occurs when tissues are exposed to a prolonged cold, wet environment at temperatures above freezing. Most cases occur in the feet and lower legs although upper extremities can also be affected. Frostnip and pernio are self-limited NFCI that do not commonly cause tissue damage or long-term sequelae. Immersion foot (trench foot) is a NFCI that occurs after prolonged exposure to wet, above-freezing conditions [8]. It is characterized by damage to the sympathetic nerves and vasculature of the feet that can also cause long-term sequelae such as sensorimotor and autonomic deficits [8]. Although classically described during World War I, immersion foot still occurs, particularly among the homeless [11]. A white vasoconstricted phase gives way to blue, mottled, edematous, and painful phase [8]. Some individuals are unable to continue to work outside in cold temperatures, which can affect their occupational as well as recreational opportunities. Prevention remains the key, with encouragement to use proper footwear, change into dry socks and/or gloves, as well as air drying feet several times a day.

Frostbite is a severe freezing injury that results in tissue destruction. The pathophysiology of frostbite consists of four phases: the prefreeze phase, freeze-thaw phase, vascular stasis phase, and late ischemic phase. In the prefreeze phase, the tissue cools, vasoconstriction occurs, but no ice crystals form. During the freeze-thaw phase, ice crystals form, causing cellular damage and derangement. Freezing is followed by thawing, which may cause inflammation and reperfusion injury, leading to further cell and tissue damage. Vascular stasis is marked by both dilation and constriction of blood vessels with concomitant blood leakage and coagulation. Finally, with late ischemia, further inflammation, microcirculation destruction, and cell death occur [10].

Although frostbite classically has four stages based on extent of physical damage, the extent of tissue damage after injury is often difficult to predict based on initial presentation or exam. Favorable signs include intact sensation, no cyanosis, and lack of blisters [12, 13]. Therefore, a simple two-tier system using either superficial (no or minimal anticipated tissue loss) versus deep (anticipated tissue loss) after spontaneous or formal rewarming is advocated by the Wilderness Medical Society [8, 10]. Triple-phase bone scanning with technetium pyrophosphate or magnetic resonance angiography (MRA) may allow an early diagnosis of viability and assist the physician and patient with probable level of amputation [8, 10, 13].

Approach to the Patient

Prehospital care of frostbite begins in the field and involves treating/preventing any hypothermia by seeking shelter, removing any wet clothing, drinking warm fluids, and placing the affected areas in a dry, warm area, such as a companion's axilla. Jewelry and other constrictive materials should be removed. Do not rub or put snow on the extremity. Ibuprofen (10–12 mg/kg divided twice daily) may help through antiplatelet and anti-prostaglandin effects. Tissue that thaws and then refreezes leads to further inflammation and damage. Therefore, the decision to rewarm must also include an evacuation plan. The patient should

Telegram: @medical_k

www.konkur.in

not walk on rewarmed feet unless only distal toes are affected [10].

The initial hospital management consists of correction of hypothermia, rapid rewarming in a 37–40 °C whirlpool, tetanus prophylaxis, and ibuprofen. Empiric systemic antibiotics are not indicated. Vasodilators (iloprost, pentoxifylline, and buflomedil) and tPA have been used with some success. Heparin, hyperbaric oxygen, and sympathectomy have been used as well in certain cases but not routinely recommended due to insufficient data [13].

Frostbite is largely preventable by maintaining core body temperature and hydration, mitigating medical conditions, utilizing medications that decrease perfusion, counseling regarding risks of alcohol consumption, proper clothing and equipment, and providing supplemental oxygen for hypoxic conditions as seen in high-altitude mountain climbers [10].

Radiation

Classification

Radiation involves the transfer of energy via high-speed particles or electromagnetic waves, and it can be ionizing or non-ionizing. Examples of ionizing radiation include X-rays and gamma rays along with alpha particles, beta particles, protons, and neutrons, the so-called particulate ionizing radiation. Examples of non-ionizing radiation include radio waves, microwaves, and the visible portion of the electromagnetic spectrum [14]. Whereas ionizing radiation has enough energy to displace electrons from orbits at multiple levels, produce free radicals, and penetrate human tissue, non-ionizing radiation cannot. Medical imaging and procedures using ionizing radiation now account for over one half of radiation exposure in the United States and some 98% of all artificial sources [15, 16].

The International System of Units (SI) of measurement for radiation dose is the gray (Gy), and for the biological risk of exposure, it is the Sievert (Sv). The effects of radiation on the body depend on the type of radiation, dose, amount of time exposed, route of exposure, and the types of tissues exposed [16]. Effects can range from no clinical significance to acute radiation exposure and increased risk of future cancers [14].

History

People are regularly exposed to radiation from cosmic radiation and radioactive elements in the environment; this is called background radiation and is largely unavoidable. The doses from background radiation are too low to cause radiation injury, although depending on geographic location, may contribute to small increases in cancer incidence [14]. Medical imaging is a significant source of man-made radiation with most of this radiation coming from computed tomography (CT) scans. As the availability of CT expands, the amount of radiation exposure is likely to increase around the world. To illustrate, a CT scan of the chest exposes a patient to about 7–8 millisieverts (mSv). A PA-lateral chest X-ray in comparison gives 0.1 mSv of radiation exposure. The background annual radiation exposure in the United States is estimated at about 3 mSv, and an exposure to an individual dose of greater than 50 mSv or a lifetime dose of greater than 100 mSv is considered above the threshold of safety [17]. Moreover, whereas exposure for healthcare and nuclear industry workers can be regulated, the exposure for patients cannot [18].

Children are especially vulnerable owing to their smaller size and increased organ sensitivity [15, 16]. There is evidence from atomic bomb survivors as well as radiation workers and recipients of radiation therapy that a dose-dependent relationship exists with ionizing radiation and an increased risk of cancer. One study found that in those less than 19 years old, more than 3 CT scans was associated with an increased risk of cancer [15, 19, 20]. The cancers most correlated to radiation exposure are leukemia, breast, lung, and thyroid [19]. Additionally, prenatal exposure to ionizing radiation has been associated with brain damage and other fetal anomalies [14, 16].

Telegram: @medical_k

www.konkur.in

Patient Education and Counseling

The most effective way to reduce the cancer risk from CT is to order fewer studies. It is estimated that approximately one third of all CT scans are not medically necessary. For example, the American College of Radiology in conjunction with the Choosing Wisely initiative recommends no imaging for an uncomplicated headache, no imaging for a suspected pulmonary embolism without a high pretest probability, and considering ultrasound before CT for children suspected of having appendicitis [21].

Radon is a radioactive, colorless, odorless gas produced from the natural radioactive decay of uranium. It is naturally released from the ground and is the main source of natural radiation [14, 16]. Exposure to radon gas has been associated with both lung cancer and non-cancer-related mortality [22]. In fact, radon is the second leading cause of lung cancer overall and the number one cause among nonsmokers [23]. Moreover, there is a synergistic risk of lung cancer among smokers also exposed to radon. In children, radon exposure has also been associated with asthma and upper respiratory infections. Many public health authorities including the Environmental Protection Agency recommend screening homes with low-cost and readily available screening kits [23].

Ultraviolet Light

Background

Ultraviolet light lies between the visible spectrum and X-rays on the electromagnetic spectrum. There is ample evidence that ultraviolet radiation in excess amounts can lead to skin and eye disease. There is also some evidence that it can affect the immune system [24]. There are three types of ultraviolet light classified based on wavelength: long or UVA, medium or UVB, and short or UVC [25]. All UVC is absorbed by the ozone, water, and gases above the earth's surface. Therefore, the ultraviolet light that reaches the earth's surface and contributes to human disease is largely UVA and UVB [24].

History and Physical Examination

Skin manifestations of excess ultraviolet exposure range from sunburn to malignant melanoma. UV radiation (UVR) also accelerates the aging of skin, leading to loss of elasticity and more coarse skin [24]. Ultraviolet exposure can play a pathogenic role in both non-melanoma and melanoma skin cancers. An estimated 63% of all cutaneous melanomas in Australia in 2010 were attributable to high ambient ultraviolet radiation [26]. Among high school students, tanning beds are a major source of ultraviolet exposure, especially among non-Hispanic white females. Fortunately, the overall prevalence appears to be decreasing [27]. With rising temperatures and ozone depletion, the incidence of skin cancers is projected to continue rising [25].

Ocular disease attributable to excess UVR includes eye and eyelid cancers, photokeratitis, pterygium, and cataracts. Cataracts are the most common cause of blindness globally and leads to significant morbidity. It is estimated that excess sunlight exposure is responsible for up to 20% of cataract burden around the world.

Patient Education

Although rigorous clinical trials proving the effectiveness of sun protection measures such as broad-brimmed hats, protective clothing, sunscreens, and sunglasses are lacking, common sense would suggest liberal use of these measures to protect against excess UVR [24, 26].

Electrical Injury

Background

In the United States, approximately 10,000 patients present to the emergency department with electrical burns or electric shock. In 2015,

Telegram: @medical_k

www.konkur.in

there were 565 recorded fatalities, and 25–50 people die each year from lightning strikes. Most electrical injuries are due to household or occupational exposures. Young children are often affected by household current, while adolescent males are affected by their high-risk behavior such as playing near high-voltage current sources, and adult males are affected by occupational hazards [28].

Approach to the Patient

Every organ system can be affected by electrical injuries resulting in thermal, electrophysiological, traumatic, and metabolic derangements. In addition, recognition of electrical injuries is challenging because they can resemble typical cardiac, trauma, and burn victims [28]. Electrical injury can cause burns, uncontrolled muscle contractions, arrhythmias, confusion, seizures, abnormal vision, weakness, and even paralysis, the onset of which can be delayed [29].

The initial management includes turning off the power source immediately and providing basic life support if needed. At the medical facility, the patient will be evaluated for burns, tissue damage, abnormal heart rhythms, and any other traumatic injuries. The family physician should note that although a skin burn may be seen at contact sites, most serious injuries are often not visible [29].

Noise

Background

At least 12% of the of the global population is at risk for hearing loss, which equates to over 600 million people. The most common preventable cause of hearing loss is exposure to excessive noise. Chronic noise exposure results in cochlear trauma which leads to hearing loss and tinnitus. Other symptoms associated with noise-induced hearing loss (NIHL) include reduced speech perception, vestibular dysfunction, stress, sleeping difficulties, and reduced performance [30]. Among noise-exposed workers, 23% have hearing loss, 15% have tinnitus, and 9% have both [31]. The highest risk occupations for hearing loss include mining, wood product manufacturing, construction, factory work, agriculture, utilities, transportation, and the military.

Recreational noise-induced hearing loss includes listening to personal devices, noisy entertainment, use of firearms, and attending clubs, bars, or concerts. In 2015, the World Health Organization (WHO) estimated that 1.1 billion young people worldwide could be at risk for developing hearing loss due to unsafe listening practices [30].

Counseling

Risk factors for developing noise-induced hearing loss includes genetics, deficiencies in magnesium or vitamin B12, pre-existing sensorineural hearing loss, use of certain medications, exposure to solvents, age, and chronic health conditions such as diabetes and hypertension [30]. Research is currently underway to determine the best hearing protective devices and treatment measures. In the meantime, education about noise-induced hearing loss to society and individual workers is important preventative steps.

Carbon Monoxide

Background

Carbon monoxide (CO) poisoning affects 50,000 people annually in the United States, with 15,000 of those being intentional poisoning. In 2014, there were 1,319 CO poisoning deaths, which is down from estimates of 2,700 in the mid-2000s. CO is a colorless, tasteless, odorless gas. It is formed by incomplete combustion of carbon compounds such as fire, engine exhaust, and faulty furnaces. In the blood, CO binds to hemoglobin (Hb) with high affinity and forms carboxyhemoglobin (COHb). CO competes with oxygen for Hb bonds and, by displacing oxygen, reduces the oxygen carrying capacity of hemoglobin. In

Telegram: @medical_k

www.konkur.in

addition, CO inhibits mitochondrial respiration which generates superoxide and leads to further damage of cells and tissues [32].

Diagnosis

CO poisoning is ideally diagnosed by a clinical triad of classic symptoms, history of exposure, and elevated COHb levels. Symptoms of CO poisoning include headache, dizziness, nausea, vomiting, dyspnea, fatigue, altered mental status, and chest pain [33].

In patients with suspected CO poisoning, the CO is traditionally measured by a co-oximeter analysis of venous or arterial blood for COHb levels. The nontoxic levels of COHb vary in the general population. Nonsmokers typically have a COHb level of less than 3%, whereas tobacco smokers have levels up to 10% [33]. Since conventional pulse oximetry cannot distinguish between COHb and oxyHb, it can miss significant COHb levels and profound hypoxia [32].

Treatment

The standard of care for treatment of CO poisoning is 100% normobaric oxygen (NBO) [34]. However, patients who receive hyperbaric oxygen therapy (HBOT) have a lower mortality rate than those who did not. In comparison with NBO therapy, HBOT leads to faster dissociation of CO from COHb. HBOT reduces the half-life of CO to 23 min compared to 80 min when administering oxygen through a nonrebreather mask [35]. In pregnant patients, there is a stronger indication for HBOT due to the slow dissociation of CO from hemoglobin in the fetus [34].

There are 5000 cases of pediatric CO poisoning annually, and children are more vulnerable because of their increased metabolic demand and inability to vocalize symptoms. They manifest different symptoms than adults and may present with symptoms resembling a viral illness with headache, nausea, and emesis being most common. NBO remains the mainstay of treatment with HBOT being controversial. However, limited research suggests that it is safe in children [36].

Counseling

Survivors of acute CO poisoning suffer long-term morbidity and some exhibit a near doubling of long-term mortality [32]. These individuals may have neurologic sequelae such as memory loss, difficulty concentrating, impaired language, and changes in affect such as depression or parkinsonism [33]. Their quality of life can be severely affected, and follow-up within 1–2 months is recommended to assess for psychiatric and neurocognitive deficits [32].

CO poisoning can be prevented by correctly installing furnace venting and running internal combustion engines in well-ventilated areas. Home CO alarms are also available, and automobiles with catalytic converters have reduced CO emissions [32]. Current research in pharmacology is focused on enhancing the CO dissociation from Hb with antidotes such as CO-scavenging molecules [32].

Bites and stings account for a small but significant number of patients seen in the primary care setting. Family physicians can provide the patient, family, and community with anticipatory guidance regarding common hazards and appropriate care if a bite or sting does occur.

Mammalian Bites

Most mammalian bites are from dogs or cats. Children are the most frequent victims of dog bites [1]. Most of the dogs involved are known to the victim and were considered friendly prior to the biting episode. Injuries inflicted by cats tend to involve the hand and upper limb.

Clinical Presentation

Significant dog bites tend to be lacerations, often with crushing or tearing of tissue. Bites are most often sustained on the extremities, head, and neck. In children, dog bites may penetrate the skull. Because of their needle-like teeth, cat and rodent bites are usually puncture wounds, often involving tendons or joint spaces. A multitude of organisms reside in the mouths of all higher primates. For this reason, these bites are notoriously predisposed to infection. Human bite wounds most commonly result from conflict or contact sports. Potentially, the most serious human bite wound is the "clenched-fist" injury. This injury is sustained when the victim strikes an adversary in the mouth with a clenched fist and suffers a laceration inflicted by the other's teeth. Microorganisms may be inoculated into the deep tissues of the hand, resulting in a devastating infection.

Diagnosis

All bites are examined meticulously for foreign bodies and devitalized tissue. Radiographs are considered if there is the possibility of fracture or a retained foreign body. The medical record should include information regarding the site, depth, and circumstances of the biting episode, as well as a sketch of the injury.

A clenched-fist injury should be examined after reproducing the position of the hand when the injury occurred. Otherwise, penetration of the wound into the deep tissues of the hand may not be appreciated.

Management

All mammalian bites should undergo copious irrigation with sterile saline. A 19-gauge or larger needle on a syringe is often used to generate a high-pressure stream. Careful debridement of all devitalized tissue is necessary (see Patient-Centered Medical Home. Further management depends on classifying the wound as high risk or low risk for infection. There is general agreement that high-risk bites are those involving the hands or feet, injuries older than 6–12 h, deep

Telegram: @medical_k

www.konkur.in

puncture wounds, crush injuries, human bites, cat bites, and bites sustained by elderly or immunocompromised individuals. Bites involving deep structures such as bones, joints, or tendons are also at high risk of infection. Individuals with high-risk bites should have their wounds debrided, packed, and reevaluated in 72 h to consider delayed primary closure. Prophylactic antibiotics should be administered. In practice, many bites otherwise considered high risk are primarily repaired if functional or cosmetic considerations strongly warrant it. Deep puncture wounds, bites of the hand, and wounds that present late should never be closed primarily [2]. Bite wounds involving the deep tissues of the hand should be surgically debrided, packed, immobilized in the position of function, and elevated. These injuries require intravenous antibiotic therapy. Low-risk wounds may be sutured immediately; antibiotic prophylaxis is not required. Cultures of an uninfected wound are not useful.

Human bites may transmit hepatitis B and C as well as herpes simplex virus. Prophylaxis against hepatitis B may be achieved by administering hepatitis B immune globulin (HBIG) 0.06 mL/kg and hepatitis B vaccine. The potential for human immunodeficiency virus (HIV) transmission by human bites is thought to be low, although there are case reports of transmission by this route [3–5]. The need for tetanus and rabies vaccination should be assessed.

Prophylactic Antibiotics

Patients with high-risk wounds should receive a 3–5-day course of prophylactic antibiotics. Amoxicillin-clavulanate 875/125 mg bid is an appealing agent for prophylaxis of human and animal bite wounds. Its spectrum of activity includes *Pasteurella multocida*, *Staphylococcus aureus*, streptococci, *Eikenella corrodens*, and β-lactamase-producing oral anaerobes. Penicillin-allergic patients may receive cefuroxime 500 mg bid or doxycycline 100 mg bid.

Established Infections

For established infections, empiric treatment with ampicillin-sulbactam 1.5–3.0 g IV q6h, cefoxitin 1 g IV every 6–8 h, or ertapenem 1 g IV every 24 h is recommended [6].

For patients with a definite penicillin allergy, alternatives include clindamycin 600 mg IV every 6 h plus a fluoroquinolone such as ciprofloxacin 400 mg IV every 12 h.

Rabies Prophylaxis

Rabies is a nearly uniformly fatal condition once symptoms begin to manifest. Therefore, a high index of suspicion for this infection must be maintained after any mammalian bite. Bats and other wild mammals are currently the major source of rabies in the United States. Assessment of risk involves a thorough history and physical examination. A break in the skin from the teeth or claws of an infected animal or contact with saliva on mucous membranes or broken skin constitutes exposure. The decision to apply prophylaxis is then guided by the specific situation and animal species. In general, bats, skunks, raccoons, woodchucks, foxes, and other wild carnivores should be regarded as rabid and immunoprophylaxis administered. If the animal is captured, it should be killed immediately, and the head sent under refrigeration to an appropriately equipped laboratory for fluorescent antibody examination. If the test is negative, the vaccination series may be discontinued. Domestic dogs, cats, and ferrets that are otherwise healthy should be confined and observed for a period of 10 days. If they remain asymptomatic, prophylaxis is unnecessary. The management of all other exposures, from either wild or domestic mammals, should be decided after consultation with the local health department.

Early, thorough wound cleansing is necessary to reduce the viral inoculum. Wounds are flushed with soap and water. Suturing the wound is avoided if possible. Human rabies immune globulin (HRIG) is administered in a dose of 20 U/kg

Telegram: @medical_k

www.konkur.in

body weight to both adults and children. This dose should not be exceeded, as passive antibody may interfere with response to the active vaccine. Half of the dose is infiltrated around the wound, if feasible, and the rest given intramuscularly in the gluteal area. Active immunization is accomplished by human diploid cell vaccine (HDCV) or purified chick embryo cell vaccine (PCECV) the first dose given simultaneously with HRIg with repeat doses on days 3, 7, and 14, in immunocompetent patients and repeat doses on days 3, 7, 14, and 28 in immunocompromised patients. The active vaccine is administered intramuscularly in the deltoid. In infants it is given in the anterolateral thigh [7].

Prevention

The role of education in the prevention of these injuries cannot be overemphasized. Dog bites are reported to be among the top 12 causes of nonfatal injury in the United States [1]. Situations reported to be potentially dangerous include approaching dogs immediately after entering their territory, waking a dog from sleep, and teasing or playing with a dog until it becomes overexcited [8]. Male dogs and dogs that have not been neutered are more likely to bite [1, 9].

Family and Community Issues

Most dog bites are preventable. Parents should be counseled never to leave a child alone with a dog, and children should be taught never to approach an unfamiliar dog. They should also be warned of the danger of startling animals. Children should learn to recognize signs of distress in familiar animals and be warned not to disturb them when they are exhibiting this behavior.

Spider Bites

In North America, two species of spider account for most medical problems after bites. The brown recluse spider (*Loxosceles reclusa)* is found primarily in the south central regions of the United States but may be transported anywhere. It is a small (1–2 cm) tan to dark brown spider with a violin-shaped pattern on the back. It produces a venom containing sphingomyelinase D, which causes endothelial swelling, platelet aggregation, and thrombosis. The black widow spider (*Latrodectus mactans*) has a shiny black color with a red hourglass-shaped marking on the ventral abdomen. Black widow venom contains α-latrotoxin, a potent neurotoxin.

Clinical Presentation

Brown recluse spider bites are painless or only mildly painful. Within 2–8 h, though, severe local pain may occur. An erythematous or cyanotic macule ("volcano lesion") may appear at the site of the bite often followed by a deep necrotic ulcer, which may take months to heal. Systemic absorption of toxin may lead to fever, malaise, vomiting, skin rash, and jaundice. Hemolysis and disseminated intravascular coagulation (DIC) may occur. Desquamation of the extremities, petechiae, and skin rashes may appear as late as 3 weeks after the bite [10].

Black widow spider bites are often painless, but 20 min to several hours later, localized pain, cramps, and fasciculations may occur. Progression to pain and rigidity in the abdomen, shoulders, and back often follows. Autonomic signs such as nausea, vomiting, fever, dizziness, hypertension, and sialorrhea may occur.

Diagnosis

Often the diagnosis of a spider bite is made presumptively by the victim. One study found that 90% of suspected spider bites were actually bites from other insects or manifestations of disease states [11]. For this reason, it has been suggested that in the absence of conclusive evidence as to the identity of the culprit, such bites be labeled "arthropod bite, vector unknown" in the medical record [12].

Telegram: @medical_k

www.konkur.in

Management

For most spider bites, wound care, ensuring current tetanus immunization status, and monitoring for infection are the only interventions required. Local symptoms are controlled through the use of ice, analgesics, and antihistamines.

Severe systemic symptoms due to brown recluse spider bites may require treatment with enteral or parenteral corticosteroids. Based on studies on rabbits, brown recluse envenomations that only have local effects do not respond to treatment with steroids, antihistamines, or hyperbaric oxygen therapy [13].

If available, specific antivenin (Antivenin, Merck, West Point, PA) may be the management option of choice for all significant envenomations due to black widow spiders [14–16] (Table 1). Parenteral narcotics, intravenous diazepam, or methocarbamol are useful for muscle cramps, as are prolonged hot baths.

Prevention

Clearing away debris, plugging openings into houses, wearing gloves and long pants, using insecticides, and avoiding heavily infested areas are the major preventive steps that can be taken to avoid bites.

Hymenoptera Stings

Stings by bees, wasps, hornets, and ants are common in most climates. Their shared manifestation is the production of localized dermal wheal and flare reactions. Full-blown anaphylaxis occurs in a subset of individuals. Domestic honeybees are relatively nonaggressive in defense of their colony. In contrast, Africanized bees ("killer bees"), endemic to parts of Arizona, Texas, and New Mexico, engage in massive stinging attacks that are often fatal. Fire ants are endemic to many southern states, and their bites are sustained by a large proportion of the population in infested areas each year.

Clinical Presentation

Wheal and flare dermal lesions are the most common presentation. The fire ant often makes a series of stings, leading to a characteristic semicircular pattern of sterile pustular lesions. Systemic toxicity may develop in the adult if more than approximately 50 bee stings are

Table 1 Antivenins

Antivenin	Indication	Dosage
Antivenin (Crotalidae immune fab) (ovine) (CroFab® BTG international) polyvalent	North American pit viper (crotalid) envenomation	4–6 vials IV q hour until symptom control Once controlled 2 vials q 6 hours x 3
Antivenin (ANAVIP® (Crotalidae immune $F(ab')_2$) (equine) (rare disease therapeutics, Inc.)	North American rattlesnake envenomation is the only FDA-approved indication	10 vials q hours until symptom control then 4 vials q hour as needed for re-emerging symptoms
North American coral Snake antivenin (equine) *(Micrurus fulvius)* (Wyeth pharmaceuticals, LLC a subsidiary of Pfizer, Inc.)	Coral snake envenomation-eastern coral snake and Texas coral snake	Initially 3–5 vials Persistent symptoms repeat 3–5 vials
Antivenin black widow spider antivenin (equine) *(Latrodectus mactans)* (Merck &co., Inc.)	Black widow spider envenomation	1–2 vials 1 M (IV in severe cases)
Scorpion antivenin Centruroides (scorpion) immune $F(ab')_2$ (equine) (ANASCORP® rare disease therapeutics, Inc.)	Bark scorpion envenomation	3 vials initially IV Pediatric and adult patients and thereafter guided by symptoms subsequent 1 vials after 60 min as needed

Telegram: @medical_k

www.konkur.in

sustained simultaneously. Generalized edema, dizziness, weakness, and vomiting may be followed by DIC, rhabdomyolysis, and acute tubular necrosis.

Management

The lesion is examined for the presence of a stinger. If one is present, it is promptly removed. Squeezing the venom sac is avoided.

Applying ice to the lesion reduces pain. Topical steroid preparations and oral antihistamines may be used for local reactions. Calamine lotion and cool, moist dressings are useful. Treatment of massive envenomation is identical to that for anaphylaxis, and it may be difficult to differentiate between the two conditions.

Prevention

Individuals at risk should avoid perfumes and brightly colored clothing while outdoors. People who clear vegetation and discarded junk are at increased risk of being stung. Individuals with a history of anaphylaxis after stings should be offered desensitizing immunotherapy. They should also carry an anaphylaxis self-treatment kit (Ana-Kit or EpiPen injectors).

Snakebite

There are two families of poisonous snakes in the United States. Elapidae, or coral snakes, are found in the South. Brightly colored with black, red, and yellow rings, they produce a neurotoxic venom. They rarely bite humans. Crotalidae, or pit vipers, which include rattlesnakes, cottonmouths, and copperheads, are distinguished by heat-sensing organs, or "pits," in the area between the eye and the nostril. Crotalid toxin primarily causes hemolysis, hemorrhage, and local soft tissue damage, although a few Mojave rattlesnakes produce a neurotoxic venom [10].

Clinical Presentation

Patients presenting after snakebite may display extreme anxiety, and it is important not to mistake it as evidence of envenomation. Local tissue changes include pain, edema, bullae, and ecchymosis. DIC and acute renal failure may occur. Coral snake envenomation may result in bulbar and respiratory paralysis.

Diagnosis

All patients who have sustained a venomous snakebite should undergo a complete evaluation regardless of the initial presentation, as effects can occur unpredictably for up to 12 h after the bite. In addition to the history and physical examination, a complete blood count, DIC screen, creatine phosphokinase assay, electrocardiogram, and urinalysis are recommended and may be repeated at intervals. Serial circumferential measurements of the affected extremity should be performed to monitor swelling. Consideration should be given to prophylactic endotracheal intubation in patients having sustained a bite of the face or head [10].

Management

Once an initial evaluation is done, contact should be made with the state poison control center to discuss the type of snake, location of bite, and signs and symptoms that the patient is having. Poison control can act as an important resource for discussion of administration of antivenin as well as other aspects of management. Intensive supportive care is often indicated. Antivenin is the only specific treatment available (Table 1). Its use for crotalid snakebites is recommended only if there is clinical evidence of envenomation [10]. Clinical assessment of the snakebite severity guides the amount of antivenin administered. Several objective scoring systems are in use [16, 17]. For minimal envenomations, up to 10 vials of antivenin are used and for moderate envenomation 10–20 vials [10]. The antivenin for crotalids

Telegram: @medical_k

www.konkur.in

(rattlesnake, copperheads, and water moccasin/cottonmouth) is Crotalidae polyvalent immune Fab (ovine) and is reconstituted in 10 mL of saline for each vial and diluted in 250 mL of saline to infuse. Start with 4–6 vials in and run the IV infusion over 60 min, proceeding slowly over the first 10 min at a 25–50-mL/h rate with careful observation for any allergic reaction. If no allergic reaction occurs, increase infusion rate to the full 250 mL/h until completion. Give an additional 4–6 vials followed by 2 vials every 6 h for 18 h for 14–18 vials total as indicated [18]. For severe cases, 20 or more vials of antivenin may be necessary. In children these doses may have to be increased by as much as 50%. A new antivenin (ANAVIP®) is available for rattlesnake bites only that is dosed based on symptoms also but has a longer half-life likely because it is a larger molecule. Effectively, it will continue to have benefit against the late effects of rattlesnake venom – in particular the coagulopathies. Specific antivenin should be administered to anyone sustaining a bite from a coral snake, regardless of initial presentation, as symptoms may progress rapidly once they appear. Antivenin administration is associated with anaphylaxis and serum sickness in a significant percentage of patients so it is important to gather history about sensitivity to horse proteins and to run a test dose for coral snake antivenin and the new rattlesnake specific antivenin of 1–2 mL over 3–5 min.

Prevention

Prevention is practiced by avoiding infested areas and high-risk behaviors, such as turning over logs and stones in the wild. Boots and long trousers provide significant protection from snakebite. Carrying a light while walking at night is an effective snake repellent.

Other Arthropods

Many other arthropods, including mosquitoes and ticks, target humans among their hosts. In the United States, mosquitoes transmit a number of arboviral encephalitides. Tick-borne diseases include Lyme disease, typhus, babesiosis, Rocky Mountain spotted fever, and ehrlichiosis (see ▶ Chap. 44, "Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome"). Scorpions native to the United States are not significantly toxic except for the bark scorpion (*Centruroides exilicauda)* endemic to Arizona and New Mexico.

Clinical Presentation

The most common presentation of a tick bite is the discovery of an attached tick. Ticks have a barbed feeding organ, or hypostome, through which they suck blood. This feeding mechanism is buried under the skin of the host, making removal of the tick difficult. Patients may also present with sequelae of a tick bite, such as erythema migrans. Rarely, injection of a neurotoxin by a female *Dermacentor andersoni* or *Dermacentor variabilis* tick results in a rapidly ascending motor paralysis known as "tick paralysis."

Most scorpion stings result in localized pain and swelling only. Systemic toxicity presents with localized numbness and paresthesias, followed by nausea, vomiting, dyspnea, and sialorrhea. Hypertension, involuntary motor activity, and seizures may occur. The severity of presentation for bark scorpion sting guides the use of the antivenin and should be done in consultation with the state poison control center. The antivenin is especially helpful for use in children – who are most commonly stung by scorpions and vulnerable older patients.

Diagnosis

Ticks may attach anywhere but are often found at the hairline or on the scalp. Tick bites may induce persistent granulomas or ulcers at the site of attachment. Tick paralysis often presents with flaccid paralysis. Bulbar paralysis and respiratory depression may occur. Cerebrospinal fluid examination is unremarkable.

Telegram: @medical_k

www.konkur.in

Management

An attached tick is removed by grasping it as close to the host's skin as possible with tweezers or protected fingers. Steady traction should be applied to detach the tick. Pulling too hard decapitates it and leaves the mouth parts embedded in the skin. Tick paralysis resolves spontaneously after removal of the tick.

Patients who display evidence of systemic toxicity from scorpion stings require supportive care. Beta-blockers are used for management of severe hypertension. Specific antivenin is available for severe envenomations. This is in the form of an antivenin developed from horse serum. The immunoglobulin is administered based on the severity of presentation of the patient. Contact the Poison Control Center for management decisions which will focus on degree of envenomation and the risk benefit of administration of the bark scorpion antivenin [19].

Prevention

Protective clothing should be worn when traveling in infested areas to avoid tick and mosquito bites. Individuals at risk should be counseled to carry out a visual inspection of the entire body twice daily to detect and remove any attached ticks. An insect repellent containing diethyltoluamide (DEET) should be applied to all exposed skin. Permethrin 0.5% spray (Nix, Elimite) applied to clothing provides further protection. There is hope for a Lyme disease vaccine in the near future. A previous vaccine, LYMErix, was withdrawn from the market voluntarily in 2002 [20].

Marine Animal Stings

In the United States, stingrays and coelenterates (sea anemones, jellyfish, corals) cause most of the significant human injuries or envenomations.

Clinical Presentation

Most commonly, the victim steps on a stingray hidden under the sand and is envenomated by a spine on the dorsum of the creature's tail. Stingray venom contains serotonin and proteolytic enzymes. The victim often experiences immediate pain and swelling of the affected extremity. Nausea, vomiting, weakness, diaphoresis, cramps, and dyspnea may occur.

Coelenterates (jellyfish) have thousands of stinging organs called nematocysts on their tentacles. Contact with these organs triggers the sting, which penetrates the skin and releases toxin.

Coral injuries are abrasions with a risk of secondary infection of the wound with organisms such as Staphylococcus aureus [21]. The exception is the fire coral which has stinging nematocysts similar to a jellyfish [22].

Diagnosis

Wounds inflicted by stingrays are often jagged and edematous. Pieces of the dorsal spine may be embedded in the wound or surrounding tissue.

Coelenterate stings present with a stinging or burning sensation involving the affected area. Erythema and papules appear in a linear distribution. Systemic symptoms include headache, nausea, muscle pain, spasm, and tachycardia. Massive envenomations have led to death.

Management

After soaking the stingray-induced wound in hot (45 °C) water for up to 90 min to deactivate the toxin, the wound is carefully irrigated and debrided. It is then packed and reevaluated at 72 h for delayed primary closure. Tetanus vaccination status is assessed and updated if necessary.

Soaking areas affected by coelenterate stings in hot, uncomfortable (not scalding) water for 5–10 min every 15 min up to 2 h helps deactivate toxins [12]. Any adherent tentacles are removed with gloved hands, and the affected areas may be

Telegram: @medical_k

www.konkur.in

shaved with a razor or sharp knife to remove any remaining nematocysts. A steroid-containing cream may be applied.

Prevention

Individuals should consider wearing sandals or shoes when wading in areas where stingrays or coelenterates are found. Stingrays, jellyfish, and other marine animals must be avoided, even when apparently lifeless.

The family physician is often a patient's first contact for health-related concerns and therefore knowledge of the proper initial evaluation and treatment of ingested poisons is crucial. This chapter should provide the office-based family physician with a sufficient overview in the diagnosis and management of common oral poisonings. The ingestion of acetaminophen, antidepressants, aspirin/salicylates, and opioids will be presented.

Introduction

Poisoning refers to contact with a substance that may result in toxicity. Toxicity may result from excess amounts of otherwise nontoxic substances, such as common medications. Poisonings are therefore dose related, distinguishing them from hypersensitivity reactions which are unpredictable. Symptoms of poisoning/toxicity may vary, and the following discussion will provide an overview of common syndromes of particular classes of drugs [2]. While poisoning may occur via various routes such as oral, inhalation, injection, and exposure of body surfaces, this chapter will focus on oral ingestion of specific common medications acetaminophen, antidepressants, aspirin/salicylates, opioids, and benzodiazepines.

Accidental poisoning is common among children, adolescents, adults, and the elderly. This chapter will focus on the office-based family physician's ability to recognize poisoning and its initial evaluation and management. The information presented today does not include intentional poisoning in individuals attempting suicide, or victims of attempted harm by others.

Signs and Symptoms

Signs and symptoms of poisoning may vary depending on the substance ingested and the individual affected. There are common toxic syndromes (Table 1) that suggest particular classes of substances; however, if multiple substances are ingested, the patients is unlikely to have symptoms characteristic of a single substance. Symptoms develop either immediately after contact, but may also be delayed. When delayed, the toxicity is a result of the metabolite and not the parent substance. Ingested toxins generally cause systemic symptoms [1].

Diagnosis

In the event that a patient contacts the family physician office by telephone or email, a rapid triage protocol should be in place. Appropriately trained health care team members should be able to quickly obtain and document any available history from the patient or representative which includes name, dose, amount of substance ingested, when ingested, intentional/

Telegram: @medical_k

Table 1 Common toxic syndromes

Drug	Symptoms and physical findings	Laboratory findings
Acetaminophen (Tylenol)	Nausea, vomiting, malaise, right upper quadrant abdominal pain, jaundice, confusion, somnolence; coma may develop later	After 24 h, increased AST (>1000 IU/L is characteristic), increased ALT, increased bilirubin, PT may increase
Salicylates	Nausea, vomiting, hyperpnea, tinnitus, fever, disorientation, lethargy, coma, seizures, diaphoresis, abdominal pain	Respiratory alkalosis with progressive anion-gap metabolic acidosis, hyperglycemia/hypoglycemia, hypernatremia/hyponatremia, hypokalemia
Cyclic antidepressants	CNS excitability, confusion, blurred vision, dry mouth, fever, mydriasis, seizures, coma, arrhythmias, hypotension, tachycardia, respiratory depression; physical condition can rapidly change	ECG findings of increased QRS interval >0.10 s, sinus tachycardia, conduction abnormalities
Benzodiazepines	Drowsiness, lethargy, dysarthria, ataxia, hypotension, hypothermia, coma, respiratory depression with severe overdoses	No characteristic findings
Narcotics	Drowsiness, nausea, vomiting, miosis, respiratory depression, cyanosis, coma, seizures, bradypnea, noncardiac pulmonary edema	With severe respiratory depression, hypoxemia, hypercarbia, respiratory acidosis, rhythm disturbances, pulmonary edema

AST aspartate aminotransferase, *ALT* alanine aminotransferase, *PT* prothrombin time, *CNS* central nervous system, *ECG* electrocardiogram

unintentional, and clinical status. The health care team may refer the patient to emergency medical services (EMS) for immediate medical attention, emergency room evaluation, or utilize local poison control centers for additional guidance.

PoisonHelp.org is an interactive website that provides critical triage and information on how to manage exposures to potentially toxic products, poisons, and medications. Users are prompted to answer a few questions regarding a human exposure to any of 1114 generic substances that encompass now more than 449,000 unique products. Recommendations are vetted by specially trained physicians, pharmacists, and nurses from our nation's 55 poison control centers. The website can be accessed from any computer or mobile device and is free, confidential, and available 24/7 [2].

For the patient who presents to the office scheduled/unscheduled the first priority is initial evaluation of the overall status of the patient. In cases of severe poisoning, rapid intervention to treat airway compromise or cardiopulmonary collapse may be necessary requiring the activation of emergency medical services (EMS). Poisoning may or not be known at the time of presentation, it should be suspected in patients with unexplained symptoms and especially altered mental status. Careful attention for intentional/self poisonings in adults as multiple substances may be involved and can have unpredictable symptom course and clinical stability.

For all patients, history is the most valuable tool, although sometimes the most difficult to obtain. History should be taken from all available sources, including the patient, friends, family, relatives, and rescue personnel. Medical record and pharmacy record information may also be useful to obtain information related to access to substances. If unknown pills are discovered, poison control centers are an important and useful resource for identification, further evaluation, and management guidance [1].

A physical exam can be helpful to determine if the classic toxic syndromes suggest a particular class of drug, if there is evidence of breath odor suggestive of alcohol use or needle marks/tracks indicating injected drug use. Immediate attention should be directed to evaluation of the airway and ventilation, cardiac function/perfusion, level of consciousness, and mental status. Unstable patients should be connected to any available cardiac monitor, oxygen if available, and measurement and documentation of vital signs every 5 min until stabilized or transferred should be noted [1].

Telegram: @medical_k

www.konkur.in

Once the patient is stabilized a more detailed physical exam is necessary to evaluate the extent of poisoning and the presence of concurrent conditions which contribute to impact of toxicity. The physical findings may also help the clinician to determine if the toxin is a stimulant or depressant. Signs of toxic ingestion of stimulants include mydriasis (pupil dilation), tremor, tachycardia, irritability, mania, diaphoresis, and convulsions. When toxic amounts of depressants are ingested, signs include lethargy, decreased responsiveness, miosis (pupil constriction), hypothermia, and coma. Consulting a professional/experience colleague or regional poison control center can help with additional physical findings [1].

Point-of-Care Testing

For poisonings that have cardiovascular effects or of an unknown substance, in office cardiac monitoring and obtaining an EKG may be helpful. Point-of-care blood glucose testing may also be helpful for concerns of hypoglycemia.

Laboratory Evaluation

For the office-based family physician, laboratory evaluation of poisoning may be limited, unless the physician has an onsite laboratory with the capability of rapid results. The standard toxic screens both urine and serum are qualitative and may only check for a limited number of substances or their metabolites. Unless the result of the laboratory evaluation is rapidly available and will guide treatment, in the office setting there is limited use.

Decontamination

Gastric Emptying

Gastric emptying is no longer routinely performed. Previously, it was considered if it could be done within 1 h of a life-threatening ingestion. Since many poisonings manifest too late, and may not always be life threatening, it is not always clearly indicated. Furthermore, ingestion of a caustic substance is a contraindication to this procedure.

When gastric emptying was used, gastric lavage was the preferred method. Gastric lavage does have associated complications such as aspiration or rarely oropharyngeal or esophageal injury. Further discussion of this no longer routinely performed method will be deferred at this time [1].

Ipecac

Ipecac is an agent used to induce vomiting through irritation of the gastric mucosa and stimulation of the chemoreceptor trigger zone in the medulla. It is no longer manufactured in the USA because of concerns for safety and ability to improve outcomes for patients who have been poisoned [3].

Activated Charcoal

Charcoal is usually given, frequently when unknown or multiple substances have been ingested. The added risk in its use includes vomiting and aspiration, however it does reduce overall morbidity and mortality. If being used, it should be given as soon as possible.

Activated charcoal is an adsorbent that works by binding the toxin throughout the GI tract to reduce systemic absorption. It is given as a single oral dose between 25–100 g within 1–2 h of the toxin ingestion to maximize efficacy. Doses are often mixed with juices or carbonated beverages to improve their palatability [4].

Although activated charcoal binds most substances, Table 2 below outlines the agents for which the use of activated charcoal is NOT recommended:

Acetaminophen

Acetaminophen is consistently one of the most common toxic drug exposures. Ingestions of 4 g or greater may cause injury in select patients. In general, acute doses of 150 mg/kg or 10 g in adults

Telegram: @medical_k

www.konkur.in

Table 2 Agents to AVOID use of activated charcoal (AC)

	Rationale
Acids – *mineral acids, boric acid* **Alkalis** – *cleaning solutions, bleach, and dishwasher detergent*	Vomiting can be damaging and the AC may cause discoloration of the stomach lining and therefore interfere with endoscopy
Alcohols **Organic solvents** – *acetic acid, acetone, ethylene glycol, glycerin, and toluene* **Cyanide/Organophosphates** – *insecticides, herbicides, and antihelminthic drugs* **Metals** – *arsenic, iron, lead, lithium, and mercury*	Bind poorly, which necessitates large doses of AC that are difficult to ingest

Complications include aspiration, accidental administration into the lung, emesis, constipation, and gastric obstruction. Contraindications include unconscious state or otherwise unable to protect the airway without endotracheal intubation and recent GI surgery

and 200 mg/kg in children are considered toxic. It is recommended that doses exceeding this threshold be managed in a health care facility.

Pharmacokinetics

The mechanism of toxicity is caused by the active metabolite N-acetyl-p-benzoquinoneimine (NAPQI), which can lead to oxidant cell injury, hepatic failure, and death. Around 90% of acetaminophen undergoes phase II conjugation to glucuronide and sulfate conjugates that are excreted in the urine. An additional 2% is excreted unchanged in the urine. The remaining amount (8–10%) is converted by cytochrome P450 (CYP2E1) to NAPQI. NAPQI is normally converted by glutathione to cysteine conjugates, which are renally excreted. In an overdose, the sulfation and glucuronidation pathways become saturated, leading to glutathione depletion and a subsequent buildup of NAPQI [5].

Clinical Presentation

Mild poisoning may not cause symptoms, and often acute poisoning symptoms are usually minor until >48 h after ingestion.

Four clinical phases are associated with an acetaminophen toxicity [6]:

Phase I – within the first 24 h after ingestion: Patients may present with minimal or no signs of distress. Potential signs and symptoms include nausea, vomiting, diaphoresis, and anorexia.

Phase II – within 24–48 h after exposure: Marked by initial damage to the hepatocytes. Patients may present with right upper quadrant pain, increases in liver transaminases, elevated total bilirubin concentrations, and prolonged prothrombin time.

Phase III – within 72–96 h after initial exposure: The peak of the hepatotoxic effects. Patients may present with lactic acidosis, acute renal failure, acute pancreatitis, and fulminant hepatic failure, as evidenced by jaundice, extensive coagulopathies, hypoglycemia, and hepatic encephalopathy.

Phase IV – about 1 week after exposure: Marks the recovery phase if the patient survives phase III.

Management

The goal of treatment is to prevent the development of hepatic toxicity and reduce mortality. Gastric decontamination with a single dose of activated charcoal can be considered if the patient presents within the first hour after exposure, is not vomiting, and has no alterations in mental status.

Antidote therapy is recommended with N-acetylcysteine. The mechanism of action for N-acetylcysteine is to increase the synthesis and bioavailability of glutathione, substitute for glutathione by binding to the reduced sulfur group of NAPQI, and supply a substrate for sulfation, thereby increasing the nontoxic metabolism.

Telegram: @medical_k

www.konkur.in

Guidelines suggest that acetylcysteine treatment should be administered to patients within the first 8 h of exposure if they can be stratified as being at possible or probable risk of hepatotoxicity by the Rumack-Matthew nomogram [7] (Fig. 1 in current textbook). If patients cannot be stratified either because of unknown time of ingestion or inability to perform acetaminophen serum assays, they should receive acetylcysteine if any of the following conditions apply (Table 3):

(a) Increased alanine aminotransferase (ALT) concentration
(b) Serum acetaminophen levels greater than 20 mcg/mL
(c) History of chronic ingestions exceeding 4 g/day with an elevated serum ALT concentration

Intravenous acetylcysteine is preferred because of its decreased overall administration time (21 h versus 72 h for oral) and minimal GI adverse effects. Oral acetylcysteine is dosed for 18 total doses; doses may be repeated if emesis occurs within 1 h of a dose. To improve palatability, doses may be diluted in juice or carbonated beverages in a covered cup with a straw. Antiemetics may be administered if significant nausea or vomiting occurs. Although treatment guidelines recommend 18 total doses of acetylcysteine administered over 72 h for oral acetylcysteine therapy and 20 h of the intravenous infusion of acetylcysteine, many poison control centers recommend early discontinuation (or prolonged therapy) if the following conditions are met [8]:

(a) Serum acetaminophen concentrations are undetectable or less than 10 mcg/mL
(b) ALT levels normal (60 IU/L or less) or improving. Some clinicians also advocate an INR (international normalized ratio) of 1.3 or less
(c) The patient is clinically improved

Patients should be monitored for improvement in vital signs and mental status. The following laboratory values should be monitored periodically for improvement as well as for potential worsening.

(a) ALT, aspartate aminotransferase (AST), total bilirubin, and prothrombin time
(b) BUN and SCr
(c) Serum electrolytes
(d) Fulminant hepatic failure: Serum bicarbonate, serum lactate, arterial blood gas, serum glucose, and ammonia levels

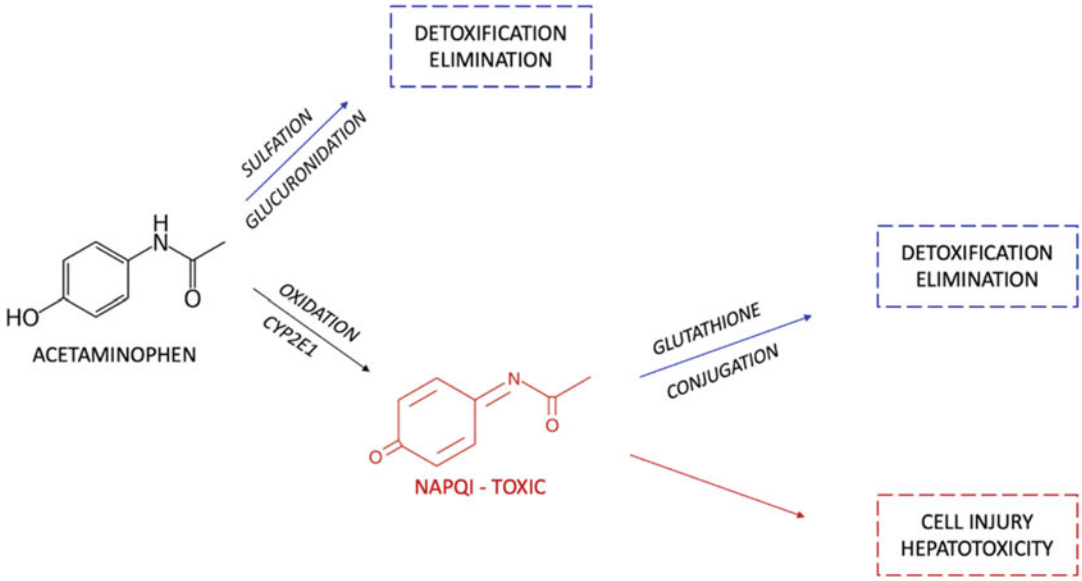

Fig. 1 Metabolism of acetaminophen

Telegram: @medical_k

www.konkur.in

Table 3 N-Acetylcysteine (NAC) dosing

Route	Dose
Oral	**Loading dose**: 140 mg/kg **Maintenance doses**: 70 mg/kg every 4 h for a total of 17 doses (72 h)
Intravenous	**Loading dose**: 150 mg/kg (max 15 g) in 200 mL of 5% dextrose in water infused over 60 min **Maintenance doses**: 1. 50 mg/kg (max 5 g) in 500 mL of 5% dextrose in water infused over 4 h 2. 100 mg/kg (max 10 g) in 1000 mL of 5% dextrose in water infused over 16 h *Patients weighing less than 40 kg require reduced volume administration*

Antidepressants: Tricyclic Antidepressants (TCAs)

Pharmacokinetics

TCAs exert many effects, including blocking the reuptake of norepinephrine and serotonin at the presynaptic neuron, blocking muscarinic cholinergic receptors, blocking antihistamine effect, and, to a lesser degree, blocking α-adrenergic receptors.

Clinical Presentation

Individuals with TCA overdoses may present with the following adverse effects [9]:

Cardiovascular: Hypo- or hypertension, tachy- or bradycardia, increased QRS or QT interval, atrioventricular conduction block, and complete heart block

Respiratory: Hypoventilation, crackles, and hypoxia

Neurologic: Delirium, lethargy, seizures, and coma

Other: Hyperthermia, dry mucous membranes, urinary retention, and blurred vision

Management

There are no specific antidotes for TCA overdoses and general supportive care is recommended, with a focus on airway, breathing, and circulation. Gastric decontamination is not typically recommended; however, single-dose activated charcoal may be administered within the first hour of exposure. Administer crystalloid or colloids fluids to maintain hemodynamics.

Alkalinization of blood to a pH of 7.45–7.55 with sodium bicarbonate is recommended for the TCAs. Proposed indications for sodium bicarbonate include: QRS greater than 100–120 milliseconds, wide complex tachycardia, cardiac arrest, right bundle branch block, refractory hypotension, and serum electrolytes replacement if QT prolongation causes [10].

Sodium bicarbonate dosing is as follows:

1. Bolus dose: 1 mEq/kg (minimum 50 mEq)
2. May repeat bolus every 15 min until ECG stabilized or arterial pH goal achieved
3. May consider a continuous infusion of hypertonic saline for patients refractory to sodium bicarbonate

Seizures should be managed with benzodiazepines. Phenobarbital may be considered if the patient is refractory to benzodiazepines and has a stable blood pressure.

Antidepressants: Selective Serotonin +/− Norepinephrine Reuptake Inhibitors (SSRIs/SNRIs)

Pharmacokinetics

Serotonin syndrome is caused by excessive serotonin concentrations leading to overstimulation of serotonin-1 A and serotonin-2 A receptors in the central and peripheral nervous systems.

Telegram: @medical_k

www.konkur.in

Clinical Presentation

Adverse effects include altered mental status, autonomic instability (hyperthermia, tachycardia, hypertension, arrhythmias), and neuromuscular changes (hyperreflexia, increased rigidity) [11].

Management

Treatment should focus on supportive care; symptoms typically resolve within 24–48 h [8].

(a) Discontinue the offending agent
(b) Benzodiazepines should be administered as first line for agitation and muscle rigidity
(c) Cyproheptadine 8–12 mg by mouth should be administered for agitation and muscle rigidity as an adjunct to benzodiazepines

Aspirin/Salicylates

Pharmacokinetics

The mechanism of toxicity for salicylates is through the interference with aerobic metabolism owing to the uncoupling of mitochondrial oxidative phosphorylation, leading to increases in anaerobic metabolism, which causes a significant lactic acidosis. This also leads to hypoglycemia because of glycogen depletion, gluconeogenesis, and catabolism of proteins and free fatty acids.

Clinical Presentation

The most common clinical symptoms associated with a salicylate overdose are hyperventilation (respiratory alkalosis), tinnitus, and GI irritation. Symptoms may vary depending on the serum salicylate level; however, these may be low to normal early in the presentation [12]:

(a) Serum level less than 30 mg/dL: Asymptomatic
(b) Serum level 15–30 mg/dL: Therapeutic levels
(c) Serum level 30–50 mg/dL: Hyperventilation, nausea, vomiting, tinnitus, and dizziness
(d) Serum level 50–70 mg/dL: Tachypnea, fever, sweating, dehydration, and listlessness
(e) Serum level greater than 70 mg/dL: Coma, seizures, hallucinations, stupor, cerebral edema, dysrhythmias, hypotension, oliguria, and renal failure

Patients should be monitored for up to 24 h because of the possibility of delayed or impaired absorption.

Management

There is no antidote for salicylate poisoning. The goals of therapy are to limit the additional absorption of salicylates and to provide supportive care. Gastric decontamination with a single dose of activated charcoal is recommended if the patient is alert and not vomiting. Otherwise, treatment is mostly symptom management [13]:

1. Administer intravenous crystalloid fluids to maintain blood pressure
2. Administer intravenous glucose for hypoglycemia or significant neurologic symptoms
3. Urine alkalinization is recommended to enhance renal elimination and increase the glomerular filtration rate
4. Consider hemodialysis if appropriate

Opiates

Pharmacokinetics

Opioids act at the mu, delta, and kappa opioid receptors, although mu is responsible for most of the opioids' clinical effects. The most common agents associated with a toxicologic death are methadone, oxycodone, morphine, and tramadol.

Clinical Presentation

The most common clinical symptoms associated with opioid overdose are respiratory depression, coma, miosis, and hypoactive bowel sounds. Additional findings may include stupor,

Telegram: @medical_k

www.konkur.in

hepatotoxicity, acute renal failure, rhabdomyolysis, compartment syndrome, hypothermia, and seizures [14].

Management

Antidote therapy is recommended with naloxone. The mechanism of action of naloxone is that it is a competitive antagonist at the opioid receptor. The intravenous route is preferred, but naloxone is also effective through the intramuscular, intranasal, inhalational, or intrapulmonary route. Onset of action of intravenous naloxone is 2 min with a duration of 30–120 min. Dosing may be affected by the specific opioid agent and dose, affinity for the mu-receptor, and patient weight.

Initial dose is 0.04 mg in adult patients and 0.1 mg/kg in pediatric patients; if no response, the dose is increased every 2–3 min to 0.5 mg, 2 mg, 4 mg, and 10 mg, followed by 15 mg. It is recommended that a continuous infusion be initiated at a dose of two-thirds the effective bolus dose per hour (0.04–4 mg/h) for patients requiring subsequent naloxone doses to sustain effect.

Adverse effects are rare and may be more related to a return of sympathetic response to opioid withdrawal. If no effect is seen, consider other causes such as secondary or alternative agents [15].

Monitoring: Observe respiratory status and vital signs for a minimum of 4–6 h after the last dose of naloxone or discontinuation of the continuous infusion.

Disposition

The first priority is hemodynamic stability and airway protection of the poisoned patient. General indications to consider hospital admission include: altered mental status, persistent abnormal vital signs, and predicted delay in toxicity (in long acting/sustained release preparation ingestion). In patients who remain hemodynamically stable, have an intact mental status and airway, and in whom laboratory test results are normal, if the patient is asymptomatic after 4–6 h of observation, these patients may be discharged. However, if the ingestion was intentional, those patients require psychiatric evaluation [1].

Prevention

While management of ingested poisons in the office based is limited, the family physician has an important role in counseling and prevention. Discussing with all patients, regardless of age, the significance of poisoning and prevention is encouraged. Recommendations such a clearly labeling household products, prescriptions, drugs, their safe storage, and disposal. The family physician should proceed with caution when prescribing opioids and use nonnarcotics when possible [1].

Introduction

A laceration is a traumatic disruption of the epidermal/dermal junction. Treatment of acute lacerations typically requires mechanical support to approximate disrupted skin layers. Assessment of lacerations should include consideration of infection risk, evaluation of nearby vital structures for damage (e.g., nerves, blood vessels, tendons, etc.), and choice of closure technique to maximize functional and cosmetic outcomes.

Skin Anatomy and Wound Healing

Skin anatomy and the phases of wound healing are important concepts for laceration repair. All skin has a keratinized epidermis with a single, basal layer of regenerative cells. Deep under this is a collagen-rich dermis overlying subcutaneous fat and muscle. The dermal layer provides the majority of skin's strength. Figure 1 represents normal skin and subcutaneous tissue anatomy.

Wound Closure

Closure of acute lacerations is called "primary closure" or "closure by primary intent." Suturing remains the most common form of primary closure; however, alternative methods (e.g., wound closure tapes, staples, and tissue adhesives) may also be used. Secondary closure or "healing by secondary intent" describes wounds left open to heal by granulation. Tertiary closure refers to delayed primary closure. Most lacerations are repaired by primary closure.

Wound healing occurs in three phases: inflammatory, proliferative, and maturation. The inflammatory phase begins at the time of injury and lasts

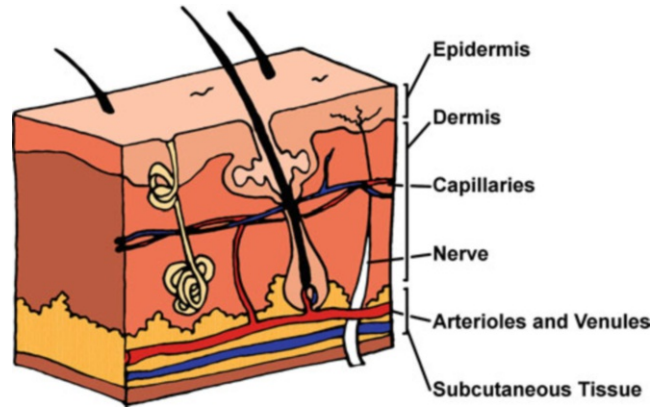

Fig. 1 Normal skin anatomy

Telegram: @medical_k

www.konkur.in

roughly 5 days. Once hemostasis occurs, macrophages and neutrophils remove foreign material and devitalized tissue. There is no gain in wound strength during this time. The proliferative phase occurs between days 6 and 14, during which time fibroblasts initiate collagen synthesis. By the end of this phase, disorganized collagen bundles are present but wound strength is poor [1]. Primary closure provides reinforcement during the first two phases of healing. Starting at 2 weeks after injury, the maturation phase involves remodeling of collagen bundle creation of the fibrotic scar. Everting skin edges (discussed below) help prevent inversion of the scar as it contracts. The healing process restores skin strength to approximately 80% of normal [2].

Indications/Contraindications to Primary Closure

There is debate over how soon after injury a laceration must be repaired to optimize healing. Infection rate does not increase with delayed repair; however, rate of healing appears slowed after 19 h [3, 4]. Grossly contaminated wounds, wounds that appear infected, and those with significant devitalized tissue such as crush injuries are at high risk for infection. These injuries should be left open and evaluated for tertiary closure in 72 h [5]. If the wound remains uninfected, delayed primary closure can occur at that time; otherwise, the wound should heal by secondary intent. If delayed repair is not an option, wound edges can be loosely approximated with interrupted sutures to reduce scar size and allow for drainage. The decision to repair a wound depends on the skill and comfort level of the individual provider; the following injuries should prompt consideration of specialty referral [6]:

Deep hand or foot wounds
Full-thickness eyelid, lip, or ear lacerations
Nerve, artery, bone, or joint involvement
Penetrating wounds of unknown depth
Severe crush injuries
Severely contaminated wounds requiring drainage Cosmetic outcome of significant importance

Anesthesia
Local Anesthesia
Topical Anesthesia

For patient comfort, it is preferable to anesthetize wounds prior to inspection and cleansing. Several routes of administration exist. Topical agents consist of one or more anesthetics with or without a vasoconstrictor (e.g., lidocaine/epinephrine/tetracaine). To apply, a cotton ball soaked with the topical agent is placed over the wound and covered with an occlusive dressing. Application is painless and wound margins are not distorted with application. Anesthetic effect is achieved gradually [6]. Topical agents are absorbed through subepidermal and mucosal tissue. Larger injuries may absorb a volume of anesthetic in excess of the recommended dose; caution should be used. Topical agents are a good choice for pediatric populations and can be used alone or as an adjunct to injectable agents [6]. Once the wound is anesthetized, distraction with toys or games helps minimize the patient's anxiety [7].

Injectable Anesthesia

Injectable anesthetics achieve effect more quickly than topical agents but are more painful. The most commonly used are lidocaine and bupivacaine. Onset of action is <5 min, but duration of anesthesia varies between agents. Bupivacaine lasts about four times longer (120–240 min) than lidocaine (30–60 min). Duration of action can be extended with the addition of epinephrine. Premixed formulations of anesthetic and epinephrine are commonly available [8]. Despite long-standing beliefs to the contrary, agents containing epinephrine do not increase the risk of necrosis in areas with end arterioles such as fingers and toes; in fact, the use of vasoconstrictors improves hemostasis and can reduce the need for tourniquets [7, 8, 9].

Discomfort from injection can be reduced by buffering the anesthetic with sterile sodium bicarbonate at a 10:1 ratio, injecting through the open wound to avoid nerve endings and infiltrating slowly with the smallest-gauge needle possible

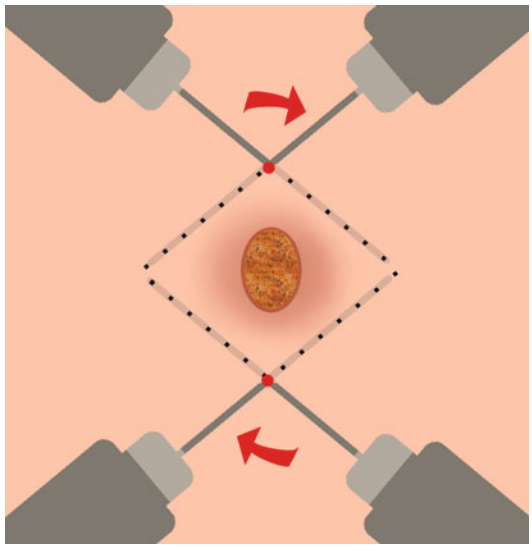
Telegram: @medical_k

www.konkur.in

[5]. Partially withdrawing the needle and changing the angle prior to advancing ("fanning") decreases the number of injection sites. Allergies to injectable anesthesia are rare; still, patients should be asked about these prior to administration.

Injectable anesthetics can be administered by direct infiltration of the wound ("local" anesthesia), infiltration around the wound (a "field block"), or by proximal infiltration of a nerve that supplies the injured area ("nerve block"). Local anesthesia is used for simple lacerations on the face, trunk, and extremities. Field blocks (Fig. 2) are most useful for injuries where maintenance of architecture is crucial (e.g., lacerations of the ear). Nerve blocks require smaller volumes of anesthetic and last longer than local or field blocks though anesthetic effect takes longer. Additionally, they can anesthetize large areas with a single injection, a property helpful for managing large or diffuse areas of injury supplied by a common nerve. Nerve blocks require a careful review of anatomy and, due to the caliber of the targeted nerve, have an increased risk of prolonged paresthesia. The digital block pictured below is one of the most common nerve blocks and illustrates the general technique required (Fig. 3).

In patients with significant anxiety or who are otherwise unable to tolerate wound repair with local anesthetic, systemic sedation with anxiolytics, analgesics, and/or sedative hypnotics is an alternative. The use of these medications is often referred to as "procedural sedation and analgesia" (PSA). PSA can be safely utilized by family physicians and advanced practice providers but requires in-depth familiarity with the medications required, their potential complications, and the monitoring and personnel required for their use.



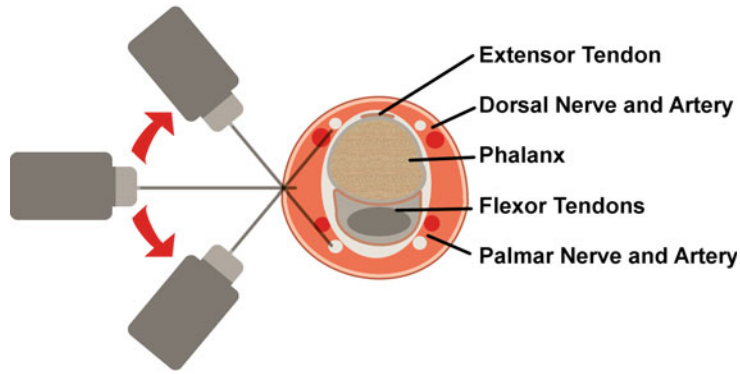


Fig. 2 Injectable anesthesia by field block

Wound Preparation and Further Assessment

The first step in wound repair is ensuring availability of the proper equipment (Table 1). Once accomplished, attention can be turned to the laceration. Now anesthetized, the wound should be inspected for debris and other foreign bodies; damage to deeper tissues; or damage to vessels,

Fig. 3 Digital nerve block

Irrigation: 60 ml syringe, tap water, splash device
Sterile field & surgical preparation: fenestrated drape, sterile drape, povidone-iodine or chlorhexidine gluconate, alcohol swabs
Sterile gloves (not needed in uncomplicated closure) [31] Suture Needle driver Pickups with teeth (less traumatic than blunt pickups)

nerves, or tendons and specialty referral considered as needed. Once this is complete, irrigation is used to wash away debris or foreign matter and dilutes the bacterial concentration present in the wound. Tap water and sterile saline have equivalent rates of post-repair wound infection, the former being more cost effective [14]. Warmed irrigation solution is less painful. A 60 mL syringe with an 18-gauge angiocatheter supplies adequate pressure without damaging tissue [5]. Commercial splash shields protect against body fluid exposure. The optimal volume of irrigation fluid has not been adequately reported; however, most sources recommend a minimum of 250 mL [15]. Visible foreign matter remaining after irrigation should be removed with sterile forceps, using caution with removal of foreign bodies located near vessels, nerves, or tendons. Wrapping a gloved finger with petroleum-embedded gauze can help the clinician remove debris or greasy contaminants remaining in the wound after irrigation. Povidone-iodine, hydrogen peroxide, alcohol-based, or other chemical solutions may be used for cleaning skin surrounding the wound but should not be applied within the wound or approximating skin edges. These solutions are toxic to underlying tissue and impede wound healing. Hair surrounding the wound should be clipped but not shaved to avoid wound contamination. Shaving is associated with increased rates of infection [15].

Radiographs are recommended for wounds sustained from glass or metal fragments. Plastic and wood are not radiopaque, so advanced imaging should be considered if the presence of these materials is suspected.

Suture Characteristics

The most common sutures used for percutaneous closure are made from nonabsorbable, synthetic polymers such as nylon and polypropylene in a single filament. These produce less tissue reactivity than natural fibers such as silk and pose decreased risk of infection compared to braided material [16, 17]. In contrast, absorbable sutures are used to reinforce the dermis and provide hemostasis. Synthetic materials are less inflammatory than "gut" sutures made from animal connective tissue and thus are preferred (Table 2) [16, 17].

A suture's thickness is inversely proportional to the number on its package (e.g., 3-0 suture is thicker than 4-0 suture). To optimize cosmetic results, providers should choose the finest suture that will provide sufficient structural support. Generally, lacerations on the trunk are repaired with 3-0 or 4-0 suture, extremities and scalp with 4-0 or 5-0, and face with 5-0 or 6-0 [15]. Sutures are most commonly tied with a square knot. Five knots (also called "ties" or "throws") per suture provides optimal stability. In nearly all cases, a 3/8 curvature of circle on a reverse cutting needle is sufficient for laceration repair. It is easier to maneuver in small areas than a 1/2 curvature and slides through skin better than a tapered needle (Table 2).

After cleansing, the wound is draped with a sterile drape or sterile towels to create a clean field. Devitalized tissue should be debrided, and wound edges trimmed so they are perpendicular to the skin surface with slight undermining to promote eversion of wound edges (Fig. 4). Undermining permits greater mobility of the skin surface by releasing subcutaneous attachments. A scalpel or pair of sharp scissors is used to make cuts of equal depth, keeping in mind that shallower cuts pose a greater risk of compromising tissue perfusion. Greater tension occurs at the center of the wound, so this area requires the widest undermining (Fig. 5) [18]. Intradermal retention sutures that bring together dermis can reduce wound tension and approximate wound edges (Fig. 6). Absorbable suture material is typically used for deep sutures. The technique for placing deep retention sutures is similar to simple interrupted and is described below.

Table 2 Suture characteristics

	Suture	Advantages	Disadvantages	Tissue reactivity
Absorbable	Catgut (plain)	Inexpensive	Low tensile strength and retention (7–10 days), high tissue reaction	High
	Chromic gut	Inexpensive	Moderate tensile strength, retention, and tissue reaction	Moderate
	Polyglactic acid (Vicryl)	Braided, coated, easy handling, mild tissue reaction		Low
	Polyglycolic acid (Dexon)	Good tensile and knot strength, low tissue reaction	Difficult to handle	Low
Nonabsorbable	Silk	Moderate tensile strength	Moderate tissue reaction	Moderate
	Nylon (Ethilon, Dermalon)	Low tissue reaction	Difficult to handle, need many knots	Low
	Polypropylene (Prolene, SurgiPro)	Permanent, minimal tissue reaction	Needs extra knots	Low
	Braided polyester (Mersilene, Ethiflex)		Greater infection risk relative to monofilament	Low

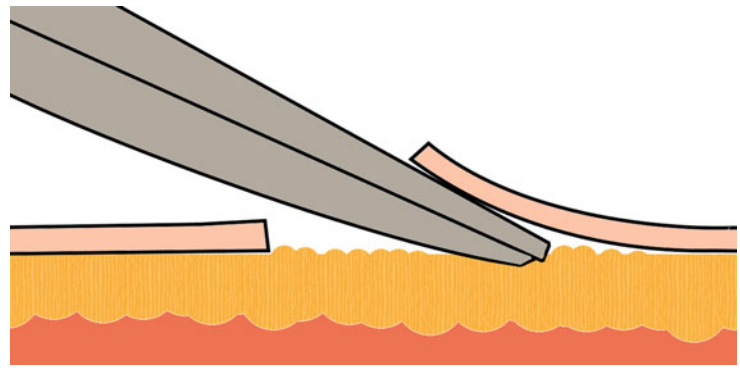

Fig. 4 Undermining wound edges, sagittal view

Various suturing techniques are discussed below. The fundamental goals for all are as follows:

1. Hemostasis: Brisk bleeding should be controlled prior to closing a wound. If direct pressure is insufficient, electrocautery or ligation of bleeding vessels with absorbable sutures may be required. Care should be taken not to cauterize the epithelium, as this will increase scarring. Attempts to cauterize capillaries may compromise blood supply and is generally unnecessary, as capillary bleeding should stop with wound closure.
2. Elimination of Dead Space: Fluid accumulation between or within tissue planes can impair healing and act as a nidus for infection. In wounds that penetrate the subcutaneous space, deep absorbable sutures are used to reduce seroma formation. The use of temporary drains (silicone or latex tubing) is of limited value and should be avoided.
3. Approximation of Tissue Layers: Sutures should approximate corresponding tissue types with enough pressure to slightly evert

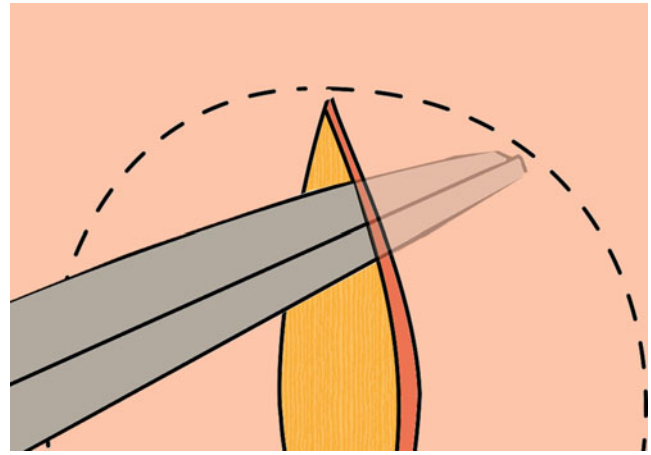

Fig. 5 Undermining wound edges

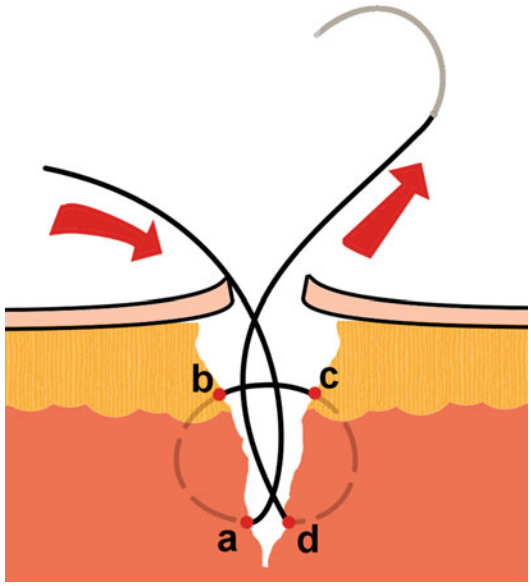

Fig. 6 Intradermal retention suture with buried knot. The suture enters the wound edge deep and, following the curve of the needle, exits superficially (still below the dermal-epidermal junction). This throw is reversed on the opposite wound edge and tied off, leaving a "buried" knot

wound edges. This ensures that keratinized epithelium does not impair healing and decreases the risk of fibrotic contraction causing a noticeable defect. Tension on wound edges should be minimized with undermining and the use of appropriate suture technique. Sutures under high tension can compromise circulation.

Simple Interrupted Closure

Simple lacerations are most commonly repaired with the simple interrupted closure. Individual sutures are placed in parallel to one another at regular intervals along the laceration to provide multiple points of tissue support. The first stitch should bisect the wound perpendicularly to facilitate a symmetric repair. Using a needle driver, the point of the needle enters the skin perpendicular to the surface and penetrates halfway through the dermis. Following the curve of the needle, the needle driver is turned 90°. The needle exits one side of the laceration and enters the other at the same depth, and the needle driver is again turned 90°. The exit point should be directly across the wound edge from the entry point. Both points should be equidistant from the wound edge. The suture should be as wide as it is deep (Fig. 7). Using an instrument tie (Fig. 8), the suture is tied tightly enough to approximate and evert wound edges but not enough to indent the epidermis. Subsequent sutures are placed in parallel (Fig. 8).

Simple Running Closure

A simple running closure can be completed quickly, an advantage in emergency situations (Fig. 9). It is useful for long, low-tension wounds but should be avoided in high-tension wounds due to the risk of circulatory compromise. Interrupted

Telegram: @medical_k

www.konkur.in

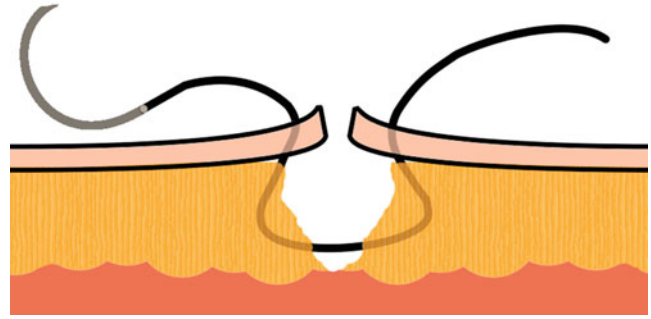

Fig. 7 Simple interrupted, sagittal view

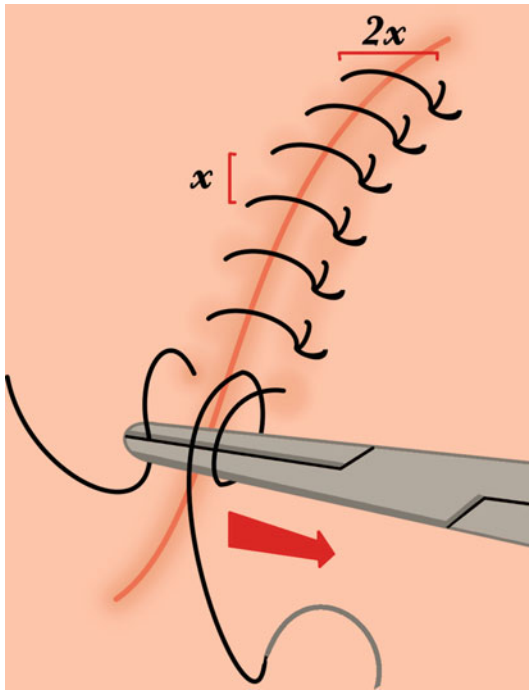

Fig. 8 Suture spacing of simple interrupted closure

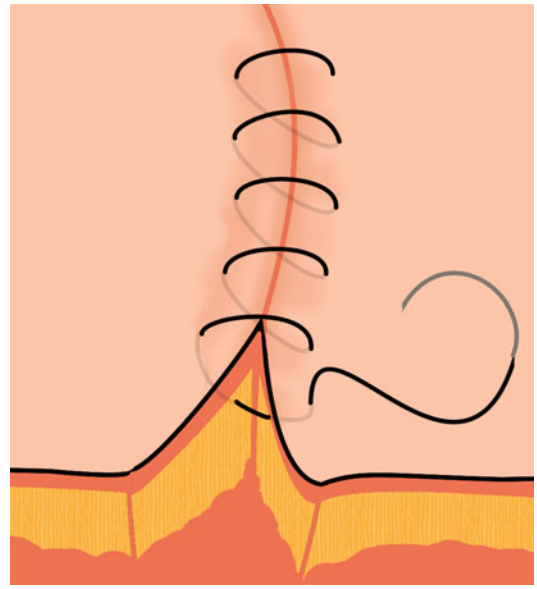

Fig. 9 Simple running closure. Symmetric "baseball stitches" are placed with a single suture and the ends are knotted. The width and depth of each bite should be equal

rather than running sutures should be used if infection risk is high to allow for selective removal of individual sutures to promote drainage without the risk of dehiscence.

Intradermal Running Closure

The term "subcuticular" refers to placement of the suture below the stratum corneum. A more apt term for this stitch is "intradermal." Intradermal sutures are accomplished by driving the needle back and forth across the laceration in parallel to the skin layers, using the dermis as an anchor. An intradermal running closure should be considered when cosmetic outcome is important, such as for facial wounds, as this method creates minimal scarring [19, 20, 21]. Intradermal sutures provide less tissue support than percutaneous sutures so should be reserved for linear, shallow wounds under minimal tension (Figs. 10 and 11).

Telegram: @medical_k

www.konkur.in

Buried knots are used to anchor absorbable intradermal sutures and are placed with the same technique as buried retention sutures). The important difference is, rather than cutting both tails, the end connected to the needle is then used for the intradermal closure. If nonabsorbable sutures are used, the skin is entered approximately 1 cm from the apex. Several techniques are used to complete an intradermal repair. The simplest of these is shown below (Fig. 11). Both "tails" are secured in place by adhesive strips. Once initial wound strength has occurred (typically 5–7 days), the suture is removed by gently pulling one end against countertraction.

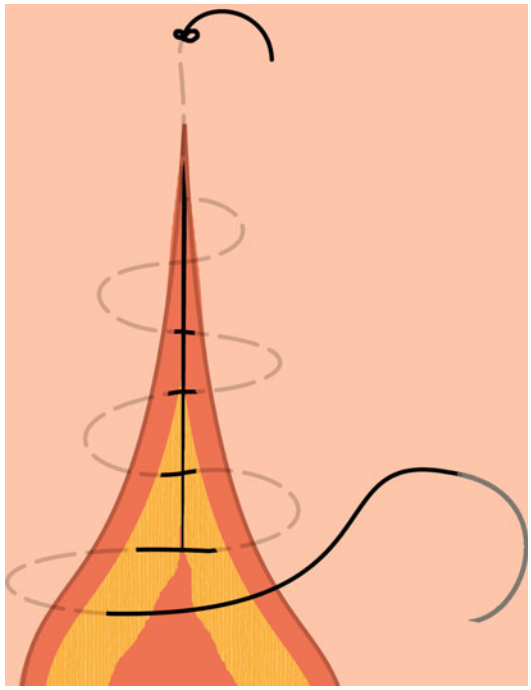

Fig. 10 Intradermal running closure. The wound is entered and exited through its apices. Horizontal "zig-zagging" passes are made with symmetric bites at the dermal-epidermal junction

Two-Layer Closure

High-tension wounds and those with significant dead space require intradermal retention sutures to approximate underlying tissue. A simple interrupted suture can then approximate the skin edges under lower tension (Fig. 12).

Horizontal Mattress Suture

In situations where intradermal sutures cannot be placed (such as palms or soles) horizontal mattress sutures should be considered for closure of gaping or high-tension wounds because they spread tension across the skin surface (Fig. 13). For this reason, horizontal mattress sutures are also useful in areas with fragile skin [6].

Vertical Mattress Suture

Like the horizontal mattress, this suture is useful in high-tension wounds. It is particularly good for injuries where skin eversion would otherwise be difficult (Fig. 14) [6].

Half-Buried Mattress Suture

Half-buried mattress sutures, (a.k.a. "corner stitches") are used to close stellate or triangular lacerations without impairing blood flow [6]. Two

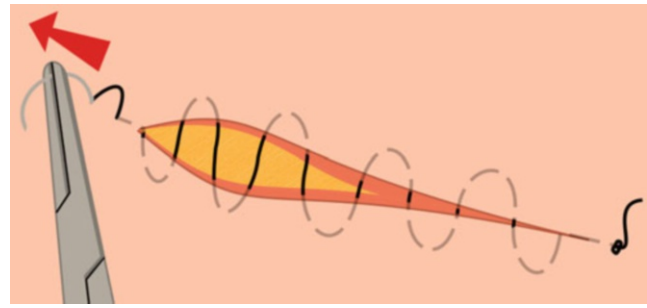

Fig. 11 Completion of intradermal closure. The needle exits the skin approximately 1 cm from the apex and is pulled taut to approximate wound edges. It is then cut 1–2 cm from the skin and the tail secured by adhesive strip

Telegram: @medical_k

www.konkur.in

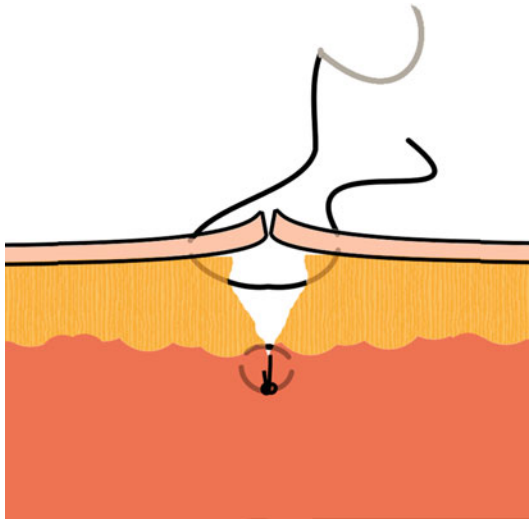

Fig. 12 Two-layer closure. A buried intradermal retention suture placed deep to a simple interrupted suture. Note the area of undermining just below the epidermis

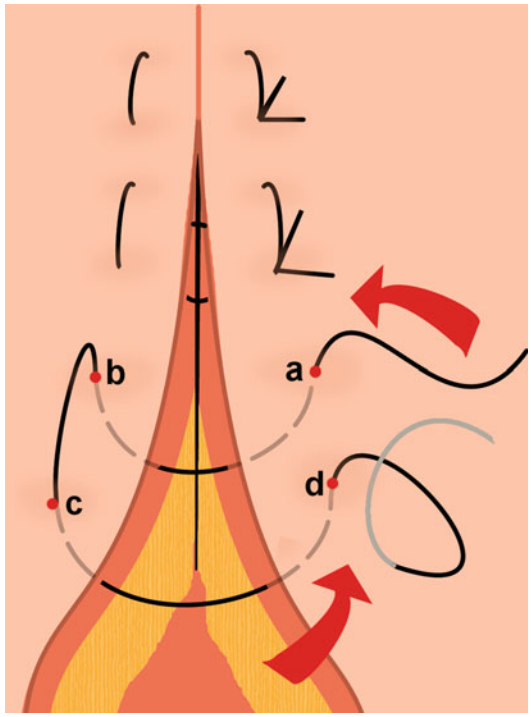

Fig. 13 Horizontal mattress suture. The needle enters 0.5–1 cm from the wound edge, passes deep into the wound and exits symmetrically at the opposite side. The needle reenters and is passed in parallel to the first suture and exits the skin. The knot is then tied in parallel with the wound

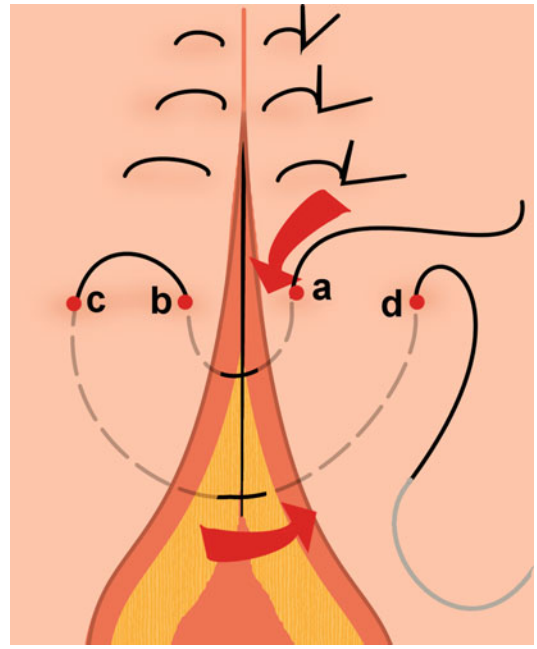

Fig. 14 Vertical mattress suture. The needle enters 0.5–1 cm from the wound edge, passes shallow and exits symmetrically at the opposite side. The needle then reenters laterally on the same side, enters deep into the wound under the previous suture and exits directly lateral to the initial entrance site. The knot is tied perpendicularly with the wound

variations of this technique are illustrated below (Figs. 15 and 16).

Dog-Ear Repair

Wound edges of unequal length (e.g., an arcuate laceration) often result in excess tissue on the longer edge at the end of the repair. Figure 17a–c demonstrates a technique for removing these "dog ears" to improve cosmetic outcomes.

Alternatives to Sutures

Sutures are not always indicated for minor lacerations. Most alternative means of wound closure take less time than suturing, and many are less painful and invasive; however, not all provide satisfactory outcomes when compared to suturing. Alternative

Telegram: @medical_k

www.konkur.in

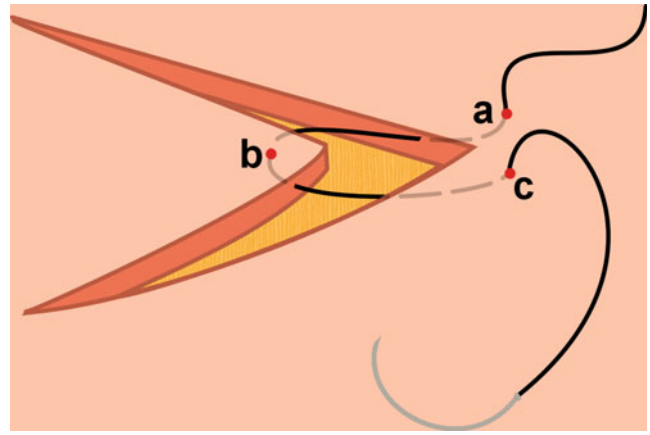

Fig. 15 V-flap repair

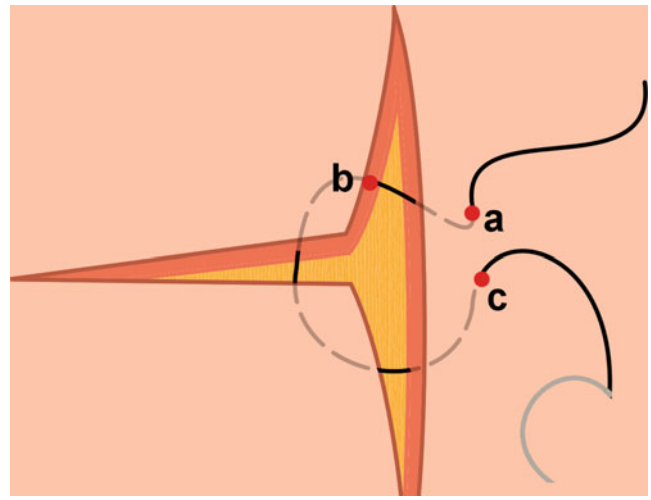

Fig. 16 T-laceration repair

wound closures fall into one of two categories: tissue adhesives and percutaneous staples.

Tissue Adhesives

The most commonly used tissue adhesives are derivatives of commercially available cyanoacrylate glues (e.g., "Krazy Glue®" or "Super Glue®") but are less histotoxic. Adhesives are sold in liquid form and come in a variety of applicators, all with the same function. Wound edges are approximated, and adhesive is applied in a thin layer and allowed to polymerize. Typically, three coats are applied creating a waterproof, antimicrobial barrier. For linear, low-tension, traumatic lacerations, cosmetic outcomes between adhesives and sutures are comparable, as are rates of infection though there is greater chance of dehiscence with adhesives [22, 23]. Sutures are more appropriate to repair infected, heavily contaminated, or devitalized wounds as well as those crossing mucocutaneous junctions and joint lines. Proper application of tissue adhesives requires the following:

Wounds should be clean, dry, and hemostatic. (Areas with high moisture such as the groin and axillae should be avoided.)

Edges should be closely approximated and in areas with minimal tension. Intradermal sutures may be used to reduce wound tension.

Telegram: @medical_k

www.konkur.in

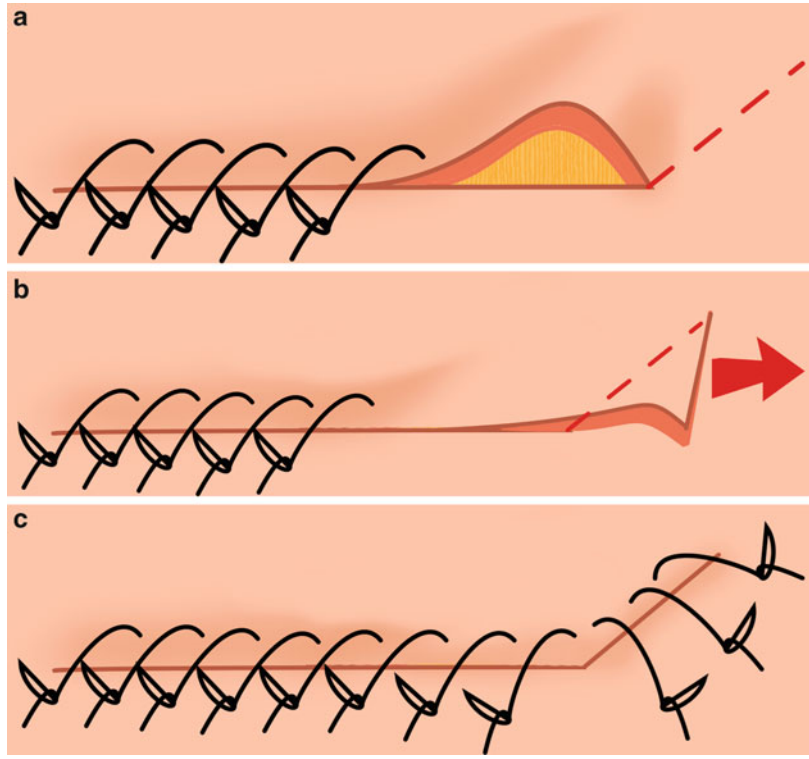

Fig. 17 Dog-ear repair 1–3. (**a**) Incise along the bulging dog ear to free the skin. (**b**) Pull freed skin edge and excise excess skin. (**c**) Close the new incision to allow skin to lie evenly

Wounds should be parallel with the floor to prevent adhesive runoff.

For scalp lacerations, the use of hair apposition (applying adhesive to the wound and then twisting together hair from opposite sides of the wound edge) provides better cosmetic outcomes than suturing with decreased pain and healing times [24]. Use of adhesives on complex lacerations (e.g., stellate, jagged edges, devitalized tissue, contaminated) is not appropriate. Care should be taken to avoid introducing adhesive into the wound as this will delay healing and may cause inflammation. Adhesive runoff into crevices or mucous membranes (especially eyes) is to be prevented. Petroleum-based products degrade adhesives, risking dehiscence. The advantages of adhesives over sutures include shortened procedure duration and decreased procedural pain.

Staples

Like tissue adhesives, staples require comparatively less time to apply than sutures. Unlike tissue adhesives, staples provide adequate support to wound edges in high-tension areas and are an appropriate alternative for more complex lacerations. Infection rates favor the use of staples, even in contaminated wounds [25, 26]. Due to concerns for poor cosmetic outcome, staples have not been compared to sutures for facial lacerations and are generally contraindicated as such; however, healing time and cosmetic outcomes with staples in comparison to sutures appear to be statistically similar for lacerations elsewhere on the body [25, 26]. Staples are safe in magnetic resonance imaging (MRI); however, they may cause interference with images in MRI and computed tomography (CT) studies. Timing of removal is the same as for sutures but requires the use of a surgical staple remover.

Adhesive Strips

Adhesive strips (typically a porous tape reinforced with polyester fibers) are most suitable for maintaining wound edge approximation after the removal of sutures in wounds that have not completely healed. They can also be used for small lacerations with very low skin tension in

Telegram: @medical_k

www.konkur.in

areas that are relatively hairless and will not become wet. Other applications are unsuitable. Generally, using a styrax resin-derived adhesive product (e.g., tincture of benzoin, mastisol) can help the strips adhere to the skin longer. As with tissue adhesives, care should be taken to avoid these adhesives from entering wounds.

Antibiotics

As a general rule, prophylactic antibiotics do not decrease rates of infection and should not be used [27]. In certain high-risk situations, however, antibiotic prophylaxis is warranted. These situations are

Patients with immunocompromise
Wounds exposing fractured bone ends, joint spaces, tendons, or cartilage wounds in which gross contamination cannot be removed
Puncture wounds (due to inability for adequate irrigation)
Crush injuries with extensive devitalized tissue, bite wounds
Wounds in the mouth
Wounds occurring >18 h prior to presentation [27]

Prophylactic antibiotics should target the most likely contaminating organisms. For most wounds, a first- generation cephalosporin provides sufficient coverage. Coverage for methicillin-resistant staphylococcus aureus (MRSA) should be considered but is not generally necessary unless the patient has a personal history of or close contact with MRSA infection. Patients with oral wounds should receive penicillin. There is a range of potential contaminants arising from specific exposures that should be considered including exposure to farm animals or marine environments and bite wounds. Specific treatments for these scenarios are discussed elsewhere [27]. Topical triple-antibiotic ointment appears to decrease infection rates in contaminated wounds compared with white petrolatum; however, these differences are not seen with sterile or clean wounds [28]. Tetanus prophylaxis should be considered as outlined in the table below (Table 3).

Table 3 Tetanus prophylaxis

	Clean, minor wounds		All other wounds	
Vaccination history	Td[a]	TIG	Td	TIG
Unknown or <3 doses	Yes	No	Yes	Yes
>3 doses	No[b]	No	No[c]	No

[a]Can use TdaP if patient is >10 years old and has not previously received TdaP
[b]Yes if >10 years since last dose
[c]Yes if >5 years since last dose

After the wound has been appropriately repaired, every effort should be taken to ensure that patients understand all instructions for wound care, monitoring for complications and, if indicated, dose, route, and timing of antibiotics. Patients should be advised to watch for signs of infection such as cloudy (purulent) drainage, increasing redness around the wound, unexpected pain, red streaks leading from the wound toward the trunk, fever, or increasing swelling of the wound >24 h after repair.

Epithelialization is not complete until after 48 h although infection from contaminants decreases significantly by 12 h post closure. The standard recommendation is to keep wounds dry and covered for the first 24 h; however, shorter times are not clearly contraindicated [29].

Wounds heal better in moist environments [29]. Patients with clean wounds closed with sutures should be advised to apply a thin layer of white petrolatum several times per day to maintain moisture. Those with contaminated wounds should do the same with triple-antibiotic ointment. Wounds closed with adhesives should not be covered in petrolatum as this may hasten breakdown of the adhesive. Application of hydrogen peroxide, iodine, or topical astringents should be discouraged as they can impair healing.

The decision of how long sutures remain in place before removal needs to balance risk of scarring with risk of wound dehiscence. There is sufficient tensile strength in a sutured wound at 7 days following a repair to safely remove sutures from most locations. Sutures in areas under higher tension (e.g., soles of feet, extensor surfaces) should stay in place for up to 14 days while those in cosmetically sensitive areas under low tension (i.e., face) should be removed after 5 days to minimize scarring. Once sutures have

Telegram: @medical_k

www.konkur.in

been removed, adhesive strips can be applied to assist with wound edge approximation [3].

Pain tolerance varies widely among individuals; however, over-the-counter analgesics should provide adequate pain control for most simple lacerations. Lacerations associated with crush injuries or with exposure of bones, tendons, joints, or nerves may require short-term opiate analgesics. The judicious use of these agents is at the prescriber's discretion, and risk for chemical dependence or abuse should be evaluated at the time of medication prescribing.

Coding and Billing

Laceration repairs are billed as simple, intermediate, or complex. Wounds may be closed with sutures, staples, or tissue adhesive. The use of adhesive strips alone does not qualify as a laceration repair. Simple repairs require standard debridement ("The removal of foreign material and/or devitalized or contaminated tissue from or adjacent to a traumatic or infected wound until surrounding healthy tissue is exposed [32]."") and no more than a single-layer closure. Intermediate wounds either require two layers of closure (subcutaneous, but not fascial, and epidermal) or, for single-layer closures, require extensive cleaning or removal of particulate contaminants. Complex wounds require "more than layered closure; scar revision, debridement (e.g., traumatic lacerations or avulsions), extensive undermining, stents, or retention sutures may be required. Necessary preparation includes creation of a defect for repairs (e.g., excision of a scar requiring a complex repair) or the debridement of complicated lacerations or avulsions [30]." In addition to these criteria, wounds are categorized by length (cm) and area of the body of the laceration. A complete list of CPT codes is beyond the scope of this chapter, but the following general categories may be useful (Table 4):

Table 4 General coding for wound care

Simple wounds	CPT 12001–12021
Intermediate wounds	CPT 12031–12057
Complex wounds	CPT 13100–13160
Wound debridement	CPT 11010–11044

Drowning	4,508

cause of death in the USA by the Centers for Disease Control's (CDC) most recent Vital Statistics Report [1]. The most common causes of injury deaths are listed in Table 1.

Many of the topics covered in this chapter may present as an impromptu emergency which a family physician may encounter while working in an emergency room (ER) or urgent care clinic or even off duty. Being familiar with these injuries illustrates how a family physician is often expected to be a "jack-of-all-trades."

Drowning and Submersion Injury

General Principles

Definition/Background

Drowning and its many associated terms have been a source of confusion in the past, and in recent years there has been an effort to be more precise in the medical use of these terms. A submersion injury is a nonspecific term that encompasses any medical sequelae related to being submersed in a liquid medium. The terms near drowning, wet drowning, or dry drowning are often misused, can be misleading, and should be avoided. Improper use of these terms also leads to difficulty collecting epidemiologic data for studies. The World Health Organization (WHO) has clearly defined drowning as "the process of experiencing respiratory impairment from submersion/immersion in liquid." Furthermore, drowning outcomes should be classified as death, morbidity, and no morbidity [2, 3]. This will be the definition used in this chapter.

Submersion involves the head being under the surface of a liquid, whereas an individual may also drown while immersed (head out) in choppy or turbulent liquid. Drowning victims suffer respiratory failure due to aspiration of water into the lungs or vocal cord spasm creating airway obstruction. Both of these pathophysiologic causes of drowning lead to hypoxia, secondary cardiac arrest, and death if the drowning process is not arrested [3]. While water is by far the most common medium to cause drowning, curious readers are encouraged to research the London Beer Flood and the Boston Molasses Disaster as examples of other fatal liquids.

Epidemiology

Drowning is a leading cause of unintentional death worldwide and is especially prevalent in children who are at the highest risk of drowning [4]. Females have much lower rates of drowning compared to age-matched males. Males have a bimodal drowning risk that sees a second spike in drowning at puberty and persists well into the 30s indicating that the risk-taking behavior of young adult males (what might be called the "show-off" stage of male life) contributes to increased drowning rates (see Fig. 1).

Approach to the Patient

History

The diagnosis of drowning is not difficult given the circumstances under which these patients present. A drowning victim will present acutely with respiratory complaints. Key historical questions to ask include the following: how long were they submersed, what were they submersed in, what resuscitation has been done prior to their arrival, and what was the temperature of the water? Inquire about symptoms of shortness of breath, chest pain, and cough.

Physical Exam

The primary survey in a drowning patient follows the basic life support (BLS) and advanced cardiac life support (ACLS) guidance discussed below. Once the patient has been resuscitated and stabilizes, the physical exam should focus on the airway and lungs as these are the most affected by drowning. Crackles, rales, and wheezing may be

Telegram: @medical_k

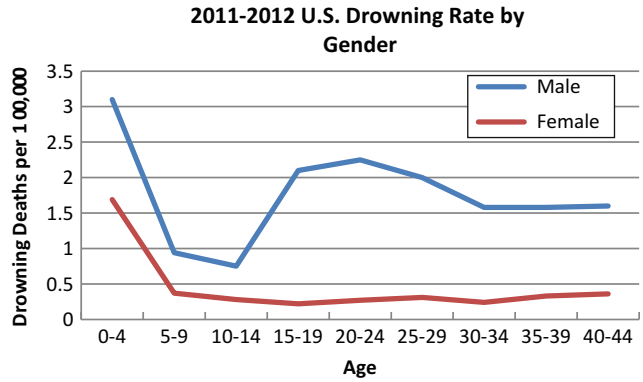

Fig. 1 US drowning death rates by age and gender, 2018 [5]

heard as the lungs often have residual edema and atelectasis due to loss of surfactant. Consider C-spine injury and immobilization if the drowning victim was in a river with white water or if they dove into shallow water [3]. Temperature is important as many drowning victims are also hypothermic due to conductive heat loss in the water. Additionally, a cold-water drowning victim can be resuscitated after extended periods of hypoxia because of decreased metabolic and oxygen requirements in hypothermia.

Treatment

First and foremost, a drowning victim needs to be removed from the water. If a patient is actively drowning, it is recommended that bystanders attempt a rescue from land or boat by throwing a flotation device or reaching with a pole or long tree branch [3, 6]. Untrained rescuers put themselves at great risk of drowning themselves if they attempt to rescue a drowning patient.

After a drowning victim is removed from the water, the patient's level of consciousness and breathing needs to be rapidly assessed. A patient that is not breathing can be assumed to have respiratory failure and possibly secondary cardiac arrest. These patients can respond to rescue breaths alone. A drowning patient that is not breathing should have their airway opened and five rescue breaths before addressing circulation [3, 6]. This is a rare exception to the current BLS algorithm which emphasizes circulation and chest compressions over airway and breathing (CAB). An unconscious patient that is breathing and has a pulse can be supported by being placed on their side in the recovery position and given supplemental oxygen, if available, while awaiting transfer to a hospital. The aspiration of fluid into the lungs washes away the surfactant [7], so patients have difficulty maintaining ventilation and may require positive pressure support to keep the alveoli open.

Evacuation to a hospital for further evaluation and monitoring should be considered in all drowning patients. Delayed respiratory failure and acute respiratory distress syndrome (ARDS) can occur as a result of surfactant loss. The severity of the patient's initial condition as well as their response to treatment will determine the length of time they need to be observed in the emergency room (ER) or as an inpatient.

Prevention

Prevention of drowning can be accomplished with adequate safety measures. Children are at the highest risk of drowning and should be the focus of prevention. Pools should be isolated with fencing (four sided and at least 4 ft. tall), and children should be supervised by an adult that is within arm's reach [8, 9]. Infants and toddlers have heads that are heavy relative to their bodies and should not have access to water in buckets or toilets because they cannot self-extricate if they fall into these head first [9]. Safety around the water should be taught at a young age, and swimming lessons are encouraged when age appropriate,

Telegram: @medical_k

www.konkur.in

potentially as early as 1 year old according to the American Academy of Pediatrics (AAP) [9]. Alcohol and drug use should be discouraged when around water as this contributes to the increased risk-taking behavior and increase in drowning fatalities seen in young men.

Barotrauma

General Principles

Definition/Background

Barotrauma is caused by the expansion and contraction of gas in confined spaces in and around the body. This property of a gas is driven by Boyle's law which states that at a constant temperature, the volume and pressure of a gas are inversely proportional. This law comes into effect when humans choose to dive underwater (increase barometric pressure) or travel to high altitudes (decrease barometric pressure). Pressure increases the further down a diver goes, causing the volume of gas to shrink. It takes only 10 m (33 ft) in depth underwater to double the barometric pressure of sea level, also referred to as 1 atmosphere absolute (ATA). Going from 1ATA to 2ATA will half the volume of a gas. Conversely, when traveling to high altitude such as in an aircraft, pressure decreases causing gas to expand; however, because water has more mass than air, it takes a much greater change in altitude to cause significant change in gas volumes. The changes in pressure and concordant changes to the volume of air confined in our body are most commonly felt as pressure in the ears [10]. Our bodies can equilibrate this pressure/volume change to some extent; however, when changes occur rapidly, such as a sudden ascent from a scuba dive or a rapid decompression of an aircraft cabin, it can cause severe or, in some cases, fatal injury.

The body has potentially confined gas in the lungs, gastrointestinal (GI) tract, middle ear, and sinuses. Rarely, teeth with a history of dental work can have confined air within a tooth. Expanding on the concepts described above, when a diver ascends from a depth of 10 m (33 ft. or 2ATA) to the surface (1ATA), the volume of air in the lungs will double. Rapid expansion of air in the lungs against a closed glottis can cause the most severe forms of barotrauma: pneumothorax, pneumomediastinum, or arterial gas embolism (AGE). For this reason, divers are taught to surface slowly while exhaling. Pneumothorax and pneumomediastinum are both caused by the expansion of gas dissecting into the pleural space or mediastinum, respectively. AGE is caused when the expanding air dissects into the pulmonary capillary beds and introduces air emboli into the circulation. Sudden cardiac arrest may occur in about 5% of AGE victims due to filling of the cardiac chambers and great vessels with air [10].

The GI tract generally has the capacity to deal with expanding gas, however, rarely; GI gas can cause intestinal rupture, especially in individuals with a history of bariatric or other gastric surgeries [10].

The middle ear is susceptible to both increased and decreased pressure, and "ear squeeze" is the most common form of barotrauma seen in divers [11]. As pressure increases, such as diving deeper underwater, the volume of gas in the middle ear decreases, and divers must Valsalva to force more air into the middle ear and maintain equilibrium. As a diver surfaces, this middle ear gas expands, and the pressure is released through the Eustachian tube. If a diver has swollen Eustachian tubes from an illness or seasonal allergies, it may lead to middle ear injury in the form of blood and engorged tissue behind the tympanic membrane (TM) or TM rupture. TM rupture causes sudden relief of pain; however, it can also cause vertigo, disorientation, and panic which are not ideal when diving. The round window of the inner ear can also rupture secondary to barotrauma; however, this is uncommon [11]. This will present with tinnitus, vertigo, and hearing loss.

The sinuses are also typically able to equilibrate pressure changes; however, in the setting of clogged sinus tracts, trapped air can cause engorgement and hemorrhage of the sinus lining. This can lead to headache and epistaxis.

Lastly, the skin may be affected by dry suits that contain trapped air or scuba masks that a diver fails to equilibrate. Many of these effects can be seen in relatively shallow water as the contraction

Telegram: @medical_k

www.konkur.in

and expansion of air are most dramatic in the first 10 m (33 ft) of diving.

Forms of barotrauma caused by waves of high and low pressure as seen with explosions and barotrauma due to mechanical ventilation are beyond the scope of this chapter. Additionally, scuba diving problems caused by dissolved gases, such as decompression sickness (DCS, aka "the bends") and nitrogen narcosis, are not covered in this chapter.

Approach to the Patient

Diagnosis

History

Patients presenting with barotrauma will have a history of recent exposure to scuba diving or, less commonly, high altitude with rapid decompression. Ask the patient how deep and how long they were down, how much diving they have been doing in the past few days, and how quickly they came up. Ask when the symptoms developed, on the descent or the ascent. Identify if they were doing scuba with compressed air or just breath holding. Identify where their symptoms are. Evaluate for symptoms of chest pain, shortness of breath, pleuritic pain, ear pain, bruising, skin crepitus, or epistaxis. Also, inquire about headache or focal neurologic findings. Gather a full medical history being sure to document any pulmonary disease, scarring, or previous diving injury as these can increase the risk of pulmonary barotrauma.

Physical Examination

A patient with suspected barotrauma has certain areas that must be examined. Look at the face and identify if there is any evidence of mask squeeze, which will be evident as ecchymosis on the face in the distribution of a diving mask and subconjunctival hemorrhages. Examine the ears for blood or fluid in the middle ear, dilated vessels in the TM, TM rupture, or small capillary rupture within the TM that have the appearance of red petechiae. Check the patient's hearing using the whisper test. Palpate the patient's frontal, maxillary, and ethmoid sinus regions for pain. Check cranial nerves, and perform a gross sensation, motor, and reflex exam to identify any focal neurologic findings. Auscultate the lungs listening of decreased lung sounds that could indicate a pneumothorax. Feel for crepitus in the neck indicative of subcutaneous air. Do a full abdominal exam, especially in patients with a history of abdominal surgeries. Examine the skin for ecchymosis due to "suit squeeze."

Laboratory and Imaging

In patients with suspected pulmonary barotrauma, obtain PA/LAT chest radiographs to identify pneumothorax or pneumomediastinum. Portable ultrasound is also a validated modality and highly sensitive and specific for detecting pneumothorax. Brain imaging with MRI is indicated in patients with suspected AGE; however, it should not delay treatment. Formal audiology testing should be considered for suspected middle or inner ear injury to document any hearing loss. Lastly, CT scan of the abdomen should be considered if there is concern for intestinal perforation.

Treatment

Treatment for barotrauma is based on the affected area. For skin barotrauma such as "mask squeeze," no specific treatment is necessary, and symptoms will resolve with time. For middle ear barotrauma, patients benefit from oral and nasal decongestants to establish normal Eustachian tube function as well as analgesia as needed. As long as no infection develops, TM rupture secondary to middle ear barotrauma will heal without complication [12]. Subspecialty consultation should be considered in patients with suspected inner ear barotrauma. Sinus barotrauma is treated with oral and nasal decongestants and pain medication as needed. GI barotrauma with perforation requires surgical evaluation.

Pulmonary barotrauma to include pneumomediastinum, pneumothorax, and AGE is managed as an emergency and should be transported without delay to an emergency room, preferably at a facility with a hyperbaric chamber. These

Telegram: @medical_k

www.konkur.in

conditions should be managed using the BLS and ACLS algorithms. The Divers Alert Network (DAN) at +1–919–684-9111 provides an international emergency hotline 24 h a day to provide first aid recommendations, evacuation assistance, and referral to the nearest hyperbaric chamber. These patients need to be monitored frequently paying close attention to respiratory status and pulse oximetry. The patient should be placed on 100% oxygen by mask if available in the prehospital setting. Administration of 100% oxygen has the intended purpose of hastening extra-alveolar gas resorption and minimizing ischemia caused by gas emboli [12]. A pneumothorax can progress to a tension pneumothorax manifested by hypotension, distended neck veins, and tracheal deviation away from the involved side. This medical emergency should be treated with urgent needle decompression of the affected side. This is accomplished using a large bore (16 gauge) needle of at least 3 in. in length inserted at the midclavicular line in the second intercostal space. Tension pneumothorax patients temporized with needle decompression will eventually need a thoracostomy tube inserted once they are at the appropriate level of care. Cases of AGE should be treated in a hyperbaric chamber as soon as possible to repressurize the patient and attempt to shrink gas emboli while the body resorbs them. Hyperbaric treatment should still be sought even if a delay in care occurs as case reports have shown improvement in patients with cerebral gas emboli as far out as 60 h [13]. Hyperbaric treatments follow the Navy treatment tables and can be repeated as necessary.

Prevention

Individuals should undergo a physical exam and clearance by a licensed provider before participating in scuba diving in order to screen for pulmonary disease such as chronic obstructive pulmonary disease (COPD) which increases the risk for pulmonary barotrauma. Prevention of barotrauma in divers can be accomplished by descending and ascending in a gradual controlled manner. A diver may need to stop changing depth to equilibrate pressure in the middle ear using a Valsalva technique as well as equilibrating the pressure within the face mask. When ascending, divers need to be sure to exhale slowly to prevent pulmonary barotrauma.

Burns

General Principles

Definition/Background

Every family physician will see patients with burns at some point in their career, and most burns may be managed on an outpatient basis. The intent of this chapter is to provide a basic understanding of burns and some clinical pearls to identify patients that can be managed in clinic and those that should see a burn specialist.

Burn terminology has changed over the years, and they are currently classified as superficial, partial, or deep. Nearly everyone has experienced a mild superficial burn at some point after being exposed to the sun for too long or touching a hot stove on accident. These burns involve the epidermis and can be extremely painful. Usually, they are self-resolving with minimal risk for complication, and lotion or aloe vera can be used to treat symptoms. The remainder of this section will cover the more severe partial- and full-thickness burns that will require more extensive medical care and knowledge.

Partial-Thickness Burns

The depth of involvement for a partial-thickness burn extends through the epidermis and some of the dermis. As the name suggests, it does not extend through the dermis into the subcutaneous layers. The partial-thickness burn is further subdivided into superficial and deep partial-thickness burns as deep partial-thickness may require surgical debridement much like full-thickness. However, burn surgeons are much more concerned with a primary care doctor's ability to differentiate between partial- and full-thickness burns. Partial-thickness burns will still have sensation on exam and are incredibly painful. The pain can be viewed as a good thing (for the provider) because

Telegram: @medical_k

www.konkur.in

it is one of the main clinical differentiators to use when diagnosing a burn as partial-thickness. Partial-thickness burns will often present with large friable bullae and blistering with surrounding erythematous, moist, weeping skin; however, blisters may be absent at initial presentation and develop later. Another physical finding is blanching erythema, which is absent in full-thickness burns.

Full-Thickness Burns

Full-thickness burns extend through the entire dermis and may involve deeper layers such as subcutaneous fat, muscle, tendon, or bone. Signs of full-thickness burns include lack of pain or sensation and a waxy, leathery, or charred appearance. The patient will also likely have some areas of partial-thickness burns around the areas of full-thickness burning.

Approach to the Patient

A detailed history of the injury needs to be taken when a burn patient initially presents. Pertinent things to ask are what caused the burn (thermal, flash, grease, chemical), when it occurred, was there a fire that may have caused airway involvement or CO poisoning, and what the patient has done to treat the burn so far. Additionally obtain date of last tetanus shot to identify those needing a booster.

Physical Examination

Burns should be managed as a trauma patient with a primary survey to evaluate for life threats followed by a secondary survey that includes a head to toe evaluation. Avoid the pitfall of focusing on the burn before managing an airway issue or active bleeding. The burn areas need to be exposed and the full extent of the burn needs to be documented. A major step is determining the percent of total body surface area (%TBSA) involved as this will play a part in referring the patient to the appropriate level of burn care and assist with resuscitation. Document the shape of the burn in cases involving children and consider child abuse. Suspicious patterns seen in child abuse include isolated lower body burns or circumferential burn to an extremity suggesting immersion into hot water, burns in the shape of an iron or curling iron, circular burns from cigarettes, or scarring from previous burns.

The burn needs to be identified as thermal or chemical as a chemical burn requires neutralization as well as proper protection for the provider. Additionally, an astute provider will need to consider compartment syndrome that can develop under full-thickness burns as a result of eschar formation and resultant loss of skin elasticity. If there is any concern for compartment syndrome, a family physician should obtain an urgent referral for surgical evaluation as these patients may require escharotomy.

Determination of Percent Total Body Surface Area (%TBSA)

Only partial- and full-thickness burns should be included in the estimation of %TBSA involved. The two classic teachings to help a provider determine %TBSA are the rule of nines and the 1% hand rule. The rule of nines divides the body into sections that are roughly 9% TBSA as seen in Fig. 2. Keep in mind that the rule of nines is not as accurate with children and infants due to their larger proportioned head and relatively smaller limbs. Another accepted method to determine % TBSA is the 1% hand rule. The palmar surface of the patient's hand represents roughly 1% TBSA for that patient. The patient can usually hold their hand close to the involved area to help to estimate the %TBSA. For burns involving most of the body, measure the unaffected area and subtract this from 100 to get %TBSA. This rule holds true in children as well.

The area involved needs to be addressed because a small localized full-thickness burn from a dropped crack pipe is not as concerning as a deep partial-thickness burn that extends over joints of the hand or involves the face (although cigarettes or crack pipes are concerning for different reasons). Most burn centers provide guidance on who should be referred for evaluation based on both %TBSA and location of the burn. Recently, a consensus statement published the following guidance on burn center referral criteria:

Telegram: @medical_k

www.konkur.in

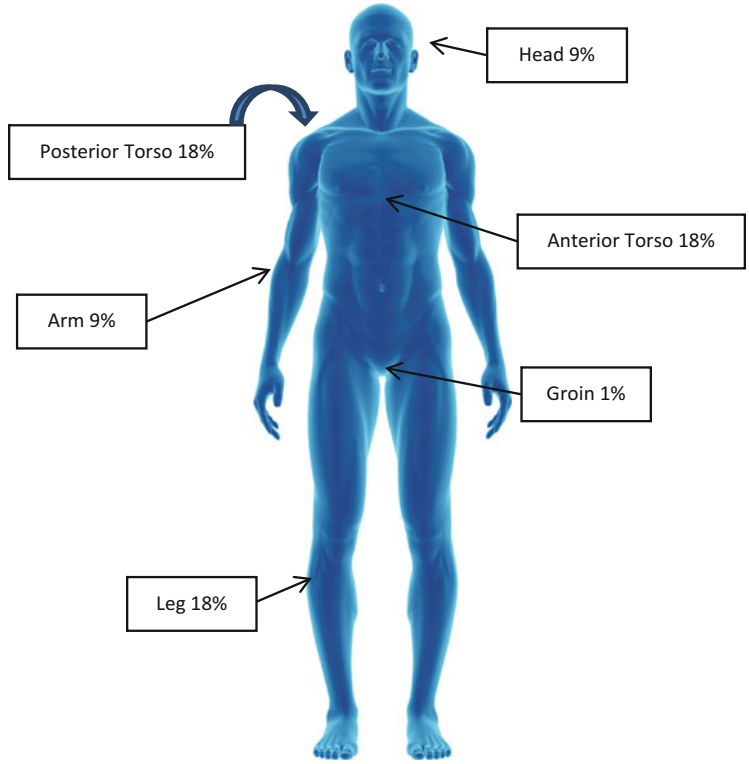

Fig. 2 Rule of nines to estimate %TBSA of partial- and full-thickness burns (Image created with adaptation of Microsoft Office© clip art)

1. Partial thickness >10% TBSA or full thickness >5% TBSA, children or elderly, or electrical/chemical/radiation
2. Smaller burns referred to outpatient burn center within a week
3. Frostbite, toxic epidermal necrolysis/Stevens-Johnson syndrome (TENS/SJS), or necrotizing fasciitis
4. Consider telemedicine if available to assist with assessment and referral guidance [14]

Treatment

Partial-Thickness Burn

The main principles for initially managing partial-thickness burns involve pain control, determination of %TBSA involved, prevention of infection, and fluid resuscitation as needed. Adequate pain control generally necessitates judicious narcotic medication and will need to be titrated to effect depending on the patient, location, and extent of the burn. Patients with extensive partial-thickness burns may need a patient controlled analgesia (PCA) to help manage their pain. Cold sterile water irrigation can be used to clean the wound once pain is controlled as cold water may reduce the depth of the burn and improve the cosmetic outcome [15]. Blisters larger than 6 mm are likely to rupture on their own and should be debrided to prevent infection and mechanical pressure on underlying tissue. Evidence suggests blisters less than 6 mm can be left intact [16]. Topical silver sulfadiazine (SSD, Silvadene) has historically been used for its antibiotic properties and to promote healing; however, a recent Cochrane review suggests higher infection rates and longer hospital stays with SSD when compared with newer synthetic or biosynthetic burn dressings or skin substitutes, of which there are numerous commercial brands [17]. SSD also requires more frequent painful dressing changes when compared to the newer occlusive dressings and as such is typically used as a last resort.

Full-Thickness Burn

Management of full-thickness burns should not be left solely to the family physician except in rare

Telegram: @medical_k

www.konkur.in

circumstances. These patients are best served by seeing a burn specialist and surgeon early in their course for possible debridement with skin grafting. The family physician will need to facilitate a consult to a burn specialist, establish pain management, document the involved area, initiate fluid resuscitation, prevent infection, and monitor for complications. Patients with large full-thickness burns will need continuous reassessment for shock and compartment syndrome while awaiting transfer to a burn center. Systemic antibiotics have not been shown to prevent infection or mortality and are currently not recommended for prophylaxis [17].

Fluid Resuscitation

Burn patients may require fluid resuscitation depending on the extent of their burns. The Parkland and modified Brooke formulas have historically been used; however, studies have indicated that these formulas lead to over-resuscitation and potentially increase morbidity and mortality [18]. More recently, burn centers and the US Army has started using the "rule of 10" to simplify fluid resuscitation. In this validated formula, the %TBSA is rounded to the nearest 10 and multiplied by 10 to give the initial fluid rate in milliliters per hour (ml/h) for an adult weighing between 40 and 80 kg. An additional 100 ml/h of fluids is recommended for every 10 kg over 80 kg the patient weighs [19]. The best marker of adequate fluid resuscitation is urine output with a goal of at least 0.5 ml/kg/h. Over-resuscitation can lead to significant peripheral edema that can complicate skin grafts, cause pulmonary edema, or cause the feared condition of abdominal compartment syndrome.

Prevention

Prevention of burns can be accomplished with education and counseling. Parents should be warned of a child's increased risk of burns and encouraged to use extra precaution when cooking or handling hot liquids around infants and children. Adolescent-age children should be supervised when around fireworks, gasoline, or open fires. Alcohol and drug use should be avoided when near open fires. Proper precautions should always be practiced when near explosive gases such as propane. Smoke detectors should be checked at least annually [15].

Swallowed Foreign Body

General Principles

Definition/Background

Ingestions of foreign bodies are most common in children who have an affinity for putting objects in their mouths. Adults with foreign body ingestion are usually food related, psychiatric, or a self-inflicted injury. Most ingested foreign bodies pass spontaneously; however, an estimated 10–20% of ingested foreign bodies require endoscopic procedure and less than 1% requires an operation [20]. Swallowed foreign bodies can be classified as blunt (coin, battery), sharp (needles, bones, razors), food bolus, or caustic/toxic (battery).

Ingestion of a foreign body may cause pain and possible airway involvement, and in severe cases, it can involve esophageal or gastrointestinal perforation. Evidence suggests that up to 50% of cases are asymptomatic in children and as such require a high level of suspicion [21]. Small batteries can cause perforation of the intestinal lumen due to their corrosive effect on mucous membranes. Magnets, especially rare-earth magnets known as BuckyBalls, can present a problem when more than one is swallowed. These strong magnets can reposition bowel and cause pressure necrosis through up to six layers of bowel wall, often requiring laparotomy to remove the magnets and repair damaged bowel [22].

Approach to the Patient

Diagnosis

History

Foreign body ingestion should be ruled out when evaluating a child with sudden onset of vomiting,

Telegram: @medical_k

www.konkur.in

stridor, or wheezing. Keeping in mind that half of these cases can be asymptomatic, a high level of suspicion should be maintained when evaluating children with decreased appetite; vague abdominal, chest, or throat pain; failure to thrive; drooling; cough; irritability; or gagging [21]. Caretakers should be questioned about the possibility of foreign body ingestion, being sure to ask about batteries, coins, or magnets that a child may have had access to. Adults with foreign body ingestions can generally provide a reliable history of what and when the ingestion occurred unless they are intoxicated or have psychiatric illness, in which case they should be approached the same as a pediatric patient.

Physical Examination

Examination should include vital signs to evaluate respiratory rate, pulse oximetry, pulse, and temperature. Tachycardia and fever can indicate potential complications of foreign body ingestion such as perforation. The oropharynx should be examined for any visible evidence of the foreign body. A standard physical exam of the neck, heart, lungs, and abdomen should be completed.

Laboratory and Imaging

Radiographs including anterior-posterior and lateral views of the neck, chest, and abdomen are the initial studies of choice to evaluate for radiopaque foreign bodies as well as evaluate for free air in the setting of perforation. CT scanning may be more sensitive for foreign bodies with one study reporting 100% sensitivity for foreign bodies including radiolucent fish bones [23]. Contrast studies such as a barium swallow are not recommended due to the risk of perforation, the risk of aspiration, and the potential to make endoscopy more challenging [24]. Unfortunately, not all foreign bodies are radiopaque, and if the level of suspicion is high enough with persistent symptoms, endoscopy should be undertaken for both diagnosis and treatment.

Treatment

The treatment of ingested foreign bodies depends on the location of the object, the type of object, and the presence of any complications. Observation is a reasonable option in some cases if the patient is asymptomatic and the object has passed the esophagus. If the object is still in the oropharynx, an attempt to remove it with Magill forceps should be done. Recommendations for endoscopic retrieval of the foreign body are outlined in Table 2. In rural or austere settings, providers have successfully removed esophageal foreign bodies, typically coins or blunt objects, by passing a Foley catheter down the esophagus, filling the bulb distal to the object, and pulling the object out in a retrograde direction. This does carry a risk of airway obstruction and should only be used as a last resort. Similarly, a bougie can be used to push a blunt object from the esophagus into the stomach as 90% of objects that make it to the stomach pass spontaneously [21]. Both of these techniques are contraindicated if the foreign body is sharp. If the object is beyond the reach of endoscopy, it should be followed with serial radiographs daily for sharp objects and weekly for blunt objects [21]. Symptoms of perforation such as fever, tachycardia, distended abdomen, free air on radiography, and/or peritoneal signs should prompt surgical consult. Patients presenting following ingestion of illicit drugs packaged into balloons

Table 2 Endoscopic management of ingested foreign bodies (Source: adapted from Ikenberry et al. [24])

Endoscopic management of ingested foreign bodies		
Emergent	Urgent	Nonurgent
Airway involvement	Blunt objects in the esophagus	Coin in the esophagus >24 h
Esophageal obstruction	Incomplete esophageal obstruction	Objects in the stomach >2.5 cm
Esophageal battery or sharp object	Sharp foreign bodies in the stomach or duodenum	Batteries in the stomach >48 h
	Magnets	

Telegram: @medical_k

www.konkur.in

should be observed as inpatients for obstruction as endoscopic removal is contraindicated for fear of rupturing the package and causing an overdose [20].

Prevention

Parents should be educated at well-child visits to keep small items, batteries, magnets, and coins out of the reach of small children.

Fishhook Removal

General Principles

Fishhooks are intended to catch fish; however, many fishermen/women have been accidentally snagged. This may present in an urgent care setting, or a family physician may be called upon to help at the scene of the injury. The hand is the most commonly affected area followed by the head and face [25]. The difficulty in removing a fishhook is due to the barb that is designed to prevent a fish from getting off the hook once it has been set (Fig. 3). When dealing with imbedded fishhooks, there are five proposed techniques for removal, each with their own risks [26]. Hooks imbedded in the eye require urgent consultation to specialized care and should not be removed by untrained individuals. To date, there have been no head-to-head comparisons between the methods described below.

Common to all methods for fishhook removal is the need for aseptic technique and local anesthesia. Infiltration of lidocaine 1% using a 25 gauge needle around the involved area or in a digital block works well to achieve adequate anesthesia. Chlorhexidine or iodine-based scrubs around the entry point are reasonable choices to clean the area prior to the procedure [27]. In austere environments, normal saline or clean tap water irrigation would be acceptable methods for cleaning and prepping the area. After the hook is removed, the puncture wound should be washed thoroughly.

Treatment

The patient's tetanus immunity status needs to be determined and appropriate prophylaxis administered after removal of the hook. Antibiotics with activity against *Aeromonas hydrophila*, such as an oral fluoroquinolone, can be considered prophylactically for contaminated deep puncture wounds [25, 26].

Removal

Retrograde pull. Barbless hooks exist and can simply be removed by pulling straight out of the skin along the path of entry (Fig. 4). Additionally, hooks that are not fully set or that are very superficial can be removed using this technique. Use

Fig. 3 Common fishhooks. The hook on the left is a treble hook. Note the barbs at the head of each hook. The far-right hook has a very small barb that might allow for retrograde pull removal

Telegram: @medical_k

www.konkur.in

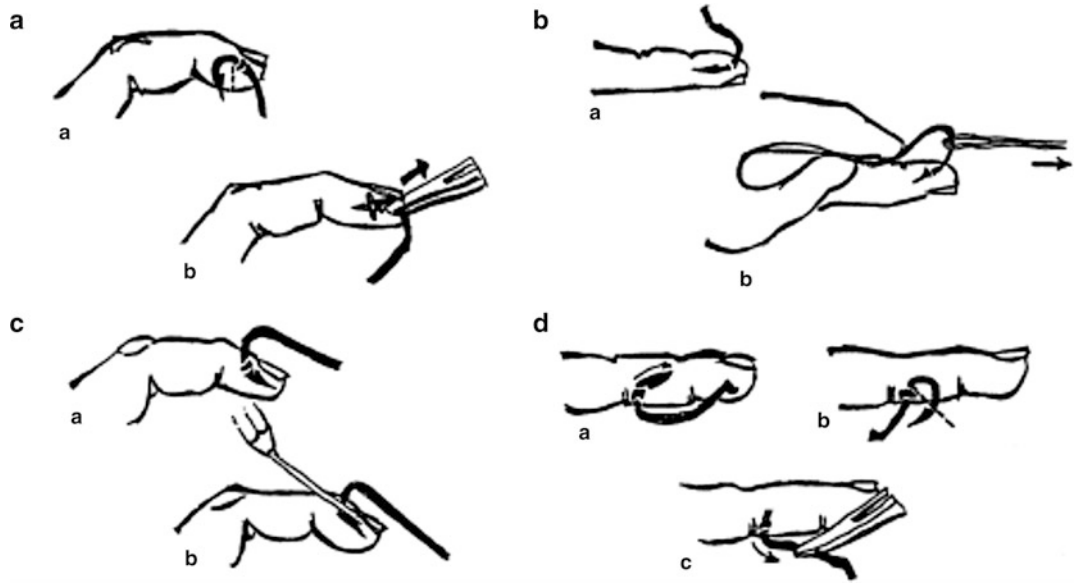

Fig. 4 Fishhook removal. (**a**) Simple retrograde pull. (**b**) String-yank technique. (**c**) Needle-cover technique. (**d**) Push and cut technique (Source: David et al. [28]. With kind permission of Springer Science and Business Media)

hemostats or needle-nose pliers to ensure positive control of the fishhook while performing this technique. This method can cause local tissue damage and is not suitable for deeply embedded hooks, hooks that are near neurovascular structures, or hooks with large or multiple barbs.

Hook depression and string pull. This technique attempts to disengage the barb by depressing the hook while simultaneously pulling the hook out using a string. The string needs to be strong enough that it will not break, and it works best if the string is wrapped around the hook at least once if not more depending on the diameter of the string. High weighted fishing line, umbilical tape, iodoform packing tape, and shoe string are examples of string that can be used. Ensure a solid grip on the string with one hand, and with the other hand, depress the eye of the hook down toward the skin. Then give a firm pull to the string in a retrograde direction to pull the hook out the way it entered the skin. This technique can cause some local tissue damage as it pulls the hook out and as such is best suited for superficial hooks that are not near nerves or vessels. Additionally, this method requires two hands and cannot be performed by an individual on themselves. Ensure eye protection is worn while attempting this method.

Needle cover. An 18 gauge needle can be utilized to cover the barb of a hook and allow it to be removed in a retrograde manner along the path of entry (Fig. 5). The needle is inserted into the skin at the site where the hook has entered and blindly follows the hook to its barb. Once the barb has been covered by the lumen of the needle, it allows the hook to be withdrawn. This technique is not ideal for deeply set hooks or hooks with large barbs.

Advance and cut. The advance and cut technique is felt to have the best initial success rate and is best suited for deeply set hooks. The downside is the additional trauma it causes. The hook is controlled with pliers or a hemostat and advanced in a direction that brings the point and barb of the hook through the skin at a different location. Once through the skin, the barb may be broken off with the pliers or the hook can be cut proximal to the barb (Fig. 6). Simply back the hook out the path of entry after removing the barb. A variation of this method involving an incision and direct visualization of the advancing hook has been used for a deep hook near the ulnar nerve and muscles of the hand [25]. This and the incision and removal technique described below are the only techniques likely to work when dealing with a hook that has

Telegram: @medical_k

www.konkur.in

Fig. 5 Needle-cover technique. Note the hook is grasped with pliers and the needle enters at same location as the hook. This is an 18 gauge needle. No pigs were harmed in the making of this image

Fig. 6 Advance and cut technique. Note the barb has been advanced through the skin and the hook will be cut proximally to the barb. No pigs were harmed in the making of this image

multiple barbs along its shaft. In this method, the hook is advanced and the end opposite the barb (where the eyelet to attach the fishing line to is located) is cut close to the skin, and the hook is advanced all the way through the skin without attempting to reverse the direction of the hook. Take note that eye protection should be worn while cutting the hook, and don't underestimate the force required to cut a hook. Powerful pliers are needed for cutting even small fishhooks.

Incision and removal. Another acceptable method for removal is to use a scalpel to make a small incision over the hook and simply remove once exposed. This method typically leaves a larger wound but can be irrigated and dressed with good healing. This method can be considered the last option if other methods fail.

Prevention

Eye protection, long sleeve clothing, and gloves may provide some protection from fishhook injuries.

Introduction

Family medicine encompasses a wide range of disease processes that can benefit from regular physical activity. In addition, the specialty serves a population that can span from elite athletes to a sedentary desk worker and from a geriatric speed walker to a peewee football player. It is important to understand how the diagnosis, management, and approach to these patients and their varying disease processes differ in the setting of exercise. This chapter examines medical conditions such as asthma, hypertension, diabetes, anemia, and various skin diseases in the setting of athletes, as well as the unique features of physical activity in several special populations.

Physical Activity Guidelines

Regular exercise has been shown to decrease the risk and improve control of many chronic diseases. Data over the last several decades clearly support the benefit of regular physical activity on improving obesity, cardiovascular disease, metabolic syndrome, bone health, and mental health. The United States Department of Health and Human Services (HHS) recently reviewed national and international data relating to physical activity and health. Their 2018 update continues to recommend the average adult engage in at least 150 min a week of moderate-intensity (brisk walking) or 75 min a week of vigorous intensity (light jogging) exercise [1]. Increased health benefits are gained when engaging in moderate-intensity physical activity for at least 300 min a week. Muscle strengthening of all major muscle groups two times per week is also encouraged [1].

Approach to the Athlete as a Patient

Exercise Physiology

Physical activity puts stress on the body that is important to understand when approaching patients that are athletes. There are two forms of exercise, anaerobic and aerobic. Anaerobic consists of short sprints and resistance training, in order to promote strength, speed, and power. Aerobic involves longer endurance training and requires more oxygen to maintain. Both forms are dependent on the ability to deliver oxygen effectively, and there are several adaptations to the cardiac, respiratory, and hematological systems that occur to optimize performance. In addition, regular exercise results in physiological adaptations of the heart that are important to understand when managing athletes.

Physical activity increases the body's metabolic demand for oxygen and energy sources. In order to meet these demands, the heart must increase cardiac output with an increase in heart rate and stroke volume. Systolic blood pressure increases with increased work, and blood is shunted from splenic and GI organs to the muscular system. In order to meet the almost exclusively aerobic metabolism of the heart, increased coronary artery perfusion is necessary and is accomplished from an increase in perfusion pressure and coronary vasodilation. Exercise also stimulates the sympathetic nervous system which results in a release of catecholamines to further increase coronary perfusion.

With regular activity, these changes that occur acutely during exercise will result in long-term changes of the cardiovascular system. Specific changes in the heart are referred to as the "athlete's heart." These changes consist of increased left

Telegram: @medical_k

www.konkur.in

ventricular mass, increased left ventricular wall thickness, and increase in left ventricular end-diastolic volume [2, 3]. Echocardiogram-based studies have also shown an increase of size in the interseptal and posterior walls of the heart as well as larger ventricular diameter [2, 3]. For reasons that are not completely understood, well-trained athletes have reduced sympathetic activity and increased parasympathetic activity resulting in baseline bradycardia. Cumulatively, these changes ultimately allow for higher stroke volumes at a lower heartrate [2].

The need for rapid exchange of oxygen and carbon dioxide during exercise results in an increase in tidal volume followed by increased respiratory rate to improve ventilation. Over time with regular physical activity, the respiratory system can adapt with an increase in maximal voluntary ventilation. Other minor changes can occur over time, but adaptations here are less than in the cardiovascular system, and it is thought that the limitations in exercise secondary to a healthy respiratory system are small [2, 3].

Oxygen delivery can also be affected by the hematologic system and the body's ability to carry and deliver oxygen to the working tissues. Red blood cells (RBC) contribute to oxygen delivery via three important mechanisms. (1) They are a source of nitric oxide which causes vasodilation and increases blood flow to tissue. (2) As the oxygen-carrying cell of the body, an increase in the number of RBC will enhance oxygen delivery. (3) The viscosity of blood, which is partially affected by RBC membranes and their deformability, affects the velocity of blood through the microvasculature. It is thought that the sequelae of exercise-dehydration, lactate production, and hypoxia-impair blood viscosity during actual episodes of exercise, ultimately results in a decrease of whole blood viscosity in the resting athlete and thus supports tissue oxygenation [4]. Anemia and sickle cell are examples of conditions that will be addressed where this oxygen delivery can be affected.

In addition to cardiac and respiratory changes, understanding the metabolic demands on a patient is important, especially when managing disease processes such as diabetes that can affect the ability to manage fuel. The main fuel source during exercise is lipid and carbohydrate breakdown from adenosine triphosphate (ATP) and glucose within the muscle. Because of this, there is an insulin-independent uptake and utilization of glucose during exercise, which can help improve overall glycemic control. Under the control of glucagon, epinephrine, and cortisol, fuel utilization will eventually shift to plasma-free fatty acids and blood glucose outside the muscle. In diabetic patients, this metabolic process can be affected due to their inability to properly regulate glucose levels.

Overtraining Syndrome

Overtraining syndrome is a diagnosis of exclusion that presents as unexplained underperformance in an athlete. It is thought to result from increased training loads without adequate recovery. The training load is affected by fatigue (both physical and mental) and recovery, including sleep, nutrition, and physical rest [5]. The exact pathogenesis of overtraining syndrome is unclear; however, there are multiple theories with alterations to the central nervous system seeming to be the leading theory, in particular, a disturbance in the hypothalamic-pituitary-axis [6].

Symptoms can be vague and broad, making a diagnosis difficult. In an attempt to simplify, symptoms can be grouped into parasympathetic (fatigue, depression, anhedonia), sympathetic (insomnia, irritability, hypertension), and other (anorexia, anxiety, ineffective sleep). Parasympathetic symptoms tend to be more common in aerobic sports, while sympathetic symptoms are more frequently seen in anaerobic sports [6].

The wide differential in symptoms requires a thorough history to include focusing on nutrition, rest, hydration, medications, mood, and exercise regimen history. When approaching diagnosis, it is important to rule out organic disease processes with objective workup being guided by specifics of the history and can include but is not limited to CBC, CMP, iron studies, CK, and thyroid studies.

Telegram: @medical_k

www.konkur.in

An important component of diagnosis seems to be mood complaints. Although subjective, mood symptoms can be easily and inexpensively obtained and tracked throughout an athletic season or a career.

Treatment focuses on controlling organic disease processes and modifying training plans to allow for appropriate recovery. If mood symptoms are a major component of the athlete's presentation, the addition of a sports psychologist or counselor would be appropriate. Treatment of mood symptoms with SSRIs could be considered; however, athletes should be informed of the potential for possible decreased performance as a side effect of the medication. As always, a risk/benefit discussion should occur with the patient [7].

Prevention is preferred and can be achieved through education and screening [8]. Athletes should be evaluated at critical points during their training, in particular during increases in training load or personal stressors. Although some screening tools have been evaluated, at this time there is not one specific tool that is recommended [9].

Chronic Disease Medical Problems

Asthma

This common medical condition affects an estimated 7.5% of the American population [10]. Symptoms including wheezing, shortness of breath, and cough are a consequence of airway hypersensitivity to various triggers resulting in bronchial spasm and inflammation. When exercise has been identified as a trigger for chronic asthmatics, it is often referred to as exercise-induced asthma (EIA). Without a diagnosis of underlying asthma, transient airway hyperresponsiveness is more appropriately classified as exercise-induced bronchospasm (EIB). The mainstay of therapy includes inhaled beta-agonist, inhaled steroids, and mast cell stabilizers. Primary care providers should be aware of which sports are associated with higher prevalence of asthma and asthma-like symptoms, identify triggers for athletes, furnish an asthma action plan (AAP), and provide rescue inhalers for all asthmatics for practices and games [11].

There are a few theories on the pathophysiology of EIB, most of which relate to the exchange of temperature and water that occurs during exercise at the bronchial epithelial level. These changes trigger an increase in cell inflammatory mediators. Additionally, exercise triggers bronchoconstriction in normal, healthy patient. Athletes with EIB have been shown to have increased levels of nitric oxide and expression of mast cell genes leading to further bronchoconstriction [4].

Breathlessness, cough, wheeze, chest tightness, and excessive mucus production within the first 5–15 min of exercise with resolution 1 h following cessation of activity are consistent with EIB; however, symptoms cannot solely be relied upon for definitive diagnosis. Pulmonary testing and clinical examination are necessary for definitive diagnosis. Spirometry is an option to assess these patients, but athletes possess a few inherent characteristics that can make result interpretation difficult. Notably, forced expiratory volume (FEV) may be increased above the normal range in conditioned athletes. Additionally, when exercise is truly the trigger, simple spirometry is not enough to induce bronchoconstriction. Patients may require additional bronco-provocation testing to elicit airway restriction occurring secondary to exercise.

To diagnose EIB, athletes need to have a $\geq$10% decline in their FEV1 values measured pre- and post-exercise (known as exercise challenge test). Methacholine challenge testing is often used in athletes exhibiting EIB symptoms with equivocal exercise challenge testing. Patients with EIB will require lower amounts of methacholine before showing an impact in FEV1. The eucapnic voluntary hyperventilation test is the gold standard set by the International Olympic Committee but is not often used in clinical practice [11].

Various environmental factors including location of training, ambient temperature, humidity, and air quality contribute greatly to the onset and perpetuation of bronchoconstriction in the athlete. Two sports disproportionally affected include swimming and cold weather athletes. Thirty percent of athletes in winter sports such as figure skating and skiing are thought to have EIB

Telegram: @medical_k

www.konkur.in

secondary to the inhalation of cold, dry air [4]. Swimmers have exhibited incidence of EIB six times greater than nonathletes and spring/summertime athletes, likely as a result of the chlorine exposure [12].

Patients with allergen-induced asthma suffer compounded risks in periods of high pollen count during seasonal and perennial pollination. Importantly, up to 40% of patients suffering from allergic rhinitis will present similar upper respiratory symptoms to asthmatics during exercising, while being asymptomatic at rest [13].

Management of EIB/EIA symptoms begins with prevention when possible. Correctly identifying symptoms of allergic rhinitis and treating with a combination of intranasal corticosteroids and antihistamines reduces the concomitant effect in chronic asthmatics. For winter athletes, breathing through a scarf can help. Education on proper warm-up including 15-min moderate warm-up period followed by a 15-min rest period which can induce a refractory period.

Pharmacologic intervention should be considered with failure of conservative measures. First-line therapy is use of a short-acting beta-agonist 15 min prior to exercise. Daily inhaled corticosteroids (ICS), leukotriene antagonists, or mast-cell stabilizing agents are second line. The Global Initiative for Asthma (GINA) recently released a major change in recommendations for mild asthma. In this, monotherapy with short-acting bronchodilators (SABA) is no longer recommended as initial treatment. Instead, GINA recommends that all adults and adolescents with any form of asthma receive ICS-containing controller treatment for maintenance and exacerbation therapy [14]. Given the significant paradigm shift with these new recommendations, further research is needed to assess the efficacy of this approach in patients with mild asthma and EIB/EIA.

Cardiac

Hypertrophic cardiomyopathy (HCM) represents the most common genetic cardiovascular disorder with an estimated prevalence of 1:500 of the general population. Common symptoms include shortness of breath (particularly with exertion), chest pain, palpitations, orthostasis, presyncope, and syncope. Many patients remain asymptomatic with a benign natural history; unfortunately, sudden cardiac arrest/death can be the first manifestation in otherwise asymptomatic young people. HCM has been positively identified in well over a third of cases (36%) of SCD in athletes under the age of 30 and cited as a possible cause in another 8%. Symptoms vary widely between individuals, even those in the same family. Differentiating between HCM and physiologic nonpathological left ventricular (LV) hypertrophy associated with extensive training ("athlete's heart") can be difficult. Definitive diagnosis has important implications as HCM will likely lead to disqualification from competition to minimize risk.

Identification of this disorder falls to the family medicine physician using specific criteria and disease-specific questions noted during the patient reported history and pre-participation physical exam. Recent American Heart Association/American Cardiology Association recommendations on pre-participation cardiovascular screening endorse a strategy of a focused medical history and physical examination [15]. This approach relies on the primary care provider to perform adequate, standardized exams that are of low-cost to the patient; *The Pre-Participation Physical Evaluation Monograph 5th Edition* is a wonderful resource to assist primary care providers in this endeavor [16].

Major risk factors for HCM include prior cardiac arrest, unexplained syncope, a family history of SCD, left ventricular wall thickness >30 mm, an abnormal BP response to exercise, and history of non-sustained spontaneous ventricular tachycardia [17]. Some examples of disease-specific questions are:

1. Has anyone in your family died suddenly for unexplained reasons before age 50?
2. Have you ever experienced chest pressure or pain while exercising?
3. Have you ever been diagnosed with a heart murmur?
4. Have you ever had cardiac imaging done?
5. Have you ever passed out or nearly passed out during or after exercise?

Telegram: @medical_k

www.konkur.in

The physical exam for HCM has been an insensitive screening tool for sole identification. This is in part due to most patients with HCM presenting with a nonobstructive disease and unremarkable cardiac exam [17]. Patients presenting with left ventricular outflow tract obstruction most commonly exhibit a late-systolic ejection murmur best appreciated at the left sternal border. This murmur commonly radiates to the aortic and mitral posts, typically heard best when the patient stands or performs the Valsalva maneuver which decreases preload to the heart.

If HCM is suspected based on patient history, physical exam, or a combination of the two, referral to a cardiologist is indicated. An in-office EKG should be considered for athletes whom you suspect to have cardiac dysfunction. Advanced imaging of cardiac function by echocardiogram and/or cardiac MRI is the gold standard for diagnosis of HCM, which is exhibited by asymmetric LV wall hypertrophy (wall thickness $\geq$13 mm) without chamber dilation. Mild concentric LV hypertrophy (13–14 mm) may be present in healthy individuals who exercise strenuously and indicative for "athlete's heart" [18]. Anterior septum thickening and abnormal systolic motion of the mitral valve may be evident as well. Following identification, disease management is tailored around disease symptoms, risk, and complications becoming largely empiric as no large-scale studies for the medical management of HCM exist to date.

Diabetes

Diabetes is a common disease that affects roughly 15% of the adult population in America [19]. It has been well established that regular physical activity can help prevent the development of diabetes as well as serve to improve glycemic control. Regular physical activity reduces the risk of cardiac death of diabetic patients by 30–40% [1]. In addition, an active lifestyle assists in reducing blood pressure, body weight, cholesterol, and A1c in diabetic patients independent of diet. HHS Guidelines recommend at least 150–300 min a week of moderate-intensity, or 75–150 min of vigorous activity per week. Preferably, aerobic activity should be spread throughout the week. The greater amount of aerobic activity, the greater the health effects seen [1]. With the increased risk for coronary artery disease in the diabetic population, it is important to consider cardiac screening in these patients; however, the benefits of regular exercise far outweigh the cardiac risks.

In type 1 diabetics, there are three considerations when participating in athletics. First, exercise lowers blood glucose independent of insulin, which puts the patient at risk for hypoglycemic events. Second, on the other hand, exercise stimulates the sympathetic nervous system and release of stress hormones such as cortisol and epinephrine and can result in hyperglycemia. This, coupled with the possibility of low insulin levels prior to starting exercise, puts the type 1 diabetes at increased risk of ketogenesis. The final concern for these athletes is delayed hypoglycemia. Tissue insulin sensitivity is increased for 7–11 h post exercise. If carbohydrates are not replaced, the athlete is at risk for hypoglycemic events for up to 12 h after finishing exercise [20, 21].

Several recommendations can be made to type 1 diabetes to avoid these complications. Adjustments to carbohydrate intake rather than insulin dosing are associated with fewer exercise-related complications [20, 21]. Athletes should check their blood sugar prior to exercise, and if less than 150 mg/dL, they should supplement with a high-carbohydrate snack [21]. Due to risk of ketogenesis, vigorous physical activity should be avoided in patients with hyperglycemia $\geq$250 mg/dL [22]. For endurance athletes, training sessions longer than 1 h should consider carbohydrate supplementation [20, 21]. All athletes should have a post-exercise snack in order to combat the delayed hypoglycemia risk as well as frequent blood sugar checks every few hours in that post exercise period [20].

The insulin pump is widely accepted tool for managing type 1 diabetes. In athletes well versed in managing their pump, this is a good way to minimize glycemic fluctuation. It can also be titrated to allow for regular exercise sessions.

Hematological Disease

Anemias

As discussed above, blood and its ability to transport oxygen are an important part of an athlete's performance ability. A phenomenon known as "sports anemia" occurs most commonly in endurance athletes. Repetitive long workouts cause hemoconcentration from dehydration which leads to an overshoot of plasma expansion post-exercise and Hgb levels up to 1.5 g/dL below normal [23]. Sports anemia is exceedingly uncommon in non-endurance athletes. Diagnosis can be tested by stopping workouts and assessing Hgb values approximately several days later. The athlete's Hgb should normalize within 5 days [23] if present. As this is an physiologic, adaptive response, no treatment course needs to be pursued.

Much like the general population, iron deficiency is the most common form of anemia seen in athletes. The rate of occurrence is no different than the general population. Iron deficiency anemia (IDA) can occur in up to 20% of menstruating females, 6% of postmenopausal women, and 4% of male athletes, respectively [23]. Etiologies for IDA include GI bleeding, NSAID use, and menstruation in females. Sport-specific causes such as hematuria, foot-strike destruction, and iron loss from sweating have been described in the sports literature, but should be low on the differential and diagnoses of exclusion [23]. Iron deficiency anemia should be worked up and treated similarly to iron deficiency anemia in the general population.

Recent studies have examined Iron Deficiency Non-Anemia (IDNA) where ferritin levels are low but true anemia is not present. Experimental treatments with both oral and IV iron supplementation have been examined for their effects on fatigue and potential benefits for VO2 Max. The evidence for these practices is currently inconclusive [24]. Given the controversial nature of this therapy, athletes thought to have IDNA should be referred to a sports specialist for evaluation and management.

Macrocytic and hemolytic anemias in the athlete have similar etiologies and treatment to that of the general population. The phenomenon of foot-strike anemia (also thought to be a cause of microcytic anemia), mentioned above, is a rare and often clinically insignificant disorder that occurs in endurance athletes from repetitive heel strike, muscle use, or cardiac valve turbulence and rarely requires treatment [25].

Hemoglobinopathies

Thalassemia results from the deletion or mutation of genes responsible for the alpha and beta chains that make up hemoglobin. Anywhere from one to four of the chains can be affected and range from asymptomatic to death in utero. Sickle cell trait (SCT) occurs when an individual is heterozygous for sickle hemoglobin (HgbAS). Under normal physiological conditions, SCT is typically benign and easily controlled; however, excessive heat, high-altitude, and intense training can result in sickling of RBCs in athletes within minutes. The exact mechanism causing the sickling is not completely understood, but it causes an increased risks of medical complications such as splenic infarction, hematuria, exertional rhabdomyolysis, and sudden death in SCT athletes. In studies of military personnel, the risk of exercise-related death in warfighters with SCT is estimated to be approximately 40 times higher than those without. Although absolute risk remains small, SCT is the leading cause of death in young African Americans in military basic training and civilian organized sports [26].

In all athletes, SCT should be a significant topic for counseling during pre-participation physical examinations. Best practice guidelines produced by the National Collegiate Athletic Association (NCAA) states that all college athletes in the United States are required to know and report their sickle cell status or sign a waiver after education of potential risks related to SCT [27]. In athletes with known SCT, appropriate precautions should be taken with regards to training and competing. The athlete should be conscientious of staying well hydrated and tapering workouts to not overexert themselves, especially in hot and high-altitude conditions.

Skin

Tinea Corporis Gladiatorum

Tinea corporis gladiatorum (TC) is a fungal rash caused by *Trichophyton tonsurans* most often seen in contact sports, especially wrestling [28]. It is transmitted by skin to surface contact and has been thought to be transmitted by asymptomatic tinea capitis. TC presents as well-defined, erythematous, scaling plaques most commonly on the head, neck, and upper extremities. It often is not as ring-shaped as typical tinea corporis. Diagnosis can be done via a KOH prep and presence of hyphae but is more often simply clinical [29].

Treatment can be either topical or oral. Topical application of clotrimazole twice daily or oral fluconazole 200 mg weekly is recommended treatment. Athletes can return to practice and competition after a minimum of 72 h of treatment. The most important aspect of treatment is prevention. Discouragement of equipment sharing among the athletes and encouragement of frequent cleaning of personal equipment are effective prevention strategies.

Herpes Gladiatorum

Herpes gladiatorum is a common rash in athletes with close physical contact such as wrestler and rugby players. This non-genital herpes simplex virus infection is commonly seen on the torso, though can present wherever skin to skin contact occurs. Presentations typically consist of erythematous papular and vesicular eruptions. Although this diagnosis is usually made clinically, definitive diagnosis can be made via viral culture or PCR testing from open ulcers. Given its limited sensitivity and specificity, the Tzanck test has fallen out of failure.

Treatment of herpes gladiatorum is initially aimed at prevention of spread. Athletic participants in wrestling and rugby should be screened for active, open lesions with prompt removal of affected athletes from participation if identified. Treatment consists of antiviral therapy, such as acyclovir or valacyclovir. For primary cases, the athlete needs to be treated for a minimum of 10 days before allowed to return to competition. If systemic signs or symptoms present during the initial outbreak, removal from competition should be extended to 2 weeks. For subsequent outbreaks, 5 days of treatment, all lesions being dried and scabbed over, and no new lesions in the past 48 h are requirements for return to participation. Antiviral prophylaxis has become a common practice in higher levels of wrestling competition.

Tinea Pedis

Another common fungal infection among all athletes is tinea pedis caused by *T. rubrum*, *T. mentagrophytes*, and *T. interdigitalis*. Walking barefoot on communal floors, wearing occlusive footwear, sweating excessively, and poor circulation all predispose athletes to this infection. Like tinea corporis, the diagnosis can be made clinically. KOH prep may be needed as tinea pedis can present similarly to other dermatological disorders such as contact dermatitis, foot eczema, psoriasis, or juvenile plantar dermatosis [29]. Over-the-counter antifungals are a reasonable first line for treatment followed by prescription topical antifungals. These should be applied twice daily for 2–4 weeks. If the rash is still resistant, then oral agents such as terbinafine (250 mg daily for 2–6 weeks) or itraconazole (200 mg daily for 2–12 weeks) should be tried.

Staphylococcus and *Streptococcus*

Staphylococcus and *Streptococcus* can cause two common rashes among athletes: impetigo and folliculitis. These are most common in contact sports such as rugby, football, and wrestlers. Impetigo is due to localized, superficial infections causing well-defined, erythematous, yellow, crusted plaques. Impetigo can be spread through skin to skin contact through breaks in the skin or even atraumatic skin [30]. Folliculitis occurs when these bacteria infect the athlete's follicles. The hair follicles become erythematous and can have

Telegram: @medical_k

www.konkur.in

pustular drainage. The rash tends to be itchy and if deeper also painful.

Topical Mupirocin can be used, but with extensive disease, treatment with penicillin or cephalosporin is recommended for a week. If MRSA infection is suspected, treatment should be considered with doxycycline or sulfamethoxazole/trimethoprim [30]. The athlete should be removed from participation for a minimum of 72 h of treatment. In team sports with multiple infections, it is important to consider the possibility of nasal carrying of *Staphylococcus*. Mupirocin ointment applied to both nares twice daily for 1 week should clear *Staphylococcus* carriage for about 6 months.

Nail Dystrophies

Trauma and pressure to the nail plate and periungual area can result in changes that often look similar to onychomycosis. Runners develop jogger's toe from repetitive thrusting of the toe into the shoe that results in a subungual hematoma. The toenail can become thickened, ridged, and discolored from this repetitive trauma. Sports with quick stops and starts such as racquet sports and basketball can result in similar destruction of the nail bed. There is typically no need for treatment, and the nail can be watched for changes that would point toward an alternative diagnosis such as fungal infection or melanoma. Occasionally, the pain from these nail changes will inhibit the athlete's ability to effectively participate. In these instances, evacuation of subungual hematoma by drilling a hole through the nail bed or complete nail removal to address nail bed changes are reasonable treatment options [30]. If pain is severe, one must further consider whether imaging is needed to evaluate for underlying fracture [30].

Talon Noir/Mogul's Palm

Talon noir and Mogul's palm are black macules that result from intraepidermal bleeding as a result of shearing forces. Talon noir occurs on the soles and is most commonly seen in basketball players [31]. Mogul's palm occurs on the hands of skiers from repetitive pole planting. These lesions can be confused with melanoma, and if concern exists, a biopsy should be done. Otherwise, paring down the lesion with a surgical blade can remove the old hemorrhage [30]. If desired, patients prone to these lesions can wear additional padding to aid in prevention [30].

Special Populations

For a family physician, the patient population ranges across all age groups, genders, and demographics. As such, it is important to highlight some of the specific considerations for athletes in these groups.

Women

There are gender-specific benefits to exercise that the family physician should know. Weight-bearing activity can increase bone mineral density and decrease the risks of fracture in postmenopausal women [32]. Studies have shown regular exercise to decrease prolactin and progesterone levels resulting in decreased fatigue, enhanced concentration, and improved premenstrual symptoms of low back pain, pelvic pain, anxiety, and depression [33, 34].

As female participation in sports has increased, a set of health problems that is increasingly prevalent in, but not exclusive to female athletes, has emerged. In 1992 the American College of Sports Medicine first described the female athlete triad as disordered eating, amenorrhea, and osteoporosis. This definition was updated in 2007 to include dysfunction related to energy availability, menstrual function, and bone mineral density. Then in 2014 and most recently in 2018, this topic was expanded further by the International Olympic Committee to be described as relative energy deficiency in sport, or RED-S [35]. RED-S refers to "impaired physiological functioning caused by relative energy deficiency and includes, but is not limited to, impairments of metabolic rate, menstrual function, bone health, immunity, protein

Telegram: @medical_k

www.konkur.in

synthesis, and cardiovascular health" [35]. The main focus underlying this disorder is a mismatch between an athletes' energy expenditure with activity compared to their intake. Low energy availability can be the result of disordered eating in the form of anorexia or bulimia as well as inadvertent decrease in energy intake or failure to increase caloric intake to match the athlete's training program [36]. This low energy availability coupled with the physical and mental stress of training can lead to menstrual irregularity [36]. Finally, this low energy state results in the decrease in insulin growth factor and hypoestrogen leading to low bone mineral density [36].

In 2018, the IOC advised that all physicians caring for athletes need to be aware of RED-S and its associated complications. Although no ideal screening tool exists for the disorder, physicians must be aware of signs and symptoms associated with RED-S including recent weight loss, recent training increases with fuel mismatch, lack of normal growth or development in adolescents, recurrent bony or soft tissue injuries, illnesses, decreased performance, mood changes, and menstrual dysfunction [35]. Ideally, physicians can help educate patients and coaching staffs regarding nutrition intake and expenditure risks, as well as treat patients suffering from complications of RED-S. Treatment should be multidisciplinary and include a physician, dietitian, and often a mental health professional. The focus of treatment is to improve energy balance through improved intake and controlled output in the athlete's training program [36]. Other treatments can include pharmacological therapies such as SSRIs and hormone replacement, but this should be left to the management of specialists.

Pregnancy is another common area in which questions relating to exercise can arise for the family physician. Exercise in pregnancy provides many benefits to include lower risk of gestational diabetes, enhanced sleep, reduced loss of BMD, reduced physical discomfort, maintenance of appropriate weight, improved mental health, and higher APGAR scores [37, 38]. The American College of Obstetricians and Gynecologists (ACOG) found that that there were no reports of exercise-induced hyperthermia leading to teratogenic affects. ACOG's current recommendations in regard to exercise during pregnancy are as follows [39]:

1. Achieve regular moderate-intensity exercise for at least 20–30 min or more on most days of the week.
2. Avoid exercise requiring the supine position after 12 weeks' gestation due to increased risk of obstruction of venous return.
3. Avoid activities that carry with them a risk of abdominal trauma.
4. Avoid physical activity above 6,000 ft.

In summary, women who were previously healthy prior to pregnancy can continue with their training programs during pregnancy. Women with significant cardiac or respiratory disease or complications with the pregnancy should be monitored carefully during exercise [39].

Elderly

The age definition of "elderly" can vary depending on the sport and required skill set. For sports requiring endurance and flexibility, separate age categories can start as early as 19 years. For those demanding a specific skill set, age categories often start at 50 years. For the general public, geriatric classification starts at age 65 with 65–75 being young old, 75–85 being middle old, and over age 85 being very old [40]. The health benefits of physical activity in reducing cardiovascular events, diabetes, and improving bone health continue through the lifetime, and as such elderly patients should be encouraged to continue to be physically active. It is important however to understand some of the physiologic changes that occur and should be considered when treating elderly athletes.

