“Thanks to all family physicians and others who provide primary care to their patients; without you, there would be no reason to publish this book.”

Telegram: @medical_k

www.konkur.in

Preface to the Eighth Edition

Family Medicine: Principles and Practice, eighth edition, is designed to provide point of care and reference information for family physicians, mid-level providers, residents, medical and osteopathic students, and all others who provide primary care for patients. The supervising editors from the seventh edition also supervised the production of this volume. The fact that only a few chapters were removed and a few chapters added is yet another tribute to Dr. Robert Taylor's book design as he published the first of this series and continues to serve on the editorial team and provide advice and counsel. Given that this project took place during the COVID-19 pandemic, the addition of a chapter covering pandemics is very timely.

The editors are very grateful to the staff and administrators at Springer and chapter authors who not only provided very good chapter manuscripts but also cared for themselves and their families during this pandemic. My personal thanks to Dr. Audrey Paulman and Dr. Laeth Nasir for their great work on the editorial team, and of course, thank you to all our readers/users of this book, as I said in the preface of the previous edition: providing good information which helps our readers improve the care of their patients will be our highest marker of success.

Stay well.
For the editors,

Preface to the First Edition

As we celebrate the publication of the 8th edition of Taylor's Family Medicine: Principles and Practice, we are also celebrating the 45th anniversary of the publication of the landmark textbook Taylor's Family Medicine: Principles and Practice, 1st edition.

This book is about people: the patient, the family, and the family physician. It presents health problems of the patient and health care by the physician in the context of mankind's most enduring societal unit – the family.

The objectives in preparation of this book have been:

1. To compile in a single textbook the fundamental principles of family medicine and the methods to implement these principles on a global basis.
2. To describe the approach of the family physician to clinical problems.
3. To help identify the clinical content of family medicine.
4. To provide a data base which can serve as a day-by-day reference source for the resident physician and clinician.
5. To explore the history and philosophy of the family practice movement.

These objectives were pursued by seeking the advice and participation of family medicine educators and practitioners around the world; preparing a book format intended to present data in a logical, cohesive manner; selecting authors based on their interests and contributions in family medicine; considering the priorities family physicians ascribe to achieving competence in various clinical areas; and including chapters telling the evolution of the modern family physician and his focus on the patient in relation to the family.

A new textbook should differ significantly from other literature in the field. The following 94 chapters represent new material prepared specifically for this first edition, including many facts and theories never before in print. There are several chapters giving personal viewpoints on topics pertinent to the specialty. The format employs units of sequential chapters that allow full elucidation of concepts. The broad scope of family medicine is covered, including sections on family medicine education, behavior and counseling, and the full spectrum of clinical medicine. The development of clinical chapters has included the Competence Priority Classification of Behavior, Concepts, and Skills in Family Medicine, a unifying taxonomy that is intended to be academically instructive and clinically relevant.

The editor expresses appreciation to the 128 contributing authors and to the four associate editors: John L. Buckingham, E. P. Donatelle, William E. Jacott, and Melville G. Rosen. Also gratefully acknowledged is the cooperation of the American Academy of Family Physicians, The American Board of Family Practice, the College of Family Physicians of Canada, and the Society of Teachers of Family Medicine. My family – Anita, Diana, and Sharon – shared in the preparation of this book, as did literally hundreds of other persons too numerous to list individually, and to whom the editors, authors, and readers are indebted.

Acknowledgments

We dedicate this book to all the workers who labored to keep us healthy, fed, and safe during the COVID-19 pandemic. There will never be adequate recognition or rewards for these incredible men and women; nevertheless, we'd like to add our thanks.

We have many more people to thank: Dr. Robert Taylor has continued to inspire us in his role as founder of this series of reference books; his advice and counsel have been invaluable.

Saskia Ellis, our production manager, provided a steady, consistent guiding hand throughout the production process. When it seemed that we had reached insurmountable roadblocks, Saskia was there to let us know how much progress we had made and how we weren't THAT far behind schedule. We appreciate your work, Saskia!