As a person ages, cardiovascular function declines resulting in a decrease in maximal heart rate, impaired compliance in diastole, incomplete emptying in systole, and reduced inotropic response to sympathetic input [41]. This can affect the elderly's activity tolerance level as well as put them at increased risk for arrhythmias and heart failure. The other major physiologic change in the elderly is sarcopenia – or a decrease in muscle

Telegram: @medical_k

www.konkur.in

mass, strength, and endurance – which can lead to a decline in functional ability and flexibility putting the elderly at an increased risk of injury and falls [32, 41].

Older adults should strive for the same multimodal exercise goals as stated above for all adults, but with special interest placed on balance training. Family physicians should assist their geriatric patients in understanding how their chronic medical conditions affect their ability to participate in regular activity and modify accordingly as their abilities allow. Ultimately, a simple goal of being more active than sedentary throughout the day is an easy one to advocate to your patients [1].

Pediatrics

The CDC estimates that 18% of children 6–11 years old and 21% of adolescents aged 12–19 were obese [42]. It is now a public health concern to encourage children and adolescents to participate in physical activity in a healthy and beneficial way. It is important to be aware of some of the medical considerations for this younger population, as well as the recommendations for appropriate physical activity. Children should participate in at least 60 min of vigorous aerobic activity daily. Resistance training such as tug of war, rope climbing, or push-ups should be incorporated three nonconsecutive days per week. Preschool children's growth and development is enhanced by regular, daily physical activity [1]. The benefits of following these recommendations include healthy body composition, increased development of bone mass, improved self-esteem, and decrease in anxiety and depression [43].

Early sports specialization has become topic of interest in the pediatric population. Early sports specialization is commonly defined as the participation in one sport at the expense of participation in other sports [44]. Over the past 20 years or so, there has been a shift in the focus of youth sports from a recreational, learning environment to one of competition and dedicated training in order to achieve excellence, scholarships, and even future careers as a professional athlete [45]. Research has found that increased sports specialization from a young age may bring with it an increased risk of musculoskeletal injury, especially with regard to chronic overuse injuries. It may be beneficial to encourage athletes to participate in various sports and activities for both development, opportunities, and to decrease injury risk [46].

In order to participate in sports, most states and sports governing bodies require a pre-participation evaluation (PPE) . In the past, PPEs were thought of as a brief evaluation in the office, often by a provider unknown to the athlete, where one could quickly go to check a box to play their desired sport. Recent changes to the PPE guidelines promote a more well child/adolescent visit approach to these encounters [16]. Ideally, the examination should be performed in the patient's medical home by their primary care physician and if able, as part of the routine wellness visit. The visit should go beyond the standard cardiac and musculoskeletal screening but now include evaluations of mental health, risky behavior screening and counseling, and promotion of healthy lifestyle. The pre-participation evaluation may be the only opportunity for a pediatric athlete to visit a doctor's office, and as such, it is an excellent chance to evaluate, teach, and treat this patient population [16].

Hypertension in the pediatric population is defined by a blood pressure that is $\geq$95th percentile for age, gender, and height, or $\geq$130/80 on three separate measurements [16]. Due to risks involved, these athletes should avoid power lifting and body building until successfully treated [16].

Mononucleosis is a common virus in the adolescent population. Athletes should be removed from activity for at least 3 weeks in order to prevent complications from splenomegaly. The restriction involves all activity, not just contact activities. Return to sport/activity is usually gradual as the patient works back into physical fitness.

Transgender

Transgender individuals identify as a different gender than their sex designation assigned at birth [47]. In 2017, the estimated prevalence of transgender individuals in the United States was 390 in 100,000 [48]. Transgender individuals are

Telegram: @medical_k

www.konkur.in

very frequently cared for by the family physician, and as such, it is important for the physician to help with their cares as a transgender athlete. This includes but is not limited to a focus on the athlete's physical and cardiovascular health, endocrine/hormonal treatments, mental health, bone health, and even being aware of surgeries they have had or plan on having in the future.

Sports and competitions are often divided by sex, but as transgender athletes become increasingly prevalent in the sports arena, controversy exists for their participation [16]. Recent policy from the IOC in February of 2019 attempted to establish guidelines for transgender participation [49]. These policies are new and constantly under scrutiny, controversy, and need of further refinement. Transgender athletes have important and difficult considerations to tackle in the sporting arena. Yet promoting these athletes' health and their ability to participate equally in sport and competition should be a priority for the family physician [50].

Introduction

With the continued increase in sports participation, musculoskeletal concerns account for a significant percentage of patient encounters within family medicine. High school athletics alone account for over two million injuries, half a million physician visits, and 30,000 hospitalizations annually [1]. Growing sports specializations within adolescents has led to an increase in overuse injuries. Adults are not immune to athletic injuries. Weekend warriors commonly experience ankle injuries, knee injuries, joint dislocations, and overuse injuries in attempts to stay active. Injuries occur after an insult to bone or soft tissue structures (muscle, ligament, or tendon) producing disruption in the normal anatomy. Acute injuries usually result secondary to trauma. In contrast, chronic injuries occur as the result of overuse, usually with associated biomechanical deficiencies. Lack of appropriate rehabilitation to injuries can lead to increased injury risk in the future. While the majority of sports-related injuries occur to the axial skeleton, concussions are becoming a growing concern within our society. This chapter will discuss both general treatment options and treatment for specific athletic injuries.

General Injury Management

The initial management of sports-related injuries involves decreasing inflammation, addressing pain control, and stabilizing surrounding tissues to prevent additional injury. Inflammation can be reduced with rest, ice, compression, and elevation (RICE). Nonsteroidal anti-inflammatory drugs (NSAIDs) can assist in both reduction of inflammation and pain control. Pain control can also be accomplished with immobilization, acetaminophen, muscle relaxants, or opioids. Opioids should be reserved for patients in severe pain

Telegram: @medical_k

www.konkur.in

after significant injuries such as joint dislocations and fractures that are not responding to the more conservative treatment options outlined above. Imaging of the injured area is usually required. Options include X-rays, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound (US). Imaging will alert the physician if anatomical alignment needs to be obtained through reduction of the affected joint or bone. After initial management with immobilization, most patients require some form of physical therapy to address underlying muscle flexibility, muscle strength, and biomechanical deficiencies. Physical therapy is important not only to treat deficiencies resulting from the injury but also address biomechanical issues that increase the risk of future injury. Unfortunately, some injuries cannot be managed conservatively, and referral for operative management is required for definitive treatment.

General Fracture Management

A large percentage of nonoperative fractures can be managed by family physicians. Physical examination at the initial visit should assess for neurovascular complications and associated soft tissue injuries; specific anatomic findings and examination findings will be addressed later in this chapter. All fractures need to be visualized in at least two different views on plain films to ensure appropriate anatomical alignment. If clinical suspicion for a fracture is high but plain films are negative, additional imaging with CT or MRI could be warranted. All fractures should be assessed for closed/open status, fracture pattern, displacement, angulation, and rotation in order to provide appropriate care.

The healing of fractures occurs over a several month period. The initial inflammatory phase occurs immediately after injury with recruitment of inflammatory cells in formation of a hematoma. Osteoblastic cells are then recruited and responsible for the initial remodeling of the injury site. Within the first 2–3 weeks, a soft callus is formed signifying the arrival of osteoclastic cells. By weeks 6–8 post injury, a hard callus replaces the soft callus; this signifies clinical union. It is important to remember that this initial callus is weaker than normal bone. Final bone strength and radiographic resolution occur 3–6 months after initial injury. Multiple factors including smoking, diabetes, and chronic oral steroid usage are can inhibit bone healing. NSAID usage, especially during the first 2–3 weeks of healing, disrupts the recruitment of inflammatory cells and the initiation of the healing process. Judicious usage of NSAIDs is advised in all fractures, with focus of pain control with acetaminophen.

Immobilization via splinting or casting throughout healing is critical. Any fracture that has significant displacement or angulation requires reduction prior to immobilization. Postreduction images and neurovascular examination are essential. Surgery is indicated if misalignment or neurovascular complications are present or if reduction cannot be maintained. If clinical suspicion for a fracture is high but radiographs are negative, immobilize the area as if a fracture is present, and then reevaluate the patient in 10–14 days with repeat imaging. Splinting should always occur for the first 3–5 days after initial injury; circumferential casting can be applied after this time for a more permanent immobilization solution. Casting a patient during the acute inflammatory process can lead to significant morbidity through compartment syndrome or improper cast fitting after swelling resolution. Appropriate cast care instructions should be given to patients. Specific treatment management of common fractures will be addressed later in this chapter. *Fracture Management for Primary Care* [2] and *Handbook of Fractures* [3] are both excellent resources for primary care physicians who provide fracture care.

Concussion

Introduction

Concussions are defined as a traumatically induced transient disturbance of brain function resulting from either direct trauma or indirect forces to the face, head, or neck [4]. In the United

Telegram: @medical_k

www.konkur.in

States, over 1 million pediatric sports-related concussions occur yearly: 400,000 of these in high school athletes [5]. Symptom presentation can include a wide variety of complaints including headache, balance disturbances, retrograde amnesia, nausea, photophobia, phonophobia, visual tracking issues, slow cognition, mood changes, sleep disorders, concentration issues, confusion, dizziness, and possible loss of consciousness. Typically, symptoms begin immediately after the injury but can be delayed for up to 72 h. For adult patients, the majority of symptoms will resolve spontaneously within 14 days of injury; however, pediatric and adolescent patients may have prolonged symptoms lasting up to 4 weeks [5].

Physical Exam

Sideline evaluation should include a thorough neurological examination and cognitive evaluation in a distraction free environment. The SCAT5 [6] and Child SCAT5 [7] assessment tools are free resources to assist in initial and follow-up evaluation of concussed individuals. These tools include a brief neurological examination, a symptom checklist, a brief cognitive assessment, and a balance assessment. In the acute setting it is also important to evaluate for associated cervical spine injuries by performing cervical palpation and a range of motion examination. If at any time there is a change in the patient's neurologic status, personality, or an acute worsening of headache, this should signify the need for additional evaluation at higher level of care like the emergency room. Follow-up evaluation should focus on the patient's cognitive status, balance testing, and neurological evaluation (reflex testing, rapid alternating eye movements, visual tracking, etc.), and symptom tracking.

Imaging

Routine imaging after a concussion is not indicated. If initial evaluation findings are concerning for an intracranial bleed, a CT scan is indicated. Imaging of the cervical spine is indicated if associated injury is suspected. MRI is not commonly used in the evaluation of sport concussion but may have value in cases with atypical or prolonged recovery [5].

Management

If there is any concern for a concussion, the athlete should be removed from competition for at least the remainder of the game/day. Signs that would warrant immediate removal include loss of consciousness, impact seizure, tonic posturing, gross motor instability, confusion, or amnesia [4, 5]. Symptom checklists like those found in the SCAT5 can be helpful to monitor symptoms after a concussion. Total rest (dark room/"cocoon therapy") is no longer recommended for concussion management, and consensus guidelines endorse 24–48 h of symptom-limited cognitive and physical rest followed by gradual increase in activity, staying below the symptom exacerbation threshold [5, 8]. Currently, symptom-limited activities including activities of daily living and noncontact aerobic exercise may begin after 24–48 h and appears to improve recovery in acute concussions. Many athletes recover quickly enough to return to the classroom right away, but schools should be notified of the injury and be prepared to provide additional support to students which may include extending deadlines on assignments, extended time for test taking, or other accommodations to help with the recovery. Return to sport should always occur after return to school. Patients must perform a graded return to play protocol and must be completely symptom free before returning to play [5].

Post-concussion syndrome is now termed persistent post-concussive symptoms (PPCS) and is defined as lingering symptoms of a concussion lasting longer than the expected recovery time frame (>2 weeks for adults, >4 weeks in children) [9]. Exercises that do not exacerbate symptoms are still recommended for PPCS.

Overall, management of a concussion should be treated with a multidisciplinary approach including pharmacologic therapy, speech therapy,

Telegram: @medical_k

www.konkur.in

vestibular rehabilitation, physical therapy, sleep hygiene, and behavioral medicine to encompass all aspects of concussion recovery.

Acute Back Pain

History

Acute back pain is defined as less than 12 weeks of pain. Patients will often first notice the pain in the morning or develop pain after minor twisting, bending, or lifting. It is important to first rule out any red flag symptoms including progressive motor or sensory loss, recent trauma, new onset bowel or urinary incontinence, loss of anal sphincter tone, saddle anesthesia, history of cancer, or suspected spinal infection [10]. Movements that worsen symptoms such as hyperextension should be noted in youth athletes, especially weightlifters, cheerleaders, and gymnasts.

Physical Exam

Physical exam should include inspection, palpation, range of motion of the lumbosacral musculature, hamstring and hip flexor flexibility, and a lower extremity neurologic exam. Palpation assists in determining if the symptoms are secondary to bony or muscular pathology. Flexibility testing of the hamstrings and hip flexors can assist in determining underlying biomechanical causes for the patient's pain. The straight leg test is commonly used for evaluation of radicular symptoms (sciatica). The test has high sensitivity but poor specificity. Loss of normal lumbar spine lordosis, tight hamstrings, and vertical position of the patient's sacrum are diagnostic clues in identifying acute spondylolysis [11].

Imaging

Without red flag findings, diagnostic imaging is not indicated. If signs or symptoms of fracture are present, then plain films including AP, lateral, and oblique views are the initial imaging of choice.

Management

Treatment should first focus on patient education and expectations, discussing that patients often need little intervention for improvement. Acetaminophen and NSAIDS are first line. In patients with muscle spasms, a short course of muscle relaxants is appropriate. Opioids should be avoided in the first episode of moderate low back pain as studies have shown no benefit of opioids compared to NSAIDs [12]. Often the pain resolves within a few weeks to few months with or without treatment. Episodes that last longer than 6 weeks have a poorer prognosis. Patients should be reminded to stay active, avoid aggravating movements, and return to normal activity as soon as possible. Early physical therapy may lessen the risk of recurrence and need for healthcare services [10]. OMT, acupuncture, superficial heat, and massage can be beneficial as well [12].

Rotator Cuff Injuries

History

Patients commonly complain of anterolateral shoulder pain that can radiate to the lateral arm that is exacerbated by overhead movements. Additionally, patients will often present with nocturnal pain occurring when lying on the affected shoulder. While some rotator cuff injuries occur from an acute injury, most result from cumulative microtrauma. Weakness may be present with rotator cuff injuries. Participating in overhead sports (baseball, swimming, weightlifting) and having a job that performs repetitive overhead tasks are risk factors for rotator cuff injuries.

Physical Exam

Inspection can reveal scapular dyskinesia and/or muscle atrophy of the supraspinatus or infraspinatus of the affected side. Palpation of the lateral shoulder over the subdeltoid bursa and rotator cuff insertions may elicit pain. Active range of motion will be decreased compared to

Telegram: @medical_k

www.konkur.in

passive range of motion. Special tests have been developed to test specific rotator cuff muscles. The drop arm test looks for a gross tear in the supraspinatus. The patient fully elevates their arm in the scapular plane and then tries to lower it slowly. A sudden drop in the arm would suggest a major tear. Jobe's "empty can" test evaluates the supraspinatus integrity as well. In this test, a downward force is applied to a humerus that has been abducted to 90°, forward flexed 30°, and pronated till the thumb is pointed down. Both the teres minor and infraspinatus are tested with resisted external rotation with the arms at the patient's side and elbow flexed to 90°. Subscapularis strength can be assessed with the "belly press." The patient is instructed to place their palm on their umbilicus and resist the examiner from pulling his/her hand off their abdomen. In all of the specific tests, pain without weakness suggests a tendinopathy, but pain with weakness should make the clinician consider a more substantial injury [13].

Imaging

Radiographs consisting of three views of the shoulder (AP, axillary, and scapular Y) may be obtained to assess the shoulder for joint degeneration, fractures, positioning of humeral head in relation to rest of shoulder joint, and soft tissue calcifications. A finding such as a "high riding humerus" (<7 mm from humeral head to acromion) is suspicious for a rotator cuff tear. If a detailed evaluation of rotator cuff anatomy is desired, an MRI should be considered.

Management

Acute full-thickness rotator cuff tears should be referred to an orthopedist for surgical evaluation. Physical therapy is the cornerstone of conservative management for all other injuries [14, 15]. Rehabilitation exercises should focus on restoring shoulder range of motion, correcting shoulder biomechanics through rotator cuff strengthening and scapular stabilization, correcting poor static and dynamic posture, and providing graded loading [14]. A short (7–10-day) course of NSAIDS and activity modification such as limiting overhead activities can complement the rehabilitation process by decreasing pain in the short term. Steroid injections are a commonly used option to decrease inflammation, but judicious use is advised. The benefit of decreased inflammation must be balanced against potential articular cartilage and rotator cuff damage from the components of the injection. As with all musculoskeletal injections, emphasis should be placed on appropriate rehabilitation in conjunction with the injection.

Shoulder Instability

History

The term shoulder instability is defined as symptomatic, abnormal translation of the humeral head on the glenoid [13] and may be due to an acute dislocation or repetitive microtrauma. This instability can then be classified by the direction of that instability (anterior, posterior, inferior, or multidirectional planes). For instability caused by dislocations, the overwhelming majority of shoulder dislocations occur in the anterior direction. Patients will often describe some type of force being applied to their upper arm while it is abducted and externally rotated. Posterior dislocations occur rarely and are associated with electrocutions or seizures. Chronic shoulder instability can also occur, and it is typically the result of prior dislocations or nontraumatic repetitive microtrauma. Athletes with repetitive overhead motions such as swimmers, baseball pitchers, and volleyball players are at increased risk of chronic instability. With acute dislocations, the patient will describe a popping sensation with subsequent pain and obvious gross deformity. In athletes with chronic instability, the patient will often describe pain and a feeling of shoulder instability with certain overhead movements. Overhead throwing athletes will also express a feeling of decreased throwing/hitting velocity. Associated soft tissue trauma to structures such as the labrum and rotator cuff are known complications of shoulder instability.

Telegram: @medical_k

www.konkur.in

Physical Examination

Gross shoulder deformity will be present with dislocations. Positioning of the patient's arms will be different with an anterior injury (slight abduction and external rotation) versus a posterior injury (adduction and internal rotation). Apprehension with movement will be universal. It is imperative to assess integrity of the axillary nerve; impaired function heralds more urgency in reduction. Testing sensory distribution over the patient's deltoid can easily assess axillary nerve function.

In chronic instability, determining the direction of instability (anterior, posterior, inferior, or multidirectional) is needed to allow appropriate treatment. Joint laxity testing can be completed using multiple testing maneuvers looking for either anterior (apprehension, relocation, and load and shift tests), posterior (load and shift, posterior stress test, jerk test), or inferior (sulcus sign) instability [13]. The labrum should also be examined as there are frequently concurrent injuries to the labrum with shoulder instability. Labral examination techniques include dynamic sheer, passive distraction, biceps load, and O'Brien's [13].

Imaging

Standard shoulder radiograph (AP, lateral, scapular Y) should be ordered with all shoulder traumas. Radiographs allow visualization of the direction of dislocation and associated fractures such as a Hill-Sachs (cortical depression of humeral head caused by glenoid rim) or bony Bankart lesion (fracture of anterior inferior glenoid) [16]. Radiographs are not acutely necessary before all reductions but are recommended after all reductions.

Treatment

Reduction of the dislocated shoulder should be completed as soon as possible. Delayed treatment will allow the patient's shoulder musculature to spasm to the point where conscious sedation may be required to complete the reduction. Techniques for anterior shoulder reductions can be broken down into two broad categories: traction and leverage. Traction options include the Hippocratic technique, Stimson technique, and scapular manipulation technique. Leverage techniques include Kocher's technique and Milch's technique [17]. Stimson's method is a relatively non-traumatic technique that is easy to complete field side. The patient should lie prone on an exam table or bench with the affected arm hanging off the table. Gentle downward traction is applied in order to facilitate the relaxation of muscles and spontaneous reduction [17]. Relocation of a posterior dislocation is done with patient supine. Traction is applied to the affected arm, while forward pressure is applied to the humerus [13]. After reduction, the patient should then be immobilized in a sling for 2–4 weeks with early physical therapy or potential surgical intervention. Positioning (internal rotation versus external rotation) of the arm during immobilization remains controversial; however, some studies have shown superior outcomes with the shoulder placed in external rotation when compared to internal rotation [18]. Surgical consultation for discussion of operative treatment options should be considered in young athletes after their initial dislocation; the risk of recurrent dislocation is approximately 90% if initial event occurs prior to the age of 20 [17]. In a systematic review, it was found that there was a 9.6% recurrence rate of dislocation after arthroscopic reconstructive surgery versus. 37.5% recurrence in conservative therapy groups [18]. Return to play in athletes after surgical stabilization is typically 4–6 months [13].

Aggressive physical therapy with strengthening of the rotator cuff and scapular stabilizing muscle remains the mainstay of treatment for chronic instability. Bracing options are available but often limit the patient's range of motion too excessively. Surgical options are available for unidirectional anterior or posterior instability if conservative measures fail. Operative results for multidirectional instability have not

Telegram: @medical_k

www.konkur.in

mirrored those of unidirectional instability but can be discussed if the patient fails conservative management [13].

Bicep Tendon Ruptures

History

Bicep tendon ruptures can occur at the long head origin within the labrum, the short head origin on the acromion, or the common distal insertion. The long head is the most common rupture site; it commonly occurs after forceful elbow flexion against resistance. Acute ruptures classically present with a sudden pop, followed by pain, ecchymosis, and swelling. In a long head rupture, pain will often originate in the anterior shoulder with radiation into the belly muscle.

Physical Exam

Patients with a proximal tendon rupture will present with swelling and ecchymosis in the upper and middle region of the bicep as well as tenderness over the anterior shoulder [19]. Loss of normal arm contour caused by the distal migration of the biceps muscle belly will give the classic "Popeye deformity," where the bicep will be more prominent over the middle of the humerus compared to the unaffected side with elbow flexion. There may also be a slight decrease in the strength of elbow flexion and forearm supination [13]. Distal bicep tendon ruptures will present with swelling and ecchymosis over the antecubital fossa along with a lack of musculature over the distal humerus. A noticeable decrease in strength will be noted with Speed's and Yergason's test [20].

Imaging

Shoulder or elbow films should be ordered depending on the injury site to evaluate for associated bone injury. Distal tendon injuries should be evaluated with MRI or musculoskeletal ultrasound of the upper extremity/elbow. Given the long head tendon's origin with the labrum, patients with proximal injuries and associated shoulder pain/instability should undergo MRI arthrogram of the shoulder to identify any associated labrum injuries.

Management

Proximal bicep tendon ruptures can be managed nonsurgically with referral to physical therapy. Physical therapy improves the strength and flexibility of the biceps and shoulder musculature, which often contributes to the patient's symptoms. If an associated labrum injury is found and the patient does not respond to physical therapy, a referral to orthopedic surgery should be placed. All distal biceps tendon tears should be referred immediately to an orthopedic surgeon for early primary repair.

Lateral Epicondylitis "Tennis Elbow"

History

Patients will regularly present with pain in the lateral elbow and upper forearm. The pain often begins after a recent increase in physical activities that require repetitive wrist extension and supination. Common inciting activities include weightlifting and racquet sports such as tennis, badminton, squash, or racquetball. Patients may also complain of decreased grip strength.

Physical Exam

Palpation will elicit point tenderness at lateral epicondyle and along the distal extensor carpi radialis brevis (ECRB) tendon. Resisted wrist extension, wrist supination, and third-digit extension with forearm in pronation will be painful. Decreased grip strength versus the unaffected side may be present also. Sensory exam should be normal. Radiation of pain from the lateral epicondyle into the proximal forearm and

Telegram: @medical_k

www.konkur.in

associated weakness with the above resisted testing should raise suspicion of an alternative diagnosis such as radial tunnel syndrome [19, 21].

Imaging

Plain films of the elbow can evaluate for fracture, tendon calcification, osteochondral defects, or radial head arthritis. Ultrasound can help identify chronic tendinosis within the origin of the ECRB.

Management

The vast majority of lateral epicondylitis cases can be managed nonsurgically [22]. Activity modification is a key component of treatment. Decreasing or stopping the instigating motions or modifying equipment such as using a wider grip on a tennis racquet can assist in managing symptoms. Physical therapy (eccentric-based exercises), NSAIDs, steroid injections, and counter load braces have been the mainstay of conservative treatment [20], but currently the use of corticosteroids is being debated [22]. Increasing evidence shows that prolonged lateral epicondylitis (greater than 4–6 months) is a tendinosis instead of tendinitis, thus calling into question the usage of NSAIDs and steroid injections in its management [33]. New treatment techniques such as dry needling, prolotherapy, autologous blood injection (ABI), and platelet-rich plasma (PRP) are emerging as treatment options [21]. There is no clinical consensus on the most efficacious treatment plan at this time [22] with multiple modalities helping improve long-term outcomes. Recalcitrant cases (greater than 18 months of symptoms without response) can be referred to orthopedics for possible operative debridement [21].

Scaphoid Fracture

History

The most common mechanism of injury involves a fall on the outstretched hand (FOOSH injury). Less frequently a sudden axial load through the wrist can cause a scaphoid fracture [23]. The patient will endorse deep, dull pain in the radial wrist. The pain is exacerbated by gripping or squeezing. A patient with radial wrist pain after an injury should be managed as if there is a scaphoid fracture until proven otherwise [24].

Physical

The patient may exhibit only mild swelling over the anatomic snuffbox. Pain is reproducible with palpation of the anatomical snuffbox. Patients can often still move the wrist, with pain elicited at the extremes of radial and ulnar deviation. Axial compression of the thumb will also elicit pain. Watson's shift test should be completed to evaluate for scapholunate dissociation. The assessment of median nerve function is needed to exclude associated injury.

Imaging

Initial imaging should include clenched fist PA, lateral, scaphoid, and oblique views. The scaphoid view puts the wrist in ulnar deviation and allows better visualization of the proximal scaphoid. The clenched fist view evaluates for scapholunate dissociation, with greater than 4 mm of space between the scaphoid and lunate being abnormal. If there is concern for scapholunate dissociation on initial films, a comparison view of the contralateral wrist should be obtained for comparison.

Management

Management depends on the location of the scaphoid fracture given the bone's tenuous retrograde blood supply. Indications for an orthopedic referral include greater than 1 millimeter (mm) of displacement, fracture comminution, scapholunate angle greater than 60°, scapholunate disassociation, and greater than 10 degrees of angulation [25]. Successful healing with nonoperative treatment occurs in 100% of distal third and tuberosity fracture, 80–90% of waist

Telegram: @medical_k

www.konkur.in

fractures, but only 60–70% of proximal fractures [25]. Early consultation with orthopedic surgery should be strongly considered in proximal third fractures because of significant morbidity from malunion, nonunion, and/or avascular necrosis [25].

If the decision is made to treat the patient nonoperatively, the exact type of cast (short arm thumb spica versus long arm spica) for the initial immobilization depends on fracture type. For each type, repeat imaging should be obtained every 2–3 weeks until radiographic union is observed. Nondisplaced distal fractures require 6–8 weeks for healing. Patients should be immobilized in a short arm thumb spica cast for 4–6 weeks. Additional time may be required if clinical union is prolonged. Middle third and distal third fracture should be immobilized with a long arm thumb spica cast for 6 weeks followed by a short arm thumb spica cast for an additional 6 weeks. Healing times for middle third/waist fracture range from 8–12 weeks, while proximal fracture healing usually requires 18–24 weeks. Due to the prolonged immobilization times required for most scaphoid fractures, patients will likely benefit from physical or occupational therapy to expedite a safe return to work or sports [25].

Patients will often present after a FOOSH injury, but their initial imaging will be negative. If a scaphoid fracture is suspected, place the patient in a thumb spica splint or brace for 2 weeks and then repeat films. At that point, there may be bone changes around a previously unrecognizable fracture. If follow-up plain films are still negative, additional imaging with MRI is indicated if clinical suspicion for a scaphoid fracture remains.

Boxer's Fracture

History

A boxer's fracture is the fracture of the 5th metacarpal neck, most commonly caused by punching a firm object or wall with a clenched fist. The patient will often present with pain and edema over the dorsum of the hand.

Physical

On exam, there may be loss of knuckle contouring. In severe angulation, pseudoclawing may present. It is imperative to evaluate for malrotation. In a semiflexed position, the plane of the fingernails should all be aligned and in full flexion; all fingers should point toward the scaphoid tubercle [26]. The hand should also be examined for teeth marks that resulted from a punching injury as that could be a source of infection.

Imaging

Plain radiographs should be obtained in the anteroposterior, lateral, and oblique views. The lateral view is used for measurement of apex dorsal angulation. When calculating the angulation, keep in mind the metacarpal neck at baseline has 15 degrees of volar angulation [27].

Management

Fractures with malrotation or angulation greater than 40–50° should be referred to orthopedics [27]. The patient should be placed in an ulnar gutter splint with the MCP in 70–90° flexion and PIP and DIP in slight flexion until seen by specialist.

In the absence of malrotation, an attempt for reduction can be made. Most patients require an ulnar or hematoma block prior to a reduction attempt. Reduction is performed by flexing the MCP joint to 90°, applying dorsally directed pressure to the volar displaced metacarpal head and volar directed pressure to the proximal fracture fragment. After reduction, the finger should be splinted as stated above. Repeat radiographs should be obtained within 1 week to assess for angulation or malrotation. Afterward radiographs should be obtained every 2 weeks following, until clinical and radiographic healing is present, typically between 4 and 6 weeks [26]. If the fracture has significantly more angulation or the reduction has slipped, the patient should be referred to orthopedics. After immobilization, it is important the patient start ROM exercises and handgrip strengthening.

Telegram: @medical_k

www.konkur.in

Mallet Finger

History

The injury is caused by an avulsion of the extensor tendon from the dorsum of the base of the distal phalanx with or without an avulsion of a bony fragment. The mechanism of injury occurs when the distal interphalangeal (DIP) joint that is being extended is suddenly forced into a flexed position. This commonly occurs when an object (usually a ball) strikes the extended finger.

Presentation and Physical Exam

Patients typically present with pain at the dorsal DIP, inability to actively extend the joint, and possible flexion deformity. For the exam, the physician should stabilize the proximal interphalangeal (PIP) joint, and the patient will be unable to fully extend his or her DIP joint. Providers should assess passive range of motion of the DIP as well to assess for possible bony or soft tissue entrapment. As with all finger injuries, the assessment of associated joint collateral ligaments, finger alignment, and possible rotational deformity should be assessed.

Imaging

AP, lateral, and oblique views of the finger should always be obtained to determine if bony avulsion has occurred as that may change the management of the injury. Radiographs may be normal if just soft tissue structures are affected.

Management

The majority of mallet finger injuries can be managed conservatively. Indications for surgical referral are controversial but include inability to adequately reduce the avulsed fragment, volar subluxation of the DIP joint, inability to obtain full passive extension of the DIP, and greater than 30% of the articular surface of the DIP being involved [26, 28]. Conservative treatment consists of splinting DIP in full extension for 6 continuous weeks. Flexing of the DIP at any time, even with splint changes, will cause the 6-week clock to start over. After the initial 6-week period of splinting, an additional 6-week period of nocturnal and activity splinting should be completed. Multiple different splints are available for the treatment of mallet finger; no splint type is superior but needs to be robust enough for daily wear [29].

Jersey Finger

History

Jersey finger is the rupture of the flexor digitorum profundus (FDP) tendon from the distal phalanx. The injury is caused by forced passive extension of the DIP joint during active flexion. This commonly occurs when an athlete's finger catches on another player's clothing, most often during football and rugby. The FDP of the 4th digit is affected in 75% of the cases [26].

Physical

The patient will present with pain and swelling at the palmar aspect of the DIP joint, and ecchymosis may be present depending on timing of presentation. The affected finger may lay extended with the hand at rest. During exam, it is imperative that the DIP joint is isolated. The patient will have a loss of active DIP joint flexion and an inability to make a fist. Finger alignment and rotation should also be assessed [26].

Imaging

PA and lateral view radiographs may show an avulsed bony fragment or fractures. Ultrasound can show a retracted tendon rupture [23].

Telegram: @medical_k

www.konkur.in

Management

The diagnosis of jersey finger requires urgent referral to orthopedics as prognosis worsens with delayed treatment. The involved finger should be splinted in a flexion until the patient is seen by orthopedics [26].

IT Band Syndrome

History

Iliotibial band (ITB) syndrome is an overuse injury that usually causes pain around the lateral femoral condyle; however, the patient can endorse pain anywhere along the IT band. The classic presentation is an active young person with lateral knee pain that increases through physical activity. Early in disease process, symptoms occur at the completion of a repetitive flexion/extension exercise. As the condition worsens, pain is often experienced earlier in activity and may begin to be present at rest. ITB issues commonly occur in runners, cyclist, soccer players, and basketball players.

Physical Exam

Inspection of the lower extremity anatomy can help determine if a person is predisposed to IT symptoms. Anterior pelvic tilt, genu varum, excessive foot pronation, and leg-length discrepancy can predispose the patient to chronic IT band irritation. The patient will likely have tenderness on palpation at the distal portion of the ITB where it courses over the lateral femoral epicondyle or Gerdy's tubercle. Ober's test reveals IT band tightness and the patient usually has a limitation of hip abduction [30]. Gait analysis may reveal a Trendelenburg gait, an indication of hip abductor weakness. Single-leg squat may also reveal subtle strength deficits in the abductors and quadriceps which can add to overload of the ITB.

Imaging

ITBS is a clinical diagnosis, and additional diagnostic studies are not necessary; however, if pain is located distally, anterior-posterior, lateral, and sunrise radiographic views of the knee can reveal arthritic changes within the knee or patellar malalignment.

Treatment

The initial goal of treatment is to reduce local inflammation and provide effective pain relief with stretching, ice, and NSAIDs. The patient can also use a foam roller to break up soft tissue adhesions in the ITB. Activity modification is essential. In mild cases, educate the patient to stay below the time or distance at which the symptoms start. In more severe cases, patients should avoid all aggravating activity. The patient can change to lower impact activities such as swimming or elliptical. Treatment should focus on correcting underlying biomechanical symptoms. Physical therapy is important as the patient should focus on strengthening pelvis/core stabilizers and improving strength and flexibility of the hamstrings. Excessive foot pronation can be corrected with appropriate orthotics. Corticosteroid injection at the lateral femoral condyle can be considered in severe cases [30].

Patella Dislocation

History

The most common mechanism for lateral patellar dislocation is typically during sport where the foot is planted and an internal rotary force is applied to the flexed knee in a valgus position (e.g., spinning, swinging a baseball bat, or quick lateral change of direction while running). Patients may complain of their knee "giving out" followed by severe pain and deformity that may or may not be accompanied by a "popping" sound. Pain and

Telegram: @medical_k

www.konkur.in

swelling are typically seen post dislocation, and many cases spontaneously reduce with knee extension. Injuries may be from an acute event or from repetitive microtrauma. History and complaint of recurrent patellar subluxation are other significant clinical clues.

Physical Exam

After an acute injury, a large knee effusion will be present. Significant hemarthrosis increases the chance that an osteochondral injury occurred [31]. An obvious deformity will be seen if relocation has not occurred. If relocation has occurred, the medial retinaculum/medial edge of the patella and the lateral femoral condyle are often tender to palpation. A positive patellar apprehension test will be noted, and laxity in patellar movement will also be observed.

Imaging

Radiographs are not necessary prior to reduction unless the diagnosis is in question. Standard three-view knee (AP, lateral, sunrise) films should be obtained to assess for fractures postreduction. If the exam does not ensure intact knee ligaments, a large hemarthrosis is present, or a fracture is seen on radiographs, then an MRI is indicated to look for associated ligamentous or meniscal injury [31].

Management

In the event that the patella has not been relocated, reduction should be accomplished. To reduce the patella, flex the hip, and apply a medial force to the patella while fully extending the knee. Immobilization of the knee in full extension should occur after reduction, and the patient should be non-weight bearing for 2–3 days until follow-up appointment. Currently, there is no consensus on length of immobilization but can range from 1–6 weeks. Non-weight-bearing status can typically be discontinued as tolerated by the patient. Controversy exists on surgical versus conservative management on primary traumatic patellar dislocation [32]; however, it is reasonable to begin with nonoperative management. Palpable defects of the parapatellar ligament structures, recurrent subluxation on initial examination, and findings of osteochondral lesion on imaging are indications for referral to orthopedic surgery. Physical therapy can assist the patient in regaining full range of motion and address underlying quadriceps' weakness to prevent recurrent dislocations or subluxations. Knee braces with patellar sleeves or a lateral J brace can assist athletes in regaining confidence in their knee; however, there is a lack of evidence supporting this practice. After the first dislocation, patients have approximately a 50% chance of recurrence or instability [33]. Patients with recurrent dislocations should be evaluated by an orthopedist [31].

Knee Ligament Sprains/Tears

History

The knee consists of four major ligaments; each has its own injury history and associated exam findings.

Anterior Cruciate Ligament (ACL): The ACL runs from its origin on the posteromedial aspect of the lateral femoral condyle to its insertion on the intercondylar tibial eminence; its main function is to prevent anterior translation of the tibia. ACL injuries most commonly occur without contact and during a sudden change in direction or pivot such as skiers and soccer players. This mechanism can occur with hyperflexion or hyperextension of the knee as well as when initiating or landing a jump. In contact sports such as football, injury of the ACL can occur in association with MCL and medial meniscus injuries, known as the "unhappy triad," after a valgus force is applied to a planted foot. The patient may report a "pop" sensation followed by significant swelling within 2 h after an acute injury [34]. Delayed presenters complain of a feeling of instability or "giving way" of the knee with twisting, pivoting, and cutting. Female athletes are at a higher risk for ACL injuries

Telegram: @medical_k

www.konkur.in

compared to male athletes secondary to an increased Q angle, quad dominance, decreased knee and hip flexion with landing, and hormone status [35].

Posterior Cruciate Ligament (PCL): The PCL runs from the posterior tibia to its insertion on the anteromedial aspect of the medial femoral condyle; the main function of the PCL is to prevent posterior translation of the tibia. PCL mechanism of injury is hyperextension from a posterior force or hyperflexion with plantar flexion of the ankle. The classic mechanism of injury is a dashboard injury of the knee during a motor vehicle accident. The most common complaint from the patient is instability of the knee.

Medial Collateral Ligament (MCL): MCL injury is a result of the lateral force to the knee with an anchored foot that creates a valgus stress. Patients will sometimes describe instability but will most often complain of swelling and pain along the medial joint line.

Lateral Collateral Ligament (LCL): An LCL injury is uncommon, but when it does occur, it is often associated with a PCL injury. Excessive anteromedial knee force when the knee is fully extended can stress the LCL. Patients will complain of pain over the lateral joint line and may feel instability with twisting, cutting, or pivoting. Patient will sometimes complain of lateral leg numbness and weakness with ankle dorsiflexion secondary to associated peroneal nerve injury.

Physical

ACL: Examination for potential ACL injury is best done immediately after the suspected injury before subsequent hemarthrosis and muscle guarding limit the exam. Significant knee effusion will occur within hours of injury. The most accurate test of an ACL injury is the Lachman test with a sensitivity of 87% and specificity of 97% [36]. Anterior drawer test is not as reliable as it can be falsely positive secondary to a PCL injury [34]. Meniscal integrity should also be checked as ACL tears often have associated meniscus tears.

PCL: Examination will show an effusion and tenderness within the popliteal fossa. The posterior drawer test is the exam of choice. If the posterior drawer test is positive, Dial's test should be completed to evaluate for posterolateral corner (PLC) injury [37]. Positive MCL/LCL testing at full extension is also suggestive of a PCL injury [34].

MCL/LCL: Assess for laxity in these ligaments with the knee in full extension and at 30 degrees of flexion with varus and valgus stress testing.

Imaging

X-rays should be obtained to assess for fractures. MRI is indicated in suspected ligament or meniscal tears where operative treatment would be indicated.

Management

ACL: Initial management includes rest, ice, compression, and elevation (RICE) along with crutch and brace usage. Weight bearing should be avoided early on as ACL is often associated with significant bone contusions. Range of motion exercises should be started as soon as pain allows. Referral to orthopedics for discussion of operative management should be made but is not emergent as surgery is often delayed allowing for resolution of hemarthrosis and increased range of motion. The American Academy of Orthopedic Surgeons (AAOS) recommends 12 weeks of nonoperative treatment for acute isolated ACL tears then reevaluation for need of surgery [35].

PCL: Surgical management is deferred unless other associated injuries such as a PLC injury occurred. Early range of motion and quadriceps strengthening should be encouraged for grade 1 and 2 injuries. Grade 3 injuries respond to immobilization in knee brace for a few weeks followed by formal physical for 3–4 months. Surgical referral should occur if the patient fails conservative management [34].

MCL/LCL: Initial management includes RICE and physical therapy. Grade 3 injuries (significant joint line gapping on varus/valgus testing) should be evaluated by an orthopedist, as they are often

Telegram: @medical_k

www.konkur.in

associated with other soft tissue injuries such as meniscal, PCL, or PLC injuries.

Meniscus Tear

History

A meniscus tear typically occurs from a traumatic forceful twisting or hyperflexion of the knee (squatting); however, chronic degenerative tears can result from years of stress and may have no acute mechanism. Meniscal injuries are also associated with other traumatic injuries such as ACL and PCL injuries. Patients may complain of mechanical symptoms such as their knee locking or buckling. Swelling after an acute injury presents 48–72 h after the trauma; however, most meniscus injuries are secondary to chronic microtrauma and will have minimal swelling.

Physical Exam

Joint line tenderness is a common finding on examination. Specialized tests including McMurray test, Apley's Compression test, and Thessaly test can assist in diagnosis. In general, one cannot make a definitive diagnosis with a single positive or negative special test.

Imaging

Knee X-rays should be obtained to assess for associated fracture especially with an acute/traumatic injury. If surgical intervention is being considered, then an MRI is warranted as it has a sensitivity of >90% for evaluation of meniscal tears [34].

Management

RICE and physical therapy will treat most chronic meniscal injuries. Steroid injections can be considered to assist in pain management during physical therapy. Indications for orthopedic referral include acute traumatic meniscus injuries and chronic injuries with mechanical symptoms.

Patellofemoral Pain Syndrome

Introduction

Patellofemoral pain syndrome (PFPS) is defined as a pain occurring around or behind the patella that is aggravated by activities that load the patella during weight-based activities on a flexed knee [38]. Pain is typically exacerbated with activities including running, climbing stairs, jumping, and squatting. Risk factors are thought to include female sex, decreased quadriceps strength, and patellar maltracking [39].

Physical Exam

Patients may complain of pain or stiffness after prolonged sitting with knee flexion sometimes known as the "theater sign." Large joint effusions and erythema are typically not seen with PFPS. Patellar maltracking or lateral deviation may be noted on exam. Multiple exam maneuvers can be used to aid in diagnosis including the Clarke test, patellar grind, pain during squatting, and pain with palpation of the medial or lateral patellar facet palpation. Additionally, the patient's gait, posture, and footwear/foot mechanics should be observed to look for potential exacerbating symptoms.

Imaging

PFPS is a clinical diagnosis, but imaging may be used to help rule out other pathologies. If radiographs are ordered, typically AP, lateral, and sunrise or Merchant views are ordered. MRI is typically not a standard component in the evaluation of PFPS.

Treatment

Initial treatment should focus on pain relief which may be accomplished through relative rest, ice, and NSAIDs, but physical therapy is the cornerstone of treatment. Due to multiple

Telegram: @medical_k

www.konkur.in

contributing factors to PFPS, no one set physical therapy regimen is recommended. Instead, treatment should be individualized to each patient [40]. While going through physical therapy, patients should remain physically active and should continue flexibility and strengthening exercises even after physical therapy has been completed.

Achilles Tendon Rupture

History

Achilles tendon ruptures are frequently seen in athletes, especially weekend warriors. The injury usually occurs during a push-off during running or a lateral movement. Patients may hear a "pop" or feel a snap sensation in their posterior ankle followed by significant pain.

Physical Exam

On inspection of the posterior lower leg, swelling and ecchymosis will be present. A palpable defect in the heel cord may be appreciated but can be unreliable in the presence of pain. The most reliable finding is a loss of resistance to passive dorsiflexion or loss of active plantar flexion; however, a patient may be able to still plantarflex because the other plantar flexors are still intact [41]. Thompson's test is diagnostic for a complete Achilles tendon rupture. It is performed by having the patient lie prone and flexing the knee to 90°. The gastrocnemius should be squeezed and look for ankle plantar flexion. Absence of plantar flexion is indicative of a full rupture. With a partial tear, the Thompson test may be positive or negative.

Imaging

MRI is the imaging modality of choice, especially for preoperative planning. Musculoskeletal ultrasound may also be helpful.

Management

Initial management includes non-weight-bearing status with the injured lower extremity splinted in a posterior splint with the ankle in plantar flexion. All patients need immediate referral to orthopedic surgery for discussion of definitive management. Management is controversial and often depends on the patient's comorbidities and goals, but ruptures can be managed both nonoperatively and operatively [41].

Achilles Tendinopathy

History

As with other tendon injuries discussed in this chapter, injuries can range from an acute inflammatory process (tendinitis) to a chronic injury with dysfunctional tendon healing (tendinosis). Patients will complain of pain in their distal Achilles at its insertion, or more commonly 2–6 cm proximal to the insertion [42]. Pain typically starts at the beginning or end of exercise, but as the condition progresses, the pain can persist throughout the entire duration of exercise. Pain often worsens with sudden acceleration, jumping, prolonged walking/jogging, or with calf stretches. A history of recent change in exercise intensity or style of training will sometimes be described by the patients as well.

Physical Exam

Minimal swelling will be seen on exam. A patient will be tender to palpation along the distal Achilles tendon. Occasionally, nodules will be palpated over the distal Achilles as well. Limited ankle dorsiflexion may be noted secondary to tight gastrocnemius/soleus complex. Pes planus can also be seen on exam. The Thompson test can also be performed to assess the integrity of the Achilles tendon to rule out a complete tear.

Telegram: @medical_k

www.konkur.in

Imaging

No imaging is indicated, as this is a clinical diagnosis. If the clinician is concerned about a possible partial tendon tear, MRI can be considered. Additionally, ultrasound is increasingly being used as a quick bedside tool to assess tendon integrity and appearance.

Management

Treatment options depend on the location of symptoms. Initial management includes risk factor modifications, relative rest, and location-specific rehabilitation exercises. Midportion tendinopathy is treated with eccentric exercises to start and then a combination of eccentric and concentric exercises [42]. Insertional tendinopathies are harder to treat and do not respond as well to eccentric exercise programs. Therefore, the main focus of rehab in insertional pathologies is concentric exercises [42]. Heel lifts or orthotics can also be added to the patient's shoes to help correct foot malalignment (typically pes planus). If the patient fails to demonstrate any improvement with conservative treatment and a short course of therapy, other modalities such as extracorporeal shock wave therapy, PRP injections, and topical nitroglycerin may be tried [42]. Steroid injections should be avoided in the management of Achilles tendinopathy given the associated increase in tendon rupture. Surgical evaluation should be reserved for severe cases that do not improve after 6 months or more of conservative management.

Ankle Sprain

History

Ankle sprains can be broken down into lateral, medial, or syndesmotic "high ankle" sprains. Most ankle sprains are injuries to the lateral ligaments of the ankle caused by inversion of the ankle. Inversion injuries will most commonly damage the anterior talofibular ligament (ATFL). This type of injury is common in basketball, soccer, and football. Medial ankle injuries are uncommon and involve eversion of the planter-flexed foot. This mechanism leads to injury to the deltoid ligament and will often lead to lateral malleolus fractures. High ankle sprains occur when a hyper dorsiflexed ankle is forcibly externally rotated. This type most commonly occurs in football, wrestling, and ice hockey and will damage the anterior inferior tibiofibular ligament (AITFL) [43]. Disruption of the AITFL can led to disruption of the dense connective tissue between the tibia and fibula, i.e., syndesmosis. For all types of ankle sprains, the patient will often complain of immediate pain, swelling, ecchymosis, and difficulty with ambulation.

Physical Exam

On inspection of the ankle, significant ecchymosis and effusion will often be present with all types of ankle injuries. Limited ankle range of motion will also be seen [44]. Palpation should occur over the bony landmarks of the Ottawa ankle rules. Palpation should also occur over the main ligaments of the ankle (ATFL, AITFL, calcaneofibular ligament (CFL), posterior talofibular ligament (PTFL), and the deltoid ligament. Tenderness to palpation of the ATFL and CFL is often found on lateral ankle injuries.

Several special tests exist for the ankle. The anterior drawer test and the talar tilt test can assist in the diagnosis of lateral ankle sprains. For high ankle sprains, the external rotation test, tenderness over the AITF, and the squeeze test should be performed to confirm diagnosis [45].

Imaging

The Ottawa ankle rules should be used to determine the appropriateness of imaging. Ottawa ankle rules are nearly 100% sensitive for detecting fractures in adults and children as young as 5 years [44].

X-rays are indicated only if any of the five physical exam findings are present:

Telegram: @medical_k

www.konkur.in

- Inability to bear weight for four steps immediately after the injury or in the exam room
- Bony tenderness over the posterior aspect of the medial malleolus
- Bony tenderness over the posterior aspect of the lateral malleolus
- Bony tenderness over the base of the fifth metatarsal head
- Bony tenderness over the navicular

Standard plain films of the ankle should include AP, lateral, and mortise views. The mortise view is essential to evaluate ankle joint stability. Physicians should consider obtaining additional plains of the proximal tibia and fibula on high ankle sprain patients with a positive squeeze test for a possible Maisonneuve fracture of the proximal fibula.

Management

Grade 1 and 2 lateral ankle sprains should be treated with RICE. Range of motion exercises or formal physical therapy should be initiated within the first 48 h. These injuries will typically heal within 1–4 weeks. Grade 3 injuries may require a short period of time in a CAM boot until full weight bearing is tolerated. In the rehabilitation period following, a semirigid or lace-up brace should be worn. Grade 3 injuries can take 5–8 weeks to heal and require up to 6 months for full rehabilitation [44]. Patients with significant ankle sprains should be reexamined in 4–6 weeks to assess for symptoms or findings of ligamentous instability. Surgical referrals to orthopedics should be reserved for chronic pain, chronic instability, and inability to return to previous functional level after an appropriate rehabilitation course. Consideration should be made for athletes to wear a lace-up ankle brace with Figure 8 straps after returning to competition.

High ankle sprains require additional immobilization compared to lateral sprains. Immobilization in a walking boot for 3–4 weeks with progressive increase in weight bearing is often needed. Formal physical therapy should begin immediately after injury. Return to athletics can take anywhere from 4 to 8 weeks depending on the severity of the injury. Providers must ensure that the patient's plain films did not demonstrate a widened mortise, as this indicates an unstable ankle joint and will require surgical fixation [46].

Proximal Fifth Metatarsal Fracture

Introduction

Proximal fifth metatarsal fractures can classically be divided into three different types based off of anatomy and history. The three anatomical areas include the metatarsal tuberosity, metaphyseal/diaphyseal junction, and proximal diaphysis, and the mechanism of injury and treatment will differ depending on the affected region.

History

Injuries to the tuberosity are typically avulsion type injuries from either the plantar fascia or peroneus brevis attachment, and the mechanism is typically an ankle inversion with the foot in plantar flexion. Acute metaphyseal/diaphyseal junction injuries (Jones Fracture) typically result from a vertical or mediolateral force placed on the base of the fifth metatarsal with the patient's weight over the lateral aspect of their foot, most likely with their foot in plantar flexion. Finally, diaphyseal stress fractures typically are caused by chronic overloading. A good history is imperative as acute fractures and stress fracture that evolved into occult injuries require different durations of treatment.

Physical Exam

Weight bearing will often be difficult. Patients will generally have pain over the lateral border of the forefoot, exaggerated with weight bearing. Resisted foot eversion will increase pain. Point tenderness at the site of the fracture will be present. If a patient presents with ankle pain after an inversion injury, the Ottawa rules should be used

Telegram: @medical_k

www.konkur.in

to determine the need for imaging to look for a proximal fifth metatarsal injury.

Imaging

Standard AP, lateral, and oblique radiographs of the foot may be sufficient; however, tuberosity fractures can be missed on foot films, so it is also recommended to get ankle films as well [47]. Likewise, if a fracture is identified on ankle films, a dedicated foot series needs to be completed as well. CT or MRI should be considered in the setting of delayed healing or nonunion.

Management

Treatment depends on the fracture location and is subdivided into zone 1, zone 2, and zone 3 injuries. Zone 1 injuries are avulsion injuries that occur at the tuberosity. Zone 2 fractures occur at the metaphyseal-diaphyseal junction, while zone 3 fractures occur in the proximal diaphysis [48]. Zone 1 fractures occur in a well-vascularized region and heal without difficulty with conservative management. Treatment focuses on allowing patient to ambulate without pain. Treatment options include a hard-soled shoe, elastic dressing, or CAM walking boot for 4–6 weeks. Zone 2 injuries are also known as Jones fractures, and the concerns for malunion and nonunion are much higher than zone 1 injuries. Malunion and nonunion complications can occur with both operative and nonoperative management and is seen in approximately 20% with each [49]. Conservative management includes 6–8 weeks of non-weight bearing in a short leg cast; then if radiographic signs of healing are present, weight bearing can slowly be reintroduced [50]. Lack of radiographic healing at 12 weeks should raise concern for malunion, and the patient should be referred to orthopedics for discussion of operative management. For elite competitive athletes, initial treatment with surgical screw fixation followed by 6 weeks of non-weight bearing in a short leg cast is another option; however, this method does not remove the risk of malunion and nonunion. The treatment for zone 3 fractures is the same as zone 2; however, more prolonged immobilization may be required for chronic stress injuries that evolved into occult fractures. Total healing times of 18–24 weeks is not unheard of in this type of injury. As with zone 2 injuries, regular radiographic monitoring is needed to evaluate for healing complications.

General Principles

Currently, there are relatively few therapeutic options that can be widely promulgated for long-term sustained weight loss, while at the same time, the rates of obesity are projected to escalate further [1–4]. These challenges make weight loss difficult for the patient with obesity. Three key points of care of the patient with obesity that the primary care provider should be aware of are:

1. The concept of obesity as a chronic disease with provision for multiple modalities of obesity therapies
2. The mitigation of obesity bias
3. Patient-centered health outcomes, rather than primarily weight loss goals

Epidemiology: Obesity is an increasingly prevalent condition in the United States (US) [5], leading the American Medical Association to declare obesity to be a disease in 2013 [6]. Currently, in the United States, the prevalence of overweight and obesity is over two thirds in adults

and one third in children and adolescents [5]. Childhood obesity continues into adulthood for the 80% of children. By 2030, it is projected that more than half of the adult US population will have obesity and one in four American adults will have severe obesity, with the most likely impact in women, non-Hispanic black adults, and low-income adults [7]. Similar prevalence of obesity is projected for most of the world [8].

Definition and Classifications: Simply stated, obesity is a condition of excess body fat. Since the distribution of fat mass is difficult to determine in the clinic, the body mass index (BMI) was developed [9]. There are four categories of BMI: underweight (<18 kg/m^2), normal weight ($\geq$19–24.9 kg/m^2), overweight ($\geq$25–29.9 kg/m^2), and obese ($\geq$30 kg/m^2). BMI has prognostic importance and directly correlates to mortality risk. BMI should be considered a screening tool and is not diagnostic of obesity-related complications [3]. Electronic medical records calculate the BMI from available weight and height and for children 2–20 years of age; age- and sex-specific BMI percentiles are available [4].

The waist circumference (WC) is reflective of abdominal fat accumulation, with weight-independent cardiovascular risk implications. The guidelines recommend measuring a WC for patients with a BMI between 25 and 34.9 kg/m^2. A WC of over 40 in. in men and 35 in. in women meets the criteria for "obese" in Caucasians.

Etiology: Obesity is due to excess energy stored in the fat cells, which may be the result of a wide variety of causes [1–4]. There are a few rare purely monogenetic causes of obesity [4]. An early onset of obesity before the age of 2, family history, or the presence of other abnormalities may indicate Prader-Willi, leptin, POMC, or MC4R deficiency [4]. The current rational is that for a vast majority of the population, a genetic predisposition for weight gain, within a setting of an obesogenic environment, is causing excess energy production. Reduction of physical activity is aggravated as sedentary behavior becomes more the "new normal." Most of the genetic influences are polygenic and associated with a variety of genes of which the "Fat mass and obesity-associated (FTO) gene" is the most prevalent and is found in up to 43% of the population [10]. Epigenetic changes may result in lifelong metabolic changes [11]. Other factors implicated in the pathogenesis of obesity include weight-promoting medications, gut microbiome, sleep disturbance, endocrine disruptors, global warming, and food policies, among others. The biopsychosocial determinants of obesity are being increasingly recognized [12].

Physiological Control of Body Weight: A complex neurobiological regulatory process mediated by the hypothalamus in the brain, adipose tissue, and the gastrointestinal tract controls food intake and energy expenditure by secreting several hormones [13]. These hormones act to protect the body from weight loss, giving rise to the concept of a set point for body weight and "the thrifty gene." Human physiology is geared for weight gain and energy storage, and attempts at volitional weight loss will be counter-regulated by many physiological changes, as confirmed by energy studies in participants from the biggest loser reality shows [14, 15]. As a result, the patient's efforts to keep weight off are difficult, and weight regain typically occurs. A pivot away from personal blame and failure is occurring. Newer clinical competencies for providers in the management of obesity therefore stress the understanding of obesity as a complex disease and call for mitigating obesity bias [16, 17].

Effects of Weight Gain: Obesity impacts every organ system resulting in overall increased morbidity and mortality and correlates directly with increasing all-cause mortality [18]. The optimal BMI for longevity is in the range of 21–25 kg/m^2. Metabolic and cardiovascular diseases are the most common associations with obesity [19]. This may be independent of total mass or BMI especially in Asian ethnicities. Metabolic syndrome and insulin resistance with characteristic dyslipidemia and hypertension typically precede the onset of type 2 diabetes. Acanthosis nigricans, polycystic ovarian syndrome, nonalcoholic fatty liver disease, and gout are also common associations of metabolic syndrome. Type 2 diabetes and obesity are the most closely related, and a common condition of "diabesity" occurs in both adults and children

Telegram: @medical_k

www.konkur.in

[20]. Obesity is a common risk factor for hypertension, and concomitant sleep apnea can contribute to hypertension.

Cardiovascular risk is increased as a result of dyslipidemia, hypertension, diabetes, and sleep apnea. The cardiovascular complications associated with obesity are due to the increased subendothelial inflammation, insulin resistance, coronary calcification, and activation of coagulation, renin-angiotensin, or the sympathetic nervous system [21]. The metabolic syndrome pattern of dyslipidemia consists of elevated total cholesterol and significantly elevated triglycerides, with low HDL. Coronary heart disease, heart failure, atrial fibrillation, venous thromboembolism, and stroke are more frequent in patients with obesity and obesity-related cardiac risk factors.

Nonalcoholic fatty liver disease is rapidly becoming the foremost cause of liver disease and major indication for liver transplant in the future for complications of liver cirrhosis [22]. Female infertility, polycystic ovarian syndrome, and male hypogonadism can impact reproductive health [5].

While the cardiometabolic effects of obesity are well known, more recently a strong association with cancer and dementia is emerging [5, 23]. A correlation between obesity, enlarged waist circumference, and dementia is becoming clearer. With increasing BMI, the incidence of every type of cancer increases. These obesity-related cancers are predominantly reproductive, or in the GI system, however, even malignant melanoma has been seen to occur more frequently in patients with obesity, than in leaner patients. In women, breast cancer and uterine cancer are the most common, while in men colon cancer and prostate cancer are more common.

Due to the impact of pro-inflammatory cytokines and immunological aspects of obesity and increased baseline inflammatory status, patients with obesity may have reduced ability to fight infections, and patients with obesity are at increased risk of getting infections, with a reduced response to vaccinations, as has been seen with influenza and more recently with the coronavirus outbreak in 2020 [24].

The mechanical impact of weight gain and body size is seen to result in increased fat mass and causes osteoarthritis, sleep apnea and breathing problems, urinary incontinence, gastroesophageal reflux, and hernias. Orthopedic involvement of the hip in children can be a serious emergency. In adults, increased body pain with difficulty with physical functioning comprises the quality of life.

The psychological impacts of weight gain and mental health are closely aligned [3]. Depression often is present with weight gain, but obesity can also exacerbate underlying depression. Increased impulsivity traits occur at the observational and genetic epidemiology level [25]. Weight bias is highly prevalent and can be toward the patients by providers or even experienced by the patients toward themselves. Perception of weight bias is associated with diminished quality of life. Economic aspects of obesity include diminished earning capacity, increased disability, and lower income with overall increased mortality, while national costs of health care increase.

Management of the Patient with Obesity

Approach to the Patient: A patient-centric approach for the patient with obesity is to be encouraged. The five A's approach should be used: for the patient with obesity, the provider should "Ask Assess, Advise, Agree, and Assist (five A's)" [3].

Clinical Management

Screening: All children over the age of 6, adolescents, and adults are screened with BMI [26]. This is followed by assessment of obesity-related risk for the individual patients. Evaluation for secondary causes of obesity is not required, unless the initial workup is suggestive of an underlying endocrine or genetic cause. In children, greater vigilance for markers of an underlying genetic or endocrine abnormality is indicated. WC can be measured.

Telegram: @medical_k

www.konkur.in

History

First, the provider will obtain the patient's history of weight, nutrition, and physical activity, along with current medical, social, and family history. Additional information regarding the presence of comorbidities and complications is needed. All medication use, prescribed and over the counter, should be carefully noted and reviewed for obesogenic potential. Reproductive history in women will include menstrual periods, acne, and hirsutism. In children, monogenetic syndromes may be evident by severe and rapid growth in early childhood or family history. Urgent referral is indicated if hip pain is present in children as slipped upper femoral capital epiphysis is likely. A holistic assessment should also include sociocultural practices and beliefs, adverse childhood experiences, and psychological factors such as mood, anxiety, binge eating disorder, attention-deficit/hyperactivity disorder, self-worth, and identity [3].

Physical Exam

Weight and height are to be accurately measured. To facilitate correct blood pressure measurements, appropriately sized blood pressure cuffs should be available. Measuring the neck circumference is appropriate if the patient has untreated sleep apnea or elevated blood pressure. The physical examination should be complete and include evaluation for suspected secondary causes of obesity only if indicated. Establishing the presence of comorbidities of obesity that will need to be treated is critical. In children, a more detailed orthopedic and systemic examination is essential.

Laboratory Testing

The routine lab testing focuses on the determination of comorbidities and cardiovascular risk of obesity and includes cholesterol profile, fasting blood sugar, HbA1C, and liver enzymes. Routine insulin testing, detailed endocrine workup, and other evaluations for secondary causes are not routinely advocated. In children genetic testing may be indicated if severe obesity presents early, particularly if other features of syndromic presentation or family history are also present.

Treatment

Goals: Moderate weight loss of 5–10% is often seen to reduce risk factors and is the initial goal of treatment in the primary care clinic. More significant weight loss is possible, but long-term durability outside of bariatric surgery has yet to be clearly established. Maintaining the current weight of the patient and improved health and quality of life are often realistic goals for adults.

Guidelines: There are several guidelines available, consisting of multidisciplinary approaches to weight management: comprehensive lifestyle modification, pharmacology, and bariatric surgery options [1–4]. The 2016 AACE guidelines have replaced some of the focus on BMI. The latest, 2020 released Canadian guidelines stress improved health and quality of life, as opposed to a weight outcome, and contain a further shift away for BMI. The management of obesity in children now includes consideration of pharmacological agents and bariatric surgery. Weight loss in the elderly is controversial with no current guidelines. Preservation of muscle mass is a priority.

Comprehensive Lifestyle Modification. The USPSTF recommends referral of all patients with obesity to a comprehensive program [26]. The components of any comprehensive program include diet, physical activity, and behavior modification [1]. The long-term efficacy of such programs is limited to about 3–5% long-term weight loss. There could be other benefits besides weight loss, and there are minimal side effects to healthier eating and increasing physical activity.

Diet

Dietary changes are mainly focused on weight reduction by producing an energy deficit. These can be an overall caloric restriction diet such as

Telegram: @medical_k

www.konkur.in

low calorie or one macronutrient as in the low-fat diet and low-carbohydrate diet. Other diets that increase proteins or ketones are popular. The most recent diet studies indicate that all diets seem to work about the same, for short periods of 3 to 6 months, with equal efficacy. Fasting and timed eating are becoming trendy, but evidence of effectiveness is currently not available. What is clearly established is that adherence to a preferred diet by the patient may be more critical. A healthy eating pattern consists of increasing the amount of nutrient-dense foods from all food groups and limiting the intake of empty calories from added sugars and saturated fat, with reduction of sodium intake [27].

Physical Activity

Both voluntary exercise and activity as part of daily living that requires the usage of energy are important for health. Physical activity directly helps avoidance of weight regain and has significant benefits that may not be weight related. The current guidelines recommend 150 min a week and twice weekly weight or resistance training; however even small amounts of physical activity may be advisable. Aerobic activity of 30–60 min on most days of the week can lead to small amount of weight loss and help keeping weight off. Physical activity reduces all-cause mortality, and for most healthy people these goals are possible, without too much effort [28].

Behavioral Management

Multicomponent psychological interventions are moderately effective, and evidence suggests that intensive, multicomponent behavioral interventions with 12 to 26 sessions per year are the most effective. Interventions proven to be effective include motivational interviewing, self-monitoring, goal setting, stress reduction, and cognitive restructuring. Group activities or in-person modalities may lead to better outcomes than those that rely only on online delivery to an individual.

Pharmacological Management of Obesity

The use of medications for weight loss is indicated for patients with a BMI of $\geq$30 kg/m^2 or $\geq$27 kg/m^2 with adiposity-related complications, as an adjunct to lifestyle therapy, and not alone [1]. There are very few medications available for long-term use, and many of the weight loss medications have been removed from the market, over the years, due to the side effects and safety concerns. The use of medications for 3 to 6 months of time is not recommended [1]. Prior to prescribing any weight loss medication, a review of the current list of medications of the patient should be undertaken to see if any changes and substitutions can be made to any weight-inducing medication. The efficacy of the FDA-approved medications has ranged from 3.9% weight loss for orlistat to 7.8% 1-year weight loss for liraglutide. All weight loss medications are contraindicated in pregnancy [1].

The older sympathomimetic medications were approved for short-term use for 12 weeks. Due to the mechanism of action, they have many adverse side effects as a result and include increases in blood pressure and heart rate insomnia and potential abuse. Phentermine is the most common medication used for obesity. More recently an 8 mg dosage is available for dosing three times a day.

The pancreatic lipase inhibitor orlistat has been available for a number of years as prescription and, for adults and children 12 years and older, and is given as 120 mg three times a day before meals. A lower dose of 60 mg has been available over the counter. Results are limited with average weight loss below 3% maintained over time. The medication is given orally, blocks the absorption of fat from the intestine, and has demonstrated metabolic benefits in delaying the outcome of diabetes and lipid profile, but use is limited due to significant gastrointestinal side effects of cramping, flatus, and fecal incontinence.

In 2012, a combination of phentermine and topiramate involved two previously approved FDA medications, reformulated into one new FDA weight loss medication. The side effects include those of phentermine with the addition

Telegram: @medical_k

www.konkur.in

of those from topiramate which consist of paresthesia, dysgeusia, cognitive changes, glaucoma, and potential for fetal toxicity. Cardiovascular risk was evaluated in two studies and was found to be favorable; however, the cost and the side effect profile have limited widespread usage.

The combination of naltrexone and bupropion into a single weight loss medication similarly includes two previously approved medications that were reformulated and subsequently approved by the FDA for long-term weight loss. Hence, the side effects consist of those from both medications. While bupropion is familiar to most primary care providers as an antidepressant, with side effects of blood pressure and heart rate elevation and lower seizure threshold, naltrexone can cause nausea and cannot be given to patients on opioids. Warnings include suicidal behavior and ideation, and contraindications include uncontrolled hypertension, seizure disorder, bulimia or anorexia nervosa, chronic use of opioid drugs, abrupt discontinuation of alcohol, and MAOI use.

Lorcaserin acts on the serotonin receptors in the brain, and helps with satiety, but has the potential of interacting with other medications affecting serotonin to produce the serotonin syndrome. Dosage is 10 mg twice a day, and the medications are well tolerated with mild side effects that include constipation, cough, dizziness, and tiredness. However, lorcaserin has been withdrawn from the market in February 2020 due to cancer potential.

Liraglutide is a long-acting glucagon-like polypeptide receptor agonist that is injected once a week, at a dosage of 3 mg. The medication is used widely for diabetes in primary care, at a lower dosage of 1.8 mg, and found to have cardiovascular benefits [29]. The most common side effects associated with liraglutide 3 mg are gastrointestinal and include nausea, diarrhea, vomiting, and constipation with warnings of pancreatitis, acute cholelithiasis, and cholecystitis. Liraglutide has been reported to cause thyroid C-cell tumors in rats, and so far not in any humans, but the drug is contraindicated in patients with a personal or family history of medullary thyroid carcinoma or with multiple endocrine neoplasia. Acute pancreatitis, including fatal and non-fatal hemorrhagic or necrotizing pancreatitis, has been observed in patients treated with liraglutide.

Emerging obesity medications include semaglutide and multiple treatment options with monotherapy or combinations of various hormones (GLP-1, GIP, glucagon, oxyntomodulin, amylin, PYY). No supplements or over-the-counter medications have been found to be useful, despite many claims on the Internet, social media, or by individual patients.

Surgical Management of Obesity

Bariatric surgery is indicated for patients with BMI over 40 or 35 with obesity-related comorbid conditions and is the most durable and effective modality for treating obesity and obesity-related complications [30]. The number of procedures has been seen to increase since results of bariatric surgery have consistently shown reduction in the weight and in type 2 diabetes. Bariatric procedures are restrictive, malabsorptive, or mixed of which the gastric sleeve and gastric bypass remain the most popular. The long-term outcomes following bariatric surgery are on average 7-year mean weight loss of 28.4% for the gastric bypass. The prevalence of dyslipidemia, diabetes, hypertension, and remission of diabetes at 7 years was 60.2% for Roux-en-Y gastric bypass and 20.3% for laparoscopic adjustable gastric banding [31].

Laparoscopic adjustable gastric band was the most commonly performed restrictive surgery with a tight adjustable band placed around the top of the stomach and an infusion port to allow for adjustments. The number of procedures for the band has been declining due to side effects and limited weight loss after 2 years.

Laparoscopic sleeve gastrectomy is a single-stage restrictive surgery where about 85% of the stomach is removed and a tube or “sleeve” is made of the remaining stomach. This is becoming the more common with durability of about 5 to 9 years. GERD symptoms may worsen in those patients with the sleeve, and weight loss is not as maintained as with the gastric bypass, with some

Telegram: @medical_k

www.konkur.in

patients requiring reoperations for severe GERD. Since there is minimal malabsorption, vitamin and protein deficiencies are relatively rare.

The Roux-en-Y gastric bypass consists of two stages: the first part consists of cutting the stomach into a small gold ball-sized upper pouch which is separated from the rest of the stomach, and the second part consists of the attachment or bypass of the remaining part of the stomach and intestine, by pulling up a loop of the jejunum and attaching it to the pouch of the proximal stomach. Due to the restrictive and malabsorptive parts of the procedure, the complications can consist of leaks, hernias, and other surgical complications, in addition to the need for lifelong supplementation of vitamins and often iron and protein.

Prevention: Once excess weight is gained, options for the management of weight loss are limited by physiological counter-regulation as well as continued exposure to the obesogenic environment. Prevention of any further weight gain is critical. A multidimensional approach as laid out by the AACE model will take decades to implement [1]. In the meantime, obesity rates are only going to increase; for family medicine providers, a focus on pregnancy weight gain optimizations, childhood weight management, and aggressive management of adult obesity-related comorbidities may be the most strategic responses in the interim.

General Principles

Definition/Background

Although the chapter title and some of the references included here will use the phrases "difficult patient" or "frustrating patient" – or even "hateful patient" – it should be made clear that this is not the author's preferred term. Any doctor/patient interaction by definition involves at least two parties, both of whom have personalities, preconceptions, and prior experiences that are incorporated into current interactions. Difficulties in physician/patient interactions also incorporate patient, physician, and healthcare system factors [1]. For these reasons, phrases such as difficult or challenging patient interactions are preferred.

Epidemiology

Family medicine physicians in the United States account for more than 214 million office visits yearly [2], and 15–37% of physicians' patients can be described as frustrating or difficult [3, 4]. It is clear, then, that in any given year, family physicians will encounter a large number of patients with whom they will have difficult, frustrating, or challenging interactions.

www.konkur.in

Approach to the Patient

To discuss difficult patient interactions, it is important to first discuss the characteristics of a therapeutic doctor/patient relationship. According to the AMA's *Journal of Ethics*, "a patient-physician relationship is generally formed when a physician affirmatively acts in a patient's case by examining, diagnosing, treating or agreeing to do so" [5]. Once a physician agrees to take on this role, the physician then owes that patient a duty to continue to treat them or to properly end the relationship [6]. Physicians are expected to provide their expertise via their sapiential authority (their medical training and competence), their moral authority (their concern for and obligation to the patient), and their charismatic/empathic authority (their emotional connection and care for their patients) [7]. Physicians must approach patients with inclusion, characterized by personal engagement, and availability, an openness to learn about others' experiences [8].

From the patient perspective, patients want physicians to help orient them to visits, to assess their understanding and preferences, and to engage in meaningful discussions [9]. Patients identified physician communication, respect for the patient, sympathy, empathy, patient-centeredness, and shared decision-making as important elements they sought in doctor/patient interactions [10].

Effective doctor/patient relationships, in turn, result in improved trust, commitment, and adherence to care recommendations [11], and effective relationships result in improved healthcare outcomes including biomedical markers, behavioral outcomes, and improved communication between physicians and patients [12, 13].

Although "difficult patients" will differ in their specifics, there are common characteristics. "Frustrating patients" report higher rates of somatic symptoms, rate their own health status poorly, and are more often diagnosed with somatization or generalized anxiety disorder than "satisfying" or "typical" patients, even though those patients' physicians did not identify any differences in the severity of underlying health issues [3]. Patients who were described as "difficult" are also more likely to screen positive for mental illness and to be diagnosed with specific psychiatric disorders such as multisomatoform disorders, generalized anxiety or panic disorder, dysthymia or depression, and alcohol dependence. "Difficult" patients were more likely to list a larger number of active symptoms and to be diagnosed with functional illnesses such as irritable bowel or fibromyalgia while not showing any difference in "organic" illnesses such as diabetes, hypertension, cardiac disease, etc. "Difficult" patients were also more likely to report higher levels of impairment or disability than "not-difficult" patients [4]. Patients who were part of difficult encounters demonstrated lower functional status. Increased numbers of patient concerns, symptoms, or symptom severity were more likely to result in a patient being described as "difficult" [14].

Family medicine physicians have identified difficult patients as those who have behavioral problems (violent, aggressive, rude, lying, demanding, exploitative), patients who present with repetitive symptoms that never improve or who have multiple complaints, and those patients with psychiatric illnesses [15]. Physicians have further identified patient behaviors that characterize difficult encounters, including insisting on an unnecessary medication, showing dissatisfaction with care provided, etc. [16]. In one study in a resident clinic, poor social support on the part of patients was also associated with problematic doctor/patient relationships [17]. A recent qualitative study explored the ways in which patients who have experienced social inequalities may be considered to be "difficult" because of the demands physicians may feel to address serious health issues in the face of social needs. The increased time required to care for these patients and the frequent feeling of ineffectiveness in being unable to address root causes of patients' problems further complicate these patient encounters [18]. Physicians were also more likely to report difficult patient encounters when patient behaviors and medical problems were opposed to physicians' personalities and approaches to care [19]. Finally, challenging patient interactions may impact physicians' diagnostic accuracy [20], which may risk additional harm to the patients involved.

Telegram: @medical_k

www.konkur.in

Diagnosis

In 1978, Groves identified four types of "difficult" (or, as described in the article, "hateful") patients and characterized them as noted below [21]. Although the language is inappropriate in today's patient-centered approach to care, a reevaluation of this model updated for the twenty-first century [22] highlights the fact that these four general categories are still relevant today and may serve as archetypes to facilitate initial approaches to caring for these patients. The update notes that illness and disease can be considered a direct threat to the patient's integrity, and this threat causes individuals to turn to behaviors or coping mechanisms that may not be beneficial or effective.

- Dependent "clingers": characterized by "repeated, perfervid, incarcerating cries" for care and reassurance and "their self-perception of bottomless need and their perception of the physician as inexhaustible" which lead to fatigue and frustration.
- Entitled "demanders": "use intimidation, devaluation, and guilt-induction to place the doctor in the role of the inexhaustible supply depot," but this approach generates from a concern for abandonment and "an effort to preserve the integrity of the self" when confronted by illness or potential harm.
- Manipulative "help rejecters": need significant amounts of physician attention, but rather than expecting or demanding to get better, they appear to doubt that any care offered will make a difference, and if one symptom is resolved, other symptoms are likely to replace it. These patients are described as having a "need/fear dilemma"; they have needs that they seek to address, but fear either being abandoned or overwhelmed. This was clarified in 2006 [22] by noting that in this case patient's goal is the relationship with the physician as opposed to a cure.
- Self-destructive "deniers": these patients are described as continuing behaviors that actively contradict or undercut physicians' attempts to help them and have "given up hope of ever having needs met."

In a small study, Schafer and Nowlis noted that patients described as difficult by physicians were more likely having personality disorders than control patients and that physicians were often unaware of these diagnoses [23]. The four categories of difficult patients listed above parallel definitions and diagnoses of personality disorders, especially those in clusters B and C. Given the fact that personality disorders are enduring, pervasive, and inflexible [24], patients with these characteristics will likely demonstrate persistent challenges in physician/patient interactions and will tend to use those approaches with each healthcare visit – allowing identification, categorization, and approaches to care as described later.

Levinson et al. categorized seven specific patient-driven themes/frustrations that contribute to difficult interactions:

1. Lack of trust or agreement
2. Lack of adherence to recommended plans of care
3. Too many problems, especially when combined with a lack of adequate time to address each of them
4. Feeling distressed (angry, overwhelmed, etc.) after office visits
5. Demanding or controlling patients/families (different from patient-centered care and the idea of shared decision-making)
6. Lack of understanding due to the use of medical jargon or lack of language proficiency
7. Specific problems that are difficult to address, such as substance abuse, chronic pain, etc. [25]

It is notable that each of these categories of frustrations does not result from a unilateral patient-side fault. There is a bilateral obligation on the part of patients and physicians to ensure proper and meaningful communication as part of the visit, and to make shared decision-making is a focus of each visit.

While considerations of personality disorders and psychopathology are important, we must also consider patients' prior experiences with the healthcare system, especially in cases where patients may have experienced active discrimination or where they have felt that their concerns have not been taken seriously. One study

Telegram: @medical_k

www.konkur.in

demonstrated the prevalence of discriminatory behaviors which patients who are members of sexual and gender minority groups included in but limited by the LGBTQ communities [26]. In other cases, patients' race or ethnicity has resulted in their medical needs being disregarded [27]. Negative past experiences with healthcare systems and healthcare providers may predispose patients to a more assertive or a more distrustful presentation, which may lead to labeling a patient as "difficult" and cause challenging interactions. Compared to personality disorders or more pervasive patient traits, however, these interactions may be improved once the patient has trust in their current physician and physicians have proven that they can be trusted.

Physician characteristics such as age, ethnicity, and number of years in practice have not consistently been associated with an increase likelihood of experiencing difficult doctor/patient interactions. However, physicians with poorer psychosocial attitudes were more likely to experience difficult patient encounters, and communication defined as "psychosocial" (as opposed to biomedical) was more likely to be associated with patient and physician satisfaction [14]. Physicians working in health maintenance organizations (HMOs) as opposed to private practice, as well as primary care physicians, have indicated higher levels of frustration [25]. Although fewer physicians work in HMOs than in the late twentieth century, this observation is still important and could carry over to physicians working as health system employees and who face similar administrative pressures and lower levels of personal control over their practice than would be the case in private practice. Physicians who reported a high frequency of difficult interactions were more likely to report feeling burned out and less likely to be satisfied with their jobs [16]. In a study that evaluated the characteristics of physicians who worked with "heartsink" patients – patients who created a sense of impotence or helplessness in their physicians – it was noted that physicians were more likely to report they worked with "heartsink" patients if they had "more than the usual workload" [28]. Finally, younger physicians, those who work longer hours, and those physicians whose patient panels include high numbers of those with substance abuse or challenging psychosocial backgrounds were more likely to report that they had a high number of "difficult" patients [29].

In addition to physicians' own assessment of issues that are likely to increase the risk of difficult patient interactions, patients have identified that they have lower trust in their physicians if their physician is not answering questions in ways that they can understand, if physicians are not taking time to answer questions, or if physicians are not giving enough medical information [30]. This lower level of trust made patients consider changing physicians and would likely present a risk for difficult or challenging doctor/patient encounters: if therapeutic relationships are at the heart of the work done by family physicians, then any experience or perception that reduces trust in that physician will interfere with this core principle.

The relationship between a high number of difficult patient interactions and reported high stress/low job satisfaction seems evident, but it is difficult to separate cause from result. Physicians working with large numbers of "heartsink" patients may report increased burnout, but that burnout may predispose physicians to more challenging interactions.

Difficult physician/patient interactions are not solely due to physicians or patients. Rather, they result from interplay of different elements. These elements include patient and physician factors as described above, but other elements must also be considered [31]. The illness itself and the health system in which patients access care play important roles in the creation of a difficult interaction. Difficult relationships may occur when physicians and/or patients do not feel that interventions are successful or effective; when patients/physicians are not flexible or adaptable in terms of addressing diversity of thought, experiences, or preferences; or when patients/physicians have misaligned expectations about goals and anticipated outcomes of care [32].

Treatment

In family medicine, it is important to consider that a patient's illness can be defined by predisposing factors, precipitating factors, and perpetuating factors [33]. This model may be used to consider how to approach a difficult physician/patient interaction. The predisposing factors would include the patient and physician factors listed earlier; the precipitating factors may be a particularly difficult interaction, a sudden stress experienced by the patient, or puzzling symptom that is hard to explain; and the perpetuating factors would be a lack of trust, poor communication between the parties, or mismatched goals of care. With this in mind, we need to consider what can be done to address predisposing factors in advance of the visit, how to recognize a precipitating factor when one occurs and how to limit the precipitating factors we can control, and how to reflect after a visit on what factors might be perpetuating the problem. This last step includes how to ensure physicians are taking care of themselves in order to sustain the resilience needed to work with challenging patients.

Before the visit: Virtue ethics describe individual traits which "dispose an individual to act justly in a particular situation," and the ethical values of courage and compassion may be especially important in working with challenging patients, given that these patients may test physicians' abilities to stay engaged with them over time and to continue to feel empathy in the face of an often-difficult relationship [34]. Strong physician job satisfaction, appropriate physician workload, and training in communication skills and in counseling are associated with a reduction in physician perceptions of patients as being difficult or frustrating, while working with complicated patients with multiple medical problems or in time-restricted settings increases physician frustrations. Postgraduate training in communication and point-of-care counseling interventions, reduced number of patients seen by physicians, and/or increased time provided for patient visits may be beneficial. Training in active listening [35] may help physicians better care for patients by incorporating patients' concerns into encounters. Encouraging ongoing doctor/patient relationships allows a stable dyad to address various ongoing medical issues without feeling obligated to address all of them at any one time.

Enhanced training and education of individual physicians can address some of these issues, but others will require reevaluation of the current practice environment. Fee-for-service payment models result in family physicians being encouraged to see more patients in any given amount of time and are at risk of perpetuating those factors that physicians have identified as making patient interactions more difficult. In comparison, models of patient care such as patient-centered medical homes or direct primary care may allow for lower volumes of care and longer visits for complicated patients and may increase job satisfaction and physician perception of control. These factors, in turn, may help enhance physician resilience and reduce the frequency of challenging or frustrating interactions. Addressing time pressures and encouraging physicians and patients to talk about concerns and shared approaches to diagnosis, evaluation, and treatment will improve patient experiences and help reduce the level of frustration felt within the relationship.

Strong patient/physician relationships, which include both a physician's empathy toward the patient and patient empathy toward the physician, may help avoid challenging interactions by improving understanding on both sides of the dyad. Graphic medicine has been proposed as a potential tool to facilitate co-learning between patients and physicians [36] to allow each to better understand the concerns and context experiences by the other.

In the exam room: During office visits with frustrating or difficult patients, there are useful approaches to identifying which patients may need more attention and to working effectively with patients who generally present challenges to the physician. It has been suggested that a physician's own frustration with a patient might be a marker for which patients may benefit from

Telegram: @medical_k

www.konkur.in

mental health evaluation and care and that using Kleinman's explanatory model [37] may help enhance communication between physician and patient [3], especially if there are discordant views of the patient's health status.

Carde suggested approaches to working with patients defined as "difficult" as a result of their social circumstances. The recommended steps include building a good relationship with patients who may have been marginalized in the past, being realistic about what care can be provided and how much progress in providing care might occur in any given encounter, and interacting with colleagues who share this work – as a way to both decompress the stress which might result from the encounter and share best practices and learn new ways to work with these patients [18]. These suggestions are broadly applicable to any challenging patient, especially if social stigma, discrimination, or injustice may be part of their histories.

Active listening, an approach in which physicians move beyond facilitation skills to become aware of cues in patients' comments or behaviors that suggest underlying concerns, may help physicians better elicit the patient's perspective on their illness. Patients may present their perspective via direct statements, expressions of feelings, or concerns about an illness, repeating certain ideas or concerns about an illness, or behaviors such as reluctance to accept recommendations, interrupting the physician, "by the way" statements as a visit closes, etc. [35]. By recognizing these cues, physicians can seek to better understand patient concerns they may not have fully addressed and will be able to refocus their energy in those areas as well as rephrase their conversations with patients to encourage further discussion and disclosure.

Providing patients with diagnoses, prognostic information, etc. is associated with fewer ongoing concerns or continued symptoms and with improvement in symptoms after medical visits, and "difficult" patients were less likely to have received such information and more likely to describe unmet expectations [38]. This suggests that using the patient's explanatory model to frame the discussion of a patient's illness (including functional illnesses) may help align a physician's diagnosis and plan of care with a patient's expectations from a given office visit. Enhanced diagnosis and treatment of mental illness, increased psychosocial awareness and improved communication on the part of physicians, and standardized approaches to manage somatization may help reduce the difficulty of physician/patient interactions [14].

Building out of the four "hateful" patients he described [21], Groves suggested approaches for caring for difficult patients, including setting firm guidelines to doctor/patient interactions, refocusing patients' demands for any and all available interventions or evaluations toward those that will actually provide benefits, noting that treatment may not be curative but that it may help address symptoms, and working to provide the best care possible under the circumstances. In each of these situations, it is important to ensure that specific underlying issues of mental illness have been considered and evaluated while recognizing that a lack of insight on the part of the patient might limit the effectiveness of such evaluations and interventions. Personality disorders are best approached with techniques such as motivational interviewing and shared problem-solving with the patient [24]. Physicians can approach "difficult" patients using empathy to try and understand the patient's concerns and circumstances, listening with patience and without judgment, setting clear guidelines for patient encounters, and using referrals and specialists judiciously and appropriately [15].

Should a physician notice there is tension or discomfort in a patient interaction, it is important to assess what has happened and to consider the appropriate approach to remedy the situation. This process includes recognizing and acknowledging that tension has developed, assessing the source and the nature of the difficulty, and using a problem-solving approach that aims to preserve the relationship as well as addressing the medical needs while not losing sight of compassion or the importance of appropriate boundaries [32]. This stepwise approach may help avoid conflict and tension and may minimize the experience of difficult interactions between patients and physicians.

www.konkur.in

One approach to difficult clinical encounters summarizes many of these considerations. The CALMER approach (Table 1) provides six steps family physicians can use during difficult patient interactions and focuses on physician responses to difficult encounters while seeing to preserve the relationship [39]. Experienced physicians have also noted that challenging medical encounters could be salvaged (or encouraged) through physician/patient collaboration and the appropriate use of power and empathy in the encounter [19].

McCarthy et al. suggested a different, more concise approach to working with difficult patient encounters, which they compare to the SOAP model often used in medical visits (Table 2).

After the visit and physician self-care: Mindfulness techniques can be an important aspect of addressing difficult clinical encounters. Relatively simple interventions such as centered breathing techniques or reflection on important events at the end of a clinic day are easily put into action [41].

Table 1 The CALMER approach

C: Catalyst for change	Identify where patients are in the stages of change model, and assess their readiness to advance to the next stage
A: Alter thoughts to change feelings	Identify the thoughts patients generate, remember not to take anything personally, and consider how to move forward without feeling angry
L: Listen and then make a diagnosis	Listen to patients, and watch for nonverbal cues in order to accurately interpret information before making a diagnosis/decision
M: Make an agreement	Share decision-making with the patient
E: Education and follow-up	Work on a treatment plan the patient has agreed to, provide information to make it successful, and then plan the next visit
R: Reach out and discuss feelings	Following the visit, reflect by yourself and with others regarding the events and the encounter

Pomm et al. [39]

Table 2 ROAR

Reflective	Validate patients' concerns, and help them open to the encounter
Objective	Encourage patients to share their histories and share their clinical data with them
Assessment	List what is known and what is still under investigation; emphasize the process involved in making a diagnosis
Reassurance	Ensure patients know you are available for questions and follow-up care

McCarthy et al. [40]

An important element of working with patients is empathy, in which physicians attempt to understand to identify with another person's situation. Empathy can enhance a physician's flexibility, ability to work within a patient's frame of reference and to maintain a professional relationship without developing negative reactions to difficult interactions. "[T]hrough patience and tolerance, the physician may get a sense of where the patient is coming from and why the patient has resorted to negative response patterns." Empathy can be fostered by recognizing one's emotions in the moment of an event, reflecting on negative emotions in themselves and in their patients, focusing on the emotional content in patients' histories, being aware of patients' behaviors and nonverbal cues to encourage and enhance communication, and accepting patients' feedback (even if it is negative feedback) as a way to improve their performance while allowing the patient to open up about their concerns and worries [42].

Physicians must also be aware of the risk of countertransference, in which they may develop feelings toward patients based on the physician's own prior experiences and life circumstances. Just as patients engage in transference (where they project experiences from their lives onto the doctor/patient interaction), physicians may project onto patients via countertransference and must be mindful of this reaction and of the patient factors that trigger it [22].

Balint groups have been suggested as a way to help physicians sustain their engagement with patients with whom they may have difficult interactions or relationships. The work of Michael and Enid Balint defined what a therapeutic

Telegram: @medical_k

www.konkur.in

relationship should look like: a shared commitment to investigating ultimate causes of both the current illnesses and the patients' reaction to them, as well as the importance of taking the whole picture into account and acknowledging the patient's concerns as a key element of the illness and the physician's role in helping the patient move forward [43]. The goal of Balint groups is to evaluate difficult patient interactions and encounters and to help physicians reach a deeper understanding of the patient's perspective of the illness, the relationship, and the current situation. Balint groups for general practitioners have been effective in enhancing physicians' sense of competence in working with patients and in better understanding difficult relationships, in strengthening professional identity, in helping identify skills used in the group that are also effective in patient encounters (active listening, etc.), and in promoting endurance and satisfaction [44]. Balint groups may be important tools in enhancing physician effectiveness and caring, avoiding burnout, and improving professional satisfaction.

Another approach to assess individual performance after difficult encounters is through use of a Critical Practice Audit. As presented by Stephen Brookfield [45], the Critical Practice Audit allows physicians to consider critical events in a preceding week, assumptions they made (and that patients may have made) that contributed to the situation being challenging, what other perspectives should have been considered during the event, and how a situation may have been handled differently.

The importance of preparing for challenging patient encounters before the office visit and in reflecting and evaluating the outcomes after the visit has been evaluated by using the BREATHE OUT process. BREATHE OUT is a brief tool that involves physician and team preparation before difficult patients are seen in clinic and provides for a structured, reflective review following the encounter (Table 3). In a randomized trial, using BREATHE OUT improved physician satisfaction with challenging patient visits [46].

Finally, other interventions that can be pursued outside of the clinic include familiarizing oneself with community resources, scheduling patients appropriately to allow longer time for more complicated patients, and ensuring continuity of care [1].

Table 3 BREATHE OUT

Before the encounter	
B	List at least one **b**ias/assumption that you have about this patient
R **E**	**Re**flect upon why you identify this patient as "difficult"
A	List one thing you would like to **a**ccomplish today
T **H**	**Th**ink about one question you'd like to address today that would enable you to further explore your assumptions, including a patient-centered social history review
E	Stop before you **e**nter the patient room, and take three deep breaths in through your nose and out through your mouth
After the encounter	
O	Reflect on the **o**utcome of the encounter. From the patient's perspective, what was their agenda? From the physician perspective, did you accomplish your agenda?
U	Did you learn anything **u**nexpected?
T	List one thing you look forward to addressing if you were to run into this patient **t**omorrow

Family and Community Issues

While patients described as "difficult" demonstrated increased use of healthcare services [4], Grove suggested that difficult patient interactions could risk harm to patients by fracturing the necessary therapeutic doctor/patient relationship via inappropriate confrontation with the patient or attempts to avoid or exclude patients from the healthcare system [21]. Using the 10-item version of Difficult Doctor-Patient Relationship Questionnaire (DDPRQ-10), physicians reported difficult patients to be frustrating, time-consuming, and manipulative and reported that they felt communication was difficult and were ill at ease and lacked enthusiasm for caring for these patients in the future [4]. Given the definition of a therapeutic doctor/patient relationship, it is clear to see that when patients are identified as challenging, it will be more difficult for their physicians to form effective relationships with

Telegram: @medical_k

www.konkur.in

them. "Difficult" patients are also less likely to be satisfied with their healthcare and to seek more medical visits and interventions [14], suggesting that finding effective ways to work with challenging patients can lower healthcare utilization and prevent complications associated with healthcare. Physicians reporting a high number of difficult interactions were also more likely to indicate that they had engaged in suboptimal patient care practices in the past year and more likely to expect future errors in their practice [16]. Though this trend did not reach statistical significance in the study cited, it does raise the concern that a physician facing a high number of difficult patient interactions could cause inadvertent harm despite best intentions.

Closing

The nature of medical care, especially family medicine, is that we will see many patients and we will all face patient encounters that are difficult and challenging. By being aware of patient factors that increase the risk of these interactions and physician and system factors that may precipitate or perpetuate challenging relationships, family physicians can take active roles in our patients' healing while also enhancing our own skills in working in these difficult circumstances and working toward the goal of changing systems to benefit our patients.

treatment can be a daunting task. Similarly, chronic fatigue syndrome (CFS), a syndrome which arises in the setting of numerous biological, psychological, and social factors, can pose a diagnostic and treatment dilemma for the family physician.

Although fatigue has been described since the beginning of written history, it was not until 1896 that Beard first coined the term *neurasthenia*, a condition resulting from the depletion of the energy of the central nervous system [2]. Over time, various terms have been used to describe similar illnesses, with various etiologies proposed, ranging from environmental changes associated with modern living to immunological and postinfectious, including Epstein-Barr virus infection [2]. Fatigue in most patients is multifactorial, and the diagnosis of chronic fatigue syndrome is one of exclusion. It is thought to arise from a combination of genetic, neurological, immunological, and social factors, without one specific etiology. In this chapter, the evaluation of fatigue will be reviewed as well as the approach to diagnosis and treatment for CFS.

Epidemiology

While fatigue is a commonly reported symptom in the primary care setting, CFS is far less common. The prevalence of CFS has been noted to be similar across many different cultures and countries but does vary between studies. Epidemiological studies of two US cities demonstrated rates between 0.23% and 0.42% [2, 3]. CFS is more common in adults than children and more common in women and minorities [3]. Special considerations for diagnosis and treatment of CFS in these populations are discussed later in this chapter.

Approach to the Patient

Diagnosis

The differential diagnosis of fatigue encompasses many medical and psychiatric conditions including metabolic, infectious, sleep disorders, depression, and malignancy, just to name a few. When fatigue is present for more than 6 months and no laboratory or physical abnormalities are found, the diagnosis of CFS can be considered.

The diagnosis of CFS can be a difficult one to determine, and many diagnostic criteria have been proposed to aid both treatment of patients and research. In 2015, at the request of several governing bodies including the Centers for Disease Control, the Institute of Medicine proposed new diagnostic criteria for CFS to facilitate a timelier diagnosis and treatment as well as improve healthcare provider and researcher understanding of the disease [4]. In addition to this, they published a guidebook for clinicians which is very helpful, if detailed review of this syndrome is available online. In the criteria outlined in Fig. 1, the duration of 6 months or more is important, because it distinguishes CFS

Must have the following three symptoms:

1. Substantial Reduction or impairment in the ability to engage in pre-illness levels of occupational, educational, social, or personal activities
    a. persists **more than 6 months**
    b. accompanied by fatigue that is
        i. often profound
        ii. New or definite onset
        iii. Not the result of ongoing excessive exertion
        iv. Not substantially alleviated by rest
2. Post exertional malaise
3. Unrefreshing sleep

AND at least one of the following:

1. Cognitive Impairment
2. Orthostatic Intolerance

Fig. 1 IOM diagnostic criteria for CFS (SEID) [4]

Telegram: @medical_k

www.konkur.in

from other causes of fatigue. In their report, it is also proposed that the name for CFS be changed to systemic exercise intolerance disease (SEID) to focus on the central characteristic of the syndrome which is that exertion of any sort (physical, cognitive, emotion) adversely affect patients in multiple organ systems [4]. The need for ongoing monitoring for those who do not meet criteria as well as comorbidities in those who do is also important [4].

History

In addition to assessing for the above symptoms, a detailed history should focus on the time course of the fatigue, the patient's social history including drug and alcohol use, and current use of medications and supplements [5]. It is also important to consider the medical and psychosocial context within which the fatigue developed as well as prior history of trauma, including adverse childhood events (ACEs) and the social support system of the patient [6]. These components of the history are important, not only for making an initial diagnosis but also for designing a treatment plan tailored to the patient's individual needs and available resources.

Physical Examination

Physical examination of the patient with fatigue should be focused on assessing for underlying infection, inflammatory conditions, and metabolic disorders in addition to gaining an overall sense of the patient's well-being and function.

Laboratory Testing and Imaging

When evaluating the cause of fatigue, prior to considering CFS as the potential diagnosis, it is important to first look for other underlying causes of fatigue. Not all tests listed in this chapter are indicated for all patients. Laboratory testing should be directed at the patient's symptoms and clinical presentation. For example, testing for viral or bacterial infections is not indicated unless the history and/or physical exam indicates an infection may be present [7] (Fig. 2).

If the above indicated laboratory testing is within normal limits and no other underlying medical or psychiatric conditions can explain the patient's fatigue, the diagnosis of CFS should be considered based on the diagnostic criteria mentioned above.

Treatment

Patient perception lies at the heart of treatment of CFS. Predictors of improvement in symptoms were not related to disease severity or chronicity of the patient's fatigue in one British study but rather the patient's attitudes and beliefs surrounding the illness [8]. For example, patients who participated in support groups had a lower

Complete blood count with differential
Basic Metabolic Panel
Calcium

Telegram: @medical_k

www.konkur.in

treatment response than those who did not, largely because the group patients tended to participate in reinforced certain illness beliefs as well as exercise avoidance [8]. The two treatments for CFS with the best evidence are cognitive behavioral therapy (CBT) and graded exercise therapy (GET). Both are thought to have an impact on the patient's beliefs about fatigue and their own limitations secondary to their fatigue. A change in patient beliefs surrounding fatigue as well as improving patient's sense of empowerment and self-efficacy whether by CBT or GET is likely to be beneficial for a patient CFS.

Cognitive Behavioral Therapy

Cognitive behavioral therapy (CBT) has been demonstrated in several studies as more effective than usual care or other psychological treatments including relaxation, counseling, and relaxation/support, though the data on the long-term effects of this are inconclusive [8]. More research is needed into whether CBT or CBT in combination with other therapies such as graded exercise is most optimal, as well as the acceptability of CBT among patients with CFS [8]. Given its demonstrated benefit, at least in the short term, it would be reasonable to offer CBT as a treatment modality to a patient with CFS regardless of the duration or severity of symptoms. CBT can also be directed at other problematic symptoms experienced by patients with CFS, such as chronic pain, depression, and poor sleep.

Graded Exercise Therapy

Graded exercise therapy (GET) has been demonstrated to be beneficial for patients with CFS [6, 7]. A Cochrane Study evaluating GET when compared to usual care or passive therapy found that GET probably has a positive effect on fatigue in patients with CFS [9]. GET is thought to work synergistically with CBT because it provides a practical context for the cognitive restructuring around fatigue that effective CBT encourages [10]. In one review of 12 studies of GET and CFS, it was determined that in order to obtain maximum benefit from GET, patients should be encouraged to focus on a time-contingent approach rather than symptom-contingent approach, as well as to engage in aerobic exercise as determined by an individually derived target heart rate [11]. Patients can also engage in a home exercise program of 5–15 min per session five times per week and gradually progress to up to 30 min [11]. Given the sensitivity of many patients with CFS to exertion, activity undertaken by patients with this diagnosis should be closely supervised by a medical professional, in order to prevent overexertion and worsening of fatigue.

Medication

Pharmacotherapy, including nutritional supplements, outside of the use of medication for specifically diagnosed comorbidities, has not been shown to be beneficial in CFS [6, 7, 12]. In one Australian study, patients with CFS reported taking a wide variety of prescribed medications such as sedatives and antidepressants in addition to over-the-counter supplements to gain relief from their symptoms [12]. A systematic review of pharmacologic therapies studied for the treatment of CFS found that no universal pharmacologic treatment can be recommended, citing the widely varied diagnostic and outcome criteria used between various studies [13]. Patients with CFS are often very sensitive to medication, and this in addition to the side effect profiles of many of these medications make them a less desirable treatment option for patients with CFS. On the other hand, it is crucial to treat comorbid conditions, particularly those that influence the patient's level of functioning. While the addition of an antidepressant or other medication in the absence of a diagnosis of a comorbid condition such as major depression has not been demonstrated to be helpful, when the diagnosis of depression is made, it is an important part of the patient's overall medical care [14].

Telegram: @medical_k

www.konkur.in

Referrals

Specialist involvement in the care of patients with fatigue should focus on the treatment of comorbid conditions and underlying causes as determined by history, laboratory workup, or physical exam. Additionally, rheumatology consult can be considered. It is important to remember, however, that the family physician plays a particularly important role in the care of patients with CFS, because coordinated care is central to the improvement in symptoms [7].

Patient Education and Activation

Patient education and involvement are central to the treatment of CFS. The patient's perception of fatigue and of their own self-efficacy plays a large role in determining their response to treatment of any kind; patient engagement and activation are absolutely critical to success [3].

Chronic Fatigue Syndrome in Children

Although CFS is thought to be less prevalent in children and adolescents than in adults, a wide range of prevalence of CFS in adolescents is thought to be between 0.11 and 1.29% found in Dutch, USA, and British populations [15]. As in adult populations, the diagnosis of CFS in children and adolescents is one of exclusion, and a detailed history and physical along with any indicated laboratory tests is indicated. In addition to the tests recommended for adults, serum ferritin should be strongly considered in children and adolescents presenting with fatigue. Two thirds of adolescents responded to CBT in one study after 6 months of treatment, and this treatment effect was sustained at 2–3-year follow-up [15]. Making a prompt diagnosis and getting children and adolescents into the appropriate treatment are of the utmost importance, as these determine the prognosis for the child's recovery [15].

Chronic Fatigue Syndrome in Elderly Adults

Fatigue is a prevalent concern in the elderly with some estimates of prevalence greater than 70% [16]. While fatigue does tend to occur with normal aging, it is important to rule out underlying conditions that may result in fatigue. It is estimated that up to two third of elderly patients presenting with fatigue will have a cause found on history, physical examination, and/or laboratory evaluation [16]. The same diagnostic criteria for CFS apply to the elderly as to the general adult population, but special attention should be paid to ruling out psychiatric and neurological conditions, including depression and dementia. In addition to this, special care should be taken in elderly patient populations to assure appropriate social support, especially if the diagnosis of CFS is made.

Chronic Fatigue Syndrome in Underrepresented Minority Populations

The prevalence of CFS is thought to be higher in minority groups, but the diagnosis in these patient populations can be more difficult if the family physician is not aware of the social and cultural context within which the patient presents [3]. One study in the UK looked at why the diagnosis is made less frequently in black and minority ethnic groups when compared to groups of white patients [17]. Their findings suggest that there was a lack of awareness of CFS among this patient population, lack of access to primary care, as well as incorrect assumptions and beliefs among physicians. They cited higher turnover of primary care physicians in inner city practices as well as lack of training in cultural sensitivity as contributing to this problem. They point to the importance of an ongoing relationship with a primary care physician as an important aspect of obtaining the correct diagnosis and providing quality care for this patient population [17].

www.konkur.in

Family and Community Issues

CFS can produce both community economic hardship through the loss of occupational productivity but also family hardship in a family for whom one member is not able to fully participate in its day-to-day operation. Focusing on function and helping patients work with their families to improve their understanding of their illness and address their fatigue are ways in which family physicians can help patients to participate more fully both at home and at work.

Conclusion

Fatigue is a symptom that is commonly reported to the family physician, and CFS is an illness which helps family physicians conceptualize and treat fatigue for which no clear etiology can be found. Patients complaining of fatigue should have a thorough history, physical examination, and laboratory workup as outlined above. The diagnosis of CFS should be considered in any patient with fatigue for greater than 6 months and associated symptoms as outlined in the diagnostic criteria proposed by the Institute of Medicine. The workup of fatigue varies depending on the patient population and presenting complaints. It is important to evaluate fatigue in the context of the patients' social situation, emotional well-being, and ability to act with self-efficacy as these are all important things to be addressed if interventions are to be successful. Coordination of care and a strong therapeutic alliance predict success in the treatment of CFS.

General Principles

Definition/Background

We spend 1/3 of our lives in the reversible state of perceptual isolation called sleep. Unsurprisingly, disruptions and disorders of this primary physiologic state can lead to declines in quality of life, diminished waking performance, more frequent

illness, as well as increases in disease morbidity and mortality. The spectrum of sleep disorders mirrors illnesses seen in the family medicine clinical population, so that most patients with sleep disturbance will receive their medical care in the primary care setting [1]. Despite high prevalence, sleep complains are often under-addressed by physicians. Recently, high-quality epidemiologic studies have documented the importance of the diagnosis and treatment of sleep disorders in primary care practice in order to reduce morbidity and mortality, improve comorbid disease processes, and improve patient quality of life [2, 3].

Classification

Sleep Disorders: The Clinical Spectrum

Sleep diagnoses range include those presenting primarily based on patient complaint (e.g., the insomnias) as well as those with strong negative affects morbidity and mortality yet effects on waking functioning that may be more difficult for the patient to understand and describe (e.g., sleep apnea). The primary sleep diagnoses are divided into six categories: insomnias, sleep-related breathing disorders, hypersomnias, circadian-rhythm sleep disturbance, parasomnias, and sleep-related movement disorders. Sleep disturbance is often secondary, associated with almost all chronic diseases that result in physical or mental discomfort for the patient, and incorporated into most psychiatric disorders as diagnostic criteria. Pregnancy and menopause, increasing age, and stress induce insomnia and sleep disruption. Pediatric sleep disorders are common.

The Insomnias

Background

Insomnia is a primary care problem. Thirty percent of the general population report symptoms of sleep disruption, and in the primary care clinic, more than 50% of patients have sleep complaints [4]. Diagnostically, over 40% of American adults occasionally struggle with insomnia, and 11–14% of the population have an ongoing problem with chronic insomnia [5]. Those at greatest risk include women and older adults. Insomnias is defined as the complaint of difficulty with sleep initiation, duration, consolidation, or quality; associated with daytime functional impairment. The daytime functional impairment in insomnia is most often fatigue, impaired memory or concentration, mood disturbance, daytime sleepiness, reduced motivation or energy, tension, headaches, or gastrointestinal symptoms. In adults, chronic insomnia can induce impaired social and vocational function and reduced quality of life. In severe cases insomnia may be associated with an increased risk of traffic and work site accidents as well as psychiatric disorders. In pediatrics, insomnia is most often an early childhood problem that develops when the child first attempts to sleep independently of parents [6].

Individuals with chronic insomnia consistently report lower values of quality of life on somatic/physical scales. Chronic insomniacs have an increased risk of depression and anxiety. Sleepless individuals are more likely to be obese. Chronic insomnia is also associated with increased pain in rheumatic disease with the degree of insomnia on any given night being a predictor of pain intensity the following day [7]. The annual direct cost of insomnia in the United States includes $1.97 billion for medications and 11.96 billion for healthcare services. Indirect costs include decreased productivity, higher accident rate, increased absenteeism, and increased comorbidity, with total annual cost estimates ranging from $30 to $107.5 billion [8].

Diagnosis

Diagnosing insomnia can be a complex task as the origin of a patient's insomnia is often multifactorial. Life stressors, concomitant illness, family, and social structure can precipitate symptomatic insomnia. The family medicine physician, who often has a more complete knowledge of these factors than the subspecialist, is in an ideal position to define the cause of the sleep–wake disturbance in a patient with insomnia. Insomnia is a subjective complaint with the diagnosis primarily based on a sleep history. Physical exam

Telegram: @medical_k

www.konkur.in

contributes little to the diagnosis and objective evaluation of sleep with polysomnography is rarely indicated. Evidence-based criteria for the evaluation and treatment of insomnia are summarized in Tables 1, 2, and 3 [9].

Treatment

Insomnia responds well to cognitive behavioral therapies (including sleep hygiene, sleep restriction, and behavioral approaches to treating conditioned insomnia). Sedatives including the barbituates and benzodiazepines induce sleepiness that extends into wakefulness after their use, induce tolerance, and have addiction potential. Sedating antidepressants and antipsychotics used for night-time sleep induction, also induce significant waking sedation. The newer GABA-specific site hypnotic medications have high efficacy, low toxicity, and minimal addictive potential. For patients with persistent insomnia, chronic use with the newer hypnotics can be justified and is indicated if medication use leads to improvement in waking performance. These hypnotic agents are less likely to have deleterious side effects than diphenhydramine the most commonly used OTC treatment for insomnia contraindicated for use in anyone over 65 years of age (Table 4) [11].

Table 1 Evidence-based symptom and diagnostic correlates for chronic insomnia

Chronic insomnia leads to poorer self-rated quality of life	A	Multiple large retrospective cohort studies
Chronic insomnia leads to increased health-care cost for affected patients	A	Multiple large retrospective cohort studies
Chronic insomnia predisposes an individual to mood disorder/depression	B	Large retrospective cohort study, longitudinal prospective study
Chronic insomnia is associated with decreased work productivity and increased time missed from work and/or school	B	Multiple small retrospective studies with consistent findings
Chronic insomnia leads to drug and alcohol abuse	C	Significant associated variables in adult and adolescent populations
Chronic insomnia leads to obesity	C	Small retrospective studies
Chronic insomnia is associated with an increase in automobile accidents	C	Retrospective review
Chronic insomnia is associated with an increase in mortality in geriatric patients	C	One large retrospective study
Chronic insomnia is associated with increased pain complaints in chronic pain patients	C	Retrospective review

Eszopiclone	6 h	Anecdotal [placebo equivalent]	Possible parasomnia associations

The Sleep-Associated Breathing Disorders

Background

Obstructive sleep apnea (OSA) is a physiologically disruptive and dangerous sleep diagnosis. OSA has a strong association with pulmonary, cardiac, endocrine, cognitive, and psychiatric disease [12]. In patients with OSA, continued breathing effort occurs despite obstruction of the airway associated with inadequate ventilation. OSA is more common among men, snorers, the elderly, and among those who are overweight. Worldwide, more than 700 million individuals now have a BMI $>$ 30 [9]. This level of obesity and an increasingly aging population have led to an epidemic of this physiologically dangerous diagnosis. The symptoms of OSA include persistent snoring (80%), daytime sleepiness (22–32%), and apneas observed by bed partners or caregivers (in adults, the report of observed apnea often

Telegram: @medical_k

www.konkur.in

indicates the present of severe apnea). OSA is present at high frequency (24–34%) in the adult primary care clinic population and must be suspected in any patients with comorbid diagnoses known to be associated with apnea [12] (Table 5).

Adult OSA has a clear association of daytime cognitive impairment (i.e., daytime sleepiness) contributing to a significantly higher rate of motor vehicular accidents in untreated patients [13]. Recent epidemiological studies have cross-matched sleep apnea evaluation with long-term prospective cardiovascular risk, pointing out the consistent and strong association between OSA and essential hypertension, increased mortality, congestive heart failure (both right and left sided), myocardial infarction, and cerebral vascular accidents [12]. Recent studies have emphasized the clinical significance of the association between atrial fibrillation and untreated OSA [14]. OSA can contribute to insulin resistance and metabolic syndrome [15]. Treatment of OSA can produce an improvement in PTSD symptoms among individuals who have both diagnoses [16] (Table 6).

Diagnosis and Treatment

In most cases in order to diagnose and treat OSA polysomnography (PSG), the recording of multiple physiological signals during sleep including channels of electroencephalography (EEG), electrooculogram (EOG), and chin electromyogram (EMG) is required. A PSG includes sleep staging as well as recordings of respiratory effort, airflow, pulse oximetry, snoring, sleep position, ECG, leg EMG, and video monitoring. Additional channels are sometimes utilized including end-tidal or transcutaneous CO_2 and additional EEG channels if potential nocturnal seizure disorders are being evaluated. The clinical indications for PGG are summarized in Table 3.

OSA is most often treated with devices that hold the airway open during sleep by utilizing positive airway pressure (PAP). This treatment is well tolerated by most OSA patients with few side effects and documented reductions in morbidity, hospitalization, and health-care utilization [17]. In evaluating OSA, a split night protocol is often utilized in which a therapeutic treatment or titration portion of the PSG is added during the night of study after a period of diagnostic sleep time. A PSG report includes data as to sleep architecture, respiratory parameters (number and index of apneas [episodes of complete respiratory cessation], hypopneas [episodes of reduced respiratory drive and hypoxia], and respiratory-related arousals), periodic limb movements, a description of any parasomnia or seizure activity, EKG abnormalities, and the results and appropriate setting for any treatment attempted during the night of study.

Alternative approaches to PSG include home screening tests (HSTs), an approach that has been shown to be particularly useful in younger patients without comorbid diagnoses [18]. These

Table 5 Clinical diagnoses associated with OSA including the approximate % of adult patients in each category with apnea–hypopnea index (AHI) > 5.0 events per hour

Obesity – 40–75%
Morbid obesity >80%
Excessive daytime sleepiness – 60–80%
Hypertension – 40–80%
Myocardial infarction (CAD) – 60–70%
Cerebral vascular accident – 60–70%
Atrial fibrillation – 60–80%
Chronic pain treated with opiates – 70–80%
Congestive failure (right and left sided) – 70–80%
Metabolic syndrome – 80%
Diabetes – 40–60%
Posttraumatic stress disorder – 60–80%

Table 6 Evidence-based associations of obstructive sleep apnea (OSA)

Adult OSA	Obesity	A – consistent systemic meta-analyses
	Cognitive impairment (daytime sleepiness)	A – Consistent systemic meta-analyses
	Motor vehicular accidents	A – Consistent systemic meta-analyses
	Hypertension	A – Cross-sectional analysis of prospective cohort studies, consistent systemic meta-analyses
	Increased mortality	B – Retrospective cohort studies
	Congestive heart failure (right and left sided)	B – Cross-sectional analysis of prospective cohort studies, inconsistent systemic meta-analyses
	Coronary artery disease	B – Cross-sectional analysis of prospective cohort studies, retrospective diagnostic cohort study
	Cerebral vascular accidents	B – Cross-sectional analysis of prospective cohort studies, retrospective cohort study
	Metabolic syndrome	B – Cross-sectional analysis of prospective cohort studies, retrospective cohort studies
	Atrial fibrillation	B – Multiple retrospective cohort studies and treatment follow-up studies
	PTSD	B – Multiple retrospective cohort studies with positive response to PAP therapy
	Diabetes	C – Retrospective cohort studies
	Other cardiac arrhythmias	C – Case series, usual practice
Pediatric OSA	Poor school performance	B – Multiple retrospective cohort studies
	Downs syndrome	B – High frequency of OSA (50–100%) in multiple small retrospective studies, positive response to therapy
	Enuresis	C – Retrospective cohort studies
	Failure to thrive	C – Case series, usual practice
	Learning disability	C – Retrospective cohort studies
	Obesity	C – Retrospective cohort studies
	Attention deficit/ hyperactivity disorder	C – Inconsistent retrospective cohort studies

Adapted table from Pagel and Pegram [9]
Strength of recommendation based on Ebel et al. [10]

studies have limitations. They cannot determine whether the patient is actually asleep during the recording, and in patients with insomnia the number of respiratory events (apneas and hypopneas) per hour will be lower than actually present due to recording time that will be in wake. Periodic limb movements and arousals from events such as parasomnias are not recorded by HSTs, and most home screeners differentiate poorly between obstructive and central apneas. Central sleep apneas (CSA) are nonobstructive apneas in which the individual exerts no respiratory effort. CSA is less common than OSA presenting most often in patients with CHF; post-ICU patients; those with a history of significant cardiovascular, pulmonary, or CNS disease; development abnormalities; opiate use; the extreme elderly; and those living at elevations above 6500 ft. [19, 20]. Treatment includes the addition of oxygen or backup rate systems to PAP therapy. HST can be coupled with PAP auto-titration to avoid full PSG testing. Auto-titrating pap systems are tolerated well by some patients; however, these systems have minimal diagnostic capacity and can report inappropriate settings for misdiagnosed patients and patients with central apnea and/or nasal congestion or mouth leaks on pap therapy [21]. OSA can also be treated with dental mouthpieces and ENT surgery, approaches that reduce rather than eliminate (as with PAP) the number of apnic events [22].

Telegram: @medical_k

www.konkur.in

In pediatric patients, OSA is most clearly associated with tonsillar hypertrophy. OSA can contribute to poor school performance [23]. Studies also support the association of pediatric OSA with failure to thrive, obesity, enuresis, attention deficit/hyperactivity disorder, Downs Syndrome and other developmental disorders, and learning disability. The treatment of pediatric OSA is most often surgical – (T&A).

Excessive Daytime Sleepiness (Other Hypersomnias)

The National Health and Safety Administration (NHTSA) in 1999 estimated that 9.5% of police-reported crashes and 4% of all traffic crash fatalities involved drowsiness and fatigue as contributing causes. Beyond the personal and social loss associated with these accidents, the cost of untreated daytime sleepiness was estimated at $12.5 billion based on workplace loss and loss of productivity [23]. The most common causes of daytime sleepiness are sleep deprivation and the use of prescription and nonprescription agents as well as drugs of abuse that induce daytime sleepiness (daytime sleepiness is among the most common of medication side effects) [24]. The next most common cause is untreated OSA. The other sleep disorders such as narcolepsy that induce daytime sleepiness occur at a much lower frequency (2/1000). The hypersomnias generally require both PSG and multiple sleep latency testing (MSLT) for diagnostic evaluation and assessment of daytime sleepiness. The MSLT includes four to five opportunities to nap in the sleep laboratory after a full-night PSG with EEG, EOG, and EMG monitored, so that sleep and REMS onset can be determined. MSLT reports should include average or mean latency to sleep and the number of sleep onset REMS periods recorded (diagnostic criteria for narcolepsy). Medications used in somnolent patients to induce alertness include the amphetamines (medications with high abuse potential) and newer alerting agents (e.g., modafinil) that have a lower potential for abuse and negative side effects.

Circadian-Rhythm Sleep Disorders

The biological clock for sleeping is based in part on the circadian rhythm of sleep and wake propensity. Chronic sleep disturbance can result from disruptions in this system or from misalignments between an individual's circadian rhythm and the 24-h social or physical environment. Delayed sleep-phase syndrome (DSPS) in which individuals go to bed and rise later than the general population is symptomatic in 7–16% of adolescents. Shift work disrupts normal sleep patterns for approximately 20% of the population. At least 10% of individuals evaluated in sleep laboratories for chronic insomnia have a definite circadian component to their disorder [8]. Melatonin is the photoneuroendocrine transducer that conveys information controlling sleep–wake cycles and circadian rhythms in the central nervous system (CNS). Low doses coupled with bright-light therapy are useful in treating these disorders [26]. Jet lag and shift work disorders can also be effectively treated with repetitive short-term use of sedative/hypnotics [27].

Parasomnias

Parasomnias are undesirable physical events or experiences that occur during entry into sleep, within sleep, or during arousals from sleep. Parasomnias encompass sleep-related movements, behaviors, perceptions, emotions, and disturbed dreaming – sleep-related behaviors and experiences in which the sleeper has no conscious deliberate control. Parasomnias become clinical diagnoses when associated with sleep disruption, nocturnal injuries, waking psychosocial effects, and adverse health effects. Many parasomnias are sleep state specific. Recurrent nightmares (the most common of the parasomnias) occur in 15–40% of normal adolescents. A wide spectrum of medications is known to induce nightmares (diphenhydramine, nicotine, and SSRI antidepressants are common culprits) [28]. Recurrent, disturbing nightmares are the most common symptom of posttraumatic stress disorder (PTSD).

Telegram: @medical_k

www.konkur.in

REM behavior disorder (RBD) in which the motor block that usually prevents the acting out of dreams is lost, is most common in late-middle-age males and in patients with progressive neurological disease (e.g., Parkinson's disease). RBD occurs in 0.38–0.5% of the population [1]. The arousal disorders of somnambulism (sleep walking, night terrors, and confusional arousals) are reported by 4% of pediatric patients. Since pediatric parasomnias often disappear with the onset of puberty, treatment is most often bed-site protection and parental reassurance. Enuresis is present in 15–20% of 5-year-old children declining to 1–2% in young adulthood.

Sleep-Related Movement Disorders

More than 12 million people in this country experience unpleasant, tingling, creeping feelings in their legs during sleep or inactivity as a symptom of a disorder called restless legs syndrome (RLS). This disorder causes an uncontrollable urge to move and to relieve the sensations in the legs. Sleep in these patients is often disrupted by periodic limb movements occurring in the extremities during sleep that can be detected by PSG. Low dosages of dopamine precursors and dopamine receptor agonists at bedtime have been demonstrated to be efficacious in these disorders [29].

The Family Physician and Sleep Medicine

On any given day up to 90% of adult patients visiting their primary care physician are experiencing sleep-related symptoms. At least 1/3 are likely to have OSA. Currently, despite the known increases in morbidity and mortality associated with this diagnosis, only 4% of the individuals likely to have OSA have been tested. Approximately 14% of the general population suffer from chronic insomnia, with 1/3 of the population reporting occasional symptoms. Up to 15% of adults suffer from RLS/PLMD [29]. Payers, concerned with the potential cost of evaluating and treating this large number of patients, have pushed sleep medicine diagnosis and treatment into the primary care setting where family physicians and physician extenders are expected to make correct diagnoses and monitor appropriate treatment. Sleep medicine consultation for difficult patients is available in many communities, and the same standard of care is expected even when diagnosis is limited to screening questionnaires, an approach known to have low sensitivity and efficacy, and treatment approaches with known limitations [30].

Few primary care physicians routinely address sleep complaints or screen for OSA. Questionnaires can be an excellent tool for obtaining information about sleep disorders, but even when sleep complaint questionnaires are highlighted on patient charts, patients at high risk for are infrequently evaluated. Studies from outside the USA indicate the potential for primary care sleep medicine. Primary care physicians with limited training in sleep medicine were shown to provide a level of care for patients with suspected OSA in South Australia comparable to that provided in the University Sleep Medicine Center in Adelaide [30]. There are a huge number of patients with sleep-associated diagnoses affecting their mortality and morbidity. The current care system has been able to address OSA in only a small percentage of the affected individuals. Sleep-associated diagnoses negatively affect the medical and psychiatric disorders most often seen in family medicine: hypertension, obesity, cardiovascular disease, arrhythmias, mood disorder/depression, and anxiety. The associated personal and medical costs of untreated sleep disorders are staggering. Associated daytime sleepiness negatively affects driving and work performance and when untreated contributes to a large number of motor vehicular accidents, injuries, and deaths. Sleep medicine care is migrating into the primary care arena where the HST is beginning to be a clinical test as commonly utilized as EKG's and pulmonary function tests.

A majority of individuals that suffer from disorders of sleep and wakefulness are undiagnosed and untreated. Primary care physicians have access to this large grouping of at-risk patients as well as training and experience in the full extent of

Telegram: @medical_k

www.konkur.in

medical and psychiatric illness affecting patients with sleep disorders. Family physicians often have close relationships with their patients and an awareness and understanding of the biopsychosocial context, an awareness often unapparent to the sub-specialist sleep physician. Family Medicine Physicians with an interest in sleep medicine can qualify for a CAQ qualifying them to interpret polysomnography reports and function as specialists in the field.

Prevention

Sleep disorders are extremely common and rarely addressed in many primary care practices, yet to date, the United States Preventive Services Task Forces, the American Academy of Family Physicians, and the Center for Disease Control have not recommended routine screening. This recommendation, made despite high incidence and excellent epidemiologic data as to negative and costly effects of sleep disorders, especially OSA, on morbidity and mortality, was made based on two factors: (1) the low sensitivity and specificity of inexpensive questionnaires designed to screen for OSA, and (2) the cost of HST screeners and polysomnography used to diagnose OSA. Current recommendations are that OSA should be considered as a potential diagnosis in every patient who has a diagnosis with high-frequency OSA comorbidity (obesity, hypertension, daytime sleepiness, cardiac disease, arrhythmias, chronic pain treated with opiates, CVA, CHF, and PTSD) (Table 3) [31].

A spectrum of poor sleep hygiene practices can induce insomnia, especially in high-risk populations such as adolescents and the elderly. High stress behavior, nicotine, caffeine, and the nocturnal use of electronic systems contribute to complaints of insomnia.

Family and Community Issues

Sleep disorders, including the common diagnoses of OSA and insomnia, are commonly found in family members based on both genetic and social factors. Daytime sleepiness in pediatric age groupings is associated with poor school performance. In adolescents, early school start times induce sleepiness and negatively affect school performance in a population prone to DSPS and social sleep deprivation [32]. In adults, daytime sleepiness whether based on OSA, sedating medication use, sleep disruption, or neurological disease is associated with a significantly higher level of motor vehicular and work-related accidents. This is a particular problem for shift workers and those who must drive for a living.

Introduction

Millions of Americans undergo surgery every year [1]. These patients must then turn to their primary care provider to undergo a preoperative evaluation. This preoperative evaluation allows the provider and the patient to optimize underlying conditions to improve surgical outcomes and minimize complications. The preoperative evaluation is not meant to clear the patient for surgery, but rather to evaluate and when necessary implement measures to better prepare high-risk patients for surgery [2]. An evaluation focusing on cardiac, pulmonary, infectious, and hematologic risk factors and determining the patient's functional capacity are essential elements for stratifying surgical risk [2].

Preoperative History

Any preoperative evaluation begins with details of the planned surgery. This entails the planned procedure, indication, surgery date, surgeon's name, and practice location. Obtaining a thorough history is an integral part of the preoperative evaluation. When discussing the patient history it is important to review all past and current medical problems, medications, previous surgeries as well as any previous surgical complications including personal or family history of reactions to anesthesia especially malignant hyperthermia or delayed awaking [3]. In children the history should include birth history, gestational age at birth, perinatal complications, congenital chromosomal or anatomic malformations, and history of recent infections [2]. If a patient has moderate or severe cardiac valvular disease, implanted cardiac devices, congenital heart disease, or severe pulmonary hypertension, current guidelines recommend evaluation by a specialist prior to a planned surgery [1, 4]. If the above conditions are not present, a preoperative evaluation completed by a primary care provider is appropriate. The majority of surgical morbidity and mortality complications generally fall into cardiac, pulmonary, infectious, or hematologic categories [2].

Cardiac Assessment

Surgical Risk

Once you have determined a patient is appropriate for preoperative evaluation to be completed by a primary care physician, you can move on to clinical assessment. Surgical risk is related to the degree of hemodynamic instability expected during the surgery or procedure [5]. Surgical risk is stratified by the American College of Surgeons into three categories and is based on the estimated 30-day cardiac event rates [5, 6] (See Table 1). Low-risk surgeries include ambulatory surgeries, breast, endoscopy, and cataract surgery. These are classified as low risk as their risk of cardiac death or nonfatal myocardial infarction (MI) is $<1\%$. Intermediate risk surgeries include surgeries that involve peripheral vascular structures, intrathoracic, intra-abdominal, head and neck surgeries, and orthopedic surgeries. Intermediate risk surgeries carry a 1–5% risk of cardiac death or nonfatal MI. Finally high-risk surgeries include any aortic or major vascular surgeries. These carry $>5\%$ risk of cardiac death and nonfatal MI [5, 6].

www.konkur.in

Table 1 Noncardiac procedure risk [1, 6]

Surgical Risk of Cardiac Death and Nonfatal MI in Noncardiac Procedures	
Risk of Procedure	Examples
High >5%	Aortic and major vascular surgery
Intermediate 1–5%	Intraperitoneal or intrathoracic, carotid endarterectomy, head and neck surgery, orthopedic surgery
Low risk <1%	Cataract, breast, endoscopy, ambulatory surgery

Risk Stratification

Risk stratification is dependent upon the patient's underlying health and the nature of the planned surgery. The American College of Cardiology/American Heart Association (ACC/AHA) recommends using a validated risk-prediction tool to predict risk of perioperative complications [1]. One of the highly utilized risk calculators is the Revised Cardiac Index (RCI). This calculator stratifies a patient's risk based on five clinical variables plus the surgical procedure being performed [1]. Each variable present increases the cardiac complication rate, which is defined as death, nonfatal MI, or cardiac arrest [1]. The presence of three or more factors carries a greater than 15% risk for cardiac complications. The RCI calculator is favored among clinicians as it is easy to implement and easy to interpret which makes it a valuable tool for preoperative assessment [1] (Table 2).

A second and newer calculator was developed by the American College of Surgeons (ACS) National Surgical Quality Improvement Program (NSQIP). This calculator was developed based on data encompassing more than one million operations and multiple surgical centers [1, 7]. The calculator uses the CPT code of the procedure being performed as well as 21 patient-specific variables. Variables include age, sex, BMI, dyspnea, steroid use, previous MI, and severe COPD, among others. Using the above variables the calculator provides an estimation of patient specific complication risk for cardiac, infectious, pulmonary, and even death compared to population averages [7]. An estimate of hospital stay and likelihood for need to discharge to a nursing or rehabilitation facility is also provided.

Functional Capacity

An important part of the preoperative history is to determine functional capacity. Functional capacity is important to discuss as it is a good predictor of perioperative cardiac complications [1]. A patient's functional capacity can be estimated by their activities of daily living. Functional capacity is often expressed as metabolic equivalents (METs). Functional capacity is described as excellent (>10 METs), good (7–10 METS), moderate (4–6 METs), or poor (<4 METs) [1]. Inability to perform activities of at least 4 METs in daily activities is correlated with increased perioperative complications [1]. Examples of activities <4 METs include: golfing with a cart, playing a musical instrument, and slow ballroom dancing [1, 8]. In contrast patients with a functional capacity greater than 4 METS are unlikely to have postoperative cardiovascular complications even if cardiac risk factors exist. Examples of activities with >4 METs include: climbing a flight of stairs, walking up a hill, and performing heavy housework (Table 3) [1, 8].

The Duke Activity Status Index (DASI) is a good self-administered questionnaire that can be used to assist the clinician in determining a patient's functional capacity [8] https://www.mdcalc.com/duke-activity-status-index-dasi.

Pulmonary Assessment

The incidence of pulmonary complications following surgery varies widely and is estimated to be between 1% and 23% [9, 10]. Preoperative risk factors for postoperative pulmonary complications (PPC) include age, type of surgery,

Table 2 Revised Cardiac Risk Index [1]

Revised Cardiac Risk Index	
High risk surgery (intraperitoneal, intrathoracic, or suprainguinal vascular surgeries)	1 point
History of ischemic heart disease	1 point
History of congestive heart failure	1 point
History of cerebrovascular disease	1 point
Preoperative treatment with insulin	1 point
Preoperative serum creatinine >2.0 mg/dL	1 point
RCRI Score	**Risk of major cardiac event**[a]
0 points	3.9% (2.8–5.4%)
1 point	6.0% (4.9–7.4%)
2 points	10.1% (8.1–12.6%
≥3 points	15% (11.1–20.0%)

[a]Major cardiac event defined as death, nonfatal MI, or cardiac arrest within 30 days of noncardiac procedures

Table 3 Functional assessment [1, 5]

Functional Assessment METs		
	Metabolic Equivalents	Examples
Poor	<4	Vacuuming, activities of daily living, 2 mph walking
Moderate	4–6	Climbing flight of stairs, cycling, 4 mph walking
Good	7–10	Hiking, leisure swimming, ballroom dancing
Excellent	>10	Jogging, singles tennis, scrubbing floors

functional status, smoking, chronic obstructive pulmonary disease (COPD), obstructive sleep apnea, and maybe nutritional status [10]. Age greater than 65 and poor functional status both increases the risk for postoperative pulmonary complications and infections.

Patients enrolling in smoking cessation programs at least 8 weeks prior to surgery decreased their risk for PPC. This time frame allowed for recovery of the mucocilliary transport mechanism within the lung to recover, thus decreasing secretions [9, 10]. Cessation of smoking less than 8 weeks is of questionable benefit and may have an increased complication rate.

Asthma and COPD should be under control prior to surgery with routine prescribed use of bronchodilator and/or steroid inhalers. Guidelines do not define a degree of pulmonary impairment that would prohibit surgery [2, 10]. Routine ordering of pulmonary function tests is therefore not warranted.

Obstructive sleep apnea (OSA) increases the risk for airway management difficulties in the postoperative period and all patients undergoing surgery should be screened for undiagnosed OSA [10, 11]. It has been estimated that approximately 60% of surgical patients with moderate to severe obstructive sleep apnea were undiagnosed [12]. Obstructive sleep apnea has a very high prevalence in the United States, the majority of which is undiagnosed. Though its influence on postoperative pulmonary complications has not been well studied, OSA is associated with several comorbidities including hypertension, diabetes, obesity, cerebrovascular and myocardial disease, placing the patient at higher risk for postoperative complications including unplanned re-intubations [11, 12]. To screen for OSA a relatively quick and efficient screening tool has been developed called the STOP-BANG questionnaire (Table 4) [12]. It consists of four subjective yes or no questions and four objective findings to arrive at a score of 0–8. The first four questions are related to sleep disturbances (snoring, tiredness, witnessed apnea periods, and high blood pressure). The remaining four questions are patient specific and include BMI ≥35 kg/m^3, age ≥50, neck circumference ≥40 cm or 15.75 in, and male gender. Each "yes" answer is one point. A score ≥5 is high risk for OSA, score of 3–4 is intermediate risk and score ≤2 is low risk [12]. A patient with a low score is very unlikely to have

Table 4 Obstructive Sleep Apnea Screening Tool [4, 12]

STOP-BANG Questionnaire	
1. **Snoring**. Have you been told that you snore during sleep?	1 point
2. **Tiredness**. Do you feel overly tired or fatigued during the day?	1 point
3. **Observed Apnea**. Have you been told you stop breathing while you sleep?	1 point
4. **Blood pressure**. Do you have elevated blood pressure?	1 point
5. **BMI ≥35 kg/m^3**	1 point
6. **Age ≥50 years**	1 point
7. **Neck circumference ≥40 cm**	1 point
8. **Male Gender**	1 point
Low risk	0–2 points
Intermediate risk	3–4 points
High risk	≥5 points

OSA and similarly a patient with a high score is very likely to have OSA. Patients who fall in the intermediate range are more likely to require further testing to confirm the diagnosis of OSA, which can be done using polysomnography or an overnight sleep study [12].

Several studies have indicated an increased risk for PPC in patients with low serum albumin levels [10, 11]. Those patients with poor functional status, limited financial resources, absent social support structure and the elderly are at highest risk for malnutrition. If there are nutritional concerns, preoperative nutritional supplementation can be provided prior to surgery. Though the exact duration of supplementation needed is uncertain, it has been suggested that a minimum of 7–15 days is required to provide benefit [2].

Upper abdominal and intrathoracic procedures are known to produce marked alterations in pulmonary function. The adverse effects on chest wall mechanics predispose patients to atelectasis and retained secretions [10]. Deep breathing exercises and incentive spirometry in the postoperative period may be beneficial in decreasing PPC in obese patients, those with lung disease, or those undergoing abdominal or thoracic procedures [2, 10].

Infection Assessment

Numerous risk factors have been identified for the development of surgical site infections (SSI) after surgery. Potentially modifiable patient risk factors include glycemic control, nutrition status, obesity, smoking status, alcohol use, immunosuppression, and total bilirubin >1.0 mg/dL [13]. Optimal blood glucose control should be encouraged for all patients; however, there is some evidence that short-term glucose control can be more impactful than long-term control of hemoglobin A1C. Target perioperative blood glucose should be between 110 and 150 mg/dL except in cardiac surgery patients where the target blood glucose is <180 mg/dL [13]. Blood glucose levels <110 mg/dL have not shown to decrease SSI rates and may be tied to an increase in adverse events [13]. All patients should be counseled to stop smoking. In this time period smoking cessation improves wound healing and decreases infection risk and other postoperative complications. In addition to PPC, malnourished patients are also at increased risk for SSI and as such patients should be screened for risk factors as previously outlined [13].

Though the prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) within the community has increased dramatically in recent years, universal screening guidelines for MRSA have not been developed. However, the American Society of Health System Pharmacists recommends screening and nasal mupirocin decolonization for *S. aureus* for all patients before total joint replacement and cardiac procedures [13]. Typical preoperative decolonization includes the use of 2% nasal mupirocin twice daily for 5 days [13].

Telegram: @medical_k

www.konkur.in

Endocarditis Prophylaxis

Infective endocarditis is a rare but life-threatening disease [14]. Due to the high levels of morbidity and mortality associated with infective endocarditis preoperative antibiotic prophylaxis has been common place for many years. Infective endocarditis is thought to develop after a transient bacteremia as a result of mucosal irritation especially the oral mucosa, GI tract, urethra, and vagina. Common pathogens include strep viridians, streptococcal species, and staphylococcal species [14, 15].

The American Heart Association/American College of Cardiology (AHA/ACC) state that antibiotic prophylaxis for high-risk patients undergoing procedures likely to result in bacteremia with a microorganism that has the potential ability to cause endocarditis is reasonable [15]. Routine prophylaxis for gastrointestinal (GI) or genitourinary (GU) procedures, even for patients with high-risk cardiac conditions, is not generally recommended [15]. High-risk patients include: patients with a history of infective endocarditis and patients with a prosthetic valve, congenital heart disease, and heart transplant patients [15]. Moderate-risk patients include: history of rheumatic fever, patients with native valve disease (bicuspid aortic valve, mitral valve prolapse, and calcified aortic stenosis), and patients with unrepaired congenital anomalies [15]. Current recommendations are based on case reports and small studies. For patients who are considered at risk for infective endocarditis antibiotic prophylaxis is recommended if undergoing the following procedures: dental procedures with gingival manipulation, respiratory procedures, and dermatologic or musculoskeletal procedures involving infected skin or tissue [15]. Appropriate antibiotic prophylaxis regimens that are preferred include: amoxicillin 2 grams orally as a single dose, 30–60 min prior to procedure in the non-penicillin allergic patient or clindamycin 600 mg orally also as a single dose 30–60 min prior to the procedure in penicillin allergic patients [15]. See Table 5.

Hematologic Assessment

When screening for perioperative hematologic disorders that may impact surgical management, assessment should ascertain risks related to the presence of anemia, polycythemia, bleeding, and/or clotting disorders. History should inquire to the presence of kidney disease, liver disease, inflammatory/autoimmune disorders, menstrual disorders or excessive bleeding, risk for nutritional deficiencies, signs/symptoms of anemia, and tobacco and alcohol use [6]. When discussing the patient history it is important to include a personal or family history of excessive bleeding or frequent blood clots. Need for further testing such as complete blood count or coagulation studies should be driven by the underlying history.

Venous thromboembolism (VTE), including pulmonary embolus (PE), is a major cause of morbidity and mortality in postoperative patients [16]. About 50% of all venous thromboembolism events occur as a result of a current or recent hospital admission for surgery or acute medical illness [17]. When performing a preoperative

Table 5 Antibiotic regiments for preoperative prevention of endocarditis [15]

Patient Scenario	Medication	Dose[a]
Able to take orals and no PCN allergy	Amoxicillin	2 g oral
PCN allergic	Cephalexin	2 g oral
	Clindamycin	600 mg oral
	Azithromycin or Clarithromycin	500 mg oral
Unable to take oral medications	Ampicillin	2 g IM or IV
	Cefazolin or Ceftriaxone	1 g IM or IV

www.konkur.in

evaluation it is important to review with the patient their risks for deep vein thrombosis. Patient risk factors include: obesity, previous VTE, cancer, age >60, prolonged immobilization, use of hormonal therapy, and comorbid conditions such as stroke, congestive heart failure, or myocardial infarction [16]. Some patients may have inheritable hypercoagulable states and that must be documented to inform the surgical team. Inherited abnormalities include deficiencies in protein c, protein s, or antithrombin, Factor V Leiden mutation, and prothrombin mutation [16]. The postoperative period is the perfect setup for VTE complications due to prolonged immobilization, endothelium disruption, and the patient's preexisting chronic or underlying diseases [16]. The perioperative evaluation is an ideal time for discussing the plan for postoperative VTE prophylaxis.

Prevention of Deep Vein Thrombosis

To prevent venous thromboembolism in the postoperative period thromboprophylaxis with both mechanical and pharmacologic means can be utilized [18]. Mechanical methods utilize compression stockings and pneumatic compression devices on the lower limbs to prevent venous stasis and promote venous outflow. Pharmacologic options include unfractionated heparin (UFH), low molecular weight heparin (LMWH), warfarin, antiplatelet agents, and novel oral anticoagulants (NOACs) [17, 18]. Pharmacologic thromboprophylaxis is utilized for moderate-risk and high-risk patients undergoing moderate- or high-risk surgeries [18].

There are two medications that are preferred for thromboembolism prophylaxis: low molecular weight heparin (LMWH) and low dose unfractionated heparin (LDUH) [17, 18]. Heparin is administered subcutaneously as 5000 Units every 8 or 12 h. Mechanism of action of heparin is via inhibition of antithrombin III (antithrombin) [16]. The mechanism of action of LMWH is via inactivation of factor Xa, but they have little effect on thrombin [16]. Types of LMWH that are approved for use in the United States include: enoxaparin, dalteparin, and tinzaparin [16]. Multiple studies have shown that both LMWH and LDUH are equally effective in prevention of VTE and PE [18]. Choice of agent is usually dependent on hospital preference and cost.

Risk of venous thromboembolism varies depending on patient characteristics and the type of surgery. High-risk surgeries include: major orthopedic surgery of lower limbs, particularly hip or knee, surgery for cancer, neurosurgery, acute spinal cord injury, and multiple trauma [16]. Recommendations for prophylaxis can be broken down into the type of surgery: general (including gynecologic and urologic), orthopedic, and neurosurgery.

General Surgery

General surgery category encompasses patients who undergo gastrointestinal, urological, gynecologic, bariatric, vascular, plastic, or reconstructive surgery. The 2012 American College of Chest Physicians (ACCP) guidelines use both the Rogers and Caprini score to determine a patients individualized risk for VTE [18]. In patients who are scheduled for general surgery and are a very low risk for VTE (Rogers score <7 or Caprini score, 0), no specific pharmacologic or mechanic prophylaxis is recommended, instead early ambulation and mobilization is encouraged [18].

For patients who are at low risk of VTE (Rogers score 7–10; Caprini score 1–2) ACCP guidelines recommend mechanical prophylaxis [18]. For patients who fall into a moderate-risk or higher category who are not at elevated risk for bleeding, it is recommended to receive pharmacologic prophylaxis in the form of LMWH in addition to mechanical prophylaxis (Rogers score >10, Caprini score >3) [17, 18].

The clinical situation becomes more complicated for those patients who are at high risk for VTE and who are also at high risk for bleeding. For patients in this category the recommendation would be to use mechanical prophylaxis only until pharmacologic prophylaxis can be safely used [18]. Ultimately this is a decision to be made by the surgical team, anesthesia team, and the patient.

www.konkur.in

Orthopedic: Hip and Knee Arthroscopy and Hip Fracture Surgery

In patients who undergo elective hip or knee arthroscopy or hip fracture surgery, guidelines suggest a minimum of 10–14 days of thromboprophylaxis and up to potentially 35 days [18]. The preferred anticoagulant is LMWH due to the safety and effectiveness profile [18]. However, guidelines do not specify a preference of LMWH, LDUH, aspirin, VKA, or intermittent pneumatic compression device [18]. If pharmacologic prophylaxis is utilized, then it is recommended that these medications be started no sooner than 12 h postoperatively [18]. Similarly the ACCP recommends dual thromboprophylaxis with a pharmacologic and mechanical device during the acute hospitalization [18].

Craniotomy and Spinal Surgery

For craniotomy patients and those undergoing spinal surgery, the recommendation would be to use mechanical prophylaxis with intermittent pneumatic compression device over pharmacological prophylaxis, unless the patient is very high risk for VTE [18]. For high-risk patients the recommendation would be to initiate mechanical prophylaxis adding pharmacological prophylaxis once adequate hemostasis is established and the risk of bleeding decreased [18].

Preoperative Testing

Preoperative testing is often ordered by primary care physicians prior to any planned surgical intervention. The decision to order preoperative testing is based on patient history, examination findings, and oftentimes surgeon preference. These tests allow for providers to properly assess surgical risk and prepare for possibility of postoperative complications [2, 6].

Electrocardiogram (EKG)

Preoperative EKG testing should be ordered in any patient scheduled for surgical intervention with history of coronary artery disease, active symptoms of cardiovascular disease, or undergoing a high-risk surgery, where the perioperative cardiac risk is greater than 5% [1, 2, 6]. Also widely accepted is the recommendation to abstain from EKG testing in any patient undergoing low-risk surgery with a less than 1% perioperative cardiac risk [1]. See Table 1 for noncardiac surgery procedure risk. To help decide then if patients undergoing an intermediate risk procedure without active cardiovascular symptoms should undergo EKG testing, the use of a surgical risk stratification tool such as the Revised Cardiac Risk Index (RCRI) can be helpful [1] (Table 2). If a patient has one of the clinical risk factors within the RCRI (cerebral vascular disease, congestive heart failure, creatinine level >2.0 mg/dL, diabetes mellitus requiring insulin, and ischemic cardiac disease), it is recommended to obtain a preoperative EKG [1]. Patients with two or more clinical risk factors are at significant higher risk for a major cardiac event [1].

Echocardiogram

For patients with dyspnea of unknown origin or with a known history of heart failure with worsening dyspnea or other changes in their clinical status, evaluation of left ventricular function would be recommended [1]. Reassessment of left ventricular function in clinically stable patients with a known history of heart failure is not necessary, but may be considered if there has been no assessment within a year [1].

Noninvasive Cardiac Testing

Exercise stress testing is not useful for patients who are low risk undergoing a low-risk surgery [1]. For patients with elevated risk, that is, perioperative cardiac risk greater than 5%, and excellent (>10 METS) functional capacity, it is reasonable to forgo exercise testing and proceed to surgery [1]. It may also be reasonable to forgo exercise testing in those patients with elevated risk and moderate to good (>4 to <10 METS)

Telegram: @medical_k

www.konkur.in

functional capacity [1]. If a patient has an elevated surgical risk and an unknown functional capacity exercise stress testing prior to scheduled surgery would be reasonable if it will change management decisions [1]. Lastly in patients with elevated risk and unknown or poor functional capacity (<4 METS), it is reasonable to perform either exercise or pharmacological cardiac stress testing with imaging prior to the scheduled procedures to assess for the presence of myocardial ischemia [1].

Chest Radiography

In otherwise healthy individuals who do not display signs of respiratory illness, chest radiography (CXR) is not recommended for preoperative evaluation [6, 11]. In patients who are presenting for a preoperative evaluation and they display signs or symptoms of a new or unstable cardiopulmonary disease a CXR would be indicated prior to preoperative risk stratification [1, 6].

Pulmonary Function Testing

The role for pulmonary function tests in patients is undefined and unproven in those undergoing extra thoracic surgeries [2, 11]. Data does not suggest a prohibitive spirometric threshold below which the risks of surgery are unacceptable [9–11]. Screening pulmonary function tests with measurement of carbon monoxide diffusion capacity is universally utilized for risk stratification and predicting mortality in patients undergoing lung resection or reduction surgery [9–11].

Electrolytes

Basic electrolyte and renal function testing are not routinely needed but should be driven by medical condition and current medication use [2, 6]. Electrolyte testing should be implemented if a patient has a history of any of the following conditions: congestive heart failure, chronic kidney disease, hypertension, diabetes mellitus, or liver disease [2, 6]. Testing should also be performed if a patient is on certain medications which include diuretics, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, nonsteroidal anti-inflammatory drugs, or digoxin [6].

Urine Analysis

Collection of preoperative urine analysis in patients has been shown to have very little predictive value in decreasing postoperative complications in asymptomatic patients [6]. Additionally, there is very little evidence that even an abnormal result leads to increased postoperative complications [6]. The general consensus is that routine urine analysis in asymptomatic patients is not recommended with the exception of the patients undergoing surgical implantation of foreign body (prosthetic joint or heart valve) or invasive urologic procedures [6]. A urine pregnancy test should be considered in all women of childbearing age [2].

Glucose Monitoring

Glucose testing should be considered in patients with signs and symptoms of undiagnosed diabetes, history of prolonged usage of glucocorticoids, or with a known history of poorly controlled diabetes [6]. General consensus states if a patient has well-controlled diabetes, routine preoperative glucose evaluation is not beneficial. In patients with known diabetes who display signs of poorly controlled diabetes, glucose evaluation with a random glucose or hemoglobin A1c may be beneficial if it would change perioperative management [3]. Short-term glucose management especially in the postoperative may decrease infection and complication rates [13].

Complete Blood Count

A complete blood count (CBC) has universally been part of the routine preoperative examination for many years, but this practice has been based on

Telegram: @medical_k

www.konkur.in

low level evidence or expert opinion [19]. Current consensus recommends preoperative CBC testing for patients who likely have an underlying anemia secondary to conditions such as chronic kidney disease, chronic liver disease, chronic inflammatory/autoimmune disorders, menstrual disorders, high risk for nutritional deficiencies, demonstrate signs/symptoms of chronic anemia, or undergoing a procedure in which significant blood loss is anticipated [2, 6, 19].

Coagulation Testing

Coagulation testing should be reserved for patients who have medical conditions associated with impaired hemostasis (liver disease, renal disease, diseases of hematopoiesis) or taking anticoagulants [6]. If history suggests problems with excessive bleeding, spontaneous bruising or a family history of a heritable coagulopathy appropriate coagulation testing should also be performed [2, 6].

Perioperative Medications

Beta Blockers

Continuation of beta blockers in the perioperative period has been well established for patients who are currently receiving long-term beta blocker therapy [20]. The benefit of initiating beta blocker therapy in the perioperative window is considered reasonable if a patient is determined to be intermediate or high risk for myocardial ischemia based on preoperative risk stratification testing [1]. It is also reasonable to initiate beta blocker therapy if a patient has three or more RCRI risk factors such as diabetes, heart failure, CAD, renal insufficiency, and CVA [1, 20]. Initiation of new beta blocker therapy in the perioperative window should be initiated in a time frame to allow the provider to assess the safety and effectiveness of the new medication [1]. Beta blocker therapy therefore should not be started on the same day as surgery [1, 20]. Perioperative beta blockade is most beneficial when initiated at least 1 week to 1 month preoperatively and continued for at least 1 month postoperatively [1, 20]. Therapy should be titrated to a resting heart rate of 55–70 beats per minute [20]. Chronic obstructive lung disease without severe reactive airway disease is not a clear contraindication for not initiating cardioselective beta blocker therapy in high-risk patients [20]. Resumption of beta blocker therapy postoperatively should be dictated by clinical circumstances and may need to be temporarily discontinued based on clinical factors such as hypovolemia, infection, significant blood loss, anemia, clinical instability, or other conditions that may complicate heart rate titration [1, 20].

Angiotensin-Converting Enzyme Inhibitor (ACE)/Angiotensin-Receptor Blockers (ARBs)

Due to their high utility in medicine, it is extremely common to encounter a patient on either an ACE or ARB. Guidelines suggest if a patient is currently stable on an ACE or ARB it is reasonable to continue these medications during the perioperative window [1, 20]. The most common adverse effect with their continuation is postoperative hypotension in those patients taking an ACE/ARB on the morning of surgery [20]. No change in postoperative cardiovascular outcomes including death, MI, stroke, or kidney failure has been noted in patients that continue to take their ACE/ARB in the perioperative period [1]. Clinical practice guidelines do support the continuation of ACE/ARB therapy when utilized in the treatment of heart failure or hypertension [1].

Statins

Statins should be continued in patients currently receiving chronic statin therapy. Perioperative initiation of statin therapy is reasonable in patients undergoing vascular surgery or those patients with clinical indications for initiating stain therapy who are undergoing high-risk noncardiac surgeries [20].

Telegram: @medical_k

www.konkur.in

Antiplatelet Medications

Antiplatelet therapy is used for both primary and secondary prevention of vascular complications. When preoperatively evaluating a patient it is important to understand the indication for the antiplatelet therapy when considering temporarily discontinuing the medication prior to the time of surgery. In cases where aspirin is used as primary prevention of stroke, MI, or CVA, this medication should be withheld 7–10 days prior to surgery to minimize postoperative bleeding complications [1, 20, 21]. Resumption of medication can begin once adequate hemostasis is confirmed and bleeding risk is deemed low. A reasonable approach would be 24 h after low bleeding risk procedures and at least 48–72 h after higher bleeding risk procedures [20, 22].

For patients with history of cerebral vascular disease, myocardial infarction, or peripheral vascular disease, aspirin therapy for secondary prevention should generally be continued through the perioperative period unless the patient is undergoing a procedure with a high bleeding risk (intracranial, spinal, posterior eye surgery, or transurethral prostatectomy) [20–22].

Patients with a history of coronary artery disease and placement of either a bare metal stent (BMS) or drug eluding stent (DES) elective surgery should be delayed until past the high-risk period for stent thrombosis. The risk for stent thrombosis is highest in the first 4–6 weeks post placement [20, 22]. Ideally patients should be continued on dual antiplatelet therapy for greater than 30 days following placement of a BMS and a minimum of 6 months, but ideally 1 year after placement of a DES before undergoing elective surgery [22]. However, if the risk of delaying surgery is greater than the risk of a major cardiac event, dual antiplatelet therapy should be maintained especially during the first 4–6 weeks post stent placement, unless bleeding risk is higher than the risk for an adverse cardiac event [1, 20, 22]. If surgery dictates discontinuation of the platelet receptor (P2Y) inhibitor, aspirin therapy should be maintained if possible and the P2Y inhibitor restarted as soon as possible after surgery [22].

Dual antiplatelet therapy should be continued for at least 12 months before undergoing elective surgery in any patient with a recent history of acute coronary syndrome (ACS) regardless of whether the ACS was treated with medical therapy alone, percutaneous coronary intervention, stent placement, or coronary artery bypass graft surgery [20, 22].

Within any scenario close communication and consensus between primary care provider, surgeon, cardiologist, anesthesiologist, and patient is essential for managing perioperative antiplatelet therapy and determining the best course of action for the patient [1, 20, 22].

Anticoagulation

Common indications for anticoagulation include atrial fibrillation, mechanical heart valve, and acute or recurrent deep vein thrombosis. Decisions regarding the continuation of anticoagulation therapy in the perioperative window can be complicated and often require a multidisciplinary approach. The perioperative management of patients on antithrombotic therapy should be based on an assessment of the patient's risk for thromboembolism and perioperative bleeding risk [18]. Addressing these issues will determine whether antithrombotic therapy is stopped prior to surgery and whether bridging therapy should be considered.

For patients who are scheduled for a minor surgery that have a lower risk of bleeding complications, such as cataract removal, minor dermatologic, or dental procedures, general recommendations would be to continue vitamin K antagonist (VKA) therapy in those scenarios [18]. Surgeries and procedures that carry an increased bleeding risk include: urologic, bowel resection, colonic polyp resection, joint arthroplasty, cancer surgery, surgeries involving highly vascular organs such as liver, spleen, kidney, implantable cardiac devices, intracranial, spinal, or cardiac [18]. Patients undergoing procedures with increased bleeding risk will need to have their VKA therapy stopped to reduce perioperative bleeding complications [18]. Once it is

Telegram: @medical_k

www.konkur.in

deemed necessary to halt VKA therapy, the VKA should be stopped 5 days prior to the planned surgery [1, 18]. Once the decision is made that VKA therapy should be halted, the patient's risk for thrombosis needs to be assessed to determine whether they will require bridging with LMWH or intravenous unfractionated heparin in the perioperative period. Risk stratification for thrombotic events in patients with atrial fibrillation is based on the CHADS 2 score, mechanical heart valve patients on the position and type of valve, and those with venous thrombosis on the time interval from the index embolus [18]. High-risk patients for thromboembolism include those with any mitral valve prosthesis, caged or tilting disc aortic valve, recent stroke or transient ischemic attack (TIA), atrial fibrillation with a CHADS2 score of 5 or 6, venous thromboembolism (VTE) with the last 3 months, or history of severe thrombophilia. These patients should receive bridging therapy with therapeutic doses of LMWH (Lovenox/enoxaparin 1 mg/kg bid or 1.5 mg/kg daily) [18]. Patients with atrial fibrillation and a CHADS2 score of 3–4, patients with a mechanic aortic valve and an additional risk factor such as atrial fibrillation or CHADS2 score above 1, and patients with a VTE in the last 3–12 months or non-severe thrombophilia are considered at moderate risk for thromboembolism and should be considered for bridging with LMWH based on surgery and individual patient factors [18]. Patients who are scheduled to undergo major cardiac surgery or carotid endarterectomy surgery are not candidates for bridging as the intraoperative bleeding risk is too high [18].

Resumption of VKA therapy in the postoperative window is dependent on surgeon preference as well as type of surgery. For most scenarios it is general practice to resume VKA therapy 24 h postoperatively, or when oral intake is tolerated [18]. Dose adjustments are dependent on postoperative medications as well as patients INR levels.

Novel oral anticoagulants (NOACs) are rapidly replacing VKA in the clinical setting; however, there is limited data to support a general consensus in their perioperative management [1]. As with the VKAs, perioperative management should be based on an assessment of the patient's risk for thromboembolism and perioperative bleeding risk. For procedures with a high risk of bleeding, or where hemostatic control is necessary, NOACs should be held 48–72 h prior to the scheduled procedure [1] (Table 6). For patients undergoing low-risk procedures who are also low risk for thromboembolism, discontinuation of NOACs can be as minimal as 24 h prior to procedure [1]. Resumption of NOACs in the perioperative window, depending on bleeding and thromboembolism risk, can be resumed between 24 and 48 h postoperative in most scenarios [1]. The rapid offset and onset of the NOACs may obviate the need for bridging anticoagulation.

Oral Hypoglycemic Agents

Preoperative evaluation of patients with diabetes should include their glycemic control history as well as the presence of any concomitant kidney disease, gastroparesis, or neuropathy which may lead to perioperative complications [23]. Patients with type 2 diabetes who take oral hypoglycemic drugs or noninsulin injectables are advised to

Table 6 NOAC discontinuation schedule [4]

Suggested Discontinuation Schedule for NOACs				
	Direct Thrombin Inhibitors (Dabigatran)		Factor Xa Inhibitors (Rivaroxaban, Apixiban, Edoxaban)	
Creatinine Clearance (mL/min)	Low Bleeding Risk	High Bleeding Risk	Low Bleeding Risk	High Bleeding Risk
≥80	≥1 day	≥2–3 days	≥1 day	≥2 days
50–80	≥1–2 days	≥3–4 days		≥2–3 days
30–49		≥4 days		≥3–4 days
15–29	Contraindicated	Contraindicated	≥36 h	≥4 days

Telegram: @medical_k

www.konkur.in

continue their usual routine of antidiabetic medications until the morning of surgery [23, 24]. On the morning of surgery, they should hold their oral hypoglycemic and noninsulin injectable drugs [23, 24]. The exception being long-acting sulfonylureas and sodium-glucose cotransporter-2 (SGLT-2) which should be held minimally 24 h prior to surgery [23, 25]. Generally the preoperative treatment regimen can be reinstated once the patient is eating well with the exception of Metformin (Glucophage) [23, 24]. Metformin has an increased risk of lactic acidosis in the perioperative window. Factors that can increase a patient's risk of developing lactic acidosis include: renal failure, administration of iodinated contrast, concomitant use of nephrotoxic medications (NSAIDs, ACE-I, diuretics), and severe left sided heart failure [24]. Due to this increased risk of lactic acidosis it is important to avoid resumption of metformin too early in the postoperative period; therefore it is recommended to wait at least 48 h after surgery to ensure the presence of adequate renal function before resuming this medication [23, 24].

Insulin

Type I diabetic patients are a subgroup in which glycemic agents should not be stopped in the perioperative window as their risk for diabetic ketoacidosis is much higher [24]. It is recommended for type 1 diabetic patients to remain on their basal insulin regimen through the perioperative period. During the preoperative evaluation it is important to include documentation of their basal regimen as well as their insulin correction factor [24]. If the patient uses an insulin pump, it is appropriate for them to continue their basal insulin and if needed bolus insulin can be administered as blood sugar levels necessitate [25]. In patients whose basal rate is calculated to keep the blood glucose in normal or low-normal ranges or when there is history of low glucose measures as an outpatient, patients may reduce the dose of long-acting basal insulin by 20–25% the evening before surgery to avoid any chance of preoperative hypoglycemia [25, 26]. If they routinely take basal insulin only in the morning, then the reduced dose should instead be administered on the morning of surgery [25]. Patients who are on twice daily basal insulin should reduce the dose by 20% to 25% in the evening prior to as well as the morning of surgery [25]. However, in patients who take high doses of basal insulin (>60% of total daily insulin) or total daily insulin dose is greater than 80 units or are at high risk of hypoglycemia (elderly, renal or hepatic insufficiency, prior hypoglycemic episodes); basal insulin dose should be reduced by 50% to 75% to minimize hypoglycemia risk [25]. During the fasting state, prandial insulin is held, and subcutaneous correctional insulin initiated with frequent blood glucose monitoring every 4 to 6 h [25].

Postoperative Monitoring

Despite proper preoperative risk stratification unfortunately 5% of patients will have a cardiac complication including death or nonfatal MI in the first 30 days following surgery [27]. Recent research is investigating additional preoperative and postoperative monitoring techniques beyond clinical risk calculators, which may be effective in helping to further mitigate postoperative cardiac complications. One such technique is laboratory measurement of brain natriuretic peptide (BNP) or N-Terminal fragment of proBNP (NT-proBNP) in the preoperative period to further identify patients at higher risk of cardiac complications.

The Canadian Cardiovascular Society has endorsed measurement of preoperative BNP levels in patients who are undergoing noncardiac surgery and are considered high risk. High-risk patients include those who are 65 or older, 45–64 years of age with significant cardiovascular disease, or patients who have a revised cardiac risk index >1 [27]. In the postoperative window, the highest risk time period for a myocardial infarction to occur is in the first 48–72 h following surgery when analgesic medications may mask cardiac ischemic pain. Patients identified as high risk should have a BNP drawn in the preoperative window. Guidelines by the Canadian

Telegram: @medical_k

www.konkur.in

Cardiovascular Society identified values as ≥300 ng/L for pro BNP and ≥92 ng/L for BNP as thresholds associated with increased risk of death or nonfatal MI in the 30-day postoperative window [27]. Patients who were found to have BNP levels above threshold values had a 21.8% risk of death or nonfatal MI compared to only 4.9% in those who value was below threshold [27]. High-risk patients received more intense monitoring in the immediate postoperative period such as continuous cardiac monitoring, EKG immediately after surgery while patient is still in the post-anesthesia care unit, higher level of care within the hospital, and daily troponin monitoring for 48–72 h [27]. In those patients who did suffer myocardial injury following a noncardiac surgery, the addition of aspirin and statin was shown to reduce the 30-day mortality in these patients [27]. Preoperative evaluation of BNP may allow providers to better predict patient perioperative cardiac risk; however, further research is needed before this laboratory monitoring is universally incorporated into surgical guidelines.

Care of the Patient with Sexual Concerns

Sex, sexuality, and sexual function are often topics that patients want to discuss with their primary care provider [1–5]. The overall prevalence of patients with sexual concerns is estimated at 30% for men and 30–40% in women both in the USA and abroad [1–3, 19, 21, 28, 30]. Sexual health is defined by the World Health Organization as a "state of physical, emotional, mental and social well-being in relation to sexuality; it is not merely the absence of disease, dysfunction or infirmity. Sexual health requires a positive and

respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences" [6, 7]. Evaluating patients with concerns about their sexual health is important and should be patient-centered [1–3, 5, 6]. Most sexual concerns are easily treated within primary care without need for referral [1–3, 5, 6, 8].

Definition of Sexual Dysfunction

The criteria for sexual dysfunction differ depending on which consensus committee or professional organization is defining the dysfunction. In this chapter, the definitions used for sexual dysfunction are based on the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* published by the American Psychiatric Association. The newest version of the DSM, the fifth revision (DSM-52013), revealed major changes to the definitions of sexual dysfunction [6, 9, 10].

Two new categories were developed: female sexual interest and arousal disorder and genito-pelvic pain/penetration disorder. Female sexual interest/arousal disorder in the DSM-IV-TR would have included hypoactive sexual desire and arousal disorders. And genito-pelvic pain/penetration disorders would have included dyspareunia and vaginismus. Female orgasmic disorder remains as a distinct category, and sexual aversion disorder was removed as it is seldom used as a diagnosis and there is little research to support the diagnosis. In men, the definition for premature ejaculation was further clarified to include ejaculation within 1 min of penile entry. Male orgasmic disorder was renamed delayed ejaculation disorder, and male hypoactive sexual desire disorder became a distinct category for men. Erectile dysfunction remained the same [6, 9–11].

Approach to the Patient with Sexual Concerns

Much of the information that is relevant to sexual (dys)function can be collected in a thorough History and Physical (H&P), such as past medical and surgical histories (including obstetrical history in women), psychosocial history, medications, family history, and a review of systems [1, 2, 5, 8, 12–15, 19, 21, 28, 30].

The history will reveal much of the information needed to make a diagnosis of sexual dysfunction and its etiology. The goal of history taking for sexual dysfunction should be to determine if there are any medical or psychiatric conditions that are known to cause sexual dysfunction (Table 1). Other important aspects of the history are any medication side effects, including herbals, supplements, and over-the-counter medications (Table 2).

Sexual History Taking

The initial question many providers ask in the sexual history varies in syntax; however, the content is the same: "When you are sexually active is it with men, women or both." Typically, providers ask about sexually transmitted infection (STI) history and current risk and/or contraceptive management as appropriate depending on the patient's needs [1, 3, 12, 19, 21, 28, 30].

There are a number of validated questionnaires for sexual functioning. The Brief Sexual Symptom Checklist (BSSC), a self-reported questionnaire for men and women, is easily adapted to primary care. This tool can easily be administered prior to the visit or with the provider. The BSSC quickly allows the provider to hone in on areas of sexual functioning that are troubling their patients and follows the DSM criteria for sexual dysfunction [1–3, 14, 21].

The BSSC begins with asking about satisfaction with sexual functioning. If the patient feels that they *do not* have any issues with their sexual functioning, it is appropriate to stop asking questions about this topic. The BSSC continues with questions about the duration of the dissatisfaction with the patient's sexual functioning and then hones in on interest in sex, pain with sex, how distressing the problem is, and whether the patient would like to discuss the problem with their provider. It also specifically asks women about genital sensation, vaginal dryness, and trouble

Table 1 Risk factors for sexual dysfunction [1, 2, 6, 12–17, 19, 21, 25, 27, 28, 30]

Age*	Neurologic disease:	Substance use:	Body image
Medical conditions:	Degenerative disease*	Tobacco (ED)*	Eating disorder ego-dystonic
Atherosclerotic risk factors*:	Spinal cord injury*	Alcoholism*	Sexuality
Obesity (ED)	Parkinson's	Drugs:	Gender dysphoria
Diabetes*	Dermatologic conditions:	Cocaine(ED)*	Women:
Hypertension	Psoriasis	Cannabis	Obstetrical complications
Hypercholesterolemia	Lichen sclerosus	Methamphetamine (ED)	Postpartum period
Coronary artery disease*	Genitourinary disease	Heroin (ED)	Breastfeeding
Peripheral vascular disease*	STI, HIV disease	Anabolic steroids	Vaginal prolapse
Stroke *	Pain with sex	Social-interpersonal:	PCOS
Endocrinopathies:	Surgical conditions:	Stress:	Menopause*
Thyroid disorders*	Genitourinary* pelvic*	Work	Men (ED):
Hypogonadism*	Spinal*	Financial	Pudendal nerve neuropathy long-distance cycling
Pituitary dysfunction	Vascular	Relational	Sedentary lifestyle
Adrenal dysfunction	Trauma	Sexual trauma* and violence	
Hypothalamic dysfunction	Injury	Social-cultural	
Rheumatologic disease	Psychological:	cultural beliefs	
Chronic renal failure	Depression*	Religious beliefs	
Cirrhosis	Bipolar	Low educational level	
COPD	Sleep disorders	Unrealistic expectations	
Cancer treatments:	Anxiety	Influence of media (internet)	
Chemotherapy*	Trauma		
Radiation*	Psychotic disorders		

*Causes with a greater prevalence of sexual dysfunction
(ED) condition associated with erectile dysfunction

Table 2 Medications with sexual side effects [1, 12, 14–16, 18–21, 25–28, 30, 32]

Global sexual dysfunction (SD):	**Women desire only:**	**Men global SD:**
SSRIs*(50% paroxetine worst)	Trazadone	Ketoconazole
Antiandrogens	Venlafaxine	Spironolactone (gynecomastia)
Women global SD:	Statins	**Erectile dysfunction:**
TCAs	Beta-blockers	Antipsychotics*
Barbiturates	Spironolactone	Antidepressants*
Lithium*	Methyldopa	Venlafaxine
Affect desire and arousal:	Danazol	Benzodiazepines
Benzodiazepines	GnRH agonists	Beta-blockers*
Clonidine	Contraceptives	Thiazide diuretics
Tamoxifen	Histamine 2 blockers	Opiates
GnRH analogues	Promotility agents	Antiretroviral
Ultralight contraceptive pills?	Indomethacin	Histamine 2 blockers (cimetidine)
Aromatase inhibiters	Ketoconazole	TCA
Chemotherapeutic agents	Phenytoin	Phenytoin
Affect desire and orgasm:	**Arousal only:**	Phenobarbital
Antipsychotics*	Anticholinergics	Lithium
Amphetamines	Antihistamines	Bromocriptine
Narcotics		Levodopa
Digoxin		Gemfibrozil
		Methotrexate
		5-alpha reductase inhibitors
		Corticosteroids

*Most commonly has sexual side effects

achieving orgasm. In men it asks about problems with getting or maintaining an erection, whether the patient ejaculates too early or has delayed ejaculation or none at all with or without orgasm, and finally if the penis has an abnormal curvature when erect [1–3, 8, 14, 21].

Physical Exam

The history should guide the physical exam and may or may not uncover the specific root cause of the sexual dysfunction. The cardiovascular exam should look for risk factors associated with atherosclerotic disease and cardiovascular disease. This includes body mass index (BMI), blood pressure, peripheral pulses, and lower extremity changes associated with peripheral vascular disease such as skin changes, lack of hair and/or claudication, as well as edema. The focus of the neurological exam is to assess for peripheral neuropathy, spinal cord disease, or trauma. The musculoskeletal exam should focus on mobility and ability to participate in sexual activity. Patients should be assessed for thyroid disorders by palpating the thyroid [1, 2, 12, 14, 15, 17, 19, 21, 28, 30].

The genital exam in all patients should assess for normal genital development, secondary sex characteristics, and any signs of anal-genital infection. Lack of pubic hair can be a sign of low androgen levels in women and low testosterone in men. In females, the breast exam can reveal the presence of galactorrhea. In addition, the female patient should be assessed for vulvar abnormalities, evidence of vaginal atrophy, and trauma/surgical repair such as episiotomy repair and STIs. The clitoris should be inspected for abnormalities, included tethering as seen in lichen sclerosus [4, 21]. A speculum and bimanual exam may reveal cystocele, rectocele and/or uterine or anal prolapse, pelvic muscle tone both hyper- and hypotonicity associated with dyspareunia, as well as vaginismus and evidence of endometriosis such as a fixed, retroverted uterus [1, 2, 5, 14, 21, 28]. In men, the exam should focus on any abnormalities or infections; the testes should be assessed for size, atrophy, varicoceles, and epididymitis. And the patient should be asked about erections, abnormal curvature, or disorders of the foreskin such as phimosis. The penis should be inspected, looking for abnormalities. The foreskin, if present, should be inspected and retracted fully if possible. The rectal exam should be used to assess for tone and in men for any signs of prostatic disease [2, 8, 12, 15, 19, 30].

Labs and Other Testing

Laboratory testing should be directed by the H&P to look for specific medical conditions associated with sexual dysfunction. Any patient with a complaint of sexual dysfunction should be screened for diabetes with a glucose and if elevated a hemoglobin A1c, atherosclerotic disease with a lipid panel, and for endocrine disease with a thyroid-stimulating hormone (TSH). In men with erectile dysfunction or hypoactive sexual desire, a total testosterone level should be drawn, ideally a morning level. Imaging should be directed by H&P [1, 2, 12, 14, 15, 17, 19, 28, 30].

Approach to Diagnosing Sexual Dysfunction

According to the DSM-5, in order for the diagnosis of any type of sexual dysfunction disorder to be made, the condition must be present for at least 6 months. Within every disorder, it is important to ascertain if the sexual dysfunction is lifelong (primary) vs. acquired (secondary) and situational vs. generalized and the amount of distress it causes to the patient defined as mild, moderate, or severe [1, 9, 10, 18].

When diagnosing sexual dysfunction, it is critical to determine if the etiology is related to a root cause such as an underlying medical condition (s) or a psychosocial issue (see Table 1). The typical pattern of a medical cause is an older patient with gradual onset of symptoms (unless related to surgery or trauma), generalized dysfunction, consistent or progressive symptoms, normal desire, and underlying comorbidities [2, 12, 19, 28, 30]. The typical pattern of a psychosocial cause is a younger patient with acute onset

Telegram: @medical_k

www.konkur.in

of symptoms in a specific situation with intermittent symptoms and decreased desire with absent or minimal underlying medical conditions [2, 12, 19, 28, 30].

It is important to note that more than one type of sexual dysfunction can exist. For example, men may have both hypoactive sexual desire disorder with delayed ejaculation and erectile dysfunction, and women may have both sexual interest/arousal disorder with delayed orgasm and anorgasmia [1, 2, 12, 14, 17, 19, 28, 30].

The DSMV states that if sexual dysfunction exists in the absence of a secondary cause, then a true primary disorder exists. If the cause of sexual dysfunction is thought to be secondary to an illness or psychosocial condition, *treatment must be medically maximized* (Tables 1, 2, 3, and 4).

Treating Sexual Dysfunction: General Principles

The periodic health exam is an excellent time to speak to patients and educate them about their sexual health and functioning. For some patients it is helpful to discuss normal anatomy. Providers will often have the female patient look at their anatomy with a mirror. And in the case of men explaining normal responses and functions such as nocturnal emission and erections. Also, it is important to emphasize the breadth of a person's sexuality, like normalizing masturbation and same-sex attraction [1, 8, 12, 14, 16, 17, 19, 21, 28].

In patients diagnosed with sexual dysfunction, it is important to address habits such as tobacco use, excessive alcohol and cannabis use, and illicit drug use as they are well-known to contribute to sexual dysfunction [12, 14, 15, 18, 19, 21, 28, 30]. Poor sleep due to an underlying physical or mental health issue affects multiple areas of functioning as does stress at work or in relationships [1, 12, 14, 15, 17, 19, 21, 28, 30]. Being overweight can affect body image, and obesity is associated with erectile dysfunction [12, 15, 18, 28]. Patients should be encouraged to be physically active, as exercise is associated with increased sex drive and better sexual functioning [12, 15, 18, 19, 21, 28, 30].

Pointing out treatable underlying causes of sexual dysfunction is an excellent way to activate patients by using motivational interviewing. For men with ED who smoke, this maybe the "hook" to engage them in behavioral change. Providers should discuss sexual side effects of medications with patients prior to starting them and as part of follow-up once initiated. Adjustments to medications can be made either by changing class, dosing, or adding adjunctive therapies [1, 12, 14, 16, 18, 19, 21, 28, 30].

Therapy is a critical aspect of treatment for sexual dysfunction. Individual therapy can address a number of concerns for sexual dysfunction, including patients with a history of trauma, such as interpersonal violence in past or current relationships and/or sexual abuse. Refugees who have experienced sexual violence and torture should be referred appropriately. Modalities like cognitive behavioral therapy (CBT) can explore negative patterns of thinking about sex, sexual function, and reduce anxiety associated with sexual (dys)function. Couples therapy can explore specific concerns in the relationship, such as conflict and communication issues. Sex therapy can explore the dynamics in the relationship or in the individuals that are preventing the couple from sharing an erotic life together. Sensate focus is used to establish communication between partners that begins with non-sensual touch and progresses to sexual intercourse. Sensate focus is easily learned by primary care physicians and is within the domain of primary care [1, 8, 12–14, 16, 17, 19, 21, 28, 30].

Diagnosing and Treating Sexual Dysfunction in Women

Decreased desire and arousal are the most common sexual complaints in women. Up to 46% of women experience disordered desire and up to 21% disordered arousal with increasing prevalence in women as they age. Orgasmic dysfunction is most associated with medication side effects and is common in primary care with a prevalence of 5–42% and a prevalence of 4–7% in the general population. Pain with intercourse

Table 3 Medical treatment of sexual dysfunction in women [1, 14, 16, 20–22, 28, 29, 34, 35, 36]

Female sexual interest/ arousal disorder	1. Postmenopausal women with only genitourinary syndrome of menopause (GSM) can be treated with vaginal estrogen (tablets, gels, cream, and rings equally effective). Lowest effective dose should be used. Duration of treatment has not been established. Usual treatment is daily dosing for several weeks and then enough use to maintain effect. Use with consultation in women with PMH of cancer 2. Postmenopausal women with GSM-related dyspareunia plus vasomotor symptoms can be treated with systemic estrogen. Women with an intact uterus must have progestin as well. Lowest effective dose should be used 3. Postmenopausal women with moderate to severe dyspareunia from GSM can use ospemifene (Osphena) or intravaginal DHEA prasterone (Intrarosa) (as an alternative to vaginal estrogen). *consultation GYN 4. Postmenopausal women with sexual interest/arousal disorder: Transdermal testosterone (not FDA approved in women) – Studies show 300mcg/day patch in women who are already on estrogen therapy. Studies show consistent improvement and least side effects at 300mcgs. Debate over dosing as this is superphysiologic. Some use of testosterone gel (this has not been studied but allows for lower dosing~1/5 to 1/10 of the dose for men). Treat for 3–6 months trial. Measure baseline testosterone and after 3–6 weeks of initial treatment. If ongoing, check levels every 6 months. If no benefit at 6 months, discontinue. There is no efficacy and safety data after 24 months. Suggest monitoring liver function and lipids. Intrinsa 300mcg/day (testosterone patch available in Europe). Side effects: Hirsutism (associated with dose, women not more likely to stop due to hair growth, acne (<10%), virilization rare, lower does mild), cv risk (risk not established). ACOG suggests women using should be "counseled about the potential risks and unknown long-term effects." *recommend initial evaluation with endocrinology or OB/GYN as off-label use and co-management 5. Small studies in women with both arousal and interest disorders showed improvement of genital sensation and satisfaction with foreplay and intercourse with sildenafil (Viagra) 25–100 mg daily. *recommend consultation. ACOG recommendation is to not use in the clinic setting.
Female orgasmic disorder	1. Testosterone for hypogonadism. Doses above 2. Antidepressant induced: Add bupropion SR 150 mg–300 mg daily (higher dose the better). *some studies show benefit for decreased libido in women without depression 3. Phosphodiesterase inhibitors (PDE5I) limited studies and mixed results. Studies showed promise in women with SSRI-induced orgasm disorder. Controversial to use. *recommend consultation
Genito-pelvic pain/ penetration disorder	1. Maximize medical treatment of underlying disorder 2. Vaginismus: Botox may improve symptoms (not well studied) 3. Vulvodynia: Overnight lidocaine ointment, amitriptyline, gabapentin (Neurontin), pregabalin (Lyrica), duloxetine (Cymbalta) 4. For treatment of GSM-related dyspareunia, see female sexual interest/arousal disorders
Other	Herbals: Not well studied. Limited data. Safety concerns 1. Maca extract may improve SSRI-induced sexual dysfunction 2. Lady Prelox (pine bark extract and other ingredients) may improve sexual function in women of reproductive age 3. *Tribulus terrestris* may increase sexual desire

often has an underlying cause and is frequently seen in the primary care setting with a prevalence of up to 46% in primary care and 3–18% in the general population [1, 14].

In 2013, atrophic vaginitis was renamed genitourinary syndrome of menopause (GSM) at a consensus conference between the International Society for the Study of Women's Sexual Health and the North American Menopause Society.

"GSM is defined as a collection of symptoms and signs associated with a decrease in estrogen and other sex steroids involving changes to the labia majora/minora, clitoris, vestibule/introitus, vagina, urethra, and bladder. The syndrome may

Table 4 Treatment of sexual dysfunction in men [8, 12, 15, 17–19, 23, 24, 30, 32, 37, 38]

Male hypoactive sexual desire disorder	Testosterone for hypogonadism: depo-testosterone (T) 200–250 mg every 2 weeks) Transdermal testosterone (closer to circadian levels) Patch applied to the arm, back, or upper buttocks alternate sites and avoid sun-exposed area as it can cause skin irritation (multiple formulations) Testosterone gel applied daily to clean dry skin over the shoulders, upper arms, or abdomen Wash hands after gel use. *In T replacement, monitor CBC, LFTS, and PSA Bupropion 150 mg–300 mg daily
Premature ejaculation	SSRIs Fluoxetine (Prozac) 5–40 mg/day Citalopram (Celexa) 20–40 mg/day Paroxetine (Paxil) 10–40 mg/day * 20 mg on demand 3–6 h before sex Sertraline (Zoloft) 25–200 mg/day * 50 mg on demand 3–8 h before sex Tricyclic antidepressants (TCAs) Clomipramine 12.5–50 mg daily * 25 mg on demand 3 to 24 h before sex
Delayed ejaculation	Almost always related to underlying cause. Also includes retrograde ejaculation
ED: First line	Phosphodiesterase inhibitors (PDE5I) (see Table 5) * requires periodic monitoring for efficacy, side effects, and change in medical conditions, including new medications
Second line	Medicated urethral system for erection (MUSE) (alprostadil). Self-administered. Primary care co-management with urologist. Needs plastic ring around penis and scrotum to maintain erection. Ring should not be in place for more than 30 min. Penile and scrotal pain common side effects. First dose in office due to low risk of hypotension and syncope. Female partners may report vaginal discomfort after ejaculation
Third line	Intracavernous injection therapy. Self-administered. Referral to urology
Other	Vacuum constriction device. Primary care. Effective, low cost. Needs plastic ring around penis and scrotum to maintain erection. Ring should not be in place for more than 30 min. Caution in patients on anticoagulation and antiplatelet therapies
Other	Herbals: Not recommended by AUA due to insufficient studies or safety concerns Yohimbine: Meta-analysis which shows efficacy of yohimbine over placebo. Dosing is daily but exact dosing unclear from studies Korean red ginseng: Two small studies outside the USA. Small sample sizes. Viable alternative before invasive measures, dose is 900–1000 mg tid Pine bark extract (Pycnogenol) may improve ED. limited data Maca extract may improve ED. limited data ED dietary supplements: Warning by FDA may have active PDE5I ingredients with the same precautions

include but is not limited to genital symptoms of dryness, burning, and irritation; sexual symptoms of lack of lubrication, discomfort or pain, and impaired function; and urinary symptoms of urgency, dysuria, and recurrent urinary tract infections. Women may present with some or all of the signs and symptoms, which must be bothersome and should not be better accounted for by another diagnosis" [14, 31]. While the quality of research on medical treatments for sexual dysfunction in women has improved over the last decade, there still is a paucity of high-quality research. There is much more research on sexual dysfunction in men, specifically erectile dysfunction. Research on herbal remedies is lacking and plagued with small sample sizes and concerns for safety as these are not FDA regulated [1, 14, 19, 21, 28, 30, 32].

Female sexual interest/arousal disorder is diagnosed if the patient lacks or has significantly reduced sexual interest and/or arousal. Specific criteria for the disorder include no or minimal interest in sexual activity, no or minimal sexual/erotic thoughts or fantasies, lack of arousal or response to erotic cues either externally or internally, decreased sexual activity and/or not interested in sex even when initiated by a partner, minimal sexual excitement and/or pleasure during

Telegram: @medical_k

www.konkur.in

sexual activity in almost all or all sexual encounters, and/or minimal arousal or sensations genitally or otherwise with sexual activity [9].

Prior to menopause, it is recommended that the provider focus on psychosocial concerns like relationship issues, underlying medical or psychiatric disorders, and medication side effects, such as selective serotonin reuptake inhibitors (SSRIs) and oral contraceptive pills (OCPs) [14, 21, 28]. As women (and men) age, interest in sex, sexual activity, and frequency does often decline. The same follows for women (and men) in relationships over time and as such may not be distressing to the patient [1, 3, 4, 21, 28]. There are two new drugs that have been FDA approved for premenopausal women with hypoactive sexual desire disorder. Flibanserin (Addyi) is only available through a restricted program from the manufacturer and therefore requires consultation. It is for women without depression and must be used with caution when mixing with alcohol. The studies on this medication show mixed results with concerns about significant side effects [14, 21, 28]. The drug bremelanotide (Vyleesi) is the most recently FDA-approved medication to treat premenopausal women with sexual interest and arousal disorder. Research on this recently approved medication is still emerging and should only be prescribed with consultation [21, 28]. In a Cochrane review, supplementation with bupropion has been shown to improve symptoms of low desire and arousal in women (and men to a lesser degree), experiencing side effects from antidepressants; higher doses show better response. Switching patients to alternative antidepressants with fewer sexual side effects is another option. However, the studies have small numbers of patients and inconsistent methodologies [1, 14, 21, 28, 32].

In postmenopausal women, vaginal atrophy and lubrication issues are common and usually are secondary to GSM (see Table 3 for treatment details) [1,14, g]. Education about masturbation is important as a treatment for arousal disorders as well as orgasmic disorders. Using adjunctive aids, such as the Eros Clitoral Device, which is FDA approved, can improve arousal through direct stimulation [1, 14, 20]. Lubricants can be helpful when sex is painful due to vaginal dryness. As the FDA categorizes these products as cosmetic, there is a paucity of research that recommends one lubricant over another. Water- and silicone-based lubricants can be used with condoms. These products should be selected with patient preference in mind [14].

The focus of medical treatment is alleviating symptoms of GSM. The best evidence and greatest consensus support use of vaginal estrogen as first line [14, 21, 28]. There are second-line treatments that can be used as alternatives to vaginal estrogen for GSM. Women with dyspareunia related to GSM and vasomotor symptoms can be given low-dose systemic estrogen with or without progestin. Ospemifene, an oral medication, is a selective estrogen receptor modulator (SERM), which has been FDA approved for moderate to severe dyspareunia secondary to GSM in postmenopausal women. And prasterone (Intrarosa) which is vaginal dehydroepiandrosterone (DHEA) can also be used [14, 21, 28] (see Table 3 for details). Research has established that systemic DHEA is *not* useful in the treatment of sexual interest and arousal disorders in women [14, 21].

In women who have maximized estrogen therapy and are still experiencing symptoms of GSM, transdermal testosterone is a good adjunctive therapy. Results are promising with some caveats. Most studies are in postmenopausal women. In one study, three women developed breast cancer taking testosterone and estrogen, prompting the FDA to not approve transdermal testosterone due to lack of long-term safety data. However, in this study the increase was considered insignificant, as a result use is off label [14, 21]. ACOG suggests women using transdermal testosterone should be "counseled about the potential risks and unknown long-term effects" (14). The use of sildenafil (Viagra) for women in both interest and arousal disorder and orgasmic disorder is controversial; studies show contradictory results. ACOG suggests that sildenafil not be used outside of clinical trials. Clinical benefit remains unclear and therefore should be prescribed in consultation with an appropriate specialist [1, 14, 21, 28].

In women with *orgasmic disorder*, most or all of the patient's sexual activity must either have

Telegram: @medical_k

www.konkur.in

absent, infrequent, or delayed orgasms or markedly reduced intensity of orgasm [9]. Anorgasmia is frequently a medication side effect, particularly with psychiatric medications (SSRIs are infamous for causing delayed orgasm or no orgasm and decreasing sexual desire). Secondary causes are typically related to underlying neurologic causes, such as neuropathy (diabetes), prior trauma, and/or surgery. Women who have male partners with ED and/or premature ejaculation may have difficulty reaching orgasm [1, 4, 16]. Behavioral interventions include psychotherapy and sexual education about anatomy and masturbation, including direct vibratory stimulation of the clitoris as well as sexual positions that focus on maximize clitoral stimulation (coital alignment) [1, 14, 16, 28]. Medications include bupropion as a possibility for improvement of anorgasmia secondary to antidepressant use; this is supported by a Cochrane review that included men and women [1, 14, 28, 32] (see Table 3 for more detail).

Women with *genito-pelvic pain/penetration disorder* must have persistent or recurrent vaginal or pelvic pain with vaginal penetration or intercourse; marked fear of the pain before, during, or after penetration; and marked hypertonicity of the pelvic floor muscles during penetration [9].

Specific treatments for pain and penetration disorders are directed by underlying cause. Treat to the type of pain: superficial (Vulvodynia, dermatologic disease, STI, Vaginismus) v. deep (Endometriosis, post surgical/obstetrical complications, bladder, uterine, ovarian and intestinal disease) [14, 21, 28]. And consider other etiologies, such as GSM or neuropathy [11,421,28]. Behavioral techniques include non-penetrating pleasuring techniques, biofeedback, relaxation therapy, and desensitization exercises. In both vulvodynia and vaginismus, these modalities are often provided by a physical therapist with expertise in these treatments [1, 14, 21, 28].

In the case of vulvodynia, vaginal hygiene is important. Patients should only wash with water and wear 100% cotton underwear during the day and none at night. Acupuncture may decrease pain. Lidocaine 2% gel or lidocaine 5% ointment on a moist cotton ball placed into the vestibule at bedtime can alleviate pain. Transcutaneous electrical nerve stimulation (TENS) may help women with vestibulodynia. Tricyclic antidepressants (TCAs) and anticonvulsants are considered first-line therapy (see Table 3) [1, 14, 21, 22].

Diagnosing and Treating Sexual Dysfunction in Men

In primary care, erectile dysfunction is a common sexual complaint. In men age 40–50, the prevalence is 2%, and at age 60–70, this increases to 40–50%. At first intercourse, fear of ED is 20%, and actual erectile dysfunction that hinders penetration is 8% [9, 12, 15, 30]. Male hypoactive sexual desire increases as men age with a prevalence of 6% in men age 18–24 to 41% in men age 66–74. Prevalence of true premature ejaculation based on the new definition of ejaculation within 1 min of vaginal penetration is 1–3%. However, prevalence of premature ejaculation with the prior definition of prematurity not including a specific time was 20–30%, making this a common complaint that causes significant distress in men [23, 24]. Delayed ejaculation is most often associated with medication side effects and substances, such as SSRIs [9, 12, 15, 19, 30] (see Table 4).

Men with *erectile dysfunction* have significant difficulty in getting and maintaining an erection and/or have significant lessening of the quality of the erection in most or all instances of sexual activity [9, 12, 15, 19, 30]. The abridged International Index of Erectile Function 5-item questionnaire is a brief questionnaire that classifies erectile dysfunction on a scale of mild to severe and can be easily used in primary care [12, 18, 19, 30]. It is important to note that ED itself is a predictor of vascular disease in men. Providers should consider screening men with diagnosed ED for peripheral vascular disease and cardiovascular disease [12, 18, 19, 30]. In addition, questions about nocturnal erections, AM erections, and quality of erections with masturbation are important when distinguishing between a psychosocial etiology vs. an underlying organic cause [12, 15, 18, 19, 30].

Phosphodiesterase inhibitors (PDE5I) are first-line therapy for ED. They are equally effective in

Telegram: @medical_k

www.konkur.in

treating ED and vary in how quickly they work and in half-life. Initially designed for men with ED secondary to antidepressant side effects, diabetes mellitus, and spinal cord injury, PDE5Is are effective and safe in men with ED due to multiple disease states regardless of cause and severity. Side effects are typically mild with some caveats [12, 15, 18, 19, 30] (see Table 5). Patient-reported treatment failure should be evaluated for new underlying medical conditions, hormonal abnormalities, food and medication interactions, timing and frequency of dosing, alcohol use or other substances, relationship concerns, and adequate sexual stimulation. An adequate trial of one PDE5I is four to six attempts for an adequate erection at the maximum tolerated dose. After failure of one PDE5I, a trial of a second PDE5I is warranted. It is reasonable to try daily dosing of tadalafil (Cialis) after one to two failed trials, after which referral to urology would be appropriate [12, 15, 19, 30] (see Table 5 for dosing). Patients with ED and hypogonadism should be supplemented with testosterone and trialed on a PDE5I together. This should be co-managed with an endocrinologist (see Tables 4 and 5 for details of treatment). Statin monotherapy has insufficient data to be recommended as treatment for ED. Surgical options are considered last resort [12, 15, 18, 19, 30].

Men with *hypoactive sexual desire disorder* have consistent lack of sexual or erotic thoughts, fantasies, or desire for sexual activity [9]. This disorder is most commonly related to aging and poor medical condition. Other risk factors include medication side effects, mental illness, stress, low erotic thoughts, and history of sexual abuse [17, 19, 21, 30]. Hypogonadism can be a cause of erectile dysfunction as well as hypoactive arousal disorder and can improve with testosterone therapy. Other endocrine etiologies such as elevated prolactin should be investigated by MRI for pituitary adenoma and are treated with bromocriptine and if necessary surgery. These two disorders may be co-managed with an endocrinologist. Bupropion may improve symptoms of sexual functioning and desire in men as in women [1, 17–19, 30].

In *premature ejaculation*, ask the patient if they ejaculate within 1 min of vaginal penetration most or all the time and are unable to control or stop ejaculation and if this is before the patient would have liked to ejaculate (i.e., level of distress). It is important to note that premature ejaculation may occur in instances of non-vaginal intercourse. The DSM-5 makes the point of stating that specific duration criteria have not been established for non-vaginal penetration [8, 9, 23, 24]. In the case of patients that do not meet criteria for premature ejaculation yet have significant distress, it is recommended that they receive reassurance, education, and psychotherapy if indicated and be counseled on pause techniques with masturbation, such as the "pinch and squeeze" to delay ejaculation [8, 23, 24]. Patients with acquired premature ejaculation should use pause techniques and psychotherapy as first line followed by medications. Patients with lifelong premature ejaculation should start with both treatment modalities. Patients with premature ejaculation may also have ED along with depression and/or anxiety. These patients often have high levels of performance anxiety [8, 23, 24]. Condoms can decrease sensitivity [8, 23, 24].

The American Urological Association (AUA) recommends offering patients topical treatment or SSRIs as first-line therapy depending on physician judgment and patient preference [23]. Topical anesthetics such as EMLA cream (lidocaine 2.5%/prilocaine 2.5%) can be used 20–30 min before intercourse. The EMLA may result in numbness of the vaginal walls, and allergies to any "caine" products for either partner are a contraindication to topical treatment [8, 23, 24]. Antidepressants (SSRIs and TCAs) with delayed ejaculation as a side effect may be used daily or "on demand" prior to intercourse (see Table 4). SSRIs are better tolerated and are safer [8, 23, 24]. Both the International Society for Sexual Medicine and the AUA have evidence-based guidelines with slightly different dosing. Daily dosing is especially warranted in patients with comorbid mood disorders. The AUA recommends men under 18 and those with a history of bipolar disorder not be prescribed these medications [8, 23, 24]. PDE5s can be used safely in premature ejaculation with signs of erectile dysfunction. There is conflicting opinion about use of PDE5I in men

Table 5 Phosphodiesterase inhibitors (PDE5I) [12, 15, 18, 19, 30]

PDE5I	Dosing	Side effects
Sildenafil (Viagra) Short acting: Tmax 1 h, 1/2 life 4 h	Range 25–100 mg/dose Starting dose 50 mg Take 1/2–4 h(s) before sex	Class effects High-fat meal can delay absorption Use lower dose if managing side effects from other medications
Vardenafil (Levitra) Short acting: Tmax 1 h, 1/2 life 4 h	Range 2.5–20 mg/dose Starting dose 10 mg Can take 2.5–5 mg daily or 10 mg prior to sexual intercourse Take 1/2–4 h(s) before sex	Class effects QT prolongation* High-fat meal can delay absorption Use lower dose if managing side effects from other medications
Avanafil (Stendra) Medium acting. Tmax 30–45 min, 1/2 life 5+ hours	Range 50–200 mg/dose Starting dose 100 mg 50 mg if concerned about drug interactions Take 30 min before sex. Can work as fast as 15 min	Class effects High-fat meal can delay absorption Use lower dose if managing side effects from other medications
Tadalafil (Cialis) Long acting: Tmax 2 h, 1/2 life 18 h	Range 2.5–20 mg/dose Starting dose 10 mg Can take 2.5–5 mg daily or 10 mg prior to sexual intercourse Take 1/2–12 h(s) before sex	Class effects Back pain Use lower dose if managing side effects from other medications
Class effects: Precautions	Side effects	Complications
Renal and liver disease require dose adjustment Use with caution in: >65 years old Liver failure Renal insufficiency BP < 90/50 Uncontrolled hypertension (BP > 170/100) Congestive heart failure Recent MI or stroke or arrhythmia (last 3–6 months) Unstable angina Retinitis pigmentosa	Most common: Headache (10–15%) Facial flushing (5–10%) Nasal congestion (5–10%) Dyspepsia(rare) Can lower blood pressure (rare) Back pain worse with Cialis **Contraindicated with nitrate therapy***** Acute myocardial infarctions no nitro 24–48 h if on PDE5I**	HIV protease inhibitors interactions Use with alpha-blockers can cause hypotension **interactions with multiple medications. Sudden loss of vision is a rare side effect. Known to cause non-arteritic anterior ischemic optic neuropathy (NAION) (RF for NAION are: 50+, cardiovascular disease, DM, HTN, tobacco use) (counsel patients to stop PDE5I if loss of vision and seek care immediately)** Sudden hearing loss with or without tinnitus, vertigo, dizziness*

with normal erectile function, as well as concerns about priapism [8, 23, 24]. There is limited evidence that surgical procedures work for premature ejaculation [8, 23, 24].

With *delayed ejaculation*, it is important to ask patients if they have significant difficulty with delayed, infrequent, or absent ejaculation [9]. The most common etiology is medication side effect (see Table 2). The treatment for delayed ejaculation is determining the cause as this is rarely a primary disorder [9]. Patients at risk for retrograde ejaculation should be evaluated for this condition [18].

In the case of *substance/medication-induced sexual dysfunction*, there must be a temporal association between the substance/medicine (either initiation or withdrawal) and the dysfunction with no other explanation. With substance-induced sexual dysfunction, cessation is the only treatment. With medications, adjustments can be made (see Table 2). The research regarding treatments for sexual dysfunction secondary to

Telegram: @medical_k

www.konkur.in

antidepressants, specifically SSRIs, is compelling. In men, the recommendation is to use PDE5Is, and in both sexes, the addition of bupropion (300 mg) at higher doses is the most studied and may improve sexual functioning. Other less studied options are waiting for drug tolerance (e.g., SSRIs usually 6 months), taking a drug holiday, adding bupropion to an SSRI regimen, or switching to medications with fewer sexual side effects (bupropion, mirtazapine, and most recently vortioxetine (Trintellix) show some promise, and further studies are needed) [1, 14, 21, 27, 28, 32, 33].

Referrals

Most diagnoses of sexual dysfunction can easily be made in the domain of primary care and referral made to mental health providers for supportive therapy as well as specialized physical therapists. Indications for specialized referral are treatment failures, contraindications to standard therapy, cases requiring surgical intervention, and patient request. Patients with complex endocrinopathies (adrenal, pituitary, hypothalamic), vascular and neurologic disease, or chronic persistent mental illness can be co-managed or referred depending on provider comfort and patient preference [2, 8, 18, 19, 30].

Overview

Alcohol, as an intoxicant, has been a part of human civilization for millennia. Alcohol's intoxicating effect appears to be due to the altering of cell membrane's action potentials, specifically modulating the activity of gamma aminobutyric acid (GABA) and *N*-methyl- d-aspartate (NMDA) channels. Enhancing GABA's inhibitory effect leads to a global decrease of membrane potentials. NMDA, an excitatory neurotransmitter, is blocked in the presence of ethyl alcohol. Acutely, this results in an anxiolytic effect and lowers inhibitions. Higher blood alcohol concentrations (BAC) lead to slurred speech, confusion, and motor impairment. Levels above 300 mg/dL (0.3 g/dL) can cause stupor, coma, respiratory depression, and finally death.

www.konkur.in

Alcohol use disorder (AUD) is an intersection of multiple variables affecting all social and ethnic groups. Genetic predisposition, social variables, family issues, and comorbid medical/psychological diagnoses factor into the development of AUD [1].

Alcohol abuse causes cirrhosis and increases the risk of cancers of the head, neck, and digestive tract. Excess alcohol intake causes or exacerbates hypertension, cardiomyopathies, stroke, and dementia. Pancreatitis and pneumonia can be the result of alcohol misuse as can an array of psychiatric disorders and other substance abuse disorders.

Prevalence

During their lifetime, 20% of men and 10% of women will be diagnosed with AUD [1]. The risk of alcohol dependence is 12.5% over a patient's lifetime [2].

Adolescents and young adults have more binge drinking, defined as males drinking five or more drinks (four for women) at any one time. Patients exposed to alcohol at a young age are more likely to develop problematic drinking or other substance abuse problems [3].

The elderly are not immune to AUD with 2–4% suffering from alcohol abuse. In the older patient, more neurologic and physiologic impairment occurs at a lower BAC. Care should be taken when prescribing medications that can be potentiated with alcohol use, such as sedative-hypnotics.

Screening

The US Preventive Services Task Force (USPSTF) recommends screening adults aged 18 years or older for alcohol misuse and providing persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce alcohol misuse [4]. For patients between the ages of 12 and 17, the USPSTF believes the evidence is insufficient to assess the balance of benefits and harms of screening by a primary care physician. The USPSTF uses the term "unhealthy alcohol use" to define a spectrum of behaviors, from risky drinking to AUD. Risky drinking is consuming more than the recommend daily, weekly, or occasion amounts.

Alcohol use during pregnancy is one of the leading causes of preventable birth defects and developmental disabilities. The physician should screen for alcohol use at every prenatal visit. Screening benefits the mother, the fetus, and the society. Because there is no safe level of alcohol consumption during pregnancy, abstinence is recommended for the entire pregnancy.

The USPSTF recommends two tools for initially screening adults for alcohol misuse in the primary care setting: the abbreviated Alcohol Use Disorders Identification Test-Consumption (AUDIT-C) and the single alcohol screening question (SASQ) method.

The AUDIT-C is comprised of the first 3 AUDIT questions and is scored from 0 to 12 points. Administering it takes between 1 and 2 min. A score of 5 or more for men (4 or more for women) is considered high risk for excessive and problematic alcohol use.

The SASQ method has the benefit of taking less than 1 min to administer. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) recommends this question, "How many times in the past year have you had 5 [for men] or 4 [for women and adults older than 65 years] or more drinks in a day?" A positive response warrants further investigation.

If a patient screens positive on a brief screening instrument, the provider should confirm unhealthy alcohol use with a longer instrument with greater specificity such as the Alcohol Use Disorders Identification Test (AUDIT) available at http://www.integration.samhsa.gov/AUDIT_screener_for_alcohol.pdf; AUDIT has ten questions and takes between 2 and 5 min to administer. The first three questions ask about the patient's consumption pattern. Questions 4–6 quantify the patient's tolerance or dependence on alcohol. The last four questions deal with alcohol-related problems the patient has experienced. A score of 8 or more has a high sensitivity and specificity for hazardous and harmful alcohol use.

Telegram: @medical_k

www.konkur.in

The CAGE questionnaire can be used for adolescents and adults, but it only detects alcohol dependence and not the full spectrum of unhealthy alcohol use. The four questions are: (1) Have you ever felt you should *Cut down* on your drinking? (2) Have people *annoyed* you by criticizing your drinking? (3) Have you ever felt bad or *guilty* about your drinking? (4) Have you ever had an *eye opener* or a drink in the morning to steady your nerves or to get rid of a hangover? A positive answer to two or more questions is sensitive and specific for AUD.

The CRAFFT questionnaire was designed for the adolescent patient [3]. If the answer to the first CRAFFT question is that they consume alcohol, then these additional questions are asked: Have you ever ridden in a *car* driven by someone (including yourself) who was "high" or had been using alcohol or drugs? Do you ever use alcohol or drugs to *relax*, feel better about yourself, or fit in? Do you ever use alcohol or drugs while you are by yourself, *alone*? Do you ever *forget* things you did while using alcohol or drugs? Do your family or *friends* ever tell you that you should cut down on your drinking or drug use? Have you ever gotten into *trouble* while you were using alcohol or drugs? If two or more of the questions are answered yes, there is the potential of a significant problem.

The USPSTF found no studies where screening for unhealthy alcohol use in any population leads to reduced unhealthy alcohol use; improved risky behaviors; or improved health, social, or legal outcomes [4].

Diagnosis

AUD diagnosis is a collection of physical and behavioral symptoms. The main features are alcohol craving, tolerance, and withdrawal. The diagnostic criteria are listed in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) (Table 1).

According to the DSM-5, remission of AUD is divided into three categories. Early remission is

Table 1 Definition of alcohol use disorder [5]

DSM-5[a]	
A problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by **at least two** of the following, occurring within a 12-month period	
Alcohol is taken in larger amounts or over a longer period than was intended	Important social, occupational, or recreational activities are given up or reduced because of alcohol use
There is a persistent desire or unsuccessful efforts to cut down or control alcohol use	Recurrent alcohol use in situation in which it is physically hazardous
A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects	Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol
Craving or a strong desire or urge to use alcohol	Tolerance, as defined by either of the following: 1. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect 2. A markedly diminished effect with continued use of the same amount of alcohol
Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home	Withdrawal, as manifested by either of the following: 1. The characteristic withdrawal syndrome for alcohol 2. Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms
Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol	

[a]*Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition

Telegram: @medical_k

www.konkur.in

when no criteria (except for craving or strong desire) have been met for at least 3 months but less than 1 year. Sustained remission is achieved when no criteria (except for craving or strong desire) have been met for 1 year or longer. And remission in a controlled environment is a special circumstance used when a patient's access to alcohol is outside of their control.

Treatment of Alcohol Use Disorder

The provider's attitude toward the patient is an important aspect of AUD treatment. Alcoholism is a particularly stigmatized mental disorder [6]. These patients provoke more social rejection and negative emotions and are deemed responsible for their condition [6].

Patients with AUD feel embarrassed and deeply vulnerable regarding their prior consequences of alcohol abuse. However, patients who screen positive for alcohol abuse show motivation to change, especially as the severity of alcohol misuse increases. To assist the patient through this difficult time, the provider should be nonjudgmental in their approach. Focus the discussion on past problems that have occurred and take a supportive role in the patient's current problem indicating treatment can be successful.

Intermittent Abuse or Binge Drinking

For patients with intermittent alcohol abuse or binge drinking, the initial treatment is a brief intervention [7]. Brief interventions can be single or multiple short duration (5–25 min) feedback sessions regarding the patient's alcohol use. The healthcare provider discusses the consequences of the patient's alcohol use (i.e., failed relationships, accidental trauma, family stress, job loss), a safe alcohol intake amount, and assesses the patient's readiness for change. The patient is told their drinking is not medically safe and they should reduce their intake (Fig. 1). Patients who drink despite brief interventions are candidates for intensive therapy.

Chronic Alcohol Abuse and Dependence

Patients with moderate to severe AUD should be confronted about the negative consequences of their alcohol use. Strongly recommend they abstain and ask about their willingness to abstain (Fig. 2). Initial interventions can be cognitive behavioral therapy, 12-step facilitation, or motivational enhancement therapy. Advising patients to cut down or eliminate consumption has been equally effective at reducing alcohol intake.

At a minimum, patients can be referred to interactional group therapy or mutual help programs, such as Alcoholics Anonymous (AA). The time and location of the local AA meetings can be found during the patient's encounter, and the patient is strongly encouraged to attend a meeting that day.

Alcohol Withdrawal Syndrome

For patients who consume large quantities of alcohol (>20 drinks/week) for a prolonged period of time (>2 weeks) and discontinue intake, approximately 50% will experience withdrawal symptoms [2]. The symptoms begin 6–24 h after the last alcohol intake or a significant reduction in alcohol intake [8].

Alcohol withdrawal involves the central nervous system, autonomic nervous system, and cognitive function [9]. Alcohol withdrawal syndrome (AWS) is any two of the following: (1) autonomic hyperactivity (sweating, tachycardia); (2) increased hand tremor; (3) insomnia; (4) nausea or vomiting; (5) transient visual, tactile, auditory hallucinations, or illusions; (6) psychomotor agitation; (7) anxiety; or (8) tonic-clonic seizures [8]. Delirium tremens (DTs), a severe hyperadrenergic state (i.e., hyperthermia, diaphoresis, tachypnea, or tachycardia) characterized by disorientation, impaired attention, and consciousness with visual and/or auditory hallucinations, can occur with either no treatment or under treatment of AWS [8]. Delirium is characterized by fluctuating changes in the level of consciousness, cognition, and psychomotor activity [10].

Telegram: @medical_k

www.konkur.in

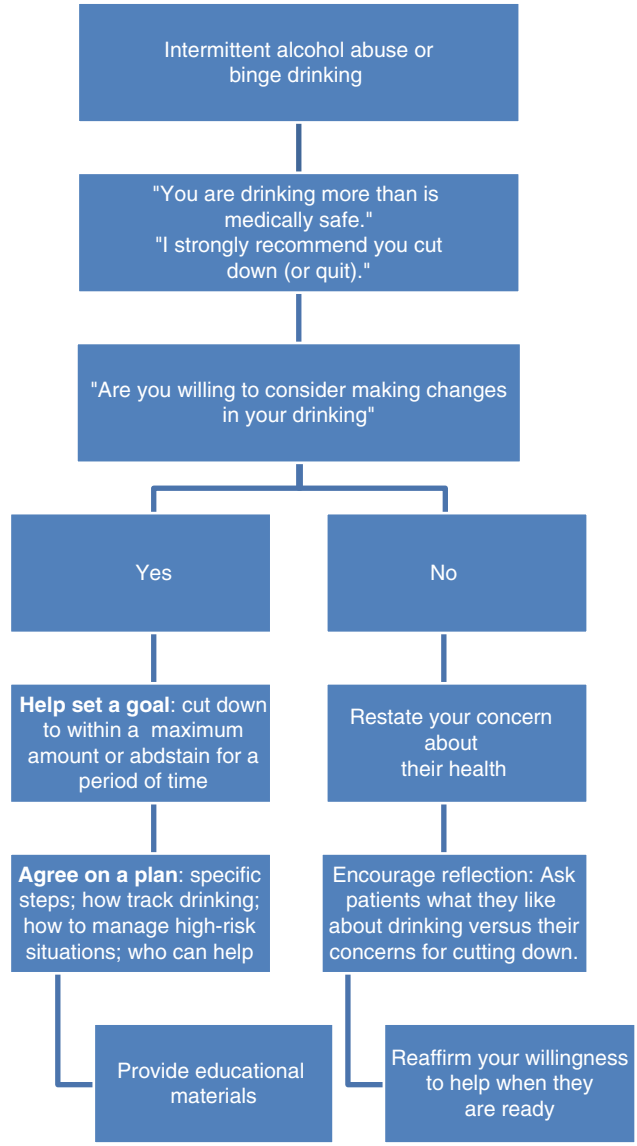

Fig. 1 Brief intervention for intermittent alcohol abuse or binge drinking http://pubs.niaaa.nih.gov/publications/Practitioner/CliniciansGuide2005/clinicians_guide7.htm#top

AWS can be viewed in three stages. Stage 1 symptoms are mild anxiety, tremor, insomnia, headache, palpitations, or gastrointestinal disturbances with normal vital signs. Stage 2 symptoms are more intense and associated with abnormal vital signs (i.e., elevated BP or pulse, increased respirations, or increased temperature). Stage 3 includes stage 2 symptoms and either DTs or seizures. Progression to stage 2 or stage 3 can proceed quickly without treatment [11].

AWS severity is assessed using a validated instrument. The instrument often recommended is the Clinical Institute Withdrawal Assessment of Alcohol, Revised (CIWA-Ar) available at http://www.mdcalc.com/ciwa-ar-for-alcohol-withdrawal/ [12]. A CIWA-Ar score of 0–7 points is absent or very mild AWS, 8–15 points is moderate AWS, and $>$ 15 points is severe AWS [2]. The self-completed Short Alcohol Withdrawal Scale (SAWS) (available at http://www.aafp.org/afp/2013/1101/p589.html) has been validated in the outpatient setting [13]. A SAWS score $<$ 12 is mild AWS and $\geq$ 12 is moderate AWS.

Telegram: @medical_k

www.konkur.in

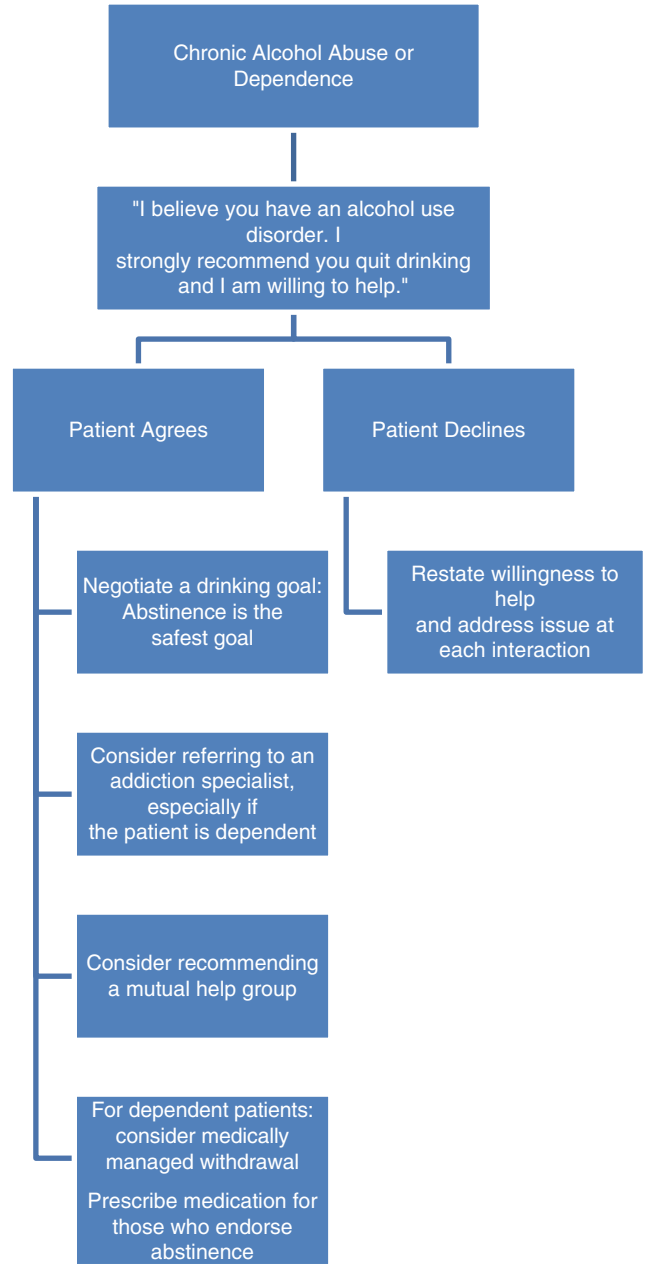

Fig. 2 Confronting chronic alcohol abuse or dependence http://pubs.niaaa.nih.gov/publications/Practitioner/CliniciansGuide2005/clinicians_guide7.htm#top

Treatment of AWS

The AWS treatment goals are to reduce withdrawal symptoms, prevent complications (e.g., seizures, DTs, or death), and prepare the patient for long-term abstinence. Adequately and promptly abating AWS symptoms diminishes the severity of future withdrawal episodes and the risk the patient will resume drinking to ameliorate their symptoms [8]. Alcohol withdrawal seizures occur 24–72 h after the last alcohol intake, are typically tonic clonic, and last less than 5 min. Up to one third of patients with an alcohol withdrawal seizure will progress to DTs.

Telegram: @medical_k

www.konkur.in

When Is Medically Supervised AWS Treatment Not Necessary?

Patients with no alcohol intake in the preceding 5 days and have not abused other drugs do not require medical treatment. They should not be given medication, and any symptoms are related to comorbidities (i.e., anxiety, depression, other drug withdrawal) and not AWS.

Outpatient Treatment of AWS

Outpatient treatment of mild or moderate AWS is safe, effective, and less expensive than inpatient treatment [8]. Treating the patient in an outpatient setting can minimize expenses and allow for less interruption of work and family life. The following conditions preclude outpatient treatment: serious psychiatric conditions (e.g., suicidal, psychosis, etc.), acute illness, severe alcohol withdrawal symptoms, high risk of delirium tremens (DTs), history of withdrawal seizure, long-term intake of large amounts of alcohol, poorly controlled chronic medical conditions (e.g., diabetes, COPD, CHF), or lack of a support network [8].

While laboratory tests are not necessary for mild AWS, significant laboratory abnormalities would preclude outpatient treatment. A positive urine drug screen, signifying a co-occurring substance abuse, would prevent outpatient treatment.

And finally, in addition to medical and social issues that prevent outpatient treatment, the patient must be able to take oral medications, commit to frequent follow-up visits, and have a support person who can stay with them and administer medication [9]. The dispensing of medication requires clinical judgment and creates issues of control; thus caregivers must be informed of their role and be in agreement [8]. Family support can be critical in the success of outpatient treatment. However, family dysfunction or home alcohol consumption triggers can make outpatient treatment success unlikely.

Inpatient Treatment of AWS

AWS patients can be admitted to the hospital if they are not appropriate for outpatient treatment or if they fail outpatient treatment. AUD patients may be admitted to the hospital for other problems (e.g., pneumonia, pancreatitis, etc.) and then experience AWS. When patients are admitted, they become accessible to healthcare professionals for an intervention. If their reason for admission is the consequence of alcohol abuse, it could represent a triggering occurrence which could serve as a catalyst for change in alcohol use. For the nondependent patient, alcohol consumption was reduced if they had more than one brief intervention during their hospital stay. A single screening and brief intervention in the emergency room or nonemergency department hospital setting did not reduce alcohol consumption [14].

Reducing Symptoms

Alcohol withdrawal symptoms are increased with external stimulation. Patients should have a quiet and subdued environment with minimal opportunities for external stimulation. Patients with mild AWS may only require supportive care [8]. Most patients are given medication to reduce symptoms, particularly if there is any question about their duration of abstinence.

Because AWS patients are often nutritionally depleted, thiamine and folic acid supplementation are usually given to patients. Thiamine 100 mg orally once a day is recommended to reduce the risk of Wernicke's encephalopathy (i.e., oculomotor dysfunction, abnormal mentation, and ataxia). Folic acid 1 mg orally daily is recommended. Magnesium supplementation may be necessary but should not be a routine practice [9]. Intravenous fluids are not beneficial for AWS unless the patient has persistent vomiting or develops DTs.

Preventing Complications

Benzodiazepines (BZD) and anticonvulsants treat alcohol withdrawal symptoms and prevent complications (Table 2). They reduce psychomotor agitation and prevent progression of withdrawal symptoms [15]. They should be administered early in the AWS course. No evidence supports the superiority of any medication in treating AWS.

BZDs are long-acting (chlordiazepoxide, diazepam) or intermediate-acting (lorazepam, oxazepam). Long-acting BZD may be more efficacious in preventing delirium [16]. They have active metabolites that prolong their sedative and

Telegram: @medical_k

www.konkur.in

Table 2 Medications used to treat AWS [8]

Medication	Typical dosage	Common side effects	Contraindications
Benzodiazepines			
Chlordiazepoxide Diazepam Lorazepam Midazolam (for DTs)	25–50 mg 10 mg 2 mg 1–4 mg (IM/IV)	Sedation, fatigue, respiratory depression, retrograde amnesia, ataxia, dependence, and abuse	Hypersensitivity to drug/class ingredient Severe hepatic impairment Avoid abrupt withdrawal
Anticonvulsants			
Carbamazepine Oxcarbazepine Valproic acid Phenobarbital	600–800 mg 450–900 mg 1000–1200 mg 1500–2000 mg/day	Dizziness, ataxia, diplopia, nausea, vomiting	Hypersensitivity to drug/class ingredient, hypersensitivity to TCAs, no MAOI within 14 days, hepatic porphyria, avoid abrupt withdrawal
Beta-blocker			
Atenolol	50 mg if pulse 50–79 100 mg if pulse ≥80	Bradycardia, hypotension, fatigue, dizziness, cold extremities, depression	Hypersensitivity to drug/class ingredient, AV block second or third, uncompensated heart failure, cardiogenic shock, sick sinus syndrome without ICD, untreated pheochromocytoma, avoid abrupt withdrawal
Alpha-adrenergic agonist			
Clonidine	0.2 mg	Hypotension, dry mouth, dizziness, constipation, sedation	Hypersensitivity to drug/class ingredient, avoid abrupt withdrawal

anxiolytic effects [16]. Experts contend that long-acting BZDs provide a smoother withdrawal experience with fewer fluctuations in symptoms; however, intermediate-acting BZD have been used successfully [15]. In patients with hepatic dysfunction, the intermediate-acting agents (e.g., lorazepam, oxazepam) may be safer because they have no active metabolites. Chlordiazepoxide or oxazepam has less abuse potential, but no data supports their superiority in treating AWS. Because BDZ can cause fatalities when combined with alcohol, they should be prescribed in small amounts.

Carbamazepine and valproic acid are effective in treating AWS. However, anticonvulsant medication efficacy data is limited, and carbamazepine is associated with dizziness, ataxia, diplopia, nausea, and vomiting [17]. Limited evidence supports the use of valproic acid over BZD. Oxcarbazepine was as effective as carbamazepine in treating AWS, although one placebo-controlled randomized trial did not support that contention [18]. Gabapentin was effective in treating AWS and reducing drinking during withdrawal [19]. Anticonvulsant medications have reduced abuse liability, but they do not prevent withdrawal seizures or DTs.

Alternative AWS Medications: Less Effective

While baclofen was effective in reducing AWS symptoms and may reduce the risk of relapse without a risk of abuse, the overall data is mixed. As adjunctive therapy, beta-blockers and the alpha-adrenergic agonist clonidine are effective in reducing adrenergic symptoms but are not effective in preventing withdrawal seizures [15]. Neither phenothiazines nor barbiturates are recommended for AWS treatment in the outpatient setting [15]. Phenytoin is not effective in the treatment or prevention of alcohol withdrawal seizures.

Outpatient BZD Dosing Options

BZD are given in a fixed-dose or symptom-triggered schedule. A front-loading or loading-dose schedule is not recommended for outpatient treatment. The fixed-dose schedule utilizes a specific dosage at specific intervals regardless of the patient's symptoms. Additional

Telegram: @medical_k

www.konkur.in

medication is given if needed to control symptoms and the dosage reduced if overmedication occurs [8].

The symptom-triggered schedule utilizes medication when the patient has significant symptoms (i.e., CIWA-Ar > 9; SAWS ≥12). This schedule reduced medication use and shortened duration of treatment for inpatients [20]. However, one trial with a long-acting BZD in ambulatory patients revealed no difference between the fixed-dose and symptom-triggered schedule regarding total BZD dosage, patient satisfaction, or time to relapse [21]. Symptom-triggered schedules rely on the patient and caregiver to rate symptoms and may not be appropriate for some outpatients. A typical fixed-dose and symptom-triggered schedule is suggested (Table 3).

Inpatient Dosing Options

For hospitalized patients, BZDs can be given with a fixed-dose, symptom-triggered, or loading-dose regimen. For the hospitalized patient or the patient with DTs, a loading dose of a long-acting BZD has been found to improve outcomes in AWS [10]. The typical diazepam loading dosage is 20 mg every hour for 3–12 h until symptoms are controlled. Then either the fixed-dose or symptom-triggered outpatient regimen is implemented. Ethanol should not be used to treat AWS.

Monitoring Withdrawal: Outpatient

Most patients are evaluated daily until their symptoms decrease and the medication dosage is reduced. Blood pressure and pulse should be measured at each follow-up visit. If available, an alcohol breath analysis could be done randomly. Reassessment of the AWS severity is done with the same instrument used initially. When the CIWA-Ar is ≤8 or SAWS is <12, medication can be reduced and eventually discontinued. Alcohol withdrawal symptoms should resolve within 7 days of abstinence regardless of the severity of the AWS. The patient can be discharged to long-term outpatient treatment when symptoms are minimal, no medication is needed, and there has been no alcohol intake for at least 3 days. Patients who have an inadequate response to BZD, miss an outpatient appointment, or resume drinking should be referred to an addiction specialist.

Monitoring Withdrawal: Inpatient

For patients admitted to the hospital, the frequency of monitoring is every 4–6 h. If possible, allow patients to use normal clothes instead of hospital gowns. One advantage of inpatient treatment is the frequent interactions with the nursing staff, who can be supportive during treatment. The patient can be discharged when the AWS symptoms are mild.

Table 3 Fixed dosage and symptom-triggered dosage options to treat AWS [8]

Treatment day	Fixed dosage schedule (orally)	Symptom-triggered schedule (orally) For SAWS ≥ 12 or CIWA-Ar > 9
Day 1	Diazepam 10 mg every 6 h Chlordiazepoxide 25–50 mg every 6 h Lorazepam 2 mg every 8 h	Diazepam 10 mg every 4 h Chlordiazepoxide 25–50 mg every 4 h Lorazepam 2 mg every 6 h
Day 2	Diazepam 10 mg every 8 h Chlordiazepoxide 25–50 mg every 8 h Lorazepam 2 mg every 8 h	Diazepam 10 mg every 6 h Chlordiazepoxide 25–50 mg every 6 h Lorazepam 2 mg every 6 h
Day 3	Diazepam 10 mg every 12 h Chlordiazepoxide 25–50 mg every 12 h Lorazepam 1 mg every 8 h	Diazepam 10 mg every 6 h Chlordiazepoxide 25–50 mg every 6 h Lorazepam 1 mg every 8 h
Day 4	Diazepam 10 mg at bedtime Chlordiazepoxide 25–50 mg at bedtime Lorazepam 1 mg every 12 h	Diazepam 10 mg every 12 h Chlordiazepoxide 25–50 mg every 12 h Lorazepam 1 mg every 12 h
Day 5	Diazepam 10 mg at bedtime Chlordiazepoxide 25–50 mg at bedtime Lorazepam 1 mg at bedtime	Diazepam 10 mg every 12 h Chlordiazepoxide 25–50 mg every 6 h Lorazepam 1 mg every 12 h

Telegram: @medical_k

www.konkur.in

Management of DTs

DTs, severe AWS, is associated with an increased risk of death and a current mortality rate ranging from 1% to 4%. DTs symptoms begin about 2–3 days after initial withdrawal symptoms develop [10]. DTs risk factors include sustained heavy drinking, age over 30, more days since last drink, and, most importantly, a prior episode of DTs [8]. Hallucinations, common in DTs and primarily visual, are not dangerous but are distressing to the patient and his or her caregiver. Hallucinations were considered necessary for the diagnosis of DTs but that is no longer true.

The treatment of DTs is a medical emergency requiring inpatient care and prompt symptom treatment. The control of agitation is the initial goal and can be achieved with a benzodiazepine (Table 2). The patient's condition determines the route of administration. Most medications will be given intravenously, intermittently, until the symptoms subside. The doses required to control agitation vary dramatically and can be quite large (e.g., >2000 mg diazepam in the first 2 days) [2]. For these patients a front-loading dosage is preferred over fixed-dose or symptom-triggered regimen [10]. However, a Cochrane review did not find enough evidence of BZD effectiveness in treating patients with delirium not in the ICU setting. The available evidence did not support the routine use of BZD for delirium in the non-ICU setting [22]. Monitoring is more frequent than either outpatient or regular inpatient care, usually every 2 h. Confusion may be reduced by limiting stimulation, good lighting, and environmental cues such as having a clock or calendar visible.

Physical restraints may be used to protect the patient and staff utilizing the institution's restraint protocol. For patients who do not respond to high doses of a benzodiazepine, phenobarbital (60 mg IV q15min) or propofol (0.3–1.25 mg/kg/h IV) can be administered in the ICU [2]. Another ICU medication is dexmedetomidine (Precedex ®) (0.4–0.7 mcg/kg/h IV); an α_2-adrenergic agonist has been administered [23]. Intravenous fluids should be utilized to maintain hydration and to treat electrolyte abnormalities [10].

To reduce the risk of Wernicke encephalopathy (WE), all patients with DTs are given supplemental thiamine. The usual dosage is 500 mg intravenously infused over 30 min 1–2 times a day. Intravenous dextrose is to be avoided until after thiamine replacement. If dextrose is administered before thiamine, it might precipitate WE.

Long-Term Management of Alcohol Dependence

Due to the chronic and relapsing nature of alcohol dependence, implementing long-term treatment is essential for the maintenance of remission. From 40% to 60% of AUD, patients relapse within 1 year after entering treatment. Following recovery from alcohol withdrawal, continuing care can be provided in an inpatient or outpatient setting.

Interventions to maintain remission are based on the patient's current clinical status, medical and psychiatric comorbid conditions, level of current use, risk for relapse, motivation for recovery, and personal preferences [24]. The American Society of Addiction Medicine (ASAM) treatment criteria for addictive, substance-related, and co-occurring conditions (available at ASAMCriteria.org) can assist clinicians in determining appropriate levels of care. Levels of care include residential programs, partial hospital programs, intensive outpatient programs, and outpatient care [25].

Levels of Care

Residential care programs are inpatient programs providing housing, peer and professional support, and an alcohol-free environment. Examples of residential treatment models include community residential treatment facilities, therapeutic communities, and Oxford House [25].

Therapeutic communities provide comprehensive care and emphasize graduated personal and social responsibility. Appropriate patients for residential care tend to be relapse prone, poly-substance abusers, often with psychiatric comorbidities and poor social support. Staff and clients reside together and interact in activities

Telegram: @medical_k

www.konkur.in

with the goals of assimilation of social norms, development of social skills, and positive impact upon attitudes, perceptions, and behaviors. Typically, stays range from 18 to 24 months with a desired minimum of 90 days.

Oxford House (www.oxfordhouse.org) is a publicly supported recovery concept where individuals live together in democratically run, self-supporting residences without addiction counselors. The residential complement ranges from 6 to 15 individuals per house, and specific residences may be designated for men, women, or women with children. Treatment interventions are self-selected by the participants.

Partial hospital programs (PHPs) allow for increased flexibility for the patient who wishes to stay at home but needs a higher level of care. Patients participate a minimum of 20 h per week but can be as much as 6 h per day 5–7 days per week. The care includes individual and group counseling, medication management, didactic sessions, and even specialized services such as occupational therapy.

Intensive outpatient programs (IOPs) are structured similar to PHPs and may be housed in the same facility as a PHP but provide only 10–20 h of treatment per week. *Outpatient care* model utilizes similar services as IOPs, but interventions are less frequent (less than 10 h/week) and shorter in duration.

Psychosocial and Behavioral Interventions

Interactional Group Psychotherapy or "self-help" groups based on the 12-step program are historically significant, but evidence supporting their effectiveness is limited. The most well-known adaptation, *Alcoholics Anonymous* (AA), was founded in 1935 and thrives today as a worldwide network [26]. The 12 steps serve as a template for behavioral interventions aimed at maintenance of sobriety, and the fellowship provides an abstinent social network to replace lost "drinking buddies." Daily meetings are offered in a wide variety of venues, and group composition varies by age, gender, and interests of the participants. Common elements include the acknowledgment of individual powerlessness over alcohol and the existence of a higher power, selection of a sober sponsor, and an emphasis on relapse forgiveness. Companion organizations for family support include *Al-Anon* and *Alateen*.

For patients uncomfortable with the spiritual aspect of the model, similar nonreligious programs exist such as *SMART Recovery*, *Rational Recovery*, and *Save Our Selves*. Though the efficacy of AA has not been sufficiently assessed in randomized controlled trials, experts generally agree that it produces positive outcomes [27]. However, a Cochrane review concluded there is a lack of experimental evidence supporting the effectiveness of 12-step programs for alcohol dependence [28].

Group therapy is a formal continuing care therapy session led by a trained professional. Sessions typically last 90 min and occur one or two times per week. They may occur in a 12-step format where patients report on their progress through the steps and they are given feedback and support, or they utilize an instructional format which utilizes elements of cognitive behavioral therapy (discussed below) or emphasize skills development. The methods are equally efficacious and more cost-effective than individual therapy. Advantages include peer influence on sobriety, role modeling of sober behavior, avoidance of social isolation, and reinforcement by example that successful remission is possible.

Individual therapy occurs in sessions typically lasting 30–60 min. The frequency and duration of such sessions are dependent on the patient's duration of remission and on continued sobriety. Initially, clinicians may interact with patients three or more times per week. Care is stepped up or down based on the patient's progress.

Cognitive behavioral therapy (CBT) is a format which identifies triggers for alcohol abuse, develops coping strategies for risky situations, and defines alternative activities to replace those activities which challenge sobriety. Patients are given homework assignments to guide them in determining what leads to alcohol use and in developing responses to avoid relapse. A meta-analysis concluded that CBT was modestly beneficial in maintenance of sobriety [29].

Telegram: @medical_k

www.konkur.in

Relapse prevention is a form of CBT specifically aimed at identifying individual risk factors for relapse and then selecting and rehearsing coping responses for those risks. A meta-analysis demonstrated effectiveness comparable with other psychosocial interventions [30].

Motivational enhancement therapy (MET) is based on the premise that responsibility and capacity for change lay within the client. Motivational interviewing techniques include open-ended questions and affirmations, reflective listening, summarizing, and eliciting "change talk." The therapist emphasizes personal responsibility, and together, the therapist and client explore the risks of continued drinking, the benefits of abstinence, the treatment options, and the strategies for relapse avoidance.

Combined behavioral intervention is a specialized technique that incorporates components of CBT, interactional psychotherapy, and MIT.

Recovering patients benefit from therapy designed for couples and families. *Couple-based therapy* engages the client's spouse or partner with improving patient participation and positively influencing the patient's behavior toward sustained abstinence. *Behavioral marital therapy* (BMT) addresses issues of marital discord by education in improved communication, conflict recognition and resolution, and engagement of the couple in shared activities. A meta-analysis concluded that behavioral couple's therapy was superior to individual therapy.

Pharmacologic Interventions

Less than 10% of patients with AUD receive medications to assist in maintaining sobriety [31]. Three medications are approved by the Food and Drug Administration (FDA) for the treatment of alcohol dependence: naltrexone (oral and injectable), acamprosate, and disulfiram [31]. Acamprosate and oral naltrexone are effective in reducing a return to drinking, although no studies demonstrate superiority of one over the other [31] (Table 4).

No treatment is approved for adolescents younger than 18 years with AUD [32].

Naltrexone

Naltrexone, available in oral (*ReVia*) and injectable formulation, has proven efficacy in reduction of alcohol consumption [33, 34]. The oral form (50–100 mg per day) may be started prior to the cessation of drinking. Naltrexone antagonizes various opioid receptors negating the reinforcing effects of alcohol [31]. Common side effects include fatigue, nausea, vomiting, abdominal pain, headache, and dizziness and should be avoided in patients with active liver disease or on opioids. Injectable naltrexone in depot form (*Vivitrol*) was developed to increase compliance while minimizing side effects [32]. Adverse effects are similar to the oral formulation with the addition of injection site reactions and interstitial or eosinophilic pneumonia [35].

Acamprosate

Acamprosate (*Campral*) is hypothesized to exert effects on both glutamate and GABA; however, its mechanism of action is not clearly elucidated. The usual dosage is 666 mg three times daily after abstinence is achieved. Several meta-analyses support its efficacy in increasing abstinence [36]. However, the *COMBINE* study comparing the efficacy of acamprosate, naltrexone, and placebo found acamprosate to be no more effective than placebo. Patients with impaired hepatic dysfunction can use acamprosate but should be avoided in patients with severe renal dysfunction [32]. Though well tolerated, common side effects include diarrhea, insomnia, anxiety, depression, nausea, and dizziness [31].

Disulfiram

Unlike the other agents, disulfiram (*Antabuse*) does not act at the level of the neurotransmitter. Disulfiram inhibits acetaldehyde dehydrogenase, thus resulting in the accumulation acetaldehyde. Excess acetaldehyde produces a constellation of distasteful symptoms including nausea, vomiting, sweating, headache, dyspnea, flushing, and palpitations thus promoting an aversion to alcohol [31]. Dosages range from 125 to 500 mg daily. A meta-analysis did not find clinically significant benefit of disulfiram over placebo. Noncompliance was a major obstacle in the trials reviewed. A study with

Table 4 (continued)

Medication	Dose	FDA approved	Mechanism of action	Side effects	Caveats
Selective serotonin reuptake inhibitors	Various	No	Serotonin mediated	Depends upon drug chosen	Use in comorbid depression More effective in late-onset alcoholism

supervised medication administration demonstrated superiority of disulfiram over acamprosate and naltrexone in reducing heavy drinking days and average weekly alcohol consumption. Additionally, the time to first drink was increased with witnessed consumption of disulfiram. Once the supervisory component was removed, the benefit dissipated.

Other Agents

Topiramate (*Topamax*) is not an FDA-approved treatment for alcohol dependence but has demonstrated moderate effectiveness in the reduction of alcohol use in dependent patients [37]. Mitigation of alcohol consumption is believed to be mediated by effects on glutamate and GABA receptors. A meta-analysis showed decreased consumption of alcohol when compared with placebo. Common side effects include dizziness, somnolence weight loss, fatigue, nervousness, and cognitive dysfunction [31].

Gabapentin (*Neurontin*) has proven efficacy in dosages of 900 or 1800 mg daily versus placebo [38]. Side effects are dizziness and sedation which are dose-dependent. One study found gabapentin was most effective in preventing relapse to heavy drinking and promoting abstinence when the patient had more severe AWS [39]. Baclofen results were mixed in clinical trials compared with placebo at both low (30–60 mg) and high (150–400) doses. Though generally well tolerated, adverse effects included dizziness, depression, headache, paresthesias, ataxia, and insomnia [40]. Selective serotonin reuptake inhibitors (SSRIs) have only been found to be effective in the management of alcohol dependence in patients with a comorbid depression diagnosis [41].

Ondansetron may reduce alcohol consumption in patients with AUD when combined with CBI [42]. The effect may be due to the serotonin-3 antagonist effect. The studied ondansetron dosages were 4–16 mcg/kg twice per day.

Other Interventions

Acupuncture has been an accepted adjuvant therapy for many decades. Experts agree that it is most effective when combined with psychosocial and pharmacological interventions [43].

Hypnosis was used to treat addiction in the late nineteenth century with some success. Hypnosis studies are very limited and the numbers of participants small. One study reported a 77% success rate in 18 clients treated intensively (20 daily sessions) with sustained benefit at 1 year follow-up, while another study using audiotapes for self-hypnosis demonstrated improvement in self-esteem and serenity and a reduction in anger and impulsivity [44].

Intervention for sleep disturbances may benefit patients in maintaining sobriety as some patients use alcohol for its sedative effects. Promotions of good sleep hygiene, bright light therapy, and meditation are options (Table 5).

Emerging Interventions

Theoretically, the most successful interventions in the management of alcoholism should be those that are most adaptable and accessible for the needs of a broad spectrum of patients. Recent studies have explored modalities which utilize modern technology to interact and monitor patients following inpatient or intensive outpatient therapy. Technologies such as e-mailing, text messaging, Internet-based social support, Internet-based cognitive behavioral therapy applications, and telephone-based counseling are being used to facilitate maintenance of sobriety. Some research of Internet- and telephone-based models have proven benefit especially for CBT [45]. However, further adequately powered

Nalmefene (*Selincro*)	20–80 mg QD	No	Opioid antagonist	Dizziness, headache, insomnia, nausea and vomiting, tachycardia		Increases compliance with treatment
Acamprosate (*Campral)*	666 mg TID	Yes	Glutamate/ GABA receptors/ NDMA receptor	Transient diarrhea Vomiting Nervousness Fatigue		Avoid use in renal failure Cannot start until abstinence is established
Disulfiram (*Antabuse*)	125–500 mg Usually 500 mg for 1–2 weeks and then 250 mg QD	Yes	Inhibits acetaldehyde dehydrogenase	Fatigue, headache, rash, hepatitis, psychosis		Avoid alcohol containing products such as mouthwash for at least 2 weeks after stopping Do not use in pregnancy Monitor LFTs Contraindicated in patients with psychosis/severe CAD Effective when administration is supervised Cannot start until abstinence is established
Topiramate (*Topamax*)	50–300 mg Q day	No	Antagonizes glutamate/ GABA receptors agonist	Cognitive dysfunction paresthesias and taste abnormalities, weight loss, headache, fatigue, dizziness		Dose must be gradually increased and decreased
Gabapentin (*Neurontin*)	900–1800 mg QD	No	GABA mediated	Sedation at higher doses, dizziness, and abuse potential		
Baclofen	30 mg QD High dose	No		Nausea, vertigo/ dizziness, depression,

Table 5 (continued)

Medication	Dose	FDA indication/	Mechanism of action	Side Effects	Cost	Caveats
	150–400 mg QD		GABA receptors agonist	sleepiness, abdominal pain, ataxia, and insomnia		Can be used in patients with liver disease
Selective serotonin reuptake inhibitors	Various	No	Serotonin mediated	Depends upon drug chosen		Use in comorbid depression More effective in late-onset alcoholism
Ondansetron	4 mcg/kg BID	No	5 HT3 receptor antagonist	Diarrhea, prolonged QT, headache		Use in early onset alcoholism Avoid use in prolonged QT or with drugs that prolong QT

randomized-controlled trials are needed to determine the efficacy of these interventions. Additionally, how these interventions can best be incorporated into a comprehensive continuing care model for the long-term management of alcoholism must be explored.

Definition and Scope of Chronic Pain

Chronic pain is pain that persists beyond the typical healing time of 3–6 months. The National Institutes of Health (NIH) and Centers for Disease Control and Prevention (CDC) estimate that over 50 million people in the United States suffer from chronic non-cancer pain (CNCP), which ends up being more than 20% of the population [1]. The annual healthcare costs for patients with CNCP are estimated at $560 billion, but despite the high prevalence, CNCP remains undertreated

[2]. However, with the surge in public awareness and multiple national endeavors, including CDC updates on prescribing recommendations, there has been a significant drop in opioid prescription, with the Medical Expenditure Panel Surveys indicating that annual share of US adults who were prescribed opioids declined from 12.9% in 2014 to 10.3% in 2016. With the push to reduce opioid use and increase non-pharmaceutical therapies, primary care physicians have had been adjusting prescribing practices to align with updated best practices.

Patients with CNCP frequently are seen in primary care offices where their treatment is often coordinated by a family physician. While these patients and their pain can often be seen as challenging to manage, using a stepwise approach and collaborative care model can safely and successfully mitigate pain and improve function.

Treating Acute Pain

Acute pain tends to have an easily identifiable cause and typically resolves when the inciting injury heals. Non-opioid medications should be considered first line for acute pain; however, if opioids are indicated for an acute injury, providers must discuss the risks of treatment as well as the expectations for healing and engage the patient in mutual decision-making [3]. The transition from acute pain to chronic pain is not always obvious and providers can easily find themselves refilling opioid prescriptions long after the acute injury should have healed and without having discussed the risks of long-term opioids with patients. The CDC and NIH recommend that if opioid use is indicated, clinicians should prescribe the lowest effective dose and prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioid pain relievers (3 or fewer days will usually be sufficient) [4]. However, as with all symptoms, the key to acute pain management is evaluation and treatment of the underlying diagnosis.

Patient Assessment

Every patient in pain requires a thorough initial health history and physical exam to assess pain characteristics including: location, intensity, quality, duration, and relieving and exacerbating factors. There was a campaign in the 1990s to make pain "the fifth vital sign" which increased visibility of pain assessments, but this heavy emphasis on addressing pain resulted in a number of unintended consequences including opioid abuse, addiction, and diversion. Although there has been growing hesitation with addressing pain in the clinical setting, by categorizing the type of chronic pain, the family physician can better determine patient treatment options.

A functional assessment is essential for patients in chronic pain [5]. Tools for use in clinic are numerous and include Numerical Rating Scales (NRS), Faces Pain Scale-Revised (FPS-R), and the Pain, Enjoyment, and General Activity questionnaire, along with the Physical Functional Ability Questionnaire by the Institute for Clinical Systems Improvement. In recent years there has been a gradual shift away from numerical assessment toward a focus on an evaluation of function and quality of life. Patients should be aware of these goals, and function should be tracked over time.

In addition to assessing the patient, family physicians must set expectations for pain management at the first visit. Chronic pain is a chronic disease and should be managed as such. Many patients will require multiple modalities, self-management skills, and more than one medication trial to achieve improvement in their daily function.

Types of Pain and Treatment Options

Pain is primarily classified as nociceptive or neuropathic. Nociceptive pain is caused by tissue injury and includes inflammatory, muscular, and mechanical pain. Neuropathic pain is caused by damage to or dysfunction of the central or peripheral nervous systems. Importantly, nociceptive

Telegram: @medical_k

www.konkur.in

and neuropathic pain systems are not mutually exclusive and patients can be affected by both types of pain. Classification of mechanism for a given patient can be helpful in guiding therapy [6].

Inflammatory pain – Arthritis, surgery, and infection are potential causes of inflammatory pain. Hallmarks of inflammatory pain on physical exam are edema, heat, erythema, and pain at the site of an injury. Treatment typically involves NSAIDs, corticosteroids, or immune-modulating agents to control the inflammation.

Muscular pain – Muscle soft tissue pain typically occurs after an injury and involves pain in one or more areas of muscle, loss of range of motion, as well as tenderness over the affected muscle groups. Myofascial pain is a common cause of chronic pain and is best managed by physical therapy and restoring muscle balance over providing medication [6]. Trigger point injections or acupuncture may be useful.

Mechanical pain – Mechanical pain is often caused by compression due to a cyst or tumor, fracture, degeneration, or dislocation. Pain is aggravated by activity and can be relieved by rest [6]. Most chronic neck pain and visceral pain fall into this category. Chronic low back pain can also be in this category but is often multifactorial. Treatment may be surgical in the case of cysts, fractures, and impingement.

Neuropathic pain – Common examples of neuropathic pain include diabetic neuropathy, postherpetic neuralgia, carpal tunnel, multiple sclerosis, and poststroke pain. Neuropathic pain is often described as "shooting" or "stabbing" but can also present as numbness, tingling, and increased sensitivity to benign touch (allodynia) [6]. Neuropathic pain is less responsive to opioid analgesics [7]. Treatment options for neuropathic pain are numerous, but can be generally divided into two categories: disease-specific treatments or symptom management. When discussing disease-specific treatments, the goal is to treat the underlying malady, such as improved glucose control for diabetic neuropathy or surgery for nerve decompression. First-line treatment options for symptom management include anticonvulsants, tricyclic antidepressants (TCAs), and serotonin-norepinephrine reuptake inhibitors (SNRIs) [6].

There is an additional classification for "other pain" that is currently evolving as we develop a better understanding of the mechanism. This has historically been known as "functional pain disorders" and includes fibromyalgia, irritable bowel syndrome, complex regional pain syndrome, and other conditions which may have started as nociceptive, but evolve to include sensitization disorders.

Non-opioid Pharmacologic Treatments for Pain

See Refs. [5, 6, 8] (Table 1)

Muscle Relaxants

Although commonly used for muscle spasms and to help alleviate acute pain, there is little evidence to support the use of muscle relaxants such as cyclobenzaprine (Flexeril) and tizanidine (Zanaflex) for chronic low back pain [6, 8]. These muscle relaxants are typically used in combination with an NSAID or acetaminophen. Carisoprodol (Soma) is structurally similar to alprazolam, has little utility in the management of chronic pain, and can be habit-forming [6]. If used chronically, muscle relaxants cause central relaxation and may carry the risk of physical dependence [8]. Baclofen is a commonly used antispasmodic agent which may improve neuropathic pain and may be less habit-forming than muscle relaxants [6, 8].

Role of Opioids in Chronic Pain

Current recommendations from the Center for Disease Control and Prevention (CDC) are to refrain from using opioids as the first line in pain therapy [9]. Although there are guidelines which have been developed to help clinicians safely and effectively treat chronic non-cancer pain (CNCP) with opioids, many of them are based on limited

Telegram: @medical_k

www.konkur.in

Table 1 Common Suggestions for Chronic Pain Medications and Dosages

Drug name	Usual dose	Maximum dose	Comments
Acetaminophen (Tylenol, others)	325–1,000 mg po q4–8 h respectively	3,000 mg/day	Recommended for noninflammatory osteoarthritis. May require maximum dose for 1 week for chronic pain trial. Avoid with chronic alcoholism. Monitor OTC medications for risk of accidental overdose
Nonsteroidal anti-inflammatory drugs (NSAIDs)			
Ibuprofen (Motrin, others)	200–800 mg po q4–6 h	3,200 mg/day	NSAIDs in recommended doses usually provide superior analgesia compared with aspirin, but do not produce the same analgesic effect in all patients. Major adverse effects are as follows: 1. Increased risk of serious cardiovascular thrombotic events, including myocardial infection and stroke. Elevated blood pressure may also be seen especially in the elderly and in conjunction with beta-blockers or angiotensin-converting enzyme inhibitors 2. Fluid retention in patients with congestive heart failure 3. Acute renal failure or renal insufficiency 4. Drowsiness and confusion 5. Reversible inhibition of platelet aggregation 6. Anaphylaxis in aspirin-sensitive patients 7. Peptic ulcer disease, regardless of mode of administration, especially in the first month of therapy Adding a proton pump inhibitor, H2-receptor antagonist, or misoprostol may decrease GI toxicity Use with caution and for the shortest time possible in the elderly
Naproxen (Naprosyn)	500 mg po q12h	1,000 mg/day	
Indomethacin (Indocin)	25–50 mg po q8h	200 mg/day	
Ketorolac (Toradol, others) For Pts <65 y/o	20 mg po, then 10 mg q4–6 h (start at 10 mg po if <50 kg)	40 mg/day	
	60 mg IM as a single dose	120 mg/day	
Diclofenac (Cataflam, Cambia)	50 mg po q8h or q12h for SR	200 mg/day	
Meloxicam (Mobic)	5–15 mg daily	15 mg/day	May be more selective for COX-2 at low dose (7.5 mg)
Nabumetone (Relafen)	1,000 mg as a single dose	2,000 mg/day	
Celecoxib (Celebrex)	200 mg po q12h	400 mg/day	Selective COX-2 inhibitors and NSAIDs have demonstrated decreased gastrointestinal complications compared with nonselective NSAIDs. They do not inhibit platelet aggregation Less effective than full doses of ibuprofen or naproxen
Tricyclic antidepressants			Primarily used for neuropathic pain. Analgesia achieved at lower dose (20–100 mg/day) than antidepressant dose (150–300 mg/day). Contraindications include heart failure, ischemic heart disease, and arrhythmias. Side effects include confusion, urinary retention, orthostatic hypotension, dry mouth, drowsiness, and nightmares Use cautiously in patients at risk for suicide or accidental overdose due to potential for lethal cardiotoxicity Nortriptyline and desipramine are better tolerated than amitriptyline and imipramine Gradually taper dosing
Nortriptyline (Pamelor)	10–100 mg qHS	150 mg/day	
Desipramine (Norpramin)	25–150 mg daily	150 mg/day	
SNRI			Better for neuropathic and "other" pain. Taper over 2 weeks to discontinue. Better tolerated than TCA Common SE of HA and nausea
Venlafaxine (Effexor)	75–150 mg po daily	225 mg	
Milnacipran (Savella)	Tapered up to 50 mg po BID	200 mg/day	
Duloxetine (Cymbalta)	Tapered up to 60 mg daily	60 mg/day	Specifically used for diabetic neuropathy, fibromyalgia, OA of the knee, chronic low back pain, and nonradicular neck pain. No known cardiovascular risk. Nausea is a common side effect

(continued)

Telegram: @medical_k

www.konkur.in

Table 1 (continued)

Drug name	Usual dose	Maximum dose	Comments
Anticonvulsants (calcium channel alpha-2-delta ligands)			Typically used for neuropathic pain and chronic headaches. Can be added to TCA. Similar efficacy to TCA
Gabapentin (Neurontin)	Titrate up to 300–1,200 mg TID	3,600 mg/day	Start at 100–300 mg qHS, and titrate to effective dose. Common side effects include fatigue, impaired concentration, and peripheral edema. May increase risk of suicidal ideation. Reduce dose in renal impairment
Pregabalin (Lyrica)	75–300 mg po BID	450–600 mg/day	FDA approved for fibromyalgia and neuropathic pain. May have anxiolytic benefits
Carbamazepine (Tegretol)	200–400 mg daily	1,200 mg/day	Important to test for HLA-B*1502 allele in patients at increased risk. Also risk of agranulocytosis and aplastic anemia. Effective for trigeminal, glossopharyngeal, or postherpetic neuralgia, and diabetic neuropathy
Oxcarbazepine (Trileptal)	300–900 mg po BID	1,800 mg/day	Off-label use, but may have fewer side effects than carbamazepine
Topical agent			
Lidocaine patch (Lidoderm)	1–3 patches for 12 h per day	3 patches/day	Approved for postherpetic neuralgia. Minimal evidence to support other uses
Diclofenac (Voltaren gel)	2–4 g topical q6–8 h	32 g/day	Topical NSAID with low risk of systemic side effects

All medications and dosages are for adults over 18 y/o, and dosage should be re-evaluated if patient has renal or hepatic dysfunction or variance in pharmacodynamics
OTC over the counter, *COX* cyclooxygenase, *NSAID* nonsteroidal anti-inflammatory drug, *SR* sustained-release, *TCA* tricyclic antidepressant, *SNRI* serotonin-norepinephrine reuptake inhibitor

data [10, 11]. Most trials involving CNCP are short (<3 months) and evaluate pain scores and not patient function, and there is mounting evidence that the potential risks of long-term opioid use outweigh additional benefit when non-opioid options are available [12]. This chapter is focused on CNCP, but even the American Society of Clinical Oncology (ASCO) advocates for the use of systemic non-opioid analgesics to relieve chronic pain and judicious use of opioids in patients who are not responding to conservative pain management approaches, along with precautions to minimize opioid abuse and addiction in these patients. General consensus for CNCP continues to be avoidance of opioids if possible, with preferential use of non-pharmacologic and non-opioid pharmacologic therapies [13].

If opioids are to be used for CNCP, they should be combined with non-pharmacologic therapy and non-opioid pharmacologic therapies as appropriate. The clinician should also establish treatment goals with all patients before starting opioid therapy, including realistic goals for pain and function, and consideration of how therapy will be discontinued if benefits do not outweigh risks [9].

Mitigating Opioid Risks

When selecting opioids, current guidelines are to prescribe immediate-release opioids instead of extended-release/long-acting opioids, prescribing at the lowest possible effective dose, and regular reassessment of patient benefits and risks. Particularly high-risk populations include patients with kidney disease, those that are 65 years of age or older, pregnant patients, those with mental health conditions, those with substance use disorder, and patients with prior nonfatal overdose. Typically, risk is mitigated with strategies like offering naloxone to those at increased risk and using validated screening tools, such as the Drug Abuse Screening Test (DAST), Alcohol Use Disorders Identification Test (AUDIT) the single question screener, the Opioid Risk Tool, Addiction

Telegram: @medical_k

www.konkur.in

Behaviors Checklist, and the Screener and Opioid Assessment for Patients with Pain in order to screen patients for substance use or misuse [5].

Treatment agreement example includes the following:

- Risks of opioid use, including psychological and/or physical dependence, addiction, and overdose.
- Agreement to keep all schedule appointments
- Alternative treatments and adjunct therapies
- Agreement to not use illicit drugs
- Agreement to not divert medication (sell or share medications)
- Agreement to not attempt to obtain controlled medication from any other provider
- Agreement that refills will be made only during regular business hours, typically at the same pharmacy
- Agreement to regular blood or urine tests
- Agreement to only use medication as prescribed

Documenting informed consent and expectations is crucial and can be accomplished using treatment agreements or "pain contracts" between the prescribing physician and the patient. There is some evidence that treatment agreements may improve patient compliance [12]. Using these agreements, providers can also discuss expectations of random urine drug testing (for both assessment of therapeutic adherence and evidence of nonuse of illicit drugs), pill counts, and replacement of lost/stolen prescriptions and counsel to avoid excessive amounts of alcohol. During the discussion of the treatment agreement, physicians should establish reasonable expectations at the start of an opioid trial (see list below). Total pain relief with opioids is not realistic. The average benefit on a 10 point pain scale is 2–3 points [11]. A successful opioid trial typically results in a 30% reduction in pain or a 30% improvement in function [12].

Legislation for prescription drug monitoring programs (PDMP) has been authorized in 49 states, DC and Guam, which has reduced doctor shopping, diversion, and prescription drug abuse [13].

Every patient on chronic opioid therapy should have periodic urine drug screening (UDS) [12]. The frequency of testing can be based on the patient's overall risk of misuse. Although utilizing these screens is important, the interpretation of results is not always straightforward and must be considered in the context of patient behavior and overall compliance [11]. Unexpected positive results should be confirmed by more specific means, and a discussion with the laboratory may be helpful to determine concentrations necessary for a positive result when the prescribed opioid is not present (see list below) [9].

Evidence also discourages clinicians from prescribing opioid pain medications and benzodiazepines concurrently whenever possible. Concurrent use likely puts patient at greater risk of central nervous system (CNS) depression and can decrease respiratory drive. Similar effects may be found if other CNS depressants are used (muscle relaxants, hypnotics).

High-risk patients and those with significant psychiatric comorbidities, cognitive impairment, or history of drug abuse should be managed only by providers experienced with this population, and comanagement with psychiatry or an addiction specialist is strongly recommended [11].

2016 CDC recommendations for prescribing opioids for chronic pain outside of active cancer, palliative, and end-of-life care [9]

- **Determining when to initiate or continue opioids for chronic pain**
  - Opioids are not first-line or routine therapy for chronic pain.
  - Establish and measure goals for pain and function.
  - Discuss benefits and risks and availability of non-opioid therapies with patient.
- **Opioid selection, dosage, duration, follow-up, and discontinuation**
  - Use immediate-release opioids when starting.
  - Start low and go slow.

Telegram: @medical_k

www.konkur.in

  - When opioids are needed for acute pain, prescribe no more than needed.
  - Do not prescribe ER/LA opioids for acute pain.
  - Follow-up and re-evaluate risk of harm; reduce dose or taper and discontinue if needed.
- **Assessing risk and addressing harms of opioid use**
  - Evaluate risk factors for opioid-related harms.
  - Check prescription drug monitoring program for high dosages and prescriptions from other providers.
  - Use urine drug testing to identify prescribed substances and undisclosed use.
  - Avoid concurrent benzodiazepine and opioid prescribing.
  - Arrange treatment for opioid use disorder if needed.

Discontinuation of Opioids

Current recommendations are to reduce and eliminate opioid therapy whenever possible. If patients have baseline improvement or are not progressing toward established treatment goals, show repeated aberrant behaviors, or are suffering intolerable adverse effects, discontinuation of opioid therapy is encouraged [11]. A conservative opioid taper, with weekly decreases of 5–10% of the original dose, is usually well tolerated, although more aggressive decreases are possible [12]. Patients are encouraged to receive appropriate psychosocial support if needed during the taper regimen. While not usually life-threatening, opioid withdrawal can be unpleasant. Autonomic symptoms (sweating, tachycardia, myoclonis) can be managed with clonidine 0.1–0.2 mg orally every 6–8 h, with baclofen or tizanidine available as alternatives. Anxiety, lacrimation, and dysphoria may be managed with hydroxyzine (25–50 mg TID PRN) or diphenhydramine (25 mg q6h PRN). Myalgia is often managed with NSAIDs or acetaminophen [14]. For patients who are abusing the medication or noncompliant with the taper schedule, referral for inpatient detoxification is encouraged [12].

All patients with aberrant behavior should be offered addiction resources [11]. Office-based treatment with buprenorphine/naloxone may be appropriate for patients with opioid dependence. This treatment is an alternative to methadone maintenance and can be offered by primary care providers after obtaining further education and a special licensure from the DEA. More information can be found at http://buprenorphine.samhsa.gov.

Other Interventions for Pain Management

Although outside the scope of a traditional primary care setting, it is important to understand the other available options for our patient population who have not improved with typical multidisciplinary outpatient therapies.

Injections – Typically a local anesthetic is used, often mixed with a steroid, and injected either directly into trigger points, the epidural, or used to temporarily dull the nerves providing sensation to the area.

Ablation – Usually performed either chemically (using local anesthetic) or using electrical current (radiofrequency ablation) for denervation, which may provide pain relief for 6–12 months.

Implantables – Intrathecal pumps allow continuous doses of a drug to be injected directly into the dura mater covering the spinal cord, which allows small doses of the drug to be released, blocking downstream innervation and acting as a neuromodulator. Another form of neuromodulation is spinal cord stimulation, which places electrodes in the epidural space to stimulate specific pathways in the spinal cord with electoral impulses using a remote control when the patient feels pain. Although the exact mechanism isn't fully understood, it seems to target multiple muscle groups directly from the spine and alter afferent innervation.

Non-pharmacologic Modalities

Treatment plans for chronic non-cancer pain must include more than just medications, and the benefits may extend to more than just the pain management. The Department of Defense, the Department of Veterans Affairs (VA), and the National Institute on Drug Abuse have been working together to create pain protocols and have found that service members who receive nondrug therapy for chronic pain had a significantly lower risk of alcohol or drug use disorder, accidental poisoning, suicidal ideation, and self-inflicted injuries. Research suggests that patients who start with physical therapy or manipulation as a first-line treatment for lower back pain are less likely to proceed to short- or long-term opioid use [15].

Exercise therapy is recommended for chronic low back pain, knee pain, as well as other types of chronic pain and can reduce functional limitations [6]. Patients with CNCP are often deconditioned due to inactivity, and providers should recommend gradually increasing general activity levels as well as formal exercise. Often an exercise physiologist can help determine appropriate exercise regimens to help recover from specific injuries or pain syndromes and can be designed to help patients break the cycle of inactivity, deconditioning, muscle dysfunction, and pain. Our current understanding of the process is that dynamic movement helps nutrient replacement in the cartilage given generally poor blood supply. It can also help strengthen collateral muscles, reducing impact on joints, and some theories point to exercise helping engage endogenous opioid systems [16].

In addition, manual therapy, like massage and musculoskeletal manipulation, has been shown to reduce chronic pain due to low back pain, knee osteoarthritis, and fibromyalgia [6]. Often, manual therapy can help with short-term pain relief, and this increased exercise and ability to participate in physical therapy can help with long-term healing.

Transcutaneous electrical nerve stimulation (TENS) therapy uses low-voltage electrical current through electrodes placed on the surface of the skin to provide pain relief. There are multiple theories on how it works, from neuromodulation and blocking transmission of pain signals, to stimulating the nerves and raising endorphins with modified pain perception [17].

Acupuncture has been used for medical treatments for millennia and has found a resurgence with the incorporation of "medical acupuncture" and physicians and other western clinicians bringing it into daily practice. Treatment typically consists of inserting fine needles into the body in patterns designed to influence the "flow of qi" in one of the subdivisions of the energy circulation networks according to the practice of traditional Chinese medicine [18]. Western theories include creating microperforations in the muscle fascia and increasing inflammation and irritation in effected trigger points, improving blood flow, and thus improving the healing process. Typically treatments are spaced out more and more, with home cares done in the interim to continue long-term treatment. It is most useful as a primary therapy for musculoskeletal pain (acute and chronic) and can be added as a complement to other treatments [19].

Psychotherapy is being utilized more frequently as a treatment modality for patients with CNCP. Psychotherapy focuses on improving the patient's quality of life, social functioning, and mood rather than decreasing the level of pain [20]. Cognitive-behavioral therapy (CBT) and mindfulness-based stress reduction are two psychological interventions that therapists can use to teach patients how to manage their pain and engage in a full life despite their pain. Unfortunately many patients struggle with the cost of these services, but mindfulness and diaphragmatic breathing are methods that can also be taught in primary care settings. Providers can also utilize modified CBT techniques when working with patients (see list below).

Brief incorporation of CBT in clinical practice

- Encourage your patient to take an active role in their pain management.
- Tell your patient that you believe the pain is real and you will work together to manage it.

Telegram: @medical_k

www.konkur.in

- Do not let pain dictate activity or appointments. Schedule regular visits and medications at regular intervals instead of as needed.

Quality of Life and the Chronic Disease Model

Chronic non-cancer pain is complex and following current treatment guidelines requires significant clinical resources. However, this is not unlike other chronic illnesses. Using a chronic care model within primary care has clearly improved the care of patients with chronic illnesses such as diabetes, congestive heart failure, and asthma [21]. Chronic non-cancer pain must be approached in the same manner. A comprehensive approach that includes risk assessment, treatment agreement, patient self-management, and care coordination can improve adherence to guidelines, pain disability, and pain intensity [22].

Sleep – Sleep disturbance is common with chronic pain, and many feel that the two exacerbate one another in the pain cycle (see Fig. 1). Some turn to hypnotics to help alleviate the issues, but typically starting with appropriate sleep hygiene and cognitive behavioral therapy and properly managing the underlying cause of the pain tend to break the cycle.

Pain diary – Keeping a pain diary may be a very useful exercise, in that it may reveal patterns in pain intensity as well as things that may make it better or worse. It can also help convey associated symptoms and quality of the pain (burning, shooting, aching, etc.), which may help with diagnosis and management in the clinical setting.

Goal setting – Setting daily targets that are achievable may help with the progression of activity and management for our chronic pain patients.

www.konkur.in

death." While the circumstances of death among the seriously ill in US hospitals are well defined – a high prevalence of pain and frequency of invasive procedures – the characteristics of a "good death" vary between patient, family, and provider [1, 2]. Frequently cited characteristics of a "good death" include control of severe pain, reduction of stress and anxiety, provider compassion, and the perceived knowledge and expertise of the physician [3]. However, patients with terminal conditions often report a sense of abandonment by their primary provider [4]. Increased end-of-life education among family physicians is critical in shifting patient deaths out of the hospital and into the comforts of home in effort to improve end-of-life care [5].

Palliative Care and Hospice

Palliative care is the field of medicine focused on improving quality of life for patients and families facing serious illness. Appropriate at any stage of illness, palliative care is often provided concurrent with curative treatment. In 2019, 72% of hospitals in the United States with at least 50 beds staffed a palliative care team, a marked increase from 2000 when only 7% reported the same [6].

Hospice is an insurance benefit that incorporates palliative care to provide a coordinated team approach for patients with a prognosis of six months or less. Hospice utilization is increasing. Compared to 2000, Medicare decedents in 2015 were more likely to be on hospice (21.6% to 50.4%) and less likely to die in an acute care facility (32.6% to 19.8%) [7]. While cancer a diagnosis previously accounted for the majority of the hospice referrals, current data reflects a broad array of terminal diagnoses. In 2017, 70% of hospice admissions were for noncancer diagnosis, with heart disease (17.6%) and dementia (15.6%) leading the list of noncancer admissions [8].

Centers for Medicare and Medicaid Services (CMS) certified hospice programs must provide core services including a physician medical director, hospice nurse, social worker, and counselors for bereavement, dietary, and spiritual needs. Additional services include physical therapy, occupational therapy, speech pathology, home aide services, and volunteer services. All recommendations from the interdisciplinary team are forwarded to the patient's primary physician, as the hospice concept aims to support the patient's personal physician as the primary provider.

Hospice eligibility guidelines vary by diagnosis, but all require a prognosis of 6 months or less as certified by two physicians. Hospice patients are certified for two initial 90-day periods, after which recertification must take place every 60 days. Recertification periods are unlimited, as long as the patient's prognosis, judged by their terminal diagnosis and progression of symptoms, continues to be 6 months or less from the date of recertification.

Surprising to many, hospice patients often live longer than similar patients not enrolled in hospice. One study found that hospice patients with CHF lived an average 81 days longer than disease-matched patients not in hospice, and similar results were noted with lung (39 days), colon (33 days), and pancreatic cancer (21 days) [9]. Researchers theorize the difference in life span is due to a combination of factors, including avoidance of side effects related to aggressive treatments, the increased monitoring and symptom management provided in hospice, and the interdisciplinary focus on the patient's emotional needs and well-being.

End-of-Life Patient Communication

Effective communication is the initial step in providing end-of-life care. However, physicians often avoid end-of-life conversations for fear of causing depression, taking away hope, and shortening life span with hospice involvement [10]. To the contrary, end-of-life discussions are associated with less aggressive medical care, earlier hospice referral, improved quality of life, and better bereavement adjustment [11].

The SPIKES Protocol provides a six-step plan to deliver bad news to a patient [12]. The protocol guides the provider in the four critical objectives

Telegram: @medical_k

www.konkur.in

in delivering bad news: gathering information from the patient and assessing understanding, delivering the medical information, providing support, and developing a follow-up plan.

- (**S**) **Setting**: Provide a quiet place for the discussion, minimize interruptions, and involve significant others. Sit, do not stand.
- (**P**) **Perception**: Determine what the patient already knows, and his/her perception of their illness. "*When you first felt the lump in your breast, how serious did you think it was*?"
- (**I**) **Invitation**: Determine how much the patient would like to know and seek permission to provide the new information. "*Is it OK if I share the results of the biopsy with you now*?"
- (**K**) **Knowledge**: Share the bad news, providing information in small amounts, using plain language and checking frequently for understanding. Preface the news with a warning. "*Unfortunately, I have some bad news to tell you today.*"
- (**E**) **Empathy**: Acknowledge and address emotions as they arise; provide empathy. "*I see this news comes as quite a shock to you*."
- (**S**) **Strategy**: Address questions, determine next step, and plan follow-up. "*I will see you again in five days, but please call if you have questions*."

Prognosis at End of Life

Physicians tend to be overly optimistic when estimating survival [13]. Physician optimism, combined with patient self-deception, is an explanation for why in a survey of nearly 1200 patients with metastatic colorectal and lung cancer, 81% and 69% of the patients, respectively, believed their therapy was likely to provide a "cure" [14]. Contrary to popular belief, an accurate prognosis does not eliminate a patient's hope but rather may help a patient make better informed decisions that allow for an improved quality of life.

While determining survival time is difficult, there are tools to aid the family physician. For malignancies, established survival statistics for each stage of a cancer provide a starting point. The Palliative Performance Scale (PPS) (Table 1),

Table 1 Palliative performance scale

	Ambulation	Activity & disease evidence	Self-care	Intake	Level of consciousness
100	Full	Normal, no disease	Full	Normal	Full
90	Full	Normal, some disease	Full	Normal	Full
80	Full	Normal with effort, Some disease	Full	Normal or reduced	Full
70	Reduced	Unable to do normal work, some disease	Full	Normal or reduced	Full
60	Reduced	Cannot do hobbies/housework, sig. disease	Occasional assistance	Normal or reduced	Full or confusion
50	Mainly sit/lie	Cannot do any work, extensive disease	Considerable assistance	Normal or reduced	Full or confusion
40	Mainly in bed	Cannot do any work, extensive disease	Mainly assistance	Normal or reduced	Full or drowsy or confusion
30	Bed Bound	Cannot do any work, extensive disease	Total care	Reduced	Full or drowsy or confusion
20	Bed Bound	Cannot do any work, extensive disease	Total care	Minimal	Full or drowsy or confusion
10	Bed Bound	Cannot do any work, extensive disease	Total care	Mouth care	Drowsy or coma
0	Death	–	–	–	–

Source: [15]

www.konkur.in

a validated scale assessing overall functioning of a terminally ill patient, can assist the physician in refining the prognosis and determining hospice eligibility [16]. While incurable malignancies tend to follow a predictable course, diseases related to end-stage organ failure follow a more erratic and less predictable course.

The Functional Assessment Staging Scale (FAST) is a tool to stage dementia and determine hospice eligibility (Table 2). While patients with mild to moderate dementia often require substantial care, hospice-appropriate dementia patients have a FAST score of at least 7C and one or more of the following comorbid predictors: aspiration pneumonia, pyelonephritis, septicemia, multiple stage three to four decubiti, and fever despite antibiotics. Similar to end-stage organ disease, there is great variability among dementia patients, and the aforementioned criteria have limitations in predicting a 6-month prognosis. Providers may use Local Coverage Determination (LCD) guidelines, provided by the Centers for Medicare and Medicaid Services (CMS), in determining hospice appropriateness for all diagnoses.

Table 2 Functional assessment staging (FAST)

Score	Characteristics
1	No difficulties
2	Subjective forgetfulness
3	Decreased job functioning and organizational capacity
4	Difficulty with complex task (personal finances, planning dinner)
5	Requires assistance with activities of daily living (ADLs)
6	(**A**) Unable to dress without help (**B**) Unable to bathe properly (**C**) Inability to self-toilet (**D**) Urinary incontinence (**E**) Fecal incontinence
7	(**A**) Speaks ≤6 intelligible different words in the course of an average day (**B**) Speech limited to the use of a single intelligible word (**C**) Cannot ambulate (**D**) Cannot sit up without assistance (**E**) Cannot smile (**F**) Cannot hold up head independently

Source: [17]

Note: A patient must fulfill criteria in successive order. For example, a patient who is incontinent of bowel and bladder, cannot ambulate (due to a recent hip fracture), and speaks 20 words is scored 6E (not 7C)

End-of-Life Pain Management

Dr. Cicely Saunders, founder of the modern hospice movement, developed the concept of total pain to describe the suffering experienced by patients and their family. The four major components of total pain – physical pain, social pain, psychological pain, and spiritual pain – are interrelated, and often the sum is greater than the individual components. Successful end-of-life pain management is dependent on attention to all four components, with recruitment of social workers, spiritual leaders, and other allied professions often needed.

Physical Pain

The World Health Organization cancer pain ladder provides a starting point for the treatment of end-of-life pain. The ladder employs a three-step approach, starting with nonopioids such as acetaminophen and ibuprofen (step 1), progressing to weak opioids such as codeine (step 2), and finally strong opioids such as morphine (step 3). However, effective management of end-of-life pain will frequently require a starting point other than step 1 and accelerated progression through the steps. While acetaminophen is an appropriate first step for mild to moderate pain, its use as an adjunct to higher doses of opioids is limited [18]. Nonsteroidal anti-inflammatory drugs (NSAIDs) are also useful as an initial step, and particularly useful as an adjunct to opioids in patients with metastatic bone lesions [19].

Effective pain control with opioid medications is best achieved with a combination of scheduled long-acting opioids in combination with short-acting "rescue" doses. For opioid-naïve patients, the starting dose is usually 5–10 mg of morphine equivalents every 4 h. Unlike pain management in the nonterminal patient, end-of-life pain management often requires quick titration. A patient's use of short-acting pain medication is calculated over

Telegram: @medical_k

www.konkur.in

the first 24 h, and then converted to a long-acting form. Thereafter, breakthrough dosing should start at 10–15% of the new scheduled daily long-acting dose of the same opioid, usually provided every 2–4 h. As a general rule, the need for four or more "rescue" doses in a 24-h period warrants an increase in the long-acting dose. Also, "rescue" doses should be given prior to potentially pain-provoking procedures and daily activities (wound care, dressing change, bed repositioning, bathing).

Methadone, due to its low cost, high bioavailability, and effectiveness at treating neuropathic pain, is frequently used in end-of-life care. It is also useful in patients with renal impairment, as 60% of its elimination is nonrenal (primarily fecal). Titration is difficult, drug interactions are numerous, and consultation with a palliative care provider is recommended.

While uncommon in hospice and palliative care, opioid toxicity presents as increased drowsiness, confusion, and hallucinations. The side effects often reverse with holding subsequent doses. If naloxone (Narcan) is required, a modified dose for end-of-life patients avoids an abrupt pain "rebound." In this circumstance, a dilute solution obtained by mixing 0.4 mg naloxone in 10 ml of normal saline is delivered by slow IV push 1 ml every 4–5 min until the side effect resolves. Myoclonus, a rare side effect that can be seen at any dose of opioid, is best handled with opioid rotation. In opioid rotation, a morphine-equivalent dose is calculated, reduced by 20–30% to account for incomplete cross-tolerance, and then started in place of the original opioid. Consultation with a palliative care pharmacist is often required.

Neuropathic Pain

There are several adjunctive therapies for treating neuropathic pain. Duloxetine (Cymbalta), in a randomized, double-blind, placebo-controlled study, demonstrated significant improvement in neuropathic pain related to chemotherapy [20]. Tramadol (Ultram), due to its action on serotonin and norepinephrine, provides relief of neuropathic pain, as well as improvement in sleep and performance status [21]. Both Duloxetine and Tramadol interact with serotonin enhancing medications, and Duloxetine can decrease the efficacy of tamoxifen. Tricyclic antidepressants (TCAs) are effective in treating neuropathic pain [22]. Dosed at bedtime, TCAs are also useful as a sleep aide. Most evidence supporting TCAs is in noncancer patients, and full response may take up to 1 month. Gabapentin (Neurontin), titrated over 3–5 days, is also an effective adjunct to opioid therapy for neuropathic pain [23]. Ultimately, a combination of medications may be needed, with titration of each medication dependent on side effects.

Bone Pain

Metastatic bone pain is common in end-of-life care, particularly in patients with breast and prostate cancer. NSAIDs are effective alone and in combination with opioids in treating pain due to skeletal metastasis. Dexamethasone (Decadron) has been shown to reduce pain associated with bony metastasis and may be favorable compared to other steroids due to less fluid retention. Steroids are also effective in treating anorexia, weakness, headache, and nausea and vomiting, with an improvement of symptom intensity seen in less than 3 days on average [24]. Bisphosphonates may be useful in patients with widespread bone pain, especially in patients with multiple myeloma and concomitant hypercalcemia [25]. Radiation therapy is a useful palliative intervention for cancer-related bone pain and appropriate for hospice patients.

Grief and Depression

Grief and depression are common among patients and families dealing with a terminal illness. Grief, while it may cause suffering, is considered both adaptive and healthy. Depression is maladaptive and can significantly increase suffering and reports of pain, decrease quality of life, and shorten survival [26]. Depression is highly associated with brain, breast, lung, pancreatic, and

Telegram: @medical_k

www.konkur.in

oropharyngeal malignancies and less associated with colon and gynecologic tumors [27, 28]. Treatment with both SSRIs and TCAs is effective in depressed patients with terminal illness, although life expectancy may limit usefulness. Both medication classes may also have secondary beneficial effects based on side effects (tricyclic for neuropathic pain and insomnia, for example). Mirtazapine (Remeron), used at night, is also helpful in the treatment of insomnia and anorexia. In patients with prognosis of less than 4–6 weeks, psychostimulants may reduce depressive symptoms within days of commencement [29].

Nausea and Vomiting

Nausea and vomiting are common complaints in the dying patient, especially in those with advanced cancer. Frequently seen as a side effect of chemotherapy, nausea, and vomiting are also a result of anxiety, obstruction, and inflammation. In addition to traditional antiemetic agents, benzodiazepines are useful in treating nausea related to anxiety, and haloperidol (Haldol) is helpful in refractory symptoms near the end of life.

Bowel obstruction is frequently associated with ovarian and colon cancers. Nonsurgical treatments include cessation of oral intake, nasal-gastric decompression, octreotide (Sandostatin), and corticosteroids. Octreotide, which is administered either intravenously or subcutaneously, inhibits the accumulation of intestinal fluid. Dexamethasone, in daily doses between 6 and 16 mg intravenously, has been shown to relieve symptoms associated with bowel obstruction.

Constipation

Constipation is a frequent pain-provoking symptom in end-of-life care. Decreased mobility, dehydration, and opioid medications are all risk factors for constipation. A stool regimen should be implemented as soon as the symptom arises, or with introduction of an opioid medication, whichever comes first. Hospice programs usually institute an algorithm which includes a daily combination of both osmotic and stimulant laxatives which are increased each day that the patient is without a bowel movement. For example, sennoside (Senna) is given 2–4 tabs nightly along with polyethylene glycol (Miralax) daily. If a patient does not have a bowel movement on the second day, the sennoside is increased by two tablets (in divided doses), and the polyethylene glycol is increased to twice daily. If a patient is without a bowel movement on day three, a rectal exam is usually indicated, with subsequent use of enemas and further titration of the laxatives. Higher-than-usual laxative doses are often required in palliative care. There is no evidence to support docusate (Colace) as softening agent in end-of-life care. For intractable opioid-induced constipation, opioid receptor antagonists such as methylnatrexone (Relistor) and naloxegol (Movantik) are effective [30].

Dyspnea

Primary management of the dying patient with moderate to severe dyspnea is achieved with opioids. Etiologies are multiple, including bronchospasm, effusions, thick secretions, and anxiety. In addition to disease-specific treatments, opioids are effective for patients with COPD, CHF, and terminal cancer [31]. Immediate-release morphine, 2.5 mg to 5 mg every 4 hours, is a reasonable starting point in the opioid-naïve patient. Titration, including the use of long-acting opioids, is similar to that for physical pain. Benzodiazepines are a useful adjunct to opioid therapy in relieving dyspnea attributed to anxiety. While evidence supporting the use of supplemental oxygen in nonhypoxic patients reporting dyspnea is anecdotal, oxygen is often trialed in the hospice patient as the usual Medicare qualification guidelines do not apply. Small studies have also demonstrated a symptomatic benefit with the gentle breeze of a low-set fan.

Recommendation for the Final Hours

Signs of active dying include irregular respirations, accumulation of oral secretions, decreased urine output, and fever unresponsive to antipyretics. It is generally accepted that dying patients

Telegram: @medical_k

www.konkur.in

may have a greater awareness than ability to respond, and family is encouraged to talk to the dying. To minimize sacral pressure, the head should be lowered to less than 30° and the patient turned every 60–90 min. Wound care goals are shifted from healing to comfort, and dressing changes are minimized. The use of dark or red-colored sheets may reduce anxiety among bedside visitors when hemorrhage is a concern. Oral care, using an artificial saliva solution, is provided for comfort. A simple home remedy is made of 5 ml salt and 5 ml of baking soda mixed in 1 l of tepid water [32].

Excessive oral secretions ("death rattle") are treated with oral administration of 1% atropine eye drops (one to two drops SL every 4 h) or glycopyrrolate (1 mg SL or 0.2–0.4 mg SC/IV every 4 h). Hyoscyamine (Levsin) and scopolamine are also used.

Terminal delirium is defined as an irreversible agitation in the final hours of life. Highly stressful for caregivers and family, it is best managed with benzodiazepines. Lorazepam (Ativan) 1–2 mg elixir is given sublingually every hour as needed. Benzodiazepines, in addition to their anxiolytic effects, also serve as muscle relaxants to decrease contractures and provide prophylaxis for seizure activity, both unsettling symptoms for caregivers and family.

Advanced Directives: Living Wills/ Health Care Proxy/POLST

An essential part of end-of-life care involves advanced care planning. Family physicians, given their familiarity with the patient and family, are optimally positioned to assist with such planning.

Traditionally, advanced directives consisted of living wills, or documents which state a patient's wishes should they develop an irreversible condition that prevents them from making a decision. However, living wills do not translate into actionable medical orders and oftentimes are not readily available and are too vague to interpret. A health care proxy is someone who is familiar with and can make decisions in accordance with a patient's values and beliefs. However, in the event of an emergency, the proxy may not be available to consult, and Emergency Medical Services (EMS) providers cannot always follow the direction of a health care proxy.

In response to the shortcomings noted above, the Physician Orders for Life-Sustaining Treatment (POLST) provides patient wishes that translate into actionable medical orders. Started by a team at the University of Oregon in the late 1990s, POLST forms are currently operational in all 50 US states, although the name may vary [33]. While traditional advanced directives are designed for all adults and direct future care, POLST orders are for the seriously ill (life expectancy less than 1 year) and reflect current care. Through an informed and shared decision-making process, a health care professional completes the POLST orders (unlike a traditional advanced directive, which is completed by the patient). A POLST document provides orders regarding resuscitation in the event of pulselessness and apnea as well as decisions regarding level of intervention in terms of transport to the hospital, intubation, mechanical ventilation, noninvasive airway support (CPAP/BiPAP), antibiotics, and artificial feeding [34]. In states where POLST or similar programs are implemented, these orders are transferable between facilities as well as being usable in the prehospital setting (EMS).

Palliative Sedation, Physician-Assisted Suicide, and Euthanasia

There are no greater ethical issues in end-of-life care than palliative sedation, physician-assisted suicide, and euthanasia. While the details of these practices are beyond the scope of this chapter, family physicians need a basic understanding of the terms, if only to dispel myths and distinguish these extreme measures from more common and widely accepted symptom-relief modalities.

While the terms are often erroneously interchanged, there is a clear distinction in intent and practice of the three concepts. Palliative sedation is a last resort practice for the very small minority of patients in which traditional palliative measures cannot relieve intolerable suffering. By way of a reduction in consciousness, symptom

Telegram: @medical_k

www.konkur.in

relief is achieved. In palliative sedation, the intent is symptom relief, which distinguishes it from physician-assisted suicide, in which the intent is to hasten death. This delineation is strengthened by medical studies which demonstrate that palliative sedation does not hasten death [35]. Physician-assisted suicide, legal in only a few states, is distinguished from euthanasia in that the physician provides the medications for the patient to take by themselves. In euthanasia, which is illegal in the USA, the physician administers the medications to achieve death.

Definition

The 1951 Refugee Convention defines a refugee as someone who, "owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group or political opinion, is outside the country of his nationality, and is unable to, or owing to

such fear, is unwilling to avail himself of the protection of that country" [1].

The United Nations High Commissioner for Refugees (UNHCR) estimates that there are over 70 million forcibly displaced people worldwide; of these, over 25 million are classified as refugees [2]. Understanding the definition of "refugee" as a person who was *pushed* out of their homeland by the fear of violence or persecution rather than *pulled* out of their homeland by economic or educational opportunities is an important aspect of navigating the needs and experiences of refugees as patients [3]. Worldwide, the people who make up refugees tend to be people who have higher skills, education, and occupational positions in their country of origin. Refugees also tend to be younger in age. The family physician should be aware that most refugees are not from poor or destitute backgrounds, but are often functional, independent, prominent, and highly successful individuals and families fleeing danger in their home country.

A second model for understanding the refugee experience highlights the stages of seeking refuge in which the affected may experience challenges that can manifest as social or medical problems that should be taken into consideration by a family physician (see section "Keller Stages of Refugee Experience" [4]). The perception of danger and making the decision to flee can be preceded by the loss of resources and/or forced unemployment. The process of escaping danger is often extremely dangerous and can expose refugees to physical and psychological traumas and the lack of food, water, and shelter. Even after arrival at their destination, refugees are often placed into camps or temporary housing of low quality and with inadequate resources. These situations often force refugees, even the most highly educated ones, into jobs of low-wage labor. Finally, the long-term consequences of flight and of assimilation to a new culture on mental health and psychological well-being are another challenge that refugees face. In addition to these interpersonal stressors, physicians should bear in mind the ways in which the residual effects of the refugee experience can include more practical barriers to providing care such as income and care-seeking behavior.

Keller Stages of Refugee Experience

- Perception of a threat
- Decision to flee
- Period of extreme danger and flight
- Reaching safety
- Camps and camp behavior
- Repatriation
- Settlement or resettlement
- Adjustment and acculturation
- Residual stages and changes in behavior caused by the experience

Despite large numbers of refugees around the world, very few well-established schema exist for dealing with the social, economic, and healthcare needs of refugees [5]. The lack of these programs is partially due to the mistaken belief that all refugee emergencies are unique problems. While there are certainly important distinctions that need to be made with regard to factors such as the cultural and educational backgrounds of refugees, the flow of refugees and the circumstances from which they are fleeing are rarely short-lived. Therefore, the structures and services that are put in place for dealing with refugee emergencies often produce a series of challenges that should be understood and addressed by the primary care physician who attends to refugees as patients.

Refugees arriving in the United States often face obstacles in accessing medical care. Access to healthcare for refugees is of particular importance because the circumstances under which these people fled their country may have had notably negative impacts on their physical and mental health. The family physician, who is oftentimes the first point of access to the healthcare system in the United States or in other countries, is in an important position to bridge the gaps between providing high-quality medical care, assisting them in efficiently navigating the complexities of the local healthcare system, and integrating their social environment into care plans. Other issues such as completing government or insurance paperwork, language and cultural differences, and socioeconomic difficulties are

Telegram: @medical_k

www.konkur.in

also important factors that contribute to difficulties in accessing healthcare [6].

Approaching the Refugee Patient

In addition to the difficulties that refugees often face during the departure, transit, and arrival stages of their journey, the family physician's approach to the refugee patient should be sure to assess for barriers to accessing or utilizing healthcare services.

Several studies have found that refugee patients and their healthcare providers cite legal, financial, and administrative processes as the greatest barriers to providing patients with healthcare services [6–9]. In the United States, only those refugees who have undergone the legal process to apply for asylum are given full access to healthcare coverage under government programming. Without an official application for asylum in the system, refugee patients are only entitled to emergency medical services. This often only compounds the patient's and family's economic strain and reduces their willingness to seek out care. While the ideal situation for these patients is waiving of the legal restraints that limit access to care, policy changes are likely a long way from implementation. Therefore, the family physician should familiarize themselves with the laws and policies in their state or country and consider advocating for needed changes that ensure equity and access to care for all people.

Language and cultural issues are also significant barriers to care for refugee patients [10, 11]. While interpretation services may be available, not every health center has access to these services [12]. Alternatively, these services may include a limited number of languages or dialects. In addition to accurate translation of language, optimal interpretative services provide a certain level of cultural mediation through limited explanations of language and expression where needed. However, even with ideal levels of interpretation, increased effort and flexibility on the part of the physician are required to understand unfamiliar cultural and linguistic nuances that may affect physician understanding, patient experience, comfort, and adherence to recommended plans of care.

Certain aspects of healthcare may come with barriers of their own that the family physician must take into account when assessing, treating, or referring refugee patients. For example, many refugees are in need of mental health services, whether for preexisting psychiatric conditions or for problems arising from the physical and psychological stressors that a refugee may have encountered on the course of their journey [12]. While studies suggest that the best way to combat mental health issues in refugee patients is to intervene as soon as possible after a patient's arrival [13], it may be a long time before the family physician comes into contact with a refugee patient. Therefore, it has been shown that approaching a patient's experience with a patient-centered, narrative approach improves their willingness to divulge psychosocial concerns and to adhere to medical advice or treatment [14].

Sexual and Reproductive Health

Quality sexual and reproductive health resources are essential to the health and well-being of refugees. As with any population, conversations and care regarding sexual and reproductive health require an understanding of the religious and cultural norms within the community [15]. For certain sexual and reproductive health screenings, procedures, or conversations, the gender of the family physician may be a barrier to providing this type of care, and flexibility on both sides may need to be negotiated. However, regardless of physician gender, some cultural groups may not be open to conversations about family planning or birth control [16, 17]. The physician may encounter patients who have been victims of female genital mutilation (FGM) or other injuries of reproductive organs. Victims of rape or sexual torture may present to the family physician and may not be willing or able to discuss their condition in a way that is conducive to treatment [18]. The healthcare team may need to partner with family members or other cultural insiders from the community who can help the physician

Telegram: @medical_k

www.konkur.in

develop an approach or pathway to follow when addressing sensitive topics with the community. Many refugees and immigrants are or have been victims of intimate partner violence, and the family physician should be vigilant to the language and behaviors that patients or their family members use that could point to such circumstances.

Taking a History

Understanding the patients history in phases – "pre-displacement," "during displacement/camp health," and "at/after arrival" health – is a good model to use when the patient is first encountered [13]. This model reflects the varying risks, experiences, and exposures during the different phases of the refugee experience, which can vary in type, severity, and duration.

Many refugee patients will lack appropriate medical records for themselves and/or for their children. This increases the need for the family physician take a strong, comprehensive, and detailed history from the patient to ensure appropriate continuity of care. While the medical history of a refugee should certainly consider the typical points of a history, the family physician should include or place emphasis on certain elements of the history to include infectious disease and vaccination history, chronic disease, medication and supplementation history, and mental health screening.

Mental Health and Mental Health History: Identifying PTSD, Depression, Anxiety Disorders, and Adjustment Disorders

Stigma of mental health in culture may be a barrier to eliciting symptoms or prior diagnoses of mental health issues from a patient history. In a similar vein, refugees who experience physical, mental, or sexual trauma or torture may be reluctant to include key information regarding these experiences in their history. Therefore, it is essential that the physician investigates such elements of patient history well, using a trauma-informed approach to ensure that the patient develops and maintains a trusting relationship with their healthcare provider and feels safe, comfortable, and understood for the duration of their care. The most frequently diagnosed mental health disorder in refugee populations is PTSD, commonly as a result of experiencing or witnessing violence or from the stressors of their journey to resettlement [19]. While a combination of selective serotonin reuptake inhibitors (SSRIs) and cognitive therapy has been proven highly effective in the treatment of PTSD, the lack of culturally suitable approaches to diagnosis, pharmacological treatment, and therapy often prevents optimal treatment outcomes for these patients [20]. An assessment of mental status is required as part of the screening examinations required by the Department of State and the US Citizenship and Immigration Services.

One should also consider the different but ongoing mental health stressors that refugees experience after resettlement. Even refugees that have been established in the United States for a long period of time can experience further mental trauma from racism and hostility imposed on them or their children from native citizens, economic stressors, and even social stressors that can push people toward unhealthy habits. These may include gambling or substance abuse [21, 22]. Often, refugees are separated from immediate family members and experience trauma from this separation and the additional lack of a social support network. Such traumas often fly under the radar, as they are not often emphasized in literature or screening protocols, and therefore it is important for the family physician to address these sources of mental health trauma.

Infectious Diseases

Refugees tend to be at higher risk for contracting infectious diseases at any stage of their journey, whether pre-flight, during travel, or upon arrival at a refugee camps or a resettlement city. Poorer living conditions and inadequate access to healthcare services contribute to the spread of such diseases. The etiology of infectious diseases among refugees depends on their country of

Telegram: @medical_k

www.konkur.in

origin, the trajectory of their journey, and other demographic characteristics that may place them at risk for certain infectious diseases [13, 23]. All refugees arriving in the United States are required to undergo a medical screening as outlined by the Centers for Disease Control and Prevention (these guidelines can be reviewed at https://www.cdc.gov/immigrantrefugeehealth/guidelines/refugee-guidelines.html). One of the major reasons for these screenings is to contain and reduce infectious diseases that may be brought into the United States. The required exams include a medical history, physical exam, chest X-ray, syphilis, tuberculosis and HIV testing, and several other specific lab tests [24]. Therefore, it is imperative that the family physician take appropriate precautions to ensure that infectious diseases are detected and treated in an efficient and timely manner. As part of the required testing for immigration to the United States, appropriate immunizations are also required.

Nutrition

Assessing dietary practices as well as concerns for food insecurity among refugee patients is an essential part of a comprehensive history for this group. In addition to economic barriers to obtaining healthy food, considerations such as cultural preferences, religious restrictions, and geographic barriers, such as residence in areas that are considered to be "food deserts," should also be taken into account.

Oral Health

A number of studies have documented poor oral health in some refugee groups [25, 26]. The importance of oral health is well-established in research and healthcare practice. The contribution of poor oral health to conditions such as diabetes, cardiovascular disease, and other health conditions in refugee populations is an important consideration for the family physician when seeing refugee patients in clinic. Many factors can contribute to the poor oral health of refugees, including but not limited to lack of knowledge or perceived importance of dental health, inevitable diet change upon arrival, time spent in camps or resettlement cities without access to dental health care, and access or lack of knowledge regarding how to access dental services once resettled. While the treatment of dental conditions falls largely outside the scope of a family physician's practice, the physician may consider implementing a program in their practice to provide refugee patients with dental hygiene equipment such as toothbrushes, toothpaste, and floss. Access to quality, affordable dental care referral sources is also important. To whom the family physician can refer refugee patients with oral health concerns is also recommended.

Trauma and Torture

The family physician should consider the possibility that refugee patients may have experienced physical or mental trauma or undergone torture at the hands of others, including military personnel or law enforcement in their country of origin or on their journey to safety. One study at an urban primary care center in the United States found that 11% of foreign-born patients had a history of torture [27]. In addition to the physical consequences of the trauma, the psychological effects of these experiences should be assessed and addressed by the family physician. These experiences are sometimes difficult to assess due to repression or minimization of the experience by the patient, whether due to psychological coping mechanisms or feelings of shame that often accompany these experiences. The family physician should consider the influence of culture in the expression of physical or psychological symptoms. While physical signs and symptoms of prior physical trauma are often obvious (e.g., scars, burns, broken bones, etc.), the psychological effects may require a more in-depth assessment by the clinician. The clinical symptoms that are displayed by patients who have experienced trauma and torture are often quite similar regardless of linguistic or cultural background. PTSD, major depressive disorder, and anxiety disorders

Telegram: @medical_k

www.konkur.in

are by far the most common disorders experienced by refugees and often present similarly [19]. The long-term consequences of physical injury, such as the effects of brain damage or vision loss, should not be forgotten as possible outcomes of physical trauma or torture.

The family physician should also be sure to analyze family members or close contacts of the refugee patient for signs of psychological disorders caused by trauma or torture.

Chronic Pain

Chronic pain has been reported to be relatively common among refugees. Both physical injury and psychic injury may contribute to this high rate. PTSD has been found to be linked to higher rates of chronic pain [28]. Additionally, physical pain may be a culturally sanctioned expression of psychic suffering in some communities and groups.

Chronic Health Problems

While certain health problems, such as infectious diseases, occur at higher rates in refugee patient populations, the physician should not overlook the common health problems that affect all patients. These include conditions such as hypertension, hyperlipidemia, coronary artery disease, obesity, diabetes, and asthma. Smoking rates may be higher among many refugee groups, and smoking cessation may require different approaches to be successful [29].

Addiction

Drug and alcohol abuse is not uncommon among refugee populations. Because of the physical and psychosocial trauma that many refugees have experienced, they may be susceptible to turning to substance abuse. The family physician should conduct a thorough social history that explores drug and alcohol use and carefully assess the patient for physical and psychological symptoms that may indicate a drug or alcohol problem.

Another addiction problem that may be encountered by refugees is gambling addiction. In addition to the psychosocial impact of gambling addiction on the patient and their family and community, in some parts of the world, gambling addictions have created major economic problems for refugees and refugee communities [30, 31]. Because of the community-oriented nature of many refugee families and groups, refugee communities may help to support or pay off the debts incurred by those in their communities struggling with gambling addictions, oftentimes pulling entire families or communities into debt along with them. The predatory nature of casinos and gambling clubs also contributes to the slipperiness of these slopes for refugees, providing comfortable spaces, free hot meals, and oftentimes transportation services to and from the gambling venue.

Cancer Screening

Immigrants and refugees are significantly less likely than the general US population to have undergone cancer screening or to have an awareness of risk factors or warning signs of cancer [32, 33]. The physician should have a plan when approaching patients about these screenings, and not be discouraged if initial offers are refused. This is true particularly if a strong physician-patient relationship has yet to be established. Even if cancer screenings cannot be conducted due to time constraints or lack of a physician-patient relationship, the family physician should counsel patients on risk factors and the importance of cancer screenings. The use of translator services both for language and cultural purposes is often very helpful here.

Refugee Children

Adjusting to new educational systems, social environments, and home environments is often a difficult experience for children whether or not other factors are contributing to stress. While studies show that refugee children usually adjust to their new environments relatively well, these

Telegram: @medical_k

www.konkur.in

children may report peer difficulties such as bullying or social exclusion in schools [34]. Such stressors can cause children to feel disconnected from their families and result in their drifting toward gangs, drug use, or alcohol abuse [35, 36]. Another consideration to be made is differing cultural practices, such as cupping or scraping in Chinese medicine, that are often mistaken as signs of child abuse by teachers, counselors, or classmates [37]. The family physician should be aware of these cultural practices and inquire about such findings with both pediatric patients and their parents.

Legal Considerations

Refugees arriving in the United States often have a very limited understanding of the US legal system. As such, they may feel unsure or unsafe about situations that might require them to report information about themselves or their families for fear that they may face legal repercussions. The patient should be assured that physician-patient confidentiality is an important element of the medical relationship and that no stage of medical intervention involves reporting immigration or immigration status to the authorities. The family physician should also be aware that many refugees find themselves in situations where landlords, employers, or businesspeople take advantage of their lack of understanding or their desperate situation. Refugees may also have a difficult time understanding how to pay bills or rent, and in these cases, the family physician should try to put refugees in touch with culturally sensitive social workers, trusted settlement agencies, or free legal clinics that can help to intervene on behalf of the patient.

Establishing a Medical Home

A 2019 study found that continuity of care was cited as the second most important factor by both healthcare providers and patients, behind language differences as barriers to providing healthcare to refugees [38]. Additional issues included the lack of availability of adequate medical records, healthcare system complexity, access to healthcare facilities, and difficulties with integration of medical appointments into the personal schedules of refugees which all contribute to the difficulties in providing continuity of care. While ensuring continuity of high-quality care is a multidisciplinary effort that requires input from primary care providers, medical specialists, social workers, legal aid, and educators, the family physician can contribute greatly to the establishment of a refugee's medical home by providing culturally competent, trauma-informed, and patient-centered care to this patient population. By doing so, the family physician can establish themselves as allies to refugee and immigrant patients, building trust between newcomers and the medical system that serves them.

Prevention and Public Health

The role of the family physician in prevention and connection of medical practice to public health infrastructure is unmatched by any other specialty in medicine. The establishment and strengthening of public health systems that target the root causes of poor health in refugee populations are essential to ensure that refugees are appropriately cared for and can integrate into and contribute to society. Screening for and treating infectious diseases, health education, vaccination, and chronic disease and cancer screenings all fall under the umbrella of the family physician's role in providing preventive and public health care to refugee populations.

Social determinants of health are a major consideration when treating refugee patients. Upon leaving their country of origin, many of these patients lost fortunes, land, belongings, and the social capital that they once had and must now exist in a new environment with new people, surroundings, and many fewer resources. Oftentimes, refugee resettlement areas (RRAs) are located in economically depressed cities or districts in the United States, exposing refugees to environmental health risks, enhanced economic challenges, and fewer social and educational opportunities. All of these public health factors must be considered in the holistic approach to the refugee patient. The family physician should

Telegram: @medical_k

www.konkur.in

collaborate with patients to prevent poor health outcomes by addressing or minimizing the effects of as many of these factors as possible.

Patient Education

Before patient education can be conducted, literacy levels must be established. Even when engaging with English-speaking patients, the physician must evaluate the patient's literacy level and provide advice and information in language that is clear and understandable to the patient. For most refugees, English is not their first language, and therefore, qualified translation services and appropriately translated educational materials that meet the level of language and functional health literacy of the target audience are essential. Despite this generalization, some refugees were educated in strong systems and do have high levels of education – low literacy should not be assumed but should be assessed and analyzed by the clinician to establish the need for appropriate educational resources for a patient and their family.

Definition and Background

A substance is any legal or illegal psychoactive material used by an individual with the potential for producing negative social and health concerns. Substances may be medically prescribed (i.e., hydrocodone) or recreational (i.e., marijuana). Substance use, misuse, and use disorder are part of a spectrum as discussed below. Substance misuse can reasonably be considered a lifestyle problem that may lead to harm. Effective preventive measures exist that may significantly reduce this harm and associated cost. Prolonged, repeated use of any addictive substances at high doses or frequency (quantity/frequency thresholds vary across substances) may lead to Substance Use Disorder (SUD). Disorders can range from mild and temporary to severe and chronic [1].

SUDs are defined as the recurrent use of drugs that causes clinically significant impairment, including health problems, disability, and failure to meet major responsibilities at work, school, or home. The coexistence of both a mental health and a SUD is referred to as a co-occurring disorder [2]. The current *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) combines the DSM-IV categories of substance abuse and substance dependence into a single disorder measured on a continuum from mild to severe. The revised substance use disorder, a single diagnosis, better matches the symptoms that patients experience, and recognizes the continuum a patient's substance use impairment may progress along with this chronic, relapsing illness [3].

This chapter will discuss substance use disorders, except for alcohol and tobacco use disorders, which are addressed in other chapters.

SUD History and Primary Care

Substance use has been viewed throughout history in various ways, including through a moral or spiritual lens, as an immoral act, or a direct action by the gods. Roman civilizations considered wine a right for every individual, while in other cultures, alcohol and other substances were completely prohibited [4]. Sigmund Freud, neurologist and founder of psychoanalysis, offered evidence from clinical observations that biological factors play a role in the addiction process. Reflecting on the influence of psychodynamic theories of etiology after World War II, the DSM-I and DSM-II emphasized those approaches in attempting to explain the addiction process. However, DSM-I and DSM-II stigmatized addiction by listing it with other society-disapproved disorders stemming from personality disorders. DSM-III and IV espoused a theoretical, descriptive diagnosis, requiring tolerance or withdrawal to diagnose dependence. DSM-IV's emphasis on biology in its concept of dependence was unchanged from its immediate predecessors. DSM-5 states that drugs taken in excess have in common the direct activation of the brain reward system [3].

Substance use, misuse, and use disorders are common in primary care patients and are a

Telegram: @medical_k

www.konkur.in

significant contributor to morbidity and mortality. Two key strategies to address substance use in primary care are the process of screening, brief intervention, and referral to treatment (SBIRT), and the integration of treatment for SUDs into primary care [5]. These concepts will be expanded on later in this chapter.

Epidemiology

According to the 2015 National Survey on Drug Use and Health, 20.8 million people in the USA are diagnosed with Substance Use Disorders [5]. Moreover, over 20% of patients hospitalized in general wards have SUD, and patients with SUD are 1.5 times more likely to be readmitted to the hospital [6]. Substance use disorder affects 16% of Americans ages 12 and older (40 million people). That is more than the number of people with heart disease (27 million), diabetes (26 million), or cancer (19 million) [7].

Figure 1 shows the prevalence of people aged 12 years or older with a Substance Use Disorder in the past year. This 2018 data set shows that more than two-thirds of people (14.8 million) diagnosed with SUD in the past year had an alcohol use disorder. Illicit drugs and marijuana use disorders followed the prevalence of alcohol at 8.1 million and 4.4 million, respectively [8].

The attitude of high schoolers toward the use of marijuana has changed substantially in the last two decades with more than half now considering marijuana use safe. As shown in Figure 2, marijuana remains the most used illicit drug (35.7%) in teens, followed by lysergic acid diethylamide (LSD) and other synthetic drugs [9].

The number of people with SUD is continually growing, and despite the availability of evidence-based interventions, a substantial implementation gap exists. There is a large treatment gap between those who need treatment for a SUD and those who receive it. In 2011, 21.6 million persons aged 12 or older needed treatment for an illicit drug or alcohol use problem, but only 2.3 million received treatment at a specialty treatment facility [10].

Classification

The cascade of care model was initially adapted for human immunodeficiency virus (HIV) and other communicable and noncommunicable diseases to highlight the gaps between current care and recommended treatment goals. A similar model is being studied to address treatment gap issues in opioid use disorders (OUD). With additional attention to prevention and identification stages, it could result in improved practices and

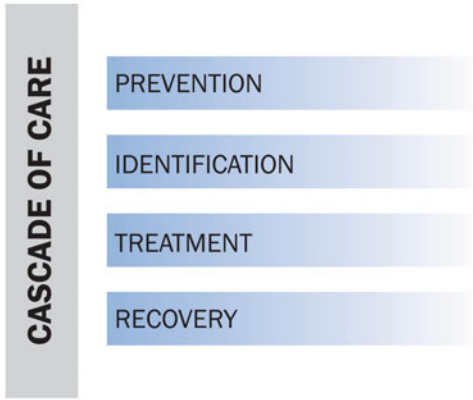

Fig. 3 National Institute on Drug Abuse Cascade of Care model recommended for opioid crisis [12]

treatment outcomes [11]. Figure 3 shows an example of this cascade of care model.

DSM-5 Criteria for Substance Use Disorders

DSM has been the standard for diagnosis and treatment in clinical, research, and administrative settings. DSM-IV, published in 1994, showed strengths in its reliability and validity of dependence. The reliability of abuse data was much lower, with nearly half of the abuse cases being diagnosed with only one criterion (syndrome requires more than one symptom). Upon further investigation, the relationship between abuse and dependence was found to be unidimensional indicating the same underlying condition. To overcome these issues and to improve diagnostic accuracy, abuse and dependence were combined in DSM-5 [13].

Two criteria, craving and consumption, were studied to increase diagnostic accuracy. While craving or "a strong desire or urge to use the substance" made it into the DSM-5 SUD criteria, consumption did not fit owing to the difficulty in quantifying illicit drug consumption. DSM-5 substance use disorder criteria were developed in 2013. Data from the general population and clinics were reviewed, and a threshold of two or more criteria was selected (with exception to supervised use of psychoactive substances for medical reasons). The criteria are based on four domains: impaired control over drug use (criteria 1–4), social impairment (criteria 5–7), risky drug use (criteria 8–9), and pharmacological effects

Telegram: @medical_k

www.konkur.in

on biological functioning (criteria 10–11). See the complete list of criteria below. The number of criteria a given patient meets assesses severity of their substance use disorder: mild (2–3 criteria), moderate (4–5 criteria), and severe (6 or more criteria) [14]. Patients meeting criteria for multiple substances are diagnosed with multiple distinct SUDs, for example, OUD severe and cocaine use disorder (CUD) moderate, and not polysubstance use disorder, which is not a recognized diagnosis in the DSM-5.

DSM-5 Diagnostic Criteria for Substance Use Disorders

- Used larger amounts/longer
- Repeated attempts to quit/control use
- Much time spent using
- Craving
- Neglected major roles to use
- Social/interpersonal problems related to use
- Activities given up to use
- Hazardous use
- Physical/psychological problems related to use
- Tolerance
- Withdrawal

General Principles

A chronic disease model of care has become the standard for addressing SUD, which is now recognized as a chronic, relapsing disease. Primary care clinicians and practices are well versed in chronic disease management, and inclusion of SUD in their repertoire increases access to care for patients suffering with SUD [15].

Approach to the Patient

Ensuring the office environment is stigma-free and welcoming of patients with SUD is key to effective patient engagement and includes having readily accessible print or electronic health information on SUDs in waiting areas, staff trained to use non-stigmatizing language, and screening for substance use routinely for new patients using standardized screening instruments. Stigma is a significant barrier to patients with SUD engaging with the healthcare system. See Table 1 for stigmatizing language to avoid and suggested alternative language [16].

Screening, Brief Intervention, and Referral to Treatment

Screening, brief intervention, and referral to treatment (SBIRT) is an evidence-based framework that is used to identify individuals with SUDs and those who are at risk for developing SUDs. It is a public health approach that can be implemented across a variety of settings, including primary care. The components are: universal screening, brief intervention, and referral to treatment. Current research demonstrates that SBIRT is effective in reducing harmful alcohol use and drug use in patients who do not have a substance use disorder. Screening should occur at least annually for all patients using a validated screening instrument such as the Single Question Drug Screen (SQDS). In primary care, screening can occur during the patient rooming process as performed by ancillary staff. Three-quarters of the patient population are likely to screen negative. For those that screen positive, a brief intervention based on motivational

Table 1 Avoiding stigmatizing language

Avoid (Stigmatizing)	Alternatives (Non stigmatizing)
Abuse, Addiction	Misuse, Use disorder
Addict, Abuser	Person/patient with a substance use disorder
Dirty/Clean (Individual)	Relapsed/in recovery
Dirty/Clean (toxicology result)	Test positive/negative for substances (list out)
Medication assisted treatment	Medications, SUD medication, medication for SUD, office based opioid treatment (OBOT)

Telegram: @medical_k

www.konkur.in

interviewing can be delivered, either by the primary care physician or a behaviorist in an integrated practice setting, to increase awareness of the risks associated with continued use and to motivate the patient to reduce or stop use altogether. For patients who may have a substance use disorder, referral to specialized treatment is warranted, if not available in the primary care office (such as with office-based opioid use disorder treatment, OBOT) [17].

Office-Based Opioid Treatment

Office-based opioid treatment (OBOT) provides buprenorphine or naltrexone medications to patients with OUD in the primary care setting to help them achieve and sustain long-term recovery. OBOT services may include on-site provision of counseling services or referral to community counseling resources.

Diagnosis

History

History of substance use and its associated impact on health and functioning are essential in making the diagnosis of SUD. While toxicology testing can indicate discrete points in time of substance use or abstinence, only a thorough history can help the clinician identify the continued use despite adverse consequences and loss of control over use that are the hallmarks of SUD. Table 2 shows the components of a comprehensive substance use history.

Additionally, current and prior relationship, employment and legal issues related to substance use, presence of cravings, and withdrawal symptoms during periods of even brief abstinence, and increasing use over time to achieve the same or diminished feelings of euphoria are important to ask about for making a SUD diagnosis using the DSM V criteria. See list of criteria above. In addition, standard past medical and surgical histories are essential for patients with SUD presenting as new to the practice. It can be helpful to focus on pertinent positive and negatives for medical and surgical sequelae of SUD including HIV, Hepatitis C, other liver or pancreas problems, heart problems such as endocarditis, and recurrent sinus infections. Family history of SUDs including alcohol and tobacco are also important given the genetic and environmental risk factors for SUD development. A complete psychiatric history is useful for establishing or ruling out co-occurring disorders, detailed later in this chapter. For the biologically female patient with SUD, an obstetric and gynecologic history is

Table 2 Components of a comprehensive substance use history

For each substance	Age at first use	Age of problematic use	Last use	Route of administration (and source of needles if injection route)	Frequency of current use (e.g. past 3 months)	Quantity (units e.g. pill count, weight or cost)
For each prior treatment episode	Date or Year	Location	Level of care (e.g., residential, outpatient, OBOT)	Length of service	Time until relapse (after treatment completed)	Relapse trigger (if known)
Mutual aid involvement	Organization (e.g. Narcotics Anonymous, SMART Recovery)	Frequency of attendance	Sponsor	Home group	Longevity (e.g. 90 days, 6 months, 4 years)	Steps completed
For each overdose episode	Person overdosed (e.g. self, friend, loved one)	Intentional vs accidental	Substance/s involved	Naloxone availability (if opioid involved)	Outcome	Link to care? (yes/no, if yes what treatment services received)

Telegram: @medical_k

www.konkur.in

also important especially current sexual activity, use of contraception and/or barrier protection during sexual intercourse, and last menstrual period. Care of the pregnant patient with SUD is discussed later in this chapter.

In addition to substance use history, the rest of the social history is important in determining the best level of SUD care for the patient. If a patient is living in a sober, safe home environment with at least one other supportive adult and is still actively engaged at least minimally in work, school, parenting, and/or their community, then ambulatory, primary care-based treatment options may be considered. Conversely if a patient is homeless, living with a violent or non-sober partner, living alone, and/or not engaged in other activities besides substance use and recovery from use, residential treatment and specialty care may be preferred.

Lastly, a trauma history can be helpful to elicit, particularly after establishing a strong therapeutic relationship with a patient, as there is a significant increased burden of traumatic experiences across the lifespan in patients with substance use disorder. In women with substance use disorders in residential treatment settings upward of 90% may have a history of trauma, often multiple experiences. Unaddressed trauma can play a significant role in risk for relapse, continued exposure to abusive relationships, and incidence and instability of co-occurring psychiatric conditions [18].

Physical Examination

A thorough physical exam for a patient with SUD focuses on looking for direct and indirect effects of substance use on the body. See Table 3.

Laboratory and Imaging

Laboratory testing to monitor for evidence of substance use is an important component of every treatment and management program. Testing adds structure and accountability that are critical aspects of helping patients regain self-control and self-respect, and presents an opportunity for reviewing the patient's recovery management. However, the usefulness of laboratory testing results is limited as stand-alone criteria for diagnosis of SUD. Blood, urine, and saliva studies do not measure severity of the disease or fully assess the associated physical harm. Laboratory testing is useful for initial assessment, screening to identify nonprescribed substances/medications, monitoring adherence to pharmacotherapy, evaluating efficacy of treatment, and assisting in treatment planning [19]. It is recommended that laboratory testing be random, observed, convenient for the patient, high quality, and provide timely results [19]. However, there is great variability in clinical protocols and requirements regarding laboratory testing characteristics (e.g., random vs. scheduled; observed vs. nonobserved) based on different healthcare provider settings. Urine is the most commonly used matrix due to its widespread and economical availability, sensitivity and specificity, and ability to detect substance use over periods of time useful for treatment planning. See Fig. 4 [19].

The most common clinical approach is to test for a panel of substances with high prevalence in a given community using screening tests (i.e., Enzyme immunoassay), which can be performed in a lab or using onsite point-of-care testing (POCT) kits [21]. Confirmatory testing

Table 3 Components of a comprehensive physical exam

General survey	Alertness, hygiene, appropriateness of dress for weather (e.g. long sleeves in hot weather to hide needle marks on arms), distress, restlessness
HEENT	Pupil dilation or constriction for ambient light, nystagmus, nasal septum perforation, dentition
Cardiovascular	Cardiac murmurs, arrhythmias
Pulmonary	Wheezes, rhonchi
Abdominal	Hepatomegaly, scars consistent with blunt or penetrating trauma history
GYN/GU	Abnormal discharge, rashes or sores
Extremities	Nail bed flame hemorrhages, edema
Neuro	Alertness and orientation, tremors, ataxia
Skin	Needle marks, abscesses, tattoos, rashes e.g. scabies or other skin infestations

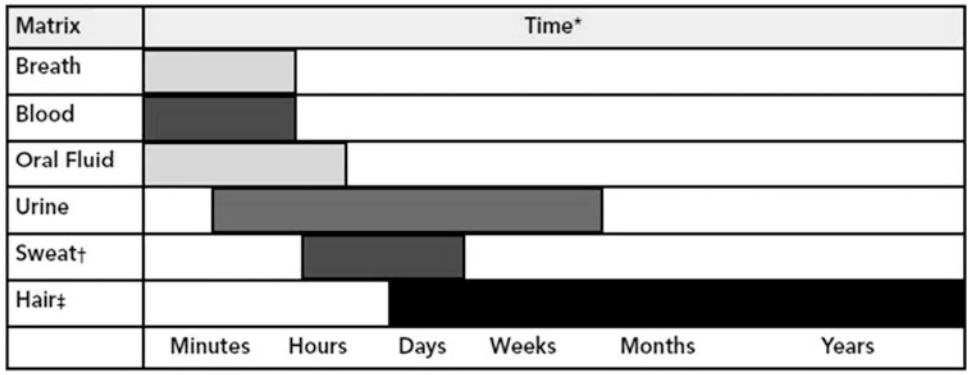

Fig. 4 Laboratory test matrices to detect substance use

(i.e., chromatography with spectrometry) should be performed only for positive results whose accuracy is important for treatment planning as it is not necessary in every case [19, 20]. Screening tests are often qualitative while confirmatory tests are often quantitative. In addition, quantitative results may be helpful for some significant false-positives (THC, alcohol, and cocaine). Synthetically crafted opioids (i.e., opiates) will not be detectable on a routine opioid screen, but will be identified with chromatography or spectrometry. A toxicology screen with the specific agent identified should be ordered if there is a clinical concern for misuse of an undetectable substance. No screen or labs are available to identify inhalants, except for hair analysis, which is rarely used. A thorough, confidential history is the most effective way to screen and diagnose SUDs.

Other laboratory studies should be considered based on clinical findings or concerns including a comprehensive metabolic panel, complete blood count, thyroid stimulating hormone (TSH), free thyroxine (fT4), urinary analysis, gamma-glutamyl transpeptidase (GGT) for suspected alcohol misuse, and human chorionic gonadotropin (HCG) for women of reproductive age to rule out pregnancy. If engaging in risky behavior (e.g., unprotected sex, injection drug use) is suspected, test for gonorrhea, chlamydia, HIV, syphilis, hepatitis C, and hepatitis B (if not vaccinated). Risk factors for tuberculosis should be considered and tuberculin purified protein derivative (PPD) placed if concerned.

Imaging

A 12-lead EKG should be obtained in those with chest pain associated with known or suspected stimulant use (e.g., cocaine, methamphetamine, 3–4 methylenedioxymethamphetamine (MDMA)) due to the risk of myocardial infarction. Extensive inhalant misuse is associated with cardiomyopathies. Echocardiography is indicated to identify intracardiac vegetations in patients with known or suspected injection drug use presenting with a new heart murmur.

Genetic Testing

Genetic testing for individuals with SUDs currently has little clinical value and is not recommended [21].

Special Testing: Adolescents

Laboratory screening for substance use among adolescents may be useful when assessing situations of concern at school or in accidents, domestic violence, or other trauma. Obtaining laboratory testing without the consent of the competent adolescent can hinder the physician–patient relationship and should only be done in emergent situations [22]. Failure to do so also causes legal consequences for the physician as substance use

Telegram: @medical_k

www.konkur.in

disorders are frequently on the list of conditions along with pregnancy and family planning for which adolescent minors have legal right of consent, with age of legal consent determined by state law. In general, drug screens should not be performed solely at the request of parents because the clinical information yielded from such testing is limited. False-positive results are common and can have significant medical and social consequences [20].

Differential Diagnosis

While acute intoxication and withdrawal syndromes can mimic other medical and mental health emergencies such as hypoglycemia, thyroid storm, and acute psychotic or manic episode, a thorough history taken when the patient is not severely intoxicated or withdrawing is typically sufficient for making a SUD diagnosis. More common are co-occurring psychiatric disorders, including bipolar disorder, other mood disorders, post-traumatic stress disorder, attention deficit hyperactivity disorder, and personality disorders. Figure 5 shows the 2018 prevalence of past year SUD and mental illness for US adults [8].

Mood disorders are the most common co-occurring psychiatric disorders in patients with SUD. Conversely patients with mood disorders have a lifetime SUD prevalence of 32%. For patients with bipolar disorder that increases to 56%. A thorough psychiatric history is indicated in patients with SUD and vice versa to avoid missing these commonly comorbid conditions, as an untreated co-occurring disorder makes achieving and sustaining SUD recovery much more difficult [23].

Treatment

Behavioral

Cognitive behavioral therapy (CBT) for substance use disorders focuses on identifying and modifying maladaptive thoughts and patterns of behavior that reinforce or enhance substance use. It is a relatively brief and directive approach that teaches patients to understand the relationship between their thoughts, feelings, and behaviors. Cognitive strategies include cognitive restructuring, which involves examining the accuracy of thoughts and developing responses that are more likely to support desired behavior (e.g., abstinence, use of adaptive coping). Behavioral strategies assist the patient in building the skills necessary to reduce use (i.e., refusal skills). CBT can be used as a monotherapy or in combination with other treatment strategies, including pharmacotherapy when indicated [24]. Its efficacy is established in the treatment of cannabis, opioids,

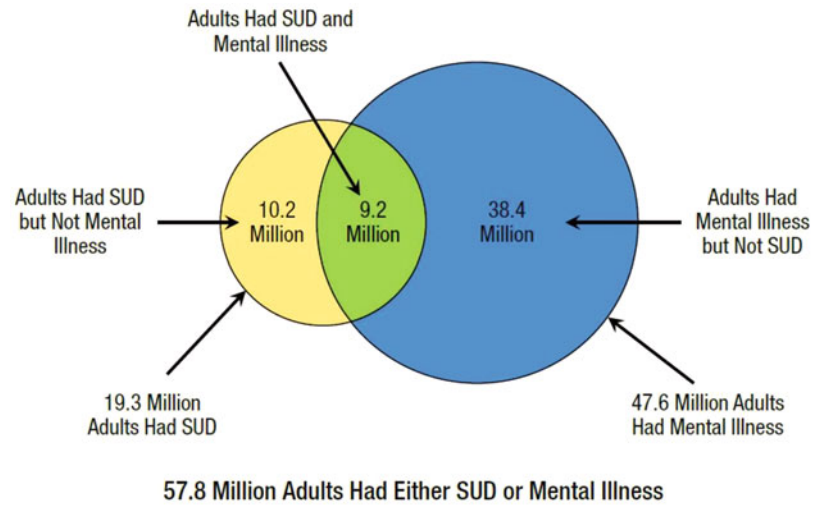

Fig. 5 Past year SUD and mental illness among US adults

Telegram: @medical_k

www.konkur.in

and cocaine use disorders. Since many individuals experiencing substance use disorders may also have comorbid mental health diagnoses, there are aspects of CBT that can address underlying triggers such as anxiety during social situations.

Motivational enhancement therapy (MET) is a counseling approach that assists patients in evoking intrinsic motivation for change and resolving ambivalence about substance use. It uses the tenets of motivational interviewing to strengthen motivation through a series of conversations to elicit the patient's reasons for sustaining substance use and reasons for stopping use [25]. MET consists of an initial evaluation session followed by two to four subsequent sessions focused on exploring substance use, eliciting change talk (i.e., language expressed by the patient as an argument for change), developing a plan for change, and identifying coping strategies. MET is tailored to the needs of the person receiving treatment and encourages autonomy in decision making. MET can be used as a part of an overall treatment approach which may include 12-step programs and CBT. This treatment approach has demonstrated efficacy in the treatment of alcohol, marijuana, and nicotine use disorders.