Sylvia Blago has also been inspirational for us and has helped us keep our eye on the prize. Having worked with Sylvia on previous projects, we have had great production experiences and she did not disappoint during this project. Thank you, Sylvia.

Our chapter authors came through with great material, while also caring for their patients and keeping themselves and their families safe from the virus. We are in your debt.

Personal thanks to Dr. Audrey Paulman and Dr. Laeth Nasir, volume editors, for their great efforts to recruit chapter authors and overcome any and all problems in order to bring this book to publication. We look forward to future editions of this reference book from Dr. Laeth Nasir and his team. Future editions of this book will be outstanding.

For the editors,
Paul M. Paulman
Editor

In its early years, the specialty of family medicine had originated within the lifetimes of its practitioners. As family medicine celebrates its 50th anniversary, the founding generation has retired, and today's family physicians (FPs) are providing care in a very different world. Few are in solo practice. Many are employed in integrated health systems. and most use electronic information systems to document care and communicate with patients. Since its beginning in 1969, family medicine has become one of medicine's largest and most successful specialties. And yet many of its current members are unfamiliar with the inspiring story of how the specialty began. For this reason, this book begins with an overview of the specialty's origin, evolution, and current status. The goal of this chapter is not simply to preserve a record of the past but also to explain how family medicine came to be the way it is, to delineate lessons learned by its first two generations of leaders, and to provide a context for building the discipline's future.

A Short History of the Specialty

Family medicine in the United States evolved from general practice, which was the dominant force in health care until the mid-twentieth century. The story of how this happened can be told in at least three ways, and each of these creation stories offers insight into the specialty's traditions and values.

Family Medicine as a Social Movement

Family practice arose as a specialty during the 1960s – the time of the Vietnam War, the civil rights movement, and widespread social unrest – a time not unlike today when the wisdom of experts was being challenged. Rapid population growth and accelerating medical specialization following World War II precipitated a decline in access to primary health care at the community level in the United States. Although a handful of general practice residencies were established in the 1950s, generalist training was inadequate in both quality and capacity. In response, the American public and farsighted health policy planners decried the fragmentation of American medicine and called for the creation of a physician who specialized in primary health care. Three influential reports, all published in 1966, made the case for what eventually became family medicine. These reports have historically been referred to by the names of their chairmen: the Folsom report, the Millis report, and the Willard report.

The Folsom report was a report of a national commission on community health services and was sponsored by the American Public Health Association and the National Health Council [1]. This commission's 4-year investigation produced 14 recommendations. The most pertinent to the evolving specialty of family practice was a task force report entitled *The Changing Role of the Personal Physician*, which concluded that all Americans should have "personal physicians" to ensure the integration and continuity of their medical services. The report emphasized the importance of preventive medicine, the use of community resources, and the importance of caring for the patient in a continuity context.

The second report was from the Citizens' Commission on Graduate Medical Education, which was sponsored by the American Medical Association [2]. This commission focused on graduate medical education. Specifically, it suggested that "primary physicians" be trained to replace the dwindling number of general practitioners. The Millis report specifically addressed the importance of comprehensive clinical skills, continuity of care,

Telegram: @medical_k

www.konkur.in

coordination of services, and preventive services to be provided by these new primary physicians.

The third report was from the Committee on Education for Family Practice, which was sponsored by the Council on Medical Education of the American Medical Association (AMA) and was charged to review AMA policy regarding the future of general practice [3]. The Willard report specifically called for a new kind of specialist in family practice and even specified the outline of a training program for "family physicians." It also recommended the establishment of a certifying board in family practice. Dr. Willard was the dean of medicine at the University of Kentucky. At that time, the chairman of the department of medicine at that medical school was Edmund Pellegrino. Because of his experience with general practice residents in the 1950s, Dr. Pellegrino chose to appoint two general practitioners to the full-time faculty in the department of medicine [4]. One of these individuals – Nicholas J. Pisacano – was an idealistic and scholarly general practitioner who was already one of the most outspoken advocates for certification in the field. When the American Board of Family Practice ultimately achieved recognition as a certified specialty board, it was Dr. Pisacano who became its founding executive director.