Dialectical behavior therapy (DBT), originally developed to treat patients with borderline personality disorder and suicidal thoughts, has been increasingly incorporated into SUD treatment. Similar to CBT, DBT is based on the belief that unhelpful or unhealthy thoughts and behaviors are learned and reinforced. Recognizing the limitations of traditional CBT in the treatment of challenging conditions, including SUDs and co-occurring SUD and personality disorders, DBT adds validation/acceptance and dialects to the treatment modality [26]. Many patients with SUDs have a history of trauma, which has resulted in emotional vulnerability that manifests as strong, dysregulated emotion that is reinforced by invalidating environments, i.e., consistently being told or made to feel as though their feelings are not valid. These experiences of invalidation may result in emotional unavailability, often leading to avoidance or escape which is facilitated by the use of substances. *Dialectical* refers to the synthesis of both acceptance and change with regard to the individual's use. An important aspect of DBT for substance use is the immediate expectation of a time period of abstinence, defined by the patient, which requires ongoing assessment and a renewal of commitment. DBT is a comprehensive approach which involves group and individual therapy, phone coaching, and DBT therapist consultation.

Twelve-step facilitation (TSF) therapy is a manualized treatment approach based on the principles of 12-step programs such as Narcotics Anonymous (NA). Originally developed as an individual intervention, it has now been adapted for use in group therapy. Individual treatment consists of 12–15 sessions intended to increase the patient's engagement in 12-step mutual-help organizations [27]. The approach is based on the concept of SUD as a spiritual and medical disease and has been shown to be effective in the treatment of alcohol use disorder. It has also demonstrated promising results with other SUDs. TSF utilizes the core principles of NA and encourages patients to make changes to their social networks in order to achieve and sustain abstinence.

Contingency management (CM) involves the use of rewards to reinforce desired behaviors such as abstinence. Patients may receive tangible rewards such as vouchers or cash prizes [28]. It has been shown to promote abstinence from alcohol, stimulants, opioids, marijuana, and nicotine. CM may be used as a stand-alone treatment or in combination with CBT, MET, or medication management.

Medications/Immunizations and Chemoprophylaxis

Medication Treatment: The use of medications to treat SUDs can be combined with behavioral therapies to provide a comprehensive approach to care. There are Food and Drug Administration (FDA)-approved medications to treat tobacco, opioid, and alcohol use disorders. For benzodiazepine and barbiturate use disorders (BUD), medically supervised withdrawal management is standard of care to prevent seizures and other

Telegram: @medical_k

www.konkur.in

potentially life-threatening complications. There are currently no FDA-approved medications for cannabis, stimulant, and other substance use disorders, and behavioral treatments remain the treatments of choice for these disorders.

Substance withdrawal is often accompanied by unpleasant symptoms that can be managed with medications as a first step in the process of recovery. Medically supervised withdrawal treatment protocols vary according to substance(s) used and symptoms present. Potentially harmful side effects can occur with acute withdrawal from benzodiazepines, barbiturates, and opioids, and withdrawal under medical supervision is preferred for adult patients with these SUDs. It is also recommended for adolescents that meet criteria for OUD and/or BUD and who display symptoms of physical dependence. BUD withdrawal is typically done in an outpatient or ambulatory setting. OUD is rarely well tolerated outside of the residential or inpatient setting, and even then relapse is common without ongoing medication support.

Opioids: Withdrawal may begin 8–24 h after short-acting and up to 36 h after long-acting opioid use. The Clinical Opiate Withdrawal Scale or COWS [29] can be used to document the patient's opioid withdrawal symptoms, see Fig. 6. Non-opioid medications commonly used for the mitigation of withdrawal symptoms to facilitate abrupt discontinuation of opioids in adults are listed in Table 4 [30, 31].

Relapse Prevention and Medication Maintenance: Due to high risk of accidental overdose and death after withdrawal from opioids or from continued opioid use, medication therapy is the standard of care for OUD. Methadone (full mu agonist) and buprenorphine (partial mu agonist) are long-acting opioid receptor agonist/partial agonist, respectively, that reduce opioid withdrawal symptoms and cravings. Methadone and buprenorphine have similar effect during opioid withdrawal, although buprenorphine is associated with less sedation and respiratory depression.

Naltrexone is a competitive antagonist at the mu and kappa opioid receptors that blocks the effects of opioids at their receptor sites in the brain and should be used only in patients who have already been medically withdrawn or otherwise off all opioids for 14 days. The monthly depot injectable formulation (XR-NTX) has shown similar efficacy to buprenorphine and methadone treatments for OUD relapse prevention, with the caveat of treatment retention which can be lower with XR-NTX [32].

Buprenorphine: Patient needs to be in mild to moderate withdrawal to start the medication, i.e., COWS >8, to prevent precipitated withdrawal. It is usually well tolerated. Common adverse effects include sweating, constipation, headache, and nausea, and are typically mild and self- limiting except for constipation. Buprenorphine/naloxone combination has less potential for diversion and overdose and is preferred over buprenorphine monotherapy for most treatment options (except pregnancy and lactation) [33, 34]. Preliminary studies of its safety and efficacy in adolescents are encouraging. Expanding OBOT to the primary care setting was the main driver for FDA approval of buprenorphine and buprenorphine/naloxone as schedule III medications. Physicians prescribing buprenorphine products for treatment of OUD must first obtain a Drug Enforcement Agency (DEA) waiver by completing 8 hours of training (free and online training programs available), and completing a brief, online registration process through the DEA's website. Additionally, there are caps on number of patients each physician may have in active treatment, based on length of time the physician has been waivered. See the Providers Clinical Support System website, https://pcssnow.org/, for additional information and resources in becoming an OBOT provider. Table 5 shows buprenorphine products FDA approved for OBOT.

Methadone: Methadone maintenance therapy for relapse prevention may only legally be provided through a licensed opioid treatment program (OTP**),** not in the primary care setting. For medically supervised withdrawal such as in the hospitalized patient with OUD, there is no need to have specific level of withdrawal to start, however, it is not recommended to start when the patient is intoxicated. The starting dose is 20–30 mg, which may need to be increased 5–10 mg to alleviate withdrawal symptoms. Dose decreases of greater than

Clinical Opiate Withdrawal Scale

For each item, circle the number that best describes the patient's signs or symptom. Rate on just the apparent relationship to opiate withdrawal. For example, if heart rate is increased because the patient was jogging just prior to assessment, the increase pulse rate would not add to the score.

Patient's Name:_____ Date and Time ____/____/____:_____

Reason for this assessment:_____

Resting Pulse Rate: _____beats/minute *Measured after patient is sitting or lying for one minute* 0 pulse rate 80 or below 1 pulse rate 81-100 2 pulse rate 101-120 4 pulse rate greater than 120	**GI Upset**: *over last 1/2 hour* 0 no GI symptoms 1 stomach cramps 2 nausea or loose stool 3 vomiting or diarrhea 5 multiple episodes of diarrhea or vomiting
Sweating: *over past 1/2 hour not accounted for by room temperature or patient activity.* 0 no report of chills or flushing 1 subjective report of chills or flushing 2 flushed or observable moistness on face 3 beads of sweat on brow or face 4 sweat streaming off face	**Tremor** *observation of outstretched hands* 0 no tremor 1 tremor can be felt, but not observed 2 slight tremor observable 4 gross tremor or muscle twitching
Restlessness *Observation during assessment* 0 able to sit still 1 reports difficulty sitting still, but is able to do so 3 frequent shifting or extraneous movements of legs/arms 5 unable to sit still for more than a few seconds	**Yawning** *Observation during assessment* 0 no yawning 1 yawning once or twice during assessment 2 yawning three or more times during assessment 4 yawning several times/minute
Pupil size 0 pupils pinned or normal size for room light 1 pupils possibly larger than normal for room light 2 pupils moderately dilated 5 pupils so dilated that only the rim of the iris is visible	**Anxiety or Irritability** 0 none 1 patient reports increasing irritability or anxiousness 2 patient obviously irritable or anxious 4 patient so irritable or anxious that participation in the assessment is difficult
Bone or Joint aches *If patient was having pain previously, only the additional component attributed to opiates withdrawal is scored* 0 not present 1 mild diffuse discomfort 2 patient reports severe diffuse aching of joints/muscles 4 patient is rubbing joints or muscles and is unable to sit still because of discomfort	**Gooseflesh skin** 0 skin is smooth 3 piloerrection of skin can be felt or hairs standing up on arms 5 prominent piloerrection
Runny nose or tearing *Not accounted for by cold symptoms or allergies* 0 not present 1 nasal stuffiness or unusually moist eyes 2 nose running or tearing 4 nose constantly running or tears streaming down cheeks	Total Score _____ The total score is the sum of all 11 items Initials of person completing assessment: _____

Score: 5-12 = mild; 13-24 = moderate; 25-36 = moderately severe; more than 36 = severe withdrawal

This version may be copied and used clinically.

www.konkur.in

Table 4 Non-opioid medications used in the treatment of opioid withdrawal

Medication	Target symptom	Dose
Alpha 2 agonist: **clonidine**	Increased pulse rate and blood pressure, anxiety, piloerection, aches, rhinorrhea, lacrimation, temperature dysregulation, diaphoresis	0.1–0.2 mg orally every 4 h up to 1 mg/day; hold dose if blood pressure <80 mm Hg systolic or <50 mm Hg diastolic; by day 5, start to decrease dose by 0.2 mg/day
Alpha 2 agonist: **lofexidine**[a]		Three 0.18 mg tabs 4 times daily up to 2.88 mg (16 tablets)
Hydroxyzine	Anxiety	25–50 mg orally up to three times daily as needed
Gut-acting opioid: **loperamide**[b]	Diarrhea	4 mg orally initially, then 2 mg as needed for loose stools, up to 16 mg/day
NSAID: **naproxen**	Bone, muscle, joint, or other pain	500 mg orally twice daily as needed (take with food)
Prochlorperazine	Nausea and vomiting	5–10 mg orally every 4 h as needed
Ondansetron	Nausea and vomiting	8 mg orally every 8 h as needed
Trazodone	Insomnia	100–200 mg at bedtime as needed

[a]FDA approval in 2018, used in Europe for years. Shown to produce more rapid resolution of symptoms, less hypotension, and retain people longer than clonidine [30]
[b]Use diphenoxylate/atropine if increase in self-treatment with loperamide – QT prolongation, Torsades de pointes [31]

Table 5 FDA approved buprenorphine products for OUD

Drug	Route	Formulation	Recommended once-daily maintenance dose
Buprenorphine			
Generic	Sublingual tablet	2, 8 mg	Target: 16 mg Range: 4–24 mg
Probuphine (Titan)	Subdermal implant	74.2 mg	4 implants for 6 months
Sublocade (Indivior) extended-release	Subcutaneous injection	100 mg/0.5 mL and 300 mg/1.5 mL	300 mg monthly for the first two months then 100 mg monthly
Buprenorphine/Naloxone			
Generic	Sublingual tablet	2/0.5, 8/2 mg	Target: 16/4 mg Range: 4/I–24/6 mg
Suboxone (Reckitt Benkiser)	Sublingual film	2/0.5, 4/1, 8/2, 12/3 mg	Target: 16/4 mg Range: 4/1–24/6 mg
Zubzolv SL (Orexo)	Sublingual tablet	1.4/0.36, 5.7/1.4, 8.6/2.1, 11.4/2.9 mg	Target: 11.4/2.9 mg Range: 2.9 0.71–17.2/4.2 mg
Buna vail (Biodelivery Sciences)	Buccal film	2.1/0.3, 4.2/0.7, 6.3/1 mg	Target: 8.4/1.4 mg Range: 2.1/0.3–12.6/2.1 mg

5 mg every several days are not well tolerated. For hospitalized patients with OUD already enrolled in an OTP, their methadone dose should be continued while hospitalized.

Naloxone for Opioid Overdose Prevention: Naloxone is an opioid antagonist used in opioid overdoses to counteract life-threatening depression of the central nervous system and respiratory system, allowing an overdose victim to breathe normally. Naloxone is a nonscheduled (i.e., non-addictive), prescription medication. Increasing awareness and availability of naloxone is a key part of the public health response to the opioid epidemic. Patients receiving long-term opioid therapy, including opioids for cancer and non-cancer-related chronic pain as well as OBOT, should be co-prescribed naloxone in case of accidental overdose [35].

Telegram: @medical_k

www.konkur.in

Benzodiazepine and Barbituate Withdrawal: After discontinuation of a therapeutic daily dose used for 4–6 months or a dose exceeding 2–3x the upper limit of therapeutic dose used for 2–3 months, symptoms of withdrawal begin 12–48 h after last use, depending on drug used. BUD withdrawal seizures can occur up to 2 weeks after discontinuation. The Addiction Research Foundation clinical institute withdrawal assessment for alcohol scale (CIWA-Ar) [36] is used to assess the severity of signs and symptoms of BUD withdrawal. Substituting a different benzodiazepine than the patient's benzodiazepine of misuse or phenobarbital with scheduled tapering is standard of care for medically managed withdrawal of BUD. The CIWA-Ar is helpful for monitoring and adjusting tapering intervals and percentages. Dose reduction is recommended of no greater than 25% per week initially, and 10% weekly is often better tolerated particularly after initial dose has been decreased by 50% [37]. Other adjunctive medications are listed in Table 6. Withdrawal-related anxiety symptoms and recurrence of underlying anxiety disorders should be anticipated.

Abscesses from injections and related conditions should be treated. HIV, hepatitis B and C, and other infections should be ruled out or treated. Up to date immunization schedule should be assessed and provided based on patient risk factors.

Referrals

One of the most commonly used resource for placement, continued stay, transfer, or discharge of patients with addiction and co-occurring conditions is the American Society of Addiction Medicine (ASAM) Placement Criteria [38]. The criteria are required in over 30 states to guide the nomenclature for describing the continuum of addiction services. The levels of care consider patient's needs, obstacles, and liabilities, as well as their strengths, assets, resources, and support structure to determine the appropriate level of care. It encompasses four broad levels of service and an early intervention level (0.5, 1, 2, 3 4). Within the five broad levels of care, decimal numbers are used to further express gradations of intensity of services.

Outpatient Services: Outpatient services are organized services that may be delivered in a wide variety of settings. Standard outpatient care comprises less than 9 hours of service/week for adults, or less than 6 hours a week for adolescents for recovery or motivational enhancement therapies and strategies. Intensive outpatient treatment programs (IOP) deliver 9 or more hours of treatment service a week for adults or 6 or more hours for adolescents. IOPs typically offer programming during the day, before or after standard business hours, evenings, and/or on weekends to accommodate clients' work, school, and caretaking responsibilities.

Residential Services: Residential services range from low-intensity, sober living with peer support structured accountability services, to medium and high intensity treatment services. Treatment services are provided by licensed counseling and (for high intensity) medical staff providing addiction, mental health, medication management, and general medical services in a structured program with 24-h living support. Some specialized residential treatment services for women support their children as well offering day care, transportation to local public school for school aged children, parenting classes, and play therapy. Most residential treatment programs offer aftercare support as well with peer recovery

Table 6 Adjunctive medications for benzodiazepine withdrawal management

Medication	Target symptom	Dose
Hydroxyzine	Anxiety	25–50 mg orally every 6–8 hours as needed
Buspirone	Anxiety	10 mg orally every 8 hours
Carbarnazepine	Reduce withdrawal symptoms and promoted abstinence	200–800 mg/day orally during and after taper
Trazodone	Insomnia	100–200 mg orally at bedtime as needed
Melatonin	Sleep quality	6–10 mg orally before bedtime as needed

Telegram: @medical_k

www.konkur.in

coaches engaging with and providing peer support to program clients for several years after graduation, and with structured programming for alumni and their families.

Mutual Aid Programs: This is one of the most easily accessible models of recovery support, though not considered formal treatment. Twelve-step programs are the most well-known of these models, i.e. Narcotics Anonymous, and are peer run self-help meetings where participants admit past mistakes, surrender to a higher power, and learn how to cope with their SUD, avoid triggers, and live sober lives. Patients who complete formal IOP and residential treatment programs, particularly those using the TSF counseling modality, often continue participating in meetings, because the 12 steps help them build and sustain a sober community and offer safe, sober social opportunities. These programs may also serve as a source of support for individuals who are waiting for formal treatment slots to open up. These programs are free and widespread in urban, suburban, and rural communities across the globe.

Patient Education and Activation

The Treatment Referral Routing Service or SAMHSA's National Helpline, 1-800-662-HELP (4357) or TTY: 1-800-487-4889, is a confidential, free, 24-h-a-day, 365-day-a-year, information service, in English and Spanish that provides referrals to local treatment facilities, support groups, and community-based organizations.

The National Institute on Drug Abuse (NIDA) website for patients and families offers information for people struggling with substance misuse and SUD, as well as resources for their families and friends (https://www.drugabuse.gov/patients-families).

Community Issues: Prevention from a Community Perspective

Opioid Overdose Prevention: A key aspect of opioid overdose prevention is to improve opioid prescribing. Healthcare and community leaders and experts can provide education to prescribers about the risk associated with opioid medication, providing guidelines about when to prescribe and how much, for how long. Additionally, state-level interventions such as the use of Prescription Drug Monitoring Programs (PDMP) can be used to inform prescribing decisions. Guidelines for prescribing opioids for chronic pain can be found at www.cdc.gov/mmwr/volumes/65/rr/rr6501e1.html.

Recovery-Oriented System of Care (ROSC): A ROSC is "a coordinated network of community-based services and supports that is person-centered and builds on the strengths and resiliencies of individuals, families, and communities to achieve abstinence and improved health, wellness, and quality of life for those with or at risk of alcohol and drug problems" [39].

A ROSC is comprised of the substance use disorder treatment community in partnership with other community stakeholders including those providing mental health and primary care services to form a system of care. Together, the system of care addresses prevention, early intervention, treatment, continuing care, and recovery. Not only does the ROSC include individuals living with SUDs, it also engages family members and the community in identifying ways to improve the quality of services and increase access to those services. Substance use is addressed along the spectrum from misuse to chronic conditions and includes prevention approaches such as community education and awareness campaigns. Inherent to the model is the belief that recovery can be achieved through several pathways and that there is room to combine alternative therapies (e.g., peer recovery coaching, acupuncture, music, and art therapy) with traditional treatment. An important function of the ROSC is to provide recovery support services (RSS). Recovery support services are non-clinical services that support recovery and encompass a wide range of social services, legal services, mutual aid groups, and the use of peer recovery coaches. Peer recovery coaches are persons with lived experience of recovery who can provide emotional support as well as guidance and assistance in accessing community resources,

Telegram: @medical_k

www.konkur.in

employment, and making connections within the recovery community.

Special Populations

Pregnant Women: As frontline healthcare professionals, primary care providers are in an ideal position to screen, counsel, and facilitate or initiate treatment for pregnant women who are using substances. Although most women stop the use of substances once they are pregnant, many do not and those who do may resume use after the pregnancy. A key aspect of providing care to women who are using substances or may have a SUD is to employ a nonjudgmental approach that invites women to discuss their use in an open manner, thus reducing the stigma. The gold standard treatment for pregnant women with OUD is the use of opioid agonist medication, such as methadone or buprenorphine [40].

Lesbian, Gay, Bisexual, Transgender, Queer (LGBTQ): Members of sexual minority groups are more likely than their heterosexual counterparts to experience a substance use disorder during their lifetime. Although research is limited regarding the experiences of LGBTQ individuals in treatment, it appears that treatment programs that offer specialized groups for LGBTQ patients demonstrate better outcomes than those that do not. Despite this, few programs have specialized services [41]. When working with LGBTQ patients, it is important to recognize how their unique experiences, particularly discrimination, internalized homophobia, and family rejection, may have contributed to initiation of use as a coping strategy. Screening for comorbid mental health conditions is also important, as comprehensive treatment for both conditions is essential to long-term recovery.

Adolescents: Nearly half of all high school seniors in the US report using an illicit drug at least once in their lifetime. After alcohol and tobacco, the most commonly used drug is marijuana. The use of other substances appears to be related to age, where younger adolescents may use inhalants, older adolescents are more likely to use prescription medications such as opioids and stimulants. Treatment options vary based on the substance being used, length and amount of use, and severity of symptoms. In general, it is recommended that adolescents receive both individual and family therapy. Evidence-based interventions for SUDs include CBT, MET, and multidimensional family therapy (MDFT).

Older Adults: Substance use disorders in individuals over the age of 50 are on the rise, nearly doubling over the past decade and a half. Older adults tend to misuse alcohol, prescription and over-the-counter medications, and marijuana [42]. Routine screening practices, using validated instruments, can help to identify problematic use and creates an opportunity to deliver a brief intervention (i.e., a short conversation aimed at motivating a person to make changes regarding their substance use behavior) or facilitate referral to treatment.

Racial/Ethnic Minorities: The use of substances by African Americans and Hispanics is very similar to that of non-Hispanic Whites. However, African Americans and Hispanics are less likely to complete treatment and more likely to have poor treatment outcomes. In addition to socioeconomic barriers, implicit discrimination by healthcare providers is also considered a variable in treatment completion [43].

forms and descriptions ranging from ice pick like in intensity and locality to a dull, pounding unilateral throbbing and to a viselike pressure grip of the entire cranium. Because the possibilities range from a benign, tension type headache to the imminently deadly subarachnoid hemorrhage, the seemingly simple complaint of "my head hurts" requires careful attention to patient history and physical examination.

Thankfully, the majority of headaches are non-serious in nature, and most are very amenable to treatment. Attentive evaluation distinguishes the life-threatening headaches from benign, yet bothersome, headaches. With this evaluation, the family medicine physician is equipped to appropriately and precisely treat this common patient complaint.

Epidemiology

It is hard to understate headaches' impact on humanity. In the year 2016, an estimated three billion people, or about 50% of the world's adult population, were thought to have suffered from either a migraine or tension-type headache [1]. Worldwide, tension-type and migraine headaches were the third most prevalent and sixth most prevalent disease. Second only to low back pain, migraine headaches were the most disabling in terms of life years spent with a disability [2].

In the Americas, migraine and tension-type headaches account each for approximately 28% of all headaches. 17% of headache sufferers have a combined migraine and tension-type headache. All secondary headaches (trauma, vascular pathologies, infections, tooth pain, etc.) account for an estimated 14% of headaches. Medication overuse headaches (MOHs) account for 10% of all headaches. Cluster headaches account for about 3% [3]. Figure 1 details the relative ratios of different headache types. Within the USA, headaches are responsible for 1% of all outpatient visits [4].

Headaches afflict males and females rather differently depending on subtype. Likely due to the hormonal differences, females are afflicted three times as often as males with migraines [3]. The rarer cluster headache, on the other hand, afflicts males three times more frequently than females [4]. Tension-type headaches (TTH) have a slight female predominance of about 5:4 [5]. Due to the higher prevalence of both migraine and TTH, females tend to suffer more frequently from headaches than males. Therefore, it is unsurprising that medication overuse headaches afflict females more frequently than males [6].

Classification

The International Classification of Headache Disorders is the mainstay of classifying headaches. In its third edition, this classification system subdivides headaches into three broad categories and over 300 subcategories [7]. The three broad categories are primary headaches, secondary headaches, and painful cranial neuropathies (see below list). For the sake of simplicity, this chapter divides all headaches into primary and secondary causes by rolling in painful cranial neuropathies into secondary headaches. The distinctive category names of "primary" versus "secondary" are largely attributed due to prevalence as opposed to any substantive differentiation in underlying pathology.

Primary and Select Secondary Headache Etiologies
Primary Causes
Cluster headaches
Migraine headaches
Tension-type headaches
Secondary Causes
Brain aneurysm
Brain tumor
Chiari malformation
Dehydration
External pressure
Ophthalmic pathology
Hypertension
Infections (brain, ear, sinus, etc.)
Medication overuse headaches
Meningitis
Stroke
Toothache
Temporomandibular joint Disorder
Trauma

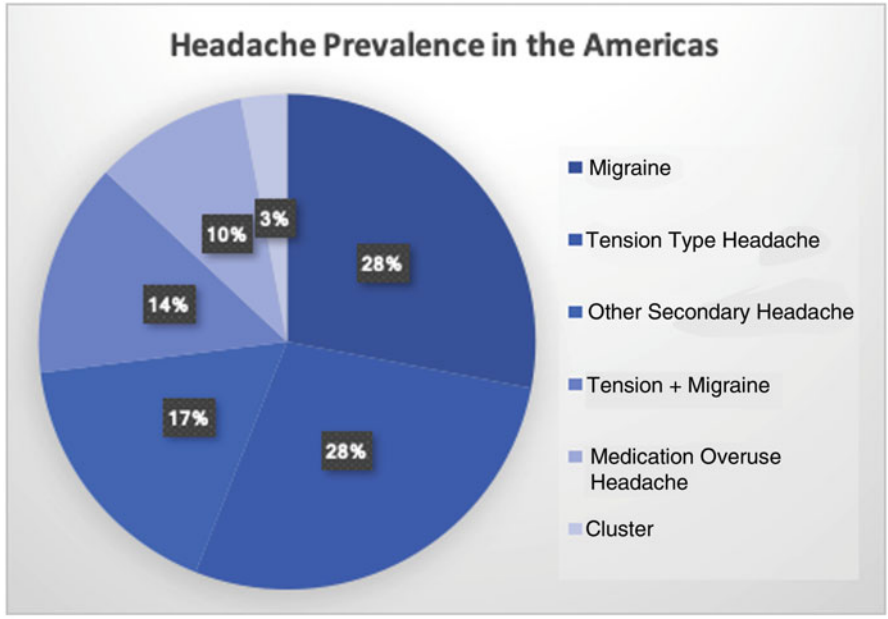

Fig. 1 Headache prevalence in the Americas [3]

Approach to the Patient

Diagnosis

General Interview Principles

Determining the headache type is almost completely dependent on history [8]. A proper headache history encounters some unique linguistic challenges. On one hand, patients will often label any severe headache a migraine, when the real culprit may be something else. On the other hand, despite the high incidence of formal medication evaluation of headache in the USA, many patients reporting migraine symptoms do not appear to be properly diagnosed with migraines [9]. Thus, the physician must carefully sift the patient's history for clues to determine the type of headache. For instance, if headache and nausea are present in the history, the patient likely does suffer from a migraine [10]. Similarly, if the patient reports headache and fever, an infection or nonvascular intracranial disorder is more likely than migraine [11].

Key facets in identifying headaches include evaluating temporal features (headache onset, duration, number of headache days per week), pain characteristics (location, quality, radiation), and precipitating and/or provoking factors. Moreover, the astute physician also explores associated symptoms such as vision abnormalities, positional changes, and other secondary body symptoms. Family headache history can often be helpful in determining the diagnosis as well. If the patient has been professionally diagnosed with a headache, discussing the changes over time can be particularly useful in directing treatment and discussing prevention strategies. To aid in diagnosis, it may be helpful to have patients catalogue their headaches along with associated symptoms on a headache diary. See Fig. 2

Finally, certain headache features are reassuring and can be used to counsel the "worried well" patient (see below).

Low-Risk Headache Characteristics
• <50 years of age
• Similar headaches in the past
• No new neurologic exam findings

Criteria adapted from Edlow et al. [12]

Conversely, specific headache features, referred to as red flags, merit special attention as

Headache Diary

Please complete a headache diary for 1 week (or 7 headaches). Under type of pain, list where the pain is located and any other describing words like pounding, vice grip or crushing. Regarding triggers, think back about an hour prior to the headache start. Was there anything unusual you ate or drank? What were you doing? This info can provide helpful clues about ways we might prevent headaches in the future. Regarding other problems, did you have other problems while suffering from the headache?

they may herald more nefarious disease and serve as indicators that more diagnostic evaluations may be necessary. To aid in diagnostic discovery, and to differentiate primary from potentially dangerous secondary headaches, neurologists developed the helpful mnemonic, SNNOOP10, to recall important red flag symptoms (see Table 1).

If the physician identifies red flags, further workup targeted at specific etiology may be appropriate. A comprehensive discussion of secondary headache causes and their evaluations is outside the scope of this chapter. This chapter will limit discussion to the primary headaches and, only the most prevalent secondary headache, medication overuse headache (MOH).

Patient History

Migraines

Migraines are characterized by unilateral and pulsatile pain lasting hours which tends to worsen with physical activity. Migraines are sometimes, but not necessarily, preceded by a heralding neurologic

Table 1 SNNOOP10 Mnemonic for Secondary Headache Etiologies

Mnemonic memory aid		Pathology
S	Systemic symptoms such as fever	Infection (meningitis, carcinoid, pheochromocytoma)
N	Neoplasm history	Primary brain neoplasm or metastasis
N	Neurologic deficit or dysfunction	Stroke; brain abscess; infection
O	Onset of headache is abrupt/sudden	Subarachnoid hemorrhage
O	Older age (after 50 years)	Neoplasm; vasculitis
P	Positional headache	Intracranial hypertension or hypotension
P	Precipitated by sneeze/cough/exercise	Chiari malformations; posterior fossa malformations
P	Papilledema	Intracranial hypertension; primary brain neoplasm or metastasis
P	Progressive headache and atypical presentations	Primary brain neoplasm or metastasis
P	Pregnancy or puerperium	Post spinal tap headache; preeclampsia, cavernous sinus thrombosis; hypothyroidism; anemia or diabetes
P	Painful eye with autonomic features	Posterior fossa, cavernous sinus, pituitary region pathology; ophthalmic primary source
P	Posttraumatic onset of headache (within 7 days)	Subdural hematoma; traumatic brain injury without hematoma
P	Pathology of the immune system (HIV)	Opportunistic infections
P	Painkiller overuse or drug side effect	Medication overuse; idiopathic drug reaction
P	Pattern change or new headache onset	Neoplasm, intracranial pathology, or vascular disease

Adapted from [11]

phenomenon known as an aura. The presence of an aura helps make the diagnosis given its high specificity for migraine headaches. An aura is a prodrome of neurologic paresthesia, classically described as a visual disturbance which precedes the development of head pain. Visual phenomena represent the most common type of aura present in 90% of patients afflicted by migraine with aura [7], but clinicians should note that other possible aura symptoms could afflict sensory, speech, motor, or brainstem neurologic symptoms. The phenomenon can be positive/additive (i.e., extra items in visual field) or negative/subtractive (i.e., partial or complete visual loss), and they are, by definition, fully reversible. Because aura symptoms (particularly dysphonia) can be extremely disconcerting, exploring aura consistency with past headaches helps avoid unnecessary repetitive workup. Thus, if a patient reports a consistent aura of left eye vision loss, repeat imaging is likely unnecessary for each subsequent similar presentation. Suffice it to say, if the aura has been present and was fully reversible in the past, this likely represents a repeat episode and not necessarily a stroke. However, if, in the same patient, the "aura" changes and is now a right-sided visual loss, imaging may be warranted.

A helpful mnemonic, POUNDing (as in headache), helps providers make the diagnosis of migraine, with the likelihood of diagnosis increasing with every positive finding after the second [13]. Similarly, the symptom triad of nausea/phonophobia/pulsation or nausea/photophobia/worsening with exertion all has likelihood ratios of 5 or greater [10]. Of all single symptoms, nausea when combined with other headache symptoms is useful for differentiating migraine from other subtypes.

Tension-Type Headaches

Unfortunately, the other primary headaches aren't as distinctive as migraine headaches and have less specific findings. Tension-type headaches tend to be a dull and more of a diffuse, mild to moderate pain described as a "band wrapping around the head." Often this discomfort may go up the scalp, through the neck, and down to the shoulders. The timeline for a tension headache tends to vary ranging from a half hour to chronic and continuous headaches lasting days to weeks.

After other primary and secondary causes of headaches have been considered, tension-type headaches are largely a diagnosis of exclusion. Although there may be some phonophobia or photophobia, those symptoms tend to be more commonly associated with migraine headaches. Although the specific etiology of the tension-type headache remains unknown, there are certain things that tend to trigger the headache, including stress, anxiety, dehydration, specific posture, sleep issues, and many others.

Cluster-Type Headaches

Cluster headaches are typically unilateral paroxysms characterized by a stabbing quality localized as being "right behind the eye." Occasionally, rhinorrhea or lacrimation accompanies cluster headaches. Subsequent episodes often develop a consistent laterality to the attack. Cluster headaches may have triggers that are patient dependent by tobacco use, alcohol use, or strong smells (typically due to work exposure, i.e., tarring, pesticide use, etc.) [14].

Usually these headaches occur in a group (or cluster) occurring every day for weeks at a time before they subside. Often when the headache episode resolves, patients may go for months or years before having another headache cluster. Treatment with oxygen is both therapeutic and diagnostic for this type of headache.

Medication Overuse Headaches (MOH)

The definition of a medication overuse headache contains two parts: a headache frequency coupled with medication overuse. These headaches are characterized by more than 14 headache days per month with regular overuse of >3 months with one or more treatment medications. Medication overuse is defined in two ways. The first definition is the use of a combination drug (such as aspirin with caffeine), ergot derivatives, opioids, and triptans for 10 or more days per month. The second definition is using acetaminophen, NSAIDs, or nonopioid analgesics for 15 or more days per month [7].

When physicians diagnose an MOH, in reality they are making two diagnoses: first a causative primary headache and then the resulting medication overuse [6]. Appropriate diagnosis and treatment of the underlying primary headache are the foundation for MOH prevention, and educating patient about the secondary etiology of the MOH may help. Through elimination of pain, the acute headache medication activates the reward pathways. As this pathway is activated and re-activated again, an MOH develops. This then sets up a feedback loop which amplifies primary headache pain [6] rendering the MOH difficult to treat.

Physical Examination

The focus on the physical exam is largely to rule out secondary causes of headaches. There are few specific physical exam findings specific to primary headaches. However, the family physician should undertake a thorough evaluation of the head and neck during the initial evaluation to determine the headache's type and then, as needed, if the headache changes or a new headache type presents. It is likely unnecessary to repeat a comprehensive head and neck examination with each stable subsequent follow-up visit.

The physician should first visually examine the head and neck for any gross abnormalities such as a herpetiform rash or other visual abnormality. Following this the cranium should be palpated with particular attention to the temporalis and

Telegram: @medical_k

www.konkur.in

paraspinal muscles. In tension-type headaches, these muscles may be tight and painful to the touch. The eyes should be inspected and assessed for light reactivity, photophobia, visual accommodation, and gross visual field deficits. The nares, mouth, and ears should be subjected to a lit otoscopic exam.

Of importance in examining headaches is the cranial nerve (CN) examination. CNs are special because they arise from the brain, and thus dysfunction greatly increases the likelihood of brain-specific pathology. Table 2 presents a structured approach to examining the cranial nerves [15].

Combining a careful history without red flags and an unremarkable physical exam, the physician will have ruled out a large number of secondary causes.

Laboratory and Imaging

Only if red flags are present, should the physician consider ordering laboratory tests. As in most other illnesses, laboratory evaluation should be tailored to the specific diagnostic considerations. For example, if the physician suspects giant cell arteritis due to funduscopic exam findings coupled with jaw claudication (the patient's complaint of "headache") or scalp tenderness, they should order an erythrocyte sedimentation rate. In diagnosing primary and medication overuse headaches, laboratory evaluation is usually unhelpful.

Absent red flags, medical literature and current guidelines recommend limiting neuroimaging. The Choosing Wisely campaign targets wasteful and ineffective medical practices by admonishing "Don't perform neuroimaging studies in patients with stable headaches that meet criteria for migraine" [16]. Imaging should be considered if red flags are present on initial evaluation or develop over time. Routine neuroimaging when diagnosing primary headaches to rule out pathology is wasteful and non-patient centered and should be discouraged.

Treatment

General Approach

While some headaches may be initially treated similarly with general analgesics, like NSAIDs, treatment imprecision may be costly and

Table 2 Cranial nerve exam components [15]

CN number	CN name	Exam technique
I	Olfactory nerve	Occlude each nostril, wave an EtOH swab or chlorhexidine swab under the open nostril, and ask if it can be smelled
II	Optic nerve	Visual acuity (with glasses worn), fields, and funduscopic exam
III	Oculomotor, trochlear, abducens	Bilateral equal pupillary response to light and object accommodation; with fixed head, patient's eyes following an H or star pattern drawn by examiner's fingers
IV		
VI		
V	Trigeminal	Light touch (fingertips) of the bilateral (V1), malar (V2), and skin lateral to chin (V3) of the face; patient should report equal sensation
VII	Facial	Upper component: patient tightly closes eyes, while physician assesses for equal strength
		Lower component: patient puffs out cheeks
VIII	Vestibulocochlear nerve	Whisper test in each ear
IX	Glossopharyngeal	Assess gag reflex or uvular deviation with patient saying "Ah"
X	Vagus	
XI	Spinal accessory nerve	Patient shrugs bilateral shoulders, while physician applies downward resistance
XII	Hypoglossal nerve	Symmetric tongue protrusion

www.konkur.in

ineffective and create medication overuse headaches. Therefore, developing a sustainable individualized treatment strategy is critical to avoid harming the patient. The prevalence of iatrogenic medication overuse headaches demonstrates this principle clearly.

Behavioral Approaches

Sleep, diet, and exercise all interact with primary headaches. By capturing these relationships in a headache diary, the patient can meaningfully contribute to the development of a comprehensive treatment plan (see Fig. 2). Incorporating this information helps the physician attain greater success than exclusively focusing on pharmaceutical management.

There is a growing consensus that sleep and headaches are interrelated, and research suggests, in at least migraines, poor quantity of sleep is associated with more severe attacks [17]. Thus, it may be useful to obtain sleep-related history and screen for common sleep disorders such as obstructive sleep apnea which have been known to precipitate headaches.

The relationship between aerobic exercise and primary headaches is complex. Several large population-based studies suggest a link between low levels of exercise and increased frequency between migraine and other headache disorders. Migraines are known to be worsened by physical exercise, but routine exercise notably reduces frequency and intensity [18].

It is well known that diet impacts headache. Just as triggers are highly individualized, any dietary treatment approach should be patient specific. Identified food triggers for headaches include aged cheese, alcohol, aspartame, caffeine, chocolate, monosodium glutamate, nitrate, food preservatives, and red wine [19]. While fasting has been demonstrated as a trigger for some patients with migraine, it has been shown in others to decrease migraine frequency and intensity. Emerging evidence suggests effective headache prophylactic strategies may include reducing omega-6, increasing omega-3 fatty acids, weight loss diets in obese patients, low calorie, and ketogenic diets [20].

Medication Strategies for Migraine, Tension, Cluster, and Medication Overuse Headaches

Migraine Treatment

The primary goals of migraine treatment are reduction of migraine frequency, function restoration, and pain alleviation [21]. The two main treatments of migraine headaches are nonspecific general analgesics (i.e., NSAIDS) and migraine-specific treatments such as triptans and ergotamine derivatives. The physician may attempt a stratified approach where mild to moderate headaches are treated with NSAIDs and moderate to severe migraines treated with triptans or ergotamine derivatives [22]. Another approach, known as abortive treatment, involves initiating triptans at the earliest onset of an aura or the start of a migraine. In head to head trials, triptans and NSAIDs are noted to have similar efficacy, but triptans are useful any time during a migraine [23].

A 2016 meta-analysis suggested that the best migraine medication treatments within each class were ibuprofen (due to tolerability) and eletriptan (due to comprehensive efficacy). Additionally, diclofenac and the combination sumatriptan/naproxen were notable for their combination of efficacy and tolerability [23]. However, despite the possible superiority of eletriptan, selecting a triptan rests on clinician-patient preference for efficacy, costs, and tolerability [23] as eletriptan costs approximately three times more than sumatriptan [24].

While comprehensive mastery of the numerous NSAIDs and triptans is impractical, understanding a few examples of the NSAID and triptan classes typically suffices for treatment success (see Table 3). As with all prescribing, it is important to note specific contraindications. For example, NSAIDs as a class carry a risk of myocardial infarction, stroke, gut bleeding, and renal injury; triptans are contraindicated for peripheral vascular disease, ischemic bowel disease, ischemic heart disease, cerebrovascular vascular disease, basilar/hemiplegic migraines, uncontrolled hypertension, arrhythmias associated with a cardiac accessory pathway such as Wolff-Parkinson-White, or severe hepatic impairment.

Telegram: @medical_k

www.konkur.in

Finally, there are other medications which may be useful in select circumstances for severely debilitating migraine attacks. These medications include the non-migraine-specific opiates and migraine-specific ergotamine derivatives. Opioid medications can relieve head pain; however, this risk must be weighed against the risk of dependence and associated development of chronic headache, such as MOH [27]. The risk of rebound headaches in ergotamine derivatives diminishes their continued utility for acute migraine treatment when better alternatives are available [25], thus rendering both of these medications ill-suited for routine migraine relief.

Preventive therapy has been shown to decrease migraine, severity, and associated disability [28]. Migraine prevention should be considered if there is significant disability caused by migraines, greater than 4 migraine headache days per month, contraindications/adverse reactions to common acute migraine treatments, or patient preference [29]. Based on large population studies, although one in three patients with episodic migraines would benefit from preventive therapy, less than half of these patients are currently taking migraine prophylaxis [28]. Thus, family physicians can greatly enhance a patient's quality of life through prevention.

Once the physician and patient agree on a prevention strategy, it is helpful to discuss goals. Goals for preventive therapy include [30]:

1. 50% reduction in attack frequency with a decreased attack intensity and duration
2. Improve acute therapy efficacy
3. Improve patient function and decreased disability
4. Prevent MOH and chronic daily headache

These goals allow the clinician to define success for any prophylactic approaches. Prior to any consideration of pharmaceutical prophylaxis, nonpharmacologic prevention strategies should be considered, such as behavioral interventions along with complementary and alternative treatments which will be discussed later in the chapter.

The basic approach when selecting a preventive medication treatment begins with starting at a low dose and titrating slowly up to a therapeutic regimen while allowing time for an adequate trial and maximizing adherence [29]. The best documented evidence for migraine preventive treatments includes select beta blockers, amitriptyline, divalproex and topiramate [31]. Because these medications are usually taken daily, careful attention must be paid to the adverse effects and the possibility of polypharmacy, particularly in older patients. In particular, females of childbearing age should have a full discussion about the risk of teratogenicity of valproic acid and other pregnancy considerations. Despite the risk of polypharmacy, an elegant approach to the patient may consist of using one medication such as propranolol to treat two different conditions, say migraine prophylaxis and concomitant hypertension.

Additionally, it is important to note the availability of onabotulinum toxin A (Botox) as a migraine prevention treatment. This approach may prove useful in select cases; however, insurance coverage varies widely. Family medicine physicians should also be aware of the emerging classes of subcutaneous and injectable prophylactic medications, specifically the calcitonin-related gene peptide inhibitors. However, their current cost renders them most appropriate for referral centers and specialists. Because of the prevalence and disability associated with headaches, the opportunities for pharmaceutical innovation are endless, and likely there will be numerous niche additions to the pharmacopeia in the coming years.

Tension-Type Headache (TTH) Treatment

The first-line acute treatment for TTH tends to be behavioral and complementary and alternative medicine (CAM) treatments given their favorable risk profile [32]. However, given that TTH lack clear definable characteristics, care should be taken to ensure that competing diagnoses are reasonably excluded before designing a sustainable treatment regimen. The first line for pharmaceutical treatment is with NSAIDS for the acute headache (see Table 3 for additional information) [33]. Often, given the name, clinicians associate TTH with muscle tension and thus prescribe muscle relaxers for acute treatment. However, there

Telegram: @medical_k

www.konkur.in

Table 3 Acute headache treatments [16, 23–26]

Drug name	Usual dosage	Notes
Acetaminophen	MH, CH, TTH: oral, 325–1000 mg; max dose 4000 mg/day	Routine use may increase risk of hepatotoxicity
Aspirin	MH, CH, TTH: 325–600 mg oral once	Negatively against with MOH
Ibuprofen	MH, CH, TTH: 800 mg by mouth up to three times per day	Negatively associated with MOH
		Correlated with better tolerability
Ketorolac	MH, CH, TTH: 20 mg by mouth followed by 10 mg every 4 to 6 h to a maximum of 40 mg per day	Perhaps more efficacious than other NSAIDs
Naproxen	MH, CH, TTH: 750 mg by mouth initially then 250–500 mg as needed up to a maximum of 1250 mg in 24 h	Combination with sumatriptan improves tolerability of sumatriptan
Sumatriptan (generic available, branded as Imitrex)	MH, CH: oral, 50–100 mg daily, the repeat the dose after 2 h as needed up. Max dose is 200 mg daily	Available forms useful if nausea prevents oral route
	MH, CH: intranasal, 20 mg once in a single nostril; if partially effective repeat dose; max dose is 40 mg/day	Often, mild migraines are mistaken for TTH, so triptans may help with symptoms in this case
	MH, CH: subQ, 6 mg once if partially effective, repeat after 1 h with a range of 1–6 mg dose; max dose is 12 mg in 24 h	Least expensive triptan (Good Rx reference)
		Combination with naproxen improves tolerability
Rizatriptan (Maxalt)	MH: oral, 5 to 10 mg, repeat after 2 h if needed; max dose is 30 mg/day	Available as an oral disintegrating tablet
Eletriptan (Relpax)	MH:– oral, 20–40 mg as a single dose, repeat after 2 h if needed; max dose is	Not available in a non-tablet form which may limit utility in nausea
		Perhaps most efficacious
		Most costly
Zolmitriptan (Zomig)	MH, CH (off label): intanasal 2.5–5 mg once	
	MH, CH (off label): PO, 1.25–2.5 mg (CH can start with 5 mg once)	
Ergotamine	MH, CH (off label): sublingual 2 mg at first sign of headache (migraine, off label for cluster), then 2 mg q30 min, max dose 6 mg/day	Contraindicated within 24 h of triptan use
Oxygen therapy	CH: 100% oxygen at 12 L/min via non-rebreather mask	First-line treatment for CH
Caffeine	MH, TTH: typical caffeine dose 130 mg	Combination with ASA, acetaminophen, or both

For treatment of all headache types, routine opioid use is not recommended [16]
MH migraine headaches, *CH* cluster headaches, *TTH* tension-type headaches

have been no good trials to prove their efficacy, and given the safety profile, they are not recommended for inclusion in a TTH treatment regimen.

In addition to acute treatments, behavioral and complementary therapies remain the first-line treatment options for prevention [32]. However, specific literature to support this prevention strategy is limited. In terms of prophylactic pharmaceutical options, tricyclic antidepressants have been utilized for decades [34]. Other prophylactic medications to consider include mirtazapine and venlafaxine, but these medications are typically reserved to simultaneously treat a secondary diagnosis, i.e., depression (see Table 4 for full details).

Telegram: @medical_k

www.konkur.in

Cluster Headache Treatment

Given the low risk of oxygen therapy, and the aiding with diagnosis of cluster headache, it is often used as a first-line treatment. 100% O_2 is typically given at a high rate (usually 12 L/min) through a non-rebreather mask. Up to 70% of patients experience relief with oxygen therapy [14]. If the oxygen therapy doesn't alleviate the headache, often subcutaneous sumatriptan is the most appropriate choice for treatment. The brevity of cluster headache attacks renders the parenteral or nasal route most appropriate for therapy. A more thorough treatment outline can be found in Table 3. For prevention, after behavioral therapy and/or CAM trial, the pharmacotherapy of choice is verapamil. Other options may include topiramate and lithium which require close monitoring of serum levels [14]. Family medicine physicians should be aware that there exist surgical nerve destruction and neurostimulation as treatment options for cluster headaches. However, these modalities have conflicting results and thus are not routinely recommended at this time.

Medication Overuse Headache (MOH) Treatment

The three mainstays of MOH treatment are patient education, detoxification/withdrawal, and prophylactic treatments [35]. Patient education centers on discussing expectations and the rationale to reduce acute treatment medication. The primary headache and concomitant MOH attacks may increase in the short term, but over the long term, the patient's overall functioning and pain level should decrease. Similar to chronic pain, finding ways to disrupt the headache cycle, like withdrawal of the offending medication, either in an abrupt or tapered manner as appropriate will help reduce recurrent episodes. If the medication taken is an opiate, abrupt withdrawal is problematic and likely best managed in an inpatient setting. However, if the offending medication is acetaminophen, then outpatient management may be more suitable. There is minimal evidence to support one MOH medication over another. In patients with chronic migraine (as the primary headache) and MOH, topiramate in doses up to 200 mg/day has moderate evidence of efficacy [35].

Table 4 Suggestions for headache prevention medications [26, 30, 31]

Drug name (all oral)	Indication and suggested dosing	Pregnancy risks
Timolol	MH: 10 mg oral twice daily titrate to 30 mg oral twice daily	C: Decreased fetal heart rate, potential postdelivery bradycardia, hypoglycemia, and respiratory depression
Propranolol	MH: 40–240 mg PO daily	Not defined; bradycardia, hypoglycemia, and respiratory depression
Divalproex	MH: 500 mg once daily to 1000 mg daily	X: Neural tube defects, decreased child IQ after birth
Topiramate	MH, CH (off label): 25 mg once daily titrated to 50 mg twice a day over 4 weeks	D: Cleft palate, small for gestational age
Amitriptyline	MH (off label), TTH (off label): 10–25 mg/day at bedtime titrate up to 100–300 mg/day	C: Case reports of limb deformities, development delay; neonatal irritability and jitteriness
Verapamil	MH (off label), CH (off label): start at 40 mg TID IR or 120 XR daily, can titrate to 120 mg TID IR or 180 mg BID XR	C: Newborns exposed to this Rx should be monitored for fetal hypoxia

Note: In 2015, the FDA moved away from pregnancy risk categorization in favor of a more nuanced discussion of risk specifics; however, as these risk categories may assist the family physician in discussing relative risk, they have been included

MH migraine headaches, *CH* cluster headaches, *TTH* tension-type headaches

Telegram: @medical_k

www.konkur.in

Complementary and Alternative Medicine (CAM)

There is a growing body of literature exploring the use of complementary and alternative medicine therapies in headaches. However, the term CAM is imprecise, covering a broad range of therapeutic techniques. Examples of this include musculoskeletal manipulation (chiropractic care, massage, etc.), herbal supplements, and alternative medical systems (acupuncture, ayurveda, homeopathy, etc.) [36]. Another treatment patients may use includes "mind-body" therapy (such as yoga, meditation, deep breathing, tai chi, etc.), which notably many patients don't often disclose during the clinical encounter as a treatment modality they are using.

The overall quality of research evaluating musculoskeletal treatment research for headaches tends to be difficult to appropriately interpret given sample size and data source. Overall there seems to be conflicting evidence with some finding that based on intent-to-treat analysis, there is no significant difference between manipulated and controlled groups (specifically when looking at tension-type headaches) [37].

However, there is some evidence that suggests that chiropractic care may improve migraines and cervicogenic headaches [38]. In the end, given that this is typically an out-of-pocket cost for patients, like all things, it becomes an individualized conversation about the theoretical benefits versus the cost of such treatments.

The line of CAM that has the most significant research behind its use is acupuncture. Acupuncture has been utilized in many functions to help alleviate various types of headaches. Current research seems to indicate that typically it can reduce the number of days with headache in a given period of time for both tension-type headaches and migraines but that there is not a significant difference between true acupuncture and sham treatments [32, 39].

This leads to the impression either that there is a deeper etiology for the headaches, such that placebo treatment has a significant role in the resolution of discomfort, or that treatments like sham acupuncture can cause inflammation that in itself helps with symptomatic resolution even though they do not go along the lines of traditional meridian treatment.

Conclusion

Headaches have plagued humanity since the dawn of medicine. Still, physicians have grown increasingly adept at accurately classifying and diagnosing this common illness. But only in the past century, have medical researchers developed safe effective treatments from ergotamine derivatives of the 1920s to the triptan class of the 1990s and even beyond. Armed with knowledge of proper diagnosis and treatment, the family physician is well equipped to alleviate great suffering. Looking forward to the future, the treatment success with both sham and real acupuncture demonstrates that much work remains to be done to better understand and treat this common scourge.

Epilepsy is a chronic neurological disorder characterized by recurrent seizures. A seizure happens when abnormal electrical activity in the brain causes an involuntary change in body movement or function, sensation, awareness, or behavior. Epilepsy is a chronic seizure disorder.

Epilepsy affects 2.3 million adults [1, 2], and more than 450,000 children 0 to 17 years old [2] in the United States. About 1 in 26 people will be diagnosed with epilepsy at some point in their lives [3].Epilepsy each year accounts for $15.5 billion in direct costs (medical) and indirect costs (lost or reduced earnings and productivity). More than one-third of people with epilepsy continue to have seizures despite treatment. Each year, about 200,000 new cases of epilepsy are diagnosed in the United States.

The International League Against Epilepsy redefined Epilepsy in 2014 [4]. Epilepsy is defined as (1) At least two unprovoked (or reflex) seizures occurring >24 h apart; (2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; (3) diagnosis of an epilepsy syndrome.

Epilepsy is considered resolved for individuals who either had an age dependent epilepsy syndrome but are now past the applicable age or who have remained seizure-free for the last 10 years and off anti-seizure medicines for at least the last 5 years. Indicating that epilepsy is no longer considered to be a lifelong disorder.

Types of Seizures and Epilepsy

The two main types of seizures are Generalized and Focal. In Generalized seizures there is involvement of both cerebral hemispheres. And in focal seizures the seizure involves one hemisphere or a lobe of a hemisphere. The vast majority of seizures are Focal seizures, between 70–80% in adults (Fig. 1).

Generalized Seizures

Generalized Seizures are conceptualized as rapidly engaging bilaterally distributed networks involving both hemispheres. Such bilateral networks can include cortical and subcortical structures. On scalp EEG they seem to be present all over and hence the use of the word generalized.

Generalized seizures are further subdivided into tonic-clonic (which is used to describe

Telegram: @medical_k

www.konkur.in

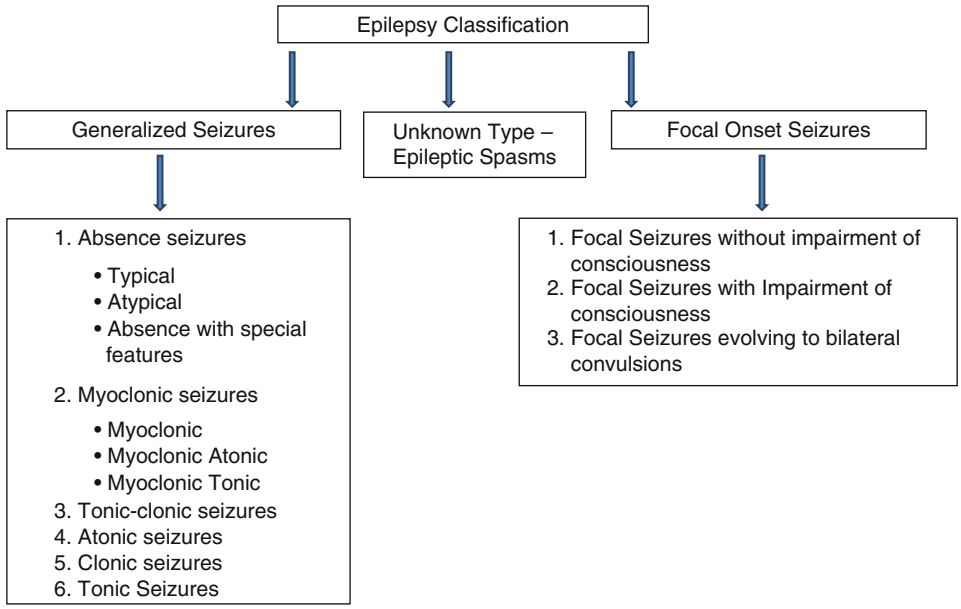

Fig. 1 Epilepsy classifications

stiffening of all four extremities in the tonic phase and rhythmic shaking all extremities in the clonic phase). This was referred to as "Grand Mal." In absence seizures, the basic phenomenon is a blank stare, absence seizures can be typical, atypical or have special features. Other kinds of generalized seizures are myoclonic seizures, clonic seizures, tonic seizure, and atonic seizures (also known as drop attacks).

Focal Epileptic seizures are conceptualized as originating within networks limited to one hemisphere or even one lobe. They may be discretely localized or more widely distributed. The focal seizures can be with or without impairment of consciousness and may secondarily generalize.

Clinical Manifestations

Epileptic seizure can have variable clinical manifestations including many types of auras. After each seizure, there might be a post ictal period, the length of which is variable. The first step in diagnosing epilepsy is obtaining a detailed description of the Aura(warning before a seizure), Ictus (the actual seizure), and Post-ictal phase (immediately after a seizure) from the patient and an observer.

Generalized Seizures

Generalized seizures are thought to arise at some point within the brain and rapidly involved both hemispheres. Different types of generalized seizures have distinct clinical and electrographic features.

Absence Seizures

Typical Absence Seizure

Absence epilepsy accounts for 10–17% of all cases of childhood onset epilepsy, making it the most common form of pediatric epilepsy. The syndrome is characterized by daily frequent brief staring spells, typically beginning at 4–8 years of age, in an otherwise apparently healthy child. The classic electroencephalogram (EEG) displays 3 Hz generalized spike-wave bursts.

Telegram: @medical_k

www.konkur.in

Majority of the seizures last between 5 and 20 sec. Seizure onset is sudden and the child becomes motionless with a vacant stare. The eyes may drift upwards and there is slight beating of the eyelids. Typical absence seizures are frequently repeated many times per day with reports to as many as 100 or more times per day.

Hyperventilation (for about 2 mins) tends to provoke these seizures and can be used in a clinic setting as a diagnostic tool but with caution.

Atypical Absence Seizures

Atypical absence seizures have less abrupt onset and offset, more pronounced changes in tone, variable impairments of consciousness, and tend to last longer than typical absences. They are most likely to occur during drowsiness and are not provoked by hyperventilation or photic stimulation .

Other types of Absence seizures include Myoclonic Absence Seizures & Eyelid Myoclonia with Absence seizures.

Generalized Tonic-Clonic (GTC) Seizures

These seizures usually begin with stiffening of muscles in all extremities along with axial and laryngeal muscles which leads to a loud moan also refer to as an "ictal cry." This is referred to as a tonic phase off the seizure. Following this there can be rhythmic jerking of the arms and legs which is referred to as the clonic phase. An aura is usually not present prior to the seizures.

During the seizure there can be tongue bite and/or urinary and fecal incontinence. During the tonic phase the patient is not breathing, and in children it can lead to perioral cyanosis. Rarely during the tonic phase, one can fracture the vertebral bodies and so back pain after a seizure should be carefully evaluated.

When the patient is having a generalized tonic-clonic seizure the area around him or her should be cleared of any sharp or dangerous objects that might cause injury to the patient if they were to bump into the objects. No attempt should be made to insert any foreign objects in to the patient's mouth. And while the patient is in the clonic phase, no attempt should be made to forcibly hold him down as this can lead to injury.

Myoclonic Seizures

Myoclonus is a brief sudden and involuntary contraction of one part of the body or muscle group. This could either be epileptic or non-epileptic. Myoclonus can occur physiologically when patients are falling to sleep. Myoclonic seizures are characterized by brief, sudden, involuntary muscle contractures involving different combination of head, trunk, and limbs. On EEG, the generalized spike wave or poly-spike and wave discharges are noted with these myoclonic jerks.

The commonest type of Myoclonic Epilepsy is Juvenile Myoclonic Epilepsy (JME). This type of epilepsy starts in the teenage years; it is obviously characterized by Myoclonic, but in about 80% of cases they also have GTC seizures. Rarely, they can also have absence seizures.

Atonic Seizures

Atonic seizures are characterized by a brief and sudden loss of postural muscle tone which usually results in frequent falls (Drop Attacks) in these patients. These last a few seconds and usually do not have any post-ictal confusion.

Focal Seizures

In the past, Focal seizures were referred to as Partial seizures. These were characterized as simple partial and complex partial seizures based on loss of consciousness. However, using the term simple and complex was misleading to the patient who could easily misinterpret these connotations as simple being easier to treat or have a better prognosis as compared to complex seizures. Hence the term focal is more appropriate in the new classification.

Telegram: @medical_k

www.konkur.in

Focal Seizures without Impairment of Consciousness

Focal seizures can present as motor, sensory or autonomic seizures. These mostly.

arise in patients with a structural brain abnormality. For example, a person with a brain tumor in the motor cortex can have rhythmic shaking of his contralateral arm without impairment in consciousness. These can be rather challenging to treat in certain cases and refractory to medications. In the past, these were known as simple partial seizures.

Focal Seizures with Impairment of Consciousness

These were previously referred to as complex partial seizures. They usually consist off an aura which is specific and stereotypical. The patient will have a sudden behavioral arrest along with automatic as well as in certain cases. Automatisms consist off lip smacking, picking hand movements, swallowing, and chewing. Automatisms are ipsilateral to seizure onset region and can be helpful in lateralizing seizure onset to right or left hemisphere.

Focal Seizures Evolving to Bilateral Convulsive Seizures

These were previously referred to as complex partial seizures with secondary generalization. This term has been now replaced with bilateral convulsive seizures. These usually consist of an aura and electrographically the seizure discharge spreads to both hemispheres including the motor strip which causes tonic-clonic seizures. These patients tend to have an aura which makes it different from generalized seizures where it might not be present. Also, paying attention to automatism and forced head deviation can help with lateralization and localization.

Focal seizures are usually referred to by the lobe of the cortex the seizures originate in (Table 1).

Seizure Syndromes by Age Group

Neonatal Period

- Benign familial neonatal epilepsy (BFNE).
- Early myoclonic epilepsy (EME).
- Ohtahara syndrome.

Infancy

- Dravet syndrome.
- West syndrome.
- Epilepsy of infancy with migrating focal seizures.
- Benign infantile epilepsy.
- Myoclonic epilepsy of Infancy.
- Myoclonic encephalopathy in non-progressive disorders.
- Benign familial infantile epilepsy.

Childhood

- Febrile seizures plus.
- Panayiotopoulos syndrome.
- Benign epilepsy with centro-temporal spikes (BECTS).

Table 1 Focal seizures clinical characteristics

Focal seizures	Clinical characteristics
Temporal lobe seizures	Aura – Epigastric sensation, déjà vu, abnormal taste or smell, intense anxiety Ictus – Blank stare, with or without oral automatisms, hand automatisms Post-ictal – Confusion & disorientation
Frontal lobe seizures	Usually motor seizures, vocalization (dominant hemispheres) nocturnal seizures, brief in duration, fencing posture, bicycling leg movements, Jacksonian march, forced eye/head deviation, may have no postictal period.
Parietal lobe seizures	Paraesthesias
Occipital lobe seizures	Visual phenomenon

Telegram: @medical_k

www.konkur.in

- Epilepsy with myoclonic atonic seizures.
- Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE).
- Gastaut syndrome.
- Epilepsy with myoclonic absence.
- Lennox-Gastaut syndrome.
- Landau-Kleffner syndrome.
- Childhood absence epilepsy.
- Epileptic encephalopathy with continuous spike and wave during sleep.

Adolescence

- Juvenile absence epilepsy.
- Juvenile myoclonic epilepsy.
- Progressive myoclonic epilepsies.
- Epilepsy with generalized tonic-clonic seizures alone.
- Autosomal dominant epilepsy with auditory features.
- Other familial temporal lobe epilepsies.

Less Age Specific

- Reflexive epilepsies.
- Familial focal epilepsy with variable foci.

Seizures in Neonates and Infants

Benign Familial Neonatal Seizures

These are also known as Third day fits. Seizures consist of tonic stiffening, apnea/cyanosis, autonomic signs, face and limb clonus, lasting about 1–3 min. These are associated with a potassium channel abnormality in the KCNQ2 & 3 channels. Seizures usually last for about 3–6 months and then resolve spontaneously.

Early Infantile Epileptic Encephalopathy (Ohtahara)

Ohtahara syndrome affects newborns, usually within the first 3 months of life (most often within the first 10 days) in the form of epileptic seizures. More common in males. Infants have primarily tonic seizures, but may also experience partial seizures, and, rarely, myoclonic seizures. Ohtahara syndrome is usually caused by metabolic disorders or structural damage in the brain, although the cause or causes for many cases can't be determined. Majority of the cases have cortical malformation. The EEG of infants with Ohtahara syndrome reveal a characteristic pattern of "burst suppression." Usually drug resistant epilepsy.

Early Myoclonic Encephalopathy

These occur typically within the first one month of life. As the name describes myoclonic seizures are the predominant type in this syndrome. Patients usually have a concurrent nonketotic hyperglycinemia. There is progression to tonic spasms as they grow older.

Infantile Spasms

These can be extensor or flexor spasms and typically occur between 4 and 8 months of life. Also known as "salaam attacks" in the past. It tends to occur in clusters and tend to be at the time of sleep wake transition. There is sudden flexion or extension of all extremities including the axial musculature which corresponds to an electrodecremental response on EEG. EEG background is high voltage slowing, disorganized pattern with multifocal sharps also referred to as hypsarrhythmia. Most patients have intellectual disability. Treatment includes ACTH and Vigabatrin.

Benign Myoclonic Epilepsy of Infancy

Onset is usually between 4 months and 3 years of age and patients eventually outgrow this. There is sudden jerking of the extremities along with eyedrops which make him look like infantile spasms. The EEG, however, shows a generalized spike and polyspike pattern instead of the classical hypsarrhythmia seen in infantile spasms . Also

Telegram: @medical_k

www.konkur.in

they have a normal development which clearly distinguishes this from infantile spasms. The main treatment is valproate; other options include levetiracetam or clonazepam.

Seizures in Childhood

Febrile Seizures

These occur between 6 months and 5 years of age. Febrile seizures are convulsions brought on by a fever in infants or small children. During a febrile seizure, a child often loses consciousness and shakes, moving limbs on both sides of the body. There are simple and complex febrile seizures.

Simple Febrile Seizure

Around 80–90% of all febrile seizures are simple febrile seizures. The setting is fever in a child aged 6 months to 5 years. The single seizure is generalized and lasts less than 15 min. The child is neurologically normal. The cause of the fever is always outside the central nervous system. No antiepileptic medications needed.

Complex Febrile Seizures

The seizure duration is greater than 15 min. There are focal seizure manifestations or there is seizure recurrence within 24 h. Abnormal neurological status of the child and a family history of epilepsy. These seizure have a worse prognosis and have a much higher incidence of subsequent epilepsy.

Occurs in about 3–5% of the US population with a median age of 18 months. About one third of these patients will have a second febrile seizure (23–42%). At about half of those, one third will have a third febrile seizure (7–30%). Higher recurrance when the age of onset is under 1 year.

Management of febrile seizures

1. Lumbar puncture to rule out infection as indicated clinically.
2. CBC, S. Calcium, S. Electrolytes, UA.
3. EEG.
4. MRI – If prolonged or focal febrile seizure or clinically indicated.

Dravet Syndrome or Severe Myoclonic Epilepsy of Infancy (SEMI)

Dravet syndrome appears during the first year of life often triggered by hyperthermia, it is usually a generalized tonic-clonic seizure or hemiclonic seizure. Later, other seizures types arise, including myoclonus. Status epilepticus may also occur. Children with Dravet syndrome typically experience poor development of language and motor skills. They are known to be hyperactive. There is a genetic cause identified – SCN1A mutation or copy number variant in 80% of cases. Usually pharmacoresistant. Medications acting via sodium channel can make seizures worse like carbamazepine, oxcarbazepine, etc. Treatment options are Valproate, Topamax, Stiripentol, and Cannabidiol.

Rolandic Epilepsy or Benign Epilepsy with Centro-Temporal Spikes (BECTS)

This is the most common focal epilepsy in childhood with onset between 2 and 13 years of age with a peak around 7–10 years of age. It is mostly bilateral although in some cases it can be unilateral. Seizures usually occur during the first part of the night but 10–20% of the patients can have daytime seizures as well. Seizures can be sensory or motor consisting of drooling as well as abnormal feeling in the tongue, lips, and gums, or abnormal movements of the tongue larynx and pharynx. Rarely they can generalize as well.

EEG shows centro-temporal spikes more during drowsiness and sleep. Carbamazepine and Valproate are useful as initial monotherapy. Treatment beyond the age of 14 to 16 years is not indicated as BECTS resolves by that age.

Lennox Gastaut Syndrome (LGS)

LGS is characterized by multiple seizure types, mental retardation and a diffuse slow spike and wave discharge on EEG [5]. LGS is characterized by the patient having multiple seizure types which include atonic, atypical absence, tonic, focal, as

Telegram: @medical_k

www.konkur.in

well as generalized tonic-clonic seizures. Seizure onset is around 3–5 years of age. LGS patients can have preceding infantile spasms. EEG shows a characteristic slow generalized spike and wave pattern with a frequency less than 2.5 Hz. Treatment options are topiramate, levetiracetam, lamotrigine, clobazam, rufinamide, and cannabidiol. Vagal Nerve Stimulation is also an option. Corpus Callosotomy and Ketogenic diets have also been used.

Landau Kleffner Syndrome

This presents with seizures along with progressive aphasia (apparent word deafness or verbal auditory agnosia) and language regression. The peak onset is around 3–6 years of age and is more common in boys. EEG shows continuous generalized spike and wave activity during sleep also known as ESES (Electrical status epilepticus of sleep). Typically they have seizures first and then there is onset of regression. Eventually, Seizures tends to resolve more than the regression. Sodium channel antiepileptic drugs (PHT,CBZ,OXC) should be avoided in these patients. Corticosteroid treatment has shown benefit in Landau Kleffner syndrome. Multiple subpial transection (MST) surgery has been used in selected cases, although of unproven benefit.

Seizures in Adolescence

Juvenile Myoclonic Epilepsy

This is the most common form of generalized epilepsy in the adolescent age group typically occurring between 12- and 8 years of age. Most of the seizures are upon awakening. They can have myoclonic seizures, absence seizures and generalized tonic-clonic seizures.

The children will have myoclonic jerks early in the morning. For example, sudden jerking of the hand while brushing her teeth or spilling milk while eating cereals. They can have generalized tonic-clonic seizures in 80% of the cases. These patients are very photosensitive and video games can often trigger seizures. EEG shows diffuse 4–6 Hz generalized spike/polyspike and wave pattern. A genetic locus for JME is in chromosome 6p11.

Sodium channel antiepileptic medications like carbamazepine should be avoided in these cases as they can make the seizures worse. Levetiracetam, Valproic acid, and lamotrigine are better choices for antiepileptic drug therapy. A large number of these patients are well controlled on antiepileptic medications which have to be continued throughout their life.

Management of Seizures

History

It is important to ask the *age of seizure onset* as this information helps in the diagnosis of the type of seizure, as explained in the preceding section. Next one should inquire about the *seizure risk factors* like perinatal hypoxia, family history of seizures, history of febrile seizures (can be associated with temporal lobe seizures), any head injury with loss of consciousness, and any history of meningitis or encephalitis. Next, it is important to get a description of the seizure from an eyewitness and the patient. The patient should be asked about any warning before the seizure – *Aura*. The eyewitness should be asked about the seizure itself – *Ictus* and then the *post-ictal phase.* Then we need to find out about the duration and frequency of the seizures. All of the above information is critical to making an accurate diagnosis. As Temporal Lobe seizures last for a minute whereas frontal lobe seizures can last for seconds, temporal lobe seizures usually occur a few times a week whereas frontal lobe seizures can occur a few times a day.

Next, we need to find out what antiepileptic drugs(AEDs) the patient is taking and also ask about the AEDs that the patient has used in the past. It is important to find out the results of the workup undertaken in the past like CT Head, MRI Brain, EEG, and Video-EEG.

Neurological Exam

A good neurological exam is of critical importance in patients being evaluated for seizures. It

Telegram: @medical_k

www.konkur.in

is important to note any external signs of trauma; a good cognitive exam is important to see if there are any associated cognitive deficits. Dysmorphic facial features should also be noted as they may be associated with cortical malformations. Head circumference should be measured. Dermatological stigmata can give clues to a neurocutaneous disorder. Deficits on motor, sensory exam can indicate a hemispheric lesion.

Neuroimaging

MRI Brain is the investigation of choice and should be done with and without Gadolinium. We are looking for obvious cortical lesions causing seizures like tumors, stroke, cortical malformation, etc. It should also be done to check for a very common abnormality seen in Temporal Lobe Epilepsy, Mesial Temporal Sclerosis (MTS). In MTS, there is unilateral atrophy of the hippocampus involved and there is an increase in the T-2 signal in that hippocampus. CT Head is done in the Emergency Department essentially to rule out a bleed or other obvious abnormalities.

Every seizure patient should get an MRI Brain and an EEG (Figs. 2 and 3).

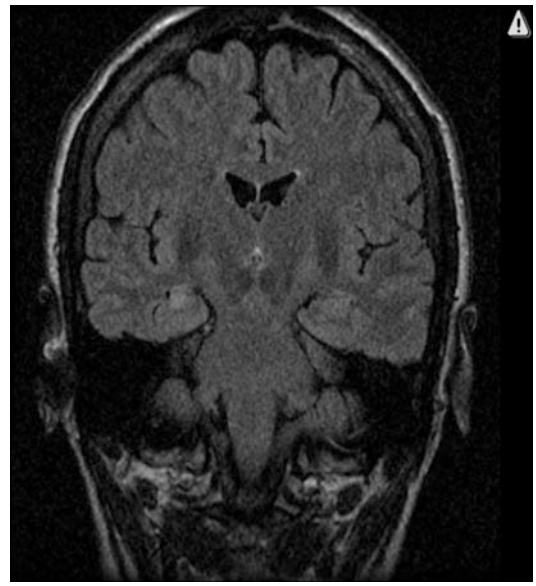

Fig. 2 MRI Brain Coronal FLAIR– Mesial Temporal Sclerosis – Increased T2 signal

Electroencephalography (EEG)

EEG is an essential test for all seizure patients. It helps in the diagnosis and classification of seizures. EEG is a graphical representation of the electrical activity of the brain as recorded by electrodes placed on the scalp of the patient (Fig. 4). It can show focal epileptic discharges suggestive of focal epilepsy or it can show generalized(diffuse) epileptiform discharges diagnostic of generalized epilepsy (Figs. 5 and 6). Spikes, sharps, polyspikes, and spike and wave discharges are the epileptic discharges indicating a tendency to have seizures.

A normal EEG does not rule out epilepsy as it is only abnormal in one third of the cases of definite epilepsy. Repeating the EEG does increase the yield in cases of epilepsy.

Video-EEG Monitoring

This is an inpatient testing in the Epilepsy Monitoring Unit of the hospital. The patient is hooked up to the EEG and is also being monitored simultaneously on video; they stay from one to a few days till the required data is gathered. Video-EEG monitoring is required in specific circumstances. It is an advanced testing done for epilepsy evaluation. It is performed when the physician needs to establish whether the paroxysmal spells represent epileptic seizures. It is also done to establish the type and frequency of seizures. And it represents the initial step in seizure focus localization for epilepsy surgery.

Other Tests

There are certain other tests done for epilepsy particularly for epilepsy surgery. These include FDG-PET Scan which determines the uptake of radiolabeled glucose by the brain. The epileptic focus is malfunctioning and so does not take up the glucose as well as the other regions. Neuropsychological Testing is done to determine the area of the brain that is not functioning optimally. The other tests done include a SPECT Scan (measures blood flow) and Magnetoencephalography.

Medical Treatment

Medications are the mainstay for the treatment of epilepsy [6]. Approximately 70% of epilepsy patients can be treated by anti-epileptic drugs (AEDs). There has been an increase in the number of medications available for the treatment of epilepsy in the last two and a half decades (Table 2).

A good clinical pearl to follow when using all AEDs is "start low and go slow," start at a low dose and titrate up slowly based on clinical response. Drug Interactions are an important thing to keep in mind while using AEDs. Hormonal contraceptives can be compromised by the following antiepileptic medications – phenytoin, carbamazepine, phenobarb, Topamax, lamotrigine, and oxcarbazepine.

All AEDs may cause suicidal thoughts or actions in a very small number of people and one should educate the patients about this possibility and monitor them for this.

Carbamazepine may worsen seizures in Myoclonic epilepsy.

Epilepsy Surgery

When patients do not respond to medications then they are candidates for resective epilepsy surgery, this is a possibility if there is a localized seizure focus that can be safely resected. Epilepsy surgery is certainly recommended in refractory Mesial Temporal Lobe Epilepsy (MTLE), as a randomized study has shown that such patients who underwent surgery (Anterior Temporal Lobectomy) had a 58% seizure freedom rate as opposed to only a 8% seizure freedom rate for those treated with further medications. Resective epilepsy surgery may involve intracranial EEG recording.

Vagal Nerve Stimulation

Vagal nerve stimulation is an FDA approved form of treatment of refractory epilepsy. It is successful in about 40% of cases and success is defined as a 50% reduction in seizures. This device is surgically implanted, pulse generator in the chest and electrodes on the vagus nerve in the neck. The stimulation parameters can be managed externally by a programming wand and a computer via radiofrequency signals.

Deep Brain Stimulation (DBS)

DBS is another FDA approved treatment for people 18 years and older with medically refractory partial-onset epilepsy. DBS for epilepsy targets the anterior nucleus of the thalamus. There are two parts to the surgery, leads are placed bilaterally in the anterior nucleus of the thalamus and the neurostimulator is implanted under the skin in the upper chest. The responder rate (percentage of subjects with $\geq$50% seizure reduction) was 43% at one year and 74% at year seven.

Responsive Neural Stimulation (RNS)

This is another treatment option for medically refractory focal epilepsy. This is an adjunctive therapy for reducing the frequency of seizures in individuals 18 years of age or older with partial onset seizures who have undergone diagnostic testing that localized no more than 2 epileptogenic foci, are refractory to two or more antiepileptic medications, and currently have frequent and disabling seizures.

Status Epilepticus

Status epilepticus is a life-threatening emergency requiring immediate medical attention and affects 65,000 to 150,000 people in the United States each year [9]. It is not a disease itself but rather a manifestation of either an underlying primary central nervous system insult or a systemic disorder with secondary effects.

Roughly 55,000 deaths are associated with status annually. There is about a 20% mortality in status epilepticus.

The definition of status epilepticus is having continuous seizure activity for greater than 30 min or 2 or more sequential seizures without

Table 2 Antiepileptic medications - summary

Name of antiepileptic medication	Indication	Major side effects	Miscellaneous
Phenytoin	Focal epilepsy, secondary generalization, GTC seizures	Hepatic insufficiency, bone density decrease, rash, Ataxia, Hirsuitism	Monitor LFTs
Carbamazepine	Focal epilepsy, secondary generalization	Bone marrow depression, hyponatremia, liver insufficiency, rash, ataxia, bone density decrease	Monitor CBC, CMP,
Valproate	Generalized seizures, secondarily generalized seizures.	Hepatic failure, tremors, hair loss, weight gain, teratogenecity	Monitor LFTs
Phenobarb	Focal seizures	Sedation	Monitor cognitive decline
Oxcarbazepine	Focal seizures	Hyponatremia (more common in elderly), rash	Hyponatremia in the first 3 months
Lamotrigine	Focal seizures, generalized seizures	Rash, including Stevens Johnson and toxic epidermal necrolysis hypersensitivity reactions.	Side effects more common with concomitant valproate use and reduced with slow titration
Levetiracetam	Focal & generalized seizures	None	Irritability/behavior change
Topiramate	Focal & generalized seizures	Nephrolithiasis, open angle glaucoma, hypohidrosis in children	Metabolic acidosis, weight loss, language dysfunction
Zonisamide	Focal seizures	Rash, renal calculi, hypohidrosis in children	Irritability, photosensitivity, weight loss
Gabapentin	Focal seizures	None	Weight gain, peripheral edema, behavioral changes in children
Pregabalin	Focal seizures	None	Dizziness, somnolence, weight gain, edema, blurred vision, and peripheral edema
Ethosuximide	Generalized – Absence seizures	Allergic reaction-DRESS, pancytopenia, nausea, abdominal pain, rash	Used only for absence epilepsy
Eslicarbazepine	Focal seizures	Allergic reaction, rash	Dizziness, sleepiness, nausea, headache, double vision, vomiting, feeling tired, problems with coordination, blurred vision, hyponatremia and shakiness
Perampanel	Focal seizures & generalized seizures	Serious or life-threatening psychiatric and behavioral adverse reactions including aggression, hostility, irritability, anger, and homicidal ideation and threats have been reported.	Dizziness, somnolence, fatigue, irritability, falls, nausea, ataxia, balance disorder, gait disturbance, vertigo and weight gain
Clobazam	In the USA, it is approved for use only as adjunctive treatment of seizures associated with Lennox-Gastaut syndrome	Stevens-Johnson syndrome and toxic epidermal necrolysis	Constipation, somnolence or sedation, pyrexia, lethargy, and drooling

(continued)

Telegram: @medical_k

www.konkur.in

Table 2 (continued)

Name of antiepileptic medication	Indication	Major side effects	Miscellaneous
Rufinamide	As adjunctive treatment of seizures associated with Lennox-Gastaut syndrome	Multi-organ hypersensitivity, known to shorten the QT interval	Headache, dizziness, fatigue, somnolence, and nausea
Cannabidiol *(Marijuauna based)*	Lennox-Gastaut syndrome and Dravet syndrome	Hepatsic injury, omnolence, hypersenstivity reaction	Somnolence; decreased appetite; diarrhea; transaminase elevations; fatigue, malaise, and asthenia; rash; insomnia, sleep disorder, and poor-quality sleep
Cenobamate	Focal or partial-onset seizures	DRESS/multiorgan hypersensitivity – Particularly with fast titration, shortening of the QT interval	Somnolence, dizziness, fatigue, diplopia, and headaches

full recovery of consciousness to baseline. However, with the need for prompt care of patients, there is an operational definition that is used for management purposes, which is seizures lasting longer than 5 min are considered to be Status Epilepticus.

The initial management is like managing any medical emergency, airway, breathing, and circulation need to be attended to. Check for blood sugar, give 50% glucose and thiamine as indicated. Establish two I/V lines as you should avoid infusing Dilantin through an I/V that has been used to give glucose. Send labs including drug levels and a toxicological screen. Treat hyperthermia, but avoid treating high blood pressure unless there is end organ damage, as the blood pressure will come down as you treat status epilepticus.

The drug treatment of status epilepticus follows a protocol. Here we describe the Creighton Status Epileptics Treatment protocol [8] (Fig. 7). The drug of choice for initial treatment is Lorazepam [7]. Then the patient is given Phenytoin. After phenytoin, there are two options, one is to administer phenobarb and the other is to go to anesthetic agents directly. However, before any of these two options are exercised, the patient must be electively intubated as both these medications will suppress the respiratory drive. These patients must be on continuous EEG monitoring to determine whether the patient has stopped having seizures, as the patient maybe in nonconvulsive status epilepticus or after paralyzing the patient for intubation this is the only way we can find out about seizure activity.

The other drug options for initial treatment of status epilepticus are intramuscular midazolam or I/V diazepam. Other medications that can be used after the initial treatment are I/V Levetiracetam or I/V Valproic Acid.

Specific Conditions

Sudden, Unexplained Death in Epilepsy (SUDEP)

Sudden Unexpected Death in Epilepsy (SUDEP) is a nonaccidental death in a person with epilepsy, who was otherwise in a usual state of health. On autopsy, no other of cause of death can be found. The death should not be due to status epilepticus, which is a prolonged life-threatening seizure episode.

The rate of SUDEP is approximately one death per 1000 in people with epilepsy per year. In people with frequent epileptic seizures that are poorly controlled with medications, the rate is approximately 1 in 150 per year.

Telegram: @medical_k

www.konkur.in

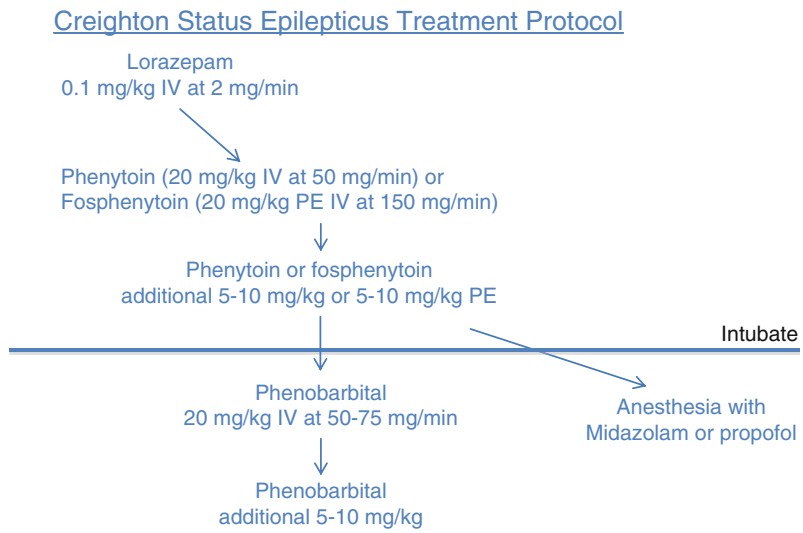

Fig. 7 Creighton status epilepticus treatment protocol

The risk factors for SUDEP include the following:

- Having uncontrolled generalized tonic-clonic seizures.
- Early age of epilepsy onset or long duration of epilepsy.
- Not taking medications as prescribed.
- Stopping or changing medications abruptly.
- Young adult age (20–40 years old).
- Intellectual disability (IQ $<$ 70).

Women with Epilepsy

There are important unique issues to consider when treating women with epilepsy. Estrogen is a proconvulsant and progesterone is an anticonvulsant [11]. During the menstrual cycle seizures can be exacerbated during midcycle, due to an estrogen peak, and then during menstruation due to progesterone withdrawal. Pregnancy in women with epilepsy causes worsening of seizures in one third of cases, no change in another third, and improvement of seizures in one third of patients. All antiepileptic medications can cause teratogenicity and so patients should be educated about this on the first clinic visit and they should be started on Folic Acid. Vaproate has the highest risk of teratogenicity and should be avoided in women in child-bearing age group. Breast feeding is recommended but the child's pediatrician or family physician should be aware of the antiepileptics the mother is on. Certain antiepileptic medications can result in failure of hormonal based oral contraceptives, like phenytoin, phenobarb, carbamazepine, and lamotrigine. Please check the prescribing information of AEDs to confirm the current teratogenic effects and its effect on hormonal contraceptives.

First Seizure

The risk of recurrence after a first seizure is about 33% without any testing. If both the MRI Brain, neurological exam, and EEG are within normal limits then the risk decreases to about 24% and thus we do not start such a patient on chronic antiepileptic medication. If both are abnormal as in the case of a cortical tumor, the risk of recurrence is high and so we do recommend treatment with an antiepileptic medication [10]. When a patient has a second seizure, then the risk of the third seizure is over 70% and so we then do recommend treatment with antiepileptic medications. And thus, the definition of epilepsy is two or more unprovoked seizures.

First Seizure Management

1. History.
2. Physical examination.

Telegram: @medical_k

www.konkur.in

3. Labs – Complete blood counts, Complete metabolic panel and urine drug screen.
4. Rule out mimics.

- Syncope.
- Hyperventilation.
- Panic attack.
- Psychogenic seizure.
- Transient ischemic attack.
- Transient global amnesia.
- Migraine equivalents.

5. Imaging – MRI brain with and without contrast (Preferable) or CT head with and without contrast.
6. EEG – Higher yield with sleep deprived EEG.

General Principles

Introduction

Cerebrovascular disease (CVD) is a general term encompassing the brain abnormalities that result from pathologies of its blood vessels (e.g., atherosclerotic stenosis, aneurysm, dissection, inflammation). CVD can manifest as an acute or chronic condition and can affect any part of the central nervous system. Stroke is essentially a clinical term and is defined as an abrupt onset neurological deficit attributable to a focal vascular cause. Imaging studies and laboratory data are used to confirm the diagnosis and determine its etiology. Stroke is a heterogeneous entity and essentially is classified as ischemic and hemorrhagic. They will be the focus of this chapter.

Epidemiology

Stroke is the fifth leading cause of death and a major cause of adult disability in the USA [1]. A stroke occurs every 40 seconds nationwide, corresponding to nearly 800,000 cases annually. Of these, three quarters are first time strokes, and the remainder are recurrent events. There are 7.0 million estimated stroke survivors (prevalence of 2.5%) in the USA [2]. Despite data showing a decline in incident stroke, the number of strokes is projected to increase by 3.4 million by 2030 (20.5% increase in prevalence from 2012) due to advancing life span [3]. Every 4 min someone in the USA dies from a stroke. In 2017, stroke was responsible for about 150,000 deaths in the USA [1]. According to the World Health Organization (WHO) stroke represents the fourth leading cause of death in the low-income countries and the second cause worldwide [4]. The risk of having a stroke varies with race and ethnicity, but prevalence is higher in women than men across all races: white females 2.5% vs 2.4%, non-Hispanic black females 3.8% vs 3.1%, Hispanic females 2.2% vs 2.0%, and non-Hispanic Asian females 1.6% vs 1.1% [2]. In the USA, each year about 55,000 more females than males have a stroke [5]. Data from the Framingham Heart Study showed that women above age 55 had a significantly higher lifetime risk of stroke (17% vs 15%), primarily because women live longer [6].

Pathogenesis

The mechanism leading to impairment of blood flow in various areas of the brain is broadly classified into two types: ischemic and hemorrhagic. Stroke definition however does not distinguish between ischemic or hemorrhagic stroke or between subtypes of ischemic stroke.

Ischemic

Ischemic stroke is caused by a blood flow obstruction to the brain and accounts for 87% of all strokes [2]. Determining the cause of stroke as early as possible is essential, as it guides the decision for further management. TOAST stroke subtype classification (Trial of ORG 10172 in Acute Stroke Treatment) was introduced in 1993 primarily to allow investigators to report the effect of various treatments based on stroke etiological subgroups [7]. The original TOAST classification denotes five subtypes of ischemic stroke:

1. Large-artery atherosclerosis
2. Cardio-embolism
3. Small-vessel occlusion
4. Stroke of other determined etiology
5. Stroke of undetermined etiology

Hemorrhagic

Intracranial bleeding could be spontaneous or secondary to trauma (subdural hematoma, epidural hematoma); the latter group is not classified under stroke per se, although a stroke syndrome could occur from compression over the brain from outside or increased intracranial pressure (ICP). A hemorrhagic stroke occurs when a weakened blood vessel ruptures (e.g., aneurysm or AVM). The most common cause of spontaneous cerebral hemorrhage is uncontrolled hypertension.

There are two main subtypes of hemorrhagic stroke: intracerebral hemorrhage (ICH) and subarachnoid hemorrhage (SAH). In ICH blood vessels rupture, and bleeding occurs within brain parenchyma, while in SAH blood vessels rupture,

Telegram: @medical_k

www.konkur.in

and bleeding occurs in the subarachnoid space. Neurological function is impaired by the mass effect exerted by hematoma on surrounding tissue, perihematomal edema and/or cerebral ischemia from associated vasospasm.

Risk Factors

Stroke risk factors have been reliably identified from prospective population-based studies such as the Framingham study. Risk factors are best thought of as modifiable and non-modifiable [8].

Non-modifiable include older age, sex, race/ethnicity, and genetic predisposition.

Modifiable stroke risks are multiple:

1. **Major** (most important and/or well described) hypertension, smoking, cholesterol, obesity, diabetes mellitus, metabolic syndrome, atrial fibrillation, structural cardiac abnormalities, atherosclerosis, prior stroke/transient ischemic attack (TIA), as well as smoking, sedentarism, alcohol, and socioeconomic class.
2. **Minor** (less described or less important): thrombophilia, oral contraceptive pills (OCP)/hormone replacement therapy (HRT), migraine, obstructive sleep apnea (OSA), homocysteine, diet, recreational drugs, infection, inflammation.

Prevention of Cerebrovascular Disease

Prevention of cerebrovascular disease includes primary and secondary prevention strategies.

Primary Prevention Strategies

Primary prevention includes measures to prevent or slow down development of cerebrovascular disease in those patients who did not suffer any stroke event.

Given the multitude of potential interventions, the long-term goal is to find a personalized approach to primary prevention. There is no ideal stroke risk assessment tool that would consider the effect of many potential contributory factors. However, the use of Framingham Stroke Profile and AHA/ASA CV Risk Calculator helps identify the individuals that may benefit from well-defined therapeutic interventions [9].

Below are evidence-based recommendations from American Heart Association/American Stroke Association Guidelines [9]. Only highest level of evidence is enumerated below:

1. Obtaining a detailed family history to identify the people who are at high risk of stroke.
2. Physical activity is recommended, being associated with a reduction in the risk of stroke. Adults should do at least 150 min/week (moderate intensity) or 75 min/week (vigorous intensity) aerobic physical activity.
3. Diet and nutrition are important lifestyle recommendations for stroke risk reduction. DASH-style diet (based on fruits, vegetables and low-fat dairy, low on saturated fat) is recommended to lower blood pressure. Reduced sodium intake and increased potassium intake (from fruits and vegetables contribution) lowers blood pressure and so the risk of stroke.
4. **Hypertension is the most important well-documented modifiable stroke risk factor.** Successful reduction in BP is more important than what specific agent is used to this goal. Patients should be screened annually for HTN and lifestyle modifications (as above).
5. Patients with prehypertension (SBP 120–139 mm Hg or DBP 80–89 mm Hg) should be discussed health-promoting lifestyle modifications. Patients with hypertension should be treated to target BP $<$140/90.
6. Self-measured BP monitoring is recommended to improve BP control.
7. Overweight (BMI 25–29 kg/ m2) and obese (BMI $>$ 30 kg/m2) individuals are recommended to lose weight in order to lower their BP as well as their risk of stroke.
8. Glycemic control in patients with diabetes is needed to reduce microvascular complications. In diabetic patients controlling BP to below 140/90 mm Hg and treatment with statin are recommended to reduce the risk of

Telegram: @medical_k

www.konkur.in

first stroke. It is unclear whether aspirin should be used in diabetic patients with low 10-year CVD risk for primary stroke prevention.

9. Smoking cessation by a combination of counseling and drug therapy (bupropion, nicotine replacement, or varenicline).
10. Smoking cessation in women suffering from migraine with aura should be strongly recommended. Alternatives to oral contraceptives (esp. those containing estrogens) might be considered in these women given their increased risk of stroke.
11. For patients with non-valvular AF with CHA2DS2-VASc score ≥ 2 and reasonably low risk of hemorrhagic complications, oral anticoagulants are recommended (warfarin INR 2–3, dabigatran, apixaban, rivaroxaban).
12. Closure of LAA can be considered in patients with high-risk AF who are not deemed suitable for long-term anticoagulation, if the risk of the procedure is acceptable.
13. Patients with asymptomatic carotid stenosis should be prescribed daily ASA, a statin, receive lifestyle counseling and be screened for other risk factors.
14. Referral of patients with atherosclerotic asymptomatic carotid artery disease above 50% for annual duplex ultrasonography monitoring and assessment of response to other treatment interventions is appropriate.
15. Screening low-risk population for asymptomatic carotid artery stenosis is not recommended.
16. For patients with valvular AF with CHA2DS2-VASc score ≥ 2 and reasonably low risk of hemorrhagic complications, long-term treatment with warfarin (goal INR 2–3) is recommended. Appropriate anticoagulation treatment in patients with valvular heart disease and no AF.
17. Appropriate referral for patients with sickle cell disease for prevention of stroke.
18. Counseling against unhealthy alcohol drinking.
19. Addressing illicit drug abuse.
20. Identifying patients with sleep apnea and referring for treatment.
21. Implementation of programs (e.g., in ED) to systematically identify and treat risk factors in all patients at risk for stroke is essential.

Secondary prevention includes measures in management of patients with cerebrovascular disease to prevent stroke recurrence and/or advancing vascular cognitive decline. The following sections of this chapter discuss this stage of prevention in more depth.

Ischemic Stroke and Transient Ischemic Attack (TIA)

Transient Ischemic Attacks

TIAs have been classically defined as stroke symptoms that resolve completely within 24 h. Most TIAs, however, last less than 1 h, and half of these are associated with acute infarction on brain MRI. With such advances in neuroimaging, a new TIA definition was proposed in 2002 to reflect tissue-based changes rather than duration of clinical symptoms. Currently, TIA is defined as a transient neurological dysfunction caused by focal ischemia of the brain, retina, or spinal cord, without MRI evidence of acute infarction, irrespective of the duration of symptoms [10, 11].

TIAs are heralds of ischemic stroke, as 10–15% are followed by a stroke within 90 days, and half of these happen in the first 48 h after TIA [12]. Urgent evaluation and treatment have been associated with up to 80% decrease in stroke risk after TIA [12]. Therefore, approach to the patients with TIA should include a thorough evaluation and identification of those patients with high risk of stroke after TIA [11, 12]. ABCD2 score is a well-validated tool to estimate risk of stroke after a suspected TIA considering age of 60 and above, presence of high blood pressure, clinical features of speech or motor impairment, duration of symptoms, and history of diabetes [13]. Because TIA patients experience only brief periods of painless neurological deficit, they may ignore their symptoms for days or weeks or may

Telegram: @medical_k

www.konkur.in

present to outpatient or urgent care setting instead of emergency centers, delaying their treatment. The pathophysiology of TIAs is identical to that of ischemic strokes (a serious transient blood clot), and recommended investigations are identical. Neuroimaging should be obtained within 24 h of onset of symptoms, preferably brain MRI. A noninvasive imaging of cerebral vessels should be done as part of a routine evaluation [11, 14]. There should be low threshold for hospital admission in patients with unreliable outpatient follow-ups for proper evaluation and monitoring [11, 14].

Ischemic Stroke

Most often the focal neurological symptoms suggesting a new stroke do persist, and when the brain MRI reveals underlying infarct, the patient is said to have suffered an ischemic stroke. Time to intervention from the onset of symptoms is very critical in the evolution and ultimately the outcome of ischemic stroke [15]. Over the last decade, several major changes in treatment have brought more hope to patients with acute ischemic stroke (AIS). However, the access to these therapies depends on patients arriving as early as possible to a specialized stroke care center. The American Heart Association (AHA)/American Stroke Association (ASA) has encouraged development and maintenance of public and medical education programs, as being essential to decrease the stroke onset to ED arrival times of the patients.

Prompt recognition of the signs and symptoms of stroke and increase use of EMS system (by calling 9–1-1 rapidly) leads to prompt evaluation of the stroke patients and increase in timely use of acute stroke interventions. Although progress has been made, still over a third of stroke patients fail to use Emergency Medical Services (EMS), leading to delay in acute stroke treatment [16].

The AHA/ASA's website is a great resource for both public and healthcare professionals for updated tools and information to increase stroke awareness [17]. In particular, the acronym **FAST** means to recognize *facial drooping*, *arm weakness*, and *speech impairment* as possible stroke symptoms, and if present then it is *time to call* for help by calling EMS [14, 17]. Other symptoms of concern may be summarized by the "five suddens"**:** sudden weakness and/or numbness of one part of the body, sudden confusion and trouble communicating, sudden imbalance, sudden severe headache, and sudden vision impairment [14, 17].

EMS will assess and transport the patient with positive stroke screen to the closest hospital that can administer iv thrombolysis and/or perform thrombectomy. These are "acute stroke ready," primary or comprehensive stroke hospitals, and their emergency departments function based on organized protocols aiming the most rapid evaluation of patients with suspected stroke. These stroke systems of care are continuously subjected to quality improvement processes to ensure evidence-based practices and improving patient care and outcomes [14]. Telemedicine solutions (Telestroke, Teleradiology) are increasingly used when on-site expertise is not available, and studies revealed that Telestroke use had no difference in mortality and functional outcome at 3 months, when compared to stroke centers [14].

Early Management of Patients with Acute Ischemic Stroke

Prehospital management of stroke patients focus on providing support to airway, breathing, and circulation as part of the adult cardiovascular life support (ACLS) program; oxygen supplementation, fluid administration in patients with hypotension, and hypoglycemia management if needed are being addressed [14]. In ED, obtaining a thorough past medical history, current medications and social history will assist the stroke team in differentiating a stroke from stroke mimics such as hypoglycemia, seizure disorder, migraine, delirium, psychosomatic disorder, alcohol and substance abuse, movement disorder, isolated cranial nerve palsy, and central nervous system neoplasm [14].

The neurological examination is focused on the National Institutes of Health Stroke Scale **(NIHSS),** a helpful tool used by healthcare

Telegram: @medical_k

www.konkur.in

professionals to assess patients with stroke symptoms rapidly, accurately, and reliably. Cardiovascular examination and looking for signs of coagulopathy are very pertinent in the acute assessment. On a side note, the blood pressure management principles differ between the types of stroke and are discussed in their respective sections later in the chapter.

NIHSS scale estimates patient's level of consciousness, orientation, attention, language, speech articulation, several cranial nerves function, motor function of each limb, ataxia, and sensory deficits and extinction. For details on the scale, please refer to the NIHSS website [18].

In principle the initial evaluation should be focused on determining whether the patient is eligible for acute reperfusion therapy. Time is brain in patients with AIS, meaning that early management is critical to optimize their outcome. Benefits of rtPA in AIS patients are time-dependent. AHA/ASA launched in 2010 Target: Stroke a national quality improvement initiative to reduce door-to- needle time to 60 min or less for eligible patients treated with iv rtPA. Since then the target has been moved to 45 min or less for rtPA start, and now goals extend to mechanical thrombectomy given its proven benefit in revascularization and patient outcomes [19].

Neuroimaging is fundamental to stroke management and helps determine if the stroke is ischemic or hemorrhagic. This is critical because the specific management of each type of stroke is different, and misdiagnosis can lead to severe consequences. The main modalities of neuroimaging are computed tomography (CT) scan and magnetic resonance imaging (MRI) of the brain. The choice of neuroimaging depends on availability and the condition of the patient. CT scan is equally effective to MRI in detecting acute intracranial hemorrhage, but it is often preferred as a more rapid test despite being associated with risk of radiation. However, diffusion-weighted MRI (DWI) is far superior to CT, having much higher sensitivity and specificity in detecting acute ischemia within minutes of the initial stroke symptoms [20]. MRI is also better in detecting subacute and chronic hemorrhages. Despite these advantages the higher cost of the investigation, unavailability of the machine at all centers, longer duration of procedure, claustrophobia, and various patient factors are limitations of MRI compared to CT scan [14]. Computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) are providing essential information about intracranial and extracranial vasculature pathology, its potential role in stroke etiology and anatomical details important for possible endovascular intervention. CTA is a more rapid technique than MRA, but effects of radiation and contrast need to be considered.

Besides neuroimaging the stroke workup includes complete blood cell count, basic metabolic panel, blood glucose, blood alcohol level, urine drug screen, cardiac enzymes, coagulation tests, oxygen saturation, electrocardiogram, and cardiac monitoring [14]. However, the only required test result prior to initiating iv rtPA is blood glucose [14].

Blood Pressure Management

Hypotension and hypovolemia should be corrected promptly to maintain adequate cerebral and organ perfusion pressure. In patients who are candidates for iv thrombolytic therapy and/or mechanical thrombectomy – elevated BP needs to be carefully lowered and maintained to SBP $\leq$ 185 and DBP $\leq$110 before the procedure is initiated. Thrombolytics are contraindicated if BP cannot be maintained below 185/110 [14]. During the intervention and for 24 h after, BP should be maintained below 180/105. Intravenous agents such as labetalol, nicardipine, clevidipine, and, if BP is refractory, sodium nitroprusside, are being used to lower BP to target [14]. In patients who are not candidates for acute reperfusion therapy, lowering SBP $\leq$ 220 and DBP $\leq$ 120 is reasonable, aiming to lower BP approximately 15% of baseline BP during first 24 h after onset of stroke. Occasional patients may require more aggressive lowering of BP (e.g., acute MI, acute heart failure, aortic dissection, post -thrombolytic sICH, preeclampsia/eclampsia) [14].

Telegram: @medical_k

www.konkur.in

Intravenous Thrombolysis

Alteplase (tPA, rtPA) is the only FDA-approved fibrinolytic agent used for the treatment of AIS. The National Institute of Neurological Disorders and Stroke (NINDS) rtPA Stroke Study showed intravenous rtPA as clearly beneficial in improving clinical outcome when used within 3 h of onset in selected patients with AIS [21]. Alteplase is a serine protease that binds to fibrin inside a blood clot and initiates conversion of plasminogen to plasmin, increasing the chance of cerebral revascularization. The treating dose is 0.9 mg/kg (total dose not exceeding 90 mg) over 60 min [21]. The bolus dose is administered as 10% of the total dose over 1 min. To date FDA has only approved rtPA for use within 3 h of stroke onset. However, randomized controlled trials showed benefit of thrombolysis with rtPA in AIS patients up to 4.5 h and AHA/ASA guidelines currently recommend a 4.5 h window for rtPA administration [14, 22]. More recently, **tenecteplase** has shown promising results and may become a preferred alternative to rtPA. A single bolus of 0.4 mg/kg (maximum 25 mg) might be considered in AIS patients with minor neurological impairment and no evidence of large vessel occlusion. Per AHA/ASA guidelines, a dose of 0.25 mg/kg tenecteplase may be chosen over rtPA to be administered in patients eligible for mechanical thrombectomy, given higher rate of revascularization achieved [23]. Tenecteplase is a bioengineered variant of rtPA with greater fibrin specificity, longer half-life and increased resistance to tissue plasminogen inhibitor-1 than rtPA. The greatest benefit from iv thrombolysis is derived when administered in the first 90 min from symptom onset, so it is critical not to delay initiation of rtPA. Eligibility criteria have evolved, and contraindications for iv rtPA have been recently revisited in the most recent AHA/ASA guidelines [14]. Subsequently, more patients can be considered for thrombolysis after careful individualized clinical judgment.

Individuals over 18 years of age diagnosed with ischemic stroke with disabling neurological deficit, with symptoms onset within 4.5 h or wake-up stroke and DWI-FLAIR imaging mismatch on MRI, are considered for acute thrombolytic therapy.

Absolute contraindications (because of no benefit or potential harm) include [14]:

1. Presence of acute intracranial hemorrhage on the initial head CT
2. History of intracranial hemorrhage
3. Symptoms and signs suggesting subarachnoid hemorrhage
4. Mild non-disabling stroke (NIHSS score 0–5)
5. Prior ischemic stroke or severe head trauma within 3 months
6. Acute in-hospital phase of head trauma
7. Intracranial/intraspinal surgery within 3 months
8. Extensive regions of clear hypoattenuation on initial head CT
9. SBP $\geq$ 185 or DBP $\geq$110 than cannot be lowered and maintained
10. Coagulopathy including platelet count $<100{,}000/mm^3$, elevated aPTT >40 s, INR >1.7, PT >15 s
11. Full treatment dose of LMWH within previous 24 h
12. Current use (last 48 h) of direct thrombin inhibitors or direct factor Xa inhibitors
13. Symptoms consistent with infective endocarditis
14. Suspected aortic arch dissection
15. Intra-axial neoplasm, AVM, or giant aneurysm
16. GI malignancy or GI bleeding within 21 days
17. Active internal bleeding

Relative contraindications now include [14]:

a. Pregnancy.
b. Seizure at onset of symptoms.
c. Blood glucose levels <50 or > 400 that can be corrected, and patient maintains eligibility.
d. Major surgery or serious trauma (not involving the head) within 2 weeks.
e. Presence of cerebral microbleeds (CMBs) on prior brain MRI.
f. Small or moderate unruptured and unsecured intracranial aneurysm.
g. Acute or recent MI within 3 months.
h. Rapidly improving stroke symptoms.

Telegram: @medical_k

www.konkur.in

After iv rtPA administration patient should be admitted to ICU or stroke unit for monitoring.

Neurological assessments and BP measurement are performed every 15 min for first 2 h, every 30 min for the next 6 h, and then hourly to 24 h. Should patient develop severe headache, acute hypertension, nausea or vomiting, or worsening neurological deficit, the infusion needs to be stopped (if still being infused) and emergent head CT obtained. Otherwise a head CT or MRI scan must be obtained at 24 h, before starting antiplatelets or anticoagulation.

Endovascular Treatment

Recent studies have conclusively demonstrated the benefit of mechanical thrombectomy performed in selected patients with AIS up to 24 h from onset of symptoms. The strongest level of evidence we have is for causative ICA or MCA M1 segment occlusion in patients who also meet the following criteria: age $\geq$ 18, mRS 0 or 1, NIHSS $\geq$6, ASPECTS $\geq$6, and treatment initiated within 6 h from stroke onset [24]. For selected patients with AIS within 6 to 16 h of last known normal and causative large vessel occlusion (LVO) in the anterior circulation and who also meet other DAWN and DEFUSE3 trials eligibility criteria, mechanical thrombectomy is recommended [25, 26]. Based on DAWN trial eligibility criteria and results, patients with AIS within 16–24 h of last seen normal and LVO in the anterior circulation are also considered for mechanical thrombectomy [26]. During and following mechanical thrombectomy, a reasonable BP to maintain is below 180/105.

Although other modalities could be considered to achieve the best reperfusion results, (e.g., intra-arterial thrombolysis, MERCI device, balloon guide catheter), stent retriever is the preferred device and is indicated as first-line therapy.

Antiplatelet Therapy

Aspirin 75–325 mg is recommended for patients to take orally within 24 to 48 h of stroke onset [14].

However, following iv rtPA administration, antiplatelet therapy is generally delayed for 24 h, unless patients have another indication for it, and the risk of not taking it is higher than the risk of bleeding.

In patients who did not receive iv rtPA and have a minor stroke (NIHSS$\leq$3) of undetermined etiology or high-risk TIA, dual antiplatelet therapy (ASA and clopidogrel) is recommended for 21 days to reduce the risk of recurrent ischemic events and mainly ischemic stroke [27, 28]. Per SAMMPRIS trial results, patients with AIS secondary to severe intracranial stenosis benefit from 3 months of dual antiplatelet therapy, followed by monotherapy [29]. Ticagrelor is not recommended over aspirin for treatment of minor ischemic stroke patients [14].

Role of Other Therapies in Acute Setting

Urgent anticoagulation treatment is not recommended for patients of acute ischemic stroke, and their usefulness in patients with internal carotid artery stenosis is not established [14]. The usefulness of emergent or urgent CEA/carotid angioplasty and stenting in patients with critical carotid stenosis or occlusion and unstable neurological status is not well established. To date, no pharmacological or non-pharmacological agents have shown benefit as neuroprotectors. The benefit of induced hypothermia in AIS is uncertain and should only be considered as part of clinical trials.

Other Considerations

Early during hospitalization patients are screened for dysphagia before they start eating, drinking, or receiving oral medications. Dysphagia is common poststroke and risk factor for aspiration pneumonia. In patients who are unable to swallow safely, enteral diet should be started within 7 days of AIS [14].

Persistent hyperglycemia in the first 24 h after AIS is associated with worse outcomes, and the

Telegram: @medical_k

www.konkur.in

recommended blood glucose is 140–180 mg/dl range with close monitor to avoid hypoglycemia [14].

If patients are febrile above 38C, they should receive antipyretics and the source of hyperthermia identified and treated, given increased risk of in hospital death outside normothermia.

Patients with stroke are best cared for in specialized stroke units that were shown to reduce their morbidity and mortality. Stroke units use standardized order sets that implement the best practices and employ rehabilitation services early during hospitalization.

In the stroke unit, patients undergo cardiac monitoring to screen for atrial fibrillation. Also, they are subjected to protocolized neurological exams and receive rehabilitation (physical, occupational, speech/language therapies) based on tolerance and anticipated benefit.

Continuation of statin therapy during hospitalization of patients with AIS is recommended.

In case of symptomatic severe carotid stenosis, patients should be evaluated for urgent CEA/angioplasty and stenting within 2 weeks of stroke ideally [30]. CTA or MRA should be obtained within 24 h in patients with AIS in the anterior circulation territories who are candidates for CEA or stenting.

Complications

Orolingual angioedema is a rare but potentially life-threatening complication of rtPA. The risk is higher in patients taking ACE inhibitors. Treatment consists of diphenhydramine (50 mg iv), ranitidine (50 mg iv), and dexamethasone (10 mg iv).

Approximately, one fourth of the patients with ischemic stroke will develop complications. The most common complications following AIS are (with incidence in parenthesis): brain edema (33%), intracranial hemorrhage (10%), recurrent ischemia (11%), and seizures (<10%). Brain swelling leads to increased intracranial pressure and further neurological deterioration and is associated with high risk of mortality. Most patients develop brain swelling in the first 48 h, but close monitoring of patients for 5 days post MCA infarctions is warranted [31]. Moderate hyperventilation and osmotic therapy can be used initially, but decline in level of consciousness indicates need for neurosurgical intervention with decompressive craniectomy.

Secondary Prevention of Stroke

The purpose of various investigations in the acute hospital setting of patients with AIS is to establish the most likely cause of the stroke and implement promptly secondary prevention measures including the most appropriate antithrombotic therapy and/or surgical interventions, if needed. Modifiable risk factors discussed previously in this chapter need to be addressed for secondary stroke prevention as well.

Antiplatelets are the mainstay of stroke prevention in non-cardioembolic stroke, and their choice in the acute setting should be individualized. Aspirin (50–325 mg daily orally), clopidogrel (75 mg by daily orally), and ASA (25 mg)/extended-release dipyridamole (200 mg) are reasonable choices for secondary stroke prevention [32]. Triple antiplatelet therapy was shown to be harmful and should not be administered. CTA or MRA will help select the patients with carotid artery disease for potential CEA/stenting and detect patients with severe intracranial stenosis that would benefit from dual antiplatelet therapy (DAPT). If revascularization is indicated, it is preferable that the procedure be performed within 2–7 days from the index event rather than more delayed intervention [30]. When the stroke is due to atrial fibrillation, anticoagulation can be initiated 4–14 days after AIS.

All patients are screened for DM using HgA1c and have their lipid profile checked to determine baseline LDL-C and assess the ASCVD risk. Adherence to lifestyle changes and effects of lipid lowering medications should be assessed at 4–12 weeks and then every 3–12 months. However, routine testing for thrombophilia, hyperhomocysteinemia and OSA is not recommended in patients with AIS. Smoking cessation must be reinforced as well as other behavioral modifications as discussed. With regard to hyperlipidemia, any adult over age 20 should have lipids checked

Telegram: @medical_k

www.konkur.in

to assess their atherosclerotic cardiovascular disease (ASCVD) risk. AIS survivors should watch diet, exercise, and take appropriate medicines to address hyperlipidemia and follow up regularly with their primary care provider to assess the results of these efforts. A follow-up fasting lipid profile test in 4–12 weeks after initiation of statin or its dose adjustment is recommended; this should be followed by periodic lipid testing at least annually to monitor adherence and safety. Patients age 75 years or younger, with clinical ASCVD (that includes AIS), should have hyperlipidemia managed with high-intensity statin with goal of reduction of LDL cholesterol by at least 50%. If there are any concerns on high-intensity statin use due to side effects or contraindications, moderate-intensity statin can be considered with goal of 30–49% reduction of LDC cholesterol [14]. Stroke education is very important and recommended. Patients should receive information, advice, and provided opportunity to talk about the impact of the illness on their lives [14].

Intracerebral Hemorrhage (ICH)

One in every ten strokes is caused by intracerebral hemorrhage (ICH) [2]. Up to 50% of all patients with ICH die within a month, and most deaths occur during the initial hospitalization [33, 34]. Prompt and excellent medical care is associated with improved morbidity and mortality. The symptoms and signs of ICH are strongly influenced by the location, size, and pattern of extension of bleeding. Severe sudden onset headache, coma, vomiting, seizures, and neck stiffness are manifestations of the largest hemorrhages. Patients with deep, small hematomas may never develop headache as part of their illness, and their focal neurological signs may be indistinguishable from those of ischemic strokes [35].

Head CT is the gold standard for distinguishing ischemic stroke from ICH, and MRI of the brain helps to determine the age of the hematoma. CT angiography (CTA) and contrast-enhanced CT are excellent tools to identify early the patients at risk for hematoma expansion, while serial head CT scans are more practical to monitor expansion of ICH during hospitalization. MRI with gadolinium, MR angiography (MRA), and MR venography (MRV) are useful tests to evaluate for underlying structural pathologies such as arteriovenous malformations (AVM) and brain tumors if there is clinical or radiological suspicion [37]. The decision to obtain a conventional cerebral angiography (DSA) early during ICH management is made on a case by case basis.

The most common cause of ICH is hypertension, but even in the absence of such history, many patients present with elevated BP on admission, and it is difficult to determine if their BP reflects elevated intracranial pressures (ICP) or chronic uncontrolled hypertension. Eliciting promptly a history of antithrombotic medications (antiplatelets, anticoagulants) and/or medical conditions associated with coagulopathies (liver disease, cancer, hematologic disorders) is critical given the high morbidity and mortality associated with abnormal hemostasis. Additional history about seizures; baseline cognitive and neurological status; vascular risks such as HTN, DM, and smoking; prior strokes; illicit drugs as well as stimulants (including diet pills); and sympathomimetics is very important as well.

A history of dementia can raise suspicion for amyloid angiopathy that is another major cause of ICH.

Presence of ICH in a female patient younger than 65 with no history of HTN, smoking, or coagulopathy and evidence of lobar hematoma and/or intraventricular extension raises probability of underlying vascular malformation.

Initial blood and urine tests should include PT/INR and aPTT, CBC, electrolytes, glucose, BUN, creatinine, troponin, and urine toxicology as well urinalysis/urine culture.

Just like in the case of ischemic stroke, the patient's airway patency and cardiovascular support are primary objectives, before specific management is initiated. Every ED should be prepared to manage patients with ICH or have a plan for rapid transfer to a stroke center with neurology, neurosurgery, and neuroradiology expertise, as well as critical care unit nursing staff capable to care for these patients. Consults via Telemedicine in ED can be a valuable

Telegram: @medical_k

www.konkur.in

alternative for the hospitals with no on-site consultants [37].

The key treatment goals in patients with ICH are halting expansion of hemorrhage by controlling BP and correcting any coagulopathy, as well as assessing necessity for surgical intervention [37].

A baseline standardized severity score such as ICH score, Glasgow Coma Score, and NIHSS should be obtained to streamline communication between providers. However, they are not meant to provide prognostic information and should not be used as a primary method to predict outcomes in patients with ICH. They should not direct treatment modalities either. These prediction models based on patient's age, GCS, hematoma volume, and location did not consider the impact of limitation of care early during ICH evolution [37]. Thus, caution is urged when providing prognostic information early in the course of ICH, particularly if this prognostication is used to guide limitation of care. The newest guidelines stress the importance of aggressive medical and surgical care early after ICH onset and deferring prognostication until at least second full day of hospitalization [37].

Up to 20% of ICH occur in patients on anticoagulation and are associated with higher mortality [38]. Patients with known coagulation factor deficiency or severe thrombocytopenia should receive appropriate replacement therapy [37]. At this point it is unclear whether patients on antiplatelet therapy should receive platelet replacement, but it was shown that these patients are at risk for early mortality as well [38]. Protamine sulfate has been used to reverse coagulopathy in patients on iv heparin at the time of ICH and may be considered [37].

Vitamin K antagonist-associated (VKA) ICH with elevated INR requires rapid administration of intravenous vitamin K, but that does not reverse the coagulopathy fast enough. Thus, use of other treatment strategies is necessary, and prothrombin complex concentrates (PCC), activated PCC factor VIII inhibitor bypassing activity (aPCC FEIBA), and fresh frozen plasma (FFP) are considered to replace vitamin K-dependent factors. Studies showed that PCCs achieve a more rapid INR reversal than FFP and may be preferred. rFVIIa is not currently recommended for warfarin reversal, and studies showed no clinical benefit in ICH not associated with oral anticoagulants (OAC) either (due to increased risk of thromboembolism). Data on reversal of NOAC is limited. PCC may be useful for rivaroxaban and apixaban, while rFVIIa or FEIBA may be helpful for dabigatran [37]. Hemodialysis is an option for dabigatran as well.

Patients with ICH and impaired mobility are at high risk for developing DVT and PE. Thus, pneumatic compression of legs should be initiated on the first day of hospitalization for prevention of DVT. Only after cessation of intracranial bleeding cautious use of anticoagulants as prophylaxis for thromboembolism can be considered, usually 2–4 days after onset. In cases with high bleeding risk, inferior vena cava (IVC) filter placement is widely used to prevent progression of DVT to PE [37].

High systolic BP is associated with greater hematoma expansion, neurological deterioration, and death and dependency [37]. However, blood pressure management in acute ICH has been the subject of controversy for decades, particularly related to concern of possible hypoperfusion in the region of edema surrounding the hematoma.

Recent smaller trials showed that acute aggressive reduction in BP within 3–6 h of ICH onset was safe, appeared to reduce the hematoma growth, and was not associated with adverse events [37]. The results of INTERACT2 a large randomized trial that enrolled patients with mild-moderate ICH and SBP 150–220 revealed that intensive BP lowering (SBP < 140) lead to no significant decrease in death or serious adverse events (SAE) and no significant reduction in hematoma growth but demonstrated improved functional outcome and better quality of life at 3 month [39].

There is less data for patients with SBP above 220, but the guidelines at this point suggest aggressively lowering BP with continuous iv infusion and frequent BP monitoring [37].

Patients with ICH require admission to an intensive care unit (ICU) and close monitoring of their hemodynamic status, intracranial pressure

Telegram: @medical_k

www.konkur.in

(ICP), cerebral perfusion pressure (CPP), neurological status, and possible seizures [37]. Care in an ICU by physicians and nursing with neuroscience expertise was associated with lower mortality.

About half of deaths after stroke are attributed to medical complications such as pneumonia, respiratory failure, pulmonary embolism, and sepsis. Protocolized screening for dysphagia has been shown to decrease the risk of pneumonia and should be performed in all patients prior to any oral intake.

Elevated blood glucose on admission predicted poor outcome and increased mortality, independent of diabetes. It is recommended that both hyperglycemia and hypoglycemia be avoided [37].

Fever is a common encounter after ICH, especially with intraventricular hemorrhage. In the absence of strong supportive data, it may be reasonable to treat fever after ICH.

Less than 10% of patients develop seizures in the first 24 h post-ICH and studies of continuous EEG monitoring reported up to 30% risk of electrographic seizures even in patients on prophylactic anticonvulsants [37]. The most important predictors of seizures are young age and lobar location of hematoma [40]. It was shown that prophylactic anticonvulsants could be associated with increased mortality (e.g., phenytoin), but clinical seizures should be treated [41]. Overall prophylactic use of antiseizure medications has not been shown to be beneficial, and they are not recommended [37].

Patients admitted for ICH need to be screened for myocardial ischemia/infarct with EKG and cardiac enzyme testing. Other complications include hyponatremia, impaired nutritional status, acute renal injury, gastrointestinal bleeding, and poststroke depression, and these should be screened and managed as needed.

Data regarding frequency of elevated ICP in patients with ICH is scarce, but it seems to be more common in young patients and those with supratentorial hematomas. Elevated ICP is caused essentially by the mass effect from hematoma and surrounding edema and/or hydrocephalus from IVH. ICP can be measured by a ventricular catheter (that allows CSF drainage and reducing ICP) or parenchymal ICP devices. Thus far, however, there is no clear evidence that management of elevated ICP improves outcome after ICH.

Most of the indications for management and treatment have been extrapolated from TBI literature and include GCS $\leq$8, clinical evidence of transtentorial herniation and significant IVH or hydrocephalus. Ventricular drainage is considered particularly in those with decreased level of consciousness. The goal is maintaining ICP $<$ 20 mm Hg and CPP of 50–70 mm Hg. Several strategies are used in ICU for ICP lowering including elevation of head of bed to 30°, mild sedation, osmotic therapy (mannitol, hypertonic saline), CSF drainage, and hematoma evacuation/decompressive craniectomy [37]. Corticosteroids should not be used as treatment for elevated ICP in ICH.

A special category is represented by patients with cerebellar hemorrhage who may be deteriorating neurologically, have brainstem compression and/or hydrocephalus from ventricular obstruction, and require prompt neurosurgical intervention to remove hematoma.

At this point the benefit of minimally invasive (stereotactic or endoscopic) surgical evacuation of IVH in terms of long-term morbidity and mortality benefits is uncertain.

Rehabilitation is started as soon as the patient is stable for mobilization and is continued in rehabilitation facilities or outpatient setting. Home-based rehabilitation programs were shown to be cost-effective and produce results comparable to conventional outpatient rehabilitation [37].

Patients with ICH are at high risk for recurrent major vascular events, and this risk is highest in the first year (cumulative risk is 1–5% per year). Risk factors for recurrence include lobar hemorrhage, older age, ongoing anticoagulation, presence of microbleeds on GRE MRI, and presence of APO e2 or e4 alleles.

Relationship between hypertension, smoking, heavy alcohol use, cocaine use, and ICH are well established, and these risk factors need to be addressed. BP optimization efforts should begin immediately after ICH, and recommended long-term goal for BP control is below 140/90.

Telegram: @medical_k

www.konkur.in

Treatment of OSA is likely to be beneficial as well.

In terms of resuming antithrombotic therapy after ICH, antiplatelet agents appear to be generally safe. Anticoagulation should be avoided though after lobar hemorrhage, but it can be considered in patients after deep ICH if the risk of thromboembolism is particularly high and BP is adequately controlled.

At this point there is insufficient data to strongly recommend restricting use of statin in ICH patients.

Subarachnoid Hemorrhage (SAH)

Subarachnoid hemorrhages represent 3% of all strokes, and most of them are due to the rupture of a cerebral aneurysm (85%) [2]. Aneurysmal SAH (aSAH) is a devastating type of stroke with mortality up to 45% and significant morbidity among the survivors [42]. Fifteen percent are non-aneurysmal SAH; their cause is often not identified even after extensive investigation [43]. Some may be due to a vascular malformation, and others, called perimesencephalic SAH, have a specific distribution and excellent prognosis compared to aneurysmal bleeds [43]. Incidence of aSAH increases with age (most common at age 40–60), and it is 1.2 times more common in women than men. Non-modifiable risk factors are female gender, history of prior aSAH, and family history of intracranial aneurysm (IA) or aneurysmal bleed [42]. Modifiable risk factors for aSAH include hypertension, smoking, alcohol abuse and cocaine use. Smoking cessation, cutting down alcohol, treatment of hypertension, and diet rich in vegetables may help prevent aSAH [42].

Sometimes intracranial aneurysms (IA) are found incidentally on cerebrovascular imaging studies. Unruptured intracranial aneurysms (UIA) are common (estimated 3.2% in the general population), but the overall risk of rupture is relatively low (approx. 0.25%). The larger aneurysms and those located in the posterior circulation (vertebrobasilar arteries), including posterior communicating artery, were shown to be at higher risk of rupture [42]. Although aneurysmal size of more than 7 mm is more prone to develop SAH, risk factors like smoking, alcohol, and psychosocial stress can increase the risk of rupture regardless of size [44–46]. UIA will need periodic monitoring, and the management decisions are usually made by a team including a vascular neurologist, vascular neurosurgeon, and interventional neuroradiologist. Routine screening for UIA in the general population is not recommended. However, CTA or MRA screening with adequate prior counseling of the patient may be considered in first-degree relatives of those with sporadic SAH and is appropriate in families with more than one member affected with IA and in those with family history of IA and evidence of autosomal dominant polycystic kidney disease, Ehlers-Danlos type IV or other predisposing conditions.

SAH should be the primary diagnosis of any patient presenting with acute onset severe headache until proven otherwise. 80% of patients present with "the worst headache of life," but many are often misdiagnosed, especially those presenting with "sentinel bleed" [42]. Other symptoms include nausea/vomiting, stiff neck, loss of consciousness, and focal neurological deficits.

Most SAH will be diagnosed with a non-contrast head CT (NHCT). The sensitivity is not 100% though, and if the initial CT scan is inconclusive, an evaluation of cerebrospinal fluid after lumbar puncture will help with the diagnosis. Other imaging modalities include CT angiography, digital subtraction angiography (DSA), and brain MRI which will assist in further management.

Treatment involves neurosurgical clipping or endovascular coiling of the ruptured aneurysm. These treatment techniques were compared in the International Subarachnoid Aneurysm Trial (ISAT), and combined 1-year mortality and morbidity were significantly greater in the surgically treated patients compared to endovascular technique (30.9% vs 23.5%; ARR 7.4%, $P = 0.00001$), mainly on the account of disability rates [47].

Given the high risk of early preoperative rebleeding, treatment should be performed as early as possible to reduce this risk. Most of the

Telegram: @medical_k

www.konkur.in

rebleeding occurs within 12 h of first bleed and is associated with high mortality. Although there is no established cutoff blood pressure as a treatment goal, AHA/ASA guidelines recommend maintaining SBP under 160 mmHg to reduce the risk of rebleeding, based on expert consensus [42]. Limited studies have shown benefit of short-term treatment with antifibrinolytic therapy (tranexamic acid or aminocaproic acid) to reduce rebleeding when there is a delay in aneurysm obliteration, but these agents are not FDA-approved for such indication [42, 48].

Cerebral arterial vasospasm leading to delayed cerebral ischemia (DCI) is a major cause of disability and death after aSAH. Vasospasm occurs usually 4–10 days after aneurysm rupture and resolves spontaneously after 21 days. Controlled studies on SAH management demonstrated no benefit on outcome from traditional hemodynamic augmentation of triple-H therapy (hemodilution, hypervolemia, and hypertensive therapy) [42]. Nimodipine, a calcium channel blocker, has been found to improve outcome in patients with aneurysmal bleed and is therefore recommended in all patients with aneurysmal SAH, unless contraindications are present [49].The mechanism of action by which the drug prevents DCI is unclear, but it has not been shown to reduce cerebral vasospasm as initially predicted. Hemodynamic stability by maintaining normal volume status of the body and induction of hypertension (if needed) are also recommended to prevent DCI [50]. A recent meta-analysis showed a significant benefit of cilostazol in reducing risk of symptomatic vasospasm, cerebral infarcts, and poor outcome suggesting clinical usefulness in preventing DCI [51]. Acute hydrocephalus in aSAH is usually managed by external ventricular drainage and less often by lumbar drainage [42].

Early seizures occur in 6–18% of patients and nonconvulsive seizures are not uncommon in the comatose patients. Short-term prophylactic antiepileptic medications are commonly used despite no high-quality evidence for benefit, and we need to be mindful to potential risks associated with these medications [52]. However, routine long-term continuation of anticonvulsants is not recommended.

Following discharge, these patients should be followed up closely to minimize their risk factors, and it is reasonable to refer them for a comprehensive cognitive, behavioral, and psychosocial evaluation [42].

Rehabilitation of Patients with Stroke

Restorative therapies play an important role to improve quality of life and functional outcome of stroke survivors. Measures of rehabilitation include prevention of complications, and it starts during the acute hospitalization. An initial evaluation by multiple disciplines: physical therapy, speech and language therapy, occupational therapy, physical and rehabilitation medicine, dietician, behavioral health, etc., is recommended to start during the initial hospitalization itself [53]. Before the patient is discharged following an acute stroke, a formal assessment of the following is important: activities of daily living (ADL), instrumental activities of daily living (IADL), communication abilities, functional mobility, as well as screening of cognitive deficits, and dysphagia screening need to be obtained to adequately plan rehabilitation interventions [53, 54].

Post-acute rehabilitation care of patients can take place in different settings as guided by the stroke survivor's recovery needs, potentials, and goals. The patients who continue to need hospital-level care can participate in intense therapy for at least 3 h a day for 5 days a week; an appropriate disposition after discharge will be "inpatient rehabilitation facility" (IRF). For other patients who have complex acute and chronic medical needs to address, a suitable disposition can be "long-term care hospital" (LTCH) or "long-term acute care" (LTAC) facility. Subacute rehabilitation in "skilled nursing facility" (SNF) would be indicated for patients who do not have potential to perform intense therapy but have skilled nursing needs (e.g., skin breakdown, bowel/bladder impairment), close monitoring requirements for health conditions, impaired ADL and IADL, nutritional deficits, and complex rehabilitation needs due to spasticity or pain management. If these medical and neurological disabilities interfere

Telegram: @medical_k

www.konkur.in

significantly with performance of ADL and IADL, the patient may need to be transitioned to a "long-term care" (LTC) facility. Some stroke survivors can eventually be transitioned to home but may require skilled healthcare oversight and intervention at home by "home healthcare" (HHC) team. Most patients discharged to home can continue their therapy needs by following up with outpatient rehabilitation services. Rehabilitation strategy should also include interventions to prevent skin breakdown and contractures; prevention of deep venous thrombosis; treatment of bowel and bladder incontinence; assessment, prevention and treatment of pain after stroke; fall prevention; assessment, evaluation, and treatment of poststroke mood disorder; and secondary stroke prevention [53].

Various disciplines play important roles in the rehabilitation of patients with stroke. These include nursing, physical therapy, occupational therapy, speech and language therapy, physician medicine and rehabilitation, neurology, primary care, social work, psychology, psychiatry, and counseling. Stroke survivors, who are suitable candidates for post-acute care, should receive an organized, coordinated, interprofessional approach for rehabilitation [53]. Coordination and communication among various disciplines is key, and primary care is positioned to facilitate this, while focusing on management of chronic illnesses and prevention of complications.

Key Considerations [53, 55]

- Stroke is a chronic disease with impact long beyond the acute phase of the illness.
- Rehabilitation of stroke patients should be addressed by a multidisciplinary team that follows seamless communication and coordination.
- Following up on any swallowing difficulties and addressing nutritional needs are important for poststroke patients.
- One third of the stroke survivors have cognitive impairment at 3 months and 12 months after stroke. Hence screening and monitoring of cognition are important.
- Proper positioning, therapy, and management of weak extremity and joint to prevent contractures and spasticity. Spasticity, imbalance, and ataxia are some examples of the complex sequelae of stroke that needs evaluation and management. Proactive fall precautions are recommended.
- Proactive care to prevent and treat skin ulcers.
- For prevention of deep venous thrombosis and pulmonary embolism, continuous anticoagulation therapy for the duration of acute hospital stay and throughout the rehabilitation or until mobility is regained. For those where anticoagulation therapy is contraindicated, mechanical methods are recommended.
- Assessing and addressing issues of bowel and bladder incontinence following stroke throughout rehabilitation process is an important method to prevent complications and improve quality of life.
- Assessment and management of poststroke pain complications should be addressed with pharmacological and non-pharmacological approach. Shoulder pain and central poststroke pain syndrome can be a serious barrier for rehabilitation efforts.
- Seizure prophylaxis is not recommended for stroke patients, and any new seizure should be investigated and managed per standard recommendations.
- Screening for depression should be routinely done. Behavioral approaches and pharmacological therapy can be utilized for addressing poststroke depression and emotional distress.
- Other considerations in rehabilitation include addressing sensory impairments such as touch, hearing, and vision, osteoporosis screening and prevention measures for appropriate poststroke patients, disability assessment, and evaluation for appropriate durable medical equipment.

Introduction

Movement disorders (MDS) are neurological diseases caused by dysfunction of the motor control systems. They are extremely common, with an overall prevalence in the general population of more than 20%. However, these disorders are vastly underdiagnosed and therefore undertreated. Movement disorders are classified as hypokinetic (those associated with paucity of movement like the bradykinesia in parkinsonism) and hyperkinetic (those with excessive movement, like in tremors, dystonia, and tics). There are about 30 different types of movement disorder phenomenologies (Table 1). Each of these phenomenologies or clinical phenomena are the external expression a number of different diseases. For example, bradykinesia is a hypokinetic phenomenology, and it is the hallmark of different parkinsonian disorders like Parkinson disease (PD), progressive supranuclear palsy (PSP and Multiple Systems Atrophy (MSA).

Initial Diagnostic Considerations

The first step in the evaluation of any movement disorder is to recognize the movement phenomenology, so to be able to generate a list of the different etiologies that share it – the differential diagnosis [1]. Jumping straight to the differential leads to misdiagnoses. This might be why 30–50% of cases with action tremors are misdiagnosed [2]. For example, a patient presenting with a head shaking could be hastily thought as to having essential tremor (ET). But if the physician determines first the phenomenology, could find that it is a dystonic tremor, leading to a completely different set of possible etiologies (spasmodic torticollis, tardive dystonia, etc. Table 1).

Table 1 Common movement disorders phenomenologies and some of their usual diseases

Phenomenologies	Associated diseases
Bradykinesia	Parkinson disease, progressive supranuclear palsy, multiple systems atrophy, dementia of Lewy bodies
Muscle stiffness	Stiff person syndrome
Akathetic movements	Medication-induced acute akathisia, tardive akathisia
Ataxia	Friedrich's ataxia, spino-cerebellar ataxias, multiple systems atrophy
Chorea	Huntington's disease, dopaminergic drug-induced dyskinesias in PD
Dystonia	Primary or secondary cervical dystonia, Blepharospasm, writer's cramp
Tics	Tourette syndrome
Tremor	Essential tremor (ET), ET-Plus, medication-induced tremor

Importance of Movement Disorders

- Some are curable, but all are treatable.
- There are many good treatment options: oral medications, botulinum toxin injections, intrathecal baclofen pump, deep brain stimulation, etc.
- Prompt diagnosis and proper treatment DOES improve quality of life.
- Frequently misdiagnosed or undiagnosed and therefore untreated.
- Some patients suffer for many years before they are given a diagnosis.

Initial Work-up

There are a number of treatable and curable conditions that present as movement disorders. Therefore, once the physician has identified a movement phenomenology, the next step is to rule out curable conditions that could cause them. In movement specialty centers, most patients undergo the battery of tests listed on Table 2. Wilson's disease is associated with copper deposition in the liver and basal ganglia. If a patient presents with any movement disorder under the age of 50, Kayser-Fleischer rings on ocular examination, or abnormal liver function studies, they should undergo further testing for Wilson's disease as this could be effectively treated with chelation [16].

Some of these treatable conditions could both cause the MDS and could make a baseline MDS worse. A good example of this dual effect is tremor and hyperthyroidism. Although not a disease, pregnancy is an important condition to keep in mind, as it can cause tremors, chorea gravidarum and exacerbate other MDS. Importantly, every patient presenting with dystonia or parkinsonism deserves a trial of carbidopa/levodopa as this could be the practical cure for a group of rare genetic conditions called dopamine-responsive dystonias.

Also, consideration of medication-induced MDS is important, as these are common and frequently under-diagnosed. Typical drugs associated with MDS include lithium, antidepressants, gabapentin and other antiepileptics (myoclonus, tremor, ataxia), dopamine blockers like metoclopramide and antipsychotics (dystonia, tremor, parkinsonism, ataxia), and many others.

Parkinson Disease

Parkinsonism is a syndrome characterized by the presence of bradykinesia associated with resting tremor, rigidity, or postural instability.

Table 2 Initial work-up in movement disorders and their associated condition

Diseases to rule-out in MDS patients	Initial work-up	Typical movement disorders
Wilson's disease	Ceruloplasmin, 24 hrs urine copper level	Need to consider it in any movement phenomenology
Hyper- and hypothyroidism	TSH, T4	Tremor, chorea, dystonia, myoclonus, ataxia
Nutritional deficiencies	Vit B12, Vit B1, methyl malonic acid, homocystein, vit D	Need to consider it in any movement phenomenology
Strokes, tumors, structural abnormalities, hypo- or hyperglycemic injuries	Brain MRI	Dystonia, myoclonus, chorea, hemiballismus, ataxia
Lupus	ANA	Chorea, ataxia, tremor
Hypo- or hyperglycemia	Glucose levels	Dystonia, myoclonus, chorea, hemiballismus, ataxia
Dopamine-responsive dystonia (DRD)	Levodopa trial	DRD presents with dystonia or parkinsonism
Medication-induced MDS	Medication reconciliation and review	Need to consider it in any movement phenomenology
Recreational or drugs of abuse	Urine drug screen	Tremors, myoclonus, ataxia, chorea

www.konkur.in

Bradykinesia is the hallmark of these conditions and presents with slowness of movement, decreased amplitude of repetitive movements (i.e., hypokinesia), and loss of normal movement (i.e., akinesia as in decreased facial expression). Parkinsonism can be caused by neurodegenerative conditions, medication side effects (like dopamine blockers), structural abnormalities, and other etiologies. The most common cause of parkinsonism is neurodegenerative [3] and medication-induced parkinsonism. The neurodegenerative categories include Synucleinopathies (Parkinson disease, multiple system atrophy (MSA), and dementia with Lewy bodies (DLB)), Tauopathies (progressive supranuclear palsy (PSP) and cortico-basal degeneration (CBD) and fronto-temporal dementias). Most of these conditions are classically called PD-Plus syndromes, as they present with additional signs that are not characteristic of PD. PD-PLUS syndromes do not respond long-term to dopaminergic agents and carry a much worse prognosis than PD, leading to mortality within 10–15 years.

Although PD can be seen in very young patients, the mean age of onset is 70 years and disease prevalence increases with age, with 1% at age 65 increasing to 4–5% by 85 years of age. Idiopathic Parkinson's disease (IPD) has a prevalence of about 0.3% in the general population with prevalence increasing to 4–5% by age 85. The pathological hallmark of IPD is accumulation of "Lewy bodies" inside the neurons, composed of alpha synuclein protein which spreads caudocranially [8].

Clinical Presentation

Parkinsonian patients usually present with symptoms related to their bradykinesia like slowness, decreased arm swing, lack of postural reflexes, small handwriting, soft speech, and slow gait with small steps. Rigidity and dystonia can present as stiffness, loss of dexterity, foot or toe curling, and abnormal postures. An acute or subacute onset is concerning for secondary etiologies, including dopamine-blockers use (up to five million Americans are exposed to antiemetic and antipsychotics) [10]. In addition to this, a response to levodopa and the absence of atypical symptoms are very suggestive of the disease [11]. Resting tremor is present in about two-thirds of patients with PD, but is less common in PD-PLUS syndromes [12]. Atypical symptoms such as early postural instability (within 3 years of onset), early gait freezing, hallucinations (not due to treatment), early cognitive impairment, medication sensitivity, and eye movement abnormalities suggest a diagnosis other than PD.

Physical Examination

Resting tremor is usually distal. PD patients might have a tremor during arm posture-holding (so-called re-emergent tremor). A useful feature to diagnose resting tremor is that its amplitude decreases or disappears as soon as the muscle involved with the tremor gets voluntarily contracted. Bradykinesia is characterized by decreased amplitude and speed of movements. Rigidity is an increase in tone irrespective of the speed of passive movement. A cog-wheel sign may be felt when tremor is associated with it. A search for atypical signs is very important as part of the examination (Table 3).

Differential Diagnosis

Drug-induced parkinsonism (DIP) is indistinguishable clinically from neurodegenerative parkinsonism. The best way of arriving to a diagnosis is through methodical withdrawal of possible causal medications. Common offenders include antipsychotics, antiemetics, calcium channel blockers, and drugs that deplete dopamine [13]. These drugs can also cause other movement disorders such as tardive dyskinesia, involuntary movement of the face causing twisting movements of the tongue or smacking of the

Table 3 PD-PLUS signs and syndromes

Additional sign	Associated syndrome	Abnormal protein accumulated	Other names/notes
Upper motor neuron signs	Multiple systems atrophy	Alpha-synuclein	Striato-Nigral degeneration
Ataxia	Multiple systems atrophy (cerebellar subtype)	Alpha-synuclein	Olivo-ponto-cerebellar atrophy
Severe dysautonomia	Multiple systems atrophy (autonomic subtype)	Alpha-synuclein	Shy-dragger syndrome
Early dementia	Dementia with Lewy bodies	Alpha-synuclein	DLB
Abnormal extraocular movements, early gait dysfunction	Progressive supranuclear palsy	Tau	PSP
Hemi-dystonia, myoclonus, agraphiesthesia	Cortico-basal syndrome	Tau	Could be Corticobasal ganglionic degeneration, FTD and others
Early dementia, late parkinsonism	Alzheimer's	Amyloid, tau	About 30% of patients with AD have some parkinsonism

lips; it may cause abnormal movements of the limbs and can persist for years or becomes permanent after discontinuation of such medications [14].

Cerebrovascular disease can cause parkinsonism. Other rare but treatable etiologies include excess mineral deposition in the brain (Copper from Wilson's disease, Manganese), metabolic, autoimmune disorders, toxic chemicals (heavy metals, MPTP+, etc.). In addition, parkinsonism may also be seen in primary dementias such as Alzheimer's Disease, DLB, and Huntington Disease. Genetic causes include monogenic Parkinson diseases, autosomal dominant and recessive ataxias, and others.

However, the main differential diagnosis in PD is other neurodegenerative parkinsonism. There are many ways of classifying these conditions. A practical approach is to divide them PD (AKA typical PD or Idiopathic PD) and PD-PLUS syndromes (AKA atypical parkinsonism). PD main features are the parkinsonism triad. But in PD-PLUS, other additional signs are present on exam, which can help expand the differential diagnosis (Table 3). It is interesting to note that REM-sleep behavior disorders are tightly associated with alpha-synucleinopathies.

Diagnosis and Initial Work-up

The diagnosis of PD is clinical in nature. One reaches the diagnosis if a patient has a slowly progressive bradykinesia with either rigidity or resting tremor and lacks atypical signs and the syndrome cannot be explained by something else. Some treatable conditions could either cause parkinsonism or make it worse, including medication use, pregnancy, Wilson Disease, Thyroid abnormalities, liver, kidney or electrolyte/glucose abnormalities, and Vit B12, D, and E deficiencies (Table 2). Basic initial work-up to consider, pregnancy test, Ceruloplasmin, thyroid function, CMP, vitamin B12 level, MMA, homocysteine, folate, 25-OH Vit D3, Vit E. Environmental exposures, use of over-the-counter, herbal or illegal drugs should be ascertained. Structural imaging (usually with MRI of the Brain) could be considered in cases suspicious for MS, strokes, ataxia, primary, and metastatic tumors, in those with rapid or unusual progression, or with associated abnormal neurological examination. Functional imaging (like PET or SPECT) can help differentiate between Parkinson disease and Essential tremor. Referral to a Movement Disorders Center might be the most cost-effective measure when the diagnosis is not clear.

Telegram: @medical_k

www.konkur.in

An accurate medication list review as in any condition or chronic disease seen by Family Medicine physicians applies.

Treatment

Dopamine replacement can be useful in PD, RLS, and some dystonias. Other antiparkinsonian drugs target GABA-ergic, cholinergic, and other systems (Table 4).

Initial Monotherapy

Most commonly used drugs for initial monotherapy are levodopa (with carbidopa), Rasagiline, dopamine agonists, and occasionally anticholinergics. Rasagiline and Selegiline have modest benefits as monotherapy and therefore are usually used on mild to moderate severity cases. However, the mainstay treatment for PD is levodopa. There is no known long-term toxicity of using levodopa as initial therapy (ELLDOPA trial); [9] however, minimum effective doses should be used to avoid long-term complications (STRIDE-PD trial) [15]. Lack of enough peak benefit with levodopa is addressed by incremental doses. However, all medications in PD should start with a small dose and titrate up slowly over a matter of weeks. Patients with severe tremors respond best to levodopa, amantadine, and trihexyphenidyl.

Motor Fluctuations

Early in the course of the disease, when patients take levodopa, they see continual, long-lasting benefits, and usually not too many side effects. As the disease progresses, motor fluctuations occur including shortening of the duration of benefit of each levodopa dose and medication-induced dyskinesias. The shortening of the benefit of levodopa can be treated by providing the medication in shorter intervals or adding

Table 4 Common medications used in Parkinson disease

	MOA	Starting dose	Common SE	Warnings
Amantadine	Likely DA and glutamate	100 mg/day	Dizziness, insomnia	Death, suicidality, seizures, cardiac failure
Carbidopa/levodopa	Increase DA	25/100 mg 0.5 tabs TID, slow titration	Nausea, vomiting, dyskinesia	Suddenly stopping Sinemet can cause a severe withdrawal reaction
Entacapone	Reversible COMT inhibitor	200 mg TID with levodopa doses	Dyskinesia, drowsiness, and dizziness. Stool decoloration	Warning against concomitant use of COMT and MAO inhibitors
Pramipexole	Dopamine receptor agonist	0.125 mg TID (IR) or 0.375 mg/day (ER)	ICD, peripheral edema	Sleep attacks without warning. Hallucinations, orthostatic hypotension
Rasagiline or Selegiline	Irreversible MAO-B inhibitor	0.5–1 mg/day (Rasag) 5 mg BID (Seleg)	Headache, GI, depression, and dyskinesia	
Ropinirole	Dopamine receptor agonist	0.25 mg TID (IR); 2 mg/day (ER)	ICD, peripheral edema	Sleep attacks without warning. Hallucinations, orthostatic hypotension
Rotigotine	Dopamine receptor agonist	2 mg/day (patch only)	ASR, drowsiness and somnolence	Tachycardia, sleep attacks, orthostatism, ICD, rash

[a]PD drugs are pregnancy category C
[b]*IR* Immediate release, *ER* extended release, *ICD* Impulse Control Disorder

Telegram: @medical_k

www.konkur.in

entacapone or rasagiline. Dyskinesias require reduction of dopaminergic agents, or the addition of Amantadine.

Advanced and Surgical Treatment

There are currently two surgical procedures for PD: deep brain stimulation (DBS) surgery or DUOPA pump placement. DBS has become the standard of care in patients with poorly controlled symptoms not only for PD, but also for essential tremor and dystonia. The brain targets include thalamus (primarily for tremor any cause), subthalamic nucleus (PD) and globus pallidus (PD and dystonia) [13, 14]. DBS is highly effective in controlling symptoms and has been shown to significantly improve quality of like. With a low mortality and morbidity rate, it is considered very safe in surgical centers with enough experience. DBS usually does not lose its efficacy over the years and can be programmed so to adapt to new needs. DBS is also indicated in severe dyskinesias or medication-resistant parkinsonian tremors. DUOPA pump provides continuous levodopa gel infusion into the jejunum, eliminating the motor fluctuations and reducing dyskinesias.

Prognosis

PD has a good prognosis with an average life expectancy close to normal. Atypical Parkinsonisms have a shorter life expectancy of 10–15 years from diagnosis.

Referral and Education

Referral to a neurologist could be useful to handle cases with an unclear diagnosis, difficult-to-treat symptoms or to evaluate need for advanced therapies. Referral to a Movement Disorder specialist could be considered any time the diagnosis is uncertain, DBS or chemodenervation might be indicated, or the patient is responding poorly to medications. The American Parkinson Disease Association (APDA) and Parkinson Disease Foundation have chapters in every state and support groups in every major city. The APDA and the American Academy of Neurology (AAN) websites have many useful patient education resources [15].

Restless Leg Syndrome

Restless leg syndrome (RLS), also known as Willis-Ekbom disease, is characterized by an irresistible urge to move the legs to alleviate the presence of crawly sensations, commonly worse in the evening [4]. Prevalence in general population ranges from 7.2 to 11.5%; however, about 3% are severe enough to require treatment. The pathophysiology is unclear although is thought by experts that involves an abnormality of dopamine transmission, circadian physiology, thalamic function, other neurotransmitters such as GABA and glutamate, also reduced central iron sores.

Clinical Presentation

The clinical presentation follows the mnemonic URGE: **U**rge to move the legs (usually accompanied by creepy-crawly sensations), **R**est makes the symptoms worse, **G**etting up and moving makes symptoms better, **E**venings are worse. It has been associated with Periodic Limb Movements of Sleep (PLMS) and PD. When severe, symptoms can spread to the upper extremities [17].

Physical Examination

Clinical examination is usually normal. It is important to look for signs of secondary causes

Telegram: @medical_k

www.konkur.in

of RLS including anemia, pregnancy, renal failure, neuropathy, and parkinsonism.

Diagnosis

Restless legs syndrome (RLS) is a clinical diagnosis that is made by history and does not require additional testing, except for an assessment of iron stores, blood urea nitrogen and creatinine if uremia is suspected. Any potentially medications as a cause should be identified [18].

Differential Diagnosis

RLS symptoms can overlap with other conditions like akathisia (generalized restlessness and urge to move, commonly tardive or medication-induced), neuropathy, radiculopathy, myoclonus, leg pain, or positional discomfort.

Treatment

In RLS, Gabapentin and Pregabalin are effective first line therapy [19]. Due to long-term complications and significant side effects, it is suggested to avoid dopaminergic therapy as first line of treatment, although they are extremely effective (Table 4). A serum ferritin concentration lower than 50 mcg/L has been associated with increased severity of RLS and iron replacement is recommended if the fasting serum level is below 75 mcg/L [20].

Essential Tremors

Shaking is not an uncommon complaint at a family medicine office. One of the most common causes of tremor is *Essential Tremor (ET)*. ET affects 2–6% of the population (prevalence 305/100,000; incidence 23/100,000/yr). Onset peaks in early adulthood (third decade) and late adulthood (sixth decade). The pathophysiology of ET includes the possible involvement of the cerebellum, the Guillain-Mollaret triangle, and GABA-ergic mechanisms [5].

Differentiating Types of Tremors

Assessment of patients that presents to the office with shakings still depends upon the history and physical exam. There are many movement disorders phenomenologies that look like shaking, including tremor, myoclonus, dystonia, and tics. But tremor is an oscillatory, mostly rhythmic movement. Once the phenomenology is ascertained as a tremor, the next step is to determine which type of tremor. The scope of this chapter constrains us to review only a few of the many types of tremors.

Resting tremor is one which amplitude decreases or disappears as soon as the muscles involved with the tremor get voluntarily contracted. Therefore, it is predominantly present during rest. This tremor might also appear after the patient has been holding arms up in front for a while (usually in the wrist or fingers), the so-called re-emergent tremor. Again, re-emergent tremor will usually disappear by contracting the involved muscles, helping differentiation from other postural tremors.

Action/kinetic tremors are those that appear or which amplitude increases as soon as the muscles involved with the tremor get voluntarily contracted.

Intention tremor is a posture-kinetic tremor which amplitude increases with target-directed movements (e.g., while comparing the tremor during finger-to-nose-finger maneuver versus just holding the arms straight). Intention tremor is regarded as a sign of disturbed function of the cerebellum and its pathways.

Posture-specific or task-specific tremor is commonly due to dystonia. Examples include the tremor present during flexion of a limb but not during extension; or the *intermittent, jerky, irregular, arrhythmic* head tremor of patients with cervical dystonia. Particular features that differentiate dystonic tremor from other tremors include the presence of abnormal posturing, muscle hypertrophy, null point (a place in the range of

Telegram: @medical_k

www.konkur.in

motion of the joint involved where tremor amplitude significantly decreases), and sensory tricks (AKA geste antagoniste, a sensory stimulus like touching the area can improve the dystonic tremor). Also to this category appertain the task specific tremors (e.g., those present only during writing or while playing an instrument) [2].

Clinical Presentation

The diagnosis is clinical. Essential tremor is a familial action hand tremor. It presents as a gradual onset of postural and action tremor in both hands and forearms, worse with stress or fatigue. Two thirds of patients notice that the tremor improves with alcohol. ET worsens over years and can involve head, voice, jaw, trunk, and legs [5]. Although ET patients can have shaking in other body parts, it would be very rare to have ET without hand tremors.

ET tremor is regular and rhythmic (jerky and irregular suggest dystonia or myoclonus), distal and does go away with true rest (tremor at rest suggests PD, dystonia or myoclonus). Head tremor can be vertical or horizontal, and voice tremor is rhythmic and regular [5].

Differential Diagnosis

Essential tremor needs to be differentiated from resting, dystonic, ataxic, physiologic, rubral, myoclonic, and medication-induced action tremors. The most common medications that can cause tremor include antidepressants, adrenergic agonists, antiarrhythmics, benzodiazepines, analgesics, anesthetic, antiepileptics, and others. When patients have action tremors with other associated signs like ataxia or dystonia, this is called ET-Plus.

Treatment and Prognosis

Drugs with most robust evidence for treatment include propranolol, primidone, and topiramate. Although propranolol is the usual first trial, drug choice is based on side effect profile (Table 5). ET has a normal life expectancy with some gradual

Table 5 Commonly used medications in various MDS

Drug and main indication	Mechanism of action	Starting dose	Common side effects	Warnings (including black box)
Clonazepam (dystonia)	GABA agonist	0.5 mg QHS	Drowsiness, ataxia	Cognitive impairment, suicidality, fetal malformation
Gabapentin (RLS)	Voltage gated Ca^{+} channel	100–300 mg TID	Somnolence, cognitive SE, dizziness	Effects on driving, sedation, suicidal behavior or ideation, multiorgan hypersensitivity
Pregabalin (RLS)	As above	50 mg BID	Blurred vision, weight gain	As above and angioedema, PR interval prolongation, decreased platelet count
Primidone (ET)	GABA agonist	50 mg QHS	Ataxia, Vertigo	CI: Porphyria Suicidal ideation or behavior
Propranalol (ET, Akathisia)	Beta adrenergic blocker	80 mg daily (XL)	Fatigue, SOB dizziness, depression	WPW, cardiac failure, bradycardia, bronchospasm, hypoglycemia, erectile dysfx
Topiramate (ET)	GABA and sodium channel	Titration from 25 mg BID	Cognitive dysfunction, fatigue	Glaucoma, visual field defects, oligohydrosis and hyperthermia, Met. Acidosis
Trihexy-phenidyl (dystonia, PD)	M1 Ach R antagonist	2 mg q day	Blurred vision Dizziness	Glaucoma, bradycardia, oligohydrosis

RLS restless leg syndrome, *ET* essential tremor, *BID* twice daily, *QHS* once every night, *Ach R* Acetylcholine receptor, *WPW* wolf Parkinson white syndrome

www.konkur.in

worsening of symptoms. However, many patients develop significant difficulties in activities of daily living, and tremor can affect professional performance.

Dystonia

Dystonia is an involuntary, sustained contraction of muscles resulting in abnormal postures or jerky tremor. Dystonia can be focal or generalized and is caused my many conditions. US incidence is 4.47/10 [5]. Its prevalence has been likely underestimated to be $16.43/10^5$ [7, 8]. Most common locations for primary etiologies are periocular (blepharospasm), cervical, and laryngeal dystonia [21].

Clinical Presentation

Presents as focal (most common neck and eyes), segmental, hemi-dystonia, or generalized. It is usually painless (except cervical dystonia) and its severity fluctuates based on stress, fatigue, and activity [21, 22]. It is important to document areas of involvement, posturing, effect of activity and distraction, presence of tremors, and associated disorders (for example PD). Blepharospasm is the most common focal dystonia, causing excessive blinking, squinting, and difficulty keeping eyes open. Cervical dystonia causes a combination of torticollis (chin to one side), anterocollis (chin pulled down), retrocollis (chin pulled up), and laterocollis (head to one side) and is commonly associated with a jerky head tremor.

Differential Diagnosis

Dystonia needs to be differentiated from ET (usually have hand tremors), ataxic tremor (other signs of ataxia), neck pain from orthopedic causes (abnormal imaging, cervical radiculopathy), and Parkinson Disease (which may or may not be present with it).

Treatment

Most effective oral drugs include Clonazepam, Trihexyphenidyl, and Baclofen. Treatment of choice for most focal dystonias is chemodenervation with botulinum toxin injections, which act by blocking the release of Acetylcholine at the neuro-muscular junction. Chemodenervation is highly effective, with sustained, safe benefit expected through many years of therapy [6] (see Table 5).

Ataxia

Ataxia is the type of clumsiness that is produced by dysfunction of the cerebellum and its pathways [9]. Mild ataxia is part of many movement disorders, and also ataxic syndromes tend to have a myriad of other movement phenomenologies [1, 9]. Therefore, the prevalence of ataxia is likely underestimated. Perhaps one of the most common causes of ataxia is medication induced. The list of the many drugs implicated includes some of the most common medications used in practice, including antidepressants, antiarrhythmics, adrenergic agonists, benzodiazepines, analgesics, anesthetic, antiepileptics, and others.

Clinical Presentation

The usual syndrome is such of hand clumsiness, abnormal or unstable gait, and dysarthria. The examination in ataxia can reflect any of the following abnormalities:

- Asynergia: decomposition of movements. Instead of the normal smooth performance, there is breakdown of the movement, rendering it irregular.
- Dysdiadochokinesia: a manifestation of asynergia is the break-up and irregularity seen while performing rapid alternating movements.
- Dysmetria: the misjudging of distance. Dysmetria includes hypermetria (overshooting), hypometria (undershooting), and loss of

Telegram: @medical_k

www.konkur.in

check (inability to stop a ballistic movement right on target).
- Intention tremor (see the Tremor Chapter): Tremor that is characteristically worse during target-directed movements (in comparison with that of posture holding or other actions).
- Hypotonia: decrease tone is common in cerebellar syndromes.
- Rebound: sudden displacement of a limb that is holding a posture produces excessive overcorrection).
- Gait/truncal ataxia: characterized by irregular stepping (worse with tip-toe or heels ambulation), increased lateral sway (not a straight line of ambulation), unstable turns, inability to walk on tandem. Wide-based ambulation, spontaneous retropulsion, and true postural instability are more advanced signs of ataxia.
- Ocular ataxia: characterized mostly by dysmetric ocular saccades, tends to be associated with nystagmus. Patients might experience diplopia.
- Ataxic dysarthria: global dysarthria but with a very strong component of lingual dysarthria, frequent volume changes (usually with overall hypophonia), scanning speech.

Diagnosis

The diagnosis of ataxia is clinical. But the diagnostic work-up to find the etiology of the ataxia is complex and long. Diagnoses not to miss in clinical practice are: medication-induced, paraneoplastic syndromes, Wilson disease, thyroid abnormalities, metabolic abnormalities (liver, kidney, or electrolyte/glucose), Vit B12, D, and E deficiencies, stroke, multiple sclerosis, hydrocephalus, and tumors (medulloblastoma, astrocytoma, ependymoma, metastasis, and others). Environmental exposures, use of over-the-counter, herbal or illegal drugs should be ascertained. Paraneoplastic ataxias often precede structural symptoms from the primary tumor and other usual cancer clues, and therefore, their diagnosis has important implications and requires checking the test. In fact, currently about a third of all cancers are been diagnosed as a paraneoplastic syndrome first, bringing an early recognition to those cancers and possible prognostic implications.

Structural myelopathy is one of the most common causes of truncal ataxia, and early diagnosis avoids progression. This presents as gait abnormality, urinary urgency, and upper motor neuron signs.

In children, important etiologies for acute ataxia include intoxication, acephalalgic (no headache) migraine, and cerebellitis (usually Varicella-Zoster Virus). Chronic ataxias would point to congenital defects of metabolism and genetic etiologies.

Basic initial work-up to consider: peripheral smear (looking for acanthocytes), Ceruloplasmin, Thyroid function, CMP, RPR, Vitamin B12 level, MMA, Homocysteine, folate, 25-OH Vit D3, Vit E, antigliadin antibody, urine drug screen, paraneoplastic panel. Consider heavy metals testing if other tests are negative. Ataxic patients usually require Brain and Spinal Cord MRI imaging (CT is not enough), unless etiology has been identified.

Other Clinical Diagnostic Considerations

If the basic initial work-up (above) is unrevealing, the next phase of the work-up might be better performed at a Movement Disorders Center, as there are hundreds of possible tests. Also, proper genetic counseling is required before proceeding with many of the tests.

Sporadic ataxias: If initial work-up is negative (see above), other etiologies include Multiple Systems Atrophy, Celiac Disease, Creutzfeldt-Jacob disease, genetic ataxias (like Friedrich Ataxia, SCA 2, 3, and 6), and paraneoplastic syndromes (false negative panel tests are expected). One of the most common causes of ataxia is alcohol abuse. Cerebellar degeneration due to alcohol is always a consideration. But a particular alcohol

Telegram: @medical_k

www.konkur.in

syndrome, the dorsal vermial atrophy, is associated with severe truncal ataxia.

Genetic Ataxias: A good source of genetic ataxia information includes the Online mendelian inheritance in Man (OMIM) and the Washington University in St. Louis Neuromuscular website [23]. Special mention is needed for a relatively new, highly prevalent, commonly undiagnosed disease called Fragile X-associated Tremor and Ataxia Syndrome (FXTAS) [22]. This syndrome is seen in those carriers of the Fragile X premutation and might also have parkinsonism and dementia. MRI of the brain is abnormal in 2/3 of the cases to include the MCP or the splenium signs.