With the support of the American Academy of General Practice (AAGP) and US general practitioners, family practice became the 20th American medical specialty in 1969. The story of these three influential reports provides the first of family medicine's creation stories – a story focused on needs identified by public policy-makers during a time of social unrest and reform.

Family Medicine as a Defense of General Practice

Family medicine also arose as a political and professional defense of the general practitioner. Leaders in the American Academy of General Practice (AAGP) were alarmed as early as the 1940s by the declining number of medical students choosing to enter general practice [5]. Declining numbers threatened the ability of general practitioners to obtain and retain hospital privileges and undermined their prestige and political influence within the profession. While the first creation story is fundamentally a story of social activism, there is also a side of the story that was about preserving a way of life for those practicing in community.

Four early decisions helped shape the future of the new specialty, and all were about enhancing the quality and prestige of the field. A *specialty certifying board* – the American Board of Family Practice – was created in 1969. *Three-year residency training programs* were established in contrast to the prior norm of a single year of internship for general practitioners. *Mandatory recertification* was pioneered by the ABFP, and all US board-certified family physicians still must undergo periodic recertification. Most other specialties have since established similar requirements. Finally, *mandatory continuing medical education* was required by both the American Academy of Family Physicians (AAFP) and the American Board of Family Practice.

The new specialty began with 15 residency training programs, most converted from the few existing general practice programs. Federal grant programs supported new departments of family medicine in medical schools, and clinical departments of family practice were formed in community hospitals across America. From 1969 until today, the family medicine movement has continued to gain momentum, with solid gains in student recruitment, more residents in training, increased numbers of board-certified FPs in practice, and family physicians in leadership positions in clinical medicine and academia.

Family Medicine as a Reform Movement Within Medicine

The birth of family practice can also be viewed as an intellectual and philosophical reform of medicine as a profession. The new specialty faced extensive opposition from both organized medicine and from the academic world of the medical schools. This criticism was usually based on the argument that there was no unique

Telegram: @medical_k

www.konkur.in

field of knowledge constituting family practice. Instead, the knowledge, skills, and attitudes of a family physician were felt to be derived from the fields of surgery, obstetrics and gynecology, pediatrics, and so on. The early residencies were largely dependent on educational rotations with each of these specialties, and this no doubt gave credence to this claim. Since medical school departments generally reflect an academic discipline instead of a practice specialty, the perceived lack of an intellectual foundation to the field severely hampered the establishment of departments of family medicine in medical schools. Departments were established most quickly in publicly funded institutions, where political pressure from state legislatures was brought to bear to effect these changes. A few private universities continue to hold out to this day.

But there was a much more fundamental reason for the opposition. After the Flexner report of 1910, American medicine had evolved into a biologic science focused on better understanding the mechanisms by which diseases arise and are treated. On the one hand, this model can be credited with astonishing advances in medical science and resulting improvements in the length and quality of life over the twentieth century. But this model was also directly responsible for a loss of patient-centeredness in favor of a disease-oriented approach to care [6]. From its very beginning, family medicine was a counterculture movement pushing back on these trends – and counterculture movements threaten the status quo. A series of essays entitled *The Intellectual Basis of Family Practice* was published by G. Gayle Stephens during family medicine's first decade [7]. Stephens' work became a rallying call for many of the first generation of family medicine residents. Family medicine has certainly been a social movement about making care available to the American people, and its founding generation of physicians was certainly interested in preserving and improving general practice. But many others entered the field to change American medicine intellectually by incorporating social, behavioral, and population scientific methods into a world dominated by biology and reductionism.