Dominant Ataxias include the SCA's (Autosomal Dominant Spino-Cerebellar Ataxias), DRPLA, and the episodic ataxias. There are more than 25 SCA's and their differentiation is difficult, rendering the SCA panel genetic testing an expensive test to consider. Recessive Ataxias include Friedreich Ataxia (FA), abetalipoproteinemia, Ataxia-Telangiectasia syndrome, and the treatable, isolated Vitamin E deficiency (TTP1 gene mutation). FA is the most common one and presents with upper motor neuron signs, neuropathy, diabetes, and cardiomyopathy. It is caused by an expanded GAA repeat on the Frataxin gene.

Treatment

The field on curative options for ataxic syndromes is expanding rapidly, including antisense oligonucleotides, gene-silencing, and other innovations. However, the treatment of most ataxic patients is supportive. Occupational therapy (OT) and physical therapy (PT) are extremely helpful in keeping patients independent. Gait and balance therapy can lead to decrease falls and improve walking. Other symptomatic management options are largely dependent on comorbid aspects of the primary cerebellar process. For example, patients with marked spasticity may benefit from oral drugs and chemodenervation.

Background

Disorders of the peripheral nervous system are caused by a variety of diseases, toxins, trauma, and metabolic causes. Neuropathies are estimated to affect 7–10% of the population with the incidence being higher in older individuals [1]. Depending on the cause a single or multiple nerves may be involved. The most common causes of polyneuropathy are diabetes, alcoholism, fatty liver disease, and malignancy.

In axonal disease typically the more distal ends of the nerves are affected first resulting in the "stocking and glove" distribution seen in diabetic neuropathy. This type of damage will also result in loss of distal reflexes (i.e., ankle jerk) with preserved reflexes elsewhere. Demyelinating neuropathies often have proximal weakness with generalized loss of reflexes. Pain, loss of temperature sensation, and autonomic features suggest involvement of small nerve fibers. Autonomic features include light intolerance (pupillary), postural hypotension (cardiovascular), nocturnal diarrhea (gastrointestinal), impaired sweating (sweat gland), and bladder dysfunction. These symptoms may occur as part of diabetic neuropathy or as a sign of more systemic nerve involvement such as with amyloidosis or autoimmune conditions. Many diseases have mixed involvement of both sensory and motor symptoms.

Compressive neuropathies often result from overuse or mechanical problems. Presentation is more common in the later decades. For all compressive neuropathies except carpal tunnel, initial presentation is usually at ages 55–64 [2]. Carpal tunnel is more likely to present initially in women aged 45–54 years, and radial nerve palsy is more common in men aged 75–84 years [2]. Prevalence rates from a UK study are shown in Table 1.

The duration of development may help provide clues as to the etiology and is divided into categories: acute (<4 weeks), subacute (1–3 months), and chronic (>3 months). Neuropathies that occur acutely tend to be related to vasculitis or Guillain-Barre syndrome [3].

Evaluation

A thorough history and physical should be performed looking for underlying causes and clues to systemic disease. Patients will typically experience burning or electrical like sensations, paresthesias, weakness, or pain from non-painful stimuli like light touch. They may also suffer from sleep disturbances, anxiety, and mood disorders.

Table 1 Prevalence of compressive neuropathies

Type	Prevalence	Female/male
Carpal tunnel	2.78%	3–1
Morton's neuralgia	1.27	2–1
Ulnar neuropathy	0.4	1–1.3
Meralgia paresthetica	0.22	1–1
Radial neuropathy	0.045	1–2

www.konkur.in

The patient should be questioned about toxin exposures including occupational exposures, prescribed medications, and chemotherapy treatments in addition to nutrition. Careful examination of the neurologic system should involve testing of sensory function including vibration, proprioception, temperature, and pinprick in addition to reflexes. Specific testing may be performed for mononeuropathies such as carpal tunnel syndrome (Tinel's, Phalen's).

Initial laboratory testing to determine causes should include a complete blood count, comprehensive metabolic profile, erythrocyte sedimentation rate, fasting blood glucose or hemoglobin A1C, vitamin B_{12}, and thyroid-stimulating hormone levels [3]. Additional testing based on clinical suspicion may include human immunodeficiency virus (HIV) antibodies, Lyme antibodies, rapid plasma reagin (syphilis), urine and serum protein electrophoresis (paraproteinemias), angiotensin-converting enzyme levels (sarcoidosis), and antinuclear antibodies (vasculitis). In at least 15% of cases, a cause may not be determined with this initial testing [3]. The etiology in these cases is often autoimmune or hereditary [3]. Lumbar puncture and cerebrospinal fluid (CSF) analysis may also be helpful in diagnosis of Guillain-Barre syndrome or chronic inflammatory demyelinating neuropathy, which usually has notably elevated protein levels.

Electrodiagnostic testing consisting of nerve conduction studies and electromyography (EMG) should be considered if the diagnosis remains unclear after initial evaluation [3]. These studies can help determine if the damage to the nerve is axonal, demyelinating, or mixed. Normal studies decrease the likelihood of the peripheral neuropathy as the cause of symptoms. These studies are not as sensitive for neuropathies of small nerve fibers (pain, temperature, or autonomic functions).

Nerve biopsy is considered when the diagnosis still remains uncertain or when confirmation is needed prior to initiating aggressive treatment (e.g., vasculitis which may require immunosuppressive medications). Sural and superficial peroneal nerves are preferred for biopsy. Epidermal skin biopsy may also be performed in patients who are suspected to have disease of their small nerve fibers [3].

Cranial Neuropathies

Bell's Palsy

Bell's palsy is an acute unilateral facial nerve paralysis of unknown etiology. Patients usually describe an acute onset of unilateral facial weakness. They may have an associated earache in addition to numbness in the distribution of the nerve. Both upper and lower parts of the face are affected which distinguishes this from a central lesion in which only the lower portion of the face is paralyzed. This condition affects 11–40 persons per 100,000 with peak incidence between the ages of 15 and 50 years [4]. Groups at higher risk include pregnant women, diabetics, the elderly, and patients with hypothyroidism [4]. The cause is unknown, though there is evidence that a reactivation of herpes virus, either herpes simplex 1 (HSV-1) or herpes zoster (HZV), is involved. Several other infectious causes have been implicated in addition to autoimmune disease (Hashimoto's), ischemia, and familial syndromes [4]. The symptoms result from inflammation and edema of the facial nerve. Most patients recover within weeks to months.

Laboratory and imaging studies are not routinely needed. They are only recommended when there is concern for Lyme disease, recurrence of symptoms, or no improvement after 3 weeks of treatment [5]. Even without treatment approximately 70% of patients with complete paralysis will recover within 6 months. A Cochrane review showed that corticosteroids had significant benefit in the treatment with faster recovery and improved nerve function when started within 72 h of symptom onset [6]. Antivirals in combination with corticosteroids may reduce the incidence of long-term sequalae, such as excessive tearing or facial spasms [7]. Care should be taken to protect the cornea due to improper lid closure caused by the disease. This may be done with lubricating drops or eye ointment during sleep. In addition,

Telegram: @medical_k

www.konkur.in

providers may need to provide psychological support to patients with this disfiguring condition [4, 5]. Surgical decompression may be considered for severe cases (complete paralysis or absent electromyographic activity). [8].

Trigeminal Neuralgia

Trigeminal neuralgia (tic douloureux) is defined as sudden, usually unilateral brief stabbing, recurrent episodes of pain in the distribution of one or more branches of the trigeminal nerve by the International Classification of Headache Disorders and further classifies the condition as classic (idiopathic) and secondary (associated with a structural abnormality) [9]. Incidence is reported as 4.3–27 cases per 100,000 people per year. The most common cause is compression of the nerve by a blood vessel. Routine neuroimaging may identify a cause in up to 15% of patients [10]. Patients with bilateral symptoms, younger age, and the presence of trigeminal sensory deficits are more likely to have secondary trigeminal neuralgia, though there is significant overlap with the classic form [10]. Secondary disease is often associated with multiple sclerosis. Carbamazepine has been shown effective for treatment in doses ranging from 300 to 2400 mg per day, as has oxcarbazepine at 600–1800 mg per day. Baclofen, lamotrigine, and pimozide have shown effectiveness in single trials [10]. When symptoms are refractory to treatment with medications, surgical therapy may be considered.

Mononeuropathies

Carpal Tunnel Syndrome

Carpal tunnel syndrome arises from compression of the median nerve. Patients complain of paresthesias, pain, and numbness in the distribution of the median nerve, which includes the thumb, index, and middle fingers and the radial half of the ring finger on the palmar side. It presents more commonly in women. Risk factors include obesity, diabetes, pregnancy, menopause, ovariectomy, and hysterectomy [11]. The condition can be caused by repetitive strain injury or other conditions causing edema and inflammation of the synovial sheath. Examination may reveal thenar atrophy and reproduction of symptoms with provocative testing such as Tinel's or Phalen's test. The diagnosis is usually made clinically. One may consider nerve conduction studies or ultrasound when the diagnosis is in question, surgery is planned, or as a predictor of symptom severity and functional status [12].Treatment is based on severity of symptoms and physical limitations [11]. In pregnant women, the symptoms usually resolve after birth. Conservative treatment may consist of behavior modification, analgesics, splinting, physical and occupational therapy, oral corticosteroids, and ultrasound [13]. Additional treatment with local steroid injection may be attempted when conservative measures fail. In patients who fail conservative treatment or have evidence of median nerve denervation, surgery should be considered [13].

Cubital Tunnel Syndrome

Cubital tunnel syndrome is the second most common entrapment neuropathy after carpal tunnel syndrome. Compression of the ulnar nerve causes pain or paresthesias in its distribution involving the fourth and fifth finger and the medial aspect of the elbow. Conservative therapy consists of splinting and activity modification. Steroid injections do not seem to offer benefit over splinting. Surgery may be considered for persistent symptoms; however, there is controversy as to which patients benefit from surgery [14].

Radial Neuropathies

The characteristic feature of radial tunnel syndrome is pain over the lateral proximal forearm with little or no motor weakness. It is difficult to differentiate this syndrome from lateral epicondylitis due to location of the pain; however, the pain from radial tunnel syndrome should be 3–4 cm distal to the lateral epicondyle [15]. Posterior

Telegram: @medical_k

www.konkur.in

interosseous nerve syndrome results from compression of the same nerve; however, it results in loss of motor function with patients complaining of motor weakness in the first three fingers. The function of the wrist should be preserved in these cases [15]. Initial therapy for both of these conditions should be rest, activity modification, splinting, and anti-inflammatory medications. Particularly for posterior interosseous nerve syndrome, one should consider removal of any masses such as lipomas or ganglions that are causative. Injection of steroids may serve therapeutic and diagnostic purposes for radial tunnel syndrome. If there is no improvement after 3 months, surgery should be considered for both conditions [15].

Posture-induced radial neuropathy, popularly known as Saturday night palsy or sleep paralysis, is a result of prolonged compression of the radial nerve and causes a wrist-drop. The most common cause is due to sleeping with the arm over the back of a chair particularly while drunk. Symptoms usually resolve with conservative treatment of splinting and avoidance of provocative activities. Patients with denervation findings on needle EMG and severe initial weakness have a poorer prognosis for long-term recovery [16, 17].

Lumbosacral Neuropathies

Trauma involving the lumbosacral plexus is much less common than that of the brachial plexus; lumbosacral neuropathy may occur perioperatively (especially with lithotomy positioning), with pregnancy and childbirth, or from compression by aortic aneurysms or tumors. Vascular lesions associated with diabetes may produce a proximal multiple mononeuropathy of the plexus.

The clinically important branches of the upper, lumbar portion of the plexus include the lateral femoral cutaneous nerve, obturator nerve, and femoral nerve. The lower, sacral portion of the plexus gives rise to the inferior and superior gluteal nerves and the sciatic nerve; the sciatic nerve branches form the common peroneal and tibial nerves.

Meralgia Paresthetica

Compression neuropathy of the lateral femoral cutaneous nerve of the thigh may occur where it passes underneath the inguinal ligament or where it pierces the fascia lata. It occurs most frequently in overweight individuals or in diabetics. Compression may also occur as the result of a tight belt compressing the nerve as it passes over the iliac crest or from prolonged extension such as may happen during surgery. Patients experience increasingly severe numbness, pain, and paresthesias, as well as decreased sensation of the anterolateral thigh; there is no weakness. Tests such as the pelvic compression test and Tinel's sign performed over the nerve as it exits the inguinal ligament region may help solidify the diagnosis. Treatment is generally conservative with avoidance of compression activities, anti-inflammatory medications, and physical therapy [18].

Femoral Neuropathy

The femoral nerve mediates extension of the leg at the knee through innervation of the quadriceps muscle. Its sensory distribution includes the anteromedial aspect of the thigh and the medial aspect of the lower leg and foot. The femoral nerve is commonly affected by diabetic vascular mononeuropathy, surgical positioning, and inguinal hernia, or tumor involving the lumbar plexus may also compress it.

Sciatic Neuropathy

The sciatic nerve arises from the sacral portion of the plexus. It leaves the pelvis through the sciatic notch and passes down the posterior thigh, where it divides into the tibial and peroneal nerves at the level of the popliteal fossa. The sciatic nerve innervates the extensors of the thigh, the hamstrings, and all of the muscles of the lower leg and foot; it also supplies sensation to the perineum, posterior thigh, lateral calf, and foot. Pain and weakness in the distribution of the sciatic nerve are most commonly the result of lumbar disk herniation, although fractures of the pelvis or femur, gunshot wounds to the buttock and thigh, or pelvic tumors may damage the sciatic nerve itself.

Telegram: @medical_k

www.konkur.in

Peroneal Neuropathy

The common peroneal nerve mediates dorsiflexion and eversion of the foot and supplies sensation to the dorsum of the foot and ankle. It is particularly prone to compression at the level of the fibular head, whether due to trauma, sitting cross-legged, improperly applied stirrups at the time of delivery, or an ill-fitting cast. Diabetic, vasculitic, and hereditary neuropathies may also affect the peroneal nerve. Treatment consists of conservative management with activity modification and bracing. Surgical treatment can be considered for severe cases, compressive masses, or lack of response to conservative treatment. [19].

Interdigital Neuralgia

Entrapment neuropathy of the interdigital nerve is a common cause of foot pain. Morton's neuroma, a benign swelling of the nerve, is usually responsible. Unlike metatarsalgia, there is palpable tenderness between the metatarsal heads in the second or third web spaces. Runners, ballet dancers, and women who wear tight shoes and high heels are particularly prone to the development of a neuroma. Conservative measures such as steroid injection and mobilization have shown some benefit. [20] Surgical resection is often necessary.[21].

Polyneuropathies

Thoracic Outlet Syndrome

Thoracic outlet syndrome (TOS) encompasses several clinical entities. Currently it is categorized as vascular (arterial and venous), neurologic (true/classic and disputed), and neurovascular/combined (traumatic and disputed). Neurologic accounts for the majority of cases. This type most commonly affects the brachial plexus due to either direct trauma or repetitive stress injury. There is a female predominance. True neurologic TOS is a unilateral disorder affecting mainly women due to fibrous bands extending from a cervical rib causing stretching and compression of the proximal lower trunk of the brachial plexus. Traumatic TOS is most commonly caused by a midshaft displaced clavicle fracture.

Patients present with hand weakness, atrophy, and loss of dexterity. They may also have a preceding history of intermittent medial upper extremity and forearm myalgias and paresthesias that are exacerbated by shoulder and neck movement. Depending on the rami, affected patients will report pain from the head, neck, thorax, shoulder (upper plexus; C5–C6) or neck, medial arm, forearm, and fourth and fifth digits (lower plexus; C8–T1). Motor function is affected preferentially with patchy sensory deficits. There may also be vascular symptoms along the forearm and medial arm. Provocative tests such as Adson maneuver, Halstead test, Roos test, and Wright maneuver may be used to potentiate symptoms. Radiographs may be helpful in revealing the presence of a cervical rib or clavicle fractures.

True neurologic TOS should be treated surgically to disrupt the fibrous band and prevent further nerve damage. Disputed TOS is initially treated medically using multiple modalities that include rest, activity restrictions, analgesics, anti-inflammatory medications, and muscle relaxants. Physical therapy modalities are numerous. Surgical therapy for disputed TOS can be considered after 3 months of attempted medical therapy [22].

Brachial Plexus

Brachial plexopathies may be due to any trauma involving the axilla or causing a violent increase in the angle between the shoulder and head, producing stretching or even tearing of various plexus elements. This injury, the cause of the "burner" or "stinger" syndrome seen in football players, results in temporary numbness, paresthesias, and diffuse weakness of the arm and shoulder [23]. Direct extension of apical lung tumors or breast cancer may cause similar symptoms. It is often difficult to distinguish between metastatic brachial plexopathy and late-onset impairment caused by radiation therapy.

Acute idiopathic brachial neuropathy also known as Parsonage-Turner syndrome or neuralgic amyotrophy is a rare disorder characterized by

Telegram: @medical_k

www.konkur.in

rapidly progressive pain of neck and shoulder followed by progressive weakness and hyporeflexia. The etiology is uncertain, but it has been reported in association with surgery, infections, trauma, and vaccination. The condition is generally self-limited with the pain lasting 1–2 weeks. The weakness may develop days to weeks after the onset of other symptoms. Treatment involves control of pain symptoms with anti-inflammatory medications, opiates, and neuroleptics. There may be some role for oral steroids, but further studies are needed to establish efficacy. Once the initial pain has abated, physical therapy plays a role in strengthening the affected muscles; timing depends on the level of denervation of the muscles [24].

Lumbosacral Plexus

Lumbosacral plexitis is a rare condition that presents with acute onset of severe lower extremity pain followed by wasting and weakness of leg muscles. It is usually unilateral, though many patients may develop bilateral symptoms. Sensory loss is variable. Patients typically have weight loss and elevated erythrocyte sedimentation rates. Mass lesions and trauma should be excluded as causes. One must also look for mimics such as diabetes or Lyme disease. Peak incidence is in children and age 40–60 years. There may be an antecedent history of viral illness or vaccination particularly in children. It is considered an autoimmune disorder with biopsies typically showing microvasculitis. This condition can often be mistaken for lumbar radiculopathy because patients will show abnormalities on magnetic resonance imaging of the spine. Those with milder disease should be offered supportive care and physical therapy. For more severe cases, immunomodulatory therapy may be considered. However, due the rarity of the condition, there is little data to support a specific regimen. Patients with milder disease will resolve over weeks to months with pain improving before the weakness. Some will go on to develop a relapse with progressive disability [25].

Infectious Neuropathies

Postherpetic Neuralgia

Herpes zoster results from reactivation of dormant varicella-zoster virus. Patients develop a vesicular rash and pain in a single dermatome. The postherpetic pain results from direct damage to the peripheral nerve. Classically the condition is defined as pain persisting at least 90 days after the appearance of the rash. Approximately 20% of patients report some pain at 3 months after onset and 15% report pain at 2 years. Risk factors for development of the condition include older age and greater severity of the prodrome, rash, and pain during the acute phase.

The only effective method of prevention is with vaccination. A live attenuated and subunit adjuvanted herpes-zoster vaccines are available for persons 50 years of age and older and have been shown to reduce the incidence of herpes zoster by 51% and incidence of postherpetic neuralgia by 66% or more. [26, 27] While the use of antiviral drugs has been shown to reduce the severity of acute pain and rash in addition to hastening rash resolution with herpes zoster, the trials did not assess the subsequent incidence of postherpetic neuralgia. Addition of steroids to antiviral treatment has not been shown to reduce the incidence of neuralgia.

Topical therapy is considered first line for mild pain, though evidence is equivocal as to its benefit. Lidocaine patches (Lidoderm) 5% and capsaicin cream 0.075% (off-label use) or patch (Qutenza) 8% may prove helpful. Side effects are minimal and mainly related to local reactions. Several studies have shown benefit with use of tricyclic antidepressants (off-label use), gabapentin, and pregabalin [28, 29].

Leprosy

While uncommon in industrialized countries, leprosy remains one of the most common treatable causes of peripheral neuropathy worldwide, particularly in tropical countries. Typically patients present with mononeuritis or mononeuritis

Telegram: @medical_k

www.konkur.in

multiplex. It causes a predominantly axonal neuropathy with more severe symptoms in the lower limbs. There is a subtype of leprosy in which patients have purely neural symptoms without the classic skin lesions. Diagnosis can be difficult in these patients as it predominantly affects small nerve fibers. Biopsy will assist in establishing the diagnosis [30].

Hepatitis C

Hepatitis C may cause several different patterns of peripheral neuropathy: polyneuropathy, mononeuropathy or multiple mononeuropathies, cranial neuropathy, or a combination of polyneuropathy and cranial neuropathy. Biopsies show inflammatory vascular lesions and axonal degeneration supporting an ischemic mechanism rather than a direct role of the virus [30].

Human Immunodeficiency Virus (HIV) Infection

Neuropathy occurs in approximately 35% of acquired immunodeficiency syndrome (AIDS) cases. The main patterns are multiple neuropathy, acute or chronic inflammatory neuropathy, polyneuropathy, and distal symmetric neuropathy (DSN). Age, use of antiretroviral medications, severity of HIV infection, diabetes, alcohol use, and race are associated with development of distal symmetric neuropathy in particular. The antiretroviral drugs stavudine, didanosine, and zalcitabine have been implicated as causative in some patients. Differentiation of these drugs versus the virus as the cause can be made by withdrawing the potentially offending agent with improvement of symptoms [30]. Early initiation of highly active antiretroviral therapy significantly lowers the risk of developing distal symmetric neuropathy.

Lyme Disease

In the acute phase, patients with Lyme disease frequently present with subacute cranial neuropathies particularly Bell's palsy. Late disease symptoms are more likely to be symmetric sensory polyneuropathies. In areas with endemic Lyme, many authorities recommend checking titers as a potentially treatable cause of peripheral neuropathies. Treatment is aimed at the underlying infection with doxycycline 100 mg orally twice daily for 14 days. Parenteral regimens may be considered for treatment failure or severe disease [31].

Acute Inflammatory Demyelinating Polyradiculoneuropathy (Guillain-Barre Syndrome)

Incidence of Guillain-Barre syndrome (GBS) is 1–2 cases per 100,000. Patients present with acute onset of symmetric ascending motor weakness, although a substantial portion of patients have sensory symptoms. Pain presents in 50–60% and will sometimes precede the weakness. Patients have decreased or absent deep tendon reflexes. Diagnosis is made mainly on clinical presentation [32], though cerebrospinal fluid examination and nerve conduction studies may aid in diagnosis in atypical cases. There is suggestion that host factors play a role, though no definitive genetic link has yet been found. *Campylobacter jejuni* gastroenteritis is the most frequently associated antecedent infection though several other infectious etiologies and vaccines have been implicated.

All patients should be hospitalized to monitor respiratory status, as 20–30% will progress to respiratory failure, and neurological consultation obtained. Treatment with plasmapheresis or intravenous immunoglobulin (IVIG) should be initiated early in the disease course. These treatments are felt to be equally efficacious [33, 34]. Supportive care with invasive ventilation may be necessary. Gabapentin and carbamazepine have shown some promise in treating pain associated with GBS [35]. Intensive rehabilitation produces greater functional improvement and reduces disability in the later stages of recovery [32]. Full recovery can take months to years [36].

Telegram: @medical_k

www.konkur.in

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is a rare acquired immune-mediated progressive or relapsing disorder causing peripheral neuropathic disease of duration more than 2 months. Incidence is reported to be 0.67–10.3 per 100,000 worldwide with a slight male predominance. Clinically patients present with proximal and distal weakness, sensory involvement, and areflexia. Lab testing may be positive for paraproteins such as anti-myelin-associated glycoprotein and anti-ganglioside antibodies. Cerebrospinal fluid protein levels are usually elevated. Nerve conduction studies help with diagnosis as does nerve ultrasound and MRI. There are now recognized to be atypical subtypes of the disease that respond differently to treatments [37]. IVIG and corticosteroids are considered first-line treatment. Small studies have shown some benefit of other immunomodulating agents [38].

Metabolic Neuropathies

Diabetic Neuropathy

Diabetic neuropathy is the most common polyneuropathy encountered by family physicians. Neuropathy may occasionally be the presenting feature of diabetes, but more commonly it is related to increasing duration and severity of the disease. Therefore good glycemic control is essential in the prevention or delay of this condition.

Diabetic neuropathies encompass the spectrum of peripheral nerve disorders. Classically, patients experience distal symmetric polyneuropathy with predominantly sensory involvement and mild motor signs (stocking and glove pattern). Damage to the small nerve fibers results in sensations of burning or lancing pains particularly on the soles of the feet. Decrease in sensation may be confirmed with testing using a 10 g monofilament. Damage to the large nerve fibers leads to decreased position sense and may progress to sensory ataxia and arthropathy (Charcot joint).

Patients with diabetes also experience a higher frequency of compression and entrapment mononeuropathies than those without the disease. Diabetic amyotrophy is a multiple mononeuropathy involving the lumbosacral plexus or motor fibers of the lower extremity as described above (lumbosacral plexopathies). This condition is felt to be partly ischemic in nature though evidence also suggests immune-mediated etiology.

Some diabetic patients will present with purely autonomic signs and symptoms. Postural hypotension is common, but gastrointestinal (diabetic gastroparesis, intestinal hypomotility, and constipation or diarrhea) and genitourinary (impotence, neurogenic bladder) symptoms may also occur.

For treatment of painful diabetic neuropathy, only duloxetine and pregabalin are FDA approved; however, studies support use of numerous other agents in the treatment of this condition. Venlafaxine, tricyclic antidepressants, gabapentin, valproate, and botulinum toxin are other options for treatment. Opioids and tramadol can be considered also. One should consider the potential side effects and interaction with other medications when choosing an agent [39].

Uremic Neuropathy

Neuropathy is a common complication of end-stage kidney disease, typically presenting as a distal symmetric process similar to diabetic neuropathy. Many of these patients also have diabetes making it difficult to determine the etiology of the neuropathy. Autonomic features may be present. Nerves of uremic patients have been shown to exist in a chronically depolarized state with the degree of depolarization corresponding to serum potassium levels [40]. It is thought that maintenance of near normal potassium levels may improve symptoms. Renal transplantation has been shown to rapidly reverse the symptoms of uremic neuropathy.

Telegram: @medical_k

www.konkur.in

Toxin Induced

Toxic neuropathies develop over several weeks to months as a result of continued exposure to various drugs, industrial toxins, or heavy metals. A progressive, symmetric, ascending polyneuropathy is most frequently seen with occupational exposures. The most commonly implicated drugs include antineoplastic agents, particularly cisplatin and vinca alkaloids, antiretroviral drugs (didanosine, zalcitabine, stavudine), as well as isoniazid, dapsone, and amiodarone. Rare cases of arsenic poisoning, either intentional or from insecticide exposure, may cause a delayed-onset progressive polyneuropathy. Chronic lead exposure causes a predominantly motor neuropathy, typically beginning in the upper limbs, with asymmetric radial neuropathy and wrist-drop. A careful review of potential occupational exposures is the key to diagnosis of neuropathy caused by heavy metals and industrial toxins.

Chemotherapy-induced peripheral neuropathy is predominantly a sensory neuropathy but may have motor and autonomic changes. There is no effective prevention strategy for this condition, and onset generally requires a dose reduction or cessation of the chemotherapeutic agent. The prevalence is 68.1% in the first month after chemotherapy and falls to 30% 6 months after chemotherapy [41]. Risk factors for development of chemotherapy-induced peripheral neuropathy are baseline neuropathy, smoking, abnormal creatinine clearance, and specific sensory changes during chemotherapy [41]. Medications used to treat other neuropathic pain conditions have not been shown to be successful with the exception of one study showing improvement after 5 weeks of treatment with duloxetine [42].

Nutritional Neuropathies

Malnutrition may affect all areas of the nervous system. Risk factors for malnutrition include alcoholism, eating disorders, older age, homelessness, and lower socioeconomic status. Absorption of nutrients may be impaired by several conditions including inflammatory bowel disease, fat malabsorption, chronic liver disease, bowel resection, gastric bypass, and celiac disease.

Alcoholic Neuropathy

The polyneuropathy related to chronic alcoholism is clinically indistinguishable from that due to vitamin deficiencies and may be better classified as toxin induced. The most important risk factor is total lifetime dose of alcohol. Prevalence is 46% when confirmed by nerve conduction studies. Alcohol causes deficiencies by replacing more nutritious foods in the diet, by increasing the requirements for B vitamins (which are needed for its metabolism), and perhaps by impairing vitamin absorption. Alcohol may also have a direct toxic effect on peripheral nerves: in a few patients, a neuropathy occurs despite an adequate diet. The prognosis for ultimate, but slow, recovery is good for patients who are able to stop drinking and resume a proper diet with multivitamin supplements [43].

Vitamin B1 (Thiamine) Deficiency

Neuropathy due to thiamine deficiency or beriberi is associated with alcoholism, recurrent vomiting, AIDS, long-term total parenteral nutrition, eating disorders, and bariatric surgery. It is also responsible for Wernicke's encephalopathy and Korsakoff's syndrome. Features include sensory loss, burning pain, or muscle weakness in the toes and feet. If untreated, the neuropathy will ascend. It may also involve the recurrent laryngeal nerve or cranial nerves manifesting with hoarseness and tongue and facial weakness. Thiamine replacement can occur either intravenously or intramuscularly at an initial dose of 100 mg daily. Symptoms may take 3–6 months to resolve [44].

Vitamin B6 (Pyridoxine) Deficiency and Toxicity

Vitamin B6 can cause neuropathy both in deficiency and excess. Dietary deficiency is rare; however, many medications interfere with B6

Telegram: @medical_k

www.konkur.in

metabolism. Culprits include isoniazid, phenelzine, hydralazine, and penicillamine. It may also be seen in alcoholics, patients on dialysis, and pregnant or lactating women due to high metabolic needs. Symptoms of deficiency are numbness, paresthesias, and burning pain in the feet that ascends. Examination will show decreased distal sensation, reduction of deep tendon reflexes, ataxia, and mild distal weakness. Toxicity causes sensory ataxia, areflexia, and impaired cutaneous sensation. Prophylactic doses of pyridoxine 50 mg per day are recommended for those treated with isoniazid or hydralazine and 10–50 mg for those undergoing dialysis [44].

Vitamin B12 Deficiency

Vitamin B12 is found in animal and dairy products and is liberated from food by stomach acid. Persons at risk for B12 deficiency include patients with malabsorption, pernicious anemia, gastrointestinal surgeries, and strict vegan diets. Additionally, prolonged use of metformin, proton pump inhibitors, and H2 blockers has been implicated. The neuropathy usually presents with sensory symptoms in the feet and may be associated with anemia or normal blood counts. Patients have increased tone, loss of proprioception and vibration, weakness in the corticospinal tract (hip and knee flexors), brisk reflexes, and extensor plantar responses in the toes. Diagnosis is made with serum levels less than 200 pg/mL or in the low normal range up to 400 pg/mL. Measuring serum methylmalonic acid or homocysteine may improve sensitivity. Treatment is with administration of B12 1000 mcg intramuscularly for 5–7 days followed by 1000 mcg monthly or alternatively starting with once weekly injections for 4 weeks followed by monthly. Oral therapy is as effective in doses of 1–2 mg daily, though improvement is slower than with injection therapy [44].

Vitamin E Deficiency

Vitamin E is a fat-soluble vitamin; therefore deficiency may take 5–10 years to manifest. Symptoms mimic Friedreich's ataxia with ataxia, hyporeflexia, and loss of proprioception and vibration. Diagnosis is made with alpha-tocopherol levels in the serum. Treatment is with oral supplementation of 400 international units twice daily until normalization of levels. Those with malabsorption syndromes may require water-soluble or intramuscular preparations [44].

Copper Deficiency

Copper deficiency can cause both a peripheral neuropathy and myelopathy. It is mainly caused by prior gastric surgery or excessive zinc intake. Patients present with gait difficulty and lower limb paresthesias. Exam will reveal loss of proprioception and vibration in addition to sensory ataxia. There may also be upper motor neuron signs such as bladder dysfunction, brisk knee jerks, and extensor plantar reflexes. MRI may show increased signal in the posterior columns. Serum levels of copper, ceruloplasmin, and urinary excretion of copper will be low in addition to anemia. If deficiency is due to excessive exogenous zinc, this should be discontinued. Replacement with 2 mg of elemental copper three times daily via oral route is preferred [44].

Hereditary Neuropathies

Hereditary neuropathies are estimated to occur in 1 per 10,000 individuals. Due to the slowly progressive, indolent course of these disorders, many patients do not recall other family members being affected, and in some cases they do not recognize the abnormalities in themselves. The hereditary neuropathies are typically associated with foot drop, high-arched feet (pes cavus), hammertoe deformities, slowly progressive weakness and wasting of peroneal muscle groups, and a high-stepping, slapping gait. Sensory symptoms are much less prominent.

The genetics and pathophysiology of numerous hereditary neuropathies have been elucidated; however, just two types of hereditary motor and sensory neuropathies (HMSN I,

Telegram: @medical_k

www.konkur.in

HMSN II) represent virtually all forms of this disorder. HMSN I, a demyelinating process with onset during the teenage years, constitutes roughly 70% of the hereditary neuropathies. Nearly all other hereditary neuropathies are HMSNII (formerly called Charcot-Marie-Tooth or peroneal muscle atrophy), a primarily axonal degeneration with secondary demyelination that occurs during the fourth decade of life or later. These two types share an autosomal dominant inheritance; however, many subtypes have been identified with varying inheritance patterns. Specific genetic tests are now available to confirm the diagnosis of many of the hereditary neuropathies [45].

There is no specific treatment for any of these disorders; genetic counseling and education are needed. Patients with this disorder frequently have deformities of the foot that can be managed with physical therapy. Disability varies widely between families. Animal trials have shown promise using ascorbic acid and progesterone antagonists. Clinical studies are ongoing.

Treatment

Appropriate treatment for any underlying diseases should be instituted (e.g., control of glucose, thyroid replacement). Offending toxins or medications should be stopped and nutritional deficiencies corrected. Other disease-specific treatments are addressed above.

Neuroleptic drugs and tricyclic antidepressants have been the mainstay of treatment for neuropathic pain. Patients can be started on amitriptyline, duloxetine, gabapentin, or pregabalin initially [29]. Gabapentin and pregabalin have the best evidence for treatment of painful diabetic neuropathy, postherpetic neuralgia, and central neuropathic pain [46]. Gabapentin and carbamazepine also show efficacy in treatment of pain associated with Guillain-Barre syndrome [35]. Other neuroleptics may have benefit in individual patients. Tramadol may be considered for acute pain, but opioids are not recommended for chronic treatment of neuropathic pain as they have questionable efficacy with deleterious side effects and safety concerns [42]. Capsaicin and lidocaine patches have weak evidence in support of their use in peripheral neuropathic pain only [1]. Interventional treatments such as nerve blocks or surgical procedures may be considered for patients with refractory neuropathic pain. Botulinum toxin A has shown some promise in treating areas of muscle hyperactivity associated with neuropathy. [47].

Psychological interventions may be considered for comorbid mood disorders and sleep disturbances. Their evidence for improving neuropathic pain is weak at best [48].

Meningitis

Background

Meningitis is defined as an acute inflammation of the meninges, which may result in significant morbidity and mortality. Meningitis may be caused by infectious agents (bacteria, viruses, parasites, and fungi) or may arise from a noninfectious etiology (cancer, systemic lupus erythematosus, certain medications, head injury, and brain surgery). When caused by an infectious agent, approximately one in four cases of meningitis is bacterial, with an additional 10% due to fungus and other nonviral agents. The remainder is due to viruses. In the United States, bacterial meningitis occurs at a rate of 1.38 cases per 100,000 population per year, with a case fatality of approximately 15%. The causative bacterial agent varies with age. Under 2 months of age, group B streptococcus is the most common bacterial agent, and in those 11–17 years of age, *Neisseria meningitides* is the most common bacterial agent. In all other pediatric age groups and in adults, *Streptococcus pneumonia* is the most common bacterial agent. Viral meningitis is most commonly caused by enteroviruses followed by herpes simplex virus type 2 and varicella zoster virus. Fungal infections are a rare cause and most common in immunocompromised individuals [1].

Presentation

About half (44%) of adults will have a "textbook" presentation of meningitis, the triad of fever, neck stiffness, and change in mental status. However, the most frequent symptom in adults subsequently found to have meningitis is headache, followed by neck stiffness, fever, and change in mental status. Using a dyad (two of four of the following: headache, fever, neck stiffness, or a change in mental status) increased the positive predictive value to 95%. Only 4% of patients subsequently diagnosed with meningitis had one symptom, with 1% having none of the four symptoms. The clinical presentation of meningitis for children under the age of 3 is usually more subtle and atypical, may not have any of the four cardinal symptoms, and may present only with irritability and lethargy.

Diagnosis

History

Aside from making the diagnosis, a carefully taken history is important to determine if there are any predisposing or complicating factors. These include infectious illness, immunocompromised state, previous neurosurgical procedure, and immunization status. However, clinical history alone is not sufficient to diagnose meningitis.

Physical Examination

The physical exam for meningitis is focused on finding and documenting neurologic deficits on presentation. In addition to documenting meningeal signs (jolt accentuation of headache, Kernig's and Brudzinski's signs), the physical exam should include an assessment of the rest of the neurologic system including the Glasgow Coma Score. The presence of meningeal irritation is assessed by laying the patient supine and gently flexing the neck

Telegram: @medical_k

www.konkur.in

forward while examining the neck for rigidity. Kernig's sign is performed with the patient supine and the hip flexed to 90°. A positive sign is present when extension of the knee from this position elicits resistance or pain in the lower back or posterior thigh. Brudzinski's sign is present with passive neck flexion in a supine position results in flexion of knees and hips. The jolt accentuation of headache is positive if the patient's headache worsens when turning his or her head horizontally 2–3 rotations per second. The classic triad of fever, neck stiffness, and a change in mental status is present in only about 44% of episodes, but 95% of cases had at least two of four symptoms of headache, fever, neck stiffness, and altered mental status. Since these bedside diagnostic tools have poor sensitivity, further diagnostic testing should not be precluded by the absence of these clinical signs [2].

Cerebrospinal Fluid Examination

Prompt examination of the cerebrospinal fluid (CSF) is required for diagnostic confirmation of meningitis. Imaging for intracranial lesions should be performed prior to lumbar puncture (LP) in patients with altered mentation, focal neurological findings, and papilledema or if there is clinical suspicion of increased cranial pressure. Other relative contraindications to performing a lumbar puncture include local infection at the puncture site, recent administration of anticoagulation within the past hour, and platelet count less than $20 \times 10^3/\mu L$. Videos of how to perform a LP are readily available online.

When possible, opening pressure of the CSF within the spinal canal should be documented. Normal opening CSF pressure is 10–100 mm H_2O in young children, 60–200 mm of H_2O after 8 years of age, and up to 250 mm of H_2O in obese patients. 1–5 ml samples of CSF are normally placed into four tubes, numbered in the order in which they were collected. Tube 1 is used for cell count, tube 2 for protein and glucose, tube 3 for specific tests as indicated (e.g., latex agglutination for bacterial and viral antigens, polymerase chain reaction), and tube 4 for cultures. Normal values are easily obtained from multiple references and may vary with the patient's underlying condition [3].

Laboratory Testing and Imaging

Additional testing should include a complete blood count with differential, complete metabolic panel, and blood culture. Cultures should be obtained from blood as well as other potential sources of infection. Additional imaging performed should be obtained as warranted by clinical suspicion.

Treatment

Antibiotic therapy should be initiated as soon as possible after the diagnosis of meningitis is entertained and should not be delayed to obtain a CSF sample. Antibiotic choice is dependent on age, comorbidities (e.g., immunodeficiency, prior neurosurgical procedures), and situation (e.g., head trauma). For most suspected meningitis cases, an initial broad-spectrum approach such as vancomycin and a third-generation cephalosporin is suggested as an empiric antibiotic regimen with subsequent changes based on culture results. For adults older than 50 years, the regimen should include ampicillin, as well as vancomycin and a third-generation cephalosporin. For infants younger than 1 month, the suggested empiric antibiotic regimen should include ampicillin and cefotaxime or ampicillin and an aminoglycoside. The use of dexamethasone remains controversial. If herpes simplex meningitis is clinically suspected, empiric treatment should include acyclovir. For uncomplicated cases of viral meningitis, no specific antibiotic therapy is necessary [4].

Course and Prognosis

Without treatment, mortality of patients with bacterial meningitis approaches 100%. However, even with treatment, the mortality rate in the United States is still 15%. This has improved significantly since the routine vaccination for Hib in the early 1990s. Hearing loss is seen in 14% of adult patients and hemiparesis in 7% of adult patients. Stroke is seen in 3% of children [5, 6].

Telegram: @medical_k

www.konkur.in

Special Considerations

Chronic Meningitis

Chronic meningitis is defined as "irritation and inflammation of the meninges persisting for more than 4 weeks associated with pleocytosis in the cerebrospinal fluid." Chronic meningitis may be caused by persistent infection, allergic inflammatory reaction to an infection, autoimmune disease, or chemical and drug exposure. Clinical presentation is often nonspecific and only becomes similar to that of acute meningitis over time. The approach to diagnosis is necessarily broad, but an accurate and detailed history and physical exam will help to narrow the differential diagnosis. Up to one-third of patients with chronic meningitis will not have a definitive diagnosis even after a thorough and complete investigation [7].

Noninfectious Meningitis

Medications [trimethoprim–sulfamethoxazole (Bactrim), ibuprofen (Motrin), and naproxen (Naprosyn)] and medical procedures (intrathecal injections and neurosurgical procedures) can rarely cause noninfectious meningitis. Brain tumors may cause "chemical" meningitis due to the lipid-induced chemical irritation and may require repeated LPs and careful examination of CSF for diagnosis. Connective tissue diseases and vasculitis syndromes have been reported to be associated with noninfectious meningitis, especially sarcoidosis, systemic lupus erythematosus, and Behçet's disease [8].

Prevention

Vaccines as primary prevention have been successful in greatly reducing the incidence of bacterial meningitis in children and adults – especially since their addition to the childhood vaccine schedule. Vaccines are available for *Haemophilus influenzae* type b, *Neisseria meningitis*, and *Streptococcus pneumonia*. Guideline for chemoprophylaxis for close contacts of individuals diagnosed with bacterial meningitis is available. In addition, universal screening of all pregnant women for group B streptococcal disease with subsequent treatment during labor has caused a marked decline in perinatal group B streptococcal disease [6].

Encephalitis

Background

Encephalitis is the presence of an inflammatory process of the parenchyma of the brain in association with clinical evidence of neurological dysfunction. Encephalitis can be caused by a large variety of pathogens. Of the cases where an etiology was identified, most were viral, followed by bacterial, prion-related, parasitic, and fungal etiologies. In the majority of cases, an etiology will not be identified. In the United States, the most commonly identified etiologies are herpes simplex virus (HSV), West Nile virus, and enteroviruses, followed by other herpesviruses. Exposure can be immediately proximate to the onset of symptoms or delayed such as encephalitis associated with measles, congenital rubella, or HIV. HSV encephalitis can be either acute (33%) or the result of reactivation of latent infection (66%).

Presentation

The presentation of encephalitis is very similar to that of meningitis and includes fever, headache, nausea and vomiting, and altered level of consciousness often associated with seizures and focal neurological findings. Other common findings include disorientation, speech disturbances, and behavioral changes. Alterations in mental functions may cause lethargy, drowsiness, confusion, disorientation, and coma.

Diagnosis

History and Physical Exam

As the differential diagnosis of encephalitis is broad, a thorough history and physical exam are necessary to narrow the differential diagnosis list. Helpful questions to ask during history taking to determine the etiology include age, animal contact, immunocompromised states, ingested items, insect contact, occupation, recent sick contacts, recent vaccinations, recreational activities, season, transfusion and

Telegram: @medical_k

www.konkur.in

Table 1 Findings associated with specific etiologies

Etiology	Findings
Herpes simplex virus	Frontotemporal signs Mucous membrane lesions
Rabies	Psychomotor excitation Bulbar dysfunction and spasm
Creutzfeldt–Jakob disease	Subacute personality changes Dementia with myoclonus

Adapted from Refs. [9, 10]

transplantation, travel history, and vaccination status. A detailed physical exam with careful attention paid to a careful neurological exam may be helpful in narrowing the differential diagnosis list as certain physical exam findings are associated with specific etiologies (see Table 1).

Laboratory Testing

Cerebrospinal fluid (CSF) analysis is essential to diagnosis in all patients with encephalitis (unless contraindicated) and will typically demonstrate lymphocytic pleocytosis with normal glucose and a modest elevation of protein. CSF should be analyzed for virus-specific IgM antibodies and nucleic acid amplification – especially herpes simplex polymerase chain reaction (PCR). Other studies should include complete blood count; tests of renal and hepatic function; coagulation studies and chest radiography; cultures of body fluid specimens; biopsy of specific tissue for cultures, antigen detection, nucleic acid amplification tests, and histopathology examination; serological testing of IgM antibodies; acute- and convalescent-phase serum samples for retrospective diagnosis of an infectious agent; nucleic acid amplification of body fluids outside of the CNS; and peripheral blood smear. Additional diagnostic studies should be performed on the basis of specific epidemiological and clinical clues.

Imaging

Magnetic resonance imaging (MRI) of the brain is the most sensitive neuroimaging test to evaluate patients with encephalitis, although computerized tomography (CT), with and without contrast, should be used in patients if MRI is unavailable, impractical, or cannot be performed. MRI may show characteristic patterns seen with specific agents in patients with encephalitis.

Treatment

All patients with encephalitis should empirically be started on acyclovir (Zovirax) 10 mg/kg (500 mg/m^2 for children <12 years) IV infused over 1 h every 8 h for 14–21 days pending results of diagnostic tests and elimination of the possibility of HSV as a causative agent. Other antimicrobial agents should be started on the basis of specific epidemiological or clinical factors, including appropriate therapy for bacterial meningitis. In patients with clinical and epidemiological clues suggestive of rickettsial or ehrlichial infection during the appropriate season, doxycycline (Vibramycin) 100 mg twice daily for 10–14 days should be added to the empirical regimen. Specific therapy should be tailored based on the results of diagnostic testing.

Course and Prognosis

Morbidity and mortality remain high with encephalitis. Poor prognostic factors include age above 60, reduced Glasgow Coma Score on admission, and, for HSV encephalitis, delay between hospitalization and starting treatment with acyclovir. The mortality rate for encephalitis is dependent on the causative organism ranging from less than 5% with ehrlichiosis to 33% with Eastern equine encephalitis virus to 100% with rabies. In addition, approximately two-thirds of survivors will have significant neuropsychiatric sequelae

Telegram: @medical_k

www.konkur.in

including memory impairment, personality and behavioral change, dysphagia, and seizures [9–11].

Brain Abscess

Background

Brain abscesses, or focal intracerebral infections consisting of an encapsulated collection of pus caused by bacteria, mycobacteria, fungi, protozoa, or helminths, are most commonly caused by bacteria. *Streptococcus* species is the most common causative agent, followed by *Staphylococcus* species, then gram-negative enteric species. Brain abscesses are rare, with the incidence estimated to be 0.3–1.3 per 100,000 people per year. The incidence is significantly higher in developing countries and in patients who are alcoholic, are immunosuppressed (e.g., acquired immune deficiency syndrome, chemotherapy, biologic drugs), have cyanotic heart conditions, or are severely debilitated by neurological conditions. Brain abscesses most often arise from direct invasion from a contiguous focus of infection (i.e., otitis, mastoiditis, sinusitis, meningitis, and odontogenic). They can also be secondary to blood-borne pathogens (i.e., pulmonary focus or heart disease) or arise in areas of previous head trauma.

Presentation

An area of damaged brain tissue allows a nidus of infection to occur with subsequent local areas of infarction. Cerebritis follows as the area becomes necrotic and encapsulated within a few weeks. Presentation is dependent on mechanism and pathogen, which includes focal mass expansion, increased intracranial pressure, diffuse destruction, or focal neurological deficit. Clinical signs and symptoms of brain abscesses are varied and commonly include fever, headache, hemiparesis of a cranial nerve, hemiparesis, meningism, altered level of consciousness, seizure, nausea and vomiting, and papilledema.

Diagnosis

Physical Exam

The most common symptoms of brain abscess are headache (69%), fever (53%), and focal neurological deficits (48%). However, as a triad, the three together only occur in 20% of patients with brain abscesses. A high index of suspicion is required to make the diagnosis, particularly in febrile patients with a history of central nervous system instrumentation.

Laboratory Studies

Laboratory studies, such as blood cultures, complete blood count, and chest radiograph, are commonly performed, but may not provide useful data, as only 28% of blood cultures were positive in one study. CSF cultures are often sterile, and lumbar puncture is not recommended and may be contraindicated due to increased intracranial pressure.

Neuroimaging

Diagnosis is dependent on neuroimaging. Classically, a hypodense lesion with a contrast-enhancing ring will be seen on computed tomography (CT) of the brain or magnetic resonance imaging (MRI) of the brain. CT of the brain allows for detection, localization, characterization, and is ubiquitous in emergency departments. In addition, CT of the brain can detect hydrocephalus, increased intracranial pressure, edema, and other associated infections. However, CT of the brain has a 6% false-negative rate. Diagnosis of brain abscess by MRI of the brain is more accurate than CT, but MRI is not as ubiquitous or available as CT and so is less commonly used.

Treatment

Treatment of brain abscess requires a combination of antibiotic treatment, surgical intervention, and eradication of the primary foci. Successful treatment of brain abscesses often requires drainage under CT guidance in addition to antibiotic therapy.

Telegram: @medical_k

www.konkur.in

Antibiotic Therapy

Until the abscess can be drained and cultured, empiric antibiotic therapy should consist of broad-spectrum antibiotics that easily cross the blood–brain, and blood–CSF barriers should provide coverage for the most common pathogens. Acceptable antibiotic choices include a third-generation cephalosporin and metronidazole. Vancomycin should be added if there is a history of penetrating trauma or recent neurosurgical procedure. Antibiotic therapy should be tailored for patients with specific immune function defects, transplant recipients, cancer, and on chronic steroid therapy. However, as cultures are often sterile, broad-spectrum antibiotics should be continued for the entire course.

Duration of antimicrobial therapy has been suggested to be 4–6 weeks for a surgically drained abscess, 6–8 weeks for a brain abscess solely treated with antibiotics, and 3–12 months for immunocompromised patients.

Neurosurgical Intervention

Emergent drainage of brain abscesses is indicated as part of the management and to establish the causative pathogen due to the high sterile culture rate. Aspiration has become the preferred method for drainage providing relief from increased intracranial pressure and avoids the possibility of damage to the surrounding brain. However, aspiration often (70%) requires repeat procedure and can possibly cause iatrogenic puncture of the ventricle and subarachnoid leakage of pus leading to extension of the brain abscess.

Adjunctive Therapy

Steroids are generally avoided except in the perioperative period. They are indicated for reduction of intracranial pressure and avoiding acute brain herniation in those patients that demonstrate signs of meningitis or disproportionate cytotoxic edema posing a life-threatening problem. Steroids should be tapered as rapidly as possible.

Anticonvulsants are commonly used to control seizures and are used as prophylaxis for subsequent seizures after resolution of brain abscesses. Anticonvulsants are recommended to be continued for 5 years after resolution of the brain abscess. However, discontinuing anticonvulsants may be considered if the patient has been seizure-free for 2 years after surgery and no epileptic activity is seen on electroencephalography (EEG). The law regarding driving with a diagnosis of seizure is dependent on the state, but usually requires being seizure-free for 6–12 months prior to resumption of driving.

Course and Prognosis

The mortality rate of brain abscesses has declined by 50%, from 20% to 10% in recent years. Approximately half of patients will have a good outcome, but the other half will either die or have neurological sequelae. Poor prognostic indicators include delayed diagnosis, rapidly progressing disease, coma, multiple lesions, intraventricular rupture, and fungal etiology. Outcomes are worse in the elderly and newborn. Neurological sequelae include focal neurologic deficits, intellectual disability, and postoperative seizures [12–14].

Neurosyphilis

Background

Syphilis is a sexually acquired condition caused by infection with *Treponema pallidum* and is known as the "great imitator" due to its varied presentation. Although syphilis was close to eradication in 2000, in the years between 2005 and 2013, syphilis has increased in annual rate from 2.9 to 5.3 cases per 100,000 population [15].

Presentation

Syphilis is divided into primary infection (ulcer or chancre), secondary infection (skin rash, mucocutaneous lesions, lymphadenopathy), neurologic infection (cranial nerve dysfunction, meningitis, stroke, acute or chronic altered mental status, loss of vibration sense, and auditory or ophthalmic abnormalities), and tertiary infection (cardiac or

Telegram: @medical_k

www.konkur.in

gummatous lesions). However, neurosyphilis can occur at any stage of infection and has three distinct patterns of occurrence. Asymptomatic neurosyphilis is defined as the presence of cerebrospinal fluid (CSF) abnormalities consistent with neurosyphilis in persons with serological evidence of syphilis and no neurological signs or symptoms. Early symptomatic neurosyphilis involves diffuse inflammation of the meninges and presents similarly to meningitis – headache, photophobia, nausea, vomiting, cranial nerve palsies, and occasionally seizures. Lastly, meningovascular syphilis consists of endarteritis of vessels anywhere in the central nervous system resulting in thrombosis and infarction.

Headache, vertigo, and insomnia often occur early in the course of infection. Dramatic symptoms such as the sudden onset of contralateral hemiparesis, hemianesthesia, homonymous hemianopsia, and aphasia lead to a more rapid diagnosis. Symptoms of syphilis involving the spinal cord include spastic weakness of the legs, sphincter disturbances, sensory loss, and muscle atrophy. Parenchymatous syphilis may manifest as either paretic neurosyphilis ("general paralysis of the insane") or tabetic neurosyphilis ("tabes dorsalis"). Early symptoms of paretic neurosyphilis include irritability, forgetfulness, personality changes, headaches, and changes to sleep habits, while late symptoms include emotional liability, impaired memory and judgment, disorientation, confusion, delusions, seizures, and other psychiatric symptoms. Tabetic neurosyphilis presents classically as ataxic gait, lightening pains, paresthesias, bladder dysfunction, and failing vision.

Diagnosis

Physical Exam

Depending on the stage and presentation of neurosyphilis, the physical exam may be unremarkable or may be similar to other disease processes. Physical exam findings may include papillary abnormalities (Argyll Robertson pupils), diminished reflexes, impaired vibratory sense and proprioception, ocular palsies, and Charcot joints (progressive degeneration of weight-bearing joints) [16, 17].

Laboratory Studies

The diagnosis of syphilis is made using a combination of serological tests [Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR)], treponemal tests [fluorescent treponemal antibody absorbed (FTA-ABS) or *T. pallidum* passive particle agglutination (TP-PA)], or dark-field examination. Laboratory testing can only be used to support the diagnosis of neurosyphilis, but no single test can be used to diagnose neurosyphilis in all circumstances. The identification of serologic changes in the cerebrospinal fluid (CSF-VDRL) has a high specificity, but low sensitivity. CSF-VDRL can be positive in early syphilis, but is a finding of uncertain significance. CSF can be tested for treponemal antibodies using FTA-ABS. This is more sensitive than CSF-VDRL, but less specific. Therefore, diagnosis of neurosyphilis is a combination of reactive serological test results and a reactive CSF-VDRL, in the presence of signs of CSF inflammation (elevated cell count and protein), with or without clinical manifestations.

Treatment

Antimicrobial Treatment

Penicillin is the preferred drug for treating all stages of syphilis – including in pregnancy. Those with a penicillin allergy should undergo desensitization and be treated with penicillin.

A frequent reaction to the administration of penicillin G at any stage of syphilis is the Jarisch–Herxheimer reaction, which is an acute febrile reaction frequently accompanied by headache, myalgia, and fever. Although this may induce early labor or fetal distress in pregnant women, this should not delay or prevent therapy.

Penicillin G 18–24 million units per day is the preferred dosage and should be administered as 3–4 million units by IV every 4 h or as a continuous infusion for 10–14 days. If

Telegram: @medical_k

www.konkur.in

compliance is an issue, an alternative regimen is procaine penicillin 2.4 million units once daily and probenecid 500 mg orally four times daily for 10–14 days.

If CSF pleocytosis was present initially on examination, repeat CSF examination should occur every 6 months until the cell count is normal. If cell count or protein is not normal after 2 years, retreatment should be considered.

Special Considerations

Persons who are exposed to syphilis via intimate contact at any stage should be evaluated clinically and serologically. If the exposure was within 90 days preceding the diagnosis of any stage of syphilis – even if the exposed person is seronegative – he or she should be treated presumptively. Persons who are exposed 90 days or more prior to diagnosis of any stage of syphilis in a sex partner should have serologic testing prior to treatment. However, the exposed person should be treated presumptively if serological testing is not available immediately and follow-up is uncertain. In addition, intimate partners of infected patients should be provided presumptive treatment if they have had sexual contact with the patient within 3 months plus the duration of symptoms for primary syphilis, within 6 months plus duration of symptoms for secondary syphilis, and within 1 year for patients with early latent syphilis [18].

Brain Tumors

Background

Primary brain tumors are rare, accounting for 1.4% of all new cancer cases with an incidence of 5.42 per 100,000 children aged 0–19 years and 27.9 per 100,000 adults aged 20 years and older. Approximately 34% of all primary brain tumors are malignant. The most common types of primary brain tumor are malignant glioblastoma and meningioma. In adults, the most common types of primary brain tumor are glioblastoma, meningioma, astrocytoma, and pituitary adenoma, while in children, the most common types of primary brain tumors are tumors of pilocytic astrocytoma, embryonal tumors, and malignant glioma (see Table 2) [19].

Metastatic disease to the CNS is much more common than primary brain tumors occurring up to ten times as often as primary brain tumors. Although primary lung cancers are the most common source of metastatic lesions, melanoma and breast cancer are becoming more frequent. Approximately 80% of brain metastases occur in the cerebral hemispheres, followed by 15% in the cerebellum, and 5% in the brainstem.

Presentation

The presenting signs and symptoms of metastatic brain lesions are similar to other mass

Table 2 Distribution of primary brain tumors by histology

Histology	Percentage of total
Meningioma	36.1%
Glioblastoma	15.4%
Tumors of the pituitary	15.1%
Nerve sheath tumors	8.0%
All other astrocytomas	6.0%
Lymphomas	2.1%
Ependymal tumors	1.9%
Oligodendrogliomas	1.6%
Embryonal tumors	1.1%
Oligoastrocytic tumors	0.9%
All other	11.8%

Table 3 Red flag symptoms that should prompt immediate imaging

Red flag	Differential diagnosis
Headache beginning after 50 years of age	Temporal arteritis, mass lesion
Sudden onset of headache	Subarachnoid hemorrhage, pituitary apoplexy, hemorrhage into a mass lesion or vascular malformation, mass lesion
Headaches increasing in frequency and severity	Mass lesion, subdural hematoma, medication overuse
New-onset headache in a patient with risk factors for HIV infection or cancer	Meningitis (chronic or carcinomatous), brain abscess (including toxoplasmosis), metastasis
Headache with signs of systemic illness (fever, stiff neck, rash)	Meningitis, encephalitis, Lyme disease, systemic infection, collagen vascular disease
Focal neurological signs or symptoms of disease (other than typical aura)	Mass lesion, vascular malformation, stroke, collagen vascular disease
Papilledema	Mass lesion, pseudotumor cerebri, meningitis
Headache subsequent to head trauma	Intracranial hemorrhage, subdural hematoma, epidural hematoma, posttraumatic headache

Adapted from Ref. [20]

lesions and can be separated into focal or generalized symptoms. Focal symptoms are dependent on tumor location. For example, focal symptoms of brain tumors in the frontal lobe include dementia, personality changes, gait disturbance, expressive aphasia, and seizures; in the parietal lobe include receptive aphasia, sensory loss, hemianopia, and spatial disorientation; in the temporal lobe include complex partial or generalized seizure, behavior change, including symptoms of autism, and quadrantanopia; in the occipital lobe include contralateral hemianopia; in the thalamus include contralateral sensory loss, behavior change, and language disorder; in the cerebellum include ataxia, dysmetria, and nystagmus; and in the brainstem include cranial nerve dysfunction, ataxia, papillary abnormalities, nystagmus, hemiparesis, and autonomic dysfunction. Generalized symptoms include headache, memory loss, cognitive changes, motor deficit, language deficit, seizures, personality change, visual problems, changes in consciousness, nausea or vomiting, sensory deficit, and papilledema [20].

Diagnosis

Diagnosis is dependent on appropriate brain imaging followed by histopathology to confirm diagnosis. Acute headaches with red flag symptoms should prompt immediate imaging (see Table 3) [21].

The imaging modality of choice is gadolinium-enhanced magnetic resonance imaging (MRI). For those who cannot have a MRI performed, computed tomography (CT) of the head and spine is acceptable; however, CT does not have as high of a resolution as MRI and is unable to adequately assess lesions in the posterior fossa and spine.

Treatment

Due to the varied course and symptoms of primary and metastatic brain tumors, prognosis and treatment are highly individualized and are dependent on age and performance status of the patient, proximity to "eloquent" areas of the brain, feasibility of decreasing the mass effect, resectability of the tumor, and time since last surgery for those with recurrent disease. In general, regardless of tumor histology, the best outcome is through a combination of maximal safe resection (stereotactic biopsy, open biopsy, subtotal resection, or complete resection) and radiation therapy (brachytherapy, fractionated external beam radiotherapy, or fractionated stereotactic radiotherapy). Whole brain radiotherapy and stereotactic radiosurgery is often reserved for metastatic disease.

Telegram: @medical_k

www.konkur.in

Symptom Treatment

Corticosteroids may be necessary to treat vasogenic edema. Often, corticosteroids need to be tapered slowly, although side effects of long-term use of corticosteroids include cognitive impairment, hypoglycemia, gastrointestinal problems, myopathy, and opportunistic infections. Seizures are common with brain tumors, including after surgery. However, prophylactic use of antiseizure medications is not indicated [22].

Course and Prognosis

Prognosis is dependent on histopathology (oligodendrogliomas have a better prognosis than mixed gliomas, which have a better prognosis than astrocytomas) and tumor grade. Younger age, good initial performance score, and O6-methylguanine methyltransferase (MGMT) gene promoter hypermethylation are associated with a more favorable prognosis [23].

Multiple Sclerosis

Background

Multiple sclerosis (MS) is a disabling demyelinating immune-mediated disease of the central nervous system (CNS) that disproportionately affects women, smokers, persons living at higher latitudes, and persons with a family history of MS. Increased exposure to sunlight and higher 25-hydroxyvitamin D levels confer lower risk. The incidence of MS ranges from 47.2 to 109.5 per 100,000 persons in the United States [24].

Presentation

The clinical presentation of MS is varied and can include symptoms such as depressed mood, dizziness or vertigo, fatigue, hearing loss and tinnitus, loss of coordination and gait disturbance, pain, sensory disturbances (dysesthesias, numbness, paresthesias), urinary symptoms, visual disturbances (diplopia and oscillopsia), and weakness and can include signs such as ataxia, decreased sensation (pain, vibration, position), decreased strength, hyperreflexia, spasticity, nystagmus, and visual defects (internuclear ophthalmoplegia, optic disk pallor, red color desaturation, or reduced visual acuity) [25, 26].

Diagnosis

History, Physical Exam, and Diagnostic Imaging

The current guideline for diagnosis of multiple sclerosis (MS), the 2010 revisions to the McDonald Criteria, requires a combination of history, physical exam, and diagnostic imaging. An attack is defined as "patient-reported symptoms or objectively observed signs typical of an acute inflammatory demyelinating event in the central nervous system (CNS), current or historical, with duration of at least 24 h, in the absence of fever or infection." The diagnostic criteria for MS based on clinical presentation are listed in Table 4 [27]. MS-typical regions of the CNS include periventricular, juxtacortical, infratentorial, or spinal cord.

Differential Diagnosis

MS has a broad differential diagnosis, and consideration should be given to testing angiotensin-converting enzyme levels, autoantibody titers, *Borrelia* titers, human immunodeficiency virus (HIV) screening, rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL), thyroid-stimulating hormone, and vitamin B12 level.

Treatment

Disease-Modifying Agents

The mainstay of treatment of MS is disease-modifying agents, which slow disease progression, preserve function, and sustain the immune system while suppressing the T-cell autoimmune cascade. Approved disease-modifying agents, which include interferon beta, glatiramer, fingolimod, teriflunomide, dimethyl fumarate, natalizumab, and mitoxantrone, are usually managed by an experienced neurologist.

Telegram: @medical_k

www.konkur.in

Table 4 Diagnostic criteria for multiple sclerosis

Clinical presentation	Additional data needed for MS diagnosis
≥2 attacks; objective clinical evidence of ≥2 lesions or objective clinical evidence of one lesion with reasonable historical evidence of a prior attack	None
≥2 attacks; objective clinical evidence of one lesion	Dissemination in space, demonstrated by: ≥1 T2 lesion in at least 2 of 4 MS-typical regions of the CNS Awaiting another clinical attack implicating a different CNS site
One attack; objective clinical evidence of ≥2 lesions	Dissemination in time, demonstrated by: Simultaneous presence of asymptomatic gadolinium-enhancing and non-enhancing lesions at any time A new T2 and/or gadolinium-enhancing lesion (s) on follow-up MRI, irrespective of its timing with reference to a baseline scan Await a second clinical attack
One attack; objective clinical evidence of one lesion (clinically isolated syndrome)	Dissemination in space and time, demonstrated by: For DIS: ≥1 T2 lesion in at least 2 of 4 MS-typical regions of the CNS Await a further clinical attack implicating a different CNS site For DIT: Simultaneous presence of asymptomatic gadolinium-enhancing and non-enhancing lesions at any time A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan Await a second clinical attack
Insidious neurological progression suggestive of MS (PPMS)	One year of disease progression (retrospectively or prospectively determined) plus two of three of the following criteria: 1. Evidence for DIS in the brain based on ≥1 T2 lesion in at least two of four MS-typical regions of the CNS 2. Evidence for DIS in the spinal cord based on ≥2 T2 lesions in the cord 3. Positive CSF (isoelectric focusing evidence of oligoclonal bands and/or elevated IgG index)

Adapted from Ref. [26]

Exacerbations

Exacerbations are common, affecting over 85% of patients with MS, and are often caused by infection or stress. Oral corticosteroids are the mainstay of the treatment of exacerbations. However, if there is no response to corticosteroids, plasmapheresis or plasma exchange may be performed.

Symptom-Specific Management

Neurogenic bladder, affecting more than 70% of patients with MS, may be alleviated with anticholinergic medications for failure-to-store symptoms; limiting evening fluid intake, desmopressin, or injections of onabotulinumtoxinA for nocturia; and clean intermittent catheterization or alpha-adrenergic blockade for failure-to-empty symptoms. Neurogenic bowel, affecting more than 75% of patients, may present with incontinence, constipation, or both and may require a colostomy if symptoms are intolerable. Sexual dysfunction is common, but often unaddressed. Men may be treated with centrally acting phosphodiesterase-5 inhibitors, although women have no similarly approved medication. Pain will affect approximately 85% of patients with MS (trigeminal neuralgia and neuropathic

Telegram: @medical_k

www.konkur.in

pain most commonly). Trigeminal neuralgia may be treated with carbamazepine and baclofen, while neuropathic pain may be treated with tricyclic antidepressants, anticonvulsants, or selective serotonin reuptake inhibitors. Spasticity should be treated with baclofen, although diazepam, gabapentin, or onabotulinumtoxinA may also be helpful. Treatment of fatigue, present in more than 90% of patients with MS, is multifocal and includes environmental manipulation (controlling heat and humidity levels) and energy conservation measures (napping and use of assistive devices for mobility). Amantadine has been used off-label for the pharmacological management of fatigue, but may cause insomnia and confusion [25].

Course and Prognosis

MS has an extremely varied course, characterized by two broad pathways. Primary-progressive MS is characterized by the invariable progression despite occasional plateaus or temporary minor improvements, with an average time to disability requiring use of a cane to ambulate of 6–21 years. Those diagnosed with relapsing-remitting and secondary-progressive MS tend to have an initial relapsing-remitting disease course, progressing to less prominent relapses and ensuing relentless progression. In these patients, the relapsing-remitting phase lasts for about 20 years prior to the secondary-progressive phase. The introduction of disease-modifying agents has increased the life span of a patient with MS, but is still approximately a decade shorter than expected from an age-matched general population [26].

General Principles

Definition/Background

Red eye is one of the most common ocular conditions that presents in the primary care setting. Most cases are benign; however, some may cause permanent vision loss. Many conditions can be treated by primary care physicians. Therefore, it is important for the provider to be able to determine those cases that require urgent ophthalmic consultation. Most causes of red eye can be diagnosed by

Telegram: @medical_k

www.konkur.in

taking a detailed patient history and careful eye examination. Obtaining certain elements in the history can aid in determining whether an ophthalmic consultation is required. Key elements in the history include pain, decreased vision, foreign body sensation, photophobia, trauma, use of contact lens, and discharge. The assessment of clinical signs should include the location of the redness (eyelids, conjunctiva, cornea, sclera and episclera, or intraocular), unilateral or bilateral involvement, associated symptoms (pain, itching, visual decrease or loss), and other ocular (mucopurulent discharge, watering, blepharospasm, lagophthalmus) or systemic (fever, nausea) findings [1]. Equally important is to perform a thorough ophthalmologic examination, including visual acuity, penlight examination, and fundus examination.

Almost half of the eye problems presenting in the primary care setting include conjunctivitis, keratoconjunctivitis sicca, and corneal abrasions [2]. Other less common causes include episcleritis, scleritis, iritis, herpes keratitis, trichiasis, and acute angle-closure glaucoma (see Table 1).

Conjunctivitis

Acute conjunctivitis affects approximately six million people annually and consists of approximately 1% of all primary care visits in the United States [3, 4]. It is estimated that 70% of all patients with acute conjunctivitis present to primary care and urgent care centers [5]. Conjunctivitis, commonly referred to as pinkeye, is the inflammation of the mucous membrane that lines the inside surface of the eyelids and the outer surface of the eye. The causes of acute conjunctivitis can be divided into infectious (e.g., bacterial, viral, chlamydial) or noninfectious (e.g., allergic, nonallergic/irritants). The most prominent signs consist of generalized conjunctival injection with gritty discomfort, mild photophobia, and variable amounts of discharge with no loss of visual acuity [1]. Generally, viral conjunctivitis and bacterial conjunctivitis are self-limiting conditions, and serious complications are rare. Since there is no specific diagnostic test to differentiate viral from bacterial conjunctivitis, most cases are treated using broad-spectrum antibiotics [2].

Bacterial Conjunctivitis

Bacterial conjunctivitis is caused by a wide range of gram-positive and gram-negative organisms; however, gram-positive organisms are more common [6]. *Staphylococcus aureus* is more common in adults, while *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* are more common in children. The incidence of *Haemophilus influenzae* has decreased as more children are immunized. Gram-negative organisms include *Escherichia coli* and *Pseudomonas* species. Hyperacute bacterial conjunctivitis is usually caused by *Neisseria gonorrhoeae* and is considered a sight-threatening infection that requires immediate ophthalmologic evaluation with hospitalization for systemic and topical therapy. It is usually transmitted from the genitalia to the hands and then to the eyes. It is characterized by a profuse purulent discharge present within 12 h of infection [7]. Additional symptoms include redness, lid swelling, and tender preauricular adenopathy. Gram staining of the purulent discharge reveals gram-negative diplococci.

History

Acute bacterial conjunctivitis initially presents with tearing and irritation in one eye but usually spreads to the opposite eye within 2–5 days. It is highly contagious and causes a rapid onset of generalized conjunctival redness, purulent discharge (yellow, white, or green), gritty discomfort, swelling of the eyelid, early morning crusting of the eyelids, and usually no loss of vision. However, one should suspect a gonococcal infection if the patient presents with profuse amounts of purulent discharge associated with a rapid progression of redness, irritation, and pain. *Neisseria gonorrhoeae* confirmed in a child should raise concern for sexual abuse. For *Neisseria meningitides*, one should consider meningitis.

Table 1 (continued)

	Etiology	Eye pain	Discharge	Visual acuity	Pupillary changes	Corneal involvement	Intraocular pressure	Immediate referral
Herpes keratitis	Predominantly HSV-1	Pain with foreign body sensation	Watery	Blurred	None	Recurrent infections cause reduced corneal sensation	Normal	Yes
Trichiasis	Abnormal positioning of the eyelids	Irritation	Watery	Untreated can cause vision loss	None	Can cause corneal scarring	Normal	Yes
Acute glaucoma	Narrowing of the ant. chamber	Severe throbbing	Watery	Decreased	Partially dilated, nonreactive	Swelling	Elevated	Yes

www.konkur.in

Physical Examination

For acute bacterial conjunctivitis, visual acuity is preserved with normal pupillary reaction and absence of corneal involvement. Additional findings include conjunctival injection and swelling of the eyelid, with mild to moderate purulent discharge. Patients will often describe that their eyelids are stuck together upon wakening due to the mucopurulent discharge. For hyperacute bacterial conjunctivitis, there is chemosis (swelling of the conjunctiva) with possible corneal involvement, pseudomembrane formation, and preauricular lymphadenopathy. Patients will complain of severe pain with copious amounts of purulent discharge and diminished vision.

Laboratory Findings

In most cases of bacterial conjunctivitis, the diagnosis and the identification of the presumed organism are based on history and clinical presentation. Further studies to identify the organism and determine its sensitivity to antibiotics are reserved for more severe cases or those that are unresponsive to initial treatment [8]. If a gonococcal infection is suspected, gram staining will reveal gram-negative diplococci.

Treatment

Most cases of bacterial conjunctivitis if uncomplicated are self-limited regardless of antibiotic therapy [9]. However, antibiotics are indicated for conjunctivitis caused by gonorrhea or chlamydia and in those patients that wear contact lenses [10]. It has also been shown that antibiotics cause earlier reduction of symptoms and therefore can be prescribed. Initial preferred treatment options include erythromycin ophthalmic ointment or trimethoprim-polymyxin B drops (see Table 2). For children or for those whom it is difficult to administer eye medications, ointment is preferred as it still maintains a therapeutic effect although none may have been directly applied to the conjunctiva. Because ointment can blur the vision and cause the eyes to feel sticky, drops are recommended for adults who require clear vision for driving or work. Sulfacetamide ophthalmic drops are not considered first line due to potential allergic reactions. Fluoroquinolones are effective and well tolerated but are usually reserved for more severe infections or contact lens wearers. For those who wear contact lenses, contact lens use should be discontinued, lens case discarded, and lenses disinfected or replaced. Once antibiotics have been completed and the eye has cleared and remains free of discharge for 24 h, contact lens wear may be resumed. Bacterial conjunctivitis that is chronic, resistant to initial antibiotic treatment, or caused by gonorrhea or chlamydia requires immediate referral to an ophthalmologist.

Viral Conjunctivitis

Viral conjunctivitis is a common, self-limiting condition that is most commonly caused by adenovirus, which consists of 65–90% of viral conjunctivitis cases [11]. Other viruses which are less likely to spread include herpes simplex virus, varicella zoster virus, picornavirus (enterovirus 70, Coxsackie A24), poxvirus (molluscum contagiosum, vaccinia), and human immunodeficiency virus (HIV). Adenoviruses 8, 19, and 37 are associated with epidemic keratoconjunctivitis, which is highly contagious, while adenoviruses 3 and 7 cause pharyngoconjunctival fever which is characterized by high fevers, sore throat, and preauricular lymphadenopathy [9]. Enterovirus 70 and Coxsackie A24 cause acute hemorrhagic conjunctivitis, which is characterized by the rapid onset of painful conjunctivitis and subconjunctival hemorrhage. Although benign and resolving within 5–7 days, it can cause a poliolike paralysis developing in approximately one in 10,000 patients infected with enterovirus 70 [12]. Conjunctivitis caused by herpes simplex virus is usually unilateral with watery discharge and ipsilateral vesicular facial rash [9]. Herpes zoster virus, commonly known as shingles, can involve the eye when the first and second branches of the trigeminal nerve are involved. Ocular involvement most commonly affects the eyelids (45.8%) followed by the conjunctiva (41.1%) [13]. Herpes zoster ophthalmicus represents approximately 10–25% of all cases of herpes zoster [14].

Table 2 Acute bacterial conjunctivitis treatment options

Medication	Dosage form	Adult dosage	Pediatric dosage	Comments
Erythromycin (Ilotycin)	0.5% ointment	Apply 1 cm ribbon up to 6×/day × 7–10 days	Apply 1 cm ribbon up to 6×/day × 7–10 days	Ointment recommended for children
Trimethoprim-polymyxin B (Polytrim)	10,000 units/1 mg/ml sol	One drop every 3 h × 7–10 days	>2 months: 1 drop every 3 h × 7–10 days	Drops better for adults
Bacitracin-polymyxin B (AK-Poly-Bac, Polycin)	500 units/10,000 units/g ointment	Apply 0.25–0.5 in. ribbon every 3–4 h × 7–10 days	Apply 0.25–0.5 in. ribbon every 3–4 h × 7–10 days	Ointment recommended for children
Sulfacetamide (Bleph-10)	10% ointment 10% solution	0.5 in. ribbon every 3–4 h and qhs × 7–10 days one to two drops every 2–3 h × 7–10 days	>2 months: 0.5 in. ribbon every 3–4 h and qhs × 7–10 days one to two drops every 2–3 h × 7–10 days	Not first line due to potential sulfa allergy
Gentamycin (Garamycin)	0.3% ointment 0.3% solution	0.5 in. ribbon bid-tid one to two drops every 4 h	>1 month: 0.5 in. ribbon bid-tid one to two drops every 4 h	May cause ocular burning
Tobramycin (Tobrex)	0.3% solution	One to two drops every 4 h	>2 months: one to two drops every 4 h	May cause ocular burning
Azithromycin (AzaSite)	1% solution	One drop bid × 2 days, then qd × 5 days	>1 year: one drop bid × 2 days, then qd × 5 days	May cause ocular burning
Ciprofloxacin (Cifloxan)	0.3% solution	One to two drops every 2 h while awake and then every 4 h while awake × 5 days	>1 year: one to two drops every 2 h while awake and then every 4 h while awake × 5 days	Reserved for severe infections or contact lens wearers
Levofloxacin (Iquix, Quixin)	0.5% solution	One to two drops every 2 h while awake and then every 4 h while awake × 5 days	>1 year: one to two drops every 2 h while awake and then every 4 h while awake × 5 days	Reserved for severe infections or contact lens wearers
Ofloxacin (Ocuflox)	0.3% solution	One to two drops every 2–4 h × 2 days and then one to two drops qid × 5 days	>1 year: one to two drops every 2–4 h × 2 days and then 1–2 drops qid × 5 days	Reserved for severe infections or contact lens wearers
Gatifloxacin (Zymar, Zymaxid)	0.5% solution	One drop every 2 h up to 8×/day × 1 day and then one drop bid-qid × 6 days	>1 year: one drop every 2 h up to 8×/day × 1 day and then 1 drop bid-qid × 6 days	Reserved for severe infections or contact lens wearers
Moxifloxacin (Vigamox, Moxeza)	0.5% solution	One drop tid × 7 days	>1 year: one drop tid × 7 days	Reserved for severe infections or contact lens wearers

History

The patient with acute viral conjunctivitis initially presents with a unilateral red eye with watery discharge and itching. Many times, the other eye becomes affected a few days later. Typically, there is absence of visual involvement or photophobia. Symptoms are typically mild with spontaneous remission in 1–2 weeks [1]. Pain, photophobia, and subconjunctival hemorrhages may be associated with keratoconjunctivitis or acute

Telegram: @medical_k

www.konkur.in

hemorrhagic conjunctivitis. Commonly, cases of acute viral conjunctivitis occur during or after an upper respiratory infection or with exposure to a person with an upper respiratory infection as it is highly contagious and spreads through direct contact via contaminated fingers, medical instruments, swimming pool water, or other personal items [2].

Physical Examination

For acute viral conjunctivitis, visual acuity is unaffected with normal pupillary reaction and absence of corneal involvement. Additional findings include follicular injection/erythema and swelling of the eyelid, with watery clear discharge. Keratoconjunctivitis is associated with preauricular lymphadenopathy and possible corneal infiltrates. Pharyngoconjunctivitis can be associated with subconjunctival hemorrhage. Herpes simplex virus causes a unilateral follicular conjunctivitis with an ipsilateral vesicular rash [9]. When involving the eye, herpes zoster can cause vesicular lesions in the distribution of the ophthalmic division of the trigeminal nerve with possible blepharitis, keratitis, uveitis, ophthalmoplegia, or optic neuritis [1]. Molluscum contagiosum usually presents as a unilateral follicular conjunctivitis with umbilicated lesions at the eyelid margin.

Laboratory Findings

Generally, viral conjunctivitis is diagnosed on clinical features alone. Laboratory testing is typically not necessary unless symptoms are severe, chronic, or recurrent infections or in patients who fail to respond with treatment. There are rapid immunochromatographic tests available to diagnose adenoviral infections in the office. In addition, Giemsa staining of conjunctival scrapings can aid in characterizing an inflammatory response. Fluorescein staining may reveal dendrites on the cornea for herpes simplex infections.

Treatment

As most cases of viral conjunctivitis are self-limiting and there is no effective treatment available, treatment is mostly supportive and can include cold compresses, saline rinse, ocular antihistamines, and artificial tears. These agents treat only the symptoms and not the disease itself. Antiviral medications and topical antibiotics are not indicated. Use of antibiotic eye drops can increase the risk of spreading the infection to the other eye due to contaminated droppers [11]. Treatment for ocular herpetic infections usually consists of a combination of oral antivirals and topical steroids and warrants immediate ophthalmology referral to monitor for sight-threatening corneal involvement. Molluscum treatment options include excision or cryotherapy of the lesions. Patients with molluscum do not need to be isolated from others while symptomatic [9]. If symptoms do not resolve after 7–10 days or if corneal involvement is suspected, referral to ophthalmologist is indicated.

Family and Community Issues

Patients should be counseled that since viral conjunctivitis although self-limiting is highly contagious, it is important to prevent spread by practicing strict handwashing and avoid sharing personal items with those infected. In cases of adenoviral conjunctivitis, the replicating virus is present 10 days after the appearance of symptoms in 95% of the patients but only in 5% by day 16 [8]. Due to the high risk of spread, children should be refrained from attending daycare and school for up to 1 week [9].

Chlamydial Conjunctivitis

Chlamydial conjunctivitis is a bacterial infection of the eye caused by *Chlamydia trachomatis*.. Chlamydial conjunctivitis can be divided into two types: trachoma and inclusion conjunctivitis. *Chlamydia trachomatis* serotypes A through C cause trachoma and are characterized by a severe follicular reaction which can develop into scarring of the eyelid, conjunctiva, and cornea leading to vision loss. It is the leading infectious cause of blindness worldwide [15]. It is endemic in developing countries with limited resources and is seen only sporadically in the United States. Chlamydial serotypes D through K cause inclusion conjunctivitis, which causes a unilateral chronic follicular

Telegram: @medical_k

www.konkur.in

conjunctivitis that usually occurs in young adults or neonates (ophthalmia neonatorum) via the birth canal from infected mothers. Chlamydial inclusion conjunctivitis is sexually transmitted from the hand to eye or from the genitalia to eye.

History

Chlamydial conjunctivitis should be suspected in sexually active patients with chronic follicular conjunctivitis that is not responsive to standard antibacterial treatment [16]. There is usually an absence of symptoms from the genital tract; however, males may have symptomatic urethritis and females may have salpingitis or chronic vaginal discharge. Ophthalmia neonatorum, also called neonatal conjunctivitis, usually occurs in the first 4 weeks of life. The incubation period is typically 7 days after delivery but can vary from 5 to 14 days if there was a premature rupture of membranes [17]. Among those neonates with known exposure to chlamydia, 30–50% will develop conjunctivitis [18].

Physical Examination

The patient usually presents with a red, mildly irritated eye with scant watery discharge to severe mucopurulent discharge with eyelid and conjunctival swelling [18]. A palpable preauricular lymph node may be present on the affected side. Vision is usually not affected, and there is usually no history of recent upper respiratory infection. Trachoma causes chronic follicular conjunctivitis that leads to entropion, trichiasis, conjunctival, and corneal scarring causing permanent vision loss.

Laboratory Findings

Diagnosis is usually made based on history and clinical presentation. However, conjunctival scrapings revealing elementary bodies via direct fluorescent antibody stain or polymerase chain reaction testing on scrapings are diagnostic. Culture of conjunctival scrapings can be performed but may take weeks to grow.

Treatment

For newborns, topical therapy is not indicated as more than 50% of affected neonates have concurrent lung, nasopharynx, and genital tract infections [10]. Recommended treatment is a systemic course of erythromycin ethylsuccinate (EryPed) 50 mg/kg/day in four divided doses per day for 14 days [19]. In order to treat inclusion conjunctivitis in adults, a systemic course of oral tetracycline (Sumycin) 250 mg four times per day for 3 weeks, erythromycin stearate (Erythrocin) 250 mg four times per day for 3 weeks, doxycycline 100 mg twice per day for 10 days, or azithromycin 1 g single dose is administered to treat the infection. Topical antibiotics may suppress the ocular symptoms but do not treat the genital disease. Pregnant patients should be treated with erythromycin since tetracyclines can cross the placenta. Sexual partners should also be treated to prevent reinfection and possible coinfection with gonorrhea should be tested.

Allergic Conjunctivitis

Allergic conjunctivitis is a type 1, IgE-mediated hypersensitivity to allergens such as pollen, animal dander, and other environmental allergens [8] and affects up to 40% of the population in the United States [20]. Seasonal allergic conjunctivitis is the most common form consisting of 90% of all allergic conjunctivitis in the United States, usually worse in the spring and summer [21]. It is often encountered in patients with atopic diseases, such as allergic rhinitis (hay fever), eczema, and asthma [22]. Perennial allergic conjunctivitis is similar to seasonal allergic conjunctivitis but occurs throughout the year, and the symptoms tend to be less severe. Other types of ocular allergies include vernal keratoconjunctivitis, atopic keratoconjunctivitis, contact allergy (contact dermatitis), and giant papillary conjunctivitis [23].

History

The hallmark for allergic conjunctivitis is itching along with watery eyes, redness, gritty discomfort, eyelid swelling, and nasal congestion. Vernal keratoconjunctivitis is more common in warmer climates and affects young patients and resolves

Telegram: @medical_k

www.konkur.in

by age 20. Atopic keratoconjunctivitis is the ocular version of atopic eczema or dermatitis. Contact ocular allergy is caused by contact with an allergen. Giant papillary conjunctivitis is commonly associated with contact lens use or ocular implants.

Physical Examination

Allergic conjunctivitis commonly presents with bilateral dilatation of the conjunctival blood vessels, large cobblestone papillae under the upper lid, conjunctival swelling (chemosis), and watery to mucoid discharge [1]. Redness or conjunctival injection is mild to moderate. Visual acuity is unaffected with normal pupillary reaction and absence of corneal involvement. Vernal keratoconjunctivitis is characterized by the giant papillae found under the upper eyelid. In atopic keratoconjunctivitis, the eyelid skin may have a fine sandpaper-like texture with mild to severe conjunctival injection and chemosis [23]. Giant papillary conjunctivitis may cause giant, medium, or small papillae under the upper lid similar to vernal conjunctivitis [23].

Laboratory Findings

Allergic conjunctivitis is diagnosed based primarily on history and clinical presentation. Giemsa staining of conjunctival scrapings can help characterize the inflammatory response and may reveal eosinophils. Allergy testing via direct skin testing or radioallergosorbent test (RAST) is indicated mostly for patients with systemic allergy or may be indicated for some with ocular allergy.

Treatment

Patients with allergic conjunctivitis should be advised to refrain from rubbing their eyes as this causes mast cell degranulation and worsening of their symptoms. Cool compresses may reduce eyelid swelling, and use of artificial tears throughout the day may help to clear out potential allergens. Patients should also refrain from wearing contact lenses as allergens have the ability to adhere to the contact lens surface. In addition, avoidance of known allergens may reduce exacerbations. Medical therapies that are topical include antihistamine/vasoconstrictor combination products, antihistamines with mast cell stabilizers, and glucocorticoids, which are reserved for resistant cases and should be used under the supervision of an ophthalmologist. Systemic oral antihistamines, such as loratadine (Claritin), fexofenadine (Allegra), and cetirizine (Zyrtec), are often used for the management of allergies in general; however, topical ocular medications are found to be more effective when ocular symptoms primarily predominate.

Keratoconjunctivitis Sicca

Keratoconjunctivitis sicca or dry eye is a condition caused by decreased tear production or poor tear quality causing inadequate moisture to the eye surface. More common in adults over age 50 (women greater than men) and may be associated with underlying autoimmune disease such as rheumatoid arthritis, Sjogren's syndrome and lupus, as well as use of certain medications such as anticholinergics, antihistamines, beta-blockers and hormone replacement therapy (especially estrogen-only pills). Chronic untreated symptoms can result in corneal ulcers and permanent scarring [1, 24].

History

Common complaints of keratoconjunctivitis sicca are soreness, burning, redness, gritty discomfort, and photophobia. Sometimes excessive tearing presents (secondary to reflex secretion), and other times unable to produce tears upon crying. Dry eyes can follow trachoma, in which the lacrimal gland ducts and conjunctival goblet cells are damaged.

Physical Examination

Keratoconjunctivitis sicca often presents with mild to moderate redness or conjunctival injection with or without watery discharge. Blurred vision or partial loss may be present. Poor tear film and corneal desiccation lead to punctate lesions that are evident with fluorescein staining and blue light examination.

Telegram: @medical_k

www.konkur.in

Laboratory Findings

Keratoconjunctivitis sicca is diagnosed based primarily on history and clinical presentation. However, use of one or more tests may be utilized to further objectify the diagnosis including the Schirmer test, tear breakup time measurement, and tear meniscometry [2, 25]. If autoimmune disease is suspected as the underlying cause of keratoconjunctivitis sicca, serum antibody testing can be performed (e.g., rheumatoid factor [RF], antinuclear antibody [ANA], antinuclear cytoplasmic antibodies [ANCA], cyclic citrullinated peptides [anti-CCP], anti-Ro [SS-A], and anti-La [SS-B] antibodies) [24].

Treatment

Treatment is initially managed by frequent and liberal application of artificial tears such as hypromellose eye drops and ocular lubricants several times daily and at bedtime. Use of a humidifier can help to decrease tear loss in dry environments. If incomplete relief, cyclosporine eye drops (0.05%, one drop in each eye every 12 h) or lifitegrast ophthalmic solution (5%, one drop in each eye every 12 h) may be used to increase tear production in adults and adolescents greater than 16 years of age [1, 26]. Severe cases not responsive to topical therapies require referral for consideration of temporary (using plugs) or permanent (using cautery) occlusion of lacrimal canaliculi [27, 28].

Other Causes of Red Eyes

Corneal Abrasion/Corneal Foreign Body

Corneal abrasions and foreign bodies interrupt the epithelial layer of the cornea resulting in the exposure of the basement membrane. Usually due to mechanical or chemical trauma, corneal or epithelial disease (e.g., dry eye), contact lens use, or foreign body superficially adherent or embedded within the cornea. Corneal foreign bodies need to be identified and removed as soon as possible to prevent infection and ocular necrosis [2, 29]. Corneal abrasion can be a complication of trachoma secondary to constant corneal trauma of affected lashes and inadequate tears. This is the leading cause of blindness in trachoma as it often progresses to corneal erosions, ulceration, and scarring [15].

History

Patients present with usually unilateral acute onset marked tearing, redness, blepharospasm, moderate to severe pain, foreign body sensation, photophobia, and possible decreased visual acuity dependent on location of the defect along the cornea. Symptoms can be present without known trauma other than aggressive eye rubbing. Bilateral symptoms may be present when associated with chemical exposure, burns, or contact lens use. Suspicion for foreign body should be high if patient engaged in landscape, construction, or manufacturing job without the use of eye protection.

Physical Examination

Corneal disruption can be confirmed by fluorescein examination under blue light and preferably utilizing a slit lamp. Instillation of topical anesthetic (e.g., proparacaine or tetracaine) may be needed for pain control during exam. A check for foreign bodies should include under the eyelids and in the conjunctival fornices [29]. A Seidel's test should be performed if there is concern for corneal laceration or globe rupture that may not be grossly obvious. A Seidel's test is performed by placing fluorescein dye gently against the bulbar conjunctiva. In the case of a positive sign, the oozing aqueous humor at the site of penetration through the cornea appears under ultraviolet light as a "dark waterfall," clearing away excess fluorescein on the cornea. It should be noted that an in intraocular foreign body does not necessarily change visual acuity [30].

Laboratory Findings

There are no specific laboratory tests for the diagnosis of corneal abrasion or foreign body. They are primarily based on clinical history and physical examination.

Telegram: @medical_k

www.konkur.in

Treatment

Corneal foreign bodies require immediate removal or urgent transfer to ophthalmology. If removal performed in office, documentation of a negative Seidel's test is good practice to confirm that there was no iatrogenic penetration of the cornea during the procedure. Treatment of corneal abrasions consists of prophylactic antibiotic eye drops and/or ointment (ciprofloxacin 0.3% solution, ofloxacin 0.3% solution, erythromycin 0.5% ointment, gentamycin 0.3% ointment or solution; see Table 2) and topical pain control drops (diclofenac, 0.1% solution, one drop four times daily or ketorolac, 0.5% solution, one drop four times daily). Oral opioid analgesics (e.g., hydrocodone/acetaminophen [Vicodin], oxycodone/acetaminophen [Percocet]) can be used to relieve moderate to severe pain and have been found to allow patients to sleep more comfortably at night. All contact lens wearers, and those whose symptoms do not improve within 24 h, require immediate referral to an ophthalmology specialist [29, 30].

Episcleritis

Episcleritis is a benign inflammatory disease that affects the episclera, which is the thin layer of tissue that is beneath the conjunctiva but is superficial to the sclera. It is usually self-limiting and resolves within 3 weeks. Most cases occur mostly in young to middle-aged females but can affect any age group. The etiology is mainly idiopathic with a minority of cases associated with an underlying systemic disease, such as rheumatoid arthritis, inflammatory bowel disease, vasculitis, and systemic lupus erythematosus [31]. Episcleritis is classified into two types. In the diffuse type, the redness involves the whole episclera, whereas, in the nodular type, the redness involves a smaller contained area.

History

Patients usually present with an abrupt onset of mild eye pain, redness, watery eyes, and mild photophobia. The pain associated with episcleritis is typically mild when compared to the pain experienced with scleritis. The diffuse type of episcleritis may be less painful than the nodular type. Eye involvement may be either localized or diffuse. There is no associated discharge and vision is not affected.

Physical Examination

There is unilateral or bilateral localized or diffuse redness of the episclera. There may be mild pain with palpation. Vision is not affected and there is no edema or thinning of the sclera. A slit-lamp biomicroscope can help visualize any changes in the sclera to differentiate between episcleritis which is benign and scleritis which causes more destructive inflammation. In addition, phenylephrine eye drops can cause transient clearing of the episcleral redness so that a more careful examination of the sclera can be made.

Laboratory Findings

There are no specific laboratory tests for the diagnosis unless a systemic disease is suspected as the cause of the episcleritis. In this case, blood tests, such as rheumatoid factor, antibodies to cyclic citrullinated peptides (anti-CCP), antineutrophil cytoplasmic antibodies (ANCA), and antinuclear antibody testing (ANA), can be drawn targeted to specific inflammatory diseases.

Treatment

Since episcleritis is self-limiting and does not cause vision loss, the treatment is based on symptom relief. Treatment options include topical lubricants/artificial tears and topical glucocorticoids for severe cases [2]. Topical nonsteroidal anti-inflammatory drugs (NSAIDs) are not indicated and have been shown to have no significant benefit versus placebo [32]. Referral to ophthalmology is recommended to definitively confirm episcleritis versus scleritis and for recurrent or worsening of symptoms.

Scleritis

Scleritis is a painful and destructive inflammatory disease that affects the sclera, which comprises 90% of the outer coat of the eye. It is associated

Telegram: @medical_k

www.konkur.in

with an underlying systemic disorder, such as rheumatoid arthritis, Wegener's granulomatosis, and systemic lupus erythematosus, in up to 50% of patients [33]. The sclera is divided into an anterior and posterior compartment. Inflammation can occur in either compartment but rarely does it affect both. Approximately 90% of scleritis involves the anterior compartment which can be further subdivided into diffuse, nodular, and necrotizing. Diffuse anterior scleritis is the most common, least severe, and usually does not recur. Nodular anterior scleritis is the second most common and tends to be recurrent. Necrotizing anterior scleritis is the least common, most severe, and more likely to cause ocular complications. Posterior scleritis can also be subdivided into diffuse, nodular, and necrotizing but is more rare and difficult to assess clinically.

History

Patients present with a gradual onset of severe, constant, piercing pain that involves the eye and radiates to the face and periorbital region. Tenderness and redness may affect the entire eye or a more localized area. Because the extraocular muscles insert into the sclera, movement of the eye tends to exacerbate the pain. The pain is usually worse at night or in the early morning hours, causing awakening from sleep. Patients also experience headache, watery eyes, and photophobia.

Physical Examination

Examination reveals a characteristic violet-bluish hue of the globe with scleral edema and vasodilatation of the episcleral plexus and superficial vessels. The globe is usually tender to the touch. Using slit-lamp biomicroscopy, one can visualize inflamed scleral vessels which are adherent to the sclera and cannot be moved with a cotton-tipped applicator, whereas the more superficial vessels of the episclera are movable. Although phenylephrine eye drops cause blanching of the superficial episcleral vessels, the deep vessels are not affected which can aid in the differentiation between scleritis and episcleritis.

Laboratory Findings

Like episcleritis, there are no specific laboratory tests for the diagnosis of scleritis. If history and physical examination indicate a systemic inflammatory condition, specialized serologic tests can be drawn. There are some imaging studies that are useful in the evaluation of scleritis, such as ultrasonography of the orbit which can confirm scleral thickening and CT and magnetic resonance imaging of the orbit which can visualize orbital lesions associated with systemic disease processes.

Treatment

If suspected, immediate referral to ophthalmology is warranted. Two-thirds of patients with scleritis require high-dose corticosteroids or the combination of corticosteroids with an immunosuppressive agent [31]. If an underlying systemic disease is suspected or known, referral to rheumatology may be indicated.

Iritis

Iritis is the inflammation of the anterior uveal tract, also referred to as anterior uveitis. It can be caused by infection such as from a wound or corneal ulcer, or it can be caused by a systemic immune-mediated disease. Spondyloarthritides, such as ankylosing spondylitis and reactive arthritis (Reiter syndrome), are the most common systemic immune diseases associated with anterior uveitis. Uveitis can occur in up to 37% of spondyloarthropathy patients, of which most are positive for the human leukocyte antigen (HLA)-B27 allele [34, 35]. Ten to 30% of patients with juvenile idiopathic arthritis develop chronic anterior uveitis, and it remains a cause of blindness in childhood [36]. Other associated systemic diseases include sarcoidosis, inflammatory bowel disease, and Behçet's disease.

History

Patients present with a gradual onset of pain (often described as an ache) developing over hours to days with the exception of trauma. Ocular erythema and excessive tearing are commonly present. In addition, photophobia with blurred vision

Telegram: @medical_k

www.konkur.in

is commonly noted. Iritis can be unilateral, bilateral, or recurrent affecting either eye, dependent on the etiology or associated disease process.

Physical Examination

The eyelids, lashes, and lacrimal ducts are not involved. Conjunctival examination reveals hyperemic injection surrounding the cornea. If discharge is present, it is minimal and watery. The pupil is constricted in the affected eye and is sluggishly reactive to light. Visual acuity may be decreased in the affected eye, but extraocular movement is not affected. Both direct and consensual photophobia may be present. With slit-lamp biomicroscopy examination, keratic precipitates (white blood cells) can be visualized in the anterior chamber which is a hallmark of iritis. With severe inflammation, the leukocytes in the anterior chamber can settle and form a hypopyon, which is an accumulation of purulent material that can be visualized without magnification.

Laboratory Findings

Iritis (anterior uveitis) is diagnosed based primarily on history and clinical presentation. Slit-lamp biomicroscopy is required to properly assess the presence of leukocytes or protein accumulation in the aqueous humor within the anterior chamber of the eye. If a systemic immune-mediated disease is suspected from the patient's history and examination, diagnostic testing to confirm the specific diagnosis is warranted.

Treatment

If iritis is suspected, immediate referral to ophthalmology is warranted. Although leukocytes may be present on examination, antibiotics are not indicated. Iritis is a diagnosis of exclusion and can be associated with serious complications, such as band keratopathy, posterior synechiae, intraocular hypertension, glaucoma, cataract formation, and increased risk of herpes keratitis. If an underlying systemic disease is suspected or known, referral to rheumatology may be indicated.

Herpes Keratitis

Herpes keratitis is caused by a recurrent herpes simplex virus (HSV) infection in the cornea. It is very common in humans as both subtypes, HSV-1 and HSV-2, have humans as their only natural host. HSV-1 accounts for most oral, labial, and ocular infections and HSV-2 accounts for most genital infections. However, there is quite a bit of overlap of their distributions. HSV-1 causes over 95% of ocular HSV infections, excluding neonatal infections [37]. HSV infection is the leading cause of corneal blindness in the United States despite the fact that only a very low percentage of infected individuals develop ocular disease. Ocular HSV-1 infections are predominately unilateral; however, up to 12% of cases involve both eyes in which the infection tends to be more severe and occurs in younger individuals [38].

History

Primary HSV infection typically presents as an acute oropharyngitis type of illness. Following the initial infection, the virus may go into a latent period within any of the divisions of the trigeminal nerve. It is the reactivation of the latent HSV that causes the primary ocular infection. Patients will present with a unilateral blepharoconjunctivitis with a vesicular rash on the eyelids and follicular conjunctivitis. Patients may present with pain, photophobia, foreign body sensation, blurred vision, tearing, and conjunctival redness.

Physical Examination

Examination may reveal mild conjunctival injection with hyperemic injection surrounding the limbus (ciliary flush). After staining of the eye with fluorescein dye, the typical branching corneal ulcer (dendritic ulcer) with terminal bulbs associated with HSV infection may be seen [39]. With resolution of the infection, patients can develop subepithelial scarring and recurrent infections can lead to focal or diffuse reduction in corneal sensation.

Laboratory Findings

The diagnosis of herpes keratitis is mostly based on clinical history and examination. The dendritic

Telegram: @medical_k

www.konkur.in

lesions are usually pathognomonic for HSV infection. Laboratory confirmation is rarely indicated, and serologic testing is not recommended due to the prevalence of latent disease and the frequency of recurrences. In severe cases or when clinical findings are atypical, ocular scrapings of epithelial lesions can be sent for viral culture, detection of viral antigen, or detection of viral DNA.

Treatment

Treatment of herpes keratitis is dependent on whether the infection is caused by active viral replication or due to an immune response from a prior infection. Regardless, HSV keratitis warrants immediate referral to an ophthalmologist. For most cases, topical corticosteroids are not indicated as it may worsen the infection.

Trichiasis

Trichiasis is an eyelid abnormality in which the eyelashes are misdirected and grow back toward the eye causing irritation of the cornea and conjunctiva. It can be caused from congenital defects, infection, autoimmune conditions, and trauma. If left untreated, permanent scarring of the cornea can occur, leading to vision loss.

History

The history is essential in directing the clinical examination and formulation of the correct diagnosis. Important questions to ask include recent history of a severe eye infection or travel to a developing country where trachoma is commonly seen, history of herpes zoster ophthalmicus, ocular cicatricial pemphigoid (autoimmune disorder), Stevens-Johnson syndrome, eyelid surgery, or trauma.

Physical Examination

The irritation from the eyelashes causes constant eye irritation, pain, redness, excessive tearing, and sensitivity to light.

Laboratory Findings

There are no specific laboratory tests for the diagnosis of trichiasis. It is primarily based on clinical history and physical examination.

Treatment

For immediate relief, the eyelashes can be plucked out; however, regrowth usually occurs. For more severe cases or for recurrent disease, permanent removal of the affected eyelashes using a radiofrequency device, electrolysis, or cryosurgery can be performed to prevent scarring of the cornea and permanent vision loss. In some cases, corrective eyelid surgery may be indicated.

Acute Closed-Angle Glaucoma

Acute glaucoma is associated with a narrowing of the anterior chamber with obstruction of the aqueous humor from the posterior chamber to the anterior chamber of the eye. This obstruction leads to a rapid increase in intraocular pressure. Acute glaucoma is an ocular emergency and can lead to permanent blindness if left untreated. Primary angle-closure glaucoma is more common in females and those with family history. It is also more prevalent in Eskimos and Southeast Asian populations with a higher risk in individuals over 40 years of age [40]. As people age, the lens of the eye enlarges and pushes the iris forward decreasing the area where the aqueous humor drains thereby increasing the risk for angle-closure glaucoma.

History

Patients present with severe throbbing eye pain, redness, blurred vision, profuse tearing, haloes around lights (due to corneal swelling), nausea, vomiting, and headaches. In acute attacks, it is common for unilateral eye involvement and more severe symptoms. Some may experience intermittent episodes of angle closure and elevated intraocular pressure without a full-blown attack, which is referred to as subacute angle-closure glaucoma. These patients typically are asymptomatic and may experience mildly blurred vision or haloes around lights. These symptoms usually self-resolve once the angle reopens. It is important to review current medications as certain medications can cause drug-induced secondary angle-closure glaucoma.

Telegram: @medical_k

www.konkur.in

Physical Examination

Examination requires slit-lamp biomicroscopy which can confirm corneal edema due to the sudden elevation in intraocular pressure. There may also be dilatation of episcleral and conjunctival vessels, shallow anterior chambers, erythema surrounding the iris, and inflammatory cells within the anterior chamber. Tonometry will reveal eye pressures above 21 mmHg and may be as high as 40–80 mmHg. Gonioscopy can be performed to assess the drainage angle of the eye, and ophthalmoscopy can be used to assess the optic nerves for any damage or abnormalities.

Laboratory Findings

There are no specific laboratory tests to confirm the diagnosis of acute glaucoma. It is diagnosed based on clinical history and examination via slit-lamp biomicroscopy.

Treatment

If acute angle-closure glaucoma is suspected, immediate referral to an ophthalmologist is indicated to initiate treatment and prevent permanent vision loss. Initially medications are used to decrease intraocular pressure in preparation for laser iridotomy (treatment of choice), which creates holes in the iris so that the aqueous humor may drain freely from the posterior chamber to the anterior chamber, thereby reducing intraocular pressures.

Conclusion

There are various causes of red eye, and many may be diagnosed based on clinical history and focused examination. In the primary care setting, it is of great importance to be able to determine those cases that require immediate referral to an ophthalmologist. Indications for immediate or emergent referral include unilateral painful red eye that is associated with nausea and vomiting, severe ocular pain or visual loss in association with a red eye, corneal infiltrates or ulcers seen with fluorescein staining, and hypopyon (purulent exudate contained in the anterior chamber of the eye).

Introduction

Fifty percent of ocular trauma cases will initially present to an outpatient primary care provider's office [1]. It is imperative that family medicine physicians be able to recognize common ocular injuries, perform a thorough ophthalmologic exam, and most importantly, promptly triage these patients to improve the likelihood of vision preservation. The most frequent etiologies for eye injuries include athletic and workplace-related

injuries, and these injuries disproportionally affect younger men [1–5]. Basketball is commonly cited as the sport with the greatest occurrence of eye injuries, and employees of manufacturing/construction companies lead the way among occupational injuries [3, 5]. Ocular trauma can lead to significant morbidity and disability, including permanent blindness, and therefore necessitates prompt evaluation and management.

This chapter aims to discuss the common yet varied forms of blunt, penetrating, and caustic eye-related traumatic injuries (Table 1). Each section will cover the pathophysiology, important history and physical exam findings, and management of these injuries.

Table 1 Categorization of ocular trauma

Blunt trauma	Caused by forceful impact, non-penetrating
Penetrating trauma	Injury with an entrance wound
Closed globe	Eyewall remains intact
Open globe	Full-thickness injury of ocular surface
Anterior segment	Involving the cornea, ant. chamber, iris or lens
Posterior segment	Involving the vitreous, retina or ocular nerve
Anterior chamber	The space between the cornea and iris

Modified from Refs. [6, 8]

Ocular Examination

A focused, systematic eye examination is essential to appropriate diagnosis of ocular trauma. The examination begins immediately upon patient contact by assessing the level of patient distress and noting any gross abnormalities with the ocular and periocular anatomy. A primary evaluation, including an abbreviated history and focused physical exam, should be completed to assess for injuries that require emergent intervention to preserve the globe and its function prior to a more generalized examination [6, 7]. This abbreviated history should focus on mechanism of injury, gross visual acuity, and whether the patient wears corrective lenses/contacts. The goal of this primary evaluation is to assess for immediate ocular emergencies such as globe rupture, large foreign body, orbital compartment syndrome, or caustic/chemical injury (Fig. 1). Once these immediate threats to the eye and its function are reasonably excluded, a more thorough history and physical exam should ensue.

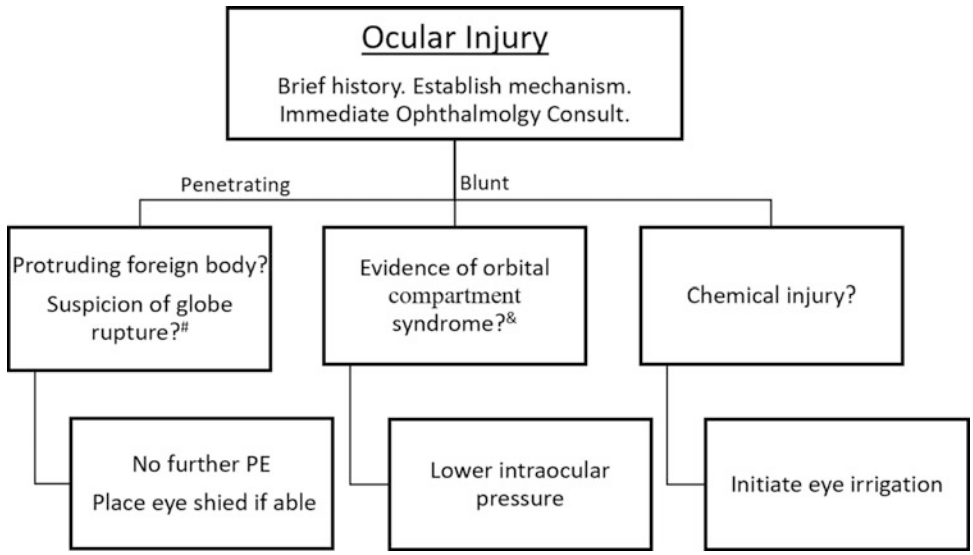

Fig. 1 True ocular emergencies. #Vitreous extrusion, a peaked or eccentric pupil, and severe subconjunctive hemorrhage. &Painful proptosis, pain with eye movements, tense orbits to palpation

Telegram: @medical_k

www.konkur.in

A complete ocular examination should begin with assessment of visual acuity. This simple check provides a wealth of knowledge and is the best predictor for potentially blinding conditions [4, 8]. A Snellen eye chart is the test of choice for assessing visual acuity. If the patient is unable to see the largest Snellen letters, even at close distance, then the provider may proceed by determining the ability to count fingers, detect purposeful movement, or simply whether light perception is possible [8]. Barring significant intracranial injury, reduced visual acuity should be assumed to have come from damage to the structures of the anterior or posterior segment of the eye (Table 1). Additional testing will assist in determining the location of the insult. Physicians should start with pupillary response to light and then proceed with direct evaluation with an ophthalmoscope or slit lamp.

Normal pupil reactivity is demonstrated through bilateral pupillary constriction to unilateral light exposure. Pupil reactivity is best appreciated by the "swinging flashlight test," in which the examiner alternates shining light directly into each eye and observing bilateral pupillary response. If the affected eye constricts with contralateral light exposure but is nonreactive and/or appears to actually dilate with direct light exposure as the light is shifted from the contralateral side, a relative afferent pupillary defect (RAPD) is diagnosed [8]. The presence of a RAPD is highly suggestive of an injury to the optic nerve or retina.

Following pupillary response, the gross anatomy of the anterior and posterior segments is evaluated using an ophthalmoscope or slit lamp. During this portion of the examination, mydriatics may be given to improve examination quality (Table 2).

The remainder of the examination involves assessing the periocular and superficial orbital structures including sclera, conjunctiva, eyelids, extraocular muscles, and surrounding bony orbit. While examining the six cardinal eye movements, patients should also be questioned on diplopia symptoms as this may be an indication of extraocular muscle entrapment or nerve paresis [6].

If the patient reports a foreign body sensation and the object is not immediately obvious, the eyelids should be everted for inspection. This should also prompt evaluation for a potential corneal abrasion through the use of fluorescein staining. To apply this stain, moisten the strip with saline or topical anesthetic (Table 2) and place the strip on the palpebral conjunctiva. Ask the patient to blink which will distribute the stain. Cobalt blue light, which is available on most ophthalmoscopes, can then be shone on the eye to highlight corneal irregularities.

In certain settings, radiographic procedures may be desired for further confirmation of the suspected diagnosis. Both computed tomography (CT) and ultrasound have a high degree of sensitivity and specificity for detecting many ocular abnormalities [9]. In clinical practice, the availability of CT scanners and the skill required to complete ocular ultrasound makes CT the imaging modality of choice. CT imaging is preferred

Table 2 Commonly used medications

Topical anesthetics[a]
Tetracaine 0.5%
Proparacaine hydrochloride 0.5%
Mydriatics + cycloplegics
MOA: paralyze iris sphincter (mm)
Tropicamide 0.5% or 1%
Cyclopentolate hydrochloride 0.5% or 1%
Pure mydriatics
MOA: stimulate pupillary dilator (mm)
Phenylephrine hydrochloride 2.5%[b]
Anti-inflammatories
Topical NSAIDs
(a) Diclofenac 0.1%
(b) Ketorolac 0.4%
Topical steroids should not be prescribed by family physicians
Antibiotics
Non-contact wearers:
Erythromycin 0.5%
Contact wearers[c]:
Ciprofloxacin 0.3%
Tobramycin 0.3%
Gentamicin 0.3%

Modified from Refs. [8, 10]
[a]Never prescribe! Corneal toxicity with repeated use
[b]Can be safely combined with low dose tropicamide in adults for additive effect
[c]Pseudomonas coverage

over magnetic resonance imaging (MRI) due to cost, speed of image obtainment, and concern of metal ocular foreign body movement with MRI.

Periocular Injuries

Eyelid Lacerations

Eyelid lacerations are commonly associated with blunt or penetrating trauma, particularly in those who wear corrective lenses [4, 7]. Proper management is essential for preservation of cosmesis as well as structural function. Many eyelid lacerations will require management by an ophthalmologist. If definitive management is not immediately available, delayed closure of 24–36 h in isolated eyelid lacerations has not been shown to lead to significant complications [4, 10, 11].

When confronted with an eyelid laceration, ruling out concurrent injuries which threaten the preservation of the globe and its function must be ensured prior to addressing the laceration. History should focus on the mechanism of injury, ocular function, sensation of foreign body, and tetanus immunization status [7]. Once emergent injuries are successfully ruled out, the laceration should be carefully examined to determine its location and depth. Small superficial cutaneous wounds that do not involve the eyelid margin can be managed by primary or secondary intention and do not require referral [10]. Of note, skin adhesives are not recommended for use around the eye. Ophthalmology or plastic surgery should be involved if any of the following characteristics are present: full thickness lesions, involvement of the lid margin, proximity to the medical canthus, lacrimal duct or sac affected, or presence of ptosis signifying levator palpebrae involvement [7, 10].

Orbital Fractures

The bony orbit is comprised of the frontal, sphenoid, zygomatic, maxillary, and ethmoid bones. Fractures of these bones are common blunt trauma from motor vehicle accidents, falls, and sports-related injuries [12]. The most common type of orbital fracture is the orbital zygomatic fracture, which follows trauma to the inferolateral orbital rim. Other common fractures involve the nasoethmoid bone, orbital floor, and orbital roof, each of which are exceedingly thin. Clinical presentation will vary, and it is not uncommon for simultaneous fractures to occur [13].

Orbital rim fractures present with pain, particularly to palpation, as well as periorbital ecchymosis. Nasoethmoid fractures may also lead to subcutaneous emphysema due to sinus involvement and are a risk for medial rectus muscle entrapment [14]. Orbital floor fractures, also known as orbital "blowout fractures," commonly occur secondary to the increased intraocular pressure associated with blunt trauma. This type of fracture may classically lead to inferior rectus muscle entrapment which causes impaired upward gaze, enopthalmos (posterior globe displacement in the orbit), diplopia with ocular movements, and numbness in the infraorbital nerve distribution [15]. Since this type of fracture has sinus involvement, antibiotic prophylaxis is indicated. Oral cephalexin (250–500 mg QID for 10 days) is an appropriate choice [10].

An orbital CT scan is the test of choice for confirmation of a suspected fracture, and the physical exam should also rule out any co-occurring ocular injuries such as abrasions, hyphema, and lens or retinal injuries, as these often co-occur in many orbital fracture cases [16].

Once a fracture is diagnosed, ophthalmology should be notified. Consider involving ENT or plastic surgery based upon the location of the fracture and noted comorbid injuries. Surgical intervention is not always necessary and is decided on a case-by-case basis [16].

Subconjunctival Hemorrhage

Subconjunctival hemorrhage (SCH) is generally a self-limited condition which may be seen in patients as a consequence of repeated/prolonged Valsalva (i.e., straining in constipation, repeated emesis, childbirth), or direct trauma [17]. Although typically mild, patients who are on blood thinners or those that occur with significant ocular trauma

Telegram: @medical_k

www.konkur.in

may be quite striking in presentation. A protuberant conjunctiva or circumferential hemorrhage should immediately raise suspicion for occult globe rupture and be managed accordingly. SCH in infants may also be suggestive of non-accidental trauma when its onset occurs outside the peripartum period [18]. Treatment of most subconjunctival hemorrhages is supportive, as they are typically benign and resolve in a few weeks.

Open Globe Injury

An open globe injury is a full-thickness insult to the ocular surface (i.e., cornea or sclera) and is a true ocular emergency (Fig. 1). Direct penetrating injuries are the most common causes, but blunt trauma may also cause globe rupture as forces are transmitted to anatomic weak points in the eye wall (such as the limbus or the coronal equator of the globe) [19].

Open globe injuries are not always immediately apparent, and suspicion must always be maintained in the setting of trauma. Findings that suggest globe rupture include vitreous extrusion, a peaked or eccentric pupil, and severe (i.e., bullous or circumferential) subconjunctival hemorrhage. Orbital CT is the gold standard imaging modality when further evaluation is warranted, but ultrasound may also be beneficial in the hands of an experienced practitioner [20].

Patients with open globe injuries are at high risk for permanent ocular damage, extrusion/prolapse of ocular contents, and development of a post-traumatic infection of the vitreous. As such, initial management consists of minimizing increases to intraocular pressure, administering infection prophylaxis, and avoiding use of eye drops of any kind, including fluorescein and topical anesthetics. Management strategies include [21, 22]:

1. No further physical manipulation of the eye or periocular structures
2. Emergent referral to ophthalmology
3. Application of an eye shield, not an eye patch
4. Avoidance of IOP elevation:
   (a) Make the patient strict NPO status (including medications)
   (b) Elevate the head of bed >30°
   (c) Consider prophylactic intravenous antiemetics
5. Administration of empiric intravenous antibiotics. Do not use topical formulations
   (a) Vancomycin (15 mg/kg) AND ceftazidime (50 mg/kg)
6. Administration of appropriate tetanus prophylaxis

Anterior Segment Injuries

Corneal Abrasions and Non-Penetrating Foreign Bodies

Non-penetrating foreign bodies are a common presenting complaint in the primary care setting. Patient presentation likely will involve eye pain, tearing, light sensitivity and a reported foreign body sensation. If concern for penetrating injury is low, removal of a visible foreign body may be attempted. Fluorescein dye should be used to evaluate for possible corneal abrasions caused by movement of the body across the ocular surface.

Removal of non-penetrating foreign bodies should be attempted in a stepwise manner after instillation of a topical anesthetic (Table 2):

1. By irrigation with water or isotonic crystalloid
2. By retrieval with cotton-tipped applicator or similar soft contact
3. By instrumentation by an ophthalmologist

If a corneal abrasion is present, antibiotic prophylaxis should be administered to reduce the risk of infectious keratitis, whether or not foreign body removal is successful [23]. Ointment formulations, such as azithromycin, are preferred due to their additional lubricating effect. If the patient is a contact lens wearer, antibiotic selection should cover *Pseudomonas* species (Table 2).

Abrasions and other corneal injuries, when present, should be reassessed regularly with fluorescein to ensure proper healing [23]. Most defects heal gradually over 3–5 days and are

Telegram: @medical_k

www.konkur.in

accompanied by steady decreases to symptoms. Lesions that do not follow this pattern, the development of corneal opacities, or change in visual acuity should prompt urgent ophthalmology referral. Ocular steroids, while often used to relieve eye irritation, inhibit epithelial healing and should not be used in these patients [23]. Topical anesthetics may be used acutely during the initial evaluation; however, it is critical to never prescribe these medicines to any patient as prolonged/recurrent use is associated with permanent corneal toxicity. Systemic analgesics may be used for as needed pain relief.

Ultraviolet Light Injury

Ultraviolet (UV) light at a high enough intensity can also lead to diffuse corneal injury known as UV keratitis. Common scenarios include improper eye protection during such activities as welding (Arc Welder's Keratitis) and tanning bed use, or snow blindness secondary to prolonged UV reflection off of snowy surfaces [10, 23]. Patients typically have a delayed presentation of several hours, and the pain can be quite severe. Fluorescein staining will demonstrate diffuse superficial punctate lesions across the cornea [23]. Corneal injury secondary to UV light is treated similarly to corneal abrasions with topical antibiotics and systemic analgesics. Referral guidelines are also the same.

Traumatic Iritis and Hyphema

The force of blunt ocular trauma can lead to traumatic iritis, an acute inflammatory state in the anterior segment involving the iris and ciliary body. Patients typically present with eye pain, tearing, significant photophobia, and visual disturbances. Inspection of the eye classically demonstrates an erythematous dilation of the vessels immediately surrounding the limbus of the eye (known as ciliary flush) [8]. During pupillary assessment, the patient may report increased pain in the affected eye when light is shone in the contralateral eye. If present, this is pathognomonic for iritis [8, 10]. In the setting of trauma, if signs and symptoms of iritis are present, the clinician should also closely evaluate for a commonly co-occurring hemorrhage in the anterior chamber of the eye known as a traumatic hyphema [6].

Hyphema refers to frankly visible blood in the anterior chamber of the eye between the cornea and pupil. The etiology of traumatic hyphema formation is likely due to a sudden increase in intraocular pressure, which creates a shearing force on the vessels of the ciliary body or iris [24]. The diagnosis is made clinically by visualizing the pooling blood behind the cornea. Sitting a patient upright will facilitate blood pooling inferiorly, making hyphemas easier to detect [24].

Initial symptomatic management includes dim lighting, placing an eye shield, and elevating the head. Most hyphemas spontaneously resolve, but there is a risk of rebleed, intraocular hypertension, and corneal injury; which can lead to permanent visual impairment [25]. Therefore, once the diagnosis is made, an ophthalmology consult should ensue.

Lens Injuries

The crystalline lens is the focusing apparatus of the eye and due to its unique structure and anterior position is at high risk of injury from blunt or penetrating insult. The lens itself is encased in a transparent capsule and is suspended in place by thin zonules just posterior to the iris and anterior to the vitreous [8]. With sufficient force, the transmission of energy from blunt trauma can disrupt the protein composition of the crystalline lens and/or damage its associated structures including the lens capsule [26]. This disruption of lens proteins, or the infiltration of foreign substances secondary to capsule rupture, can lead to rapid cataract formation [26, 27]. Direct ophthalmoscopic findings, particularly with dilated eye exam, may include opacification of the lens leading to an abnormal red reflex and obscuration of fundus visualization [6, 27]. A careful dilated eye examination is also crucial to evaluate for lens subluxation/dislocation, indicative of damage to

Telegram: @medical_k

www.konkur.in

the filamentous zonules which suspend the lens [26, 27]. Any evidence of cataract formation or lens subluxation should prompt consultation with ophthalmology.

Posterior Segment Injuries

Retinal Detachment and Vitreous Hemorrhage

The retina is a thin neurovascular structure which lines the inside surface of the posterior globe and is responsible for transmitting visual signals to the optic nerve [8]. In blunt trauma injuries, energy transmission through the vitreous can cause a traction injury, separating the retina from its underlying structures leading to compromise of sensory input. Retinal detachment should be suspected if the patient reports new monocular flashes of light (known as photopsias) or floaters in their visual field. Patients with extensive detachment may also experience decreased visual acuity and/or demonstrate a RAPD in the affected eye [8, 28]. Definitive diagnosis is achieved through visualization of abnormal surface architecture of the retina with ophthalmoscopic examination. Ocular ultrasound is also sensitive and specific for making the diagnosis [9].

Bleeding into the vitreous of the eye may also occur following a post-traumatic retinal detachment if vascular structures are compromised. If the hemorrhage is significant, these patients will have decreased visual acuity, a RAPD, as well as a diminished or absent red reflex [8]. Regardless of the etiology, when faced with a suspected retinal detachments and/or vitreous hemorrhage, urgent referral to an ophthalmologist is indicated for definitive management. Table 3 summarizes the signs and symptoms which should prompt ophthalmology consultation discussed in this chapter.

Table 3 Signs and symptoms that warrant ophthalmology referral

Loss of vision, diplopia, or abnormal visual field	Embedded foreign body
Suspected globe rupture	Complex eyelid laceration
Painful proptosis	Hyphema
Reported flashes or floaters	Pain with ocular movements
Irregular pupil	Photophobia

Modified from Refs. [4, 27, 33]

Retrobulbar Hemorrhage and Ocular Compartment Syndrome

The bony orbit is relatively incapable of accommodating increases in intracavitary pressure. Retrobulbar hemorrhage is a rare, but potentially catastrophic complication of orbital/midface trauma. Bleeding into the retrobulbar space causes a rise in intracavitary pressure. If the pressure is great enough, it can precipitate a compartment syndrome of the orbit, which is a true ophthalmic emergency (Fig. 1). Irreversible ischemic injury can occur to the retina and optic nerve leading to monocular blindness in as little as 60 min [29].

Retrobulbar hemorrhage is a clinical diagnosis and should be suspected in all cases of facial trauma, especially if the patient has a known bleeding diathesis or is on anticoagulation. If compartment syndrome is developing, the patient will typically present with painful proptosis, pain with extraocular eye movements, decreased visual acuity, and tense orbits to palpation [29, 30]. Presence of a RAPD is an ominous sign, indicating that ischemic retinal/optic nerve damage is already developing [30]. Tonometry will confirm increased intraocular pressure (IOP >22 mmHg). If diagnosis remains uncertain, advanced imaging with CT can assist [9]. Immediate ophthalmologic surgical consultation is warranted. Until definitive surgical evaluation, management strategies to reduce swelling and IOP may improve outcomes [10, 30]:

1. Elevate head of bed to >30°
2. Make the patient NPO and consider prophylactic antiemetics
3. Methylprednisolone 125 mg IV
4. Acetazolamide 500 mg IV (avoid in sulfa allergic patients)
5. Timolol 0.5%, one drop in affected eye

Chemical Injuries

Chemical injuries are another ocular emergency as rapid and permanent damage may ensue (Fig. 1) [31, 32]. The mainstay of treatment for all suspected chemical injuries is copious irrigation, ophthalmology consultation, and prophylactic topical antibiotic administration. Normalization of pH should only be performed with water or isotonic crystalloid. Instillation of topical analgesia should be performed if blepharospasm occurs in response to pain, in order to promote eye lid opening and enhance ease of irrigation [31]. Contact lenses should be removed if present. After irrigation for least 30 min, pH neutrality (7.0–7.3) may be assessed with a pH strip. After irritative symptoms have resolved and pH neutrality has been sustained, empiric topical antibiotics (Table 2) should be prescribed [31, 32].

Of note, alkaline exposures generally pose a greater risk to the eye, in part due to the lack of physiologic base buffering in the body [32]. Greater irrigation time may be required before pH neutrality is sustained in patients with base exposures (e.g., wet concrete, ammonia, oven cleaner, drain cleaner).

Presenting complaints of eye disorders need to be quickly divided into complaints that are serious and require an emergent or urgent examination and treatment and complaints that are less serious. Urgent symptoms include recent visual loss, double vision, pain, floaters, flashes, and photophobia. Less serious symptoms, which can be evaluated less urgently, include vague ocular discomfort, tearing, mucous discharge, burning, or eyelid symptoms.

The basic eye examination includes testing for visual acuity with the Snellen chart or starting at 3 years old with a picture chart or matching chart [1]. Along with visual acuity, confrontation visual fields, ocular motility testing, pupillary examination, intraocular pressure measurement, corneal staining, and ophthalmoscopy are essential elements of a complete urgent exam [2].

The Pupil

The pupil regulates the amount of light that enters the eye. Normal pupils are round, regular in shape, and nearly equal in size. The pupillary examination is designed primarily to detect neurologic abnormalities that disturb the size of the pupils. Pupillary reflexes include the direct light reflex and the indirect, or consensual, reflex, a response to light falling on the opposite eye. The measurement of pupil size in dim light assesses the motor (efferent) limb of the pupillary reflex arc; the evaluation of pupil response to direct light assesses both the motor and the sensory (afferent) limbs; the swinging light test (testing for the consensual reflex) assesses only the sensory limbs.

Constriction of the pupil to less than 2 mm is called miosis, if it does not dilate in the dark. Topical cholinergic-stimulating drops and systemic narcotics are the most frequent causes.

Dilatation of the pupil to more than 6 mm is called mydriasis, with failure to constrict to light stimulation. Topical atropine-like drops, trauma, and oculomotor nerve abnormalities are the most common causes.

Anatomic variation in the diameter of the pupil is less than 1 mm. It is best to determine this parameter in the dimmest light possible, measuring with the pupil gauge found on the near vision card. True inequality of pupil size (anisocoria) is caused by drugs, injury, inflammation, angle-closure glaucoma, ischemia, paralysis of the sphincter pupillae muscle (dilated) and dilator pupillae muscles (constricted), Horner syndrome, neuronal lesions (Argyll Robertson pupil), or, most commonly, physiologic variations [3]

The Eyelids

The eyelids protect the cornea, aid in the distribution and the elimination of tears, and limit light entering the eye. Abnormalities can occur in the skin, mucous membranes, glands, and muscles [3].

Telegram: @medical_k

www.konkur.in

Congenital Abnormalities

The most common congenital variation is an epicanthus, which is a vertical skinfold in the medial canthal region. This may simulate an esotropia (pseudostrabismus) [1].

Positional Abnormalities

Entropion

Entropion is the inversion of the lid margin. Etiologies are age-related (involutional), cicatricial, spastic, and congenital. Involutional entropion of aging is common, causing misdirected eyelashes (trichiasis) that irritate the eye. Secondary conditions include conjunctivitis, corneal ulcers, keratitis, and tearing. Treatment includes lubricating agents, and topical antibiotic ointment. Everting the eyelid margin away from the globe and taping can be temporary while awaiting definitive surgical procedures for symptomatic patients [4].

Ectropion

Eversion of the lid margin, or ectropion, can be age-related, cicatricial, mechanical, allergic, and congenital. Severe cases may follow Bell's palsy. Ocular manifestations include chronic conjunctivitis, keratitis, epiphora, and keratinization of the lid. Treatment options are similar to those for entropion [5].

Blepharoptosis

The etiology of blepharoptosis lies either in the innervation or the structure of the levator palpebrae superioris muscle, leading to a drooping upper eyelid and a narrow palpebral fissure. The congenital type can be unilateral or bilateral. Acquired forms include dehiscence of the levator aponeurosis, neuropathy, intracranial disorders, Horner syndrome, myotonic dystrophy, and myasthenia gravis. Surgical therapy is the only successful management strategy [6].

Inflammation

Blepharitis

Blepharitis is an inflammatory condition of the lid margin oil glands. It may be infectious, usually due to *Staphylococcus aureus*, involving the eyelash roots, glands, or both. It has been described as "acne" of the eyelids. Individuals who have acne rosacea or seborrheic dermatitis of the scalp and face are particularly vulnerable. Symptoms include swelling, redness, debris of the lid and lashes, itching, tearing, foreign body sensation, and crusting around the eyes on awakening. Management of blepharitis is primarily lid hygiene using warm compresses with baby shampoo or an eyelid cleansing agent applied with a finger, washcloth, or cotton-tipped applicators. Nightly application of bacitracin or erythromycin ointment to the lid margins is helpful when there are signs of secondary infection. For severe or recurrent cases, systemic therapy with tetracycline or doxycycline can be used for several months [7].

Hordeolum

Also known as a stye, an external hordeolum is an inflammation of the ciliary follicles or accessory glands of the anterior lid margin. It is a painful, tender, red mass near the lid margin, often with pustule formation and mild conjunctivitis. An internal hordeolum, which presents in a similar manner, involves an infection of the meibomian gland away from the lid margins. Treatment is usually simple for this self-limited condition: intermittent hot, moist compresses plus topical ophthalmic antibiotics such as tobramycin, bacitracin, erythromycin, gentamicin, or sulfacetamide to prevent infection of the surrounding lash follicles. One method to hasten drainage of the external hordeolum is to epilate (remove a hair and its root) the lash, which effectively creates a drainage channel. Occasionally an incision or puncture for drainage and administration of systemic antistaphylococcal antibiotics are necessary [8].

Telegram: @medical_k

www.konkur.in

Chalazion

A chalazion (lipogranuloma) is a chronic granuloma that may follow and be secondary to inflammation of a meibomian gland. During its chronic phase, it is a firm, painless nodule up to 8 mm in diameter that lies within the tarsus and over which the skin lid moves freely. It usually begins as an internal hordeolum. Asymptomatic chalazia usually resolve spontaneously within a month. Treatment options for persistent chalazia include an intralesional long-acting corticosteroid injection, which may cause hypopigmentation, or a surgical incision and curettage with a clamp [8].

Dermatitis

Dermatitis may be either infectious or of contact etiology. Contact dermatitis is common because of exposure to sensitizing irritants such as neomycin, atropine, cosmetics, lotions, soaps, nickel, thimerosal (often in artificial tears), chloramphenicol, poison ivy, and others. Manifestations include erythema, vesiculation, scaling, edema, and itching. Therapy, most importantly, is the removal of the offending agent. During the acute stages, cool compresses, antihistamines, and topical corticosteroids provide relief. Occasionally, systemic steroids are necessary such as for severe poison ivy dermatitis. The most common infectious causes are impetigo, erysipelas, and herpes zoster, with treatment the same as indicated for other locations [8].

Conjunctiva

Subconjunctival Hemorrhage

Subconjunctival hemorrhage not caused by direct ocular trauma is usually the result of a sudden increase in intrathoracic pressure, as when sneezing, coughing, or straining to evacuate. Rupture of a conjunctival blood vessel causes a bright red, sharply delineated area surrounded by normal-appearing conjunctiva (Fig. 1). The blood is located underneath the bulbar conjunctiva and gradually fades in 2 weeks. Usually no cause is found, but it is seen with hypertension, with anticoagulation, and in neonates or their mothers as a result of labor and delivery. No treatment is indicated [9].

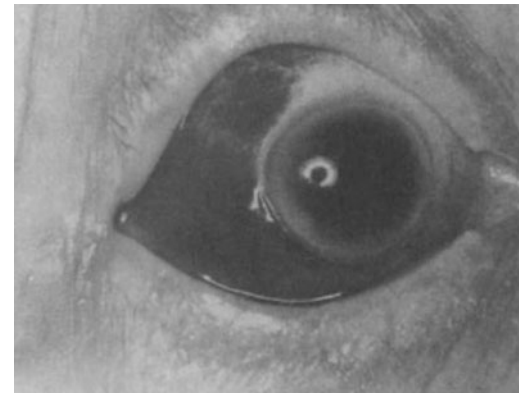

Fig. 1 Subconjunctival hemorrhage

Pingueculum and Pterygium

A pingueculum is an area of the nasal or temporal bulbar conjunctiva that contains epithelial hyperplasia, a harmless yellow-white, plaque-like thickening.

A pterygium is a triangular elevated mass consisting of vascular growth of the conjunctiva, usually nasal, that migrates onto the corneal surface. Environmental factors such as prolonged sunlight exposure and exposure to heat, wind, and dust contribute to its formation. It may be unsightly and uncomfortable, and it may interfere with vision.

Occasionally inflammatory discomfort of either a pingueculum or pterygium may require a mild topical steroid or nonsteroidal anti-inflammatory drop [3].

Surgical removal may be necessary if vision is impaired or for excessive irritation.

Recurrence may occur, but using a conjunctival autograft or amniotic membrane graft may decrease the recurrence [3, 10].

Lacrimal System

Epiphora

Epiphora is a condition in which tearing occurs because of either hypersecretion or impaired drainage of tears through the lacrimal passages. Causes

Telegram: @medical_k

www.konkur.in

include muscle weakness, allergy, ectropion, occlusive scarring, glaucoma, dacryocystitis, canaliculitis, and inflammation [3]. In infancy, it is usually due to congenital nasolacrimal duct obstruction, which has a high rate of spontaneous resolution during the first year. Nasolacrimal duct massage may help [1].

Dry Eye

The tear film is a complex, delicately balanced fluid composed of contributions from a series of glands. Alacrima, decreased or absent tears, occurs with keratoconjunctivitis sicca, associated with the autoimmune systemic complex of Sjogren syndrome, most frequently from rheumatoid arthritis or thyroid diseases. Other causes of dry eye can be blepharospasm, blepharitis, allergies, systemic medications, and toxins [10]. Tear film deficiency also causes nonspecific symptoms of burning, foreign body sensation, photophobia, itching, and a "gritty" sensation. Physical findings include hyperemia, loss of the usual glossy appearance of the cornea, and a convex tear meniscus less than 0.3 mm in height. Treatment is difficult and lifelong with artificial tears containing methylcellulose, polyvinyl alcohol, or 2% sodium hyaluronate four times a day to hourly. Punctal occlusion with a silicone plug or permanent punctal closure via thermal cautery can produce dramatic symptomatic improvement. Severe cases occasionally require mucolytic agents or autologous serum tears. Topical cyclosporine treatment is used in the treatment of dry eye and has shown to have clinical benefits [7, 11, 12].

Dacryocystitis

Dacryocystitis is a painful inflammation of the lacrimal sac resulting from congenital or acquired obstruction of the nasolacrimal duct. Even though congenital nasolacrimal duct obstruction occurs commonly in infants, dacryocystitis is rare and is commonly associated with nasolacrimal duct cysts. In adults, it is idiopathic or the result of an obstruction from infection, a facial trauma, or a dacryolith, rarely neoplasm. The medial lower lid location has a domed mass that is tender and painful, with discharge and tearing. Treatment includes hot packs with topical and systemic antibiotics for penicillinase-producing staphylococcal organisms. Incision and drainage may be performed for select cases; if the acute episode has resolved and is now chronic, surgical correction may be considered (dacryocystorhinostomy with silicone intubation) [8].

Dacryoadenitis

Dacryoadenitis, an enlargement of the lacrimal gland, may be granulomatous, lymphoid, or infectious in origin. If acute, this lesion is painful, tender, suppurative, and inflamed; if chronic, it may manifest simply as a swollen, hard mass. Treatment of dacryoadenitis is determined by its etiology and ranges from supportive heat therapy and massage to incision and drainage, followed by the use of systemic antibiotics and, if not responsive, by steroids [8].

Orbit

Preseptal (periorbital) and postseptal (orbital) cellulitis are bacterial infections of the periocular tissue that are serious and potentially vision threatening and lethal. Preseptal cellulitis involves only the lid structures and periorbital tissues anterior to the orbital septum. Postseptal cellulitis involves tissue behind the septum, which children and adolescents have it more commonly than adults. Routes of infection include trauma, bacteremia, upper respiratory infection, and sinusitis. Cellulitis should be considered in every patient with swelling of the eye. Critical signs include pain, fever, erythema, tenderness, swelling, and conjunctival injection. With postseptal infection, impaired ocular motility, afferent pupillary defect, proptosis, and visual loss also occur. Cavernous sinus thrombosis may develop. Leukocytosis is usually present,

Telegram: @medical_k

www.konkur.in

and a peripheral white blood cell count of more than 15,000/mm^3 suggests bacteremia. Computed tomography (CT) of the orbit is indicated to identify the extent of infection [8].

A bacterial pathogen is identified as the cause of periorbital cellulitis in only 30% of cases. Treatment must cover gram-positive and gram-negative anaerobes and potential methicillin-resistant *Staphylococcus aureus*. Antimicrobial therapy should be intravenous, and guidelines suggest amoxicillin/clavulanic or ceftriaxone with metronidazole as empiric treatment. Emergency consultation with hospitalization should be obtained from both an ophthalmologist and an otolaryngologist [8, 13].

Retina

Disorders of the retina often present with complaints of decreased vision. Assessing visual acuity, examining the eye, and looking for underlying medical problems are important to direct appropriate referral and care.

Arterial Occlusive Retinal Disease

Central artery occlusion (CRAO) is a severe sudden loss of vision due to an embolic or thrombotic occlusion, or obstruction, of the central retinal artery. It is usually painless and is usually monocular. Occasionally it is preceded by symptoms of amaurosis fugax, lasting 5–20 min. A cherry-red spot is often seen in the central macula. Treatment consists of immediate decompression of the eye by pharmacologic or anterior chamber paracentesis. It is important to evaluate for giant cell arteritis as this can cause a CRAO [14].

Branch retinal artery occlusion (BRAO) is a painless, less severe, more peripheral embolic phenomenon in the retinal arterial circulation, where an immediate blank or dark area is noted in the patient's visual field. It is almost always monocular. Treatment is based on finding the systemic source of the problem. Common causes include carotid plaques and cardiac valvular disease [14].

Venous Occlusive Retinal Disease

Central and branch retinal vein occlusions (CRVOs, BRVOs) must be suspected with unilateral loss of vision. A CRVO presents as a sudden loss of vision secondary to compression of the venous return by a retinal artery, causing thrombosis at that location. If an occlusion occurs at the optic nerve head, it is a CRVO; if it is seen more peripherally, it is a BRVO. The CRVO is diagnosed by the presence of flame-shaped and blot hemorrhages throughout the entire retinal field, often obscuring the view of the underlying retina (Fig. 2) [14].

A BRVO causes less severe visual loss, often not noticed by the patient. It leads to stasis of the venous flow more peripherally, which if it involves the macula causes central loss of vision. Here again, flame-shaped hemorrhages are present upon examination [14]. Treatment involves intravitreal injections of anti-vascular endothelial growth factor (anti-VEGF) therapies or laser [15].

Retinal Detachment

The annual incidence of retinal detachment is 12.9:100,000. People with high myopia and lattice degeneration of the retina have about 1% chance of a retinal detachment. Retinal detachment can occur in about 10% of patients with

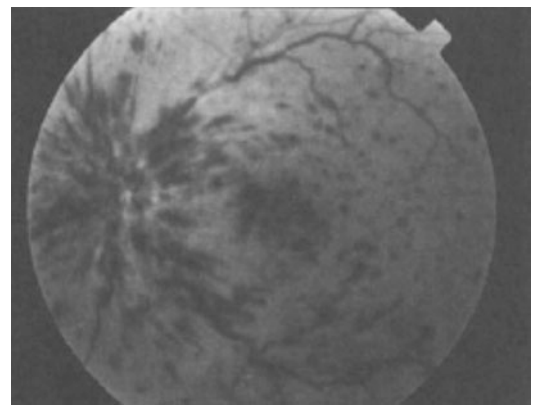

Fig. 2 Central retinal vein occlusion

Telegram: @medical_k

www.konkur.in

vitreous detachment which commonly occurs between the ages of 60 and 80 years. A frequent symptom of retinal detachment is a gray curtain or cloud covering a portion of the visual field. These symptoms may be preceded by a quick flash of light and a new onset of many small black floaters. On physical examination with a dilated pupil, one sees a corrugated bulbous elevation of the retina. If a detachment can be surgically repaired immediately, prior to a macular detachment, the resulting visual acuity is much better [16].

Diabetic Retinopathy

Early detection of diabetic retinopathy is important. Diabetics should have regular ophthalmologic examinations.

Nonproliferative Diabetic Retinopathy

Nonproliferative diabetic retinopathy is graded as mild, moderate, or severe. With the more severe retinopathy, cotton wool spots are present, and dot and blot hemorrhages and lipid accumulation are seen throughout the retina (Fig. 3). If there is thickening of the retina in the central macular zone, diabetic macular edema is present and can cause profound visual loss. Laser and intravitreal injections are used to stabilize and improve visual function [14, 17, 18].

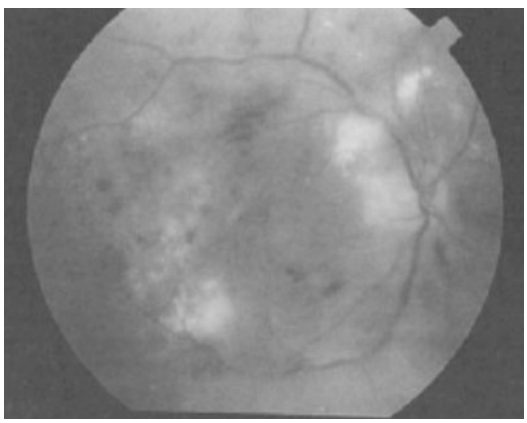

Fig. 3 Nonproliferative diabetic retinopathy

Proliferative Diabetic Retinopathy

Proliferative diabetic retinopathy is diagnosed when neovascularization is detected at the optic nerve or elsewhere in the retina. It poses a risk of retinal and vitreous hemorrhage, tractional retinal detachment, fibroglial proliferation, and retinal fibrosis. With a dilated pupil, a lacy network of fine vessels is seen, indicating retinal ischemia (Figs. 4 and 5). Panretinal photocoagulation (PRP) eliminates the mid-peripheral retina. PRP may cause some night and central vision loss but prevents progressive severe visual loss [14, 18, 19].

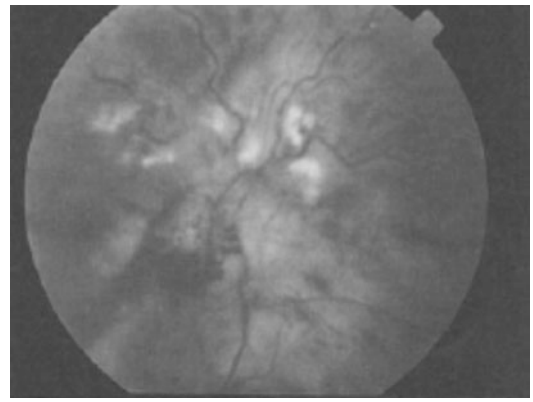

Fig. 4 Proliferative diabetic retinopathy

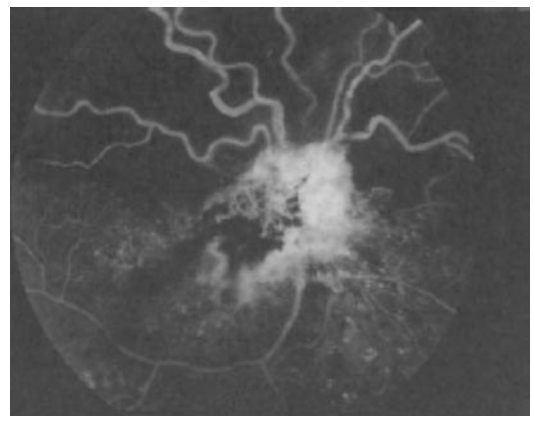

Fig. 5 Angiogram of proliferative diabetic retinopathy

Telegram: @medical_k

www.konkur.in

Amaurosis Fugax

Amaurosis fugax is the sudden, painless, monocular loss of vision, described as a curtain or a shade being pulled down or up, blanketing the field of vision. It totally resolves in 5–30 min. A cholesterol plaque in the carotid artery, or rarely, a calcific cardiac valvular condition, is the etiology. Treatment is directed toward anticoagulation or antiplatelet therapy. Based on the patient's risk threshold, surgical intervention, such as carotid endarterectomy or stenting, is undertaken [2].

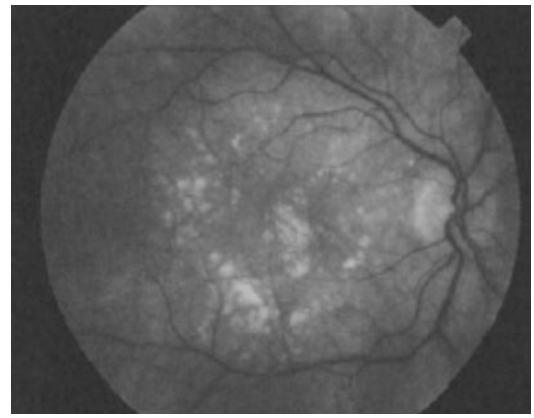

Fig. 6 Dry age-related macular degeneration

Ocular Migraine

Ocular migraine is a common condition in individuals over age 40. It presents often as a migraine aura, a fortification scotoma of jagged, multicolored lights that expand in a gradual fashion across the entire field of vision, leaving in its wake a darker or blank scotoma. Often associated with the migraine symptoms is a queasy feeling. If the episode lasts longer than 1 h, the diagnosis is in question. The eye examination at the time is entirely normal. Treatment is directed to the underlying migraine. Neuroimaging may also be considered if the symptoms are not classic or the duration exceeds 1 h [2, 14].

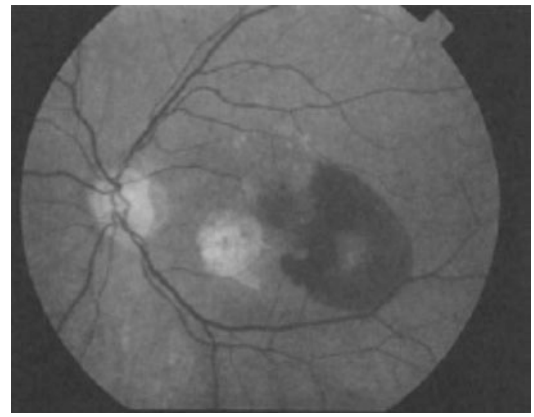

Fig. 7 Wet age-related macular degeneration

Macular Degeneration

Macular degeneration is an aging phenomenon of the inner retina that results in visual loss due to deterioration of the retinal photoreceptors. There are two types of macular degeneration: dry and wet.

Dry Age-Related Macular Degeneration

Dry age-related macular degeneration presents with slow visual loss in the central field of vision. Often the first signs are reduced reading vision and later scotoma in the central field of vision as the severity increases. There is a loss of photoreceptor function in the central macular zone (Fig. 6) [14].

Neovascular Age-Related Macular Degeneration

Neovascular age-related macular degeneration presents with sudden visual loss and hemorrhage in the central macular zone. The underlying retina develops a defect, allowing the choroidal vessels to grow through the retinal pigment epithelium (Fig. 7). The patient presents with a dark or distorted spot in the central field of vision. As the hemorrhage progresses, the vision deteriorates further. Any sudden change in vision of a patient with macular degeneration should result in immediate referral to an ophthalmologist, as neovascular age-related macular degeneration can be treated by intravitreal injection of anti-vascular endothelial growth factors or in some instances laser therapy [14, 20].

Telegram: @medical_k

www.konkur.in

Optic Nerve

Optic Disc Edema

Optic nerve disc edema is a common end point for several ocular disorders that result in swelling of the optic nerve head and hemorrhage in the surrounding peripapillary retina. Blood vessel margins are often blurred as they cross over the optic nerve, and splinter hemorrhages are present, distinguishing this disorder from pseudopapilledema (Fig. 8). The ocular causes of disc edema include the following: optic neuritis, anterior ischemic optic neuropathy (arteritic and nonarteritic), ischemic papillitis as in diabetes, and increased intracranial pressure. When optic disc head edema is secondary to increased intracranial pressure, it is termed papilledema. Papilledema occurs in both eyes but may be asymmetric [21, 22].

Pseudopapilledema

Pseudopapilledema is a benign, anomalous appearance of the optic nerve head due to optic disc drusen, often seen during a normal eye examination. The optic nerve head has an elevated, lumpy appearance. No nerve fiber layer edema or splinter retinal hemorrhages are seen, as would be seen with disc edema [22].

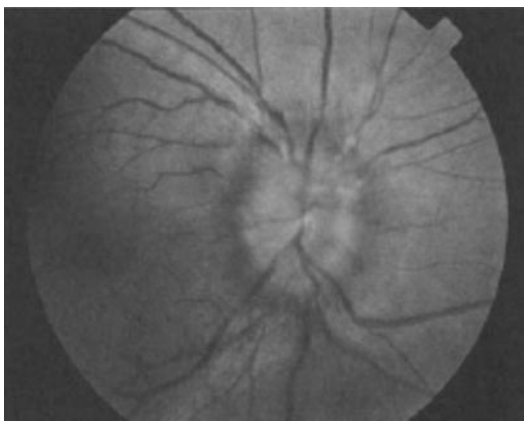

Fig. 8 Optic nerve head edema (papilledema)

Lens

Cataracts, or a clouding of the lens of the eye, are increasingly common among our aged population in the United States. The three of the more common types of cataract can be described based on the location of the lenticular opacity.

A nuclear sclerotic cataract is the hardening of the central nucleus of the lens and leads to gradual yellowing of the nucleus. With further progression, it may turn brown. Frequently this type of cataract is not appreciated at an early stage because of the gradual progression and bilateral aspect of presentation.

Cortical cataract is the whitening of the peripheral lens cortex. As the opacity progresses more centrally, more visual deprivation results. Frequently people complain of glare from lights with this type of cataract. Occasionally, double vision is noted, as cortical opacity splits light into different focal points.

Posterior subcapsular cataracts are the most visually disabling, and the progression can be rapid. Near vision is more impaired than distance vision. The disorder is often seen in patients on chronic steroids (topical or systemic) or diabetes.

The diagnosis can be easily made by dilating the pupil and using the red reflex test. Examination indicators are a hazing over with a nuclear sclerotic cataract, a spoke-like defect with a cortical cataract, and a central dark opacity with a posterior subcapsular cataract. Treatment normally is surgical, but if the patient is not a surgical candidate, chronic dilation of the pupil improves the vision in some patients. Visual recovery from surgery is frequently rapid [23].

Glaucomas

Primary Open-Angle Glaucoma

Primary open-angle glaucoma (POAG) is a relatively common disorder whose incidence increases with advancing age. There is an obstruction of aqueous outflow at the level of the trabecular meshwork. Predisposing factors include a family history of glaucoma, severe blunt trauma to the eye, and possibly high myopia. In 2018, the

Telegram: @medical_k

www.konkur.in

prevalence of POAG for adults 40 and older in the globally is estimated to be 3.5% [24].

Glaucoma can occur without elevated intraocular pressure. Computer-based visual field testing can be used to screen for glaucoma, but the US Preventive Services Task Force does not recommend for or is not against screening. Physical exam findings of glaucoma show damage to the optic nerve. Elevated intraocular pressure does tend to raise the risk threshold of developing glaucoma. The diagnosis is based on a triad of findings: increased intraocular pressure, optic nerve head cupping, and visual field defect. A cup/disc ratio of more than 0.60 is often a diagnostic clue, as is asymmetry between the two eyes. When a family history of glaucoma is present, or an enlarged cup-to-disc is seen, referral to an ophthalmologist is indicated (Figs. 9 and 10).

The treatment options are pharmacologic lowering of intraocular pressure, laser trabeculoplasty to attempt to increase the aqueous outflow, or surgical decompression of the eye by trabeculectomy or aqueous shunts [14, 24–27].

Angle-Closure Glaucoma

An acute angle-closure glaucoma attack is precipitated by abrupt closure in the aqueous outflow. The iris, with slight dilation, occludes the trabecular meshwork, resulting in progressively increasing pressure within the eye. The acute symptoms include pain, decreased vision, halos around lights, nausea, and vomiting. Examination reveals a cloudy or "steamy" appearance of the cornea, a nonreactive mid-dilated pupil, an area of injection around the limbus, and elevated intraocular pressure. Immediate referral to an ophthalmologist is mandatory. A laser iridotomy is often necessary, and close monitoring is needed in the uninvolved eye [27].

Oculomotor Motility

Strabismus

Strabismus is commonly defined as a deviation of the visual axis. This ocular misalignment can be found at almost any age. The malalignment of the eyes prevents binocular vision. Esotropia (in-turning of one eye) or exotropia (out-turning of one eye) are identified by examining the eyes of the newborn and children for symmetric corneal light reflex and using the cover/uncover test. At birth most infants have a small degree of exotropia that resolves during the first few months of life. Infants can reliably fix with both eyes by 4 months old. An abnormal cover/uncover test or caregiver report of deviation after 4 months old needs evaluation for potential amblyopia [1].

The treatment of strabismus is based on first correcting any refractive disorder, patching for amblyopia if present, and, lastly, surgically

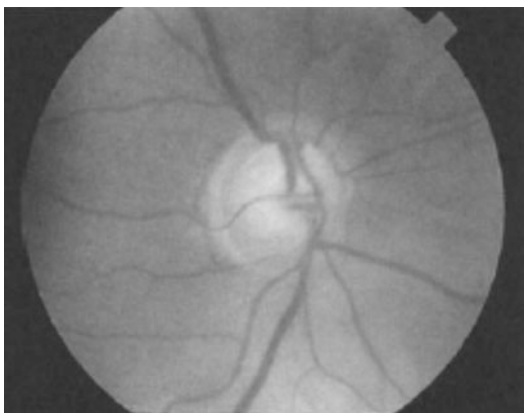

Fig. 9 Chronic open-angle glaucoma with loss of axons; note the centrally excavated optic cup

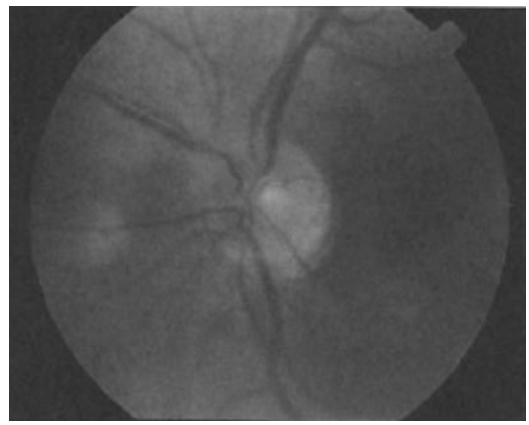

Fig. 10 Normal optic nerve with a healthy, nonexcavated optic cup

Telegram: @medical_k

www.konkur.in

realigning the eyes. Visual outcome is best when the problem is diagnosed early [1, 28].

Amblyopia

Amblyopia is defined as a poorly sighted eye secondary to some form of visual deprivation at an early age. Treatment is best when started at a younger age. The US Preventive Services Task Force recommends assessing visual acuity at least once between 3 and 5 years of age to detect amblyopia. Amblyopia is seen in association with strabismus and with refraction disorders [28].

Strabismus produces amblyopia by preventing image stimulation in the fovea of the deviated eye. Occasionally, the diagnosis is made using a red reflex test with a direct ophthalmic scope held about 3 feet from the child's eyes. A difference in the red reflex may indicate a refractive error, amblyopia, or an opacity in the ocular media [28].

Anisometropia is a difference in the refractive status between the eyes leading to amblyopia. Treatment of amblyopia is aimed at restoring the suppressed visual input by occluding the more favored eye with a patch, colored lenses, or pharmacologic intervention. Treatment is more successful when started under 7 years old, but older children may benefit from treatment [1, 28].

Optical Defects

Refractive Disorders

A refractive disorder occurs because the focal point of light does not fall on the retina. In addition to glasses, excimer laser surgery has produced safe and accurate correction of refractive disorders. Laser-assisted in situ keratomileusis (LASIK) is the most common refractive procedure performed today. In LASIK, the corneal stroma is remodeled with computer-controlled assistance to focus images on the retina of the eye. Recovery is usually within days to weeks. Complications, although rare, include under- and overcorrections, diffuse keratitis, and infection. Phakic intraocular lenses are an emerging option for surgical correction with very high myopia [29].

Accommodation Loss or Presbyopia

Accommodation, the ability to adjust the optic power of the eye, decreases from childhood to about age 75. In the normal human eye, as accommodation occurs, the ciliary body contracts, relaxing the zonules (or fibers) to the lens of the eye, and an active increase in lens curvature occurs, increasing the optical power of the eye. As the eye ages, hardening (sclerosis) of the lens reduces the elasticity of the lens capsule and plasticity of the lens core, resulting in a loss of accommodative amplitude. To correct this loss, reading glasses and monocular vision using contacts are prescribed. Options for surgical treatment include LASIK to achieve monovision and multifocal or accommodating intraocular lenses if cataract surgery is indicated [30].

Acute Otitis Media

Acute otitis media (AOM), an infection most often caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis*, will affect one in four children by age 10 [1]. Differentiating the infectious AOM from the noninfectious otitis media with effusion (OME) is a critical skill for accurate diagnosis as both conditions demonstrate fluid trapped in the middle ear on physical exam.

Epidemiology

Acute otitis media is a common diagnosis in young children. Each year in the United States, more than 2.2 million episodes of acute otitis media occur [2]. Risk factors for acute otitis media include male gender, Native American ethnicity, having multiple siblings in the home, premature birth, bottle-fed status, tobacco smoke exposure, family history of recurrent AOM, and attendance at an out-of-home day care [3, 4]. Typically, incidence peaks in the first year of life and declines after age 5 years with more than 80% of children having an acute otitis media infection before starting school [5]. Additionally, children with earlier onset of first episode of AOM may be more likely to have recurrent disease and complications leading to morbidity and mortality [4].

Diagnosis

Acute otitis media is a clinical diagnosis that should be based on history and physical exam findings. The American Academy of Pediatrics published guidelines in 2013 to help clinicians to limit over diagnosis and subsequent overtreatment of AOM. Bulging of a tympanic membrane with either associated intense erythema or recent onset of ear pain or new onset of otorrhea not explained by otitis externa are common presentations of AOM [6]. Middle ear effusion alone is not sufficient to diagnose acute otitis media, as otitis media with effusion (OME) may also present in this manner [6]. The major factor that distinguishes acute otitis media and otitis media with effusion is that OME is not an infectious process and as such there should not be signs of infection such as an erythematous tympanic membrane or otalgia.

Treatment

Treatment for AOM has been controversial in recent years as guidelines designed to promote watchful waiting in lieu of immediate antibiotic therapy often had poor adoption by physicians [7]. Current guidelines published by the American Academy of Pediatrics in 2013 emphasize the need for adequate analgesia for children during an AOM episode and offer clear definitions of children who would be most likely to benefit from observation rather than immediate antibiotic therapy. A Cochrane review of 13 randomized controlled trials that included 3401 children and 3938 episodes of acute otitis media concluded that antibiotics did not significantly reduce pain in the immediate infection phase or abnormal tympanometry findings in the long term [8]. Severe complications were rare regardless of treatment with antibiotics or watchful waiting; however, adverse effects such as vomiting, diarrhea, or rash were common with 1 child affected for every 14 children treated [8].

Analgesia

Acute otitis media is associated with significant pain that may persist for up to 7 days, despite antibiotic therapy [9]. Both oral and topical medication choices exist to alleviate pain associated with AOM. Oral ibuprofen or acetaminophen as well as topical procaine, phenazone, or benzocaine has all been shown to be effective for AOM-related pain [10, 11]. Narcotic pain medications, antihistamines, and decongestants are associated with significant side effects that outweigh any potential analgesic benefit for AOM [10, 12]. Other pain relief options may include naturopathic remedies or osteopathic manipulation though randomized controlled trials that demonstrate effectiveness of these options are limited [13, 14].