The Evolution of Family Medicine

At its birth, the specialty's name was *family practice* in large measure as a tribute to its roots in general practice. The term *family medicine* was used to refer to the academic discipline as something separate from the clinical specialty. Family physicians in the 1970s still largely practiced in solo practices and small groups with one another. Most were self-employed small business owners, and the care was delivered in one-on-one relationships between the doctor and patient. By the 1980s, a growing number of family physicians were in group practices; solo practice was becoming rare as the administrative complexities of medicine made economies of scale and shared administrative resources more efficient. The 1980s also brought increasing scrutiny to the high cost of medical care and insurance companies evolved from simply paying claims to mounting efforts to manage care. This inevitably resulted in attempts to limit specialty referrals, emergency department visits, and hospitalizations and the responsibility to manage cost often fell to those practicing primary care. The 1990s witnessed a substantial increase in medical student interest in family medicine and, for a while, it seemed that the imbalance between primary and specialty care was being corrected. Family physicians even began to play important roles in the management of health plans and medical groups.

Unfortunately, these gains were short lived. By the early 2000s, it became clear that the administrative complexity of the managed care era had failed to adequately control health-care inflation. The insurance system moved away from structures based on primary care utilization management and began passing increasing costs to patients as out-of-pocket deductibles and copayments. Primary care again fell in prestige and student interest declined. In 2002, the specialty of family medicine conducted a strategic planning process call the *Future of Family Medicine* project (FFM) [8]. The outcome of this process was documented in six reports, all published in the discipline's new research journal the *Annals of Family Medicine* in 2004. One recommendation from this process was that the

Telegram: @medical_k

www.konkur.in

specialty name should change from family practice to family medicine and organizations like the American Board of Family Medicine changed their names accordingly. The most important recommendations of the FFM all related to a proposed new model of clinical care that eventually came to be known as the patient-centered medical home (PCMH) [9]. At its heart, the PCMH called for an evolution from the one-on-one doctor patient relationship to a notion of team-based care in which family medicine practices were asked to create and empower teams of providers to share responsibility for their patients. Systems were devised to certify practices as PCMHs and, by the end of the decade, electronic information and communication systems became requirements for PCMH designation. Although some of the initial cost of these electronic health records was supported by the federal government, their ongoing cost led to practice expenses that could not easily be borne by the revenues generated from primary care practice alone. This further catalyzed consolidation of practices into larger and larger groups and, in many cases, to practice networks owned and supported by hospital-based systems.

Following the great recession of 2008, cost containment efforts had again failed to limit continuing increases in health-care spending and large delivery systems managed to increase revenues even as the overall economy lagged. But as cost pressure increased on these systems, the need for larger and more effective primary care systems became apparent. While large delivery systems supported growth in primary care, they generally opposed increasing reimbursement for these services, preferring instead to move hospital and specialty profits into primary care investments. Under such conditions, more and more family physicians became employees of large health systems and medicine evolved from loosely linked small businesses to influential and sometimes monopolistic corporate entities.

As the decade of the 2010s ends, family medicine again stands at crossroads. On the one hand, its values remain rooted in the one-on-one doctor-patient relationship with personal accountability resting on the physician. But the discipline has also embraced the need for improvements in population outcomes as measured by electronic health data, with accountability lying with practice organizations. In 2014, another specialty-wide strategic planning effort was undertaken. This project, called *Family Medicine for America's Health*, eventually recommended an expansion of the PCMH model to fully integrate mental health and population health into the primary care system [10]. Today, practices throughout the country are struggling to make these recommendations a reality. But this enhanced PCMH model adds even more costs to the primary care system, and it remains to be seen if reimbursement reform will support such systems in the long term.

Throughout its history, family medicine has struggled to attract a sufficient number of new family physicians even as more and more responsibility has fallen to the primary care system. By 2020, the number of medical schools and the number of graduating medical students have grown substantially, but family medicine still struggles with the inescapable reality that there are not enough family physicians to care for the American people. So a gap widens between family medicine ideals and the pressing realities of family physicians' day to day work.

In 1987 Pellegrino [11] commented: "The birth of Family Practice two decades ago, and its development as a genuine specialty within the bodies of both medical practice and academia is surely one of the most remarkable stories in contemporary medical history." Now 50 years old, the specialty remains one of the shining accomplishments of twentieth-century medicine. Family medicine was born in an era of social change to protect and professionalize general practice and to reform American medicine. The need for the discipline has never been more apparent than it is today.