Antibiotic Therapy

All children older than 6 months with evidence of acute otitis media with otorrhea or who have severe symptoms should receive immediate antibiotic therapy [6]. Severe symptoms include toxic appearance, persistent otalgia for more than 48 h, temperature greater than 39 °C in the last 48 h, or uncertain ability to follow-up [6]. Severe bulging of the tympanic membrane may also be a sign that

Telegram: @medical_k

www.konkur.in

antibiotic treatment is warranted. Additionally, children less than 2 years of age with bilateral acute otitis media should receive immediate antibiotic therapy [6].

First-line antibiotic treatment for acute otitis media remains amoxicillin 80–90 mg/kg/day [3]. Currently, amoxicillin (90 mg/kg/day)-clavulanate (6.4 mg/kg/day) remains the second-line choice for antibiotic treatment of otitis media. However, new studies suggest that lower doses of clavulanate (2.85 vs. 6.4 mg/kg/day) may provide similar effectiveness with less diarrhea or diaper rash [15].

Special circumstances that may necessitate the use of an alternative antibiotic are described in Table 1.

Children less than 2 years of age should be treated for 10 days with antibiotics, while older children may be offered a 5–7-day course of therapy [6]. Any child who fails to improve after appropriate antibiotic therapy should be considered a candidate for tympanocentesis and culture of middle ear fluid to guide therapy [6].

Observation

Children who are older than 6 months with unilateral AOM without otorrhea or severe symptoms or children older than 2 years with bilateral AOM without otorrhea or severe symptoms are candidates for observation rather than immediate antibiotic therapy [6]. Severe complications are rare regardless of whether or not a child receives antibiotics [8]. No child should be offered observation as a treatment option if there is concern that the child will not be able to return for evaluation or obtain antibiotics if they fail to improve in 48–72 h of onset of symptoms [6]. As 78% of AOM episodes will resolve spontaneously and antibiotic side effects such as rash and diarrhea are common, observation in well-chosen patients is a reasonable option [17].

Table 1 When to use antibiotics other than amoxicillin for AOM [6, 16]

Special circumstance	Antibiotic choice instead of amoxicillin
Child had amoxicillin in prior 30 days	Amoxicillin-clavulanate (90 mg/kg/day amoxicillin and 6.4 mg/kg/day clavulanate)
Child has concurrent bacterial conjunctivitis	Amoxicillin-clavulanate (90 mg/kg/day amoxicillin and 6.4 mg/kg/day clavulanate)
Child has penicillin allergy	Cefdinir, cefuroxime, cefpodoxime, or ceftriaxone
Child has tympanostomy tubes in place	Topical ciprofloxacin/dexamethasone
Child on amoxicillin not improving in 48–72 h	Amoxicillin-clavulanate (90 mg/kg/day amoxicillin and 6.4 mg/kg/day clavulanate), ceftriaxone, or clindamycin

Surgical Options

Children who have more than three episodes of AOM within a 6-month period or more than four episodes of AOM within a year should be referred for evaluation for tympanostomy tubes [18]. Tympanostomy tubes may result in improved hearing initially though continued superiority to watchful waiting with respect to improved hearing is not sustained at 12–24 months [19]. Referral should focus on a careful weighing of risks and benefits of tympanostomy placement individualized for each child.

Complications

Acute otitis media can be associated with significant complications. Hearing loss may be a temporary result of fluid within the middle ear. Unfortunately, fluid may remain for weeks or months following an episode of AOM. Though hearing loss may be frustrating for both child and parents during this time, little evidence exists that speech and language delays result from this hearing loss alone [20–22]. Of note, however, rarely permanent sensorineural hearing loss may occur as a result of AOM.

Balance problems, tympanic membrane perforation, and cholesteatoma may also result from acute otitis media with recurrent episodes increasing risk [23]. Chronic suppurative otitis media, mastoiditis, petrositis, labyrinthitis, meningitis,

Telegram: @medical_k

www.konkur.in

abscess in the brain or epidural space or thrombosis of the lateral sinus, cavernous sinus, or carotid artery may also result from acute otitis media. Thankfully, these complications are rare. Of note, no studies have demonstrated an increase in meningitis or mastoiditis since implementation of observation guidelines in children [4].

Prevention

Effective prevention strategies would yield large benefits given the prevalence of AOM. While no targeted acute otitis media vaccine exists, introduction of higher-valent pneumococcal vaccines as well as increased influenza vaccination rates have resulted in risk reduction for AOM [24–26]. Supplementation with vitamin D and zinc has been shown to be beneficial only in children with documented nutritional deficiencies [27–29]. Xylitol, a polyol sugar alcohol found in raspberries, has been demonstrated to be effective at preventing acute otitis media though current dosing requirements of administration five times daily make its use limited [30]. Formula-fed infants may benefit from probiotics such as *Lactobacillus rhamnosus* GG, and *Bifidobacterium lactis* Bb-12 [31]. However, exclusive breastfeeding may be more beneficial as a risk reduction strategy than probiotic-supplemented formula [3]. Overall, more research into the role of probiotics is needed as early studies are promising, but limited evidence exists to identify the optimal strain, duration, dose frequency or timing of probiotic administration [32]. In infants, eliminating exposure to passive tobacco smoke and reducing pacifier use after 7 months of life may also lead to reduced incidence of AOM [3].

Otitis Externa

Otitis externa may result from infectious or allergic causes that lead to inflammation of the external auditory canal. Usually inflammation is diffuse throughout the ear canal. Three forms of otitis externa have been described, namely, acute otitis externa (AOE) which lasts for less than 6 weeks, chronic otitis externa (COE) which lasts for more than 3 months and malignant otitis externa. AOE is likely to be the result of a bacterial infection whereas COE most often results from allergy or underlying dermatologic condition [33].

Epidemiology

While the exact incidence of otitis externa is unknown, estimates suggest 10% of people will be affected at some time throughout their lives [34]. Acute otitis externa tends to occur in warm, humid climates and in individuals with narrow ear canals [33]. While children aged 7–12 may be affected, acute otitis externa is seen more commonly in adults [33]. Risk factors for disease include ear trauma such as from cotton swab use, hearing aids, and dermatologic conditions such as eczema or psoriasis. Water exposure is also a risk factor leading to the common name for AOE of swimmer's ear.

Pathophysiology

Acute otitis externa is most often caused by bacterial infection with *Pseudomonas aueriginosa* accounting for 22–62% of infections and *Staphlyococcus aureus* accounting for 11–34% of cases [35]. Polymicrobial infection is common. While only accounting for 10% of cases of acute otitis externa, infection with *Aspergillus niger* and *Candida* species has been reported after prolonged antibiotic use [33]. Polymicrobial infections have also been reported.

Cerumen provides a critical protective function in the ear by limiting exposure of skin to moisture and creating an acidic pH that is inhospitable to bacterial growth. Removal of cerumen with cotton swabs eliminates this protective barrier and creates a trauma to the ear canal that can result in infection. Similarly, water exposure can cause epithelial breakdown also leading to infection [36].

Diagnosis

Most often, patients with acute otitis externa present with symptoms of ear inflammation such as pain, itching or fullness with sudden onset

Telegram: @medical_k

www.konkur.in

[37]. Pain is often worsened with manipulation of the pinna or tragus. Additionally, patients may experience otorrhea, hearing loss or jaw pain [37].

Diagnosis of acute otitis externa should be made clinically with history and otoscopic examination of the affected ear. Visualization, or inability to do so, of an intact tympanic membrane is an important physical examination element to guide treatment. Findings of ear canal edema or erythema are also common. Secretions may be present and can be collected for culture, though it is not necessary to do so. Individuals who are immunocompromised or experience frequent infections may benefit from culture.

A differential diagnosis should include consideration for other infections such as perichondritis, erysipelas, otitis media with perforation and herpes zoster oticus as well as eczema, cholesteatoma and carcinoma of the external auditory canal [36].

Treatment

Acute otitis externa is best treated with pain control and topical therapies. Oral antibiotics should only be offered if the patient has poorly controlled diabetes mellitus, immunosuppression, or if the infection has spread beyond the ear canal [38]. Both antiseptic and antibiotic medications can be utilized for treatment with similar effectiveness [38].

Because there are many effective regimens, consideration of side effects, cost and dosing schedule are important when choosing a treatment strategy. For example, neomycin is effective, but ototoxic and cannot be used with a perforated eardrum. Too, neomycin may cause contact dermatitis, worsening itching, and irritation, in up to 30% of patients [39–42]. Fluoroquinolones are often preferred due to twice daily dosing and safety even if the eardrum is ruptured. However, these tend to be more expensive than other options. Some clinicians will offer ophthalmological antibiotic preparations as off label treatment for otitis externa due to cost considerations [38, 43]. Many of the combination regimens will include corticosteroids to lessen edema and hasten resolution of pain and itching [44].

Up to 20–40% of patients receive systemic antibiotics for treatment of acute otitis externa despite efficacy of topical options [20, 21]. Such treatment can increase risk of side effects and antibiotic resistance without offering improved treatment rates. Table 2 describes commonly prescribed regimens.

Regardless of medication chosen, any topical therapy will not be effective if significant cerumen is occluding the canal or if significant edema is present. Also, debris may contain exotoxins such as *Pseudomonas* exotoxin A that can promote inflammation. Gentle suction or direct visualization may be used to remove any cerumen or debris, though irrigation should be avoided in those patients who do not have an intact tympanic membrane, who are immunocompromised, or who have diabetes mellitus as an increased risk of malignant otitis externa has been reported

Table 2 Common topical preparations for acute otitis externa [45]

Component	Cost	Frequency of dosing	Comments	Ok if eardrum perforation
Acetic acid 2% solution	$	Four to six times daily	May increase pain and irritation	No
Acetic acid 2%/hydrocortisone 1% solution	$$$	Four to six times daily	May cause local irritation	No
Neomycin/polymyxin B/hydrocortisone solution	$$	Three to four times daily	Risk of contact hypersensitivity	No
Ciprofloxacin 0.2% solution	$$	BID	Single-use containers	Yes
Ciprofloxacin 0.2%/hydrocortisone 1% suspension	$$$$	BID		Yes
Ciprofloxacin 0.3%/dexamethasone 0.1% suspension	$$$$	BID		Yes
Ofloxacin 0.3% solution	$$$	Daily-BID		Yes

Telegram: @medical_k

www.konkur.in

[46]. An ear wick may be used with canal edema to improve drug delivery.

Topical medications should be placed into the ear with the patient lying with the affected ear up. Further, patients should be cautioned that once drops are instilled, a 3–5-min waiting period is necessary before sitting up to allow the medication to be effective [37].

Typical treatment courses are 7 days, though this may be extended to 10 days if patient is not improving. Improvement can be expected within 72 h and significant symptoms beyond 72 h should prompt reevaluation of the patient. Referral to an otolaryngologist is indicated if there is lack of expected improvement, inability to remove debris, or suspected malignant otitis externa.

Over the counter medications such as acetaminophen and ibuprofen are also helpful for pain control. Of note, benzocaine should be avoided as it can lead to contact dermatitis and worsening of symptoms. Patient should be cautioned to avoid water immersion of an affected ear until treatment is concluded. Too, hearing aids should be avoided until pain is improved.

Complications

Infection may extend to surrounding structures, causing chondritis, perichondritis, or facial cellulitis. Over time, patients with chronic infection may develop canal stenosis and conductive hearing loss.

Prevention

Episodes of acute otitis externa may be prevented by avoiding water exposure by either using well-fitting earplugs or using a hair dryer on the lowest setting to dry ears after swimming. Acetic acid 2% drops may also be helpful in acidifying the pH of the ear canal.

Chronic Otitis Externa

Chronic otitis externa is defined as acute otitis externa lasting more than 3 months or with more than four episodes per year [45]. Rather than resulting from bacterial infection, chronic otitis externa is often the result of an underlying skin condition such as atopic dermatitis or psoriasis [45]. Symptoms typically include itching and conductive hearing loss. Unlike acute otitis externa, pain is a rare finding [47]. The physical examination may show erythematous skin with either dry, scaling, or moist debris noted [47]. More than half of individuals have both ears affected [47]. Of most concern with chronic otitis externa is conductive hearing loss as well as chronic fibrosis of the canal which can make it difficult to fit hearing aids [45].

Treatment for chronic otitis externa includes removal of all irritants such as shampoo and soap as well as careful attention to keeping the ear canal dry as much as possible. Too, any underlying skin or autoimmune disease should be treated to improve the overall condition as well as the chronic otitis externa [45].

Malignant (Necrotizing) Otitis Externa

Malignant otitis externa occurs most often in elderly men with diabetes mellitus or immunosuppression [48]. Malignant otitis externa causes destruction of the external auditory canal, perichondritis, and osteomyelitis of the lateral skull base, thus early diagnosis is essential.

Symptoms of malignant otitis externa include intense, nonspecific ear pain, conductive hearing loss, and otorrhea with exam findings of granulations, polyps, or exposed bone [24]. Any individual not responding as predicted to therapy for otitis externa or with severe symptoms should be closely evaluated for malignant otitis externa. Imaging should include both fluorodeoxyglucose positron emission tomography/magnetic resonance imaging as well as high resolution computed tomography to detect osteitis before bone erosions can be appreciated [49]. Additionally, biopsy of the external auditory canal, to rule out tumor or cholesteatoma, and cultures, to guide antibiotic treatment, should be obtained.

Treatment of malignant otitis externa should include at least 4–6 weeks of antibiotics tailored to culture findings [48]. While awaiting

Telegram: @medical_k

sensitivities from culture specimens, empiric therapy directed against *Pseudomonas aeruginosa* is appropriate. Surgery may be needed to remove necrotic tissue.

The mouth has been described as a window to general health. Oral health can directly affect overall health and can have a significant impact on the overall quality of life of the individual patient [1]. Disease in the mouth can cause systemic disease such as endocarditis, make chronic disease management such as diabetes more difficult, or lead to adverse pregnancy outcomes [2, 3]. In addition, a thorough oral exam may provide clues to the timely diagnosis of systemic infections, immunologic diseases, hematologic conditions, and nutritional disorders [2, 3].

Caries

Dental caries or tooth decay is the most common chronic disease worldwide [1]. Fifty percent of children between the ages of 6 and 8 years old have dental caries, and nearly 24% of adults age 24–64 have untreated dental caries [3–5]. Dental caries develops through the complex interaction of oral microorganisms (*Streptococcus mutans* and lactobacilli), metabolizing dietary sugars into lactic acid creating an acidic environment [3, 5–6]. This acidic environment leads to demineralization of the tooth's protective enamel coating and subsequent tooth decay. When the subsequent caries or decay penetrates through the full thickness of the enamel to reach the underlying dentin layer, patients will begin to typically experience mild intermittent tooth pain or sensitivity to thermal changes or sugary foods. This process is also known as reversible pulpitis and is treated through the mechanical removal of the decayed area and restoration through the placement of a dental filling [1, 4, 6]. As the demineralization process progresses, areas of dental caries may become brown or black stained making them more visible to the naked eye. If the caries goes untreated, irreversible pulpitis may ensue resulting in severe persistent dental pain despite removal of any inciting stimulus. The patient with irreversible pulpitis will often present with poorly localized pain or even pain referred to the opposite jaw [4, 6]. Once again definitive treatment involves mechanical removal of the decay through restoration, root canal or extraction by a dentist. Insufficient evidence exists in the literature to recommend antibiotic therapy, unless infection has spread to the surrounding soft tissue [4–6].

Dental exams should begin by the time patients are 1 year of age. However, the most cost-effective intervention for prevention is the public health policy of adding 0.7–1.0 parts per million of fluoride to the municipal water supply [4]. Fluoride's mechanism of action helps to strengthen tooth enamel and also has a bacteriostatic effect. Whether or not local water has been fluoridated, the effectiveness of topical fluoride has been well established. When compared with mouth rinses or gels, fluoridated toothpastes have a similar degree of effectiveness for the prevention of dental caries in children [4]. Parents should introduce tooth brushing with a smear of low-fluoride toothpaste to children as the first teeth erupt and younger than 2 years of age. Children 2–5 years of age should use a pea-sized amount of fluoride toothpaste [1]. The use of mouth rinses and gels at home is not recommended for children younger than 6 years. Tooth brushing with fluoridated toothpaste twice a day after meals is recommended as an effective way to prevent tooth decay on exposed surfaces, and flossing daily helps prevent plaque build-up on interdental surfaces. Children and adolescents should also be considered for dental sealants when they are most likely not to be compliant with daily dental hygiene regimes [1, 6]. Sealants are resinous materials that are professionally applied to the biting surfaces of teeth most susceptible to decay (molars and premolars). These sealants create a barrier against acid environments and bacterial penetration. Within the adult population, medications that decrease saliva production can be an added risk factor for carries formation [1, 3]. Additionally, dietary changes such as reducing the amount and frequency of foods with caffeine or high sugar content may further decrease dental caries rates [1, 3].

Periodontal Diseases

Periodontal disease is an inflammatory response caused mainly by bacterial colonization within the subgingival dental plaque. Though bacterial colonization is an essential component to the development of periodontal disease, certain conditions such as Down syndrome, Papillion–Lefevre syndrome, diabetes, xerostomia, medications, and smoking may further dispose a patient to periodontal disease [3, 4]. Some evidence also suggests that the presence of chronic periodontal disease may exacerbate the progression of certain diseases such as diabetes and cardiovascular disease and maybe associated with an increased incidence of preterm labor [4, 5, 7]. Periodontal disease can be divided into gingivitis and periodontitis.

Telegram: @medical_k

www.konkur.in

Gingivitis

Gingivitis is characterized by reversible inflammation of the gums. Patients present with erythematous swollen tender gums that bleed with routine brushing or flossing. Halitosis may also be present. Pregnancy or other hormonal changes may increase the prevalence of gingivitis in female patients [7]. Medications such as phenytoin, calcium channel blockers, and cyclosporine can also lead to increased inflammatory or non-inflammatory gingival hyperplasia [5]. Care should include removing any offending agents such as medications and tobacco and improved daily oral hygiene. General measures for treating and future prevention include improved oral hygiene with frequent tooth brushing, daily flossing, and use of warm saline or chlorhexidine gluconate 0.12% rinses [1, 4, 5]. Mouth rinses containing essential oils such as Listerine has been shown to be as effective as chlorhexidine but with less tooth staining [4, 5]. Antibiotics are not necessary unless patient presents with acute necrotizing ulcerative gingivitis also known as Vincent's disease or trench mouth [6]. Trench mouth is caused by anaerobic bacteria (*Treponema*, *Selenomonas*, *Fusobacterium*, and *Prevotella intermedia*) and typically presents in patients whose host defenses are compromised by poor oral hygiene, poor nutrition, or systemic illness. Clinically the gingival tissue is denuded with punched-out crater-like areas of necrosis and is accompanied by pain, fetid breath odor, fever, malaise, and cervical lymphadenopathy. In addition to the general measures for treating gingivitis, patients should be prescribed penicillin VK 500 mg orally every 6 h or metronidazole 500 mg orally twice daily [6]. Patients should be given a 7-day course of either regime depending on patient allergy history and/or prescriber preference.

Periodontitis

If left untreated, chronic gingivitis over a period of months to years progresses to periodontitis. Persistent exposure of the mouth to plaque-associated bacteria leads to a local and systemic inflammatory response. This inflammatory response leads to the destruction of the tooth's underlying supporting tissue and alveolar bone. Clinical presentation may demonstrate deep inflamed painful gums with deep gum pockets that bleed easily, heavy tooth plaque, receding gums with exposed root, and loose teeth. Proliferation of bacteria within the deep gum pockets can lead to periodontal abscess formation, which in addition to pain and swelling is further characterized by suppurative drainage. The most common organisms implicated in periodontitis are gram-negative bacteria such as *Actinobacillus actinomycetemcomitans*, *Porphyromonas gingivalis*, and spirochetes [6]. General measures for treating periodontitis should be aggressive plaque descaling by a dentist, incision and drainage of local abscess, and good oral hygiene practices as outlined in the gingivitis section. Antibiotics are indicated when an abscess spreads to the deeper tissues of the oral cavity causing facial swelling and lymphadenopathy or if generalized periodontitis exists where the patient has multiple loose teeth [4–5]. Antibiotic regimes include doxycycline 100 mg daily, metronidazole 500 mg orally twice daily, or topical application of metronidazole, doxycycline, or minocycline [4–5]. Periodontitis is a common and serious condition affecting approximately 20% of all adults and is the leading cause of tooth loss [5]. Besides causing focal oral disease, multiple studies demonstrate an association between periodontitis and cardiovascular disease, worsening diabetes, and increased risk for preterm labor [5, 7]. However, no study has demonstrated whether treating or preventing periodontal disease leads to improved systemic disease outcomes [5].

Candidiasis

Candida species are normal inhabitants of the gastrointestinal tract and present as part of the normal oral flora in 60% of healthy adults [3, 5, 8]. Certain local and systemic factors may make certain individuals more susceptible to oral candidal infections. These include infection with

Telegram: @medical_k

www.konkur.in

human immunodeficiency virus (HIV), diabetes or glucose intolerance, xerostomia, malnutrition, presence of dentures, patients with cancer, medications (broad spectrum antibiotics, inhaled or systemic steroids, chemotherapy), and reduced immunity related to age [3, 5, 8]. Oral candidiasis is common in infants, affecting 1–37% of newborns [8]. Diagnosis is usually made through a history of risk factors and symptoms. The most common presentation is of painless adherent curd-like white patches along the oral mucosa and/or tongue. These white patches can be partially wiped off using a tongue blade or gauze and diagnosis confirmed either by culture or by preparing a potassium hydroxide slide looking for hyphae. Oral candidiasis may also present as erythema of the oral mucosa especially in denture wearers and/or as angular cheilitis/perleche (painful, erythematous fissures at the corners of the mouth). Common treatments include nystatin suspension 100,000 U/ml four to six times daily, Mycelex (clotrimazole) troches 10 mg five times a day, or fluconazole (Diflucan) 200 mg orally on day one then 100–200 mg daily [3, 5, 8]. Infants should be treated with nystatin suspension 0.5 ml in each cheek, massaging the cheeks to spread throughout the oral cavity. Fluconazole 6 mg/kg orally on day one and 3 mg/kg thereafter may be used as an alternative for resistant cases. All regimes are used for an average of 7–14 days [5, 8]. All pacifiers and bottle nipples should be boiled. In breastfed infants, mother's nipples may be treated if needed, with topical antifungal creams or ointment. The use of probiotics for either prophylaxis or adjunctive treatment of recurrent or primary candidiasis has shown some favorable benefit; however, further studies are needed to confirm effectives, dosages, and side effects [9].

Stomatitis

Characterized by inflammation of the mucosal lining of the mouth, lesions are erythematous, painful, and can be ulcerated. Most common conditions include hand–foot–mouth disease, herpetic stomatitis, and recurrent aphthous stomatitis/ulcers. Additional causes include herpangina, nicotinic stomatitis, and denture-related stomatitis. Any remaining causes are considered rare and uncommon. The most common forms of stomatitis present with shallow ulcerations less than 1 cm in diameter and resolve spontaneously over 10–14 days [5, 8]. Patients usually present with complaints of burning sensation, localized pain, irritation with certain foods, and intolerance to temperature changes. Recurrent aphthous ulcers or "canker sores" affects 5–21% of the population and etiology remains unclear [8]. Treatment focus is on providing topical relief. Topical agents that can be used include 2% viscous lidocaine or topical steroid such as Kenalog in Orabase applied in small amounts with a cotton swab three to four times daily. Additionally various combinations of "Magic Mouthwash" can be compounded for a swish and spit rinse three to four times daily. Suggested compounds mixed in equal parts have consisted of a thick base coating liquid such as Maalox, Mylanta, Carafate, or Nystatin mixed with, diphenhydramine, plus 2% viscous lidocaine or hydrocortisone. Caution should be noted that overuse of products containing lidocaine may cause cardiac arrhythmias. Since disease course is generally self-limited, when an ulcer persists beyond 3 weeks, other causes should be considered. Nutritional deficiencies, such as folate, B_{12}, B_6, or iron, drug reactions, Behcet's disease, Reiter's syndrome, inflammatory bowel disease, celiac sprue, lichen planus, and HIV infection have all been associated with recurrent aphthous ulcers [5, 8, 10]. Additionally, squamous cell cancer may present as a non-healing or non-resolving ulcer, and biopsy of the ulcer should be considered [5].

Lichen Planus

Lichen planus is a chronic inflammatory condition that is most likely a T cell-mediated autoimmune disease [11]. Lichen planus affects approximately 1–2% of the population, more often in those over age 40 and a slight predilection in perimenopausal women [5, 8, 12]. In women with oral lichen planus, 20% of them will also have concomitant

Telegram: @medical_k

www.konkur.in

involvement of the vulva and vagina [11, 12]. Patients with lichen planus have also showed a greater prevalence for exposure to hepatitis C (HCV), making it appropriate to screen patients with lichen planus for HCV infection [12]. There are four forms of oral lichen planus: reticular, atrophic, bullous, and erosive. The reticular form is the most common and manifests as asymptomatic bilateral white lace striations on the oral mucosa. The atrophic form presents as erythematous atrophic-appearing lesions within the oral mucosa and may be more painful than the reticular form. The bullous form manifests as fluid-filled vesicles, while the erosive form leads to ulcerated erythematous, painful lesions. Patients can often have a burning sensation within their mouth. Management options should start with good oral hygiene, avoiding irritating foods and tobacco products. Medium- to high-potency topical steroids are first-line therapy to treat symptomatic lichen planus [5, 12]. Clobetasol 0.05% or fluocinonide 0.05% is applied twice daily to lesions [11, 12]. Patients with widespread oral disease or diffuse ulcerations may not adequately respond to corticosteroids alone. Topical calcineurin inhibitors such as pimecrolimus 1% (Elidel) or tacrolimus 0.1% (Protopic) or topical retinoids can be effective second line or adjunctive forms of therapy for these patients [11, 12]. Patients refractory to standard topical therapies may have using oral retinoids such as alitretinoin [13].

Glossitis

Geographic tongue also known as known as benign migratory glossitis affects 1–14% of the population and is of unknown etiology [14, 15]. Geographic tongue is characterized by areas of papillary atrophy that appear smooth and are surrounded by raised wavy borders. The regions of atrophy spontaneously resolve and migrate giving the tongue a topographic map appearance. The condition is benign, but some patients may have sensitivity to hot or spicy foods. Treatment for symptomatic patients may include bland foods, use of topical steroids triamcinolone 0.1% (Oralone) or antihistamine mouth rinses which can also be used to help reduce tongue sensitivity [14, 15].

In fissured tongue, deep groves develop within the tongue usually due to the physiologic deepening of normal tongue fissures secondary to aging. The deeper fissures can lead to food trapping causing inflammation of the tongue and halitosis. Gentle brushing of the tongue is useful in symptomatic patients. Down's syndrome, Sjogren syndrome, Melkersson–Rosenthal syndrome, psoriasis, and geographic tongue have all been associated with fissured tongue [14].

Hairy tongue results from the accumulation of keratin on the filiform papillae of the dorsal tongue leading to hypertrophy of the papillae. The hypertrophied papillae tend to resemble elongated hairs. Bacteria and debris get trapped in the elongated hairs causing discoloration of the tongue. Color of the tongue can range from white to tan to black. This condition is most often associated with smoking, poor oral hygiene, and antibiotic use [4, 14, 16]. Most patients are asymptomatic but some may experience halitosis or abnormal taste. Daily debridement with a soft toothbrush or tongue scrapper can remove the keratinized tissue.

Oral hairy leukoplakia is characterized by white hairy-appearing lesions on the lateral borders of the tongue either in a unilateral or bilateral fashion. This condition is associated with Epstein–Barr super infection or immunocompromised condition [14, 16]. In the absence of a known immunocompromised condition, testing for human immunodeficiency virus (HIV) should be considered. Treatment consists of the use of antiviral medications though recurrences are common. Acyclovir (Zovirax) 800 mg orally five times daily or ganciclovir 100 mg orally three times a day for 1–3 weeks may be used [14].

Atrophic glossitis results from the atrophy of the filiform papillae and is also referred to as smooth tongue. The tongue has a smooth glossy appearance with a red or pink background, and the patient will often complain of a painful sensation within the tongue. Atrophic glossitis is most commonly caused by nutritional deficiencies [14]. Nutritional deficiencies of iron, folic acid,

Telegram: @medical_k

www.konkur.in

riboflavin, niacin, and B_{12} are most often implicated [14]. Other possible etiologies include syphilis, candidal infection, amyloidosis, celiac disease, Sjogren syndrome, protein malnutrition, and xerostomia [14].

Halitosis

Halitosis is an unpleasant or offensive odor emanating from the oral cavity. In approximately 80% of the cases, halitosis is caused by conditions of the oral cavity [17]. The most likely cause of oral malodor is the accumulation of food debris and bacterial plaque along the teeth and tongue. The oral malodor arises from the microbial degradation of these organic substrates into volatile sulfur-containing gas compounds. Though the majority of cases of halitosis originate in the oral cavity, non-oral etiologies may include infections of the upper or lower respiratory tract, metabolic disturbances, carcinomas, systemic diseases, and medications [17]. Therefore, before halitosis can be managed effectively, an accurate diagnosis must be made. Achieving an accurate diagnosis starts with first determining whether the source of the odor is of an oral or non-oral etiology. One of the simplest ways to distinguish oral from non-oral etiologies is to compare the smell coming from the patient's mouth with that exiting the nose. To perform this sniff test, have the patient tightly hold their lips together and forcibly blow air through the nostrils. Repeat the test with the patient holding their nostrils closed and passively breathing through their mouth. One can then compare the odors emanating from each cavity and further characterize the intensity and quality of the odor. A systemic origin may be suspected in the case where the odor from the mouth and nose are of the same intensity and quality [18].

As noted, the majority of cases of halitosis originate from the oral cavity. The oral cavity should be inspected for evidence of gingivitis, periodontal disease, and oral cancers. All of which can produce foul putrid-smelling breath. In patients where a rigorous oral hygiene regime of twice daily brushing, flossing, and professional cleaning does not improve the problem, the tongue especially the posterior region should be suspected [17, 18]. The posterior tongue can be assessed by obtaining a gentle scrapping of the area using a plastic spoon. The spoon can be smelled to compare the odor with the overall mouth odor [17]. Gentle but thorough tongue cleaning using either a tongue scrapper or toothbrush should be added to the daily oral hygiene routine. Faulty dental restorations or dentures can be another etiology of bad breath. The odor from dentures may have a somewhat sweet though unpleasant nature and can be more easily identified when the dentures are placed in a sealed plastic bag and smelled after a few minutes [17]. Saliva also affects bad breath. Xerostomia or dry mouth may be a contributor to halitosis secondary to decreased salivary flow and the resultant increased risk for dental infections. A transient odor associated with acute tonsillitis is common especially in children. Tonsillectomy, however, is rarely indicated for chronic halitosis [17, 18].

Nasal sources are second in frequency to oral etiologies as causes of halitosis [17, 18]. Nasal odor is often indicative of sinus infection, but may also signal an obstruction to normal air flow that could occur with nasal polyps, craniofacial anomalies, or foreign body (especially in small children). Nasal discharge can have a fetid cheesy odor [17]. The lungs are also a source of some odors secondary to infection and/or metabolic disorders. A pulmonary source is suggested when the odor intensity increases during expiration. Lung abscess, necrotic tumors, tuberculosis, and bronchiectasis are all possible infections causing bad breath. Because of the associated pus production and tissue necrosis with these diseases, a putrid foul odor similar to rotting meat is produced [17]. Hepatic failure, renal failure, and diabetes are all systemic diseases that may contribute to or present as halitosis. Hepatic failure or cirrhosis may have a mousy, musty, or rotten egg smell, while the uremia from kidney failure can impart a fishy ammonia-type smell to the breath [17]. Trimethylaminuria is a rare genetic metabolic condition that can also produce a foul fishy odor [17, 18]. Diabetes is best known for its distinct sweet fruity odor [17]. GI causes are rarely implicated, though some sources have reported halitosis can be intensified or aggravated by the presence of a *Helicobacter pylori* (*H. pylori*) infection

Telegram: @medical_k

www.konkur.in

[17, 19]. *H. pylori* is thought to contribute to the development of halitosis by increasing the production of volatile sulfur compounds (VSC). Reduction or elimination of *H. pylori* in patients with antibacterial therapy therefore may have in the indirect consequence of improving halitosis symptoms by decreasing overall VSC production [19]. Probiotic studies using Lactobacillus strains have not shown clear and definitive benefits in the management of halitosis [20].

Temporomandibular Disorders

Temporomandibular joint (TMJ) disorders are a constellation of conditions characterized by pain and/or dysfunction of the TMJ and surrounding tissues. Incidence is approximately 15% in the general population, although a much smaller percentage seeks medical care for their symptoms [21] TMJ disorders are thought to be three to four times more common in women, with onset of symptoms usually in the first half of life [21]. In most cases, these disorders lack organic pathology, are self-limited, and resolve spontaneously [21–22]. Underlying causes of TMJ disorders and treatment options are poorly understood. Behavioral, psychological, and structural factors all appear to contribute to the formation of TMJ disorders. The diagnosis of TMJ disorders is based largely on history and physical examination [21]. Patients complain of pain, clicking or popping of the jaw, and occasionally limited range of motion. Pain severity is often poorly correlated with the degree or presence of organic pathology. Examination may reveal tenderness of the TMJ and/or muscles of mastication. Occasionally there is palpable crepitus or audible clicks; however, these findings are also commonly found in asymptomatic individuals as well. Based on clinical findings, TMJ disorders are divided into intra-articular or extra-articular (involving muscles of mastication) categories [21]. The differential diagnosis of TMJ disorders should include, but not limited to, dental caries/abscess, oral lesions/ulcerations, osteoarthritis, rheumatoid arthritis, temporal arteritis, and claudication of the masticatory muscles [21, 22]. Oral habits such as frequent gum chewing or bruxism may aggravate symptoms or cause inflammation within the joint. Imaging is rarely useful in the diagnosis of TMJ disorders, since most symptoms are self-limited and should be reserved for patients with persistent symptoms where conservative therapy has failed or internal joint derangement is suspected from degenerative articular disease, fracture, or dislocation. To screen for organic pathology, the panoramic radiograph is the preferred initial study [21, 22]. More advanced imaging such as ultrasound, CT or MRI should be ordered based on the findings of the panoramic film. Patient education should be at the forefront of treating nonorganic and chronic TMJ disorders [21, 22]. It is important for patients to understand that TMJ is generally not related to oral pathology and these disorders are self-limiting and nonprogressive in the absence of any systemic disease. The mainstay and most common dental treatment for TMJ has been dental splinting or interocclusal orthosis. Dental splints work to primarily open the mouth, release muscle tension, and prevent teeth clenching or grinding [21, 22]. Generally most patients perceive the splint to be effective in providing symptomatic improvement. Cognitive behavioral therapy, muscle relaxation techniques, biofeedback, physical therapy, and acupuncture have all shown to be helpful in at least temporarily reducing the pain associated with TMJ [21, 22]. Nonsteroidal anti-inflammatory agents are frequently utilized as first-line pain medications. Other medications to be considered include corticosteroids, muscle relaxants, antiepileptics, anxiolytics, and tricyclic antidepressants. Caution should be used in utilizing selective serotonin or serotonin-norepinephrine reuptake inhibitors, as these medications can induce bruxism [21, 22]. Botox may be effective in treating TMJ disorders, but current evidence is inconclusive [21]. Referral for surgical evaluation is rarely indicated in the absence of organic pathology [21, 22].

Oral Cancer

Cancers of the oral cavity and oropharynx are the ninth most common cancer in the United States [23]. African-Americans have a higher incidence than Caucasians, and males have a slight predominance over their female counterparts [23]. Patients are typically over age 40 at time of

Telegram: @medical_k

www.konkur.in

presentation. Squamous cell carcinomas account for approximately 90% of all oral cancers [5, 23, 24]. Oral cancers most commonly occur on the anterior two-thirds of the tongue, floor of the mouth, hard palate, buccal mucosa, and vermillion border of the lower lip [24]. The major risk factors for developing oral cancer are tobacco use of any kind and heavy alcohol consumption [5, 23]. Over 75% of all head and neck cancers are linked to one or both of these risk factors, and there does appear to be a synergistic effect when the two are used concomitantly [5]. Despite decreased smoking rates over recent years, the incidence of oropharyngeal cancers have continued to rise while those of oral cancers have decreased [24]. Oropharyngeal cancers include those found on the posterior one-third of the tongue, soft palate, or tonsils [24]. The increased incidence of oropharyngeal cancers is largely explained by the rise in human papillomavirus (HPV)-positive cancers [24–25]. The vast majority of HPV-related oropharyngeal cancers is caused by HPV-16 [25]. These cancers tend to occur more frequently in middle-aged Caucasian males with sexual behavior as the main risk factor [25]. Other potential risk factors for oral and oropharyngeal cancers include ultraviolet light exposure, history of previous head and neck radiation, HIV, and chronic mechanical irritation from poor fitting dentures or restorations. Overall 5-year survival rate for oral cancer is 50–55%, but if detected at an early stage, survival rates can approach 90% [5]. HPV-related oral cancers tend to have better survival rates and lower rates of recurrence [5, 25]. Oral cancers can be subtle and asymptomatic in the early stages and may present as a solitary chronic ulceration, red or white lesion, indurated lump, fissure, or enlarged cervical lymph node. Other concerning symptoms include bleeding, unexplained mouth or ear pain, odynophagia, chronic sore throat, or hoarseness. Oral leukoplakia is the most commonly known premalignant lesion and is defined as a white patch or plaque that cannot be explained by another clinical cause [5, 23]. Similar red lesions are called erythroplakia, and combined red and white lesions are known as speckled leukoplakia or erythroleukoplakia. Erythroplakia and erythroleukoplakia are more likely than leukoplakia to microscopically demonstrate dysplastic or cancerous changes [23]. Any abnormality, ulcer, white, red, or mixed lesion that is not resolving in 3–4 weeks, especially after removing any irritating precipitant such as tobacco, alcohol, and ill-fitting dental restorations, should be considered for biopsy to exclude malignancy [5, 23]. Treatment generally involves surgery and/or radiation therapy. Radiation therapy and/or chemotherapy can be used for patients not amenable to surgery or palliation for unresectable tumors. Counseling of patients regarding risk factors (tobacco, alcohol, sun exposure, and sexual habits) and providing HPV vaccination to adolescent patients can help reduce the future incidence of oral cancers [25]. The American Cancer Society recommends that adults 20 years or older have thorough oral cavity exams as part of any cancer-related check-up [24]. The United States Preventive Services Task Force has found inadequate evidence to make any similar recommendation [24].

Other Oral Lesions

Bony Tori

Tori are benign, non-neoplastic bony protuberances that arise from the cortical plate. They are more common along the hard palate of the mouth but can also arise from the floor of the mouth. Those that form along the hard palate are known as palatal torus or torus palatines, while those located along the lingual aspect of the mandible are known as mandibular torus or torus mandibularis. The overall prevalence in the general population is 3%; palatal tori are three to four times more common than mandible tori [5, 23]. These lesions are thought to be congenital anomalies though they usually do not develop until adulthood. They can be confused for cancerous growths. Bony tori are usually painless and do not cause any symptoms. No management is necessary; unless the tori are interfering with oral function, denture fabrication, or subject to recurrent traumatic ulceration, then surgical removal by an oral surgeon is recommended [5, 23].

Telegram: @medical_k

www.konkur.in

Mucocele

Mucoceles are benign fluid-filled sacs which result from disruption of a salivary gland duct with extravasation of mucus into the surrounding tissue, usually secondary to mild local trauma such as biting [26]. Most frequently they occur on the lower lip and are more prevalent in children and young adults [23, 26]. Patients typically present with a pinkish/blue dome-shaped fluctuant papule or nodule. The underlying gelatinous sac can often be felt with palpation. Patients are seldom symptomatic, but often find the lesions irritating because of the recurrent trauma that occurs while eating. Lesions will often resolve on their own due to spontaneous rupture. If the lesion becomes symptomatic, it can be excised, which should include the entire cyst to prevent recurrence. Once excised, the specimen should be sent for pathologic examination to rule out neoplastic changes [5, 23]. As with any lesion in the mouth that does not resolve on its own within 3–4 weeks, consideration should be given for further assessment and pathologic examination either by biopsy or excision [5].

Pyogenic Granuloma

A pyogenic granuloma or lobular capillary hemangioma is an acquired benign vascular growth on the skin and mucous membranes, occurring more often in children and young adults [27]. Pyogenic granulomas appear as erythematous rapidly growing lesions which develop in response to local irritation, trauma, immunosuppression, or increased hormone levels related to pregnancy [7, 23]. These lesions may be smooth or lobulated, easily bleed when touched, and are non-painful. Oral pyogenic granulomas vary in size and most often develop along the gingival border, but can be found anywhere within the oral mucosa. Treatment is generally necessitated by the risk for recurrent bleeding, ulceration, cosmetic concerns, and the low likelihood of spontaneous regression. Options for treatment include surgical excision, laser therapy, systemic or topical therapies, especially beta-blockers [27–29]. Recurrence is uncommon but can be as high as 15% [29]. Pyogenic granulomas induced by pregnancy, however, are more likely to reoccur due to the associated hormonal changes, but are also more likely to spontaneously resolve following childbirth. Therefore observation alone may be an adequate treatment in this patient population [7, 23].

Adult Hearing Loss

General Principles

Hearing impairment affects over 30 million people in the United States and is the fourth leading cause of disability worldwide [1, 2]. As hearing loss is primarily associated with increasing age, its prevalence is expected to rise with an aging population [2]. Hearing loss can significantly degrade quality of life and physical function and has been associated with cognitive decline, dementia, and depression [3, 4].

Pathophysiology

There are three different types of hearing loss: adult – (1) conductive hearing loss, (2) sensorineural hearing loss, and (3) mixed conductive and sensorineural hearing loss.

Conductive hearing loss is secondary to anomalies of the outer or middle ear, which may be due to obstruction of the external auditory canal, impairment of the tympanic membrane function, or middle ear pathology [1, 2]. Examples of conditions that cause conductive hearing loss include (but are not limited to) cerumen impaction, foreign body in the auditory canal, otitis externa or media, exostoses or osteomas of the external auditory canal, tympanic membrane perforation, tympanosclerosis, cholesteatoma, and otosclerosis [1].

Sensorineural hearing loss is due to dysfunction of the inner ear or neural pathways to the auditory cortex. Age-related hearing loss, or presbycusis, is the most common type of sensorineural hearing loss and usually affects high frequencies before progressing to lower frequencies [1, 2]. Noise exposure due to occupational, recreational, or accidental noise also results in sensorineural hearing loss. Prolonged and chronic

Telegram: @medical_k

www.konkur.in

noise exposure to levels of greater than 85 dB or sudden noise exposure of greater than 130 dB can lead to permanent and irreversible hearing loss [1]. Exposure to ototoxic medications (diuretics, salicylates, aminoglycosides, chemotherapeutics, etc.) can lead to sensorineural hearing loss, which may be temporary and reversible if identified early. Autoimmune hearing loss is characterized by a rapidly progressive or fluctuating bilateral sensorineural hearing loss with poor speech discrimination as well as vertigo and disequilibrium [1, 2]. Infections such as meningitis or labyrinthitis may also lead to hearing loss [1]. Sudden hearing loss occurring within 72 h window and unilateral hearing loss are additional categories of hearing loss that may occur due to a variety of reasons which include but are not limited to fracture to the temporal bone or other trauma to the inner ear, acoustic neuromas, or other cerebellopontine angle tumors, autoimmune, infectious, or may be considered idiopathic [2, 4].

Evaluation and Diagnosis

Hearing loss may simply be identified by asking, "Do you have trouble hearing?" Other hearing loss questionnaires exist, such as the "Hearing Handicap Inventory for the Elderly – Screening Version." Positive answers should further be questioned as to duration of hearing loss, if it has been sudden or gradual hearing loss, and whether it is unilateral or bilateral. It is important to ask occupational history as well as history of noise exposure. Further information may be elicited regarding family history of hearing loss, chronic medical problems, medication use, and any associated tinnitus, dizziness, or other ear problems [4].

The physical exam should consist of examining the auricle and periauricular tissues. An otoscope may be used to evaluate the external auditory canal for any cerumen or foreign objects. The tympanic membrane should be evaluated for surface anatomy, color, and mobility. The pneumatic bulb will aid in evaluating the tympanic membrane movement and aeration of the middle ear. Tuning fork tests can help differentiate between conductive and sensorineural hearing loss [1, 4]. Finally, evaluate the head, neck, and cranial nerves if clinically indicated [1].

Objective evaluation of hearing is commonly performed by pure tone audiometry. This is a diagnostic test that gives information on hearing loss to include the type and degree of hearing loss at a specific frequency threshold [1, 4]. A speech discrimination test can assess a patient's ability to understand speech and identify good candidates for hearing amplification with hearing aids [4]. Tympanometry is another simple test performed in the office, which evaluates the mobility of the tympanic membrane and function of the middle ear and Eustachian tube. Imaging may be indicated to further evaluate certain cases such as those with asymmetric or sudden hearing loss [1].

Treatment

A three-tiered approach is recommended for treatment of hearing loss: adult – assessment, education/counseling, and technology [4]. If a concern of hearing loss is identified and proper equipment is not available in the primary care office for appropriate evaluation, further assessment by audiology and/or otolaryngology is indicated [1, 5]. Counsel on and eliminate environmental noise and ototoxic agents if possible. Technological intervention is important, not only for hearing improvement but also for social and emotional function as well as for communication and cognition [3, 5].

In some cases, the only treatment option is hearing amplification. Hearing aids have several models to include those which fit behind the ear or in the canal. Assisted listening devices may be used for those unable to utilize hearing aids. Recent legislation in the United States has required the FDA to create a new class of over-the-counter hearing devices, which should increase access and decrease costs for hearing-impaired patients in the near future [2, 4]. Cochlear implant surgery is an option for those with severe

Telegram: @medical_k

www.konkur.in

sensorineural hearing loss [1, 4, 5]. Many etiologies of conductive hearing loss may also be corrected with surgery [1].

Referral to rehabilitation services may help teach patients to use nonverbal clues and vocational modification to ensure safe functioning despite his or her hearing impairment [1, 4].

Prevention

Prevention of some types of hearing loss may be impossible; however, prevention of exposure to ototoxic agents is possible by carefully choosing medications and discontinuing offending agents. Additionally, noise-induced sensorineural hearing loss may be prevented by screening for noise exposure, counseling about proper hearing protection, and avoidance of overexposure [1, 4].

Pediatric Hearing Loss

General Principles

Pediatric hearing loss is one of the most common sensory birth condition abnormalities in the United States affecting 1 to 3 per 1000 newborns [6–8]. Early detection of hearing loss before the age of 6 months is essential to prevent delays in language and other developmental milestones [7]. Although children with hearing loss often have complex needs, the consequences are treatable if hearing loss is detected and treated early in life [6].

Pathophysiology

Hearing loss in the neonate or child can be classified as congenital, acquired, or idiopathic. Of the congenital etiologies, it can be further classified as either syndromic or non-syndromic (non-syndromic can be autosomal recessive, autosomal dominant, or X-linked). Of the acquired cases of hearing loss, the great majority is considered environmental. Environmental risk factors to the neonate include cytomegalovirus, rubella, measles, syphilis, and exposure to alcohol. Other risk factors for neonates and children may include exposure to ototoxic drugs such as aminoglycosides or antineoplastic agents, hypoxic ischemic injury, or hyperbilirubinemia [7, 8].

Hearing loss may also develop later in childhood. Additional risk factors of childhood hearing loss include family history of childhood hearing loss, history of admission to the neonatal intensive care unit for greater than 5 days, history of mechanical ventilation/oxygenation requirement, craniofacial anomalies, infections associated with late onset hearing loss, head trauma, chemotherapy, recurrent otitis media, and caregiver concern [6, 7].

Hearing loss can be defined by degree, configuration, and type of loss. There are two major types of Hearing loss: adult – conductive hearing loss and sensorineural hearing loss. Conductive hearing loss is caused by problems with the outer or middle hear, whereas sensorineural hearing loss is caused by problems with the inner ear, auditory nerve, or central auditory pathway. Some children have mixed conductive and sensorineural hearing loss [2, 3].

Evaluation and Diagnosis

Newborn hearing screening is mandated in nearly every state in the United States. There are two main screening methods in the United States: the otoacoustic emission (OAE) test and the automated auditory brainstem response (AABR) test. The OAE allows for individual ear testing at any age and assesses for middle ear pathology. The AABR test evaluates the function of the auditory pathway to include the auditory nerve. The AABR is also often used as a follow up test if the OAE is failed during the initial newborn hearing exam. The Joint Committee on Infant Hearing (JCIH) recommends that infants who are admitted to the neonatal intensive care unit (NICU) for greater than 5 days be screened with the AABR [7].

If an infant does not pass initial screening tests, additional evaluation and referral should be completed before 3 months of age with intervention by 6 months of age. Other diagnostic tests exist but are primarily completed by an audiologist. These tests include diagnostic auditory brainstem response, tympanometry, diagnostic otoacoustic emissions, and behavioral hearing assessment [7].

Telegram: @medical_k

www.konkur.in

The physical exam should consist of particular attention to head size and symmetry, jaw size and symmetry, facial movement and symmetry, as well as external and middle ear morphology. Signs of the head and neck exam which may be related to hearing loss include malformation of the auricle or ear canal, dimpling or skin tags around the auricle, cleft lip or cleft palate, asymmetric facial structures, microcephaly, or tympanic membrane abnormalities. Many times, the physical exam will be normal. CT, MRI, and lab tests may further be ordered if clinically indicated [9].

Treatment

Any abnormal hearing test requires intervention. Appropriate referrals include those to otolaryngology, audiology, speech and language pathology, and a genetics specialist. Referrals to early intervention programs are essential. Early intervention services should be provided by professionals with expertise in hearing loss, speech and language pathology, and audiology. An ophthalmologic evaluation may also be appropriate if syndromic associations are identified [7].

Hearing aids are devices that amplify sound and transmit to the ear with the desired frequencies depending on the patient's diminished areas. These benefit patients with sensorineural hearing loss and some with conductive hearing loss. Assistive listening devices can be used in public places to help override poor acoustics [7].

Surgical implants are also an option in care for patients with severe hearing loss: adult – bone-anchored hearing aids are beneficial in children older than 5 who suffer from permanent conductive hearing loss. Cochlear implants amplify sound for children that are at least 1 year old and have profound bilateral sensorineural hearing loss [7].

Tinnitus

General Principles

Tinnitus is the perception of continuous or intermittent sound within the ears or head without an objective external stimulus. The noise has been described as ringing, buzzing, clicking, pulsations, roaring, hissing, sizzling, music, or voices. Although much of what we understand about tinnitus remains an enigma, it is considered a symptom, not a disease in and of itself. Tinnitus is often associated with sensorineural hearing loss, making inner ear or auditory tract dysfunction a viable source of tinnitus; however, the precise mechanisms and possible sites of involvement remain unclear [10]. Even when tinnitus is not severe, the perception can be extremely bothersome and often interferes with the daily activities of symptomatic individuals [10–12].

Pathophysiology

While there is no clear etiology of tinnitus, investigators suspect possible lesions or cochlear alterations within the limbic and nervous systems as the source of irregular neuronal activity in the lower auditory pathway. It is theorized that this stimulation of the auditory tract is the perceived sensations we collectively characterized as tinnitus [13]. There are some known risk factors for tinnitus [11, 13]:

- Exposure to high levels of recreational and occupational noise
- Ototoxic drugs: salicylates, quinine, aminoglycosides, antibiotics, antineoplastic agents
- Otologic diseases: otosclerosis, Meniere's disease, vestibular schwannoma (acoustic neuroma)
- Obesity
- Alcohol use
- Smoking
- Arthritis
- Hypertension
- Anxiety
- Depression
- Dysfunction of the temporal mandibular joint
- Hyperacusis

Tinnitus is most notable in patients who have been exposed to hazardous levels of industrial, recreational, or military-related noise [11]. Other underlying associations to tinnitus include nerve

Telegram: @medical_k

www.konkur.in

damage from brain trauma or lesions, inner ear damage, acute ear infections, foreign objects in the ear, allergies, ototoxic medications (aminoglycosides, aspirin, chemotherapeutics), stress, or low serotonin activity [11, 13].

Tinnitus can be characterized in several different ways, but most commonly, it is characterized as either "objective" or "subjective" tinnitus. Objective tinnitus can be heard by the examiner, usually with a stethoscope, and it is generally referred to as "pulsatile" tinnitus. If it synchronized with the heartbeat, it may be considered vascular in origin. If it is not, it may be originating from the middle ear or palatal muscles. Subjective tinnitus, on the other hand, is only heard by the patient. The tinnitus may be chronic or intermittent. It may be heard in one ear, both ears, or centrally within the head. The onset may be abrupt or insidious, and the severity may change with time as well [12, 13].

Evaluation and Diagnosis

The severity and sensation of tinnitus significantly vary among affected individuals. There is no current standardized guideline for the evaluation of tinnitus. Although serious pathology leading to tinnitus is rare, it is important to get a complete medical history to understand of any possible underlying causes [11, 12]. Assess the character of the tinnitus: (1) subjective versus objective, (2) location and quality, and (3) distinguished chronicity (chronic is considered at least 6 months duration). Subjective idiopathic tinnitus is the most commonly diagnosed type of tinnitus. There are several questionnaires to evaluate tinnitus to include the "Tinnitus Handicap Inventory" (THI) and the "Tinnitus Functional Index" [11]. Evaluate for any associated hearing loss and tympanic membrane dysfunction [12].

If asymmetric tinnitus is associated with asymmetric hearing loss or any other neurological deficits, further investigation and imaging is indicated. Likewise, for any heartbeat-synchronous pulsatile tinnitus, further evaluation with advanced imaging is indicated: this may include but is not limited to CT, MRI, CT angiography, MRI angiography, or ultrasound. If the tinnitus is unilateral and pulsatile or the tinnitus is associated with vertigo, it is recommended that the patient be referred to a specialty clinician [11].

Treatment

There have been multiple medications, to include complementary and alternative, studied to evaluate treatment of tinnitus, but none so far have demonstrated statistically significant improvements [11, 12]. There have been medical interventions studied such as transcranial magnetic stimulation, electromagnetic stimulation, low-level laser therapy, and acupuncture; however, none of these has shown consistent improvement of tinnitus either [11].

Sound therapy or sound maskers, which produce sound to cover the tinnitus, have not shown statistically significant improvement. Sound technologies, such as hearing aids (if the patient has associated hearing loss), may help mask tinnitus by increasing the overall level of ambient sound delivered to the patient. Cochlear implants may also help to mask tinnitus and improve perception of external noise; however, these are only for patients with profound sensorineural hearing loss [11].

Much of the treatment involved for treating tinnitus is truly aimed at treating the comorbid conditions associated with tinnitus such as anxiety, depression, hearing loss, and sleep disorders. Psychological and behavioral interventions are recommended to improve associated distress [11, 12].

Mindfulness-based cognitive therapy (MBCT) uses mediation techniques to address the burdens of tinnitus [14]. The goal of MBCT is to reframe an individual's outlook on the unpleasant experience of living with a chronic condition. This technical approach focuses on helping individuals adapt to distressing experiences by validating their personal thoughts, emotions, and sensations. Once acceptance is achieved, theorists believe the patient can focus on improving adaptive behaviors to combat the distressing experience such as tinnitus [14].

A recent study by Takahashi et al. expands on reports investigating the impact of psychological

Telegram: @medical_k

www.konkur.in

background on patients with tinnitus. Investigators argue that in order to improve the treatment of tinnitus, grading systems and protocols should take into consideration both psychological state and severity of tinnitus perception by affected individuals. Currently, THI does not incorporate the psychological background of patients with tinnitus into its severity grading system. Limited reports have found depression to be a significant factor on how the severity and sensation of tinnitus was perceived. Studies have found that patients with moderate to severe tinnitus have better therapeutic response to interventions when their psychiatric conditions were treated concurrently. This discovery has led some healthcare professionals to advocate for developing new protocols and parameters that utilize the Hospital Anxiety and Depression Scale (HADS) and the Diagnostic and Statistical Manual of Mental Disorders (DSM-V)'s criteria for major depression and catastrophic events in addition to the THI when grading tinnitus severity and assessing for therapeutic intervention [10].

Unfortunately, there is no single effective treatment regimen to cure or significantly alleviate tinnitus. It is important to treat or eliminate comorbid conditions. Any surgical otologic disorders should be evaluated by otolaryngology [11].

Prevention

Because there is no effective treatment for most cases of tinnitus, the focus should be on prevention of known causes: reduce exposure to ototoxic drugs as well as avoid occupational and recreational loud noises [12].

Salivary Gland Inflammation and Salivary Stones

General Principles

Saliva plays an important role in the oral and digestive health. Composed of enzymes, electrolytes, and other molecules, saliva is an enrichened fluid that provides lubrication for the function of swallowing as well as aids in the digestion of starches through with salivary amylase [15]. Saliva also acts as a layer of protection against dental caries and oral pathogens. Major salivary glands include the parotid, submandibular, and sublingual glands. Additionally, there are minor salivary glands lining the oral cavity, pharynx, lips, and tongue [15]. Inflammatory conditions of the glands, also known as sialadenitis, are most common in the major salivary glands, with obstructive sialadenitis accounting for approximately one-half of benign salivary disorders treated in a primary care setting [15]. Other causes of inflammation of the salivary glands include infections (viral and bacterial), autoimmune disorders, and neoplasm of the salivary gland. While neoplasm of the salivary glands is relatively rare, they make up about 6% of all head and neck tumors [15]. Inflammation may be acute or chronic and can lead to salivary stone formation which will further enhance the inflammation in some cases [16].

Pathophysiology

Salivary gland stones, also known as sialoliths, develop when calcified mass forms within the salivary duct or gland [17]. The accumulation of salivary calculi can lead to mechanical obstruction within the duct, thus predisposing the gland to inflammation. The precise mechanisms leading to the developing of salivary stone are unclear. The "retrograde theory" of sialolith development postulates the migration of bacteria or food debris into the salivary gland ducts which later serves as a nidus for stone formation [17]. Another popular theory suggests that a localized inflammatory process causing the calcification of a mucus plug leads to the formation of sialoliths [18]. Other potential risk factors include use of tobacco products such as cigarettes. Very few studies have shown significant correlation between poor hygiene and salivary gland inflammation and stone development [17].

Acute bacterial sialadenitis is most often seen in the parotid gland in medically debilitated patients. Debilitation and dehydration may lead

Telegram: @medical_k

www.konkur.in

to the stasis of salivary flow which can generate stone precipitation and strictures of the salivary ducts. This environment favors bacterial infection, most commonly from *Staphylococcus aureus*, streptococcal species, and *Haemophilus influenzae* [15, 16]. Other infectious etiologies include *Mycobacterium*, *Toxoplasma*, and *Actinomyces* species [16].

Acute viral sialadenitis is most commonly found in the setting of mumps in children aged 4 through 6. Other viral causes include *Cytomegalovirus*, lymphocytic choriomeningitis virus, Coxsackie virus A, echo virus, and parainfluenza virus type C [16]. Predisposing factors for non-infectious acute sialadenitis include autoimmune disorders such as Sjogren's syndrome as well as chronic metabolic conditions such as diabetes mellitus and hypothyroidism [15].

Chronic sialadenitis is characterized by repeated episodes of pain and edema. Affected patients will often complain of intermittent pain and swelling of the gland, which is exacerbated during prandial salivary stimulation [14]. Furthermore, commonly prescribed medications such as diuretics, antihypertensive, antihistamines, antipsychotics, and antidepressants are known to decrease the salivary flow rate, which may play a limited role in facilitating stone formation and sialolithiasis [18, 19].

Neoplasms may be benign or malignant. Malignancies of the salivary gland are rare, encompassing only 16% of all salivary gland neoplasm cases [15].

Evaluation and Diagnosis

Acute bacterial sialadenitis has characteristic clinical findings of salivary gland pain and edema. Mucopurulent material can sometimes be expressed at the orifice of the nearby salivary duct [15, 16]. Acute viral sialadenitis is most commonly due to mumps offending the parotid gland, which is characterized by parotid edema with symptoms of fever, malaise, myalgias, and headaches in the weeks preceding the incubation period. Some children can experience recurrent viral sialadenitis. This can last weeks and recur every few months. Viral serology may help to confirm the diagnosis.

Chronic sialadenitis has characteristic findings of repeated episodes of pain and edema of the salivary glands. Generally, this occurs from little to no salivary flow and due to stones, strictures, or stenosis. It is sometimes possible to palpate the stone along the nearby duct [15].

Neoplasms typically present as painless, asymptomatic, slow-growing masses. Malignant neoplasms may present with findings such as facial paresis, fixation of the mass, and lymphadenopathy. Specialty referral to an otolaryngologist for further evaluation and possible biopsy is essential for an accurate diagnosis. A CT scan with contrast or MR with MR sialography may also be used to identify the mass's characteristics [15].

CT is the preferred modality for acute sialadenitis due to its sensitivity to calcification and spatial resolution. Extensive dental artifacts on CT imaging are a common limitation of this modality [19]. Ultrasound and MRI are also options; the clinical scenario will ultimately dictate the appropriate diagnostic imaging necessary for further evaluation. When imaging is inconclusive, further referral for US-guided fine needle aspiration and cytology may be indicated [19].

Treatment

Acute bacterial sialadenitis is treated by empiric antimicrobial therapy (i.e., Augmentin, etc.). Increasing salivary volume and flow by increasing hydration and utilizing sialagogues is also recommended. Salivary gland massage may also be useful.

Recurrent parotitis of childhood and chronic sialadenitis in adults are treated similarly as in acute cases as outlined above. It generally resolves spontaneously over time. Anti-inflammatory medications may also be considered.

Viral parotitis or mump treatment is primarily supportive and focuses on hydration and pain control. Mumps usually resolves spontaneously within weeks. Any stones contributing to acute

Telegram: @medical_k

www.konkur.in

or chronic sialadenitis may need surgical removal if conservative management fails [15].

Prevention

Vaccination has reduced the incidence of mumps by 99%. It is important to promote hydration and use sialagogues for enhancement of saliva production and prevention of stone formation [16].

Xerostomia

General Principles

Xerostomia is the subjective sensation of dry mouth. Its prevalence increases with age and tends to be higher in women than in men [20]. Major and minor salivary glands produce the saliva, which is composed of electrolytes, organic compounds, and water. Normal salivary function is to aid in digestion through oral processing and swallowing of food. Saliva protects the oral cavity by cleansing it, sustaining a neutral pH, preventing tooth demineralization, and adding an antimicrobial effect [21].

Pathophysiology

Xerostomia can occur with the reduction in the quantity, flow rate, or composition of the saliva produced. Hyposalivation is a pathological condition in which there is insufficient or decreased production of saliva [21]. Some cases of xerostomia may correlate with hyposalivation while others do not. Symptoms of xerostomia may range from oral discomfort to significant oral disease such as dental caries, periodontitis, dental erosion, and intraoral candidiasis that can negatively impact a patient's health, dietary habits, and quality of life [20, 21].

There are several causes of xerostomia such as dehydration, poor nutritional status, head or neck radiation, chemotherapy, salivary gland aplasia, Sjogren's syndrome, depression, smoking, and a variety of medications [21]:

- Antihypertensives
- Anticholinergics
- Antidepressants
- Antipsychotics
- Anxiolytics
- Diuretics
- Muscle relaxants
- Diuretics
- Muscle relaxants
- Sedatives
- Antiepileptics
- Antiparkinsonisms
- Antihistamines
- Cytotoxics
- Analgesics

Evaluation and Diagnosis

As with all ailments, a thorough medical history and exam are the chief means of attaining a diagnosis. It is important to identify any diseases that may put the patient at risk for the development of xerostomia or if the patient is on a medication regimen that may be inducing xerostomia, which is more common [20]. Patients may complain of dry mouth or other symptoms from dry mouth like a burning sensation or difficulty with speech and swallowing. He or she may also note a change in taste. On exam, the mucosal surfaces may be dry and the tongue swollen and dry, erythematous and atrophic oral mucosa, angular cheilitis or peeling lips [21].

Treatment

Treatment is aimed at identifying the underlying cause. Underlying systemic medical conditions such as Sjogren's disease, lymphoma, sarcoidosis, or amyloidosis may lead to xerostomia; treatment of these conditions may help the symptoms of dry mouth. If a medication is identified as causation, then it should be changed or eliminated if possible. It is important to encourage hydration, especially in the elderly and those with poor nutrition. Avoidance of food and drinks such as alcohol, sugar, and caffeine, which may lead to dry mouth or dental caries, is an essential dietary

Telegram: @medical_k

www.konkur.in

modification. Furthermore, if the patient is a current tobacco user, tobacco cessation should be encouraged [21].

There are a number of over-the-counter treatments available – toothpastes, rinses, lozenges, sprays, gels, oral patches, and chewing gums. Research suggests that when used in conjunction with prescription medication, the benefits can be additive, but when used alone, their efficacy is undetermined.

Two systemic medications available in the United States which may help stimulate saliva production (sialagogues): pilocarpine or cevimeline drops [21].

Hoarseness

General Principles

Hoarseness (or dysphonia) is a term used to describe a symptom or sign of altered voice quality [22]. The change in voice may be an alteration in quality, pitch, and loudness or may be described as breathy, strained, rough, or raspy [22, 23]. It is a common problem in the United States adult population affecting up to one-third of all adults at some point in time and leads to 2.5 million dollars in lost work cost [22].

Pathophysiology

The larynx houses the vocal folds, which are responsible for the production of sound as airflows pass these structures. The larynx extends from the base of the tongue to the trachea and is innervated by the superior and recurrent laryngeal nerves. There is a multitude of etiologies which may cause hoarseness. In general, these etiologies may be from irritants, inflammation, neuromuscular, psychiatric, systemic, or neoplastic disorders [23]. Table 1 outlines details of each of these categories.

Table 1 Etiologies of hoarseness (or dysphonia) in the adult population [23]

Irritants and inflammation	Acute laryngitis: viral, vocal abuse, allergies Chronic laryngitis: smoking, voice abuse, laryngopharyngeal reflux, allergies, inhaled corticosteroids
Neuromuscular	Vocal cord paralysis: Injury to recurrent laryngeal nerve, head and neck surgery (especially thyroid surgery), endotracheal intubation, mediastinal or apical immersion of lung cancer Muscle tension dystonia Spasmodic dysphonia (laryngeal dystonia)
Psychiatric	Stress and other psychiatric disorders
Systemic	Parkinson's disease Myasthenia gravis Multiple sclerosis Hypothyroidism Acromegaly Inflammatory arthritis
Neoplasms	Laryngeal papillomatosis Laryngeal leukoplakia Dysplasia or squamous cell carcinoma (risk factors: Smoking, alcohol use, chronic reflux)

Evaluation and Diagnosis

A careful history and physical exam are important to understand the etiology of the patient's hoarseness. Evaluate the onset and duration of voice changes. In the medical history, it is prudent to ask about any recent upper respiratory infections, allergies, or chronic medical problems. Assess for any associated symptoms of gastroesophageal reflux. In the social history, it is important to discuss any environmental exposures, tobacco use, or alcohol use. In addition, vocations in singing, teaching, and of the clergy are more at risk for this condition. Learning of any recent surgeries is also key. Associated symptoms such as cough, dysphagia, and odynophagia are important and may lead to more serious underlying causes of hoarseness [22, 23].

During the physical exam, it is important to assess for rhinorrhea, sneezing, or watery eyes which may suggest a more benign cause such as allergies or viral irritation; however, findings such as lymphadenopathy, stridor, and weight loss may be more concerning for serious etiologies such as malignancies. Stridor may indicate airway obstruction due to mass [23].

Telegram: @medical_k

www.konkur.in

Laryngoscopy may be performed at any point in time. Different recommendations exist as to when direct visualization is required. More recent guidelines suggest direct visualization is indicated if hoarseness persists for greater than 4 weeks [22]. The procedure should be done in the primary care office or referred to a specialist who has this capability. Direct visualization of the larynx should be done sooner if there is any suspicion of serious underlying condition. In case of tobacco or alcohol use, a neck mass, hemoptysis, dysphagia, odynophagia, neurological symptoms, unexplained weight loss, aspiration of a foreign body, and persistent symptoms after surgery or if the hoarseness significantly impairs the quality of life of the patient, then visualization is more urgent [22, 23].

Imaging, such as a CT or MRI, may be used to assess specific pathology; however, it is recommended that direct visualization be performed prior to any imaging [22].

In cases of pediatric hoarseness, it is generally indicated for the patient to be referred to otolaryngology and speech and language pathology early [24].

Treatment

If hoarseness duration is less than 2 weeks (acute), it is more likely to be benign. Reassurance is appropriate but also address and treat any underlying etiologies such as viral infections, allergies, and reflux. If reflux is suspected through history or visualization of chronic laryngitis, then a trial of a high-dose proton pump inhibitor (PPI) is warranted; however, isolated dysphonia should not be treated with PPI therapy without visualization first. Likewise, antibiotics are usually not indicated in treating hoarseness [22, 23]. If corticosteroids are on the patient's medication list, the clinician may recommend a decrease or alteration in the dose or type of corticosteroid used for 4 weeks. Inhaled fluticasone (Flovent) is the most common offending agent [23]. Oral corticosteroids to treat hoarseness are not recommended without visualization of the larynx [22]. If there is a systemic condition which has a known symptom of hoarseness (such as hypothyroidism), optimize treatment for the condition, and reassess after 4 weeks.

If laryngoscopy is completed and no serious pathology is found, it is recommended the patient be referred for vocal hygiene training and voice therapy by a speech and language pathologist.

Surgery may be indicated for any findings of benign or malignant masses, glottic insufficiency, or if airway obstruction is a risk [22, 23].

Prevention

Educate of the patient on measures to reduce voice disorders: adequately hydrate with water, use amplification devices to reduce voice strain, rest the voice briefly, and provide indoor air humidification. Additionally, educate the patient on avoidance of triggers such as tobacco smoke, certain medications, environmental irritants or allergens, and vocational abuse of the voice [22, 23].

Epistaxis

General Principles

Epistaxis is a common condition that can affect up to 60% of the general population [25]. Up to 9% of the pediatric population experiences recurrent epistaxis. Epistaxis is generally categorized as anterior (90%) or posterior (10% of cases but more severe). Epistaxis has a bimodal distribution 2–10 and 50–80 years of age [25, 26]. Anterior epistaxis generates from either Kiesselbach's plexus or the anterior inferior turbinate [26]. Posterior epistaxis results from bleeding of the posterior edge of the nasal septum or the posterior lateral nasal wall mucosa [29].

Pathophysiology

The etiology of epistaxis can be divided into two general causes: local and systemic. Local causes refer to specific complications to the nasal mucosa. Systemic causes refer to more systemic

Telegram: @medical_k

www.konkur.in

etiologies causing epistaxis to be more likely [25, 29]. See Table 2 for a list of local and systemic causes of epistaxis.

In children, the most common etiology of anterior epistaxis is trauma (usually nose picking) [29]. Idiopathic nose bleeding occurring at night is also common in children but is eventually outgrown. Posterior epistaxis in children is most often due to juvenile nasopharyngeal angiofibroma, which is most commonly seen in teenage boys. Similar to adults, systemic disease of childhood may also lead to epistaxis such as (1) vascular anomalies: hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome); (2) hematologic problems (genetic or acquired) such as primary idiopathic thrombocytopenic purpura, leukemia, or aspirin use; or (3) coagulopathies (genetic or acquired) such as von Willebrand disease, hemophilia, warfarin use, liver diseases leading to coagulopathy, or drug-related thrombocytopenic purpura [28].

Evaluation and Diagnosis

Anterior epistaxis is generally obvious to the examiner, and blood loss is usually not significant.

Table 2 Local and systemic causes of epistaxis [25, 29]

Local causes	Systemic causes
Trauma	Hypertension
Nose picking	Antiplatelet medications
Foreign objects stuck in nose	Hereditary hemorrhagic telangiectasia
Neoplasms or polyps (nasopharyngeal angiofibroma)	Hemophilia
Rhinitis or sinusitis (chronic, acute, allergic)	Leukemia
Medications (inhaled corticosteroids)	Liver disease
Irritants (occupational exposures, cigarettes, etc.)	Medications (aspirin, anticoagulants, NSAIDS)
Septal perforation	Platelet dysfunction
Vascular malformations or telangiectasia	Thrombocytopenia
Environmental: Dry and low humidity	

Posterior epistaxis may be associated with a large volume of blood loss but may present insidiously with symptoms such as nausea, hematemesis, hemoptysis, or melena [25, 27]. It is important to identify the likely source of bleeding (anterior or posterior) as well as inquire about the history leading up to the epistaxis episode in order to understand if further workup is necessary. Estimate the volume of blood loss, time of onset, frequency of any prior episodes, any medical comorbidities, acute respiratory infections, use of medications, recreational drug use, and any recent surgery or trauma. In more severe cases, airway protection and hemodynamic stability must be considered. Any concern of clinical instability should be managed in the emergency department [26, 27, 29].

In stable scenarios, the physical exam may be performed with the aid of a vasoconstrictor spray or gauze soaked in a vasoconstrictor. Physical exam ideally should be done with nasal speculum and light source. This in combination with an anesthetic may be helpful during the physical exam to successfully identify the source of bleeding [25, 26].

Treatment

Because 90% of epistaxis cases are anterior, most cases of epistaxis are treated successfully with conservative therapies [26]. Initial treatment consists of pinching the lower portion of the nose against the anterior nasal septum placing pressure along the ala for several minutes. Cotton-tipped applicators or cotton balls can be used to place pressure against the source of bleeding. These items may be soaked in topical vasoconstrictors or decongestants if needed [25–27]. It is important to tilt the head forward, not backward, in order to avoid pooling of the blood, which can lead to airway obstruction [26]. If direct pressure is not helpful, silver nitrate sticks or electrocautery may be applied to the area of bleeding. Apply the cauterization instrument directly to the source of bleeding to avoid any excessive soft tissue damage; do not cauterize blindly [25, 27]. Avoid cauterizing bilaterally due to risk of septal necrosis

Telegram: @medical_k

www.konkur.in

and perforation. If bilateral cauterization is needed, it is optimal to perform cauterization 4–6 weeks apart [26, 27].

If this initial management is unsuccessful, nasal packing may be an effective next step. There is data showing that using tranexamic acid (TXA) soaked pledgets before nasal packing may stop bleeding within 10 min of application in up to 71% of subjects [27]. There are many commercial products or commercial nasal tampons available for nasal packing. The principle is to localize the source and apply packing to stop the site of bleeding. The packing may be left in for several days [26, 27]. If anterior packing is unsuccessful, then one can move to posterior packing, which is a more complex procedure. If this is necessary, specialty consultation and admission to the hospital are recommended due to complexity and risks involved in the procedure. Toxic shock syndrome is a risk in the setting of any type of packing techniques. Anti-staphylococcal antibiotic (oral or topical) may be considered as prophylactic therapy, with special attention for patients who are immunocompromised, have heart valve disease or receiving posterior nasal packing [27]. Similar to posterior packing for persistent anterior bleeding, posterior bleeding should be treated in the hospital setting and with specialty consultation. Additional intervention may be indicated such as arterial embolization or arterial ligation [25–27].

In summary, epistaxis, in particular anterior epistaxis, is a common condition that can be treated in the outpatient setting with conservative measures; however, in cases of persistent bleeding or posterior epistaxis, more invasive measures performed with specialty consultation in the hospital may be necessary.

Prevention

If recurrent anterior epistaxis persists, consider underlying etiologies. If underlying pathology is ruled out, various treatments may be helpful in prevention such as humidification of air, application of petroleum jelly to the local area to maintain humidity, or application of antiseptic creams. Abstain from alcohol and avoid hot drinks that cause vasodilation [27, 29].

Foreign Bodies in the Ear and Nose

General Principles

Foreign bodies lodged in the ear and nose are a problem commonly seen in children and patients with mental handicaps. At times, it can be difficult to diagnose as the object placement may not have been observed by the parent or caregiver. Common foreign bodies found in the ear or nose include beads, rubber erasers, toy parts, pebbles, food, marbles, and button batteries [30–32].

Pathophysiology

Although a nasal foreign body can be found in any portion of the nasal cavity, it is most commonly found in one of two places: below the inferior turbinate and anterior to the middle turbinate.

A foreign body within the ear is usually lodged at the point where the external auditory canal narrows into a bony cartilaginous junction. If lodged too far, the tympanic membrane can be damaged [30, 32].

Evaluation and Diagnosis

A nasal cavity foreign body may be asymptomatic; however, it may also present as unilateral, malodorous, mucopurulent nasal discharge or intermittent epistaxis. Other complications include posterior dislodgement with risk of aspiration, trauma due to initial placement or self-removal attempts, and infection [31].

When evaluating a patient for a nasal foreign body, it is useful to apply a topical vasoconstriction agent to reduce mucosal edema, such as 0.5% phenylephrine or oxymetazoline [30, 32]. Anesthesia may also be accomplished with a topical spray such as 4% lidocaine. If no foreign body is visualized on physical exam, a plain film of the sinus or CT scan may be considered [30].

Telegram: @medical_k

www.konkur.in

A foreign object in the ear may also be asymptomatic or an incidental finding on exam. Symptoms can include otitis, hearing loss, or purulent drainage. It is important to appropriately visualize the object in order to decrease trauma. If it is not easily visualized or if there is evidence of a perforated tympanic membrane, it may be necessary to refer to a specialty physician. Topical anesthesia of the ear is generally not required for foreign body removal [30].

Treatment

In most cases, a foreign object in the nose or ear is not an emergency, so removal may be delayed if it is not easily achieved in the family physician's office. It is appropriate, then, to refer to an otolaryngologist. In the event a caustic object is present (batteries, etc.) irrigation should not be used, and a referral is urgent [30].

Removal of a nasal cavity foreign object may be completed by several different techniques. Most commonly, if the object is in the anterior passage, it may be graspable with a forceps, curved hooks, cerumen loops, or suction catheter [32]. A balloon tip catheter may be used by lubricating the balloon tip, passing the tip past the foreign body, inflating, and then pulling forward [31]. The "parental kiss" is a less invasive option in children in which the parent provides a puff of air through the child's mouth with the unaffected nostril occluded, providing positive pressure to expel the foreign body [30–32]. Once the object is removed, it is important to reinspect the nasal cavity for any additional objects or localized trauma. If the object is not successfully removed, it may be necessary to refer to an otolaryngologist.

Removal of a foreign object within the external auditory canal may be performed using similar techniques as mentioned above. Irrigation is another option, which may be helpful to flush out small objects closer to the tympanic membrane [30, 32]. If a live insect is present, it is important that it be killed prior to removal. Alcohol, 2% lidocaine, or mineral oil may be instilled in the canal [32]. This should be done only if the tympanic membrane is intact. If the object is not easily graspable, however, there are higher rates of complications such as canal lacerations and tympanic membrane damage. In the event of unsuccessful removal, high risk of trauma, or if there is need for anesthesia, specialty referral is recommended [30].

General Principles

Hypertension, also referred to as high blood pressure (BP), is one of the most common conditions seen in adult primary care practices. In 2016, there were nearly 33 million visits to provider offices with essential hypertension as the principle diagnosis [1]. In 2017, age-adjusted prevalence data in the United States reveals that 46% of adults aged ≥20 years have hypertension, which equates to an estimated 116.4 million men and women [2]. Worldwide, at least 1.39 billion adults have high blood pressure [3].

Hypertension remains a major risk factor for cardiovascular and cerebrovascular disease. From a population health perspective, the elimination of hypertension could reduce cardiovascular mortality by 30% in men and 38% in women, which translates to a larger impact on mortality for all risk factors among females and all but smoking cessation among males [4]. In addition to a reduction of mortality, management of uncontrolled hypertension substantially reduces the risk of heart failure, stroke, myocardial infarction, and chronic kidney disease.

As knowledge and analysis of population trends deepen, it has become apparent that certain populations bear a greater burden of illness from hypertension and its consequences both in the United States and globally. There is a widening disparity of prevalence and control among individuals from low- and middle-income countries compared to those from high-income countries [5]. In addition, regarding race/ethnicity, non-Hispanic blacks in the United States have higher age-adjusted prevalence and unmet treatment goals for hypertension than other racial groups. When compared to non-Hispanic white patients, there is a larger proportion of Mexican-Americans and people of other races/ethnicities not receiving treatment for hypertension despite the indication [5].

The diagnosis and management of hypertension has been complicated by the release of multiple guidelines in the last decade which are supported by varying degrees of evidence. In addition to age, race/ethnicity, and comorbid condition-specific management recommendations, these guidelines contain potentially conflicting recommendations for diagnostic and treatment thresholds. Thankfully, they are consistent regarding the first-line pharmacological treatments recommended which include diuretics, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and calcium channel blockers. In addition, among all guidelines, recommendations are consistent regarding renewed emphasis on and reaffirmation of the importance of accurate diagnosis, lifestyle modifications, and individualized management approaches.

Overall, management of hypertension remains a challenge in primary care. Providers are tasked with accurately detecting high blood pressure, managing comorbidities, minimizing side effects, maintaining quality of life, and promoting healthy lifestyle choices, all with the goal of reducing cardiovascular risk.

Detection and Diagnosis

There is ample evidence to support the benefits of screening for high blood pressure in adults. In the landmark report made by the seventh Joint National Committee (JNC 7) in 2003, recommendations were made to screen adults every 2 years if blood pressure was recorded as less than 120/80 mm Hg and every 1 year for systolic blood pressures 120–139 mm Hg or diastolic pressures 80–90 mm Hg [6]. The report from the eighth Joint National Committee (JNC 8) did not address nor define the diagnosis of hypertension in its 2014 guideline [7]. Rather, the 2014 guideline focused on management principles based upon age (greater than or younger than 60) as well as comorbid conditions like diabetes and chronic kidney disease.

The American Academy of Family Physicians (AAFP) supports the US Preventive Services Task Force (USPSTF) clinical preventive service recommendations on this topic which suggests screening all adults over 18 for hypertension. The USPSTF recommends annual screening for adults aged 40 years or older and for those at increased risk for high blood pressure. Persons deemed at increased risk include those who have high-normal blood pressure (130 to 139/85 to 89 mm Hg), those who are overweight or obese, and African Americans. Adults aged 18–39 years with normal blood pressure (<130/85 mm Hg) who do not have other risk factors should be rescreened every 3–5 years. It is important to note that previous recommendation statements from the USPSTF did not differentiate blood pressure measurement protocols nor create a reference standard for measurement confirmation. The most current USPSTF recommendation, however, added to the yearly screening guidance by including language regarding method of measurement, specifically assessing the diagnostic accuracies of office blood pressure measurement,

Telegram: @medical_k

www.konkur.in

ambulatory blood pressure monitoring (ABPM), and home blood pressure monitoring (HBPM). The USPSTF concluded that obtaining measurements outside of the clinical setting is necessary for diagnostic confirmation before starting treatment [8].

Guidelines and typical practice patterns suggest that the diagnosis should be based on at least two separately recorded elevated blood pressure readings. In a patient with a single greatly elevated blood pressure reading in the office setting who already has hypertensive-related target organ damage, the diagnosis can generally be made without follow-up readings. Table 1 gives an overview of office-based blood pressure and hypertension classifications based on current guidelines. This table includes information from the 2018 European Society of Cardiology (ESC) and the European Society of Hypertension (ESH) definition of high blood pressure, which is defined as office systolic blood pressure value of >140 mm Hg and/or diastolic blood pressure value of >90 mm Hg [9].

Traditionally, blood pressure is recorded in the office with an auscultatory or oscillometric method manually or via an automated device. Patients should be seated quietly for at least 5 min in a chair with feet on the floor and arm supported. Transient elevations in blood pressure can occur as a result of certain substances like nicotine, alcohol, cocaine, or caffeine in addition to commonly utilized medications like nonsteroidal anti-inflammatory medications, antidepressants, oral contraceptives, and decongestants [10]. Table 2 outlines some more of these common substances. As mentioned, the JNC 8 report does not address screening intervals, nor does the American College of Cardiology (ACC)/American Heart Association (AHA) guideline, which was released as an update to the JNC 7. It does, however, conclude that the diagnosis of hypertension should be based on accurate measurement and confirmation, which ultimately aligns with other US and international guidelines [9, 10, 11].

The USPSTF found convincing evidence that ABPM is the best method for diagnosing hypertension. However, ABPM is not widely available. The USPSTF found good quality evidence that HBPM may be an acceptable alternative [8]. Both ABPM and HBPM permit recognition of white coat hypertension (i.e., elevated blood pressure level that occurs only in clinical settings), thus helpful in confirmation of a hypertension diagnosis. HBPM also facilitates self-monitoring of blood pressure, which likely has benefits in awareness, adherence, and ultimately blood pressure reduction. Home blood pressure measurement technique is also important, and providers should instruct patients on proper monitoring protocols. The 2017 ACC/AHA guidelines provided a reference regarding the relationship between HBPM blood pressure readings, ABPM readings, and corresponding office-based measurements, which is summarized in Table 3 [10]. Note that the threshold for stage 1 and stage 2 hypertension based on these guidelines is achieved with lower HBPM and ABPM measurements.

Approach to the Patient

Cornerstones in the evaluation of patients with newly diagnosed hypertension include (1) assessing overall cardiovascular mortality

Table 1 Classification of blood pressure level for adults

Guideline (year released)	Normal blood pressure	Elevated blood pressure or prehypertension[a]	Stage 1 hypertension[b]	Stage 2 hypertension[b]
JNC 7 (2003)	<120/80	120–139/80–89	140–159/90–99	>160/100
JNC 8 (2014)	Not defined	Not defined	Not defined	Not defined
ACC/AHA (2017)	<120/80	120–129/80	130–139/80–89	>140/90
ESC/ESH (2018)	120–129/80–84	130–139/85–89	140–159/90–99	160–179/100–109

[a]Prehypertension category was removed from JNC 8 and AHA/ACC guidelines.
[b]ESC/ESH guidelines use "Grade" language instead of "Stage" and defines Grade 3 HTN as >180/110.

risk and presence of comorbid cardiovascular disease risk factors, (2) investigating for secondary causes of high blood pressure, and (3) determining if the patient has evidence of end-organ damage. A thorough history and physical examination with targeted laboratory and diagnostic studies will assist the clinician in a comprehensive evaluation toward these goals.

History

Hypertension is the result of a complex interaction between genetic predisposition and various environmental exposures including diet, physical activity, and medication/substance use. Physical inactivity, being overweight or obese, and excess intake of alcohol or nicotine contribute to a large proportion of underlying hypertension. Providers should inquire about a patient's history of previously elevated blood pressures and specific conditions like diabetes, hyperlipidemia, and obstructive sleep apnea as well as specific risk factors. Table 4 outlines some of the well-documented modifiable and fixed risk factors common in patients with high blood pressure. Given evidence of disparities of disease prevalence and burden previously mentioned, stress and even discrimination have been linked to hypertension [12], so providers should strongly consider asking patients and their families about social determinants of health that may influence decision-making, adherence, and overall wellness.

Table 4 Cardiovascular disease risk factors common in patients with hypertension

Age (>55 men or >65 women)
Chronic kidney disease
Cigarette smoking
Diabetes obesity (body mass index >30)
Dyslipidemia/hypercholesterolemia
Family history of hypertension
Family history of premature cardiovascular disease (first-degree male relative <55 years, female <65 years)
Microalbuminuria or GFR <60 mL/min
Obstructive sleep apnea
Overweight/obesity
Physical inactivity/low fitness level
Poor/unhealthy diet
Psychosocial stress

Physical Examination

Each patient newly diagnosed with hypertension should have a physical exam including more than one blood pressure measurement with adherence to proper technique. At least at the initial diagnosis, blood pressure should be measured in both arms in addition to assessments in both the standing and sitting positions. In subsequent visits, the arm with the higher reading should be used. The exam should also include (1) calculation of the body mass index (BMI), (2) evaluation of the optic fundi, (3) exam of the neck including palpation of the thyroid gland and auscultation for

Telegram: @medical_k

www.konkur.in

carotid bruits, (4) cardiac exam, (5) lung exam, (6) abdominal examination with special attention for enlarged kidneys, masses, abdominal aortic pulsation, and abdominal or renal bruits, (7) examination of the lower extremities for pulses and edema, and (7) a neurological evaluation.

Laboratory Tests and Diagnostic Procedures

Laboratory and diagnostic testing are valuable tools not only in determining the presence of end-organ damage at the time of diagnosis but also in identifying secondary causes of hypertension. In addition, baseline laboratory tests are also important in cardiovascular risk factor profiling which facilitates effective treatment planning. Recommended tests include serum potassium and sodium levels, blood urea nitrogen, and creatinine level. An electrocardiogram (ECG), blood glucose, hematocrit, and fasting lipid panel are also recommended, if not done previously, to help assess overall cardiovascular risk. The ECG also may reveal target organ damage in the form of left ventricular hypertrophy or prior myocardial infarction (Q waves). Optional tests include a TSH level and calcium. A decision to perform other tests such as a chest radiograph, uric acid level, or echocardiogram are appropriate if indicated based on findings from history, physical exam, or ECG or in instances of historical clues suggesting a secondary cause of hypertension.

Secondary Causes

Though most cases of hypertension are considered idiopathic or primary, it is important to consider secondary causes of hypertension at the time of diagnosis. Secondary causes of hypertension are identifiable and potentially reversible causes of elevated blood pressures. It is estimated that one of these specific and remediable causes is identified in approximately 10% of patients (9). The most common secondary causes are obstructive sleep apnea, renal artery stenosis, and hyperaldosteronism. Secondary hypertension should be suspected in younger patients (less than 30 years of age) as well as in patients with treatment-resistant high blood pressure. As noted in Table 2, there are multiple substances and medications that cause elevations in blood pressure. A trial off potentially offending medications (if possible), or a change in diet, may be warranted before embarking on pharmacologic treatment. Specialty colleague consultation is often necessary in the evaluation of secondary hypertension due to the complex measurements and data interpretation necessary to properly diagnose these conditions.

Management

Benefits of Treatment

In clinical trials, antihypertensive therapy has been associated with reductions in stroke incidence averaging 35–40%; myocardial infarction, 20–25%; and heart failure, more than 50% [13]. These data support the importance of treating patients to not only reduce BP but to also, more importantly, prevent the morbidity and mortality associated with hypertension.

The panel members appointed to the eighth Joint National Committee (JNC 8) provided an evidence-based update to BP treatment goals. Per their report, in the general population aged $\geq$60 years, pharmacologic treatment should be initiated to lower BP at systolic BP $\geq$150 mm Hg or diastolic BP $\geq$90 mm Hg and treat to a goal systolic BP $<$150 mm Hg and goal diastolic BP $<$90 mm Hg. This recommendation is made with Grade A (i.e., highest level) evidence. For patients $<$60 years of age, expert opinion recommendation is to initiate treatment with a systolic BP of $\geq$140 mm Hg and treat to a goal of $<$140 mm Hg, and grade A recommendation is to initiate pharmacologic treatment to lower BP at diastolic BP $\geq$90 mm Hg and treat to a goal $<$90 mm Hg. In the population aged $\geq$18 years with chronic kidney disease (CKD) or diabetes, the recommendation is to initiate pharmacologic treatment at systolic BP $\geq$140 mm Hg or diastolic BP $\geq$90 mm Hg and treat to goal $<$140/90 mm Hg [7].

Telegram: @medical_k

www.konkur.in

The 2017 ACC/AHA guidelines recommend incorporating cardiovascular risk estimates with BP levels to determine when to initiate antihypertensives. The guidelines suggest initiating medication in those at high cardiovascular risk when systolic BP is 130 mm Hg or greater or diastolic BP is 80 mm Hg or greater. In those at lower risk, they suggest initiating antihypertensives when systolic BP is 140 mm Hg or greater or diastolic BP is 90 mm Hg or greater (10). High risk is defined as a history of clinical cardiovascular disease or an estimated 10-year atherosclerotic cardiovascular disease (ASCVD) risk of 10% or higher according to the pooled cohort equations. Clinical disease is defined as coronary artery disease, heart failure, or stroke [10]. A target close to 120/80 mmHg is generally better than a higher BP target.

Nonpharmacologic Interventions

All patients with blood pressures above normal should be treated with nonpharmacologic interventions: heart-healthy diet, reducing sodium intake, potassium supplementation, increasing physical activity, limiting alcohol consumption, and losing body weight for those who are overweight [10]. Table 5 is a summary of some key recommendations for lifestyle changes that lower blood pressure. For overall cardiovascular disease risk reduction, all patients who smoke should be counseled about smoking cessation and provided with assistance modalities.

The DASH eating plan emphasizes intake of vegetables, fruits, and whole grains. Additionally, low-fat dairy products, poultry, fish, legumes, and nuts should be included. Diet should be rich in calcium and potassium. Intake of sweets, sugar-sweetened beverages, and red meats should be limited. Sodium intake should be no more than 2400 mg each day. Research has shown that a DASH eating plan with no more than 1600-mg sodium has effects similar to single drug therapy [14].

Adults with elevated BP should be encouraged to engage in aerobic physical activity to lower BP. The recommendation is to include three to four sessions per week lasting an average of 40 min per session and involving moderate- to vigorous-intensity physical activity [15].

Some research has shown increased blood pressure to be positively correlated to more than 2 ounces/day of alcohol. Therefore, it is important to limit alcohol intake [16]. Alcohol should be limited to no more than one ounce (30 mL) of ethanol per day for women and no more than two ounces (60 mL) per day for men.

Pharmacologic Treatment

When deciding on pharmacologic therapy, the individual patient characteristics, including age, race, sex, family history, cardiovascular risk factors, and concomitant disease states, should be considered. Additionally, the patient's ability to afford the prescribed therapy as well as their compliance must be considered.

In the general population, including those with diabetes, initial antihypertensive treatment should include a thiazide-type diuretic, calcium channel blocker (CCB), ACE inhibitor, or ARB. In the

Table 5 Lifestyle recommendations for hypertension

Recommendation	Description	Approximate systolic BP reduction
DASH eating plan	Diet rich in fruits, vegetables, and low-fat dairy with reduced fat intake	8–14 mm Hg
Exercise	Regular aerobic activity at least 30 min per day	4–9 mm Hg
Reduced dietary sodium intake	Maximum 2400 mg (ideally 1600 mg) of sodium daily	2–8 mm Hg
Moderate alcohol drinking	Maximum 2 ounces ethanol per day for men; maximum 1 ounce per day for women	2–4 mm Hg
Weight loss	Achieve/maintain BMI of 18.5–24.9 kg/m^2	5–20 mm Hg

Telegram: @medical_k

www.konkur.in

population aged ≥18 years with chronic kidney disease (CKD), initial (or add-on) antihypertensive treatment should include an ACE inhibitor or ARB to improve kidney outcomes. This recommendation applies to all CKD patients with hypertension regardless of race or diabetes status. Note that an ACE inhibitor and ARB should not be used together [17].

The main objective of hypertension treatment is to attain and maintain goal blood pressure. If goal BP is not reached within a month of treatment, the initial drug dose should be increased or a second drug such as a thiazide-type diuretic, CCB, ACE inhibitor, or ARB should be added. If the goal BP cannot be reached with two agents, a third drug should be added [7]. It has been suggested that a 6-month period of undertreated hypertension increases cardiovascular morbidity [18] (Fig. 1).

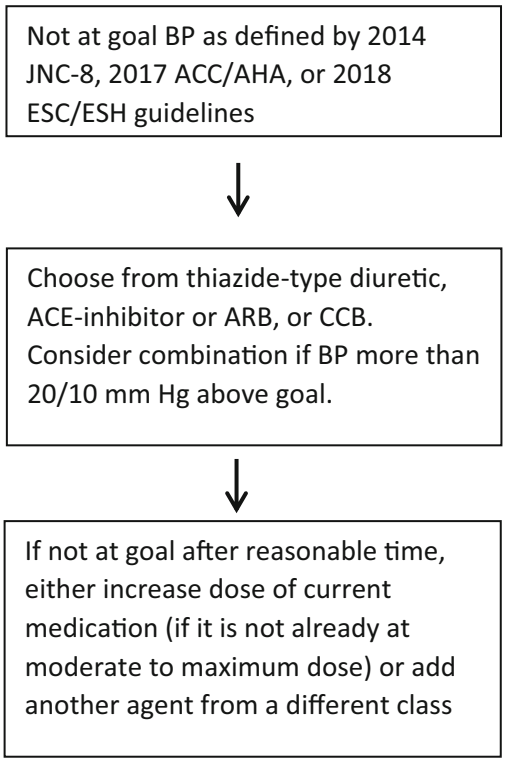

Fig. 1 Evidence-based simplified algorithm for hypertension treatment

Diuretics

Thiazide-type diuretics (chlorthalidone, hydrochlorothiazide) increase renal excretion of sodium and chloride at the distal segment of the renal tubule which results in decreased plasma volume, cardiac output, and renal blood flow and increased renin activity. With these agents, potassium excretion is increased, while calcium and uric acid elimination is decreased. Because of its greater potency and longer duration, chlorthalidone should be preferred over hydrochlorothiazide, especially when used alone. Potential side effects of all thiazide-type diuretics include hyponatremia, hypokalemia, dizziness, fatigue, muscle cramps, gout attacks, and impotence. Special attention should be paid when starting these agents in patients with diabetes, elevated cholesterol, or gout as thiazides can worsen each of these conditions. None of these conditions is a contraindication, however.

Loop diuretics and potassium-sparing diuretics can be used as adjunct therapy when thiazide-type diuretics are not sufficient (e.g., in patients with decreased glomerular filtration rate). Loop diuretics (furosemide, torsemide, and bumetanide) inhibit sodium and chloride reabsorption in the proximal and distal tubules and the loop of Henle. Side effects include diarrhea, headache, blurred vision, tinnitus, muscle cramps, fatigue, or weakness. When used in high doses in patients with significant renal disease, ototoxicity may occur.

Potassium-sparing diuretics (spironolactone, triamterene, amiloride) are useful for preventing potassium wastage that occurs with thiazide and loop diuretics. Spironolactone competitively inhibits the uptake of aldosterone at the receptor site in the distal tubule, in turn reducing the effect of aldosterone. This drug is an evidence-based fourth-line medication for resistant hypertension (described below). Main adverse effects to be aware of include gynecomastia and hyperkalemia. Triamterene and amiloride are typically used more specifically to stop potassium loss, and both have side effect profiles similar to the thiazide diuretics [19].

ACE Inhibitors

ACE inhibitors block the conversion of angiotensin I to angiotensin II, resulting in decreased aldosterone production with subsequent increased

Telegram: @medical_k

www.konkur.in

sodium and water excretion. As a result, renal blood flow is increased and peripheral resistance decreases. Renin and potassium levels typically increase. Major side effects include cough, angioedema, and the possibility of acute renal failure (in patients with renal artery stenosis). Importantly, this class of medication can cause syncope in patients who are salt, or volume, depleted. This drug class is teratogenic in the human fetus and should therefore be avoided in pregnancy and in women who may become pregnant.

ACE inhibitors have little effect on insulin and glucose levels or lipid levels, making them a good choice for most diabetics and patients with hyperlipidemia. ACE inhibitors are a particularly good choice for patients with congestive heart failure, peripheral vascular disease, and renal insufficiency as well.

Angiotensin Receptor Antagonists

ARBs bind to angiotensin II receptors, blocking the vasoconstrictor and aldosterone-secreting effects of angiotensin II. Aldosterone production decreases, while plasma renin and angiotensin II levels rise. There is no notable change in the serum potassium level, renal plasma flow, glomerular filtration rate, heart rate, cholesterol level, or serum glucose.

ARBs are generally well-tolerated but can cause hyperkalemia. ARBs are also teratogenic and should be avoided in patients of childbearing age. The major use of ARBs is for patients who cannot tolerate an ACE inhibitor due to cough.

Calcium Channel Blockers

CCBs reduce the influx of calcium across cell membranes in myocardial and smooth muscles. This in turn dilates coronary arteries, as well as peripheral arteries. This dilation reduces total peripheral resistance leading to decreased BP. Structural differences exist between agents in this class, which lead to different adverse effect profiles as well as differences in their effect on cardiac conduction. Verapamil and diltiazem (non-dihydropyridines) work to slow the conduction through the AV node and prolong the effective refractory period in the AV node. Dihydropyridines (e.g., amlodipine, nifedipine) increase cardiac output and have a more profound vasodilatory effect, making them the preferred CCBs for hypertension.

The main noteworthy side effect of dihydropyridine CCBs is peripheral edema, but they can also cause constipation, flushing, and tachycardia. CCBs are contraindicated in patients with heart block, acute myocardial infarction, and cardiogenic shock. CCBs have no effect on glucose metabolism or lipid levels. CCBs are a particularly good choice for patients with migraine headaches, angina, chronic obstructive pulmonary disease or asthma, peripheral vascular disease, renal insufficiency, supraventricular arrhythmias, and diabetes.

Beta-Blockers

Beta-blockers are not indicated for first-line treatment of uncomplicated hypertension but are recommended for patients following a myocardial infarction and for patients with congestive heart failure. Beta-blockers antagonize the effects of sympathetic nerve stimulation or circulating catecholamines at beta-adrenergic receptors, which are widely distributed throughout the body. Beta-1 receptors are predominant in the heart (and the kidney), while beta-2 receptors are predominant in other organs such as the lung, peripheral blood vessels, and skeletal muscle. In the kidney, the blockade of B1 receptors inhibits the release of renin from the juxtaglomerular cells and thereby reduces the activity of the renin-angiotensin-aldosterone system. In the heart, blockade of B1 receptors in the sinoatrial (SA) node reduces heart rate, and blockade of the B1 receptors in the myocardium decreases contractility. It is likely a combination of these effects that leads to BP reduction. The overall clinical response to beta-blockers is a decreased heart rate, decreased cardiac output, lower blood pressure, decreased renin production, and bronchiolar constriction.

The side effect profile of beta-blockers depends on their receptor selectivity. In those without intrinsic sympathomimetic activity, the heart rate is slowed, a decrease is seen in cardiac output, and an increase is noted in peripheral vascular resistance. Bronchospasm may also be

Telegram: @medical_k

www.konkur.in

the cause. Typical side effects seen with these agents include fatigue, erectile dysfunction, dyspnea, cold extremities, cough, drowsiness, and dizziness. These agents tend to increase the triglyceride level and decrease the HDL level but have little effect on blood glucose levels. Beta-blockers should not be used in patients with sinus bradycardia, second- or third-degree heart block, cardiogenic shock, cardiac failure, and/or severe COPD/asthma.

Central Acting Drugs

Methyldopa, clonidine, guanfacine, and guanabenz are central alpha-2 agonists. These agents act to decrease dopamine and norepinephrine production in the brain, resulting in decreased sympathetic nervous activity throughout the body. BP declines with the decrease in peripheral resistance. Methyldopa is unique in its adverse effect profile as it can induce autoimmune disorders such as those with positive Coombs' and antinuclear antibody (ANA) tests, hemolytic anemia, and hepatic necrosis. The other agents can lead to sedation, dry mouth, and dizziness. Importantly, abrupt clonidine withdrawal can lead to rebound hypertension.

Alpha-Blockers

Alpha-1 receptor blockers, such as prazosin, terazosin, and doxazosin, block the uptake of catecholamines by smooth muscle cells. In the peripheral vasculature, this results in vasodilation. A marked reduction in BP may be noted with the first dose of these drugs; therefore, it is recommended they be started at low doses and slowly titrated upward. Side effects of these agents include dizziness, sedation, nasal congestion, headaches, and postural effects. They have no effect on lipid levels, glucose, exercise tolerance, or electrolytes. These agents are probably best reserved for men with hypertension and comorbid BPH symptoms.

Vasodilators

Hydralazine and minoxidil dilate peripheral arterioles, resulting in a fall in BP. Several other responses simultaneously occur including a sympathetic reflex which leads to increased heart rate, renin and catecholamine release, and venous constriction. The kidneys retain sodium and water. Side effects include tachycardia, flushing, and headache. A beta-blocker and a loop diuretic are usually used with these drugs to minimize side effects. These agents are used mainly for resistant hypertension.

Special Considerations

Hypertensive Emergency

A hypertensive emergency is described as a severe elevation in BP accompanied by evidence of impending or progressive target organ dysfunction. Note that the actual BP measurement is not likely as important as the rate of the rise in blood pressure since patients with chronic hypertension often tolerate higher BP levels than normotensive individuals.

The most common origin of hypertensive emergency is an abrupt increase in BP in patients with chronic hypertension, which may be related to medication noncompliance. Hypertensive emergency can also be caused by certain medications or substances. Examples include withdrawal syndrome from antihypertensives including clonidine and beta-blockers as well as stimulant intoxication with cocaine, methamphetamine, and phencyclidine (PCP).

Clinical manifestations of target organ damage usually involve derangements in the neurologic, cardiac, or renal systems. The patient with hypertensive emergency may present with encephalopathy, pulmonary edema, myocardial infarction, or unstable angina.

Upon presentation, a focused physical exam should include repeated BP recording in both arms. Direct ophthalmoscope exam should be completed with special attention to look for papilledema. A brief neurologic examination should be done to assess for focal deficits and to assess for altered mental status. The cardiac and pulmonary examination should be complete with attention to possible arrhythmias and pulmonary edema. Abdominal exam should focus on palpating for abdominal masses and tenderness as well as auscultation for abdominal bruits. Peripheral pulses should be palpated.

Telegram: @medical_k

www.konkur.in

The immediate goal when treating hypertensive emergency is to reduce the systolic by no more than 25%, within the first hour, and if the patient is then stable, to 160/100–110 mm Hg over the ensuing 2–6 h [10]. Treatment should be more aggressive for certain patients, however. For adults with a compelling condition like severe preeclampsia/eclampsia or pheochromocytoma crisis, blood pressure should be reduced to less than 140 mm Hg during the first hour. For patients with aortic dissection, blood pressure should be reduced to less than 120 mm Hg in that same time [10]. The selection of an antihypertensive agent is an individualized one. Beta-blockers, vasodilators, dopamine agonists, and calcium channel blockers are all potential agents. The selection of which medication should be based on the drug's pharmacology, the underlying pathophysiology of the patient's hypertension, the degree of target organ damage, the rate of desired blood pressure decline, and the presence of comorbidities [10].

Hypertension Treatment in Older Adults

While current JNC 8 guidelines and the USPSTF recommend treating patients over age 60 to a blood pressure of <150/90, several studies are in support of tighter blood pressure control in order to reduce cardiovascular events. The Hypertension in the Very Elderly Trial (HYVET) was one of the first large-scale clinical trials to establish the benefit of lowering blood pressure in patients 80 years and older [20]. The Systolic Blood Pressure Intervention Trial (SPRINT) was a sentinel clinical trial that compared cardiovascular outcomes in patients with increased cardiovascular risk who were randomized to an intensive blood pressure goal of less than 120 mm Hg or a standard blood pressure goal of less than 140 mm Hg [21]. A subanalysis of the SPRINT trial was completed on patients over the age of 75 which also supported more intensive blood pressure control as a way of preventing cardiovascular events, even in frail older adults. On the other hand, several cohort studies of adults 80 years of age and over have shown that participants with low blood pressure at baseline had higher all-cause mortality rates [22–25]. These findings suggest that lowering BP among the oldest-old might be harmful. While these findings could be related to patient selection, frailty or other poor health indicators, or confounding causality, the current recommendations for adults over the age of 75 remain to control blood pressure to <150/90 mm Hg.

"Race"-Based Treatment

JNC 7 was one of the first hypertension guidelines to mention race-specific recommendations for treatment of high blood pressure. In the JNC 7, thiazide diuretics were considered as the first-line therapy for black patients [6]. The JNC 8 guidelines were similar in the recommendation of thiazide-type diuretics being considered first line, but also added that calcium channel blockers should be used as the antihypertensive treatment of choice in the general black population, including those with diabetes [7]. The authors of this chapter chose to deemphasize these race-specific recommendations since a large body of anthropological and contemporary genetic evidence suggests that "race" is a social construct, not a biological one. Insights into genetic variation support the notion that humans are essentially the same, and there is greater variation within identified racial groups than across groups [26]. In addition, while there is ample evidence from clinical trials that demonstrate differences in cardiovascular outcomes among populations in the United States, the participation of various racial/ethnic groups other than white populations in multiple trials has been inconsistent, inadequate, or not measured [27]. Since there are multiple complex factors that affect blood pressure control in patients of all racial/ethnic backgrounds (i.e., socioeconomic standing, lifestyle, clinical inertia, and even discrimination or bias), the interpretation of medical literature and guidelines utilizing "race" is challenging. Until future studies analyze concepts of ancestry, which incorporates ethnicity, geography, and genetics, clinicians should take care with "race"-based recommendations, and instead approach patients in

Telegram: @medical_k

an individualized manner, prioritizing care that is simultaneously culturally aware and evidence based.

General Principles

Ischemic heart disease (IHD) refers to the condition of inadequate blood supply to the myocardium. It is also commonly referred to as heart disease, coronary heart disease (CHD), or coronary artery disease (CAD). From 2013 to 2016, the total number of people age 20 and older in the United Sates affected by IHD was estimated to be 18.2 million [1]. Each year about 605,000 Americans have their first myocardial infarction (MI), with more than 200,000 experiencing a subsequent event [1]. While deaths from IHD have declined since 2000, it remains the leading killer of both men and women [1, 2]. In addition to the loss of life, IHD has a large financial impact. The National Heart, Lung, and Blood Institute estimates a loss of 218 billion dollars in 2014 including loss of productivity [1].

Angina pectoris, or simply angina, refers to the chest pain that occurs when myocardial oxygen supply cannot keep up with demand. Most patients with IHD experience angina. Thus, the evaluation of angina or chest pain is ultimately what leads to the diagnosis in most instances. Acute coronary syndrome (ACS) is a term used

to describe a range of conditions associated with sudden, reduced blood flow to the heart [3]. This chapter will review the diagnosis of IHD when patients present with chest pain, distinguish between the acute coronary syndromes, and describe the management of acute coronary syndrome as well as stable IHD.

Diagnosis

History

The first task when evaluating a patient with chest pain is to quickly establish whether it is secondary to a life threatening cause such as an acute MI or other emergent cause such as pulmonary embolism, aortic dissection, or tension pneumothorax, to list a few. It is important to note that few patients with chest pain seen in the primary care setting have emergent or cardiac causes. Most patients presenting with chest pain in the outpatient setting have musculoskeletal (36%), gastrointestinal (19%), or anxiety-related causes (7.5%) [4]. These prevalence estimates reinforce the need for confidence in understanding the presentations of IHD.

The clinical history is one of the most important tools in the evaluation of the patient presenting with chest pain. Typical angina is described as substernal chest pain or discomfort that is provoked by exertion or emotional stress and relieved by rest or nitroglycerin. Its onset is usually not abrupt, and its duration is usually only a few minutes. When the chest pain has two of these criteria, it is classified as atypical angina. Nonanginal chest pain has only one of these clinical features [5]. While certain characteristics of the chest pain history are associated with increased or decreased likelihoods of a diagnosis of ACSs or MI, none of them alone or in combination are sufficient to diagnose a cardiac etiology [6]. Angina can be specified further by the level of exertion needed prior to onset. The tables below outline a general perspective on how to think about chest pain of possible cardiac origin (Tables 1 and 2).

As mentioned above, it is important to note that atypical angina or nonanginal chest pain does not mean that IHD is not the cause, only that the pain is much less characteristic. Pretest probability for IHD is assessed by taking into consideration the type of chest pain (typical angina, atypical angina, nonanginal) and a patient's age and sex (Table 3). Additional pretest estimates may take into consideration changing demographics, comorbidities, and improvements in imaging and diagnostics [8]. While pretest probability is helpful, clinicians should not solely rely on this estimate to determine need for further evaluation of a patient with chest pain.

Gender differences make correlating symptoms to anatomic causes challenging. The WISE (Women's Ischemic Syndrome Evaluation) study highlighted that women ultimately diagnosed with IHD did not have typical angina 65% of the time [10]. Women also have a higher likelihood of ACS related to *microvascular etiology* rather than to stenosis of coronary arteries [11]. Finally, some patients lack the chest discomfort and are thus characterized as having silent ischemia.

Table 1 Clinical criteria of angina

	Typical	Atypical	Nonanginal
Angina	Substernal chest pain or discomfort; may radiate to arm or jaw. Provoked by exertion or emotional stress. Relieved by rest and/or nitroglycerin.	2 of the three features of typical chest pain. Pain is often located elsewhere, right side or left side of chest, for example.	1 of the three features. Note that "nonanginal" does not necessarily mean not of cardiac origin.

Table 2 Clinical criteria of stable versus unstable angina

	Stable	Unstable [7]
Angina	Symptoms of angina provoked by a consistent level of exertion or emotional stress. Relieved by rest.	Unprovoked chest pain or provoked by less exertion than previously. Generally not relieved by rest or medications. Lasting for longer periods of time.

Telegram: @medical_k

www.konkur.in

Table 3 Estimating pretest probability of ischemic heart disease, Diamond Forrester model [9]

	Men			Women		
Age range	Nonanginal	Atypical	Typical	Nonanginal	Atypical	Typical
30–39 years	5.2	21.8	69.7	0.8	4.2	25.8
40–49 years	14.1	46.1	87.3	2.8	13.3	55.2
50–59 years	21.5	58.9	92.0	8.4	32.4	79.4
60–69 years	28.1	67.1	94.3	18.6	54.4	90.6

Other important symptoms to inquire about include pain radiating to arm(s) or jaw, epigastric pain, dyspnea, and any association of the pain with nausea, diaphoresis, or syncope [12]. Such clinical features increase the probability of a myocardial infarction in patients presenting with chest pain. Interestingly, pain radiating to both arms is the clinical feature that has the strongest positive likelihood ratio (approximately 7) for acute MI [13]. Pain that is pleuritic, sharp, or positional tends to lower the likelihood of MI as the etiology [14].

Obtaining a thorough past medical history is extremely valuable when assessing a patient for possible IHD. A history of hypertension, hyperlipidemia, diabetes, and any prior cardiovascular events should be noted.

ACS, in addition to unstable angina (UA), includes ST segment elevation myocardial infarction (STEMI) and non-ST segment elevation myocardial infarction (NSTEMI). In patients with previously stable angina, a change of chest pain from baseline in terms of increase in frequency, new occurrence with lower levels of activity, or increase in length of symptoms also is consistent with UA [3]. UA and MI cannot be differentiated by history alone. The use of electrocardiogram and cardiac biomarkers (discussed below) is essential to distinguishing amongst these clinical entities.

Physical Exam

The physical exam is less helpful in the diagnosis of IHD. The physical exam of the patient presenting with chest pain that may represent underlying IHD begins with an assessment of vital signs. Note the pulse and blood pressure. Significant hypotension may be a manifestation of MI. Diaphoresis may be present, and sweating in association with typical or atypical angina is a much better predictor of STEMI or NSTEMI than UA [13]. A third heart sound or pulmonary crackles on auscultation also would be concerning for possible MI [14]. Tenderness or reproducibility of chest pain on chest wall palpation argues against IHD as a diagnosis but does not necessarily rule it out [15].

Electrocardiogram and Biomarkers

The electrocardiogram (ECG) is a critical component of the evaluation of chest pain suggesting IHD, whether stable or possible ACS. A pathologic Q-wave is indication of prior MI. ECG abnormalities that may indicate myocardial ischemia include changes in the PR segment, the QRS complex, and the ST-segment. In the setting of possible ACS, a careful evaluation of ECG changes can assist in estimating time of the event, amount of myocardium at risk, patient prognosis, and appropriate therapeutic strategies. ST segment elevation found on an ECG is the hallmark sign of an acute STEMI [12]. The ECG alone is often insufficient to make the diagnosis of an acute MI, and the sensitivity and specificity of ECG are increased by serial assessments [16]. ECG changes such as ST deviation may be present in other conditions, such as left ventricular hypertrophy, left bundle branch block, or acute pericarditis. Note that in addition to patients diagnosed at the time of presentation of their chest pain, each year an additional 170,000 Americans experience a "silent" MI [1].

Like the ECG, cardiac biomarkers are an important extension of the history and physical examination in the evaluation of the patient with

Telegram: @medical_k

www.konkur.in

possible ACS. They are not part of the evaluation of patients with stable IHD. Cardiac troponins, the gold standard, are biochemical markers of active or recent myocardial damage. Increases in cardiac biomarkers, notably conventional cardiac troponins (cTnI or cTnT), or the MB fraction of creatinine kinase (CKMB), signify myocardial injury leading to necrosis of myocardial cells. Patients may present for evaluation before cTn values elevate, and others may have values that do not change on serial measurement [17]. High-sensitive troponin (hsTn) may assist with ruling out MI when not elevated. Elevated hsTn may also signal ischemia without infarction [17].

Troponin levels should be measured on initial assessment, within 6 h after the onset of chest pain, and in the 6–12 h time frame after onset of pain. In addition, it is important to understand that elevations in troponin may be seen for up to 14 days after the onset of myocardial necrosis. The preferred cardiac biomarker is troponin, which has high clinical sensitivity and myocardial tissue specificity [18]. If troponin concentrations are unavailable, then CKMB should be measured. Ideally, both troponin and CKMB should be obtained during evaluation for ACS due to the different concentrations of these biomarkers over time and the added diagnostic value of serial testing.

However, elevated cardiac biomarkers in and of themselves do not indicate the underlying mechanism of injury and do not differentiate between ischemic or nonischemic causes. There are several clinical conditions that have the potential to result in myocardial injury and cause elevations in cardiac biomarkers, including acute pulmonary embolism, heart failure, end stage renal disease, and myocarditis [19]. As a result, cardiac biomarker elevations cannot be utilized in isolation to make a diagnosis of MI.

Stress Testing and Cardiac Imaging

In the evaluation of a patient with possible IHD who is otherwise stable and not experiencing ACS, the first step before ordering or conducting a stress test is to gauge clinical utility. For patients with a low pretest probability, a stress test is unlikely to be helpful. The sensitivity and specificity of a standard exercise tolerance test varies depending on the extent of disease (e.g., >70% stenosis), but in general has a sensitivity of approximately 50–65% and specificity of approximately 75–85% [20, 21]. For example, a 36-year-old woman with atypical chest pain has an estimated pretest probability of 4%. If an exercise tolerance test is positive, her posttest probability of having IHD is only about 9–10%; and if the test is negative, her posttest probability of having IHD is about 2%. The test is most useful for people with a moderate pretest probability, although the testing range spans from 10% to 90%. For people with a high pretest probability, a negative stress test does not reduce the post-test probability sufficiently. In addition to the predicted posttest utility of stress testing, the clinician should take into consideration other factors such as clinical presentation, comorbidities, and other variables in considering stress testing and further diagnostic workup.

Before embarking on standard exercise tolerance testing, it is also important to know that the patient can exercise sufficiently for the test. An ECG should be obtained prior to ordering the stress test to make sure that there are no baseline ECG abnormalities that will make interpretation of the stress test difficult. Patients with a bundle branch block (especially left) or irregularities in the ST segment (e.g., due to digitalis or strain pattern) are not candidates for standard exercise tolerance testing.

There are many alternatives to a standard exercise tolerance stress test, and when considering concomitant imaging, the decision making can seem complicated. Factors to consider are the patient's ability to exercise, previous history of MI, baseline ECG including any rhythm abnormalities. The most common alternative to standard exercise tolerance testing is radionuclide perfusion imaging. It can be accomplished with or without exercise. A radionuclide (e.g., technetium-99 m sestamibi) is injected intravenously and its uptake by the myocardium is compared via imaging during rest and at peak exercise. For patients unable to exercise, adenosine or dipyridamole is used to dilate the coronary arteries and induce a relative

Telegram: @medical_k

www.konkur.in

difference between stenotic and nonstenotic vessels. Sensitivity and specificity are greater with perfusion testing (approximately 75% and 85%, respectively). Stress echocardiography is another test that can be used to evaluate for possible IHD. Areas of the myocardium that are not perfused will exhibit a wall-motion defect. Like radionuclide imaging, stress echocardiography can be performed with or without exercise, the latter method using dobutamine.

Coronary Angiography

Patients with a positive stress test or those with a high pretest probability or for whom the diagnosis remains equivocal should be referred for possible coronary angiography. Coronary angiography is the gold standard for diagnosing coronary artery disease, and depending on the findings, therapeutic interventions can be accomplished simultaneously.

Management

Acute Coronary Syndrome

Initial management of ACS consists of identifying whether a patient should be managed with an early invasive strategy versus an initial conservative strategy. Early risk stratification should take into account a patient's age and medical history, physical exam, ECG, and cardiac biomarker measurements [3]. A risk assessment tool can be used to predict the patient's risk of recurrent ischemia or death following an ACS event. The Thrombosis and Myocardial Infarction (TIMI) risk score is a scoring system for unstable angina and NSTEMI that incorporates seven variables upon hospital admission and has been validated as a reliable predictor of subsequent ischemic events (Table 4) [3].

For patients presenting with a STEMI with symptom onset within the prior 12 h, reperfusion therapy should be considered [22]. Percutaneous coronary intervention (PCI) is the recommended method of reperfusion when it can be performed with the goal of time from first medical contact to device time of less than or equal to 90 min [22].

Table 4 The thrombosis and myocardial infarction (TIMI) risk score for UA/NSTEMI [3]

Baseline characteristics	TIMI risk score (points)	Rate of composite endpoint (%)[a]
1 point for each of the following: Age ≥ 65 years At least 3 risk factors for IHD[b] Prior coronary stenosis ≥50% ST segment deviation At least 2 anginal events in last 24 h Use of aspirin in last 7 days Elevated serum cardiac biomarkers[c]	0–1	4.7
	2	8.3
	3	13.2
	4	19.9
	5	26.2
	6–7	40.9

[a]All-cause mortality, new or recurrent MI, or severe recurrent ischemia requiring urgent revascularization through 14 days after randomization
[b]Risk factors include family history of IHD, hypertension, hypercholesterolemia, diabetes, or being a current smoker
[c]CKMB fraction and/or cardiac-specific troponin level

If patients are unable to get to a PCI-capable hospital within 120 min of a STEMI, then fibrinolytic therapy should be administered within 30 min of hospital arrival, provided there are no contraindications. The benefits of an early invasive strategy for patients initially presenting with NSTEMI or unstable angina are less certain. A meta-analysis was inconclusive in regard to survival benefit associated with early (typically <24 h) vs. delayed invasive strategy in patients presenting with NSTEMI [23]. However, early invasive coronary angiography is recommended in NSTEMI/unstable angina patients who have refractory angina or hemodynamic or electrical instability [24]. Early invasive strategy is reasonable for higher risk NSTEMI/UA patients previously stabilized who do not have serious comorbidities (e.g., liver or pulmonary failure, cancer) or contraindications to the procedure [old 18 new 25]. There is no clear benefit to PCI for individuals with stable angina, and studies show that medical management is just as effective in preventing mortality [25].

Telegram: @medical_k

www.konkur.in

Antiplatelet therapy is a foundational in the management of ACS because it reduces the risk of thrombosis [24]. Well-established antiplatelet therapies in the management of ACS include aspirin, adenosine diphosphate P2Y12 receptor antagonists, and glycoprotein IIb/IIIa inhibitors. Aspirin should be started as soon as possible after an ACS event with an initial loading dose of 162 mg to 325 mg, unless contraindicated. Aspirin should be continued at a dose of 81-mg daily. A P2Y12 antagonist should be added to aspirin for patients with ACS who are medically managed as well as those undergoing PCI [23, 24]. P2Y12 receptor antagonists frequently used in the management of ACS include clopidogrel (Plavix), prasugrel (Effient), and ticagrelor (Brillinta) [26–29]. Triple antiplatelet therapy accomplished by adding GP IIb/IIIa inhibitors has been shown to be efficacious when used during PCI in reducing ischemic complications. However, triple antiplatelet therapy has also been associated with an increased bleeding risk [24].

Parenteral anticoagulants (unfractionated heparin (UFH), low molecular weight heparin (LMWH), fondaparinux, or bivalirudin) are used in combination with antiplatelet agents during the initial management of ACS. The choice of anticoagulant agent is dependent upon the initial management strategy and the recommended duration of therapy varies based on the chosen agent [22, 24].

For patients presenting with unstable angina, NSTEMI, or STEMI, oral beta-blocker therapy should be initiated within 24 h of the onset of the event unless the patient has evidence of low-output state, signs of heart failure, increased risk for cardiogenic shock or other contraindications to therapy [3]. The use of intravenous beta-blockers is reasonable in patients who are hypertensive and do not have contraindications. Beta-blockers decrease cardiac work and reduce myocardial oxygen demand by reducing myocardial contractility, sinus node rate, and AV node conduction velocity. Beta-blocker should be continued in the post-MI setting unless contraindicated or not tolerated. The duration of benefit of long-term oral beta blocker therapy is uncertain, but many clinicians choose to continue beta blockers indefinitely. If patients are experiencing side effects from beta blocker use, it may be reasonable to discontinue therapy at least 1 year after an MI [30]. For patients who are unable to take beta blockers and experience recurrent ischemia, consideration should be given to starting a non-dihydropyridine calcium channel blocker (i.e., verapamil or diltiazem) [3, 22].

As long as no contraindications exist, an angiotensin converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) should be initiated within the first 24 h of patients presenting with ACS who have pulmonary congestion, heart failure, STEMI with anterior location, or left ventricular ejection fraction (LVEF) $\leq$ 40% [3, 22]. ACE inhibitors have been shown to reduce mortality in a broad spectrum of patients following MI, including those with and without LV dysfunction [31–36]. Patients with stable CAD who are not medically optimized (i.e., cannot tolerate a beta blocker or statin), who are not able to be re-vascularized, and/or who have poorly controlled diabetes have shown mortality benefit with continued treatment with ACE inhibitors [37]. When initiating inhibitors of the renin-angiotensin system, it is important to monitor for adverse effects associated with these agents including hyperkalemia, elevations in serum creatinine, and hypotension.

Statin (HmG-CoA reductase inhibitor) therapy is recommended for all patients presenting with ACS who have no contraindications [22, 24]. High-intensity statin therapy following an ACS event was shown to confer an absolute risk reduction of 4% over 2 years compared with a moderate intensity statin for the composite endpoint of death from any cause, recurrent MI, UA requiring rehospitalization, revascularization, and stroke [38]. Statin therapy is beneficial following ACS even in patients with baseline low-density lipoprotein (LDL) cholesterol levels of $<$70 mg/dL [22, 24]. Recently published American College of Cardiology and American Heart Association Guidelines on treatment of cholesterol recommend high intensity statins (i.e., $\geq$ atorvastatin 40 mg daily or $\geq$ rosuvastatin 20 mg daily) for high-risk patients, which include patients who have an ACS

Telegram: @medical_k

www.konkur.in

event [39]. Lower dose statins can be considered if patients are >75 years old or if patients cannot tolerate high intensity statins. Ezetimibe and then PCSK9 inhibitors may be utilized in very high risk patients who have LDL levels that remain at 70 or above [39]. Other medications such as colchicine are showing promise to prevent further ischemic events after MI [40].

Stable Ischemic Heart Disease

Stable ischemic heart disease represents an established pattern of angina, a history of myocardial infarction, or the diagnosis of coronary artery disease on catheterization. The goals of managing stable IHD are to prevent progression of disease and reduce the likelihood of cardiovascular disease events (secondary prevention), ultimately reducing premature mortality. The "ABCss" of management are shown in Table 5.

Low-dose aspirin (typically 81-mg) is recommended for all patients for secondary prevention unless it is contraindicated (e.g., allergy) or poorly tolerated. Aspirin inhibits cyclooxygenase, and the resultant reductions in prostaglandin and thromboxane-A prevent platelet aggregation. Numerous studies have demonstrated the benefit of aspirin for secondary prevention.

Control of blood pressure is important in the management of IHD. Recent evidence-based guidelines recommend initiation of treatment for hypertension at blood pressure > 140 mm Hg systolic and/or > 90 mm Hg diastolic in patients with diabetes, CKD, or in patients younger than 60 years old without these comorbidities [33]. These new guidelines support permissive elevation of systolic blood pressure to 150 mm Hg prior to initiation of therapy in patients 60 years and older. See ▶ Chap. 79, "Hypertension" for further discussion of BP-lowering.

Cholesterol Lowering. The ACC/AHA Lipid Guidelines support use of a high-dose statin in all patients less than 75 years old who will tolerate this treatment [39]. The LDL goals seen in previous guidelines are no longer recommended. Consider at least a moderate dose statin in patients older than 75 [39]. Statins are the preferred treatment, but for patients who do not tolerate them or have other risk factors that may classify them as very high risk, ezetimibe, PCSK9 inhibitor, or a bile acid sequestrant can be considered. Niacin and fibrates can be prescribed for patients with elevated triglycerides [39].

Patients with IHD should be counseled to make smoking cessation a priority. See ▶ Chap. 6, "Clinical Prevention" for information on strategies and clinical interventions that may help patients become smoke free.

Options for antianginal therapy include beta-blockers, nitrates and calcium channel blockers. Beta-blockers are the first-line recommendation for control of angina. By reducing myocardial oxygen demand, they reduce the frequency of chest pain episodes and improve exercise tolerance. In addition to their benefit for symptom

Table 5 Management of stable ischemic heart disease

	Recommendation	Comment
Aspirin	81-mg daily unless contraindicated	Clopidogrel can be used for patients allergic to aspirin
Blood pressure lowering medication(s)	Goal BP < 140/90 mm Hg for most patients	Beta-blocker recommended as part of regimen for post-MI patients
Cholesterol lowering medication	Statin therapy	Use at highest tolerated dose
Smoking cessation	Any patient who smokes should be provided recommendation, counseling and resources to quit	
Symptom management	Control angina symptoms with beta-blocker, nitrates, and/or calcium channel blocker	Beta-blocker is first-line; calcium channel blocker should be long-acting nondihydropyridine or dihydropyridine (avoid nifedipine); long-acting nitrate can be added to help manage chronic angina

Telegram: @medical_k

www.konkur.in

control, beta-blockers help prevent reinfarction and reduce mortality in patients who have suffered an MI. When beta-blockers are contraindicated or not effective as monotherapy, a nitrate or calcium channel blocker can be used.

Sublingual nitroglycerin or nitroglycerin spray is provided for relief of acute episodes of IHD related chest pain. These preparations can also be used a few minutes before activity to prevent effort-induced angina. A long-acting nitrate (e.g., isosorbide mononitrate) can be provided as a supplement to beta-blocker or calcium channel blocker for controlling chronic angina. Nitrate tolerance is minimized by having a nitrate-free interval of about 12 h.

Anolazine can be considered as an add-on for angina control. It is a sodium channel blocker that reduces oxygen demand by decreasing tension during ventricular relaxation. The medication can be a useful when angina is not controlled with the above strategies or can be prescribed instead of beta-blockers if beta-blockade is contraindicated or poorly tolerated [5]. Ranolazine can be used in patients with bradycardia or low blood pressure.

Lifestyle modifications for all patients include weight loss if overweight, regular physical activity, and an eating plan that is low in saturated fats, trans fats, and cholesterol [5]. Referring a patient to a dietitian may be reasonable.

www.konkur.in

or both in the heart cycle. While some arrhythmias are benign and pose no significant cardiovascular compromise, others degrade the mechanical pumping activity and lead to hemodynamic compromise and, in some cases, to collapse and/or death.

Arrhythmias are commonly seen in primary care, and many are diagnosed and managed by primary care physicians, either alone or along with a cardiologist. Although more common among the elderly and those with heart disease, they must be considered in the differential diagnosis of all patients presenting with syncope, lightheadedness, palpitations, fatigue, dyspnea on exertion, and shortness of breath. The main goal in evaluating patients is to first assess cardiopulmonary stability and, in life-threatening situations, activate the emergency response system. In stable patients the work-up focuses on identifying the arrhythmia, its cause(s), its effect on cardiac function, and treating it to improve patients' symptoms and reduce morbidity and mortality.

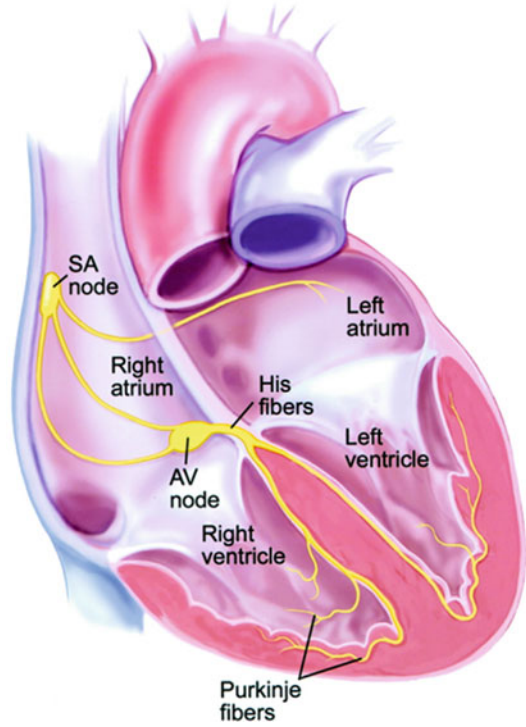

Fig. 1 Diagram of the heart and the electrical conduction system of the heart (From Wang and Estes [1])

Electrophysiology of the Heart

The heart generates its own electrical impulse, an action potential (AP) transmitted through specialized cells and conductive fibers to activate myocardial cells to contract and relax in a highly coordinated fashion. This determines heart rate and rhythm.

In a simplified view, at the molecular level, the generation of the AP is due to unstable transmembrane potential caused by a slow sodium (Na+) leak into the cells, depolarizing the membranes until the threshold that triggers an AP is reached. Cardiac cells have several voltage-gated ion channels, and the in- and outflow of mostly Na, K, and Ca ions through these gated channels (fast and slow) play key roles in generating the AP and repolarizing cell membranes. Through the cycle, cells exhibit absolute and relative refractory periods. Sympathetic and parasympathetic fibers innervate the heart and modulate cardiac function.

Figure 1 [1] shows a schematic and simplified view of the normal electrical conduction system. The AP originates at sinoatrial node (SA), a group of specialized cells in the upper posterior wall of the right atrium. It is transmitted to the atria and to the atrioventricular node (AV), a group of cells in the posterior region of the atrial septum. In the AV node, the impulse is delayed, allowing atrial contraction to occur before the ventricular activation. The AV node transmits the impulse through the bundle of His, fast-conducting fibers in the upper interventricular septum, which splits into two branches, right and left. Then the impulse continues through the Purkinje fibers, which transmit it to all ventricular cells, resulting in ventricular contraction and ejection of blood into the circulation. Although the AV node, bundle of His, and Purkinje can act as pacemakers, the SA node has the highest intrinsic rate of depolarization, and it serves as the pacemaker. At rest, the SA node triggers APs at a rate of 60 to 100 times per minute. In an ECG this pattern is seen as regular waves known as P, QRS, and T waves, which is normal sinus rhythm (NSR).

Detailed knowledge of the variety of ion channels and their electrophysiology is beyond the

Telegram: @medical_k

www.konkur.in

scope of this chapter. However, it is essential to point out some highlights which have clinical and pharmacologic significance.

Various types of ion channels exist in myocytes. Some channels are present in all cells, while others only on certain cells, or preferentially on specific areas of the conduction system. Although the major ions involved are Na, K, and Ca, other ions may also play a role and/or serve to modulate their responses. Some channels are fast, while others are slow; some are voltage gated, and some are modulated by local current across gap junctions with adjacent cells, while others are affected by local currents within the cells (e.g., across their sarcoplasmic reticulum), or via special proteins, ion transport mechanisms, and other intracellular signals. Some channels are up- or downregulated, and some have mutations (leading to familial channelopathies). Some channels are transient responding to immediate changes in the cells in ways to achieve homeostasis, while others undergo permanent changes due to long-standing chronic ischemia, scarring, and remodeling.

Three main mechanisms have been identified as the causes of arrhythmias: increased automaticity, triggered activity, and re-entry. Re-entry is the most common cause of arrhythmias. It occurs when the normal electrical impulse does not dissipate and re-excite cardiac cells after the refractory period.

Arrhythmias are described according to where they originate (in the atria or ventricles, along the multiple sites of the electrical conduction system, or on myocardial cells); according to their effect on heart rate (HR) (fast, tachyarrhythmias, $>$ 100 beats per minute, or slow, bradyarrhythmias, $<$ 60 beats per minute); and according to their effect on heart rhythm (regular versus irregular patterns). All these characteristics define a unique pattern in the ECG.

Evaluation of Patients with Arrhythmia

History and Physical Exam (H&P)

Although studies have shown poor correlation between symptoms and actual arrhythmias, the H&P helps to identify potential causes, risk factors, and comorbidities. Elements of the history must consider both cardiac and non-cardiac causes of arrhythmia. As usual, it must include onset, patient's description of symptoms, duration, aggravating and alleviating factors, severity, and course of symptoms. The review of systems must inquire about shortness of breath, palpitations, dizziness, edema, orthopnea, paroxysmal nocturnal dyspnea, fatigue, lightheadedness, chest pain, syncope, orthostatic hypotension, symptoms of sleep apnea, pedal edema, new medications (prescribed or over the counter), herbal and other supplements, symptoms of thyroid disease, and recent illnesses. The social history provides information about the use of recreational drugs, alcohol, and diet pills as possible causes or contributors. Table 1 presents the most common causes of arrhythmias. Rare conditions such as infiltrative heart diseases, pheochromocytoma, and other endocrine conditions must be considered. All patients must have a complete PE, vital signs, and BMI. The cardiovascular exam should include inspection, palpation, percussion and auscultation of the heart, assessment of heart rate and rhythm, presence of murmurs, carotid bruits, patient's JVD, peripheral pulses, and edema.

Table 1 Most common causes of arrhythmias

Cardiac	Non-cardiac
CAD: Myocardial ischemia or infarction	Pulmonary disease
Heart failure	COPD, PE, pneumonia
Structural heart disease:	Cor pulmonale
Congenital or acquired	Thyroid disease
Dilated cardiomyopathy	Drug toxicity
Ventricular hypertrophy	Antiarrhythmics
Valvular disease	Beta agonist inhalers
Atrial septal defect	Lithium
Ebstein anomaly	Drugs that increase
Epicardial, myocardial, and endocardial diseases:	QT interval
Infectious, injury, or drug toxicity	Electrolyte abnormalities
Iatrogenic	Recreational drugs
Post-cardiac catheterization	Diet pills
Post-cardiac surgery	Collagen vascular disease
Post-ablation	Infiltrative disease
Post-ICD placement	Hypothermia

Evaluation of Cardiac Arrhythmia

Because patient symptoms often do not correlate with actual arrhythmias and the H&P cannot characterize the arrhythmia, the first step is to get an ECG. The ECG provides immediate information of the HR and rhythm and changes in P wave, PR interval, QRS complexes, ST segment, and T waves. Since a normal ECG cannot capture a paroxysmal arrhythmia, a Holter monitor (24-h recording) or an event monitor (7–30 days recording) may be required. In some cases a long-term implantable loop recorder may be necessary [2]. An echocardiogram is also needed to evaluate heart function and assess for possible structural diseases.

Initial blood tests include a complete blood count with differential, a comprehensive metabolic panel, magnesium, lipid panel, and TSH. Additional tests may be necessary depending on the patient's H&P and risk factors. These include stress echocardiogram, nuclear perfusion imaging or cardiac catheterization for ischemia or coronary artery disease, table tilt test for vasovagal syncope, drug screen (if suspected), and urine vanillylmandelic acid and serum metanephrine for evaluation of possible pheochromocytoma.

Treatment Options for Cardiac Arrhythmia

Several options are available to treat arrhythmias. They include cardioversion, drugs with AV nodal suppression, antiarrhythmic drugs acting on different ion channels, radiofrequency ablation, pacemakers, defibrillators, and surgery. Based on best evidence from clinical trials, the most updated knowledge of pharmacology and pathophysiology, the American Heart Association, the American College of Cardiology, the European College of Cardiology, and the Heart Rhythm Society, AHA/ACC/ECC/HRS, have developed guidelines for the evaluation and treatment of arrhythmias [3–8]. These guidelines are frequently revised and updated to include latest knowledge, and they provide a framework for a discussion with patients and their families about treatment options. Therapeutic decisions also must reflect patients' preferences and choices. Prior to initiating a specific therapy, it is essential to identify and treat reversible causes of arrhythmias.

Cardioversion

It is the attempt to return the heart rhythm to NSR and can be achieved by an electrical current shock or by drugs. The goal is to override all abnormal electrical activity and synchronize the heart rhythm again. Unless done in an emergency basis, it requires preparation: IV access, continuous cardiac monitoring, sedation and/or anesthesia, resuscitation equipment, proper anticoagulation, normal electrolytes and short fasting, etc.

Electrical cardioversion is accomplished by delivering a direct current electric shock of 50–360 joules of energy. Shocks are delivered in synchrony with the R or S wave of the QRS complex, to avoid the relative refractory period and minimize triggering of other arrhythmias. One or more shocks may be necessary, starting at the lowest energy. The main indications for cardioversion are unstable or poorly tolerated narrow QRS complex tachycardias (atrial fibrillation (AF) or flutter) and ventricular tachycardia not responsive to drug therapy.

Pharmacological cardioversion and maintenance of NSR has been challenging due to limited long-term efficacy of drugs, the risk of triggering ventricular arrhythmias, and their long-term adverse side effects [3–5]. It is more successful in young patients with healthy hearts who have recently developed an arrhythmia. Most commonly used drugs include ibutilide (Corvert), flecainide (Tambocor), dofetilide, propafenone (Rythmol), and amiodarone (Cordarone, Nexterone, Pacerone). Contraindications for cardioversion include digitalis toxicity, multifocal atrial tachycardia, and suboptimal anticoagulation.

Antiarrhythmic Drug Therapy

Multiple drugs are available to suppress and treat arrhythmias, but their use is complex. Many drugs

Telegram: @medical_k

www.konkur.in

can trigger arrhythmias, some have serious short- and long-term adverse side effects, some require hospitalization to initiate therapy, some have limited long-term benefit, many have drug interactions, etc. Therefore, the patient should be referred to cardiology.

Antiarrhythmic drugs have various effects on ion channel function; most have more than one action. They may slow down, accelerate, or modify ion movement across cell membranes. They act at various phases of the AP and in unique ways along the specialized conduction system. Advances in electrophysiology and the development of new drugs led to the revision and expansion of the well-established Vaughan-Williams classification of antiarrhythmic drugs [9].

Table 2 presents the new drug classification, mode of action, indications, and contraindications for their use [3, 5, 9–12].

Class 0. This new class identifies drugs that have an effect on the automaticity of the SA node. Ivabradine is a drug that reduces heart rates in inappropriate sinus tachycardia [10].

Class I. These drugs block Na channels and therefore act on the depolarization phase of the cardiac AP. New classification identified a variety of Na^+ channels. Some of these drugs act early or late in the phase of the AP, while others act on voltage gated channels in the atria, Purkinje fibers and ventricles. They are further subdivided into four subclasses according to their effect on the duration of the AP [10]:

- Class Ia agents prolong the initial phase of the AP, thus delaying depolarization. They also increase the effective refractory period. Some examples are quinidine (Qualaquin), procainamide, and disopyramide (Norpace).
- Class Ib. These drugs shorten the duration of the AP by increasing repolarization. Some examples are lidocaine, phenytoin (Phenytek), mexiletine, and tocainide.
- Class Ic. These drugs have no effect on AP duration, but they significantly slow the initial depolarization of the AP and have no effect on refractory period. Some examples are encainide, flecainide (Tambocor), propafenone (Rythmol), and moricizine.
- Class Id. These drugs inhibit late Na + channels after the rapid initial repolarization phase. They shorten AP recovery and increase refractoriness. Examples include ranolazine, GS-458967, and F15845.

Class II. This classification includes drugs that have effect on sympathetic and parasympathetic activity, as well as drugs that act through cell membrane proteins, particularly G-proteins. They have ionotropic, chronotropic, and lusitropic (myocardial relaxation) effects on the heart:

- Class IIa include non-selective (carvedilol and propranolol) and selective (atenolol) $\beta 1$ adrenergic blockers. They inhibit Ca^{++} entry and release from the sarcoplasmic reticulum.
- Class IIb. In contrast to class IIa, these drugs stimulate Ca^{++} entry and release from the SR. An example is non-selective isoproterenol.
- Class IIc. These are drugs that act on muscarinic receptors via various G-proteins. An example is atropine.
- Classes IId and IIe. These drugs mediate their effects by inhibiting G-proteins. Examples are carbachol (IId) and adenosine (IIe) [10].

Class III. These drugs block K^+ channels, subtype and auxiliary subunits. They prolong repolarization and refractory period of myocytes:

- Class IIIa. They act on voltage-gated ion channels.
- Class IIIb. They affect specific K^+ channels via specific transmitters.
- Class IIIc. Act on K^+ channels affected by specific transmitters.

Class IV. These drugs are referred as calcium channel modulators. Overall, they delay conduction at the AV node, slowing HR. Subclasses in the surface of cells and within cell membranes (sarcoplasmic reticulum) have been identified. These channels have complex mechanisms affected by local currents, voltage, and Ca homeostasis and intracellular signals. Their activation at different times and sites and their

modulation by protein kinases are the target of new drug effects:

- Class IVa. They act on surface membranes of cells' Ca channel blockers.
- Class IVb. They act on intracellular Ca channel blockers.
- Class IVc. They act on sarcoplasmic reticulum Ca ATPase activators.
- Class IVd. They act on surface membrane ion exchange inhibitors.
- Class IVe. They act on phosphokinase and phosphorylase inhibitors cellular signals.

Class V. These drugs act on cation mechanosensitive ion channels and transient channels which suppress ectopic activity in hypertrophic cardiomyopathy. These drugs modulate the activity of channels in fibroblasts after cell death.

Class VI. These drugs act on connexins-associated channels. The initiation and propagation of AP is also affected by local currents through gap junctions, hemichannels, and cell-to-cell connections (connexin currents). Blocking gap junction currents can increase or reduce arrhythmias. These channels are important in remodeling process in the heart. Examples are carbenoxolone and peptide analog ZP-123.

Class VII. These drugs act on upstream modulatory targets. Fibrotic changes post-MI and chronic scarring in the heart lead to arrhythmias. This class includes drugs which inhibit remodeling and fibrosis. Examples are those who block the renin-angiotensin-aldosterone inhibitors, omega-3 fatty acids, and statins.

Ablation Therapy

Ablation therapy has gained a prominent role in the treatment of some tachyarrhythmias. Its aim is to deliver radiofrequency energy to destroy abnormal foci and pathways that cause the arrhythmia. The injury to heart tissue is thermal and creates scarring, inflammation, and then necrosis. Electrophysiology studies are used to identify, study, and accurately map the foci of arrhythmia. Indications for ablation therapy include WPW syndrome (usually curable), unifocal atrial tachycardia, AF, and idiopathic VT. Patients with VT may choose this as first-choice therapy. Ablation can be helpful in patients with structural heart disease, when drug therapy is not effective and when patients' ICDs have frequent discharge [4, 6–8, 13–15].

www.konkur.in

Pacemakers and Defibrillators

Pacemakers and defibrillators are sophisticated computers which can pace, sense, and respond to arrhythmias by inhibiting and/or stimulating electrical activity in the atria, ventricles, or both. Pacemakers can also modulate their responses in a graded fashion. Patients at risk of life-threatening arrhythmias, or when arrhythmias severely compromise their cardiac function, must be referred to a cardiologist for evaluation of pacemaker and/or defibrillator placement. Several studies have demonstrated their effectiveness in preventing sudden death from arrhythmias [5–8].

The ACC/AHA and the North American Society of Pacing and Electrophysiology recommend the implantation of pacemakers in patients with complete third degree AV block; advanced second degree AVB (block of two or more consecutive P waves); symptomatic Mobitz I or Mobitz II AV block; second degree AV block with a widened QRS or chronic bi-fascicular block; and exercise-induced second or third degree AV block (in the absence of myocardial ischemia). They also recommend biventricular pacing for patients with dilated cardiomyopathy (ischemic and non-ischemic); those with an LVEF $<35\%$; those with QRS complexes >0.12 ms; and patients with New York Heart Failure class III or IV, despite optimal medical treatment [4–8].

Patients with implanted pacemakers need to be monitored regularly by cardiologist for proper function and programming, to check the battery life, and to monitor pacemaker activity and patient's clinical symptoms.

Defibrillators deliver unsynchronized electrical shocks to the heart with the aim to stop a lethal arrhythmia and re-establish a viable cardiac rhythm [15, 16]. There are several types of defibrillators: external, transvenous, implantable in the form of a cardioverter-defibrillator (ICD), or as part of a pacemaker. Some have become part of the general public domain, known as automated external defibrillators (AEDs), allowing even the lay public to use them successfully [16]. Today, most defibrillators deliver shocks in a biphasic truncated waveform which is more efficacious while using lower levels of energy to produce defibrillation. Defibrillation is only recommended for ventricular fibrillation and pulseless ventricular tachycardia.

Surgery

Two surgical therapies for atrial fibrillation are available: the obliteration of the left atrial appendage (LAA) and the Cox-Maze procedure, in which surgical disruption of abnormal conduction pathways within the atria is made.

LAA obliteration is a surgical procedure aimed at reducing the risk of thromboembolic events in patients with AF and possibly avoiding long-term anticoagulation. The rationale for obliteration is based on the observation that $>90\%$ of the thrombus forms in the LAA and is the main source of thromboembolism [3, 17–20]. Recently, the development of percutaneous procedures to obliterate the left atrial appendage has shown to be equal or superior to warfarin in reducing stroke and adverse cardiovascular events and all-cause mortality [16–20]. This approach should be considered when contraindication for long-term anticoagulation exists [3].

In the Maze procedure, incisions are made in the atria to isolate and interrupt re-entry circuits while maintaining the physiologic activation of the atria. The Maze procedure has undergone multiple revisions since its development, and it is considered for patients who need invasive cardiac surgery for other reasons [21].

Referral to Cardiologist

Cardiology referral is warranted when patients have complex cardiac disease, cannot tolerate the arrhythmia, need rhythm control, require ablation therapy, may benefit from surgical treatment, or need a pacemaker or defibrillator.

Supraventricular Tachyarrhythmias (SVT)

These arrhythmias originate above the ventricles and involve the atria, the AV node, or both for initiation and propagation. These are due to

Telegram: @medical_k

www.konkur.in

re-entry circuits or accessory pathways, most commonly the AV nodal re-entrant tachycardia, the atrioventricular re-entrant tachycardia, or the atrial tachycardia. In the absence of other conduction defects, the ECG shows a rapid HR with narrow QRS complexes. Wide QRS complexes indicate additional conduction abnormalities distal to AVN, such as bundle branch block and/or accessory pathways. These arrhythmias are treated as ventricular tachycardias.

In an acute setting, IV access and continuous cardiac monitoring are necessary. The first line of therapy is either IV adenosine or IV calcium channel blocker; they are both equally effective in terminating SVT. However, adenosine has quicker action, and it is short lasting. In patients with rare episodes and able to tolerate the episodes, a "pill on the pocket" (flecainide, diltiazem, or propranolol) is a reasonable choice. Patients with persistent or frequent episodes need continuous drug therapy, or they may benefit from radiofrequency ablation therapy which has high success rate in patients with AVN re-entry tachycardia [22].

When evaluating SVT, the following questions should be answered: "What is the ventricular response?", "Does it lead to a narrow or wide QRS?", "Is the arrhythmia regular or irregular?", and "What is the effect on cardiovascular status of the patient?"

Atrial Fibrillation (AF)

AF is the most common SVT seen in primary care. In addition to adverse effects on cardiac function, it increases the risk of stroke. AF has been identified as an independent risk factor for death [4, 22–26]. It worsens heart failure and increases mortality in the setting of myocardial infarct [22–26]. It causes about 10% of strokes, and these are more devastating and a major cause of disability [27–30]. Figure 2 shows the deleterious effect of AF [31].

AF results from uncoordinated atrial activation leading to deterioration of mechanical function. In the ECG, the normal P waves are lost, and irregular impulses reach the AV node and activate the ventricles at an irregular rapid rate, usually between 90 and 170 beats/min. The QRS complex remains narrow unless other conduction abnormalities coexist (Fig. 3). Enhanced automaticity of depolarizing foci and re-entry in one or more circuits are responsible.

AF may result from several disease processes with different prognoses and associated morbidities and mortalities. AF in patients younger than 60 with no underlying heart disease is known as lone AF and has good prognosis. AF due to congenital or acquired valvular disease carries the highest risk for stroke. Valvular vs non-valvular AF is defined by the presence or absence of

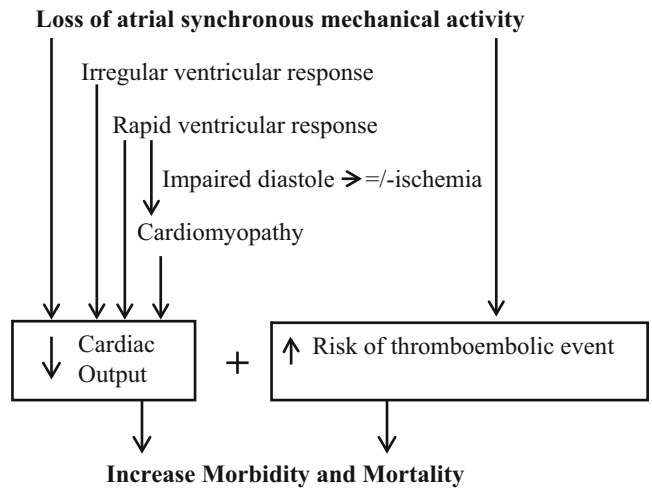

Fig. 2 Clinical implications of atrial fibrillation (Reproduced with permission from Atrial Fibrillation: Diagnosis and Treatment, January 1, 2011, Vol 83, No 1, issue of American Family Physician Copyright © 2011 American Academy of Family Physicians. All Rights Reserved.)

Telegram: @medical_k

www.konkur.in

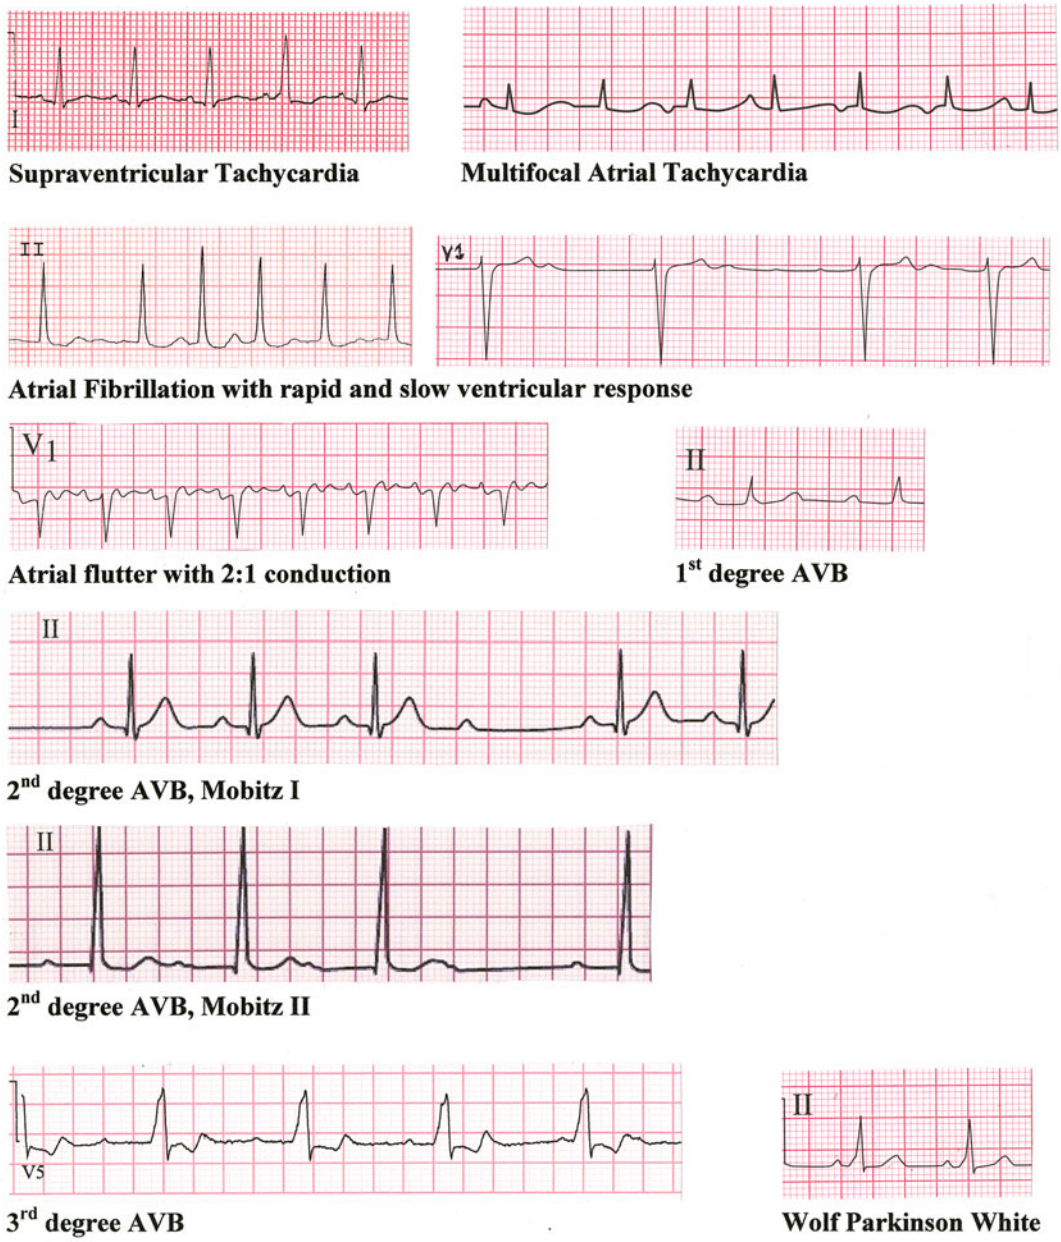

Fig. 3 Supraventricular Arrhythmias

moderate to severe mitral stenosis. Valvular AF that needs valve replacement requires long-term anticoagulation with warfarin [3]. AF due to non-cardiac disease such as hyperthyroidism or pulmonary disease is referred as secondary AF, and treating its cause resolves it. AF treatment and prognosis are affected by its duration and persistence. Paroxysmal AF is defined as episodes of self-resolving AF. Persistent AF lasts for >7 days and can still be terminated by cardioversion. Chronic AF is continuous and unresponsive to cardioversion. Paroxysmal and chronic AF carry the same risk for stroke. Persistent AF causes atrial remodeling (anatomical and physiologic changes)

Telegram: @medical_k

www.konkur.in

which leads to its perpetuation [3]. Patients with AF may be asymptomatic, have vague symptoms, or present with myocardial infarction, a stroke, or complete hemodynamic collapse. The diagnosis requires the typical ECG pattern: loss of P waves, narrow QRS complexes with a fast and irregular ventricular response. An event or Holter monitor may be needed to capture the arrhythmia.

The management of AF depends on the patient's clinical presentation. In cases of hemodynamic instability, stroke, or myocardial infraction, emergency evaluation and treatment is warranted, including emergency cardioversion.

The long-term treatment of AF poses three main therapeutic challenges: 1. Reverse to NSR by cardioversion or ablation; 2. control the ventricular rate and allow AF to continue; and 3. in either case, start anticoagulation.

Cardioversion can be achieved electrically or pharmacologically. Unless done emergently, or if AF is known to be less than 48 h, cardioversion requires 4 weeks pre- and 4 weeks post-anticoagulation. Pharmacologic cardioversion with antiarrhythmic drugs has limited efficacy. Commonly used drugs include flecainide (Tambocor), propafenone (Rythmol), dofetilide (Tikosyn), amiodarone (Cordarone, Nexterone, Pacerone), dronedarone (Multaq), and sotalol (Betapace, Sorine). Because they can trigger additional arrhythmias and have long-term adverse side effects, it is suggested to refer or co-manage patients with a cardiologist.

Ablation therapy is another way to restore NSR. It is gaining acceptance after the discovery of specific foci that trigger AF. These foci are at or near the pulmonary veins, the crista terminalis, and the coronary sinus [14, 28]. The ACC/AHA/HRS AF guidelines recommend it for patients with recurrent AF who are symptomatic but who have no structural heart disease [3, 4].

Most patients are treated with ventricular rate control vs rhythm control [3, 4, 28–30]. Rate control slows the ventricular response and improves diastolic ventricular filling, reduces myocardial oxygen demand, and improves coronary perfusion and mechanical function. β-blockers, metoprolol, esmolol, and propranolol, and non-dihydropyridine calcium channel blockers (CCB), diltiazem and verapamil, are used to achieve rate control with a goal of <80 during rest and <110 during exercise. More lenient rate control to a resting heart rate of <110 is reasonable in asymptomatic patients with normal left ventricular function. Digoxin is no longer a first or sole choice, but it can be used in addition to β-blockers or CCB [3]. Rhythm control is an option for patients in whom rate control cannot be achieved or who remain symptomatic.

Surgical treatments for AF include left atrial appendage obliteration and the Maze procedure. Both are invasive and are only considered in patients undergoing cardiac surgery for other reasons [17–21].

Anticoagulation

Although anticoagulation increases the risk for bleeding, it significantly reduces the risk of stroke and thromboembolic events, and therefore, it is an essential part of AF treatment. Several stratification tools to assess both the risk of stroke and the risk of bleeding have been developed. In spite of their limitations, they are useful in evaluating patients' risks and benefits for long-term anticoagulation.

The CHAD2DS2-VASc is an acronym that describes the main risk factors for stroke; it has been well established [32]. Table 3 shows the current risk stratification and recommendations for anticoagulation [3]. In general, anticoagulation is recommended for patients whose CHAD2DS2-VASc scores are >2 in males and for female patients >3. Similarly, the ATRIA and HAS-BLED are tools used to assess risk of bleeding [32–35]. Risk factors include anemia, severe renal disease, age, previous bleeding, hypertension, liver disease, labile INR, and drug or alcohol use.

Anticoagulation treatment has changed since the development of non-vitamin K antagonist drugs known as NOACs. Over decades warfarin (Coumadin, Jantoven) had been the cornerstone of anticoagulation therapy.

NOACs include direct thrombin inhibitor dabigatran and the newest factor Xa inhibitors rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa). All NOACs have been consistently shown to be non-inferior to/or superior to

warfarin in preventing stroke and systemic thromboembolism while having a safer profile, particularly in regard to intracranial bleeding [36–41]. The PROSPER study showed that in patients being treated for acute stroke, NOACs have better long-term outcomes relative to warfarin [40].

Due to warfarin's narrow therapeutic range, multiple drug and food interactions, need for frequent monitoring, and increase risk of bleeding, NOACs are recommended over warfarin in patients who have non-valvular AF, no mechanical valve, and no contraindications.

Warfarin is still the choice for patients who have moderate to severe mitral stenosis and mechanical valve. Many patients still take warfarin due to the higher cost of NOACs. The target goal is measured as the international normalized ratio (INR), and for most patients it is between 2 and 3 with non-valvular AF and an INR of 2.5–3.5 for those with valvular AF.

Warfarin is more effective than aspirin (Bayer Aspirin, Bufferin, Ecotrin) and clopidogrel (Plavix) alone or in combination, but it carries a higher risk for bleeding. It is estimated that warfarin lowers the risk of thromboembolic events by 68% while aspirin by 21% [42–46].

NOACs dosing needs to be adjusted for age, weight, kidney function, and liver disease. Table 4 shows a summary of approved anticoagulants available and their characteristics [36–41].

The main advantages of NOACs over warfarin include fixed dosing, no food interactions, fewer drug interactions, and no need for monitoring. Their major drawback is still high cost. Reversal therapy is now available for dabigatran and factor Xa inhibitors [47, 48]. The FDA has not approved them for valvular AF, pregnant, or lactating patients, and some are contraindicated in patients with advanced kidney disease.

Anticoagulation therapy must consider the patients' preferences. This requires a discussion regarding the risks, benefits, and a shared decision between physicians and patients.

Stopping anticoagulation due to emergencies and/or medical procedures may be necessary. The risk and benefits of doing so must be carefully assessed. Some data has shown worsening outcome when stopping anticoagulation [49]. If interruption is necessary, the recommendation is to bridge using unfractionated heparin or low molecular heparin [3, 4].

Atrial Flutter

Atrial flutter is an organized regular rhythm caused by a re-entry circuit around the tricuspid valve. It is often seen after cardiac surgery or cardiac ablation. AF and atrial flutter can occur

back and forth and sometimes coexist, but they are different. In atrial flutter waves of depolarization activate the atria to contract regularly at about 280–300 times per minute, and if there are a healthy AVN and no AV node-blocking drugs, there is a 2:1 conduction resulting in a ventricular rate of about 150 beats per minute (Fig. 3). The preferred treatment for atrial flutter is ablation. AV node suppression drugs often change atrial flutter to AF, which may be better tolerated by patients. In the setting of cardiovascular compromise, electrical cardioversion may be necessary using biphasic defibrillator starting at 50 J energy shock.

Atrial or Sinus Tachycardia

Sinus tachycardia (Fig. 3) is in most cases a normal response of the heart to physiologic stressors such hyperthyroidism, dehydration, anemia, hypoxia, etc. A rare type of atrial tachycardia, called inappropriate sinus tachycardia (IST), is diagnosed when all possible causes have been excluded.

Frequent or Premature Atrial Contractions (PACs)

These are not classified as SVT. They generate from a single focus tachycardia but 1:1 P/QRS ratio with a single P wave morphology. When more than one focus triggers the arrhythmia, this is referred as multifocal atrial tachyarrhythmia (MAT). In this case the heart rate is greater than 100 beats/min, and the EKG has at least three different P wave morphologies with variable PP, PR, and RR intervals (Fig. 3). MAT is seen in heart disease, pulmonary disease, hypokalemia, and hypomagnesemia. When patients have different P wave morphologies and heart rate is <100 beats/min, the condition is referred as wandering pacemaker. Therapy is mostly focused at reversing potential causes, and CCB and BB are used to slow heart rate.

Wolff-Parkinson-White (WPW) Syndrome

It occurs when one or more accessory pathways exist bypassing the AVN, allowing the ventricles to activate earlier than normal and resulting in tachyarrhythmia. The ECG shows a short PR interval with a slurring of the initial part of the QRS, making it wider, which is known as "delta wave" and represents pre-excitation (Fig. 3). Ablation therapy is curative and recommended. Drugs with AV node suppression effect such as BB, CCB, digoxin, and adenosine are contraindicated [5, 7].

Atrioventricular Arrhythmias

Atrioventricular block (AVB) results from an abnormal delay or interruption in the conduction of AP from the atria to the ventricles. This block can occur in the atria and at AVN and the His-Purkinje fibers, and it can be intermittent, complete or incomplete, and uni-fascicular, bi-fascicular, or tri-fascicular depending on the location of the lesion. The severity is described in degrees.

In first degree AVB, the delay conduction is at the AVN, but each AP from the SA reaches the ventricles. The ECC shows a prolonged PR interval, >0.2 s (Fig. 3). Usually this block does not cause significant symptoms, and it does not require treatment. Drugs with nodal suppression effects such as digoxin, verapamil, diltiazem, and beta blockers can be the culprit.

There are two types of second degree AVB, known as Mobitz I and II. Mobitz I occurs when the PR intervals progressively increase in length until a QRS is dropped. This phenomenon is also known as Wenckebach (Fig. 3). In Mobitz II, the PR interval remains constant, but not all APs from the SA are transmitted to the ventricles. Thus, the 1:1 P/QRS ratio is lost, and 2:1 or 3:1 conduction pattern appears. In patients with bi-fascicular block, a pacemaker is recommended.

In third degree AVB, there is complete blockage of conduction between the SA and AV nodes, and the atria and ventricles contract at different rates (Fig. 3). Depending on the ventricular response, the rate may be too slow to sustain appropriate circulation, and in some cases, it can lead to complete heart block. Most patients are symptomatic and require a permanent pacemaker.

Sick Sinus Syndrome (SSS) Also Known as Sinus Node Dysfunction (SND)

SSS describes a bradyarrhythmia caused by a sick SA node unable to be pacemaker, usually as a result of aging or heart disease. The SA node generates AP at a very slow rate leading to severe bradycardia, sinus pauses, and sometimes arrest. As the heart is unable to maintain adequate perfusion, patients experience lightheadedness, pre-syncope, syncope, dyspnea, and angina. Some patients develop brady-tachy syndrome with paroxysmal atrial tachycardia (most commonly AF) in response to the bradycardia. It is crucial to establish a correlation between the arrhythmia and symptoms to make the diagnosis of SSS, and a Holter or an event monitor is required. Treatment is focused at treating reversible causes, such as stopping drugs that suppressed the SA node, correcting electrolyte imbalances and hypoxia. Drug therapy has not been successful, and most patients require the implantation of a pacemaker [5, 7]. Patients with asymptomatic bradycardia do not need treatment but need close follow-up.

Ventricular Arrhythmias (VA)

VA are caused by electrical activation of ventricular cardiac cells without atrial or nodal influences, most commonly triggered by re-entry mechanism. Their characteristic ECG pattern shows wide QRS complexes (>120 ms), bizarre shape, no preceding P wave, and large T wave usually of opposite polarity to the QRS complex. They are serious arrhythmias associated with sudden cardiac death especially among patients with underlying cardiac disease and require cardiology referral. VA are classified according to their frequency, persistence, and effect on ventricular contraction [50].

Premature Ventricular Contractions, PVCs

PVCs show a wide QRS, no preceding P wave, and T wave is large and opposite to the QRS, giving a bizarre appearance (Fig. 4). They may

Telegram: @medical_k

www.konkur.in

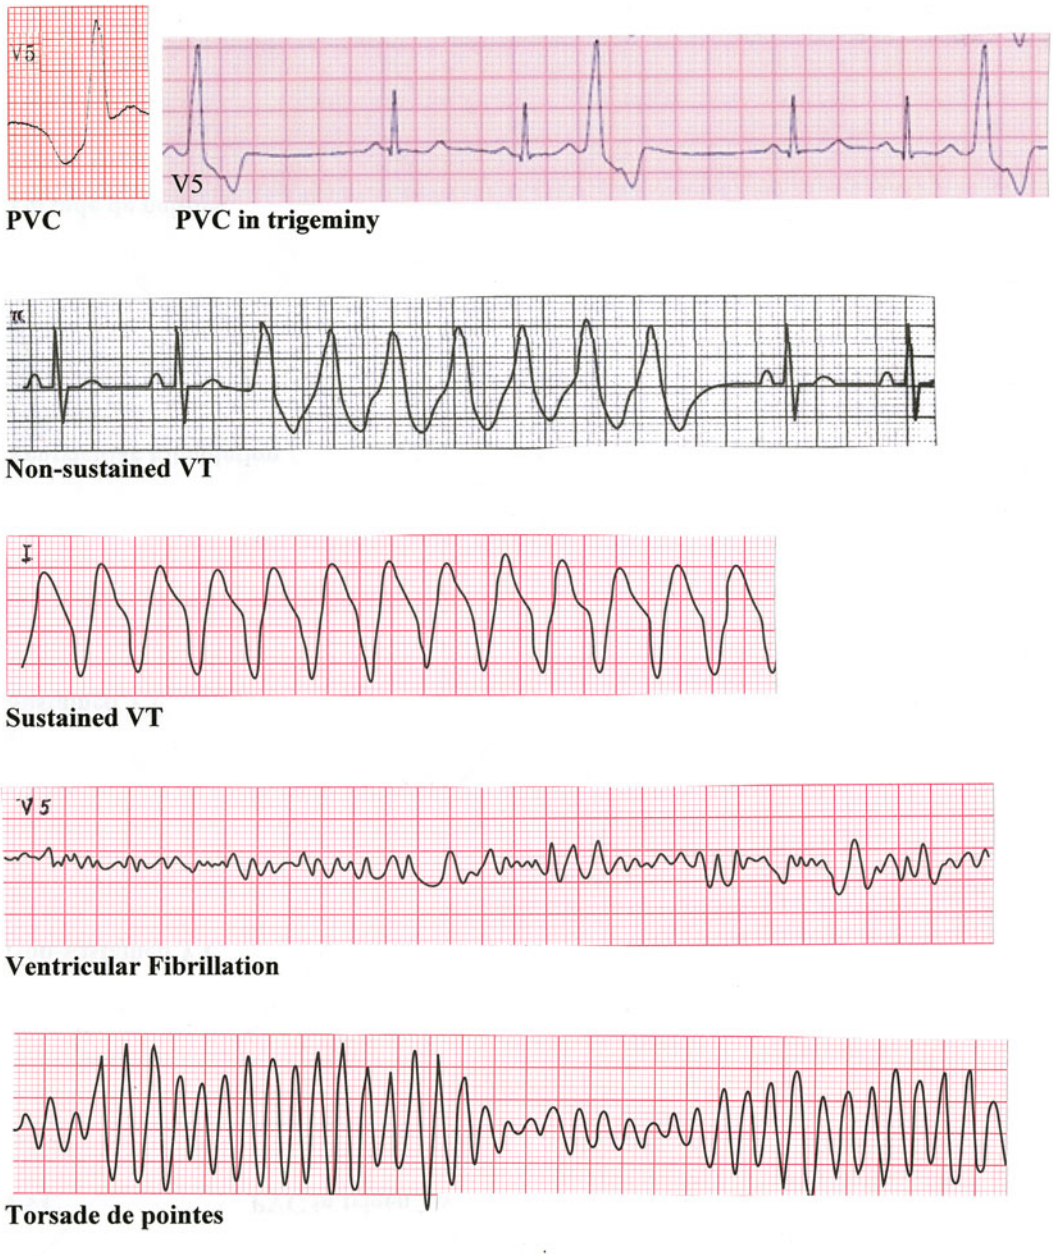

Fig. 4 Ventricular Arrhythmias

be triggered by electrolyte abnormalities (particularly hypokalemia, hypomagnesemia, and hypercalcemia), certain drugs, and stimulants. In addition to check electrolytes, magnesium and calcium, EKG, echocardiogram, a 24 h. Holter monitor is needed to assess their frequency, morphology, and effect on cardiac function.

PVCs are very common in the general population, and isolated events in patients with healthy hearts do not require treatment. However, in the

Telegram: @medical_k

www.konkur.in

setting of MI, ischemia, HF, and structural heart disease, they warrant immediate cardiology referral. First-line therapy for symptomatic patients is either a β-blocker, or non-dihydropyridine CCB, or antiarrhythmic drugs. Some patients may benefit from electrophysiology study (EPS) and catheter ablation if specific foci are identified. PVCs also can present in bigeminy, trigeminy, or quadrigeminy patterns when followed by one, two, or three normal beats, respectively (Fig. 4). Their clinical significance depends on their frequency, morphology, complexity, and patient's hemodynamic response.

Ventricular Tachycardia (VT)

It is defined as more than 3 PVCs in a row and HR > 100 beats/ min. VT is further characterized by duration and morphology [50]. Non-sustained VT lasts for <30 s. Sustained VT lasts >30 s, is symptomatic, and causes hemodynamic instability. VT may have single morphology (single focus), or may be polymorphic (two or more foci). Polymorphic rhythms are seen in patients with structural and ischemic heart disease, and they are associated with worse prognosis. It is key not to confuse VT with SVT associated with BBB or aberrant conduction since treatment is different.

Sustained VT requires emergent cardioversion and eventual ICD placement. Unstable polymorphic rhythms require defibrillation. Antiarrhythmic drugs (procainamide, amiodarone, and, less commonly, lidocaine) can be given to patients with monomorphic, stable, sustained VT, or when VT is refractory to cardioversion. Transvenous pacing may be necessary until a permanent ICD is placed. Patients with VT and ischemic heart disease benefit from β-blockers, ACEI or ARB, and aggressive treatment of HF. Class I antiarrhythmic agents are contraindicated post-MI and in HF. Patients with syncope should have EPS and ablation therapy if indicated.

Ventricular Fibrillation (VF)

This is life-threatening arrhythmia caused by the activation of multiple foci in the ventricles leading to loss of effective ventricular contraction. The EKG shows chaotic rapid polymorphic QRS complexes (Fig. 4). It requires immediate cardiopulmonary resuscitation and emergent defibrillation. VF is a common cause of cardiac arrest, and the use of automatic external defibrillators in the community is aimed to increase the chances of survival while activating the emergency response system. The most common cause of VF is severe CAD, history of MI, ischemia, and scarring. Patients with dilated cardiomyopathy have high mortality. More rare causes include genetic mutations. Long-term treatment of VF include revascularization, beta blockers, and ICD placement [5, 16, 51, 52].

QT Interval Prolongation

The QT interval in the EKG represents the time from the initial depolarization of the ventricles to their full repolarization. Prolongation of this interval can lead to deadly polymorphic ventricular arrhythmias and sudden death, such as torsades de pointes.

The QT interval varies with heart rate and it is necessary to correct for this. A corrected QT interval (QTc) also varies according to gender, for males 470 ms and for females 480 ms.

Hundreds of genetic mutations in K^+ channels which can cause QT prolongation have been identified. Recent progress in electrophysiology and genetic testing helps to identify and stratify patient's risk for these arrhythmias [53].

In addition to antiarrhythmic drugs, there are commonly used drugs in primary care, which can also prolong QT interval. Some examples include macrolide and fluoroquinolones antibiotics, some antihistamines, methadone, antipsychotic, and others.

Therefore, it is important for physicians to be aware of drugs that can prolong QT interval, their potential additive effects, and magnifying effect in the setting on hypokalemia and hypomagnesemia and any condition that causes hypoxia [54].

Torsades de Pointes

It is a rare form of VT characterized by repeated cycles of QRS complex changing in amplitude

Telegram: @medical_k

www.konkur.in

and twisting along the isoelectric axis, giving a unique pattern in the ECG (Fig. 4). It is associated with a significant QT prolongation, >600 ms. Although torsades can self-terminate, it can also degenerate into VF. Treatment requires IV magnesium given under continuous cardiac monitoring (even when Mg is normal). Temporary transvenous pacing can be used, with atrial pacing preferred to maintain the atrial filling, except in patients with AVB where ventricular pacing is best. Long-term therapy includes β-blockers (except in congenital torsades) and permanent pacing. In refractory cases an ICD is necessary, and rarely, thoracic sympathectomy is done.

VF and torsades are associated with sudden cardiac death. Since most events occur outside the hospital, recognition by lay persons, activation of the emergency system, immediate CPR, and defibrillation when indicated are key to survival [16, 51]. This has been the reason to install automatic external defibrillators (AEDs) in public places [51].

Summary

Arrhythmias are commonly seen by family physicians in the office. Immediate recognition of arrhythmias causing cardiovascular instability is key to improving patients' survival, sometimes requiring activation of the emergency system. Full evaluation, diagnosis, and treatment are warranted for all patients presenting with an arrhythmia or with suggestive symptoms, despite normal exams and/or EKGs. Reversible causes should be treated as well as comorbidities. Treatment option is tailored to the type of arrhythmia and must reflect a shared decision-making between patients and doctors, based on best available evidence and the patients' preferences.

Introduction

Valvular heart disease occurs when one or multiple valves of the heart are damaged or diseased. About 2.5% of the US population has valvular heart disease, but it is more common in older adults. About 13% of people born before 1943 have valvular heart disease [1]. In 2017, there were 3046 deaths due to rheumatic valvular heart disease and 24,811 deaths due to non-rheumatic valvular heart disease in the USA. Nearly 25,000 deaths in the USA each year are due to heart valve disease from causes other than rheumatic disease. Valvular heart disease deaths are more commonly due to aortic valve disease [2]. There are several causes of valvular heart disease, including congenital conditions, infections, degenerative conditions (wearing out with age), and conditions linked to other types of heart disease [1]. Valvular heart disease is recognized by finding a heart murmur. Here, even more than elsewhere in cardiology, the physical findings are all important to making a diagnosis and assessing severity. Often, they trump the results of special testing. Murmurs may first be detected in a symptomless patient, perhaps a young would-be athlete at a high school physical examination, or they may be the clue in someone with dyspnea and fluid retention that valvular disease is the reason for their cardiac failure [3]. The family physician is in a particularly challenging position because we will be addressing these potential concerns at every stage of life and often may be dealing with determining the significance of a new heart sound as an incidental finding. Valvular disease may lead to decreased functional status, permanent structural changes, and increased mortality. Timely diagnosis and appropriate testing and consultation are the goals of the family physician, in order to prevent the negative sequelae of inappropriately addressing valvular disease. Learning maneuvers and understanding the sounds present within the heart facilitate appropriate diagnosis [4].

The Third Heart Sound

The third heart sound (S3) is the most difficult heart sound to identify on auscultation. S3 occurs in early diastole (during passive filling) when the ventricle is dilated and noncompliant. It will be heard after

Telegram: @medical_k

www.konkur.in

S2, with low frequency. Its significance varies depending on to the age of the patient. It can be interpreted as physiologic in patients under 30 years old with no structural or functional cardiac condition (thyrotoxicosis, pregnancy, and anemia). It is suspicious in patients between 30 and 40 years of age and it is considered pathologic in patients older than 40 years old often correlating with dysfunction or volume overload what is seen in patients suffering from pregnancy, thyrotoxicosis, valvular regurgitations, and excessive fluid overload. Right ventricle S3 is best heard (sometimes only) during inspiration because negative intrathoracic pressure increases RV filling with the patient supine. Left ventricle S3 is then best heard during expiration with patient in left lateral decubitus position [5–7].

The Fourth Heart Sound

The fourth heart sound (S4) is produced by augmented ventricular filling, caused by atrial contraction, near the end of diastole. It is auscultated immediately prior to S1 and it is a result of decreased compliance within the ventricles. S4 is similar to S3 and is best heard with the bell of the stethoscope. During inspiration, RV S4 increases while LV S4 becomes less intense. S4 is typically associated with hypertrophy of the ventricles. The fourth heart sound is best heard at the level of the apex and can be also palpable. In general it is accepted that the presence of S4 is highly associated with pathology although there is some disagreement in regards of the presence of audible S4 in absence of cardiac pathology [7, 8].

Physical Exam and Diagnostic Approach

Auscultating heart murmur can be difficult sometimes. In general physicians must exam the patient in a quiet room minimizing external surrounding noises in order to be able to fully characterize the murmur. First step when examining a murmur is to determine relation with the cardiac cycle since all diastolic murmurs must be considered pathologic until proven otherwise. The second step would be grading the murmur. There are several approaches to determine the grade of the murmur. In general every murmur whose intensity is louder than S1-S2 should be considered Grade III or greater and requires further evaluation with echocardiogram. Grade VI can be heard even without the stethoscope. Grade V can be auscultated with the stethoscope half off the chest wall. Grade IV, V, and VI have associated thrill.

Classification of cardiac murmurs (six):

- **Grade I:** Audible under optimal conditions by an expert.
- **Grade II:** Easy to hear with stethoscope but soft.
- **Grade III:** Moderately loud, no thrill.
- **Grade IV**: Very loud with a palpable thrill, with stethoscope on chest.
- **Grade V:** Audible with stethoscope partly off chest with a thrill.
- **Grade VI:** Audible without a stethoscope with a thrill.

Most of the murmurs foundin children and adults are benign innocent murmurs in adults [8]. In general and for practice purposes further workup is warranted in patients with systolic murmurs Grade III or more and in every patient with a diastolic murmur. In such cases an echocardiogram should be ordered as the best initial step.

Physical Maneuvers

Exam room maneuvers may alter the qualities of a murmur and may help to define and diagnose innocent versus pathological murmurs. Maneuvers that increase afterload are better for ruling out murmurs than ruling in. Methods of increased peripheral resistance, such as the patient gripping something hard, decreases outflow from the heart and thus decreases outflow, physiologic, and innocent murmur volumes. Decreased preload maneuvers decrease venous return to the heart, so murmurs affected by filling, including innocent and physiologic murmurs and outflow, mitral valve, and tricuspid valve murmurs, will all have a decrease in audible volume.

Telegram: @medical_k

www.konkur.in

Decreasing preload is done best by Valsalva maneuvers. A Valsalva maneuver is executed by asking the patient to take a deep breath, hold it, and bear down like performing a bowel movement.

Increased preload maneuvers increase venous return and filling of the heart. Squatting position is the easiest method to increase preload. Though maybe variable, most outflow murmurs increase in volume when a patient is squatting, and murmurs caused by hypertrophic cardiomyopathy (HCM) or mitral valve prolapse (MVP) decrease in volume [6, 8].

In other words, a larger volume of blood in the heart (increase preload through squatting and lift legs) will increase the audible volume of the murmur except in patients with mitral valve prolapse and hypertrophic cardiomyopathy. Less volume of blood in the heart (decrease preload through Valsalva maneuver) will cause the opposite effect.

Definitions of Severity of Valve Disease

It is important to access the severity of a valvular disease. This allows us to determine if valvular replacement is indicated. Valve replacement are reserved for patient with severe valvular disease. Severity is based on multiple criteria, including symptoms, valve anatomy, valve hemodynamics, and the effects of valve dysfunction on ventricular and vascular function. Indications for intervention and periodic monitoring are dependent on:

1. The presence or absence of symptoms
2. The severity of VHD
3. The response of the LV and/or RV to volume or pressure overload caused by VHD
4. The effects on the pulmonary or systemic circulation [6]

Stages of Valvular Heart Disease

Stage A: Patient with risk factors for developing VHD

Stage B: Patient with a progressive VHD and presence of mild to moderate severity and asymptomatic

Stage C: Patient with asymptomatic severe VHD

- C1: Patient with severe VHD, no symptoms with left/right ventricular function remains compensated
- C2: Patient with severe VHD, no symptoms with decompensated left/right ventricular function

Stage D: Patient with severe VHD who has developed symptoms already [9]

Key Points in Treatment

Treatment and management will be discussed in details under specific topics. In general, valvular diseases are treated either medically or with surgery. Considering that an increase in preload will worsen the severity of the murmur except in mitral valve prolapse and hypertrophic cardiomyopathy, medical management of almost all murmurs must focused on the reduction of the preload and decrease afterload. In MVP and HCM the goal is to improve the filling of the heart. This is achieved by the use of beta blockers (increase filling time/diastole) and avoiding dehydration or any condition that decrease circulating volume.

Aortic Regurgitation (AR)

Aortic regurgitation occurs when the aortic valve does not close tightly due to incompetence of the aortic causing flow from the aorta into the left ventricle during diastole. Causes include idiopathic valvular degeneration, rheumatic fever, endocarditis, myxomatous degeneration, congenital bicuspid aortic valve, syphilis, and connective tissue and rheumatologic disorders. Acute aortic regurgitation is an early diastolic murmur that is the result of the blood flowing retrograde into the left ventricle and has been described as a blowing decrescendo at the left sternal border best heard when patient has held breath after exhalation and is leaning forward [4, 7]. AR can be classified as acute or chronic depending on the onset of presentation. Acute aortic regurgitation derives from a rapid change in the aortic valve causing an acute abnormality, which may arise from etiologies

Telegram: @medical_k

www.konkur.in

including infective endocarditis or changes in the aorta such as aortic dissection. Acute aortic regurgitation is the result of life-threatening abnormalities, and early diagnosis with echocardiogram or CT imaging is crucial to facilitate rapid surgical intervention [4].

Chronic aortic regurgitation is also a diastolic murmur, and as with all diastolic murmurs, a referral to a cardiologist should be considered for echocardiography and further recommendations [4].

Etiology

Acute aortic regurgitation (AR) may result from abnormalities of the valve, most often endocarditis, or abnormalities of the aorta, primarily aortic dissection. Acute AR may also occur as an iatrogenic complication of a transcatheter procedure or after blunt chest trauma. The acute volume overload on the LV usually results in severe pulmonary congestion, as well as a low forward cardiac output. Urgent diagnosis and rapid intervention are lifesaving [9].

Chronic AR has a wide variety of causes that requires early identification before determining treatment options. Causes can be divided in three groups including conditions that involves the valve itself, the aorta, and diseases affecting both the valve and the aorta [3].

Diseases of the Valve

- Bicuspid aortic valve
- Following endocarditis
- Rheumatic valve disease

Diseases of the Aorta

- Connective tissue disorders
- Marfan syndrome
- Familial aortic ectasia
- Other rare, inherited vascular disorders
- Aortic dissection
- Inflammatory disorders
- Vasculitis (Takayasu disease)
- Giant-cell arteritis
- Syphilis

Diseases Affecting Aorta and Valve

- Spondyloarthropathies
- Ankylosing spondylitis
- Reiter syndrome
- Psoriatic arthropathy

Symptoms and Physical Findings

Acute AR causes symptoms of HF and cardiogenic shock. Patient will present with dyspnea on exertion that can progress to dyspnea at rest, orthopnea, and paroxysmal nocturnal dyspnea (PND), with physical findings typical of left side heart failure such us bilateral symmetric and progressively ascending crackles, associated with tachycardia, hypotension, JVD, and other signs consistent with cardiogenic shock [7].

Chronic AR is typically asymptomatic for years with signs and symptoms of HF developing insidiously. Symptoms associated with chronic aortic regurgitation include syncope, angina, and reduced exercise tolerance. As the disease progresses and left ventricular function begins to decrease, symptoms associated with systolic heart failure may arise including lower extremity edema and increasing dyspnea [4, 7].

The findings on physical examination in patients with chronic AR are primarily related to the increased stroke volume and widened pulse pressure. The peripheral pulses demonstrate an abrupt rise of the upstroke and a quick collapse (water hammer or Corrigan pulse). Apical impulse is hyper-dynamic lateralized to the left and inferiorly. Depending on severity is possible to auscultate a thrill usually over the base of the heart but also can be heard over the carotids and suprasternal notch. The classic murmur of AR is a high-frequency, blowing, and decrescendo diastolic murmur, usually heard in the aortic area but also audible in the left third and fourth intercostal spaces along the sternal border. Initial phases of the disease murmur are mild and present

Telegram: @medical_k

www.konkur.in

only during early diastole but with progression it starts becoming more like a holodiastolic murmur. AR murmur will increase in intensity with increase preload or afterload maneuvers and will feel less intense with maneuvers that decrease blood pressure, such as standing, amyl nitrate inhalation, or the strain phase of the Valsalva maneuver [10].

Most common signs seen in patients with chronic AR are summarized below [3].

Quincke's sign: Nail bed pulsation
Corrigan's pulse: Visible carotid pulsation
de Musset's sign: Head bobbing to pulse
Müller's sign: Uvula bobbing to pulse
Duroziez's sign: Diastolic bruit with compression of the femoral artery at the groin
Hill's sign: Systolic pressure in the leg >10 mmHg higher than measures at the brachial artery
Traube's sign: Pistol-shot sounds best heard over the femoral artery

Diagnosis of Aortic Regurgitation

The initial diagnosis of any suspected valvular disease is with a transthoracic echocardiogram (TTE) which is the best tool to assess valve anatomy and etiology, concurrent valve disease, and associated abnormalities, such as aortic dilation. Doppler echocardiography provides accurate noninvasive determination of valve hemodynamics. For regurgitant lesions, calculation of regurgitant orifice area, volume, and fraction is performed, when possible in the context of a multiparameter severity grade based on color Doppler imaging, continuous- and pulsed-wave Doppler recordings, and the presence or absence of distal flow reversals. Other more invasive procedures sometimes can be used in order to determine a final diagnosis and stratified severity of AR especially when noninvasive tests like TTE cannot provide accurate information or when there is no correlation between noninvasive imaging and clinical findings. In these cases cardiac catheterization should be considered and will provide valuable information that will help significantly in the decision-making process regarding surgical intervention. Exercise testing can be considered in patients which physician is not sure about the real physical limitations the patient is experiencing. Cardiac magnetic resonance imaging is another option for initial evaluation and further follow-up since it can provide highly accurate assessment of LV volumes, mass, and ejection fraction; it can also provide excellent visualization of the aortic root and ascending aorta.

Cardiac MRI can be used to obtain accurate information regarding regurgitant volumes and flow [9, 10].

Natural History, Complications, and Follow-Up

Aortic regurgitation is a chronic progressive condition which causes significant hemodynamic changes in the heart that leads to compensatory remodeling of the left ventricle over time with a subsequent decreased LV function and can eventually lead to severe HF. Once such remodeling is established the probability of full recovery even with appropriate treatment including valve replacement is minimal. With treatment, the 10 years survival for patients with mild to moderate AR is about 80–95%. With timely valve replacement before HF, long-term prognosis is good, however for those with severe AR and HF is really poor. That is why early diagnosis is important and adequate initial workup and follow-up of these patients in order to intervene in a timely manner [4]. Patients with AR requires appropriate clinical and echocardiographic follow-up. New guidelines have established a regular follow-up with transthoracic echocardiogram (TTE) depending on the severity of the disease. For patient with AR Stage B (Progressive) evaluation is needed with TTE every 3–5 years if mild severity symptoms are present. Patients with AR Stage B (Progressive) will be evaluated with TTE every 1–2 years if moderate severity symptoms are noticed. And for severe asymptomatic (Stage C1) patient will need TTE every 6–12 months with the possibility of more frequent evaluation if LV dilation is present [7, 9].

Telegram: @medical_k

www.konkur.in

Medical Therapy and Timing for Surgery

Treatment for acute AR is aortic valve replacement plus treating any underlined medical conditions that led to the AR. Treatment for chronic AR varies depending on symptoms and the degree of LV dysfunction. Patient experiencing symptoms during an exercise testing will require valve replacement before developing signs and symptoms of HF [8]. For asymptomatic patient with chronic AR (Stages B-C), treatment for HTN is recommended when BP is >140/90 (level B recommendation). In patients with severe AR with symptoms and/or LV systolic dysfunction (Stages C2 and D) but prohibited surgical risk guideline–directed medical management (GDMT) for LVEF with ACEI, ARBs and sacubitril-valsartan (Entresto) are recommended (also level B recommendation) [9].

Valve replacement is the goal for treatment of chronic AR. Most recent recommendations are summarized below:

- Surgery is recommended for patients that are symptomatic regardless of LV function
- Asymptomatic patient with LVEF <=55%
- Patients with moderate/severe AR that are undergoing cardiac surgery for other reasons
- Asymptomatic patients with LVEF >55% but left ventricular end systolic diameter >50 mm on echocardiogram, surgery can be considered
- Asymptomatic patients with severe AR and normal LVEF >55%, but with declining EF in at least three serial studies, or if progressive increase LV dilation into the severe range (>65 mm end diastolic dimensions LVEDD) [9]

Aortic Stenosis

Aortic stenosis (AS) is narrowing of the valve orifice obstructing blood flow from the left ventricle to the ascending aorta during systole. Causes include congenital valve disease (unicuspid and bicuspid valve), degenerative sclerosis, and rheumatic disease. Progressive untreated AS will result in a classic triad of syncope, angina, and exertional dyspnea. Eventually heart failure and arrhythmia may develop. A carotid pulse with small amplitude and crescendo-decrescendo ejection murmur are typical of the disease. Diagnosis is based on physical findings and echocardiography. Asymptomatic patient will not require treatment while symptomatic cases can be treated with balloon valvulotomy (especially in children) and valve replacement more commonly used in adults [7].

Etiology

Aortic stenosis (AS) etiologies are diverse. Causes can be divided for practical purposes in congenital and degenerative calcific disease. Congenital causes are unicuspid aortic valve, usually severe and presents in children, and congenital bicuspid aortic valve with a murmur that can be present since childhood and it is recognized as the most common cause of AS as well as AR. AS secondary to bicuspid aortic valve develops in middle age with associated valve calcification.

Degenerative calcific AS develops usually later in life (late middle age) and it is not associated with any congenital anatomic defect (trileaflet aortic valve). The earliest manifestation is the aortic sclerosis characterized as thickening of the leaflets, with the presence of heart murmur, and a gradient less than 25 mmHg. Progression of this sclerosis is pathologically similar to that of atherosclerosis and it is linked to the same risk factors [11–13].

Another significant cause of AS is rheumatic disease which tends to be much more common in developing countries where rheumatic fever is highly prevalent. Patients who have suffered rheumatic fever can have not only aortic valve disease but also mitral regurgitation/stenosis. Rheumatic valve disease is characterized by fusion of the commissures between the leaflets resulting in stenosis of the orifice which is histologically typical of rheumatic disease [14].

Symptoms and Physical Findings

Congenital AS is usually asymptomatic until around the ages between 10 and 20 years old

Telegram: @medical_k

www.konkur.in

when symptoms start to develop insidiously. Regardless of the etiology untreated AS ends up a classic triad that includes syncope, angina, and exertional dyspnea. Other clinical manifestations and physical findings are those related to heart failure and arrhythmia, when ventricular fibrillation can be potentially fatal. In general symptoms of AS are absent until AS is severe enough (valve area <1 cm^2, the jet velocity is over 4 m/sec, and/or the transvalvular gradient exceeds 40 mmHg).

Unlike AR there are no visible signs associated with AS. Carotid and other peripheral pulses are diminished and delayed on exam compared to LV contraction (pulsus parvus et tardus). LV impulse is displaced when signs and symptoms start to develop. A palpable fourth heart sound can be felt at the apex with a systolic thrill best felt at the level of the left upper sternal border present in severe cases only. Systolic blood pressure is elevated in mild and moderate cases with a drop when AS becomes severe.

The classic sign on auscultation is a crescendo-decrescendo ejection murmur best heard with the stethoscope placed at the left upper sternal border with the patient sitting and leaning forward. The intensity of the murmur is soft when obstruction is not severe and louder when progresses to a severe form of the disease, when the crescendo phase tends to longer and the decrescendo phase becomes shorter. Murmur is louder with maneuvers that increase left ventricular volume [7, 15].

Diagnosis of Aortic Stenosis

Diagnosis of AS is suspected by symptoms and physical exam and finally confirmed by echocardiography. Medical and interventional treatments rely on an accurate diagnosis and staging of the disease. As any other valvular disease staging is based on the presence of symptoms and hemodynamics identified on echocardiogram. Stage A are patients identified as at risk of having AS and includes patients with congenital aortic disease and aortic sclerosis. Stage B are patients with no symptoms with mild to moderate AS. And Stage D are considered patients with severe AS with the classic clinical manifestations.

Transthoracic echocardiogram (TTE) is the recommended test for an accurate diagnosis of the cause, hemodynamic assessment of the severity, and to determine LV size and systolic function in order to understand prognosis and timing for valve intervention, as well as other associated valvular diseases. Severity of AS can be misinterpreted in the presence of elevated uncontrolled hypertension and thus is recommended to reassess with TTE in such cases when BP is adequately controlled.

Dobutamine stress echocardiography is used to distinguish severe AS with LV systolic dysfunction and primary causes of myocardial dysfunction with less than severe AS.

Aortic valve calcification is a strong predictor of progression and clinical outcome. Calcium deposition can be determined by CT imaging. Agaston score threshold for severe AS in women is 1300 and 2000 in men. CT imaging also is used for procedural planning in patients undergoing TAVI, for measurement of annulus area, leaflet length, and the annular-to-coronary ostial distance.

Cardiac catheterization is used sometimes to determine if the presence of angina is secondary to coronary artery disease or when there is discordance between clinical findings and echocardiographic results. EKG and chest X rays can be useful and may show signs of LVH, axis deviations, electrical blocks, ST-T changes, cardiomegaly, and calcification of the aortic cusps. Exercise stress test can be useful in patients with AS that are asymptomatic and when the functional capacity of the patient is not clear. Exercise-induced angina, early dyspnea on exertion, dizziness, and syncope during test are considered symptoms of AS [7, 9].

Natural History, Complications, and Follow-Up

The natural progression of AS could be either slow or rapid and thus requires regular follow-up and evaluation especially in sedentary elderly patient in which functional status sometimes is unclear. Patients with mild disease are unlikely

Telegram: @medical_k

www.konkur.in

to develop symptoms due to AS over the course of 5 years. Untreated patient has a mean survival of 5 years after angina starts, 4 years after syncope, and 3 years after signs and symptoms of CHF appear. Progression has significant individual variability. Older patients are more likely to have rapid progression [7, 9, 15, 16]. For asymptomatic patients with severe AS the event-free survival rate is 56–63% at 2 years and 25–33% at 4 to 5 years [17].

Regular follow-up is very important considering that symptoms tend to progress insidiously and patients cannot recognized them clearly. Follow-up visits must include clinical and echocardiographic (TTE) assessments with the main goal of preventing severe irreversible diseases. Stage B patient with mild and moderate disease will require TTE every 3–5 years and 1–2 years, respectively. Stage C1 patient needs to be evaluated with TTE every 6–12 months. Patients classified in higher categories are candidates for interventions and need a different approach [9].

Medical Therapy and Timing for Surgery

Treatment of AS will depend on if the patient is asymptomatic or symptomatic. For asymptomatic patients regular clinical follow-up and TTE are indicated in order to identify early symptoms and signs of AS. Even when there is no medical therapies that have proven to delay the progression it is still recommended a conventional CVD risk assessment and treatment based on guidelines considering that some studies have shown that valve calcification and progression are increased in patients with LDL cholesterol >130 [6, 15, 18]. Patients with associated hypertension must be adequately controlled with close monitoring and careful titration of the medications to avoid hypotension. Hypertensive patients with more severe AS requires a greater degree of caution when treated. There are no studies studying the use of specific antihypertensive medications, although it is known that diuretics decrease the stroke volume and thus should be avoided in AS patients. ACE inhibitors may be beneficial preventing LV fibrosis, in addition to control of hypertension [6, 17, 19]. Patients requiring medical management must be treated with ACE inhibitors, ARBs, and beta blockers in order to optimize left ventricular systolic dysfunction [4]. Nitrates are contraindicated because of its effects lowering preload. Patients with AS may require antibiotic prophylaxis prior to dental work and other potentially contaminated procedures [3].

Aortic valve replacement (AVR) is the definitive treatment for AS. All symptomatic patients thought to be secondary to AS are candidates for AVR. Asymptomatic patients with severe AS with or without LVEF <50% are also accepted as candidates for AVR. Other clinical scenarios must be evaluated more carefully before recommended surgical intervention [9].

Hypertrophic Obstructive Cardiomyopathy

Etiology

Hypertrophic obstructive cardiomyopathy (HOCM) is a heart condition that arises from genetic mutations in multiple sarcomere genes. These genes are responsible for the proper structural integrity of protein that makes up the contractile apparatus of the heart. There is an incidence of 1 in every 500 individuals worldwide, with an estimated 1% annual mortality rate [20]. It is among the most common causes of sudden cardiac death in young athletes in the USA. Hypertrophic cardiomyopathy is inherited in an autosomal dominant pattern. However, there is varying penetrance depending on the genetic mutation involved [21].

Signs and Symptoms

Individuals tend to have a thickened interventricular septum of the heart leading to left ventricular outflow obstruction. While some patients may be asymptomatic, others present with symptoms due to this outflow obstruction,

Telegram: @medical_k

www.konkur.in

especially with exertion. This may include chest pain, dyspnea, palpitations, malaise, presyncope, or exertional syncope due to cardiogenic shock. Cardiogenic shock in such patients may not always present with autonomic prodromal symptoms as in the case of other benign syncopal etiologies. Syncope due to cardiogenic shock tends to resolve once cardiac output is restored [22].

Physical Findings

There are no clear specific findings for HOCM, but there are those that would prompt further evaluation leading to this diagnosis. On examination, a systolic ejection murmur can be heard on auscultation. There are different maneuvers that change the intensity of the murmur. Standing and Valsalva strain phase causes decreased venous return to the heart, resulting in decreased left ventricular cardiac output. The left ventricular outflow track is narrowed, and can be exacerbated by anterior motion of the mitral valve leaflets. This then increases the intensity of the murmur. Squatting, handgrip, or supine leg raise, however, causes increased venous return. This volume increases the left ventricular outflow tract and lessens obstruction by systolic anterior motion of the mitral valve. As a result, squatting, handgrip, or supine decreases the intensity of the murmur. Some nonspecific findings for individuals with HOCM include voltage changes as seen on EKG, confirming left ventricular hypertrophy. Echocardiogram and cardiac MRI are specific and diagnostic. Chest X-Ray may reveal left atrial enlargement due to mitral regurgitation [23].

Natural History and Complications

Medical Therapy and Timing of Surgery

Some patients may be hypotensive in response to exercise, or have episodes of ventricular tachycardia resulting in cardiogenic shock and syncope. Complications include sudden cardiac death. There are those that develop heart failure or atrial fibrillation as a sequela of left ventricular dysfunction.

Individuals diagnosed with hypertrophy obstructive cardiomyopathy are to avoid high-intensity physical activity that could further exacerbate cardiac outflow. Patients that are clinically stable can be actively monitored with echocardiogram every one to two years. Those with left ventricular outflow tract obstruction can be managed with non-vasodilating beta blockers as first-line therapy. Non-dihydropyridine calcium channel blockers, including Verapamil and Diltiazem, are second-line agents for those that are unable to tolerate beta blockers. Individuals that develop atrial fibrillation or heart failure as a sequela of poor left ventricular function can be managed by using respective agents for atrial fibrillation and heart failure. In the setting of atrial fibrillation, anticoagulation therapy is indicated irrespective of CHA2DS2-VASc score. Other more invasive measures such as implantable defibrillators may be indicated for those with increased risk of sudden cardiac death. Those increased risks include prior history of cardiac arrest, a family history of sudden cardiac death, ventricular tachycardia, or recurrent exertional syncope [24].

Mitral Stenosis

Etiology

The most common cause of mitral stenosis is rheumatic heart disease. Rheumatic mitral stenosis is commonly seen in developing countries more so than developed countries. If seen in developed countries such as the USA, the outbreak tends to arise from increased virulence of streptococcal strain or from someone that is from an area with high prevalence of the disease. Rheumatic mitral stenosis is caused by cross-reactivity of the streptococcal antigen and the valvular tissue, and not due to an infectious process on the valve. This cross-reactivity causes an inflammatory process to occur that damages the mitral valve. Calcifications of the mitral valve leaflets, fusion of the leaflet commissures, and fibrotic changes to the chordae tendinae can occur. The severity of this inflammatory process in addition to recurrence determines the extent of the structural damage. Other causes of mitral stenosis,

Telegram: @medical_k

www.konkur.in

although less common, include congenital, systemic rheumatic disease (as seen in patients with systemic lupus erythematosus, rheumatoid arthritis) as well as radiation therapy as seen in patients with a history of Hodgkin's lymphoma [25].

Signs and Symptoms

Individuals tend to present with shortness of breath and exertional dyspnea. Due to increased left atrial pressure and resultant pulmonary edema, some patients may present with hemoptysis. Hoarseness and cough due to compression of the recurrent laryngeal nerve by increased left atrial pressure can also be seen. Hoarseness would be part of a constellation of other symptoms as seen in cardiovocal syndrome (Ortner's Syndrome) [26].

Physical Examination

On auscultation, a loud first heart sound can be heard, accompanied by an opening snap and mid-diastolic rumble. This can be best heard at the cardiac apex. Mitral stenosis, when severe, can cause pulmonary hypertension from increased left atrial pressure. Patients with pulmonary hypertension can develop mitral facies, with pink-purplish patches noted on examination due to capillary vasodilation. Patients that develop right heart failure can present with edema. Chest X-ray imaging may show dilated pulmonary vessels, and flattening of left heart border due to left atrial enlargement [27].

Natural History and Complications Medical Therapy and Timing of Surgery

Mitral stenosis is generally slow to progress from asymptomatic to severe. Thus asymptomatic patients can be monitored by echocardiograms. The frequency of echocardiograms is every 3–5 years when the mitral valve area is >1.5 cm squared; then, in severe mitral stenosis, it is every 1–2 years when the mitral valve area is 1.0–1.5 cm squared; then it is once a year when the mitral valve area is <1.0 cm squared [28].

Patients with rheumatic mitral stenosis associated with atrial fibrillation, left atrial thrombus, or prior history of an embolic events should be placed on anticoagulation. Patients with tachycardia at rest or with exertion are considered symptomatic and may benefit from a beta blocker to manage symptoms. Surgical/operative management may be indicated in some instances.

Mitral Regurgitation

Etiology

Mitral regurgitation can be classified as acute versus chronic, and divided into primary versus secondary depending on the etiology.

In primary mitral regurgitation, there is organically or structurally a component of the mitral valve (leaflets, chordae tendinae, annulus, or papillary muscles) that is defective, incompetent, or damaged resulting in backflow during systole. The leading cause of primary mitral regurgitation, and mitral regurgitation in general, is mitral valve prolapse among other degenerative mitral valve diseases. Although uncommon in the USA, rheumatic heart disease often results in mitral regurgitation in the first two decades of life. Other causes of primary mitral regurgitation include infective endocarditis, trauma, mitral annular calcifications, or drug induction [29].

Mitral regurgitation due to secondary causes arise from functional incompetence of the valve, and not due to structural defect. This is typically seen in patients with coronary artery disease or cardiomyopathy. Patients with coronary artery disease, including those with a history of myocardial infarction, can have resultant regional wall motion abnormalities. This leads to improper closure of mitral valve leaflets. In patients with hypertrophic cardiomyopathy, mitral regurgitation can occur due to anterior motion of the mitral leaflets. In dilated cardiomyopathy, findings are a result of dilation of the annulus and displacement of the papillary muscles.

Telegram: @medical_k

www.konkur.in

Signs and Symptoms

In acute mitral regurgitation, patients can present with symptoms of hypotension, pulmonary edema, and cardiogenic shock. Such a scenario would be considered a cardiac emergency and can be seen in patients with infectious endocarditis and inferior myocardial infarction due to rupture of papillary muscles. In chronic mitral regurgitation, there is a compensatory left atrial enlargement and left ventricular dilation that allows for adequate support of cardiac backflow and increased preload. In this setting, patients may not always be symptomatic. In severe cases of chronic mitral regurgitation, patient can present with exertional dyspnea and fatigue. Patients with mitral valve prolapse may complain of palpitations. Although less common than in mitral stenosis, patient may present with hemoptysis, thromboembolism, and symptoms of right heart failure.

Physical Examination

On auscultation, a holosystolic murmur can be heard best at the cardiac apex, with radiation to the axilla. The murmur can be blowing with a high-pitched S3. The murmur is louder with leg raise, squatting, and hand grip, as this increases venous return and arterial pressures. Standing tends to decrease the murmur, as this reduces venous return. Some patients have paroxysmal or persistent atrial fibrillation as a consequence of mitral regurgitation. A midsystolic click followed by systolic murmur can sometimes be heard in patients with mitral valve prolapse [30].

Natural History and Medical Therapy

Some studies show that vasodilators improve hemodynamic compensation in acute mitral regurgitation. They tend to reduce aortic pressure, decrease afterload as well as the regurgitant flow. Timely surgical intervention may still be indicated. Surveillance with echocardiogram is key in closely following for any progressive changes with mitral regurgitation. Echo every 3–5 years for mild mitral regurgitation, every 1–2 years for moderate, and 6–12 months in severe mitral regurgitation [31].

Cardiovascular Evaluation of the Young Athlete

Pre-participation screening of young athletes is used to identify any relevant history, physical findings, or symptoms that would raise concern for sudden cardiac death. Young athletes, defined as those under the age of 35, who suffer from sudden cardiac death (SCD) likely had an underlying structural or nonstructural cardiac condition [32]. Structural causes can arise from congenital coronary anomalies or hypertrophic obstructive cardiomyopathy (HOCM). Nonstructural causes such as in Wolf Parkinson White, Long QT Syndrome, and Brugada Syndrome are other possibilities. Even though SCD is rare, it is important to identify any young athletes at risk and further investigate.

Screening should include a focused history and physical examination. Young athletes should be asked if they have experienced symptoms of chest pain, heart palpitations, exertional dyspnea, presyncopal episodes, or syncope especially in the absence of autonomic prodromal symptoms [33]. Any history of myocarditis, endocarditis, elevated cholesterol, elevated blood pressure, or murmurs should be noted. A thorough family history should be taken to determine if any family members younger than 50 years of age died unexpectedly, or passed away from SCD [34, 35]. On physical examination, murmurs should prompt further workup. Although some connective tissue disorders such as Marfan syndrome have a genetic predisposition, there are some mutations that can arise de novo. As such, general inspection is an important component of any examination. Physical features suspicious for Marfan syndrome such as abnormal arm length to height ratio should prompt further cardiac evaluation.

Obtaining an EKG as part of the pre-participation evaluation is still an ongoing debate. When seen, EKG findings help to solidify a

Telegram: @medical_k

www.konkur.in

diagnosis. In HOCM, EKG findings of left ventricular hypertrophy can be seen. In Wolf Parkinson White, EKG would show shortened PR interval, delta wave, and widened QRS. However, the absence of EKG findings does not rule out the possibility of a cardiac condition, especially in the setting of red flags on history. In some instances, patients with cardiac conditions can have a normal EKG, making history taking a reliable tool in screening young athletes [36].

Even with a thorough history and physical examination, there is the chance of overlooking a patient at risk. Having an automated defibrillator in sight and being CPR certified helps to reduce an adverse outcome in symptomatic patients [37].

Definition

Heart failure (HF) is a syndrome in which the heart is unable to pump blood at a sufficient output to meet tissue requirements, or in which the heart can do so only with an elevated filling pressure. The heart's failure to pump is caused by impairment of cardiac contractility (systolic dysfunction) or cardiac filling (diastolic dysfunction). HF is associated with a variety of interrelated structural, functional, and neurohumoral changes. Structurally, this could result from left ventricle dilation, hypertrophy, or both. Functionally, systolic or diastolic dysfunction can cause reduced ventricular filling or ejection of blood, and to compensate, activation of the sympathetic nervous system and renin-angiotensin-aldosterone systems occurs. These neurohormonal changes increase blood pressure and blood volume, further enhancing venous return (preload), stoke volume, and cardiac output to compensate for the cardiac dysfunction. Despite these compensatory mechanisms, the ability of the heart to contract and relax declines with time. These changes also cause HF symptoms of dyspnea on exertion, fluid retention, and fatigue. Because some patients present without signs or symptoms of volume overload, the term "heart failure" is preferred over "congestive heart failure." Early recognition is important because without appropriate therapies and interventions, HF can progressively worsen [1].

Epidemiology

Heart failure is an ongoing public health challenge in the USA. Americans over 40 years old have a 20% lifetime risk of developing HF [1]. With aging of the population, the prevalence of HF continues to rise over time. An estimated 6.2 million American adults $\geq$20 years of age had HF between 2013 and 2016, compared with an estimated 5.7 million between 2009 and 2012.

Telegram: @medical_k

www.konkur.in

The prevalence of HF will increase 46% from 2012 to 2030, resulting in >eight million people ≥18 years of age with HF [2]. Worldwide, there are an estimated 23 million people with HF [3]. The prevalence of HF is highly variable across the world. Prevalence of HF risk factors also varies worldwide, with hypertension being most common in Latin America, the Caribbean, Eastern Europe, and sub-Saharan Africa. Ischemic heart disease is most prevalent in Europe and North America. Valvular heart disease is more common in East Asia and Asia-Pacific countries [3]. The overall prognosis of HF is poor with a 50% mortality rate within 5 years of symptom onset. Appropriate management of HF can significantly stabilize the disease with improvement in symptoms, cardiac function, and survival [1].

Hypertensive men and women have a substantially greater risk for developing HF than normotensive men and women [4]. The incidence of HF is greater with higher levels of blood pressure, older age, and longer duration of hypertension. Long-term treatment of both systolic and diastolic hypertension reduces the risk of HF by approximately 50% [4]. Obesity and insulin resistance are also important risk factors for the development of HF. The presence of clinical diabetes markedly increases the likelihood of developing HF in patients without structural heart disease and adversely affects the outcomes of patients with established HF [1]. Fortunately, the appropriate treatment of hypertension, diabetes mellitus, and dyslipidemia can significantly reduce the development of HF.

Classification

HF is classified based on the left ventricular ejection fraction (EF). The echocardiogram will define HF preserved EF (HFpEF) as greater than 50%, mid-range EF (HFmrEF) between 49 and 41%, and reduced EF (HFrEF) as lower than 40% [5]. Symptom severity is graded according to the New York Heart Association (NYHA) functional class designations (class I, no limitation in normal physical activity; class II, mild symptoms only during normal activity; class III, marked symptoms during daily activity, comfortable only at rest; and class IV, severe limitations and symptoms even at rest). While the NYHA classification is a simple way to classify HF symptoms, it is nevertheless a subjective measure affected by the patient and physician expectations. The American College of Cardiology (ACC) and the American Heart Association (AHA) created HF stages that emphasize the progressive nature of HF and defines the appropriate therapeutic approach for each stage. Table 1 demonstrates the overlap and progression of the ACC/AHA stages and NYHA classes [1]. HFrEF has effective evidence-based therapies that improve morbidity and mortality, while HFpEF still lacks the same amount of therapies.

Table 1 Classification of HF: ACC/AHA HF stage and NYHA functional class

ACC/AHA HF Stage[1]		NYHA Functional Class[2]	
High risk, no structural heart disease	A	Not applicable	–
Asymptomatic but with structural heart disease (MI, reduced LVEF, valvular disease)	B	Asymptomatic	I
Current or history of symptomatic HF with cardiac structural abnormalities	C	Symptoms with significant exertion	II
		Symptoms on minor exertion	III
Refractory end-stage heart failure	D	Symptomatic at rest	IV

www.konkur.in

Approach to the Patient

The approach to determining the cause and severity of heart failure (HF) includes the history, physical examination, and diagnostic tests. Initial tests include an electrocardiogram, initial blood tests, echocardiogram, and assessment for coronary artery disease. Demonstration of an underlying cardiac cause is key to the diagnosis of HF. This is usually a myocardial abnormality causing systolic and/or diastolic ventricular dysfunction. However, abnormalities of the valves, pericardium, endocardium, heart rhythm, and conduction can also cause HF (and more than one abnormality is often present). It is crucial to identify the underlying cardiac problem for therapeutic reasons, as the precise pathology determines the specific treatment used.

Diagnosis

History

A detailed history and physical examination should be obtained in patients presenting with HF to identify cardiac and noncardiac disorders or behaviors that might cause or accelerate the development or progression of HF. Typical symptoms include dyspnea, orthopnea, paroxysmal nocturnal dyspnea, fatigue, and ankle swelling. Other symptoms of right-sided heart failure that may be present but are more nonspecific include abdominal bloating, right upper-quadrant discomfort, and early satiety. In patients with idiopathic dilated cardiomyopathy, a three-generational family history should be obtained to aid in establishing the diagnosis of familial dilated cardiomyopathy [1].

Physical Examination

Patients should be examined for markers of congestion and reduced peripheral perfusion (Table 2). Patients with more signs of congestion (jugular venous distension, edema, lung rales, and S3 gallop) are at higher risk of cardiovascular death or heart failure hospitalization independent of symptoms, natriuretic peptides, and validated risk scores. As a result of compensatory upregulation in lymphatic drainage, patients with chronic HF may lack lung rales or peripheral edema, even when pulmonary capillary wedge pressure is elevated [6]. The clinical assessment of left-sided filling pressures relies heavily on the presence of symptoms (e.g., dyspnea, paroxysmal nocturnal dyspnea, orthopnea, and S3 gallop) and evidence of elevation in right-sided filling pressures (e.g., jugular venous distension, hepatojugular reflux, and edema). Markers of low cardiac output state include diminished peripheral pulses, cool extremities, pallor, peripheral cyanosis, sluggish capillary refill, presence of pulsus alternans, and a low pulse pressure.

Table 2 Initial evaluation for diagnosing symptoms and signs in heart failure with reduced ejection fraction

Typical symptoms
Dyspnea
Orthopnea
Paroxysmal nocturnal dyspnea
Fatigue
Reduced exercise tolerance
Ankle swelling
Cough
Abdominal distension
Wheeze
Abdominal bloating
Early satiety
Bendopnea
More specific signs
Elevated jugular venous pressure
Positive abdominojugular reflux
S3 (gallop rhythm)
Laterally displaced apical impulse
Less specific signs
Lung rales
Peripheral edema
Ascites
Cool and/or mottled extremities
Narrow proportional pulse pressure (pulse pressure: Systolic blood pressure ratio 0.25)
Murmur of valvular regurgitation or stenosis
Weight loss and cachexia (advanced HF)

Modified from Murphy et al. [6]

Laboratory and Imaging

A number of laboratory tests can aid in the diagnosis of HF and can help risk stratify patients with known HF. At the time of diagnosis, laboratory

Telegram: @medical_k

www.konkur.in

work should focus on evidence of end-organ involvement, including assessment of renal function and liver abnormalities. Initial testing involves the measurement of natriuretic peptides, electrocardiography, chest X-ray, and echocardiogram. Further laboratory assessment should be considered based on suspicion of other causes or if findings suggest further investigation (Table 3).

B-Type Natriuretic Peptide

B-Type natriuretic peptide (BNP) is a cardiac neurohormone secreted from the ventricles in response to stretching and increased wall tension from volume and pressure overload. Cleavage of the prohormone proBNP produces biologically active BNP as well as biologically inert NT-proBNP. Changes in natriuretic peptide levels in response to HF therapy have been shown to correlate with changes in pulmonary wedge pressure. The measurement of natriuretic peptide levels in patients presenting with dyspnea in the emergency department outperforms clinical judgment for the diagnosis of HF (Table 4). It is important to realize that natriuretic peptides can be elevated in disease processes other than HF (e.g., acute pulmonary embolism, COPD, cor pulmonale, anemia, renal failure, sepsis, atrial fibrillation, and myocardial infarction).

Electrocardiogram

An electrocardiogram (ECG) is a useful initial test to evaluate the heart for structural or physiological abnormalities. An abnormal ECG increases the likelihood of the diagnosis of HF, but has low specificity. It is most useful in evaluating other possible causes of HF or reasons for a worsened clinical status. HF is unlikely in patients presenting with a completely normal ECG (sensitivity 89%) [7]. Therefore, the routine use of an ECG is mainly recommended to rule out HF. Signs of previous MI or ischemia, left ventricle hypertrophy, left bundle branch block (LBBB), or atrial fibrillation can all be present and assist in guiding further treatment options. A LBBB in the presence of HF is a very poor prognostic sign with

Table 3 Laboratory evaluation for heart failure and selected alternate causes

Initial tests
BNP or NTproBNP level (Heart failure)
Complete blood count (Anemia, infection)
Serum electrolytes (Diuretics, cause of arrhythmia)
Liver profile (Hepatic congestion, alcoholism)
Renal function (Renal disease, volume overload)
Thyroid stimulating hormone (Thyroid disorders)
Urinalysis (Renal disease)
Other tests for alternative causes
Arterial blood gases (Hypoxia, pulmonary disease)
Blood cultures (Endocarditis, systemic infection)
Human immunodeficiency virus (Cardiomyopathy)
Lyme serology (Bradycardia/heart block)
Thiamine level (Deficiency, beriberi, alcoholism)
Troponins, creatinine kinase-MB (Myocardial infarction)
Ferritin, iron levels (Hemochromatosis)
Urine or serum drug screen (Cocaine use)
Tests for comorbid conditions, risk management
A1C level (Diabetes mellitus)
Lipid panel (Hyperlipidemia, cardiovascular risk)

increased one-year mortality overall and from sudden cardiac death [8]. A QRS interval of >0.12 and a LBBB pattern in a HF patient would be a consideration to refer to a cardiologist or electrophysiologist to evaluate for an implantable device after medical optimization.

Chest Radiograph

A chest radiograph in HF can reveal cephalization, interstitial or alveolar edema, the presence of effusions, or Kerley B lines. The absence of these findings does not rule out HF. Of note, the chest radiograph can help identify other etiologies of dyspnea such as pneumonia, COPD, thoracic mass, or pneumothorax.

Cardiac Imaging

Echocardiography is the most important imaging tool to diagnose HF. It provides assessment of chamber dimensions, biventricular function, valvular stenosis/regurgitation, wall thickness, wall motion, and filling pressures/patterns (diastolic function), including hemodynamics.

Cardiac magnetic resonance imaging, although not readily available, provides high anatomical resolution of all aspects of the heart and surrounding structure, leading to its recommended use in known or suspected congenital heart diseases [1]. It can also evaluate ischemia and identify inflammatory or infiltrative causes of HF without radiation exposure. Cardiac magnetic resonance imaging allows accurate assessment of biventricular function, quantitation of valvular regurgitation and/or stenosis, tissue characterization, and assessment of both microvascular and epicardial perfusion. It can assist in the diagnosis of the underlying etiology of cardiomyopathy, such as infiltrative cardiomyopathies, myocarditis, prior infarction, suggesting an ischemic etiology. Also, a cardiac magnetic resonance is an excellent method to assess myocardial viability in patients with impaired LV function and significant coronary disease when deciding on the utility of revascularization.

Given that 50% of HFrEF cases are of ischemic etiology, patients with a new diagnosis of HFrEF usually require an evaluation for coronary artery disease, although other patient-specific factors (e.g., advanced age, multiple severe comorbidities, noncandidates for revascularization, or choosing not to undergo coronary revascularization procedures) should be considered prior to referral. Coronary angiography is the criterion standard test for identification of obstructive epicardial coronary artery disease, although noninvasive testing with coronary-computed tomography angiography may be considered in patients with low pretest probability for coronary atherosclerosis. Stress testing is less useful because of lower sensitivity and specificity [6].

Special Testing

Hemodynamic monitoring is indicated in patients with clinically indeterminate volume status, those refractory to initial therapy, patients with hypotension, and/or worsening renal function particularly if intracardiac filling pressures and cardiac output are unclear.

To allow physicians to discuss prognostic information with patients and aid in decision-making, a commonly utilized model is the Seattle Heart Failure Model (SHFM). The model also allows the clinician to add or subtract an assortment of treatment regimens, including medical therapies and devices, to assess how these changes affect mortality. There is a simple, free, online score calculator that is readily accessible.

Differential Diagnosis

Patients with HF may present with complaints of decreased exercise tolerance, fluid retention, or both. Many of the symptoms and signs of HF are nonspecific, so other potential causes should be considered such as cardiac and noncardiac causes. Cardiac causes include arrhythmias, structural heart disease, valvular disease, and myocardial infarction. Noncardiac causes include processes that increase the preload (volume overload and renal failure), increase the afterload (hypertension), reduce the oxygen-carrying capacity of the

Telegram: @medical_k

www.konkur.in

blood (anemia, pulmonary diseases), or increase demand (sepsis).

Treatment

In heart failure management, the goals are to reduce mortality and morbidity by improving functional status and health-related quality of life, reducing symptoms, and decreasing the risk of hospitalization [9]. Based on the severity of the illness, nonpharmacologic therapies include dietary sodium and fluid restriction and physical activity as appropriate. Figure 1 shows a treatment strategy for the use of drugs (and devices) in patients with HFrEF. The recommendations for each treatment will be summarized ahead.

Heart Failure with Reduced Ejection Fraction

The standard therapy for HFrEF includes loop diuretics for fluid and symptom control as well as angiotensin-converting enzyme inhibitor (ACEI), an angiotensin receptor blocker (ARB), or an angiotensin receptor neprilysin inhibitor (ARNI), and beta-blocker therapy,

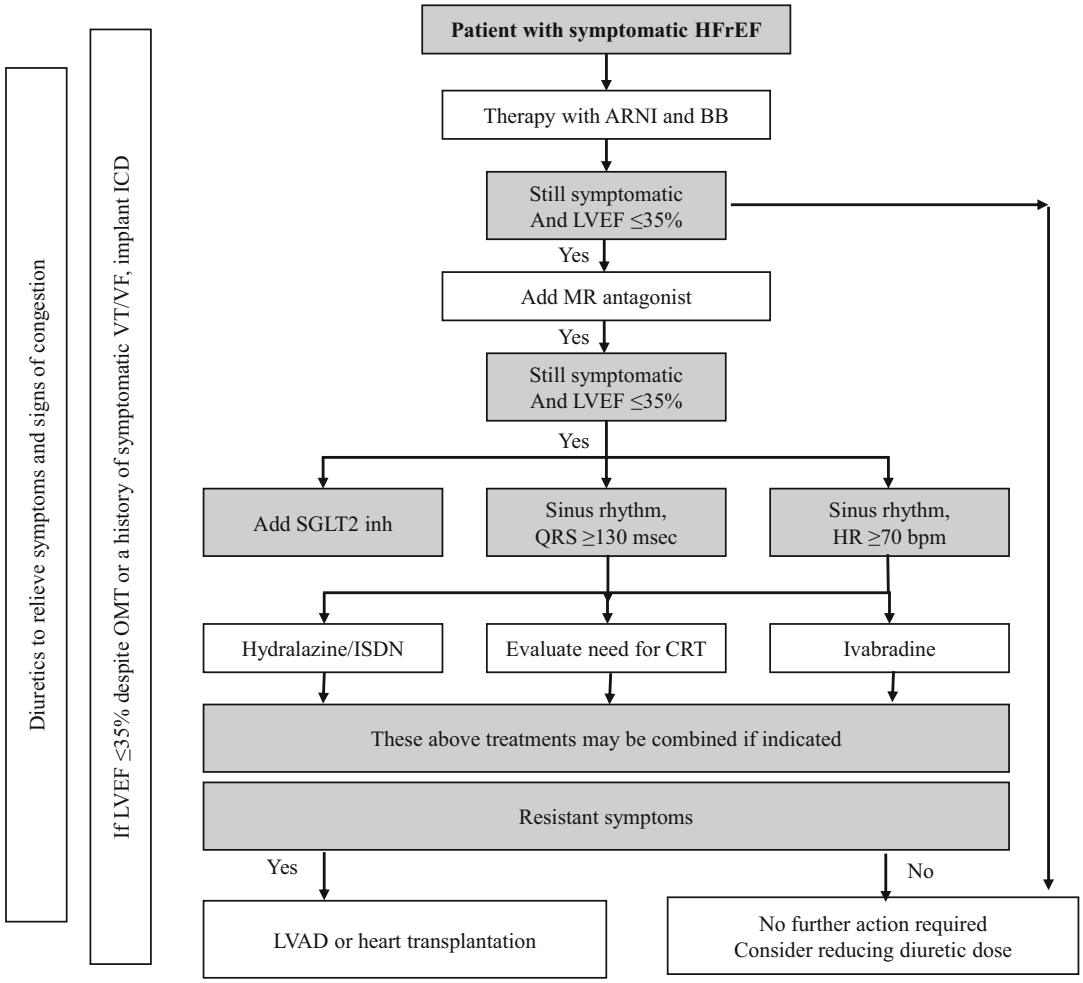

Fig. 1 Therapeutic algorithm for a patient with symptomatic heart failure with reduced ejection fraction. (Modified from Ponikowski P, et al. [22])

Telegram: @medical_k

www.konkur.in

mineralocorticoid receptor antagonist (MRA), and more recently SGLT-2 inhibitors to improve morbidity and mortality. Appropriate starting doses of drug therapies and evidence-based targets are listed in Table 5.

Diuretics

Diuretics are an important treatment for patients with HF and evidence of volume overload. They also have not been proven to have a long-term mortality benefit [1]. The goal of loop diuretic therapy is to manage fluid retention and achieve and maintain a euvolemic state. The majority of HF patients are treated with loop diuretics, such as furosemide, bumetanide, or torsemide. Torsemide has the advantage of greater, and more consistent, bioavailability following oral dosing, Diuretic resistance can be due to inadequate diuretic dose, excess sodium intake, reduced diuretic absorption, impaired diuretic urinary excretion (due to chronic kidney disease, advanced age, or poor cardiac output), and concomitant medications (e.g., nonsteroidal anti-inflammatory agents). Treatment approaches to refractoriness to loop diuretics include increased dose, dividing into multiple daily doses, switching from furosemide to torsemide, and adding a thiazide diuretic, such as chlorothiazide or metolazone. It is important to monitor electrolytes as well as the renal function during titration of diuretics. Initial,

maximum, and equipotent oral and intravenous (IV) dose equivalents are listed in Table 6.

Renin-Angiotensin System Inhibition

Renin-angiotensin system inhibition with ACE Inhibitor, ARB, or ARNI angiotensin-converting enzyme inhibitors (ACEI) reduce morbidity and mortality in HFrEF. Clinical trials clearly establish the benefits of ACEI in patients with mild, moderate, or severe symptoms of HF. ACEI can produce angioedema and should be given with caution to patients with low systemic blood pressures, renal insufficiency, or elevated serum potassium. They also inhibit kininase and increase levels of bradykinin, which can induce cough but also may contribute to their beneficial effect through vasodilation [10].

Angiotensin receptor blockers (ARBs) do not inhibit kininase and are associated with a much lower incidence of cough and angioedema than ACE inhibitors. Long-term therapy with ARBs produces hemodynamic, neurohormonal, and clinical effects consistent with those expected after interference with the renin-angiotensin system and have been shown to reduce morbidity and mortality, especially in ACE inhibitor–intolerant patients.

In ARNI, an ARB (valsartan) is combined with an inhibitor of neprilysin (sacubitril), an enzyme that degrades natriuretic peptides, bradykinin, adrenomedullin, and other vasoactive peptides. In a landmark trial that compared the first approved ARNI, valsartan/sacubitril, with enalapril in symptomatic patients with HFrEF tolerating an adequate dose of either ACE inhibitor or ARB, the ARNI reduced the composite endpoint of cardiovascular death or HF hospitalization significantly, by 20% [11]. The benefit was seen to a similar extent for both death and HF hospitalization and was consistent across subgroups. The use of ARNI is associated with the risk of hypotension and renal insufficiency and may lead to angioedema as well.

Beta-Blockers

Use of beta-blockers is recommended for all patients with current or prior symptoms of HFrEF, unless contraindicated, to reduce morbidity and mortality [1]. Carvedilol (Coreg), metoprolol succinate (Toprol XL), and bisoprolol (Zebeta) are recommended and have proven mortality benefits over other beta-blockers likely due to how they inhibit the sympathetic nervous system which is activated in HF. Even among these three proven beta-blockers, there are some differences. Beta-blockers benefit mortality and disease progression in addition to ACEI therapy and are recommended early after the diagnosis of HFrHF with initiation at low doses along with low-dose ACEI and appropriate titration (Table 5). Beta-blockers should be hemodynamically stable with minimal to no fluid retention before initiation and are contraindicated with bradycardia, hypotension, hypoperfusion, second- or third-degree atrioventricular block, or severe asthma or COPD [1].

Mineralocorticoid Receptor Antagonists

Mineralocorticoid receptor antagonists (MRA) are recommended in patients with NYHA class

Telegram: @medical_k

www.konkur.in

II–IV HF and who have LVEF of 35% or less, unless contraindicated, to reduce morbidity, mortality, and HF hospitalization. MRA block receptors bind aldosterone and, with different degrees of affinity, other steroid hormone (e.g., corticosteroids and androgens) receptors. Caution should be exercised when MRAs are used in patients with impaired renal function and in those with serum potassium levels >5.0 mmol/L. Regular checks of serum potassium levels and renal function should be performed according to clinical status.

Hydralazine and Isosorbide

The combination of hydralazine and isosorbide dinitrate is recommended to reduce morbidity and mortality for patients self-described as African Americans with NYHA class III–IV HFrEF receiving optimal therapy with ACE inhibitors and beta-blockers, unless contraindicated [1]. It can be useful to reduce morbidity or mortality in patients with current or prior symptomatic HFrEF who cannot be given an ACE inhibitor or ARB or ARNI because of drug intolerance, hypotension, or renal insufficiency, unless contraindicated.

Ivabradine

Ivabradine is an agent that selectively inhibits current in the sinoatrial node, providing heart rate reduction without affecting blood pressure, myocardial contractility, or intracardiac conduction. Ivabradine can be beneficial to reduce HF hospitalization for patients with symptomatic (NYHA class II-III) stable chronic HFrEF who are receiving guideline medical therapy, including a beta-blocker at maximum tolerated dose, and who are in sinus rhythm with a heart rate of 70 bpm or greater at rest [10].

Digoxin

Digoxin may be considered in patients in sinus rhythm with symptomatic HFrEF to reduce the risk of hospitalization (both all-cause and HF hospitalizations) [5]. Digoxin level should be monitored a week after initiation for a goal level less than 1 ng/mL, also toxicity risk is higher in the elderly, causing hypomagnesemia, hypokalemia, and renal dysfunction.

New Therapies Awaiting Guideline Recommendation

SGLT-2 Inhibitors

The US Food and Drug Administration recently approved the use of dapagliflozin for treatment of HFrEF, irrespective of diabetes status, and it is anticipated that dapagliflozin will be added to guideline-directed medical therapy for all patients with HFrEF in the 2021 American College of Cardiology/American Heart Association heart failure guideline [6]. The DAPA-HF (Dapagliflozin and Prevention of Adverse Outcomes in Heart Failure) trial evaluated the effect of dapagliflozin in patients with HFrEF with and without type 2 diabetes [12]. Dapagliflozin reduced the primary end point of worsening heart failure or cardiovascular death, cardiovascular mortality, and all-cause mortality compared with placebo. SGLT2 inhibitors are contraindicated in patients with type 1 DM, type 2 DM with risk factors for ketoacidosis, or severely impaired or rapidly declining kidney function. In the DAPA-HF trial, dapagliflozin demonstrated a reduction in CV death and HF hospitalization in patients with and without type 2 diabetes (T2D) [12]. In addition, the EMPEROR-reduced (Empagliflozin Outcome Trial in Patients with Chronic HFrEF) trial demonstrated a reduction in HF hospitalization/CV death from empagliflozin treatment in patients with HFrEF with and without diabetes [13]. As such, it is clear that SLGT2 inhibitors exhibit a beneficial class effect in patients with HFrEF.

Vericiguat

Vericiguat is an oral soluble guanylate cyclase stimulator that increases activity of the second messenger cyclic guanosine monophosphate

Telegram: @medical_k

www.konkur.in

(cGMP), which is involved in regulation of protective cardiovascular, kidney, and metabolic actions. The VICTORIA (Vericiguat Global Study in Subjects with Heart Failure with Reduced Ejection Fraction) trial enrolled patients with higher-risk HFrEF than those included in other contemporary clinical trials, and found that vericiguat reduced the composite primary outcome of cardiovascular death or first heart failure hospitalization over median follow-up of 10.8 months, although this was driven by the reduction in heart failure hospitalization [15]. Given its vasodilation properties, vericiguat resulted in symptomatic hypotension in 9.1% of patients, although these were not significantly higher than placebo.

Omecantiv Mecarbil

This is a novel cardiac myosin activator, or myotrope – significantly reduces the combined risk of first heart failure events or cardiovascular death in patients with chronic HFrEF, as shown in the GALACTIC-HF trial [16]. The benefit was modest, with an absolute reduction of 2.1% and a relative reduction of 8% over a median follow-up of about 22 months. One of the benefits is that it is well tolerated and does not affect the blood pressure nor the heart rate.

How to Initiate Therapies

The ACC Expert Consensus recommends titration of therapies as follows: In a patient with new-onset stage C HFrEF, the writing committee recommends that either an ARNI/ACEI/ARB or beta-blocker should be started. In some cases, an ARNI/ACEI/ARB and a beta-blocker can be started at the same time. Regardless of the initiation sequence, both classes of agent should be up-titrated to the maximum tolerated or target doses in a timely fashion (every 2 weeks). Initiation of an ARNI/ACEI/ARB is often better tolerated when the patient is still congested, whereas beta-blockers are better tolerated when the patient is less congested with an adequate resting heart rate; beta-blockers should not be initiated in patients with decompensated signs or symptoms. Only evidence-based beta-blockers (bisoprolol, carvedilol, and metoprolol succinate) should be used in patients with HFrEF. With recent clinical trial data supporting the use of SGLT2 inhibitors in a reasonably broad spectrum of HFrEF severity, the addition of this class of therapy to the regimens of patients with HFrEF provides improvements in clinical outcomes and in patient-reported outcome measures [14].

Adverse Therapies

Non-dihydropyridine calcium channel blockers (CCBs) are not indicated for the treatment of patients with HFrEF. Diltiazem and verapamil have been shown to be unsafe in patients with HFrEF. There is a variety of dihydropyridine CCBs; some are known to increase sympathetic tone and they may have a negative safety profile in HFrEF. There is only evidence on safety for amlodipine [5].

Implantable Devices

Implantable cardioverter defibrillators (ICDs) are effective in preventing bradycardia and correcting potentially lethal ventricular arrhythmias. Sudden cardiac death (SCD) from cardiac arrest and ventricular arrhythmias is estimated to occur in a third to half of all HF deaths, thus automatic ICDs are indicated. ICD implantation is recommended only after a sufficient trial (minimum 3 months) of optimal medical therapy (OMT) has failed to increase the LVEF to 35% [1]. In primary prevention, ICDs are recommended for HF patients with a reasonable life expectancy (>1 year), no history of recent MI (within 40 days), NYHA Class II–III and a LVEF ≤35%, or NYHA Class I and a LVEF <30% [1]. In secondary prevention, ICDs are recommended for patients with history of cardiac arrest, ventricular fibrillation, or sustained ventricular tachycardia regardless of the EF [1]. Multiple studies have proven the benefit in NYHA Class II–III reducing mortality by 23–31%. Subcutaneous defibrillators may be as effective as conventional ICDs with a

Telegram: @medical_k

www.konkur.in

lower risk from the implantation procedure. They may be the preferred option for patients with difficult access or who require ICD explantation due to infection. A wearable ICD (an external defibrillator with leads and electrode pads attached to a wearable vest) that is able to recognize and interrupt VT/ventricular fibrillation may be considered for a limited period of time in selected patients with HF who are at high risk for sudden death but otherwise are not suitable for ICD implantation. However, no prospective randomized clinical trials evaluating this device have been reported [5].

Cardiac Resynchronization Therapy

Cardiac resynchronization therapy (CRT) involves implantation of pacing leads to the right and left ventricles via the coronary sinus, which are timed to pace at an interval maximizing synchrony. CRT is indicated for patients with NYHA Class III or IV symptoms, a LVEF $\leq$35%, a QRS interval $\geq$ 0.15 ms, a left bundle branch block (LBBB) pattern, and sinus rhythm to improve mortality and hospitalizations. Studies of CRT include dNYHA Class II, a QRS $\geq$0.12 ms, or a non-LBBB pattern, resulting in varying mortality and hospitalization decreases from 19% to 37%. CRT also improves symptoms and quality of life in these studies. Patients who meet criteria for CRT and an ICD should receive a combined device, unless contraindicated [1].

Transcatheter Mitral Valve Repair

Transcatheter mitral valve repair (tMVR) may be considered for patients with HFrEF and severe secondary mitral regurgitation (MR) after the use of maximally tolerated guideline-directed medical therapy [17]. In the COAPT (Cardiovascular Outcomes Assessment of the MitraClip Percutaneous Therapy for Heart Failure Patients with Functional Mitral Regurgitation) trial, there was a significant reduction in the primary end point of heart failure hospitalization and the secondary end point of all-cause mortality in patients treated with tMVR compared with placebo.

Wireless Pulmonary Artery Pressure

Patients with persistent NYHA class III symptoms may be considered for implantation of a wireless pulmonary artery pressure monitor. In the CHAMPION trial, the device reduced heart failure hospitalizations, and there was a statistically nonsignificant reduction in mortality over a mean follow-up period of 18 months [6].

Cardiac Rehabilitation

A prescribed exercise training program modestly reduced clinical events when added to optimal medical therapy. After adjustment for prognostic variables, the risk of all-cause mortality and hospitalization was 11% lower in cardiac rehabilitation participants, and cardiovascular mortality and heart failure hospitalization was reduced by 15%. Cardiac rehabilitation was safe, with no excess risk of cardiovascular adverse events or hospitalization after exercise [6].

Heart Failure with Preserved Ejection Fraction

HFpEF has been defined by the European Society of Cardiology (ESC) as preserved left ventricular EF (LVEF $\geq$50%), with evidence of diastolic dysfunction or structural heart disease, in the context of classic signs and symptoms of heart failure and elevated natriuretic peptides [5]. HFpEF represent about a third to one-half of the total number of HF patients [18].

The H2FPEF score and the HFpEF nomogram are recently validated highly sensitive tools employed for risk assessment of subclinical heart failure. These tools are based on clinical and echocardiographic parameters, including body mass index (BMI) > 30 kg/m2 (H); use of two or more antihypertensive medications (H); the presence of atrial fibrillation (F); pulmonary hypertension (pulmonary artery systolic pressure > 35 mmHg) (P); elderly with an age > 60 years (E); and elevated filling pressures ($E/e' > 9$) [18]. With a score of 0–1 consider a

Telegram: @medical_k

www.konkur.in

noncardiac cause, a score of 2–5 with abnormal natriuretic peptides and abnormal wedge pressure, or a score of 6–9 is diagnostic of HFpEF.

Clinical trials in HFpEF have produced largely neutral results to date and most management is directed toward associated conditions (e.g., hypertension) and symptoms (e.g., edema). Overall with HFpEF, no treatment has been well validated to show a reduction in morbidity and mortality. The treatment of HFpEF is directed by management of associated conditions (e.g., hypertension, atrial fibrillation, sleep apnea, obesity, and diabetes) and symptoms [1]. Amyloidosis is also an increasingly common cause of HFpEF and must be excluded in patients suspected of HF [18]. In the near future, SGLT2 inhibitors trials will be showing results in this patient population.

Acute Heart Failure

Acute heart failure (AHF) refers to rapid onset or worsening of symptoms and/or signs of HF. It is a life-threatening medical condition requiring urgent evaluation and treatment [5]. AHF may present as a first occurrence, or, more frequently, as a consequence of acute decompensation of chronic HF, and may be caused by primary cardiac dysfunction or precipitated by extrinsic factors, often in patients with chronic HF. Acute myocardial dysfunction (ischemic, inflammatory, or toxic), acute valve insufficiency, or pericardial tamponade are among the most frequent acute primary cardiac causes of AHF. Clinical classification is based on bedside physical examination in order to detect the presence of clinical symptoms/signs of congestion (wet versus dry) and/or peripheral hypoperfusion (cold versus warm). Initial diagnosis of AHF should be based on a thorough history assessing symptoms, prior cardiovascular history and potential cardiac and noncardiac precipitants, as well as on the assessment of signs/symptoms of congestion and/or hypoperfusion by physical examination and further confirmed by appropriate additional investigations such as ECG, chest X-ray, laboratory assessment (with natriuretic peptides biomarkers), and echocardiography. An arterial blood gas and lactic acid are warranted to accurately assess acid-base abnormalities and hypoxia. Invasive hemodynamic monitoring can be considered when there is evidence of impaired perfusion, uncertainty of fluid status, uncertainty of systemic or pulmonary vascular resistance, worsening renal function, or a need for vasoactive agents [1].

The initial goal of treatment should be stabilization to control hypoxemia or hypotension that can cause under perfusion of vital organs, the heart, kidneys, and brain [5]. Intravenous loop diuretics are the first-line therapy to treat pulmonary edema and volume overload by lowering central venous capillary wedge pressures and improving hemodynamic status. Loop diuretic dosing should be equal or 2.5 times higher than the patient's normal oral dose (for dosing and equivalents, see Table 6). A continuous infusion of loop diuretics is not more effective than IV bolus therapy. If necessary, adding a second diuretic to potentiate a diuresis is an option, either with oral hydrochlorothiazide, metolazone, or spironolactone. Careful monitoring of congestive symptoms, volume status, blood pressure, oxygenation, daily intake and out-take, and daily weights should be utilized. To reduce adverse effects of treatment, daily monitoring of renal function, for overdiuresis or azotemia, and electrolyte disturbances to appropriately replace depleted potassium and magnesium is considered [1]. Intravenous vasodilators, nitroglycerin or nitroprusside, are recommended for persistent congestive symptoms and rapid symptom relief in acute pulmonary edema or severe hypertension not responding to diuretics alone [19]. Inotropic agents such as dobutamine or milrinone are indicated in AHF when LVEF is reduced and hypotension causes diminished perfusion and end-organ dysfunction (low-output syndrome). When initiating a vasodilator or inotropic therapy, consideration should be given for cardiology or pulmonary consultation. In patients with HFrEF experiencing a symptomatic exacerbation of HF requiring hospitalization during chronic maintenance treatment with guideline-directed medical therapy (GDMT), it is recommended that GDMT be continued in the absence of hemodynamic instability or contraindications [1].

Referrals

Early identification and timely referral of select patients to a heart failure specialist is critical so that those with advanced disease can be considered for heart transplantation or LVAD placement. This window of opportunity is missed if referral is delayed until multiorgan failure develops, as such patients may no longer candidates for these therapies. A useful acronym "I-NEED-HELP" was developed to assist clinicians recognize such appropriate patients [20] (Table 7).

Counseling and Patient Education

HF management and self-care behavior are complicated by ageing, comorbid conditions, cognitive impairment, frailty, and limited social support. HF is also a leading cause of hospital admission in the older adult, where it is associated with increased hospital length of stay and risk of mortality [9]. Counseling patients with HF education and strategies for self-care are critically important to enhance treatment compliance, improve transitions of care and manage worsening signs and symptoms of fluid retention. Although frequently utilized, there is limited evidence to support the daily 2–3 gram sodium restriction or the 1.5–2 L fluid restriction recommended by current guidelines. Daily weights are important to detect early fluid retention, and a weight gain of 2 lb. in a day or $\geq$ 5 lb. in a week should prompt contacting or seeing a health care provider. Exercise training or regular physical activity is highly recommended as safe and effective to improve symptoms and functional status. Formal cardiac rehabilitation can be useful and effective when clinically stable to improve functional capacity, exercise duration, quality of life, and mortality [9].

Table 7 When to refer to advanced heart failure

I	IV inotropes
N	NYHA III/IV or persistently elevated natriuretic peptides
E	End organ dysfunction
E	Ejection fraction $\leq$35%
D	Defibrillator shocks
H	Hospitalizations >1
E	Edema despite escalating diuretics
L	Low BP, high heart rate
P	Prognostic medication – Progressive intolerance or down-titration of GDMT

Modified from Yancy et al. [20]

Prevention

Effective systems of care coordination with special attention to care transitions should be deployed for every patient with chronic HF that facilitate and ensure effective care that is designed to achieve GDMT and prevent hospitalization [1]. Every patient with HF should have a clear, detailed, and evidence-based plan of care that ensures the achievement of GDMT goals, effective management of comorbid conditions, timely follow-up with the health care team, appropriate dietary and physical activities, and compliance with secondary prevention guidelines for cardiovascular disease. Palliative and supportive care is effective for patients with symptomatic advanced HF to improve quality of life [1].

Management of HF often entails adherence to a complex medication regimen in conjunction with dietary sodium restriction and limitation of fluid intake. In addition, HF usually occurs in the context of one or more comorbid conditions, such as hypertension, diabetes mellitus, and coronary artery disease, which further increase the complexity of care. A significant proportion of early HF readmissions are due to nonadherence to medications or diet, inadequate patient education, or lack of timely follow-up. Heart failure disease management (HFDM) is an opportunity to provide a patient-centered, multidisciplinary, coordinated approach to care that incorporates optimization of the medication regimen, effective patient education, and close follow-up designed to improve clinical outcomes, including quality of life, readmission rates, and survival. Performance measures based on professionally developed clinical practice guidelines should be used with the goal of improving quality of care for HF [1].

General Principles

Cardiovascular death remains the number one cause of death in the United States. It causes more deaths than lung cancer, breast cancer, prostate cancer, colon cancer, stroke, and chronic lower respiratory diseases combined [1, 2]. While most of these conditions require specialist care, often in a hospital setting, patients will present with these complaints to their family physician, and one must be able to recognize and assess them. Furthermore, family physicians will continue to care for these patients as they live with these conditions. These patients will turn to their family physician for information, second opinions, and advice. This chapter will look at some of these conditions.

Cardiogenic Shock

Shock is caused when oxygen demand exceeds available supply. This can be caused by increased demand of tissue due to infection, metabolic or endocrine disease, decreased supply due to hypovolemia, or a combination of the two. Sometimes, inability of tissue to use oxygen can contribute as well.

There are five categories of shock: cardiogenic, obstructive, hypovolemic, distributive, and endocrine (see Table 1).

When oxygen supply to tissues is decreased, cells can extract more oxygen from red blood cells to meet demands. However, this can only compensate so much, and once supply drops below a critical level, this mechanism can no longer meet the demands of the tissues (compensated vs decompensated shock).

Cardiogenic shock is due to primary cardiac dysfunction. While there may be adequate volume, the heart is unable to circulate it, and tissues suffer from hypoperfusion and hypoxia.

Myocardial infarction (MI) is the most common cause of cardiogenic shock. Arrhythmias, valve rupture, myocarditis, endocarditis, cardiomyopathy, and contusion after chest wall trauma can cause cardiogenic shock as well [3].

Pathophysiology

Ischemia reduces both contractility and relaxation of the heart. This leads to reduced cardiac compliance and reduced filling. As a result, stroke volume is reduced. This in turn reduces cardiac output (cardiac output = stroke volume X heart rate), which then reduces blood pressure. Compensatory mechanisms such as the sympathetic nervous system and the renin-angiotensin system increase heart rate, afterload, and fluid retention. These in turn cause increased oxygen demand on the heart which already has an inadequate supply [4]. This further widens the gap between oxygen need and available oxygen, exacerbating shock and end-organ dysfunction.

Definition

Cardiogenic shock is defined as a systolic BP < 80–90 mmHg in the absence of hypovolemia and must be associated with end-organ damage such as cold extremities, oliguria, or mental status changes. This can also be measured as reduced cardiac index (CI) < 2.2 l/min/m^2 (cardiac output to body surface area)

Telegram: @medical_k

www.konkur.in

Table 1 Shock classification

Name	Causes	Examples
Cardiogenic	Myocardial disease	MI Myocarditis
Obstructive	Mechanical blockage of blood flow beyond the heart	Pulmonary embolus Cardiac tamponade
Hypovolemic	Loss of circulating volume	Blood loss Third spacing
Distributive	Vasodilation and relative inadequate circulating volume	Sepsis Neurogenic shock Anaphylaxis
Endocrine	Thyroid disease Adrenal insufficiency	Thyroid storm Stopping steroid use abruptly

or elevated pulmonary capillary wedge pressure > 15 mmHg [4].

Despite numerous advances in revascularization, medications, and mechanical support, cardiogenic shock is still the number one cause of mortality due to acute myocardial infarction (AMI). Overall, however, the rate of cardiogenic shock has decreased from around 7.5% (range 5–15%) in the 1970s to around 4% in 2003 [5].

Patients who develop cardiogenic shock during a hospitalization for AMI are more than ten times more likely to die than patients hospitalized for AMI who do not develop cardiogenic shock.

Patients who develop cardiogenic shock after an AMI tend to be older, be female, and have a do-not-resuscitate (DNR) order, a history of diabetes mellitus (DM), a history of heart failure (HF), or prior MI.

Management

If a patient develops cardiogenic shock from any cause, the keys to management are improving perfusion and oxygenation. Ideally, PaO_2 (partial pressure of arterial oxygen) levels should be maintained at more than 60 mmHg using bilevel positive airway pressure (BPAP) or intubation as needed. Maintain hemoglobin >8 to allow for adequate oxygen delivery. Fluid resuscitation needs to be monitored carefully as improving filling pressures is important but must be balanced against fluid overload.

Vasopressors such as norepinephrine (Levophed), dopamine, and dobutamine and intraaortic balloon pump counterpulsation (IABP) are used to give BP support while stabilizing and preparing the patient for revascularization procedures. While dopamine was originally considered the first-line vasopressor in cardiogenic shock, recent evidence suggests better outcomes with norepinephrine. Dobutamine doesn't help hypotension and should only be used in patients who have less hypotension, i.e., SBP > 80 mm Hg, in conjunction with vasodilators [6].

Results from the GUSTO-I and SHOCK trials suggest improved survival with emergent revascularization in patients with cardiogenic shock. Percutaneous coronary interventions (PCI) have a class 1A indication in AMI with cardiogenic shock as do coronary artery bypass grafts (CABG) if the patient has suitable coronary anatomy [5]. A class 1A indication means that there are multiple randomized controlled trials showing that the procedure is both effective and useful.

Cardiopulmonary Resuscitation (CPR)

CPR was developed in the 1960s and has been saving lives ever since.

Every 5 years, the International Consensus of CPR and Emergency Cardiovascular Care (ECC) Conference convenes and evaluates the guidelines. The most recent conference took place in 2015, and the American Heart Association (AHA) guidelines for CPR and ECC were updated.

In a major shift, the usual "A-B-C" (airway-breathing-circulation) protocol was changed to "C-A-B" (circulation-airway-breathing). This change was made to stress that reduced time to first compressions and early use of a defibrillator are the priorities for survival. The AHA has found

Telegram: @medical_k

www.konkur.in

that oxygen demand is lessened during cardiac arrest, and therefore pumping blood to a victim's brain is more important than oxygen [7]. In fact, bystander hands-only CPR, where compressions are done without breaths, shows similar outcomes to conventional CPR in adults [8].

The compression rate has been changed from "at least 100 compressions a minute" to "no slower than 100 compressions per minute and no faster than 120 compressions per minute" [9].

Compression depth is now 2 in. for adults as opposed to 1½–2 in. for adults. The depth has changed for children as well [10]. The latest recommendations also suggest not compressing further than 2.4 in. for adults [9].

Minimizing interruptions to compressions is also emphasized by changes in pulse checks. These should not last for more than 10 s, and if an obvious pulse isn't noted, compressions should continue. Again, trying to confirm a faint pulse may delay in needed compressions, and there are rarely significant injuries caused by chest compressions to patients who were not in cardiac arrest.

Additional changes include the removal of atropine (AtroPen) from the pulseless electrical activity (PEA) and asystole protocol.

Waveform capnography has been added to confirm endotracheal tube placement and quality of compressions. Cricoid pressure is no longer recommended during airway management.

Therapeutic hypothermia has been shown to improve outcomes for comatose patients after out-of-hospital arrests with a presenting rhythm of ventricular fibrillation (VF). New evidence shows a wider range of temperatures are acceptable. Providers should select a temperature between 32 and 36 degrees Celsius and maintain it for at least 24 h [9].

Aortic Dissection

Classification

There are two classification systems used: DeBakey and Standford (see Tables 2 and 3).

Table 2 DeBakey classifications

Type I	Originates in the ascending aorta and propagates to at least the arch
Type II	Originates in and is confined to the ascending aorta
Type IIIA	Dissection tear only in the descending thoracic aorta
Type IIIB	Tear extending below the diaphragm [12]

Table 3 Stanford classifications

Type A	All dissections that involve the ascending aorta
Type B	All dissections that do not involve the ascending aorta

Additionally, there are newer classifications based on other characteristics that pertain to suitability for endovascular repair, in particular, the DISSECT mnemonic: duration of dissection (D) less than 2 weeks, 2 weeks to 3 months, and more than 3 months from initial symptoms; intimal tear location (I) in the ascending aorta, arch, descending, abdominal, or unknown; size of the aorta (S); segmental extent (SE); clinical complications (C) such as aortic valve compromise, tamponade, rupture, and branch malperfusion; and thrombosis (T) of the false lumen and the extent [12].

There are three syndromes included in acute aortic disease: aortic dissection, aortic intramural hematoma (IMH), and penetrating atherosclerotic ulcer (PAU). Aortic dissections comprise 90% of acute aortic disease. Classic aortic dissection occurs when there is an intimal flap between the true lumen and the false lumen. An IMH occurs when there is bleeding into the aortic wall without a tear. This occurs by rupture of the vasa vasorum into the media of the aortic wall. This can happen either spontaneously or by a penetrating atherosclerotic ulcer [11].

Aortic dissection is often seen later in life, occurring after age 50. In cases that occur in younger patients, physicians should consider underlying connective tissue disorders such as Marfan's syndrome, Ehler-Danlos syndrome, or familial forms of dissection.

Chronic hypertension is the number one cause of aortic dissection and occurs in 75% of cases. Smoking, dyslipidemia, direct blunt trauma, and

Telegram: @medical_k

www.konkur.in

cocaine and methamphetamine use can all contribute to aortic dissection [12].

Aortic dissection is twice as prevalent in men as women. The incidence is hard to determine as patients may die before reaching care but is estimated to be between 2 and 3.5 cases per 100,000 patient-years [13].

Symptoms

More than 90% of patients with aortic dissection present with pain. Of the patients that present with pain, 90% describe it as severe. The pain is abrupt and maximal at outset and is described as sharp, tearing, or stabbing. Some patients may have uncommon presentations which can confound the diagnosis. They may present with acute heart failure, stroke, or syncope and either not have pain or not mention pain due to other distracting symptoms.

Type A dissections occur in 65% of cases and are more commonly seen in patients between 50 and 60 years of age. Type A dissections are lethal with a 1–2% mortality rate per hour after onset of dissection. Patients usually have symptoms of immediate, severe chest pain and/or back pain. Patients can also have abdominal pain, syncope, and/or stroke. Acute heart failure is also possible if the dissection involves the aortic valve. Type A dissections are surgical emergencies. Medical treatment alone results in approximately 20% mortality in the first 24 h. Mortality increases as time passes, with 50% mortality by day 30. Surgery improves chance of survival, but the 24-h mortality is still high at 10%.

Type B dissections occur more commonly over age 60. Type B dissections have similar presentations with chest and back pain as the common symptoms. Type B dissections are treated medically, and uncomplicated type B dissections have 10% mortality at day 30 [14].

Diagnosis

A routine chest x-ray (CXR) will be abnormal in 60–90% of patients, but 12–15% of patients can have normal CXR, and this cannot be used to exclude the diagnosis.

Electrocardiography (ECG) may be completely normal or extremely abnormal if the dissection involves the coronary circulation. This too cannot be used to exclude the diagnosis.

According to the International Registry of Acute aortic Dissection (IRAD) which is a clearinghouse of information on aortic dissections, transthoracic echocardiography (TTE), or transesophageal echocardiography (TEE), was used as the initial imaging test in 33% of patients, computed tomography (CT) in 61%, magnetic resonance imaging (MRI) in 2%, and angiography in 4%. For confirmation or further evaluation, TTE/TEE was used in 56% of patients, CT in 18%, MRI in 9%, and angiography in 17% [14].

CT is useful for allowing clinicians to evaluate involvement of surrounding organs, local anatomy, and possible ruptures or leaks. However, CT must be done with contrast in order to detect a false lumen and is contraindicated in patients with nephropathy. Contrast-induced nephropathy is a complication even for patients without underlying renal disease. CT imaging is limited by cardiac motion artifact as well as streak artifact from any implanted devices.

MRI is better than CT at seeing the aortic valve and coronary arteries. It does not require radiation or iodinated contrast material. However, MRI is not readily available in all sites and requires the patient to undergo imaging for a longer period of time. Also certain medical devices make it impossible to use MRI [13].

TTE has excellent specificity in the range of 93–96%, but the sensitivity is lower at only 77–80%. As such, a normal TTE does not rule out an aortic dissection. TEE, on the other hand, has both excellent sensitivity at around 98% and specificity at around 95%. Like all ultrasonography, both modalities are operator dependent [13]. This may be a concern in smaller centers where aortic dissection isn't diagnosed frequently.

Additionally, biomarkers are now being looked at for information regarding aortic dissection as it is a disease of the medial layer of the aorta. Currently, only D-dimer has any clinical value though other biomarkers are being studied. D-dimer has a sensitivity of 97% and a specificity of 47%. Therefore, a negative D-dimer may exclude the disease [12].

www.konkur.in

Management

Initial management for any type of dissection should include stabilizing the patient, controlling pain, lowering blood pressure, and reducing left ventricular contraction with beta-blockers. Initial blood pressure management is aimed at getting systolic blood pressure < 130 mmHg. IV beta-blockers are the first-line therapy. These should be used to control heart rate as well, aiming for a pulse <60 BPM. Nitroprusside (Nipride, Nitropress) can be used but only in conjunction with beta-blockers as nitroprusside can increase LV contractility. If a patient has a contraindication to a beta-blocker, verapamil (Calan, Isoptin SR, Veralan) or diltiazem (Cardizem, Cartia XT, Dilacor XR, Dilt-CD, Taztia XT, Tiazac) can be used. While stabilizing the patient, additional management depends on whether the patient has a type A or type B dissection.

Type A Dissections

Type A dissections should be managed as surgical emergencies. Medical management of type A dissections has a 20% mortality rate in the first 24 h and 30% in the first 48 h. Surgical management leads to improved outcomes for these patients. The aim of surgical management is to prevent aortic rupture, pericardial effusions which can lead to cardiac tamponade and death, and aortic regurgitation which can impair coronary artery blood flow leading to myocardial infarction and death. At 30 days, the mortality rate for type A dissections managed surgically is between 17% and 26%. If managed medically, the 30-day mortality is between 55% and 60% [13, 15]. The patient's hemodynamic stability immediately prior to surgery is a key predictor of how well the patient will do during and after surgery. Therefore, it is critical that surgery not be delayed for type A dissections.

Type B Dissections

Type B dissections have traditionally been managed medically. Uncomplicated type B dissections should be managed medically, and those that only require medical management have a low mortality rate around 6%. Additionally, the 5-year survival rate for these patients with optimal medical management is 89% [15]. The overall mortality rate for type B dissections treated medically was 10.7% in the International Registry of Acute aortic Dissection (IRAD), while those requiring surgery had a 31% mortality rate. Surgical management is required for complications such as limb ischemia, impending or actual rupture, increasing aortic diameter, intractable pain, or retrograde dissection (type A). Looking at 571 patients in the IRAD with type B dissection, 32% were complicated. The type of surgery required affected the mortality rate for type B dissections requiring surgery. Open surgical repairs had 33% mortality, whereas those who had an endovascular repair had only an 11% mortality rate [13]. As a result, endovascular procedures have a 1A recommendation for surgical repair of complicated type B dissections [14A]. About 25% of type B dissections are complicated at presentation [15].

Almost all patients with a type B dissection require intravenous antihypertensives with most requiring more than one antihypertensive medication during hospitalization. Beta-blockers, calcium channel blockers, nitroglycerin (Nitrolingual, NitroMist, Nitrostat), and nitroprusside were the most common initial antihypertensives used in one study of 129 patients. Mean hospital stay is more than 2 weeks with most patients spending a week in the intensive care unit as well [16]. All patients went home on an oral antihypertensive medication. These patients should be closely followed for at least the first 6 months after discharge as most complications that require intervention occur within this time frame. These patients are at risk for future dissections, aneurysms, and rupture. Systemic hypertension, advanced age, aortic size, and a patent false lumen are characteristics that put patients at higher risk for complications. Estimates are that 1/3 of all patients with original medical management will have an aneurysm, further dissection, or surgical requirement within 5 years [17].

Telegram: @medical_k

www.konkur.in

Beta-blockers are the cornerstone of therapy as they affect both BP and contractility and are recommended even for patients with well-controlled BP. Ideal BP control should be <120/80 mmHg. Smoking cessation and risk factor modification for atherosclerotic disease are also key components for chronic management of aortic dissection. Surveillance with CT or MRA should occur at 1, 3, 6, and 12 months. After the first 12 months, imaging can be continued annually. Primary care doctors can oversee this surveillance along with cardiologists or cardiothoracic surgeons as appropriate.

Cardiac Syncope

Syncope is defined as sudden temporary loss of consciousness (LOC) with complete spontaneous recovery. It is very important to obtain a good history and physical exam in order to determine if the patient experienced syncope or if another diagnosis is more likely. If the patient did indeed have a syncopal event, the history and physical exam will help the clinician distinguish between the five types of syncope: cardiac, reflex mediated, neurologic, orthostatic, and psychogenic (see Table 4) [18].

The differential for syncope includes seizures, dizziness, presyncope, drop attacks, vertigo, and near sudden cardiac death events [19]. The history can usually elicit which of these the patient experienced. The input of any witnesses is vital as the patient often does not remember the event or does not remember the entirety of the event. Studies have shown that the elements that distinguish seizure from syncope include disorientation after the event (postictal phase), tongue-biting, frothing at the mouth, and loss of consciousness for more than 5 min. An aura preceding and a headache after the event also suggest seizure [20]. Urinary or fecal incontinence can be seen with either condition but is more common in seizures.

Cardiac syncope is important to distinguish from other causes as it is associated with an increased risk of death from all causes, such as stroke, and from cardiac causes, such as myocardial infarction or arrhythmia. Cardiac syncope is the second most common type of syncope and is seen in about 10–20% of cases. Patients tend to be older, have a cardiac history, and/or have risk factors for cardiac disease such as diabetes and HTN. They may also have palpitations, syncope related to exercise, and/or a family history of sudden cardiac death. They may complain of chest pain or shortness of breath in addition to the syncopal episode. Ventricular tachycardia (VT) is the most common tachyarrhythmia that leads to syncope. Supraventricular tachycardia (SVT) can lead to syncope but this is less common. More often, patients with SVT have less severe symptoms such as lightheadedness, palpitations, and shortness of breath. Bradyarrhythmias such as sick sinus syndrome can also lead to syncope. A massive pulmonary embolism and aortic stenosis are obstructive causes of cardiac syncope. Increased age and male sex, both risk factors for cardiac disease, also suggest a cardiac etiology for syncope.

Risk Factors for Serious Adverse Events After a Syncopal Episode

The San Francisco Syncope Rule (SFSR) is a tool used to determine if a patient has an increased risk of death after a syncopal episode. Systolic blood pressure <90 mmHg, shortness of breath, congestive heart failure, ECG abnormalities, and hematocrit <30 were all predictors of serious outcomes [3S]. Another tool is the Risk stratification Of Syncope in the Emergency department (ROSE) rule. This states that if any of the following seven risks are present, the patient should be considered high risk: BNP > 300 pg/ml, HR <50, hemoglobin <9, positive fecal occult blood, chest pain, ECG with Q waves, or oxygen saturation <94% [21].

Another study looked at death or significant cardiac arrhythmias in the year after a syncopal episode and found that the four most important risk factors were age > = 45, a history of heart failure, a history of ventricular arrhythmia, and an abnormal ECG. Patients with none of these risks had a 4–7% chance of death or a significant

Telegram: @medical_k

www.konkur.in

Table 4 Types of syncope

Name	Situation	Prevalence (%)	Risk of death
Cardiac	Exertional, arrhythmias, palpitations, unprovoked	18	2X increased risk of death from any cause
Reflex mediated	Vasovagal, situational, micturition, defecation, sight of blood	24	None
Neurologic	Steal syndrome, TIAs, neurologic symptoms	10	Increased risk of death
Orthostatic	Dehydration, medication, alcohol, occurs with standing	8	None
Psychogenic	Depression, anxiety, normal exam findings, panic attacks	2	None

All other episodes of syncope are of unknown etiology, 38%

cardiac arrhythmia as opposed to those with three or four of these risks who had a 58–80% chance [21].

History and Physical Exam

Diagnosing and distinguishing between types of syncope, history, and physical exam allow for more accurate diagnosis than any other modality, establishing the cause up to 65% of the time [18]. ECG was next at only 10%.

It is important when taking the history to ask about the patient's position prior to and at the time of the event, last PO intake including fluids, recent exertion, any situational stressors, any new or recently taken medications or drugs, the presence of palpitations or dyspnea, and any family history of cardiac disease and sudden cardiac death. Also ask if the patient has experienced prior episodes of syncope. It is also important to know if the patient has a personal cardiac history including a pacemaker or defibrillator.

The physical exam should include vitals particularly any orthostatic changes and oxygen saturation, cardiac murmurs, arrhythmias, any neurologic changes, or any gastrointestinal blood loss.

Testing

Routine lab testing has little diagnostic value in assessing syncope with <3% of cases having any significant lab abnormalities [21]. It may be reasonable to check glucose, CBC, and BNP in certain patients.

Carotid massage can be used to check for neurally mediated carotid sinus hypersensitivity in patients over age 40 only after ruling out the presence of bruits. This test should not be performed in patients with a history of transient ischemic attack (TIA), recent stroke, or neurologic findings on exam. The test is positive if the patient experiences a pause in heart rate for >3 s or whose systolic BP drops by more than 50 mmHg. The test should be done in the supine and upright positions [20]. While this is mentioned in most texts, it is not often done in practice.

ECG should be ordered for patients where cardiac syncope is suspected. The ECG can establish the diagnosis in 5–10% of cases of syncope. One should look for QT prolongation, delta waves, and short PR interval which suggest Wolff-Parkinson-White (WPW) syndrome, bundle branch block (BBB), and particularly right BBB with ST elevation which is seen in Brugada syndrome. One should also look for ST elevations suggestive of myocardial infarction, bradycardia, second- or third-degree atrioventricular (AV) node block, SVT, or VT. Any abnormality in the ECG should raise the concern for a cardiac cause of syncope and increased mortality [20].

Telemetry is often ordered for patients who present with syncope but does not frequently help identify the cause. Holter monitoring and more recently loop monitoring may be useful in cases of suspected arrhythmia. These allow for longer periods of monitoring with implantable

Telegram: @medical_k

www.konkur.in

loop recorders being able to monitor patients for more than 12 months. Symptoms attributable to arrhythmias can be found with loop recorders in 50–85% of cases [21].

Stress testing and cardiac catheterization should only be used in cases where myocardial ischemia is highly suspected.

Echocardiography is useful to evaluate for structural cardiac abnormalities. It is also useful for determining left ventricular ejection fraction (EF) as an EF <35% is an indication for an implantable cardioverter-defibrillator (ICD). These patients are at high risk for arrhythmias and sudden cardiac death. In these patients, syncope is an ominous sign. Echocardiography is also useful in establishing aortic stenosis as the cause of syncope. This should be suspected in older adults presenting with syncope during exertion.

Electrophysiologic (EP) testing can be useful in establishing the diagnosis for patients suspected of having sick sinus syndrome, heart block, ventricular tachycardia (VT), or supraventricular tachycardia (SVT). Those patients with structural heart abnormalities, ECG abnormalities, a clinical history that suggests arrhythmia, or a family history of sudden death should undergo EP testing.

Management

Management of cardiac syncope depends on the underlying cause. If the cause is ischemic, patients should receive optimal medical management along with surgical interventions as needed. Most arrhythmias will require ICD implantation. Patients with sick sinus syndrome and AV node block can be treated with pacemakers. WPW can be treated with catheter ablation therapy.

Sudden Cardiac Death

Sudden cardiac death (SCD) affects between 300,000 and 500,000 people in the United States annually. SCD is usually caused by VT decompensating to ventricular fibrillation (VF) though it may also result from heart failure, bradyarrhythmias, heart block, or pulmonary emboli. SCD is responsible for more deaths annually in the United States than stroke, lung cancer, and breast cancer combined. Worldwide, it is responsible for 50% of overall cardiac deaths [22]. It is the most common presenting sign of coronary artery disease. Risks for SCD include decreased left ventricular EF, acute MI, prior MI, prior ventricular arrhythmia, and congestive heart failure.

Seventy-five percent of cases occur in men with a fourfold to sevenfold higher risk of SCD in men than women <65 years of age. After age 65, the ratio of SCD in men to women is 2:1 or less [22]. Pre-menopausal women have some cardioprotection that decreases their risk of SCD and cardiac disease. However, in women over age 40, coronary artery disease is the most common cause of SCD. Further, women with SCD are less likely to have severely reduced left ventricular ejection fraction or known heart disease which makes it that much harder to establish a risk profile for women.

Studies show that more than 50% of people with SCA had warning symptoms before the event; however, they often went unrecognized or minimized. The most common symptoms were chest pain and dyspnea. Women experienced dyspnea more than chest pain.

Risk factors for SCD (or SCA) are the same as for coronary heart disease (CHD): smoking, obesity, inactivity, dyslipidemia, diabetes, hypertension, and family history of CHD [23].

Primary Prevention

Given that the first arrhythmic event is usually fatal in SCD (or perhaps more appropriately, sudden cardiac arrest (SCA)), it is critical to try to identify people who are at high risk for these events and intervene early. People with known cardiac disease and ejection fraction (EF) < 30–40% are known to be at very high risk for SCD. An EF < 30% is the biggest independent predictor for SCD, and reduced EF predicts SCD in both ischemic and nonischemic dilated cardiomyopathies. The American College of Cardiology (ACC), American Heart Association (AHA), and Heart Rhythm Society (HRS) published guidelines

Telegram: @medical_k

www.konkur.in

recommending ICD implantation in people with EF less than 30–35% with heart failure [24]. Therefore, it is critical that any patient with known cardiac disease have an evaluation for ejection fraction. Patients with low functional capacity who don't have a reasonable expectation to live more than 1 year are not candidates for ICDs.

Secondary Prevention

Three studies have shown that ICDs decrease mortality in patients with aborted SCD, VT, or VF. Therefore, any patient with a history of VT, VF, SCA, or aborted SCD should be evaluated for possible ICD implantation. VT or VF that occur within 48 h of an MI do not need to be evaluated for ICD placement.

Hypertrophic Cardiomyopathy

Definition

Hypertrophic cardiomyopathy (HCM) is defined as LV hypertrophy associated with nondilated ventricles that is not caused by cardiac or other systemic illness. HCM affects approximately 600,000 people in the United States. Most of those have no symptoms and most have a normal life expectancy. Those that do die from SCD suffer from ventricular tachyarrhythmias. This occurs most often in asymptomatic patients younger than 35. The other two serious complications of HCM are atrial fibrillation (AF) and heart failure with dyspnea.

The complications of HCM are caused by left ventricular outflow tract (LVOT) obstruction, arrhythmias, myocardial ischemia, diastolic dysfunction, and mitral regurgitation [25]. It is critical to establish whether LVOT obstruction is present as management strategies are based largely on this complication.

Diagnosis

The diagnosis of HCM is made by transthoracic echocardiography (TTE) and more recently, cardiac MRI. Once HCM is diagnosed, first-degree relatives should be screened with TTE. Patients with HCM can undergo genetic testing. If a patient screens positive for one of the genetic markers of HCM, first-degree relatives can be screened with genetic testing as well.

If a patient is diagnosed with HCM, ECG, and Holter monitoring should be done to look for any tachyarrhythmias. This should be repeated annually or whenever the patient has worsening symptoms of HCM [25].

Children of patients with HCM should be screened annually with TTE starting at age 12 or earlier if puberty or growth spurt begins before age 12. Children in intense competitive sports should also be screened earlier. Adult relatives can be surveyed every 5 years with TTE.

Management

Providers should aggressively manage patients with asymptomatic HCM by evaluating them for other risk factors for cardiovascular disease as these may contribute to complications of HCM. These patients should not participate in strenuous activities or competitive sports. Patients with resting or provoked LVOT obstruction should not be given high-dose diuretics or pure vasodilators as these are harmful. Beta-blockers should be used as first-line medications for symptoms of dyspnea and angina. If patients cannot tolerate these, verapamil can be used. Disopyramide (Norpace) can be added to a beta-blocker or verapamil if symptoms cannot be controlled; however, it should not be used alone. Dihydropyridine calcium channel blockers such as amlodipine (Norvasc) should not be used in patients with HCM who have LVOT obstruction. ACE inhibitors have not been shown to be useful or harmful in the treatment of symptoms of HCM. Beta-blockers can be used in children but watch for side effects such as depression or difficulty in school.

Surgical interventions such as septal reduction or alcohol septal ablation should only be considered in cases of refractory LVOT obstruction and symptoms that interfere with daily living despite optimal medical management. These should only be performed at experienced centers.

Telegram: @medical_k

www.konkur.in

Implantable cardiac defibrillators (ICDs) have been shown to decrease mortality in patients with HCM and tachyarrhythmias. Patients with HCM should receive risk stratification for SCD to determine if an ICD if appropriate. These include prior personal cardiac arrest, history of VF, sustained VT, sudden cardiac arrest (SCA) (recurrence is 10% per year), family history of SCD, unexplained syncope, documented nonsustained VT, or LV thickness > = 30 mm [25]. An ICD can be implanted in children as well who have any of these high-risk factors.

Patients with HCM, regardless of symptoms, should not participate in intense or competitive sports. One third of all SCD in young athletes are due to HCM. Low-intensity aerobic exercise is recommended.

Introduction

DVT and PE have shared pathophysiology and together, along with superficial venous thrombosis, comprise the spectrum of venous thromboembolism (VTE). PE is the most serious of these, causing up to 10% of deaths in the hospital setting, and represents the most common preventable cause of death in patients with misdiagnosed

or improperly treated PE or DVT [1]. Even though the number of in-hospital deaths due to PE has decreased in the US, up to 30% of patients still die within the first year of diagnosis [2]. It is critical to maintain a high clinical suspicion in patients at risk of VTE and apply current diagnostic tools appropriately in order to initiate prompt therapy.

Pathophysiology

The major theory describing the pathogenesis of VTE is a triad derived from the extensive research of Virchow almost 100 years after his passing. This theory states that thrombosis occurs due to a combination of endothelial injury, hemodynamic changes (such as stasis or turbulence), and changes in the balance or properties of blood components involved in the coagulation cascade (i.e., inherited or acquired states of hypercoagulability) [3]. The role of inflammation is apparent by the increased frequency of DVT and PE formation in chronic inflammatory conditions such as inflammatory bowel diseases and systemic vasculitis [4]. C-reactive protein elevation has been linked to increased VTE risk. In the Atherosclerosis Risk in Communities (ARIC) study, an elevated C-reactive protein above the 90th percentile was associated with a 76% increased risk of VTE formation compared to lower percentiles [4]. Endothelial injury and stasis also increase VTE risk via increasing coagulation factors and preventing adequate mixing of anti-clotting factors, respectively [4, 5]. Local injury from indwelling devices, such as pacemaker leads or long-term indwelling central venous catheters, also increases upper extremity DVT formation [5].

Inherited and acquired thrombophilias affecting anticoagulant or pro-coagulant pathways lead to hypercoagulopathy [6]. Common inherited disorders include factor V Leiden mutation, which causes resistance to degradation by activated protein C, G2021A mutation, and deficiencies in proteins C and S, and antithrombin III. Hyperhomocysteinemia spans both categories, as it involves inheriting a defective enzyme, but is acquired through dietary folate, B6 and B12 deficiency [7]. Antiphospholipid antibody syndrome is an acquired autoimmune disorder characterized by abnormal levels of lupus anticoagulant, anti-β-2 glycoprotein-1, and anticardiolipin antibodies that increase the risk of recurrent VTE [8].

Inherited coagulopathies are among the rare, but significant risk factors for development of VTE, particularly in younger populations. However, thrombophilia testing remains controversial as absolute VTE risk is only mildly affected by these disorders, and currently available thrombophilia tests are insufficient to identify inherited risks of VTE [8]. The majority of patients with VTE should not be tested for thrombophilia, and most patients with inherited thrombophilia can accurately be identified based on the patient's personal and family history of VTE and not require testing [8]. Of those risks mentioned, family history of an unprovoked VTE in a first-degree relative, especially under age 50, may be more important in terms of counseling patients on their inherent risk (i.e., during pregnancy) than specific testing results [8, 9].

Epidemiology

Only myocardial infarction and stroke are more common in terms of cardiovascular disease than VTE [1]. The annual frequency of first-time VTE in adults is 1–2:1000 (rising to 1:200 in those over age 70), and if left untreated, the 30-day mortality rate for a first-time DVT is 5% and as high as 33% for those with a PE [9, 10]. The incidence of VTE increased significantly from 2001 to 2009 and may in part reflect improvement in imaging quality and increased use of diagnostic studies [9].

Approximately 33% of patients with VTE have recurrence within the following 10 years [10]. Predictors of recurrence include prior VTE, increased age, increased BMI, male gender, active cancer, and leg paresis among others. VTE accounts for approximately 1% of hospital admissions in the USA annually, and two-thirds of VTE cases occur in patients who have been hospitalized within the past 90 days [7]. Hospitalization, illness with

Telegram: @medical_k

www.konkur.in

resulting inflammation, recent surgery, and chemotherapy can all increase the risk of VTE by up to 100-fold [6, 7].

Men over age 45 are typically higher risk than similarly aged women, but women are 2–4 times higher risk during pregnancy, and the risk to postpartum women is as much as 5 times that during pregnancy [9]. In terms of race, the age-adjusted VTE incidence for those of European descent appears to be 104–183 per 100,000. Most data indicate the risk for African-Americans is slightly higher than this, but the risk may differ based on the region in the USA. The risks in Asian and Native Americans are estimated to be much lower [5, 9]. Among the highest incidence of VTE in the community include patients with a central venous catheter or transvenous pacemaker (9%) nursing home patients (10%) and active cancer (20%) [9]. Cancer may increase the risk of VTE in various ways such as through the elaboration of pro-inflammatory products which activate the coagulation cascade or through a tumor compressing vessels which causes stasis. The incidence of VTE during the first 6 months after a cancer diagnosis is 12.4 per 1,000 [11].

Modifiable risk factors for VTE include obesity, hypertension, tobacco use, dyslipidemia, diabetes, diet, stress, hormone replacement therapy, and contraceptive use. Patients with a BMI >30 have a two- to threefold higher risk for VTE, and may be related to impaired venous return or increased coagulation and inflammation [7]. Regarding contraceptive use, while the levonorgestrel intrauterine device imparts no additional risk, first- and third-generation oral contraceptives are at higher risk than second-generation contraceptives, and the depo-medroxyprogesterone injection carries a threefold increased risk for VTE from baseline [9]. Table 1 includes further risk factors for VTE.

The most significant sequelae of VTE are venous stasis syndrome, venous ulcers, and chronic thromboembolic pulmonary hypertension. The 20-year incidence of venous stasis syndrome after VTE and proximal DVT is close to 25% and 40%, respectively, while that of venous ulceration is 3.7% [6].

Table 1 Risk factors for venous thromboembolism

Strong risk factors (odds ratio ≥ 10)
Fracture (hip or leg)
Hip or knee replacement
Major general surgery
Major trauma
Spinal cord injury
Moderate risk factors (odds ratio 2–9)
Arthroscopic knee surgery
Central venous lines
Chemotherapy
Congestive heart or respiratory failure
Hormone replacement therapy
Malignancy
Oral contraceptive therapy
Paralytic stroke
Pregnancy/Postpartum
Previous venous thromboembolism
Thrombophilia
Weak risk factors (odds ratio ≤ 2)
Bed rest >3 days
Immobility due to sitting (e.g. prolonged car or air travel)
Increasing age
Laparoscopic surgery (e.g. cholecystectomy)
Obesity
Pregnancy/Antepartum
Varicose veins

Diagnosis

Evaluating the history, signs, symptoms, and the individual's risk factors for VTE is essential for the diagnosis of DVT and PE (see Table 1). Patients with symptomatic DVT classically present with unilateral calf or thigh swelling, warmth, and tenderness. However, peripheral arterial disease (PAD), trauma, infection, and compartment syndrome may share these features. Likewise, patients suspicious for PE commonly present with one or more symptoms of chest pain, tachypnea, tachycardia, dyspnea, cough, and syncope. Concurrent DVT symptoms may also be present in those with suspected PE. Congestive heart failure (CHF), acute coronary syndrome (ACS), and chronic obstructive pulmonary

Telegram: @medical_k

www.konkur.in

disease (COPD) share similar signs and symptoms as PE and may confound the diagnosis [12].

Clinical Approach

Because none of the signs and symptoms of DVT or PE are specific, clinical probability assessment is an essential component in the diagnosis. Clinical prediction rules that incorporate signs, symptoms, and patient risk factors are frequently utilized to categorize patients as low, moderate, or high probability of having VTE [13]. Numerous guidelines recommend the use of validated clinical prediction rules to assess pretest probability of VTE to guide diagnostic decision-making [12, 14, 15].

A variety of formal scoring systems have been developed and validated to assist in stratifying patients with suspected DVT or PE [12]. Wells' DVT criteria is frequently used for DVT assessment and assigns a pretest probability category based on risk factor scoring. Patients are determined to be low (≤0), moderate (1–2), or high risk (≥3) for DVT based on their scores [15]. Wells' DVT criteria are shown in Table 2. Meanwhile, Wells' PE criteria [16] and the modified Geneva criteria [17] have similar predictive value and assist providers in determining pretest probability for PE [14]. Similar to the Wells' DVT criteria, the physician assigns points for different clinical criteria to obtain a pretest probability score. For the Wells' PE criteria, a patient's pretest probability is considered low for scores less than 2, moderate for scores between 2 and 6, and high for scores greater than 6. Wells' and the modified Geneva criteria are shown in Table 3. Simpler, two-tier/dichotomous versions of the Wells' and Geneva scores do exist (e.g., low risk vs high risk), but caution is advised since prospective validation of these models is still needed [14]. Also, though some suggest a simple gestalt approach to pretest probability, determination based on experience is often inaccurate and should be used cautiously [12]. Pretest probability for DVT or PE, along with test availability and risk, should guide subsequent D-dimer and diagnostic imaging (see algorithm) [18]. For those patients at low risk for PE determined by Wells' criteria, the Pulmonary Embolism Rule Out Criteria (PERC rule) can be used to effectively rule out PE (<1% of low-risk patients who are PERC negative will develop PE within 30 days) [18, 19].

Table 2 Wells' DVT Criteria

Variable	Points
Active cancer (treatment ongoing or within previous 6 months of palliative treatment)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for >3 days or major surgery within 4 weeks	1
Localized tenderness alone the distribution of the deep venous system	1
Entire lee swollen	1
Calf swelling by >3 cm when compared with the asymptomatic leg	1
Pitting edema (greater in the symptomatic leg)	1
Collateral superficial veins (not varicose)	1
Alternative diagnosis as likely or more likely than that of deep-vein thrombosis	-2
Analysis	
Probability of DVT is low	≤0
Probability of DVT is moderate	1 or 2
Probability of DVT is high	≥3

D-Dimer Testing

D-dimers are a byproduct of fibrinolysis formed by the degradation of fibrin within a clot and are acutely elevated in VTE [12]. The use of D-dimer testing with diagnostic algorithms that include pretest probability assessments can effectively exclude VTE in roughly 30% of patients suspected of having DVT or PE [2, 20]. Current assays are fast, readily available, and highly sensitive for DVT (over 93%) and PE (over 95%), but not nearly as specific [14]. False positives can be seen in patients with malignancy, infection, recent surgery or trauma, and pregnancy [13]. It is worth noting that since D-dimer levels increase naturally with age, for patients 50 years or older, using an

age-adjusted D-dimer, defined as a patient's age multiplied by 10, may be more accurate at ruling out VTE than using the typical fixed D-dimer cutoff of 500 ug/L [20, 21]. This approach appears very useful in ruling out PE, but prospective validation of its use to rule out DVT is currently ongoing [2].

Compression Ultrasound (CUS)

Widely available and noninvasive, CUS is the imaging procedure of choice for the diagnosis of DVT, with a sensitivity and specificity of 95% and 98%, respectively, when performed by a well-trained operator [14]. Inability to compress a vein with the transducer is diagnostic for DVT, while signs of distention, decreased flow, and abnormal Doppler signal support the diagnosis [13]. In patients with moderate to high pretest probability of DVT, negative CUS alone, especially if just proximal vessels were tested, cannot exclude the diagnosis of DVT [14]. Repeat CUS 1 week later is recommended for this group [13]. Some limitations include decreased reliability in detecting calf and upper extremity thrombi or poorer detection of thrombi isolated to the pelvis and difficulty distinguishing between old and new clots [12].

Venography

Once considered the gold standard for DVT detection, venography involves injecting contrast into the venous system to assess for filling defects or collateral flow. The PIOPED II trial demonstrated CT venography to be diagnostically equivalent at identifying DVT compared to CUS at the risk of higher contrast and radiation exposure [22]. Currently, venography is reserved for times when noninvasive tests cannot be performed or when noninvasive tests yield results counter to clinical suspicion [12].

www.konkur.in

Computed Tomographic Pulmonary Angiography (CTPA)

Multi-detector CT angiography has replaced conventional pulmonary angiography as the reference standard for diagnosing PE with high sensitivity and specificity of up to 100% and 97%, respectively [23]. Not only does it meet or exceed pulmonary angiography in ability to rule out PE, but it also generates diagnostic information that may suggest alternative or additional diagnoses [23]. Additionally, the PIOPED II trial showed that for those with high or intermediate pretest probability and positive CTPA results or those with low pretest probability and normal CTPA results, predictive values in the mid-90s were achieved [22]. Due to increased ionizing radiation and contrast exposure, consider ventilation-perfusion (V/Q) scanning for pregnant women, obese patients, or those with compromised renal function [12, 18].

Ventilation-Perfusion (V/Q) Scanning and V/Q SPECT

Ventilation-perfusion (V/Q) lung scans are reported as low, intermediate, or high likelihood for the presence of PE. A normal scan effectively excludes PE (negative predictive value of 100%) [23], while high pretest probability and a high-probability V/Q scan have a positive predictive value of 96% [18]. Unfortunately, approximately two-thirds of scans are not definitive and fall in the intermediate/non-diagnostic range [18]. As with CTPA, results discordant with pretest probability require further workup. Advances in V/Q single-photon emission CT (SPECT) have increased its sensitivity and specificity while limiting non-diagnostic results, which plague typical planar V/Q scans [18]. Though not available in all centers, its interobserver variability and diagnostic accuracy (both sensitivity and specificity of 96–97%) are superior to planar V/Q scans [24]. A single systematic review and meta-analysis also showed V/Q SPECT to be equivalent to CTPA in terms of diagnostic accuracy while allowing less radiation exposure but at a cost approximately twice that of CTPA [25].

Other Diagnostic Testing

Pulmonary angiography may still be considered in select cases where clinical suspicion for PE remains high despite negative prior testing, but it is more invasive and requires higher contrast exposure than CTPA [12]. Those with normal angiography results have a 3-month VTE incidence less than 2% with 0.3% incidence of fatal PE [26]. Meanwhile, the PIOPED III trial did show magnetic resonance angiography and venography (MRA and MRV) to have good sensitivity and specificity at detecting PE, but their high percentage of technically inadequate results currently do not support routine use [18, 27]. Additionally, tests like a chest x-ray showing pleural infiltrates, or engorged central pulmonary artery vasculature with a paucity of peripheral vessels, or an electrocardiogram showing right bundle branch block with the a S1Q3T3 pattern may increase suspicion for PE but are not specific [12] (Fig. 1).

Management

Management of VTE centers on initial stabilization of the patient, selection of anticoagulation therapy, and determining treatment duration. Providers may start empiric pharmacological treatment in high-risk patients (based on pretest probability) while undergoing testing, and delay treatment until testing is finished for low-risk patients, but there is insufficient data to support that administering anticoagulation prior to imaging improves morbidity or mortality [18]. A distal DVT is less likely to embolize than a proximal DVT, and a DVT that does not extend within a period of 2 weeks is unlikely to extend into the proximal veins. Therefore, for acute isolated distal DVT in a patient without severe symptoms or risk factors (i.e., positive D-Dimer, extensive thrombosis, thrombus near proximal veins,

Telegram: @medical_k

www.konkur.in

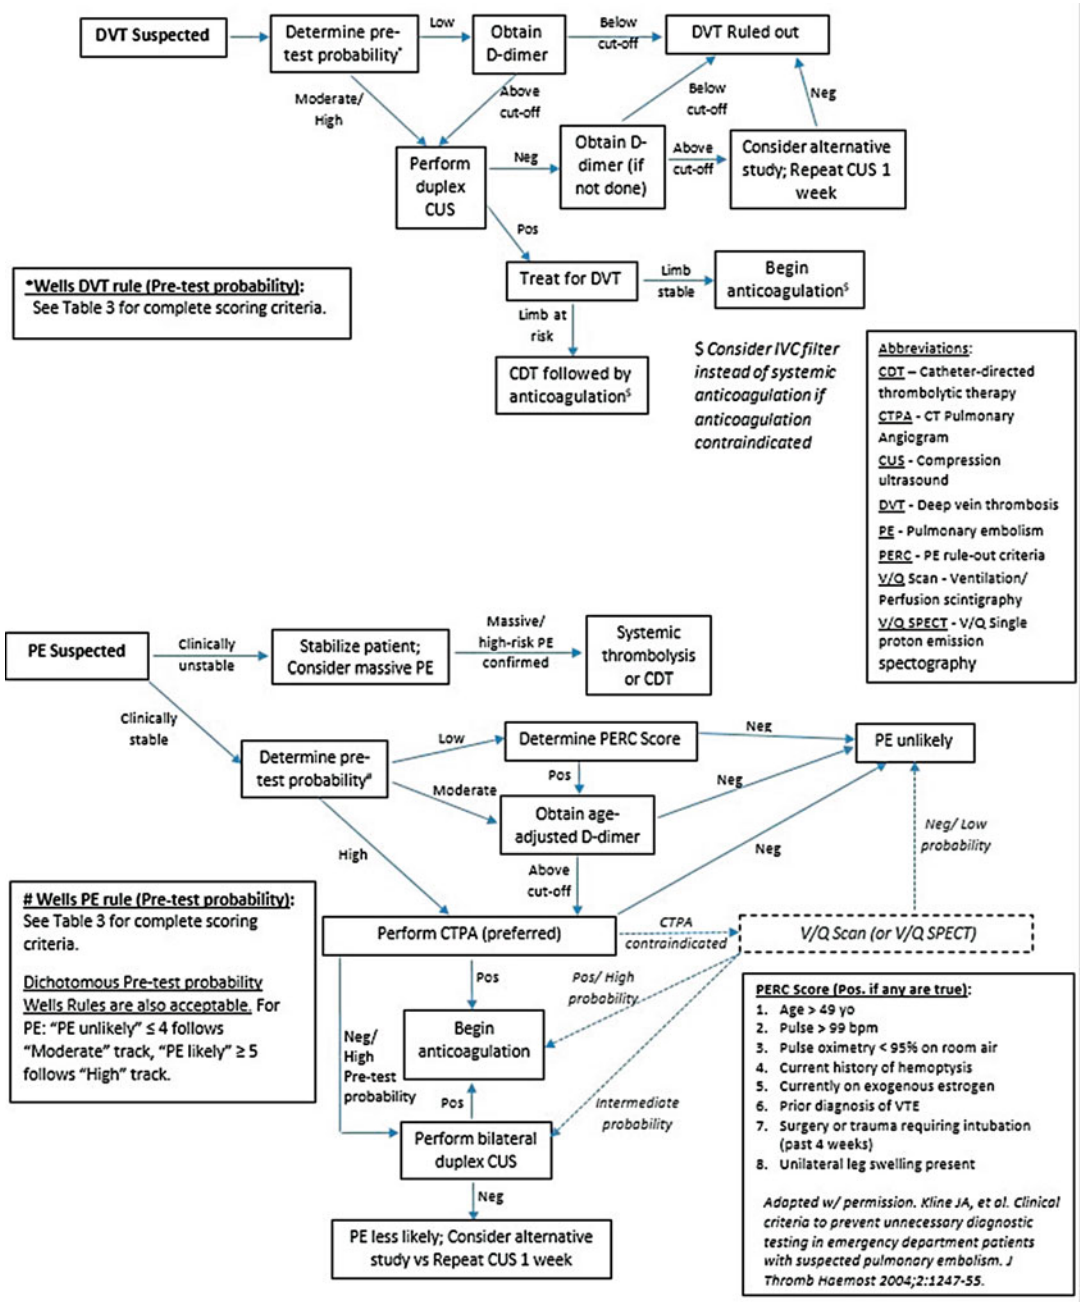

Fig. 1 Diagnostic algorithms for DVT (top) and PE (bottom) [14, 15, 18]

absence of reversible provoking factor, prior VTE, or inpatient status), the physician may delay anticoagulation and repeat imaging of the deep veins in 2 weeks [28]. Similarly, for asymptomatic patients with small, sub-segmental PEs and no DVT, recent guidelines suggest clinical surveillance over anticoagulation [28].

Telegram: @medical_k

www.konkur.in

Initial Management

Given the variation of severity in patients who present with PE, the provider must ensure hemodynamic stability. For patients who are stable (such as with an isolated single DVT of the leg or segmental PE with hemodynamic stability), initial therapy can be initiated with a goal to move to long-term anticoagulation. However, in more critical situations, such as acute massive PE, PE in a patient who is hypotensive, PE with significant right ventricular strain (i.e., cardiac biomarker elevations or right ventricular strain shown on echocardiogram or CTPA), or extensive acute proximal DVT, early thrombolysis may be needed in addition to respiratory and hemodynamic support [28]. Early lysis of the thrombus and reducing post-thrombotic morbidity [28, 29] may be achieved through venous infusion of a thrombolytic agent (systemic thrombolysis) or delivery into the thrombus via catheter-direct thrombolysis (CDT). Current guidelines still prefer systemic thrombolysis over CDT [28] as most data show that systemic thrombolysis and CDT have similar effectiveness [30], but the resources required for systemic thrombolysis are more widely available. However, in certain circumstances (such as severe PE or failure of systemic thrombolysis), CDT may be more appropriate assuming the resources and expertise to perform the procedure are available [2]. Emerging techniques, such as pharmacomechanical thrombectomy (PMT), are still being developed, and no specific guidelines yet exist regarding them. Once the patient is stable, the treatment focus may be shifted toward anticoagulation, which is broadly the same in patients with PE or DVT [13, 28].

Anticoagulation has traditionally been accomplished with initial treatment with unfractionated heparin (UH) or low-molecular-weight heparin (LMWH) to achieve immediate anticoagulation, along with a vitamin K antagonist (VKA, typically warfarin) to achieve long-term anticoagulation [31]. Initial treatment with subcutaneous UH, LMWH, or fondaparinux is required to allow time for the VKA to begin to work [32], after which frequent testing via PT/INR is required to ensure the VKA is dosed within an effective range [28, 33].

UH has long been utilized in the initial treatment of VTE and when given intravenously (IV), is dosed via a nomogram based on periodic monitoring of the patient's activated partial thromboplastin time (aPTT) [34]. IV UH is preferred in patients with PE who will likely undergo thrombolysis (due to its shorter action and easier reversibility), those with impaired subcutaneous absorption, or those with increased bleeding risk [31]. UH carries the risk of heparin-induced thrombocytopenia (HIT), hemorrhage, and anaphylaxis. The risk of hemorrhage increases with age, comorbidities, and previous bleeding. Due to the risk of HIT, patients on heparin should have their platelet count monitored daily. Despite UH's long history of use, LMWH and fondaparinux have become the favored initial treatment for uncomplicated VTE as both have equal efficacy, increased bioavailability, and less frequent dosing when compared to heparin [32].

While the traditional regimen of bridging initial subcutaneous anticoagulation with long-term oral anticoagulation is still a viable method of treatment, evidence has shown that immediate therapy with either rivaroxaban or apixaban can safely replace the traditional regimen, eliminating the need for the use of heparin injections or frequent monitoring required by VKAs [28, 35, 36]. Direct oral anticoagulants (DOACs) are now preferred as first-line anticoagulant therapy in most patients [28, 33, 37] due to their rapid onset of action, predictable pharmacokinetic profile, and comparative effectiveness for treating VTE compared to LMWH and warfarin [2]. An exception to this management strategy is VTE associated with malignancy where most guidelines recommend that the patient be anticoagulated with LMWH for the duration of their treatment [28, 31, 37]. However, evidence from recent randomized control trials (Hokusai-VTE Cancer [38], SELECT-D [39], and CARAVAGGIO [40]) shows that DOACs (edoxaban, rivaroxaban, and apixaban) are non-inferior to LMWH for treatment of VTE in patients with cancer without significant increased bleeding risk (highest risk found in those with

Telegram: @medical_k

www.konkur.in

gastrointestinal malignancies) and could be an option for this group of patients.

Outpatient initial management may be appropriate in low-risk patients. Criteria for outpatient therapy include patients with good cardiorespiratory reserve, no excessive bleeding risks, a creatinine clearance greater than 30 mL/min, and ability to safely self-administer the medication [28, 33]. Well-validated clinical scores, like the Pulmonary Embolism Severity Index (PESI) and simplified-PESI (sPESI), can also be used to provide objective measures of a patient's appropriateness for initial outpatient management and hospital discharge [33]. Each provides reliable identification of patients at low 30-day mortality risk using baseline indicators of PE severity and the individual's comorbidities and potentially aggravating conditions. For the sPESI, a high-risk patient meets at least one of the following requirements: age over 80 years old, history of cancer, chronic cardiopulmonary disease (i.e., chronic obstructive pulmonary disease or congestive heart failure), pulse over 100 beats per minute, systolic blood pressure under 100 mmHg, or oxygen saturation less than 90% [33]. See Table 4 for a summary of treatment options.

Long-Term Anticoagulation

Goals of long-term anticoagulation therapy include preventing clot propagation, preventing possible PE (primary or subsequent), and minimizing complications. Resolution of an existing clot is not a direct goal of anticoagulation therapy [13, 28]. Recommended duration of therapy varies based on clinical circumstances, with a minimum treatment length of 3 months [28, 31]. Generally (with the exception of UH), the initial form of anticoagulation can be continued as the patient's long-term anticoagulation agent. However, given that LMWH and fondaparinux are both administered subcutaneously, it is typically favored to transition to an oral anticoagulant.

VKAs, LMWH, fondaparinux, and direct oral anticoagulants (DOACs) may be used to provide long-term anticoagulation [31]. The longest used agent is warfarin, a VKA. Warfarin was previously preferred due to time-proven efficacy, oral administration, reversibility, and low cost. However, periodic lab testing, narrow therapeutic window, need for dosage adjustments, and its interactions with many drugs and foods may limit its use [31]. When using warfarin for long-term anticoagulation, initial therapy should be continued for a minimum of 5 days and at least 24 h after the patient's international normalized ratio (INR) is above 2.0. The initial subcutaneous or IV therapy provides adequate anticoagulation, while the vitamin K-dependent clotting factors are depleted. The goal INR value for treatment is 2.5, with an acceptable range of 2.0–3.0 [28, 31]. Various tables and algorithms are available to guide warfarin dosing based on INR testing. One such validated protocol suggests monthly INR testing for patients within their therapeutic window, and weekly testing for those outside of this range, which is supported by groups like the American Society of Hematology [37].

LMWH is also a viable option with similar efficacy and risk profile when compared to warfarin for long-term anticoagulation [41]. LMWH is advantageous due to its ease of dosing, wide therapeutic window, no need to monitor, and fewer drug/food interactions compared to warfarin. However, it is also more expensive than warfarin, more difficult to reverse, requires subcutaneous dosing, and carries a risk of drug-induced osteoporosis. LMWH is preferred in patients with malignancy for long-term treatment by most guidelines [28, 37]. Fondaparinux is a subcutaneous agent that is similar to LMWH in use and may also be used in long-term treatment [31, 37].

DOACs are quickly becoming the treatment of choice for long-term anticoagulation as evidence supports their effectiveness compared to warfarin for long-term therapy [35, 36, 42]. Also, most current guidelines recommend these as first-line treatment for VTE that is not associated with malignancy due to continued evidence demonstrating their safety and efficacy [28]. Compared with LMWH treatment followed by long-term VKA treatment, DOACs are non-inferior for recurrent VTE and have a lower risk of major bleeding [43]. Meta-analyses have also

www.konkur.in

Dabigatran[a]	Direct thrombin inhibitor	150 mg BID; CrCl 30–50 or age > 75 yo: 110 mg BID; CrCl 15–30: 75 mg BID	14–17 h	P-glycoprotein inducers/inhibitors	Idarucizumab	None required	Initially required, 5–10 days	CrCl <15, not defined
Apixaban[a,b]	Factor Xa inhibitor	10 mg BID for 7 days, then 5 mg BID. 2.5 mg BID if treating beyond 6 mos	8–12 h	CYP3A4/5. P-glycoprotein inducers/inhibitors	Andexanet alfa	None required	None required	2.5 mg BID if at least 1 criterion is met: Serum Cr ≥ 1.5 mgdL, age 80 yo, weight 60 kg or less
Rivaroxaban[a,b]	Factor Xa inhibitor	15 mg BID for 21 days, then 20 mg daily (15 mg daily if CrCl 15–50). 10 mg daily if treating beyond	7–11 h	CYP3A4, CYP2J2, P-glycoprotein inducers/inhibitors	Andexanet alfa	None required	None required	If CrCl <30, consider alternative agent.
Edoxaban[a,b]	Factor Xa inhibitor	30 mg (if ≤60 kg, or CrCl 15–50) or 60 mg daily (if >60 kg & CrCl >50)	6–11 h	P-glycoprotein inducers/inhibitors	None	None required	Initially required, 5–10 days	CrCl <15, consider alternative agent

aPTT activated partial thromboplastin time, *BID* twice daily, *BMI* body mass index, *CrCl* Creatinine clearance (mL/min), *INR* international normalized ratio, *IV* intravenous, *SC* subcutaneous

[a]Limited data in those with creatinine clearance (CrCl) less than 30, antiphospholipid syndrome, heparin-induced thrombocytopenia, BMI >40 kg/m^2, or VTE at unusual sites

[b]Generally avoided if concurrent use of azole antimycotics (e.g., ketoconazole), certain protease inhibitors (e.g., ritonavir), and antiepileptic drugs (e.g., carbamazepine & phenytoin). Note: information on conversion to and from DOACs and warfarin can be found in reference [31] (eTable A). https://www.aafp.org/afp/2017/0301/hi-res/afp20170301p295-ta.gif (Accessed March 1, 2020)

www.konkur.in

shown good tolerability in elderly patients [44]. In addition, as mentioned above, evidence for DOACs effectiveness and safety for treatment of VTE in patients with cancer is growing [38–40].

Length of Therapy and Extended Anticoagulation

The length of therapy for anticoagulation depends upon the clinical picture surrounding the VTE with the standard length of anticoagulation therapy being at least 3 months. Anticoagulation that lasts for 3–6 months is considered "long-term anticoagulation," whereas anticoagulation extending beyond 3–6 months without a scheduled stop date is considered "extended anticoagulation" [2]. The decision to extend therapy beyond 3 months is based on balancing the benefits of treatment (i.e., reduction in VTE recurrence based on patient risk factors) and the risks of treatment (i.e., increased bleeding) [2, 31]. For provoked VTE (i.e., a VTE with a known cause such as surgery or non-surgical risk factors), whether a DVT of the leg or PE, anticoagulation can be stopped after 3 months as long as there is no recurrence. For those with unprovoked VTE, the decision to extend anticoagulation beyond 3 months should be based on their bleeding risk. If they have a low or moderate bleeding risk, extended therapy (no scheduled stop date) is preferred. If they have a high bleeding risk, 3 months of therapy is preferred [28, 33]. Reasons to treat for longer than 6 months include those with a first or second unprovoked PE or proximal DVT of the leg, patients with active cancer and VTE, or those with genetic thrombophilias, so long as they are at low or moderate risk of bleeding [28, 31]. Prediction models for quantifying bleeding risk like the HAS-BLED or VTE-BLEED scores can be used to help the clinician stratify bleeding risk [33]. For extended therapy with DOACs beyond 6 months, current guidelines recommend the use of the prophylactic doses of apixaban and rivaroxaban (2.5 mg twice per day and 10 mg daily, respectively) [2, 33].

Additional Therapy

Daily low-dose aspirin (~100 mg) after the initial anticoagulation treatment period may be considered, particularly in patients on extended anticoagulation who elect to stop anticoagulation [28, 33]. Pooled results of the randomized, multicenter WARFASA and ASPIRE trials showed a 32% reduction in the rate of recurrence of VTE in patients receiving aspirin following anticoagulation therapy [45]. The use of compression stockings can be justified to lessen symptoms of existing acute or chronic post-thrombotic syndrome (PTS), but are not recommended for the use of prevention of PTS [28]. Inferior vena cava (IVC) filters are reserved for those with PE or proximal DVT and a contraindication to or a complication from anticoagulant treatment [28]. They have not been shown to reduce recurrent PE in previously anticoagulated patients who have additional risk factors for recurrence [33].

Prevention

Recognizing those factors that increase one's risk for VTE is essential for prevention. Extended or life-long anticoagulation may be appropriate for those with multiple risk factors. ▶ Chap. 55, "Athletic Injuries," discusses VTE prophylaxis for hospitalized and surgical patients in more detail.

Superficial Vein Thrombosis and Superficial Thrombophlebitis

Traditionally considered to be a more benign and self-limiting condition, thrombosis of the superficial venous system is often considered distinct from deep vein thrombosis and, as a result, studied less [46]. Superficial vein thrombosis (SVT) is currently the preferred term for a thrombus in the superficial vein system (especially the axial veins like the great and small saphenous veins), while the term superficial thrombophlebitis can more appropriately be used to describe confirmed

Telegram: @medical_k

www.konkur.in

thrombus accompanying phlebitis (inflammation within a vein) of the tributary veins. Phlebitis can develop for a variety of reasons including injury, infection, or thrombus [47]. The distinction between SVT and superficial thrombophlebitis is important because thrombosis of axial veins can lead to thromboembolism, especially if the proximal aspect of the larger axial veins is affected [46]. Patients with superficial venous thrombosis are at higher risk of developing DVT [31].

The risks for developing SVT and superficial thrombophlebitis are similar to those previously described for VTE (Table 1) and include advanced age, obesity, active cancer, previous thromboembolic episodes, pregnancy, oral contraceptive use, hormone replacement therapy, recent surgery, autoimmune diseases, and varicose veins (this last one being unique to SVT) [46]. Phlebitis and thrombosis of the lower extremities are more likely to occur in varicose veins, which account for over 60% of SVT cases, while lack of physical activity and trauma are among the risk factors for the development of a clot in varicosities [48]. The most consistent risk factor for developing phlebitis or thrombosis of the upper extremities involves the use of venous cannulation, and while this discussion focuses more on lower extremity conditions, the same principles may be applied to the upper extremities with regard to SVT [49]. Saphenous vein thrombosis is thought to be more common than DVT, and the great saphenous vein is more commonly involved than the small saphenous vein [48, 49].

On exam, one can expect to find pain, redness, and swelling along the path of a superficial vein [48]. If a thrombus is present, it may appear as a thickened cord, especially if it persists when the extremity is raised, and may be accompanied by low-grade fever. High fever or redness extending significantly past the margin of the vein should prompt evaluation for suppurative infection, and is usually associated with invasive procedures [46]. Superficial thrombus is usually identified with the use of duplex ultrasound, which will also help to identify whether DVT is present; however, some favor a period of observation in isolated findings of thrombophlebitis remote from the great and small saphenous veins [46].

Patients with isolated uncomplicated phlebitis not involving the saphenous veins, with no other risk factors for DVT, can be treated symptomatically with repeat evaluation in 7–10 days. Treatment depends on several variables, including size, location, and severity of symptoms [46]. For the management of uncomplicated thrombi at low risk for VTE (>5 cm from the saphenofemoral or saphenopopliteal junction, <5 cm in length, and no other risk factors), supportive therapy with elevation of the affected extremity, cool/warm compresses, non-steroidal anti-inflammatory drugs (NSAIDS), encouraging patient mobility, and possibly compression stockings in appropriate candidates are preferred initial therapies [46]. Most uncomplicated cases respond to supportive care within a few days and pain usually resolves in a week. Ultrasound should be performed if extension does occur, and the thrombosed vessel may still be palpable for months after resolution of pain [46, 50].

For higher-risk thrombi (i.e., SVT ≤5 cm from the saphenofemoral or saphenopopliteal junction, a thrombosed segment ≥5 cm in length, or other medical risk factors for VTE), anticoagulation should be considered [46]. Suggested therapies include subcutaneous fondaparinux (2.5 mg daily), subcutaneous low-molecular-weight heparin (enoxaparin 40 mg daily), or oral rivaroxaban (10 mg daily) for 45 days [46, 50]. If anticoagulation is not possible, or if thrombus recurs, ligation or excision may be needed to prevent extension. Antibiotics should be used only if signs of infection are present [46].

Peripheral Artery Disease

The prevalence of peripheral artery disease (PAD) increases with age from <5% before age 60 to over 20% after age 74 with over 80% of PAD patients identified as current or former smokers [1]. Coronary artery disease (CAD) and cerebrovascular disease occur two to four times more often in patients with lower extremity PAD compared to those without PAD. The amputation rate in the general PAD population is 1% or less per year but is significantly more common in current smokers and diabetics (7–15-fold increase). Recent trials have reported a combined rate of myocardial infarction (MI), stroke, and vascular death of 4–6%, while epidemiological studies report annual mortality of 4–6%. Unfortunately, too few patients with PAD receive guideline-directed management and therapy (GDMT) to reduce morbidity and mortality from CAD and other cardiovascular diseases [2].

Presentation and Diagnosis

Intermittent claudication, defined as fatigue, discomfort, cramping, or pain that occurs in lower extremity muscle groups during exercise which is relieved by rest (in 10 min or less), is the presenting symptom in 10–35% of patients. Atypical lower extremity pain (including numbness, tingling, or paresthesia) is the presenting symptom in 40–50% of cases, although in many of these patients, PAD is an incidental finding and not the cause of their leg pain. When combined with cases found through screening, 20–50% of patients are asymptomatic from their PAD at the time of diagnosis. Acute limb ischemia (ALI), where symptoms are present for less than 2 weeks, is characterized by the 6 "Ps": pain, paralysis, paresthesias, pulselessness, pallor, and poikilothermia. ALI represents a medical emergency which is subdivided into three severities: viable (no immediate threat), threatened, and irreversible (major tissue loss or permanent nerve damage is inevitable). Critical limb ischemia (CLI) includes chronic rest pain (≥2 weeks), nonhealing ulcers/wounds, or gangrene due to occlusive arterial disease. CLI is the presentation in 1–2% of cases, and after 1 year only 50% will be alive with both legs (25% will die and 25% will have at least one amputation). Additional signs on physical exam include diminished pulses and vascular bruits, while dependent rubor, early pallor when elevating the limb, reduced capillary refill, hair loss, and muscle wasting are signs of chronic ischemia. Arterial ulcerations are typically quite painful unless neuropathy is also present as can occur in patients with concomitant diabetes mellitus.

A resting ankle-brachial index (ABI) in both legs is recommended for diagnosis of lower extremity PAD and should be reported as follows: noncompressible >1.40, normal 1.00 to 1.40, borderline 0.91 to 0.99, or abnormal ≤0.90 [2]. A toe-brachial index should be used in patients with noncompressible vessels (≤0.70 diagnoses PAD). Patients with typical exertional claudication and a normal or borderline resting ABI should complete an exercise treadmill ABI. Further imaging is reserved for patients in whom revascularization is considered or who continue to experience lifestyle-limiting claudication despite GDMT. Anatomic assessment may be completed with duplex ultrasound (which localizes diseased segments and grades lesion severity), MR angiography (especially good for evaluation of arterial dissection and wall morphology), or CT angiography (when MR is contraindicated). Invasive angiography is often the first-line choice for patients with CLI but remains a second-line

Telegram: @medical_k

www.konkur.in

choice for patients without CLI if they are candidates for revascularization.

Differential Diagnosis

Atherosclerosis is the most common cause of PAD, just as it is for CAD and stroke. Lower extremity PAD may also be caused by thromboembolism, trauma, vasculitis, physiological entrapment syndromes, fibromuscular dysplasia, or congenital abnormalities [2]. The differential considerations for claudication include neurogenic claudication (due to lumbar disk disease, spinal stenosis, or osteophytic changes), osteoarthritis (hip, foot, or ankle), severe venous obstructive disease, chronic compartment syndrome, symptomatic Baker's cyst, or shin splints (in younger persons). The differential considerations for nonhealing wounds include trauma, infection, malignancy, autoimmune injury, drug reactions, neuropathic, microangiopathy, or venous ulceration.

Intervention

Atherosclerotic cardiovascular disease (ASCVD) risk factors, including hypertension and diabetes, should be managed according to current evidence-based guidelines [2]. Statins are recommended for all patients with PAD. Tobacco cessation is essential, and pharmacologic therapies should be combined with behavioral treatment if there are no contraindications. Antiplatelet therapy (aspirin 75–325 mg or clopidogrel 75 mg daily) is recommended for all patients with PAD to decrease the risk of myocardial infarction, ischemic stroke, and vascular death. Vorapaxar (2.5 mg daily with aspirin or clopidogrel), a novel antiplatelet agent which is contraindicated in patients with a history of transient-ischemic attack or stroke, and rivaroxaban (2.5 mg BID with low dose aspirin) are also FDA approved for patients with both PAD and CAD; however, their use is limited by an increased risk of bleeding complications [3]. Supervised exercise training for a minimum of 30–45 minutes, three times per week for at least 12 weeks, improves intermittent claudication [2]. Cilostazol (100 mg twice per day) is the first-line pharmacologic treatment for claudication in the absence of heart failure (HF). Pentoxifylline is no longer recommended as a second-line therapy since the evidence now shows that it has no benefit. Oral vasodilator prostaglandins, vitamin E, chelation therapy, and homocysteine lowering with B-complex vitamins should also not be used to treat PAD. While warfarin anticoagulation should not be used to decrease the risk of cardiovascular ischemic events, it may have a role in improving graft patency. Consultation for surgical or endovascular revascularization is indicated for occupation or lifestyle-limiting symptoms where nonsurgical therapy has failed or for signs or symptoms of ischemia at rest.

Pericarditis

Acute pericarditis is an inflammation of the pericardium, the avascular fibrous sac that surrounds the heart. Constrictive pericarditis is a term reserved for post-inflammatory changes affecting the pericardium, resulting in impaired diastolic filling of the heart. Acute pericarditis is relatively common and accounts for 5% of emergency room admissions for chest pain [4]. Some cases are mild and patients may not present for medical care; others can be life-threatening. There are numerous etiologies of pericardial inflammation (Table 1). In developed countries, 80–90% of cases are idiopathic, as no specific cause is found after routine evaluation. These cases are typically thought to be viral in origin. The remaining cases are most often found to be related to post-cardiac injury syndromes, autoimmune disease, and malignancy. Tuberculosis remains the leading cause of pericardial disease in the developing world.

Presentation and Diagnosis

Patients typically present with chest pain. The pain is often sharp, severe, retrosternal, exacerbated with breathing, and relieved with sitting

Telegram: @medical_k

www.konkur.in

Table 1 Etiologies of pericarditis

Infectious
Viral: Coxsackievirus, echovirus, Epstein-Barr virus, cytomegalovirus, adenovirus, parvovirus B19, human herpesvirus 6
Bacterial: Tuberculosis, *Coxiella burnetii*, rare other bacteria (pneumococcus, meningococcus, gonococcus, haemophilus, streptococcus, staphylococcus, chlamydia, mycoplasma, legionella, leptospira, listeria)
Fungal: Histoplasma (more likely in immunocompetent patients), aspergillus, *Blastomyces*, candida (more likely in immunosuppressed patients)
Parasitic: *Echinococcus*, toxoplasma (overall very rare)
Autoimmune
Pericardial injury syndromes: Post-myocardial infarction syndrome, post-pericardiotomy syndrome
Connective tissue diseases: Systemic lupus erythematosus, Sjögren syndrome, rheumatoid arthritis, systemic sclerosis, systemic vasculitides, Behçet's syndrome, sarcoidosis, amyloidosis
Autoimmune diseases: Familial Mediterranean fever, tumor necrosis factor receptor-associated periodic syndrome (TRAPS)
Neoplastic
Primary tumors: Pericardial mesothelioma (overall rare)
Secondary metastatic tumors: Lung cancer, breast cancer, lymphoma
Other
Trauma: Blunt chest trauma, penetrating thoracic injury, esophageal perforation, radiation
Metabolic: Uremia, myxedema (rare)
Drugs: Lupus-like syndrome (procainamide, hydralazine, isoniazid, phenytoin), hypersensitivity pericarditis with eosinophilia (penicillins), direct toxic effects (doxorubicin and daunorubicin; often associated with cardiomyopathy)

Source: Little and Freeman [5]

forward. This pain may mimic other diagnoses. Acute pericarditis is diagnosed if at least two of four key findings are present: chest pain consistent with pericarditis, pericardial friction rub ("Velcro-like" sounds heard best at the apex), typical electrocardiogram (ECG) changes (diffuse upsloping ST elevation with PR depression), or significant pericardial effusion (seen on echocardiogram) [4]. The auscultative and electrographic signs may be transient, and repeated examination may be warranted.

Patients with pericarditis may report a viral prodrome. Many have sinus tachycardia and low-grade fever. Signs of systemic inflammation commonly arise, such as elevated white blood cell count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). Troponin may be elevated. Rarely, patients will present with cardiac tamponade and likely will have chest pain and dyspnea. Exam shows jugular venous distention, muffled heart sounds, hypotension, and a paradoxical pulse.

Once the diagnosis of pericarditis is confirmed, the next step is to search for the cause of inflammation. This can be tailored to the patient's presentation and history, to identify possible treatable or life-threatening etiologies outlined in Table 1. Diagnostic pericardiocentesis is typically done only for large effusions. If the diagnosis is not confirmed, but clinical suspicion remains for pericarditis, routine lab evaluation can be done with frequent reexamination and repeat ECG. At times, CT or MRI is used to show pericardial thickening.

Differential Diagnosis

Differential considerations for acute pericarditis include most cardiac syndromes. This includes acute myocardial infarction (AMI), pulmonary embolus, aortic dissection, cardiac contusion, and myocarditis. Consideration must also be given to the other structures in the thorax, to include mediastinitis, esophageal spasm, esophagitis, gastroesophageal reflux, costochondritis, and pneumonia. The ECG changes of pericarditis may be confused with early repolarization [4]. Often the most difficult distinction to make is between acute pericarditis and AMI. Cardiac catheterization may

Telegram: @medical_k

www.konkur.in

be performed. There will be a lack of angiographic evidence of CAD in cases of acute pericarditis.

Intervention

Initial management of acute pericarditis focuses on treating the underlying cause, if possible. Otherwise, most idiopathic or viral pericarditis resolves spontaneously or with simple, first-line treatment. Nonsteroidal anti-inflammatory drugs (NSAIDs) and colchicine are the basis of the treatment regimen. Often aspirin is used, especially in post-MI patients, but at higher anti-inflammatory doses (650 mg every 6 h) [5]. Indomethacin (50 mg every 8 h) and ibuprofen (600 mg every 8 h) can also be used. NSAIDs can be discontinued or tapered after 7–10 days if the patient's pain is resolved. Some clinicians use the CRP level to guide discontinuation. A proton-pump inhibitor is often used in conjunction for gastric protection. Colchicine (0.5 mg twice daily if weight >70 kg, once daily if weight <70 kg) is used in addition to NSAIDs to decrease the likelihood of persistent symptoms and the risk of recurrent pericarditis [4]. Colchicine is typically continued for 3 months. Corticosteroids do have strong anti-inflammatory properties, but their use is associated with an increased chance of recurrence. They may be required in refractory cases. Patient's lacking high-risk indicators can be managed in the outpatient setting (Table 2). Bacterial pericarditis, while rare, can be life-threatening. In addition to antibiotics, intrapericardial fibrinolysis can be effective to prevent evolution to constrictive pericarditis.

Adequate treatment of acute pericarditis is key to prevent recurrent pericarditis or constrictive pericarditis. If symptoms recur, NSAID therapy should be reinstated. Colchicine should be added if it was not used in the initial case. The most significant complication of acute pericarditis is constrictive pericarditis. Since diastolic filling of the heart is impaired by a fibrotic pericardium, patients develop symptoms of HF and fluid overload. If the initial case of acute pericarditis was not recognized, the diagnosis may not be initially clear. At times the constriction is transient, but patients often require pericardiectomy for treatment.