Family Medicine in the United States in 2020

In 2018, there were 985,000 licensed physicians in the United States [12] of which 139,000 were professionally active FPs [13]. There are 131,000 members of the AAFP [14] and 92,000

Telegram: @medical_k

www.konkur.in

diplomates certified by the ABFM [15]. The specialty had 679 accredited residency programs with 13,924 residents in training during the 2019–2020 academic years making it the largest specialty in terms of programs and the second largest in terms of resident enrollment [16]. Family medicine is well-established in nearly all of the nation's medical schools, and there are required courses and established research programs throughout the country. In 2015, 6738 faculty members in 134 academic departments of family medicine published 3002 peer-reviewed scientific papers and federal research funding supported over half of this work [17].

The specialty has been undeniably successful as measured by these accomplishments. And yet there are concerning trends. Most of what is known about the clinical work of family physicians is based on studies of ABFM diplomates, admittedly a subset of all family physicians. But evidence from the ABFM suggests steep declines in the number of family physicians delivering maternity care, caring for hospitalized patients, and caring for children, and these changes have begun to impact the availability of basic health services, particularly in rural and under-served communities that are most likely to be served by family physicians [18]. Burnout and career dissatisfaction are major problems among physicians overall, and studies estimate that over half of the nation's family physicians describe themselves as burned out. Although there has been rapid growth in the number of residency programs, family medicine attracted only 12.6% of US allopathic and osteopathic medical school seniors in 2018 [19]. Even more concerning, striking racial and geographic disparities in health status have widened even though more Americans than ever have health insurance coverage. As proud as family physicians justifiably are, the true promise of family medicine remains unachieved in America.

Family Medicine and General Practice Around the World

The international group uniting family medicine and general practice is the World Organization of National Colleges, Academies, and Academic Associations of General Practitioners/Family Physicians (WONCA). More commonly known as the World Organization of Family Doctors, WONCA is comprised of 118 member organizations in 131 countries, with membership of about 500,000 family doctors worldwide [20]. WONCA advocates for family medicine internationally and hosts regional meetings in seven regions around the world. Some countries have retained the title general practitioner while others have adopted the name family physician, but around the world, the core principles of the discipline are pretty much the same. Much of WONCA's international work has referenced the Alma-Ata Declaration of 1978 which was adopted by the World Health Organization and defines the international importance of primary care. Alma-Ata stands as one of the most important statements of public health principle of the twentieth century, and this work has catalyzed the development of family medicine in most of the countries in the world with special emphasis on developing countries.

The nature of day-by-day practice in family medicine varies from country to country. In some areas, such as the United States and Canada, family physicians often have an active role in hospital care. In other settings, such as in the United Kingdom and Latin America, family medicine is chiefly office-based, often supplemented by home care. But family physician and general practitioners around the globe deliver care based on shared academic principles.

Academic Principles of Family Medicine

The official definition of family medicine is:

> Family medicine is the medical specialty which provides continuing, comprehensive health care for the individual and family. It is a specialty in breadth that integrates the biological, clinical and behavioral sciences. The scope of family medicine encompasses all ages, both sexes, each organ system and every disease entity. [21]

This definition focuses on family medicine as a specialty of medicine and not on family medicine

Telegram: @medical_k

www.konkur.in

as an academic discipline. From the specialty's early days, some authors have considered *family medicine* to be the name of the academic discipline on which the specialty is based and have discriminated between an academic discipline and a medical specialty. Now that the specialty name is also *family medicine*, the distinction might be a moot point. Nevertheless, the specialty's 50-year history has produced a body of scholarly work that is uncontestably unique and important, and this body of work represents an academically rigorous intellectual field. Although this chapter will not attempt to list them all (in fear of offending by omission), there are currently at least 20 English language family medicine journals worldwide as well as hundreds of books and thousands of scholarly publications in clinical and health policy journals [22]. So, while the earliest scholarship in the field was focused on describing what family physicians do, the field has now broadened to the study of how practice outcomes can be optimized. Although there continues to be considerable debate about the precise definition and content of family medicine as an area of study, family medicine as an academic field is best defined as *the study of how best to deliver efficient and affordable primary care to populations and communities* [23].