Table 2 Predictors of poor outcome in pericarditis

Fever >38 °C
Symptoms developing over several weeks in association with an immunosuppressed state
Traumatic pericarditis
Pericarditis in a patient receiving oral anticoagulants
Large pericardial effusion (>20 mm echo-free space or evidence of tamponade)
Failure to respond to nonsteroidal anti-inflammatory drugs

Bacterial Endocarditis

Infectious endocarditis (IE) is an infection of the endocardial surface mainly due to bacteria but rarely may be caused by fungi and protozoa [6]. Bacterial endocarditis (BE) may give rise to the classic though not universally found lesion of IE: the valvular vegetation. These vegetations may interfere with valvular function leading to HF and may embolize to produce a wide variety of focal and systemic signs and symptoms. The overall incidence of IE in the United States has risen to 13 cases per 100,000 patient-years, with a slight male predominance (58%) and a median age of 61 years [7, 8]. While valvular disease is still a major risk factor, it is now uncommonly due to rheumatic heart disease, having dropped from 50% of cases to less than 5% over the last 40 years. Untreated BE is almost uniformly fatal; therefore, if BE is suspected, aggressive evaluation and treatment, to include early surgery in some cases, are essential. In-hospital mortality rates have been stable over the past 25 years at 15–20% with 1-year mortality of almost 40%.

Effective management of BE relies on targeting treatment to specific organisms. Gram-positive bacteria (predominantly *streptococci*, *staphylococci*, and *enterococci*) are the most common cause of IE and now account for over 90% of the cases with a known organism, in part due to an increasing incidence of *Staphylococcus aureus* [7]. Fungal, protozoal, and gram-

Telegram: @medical_k

www.konkur.in

negative causes increase with prosthetic valve endocarditis (PVE) and other invasive cardiovascular devices [6]. The HACEK group (*Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) occurs in 2% of cases worldwide. Intravenous drug users (IVDUs) have a very high incidence of right-sided valvular involvement, especially the tricuspid valve which is uncommon in non-IVDUs. Nosocomial BE is most commonly related to indwelling catheters or invasive procedures. BE caused by HACEK most commonly occurs in native valve, non-IVDUs.

Presentation and Diagnosis

Though the primary lesion in BE is in the heart itself, many of its presenting signs and symptoms reflect the systemic nature of the disease [6]. Fever, myalgias, fatigue, headache, and abdominal pain are common in all types of BE. Heart failure is the most common complication and develops in approximately 30% of cases. Vegetations can embolize to almost any location, causing distant infection or infarction. Right-sided embolic events may lead to specific complaints of chest pain, cough, and hemoptysis. Left-sided embolic events can present as mental status changes, stroke, myocardial infarction, splenic infarction, and renal abscess. Stroke occurs in approximately 9–13% of patients, while myocardial infarction occurs in 3–7% of cases [7]. Other complications of BE include osteomyelitis, septic arthritis, and mycotic aneurysms.

With the exception of Janeway lesions, which occur in only 5% of cases, few physical findings are highly specific for BE. Likewise, Roth's spots (2%), Osler's nodes (3%), splinter hemorrhages (8%), and splenomegaly (11%) are relatively uncommon since the diagnosis of IE is now occurring earlier in the clinical course [7, 8]. Cardiac murmurs are most often regurgitant with a new murmur occurring 48% of the time and worsening of an old murmur is present in an additional 20% of cases. With the exception of blood cultures, laboratory evaluation is frequently of less value in making the early diagnosis of BE compared to the history and examination. Antibiotic therapy should not be given prior to blood culture collection, particularly in patients with known valvular heart disease and an unexplained fever [8, 9]. Antimicrobial therapy can be delayed in patients with a chronic or subacute presentation to allow for the collection of three sets of blood cultures from peripheral sites with the first and third drawn at least 1 h apart from each other [6]. At least two, but preferably three, sets of blood cultures separated by 30 min should be obtained from patients who present in severe sepsis or septic shock. Other laboratory findings and imaging may reflect other complications as mentioned above. Blood culture negative IE (as high as 31% of IE) may require serologic testing or PCR of surgical specimens to identify the causative organism [9]. ECG may reveal conduction abnormalities, indicating the extension of an aortic valve infection to a valve ring abscess, which carries a worse prognosis.

The 1994 Duke criteria were modified in 2000 to redefine "possible IE" (reducing the number of patients in this category) and modify the major and minor criteria (increasing the sensitivity) [10]. The diagnosis of "definite IE" is arrived at either through one of two pathologic criteria or through one of several combinations of major and minor clinical criteria (Table 3). The clinical criteria emphasize two main areas: positive blood cultures and evidence of endocardial involvement (Table 4). The second major criterion takes advantage of both transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE) as a safe yet highly sensitive means for identifying endocardial lesions. Guidance as to when TEE is preferred over TTE was added to the major criteria definitions as part of the modifications in 2000.

The Duke criteria have been extensively studied and found to have a sensitivity around 80% while maintaining a specificity of 92–99% [6, 8, 9]. These criteria have also been validated for both the adult and pediatric populations, as well as special groups such as those with PVE. However, since an adequate amount of clinical data must be collected before the Duke criteria can be applied, early empiric therapy should not

Table 3 Definition of infective endocarditis according to the modified Duke criteria, with modifications shown in boldface

Definite infective endocarditis
Pathologic criteria
Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen
Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
Clinical criteria[a]
2 major criteria
1 major criterion and 3 minor criteria
5 minor criteria
Possible infective endocarditis
1 major criterion and 1 minor criterion
3 minor criteria
Rejected
Firm alternate diagnosis explaining evidence of infective endocarditis
Resolution of infective endocarditis syndrome with antibiotic therapy for ≤4 days
No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for ≤4 days
Does not meet criteria for possible infective endocarditis, as above

Source: Li et al. [10], "Proposed Modifications to the Duke Criteria for the Diagnosis of Infective Endocarditis," *Clinical Infectious Diseases*, 2000; 30:633–8, by permission of the Infectious Diseases Society of America
[a]See Table 4 for definitions of major and minor criteria

be delayed if IE is suspected. In this regard, the criteria are best used to assist in sculpting medical therapy and determining a need for surgical intervention.

Differential Diagnosis

Virtually any systemic infection should be considered in the differential diagnosis of IE. These include, but are not limited to, pneumonia, meningitis, pericarditis, abscess, osteomyelitis, tuberculosis, and pyelonephritis. Noninfectious etiologies to be considered include stroke, myocardial infarction, rheumatic fever, vasculitis, malignancy, and fever of unknown origin.

Intervention

Once the diagnosis of IE is suspected, antibiotic therapy should be instituted without delay after blood cultures are obtained [6, 9]. Because bacteria in valvular vegetations are relatively protected from host immune defenses, antibiotics chosen to treat IE must be bactericidal, and regimens for their administration must be aggressive and of adequate duration to completely eradicate the organism and prevent relapse. Empiric therapy should be guided by local resistance patterns, but as a general rule for all native valves and prosthetic valves greater than 12 months after surgery, treatment may begin with ampicillin-sulbactam (3.0 g IV q6h) and gentamicin (1.5 mg/kg IV/IM q12h or 1.0 mg/kg IV/IM q8h). In patients with a β-lactam allergy, vancomycin (15/mg IV q12h) and ciprofloxacin (400 mg IV q12h or 500 mg PO q12h) may replace ampicillin-sulbactam. Empiric therapy for prosthetic valves less than 12 months after surgery may begin with vancomycin (15 mg/kg IV q12h), gentamicin (1.5 mg/kg IV/IM q12h or 1.0 mg/kg IV/IM q8h), and rifampin (600 mg PO q12h). The full course of antibiotics is tailored to culture results with some native valve regimens as short as 2 weeks, while all PVE regimens last a minimum of 6 weeks (Tables 5 and 6).

At least two sets of blood cultures should be collected every 24–48 h until a negative culture is

www.konkur.in

Table 4 Definition of terms used in the modified Duke criteria for the diagnosis of infective endocarditis (IE) with modifications shown in boldface

Major criteria
Positive blood culture for IE
Typical microorganisms consistent with IE from 2 separate blood cultures:
Viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*
Community-acquired enterococci, in the absence of a primary focus
Microorganism consistent with IE from persistently positive blood cultures, defined as follows:
At least 2 positive cultures of blood samples drawn >12 h apart
All of 3 or a majority of ≥4 separate cultures of blood (with first and last drawn at least 1 h apart)
Single positive blood culture for *Coxiella burnetii* or antiphase I IgG titer ≥1:800
Evidence of endocardial involvement
Echocardiogram positive for IE (TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE [paravalvular abscess]; TTE as first test in other patients), defined as follows:
Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation
Abscess
New partial dehiscence of prosthetic valve
New valvular regurgitation (worsening or change in preexisting murmur not sufficient)
Minor criteria
Predisposition: Predisposing heart condition or injection drug use
Fever: Temperature >38 °C
Vascular phenomena: Major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhages, conjunctival hemorrhages, and Janeway lesions
Immunologic phenomena: Glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor
Microbiologic evidence: Positive blood culture but does not meet a major criterion as noted above[a] *or* serological evidence of active infection with organism consistent with IE
Echocardiographic minor criteria eliminated

Note: *TEE* transesophageal echocardiography, *TTE* transthoracic echocardiography
Source: Li et al. [10], "Proposed Modifications to the Duke Criteria for the Diagnosis of Infective Endocarditis," *Clinical Infectious Diseases*, 2000; 30:633–8, by permission of the Infectious Diseases Society of America
[a]Excludes single-positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis

obtained. The first day of therapy for determining the duration of antibiotics is the day when blood cultures were initially negative (if initial cultures were positive). If a native valve is replaced or repaired with prosthetic material during the initial course of antibiotics, European guidelines recommend continuation of native valve treatment, while US guidelines now state that there is no consensus regarding regimen selection in this situation. If the resected tissue is culture positive, then the first day of a complete course for PVE should be the day of surgery (if blood cultures were negative before the operation). If the resected tissue is culture negative, the previously completed days of treatment can be subtracted from the total required duration of treatment. When multiple antibiotics are recommended, they should be given simultaneously or in short succession to maximize pharmacologic synergy.

Careful attention should be given to identifying and treating complications. HF in particular must be treated aggressively, since there is a dramatic worsening of prognosis as HF becomes more severe. Therapy of HF should be initiated with GDMT, but the timing of surgical intervention should be given particular emphasis as the mortality without surgery when HF is present may exceed 50%. To that end, early consultation with cardiovascular surgery, infectious disease, and cardiology is warranted for all patients with

Table 5 Antibiotic regimens for native valve endocarditis

Viridans group streptococci and *Streptococcus gallolyticus (bovis)* (highly penicillin susceptible: MIC ≤0.12 μg/mL)
Penicillin G IV or ceftriaxone IV/IM for 4 weeks[a]
[Penicillin G IV or ceftriaxone IV/IM] and gentamicin IV/IM for first 2 weeks[a,b]
Vancomycin IV for 4 weeks (with trough of 10–15 μg/mL)
Viridans group streptococci and *Streptococcus gallolyticus (bovis)* (relatively penicillin resistant: MIC >0.12 to ≤0.5 μg/mL)
Penicillin G IV for 4 weeks and gentamicin IV/IM for first 2 weeks[a]
Ceftriaxone IV/IM for 4 weeks if the isolate is susceptible
Vancomycin IV for 4 weeks (with trough of 10–15 μg/mL)
Viridans group streptococci (fully penicillin resistant: MIC >0.5 μg/mL), *Abiotrophia defectiva*, and *Granulicatella* species
Infectious disease consultation required to determine duration:
[Ampicillin IV or penicillin G IV] and gentamicin as done for *Enterococcus* species
Ceftriaxone IV/IM if the isolate is susceptible and gentamicin
Vancomycin IV (with trough of 10–15 μg/mL)
Streptococcus pneumoniae, *Streptococcus pyogenes*, groups B, C, F, and G β-hemolytic streptococci
Consult infectious disease as there is little published evidence to guide therapy
Staphylococci
Oxacillin-susceptible
Nafcillin IV (preferred if brain abscess also present) or oxacillin IV for 6 weeks
For 2 weeks for uncomplicated right-sided IE
Cefazolin IV for 6 weeks (in patients with non-anaphylactic penicillin reactions)
Vancomycin IV for 6 weeks (with trough of 10–20 μg/mL, in patients with immediate-type hypersensitive reactions to β-lactams)
Daptomycin IV for 6 weeks (in patients with immediate-type hypersensitive reactions to β-lactams; or for 2 weeks for uncomplicated right-sided IE)
Oxacillin-resistant
Vancomycin IV for 6 weeks (with trough of 10–20 μg/mL)
Daptomycin IV for 6 weeks (or for 2 weeks for uncomplicated right-sided IE)
Enterococcus susceptible to penicillin, vancomycin, and gentamicin or streptomycin
Gentamicin should be given in three divided doses, with peak of 3–4 μg/mL and trough of <1 μg/mL
[Ampicillin IV or penicillin G IV] and gentamicin IV/IM for 4 weeks (symptom duration <3 months)
[Ampicillin IV or penicillin G IV] and gentamicin IV/IM for 6 weeks (symptom duration ≥3 months)
Vancomycin IV (if unable to tolerate β-lactam; with trough of 10–20 μg/mL) and gentamicin IV/IM for 6 weeks
Ampicillin IV and ceftriaxone IV for 6 weeks (for patients with CrCl <50 mL/min, or if gentamicin resistant and rapid streptomycin serum concentrations not available)
Streptomycin may replace gentamicin, if isolate is sensitive to the former and resistant to the latter, with a peak of 20–35 μg/mL and a trough of <10 μg/mL
Enterococcus resistant to penicillin but susceptible to aminoglycoside and vancomycin
Gentamicin should be given in three divided doses, with peak of 3–4 μg/mL and trough of <1 μg/mL
β-lactamase-producing strain
Ampicillin-sulbactam IV and gentamicin IV/IM for 6 weeks
Vancomycin IV and gentamicin IV/IM for 6 weeks
Intrinsic penicillin resistance
Vancomycin IV and gentamicin IV/IM for 6 weeks
Enterococcus resistant to penicillin, aminoglycoside, and vancomycin
Linezolid IV/PO for >6 weeks
Daptomycin IV for >6 weeks
HACEK microorganisms
Ceftriaxone IV/IM for 4 weeks (cefotaxime or another 3rd-/4th-generation cephalosporin may be used)

(continued)

Table 5 (continued)

Ampicillin-sulbactam IV for 4 weeks
Ciprofloxacin IV/PO for 4 weeks (third-line treatment due to limited published in vivo evidence for IE; levofloxacin or moxifloxacin may be used)
Culture-negative endocarditis
Cefepime IV and vancomycin IV for acute presentations (days of symptoms)
Ampicillin-sulbactam IV and vancomycin IV for subacute presentations (weeks of symptoms)
Duration to be determined with infectious disease consultant

Source: Baddour et al. [6]
[a]Ampicillin is a reasonable alternative to penicillin if a penicillin shortage exists
[b]The 2-week regimen is not appropriate for patients with known abscesses, impaired 8th cranial nerve function, creatinine clearance <20 mL/min, or infection with *Abiotrophia*, *Granulicatella*, or *Gemella* species

suspected IE. Nearly 50% of patients will undergo surgical intervention, and in general, surgery should not be delayed because of active IE [6, 8]. Reinfection of newly implanted valves occurs in 2–3% of cases; however, surgery is associated with a marked reduction of in-hospital mortality. Indications for surgical intervention are listed in Table 7.

Patients who survive an episode of IE remain at increased risk for recurrent infection for the rest of their life. All patients should undergo a complete dental evaluation for the eradication of sources and education on the need for lifelong follow-up care with a dental professional. IVDUs should be referred to a drug treatment program. At the completion of therapy, all patients should have an echocardiogram repeated in order to establish a new baseline for valvular function and morphology. They should be educated on the signs and symptoms of IE and HF as well as any procedural antibiotic prophylaxis that may be needed in the future. Patients who were exposed to aminoglycosides are at risk for ototoxicity, and *Clostridium difficile* diarrhea may present up to 4 weeks after the last dose of antibiotics. All survivors of IE should have ≥3 sets of blood cultures drawn prior to starting antibiotics for a subsequent febrile illness.

Prevention

Prevention of IE in those with abnormal valvular architecture is covered in detail in ▶ Chap. 60, "Medical Care of the Surgical Patient." In those with normal native valves, prevention is mainly an issue of education on the avoidance of IV drug use.

Cardiomyopathy

The American Heart Association (AHA) published a scientific statement in 2006 which updated the definition and classification of the cardiomyopathies (CMs) [11]. The primary CMs mainly, or only, involve the heart muscle, while the myocardial dysfunction of the secondary CMs represents just one of the many organs damaged by a systemic disorder. This chapter focuses on the primary CMs which are further subdivided into three categories: genetic, mixed (genetic and nongenetic), and acquired. The AHA definition of the CMs specifically excludes myocardial dysfunction directly caused by other cardiovascular abnormalities such as systemic hypertension, valvular heart disease, congenital heart disease, and ischemia from ASCVD.

Most CMs present with the typical manifestations of either heart failure with reduced ejection fraction (HFrEF) or heart failure with preserved ejection fraction (HFpEF) [12]. Management of the CMs typically includes early consultation with a cardiologist well versed in the pertinent and complex issues surrounding diagnosis and treatment. Possible treatments include lifestyle changes, pharmacologic modification of the neurohormonal axes which contribute to HF progression (angiotensin-converting enzyme inhibitors [ACE-Is], angiotensin receptor blockers [ARBs], aldosterone

Table 7 Indications for surgery in infectious endocarditis (IE)

Early surgery (before completion of antibiotics, during initial hospitalization)[a]
Valve dysfunction causing signs or symptoms of heart failure
Left-sided IE caused by *S. aureus*, fungi, or other highly resistant organisms
New heart block
Annular or aortic abscess
Destructive (valve dehiscence, rupture) or penetrating lesions/fistulas
Persistent bacteremia or fevers for more than 5–7 days after starting appropriate antibiotics
Recurrent emboli and persistent or enlarging vegetations despite appropriate antibiotic therapy
Native valve endocarditis with severe regurgitation and mobile vegetations >10 mm
Relapse of prosthetic valve endocarditis
Complete removal of pacemaker or defibrillator with proven infection of pocket or leads
Surgery (variable timing)
Repair rather than replacement of right-sided IE when possible, especially in intravenous drug users
Prosthetic valve endocarditis with recurrence of bacteremia after complete course of antibiotics and negative blood cultures with no other source of infection
Complete removal of pacemaker or defibrillator when valvular IE is caused by S. aureus or fungi
Complete removal of pacemaker or defibrillator when undergoing valve surgery for IE

Source: Baddour et al. [6] and Nishimura, et al. [8]

[a]Early surgery is still appropriate in patients with a stroke provided there is no evidence or extensive neurological damage and no intracranial hemorrhage. If either of those findings is present, surgery should be delayed at least 4 weeks in a hemodynamically stable patient

at specific underlying causes (chelation, phlebotomy, bone marrow transplant, etc.).

Hypertrophic Cardiomyopathy (Genetic)

Hypertrophic cardiomyopathy (HCM) is defined as "a disease state characterized by unexplained left ventricular (LV) hypertrophy associated with non-dilated ventricular chambers in the absence of another cardiac or systemic disease that itself would be capable of producing the magnitude of hypertrophy evident in a given patient" [13]. Over 1500 autosomal dominant mutations have been identified in at least 8 genes that encode sarcomere proteins (3 other genes are still considered potentially causative). HCM is seen throughout the world with a global prevalence of approximately 0.2% which in the United States represents at least 600,000 individuals.

Presentation and Diagnosis

Most affected individuals likely have a normal life expectancy; however, in those who develop symptoms, HCM manifests in three different patterns which are not mutually exclusive: sudden cardiac death (SCD), atrial fibrillation/stroke, and HF that may progress to end-stage disease. SCD due to ventricular tachyarrhythmia may be the initial presentation of HCM with the highest risk in patients <35 years of age.

Dynamic left ventricular outflow tract (LVOT) obstruction, defined as an outflow gradient ≥30 mmHg, is typically caused by a narrowing between the hypertrophied ventricular septum and anterior displacement of the mitral valve during systole. Basal obstruction is present at rest, while labile obstruction is only present when physiologically provoked. LVOT obstruction is increased by activities that increase myocardial contractility (e.g., strenuous exercise) or by maneuvers or agents that decrease afterload (e.g., Valsalva, diuretics). Conversely, obstruction is decreased by agents that decrease myocardial contractility (e.g., beta-blockers) or by maneuvers that increase afterload (e.g., squatting).

In addition to common HF symptoms such as fatigue, dyspnea, and orthopnea, patients with

Telegram: @medical_k

www.konkur.in

HCM often complain of palpitations (due to atrial fibrillation caused by left atrial enlargement), pre-syncope, and syncope. Since most HCM is nonobstructive (outflow gradient <30 mmHg at rest and with provocation), auscultation generally reveals no murmur. Patients with LVOT often demonstrate a 3–4/6 systolic murmur heard over both the left sternal border (due to outflow obstruction) and apex with radiation to the axilla (due to mitral regurgitation). An S_4 is often heard due to increased filling from the enlarged atria. Pulmonary congestion is rare except with severe outflow obstruction or end-stage HCM (when systolic and diastolic dysfunction become manifest) or with atrial fibrillation. The ECG usually reveals a wide array of nonspecific changes including LV hypertrophy, ST changes, T wave inversion, left atrial enlargement, and Q waves. 24-hour electrocardiographic monitoring is recommended to identify patients who may be a candidate for an ICD, due to ventricular tachycardia, and may also identify atrial fibrillation or flutter. The chest radiograph is often normal or suggestive of atrial enlargement. TTE with Doppler imaging is essential and may be combined with exercise testing to identify labile obstruction. The transesophageal approach may help define subtle mitral valve abnormalities or guide surgical intervention. Cardiovascular magnetic resonance imaging (CMR) can diagnose HCM in patients where echocardiography is inconclusive, or hypertrophy is limited to areas that are poorly visualized on echocardiography, such as the anterolateral wall or apex.

Family history, morphology on imaging, response to a short period of deconditioning, and genetic testing can be used to differentiate between HCM and other conditions with LV hypertrophy including physiologic remodeling ("athlete's heart"), hypertensive heart disease, and metabolic or infiltrative storage diseases. In patients with a confirmed mutation, genetic counseling and testing of first-degree relatives is critical as mutation-positive family members may benefit from early identification and treatment, while mutation-negative family members need no further evaluation.

Intervention

All patients with HCM should be counseled to avoid particularly strenuous activity, avoid certain competitive athletics, undergo risk stratification for SCD, and have comorbid ASCVD risk factors managed according to current guidelines since comorbid coronary disease significantly reduces survival in HCM patients. All asymptomatic patients should receive an annual clinical evaluation. Asymptomatic patients with obstructive physiology should maintain proper hydration while avoiding vasodilators, high-dose diuretics, and environmental situations which may cause vasodilation.

Non-vasodilating beta-blockade is the first-line treatment for symptomatic patients since the negative inotropic and chronotropic effects decrease outflow obstruction through increased diastolic filling time and decreased filling pressures. Patients without obstructive physiology who also have a reduced ejection fraction (EF <50%) should be managed according to the current HF guidelines. End-stage HCM may present as a dilated cardiomyopathy. Patients without obstruction who have a preserved EF and remain symptomatic after, or do not tolerate, beta-blockade may be managed with verapamil, diltiazem, diuretics, ACE-I, or ARB.

For symptomatic patients with obstruction, negative inotropic agents other than beta-blockers may be used with caution since the vasodilating properties of verapamil and diltiazem may lead to decreased filling, increased obstruction, and sudden death in patients with severe obstruction. Oral disopyramide may be added to a beta-blocker or verapamil if symptoms persist, but it should not be used as monotherapy. If medical management fails, surgical myectomy by experienced operators achieves technical success in 90–95% of appropriately selected patients. Alcohol septal ablation can be used in patients who are not candidates for open-heart surgery.

In HCM patients with atrial fibrillation, anticoagulation with a vitamin K antagonist to an international normalized ratio (INR) of 2.0–3.0 or a direct oral anticoagulant (dabigatran, rivaroxaban, apixaban, edoxaban) is strongly recommended regardless of the patient's

Telegram: @medical_k

www.konkur.in

CHA_2DS_2-VASc score. Rate control may be achieved with beta-blockers, verapamil, or diltiazem with AV node ablation and pacemaker placement reserved for failures of medical management. First-line agents for rhythm control include disopyramide (with a rate control agent) or amiodarone. Catheter ablation and AV nodal ablation with pacemaker implantation remain rhythm control options in refractory cases.

Arrhythmogenic Right Ventricular Cardiomyopathy (Genetic)

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is caused by a progressive replacement of the myocardium by fibrofatty tissue [14]. The disease is more common in men with a prevalence estimated as 1 in 2000–5000, and it usually demonstrates autosomal dominant transmission with variable penetrance. Mutations identified to date implicate a degenerative process of the cardiomyocyte involving the intercellular mechanical junction (desmosome). Symptoms may include palpitations (due to ventricular tachycardia [VT] of a left bundle branch block morphology), syncope, or aborted sudden death with initial presentation most likely after puberty but before 60 years of age. Sudden cardiac death occurs with an annual incidence of 0.1–3.0% in adults, and ventricular fibrillation (VF) can occur at any age.

The diagnosis is challenging and requires a high index of suspicion since there is no single gold standard test. The current highly specific criteria from an expert task force combine the results of multiple tests (echocardiography, CMR, endomyocardial biopsy, ECG, Holter, exercise stress) using major and minor criteria. Modifications to the original criteria for first-degree relatives of affected patients increased the overall sensitivity.

Treatment focuses on the prevention of sudden cardiac death. As with HCM, all affected individuals should limit strenuous activity and competitive athletic participation since this has been shown to increase the risk of life-threatening arrhythmias. Universal pre-participation screening in a region of Italy with a high prevalence of ARVC has reduced the annual incidence of SCD in young competitive athletes from 3.8 to 0.4 per 100,000. While an ICD is reasonable in patients with hemodynamically stable VT, medical therapy with beta-blockers or amiodarone can be used. An ICD is strongly recommended in patients with a history of cardiac arrest, syncope, VF, or hemodynamically unstable VT. As with HCM, oral anticoagulation is recommended for patients with ARVC and AF.

Other Genetic Cardiomyopathies

Other less common genetic cardiomyopathies include left ventricular non-compaction, conduction system disease, and the ion channelopathies (long QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia, short QT syndrome, and idiopathic ventricular fibrillation) [11].

Dilated Cardiomyopathy (Mixed)

Dilated cardiomyopathy (DCM) is characterized by an increase in LV volume with an associated reduction in LVEF that is not caused by another cardiovascular condition [15]. The previously estimated prevalence of 1 in 2700 may have underestimated the true disease burden by an order of magnitude, and DCM could be twice as common as HCM. Up to 48% of patients currently diagnosed with idiopathic DCM likely have a familial cardiomyopathy. The DCM phenotype is seen in other primary and secondary cardiomyopathies, particularly in their end stage, but these etiologies are no longer considered primary DCM. Some of the causes previously classified as DCM include myocarditis, infiltrative disease (amyloidosis, sarcoidosis, hemochromatosis), peripartum cardiomyopathy, HIV, connective tissue disease, substance abuse (alcohol, cocaine), and doxorubicin administration. HF caused by ASCVD, valvular heart disease, systemic hypertension, and congenital heart disease may also share the

Telegram: @medical_k

www.konkur.in

DCM phenotype. While the DCM phenotype as a whole has a poor prognosis, with 25% mortality at 1 year and 50% mortality at 5 years, truly idiopathic DCM appears to have a better prognosis than many of the secondary cardiomyopathies with less than 50% mortality at 10 years.

Patients with DCM often present with generalized symptoms of fatigue and dyspnea worsening over months to years. The classic HF symptoms of orthopnea and paroxysmal nocturnal dyspnea are also common. Physical examination reveals pulmonary and, less often, systemic venous congestion. Laboratory tests are recommended to identify other cardiovascular conditions or systemic diseases which may result in the DCM phenotype. The ECG may be normal but often shows T wave changes, septal Q waves, atrioventricular conduction abnormalities, and bundle branch blocks. Sinus tachycardia and supraventricular dysrhythmias are common, especially atrial fibrillation, while non-sustained ventricular tachycardia occurs in 20–30%. Echocardiogram with Doppler imaging is still the first-line test for diagnosis. As in HCM, CMR provides imaging of the entire myocardium while still assessing valvular regurgitation, dyssynchrony, and even ischemia when combined with late gadolinium contrast. Treatment for DCM should adhere to the current evidence-based guidelines for the management of HF as discussed in ▶ Chap. 83, "Heart Failure."

Primary Restrictive Nonhypertrophied Cardiomyopathy (Mixed)

Severe diastolic dysfunction is the hallmark of the restrictive cardiomyopathy (RCM) phenotype; LV size, shape, and systolic function are either normal or nearly so [16]. This phenotype may be seen in both HCM and hypertensive HF as well as many secondary cardiomyopathies. These include infiltrative diseases such as hemochromatosis and amyloidosis (the most common systemic cause of RCM), scleroderma, carcinoid, sarcoidosis, radiation therapy, and anthracycline use. Primary restrictive nonhypertrophied cardiomyopathy, or idiopathic RCM, is the least common etiology and occurs both sporadically and in familial forms [11].

The pathophysiology is characterized by decreased cardiac output, increased jugular venous pressure, and pulmonary congestion [16]. Biatrial enlargement accounts for an increased incidence of atrial fibrillation and frequent thromboembolic events. Both right- and left-sided HF symptoms are common presenting scenarios. Examination reveals increased jugular venous pulse and decreased pulse pressure. An S_3 gallop due to abrupt cessation of early rapid filling is common. Echocardiography is essential to rule out other causes of the patient's symptoms and to assess filling rates and pressures. The myocardium may also demonstrate patterns on echocardiography that are suggestive of a specific secondary etiology. CMR or even biopsy may be necessary in some cases to distinguish RCM from constrictive pericarditis.

Treatment with diuretics is indicated for congestive symptoms, and beta-blockers may also help with symptom control as described in HFrEF management guidelines. Transplantation is considered in refractory cases, and there may be less chance of recurrence with idiopathic RCM compared to the secondary cardiomyopathies.

Myocarditis (Acquired)

Myocarditis is an inflammatory disease of the heart muscle [17]. The gold standard diagnosis is by histologic and immunologic criteria from endomyocardial biopsy (EMB); however, the diagnosis is often made clinically. Due to the discrepancies in diagnosis, the true incidence of myocarditis is difficult to estimate. It affects children and adults, but it is more common in younger patients. Myocarditis may be caused by infections (most commonly viral), autoimmune disease, medications, and toxins (Table 8). There is significant geographical variation with parvovirus B19 and human herpes virus-6 extremely common in some areas, while coxsackievirus type B remains common in other regions [18].

The inflammation of myocarditis is first caused by either direct microbial damage or toxic damage

www.konkur.in

Table 8 Etiologies of myocarditis

Infection		
Bacteria	Staphylococcus, streptococcus, pneumococcus, meningococcus, gonococcus, salmonella, *Corynebacterium diphtheriae*, *Haemophilus influenzae*, mycobacterium, *Mycoplasma pneumonia*, brucella	Diphtheria is a common cause in areas without adequate vaccination
Spirochetes and rickettsia	Borrelia (Lyme disease), leptospira, *Coxiella burnetii* (Q fever), *Rickettsia rickettsii* (Rocky Mountain spotted fever), *Orientia tsutsugamushi* (scrub typhus)	Patients with Lyme myocarditis can be co-infected with *Ehrlichia* or babesia
Fungi	Aspergillus, actinomyces, *Blastomyces*, candida, *Coccidioides*, cryptococcus, histoplasma, mucormycoses, nocardia, sporothrix	
Protozoans and parasites	*Trypanosoma cruzi*, *Toxoplasma gondii*, *Entamoeba*, leishmania, *Trichinella spiralis*, *Echinococcus granulosus*, *Taenia solium*	*Trypanosoma cruzi* (Chagas disease) is a common cause in Central and South America, may also have bundle branch block
Viruses	RNA viruses: Coxsackieviruses A and B, echoviruses, polioviruses, influenza A and B viruses, respiratory syncytial virus, mumps virus, measles virus, rubella virus, hepatitis B virus, dengue virus, yellow fever virus, chikungunya virus, Junin virus, Lassa fever virus, rabies virus, human immunodeficiency virus-1 (HIV)	Viral myocarditis is the most common cause in the developed world Myocarditis is found in autopsies of more than 50% of patients with HIV (may also be due to antiviral medications)
	DNA viruses: Adenovirus, parvovirus B19, cytomegalovirus, human herpesvirus 6, Epstein-Barr virus, varicella zoster virus, herpes simplex virus, variola virus, vaccinia virus	
Autoimmune/immune-mediated disease		
Allergens	Tetanus toxoid, vaccines, serum sickness	
	Drugs: Penicillin, cefaclor, colchicine, furosemide, isoniazid, lidocaine, tetracycline, sulfonamides, phenytoin, phenylbutazone, methyldopa, thiazides, amitriptyline	Drug-induced hypersensitivity can improve after withdrawal of the drug; steroid treatment may be required
Alloantigens	Heart transplant rejection	
Autoantigens	Infection-negative lymphocytic myocarditis, infection-negative giant cell myocarditis	Considered idiopathic if no viruses are found on EMB
	Associated with autoimmune or immune-oriented disorders: systemic lupus erythematosus, rheumatoid arthritis, Churg-Strauss syndrome, Kawasaki disease, inflammatory bowel disease, scleroderma, polymyositis, myasthenia gravis, insulin-dependent diabetes mellitus, thyrotoxicosis, sarcoidosis, Wegener's granulomatosis, rheumatic heart disease (rheumatic fever)	Cardiac sarcoidosis (idiopathic granulomatous myocarditis) must have negative stains for infectious causes for diagnosis
Toxins		
Drugs	Amphetamines, anthracyclines, cocaine, cyclophosphamide, ethanol, fluorouracil, lithium, catecholamines, hemetine, interleukin 2, trastuzumab, clozapine	
Heavy metals	Copper, iron, lead

[19]. Myocyte death causes the release of cytokines and activation of the immune system. This exposes antigens that are normally hidden from the immune system which induces both a cellular and humoral immune response. This immune response may resolve, as in acute myocarditis, or persist and result in chronic myocarditis. Ongoing destruction and remodeling of the myocardial tissue will eventually lead to the DCM phenotype.

Presentation and Diagnosis

Some patients have minimal symptoms and may never present to a clinician, while others have a severe course of illness and develop severe, life-threatening symptoms. The European Society of Cardiology has described four main presentations of significant acute myocarditis (Table 9). The most common presenting symptom is dyspnea, but patients will frequently report chest pain or palpitations. Because myocarditis is often caused by viral infection, the patient may report respiratory or gastrointestinal illness 1–4 weeks before symptom onset. Myocarditis should be considered as a possible diagnosis for patients presenting with any cardiac syndrome [18]. These include AMI, HF, pericarditis, arrhythmias, heart block, and SCD. Myocarditis must be excluded in a suspected case of sudden infant death syndrome. The evaluation is complicated by the fact that all of these conditions may coexist with myocarditis.

All patients suspected to have myocarditis should first be evaluated with ECG and echocardiogram. The findings of these studies in myocarditis are variable as described in Table 9. Troponin, ESR, and CRP are often elevated and should be measured. Routine viral serology is not recommended. If the initial evaluation of the patient still indicates myocarditis is likely, the patient should be managed in a center capable of hemodynamic monitoring, cardiac catheterization, and EMB. Patients will frequently require cardiac catheterization to rule out acute coronary syndrome (ACS) as the cause for their symptoms, as there is significant overlap in presentation. CMR is being used more frequently in the evaluation of myocarditis, but current evidence does not justify using it for definitive diagnosis. EMB is safe when done by an experienced clinician and can guide specific therapies.

Intervention

If the patient is hemodynamically unstable, they must be stabilized for transfer to the appropriate care team and intensive care initiated. Ventricular assist devices or extracorporeal membrane oxygenation may be used, often as a bridge to transplant. Stable patients may decompensate quickly, so at a minimum, they should be hospitalized for initial evaluation and observation [19]. All patients with HF should be treated according to current guidelines which include diuretics, beta-blockers, and ACE-I or ARB. Arrhythmias should also be managed according to current guidelines. Digoxin is not recommended as animal studies have shown that it may increase myocardial injury [17]. Temporary pacing may be required if complete heart block is present. ICDs are often not indicated until the acute phase of myocarditis has subsided, as the arrhythmia may also subside. All patients with myocarditis should avoid NSAIDs, as they may increase mortality [19]. Exercise should be avoided

www.konkur.in

Table 9 Clinical presentation of patients with myocarditis

Clinical presentation	Diagnostic and clinical findings	Length of illness
Chest pain similar to acute MI	ST/T wave changes (ST segment elevation or depression, T wave inversion), elevated troponin (may have time course similar to acute MI or may be elevated for a prolonged period of time), no angiographic evidence of coronary artery disease	Several hours or days
New onset or worsening heart failure	Absence of CAD, no known cause of heart failure, impaired systolic function (LV or RV) seen on echocardiogram, nonspecific ECG signs, bundle branch block, AV block, and/or ventricular arrhythmias	2 weeks to 3 months
Chronic heart failure with symptoms and recurrent exacerbations	Absence of CAD, no known cause of heart failure, impaired systolic function (LV or RV) seen on echocardiogram suggestive of dilated cardiomyopathy or nonischemic cardiomyopathy, nonspecific ECG signs (see point 2 above)	More than 3 months
"Life-threatening condition" in the absence of CAD and known heart failure	Life-threatening arrhythmias and aborted sudden death, cardiogenic shock, *or* severely impaired LV function	Any duration

Note: *CAD* coronary artery disease, *LV* left ventricle, *RV* right ventricle, *ECG* electrocardiogram
Source: Caforio et al. [19], Fung [18]

until complete resolution and for at least 6 months in competitive athletes. There are no specific preventive measures for myocarditis.

Specific therapies may be indicated in certain cases, especially if an etiology is found on EMB. Antiviral treatment with ribavirin and interferon alfa has shown some benefit; however, it is most helpful early in the course of the viral illness, and myocarditis is often diagnosed too late. Interferon beta has been shown to be effective in some chronic cases. Intravenous immunoglobulin is often used, particularly in pediatric cases; however, the overall data supporting its use is inconclusive, especially for adults. Immunosuppressive therapy can play a role in some cases, especially giant cell myocarditis and chronic myocarditis with DCM unresponsive to traditional treatment. Immunosuppressive agents include cyclosporine, azathioprine, and prednisone.

Stress-Induced ("Takotsubo") Cardiomyopathy (Acquired)

Stress-induced cardiomyopathy, or apical ballooning syndrome, first described in Japan, is characterized by a ventricle which resembles an octopus trap (a takotsubo) which is triggered by acute physical or psychological stress [15]. It is more common in postmenopausal women with a presentation that mimics ACS, often with ST elevation and elevated cardiac enzymes, and is seen in 1–2% of patients undergoing angiography for ACS. Subsequent studies demonstrate no evidence of ischemia, no pheochromocytoma, and no myocarditis. The LV dysfunction often resolves within days to weeks after initial presentation.

Peripartum Cardiomyopathy (Acquired)

Peripartum cardiomyopathy (PPCM) shares the DCM phenotype and develops within the last trimester of pregnancy or first 5 months postpartum with an incidence of 1 in 300–4350 live births [15]. Risk factors include multiparity, advanced maternal age, long-term tocolysis, and African descent. It is a diagnosis of exclusion that requires no identifiable cause of HF and no history of heart disease prior to diagnosis. Many patients experience spontaneous recovery in the first 6 months after diagnosis and have an excellent prognosis; however, if cardiomegaly persists past 4–6 months, mortality increases to 50% at 6 years. PPCM can recur in subsequent pregnancies with the highest risk in patients whose LVEF has not

Telegram: @medical_k

www.konkur.in

normalized. GDMT for HFrEF must be adjusted if the patient is still pregnant or breastfeeding. Anticoagulation is particularly important due to a high rate of venous thromboembolism. European guidelines suggest that bromocriptine may improve outcomes in patient with severe PPCM, but this is controversial, and bromocriptine will inhibit lactation [20].

Tachycardia-Induced Cardiomyopathy (Acquired)

The severity of tachycardia-induced cardiomyopathy is correlated with the duration and rate of the inciting tachycardia [15]. Any ventricular tachycardia, frequent premature ventricular complexes, or supraventricular tachycardia with rapid ventricular response may induce this largely reversible cardiomyopathy. Treatment is directed at correcting the causative tachycardia, and subsequent improvement of the cardiomyopathy, while not guaranteed, is expected.

Pulmonary Hypertension and Cor Pulmonale

Pulmonary hypertension (PH) is a complex disease with multiple etiologies. Regardless of the underlying cause, it is defined by a mean pulmonary artery pressure >25 mmHg at rest measured by right heart catheterization (RHC) [21]. The World Health Organization (WHO) classifies PH into five groups based on etiology and pathophysiology (Table 10). All etiologies of PH are felt to

Table 10 Classification and epidemiology of pulmonary hypertension (PH)

WHO classification		Associated diseases	% of all PH cases	Others
Group 1	Pulmonary arterial hypertension (PAH)	Idiopathic (IPAH), familial, "associated with" (connective tissue disorder, congenital systemic-to-pulmonary shunts, portal hypertension, HIV infections, drugs, and toxins), persistent pulmonary hypertension of the newborn, others	4.2%	PAH 15 cases/million adult population IPAH 5.9 cases/million adult population
Group 2	Pulmonary hypertension with left heart disease	Left-sided atrial or ventricular heart disease, left-sided valvular heart disease	78.7%	Up to 60% of with severe LV systolic dysfunction have PH Almost all patients with symptomatic mitral valve disease have PH
Group 3	Pulmonary hypertension associated with lung diseases and/or hypoxemia	Chronic obstructive pulmonary disease (COPD), interstitial lung disease, sleep-disordered breathing, alveolar hypoventilation disorders, chronic exposure to high altitude, developmental abnormalities	9.7%	More than 50% of patients with advanced COPD have PH
Group 4	Pulmonary hypertension due to chronic thrombotic and/or embolic disease	Proximal pulmonary arteries, distal pulmonary arteries, non-thrombotic pulmonary embolism (tumor, parasites, foreign material)	0.6%	Incidence is 0.5–2% of survivors of acute pulmonary embolism
Group 5	Miscellaneous	Sarcoid, histiocytosis X, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)	6.8%	These cases cannot otherwise be classified

Note: *LV* left ventricle, *HIV* human immunodeficiency virus

Telegram: @medical_k

www.konkur.in

have one or more underlying pathophysiologic mechanisms: vascular injury, an alteration in the balance of vasodilatation and vasoconstriction, and thrombotic changes in the pulmonary vasculature. Rarely, PH can be familial, and 70% of these cases have been associated with mutations of the BMPR2 gene [22]. The right ventricle (RV) is a low-pressure chamber with thin walls, as it normally pumps against the low resistance of the pulmonary vascular bed [23]. With the increased resistance of PH, the RV can hypertrophy and/or dilate, causing right ventricular failure (RVF). While RVF can result from any type of PH, the term "cor pulmonale" has historically been used to describe RVF secondary to diseases affecting the function or structure of the lungs, which would imply WHO group 3 disease.

Presentation and Diagnosis

The presentation of PH is very nonspecific, so the physician's challenge is to be aware of the risk factors for PH and to have an appropriate index of suspicion. The goal of the evaluation and early consultation is to identify an underlying cause, prognosis, and treatment options. The most common presenting symptoms include dyspnea (initially only with exertion), fatigue, chest pain, pre-syncope/syncope, lower extremity edema, and palpitations. Physical exam may be benign at first. With more severe PH, one may appreciate an S_3 heart sound, the holosystolic murmur of tricuspid regurgitation, or the early diastolic murmur of pulmonic regurgitation. As PH progresses, signs of RVF may develop with increased jugular venous distention, RV heave, and a prominent P2. Significant RVF may be evidenced by an S_4 heart sound, peripheral edema, hepatomegaly, and ascites.

If a patient has signs, symptoms, or history suggestive of PH, echocardiography is the next diagnostic step [21]. If there is evidence of PH, the most common causes of PH should be considered first (left heart disease, lung disease, and hypoxia; group 2 and 3 disease). A focused evaluation can include further history taking, ECG, X-ray, pulmonary function tests, blood gas analysis, polysomnography, and high-resolution computed tomography. Chest radiograph may show increased hilar structures and enlarged RV and right atrium. ECG usually reveals normal sinus rhythm with right chamber enlargement and a strain pattern. If the diagnosis of heart or lung disease is confirmed, and there are no signs of severe PH or RVF, the physician can continue with appropriate care for the underlying disease. If severe PH or RVF is present, the patient should be referred to a PH expert center for further investigation, including RHC. If heart or lung disease is not evident, the next step is to search for chronic thromboembolic pulmonary hypertension (CTEPH, group 4) with V/Q scintigraphy. This should be done even if the patient does not have a known history of pulmonary embolism, as CT pulmonary angiography may not be sensitive enough to confidently rule out group 4 disease [25]. Patients with CTEPH will also require referral and RHC. If this evaluation does not elucidate a cause of PH, broad work-up for pulmonary arterial hypertension (PAH, group 1) and miscellaneous other causes (group 5) is needed at a PH referral center.

Differential Diagnosis

CAD and cardiomyopathies leading to RVF may present with the same symptoms and signs as PH. The nonspecific presentation of the disease often results in significant diagnostic delays.

Intervention

Treatment of PH primarily focuses on supportive care and management of the underlying disease process [25]. All patients should use supplemental oxygen as needed to keep oxygen saturation $\geq$90% during rest, exercise, and sleep. If patients have RVF, it should be treated appropriately, typically with diuretics and salt restriction. Patients with CTEPH require long-term anticoagulation. These patients may also require pulmonary thromboendarterectomy, which can be curative. Pulmonary rehabilitation may be valuable for

Telegram: @medical_k

www.konkur.in

some patients to counter deconditioning. Patients should remain active and exercise but avoid isometric exercises which can increase risk of syncope. Female patients should be counseled to avoid pregnancy, a high-flow state that can worsen symptoms.

Several specific therapies exist for patients with PAH (WHO group 1). Vasodilator response testing should be completed during RHC to identify appropriate candidates since an empiric trial of therapy in a nonresponder can have negative hemodynamic outcomes. Pharmacologic options include calcium channel blockers, prostacyclin derivatives, endothelin receptor antagonists, and drugs that target nitric oxide pathways [26]. These group 1-specific drugs are typically not used for group 2–5 disease and may worsen outcomes in those patients. The choice of agent is based on severity of disease; oral medicines are used in lower-risk patients, while parenteral therapies are reserved for higher-risk patients. The 6-minute walk test or graded treadmill test can be used for risk stratification. The presence of RVF is a poor prognostic factor [23]. Patients with group 1 disease may also benefit from anticoagulation, typically with warfarin to an INR of 1.5–2.5. Lung transplantation may be considered in patients with group 1 disease who fail medical therapy and in group 3 patients who progress to end-stage lung disease.

Asthma

General Principles

Definition/Background

Asthma is a respiratory disease characterized by chronic airway inflammation and is defined by symptoms including shortness of breath, wheeze, chest tightness and cough along with variable limitation in expiratory airflow [1]. Advances in medical therapy have greatly increased the options for treatment for patients with asthma; however it remains one of the most common major non-communicable diseases and has a substantial impact on quality of life. Adequate care of patients suffering from asthma involves the triad of systematic chronic care plans, support for self-management, and appropriate medical therapy [2].

Epidemiology

Asthma afflicts around 300 million people worldwide, ranking 16th among the leading causes of years lived with disability and 28th among the leading causes of burden of disease. While high-income countries have a higher asthma prevalence, low- to middle-income countries account for most asthma-related mortality [3]. In 2018, 7.5% of children and 7.7% of adults in the USA had been diagnosed with asthma, including 9.1% of females and 6.2% of males. Impoverished persons or those less

www.konkur.in

than 100% of the poverty threshold are more likely to suffer from asthma (10.8%) compared to those at 450% of the poverty threshold (6.5%) [4].

Classification

Asthma may be classified as intermittent, mild persistent, moderate persistent, or severe persistent as detailed in Table 1.

There are several different clinical phenotypes of asthma that have been identified including allergic asthma, non-allergic asthma, adult-onset asthma, asthma with persistent airflow limitation, and asthma with obesity [1].

Diagnosis

The diagnosis of asthma should be based on detailed history and physical examination in combination with spirometry and/or peak expiratory flow.

History

Patients with respiratory symptoms should be asked about a history of allergies, atopic dermatitis, and symptoms starting in childhood, all of which increase the likelihood that symptoms are secondary to asthma. Family history of allergy and asthma also increase the likelihood of asthma [1].

Respiratory symptoms including wheeze, shortness of breath, cough and/or chest tightness are suggestive of asthma. Table 2 lists features that increase and decrease likelihood of asthma as a diagnosis [1].

Physical Examination

The most common abnormality on physical is expiratory wheezing; however, there are often no abnormalities detected on exam, especially if the patient is not in an acute exacerbation. Wheezing may also be caused by inhaled foreign body, tracheomalacia, or respiratory infections. Other signs on physical exam such as nasal polyps or atopic dermatitis would not be specific for asthma but suggest associated conditions such as allergy and atopy [1].

Laboratory and Imaging

Laboratory testing for specific immunoglobulin E may suggest the presence of atopy which increases the likelihood a patient that has respiratory symptoms is suffering from allergic-type asthma; however this test is not specific for asthma itself. Similarly, skin prick testing suggests the presence of atopy but is not a specific diagnostic test for asthma [1].

Table 1 Classification of asthma severity in adults and adolescents age ≥ 12 years [1]

	Intermittent	Mild persistent	Moderate persistent	Severe persistent
Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
Nighttime awakenings	≤2x/month	3–4x/month	>1x/week but not nightly	7x/week
SABA[a] use for symptom control	≤2 days/week	>2 days/week but not daily and not more than once on any day	Daily	Several times/day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
FEV_1[a] (% predicted)	>80%	>80%	60–80%	<60%
FEV1/FVC[a]	Normal	Normal	Reduced 5%	Reduced >5%
Asthma exacerbations requiring oral systemic corticosteroids	0–1/year	≥2/year	Generally, more frequent and intense events indicate greater severity	Generally, more frequent and intense events indicate greater severity

[a]SABA, short-acting beta agonist; FEV_1, forced expiratory volume in 1 s; FVC, forced vital capacity [5]

Telegram: @medical_k

www.konkur.in

Table 2 Characteristic symptom features of asthma [1]

Features that increase probability of asthma	Features that decrease probability of asthma
Often worse at night or early morning	Isolated cough with no other respiratory symptoms
Vary over time and in intensity	Chronic production of sputum
Symptoms are triggered by viral infections, exercise, allergen exposure, or environmental irritants	Shortness of breath associated with dizziness, lightheadedness, or peripheral tingling
Having more than one symptom of wheeze, cough, shortness of breath, chest tightness	Exercise-induced dyspnea with noise on inspiration
	Chest pain

Imaging does not play a role in diagnosis of asthma but may evaluate for other causes of respiratory symptoms such as pneumonia, congestive heart failure, lung cancer, etc.

Special Testing

Spirometry is the preferred initial test to measure presence and severity of airflow obstruction in adults [6]. Improvement of the forced expiratory volume in 1 s (FEV1) of $\geq$12% and 200 mL is suggestive of asthma.

Once a diagnosis of asthma has been made, peak expiratory flow (PEF) monitoring may be used in the short term to establish a baseline and initial response to treatment [1].

Nitrous oxide is a biological mediator that has been implicated in pathophysiology of lung diseases including asthma. Measurement of fractional nitrous oxide concentration (FE_{NO}) in exhaled breath is a quantitative method of measuring airway inflammation and can also predict corticosteroid responsiveness [7].

Bronchial provocation tests are another way to test for airflow limitation. Challenge agents include methacholine, histamine, exercise, and inhaled mannitol. These tests are moderately sensitive but not very specific for the diagnosis of asthma, as multiple chronic lung conditions can also cause abnormal results [1].

Differential Diagnosis

The differential diagnosis of asthma in adults is listed in Table 3 [6]. In children aged 6–11 who present with recurrent infections and productive cough, bronchiectasis and primary ciliary dyskinesia must be considered. A heart murmur may suggest congenital heart disease as a possible cause of symptoms. If a child presents with excessive cough and mucous production as well as gastrointestinal symptoms, cystic fibrosis should be considered [1].

Treatment

Medications/Immunizations and Chemoprophylaxis

Choice of initial treatment is based on the patient's presenting symptom severity and frequency. For those age 12 and above with infrequent asthma symptoms (less than twice a month) and with no risk factors for exacerbations, the preferred initial treatment is with as-needed low-dose inhaled corticosteroid (ICS)-formoterol, or with an ICS whenever a short-acting beta agonist (SABA) is taken. Sole prescription of SABAs is no longer recommended. If a patient presents with symptoms twice a month or more but less than daily, a daily low-dose ICS with as-needed SABA or as-needed low-dose ICS-formoterol is recommended. For patients with asthma symptoms most days or nighttime awakenings due to asthma once a week or more, it is recommended to initiate treatment with a low-dose ICS-long-acting beta agonist (LABA) as maintenance and reliever therapy, known as the single maintenance and reliever therapy (SMART) approach [8]. Maintenance-only ICS-LABA with as-needed SABA or medium-dose ICS with as-needed SABA may also be used for these patients. If a patient presents initially with severe uncontrolled asthma or in an acute exacerbation, start regular controller treatment with a high-dose ICS or medium-dose ICS-LABA and consider a short course of oral corticosteroids [1].

Table 3 Differential diagnosis – cough and/or dyspnea [1, 12]

Chronic cough and/or dyspnea		Acute cough and/or dyspnea	
Source	Differential	Source	Differential
Pulmonary	Asthma	Pulmonary	Asthma exacerbation
	Lung cancer		Pulmonary embolism
	Interstitial lung disease		Pneumothorax
	Bronchiectasis		Pleural effusion
	Obliterative bronchiolitis	Infectious	Pneumonia
	Diffuse pan-bronchiolitis		Bronchitis/bronchiolitis
	Sarcoidosis	Cardiovascular	Congestive heart failure exacerbation
Infectious	Tuberculosis		Ischemic heart disease
	Atypical mycobacterial infections		Arrhythmia (e.g., atrial fibrillation)
Cardiovascular	Congestive heart failure	Irritants	Smoke, dust, or chemical exposure
	Ischemic heart disease		
Upper airway	Chronic allergic rhinitis		
	Upper airway cough syndrome		
Gastrointestinal	Gastroesophageal reflux		
Medications	ACE inhibitors		
Irritants	Smoke, dust, or chemical exposure		
Genetic	Cystic fibrosis		

After starting initial treatment, in most circumstances obtaining a measure of lung function with PFTs is beneficial. Review patient's response to initial therapy and consider step-down treatment after good control has been maintained for 3 months [1] (Fig. 1).

Treatment of asthma exacerbations in adults is dependent on exacerbation severity. For mild (peak expiratory flow rate [PEFR] > 75%) to moderate (PEFR 50–75%) exacerbations, outpatient management is appropriate with increased frequency of SABA or short-acting muscarinic antagonist (SAMA) use, temporarily quadrupling ICS, and systemic corticosteroids if no response to initial therapy. The recommended steroid dose is 1 mg/kg/day of prednisolone (or equivalent) per day up to 50 mg for 5–7 days. For severe exacerbations (PEFR 33–50%), management in an emergency room or urgent care facility is warranted with increased frequency of SABA or SAMA use along with systemic corticosteroids and consideration of a single dose of IV magnesium sulfate. Inpatient hospitalization is indicated if improvement is not obtained with these measures or the patient is pregnant or has one or more of the following: respiratory rate greater than 25/min, heart rate greater than 110/min, inability to speak in full sentences in one breath, or adherence concerns. For patients with life-threatening exacerbations (PEFR<33%) who may present with worsening hypoxia, hypercapnia, altered level of consciousness, hypotension, or cyanosis, treatment in an intensive care unit is required with possible noninvasive ventilation or intubation [9].

For children aged 5–11, SABA therapy is recommended to treat symptoms of intermittent asthma. Moderate or severe exacerbations due to viral respiratory infections which are common in children should be treated with a short course of oral corticosteroids, 1–2 mg/kg/day up to a maximum of 40 mg/day for 3–5 days. Daily low-dose ICS is the preferred step 2 treatment, while alternative treatment options include cromolyn, leukotriene antagonists (LTRA), nedocromil, and theophylline. For step 3 care, a low-dose ICS plus LABA, LTRA, or theophylline and medium-dose ICS are equivalent options. The preferred step 4 treatment is medium-dose ICS and LABA, and the preferred step 5 treatment is high-dose ICS and LABA. For step 6 care, oral systemic corticosteroids long term added on to high-dose ICS and LABA is preferred [1].

www.konkur.in

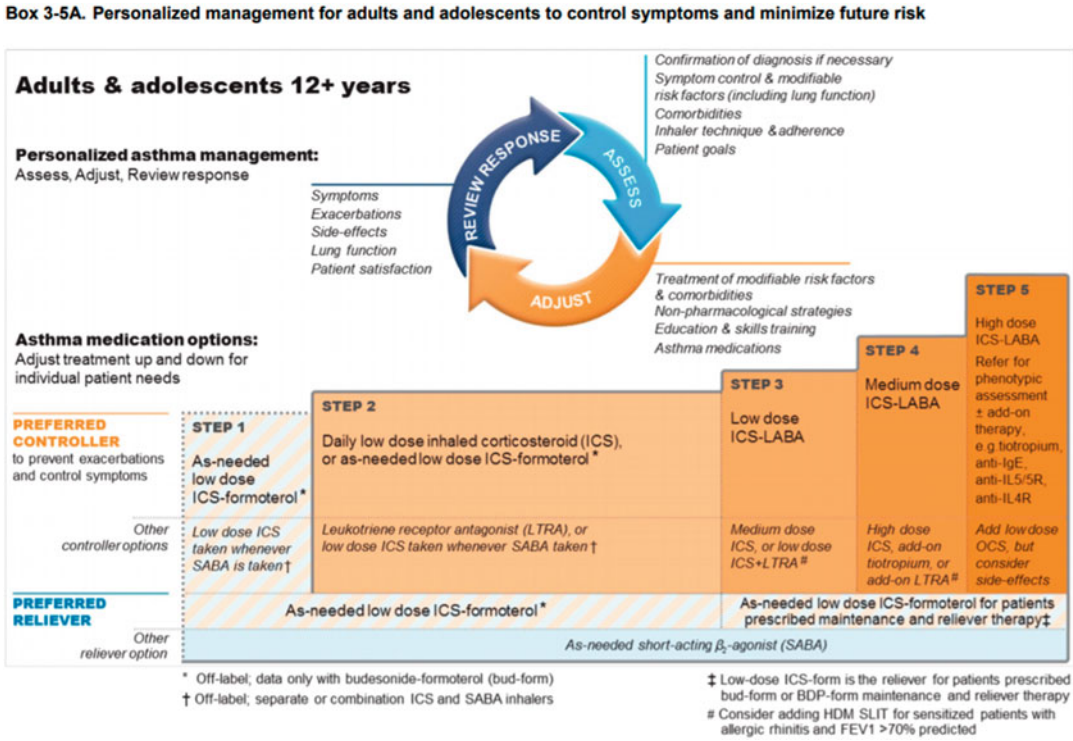

Fig. 1 Asthma management. (Reprinted with permission [1])

Referrals

In general, asthma is managed by primary care physicians, but in certain instances referral to a pulmonologist is indicated (Table 4) [6].

Counseling

Patient Education and Activation

Patient education is key in effectively managing asthma and preventing complications. A comprehensive strategy includes skills training to ensure effective use of inhalers and guided self-management with self-monitoring of symptoms or peak flow with a written action plan. For children and adolescents with asthma, a written asthma management plan should be provided for the student's school, and prompt, reliable access to medication should be ensured. Review of inhaler technique is important for all patients.

Prevention

Exposure to tobacco smoke should be eliminated if possible and those who smoke should be given cessation resources. Patients with obesity should be counseled on weight reduction strategies and distinguishing asthma symptoms from symptoms that may be due to deconditioning, mechanical restriction, or sleep apnea. Low socioeconomic status and inability to afford medications are associated with increased emergency department visits for asthma exacerbations and should be addressed [10]. Those with confirmed food allergies should be counseled on avoidance strategies and prescribed with injectable epinephrine. Allergen-specific immunotherapy may help reduce exacerbations in patients where allergy plays a significant role. Adults with asthma should be screened for occupational triggers and removed from them as soon as possible. Avoidance of indoor allergens such as mold, dust mites, and pets can be helpful in

Table 4 Criteria for referral for asthma [6]

Unclear diagnosis	Prominent systemic features (myalgia, fever, weight loss)
Unexpected clinical findings (crackles, cyanosis, clubbing, cardiac disease)	Chronic sputum production
Unexplained restrictive spirometry	CXR shadowing
Suspected occupational asthma	Marked blood eosinophilia
Monophonic wheeze or stridor	Poor response to asthma treatment
Persistent non-variable breathlessness	Severe asthma attack

some, but these strategies can be complicated and expensive [1].

Family and Community Issues

According to epidemiological studies, approximately 21.5% of adults with asthma suffer from work-exacerbated asthma (WEA), defined as pre-existing asthma which is exacerbated by workplace conditions. WEA is associated with more symptomatic days and utilization of healthcare resources and is similar to occupational asthma in that both are associated with unemployment and loss of income. The possibility of WEA or occupational asthma should be ascertained by asking about relatedness of a patient's symptoms to the workplace [11].

Chronic Obstructive Pulmonary Disease

General Principles

Definition and Background

Chronic obstructive pulmonary disease (COPD) is a syndrome of abnormal lung physiology characterized by irreversible obstructive limitation in airflow (Fig. 2) [12]. The disease is defined by measurement through spirometry [12, 13]. Emphysema and chronic bronchitis often accompany and may be confused with COPD. Emphysema is an anatomic diagnosis, referring to destruction of alveoli. Chronic bronchitis refers to chronic cough with sputum production for at least 3 months in 2 consecutive years. Either or both of these diagnoses can occur together with or separate from COPD [12]. COPD patients may experience exacerbations, characterized by increased dyspnea, cough, and sputum production and purulence [13]. Triggers for exacerbations include viral infections, bacterial infections, and environmental causes such as pollution. Exacerbations typically last 7–10 days, but symptoms may persist for more than 8 weeks [12].

Epidemiology

COPD is common and deadly. 11.7% of the population worldwide suffered from the disease in 2010, resulting in three million deaths [12], making it the most common cause of death from chronic lung disease worldwide [14]. Cigarette smoking is the most common cause of COPD. Other tobacco smoke and secondhand smoke and smoking marijuana also increase risk [12]. Other potential causes of COPD include occupational exposure, including dust and fumes, and smoke from indoor cooking [12, 13]. Patients with asthma and chronic bronchitis are more likely to develop COPD. Alpha-1 antitrypsin deficiency is a rare genetic cause of the disease [12]. Associated conditions are listed in Table 5 [12, 13].

Classification

The 2020 Global Initiative for Chronic Lung Disease (GOLD) COPD classification system recommends a "grade (number) group (letter)" classification for each patient with COPD (Fig. 3) [12]. Symptom assessment tools include the Modified British Medical Research Council (mMRC), a brief questionnaire which assesses breathlessness and predicts future mortality risk (Table 6) [15]. The COPD Assessment Test (CAT) is more comprehensive but longer [16]. The mMRC is reproduced here for its simplicity.

assessed by 6-min walk test) predicts 4-year survival [17]. The ADO index (age, dyspnea, airflow obstruction) incorporates age, mMRC, and FEV1 and predicts 3-year mortality without the 6-min walk test [13].

Diagnosis

History

The most common presentation for patient with COPD is chronic cough and dyspnea. Cough is not necessarily productive. Dyspnea is typically worse with exertion. Risk factors should be assessed (Table 7). Weight loss, fatigue, and anorexia occur later in the course of the disease [12].

Symptom severity should be assessed through the mMRC or CAT questionnaires. Patients with known COPD should be evaluated for triggers, the presence or absence of sputum as well as its volume, and healthcare utilization, particularly hospitalizations (duration, need for critical care or mechanical ventilation) [12].

Physical Examination

Physical examination has low specificity and sensitivity for diagnosis. Physical signs can include decreased breath sounds, lung hyperinflation with chest expansion, and prolonged forced expiration. With severe disease, pulmonary hypertension can result in cor pulmonale leading to leg swelling. In the context of an acute exacerbation, wheezing and rhonchi are common. The presence of rales suggests heart failure or pulmonary fibrosis [12].

Laboratory and Imaging

Complete blood count with peripheral eosinophil absolute count and percentage can help direct therapy [13]. Vitamin D levels should be checked. CRP may be useful in directing antibiotic use during exacerbations [12]. Alpha-one antitrypsin deficiency screening is recommended for all patients diagnosed with COPD [12, 13]. Chest X-ray is indicated for all nonsmokers with chronic cough who do not take ACE inhibitors [18] and may be useful in identifying comorbidities among patients with COPD [12]. Chest X-ray should also be obtained in the context of severe COPD exacerbations [12]. Chest CT is necessary prior to consideration of lung volume reduction surgery or lung transplant but is otherwise not routinely indicated [12, 13].

Special Testing

Spirometry demonstrating post-bronchodilator FEV1/FVC ratio of less than 0.70 determines the diagnosis of COPD [12]. This cutoff results in over-diagnosis in the elderly and under-diagnosis in younger patients [13]. The American Thoracic Society/European Respiratory Society guidelines recommend FEV1/FVC less than the lower limit

Telegram: @medical_k

www.konkur.in

of normal (LLN) as a diagnostic cutoff [19]. However, patients with FEV1/FVC greater than the LLN but less than 0.70 have worse outcomes [13]. Patients with post-bronchodilator spirometry demonstrating FEV1/FVC ratio of 0.6 to 0.8 should be repeated due to variability in test results. Spirometry should be repeated annually [12].

Oximetry is indicated with symptoms concerning for respiratory failure [12, 13]. Arterial or capillary blood gas should be considered in the setting of hypoxia to evaluate for hypercapnia. The 6-min walk test and paced shuttle walk test are standardized measures of exercise capacity [12].

Differential Diagnosis

Multiple conditions can mimic COPD. The differential diagnoses are summarized in Table 3.

Treatment

Treatment of Chronic COPD

The goals of chronic COPD treatment are to reduce symptoms, risk of exacerbations, disease progression, and death. Treatment includes behavioral techniques, medications, oxygen and ventilatory support, and surgery.

Behavioral counseling is recommended to foster understanding of disease process and progression, management of breathlessness and stress, energy conservation, and the role of the patient and provider. Counseling should include a written action plan for exacerbations. Smoking cessation can reduce progression of disease and risk of exacerbations, and other triggers should be avoided as well. Nutrition should be assessed and addressed through supplements where appropriate. Regular exercise has been shown to be beneficial. Pulmonary rehabilitation, a combination of exercise and counseling, has been shown to be highly effective at improving quality of life and exercise tolerance in patients with moderate to severe COPD (GOLD Groups B, C, and D) [12].

Multiple classes of medications are used to treat chronic COPD (Table 8); however medication treatment does not appear to change the trajectory of decreased lung function over time [12]. Medications are typically delivered through inhalers, which come in multiple formats and are frequently used inappropriately [12, 13]. Teaching and assessment of proper inhaler technique and adherence is essential. Nebulized delivery is only more effective for patients who are unable to adequately tolerate inhaler administration [12].

SABAs and SAMAs are effective for mild disease. More persistent symptoms should be treated with a long-acting muscarinic antagonist (LAMA) or LABA. If either of these classes alone are ineffective, they can be combined. Side effects of beta agonists include tremor, arrhythmia, and hypokalemia. Muscarinic antagonist side effects include dry mouth. Ipratropium has been associated with increased risk of cardiovascular events, an effect not seen to date with tiotropium. Nebulized LAMAs delivered by facemask can precipitate acute glaucoma [12].

Inhaled corticosteroids alone do not improve outcomes in patients with COPD. Combination ICS + LABA treatment has been shown to reduce the risk of exacerbations and hospitalizations in patients with moderate disease who have frequent exacerbations, particularly those with serum eosinophil counts of $\geq$300 cells/μL [12]. Eosinophil counts of $\leq$100 cells/μL are associated with poor response to inhaled corticosteroids [12, 13]. For appropriately selected patients (persistent symptoms on LAMA + LABA, with asthma or high eosinophil count), the combination of LABA, LAMA, and ICS is more effective than LABA + LAMA [20, 21]. ICS treatment is associated with hoarseness, oral thrush, bruising, and in severe COPD increased risk of pneumonia [12, 13]. Figure 4 demonstrates use of GOLD Group assignment as a guide for medication selection.

Phosphodiesterase-4 (PDE4) inhibitors work by reducing inflammation. They decrease moderate and severe exacerbations for patients with chronic bronchitis or severe COPD with an FEV1 of <50%. Side effects include diarrhea, reduced appetite, weight loss, and abdominal pain but diminish with time [12].

In patients with frequent exacerbations, azithromycin 250 milligrams per day or 500 milligrams three times a week reduce exacerbation frequency. It is less effective in smokers.

Table 8 COPD medications[a,b]

Generic (trade)	Delivery methods	Typical adult dosing [22]
Short-acting beta agonists (SABA)		
Albuterol (Proventil, Ventolin, ProAir)	Inhaler	2 inh every 4–6 h as needed with spacer
	Nebulizer	2.5 mg every 4–6 h as needed
Levalbuterol (Xopenex)	Inhaler	2 inh every 4 h as needed with spacer
	Nebulizer	0.63 mg three times daily
Short-acting muscarinic antagonists (SAMA)		
Ipratropium (Atrovent)	Inhaler	2 inh four times daily
	Nebulizer	0.5 mg every 4–6 h
Short-acting beta agonist/short-acting muscarinic antagonist combinations		
Albuterol/ipratropium (Combivent)	Inhaler	1 inh four times daily
	Nebulizer	1 vial (3 ml) (ipratropium 0.5 mg/albuterol 2.5 mg) every 6 h
Long-acting beta agonists (LABAs)		
Arformoterol (Brovana)	Nebulizer	15 mcg twice daily
Formoterol	Inhaler (Foradil)	12 mcg every 12 h
	Nebulizer (Perforomist)	20 mcg twice daily
Indacaterol (Arcapta)	Inhaler	75 mcg (1 inh) once daily
Olodaterol (Striverdi)	Inhaler	2 inh once daily
Salmeterol (Serevent)	Inhaler	1 inh twice daily
Long-acting muscarinic antagonists (LAMAs)		
Aclidinium bromide (Tudorza Pressair)	Inhaler	400 mcg (1 inh) twice daily
Glycopyrrolate (Lonhala Magnair, Seebri Neohaler)	Inhaler	15.6 mcg (1 capsule) inhaled twice daily
	Nebulizer	25 mcg (1 vial) inhaled twice daily
Revefenacin (Yupelri)	Nebulizer	175 mcg (1 vial) once daily
Tiotropium (Spiriva)	Spiriva Respimat 2.5 mcg/actuation	5 mcg (2 inh) once daily
	Spiriva Handihaler	18 mcg (1 capsule) once daily
Umeclidinium (Incruse Ellipta)	Inhaler	62.5 mcg (1 inh) once daily
LABA/LAMA combinations		
Formoterol/aclidinium (Duaklir Pressair)	Inhaler 12 mcg/400 mcg per actuation	1 inh twice daily
Formoterol/glycopyrrolate (Bevespi Aerosphere)	Inhaler 4.8 mcg/9 mcg per actuation	2 inh twice daily
Indacaterol/glycopyrrolate (Utibron Neohaler)	Inhaler 27.5 mcg/ 15.6 mcg per capsule	1 capsule inh twice daily
Vilanterol/umeclidinium (Anoro Ellipta)	Inhaler 25 mcg/62.5 mcg per actuation	1 inh once daily
Olodaterol/tiotropium (Inspiolto Respimat)	Inhaler 2.5 mcg/2.5 mcg per actuation	2 inh once daily

www.konkur.in

Azithromycin is known to prolong the QTc interval, and frequent use can lead to antibiotic resistance as well as reversible hearing loss [12, 13].

Medications of poor or uncertain efficacy for chronic use include mucolytics, oral glucocorticoids, methylxanthines, biologics, and statins. Mucolytic N-acetylcysteine may reduce exacerbations, though which patients will benefit is uncertain, and it has not been studied in patients taking modern inhaled medications. Chronic daily oral corticosteroids are not recommended for COPD as they result in significant side effects including steroid myopathy, which reduces functional capacity and increases risk of respiratory failure [12, 13]. Methylxanthines (e.g., theophylline) act as bronchodilators and improve FEV1, but given their narrow therapeutic window and risk of life-threatening arrhythmias and seizures, they are not recommended unless other long-acting bronchodilators are unavailable [12].

Oxygen (O2) and ventilatory support can be helpful for patients with severe disease. Those with resting O2 saturation $< 89\%$ who use oxygen >15 h per day demonstrate improved survival. O2 supplementation does not improve mortality or hospitalization for patients with stable COPD and exertional hypoxemia, but it can mitigate exertional dyspnea. Hypercapnic patients discharged from the hospital may benefit from positive pressure ventilation [12].

Procedures for COPD include surgery and bronchoscopic interventions. Lung volume reduction surgery removes part of the lung to optimize ventilatory mechanics and has been shown to improve mortality for patients with severe emphysema, upper lobe emphysema, and poor post-rehab exercise capacity. It is less effective for patients with homogeneous emphysema, high exercise capacity, and decreased diffusion capacity. Bullectomy can improve dyspnea and exercise tolerance when large bullae are present. Lung transplant is indicated for patients who are not candidates for other surgeries and who have severe progressive COPD. Transplant improves health status and functional capacity but not necessarily mortality and is associated with complications including rejection, bronchiolitis obliterans, and infection. Bronchoscopic interventions include endobronchial valves, thermal ablation, and nitinol coils and have been shown to improve exercise capacity and quality of life [12].

Referral to pulmonology is appropriate for patients with persistently impaired quality of life or recurrent hospitalization despite optimized medical therapy and pulmonary rehab. Indications for hospice include disabling dyspnea and recurrent hospitalization. End of life discussion should start early due to difficulty accurately predicting prognosis. Palliative care for end-stage COPD focuses on treatment of symptoms such as dyspnea, for which effective interventions include opiates, neuromuscular electrical stimulation, chest wall vibration, oxygen, pulmonary rehabilitation, fans blowing air onto the face, and noninvasive ventilation. Benzodiazepines have not been shown to be effective. Depression, panic, anxiety, and fatigue can be improved by pulmonary rehab, cognitive behavioral therapy, and mind-body interventions [12].

Treatment of Acute COPD Exacerbations

The goals of treating COPD exacerbations include reducing severity and preventing recurrences. Indications for hospitalization are listed in Table 9. Written action plans reduce risk of hospitalization during exacerbations [12].

COPD exacerbations are treated with a combination of bronchodilators, oral corticosteroids, antibiotics, and/or oxygen and ventilatory support. Bronchodilators can be given via any available delivery method. Continuous nebulizers should be avoided. Inhalers dosed hourly for 2–3 h then every 2–4 h are recommended for acute symptoms. Combinations of SABA + SAMA are more effective than either alone. Oral corticosteroids (prednisolone [Prednisone] 40 mg daily for $\leq$5–7 days) improve rates of treatment success, reduce relapse, and improve symptoms but are associated with increased risk of pneumonia, sepsis, and death. Antibiotics for 5–7 days are indicated in COPD exacerbations featuring increased sputum purulence, but not when sputum is white or clear. Normal C-reactive protein may indicate that antibiotics are not needed [12]. First-line antibiotics include trimethoprim-sulfamethoxazole

Telegram: @medical_k

Table 9 Indications for hospitalization during COPD exacerbation [12, 13]

Category	Examples
Acute respiratory signs and symptoms	Resting dyspnea
	Tachypnea
	Hypoxia
	Respiratory failure
Acute central nervous system symptoms	Confusion
Failure of outpatient treatment	Persistent symptoms despite oral steroids, antibiotics, and bronchodilators
Life-threatening comorbidities	Heart failure
	New-onset arrhythmia
Inadequate social support	Lack of monitoring or transportation

(Bactrim), amoxicillin-clavulanic acid (Augmentin), macrolide such as azithromycin (Zithromax), or a tetracycline such as doxycycline (Vibramycin) [12, 13]. Patients with hypoxia should receive supplemental O2 with a goal O2 saturation between 88% and 92%. Arterial blood gases may be beneficial to monitor for CO2 retention. Noninvasive positive pressure ventilation is preferred over intubation for patients with acute respiratory failure. Intubation should be reserved for patients that are unable to tolerate noninvasive ventilation. Hospitalized patients should be monitored for fluid balance and nutrition and offered DVT prophylaxis and assistance with smoking cessation. After discharge, they should be contacted within 48 h and seen within 7 days to ensure stability. Pulmonary rehab and follow up within 3 months are recommended [12].

Prevention

Routine screening for COPD is not recommended. Smoking cessation is the most important preventative intervention and can be facilitated by counseling, pharmacotherapy, and nicotine replacement [12]. Excessive work or home exposure to dust, smoke, or pollution should be avoided. Influenza vaccination is recommended annually [12, 13]. Pneumococcal polysaccharide vaccine (PPSV23 [Pneumovax]) is recommended for all patients with COPD and all patients who smoke. Pneumococcal conjugate vaccine (PCV 13 [Prevnar]) is recommended for COPD patients age 65 or older or those who are frail or require frequent systemic steroids [13]. Vitamin D supplementation can reduce exacerbation frequency. Legislative bans can reduce smoking rates [12].

Introduction

Pneumonia is a lung infection involving the alveoli and can be caused by a variety of microbes including bacteria, viruses, and fungi. It is the leading infectious cause of hospitalization and death in the United States [1].

Most instances of pneumonia are attributable to self-infection with one or more types of microbes that originate in the nose and mouth. In healthy individuals, typical upper airway bacterial residents such as *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most common bacteria causing community-acquired pneumonia. Other causes of pneumonia include *Staphylococcus aureus*, *Klebsiella pneumonia*, *Pseudomonas aeruginosa*, and *Escherichia coli* that are generally seen in patients at higher risk for resistant bacteria.

In those with a serious impairment of their immune system, opportunistic microbes are more readily apparent such as fungi, viruses, and mycobacteria [1].

There are many mechanisms used by the lungs to resist infection. Physical mechanisms are structure of the upper airway, branching of the bronchial tree, sticky mucous layer lining the airways, cilia that propel mucous upward, and the cough reflex. If microbes do reach the alveoli, the immune system is usually able to destroy them [1].

A variety of strategies have been used to reduce the incidence of pneumonia. Elements of a healthy lifestyle that reduce the incidence are adequate nutrition, dental hygiene, and not smoking. For those with lung disease or impaired clearance of mucous, aerobic exercise, deep breathing maneuvers, and cough assist devices can facilitate expectoration and lung hygiene. Immunity to certain microbes can be enhanced by immunization [1].

Bacterial Pneumonia

General Principles

Definition/Background/Epidemiology

Pneumonia is a common infection in the parenchyma of the lower respiratory tract that can affect all age populations. There is significant morbidity and mortality associated with pneumonia, especially in the very young and elderly populations. Pneumonia is the leading cause of death in children younger than 5 years of age worldwide [2]. The average yearly incidence of pneumonia, specifically community-acquired pneumonia, is 5–11 per 1000, with most incident cases occurring in the winter months [3]. It is passed from person to person by viral particles on respiratory droplets.

Decisions on how to treat, whether to admit to the hospital or treat outpatient and potential prognosis, depend upon the most likely pathogen and the current clinical picture. In most cases, the pathogen is never isolated – only suspected – prior to initiation of treatment.

Classification

Pneumonia classification is based upon a variety of factors – age, clinical presentation, and comorbidities. Additionally, patients are further

Telegram: @medical_k

www.konkur.in

classified according to their risk factors for multidrug-resistant bacteria.

The best approach is a good history and physical exam in combination with knowledge of the most common causes of pneumonia for the presenting age patient being seen.

In 2019, the American Thoracic Society (ATS) and the Infectious Diseases Society of America (IDSA) updated the community-acquired pneumonia (CAP) guidelines [4]. Previous guidelines classified pneumonia based on the site of care (outpatient, inpatient, or ICU) and utilized terms such as healthcare-associated pneumonia, hospital-acquired pneumonia, and ventilator-associated pneumonia. These terms have been eliminated in the new guidelines and instead base classifications solely on the severity of illness and risk factors for multidrug-resistant bacteria. The IDSA/ATS CAP severity criteria have been validated and can be used to define severe community-acquired pneumonia. Validated definition includes either one major criterion or three or more minor criteria.

2007 Infectious Diseases Society of America/ American Thoracic Society Criteria for Defining Severe Community-Acquired Pneumonia

Minor Criteria

Respiratory rate $\geq$ 30 breaths/min.
PaO_2/F_IO_2 ratio $\leq$ 250
Multilobar infiltrates
Confusion/disorientation
Uremia (blood urea nitrogen level $\geq$ 20 mg/dL)
Leukopenia (white blood cell count <4000 cells/mL)
Thrombocytopenia (platelet count <100,000 mL)
Hypothermia (core temperature < 36 °C)
Hypotension requiring aggressive fluid resuscitation

Major Criteria

Septic shock with need for vasopressors Respiratory failure

If a patient does not meet severe criteria, in general, it is safe to attempt treatment as an outpatient. The inpatient categories are then further classified by patient specific factors such as prior respiratory isolation of either MRSA or *Pseudomonas*, recent hospitalization and parenteral antibiotics (within 90 days), and locally validated risk factors for MRSA and/or *P. aeruginosa*.

In children, the suspected organism that has caused the pneumonia is based upon the age of the child: [3].

- *Birth to 3 weeks*: Group B streptococcus, *Haemophilus influenzae* type b (Hib), *Listeria monocytogenes*, and cytomegalovirus
- *3 Weeks to 3 months*: *Streptococcus pneumoniae*, *Chlamydia trachomatis*, respiratory syncytial virus (RSV) or other respiratory viruses, and *Bordetella pertussis*
- *4 Months to 4 years*: RSV and other respiratory viruses, *S. pneumoniae*, and group A streptococci
- *5–18 Years*: *S. pneumoniae*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*

Approach to the Patient

The most important point to consider when evaluating for pneumonia is the patient's age, the time of year, social habits, existing disease processes, travel history, or other exposure history – animals, geography, and other people. This information is best obtained from a thorough history and physical exam.

Diagnosis

History

The most common presenting symptoms in an immunologically competent patient include sudden or recent onset of:

- Cough with purulent sputum
- Dyspnea
- Fever ± chills
- Pleuritic chest pain

Other important information to obtain from the patient is with regard to recent hospitalizations, current resident location (in elderly patients), medical history, and recent medication (antibiotic) use.

Telegram: @medical_k

www.konkur.in

Physical Exam

Physical exam findings can vary from one patient to another, let alone one age population to another. The following exam findings are the most consistent findings in patients with pneumonia:

Vital signs:

- Temperature > 100 °F (37.8 °C)
- Tachypnea (>20 breaths/min)
- Tachycardia (>100 beats/min)
- Decreased pulse oximetry readings on room air (<92%)

General:

- Septic appearance

Respiratory exam:

- Increased tactile fremitus
- Crackles, rhonchi
- ± Egophony
- Dullness to percussion
- Decreased breath sounds/air movement

Make sure to look for red flags in patients presenting with pneumonia-type symptoms. Red flag symptoms:

- Accessory muscle use (sternal retractions)
- Grunting
- Nasal flaring
- Altered mental status
- Apnea

The presence any of these symptoms may indicate a more severe infection requiring admission to an intensive care unit.

Laboratory and Imaging

Chest radiography is the test of choice in patients with clinically suspected CAP. The presence of an infiltrate or consolidation on X-ray is required for the diagnosis of CAP (Fig. 1).

Chest radiography should be performed in:

Any patient with at least one of the following abnormal vital signs:

- Temperature > 37.8 °C (100 °F)
- Heart Rate > 100 beats/min
- Respiratory rate > 20 breaths/min

Or

Any patient with at least two of the clinical findings:

- Decreased breath sounds
- Crackles (rales)
- Absence of asthma

Routine laboratory testing is not required to establish diagnosis in an outpatient setting. Laboratory testing recommendations differ, though, for patients who are requiring admission to hospital or the intensive care unit for treatment. These include:

- Complete blood count (CBC)
- Basic metabolic panel (BMP)
- Sputum gram stain and culture
- Blood cultures drawn from two separate sites
- Arterial blood gas (ABG) if patient is experiencing respiratory distress

For patients who are being treated empirically for MRSA or *Pseudomonas*, lower respiratory tract specimens should be cultured. These specimens can come from expectorated sputum or from a bronchoalveolar lavage (BAL) [4].

Special Testing

In patients presenting with severe CAP, special testing for urinary antigens of *Streptococcus pneumoniae* and *Legionella pneumoniae* serogroup 1 has been approved [6]. Recent guidelines, however, recommend against urinary antigen testing for *Streptococcus pneumoniae* and *Legionella* [4].

Differential Diagnosis

The following might be considered in the differential based upon the patient's signs, symptoms, and comorbidities:

- Influenza
- Viral pneumonia

Telegram: @medical_k

www.konkur.in

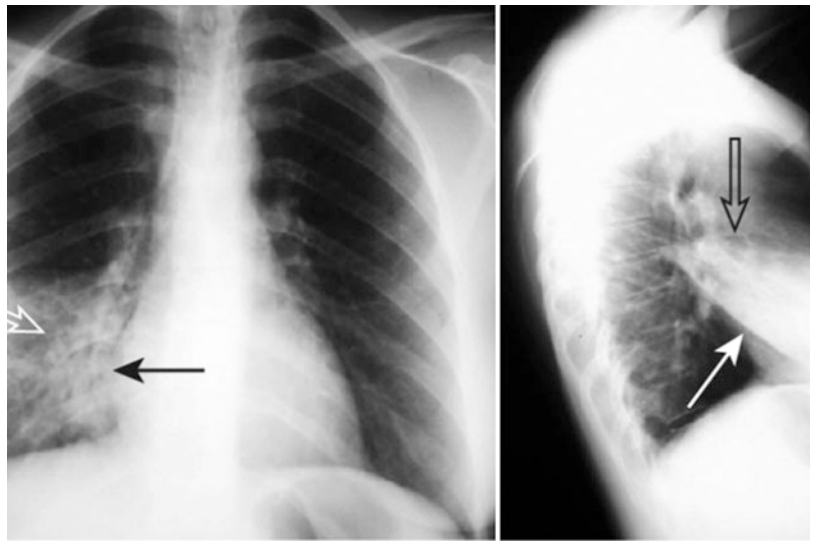

Fig. 1 X-ray of infiltrates in pneumonia [7]

- Atypical pneumonia
- Acute bronchitis
- COPD exacerbation
- Congestive heart failure (CHF)
- Pleural effusion
- Pulmonary embolism

Treatment

Medications

Severity of illness is the most important first determination to make in treatment for a patient with pneumonia; this should direct the "site-of-care" decision (hospital vs. outpatient, ICU vs. medical ward). Two scoring systems for assisting with the decision on hospitalization are the pneumonia severity index (PSI) and the CURB-65 (*c*onfusion, *u*remia, *r*espiratory rate, low *b*lood pressure, age *65* years or greater). Using one of these criteria, in addition to the clinical picture of the patient, will help guide the appropriate medication and site of treatment [4]. In the 2019 guidelines, the PSI is recommended over the CURB-65. The PSI has been shown to more consistently serve as a decision aid to increase outpatient treatment of patients with CAP and has potential to decrease unnecessary variability in admission rates, the high cost of inpatient pneumonia treatment, and the risk of hospital-acquired complications.

After deciding to admit a patient to the hospital for treatment, the next decision to be made is whether or not the patient needs ICU treatment. As mentioned, previously, according to the Infectious Diseases Society of America/American Thoracic Society, there are several clinical criteria that should be considered for ICU admission – meeting three or more of the following:

- Tachypnea, RR >25–30 breaths/min
- PaO_2 or FiO_2 ratio <250
- Multilobar infiltrates
- Altered mental status/confusion
- BUN >20 (uremia)
- White blood cell count <4000
- Thrombocytopenia, platelet count <150 k
- Temperature <36 °C
- Hypotension/septic shock requiring aggressive fluid hydration [4]

Severity of illness, presence of comorbidities and/or risk factors for MRSA or *P. aeruginosa* guides antibiotic choice for treatment. In most cases, it can be difficult to establish exact organism(s) affecting a patient; therefore, empiric antibiotic therapy guidelines have been established.

For patients who do not meet severity criteria requiring inpatient or intensive care unit admission, with or without comorbidities, treatment can be attempted outpatient. *S pneumoniae* is still the most common cause of community-acquired pneumonia and is the main target of antibiotic

Telegram: @medical_k

www.konkur.in

therapy. The 2019 ATS/IDSA guidelines highlight using amoxicillin as a first-line agent for outpatient CAP treatment. Previously, macrolides were recommended as first-line outpatient CAP antibiotic treatment, but increasing macrolide resistance in the United States has emerged, causing a shift away from this practice.

If attempting outpatient community-acquired pneumonia treatment in a patient with comorbidities (i.e., diabetes mellitus, alcoholism, malignancy, asplenia or chronic heart, liver, lung or renal disease), combination therapy with amoxicillin/clavulanate or cephalosporin *and* a macrolide or doxycycline *or* monotherapy with a respiratory fluoroquinolone is recommended (Table 1).

For inpatient treatment of pneumonia, the same severity criteria are applied to determine patient treatment. For nonsevere inpatient pneumonia, recommended empiric treatment is a beta-lactam + macrolide OR respiratory fluoroquinolone. For severe inpatient pneumonia, the recommended treatment would be a beta-lactam + macrolide or beta-lactam + fluoroquinolone. As the new guidelines eliminate the term healthcare-associated pneumonia, it is recommended that patients in nursing homes or with recent hospitalization only be treated for methicillin-resistant *Staphylococcus aureus* (MRSA) and *Pseudomonas aeruginosa* if they meet criteria for locally validated risk factors or antibiotic-resistant bacteria. Risk factors would include previous respiratory isolation of MRSA or *P. aeruginosa* or recent hospitalization AND receipt of parenteral antibiotics within the last 90 days. It is also recommended that sputum and blood cultures should be ordered for any patients started empirically on anti-MRSA or antipseudomonal antibiotics to allow for more rapid de-escalation when culture findings are negative for these bacteria.

Table 1 Initial treatment strategies for outpatients with community-acquired pneumonia

	Standard regimen
No comorbidities or risk factors for MRSA or *Pseudomonas aeruginosa* (risk factors for MRSA/ *P. aeruginosa* include prior respiratory isolation of MRSA or *P. aeruginosa* or recent hospitalization AND receipt of parenteral antibiotics in the last 90 days)	Amoxicillin or Doxycycline or Macrolide (if local pneumococcal resistance is <25%)
With comorbidities (such as chronic heart, lung, liver, or renal disease; diabetes mellitus, alcoholism, malignancy, or asplenia)	Combination therapy with amoxicillin/clavulanate or cephalosporin AND Macrolide or doxycycline OR Monotherapy with respiratory fluoroquinolone

Bacterial pneumonia is typically treated for a minimum of 5–14 days, with length of treatment being dependent upon degree of illness at presentation, age, comorbidities, initial response, and whether patient was hospitalized/ICU or not. Attention should be directed at monitoring length of intravenous therapy and recognizing when to switch to oral therapy. Once a patient is clinically improving and requiring no intervention to maintain hemodynamic stability, he/she can safely be switched to oral therapy to complete the course of treatment [4].

In addition to following the most updated guidelines, it is also important to be aware of local epidemiological data, as well as potential antibiotic-resistant changes with typical bacterial pneumonia treatment [5].

Patient Education

Decreasing a patient's chance of becoming ill with pneumonia is an important part of a primary care physician's job [6]:

- Counsel patients who smoke on the importance of smoking cessation.
- Encourage scheduled vaccinations.
- Educate patients on accepted hand hygiene standards: wash hands regularly with soap and warm water for at least 20 s.
- Disinfect frequently touched surfaces.
- Teach them about cough etiquette: cover the mouth and nose with a tissue when they cough or sneeze, and put used tissues in the waste basket.
- If they do not have a tissue, teach them to cough or sneeze into their upper sleeve or elbow, not their hands.

Telegram: @medical_k

www.konkur.in

Prevention

Immunizations

Vaccinations against preventable illnesses have long been proven effective in overall patient and population morbidity and mortality. Risk for infection with the most common bacterial pneumonia – *Streptococcus pneumoniae* – can be decreased with immunization. According to the Centers for Disease Control, the following vaccinations are important for prevention of pneumonia:

- Pneumococcal
- *Haemophilus influenzae* type b
- Pertussis (whooping cough)
- Influenza (flu) – yearly
- Measles [2, 7]

Atypical Pneumonias

Mycoplasma Pneumoniae

General Principles

M. pneumoniae is considered the most common "atypical" pathogen for community-acquired pneumonia (CAP). The prevalence of *M. pneumoniae* in adults with pneumonia can range between 1.9% and 32.5%. Outbreaks can occur in institutional settings such as schools and military bases [8]. It is usually transmitted from close person to person contact via respiratory droplets. The average incubation period is around 2–3 weeks [9], and infections tend to occur during the summer and early fall. *M. pneumoniae* pneumonia is most frequently seen among children around 5–15 years of age [10].

Approach to the Patient

Diagnosis

History and Physical

The onset of symptoms is typically gradual over the course of several days. Common symptoms include sore throat, muscle pain, headache, malaise, and chills. Patients also complain of a cough that is initially dry but becomes productive over the course of the infection. The cough is typically worse at night. Sinus pressure and otalgia can also occur. The lung exam can be normal on initial examination but can develop into scattered rales or wheezes during its progression. Extrapulmonary complications can include maculopapular rashes, arthralgia, aseptic meningitis, transverse myelopathy, and Guillain-Barré syndrome. Since the progression is gradual, a patient may not seek medical attention until a few days to a week.

Laboratory and Imaging: Special Testing

Obtaining a chest radiograph may reveal diffuse, interstitial infiltrates [10] and may be more prominent if the illness has been present for at least 2 weeks [9]. Traditionally a throat culture was obtained; however, the incubation period in a culture can take up to 3 weeks. Nuclear acid amplification testing (NAATs) is now considered the "gold standard" and has a high sensitivity and shorter turnaround time [10, 11]. A cold agglutinin test can be used as well and usually appears by the end of the first week of illness. Around 72–92% of patients with pneumonia and positive cold agglutinins (>1:32) will develop a serologic response to *M. pneumoniae*. Serology can be obtained by complement fixation (CF) or enzyme immunoassay (EIA) [8, 11].

Treatment

With the absence of a cell wall, *Mycoplasma pneumoniae* is typically resistant to glycopeptides, fosfomycin, and beta-lactam antimicrobials. Macrolides (erythromycin, azithromycin), tetracyclines (doxycycline), and fluoroquinolones (levofloxacin, moxifloxacin) are the typical therapies used to treat *M. pneumoniae*. If central nervous system involvement is suspected, consider the use of tetracyclines. In a patient with an impaired immune system and a suspicion of a systemic infection outside the respiratory system, consider the use of a fluoroquinolone [11]. Macrolides, particularly azithromycin, tend to be the most active against *M. pneumoniae* in in vitro studies [8]. The duration of antibiotic treatment is typically 5 days of azithromycin or 7–14 days with a tetracycline or fluoroquinolone.

Telegram: @medical_k

www.konkur.in

Prevention
Use of appropriate hand hygiene and cough etiquette.

Chlamydial Infection

General Principles

Chlamydia is a set of gram-negative obligate intracellular organisms. It includes *Chlamydia trachomatis*, *Chlamydophila* (formerly *Chlamydia*) *pneumoniae*, and *Chlamydophila psittaci. C. trachomatis* generally presents as a genital tract or ocular infection, but the latter two can present itself as an atypical pneumonia. Around 10% of cases of community-acquired pneumonia (CAP) are related to *C. pneumoniae* [12].

Approach to the Patient

Diagnosis

History and Physical
Along with other atypical pneumonias, patients can present with productive cough, sore throat [13], sinus congestion, and malaise.

Patients who have psittacosis, caused by *C. psittaci*, tend to have a history with exposure to infected birds, which is also known as parrot fever, ornithosis or avian chlamydiosis [14]. *C. psittaci* comprises around 1% of all community-acquired pneumonia cases, and less than 50 cases a year of psittacosis are reports in the United States [14, 15]. It often presents in young to middle-aged adults. Symptoms include abrupt fever, headache, dry cough, myalgia, and malaise.

Laboratory and Imaging: Special Testing
Chest radiographs may show infiltrates. For diagnosis, oropharyngeal swabs can be used to culture *Chlamydophila* species. Serology tests, EIA, and polymerase chain reaction (PCR) can be used as well [13]. Laboratory testing may show abnormal liver enzymes, hyponatremia, elevated BUN/creatinine levels, and elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). The patient may also have a normal white blood cell count with a "left shift" [14]. A chest radiograph can reveal interstitial or lobar infiltrates [16]. As with *C. pneumoniae*, *C. psittaci* can be diagnosed with serologic testing.

Treatment
Tetracyclines such as doxycycline (100 mg orally twice daily) or tetracycline (500 mg orally four times per day) for 7–10 days are the treatment of choice for both *C. pneumoniae* and *C. psittaci* [14]. Macrolides (azithromycin) can be used as well and are usually the choice for empiric treatment for atypical pneumonia [13, 16]. For children, macrolides are the treatment of choice.

Prevention
Counsel patients about the importance of hand hygiene and cough etiquette [17].

Viral Pneumonia

General Principles

Worldwide, 900,000 children aged less than 5 years die from pneumonia every year. Despite advances, a cause is not always ascertained in a patient with pneumonia. Recent prospective pneumonia etiology studies have failed to detect a pathogen in greater than 50% of adults and approximately 20% of children hospitalized with pneumonia. In these same studies, viruses were more commonly detected than bacteria in both adults and children, accounting for greater than 25% of detections in adults and greater than 70% in children [18].

Epidemiology

More studies are showing that viral pathogens are an important cause of community-acquired pneumonia (CAP), including viruses other than influenza. In a large epidemiological study conducted by the Centers for Disease Control and Prevention despite an extensive diagnostic workup performed, no pathogen was detected in 62% of cases, vital pathogen was detected as the single pathogen in 22% of cases, bacterial pathogens were detected in 11% of cases, and co-infection virus-bacteria were detected in 3% of cases.

Telegram: @medical_k

www.konkur.in

Among the viral pathogens, human rhinovirus was the most commonly detected followed by influenza virus [19].

In the EPIC (Etiology of Pneumonia in the Community) study among the 2222 children with pneumonia, the most commonly detected viruses were respiratory syncytial virus (28%), human rhinoviruses (27%), human metapneumovirus (13%), adenoviruses (11%), parainfluenza 1 to 3 viruses (7%), influenza A and B viruses (7%), and coronaviruses (CoV, 5%) [18].

As of the time of writing this chapter, there has been a declaration of a pandemic with COVID-19 which is part of the group of coronaviruses responsible for severe acute respiratory syndrome (SARS) and Middle East Respiratory Syndrome (MERS). Coronaviruses are single-stranded RNA viruses, and there are six that have been identified in humans. In SARS, nosocomial transmission was an important factor in epidemic spread. In MERS, direct contact with dromedaries in the 2 weeks before illness onset was a strong association [20].

Transmission

For influenza and RSV, droplet and fomite transmission are the most common methods of transmission.

Influenza has an incubation period of 1–3 days, and viral shedding begins before the appearance of symptoms and within the first 24 h of inoculation. Viral shedding peaks on the second day and in healthy adults is no longer detectable 6–10 days later. In children and immunocompromised adults, prolonged viral shedding occurs up to 21 days [21]. RSV viral shedding has a mean of 6.7 days with a range of up to 21 days [22].

Approach to Patient

Diagnosis

History

Infants with RSV initially present with rhinorrhea and decreased appetite followed by a cough within 1–3 days. Soon after the cough, sneezing, fever, and wheezing occur. In very young infants, the only symptoms may be irritability, decreased activity, and apnea [22].

In adults the presentation is similar to that of community-acquired pneumonia, but they may have symptoms of an upper respiratory infection for less than 5 days prior. The symptoms of an upper respiratory infection are rhinorrhea, sore throat, cough, headache, fatigue, and fever [6].

Physical Examination

The physical examination should target the following areas: general appearance and vital signs, head, eyes, ears, nose, and throat, cardiac, and pulmonary and thorax.

General appearance and vital signs are important in discerning the severity of illness. Is the patient lethargic or confused? Is the patient tachycardic or hypotensive? These are signs of more severe illness and most likely will require hospitalization.

Examination of the head, eyes, ears, nose, and throat can provide evidence for a preceding upper respiratory infection which would indicate a more viral etiology.

On cardiac examination, if there is a new gallop or murmur, then that can indicate increased severity of illness.

Pulmonary and thorax examinations are done to look for abnormal breath sounds and evidence of a consolidation or effusion which again can indicate a higher level of severity (Table 2) [6].

Treatment

Medications are given based on etiology of viral pneumonia. Influenza is treated with oseltamivir (although peramivir can also be used) [19].

Herpes simplex and varicella zoster are treated with acyclovir. No antiviral treatment of proven value is available for other viral pneumonias, and a high clinical suspicion for bacterial superinfection should be maintained. For RSV infection, high-risk infants and young children likely to benefit from immunoprophylaxis based on gestational age, certain underlying medical

Telegram: @medical_k

www.konkur.in

Table 2 Laboratory and imaging recommendations for viral pneumonia [23]

Office-based	
RSV	Antigen detection test supplemented by cell culture Sensitivity of antigen detection tests range from 80% to 90% and is reliable in young children Real-time polymerase chain reaction (RT-PCR) assays are more sensitive in older children and adults who may have a lower viral load
Influenza	Rapid influenza diagnostic tests Sensitivity tests range from 50% to 70% and specificity tests range from 90% to 95%
Hospital-based	
Serology	Complete blood count with differential – To assess severity of infection Electrolytes – To assess hydration, kidney function, and glucose Blood culture for bacterial pathogens
Sputum	Culture and sensitivity for bacterial pathogens
Nasopharyngeal	For RSV and influenza
Chest X-ray	Initially, to assess for presence of consolidation or effusion
CT of chest	For those not responding to initial therapy
Specialized testing	
Serology	Titers for acute and convalescent phase – More important for seroprevalence and epidemiological studies

conditions, and RSV seasonality, palivizumab is available. This is a monoclonal antibody given in monthly intramuscular injections during RSV season [23]. In immunocompromised patients, ribavirin has been used anecdotally for severe parainfluenza and human metapneumovirus infections; cidofovir for severe adenovirus infection in both immunocompromised and immunocompetent patients; and ganciclovir in CMV pneumonitis [19].

For coronoviruses, symptomatic and supportive care are, again, the mainstay of therapy. The most commonly prescribed antiviral regimens in the clinical settings are ribavirin, interferons, and lopinavir/ritonavir [20].

Family and Community Issues

Prevention using standard precautions and droplet precautions for at least 5 days is recommended. Wash hands frequently and correctly with soap and water for at least 20 s, or use alcohol-based hand gels. Use respiratory hygiene measures such as masks or tissues to cover the mouth for patients with respiratory illness. Avoid sharing cups and utensils. Clean contaminated surfaces.

Yearly influenza vaccination is recommended, and for those whom vaccination is contraindicated, antiviral chemoprophylaxis is recommended. Encourage patients to alert providers when they present for a visit and have symptoms of respiratory infection [22, 21].

Tuberculosis

General Principles

Definition

Tuberculosis is caused by *Mycobacterium tuberculosis* (MTB). This is a large nonmotile rod-shaped obligate aerobic bacterium requiring oxygen for survival. It is commonly introduced to the body through inhalation of droplet nuclei. MTB is usually found in well-aerated upper lobes of the lungs. MTB is a facultative intracellular parasite that is engulfed by macrophages. MTB is released into the alveoli upon death of the macrophage, and the health of the host's immune system is the key factor in expression of TB disease [24].

Epidemiology

One-third of the world's populations is infected with tuberculosis (TB). In 2012, nearly nine million people around the world became sick with TB disease, and there were approximately 1.3 million TB-related deaths worldwide. TB is a leading killer of people who are HIV-infected. A total of 8920 TB cases (or 2.8 per 100,000 persons) were reported in the United States in 2019 [25]. Up to 13 million people in the United States are living with latent TB infection [25].

Telegram: @medical_k

www.konkur.in

Classification

MTB may be cleared by the host immune system or may progress to latent TB infection or to primary TB. Latent tuberculosis infection (LTBI) means that the host immune system has used the cellular immune system mediated by T-helper cells to contain MTB in a granuloma. 5–10% of persons with LTBI are at risk of progressing to active TB disease. Immunocompromised persons (HIV, cancer, on immunosuppressing medications) are at greater risk for progression to active TB disease [24].

Approach to the Patient

Diagnosis

Screening

The Centers for Disease Control (CDC) recommends that high-risk populations be screened for latent infection. This includes HIV patients, IV drug users, healthcare workers who serve high-risk populations, and contacts of individuals with pulmonary tuberculosis. A validated risk assessment questionnaire may be used to identify children who are likely to benefit from screening.

History/Physical Examination

Classic clinical features of pulmonary tuberculosis include chronic cough, sputum production, appetite loss, weight loss, fever, night sweats, and hemoptysis. Extrapulmonary tuberculosis occurs in 10–42% of patients. In HIV-infected persons, the risk of active tuberculosis increases soon after infection with HIV. Those with a CD4 count of less than 200 cells/mm^3 may have an atypical presentation of tuberculosis with subtle infiltrates, pleural effusion, hilar lymphadenopathy, and other forms of extrapulmonary tuberculosis. At CD4 counts of less than 75 cells/mm^3, pulmonary findings may be absent, and disseminated tuberculosis is more frequent. Disseminated tuberculosis presents as a nonspecific chronic febrile illness with widespread organ involvement [24].

Laboratory/Imaging

Latent infection is diagnosed using the tuberculin skin test (TST) or interferon-gamma release assay (IGRA).

In the TST a small amount of tuberculin is injected into the dermis of the skin creating a small, pale bump. In 2–3 days the TST must be read by a trained healthcare worker. A positive reaction is induration measured in millimeters. Those people who have previously been vaccinated with bacillus Calmette-Guérin (BCG) may have a false-positive TST [26]. IGRA measures a person's immune reactivity to MTB. White blood cells from most persons infected with MTB will release interferon-gamma when mixed with antigens derived from MTB. IGRA requires a single patient visit and results can be available within 24 h. Vaccination with BCG does not cause a false-positive IGRA test. However, IGRA is more expensive than TST [26].

Active tuberculosis infection is diagnosed using sputum microscopy and culture along with chest radiography. Three sputum samples are obtained for acid-fast bacilli (AFB). In addition a nucleic acid amplification test (NAAT), a complete blood count, and electrolytes are also ordered. Sputum culture is more sensitive than smear staining, facilitates identification of the mycobacterium species by nucleic acid amplification, and evaluates drug sensitivity. Cultures may take 4–8 weeks [26]. 40–50% of TB cases are AFB smear negative and 15–20% have negative cultures [26]. Chest X-ray is often normal but hilar adenopathy is the most common abnormality found in as much as 65% of cases. Hilar changes can occur 1–8 weeks after skin test conversion. The findings often resolve within the first year of detecting a positive skin test for primary TB [24]. Pleural effusions are also common in active TB infection.

Treatment

Treatment depends on whether latent or active infection is diagnosed.

Latent infection is treated with isoniazid 300 mg daily for at least 6 months and preferably for 9 months. Alternative treatment regimens are listed on the Centers for Disease Control and

Telegram: @medical_k

www.konkur.in

Prevention website. All treatment regimens require directly observed therapy – a person employed by the state health department administers and ensures that the patient diagnosed with latent infection takes their medication [27].

Active drug-susceptible TB is treated with a four-drug regimen: isoniazid (INH), rifampin (RIF), ethambutol (EMB), and pyrazinamide (PZA). There is an intensive phase of treatment for 2 months followed by a continuation phase of either 4 or 7 months for a total of 6 to 9 months of treatment. There are four different regimens recommended by the Centers for Disease Control. The 4-month continuation phase is used in most patients. The 7-month continuation phase is recommended for the following groups: those with cavitary pulmonary TB and the sputum culture obtained at 2 months of treatment which is positive; those whose intensive phase of treatment did not include PZA; patients with HIV who are not receiving antiretroviral treatment during TB treatment; and patients being treated with once weekly INH and rifapentine and whose sputum culture obtained at the completion of the intensive phase is positive.

Pyridoxine supplementation is recommended to prevent isoniazid-induced neuropathy [27]. If there is multidrug-resistant disease, then initial treatment is based on local disease patterns and pending drug-susceptibility results; later-generation fluoroquinolones are preferred (e.g., moxifloxacin or levofloxacin) [27].

For those with active TB, sputum analysis should be done weekly until sputum conversion is documented. Patients who receive pyrazinamide should undergo baseline and periodic serum uric acid assessments. Those who receive long-term ethambutol therapy should undergo baseline and periodic visual acuity and red-green color perception testing. Also patients should be monitored for toxicity with baseline and periodic liver enzymes, complete blood cell count, and serum creatinine [27].

Drug-resistant TB is caused by TB bacteria that are resistant to at least one first-line anti-TB drug. Multidrug-resistant TB is resistant to more than one anti-TB drug and at least INH and RIF. Extensively drug-resistant TB is a rare type of multidrug-resistant TB that is resistant to isoniazid and rifampin, plus any fluoroquinolone, and at least one of three injectable second-line drugs (i.e., amikacin, kanamycin, or capreomycin). Extensively drug-resistant TB is of special concern for people with HIV infection or other conditions that can weaken the immune system [27].

Causes of multidrug-resistant TB include drugs used to treat TB that are misused or mismanaged (e.g., people do not complete a full course of TB treatment); healthcare providers prescribe the wrong treatment (wrong dose or length of time); drugs for proper treatment are not available; drugs are of poor quality [27].

Family and Community Issues

Tuberculosis is required to be reported to local public health authorities. For control of pulmonary tuberculosis, control of infectivity is most efficiently achieved through prompt specific drug treatment. It takes 2–4 weeks for vital organisms to disappear in the sputum and 4–8 weeks to be cleared in the sputum.

Patients with sputum smear-positive TB who live in congregate settings should be placed in an airborne infection isolation room with negative pressure ventilation. Patients should cover their nose and mouth while sneezing. Persons entering rooms where TB patients reside should wear personal respiratory protective devices capable of filtering particles less than 1 micromillimeter in diameter. Patients whose sputum is negative for bacteria and who do not cough and who are known to be on adequate drug treatment do not require isolation. Handwashing and good housekeeping practices must be maintained according to policy [17].

Histoplasmosis

General Principles

Definition/Background and Epidemiology

Histoplasmosis is a pulmonary infection caused by *Histoplasma* – a fungus found in soil with large amounts of bird and bat guano [28]. People

Telegram: @medical_k

www.konkur.in

acquire histoplasmosis after breathing in the microconidia (microspores) from the air, often after participating in activities that disturb the soil. Although most people who breathe in the spores become mildly ill, moderate infection may present with a fever, cough, and/or fatigue. Not every person infected with this spore becomes ill; but in patients with weakened immune systems, the infection can become severe, especially if it becomes a systemic infection [28].

Anyone is susceptible to histoplasmosis if they live or have traveled to an area where *Histoplasma* lives in the soil. In the United States, *Histoplasma* mainly lives in soil in the central and eastern states, especially in the Ohio and Mississippi River valleys. *Histoplasma* has been reported worldwide, with localized foci located in Central America, Europe, Africa, and Asia [29]. Outdoor activities often associated with this fungus include cave spelunking, mining, construction/demolition, excavation, chimney cleaning, and farming/gardening.

There are specific populations who are at higher risk for developing the severe forms of histoplasmosis. This population includes patients who have weakened immune response (HIV/AIDS, previous organ transplant, or who are on chronic immune-suppressing medications), infants, and older adults (55 and older).

Approach to the Patient

Diagnosis

History

A majority of patients either will have no symptoms or will present with subacute influenza-like symptoms – dry cough, fever, myalgias, and fatigue – possibly weeks to months after exposure. In patients with acute illness, presenting symptoms can include high fever, headache, nonproductive cough, chills, weakness, pleuritic chest pain, and fatigue. Patients who are immunocompromised are at increased risk for systemic dissemination.

For patients not living in the areas of highest incidence, travel and activity history are important factors in diagnosing this illness.

Physical Examination

In general, the physical exam findings for any acute pulmonary infection will be similar to those for bacterial pneumonia:

- Tachycardia
- Tachypnea, +/− hypoxia
- Decreased or adventitious breath sounds
- Fever >40 °C (102 °F)
- Possible septic appearance

Laboratory and Imaging

Initial presentation resembles community-acquired pneumonia; therefore, the typical lab tests and imaging are completed at that time. These include a CBC and chest X-ray. Based on initial exam and diagnostic findings alone, most patients will likely be treated for a bacterial CAP; not until the patient's condition has worsened or initial antibiotic therapy has failed will additional special testing be completed.

Chest X-ray findings with acute pulmonary histoplasmosis include patchy or diffuse reticulonodular infiltrates; CT scans show +/− mediastinal or hilar lymphadenopathy [30]. At this point, further testing with treatment plan adjustments is recommended.

Special Testing

Definitive testing for histoplasmosis requires cultured growth of the organism, but this can take 4–6 weeks. Several tests are available for diagnosis of histoplasmosis once it is considered the cause of illness. Table 3 provides a list of testing available [29, 30].

For patients who present with diffuse disease or chronic disease with cavitating lesions, HIV testing or differentiation of cause of immunocompromised state should be completed.

Differential Diagnosis

- Pneumonia – bacterial, atypical, viral
- Sarcoidosis

Telegram: @medical_k

www.konkur.in

Table 3 Testing methods for histoplasmosis

Diagnostic method	Comments
Antigen detection Urine Serum	Most sensitive if both urine and blood are tested Acute and chronic infection *CON*: Not as useful in immunocompromised patients – Unable to mount antibody response
Culture	Diagnostic *CON*: Takes 4–6 weeks for culture to grow

- Other pulmonary fungal infections – blastomycosis, aspergillosis, coccidioidomycosis
- Lung cancer

Treatment

Medications

Table 4 summarizes the most recent recommendations on treatment of histoplasmosis. There has been a recent change in the treatment recommendations, with increased use of itraconazole. Amphotericin B is still highly recommended for patients with severe pulmonary histoplasmosis and for immunosuppressed patients [38, 29–31].

Prevention and Patient Education

For patients who are immunocompromised, education on high-risk behavior in endemic areas – cave exploration/spelunking, for example – should be provided.

Table 4 Treatment recommendations for histoplasmosis [29]

Disease acuity	Medications
Mild to moderate	Itraconazole 200 mg orally three times a day for first 3 days and then 200 mg orally once or twice daily for 6–12 weeks
Moderate to severe	Amphotericin B (lipid formulation) 3–5 mg/kg daily IV for 1–2 weeks, followed by itraconazole 200 mg orally three times daily for 3 days and then 200 mg twice daily, for a total of 12 weeks *Plus* Methylprednisolone 0.5–1 mg/kg daily IV for the first 1–2 weeks of therapy, in patients with ARDS[a]

[a]*ARDS* acute respiratory distress syndrome

Coccidioidomycosis

General Principles

Definition/Background and Epidemiology

Coccidioides is a dimorphic fungus that is found in the soil of the southwest region of the United States. Coccidioidomycosis is an infection caused by *Coccidioides immitis* or *Coccidioides posadasii*, and it is due to the inhalation of spores [32]. The incidence of reported coccidioidomycosis has increased, from 5.3 per 100,000 population in 1998 to 42.6 per 100,000 in 2011 [33]. The reports were from the endemic areas of Arizona, California, Nevada, New Mexico, and Utah. Due to population increases in Arizona and California, the number of infections has risen to about 150,000 per year. It is also known as "valley fever" [34], or in California, San Joaquin valley fever.

Approach to the Patient

Diagnosis

History and Physical Examination

Infection is usually acquired by inhalation of the spores and living around the endemic regions of the southwestern United States. Most commonly, coccidioidomycosis usually presents itself as a self-limiting acute or subacute community-acquired pneumonia. This can develop around 7–28 days infection. The patient can present with respiratory complaints, fatigue, or arthralgia. Around 75% of patients with primary pulmonary coccidioidomycosis develop a flu-like syndrome with fever and cough [15]. For some patients, fatigue can last from weeks to months. A few patients (0.5%) infected may develop a progressive pulmonary or disseminated infection (skin, meninges, and bones). Persons of African or Filipino descent and pregnant, diabetic, and

Telegram: @medical_k

www.konkur.in

immunosuppressed patients have a higher risk of extrapulmonary complications.

Obtaining an accurate travel history is important. The patient should have been exposed in a region where exposure is possible (southwestern United States). The most common symptom is a respiratory illness, particularly if it involves the lower respiratory tract (i.e., pneumonia). The severity of illness varies from a mild respiratory infection to progressive pulmonary lesions or dissemination. The diagnosis of coccidioidomycosis from other causes is difficult without further testing.

Laboratory and Imaging: Special Testing

A sputum culture growing *Coccidioides* species establishes the diagnosis; however, it could take weeks for the culture to grow. *Coccidioides* species is considered by the Centers for Disease Control (CDC) as a select agent, so there are specific guidelines to oversee its handling [35]. Usually a culture is reserved for patients who require hospitalization. For most patients in an ambulatory setting, serologic testing can be used to diagnose coccidioidomycosis. IgM and IgG anti-coccidioidal antibodies are usually the screening test of choice. In 25%–30% of cases, eosinophilia is seen on a white blood cell differential [15].The most common chest radiograph abnormality is airspace opacity (58% of patients), followed by pulmonary nodules (22.8%) and a cavitary lesion (13.2%) [36].

Treatment

If there are no risk factors or no evidence of extensive coccidioidal infection, a majority of patients do not need any antifungal medication. Follow-up visits every 3–6 months for up to 1–2 years are recommended with serial chest radiographs. This is done to document radiographic resolution or to identify extrapulmonary complications. *Coccidioides* nodules generally do not calcify, which is in contrast to histoplasmosis [15]. For patients presenting with a severe illness or have risk factors (i.e., pregnancy), it is recommended to start antifungal therapy. Common antifungals used are ketoconazole 400 mg PO (per os/by mouth) daily, fluconazole 400–800 mg by PO daily, and itraconazole 200 mg PO two to three times per day. For pregnant patients, amphotericin B deoxycholate (0.5–1.5 mg/kg intravenously daily or alternate day) or amphotericin B lipid formulation (2.0–5.0 mg/kg or greater intravenously daily) is used as the antifungal of choice. Depending on the severity, the duration of therapy can range from 3 to 6 months to years.

Prevention

Dust control measures in endemic areas such as face masks, air-conditioned cabs, and wetted soil are recommended. Concurrent disinfection of discharges and soiled surfaces and terminal cleaning must be accomplished [17].

Legionnaire's Disease

General Principles

Definition/Background

Legionnaire's disease is a waterborne, pulmonary infection caused by a gram-negative, nonspore-forming, aerobic bacterium, *Legionella pneumophila*. This pulmonary infection was coined Legionnaire after an outbreak of pneumonia that occurred in people who had attended a convention of the American Legion in Philadelphia in 1976. *Legionella* is the third most common cause of pneumonia in immunocompetent patients [35].

The bacterium, *Legionella pneumophila*, loves warm water and can be found naturally in the environment. This bacterium can live in and be spread to humans from hot tubs, cooling towers, hot water tanks, large plumbing systems, or fountains. The bacteria reside on droplets of water (vapor or mist) and are inhaled from environments containing water features as described above. The incubation period is usually 2–14 days before patients notice any symptoms.

This organism should be suspected in a patient who has had progressive pneumonia-like symptoms and is resistant to standard treatment for CAP.

Telegram: @medical_k

www.konkur.in

Epidemiology

Since being discovered, an estimated 8000–18,000 people are hospitalized yearly in the United States with this infection [36]. It is considered the second most common pathogen detected in cases of pneumonia requiring admission to ICUs and is the third most common cause of pneumonia in immunocompetent patients [35, 36]. In the past 10–12 years, there has been a notable increase in the number of cases reported. This infection is most often reported in the fall and summer, peaking in August [36].

Approach to the Patient

Factors to consider in a patient presenting with a pneumonia-type picture and potential diagnosis of *Legionella* are:

- Older age, >65 years of age
- Smoking status
- Male
- COPD or other chronic lung diseases
- Immunosuppressed or immunocompromised
- Lung cancer
- Diabetes mellitus

Diagnosis

Prompt diagnosis and early initiation of therapy are important for adequate treatment of Legionnaire's disease [6].

History and Physical Examination

Many symptoms are associated with Legionnaire's disease, but symptoms that are consistently reported include fever, loss of appetite, dyspnea, cough, headaches, and malaise. Some patients have reported diarrhea, confusion, phlegm, and/or blood-streaked sputum/hemoptysis. In most cases, symptoms have an abrupt start. If not recognized and treated appropriately, a mild infection can rapidly turn fatal.

Additional information to glean from a patient is recent travel history (including hotel or cruise ship stay) within 2 weeks of onset of symptoms [37].

Physical exam findings might include:

- Tachypnea, RR >20
- Temperature > 40 °C (102 °F)
- Mental status changes, confusion
- Rales on auscultation
- Relative bradycardia
- Generalized abdominal tenderness

Use of special scoring systems, like the Modified Winthrop-University Hospital Infectious Disease Division's Weighted Point System for Diagnosing Legionnaire's Disease in Adults, can be crucial in early infection to diagnose correctly for treatment of Legionnaire's disease.

Laboratory and Imaging

Chest X-rays of patients with *Legionella pneumoniae* can appear identical to X-rays from other types of bacterial pneumonia; therefore, additional testing is required. In general, if these patients are admitted to the hospital, standard blood work should be collected (CBC, BMP, blood cultures × 2, sputum culture/g stain). If *Legionella* is being suspected, there are several options in testing for this organism – the choice of test will likely be driven by what is available within the clinic or hospital laboratory.

Special Testing

When Legionnaires' disease is suspected, both a urinary antigen test and *Legionella* culture of a respiratory specimen should be ordered. The culture requires a special medium, buffered charcoal yeast extract agar (BCYE). The "gold standard" and most sensitive test is the isolation of the organisms by culture from sputum or BAL. The disadvantage to culturing *Legionella* is that it can take 5–10 days for results and is a meticulous process. Cultures can yield a sensitivity of 20–80%, with a specificity of 100% [35, 36].

A serum test has been developed utilizing immunofluorescent assay (IFA) and enzyme-linked immunosorbent assay (ELISA). These tests evaluate and aid in diagnosis when the antibody titer increases greater than fourfold [31]. The time required for adequate testing

Telegram: @medical_k

www.konkur.in

using this method can take up to 3–8 weeks. Sensitivity and specificity of blood serum testing are 70–100% and 100%, respectively [35, 36].

A newer test being used in hospitals is the urinary antigen test. An advantage to this test is a fast turnaround time (<1 h) allowing a shorter time from presentation to diagnosis to targeted treatment. The main disadvantage to using this test for detection of *Legionella* is that it is specific for *L. pneumophila* serogroup 1 only [36]. The urinary antigen test yields a sensitivity and specificity of 80–90% and > 99%, respectively [35, 36].

Differential Diagnosis

- Bronchitis
- Q-fever
- Acute respiratory distress syndrome
- Pneumonia – viral, atypical, bacterial
- Pleural effusion

Treatment

Medications

First-line treatment for *Legionella pneumoniae* follows the guidelines for bacterial CAP – utilizing either a respiratory fluoroquinolone or azithromycin [37, 38, 36] (Table 5).

Immunizations and Chemoprophylaxis

There are no vaccines available for prevention of *Legionella* infections.

Prevention

The most important factor in preventing infection is continued maintenance of water areas, such as hot tubs and heating/cooling water systems.

Table 5 Antimicrobial therapy for *Legionella pneumoniae*

First line	**Levofloxacin** 500 mg IV or orally every 24 h for 7 days or 750 mg IV orally every 24 h for 5 days **Azithromycin** 500 mg IV or 500 mg IV daily for 7–10 days
Second line	**Doxycycline** 100 mg orally twice daily for 5–7 days

Family and Community Issues

Awareness of outbreaks and potential contaminants should be considered when multiple cases within a community are diagnosed with *Legionella*.

Mycobacterium Avium Complex

General Principles

Definition/Background and Epidemiology

Mycobacterium avium complex (MAC) is considered to be nontuberculous mycobacteria. MAC includes several subspecies: *Mycobacterium avium* subsp. *avium*, *M. avium* subsp. *silvaticum*, *M. avium* subsp. *hominissuis*, *M. avium* subsp. *paratuberculosis*, *M. avium* subsp. *intracellulare*, *M. arosiense*, *M. chimaera*, *M. colombiense*, *M. marseillense*, *M. timonense*, *M. bouchedurhonese*, and *M. ituriense* [39].

Nontuberculous mycobacteria (NTM) are normal inhabitants of soil and water. Infections occur because their occupied habitats are shared with humans, animals, fish, and poultry. The habitats include drinking water distribution systems and household plumbing [39].

Patients who receive TNF-α blockers are susceptible to NTM infections, and MAC was the most commonly implicated [40].

Approach to the Patient

Diagnosis

History and Physical Examination

Symptoms are nonspecific. Most patients present with a chronic cough, with or without sputum production or hemoptysis, and slowly progressive fatigue or malaise. Constitutional symptoms such as weight loss, fever, and night sweats are less frequent, occurring in 30–50% of patients, and often indicate advanced disease. Physical examination would be the same as for other types of pneumonia [41].

Laboratory and Imaging

Radiographic abnormalities are more specific and generally follow two distinct patterns. The first is bronchiectasis and nodular lesions mostly

Telegram: @medical_k

www.konkur.in

involving the lingual and middle lobe. The second is fibrocavitary lesions that mostly involve the upper lobes and resemble pulmonary tuberculosis [41].

Differential diagnoses for cavitary lesions include pulmonary malignancy, sarcoidosis, and infections by non-mycobacterial pathogens such as fungi and *Nocardia* species [41].

Special Testing

Sputum culture is required to make the diagnosis. This can be from at least two separate expectorated sputum samples or at least one bronchial wash or lavage.

Management

Treatment regimens should consist of a rifamycin (rifampin or rifabutin), ethambutol, and a macrolide (azithromycin or clarithromycin). Therapy can be given daily or intermittently depending on the disease type and severity. Nodular bronchiectasis patterns can usually be treated by three times weekly therapy. Cavitary MAC disease involves daily three-drug therapy in addition to IM streptomycin or IM/IV amikacin usually given three times weekly [40].

Pneumocystis Pneumonia

General Principles

Definition/Background and Epidemiology

Pneumocystis pneumonia (PCP) is an opportunistic infection that occurs in immunocompromised patients, such as persons infected with the human immunodeficiency virus (HIV). Patients who are on chronic immunosuppressive therapy are also at risk [42]. Traditionally the nomenclature of the organism was *Pneumocystis carinii pneumonia* (*P. carinii* ***p***neumonia), but the name has been changed to *Pneumocystis jiroveci* to distinguish the species that affects humans. The acronym "PCP" is still used today (*Pneumocystis p*neumonia) to avoid confusion in medical literature [43]. For patients with acquired immunodeficiency syndrome (AIDS), PCP is the most common opportunistic infection, but since the introduction of highly active antiretroviral therapy (HAART), the prevalence of PCP has decreased [44]. Most HIV-associated cases of PCP occur in undiagnosed HIV patients [14].

Approach to the Patient

Diagnosis

History and Physical

Patients typically have to be in an immunocompromised state to develop *Pneumocystis* pneumonia. The risk of PCP increases as the T-helper cell count (CD4) decreases in a patient. PCP usually occurs when the CD4 count is less than 200 cells/mm^3. Symptoms can include a low-grade fever, progressive dyspnea, or a nonproductive cough. Upon physical examination, a patient may have tachycardia and tachypnea. Auscultating the lung can be within normal limits but may reveal nonspecific crackles.

Laboratory and Imaging: Special Testing

With PCP, a chest radiograph can show perihilar interstitial infiltrates, which may become more dispersed as the disease process worsens. The interstitial infiltrates may progress into bilateral consolidations [14]. One may also see lung nodules. If the chest radiograph is normal, a high-resolution computed tomography (CT) scan may show ground-glass opacification or lesions cystic in nature. For diagnosis of PCP, an induced sputum (with hypertonic saline) culture should be the initial test of choice. If the culture is negative and still suspected, bronchoscopy with bronchoalveolar lavage is indicated [43]. In the HIV-infected population, an elevated serum lactate dehydrogenase (LDH) is suggestive of PCP, with levels reaching >500 ml/dL [14].

Treatment

In not acutely ill patients with PCP (PaO2 > 70 mmHg), the treatment of choice is trimethoprim-sulfamethoxazole (TMP-SMX) 20 mg/kg PO daily in two to four divided doses

Telegram: @medical_k

www.konkur.in

[14]. For patients who are acutely ill (PaO2 < 70 mmHg, unable to take PO), a 3-week corticosteroid taper should be added in conjunction with TMP-SMX. The patient should take prednisone 40 mg twice daily for 5 days, followed by 40 mg daily on days 6–11, and then 20 mg daily on days 12–21. For those patients who cannot tolerate TMP-SMX, alternative regimens include oral primaquine (30 mg daily) plus clindamycin (600 mg three times daily), atovaquone 750 mg orally twice a day [45], trimethoprim (5 mg/kg orally three times daily) plus dapsone (100 mg orally daily) [46], or pentamidine 4 mg/kg intravenously daily. Glucose-6-phosphate dehydrogenase (G6PD) deficiency must be checked prior to using primaquine or dapsone [44]. The duration of treatment should be 21 days. Following therapy, it is recommended for the patient to start on PCP prophylaxis.

Prevention and Community Issues

For patients with HIV, primary prophylaxis should be started when the CD4 count is less than 200 cells/mm^3. The prophylactic treatment of choice is TMP-SMX at one tablet (single or double strength) by mouth daily. Other options can include dapsone 100 mg PO daily, atovaquone 1500 mg PO daily, or pentamidine 300 mg PO nebulized every 4 weeks. With the introduction of HAART, prophylaxis can be discontinued if the CD4 levels go above 200 cells/mm^3 [42].

General Principles

In the USA, primary lung cancer is the most common cause of cancer death and, after skin cancer, the second most commonly diagnosed cancer. It is one of the leading causes of morbidity and mortality in the USA. In 2019, there were an estimated 228,150 new cases of, and 142,670 deaths from, primary lung cancer [1]. Lung cancer also imposes a large financial burden on the healthcare system, with 2018 national expenditure for diagnosis and treatment totaling $14.2 billion [2].

www.konkur.in

However, since 1992, the rates of new cases and deaths from lung cancer in the USA has been steadily decreasing. In 1999, the age-adjusted rate of lung cancer was 71 per 100,000 Americans. By 2016, it had steadily declined to 58 per 100,000 Americans, with a concomitant decrease in death rates as well, across most ethnicities and in both genders [3]. By ethnicity, African-American men, of all subgroups, have consistently had the highest incidence and death rate over the last decade. Although the gap between African-American men and other groups has been closing, this disparity still serves as a reminder of the significance of socioeconomic factors in the incidence and death rates from lung cancer.

Prevention

Efforts at the prevention of lung cancer can be divided into two separate categories: primary prevention through risk factor modification and secondary prevention through early detection of asymptomatic disease.

Primary Prevention

The CDC has declared that reducing tobacco use is a "Winnable Battle." As the vast majority of lung cancers develop in association with cigarette smoking, the primary prevention of most lung cancers can be achieved through increased smoking cessation and decreased smoking initiation. As with other neoplastic disease, there are additional risk factors involved, including environmental and occupational exposure, nutrition, and genetic predisposition.

Cigarette Smoking

It is estimated that tobacco cigarette smoking causes 80% of the lung cancer deaths in women and 90% in men. Men and women who smoke are 23 times and 13 times more likely to develop lung cancer than men and women who do not smoke, respectively. In addition, exposure to secondhand smoke among nonsmokers increases the risk of lung cancer by 20–30% [4]. Promisingly, the overall prevalence of current smokers in the USA has been steadily decreasing: from 1965 to 2017, the percentage of current cigarette smokers decreased from 42.4% to 14.0% [5]. Among high school students, the overall prevalence has also been decreasing: from 1991 to 2015, the percentage of those who smoked a cigarette within the last 30 days decreased from 36.4% to 9.3% [6]. In 1997, the prevalence had peaked at 37.7% in high school boys and 34.7% in high school girls. It has steadily declined to current levels following the 1998 Tobacco Master Settlement Agreement, perhaps demonstrating the importance of public policy in curbing cigarette use among minors. Still, with the decline in combustible cigarette use, there has been a recent increase in the use of electronic nicotine delivery systems among both minors and adults. Their effects on long-term lung cancer risk are as of yet unknown [7].

From the public health perspective, and for the primary physician, encouraging smoking cessation and preventing smoking initiation are among the most important measures that can be taken to prevent lung cancer.

Occupational and Environmental Exposure

It is estimated that occupational carcinogen exposures are responsible for 9% to 15% of cases (approximately 20,000–34,000) of lung cancer in the USA [8]. Lung cancer is known to be associated with a vast number of workplace exposures, most notably tar and soot, heavy metals (including arsenic, chromium, and nickel), asbestos, silica, and radioactive materials. The list of occupations that involve these substances is extensive and includes mining, manufacturing, printing, painting, and ionizing radiation. Cigarette smoking has been shown to potentiate the effects of some of the occupational carcinogens. In the case of asbestos, arsenic, and radiation, the combined carcinogenic effect can be multiplicative.

Air pollution is becoming increasingly recognized as a risk factor for lung cancer. While different geographic areas have varying components of particulate air pollutants, a 2014 meta-analysis by the World Health Organization classified general outdoor air pollution as a Group 1 (highest

Telegram: @medical_k

www.konkur.in

risk) lung carcinogen. Indoor air pollution from burning biomass is also a well-known risk factor for lung cancer and is an issue more commonly encountered in the developing world.

Ionizing radiation is also classified as a Group 1 lung carcinogen. In the USA, approximately half of an average individual's annual ionizing radiation exposure is iatrogenic, and most of the remainder is from radon-222 exposure. About half of iatrogenic radiation is due to computed tomography (CT), and the rest is from fluoroscopy and nuclear medicine. In the USA, CT scan usage is sharply rising, and it is estimated that in 2007, 1.5–2% of all types of cancers (including lung cancer) were attributable to radiation from CT scans [9]. Non-occupational radon exposure in nonsmokers is estimated to be responsible for approximately 15,000 deaths from lung cancer annually [10]. The EPA has reported that 1 in 15 US homes has radon levels at or above the recommended levels and that lowering levels in these homes could prevent 5,000 lung cancer deaths annually.

Nutrition and Exercise

There is growing evidence that diet and exercise play a role in modifying lung cancer risk. A 2009 review found that the risk for lung cancer was 22% lower in those who ate the highest amount of cruciferous vegetables compared to those who ate a minimal amount [11]. Additionally, a 2018 World Cancer Research Fund report noted that high fruit intake consistently protected against lung cancer (in one analysis, reducing risk by 23% compared to low fruit intake) and that carotenoid-containing foods probably protect against lung cancer [12]. There was also limited evidence suggesting that non-starchy vegetables, selenium, and physical activity were protective against lung cancer, whereas red meat, processed meat, butter, and high overall fat intake were causes of lung cancer. Attempts to isolate the antioxidants thought to be responsible for the protective effects from carotenoid-containing vegetables have not been successful; high-dose vitamin A supplementation in smokers was actually associated with an increased risk of lung cancer.

The interplay of antioxidants contained within foods and the possibility that carotenoids are a marker for a healthier lifestyle rather than protective on their own create uncertainty regarding to the mechanisms of the protective effects of a healthy diet. However, the evidence clearly shows that a diet high in fruits and cruciferous vegetables, combined with physical activity, is a significant part of overall lung cancer prevention.

Genetics

The lifetime risk of being diagnosed with lung cancer in smokers is approximately 17.2% in males and 11.6% in females (compared to 1.3% and 1.4% in nonsmokers, respectively) [13]. That a majority of smokers do not develop lung cancer shows that other factors are involved in the pathogenesis of lung cancer, especially genetic susceptibility. In one study, after adjusting for smoking, age, and gender, a positive family history of lung cancer conferred an odds ratio of developing lung cancer of 1.6, with an increase to 3.6 if two or more family members had been diagnosed [14].

As with other cancers, lung carcinogenesis is a multistep process, involving DNA damage at multiple levels that ultimately causes unchecked cell proliferation. Specifically, mutations within tumor suppressor genes, DNA repair genes, and oncogenes work synergistically to promote tumor growth. Dozens of genes have been noted to have mutations in those with lung cancer, including K-*ras*, *EGFR*, and p53. Recent developments in genomic profiling allow for a million or more genetic variants to be concurrently sequenced, allowing more widespread identification of mutations that may indicate an increased risk of lung cancer. Though genetic testing is not currently used for screening in clinical practice, ongoing research may make it possible that it could one day play a major role in determining susceptibility to lung cancer.

Secondary Prevention

Efforts at secondary prevention have been geared toward early detection through imaging, as other noninvasive tests (serologic, sputum, and breath

Telegram: @medical_k

www.konkur.in

testing) remain in developmental stages. In 2013, the United States Preventive Services Task Force (USPSTF) recommended annual low-dose computed tomography (CT) screening for high-risk current or former smokers (those with a 30 pack-year history and who have smoked in the last 15 years) aged 55–80 years old, to detect asymptomatic disease.

This recommendation was primarily based on the National Lung Screening Trial (NLST), a landmark trial which enrolled over 53,000 patients in academic medical centers across the USA. The NLST demonstrated a 20% reduction in lung cancer mortality with annual low-dose CT compared to chest X-ray, with a number needed to screen (to prevent one death from lung cancer) of 320 [15]. The subsequent NELSON trial, which enrolled 13,000 men and 2,500 women in the Netherlands and Belgium, showed a reduction in lung cancer-specific mortality of 24% in men and 33% in women over 10 years, with a number needed to screen of 133 in men. The NELSON trial used a protocol based on lung nodule volume (as opposed to nodule diameter, used by previous studies) which significantly reduced false positives and unnecessary harms, a noted concern with the NLST findings. In addition, the NELSON trial used longer intervals between screenings, suggesting that biennial screenings may be as effective as annual screenings in select populations [16, 17].

Since the USPSTF recommendation, analyses have estimated the cost of annual low-dose CT screening to cost between $53,000 and $75,000 per quality-adjusted life-year (QALY) gained which is not dissimilar to the costs of screening mammography and colonoscopy [18].

Classifications

Lung cancer originates from cells in the respiratory epithelium (resulting in small cell lung cancer, adenocarcinoma, squamous cell carcinoma, and large cell carcinoma) and the pleura (resulting in mesothelioma). Much rarer forms of lung cancer include spindle cell carcinoma, giant cell carcinoma, and carcinosarcomas; they are classified as non-small cell lung cancers. The relative incidence of the most common types is shown (*see* Table 1) [19]. In recent decades, adenocarcinoma has become the most prevalent type of lung cancer. This may be due to the widespread use of filtered cigarettes, which allow carcinogens to travel further down the bronchial tree, bypassing protective epithelium. Smoking is associated with nearly all types of lung cancer, but is most closely associated with small cell and squamous cell cancers. In those who have never smoked, adenocarcinoma is the most common type of cancer [20].

Table 1 Incidence of Lung Cancer type by histology

Lung cancer type by histology	Incidence (%)[a]
Small cell lung cancer (SCLC)	18%
Non-small cell lung cancer (NSCLC)	74%
Adenocarcinoma	46%
Squamous cell carcinoma	25%
Large cell carcinoma	8%
Mesothelioma	<0.02%

[a]Due to a combination of sources, the total may not add up to 100%

The stage of disease is the strongest predictor of survival, though histology also plays an important part in prognosis [21]. Among the major histological types, adenocarcinoma generally has the highest 5-year survival, and small cell has the poorest survival. For localized disease, the 5-year survival is approximately 69% for adenocarcinoma, 46% for squamous cell, 48% for large cell, and 27% for small cell. For regional disease, the survival drops to 42% for adenocarcinoma, 26% for squamous cell, 29% for large cell, and 15% for small cell. With the new implementation of screening CT for lung cancer, cancers may be detected at earlier (more local) stages, which may improve survival and increase the amount of disease amenable to a cure.

Diagnosis

Clinical Presentation

The clinical presentation of a lung cancer is driven by the site of origin and the extent of the disease. It is not uncommon for it to be an asymptomatic finding

Telegram: @medical_k

www.konkur.in

on a chest X-ray or CT scan of the abdomen or chest obtained while working up another problem. Other common presentations are non-resolving infiltrates after treatment for pneumonia, as a pleural effusion or with persistent chest wall or shoulder pain. Because of the endobronchial origin of many lung cancers, cough, hemoptysis, dyspnea, and unilateral wheezing or stridor may be the original complaint. Patients presenting with advanced disease may have weight loss, anorexia, fatigue, persistent fevers, or clubbing.

Lung cancers are associated with a number of syndromes, which can be divided into general categories: (1) the consequences of tumor invasion of the surrounding tissues, (2) the systematic effects of hormonal substances produced by cancers, and (3) cytokines or antibodies triggered by the immune system's response to the tumor (paraneoplastic syndromes). Local invasion of nerves at the apex of the lung causes Horner's syndrome (cervical sympathetic) or Pancoast syndrome (brachial plexus). Tumor invasion of the mediastinum can block venous return to the heart causing superior vena cava syndrome, invasion of the pericardium causing cardiac tamponade, or erosion into the esophagus causing obstruction or fistulas. Metastatic lesions in the spine can cause spinal cord compression with distal weakness and pain. Tumors can secrete antidiuretic hormone causing hyponatremia, parathyroid hormone causing hypercalcemia, or adrenocorticotrophic hormone leading to Cushing syndrome. These latter hormonal syndromes are more common with SCLC and reflect the neuroendocrine nature of these cancers. The most common paraneoplastic syndrome associated with lung cancer, occurring in 5–15% of patients, is periosteal swelling of the distal phalanges causing clubbing of the fingers. The myasthenia-like Lambert-Eaton syndrome develops from the production of antibodies to the postsynaptic acetylcholine receptor of the motor end plate.

Diagnostic Approach

Typically, patients with lung cancer present with advanced tumors causing a range of symptoms. Diagnostic decisions center on identifying the tumor cell type and accurately staging the extent of the cancer. With increasing frequency, especially in the context of screening for asymptomatic cancers using low-dose CT scans of the chest, diagnostic decisions revolve around the safest way to evaluate small, indeterminate lung nodules. Recent years have seen a rapid expansion in the complexity of diagnostic algorithms for both clinical scenarios. This complexity makes it beyond the scope of this chapter to make any detailed suggestions about workups for particular clinical presentations.

Evaluating a Lung Nodule

Lung nodules may be found incidentally on a chest X-ray or through a screening protocol using a CT scan. Incidental lung nodules should be compared with any prior imaging tests. An indeterminate nodule that can be shown to have been stable for at least 2 years requires no further diagnostic evaluation. Nodules found by chest X-ray that cannot be shown to be stable for 2 years should have a diagnostic, thin-section CT of the chest performed. Further evaluation is determined by the pretest probability of malignancy, the size of the nodule (greater than 8 mm or smaller), and nodule characteristics. Further diagnostic steps may include serial CT studies over 2 years, functional imaging with positron emission tomography (PET), bronchoscopy with biopsy, CT-guided needle biopsy, or surgical wedge resection. Based on the NELSON Trial, measuring nodule volume doubling time improves sensitivity and specificity for nodule characterization [22]. The choice of which technique to use should involve a team approach involving input from radiologists, pulmonologists, thoracic surgeons, and the patient's preferences. The family physician can play a crucial role explaining the risks and benefits of the various options to the patient and helping to make sure the final decision reflects the patient's values.

Staging Non-small Cell Lung Cancer

The diagnostic workup for a patient with a suspected lung cancer is based on the size and location of the

Telegram: @medical_k

www.konkur.in

suspected tumor, evidence for mediastinal or distant metastatic disease, the efficiency of the proposed workup, the invasiveness and risks of any procedures, the technologies and expertise locally available, and the patient's comorbidities and preferences. Diagnostic technologies are in a period of rapid evolution. It is reasonable to consult a team representing interventional radiology, thoracic surgery, pulmonology, and oncology. Accessing websites from groups such as the National Comprehensive Cancer Network or the American College of Chest Physicians can provide family physicians with current diagnostic guidelines. The family physician should conduct a thorough history and physical examination, including performance status and noting any weight loss. Routine studies should include the following: a CBC with platelets, a comprehensive metabolic profile, a CT scan of the chest and upper abdomen (including the adrenal glands), and a pulmonary function testing. Counseling on smoking cessation should be performed for current smokers. Discuss with the patient and participating consultants a plan for integrating palliative care into the treatment plan. When there is a high clinical suspicion for advanced disease, PET imaging allows for the choice of a diagnostic biopsy site to confirm the highest stage to be assigned to the cancer.

Staging Small Cell Lung Cancer

The diagnostic evaluation for suspected or known small cell lung cancer follows the same outline as for non-small cell lung cancer discussed above. The aim is to categorize the disease as in either a limited or extensive stage. In addition to the general workup reviewed above, a brain MRI is obtained. For equivocal bone lesions on PET imaging, bone imaging with MRI/radiographs as well as bone marrow aspiration/biopsy may be needed [23].

Treatment

Algorithms for treating lung cancer are now evolving rapidly after years of very modest progress. This has come about through an increased understanding of cancer genomics. Tumors harboring specific acquired genetic alterations are being treated with targeted inhibitors of altered enzymes that are driving cancer growth. Monoclonal antibodies targeted at altered epidermal growth factor receptor (EGFR), anaplastic lymphoma kinase (ALK), and receptor tyrosine kinase (ROS1) are producing exciting clinical response rates [24–26]. The list of targeted mutations is growing rapidly [27]. An era of personalized treatment, based on whole tumor genome sequencing, is imminent. The family physician is in the position, working collaboratively with the consulting oncologist, to educate patients about these treatment options and to counsel them about the option of participating in an experimental treatment protocol. In addition, palliative care needs should be addressed throughout the treatment process.

Non-small Cell Carcinoma

Treatment algorithms are driven by stage, pathology, and mutation testing of the tumor. It is now possible to identify genetic mutations in lung cancer cells through circulating tumor DNA (ctDNA). This technology is beginning to replace invasive biopsies in some centers. This genetic focus on the tumor cell is shifting the treatment focus from cytotoxic chemotherapy to personalized choices of targeted monoclonal antibody based therapies [27]. Treatment decisions need to be worked out consensually between the patient and the treatment team of medical oncologists, radiation oncologists, and thoracic surgeons [28]. The family physician can help to facilitate these decisions and advocate for the patient's values and preferences.

Small Cell Carcinoma

The performance status of the patient with limited stage disease drives treatment decisions ranging from concurrent chemotherapy and radiation therapy for high-functioning patients to hospice care for patients with extensive

Telegram: @medical_k

www.konkur.in

comorbidities. Patients with extensive disease are treated with chemotherapy. Whole brain radiation therapy is used for patients with brain metastases. Palliative external beam radiation therapy can be used for bone metastases, superior vena cava syndrome, lobar obstruction, or spinal cord compression.

Posttreatment Follow-Up

With the earlier detection of lung cancers and more effective treatments, the family physician will be involved with a growing number of patients who have undergone therapy with curative intent who will need surveillance for recurrent disease. Coordinate this care with the treating oncologist. A history and physical examination, along with CT examinations of the lungs, should be done every 4–6 months for the first 2 years and then yearly thereafter. Encourage patients to remain current with influenza and pneumococcal vaccinations [29].

Palliative Care

The family physician can play a key role in ensuring as high a quality of life as possible for patients as they move through the continuum from diagnosis to treatment with intent to cure and finally to end-of-life care. The family physician can educate patients about creating a living will and a durable power of attorney to establish their care preferences. They can explore the patients' interest in the use of complementary and integrative therapies alongside standard cancer therapies. They should question patients about common symptoms such as pain, anorexia, constipation, breathlessness, fatigue, depression, and insomnia and provide care to ameliorate these as much as possible [30–32].

There are many respiratory disorders that will commonly be encountered by family physicians that are not addressed in other chapters of this text. This chapter briefly discusses the etiology, epidemiology, presentation, diagnostic criteria, and management of several selected disorders: pulmonary hypertension, pneumothorax, pleural effusion, interstitial lung disease, lung cancer, pulmonary sarcoidosis, and vaping-induced pulmonary injury.

Pulmonary Hypertension

The term pulmonary hypertension (PH) is used to describe a diverse group of disorders causing increased pulmonary arterial pressures; specifically, the mean resting pulmonary arterial pressure is greater than or equal to 25 mmHg. Symptoms may include fatigue and shortness of breath, although many patients are asymptomatic until later in the disease course [1]. The true prevalence of pulmonary hypertension is not clear with estimates ranging from 5 to 52 cases per million people [2]. Pulmonary hypertension can be broadly divided into five groups based on presentation, pathophysiology, and potential treatments [3]. The five groups can then be further subdivided based on the exact etiology of the patient's symptoms. Group 1, or pulmonary arterial hypertension, is associated with drug toxicity, connective tissue disorders, and congenital disease etiologies. Group 2 is due to left heart disease. Group 3 is due to lung disease or hypoxia. Group 4 is due to chronic thromboembolic disease or other pulmonary obstructions. Group 5 is due to unclear or multifactorial mechanisms [Table 1].

Diagnosis

The diagnosis of pulmonary hypertension is difficult as the symptoms tend to be vague and non-specific. Common presenting symptoms include fatigue, dyspnea on exertion, cough, and syncope [4]. Comorbid conditions such as COPD, obstructive sleep apnea, heart failure, and history of chronic thromboembolic disease should raise the index of suspicion, especially if symptoms were previously well controlled and have now worsened. Physical exam findings cannot be used to rule out pulmonary hypertension; however, elevated jugular venous pressure, peripheral edema, and parasternal heave may suggest severe disease [5].

Lab evaluation is not indicated as no specific findings exist. Ancillary testing with electrocardiogram (ECG) and chest X-ray (CXR) may be performed. CXR may reveal right-sided heart enlargement and/or dilation of the pulmonary arteries. ECG may reveal right heart strain, right axis deviation, and right atrial enlargement. Of note, a normal CXR or ECG does not exclude pulmonary hypertension. Pulmonary function testing may aid in the diagnosis of pulmonary hypertension by ruling in underlying conditions including COPD or pulmonary fibrosis. Patients may frequently have decreased diffusion capacity [3].

The most important non-invasive test in diagnosis of pulmonary hypertension is transthoracic echocardiography (TTE). TTE will assess peak tricuspid regurgitation in order to estimate pulmonary artery pressure and assign patients to low-, intermediate-, and high-risk groups. Right heart catheterization remains the gold standard to confirm the diagnosis of pulmonary hypertension [3].

Table 1 Adapted from ECS/ERS guidelines comprehensive clinical classification of pulmonary hypertension [3]

Group 1: pulmonary arterial hypertension	Group 2: left heart disease	Group 3: chronic Lung Disease	Group 4: pulmonary artery obstruction	Group 5: multifactorial/ unclear
Idiopathic Hereditary Schistosomiasis infection Drugs: appetite suppressants, rapeseed oil, benfluorex Connective tissue disorders: systemic sclerosis, Raynaud's disease, SLE, mixed connective tissue disease Congenital heart disease	HFpEF HFrEF Valvular Disease Restrictive cardiomyopathy Constrictive pericarditis Pulmonary vein stenosis	Obstructive sleep apnea COPD Interstitial lung disease Restrictive lung disease Pneumoconiosis	Chronic thromboembolic Malignancy Benign tumors Parasites	Hemolytic anemia Sickle cell disease Thalassemias Gaucher's disease Glycogen storage diseases Sarcoidosis Chronic kidney disease

Based on current recommendations, several populations are at increased risk of developing pulmonary hypertension and therefore should be screened. Individuals with HIV should be screened if they possess an additional risk factor: female sex, hepatitis C positive status, or African American. Additionally, patients with hereditary hemorrhagic telangiectasias, congenital heart disease, and familial pulmonary arterial hypertension be screened as well [4].

Management

The most important aspect of primary care management of PH is early recognition and referral to pulmonary hypertension specialists for definitive management. Family physicians play an important part in the treatment of pulmonary hypertension and should help facilitate treatment once the underlying cause has been identified. There are also disease-specific considerations and monitoring guidance that primary care physicians should keep in mind for patients with pulmonary hypertension. All patients with pulmonary hypertension should receive age- and comorbidity-appropriate vaccinations.

Most published data on treatment of PH is specific to group 1 patients. Every 3–6 months these patients should be seen and undergo ECG to monitor for arrhythmias, dyspnea monitoring, and labs including CBC, BMP, and pro-BNP [3]. Every 6–12 months additional lab evaluation including TSH, troponin, iron studies, and blood gas analysis should be considered. Iron deficiency frequently exists in these patients and should be treated accordingly. Repeat echocardiogram and right heart catheterization occur every 6–12 months for disease monitoring [3]. Group 1 patients should be encouraged to exercise within the limitations of their symptoms.

Given the increased risk of serious obstetric complications, pregnancy and birth control should be discussed in all female patients with PH. Contraceptive management strategies are controversial as some treatment modalities for PH may interfere with estrogen, and vasovagal reactions during IUD placement may be poorly tolerated [3]. Appropriate preventative health strategies such as vaccinations against influenza and pneumococcal pneumonia should be emphasized.

The goal for patients with group 2 and 3 is optimal management of their underlying medical condition. Patients in group 4 generally benefit from lifelong anticoagulation and oxygen when needed for hypoxemia. There is limited data regarding treatment of group 5 disease. Encouraging social support and end of life planning are important tasks for family physicians in all patients with PH regardless of which group they belong to [3].

Pneumothorax

Pneumothorax is defined as the presence of air in the pleural space. It takes one of the following abnormal circumstances to allow air accumulation

Telegram: @medical_k

www.konkur.in

in the pleural space: communication between the alveolar spaces and pleura, communication between the atmosphere and pleural space, or gas-producing organisms in the pleural space. From a clinical standpoint, pneumothorax is classified as either spontaneous or nonspontaneous (iatrogenic or traumatic). Spontaneous pneumothorax is further subdivided as primary (without clinically apparent underlying pulmonary disease) and secondary (underlying pulmonary disease) [6].

Primary Spontaneous Pneumothorax

Primary spontaneous pneumothorax (PSP) has long thought to occur due to spontaneous rupture of a subpleural bleb (small thin-walled air pockets); however, recent evidence points to diffuse emphysema-like changes of the lung parenchyma as the more likely cause [7]. The classic patient with PSP is a tall, thin male. The most important risk factor is tobacco smoking, though cannabis smoking also has demonstrated strong association with bullous parenchymal disease [8]. PSP doesn't usually have a known trigger but may be preceded by precipitating factors including atmospheric pressure changes, exposure to loud music, and pollution. These precipitating factors explain why cases of PSP tend to exhibit a clustering effect. PSP has an incidence of 7.4–18 cases/100,000 in males and 1.2–6 cases/100,000 in females per year [6].

Diagnosis

Typically, patients present with an abrupt onset of ipsilateral chest pain with or without dyspnea. Pain may be localized over the site of pneumothorax or radiate to the ipsilateral shoulder. Symptoms can often be minimal and even totally absent (in stark contrast to the presentation of secondary spontaneous pneumothorax). Symptoms also tend to improve following presentation; worsening of symptoms is rare and suggests the development of complications such as hemopneumothorax [8].

Physical exam can be completely normal in small pneumothoraces [6]. Findings that may indicate pneumothorax include decreased or absent breath sounds, percussive hyperresonance, and reduced ipsilateral chest expansion. Significant hemodynamic compromise (tachycardia, tachypnea, hypoxia, etc.) is usually absent. Radiographic imaging confirms the diagnosis and allows estimation of pneumothorax size, with an upright posteroanterior chest radiograph being the modality of choice. Findings on X-ray include the displacement of the pleural line and absence of lung markings between the pleural edge and chest wall. Inspiratory images alone are sufficient for diagnosis. Occasionally the pneumothorax cannot be detected on simple radiographs, and a CT is required. Ultrasound can also be a very sensitive modality but is not routinely used to evaluate PSP [6, 8].

Management

Therapeutic options for PSP depend on the size of the pneumothorax and the severity of the patient's symptoms. Treatment focuses on evacuation of air, if necessary, and prevention of recurrence. As tension and hemodynamic compromise is rare in PSP, conservative initial management is an option. Assuming mild symptomatology and small size of the pneumothorax (less than 20% or less than 3 cm between the lung and chest wall), outpatient management with observation and close radiographic follow-up is a reasonable option [6]. If air evacuation is necessary, needle aspiration and chest drain insertion are both options; however, no consensus guidelines exist on recommended treatment. Recent evidence suggests that needle aspiration is effective for the initial management of PSP [7]. A large pneumothorax or significant symptoms increase the likelihood that simple aspiration will not be sufficient, thus requiring chest tube placement for definitive management [8].

Recurrence rates for PSP are approximately 33% irrespective of treatment modality. Recurrence prevention with pleurodesis

Telegram: @medical_k

www.konkur.in

procedure should be offered after a single episode of recurrence to those who are at professional risk (aviation personnel, divers) or if chest tube therapy fails to result in lung expansion [6, 8].

Secondary Spontaneous Pneumothorax

Secondary spontaneous pneumothorax (SSP) results as a complication of underlying lung disease. The most frequent associated underlying disorders are COPD with emphysema, cystic fibrosis, tuberculosis, lung cancer, and lung infections. Because these conditions already represent some level of lung compromise, SSP often presents as a more life-threatening event requiring intervention as opposed to PSP. Incidence is similar to that of PSP with a peak incidence between 60 and 65 years of age [6].

Diagnosis

As opposed to PSP, dyspnea is usually the most prominent clinical feature in SSP; other symptoms including chest pain, cyanosis, hypoxemia, hypercapnia, and acute respiratory failure can also be present and are generally much more severe. As with PSP, imaging with CXR and/or CT scan will confirm the diagnosis. Recurrence is much more common than in PSP; rates up to 80% are seen in conditions such as cystic fibrosis [6].

Management

Management of SSP targets air evacuation, symptomatic control, and prevention of recurrence. As the majority of patients with SSP have significantly decreased pulmonary reserve, most will require pleural drainage. No consensus exists on initial management, but most guidelines recommend immediate chest tube insertion. Given the increase risk of recurrence, prevention by pleurodesis procedure should be performed after the initial event [6].

Tension Pneumothorax

A tension pneumothorax constitutes a life-threatening emergency. It develops as a result of air moving through a pleural defect that acts as a one-way valve, opening during inspiration and closing during expiration, resulting in progressive pneumothorax volumes and further lung collapse. Eventually, shifting of the trachea and mediastinum away from the pneumothorax occurs leading possible cardiopulmonary compromise. Tension pneumothoraxes most often occur secondary to major chest wall trauma. Classically, patients with tension pneumothorax develop jugular venous distension and contralateral tracheal deviation; however, these are very late signs and much less commonly observed in real studies [9]. Acute respiratory distress is often the initial presentation, and cardiovascular collapse can rapidly occur without prompt intervention. Immediate needle decompression by insertion of a large bore needle into the pleural cavity at the midline of the second intercostal space releases the trapped air and results in improved cardiopulmonary status. Following needle decompression, placement of a chest tube and treatment of chest wall injuries are required [6, 9].

Family and Community Issues

Given the strong association between smoking and PSP in addition to its link to underlying respiratory disorders, smoking cessation interventions provide an excellent opportunity for family physicians to intervene at a population level to decrease risk factors for initial PSP, prevent recurrent pneumothoraces, and minimize the risk for underlying respiratory disorders that cause SSP.

Pleural Effusion

Pleural effusions are an accumulation of fluid in the pleural space as a result of disparity in the formation and resorption of pleural fluid. The presence and amount of pleural fluid is typically regulated by capillary oncotic pressure as well as

Telegram: @medical_k

www.konkur.in

capillary and interstitial hydrostatic pressure. Pleural effusions are very common in clinical practice, with an estimated prevalence of 400 cases/100,000. A plethora of disease processes can cause pleural effusions with the most common being congestive heart failure, hepatic cirrhosis, pulmonary infections, and malignancy [10].

Diagnosis

Patients with pleural effusions can present with a variety of symptoms including dyspnea, pleuritic chest pain, cough, and referred pain to the shoulder or abdomen. Some patients are asymptomatic. Due to the breadth of the differential diagnosis and the presenting complaints, a systematic evaluation must be undertaken to diagnose the underlying cause. Pulmonary exam may reveal decreased breath sounds, percussion dullness, or even a friction rub. Given the prevalence of congestive heart failure as a cause of pleural effusion, a careful cardiac exam can provide valuable insight. A chest radiograph is often the initial diagnostic study, while more sensitive CT is not usually necessary to diagnose a pulmonary effusion [11].

While history and physical examination can provide clues to the causes of pleural effusions, determination of the exact etiology can be very difficult. Thoracentesis and pleural fluid analysis (PFA) are the next steps in the evaluation process; PFA can lead to a definitive or presumptive diagnosis in approximately 95% of cases [10].

The initial step of PFA is determining if the effusion is transudative or exudative. The rationale for differentiating is that a transudative effusion can be effectively treated by addressing the underlying cause such as heart failure or hepatic cirrhosis. If the effusion is exudative, further investigation is required to identify the local pathology causing the effusion. Differentiating transudative from exudative effusions is best achieved by using Light's criteria. Table 2 outlines how pleural and serum protein and LDH are utilized in Light's criteria.

Gross appearance, cell count, and pH studies of the pleural fluid can also be of use. Limitations with Light's criteria do exist. Almost all exudative effusions will be correctly identified; however, in approximately 25% of cases transudates will be misclassified as exudates, usually in the case of diuretic usage in CHF patients. The majority of these errors occur in patients where exudative criteria are barely met and usually in only one of the three elements of Light's criteria [11]. If clinical suspicion exists that the effusion has been misclassified, additional calculations using serum-pleural fluid albumin gradient or serum-pleural fluid protein gradient can be helpful [12].

Transudative Effusions

Transudative effusions occur secondary to processes that increase the hydrostatic pressure or decrease the oncotic pressure in pulmonary capillaries. Additionally, an increase in negative pressure in the pleural space can also lead to these types of effusions. Congestive heart failure and cirrhosis are the two most common causes of transudative effusions [10]. Pleural effusions associated with CHF tend to be bilateral. In contrast, around 80% of effusions from cirrhosis with ascites are right sided. Less common causes of transudative effusions are nephrotic syndrome, urinothorax, peritoneal dialysis, and trapped lung [10].

Exudative Effusions

In contrast to transudates, exudates are caused by local processes that lead to increased capillary permeability causing leakage of serum contents. Malignancy and infections of the pleural space or lung parenchyma commonly produce exudative effusion. A plethora of less common etiologies also cause exudative effusion; these include chylothorax, pulmonary embolism, superior vena cava syndrome, aortic dissection, rheumatoid arthritis, systemic lupus erythematous, liver abscesses, and hepatitis [10].