Primary care is a term derived from the public health literature and refers to first-contact health services delivered at the community level, in contrast to secondary care (care delivered by specialty consultants and in community hospitals) and tertiary care (care delivered in specialized academic settings). The most uniformly accepted definition of primary care was published after extensive study by the National Academy of Sciences Institute of Medicine in 1996:

> Primary care is the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community. [24]

Nearly all family physicians provide primary care, but historically they have also provided services such as maternity and hospital care that would be characterized as secondary care. Furthermore, while other physician groups (general internal medicine and general pediatrics) and other professionals (nurse practitioners and physician assistants) deliver primary care, the study of how primary care is optimized has largely become the domain of scholars in family medicine. Importantly, the term "scholars of family medicine" is not limited to family physicians. Departments of family medicine now contain faculty members with backgrounds in over a dozen fields including the social and behavioral sciences, health economics, public health, statistics, nursing, and communications in addition to medicine.

The scholarly development of family medicine is exemplified by the work of Barbara Starfield, a pediatrician and health services researcher who spent her career studying the core elements of primary care from a health policy perspective [25, 26]. Starfield first demonstrated that primary care is strongly associated with better health outcomes and lower health costs after examining data from nations around the world. These same associations were present when her team examined data comparing American states and local communities. Starfield then became interested in distilling primary care to its core elements as a way of measuring its effectiveness in improving population health outcomes. Based on this work as well as the work of many others, the academic principles central to primary care's positive impact on public health constitute family medicine's core academic principles. These are *access*, *continuity*, *comprehensiveness*, *care coordination*, and *contextual care* [23].

Access

Most of the care delivered by family physicians is first-contact care with patients who choose when and how to access that care as opposed to being referred by another clinician. Access to care encompasses the study of how patients make these choices. Family physicians need to understand how barriers to access limit the patient's ability to get the care he or she needs. Also important, however, is the study of why some patients overuse health care and how to manage and modify access. Understanding access to care includes

Telegram: @medical_k

www.konkur.in

office-based care but also addresses how patients use after-hours care, emergency care, the hospital, home care, and end-of-life care.

Continuity

Continuity of care involves the study of how the doctor-patient relationship develops, changes, and ultimately ends. There are at least four dimensions of continuity, including chronologic continuity, geographic continuity, interpersonal continuity, and continuity for families. Continuity can be measured, and its impact on patient satisfaction and health outcomes can be studied. Finally, continuity in the doctor-patient relationship can be adapted and applied to caring for patients within interdisciplinary teams and to caring for families as a group. A rich literature now exists establishing that continuous interpersonal relationships between patients and care teams are central to quality primary care, but these relationships are affected by changes in insurance coverage and by new forms of information and communication technology.

Comprehensiveness

Comprehensive care involves the study of the scope of practice and extent of services delivered by family physicians. This includes an examination of which clinical services are most essential to the health of the community being served. Comprehensive care includes skills in community-oriented primary care and the study of how the scope of services offered by a family physician changes over time. How are family physicians able to care for such a broad range of problems affecting patients of all ages and both genders in the office, the hospital, and the community environment? Which health problems are common, and how does the family physician care for these common problems? Which clinical procedures are performed by family physicians, and how does a family physician determine when to perform a procedure or refer the patient to another specialist?

Care Coordination

Care coordination involves the study of how family physicians organize and manage the care they deliver to patients and communities. This includes the coordination of preventive services, including disease screening and immunizations. It includes a study of how family physicians organize their medical offices and build working health-care teams to care for patients. Coordination of care includes the study of the specialty referral process, chronic illness management, and the organization of care for special patient populations, such as geriatrics.

Contextual Care

Contextual care is the study of how the health-care problems of each patient are understood in the context of the patient's life. Patients present to family physicians with undifferentiated health problems. Sometimes these are best understood in a biomedical context (acute infections, heart disease). In other cases, the psychological context is most applicable to the presenting problem (depression, anxiety). The developmental context might be most important for some patient problems (behavioral problems and disabilities in children), while the family context might be most important for others (family violence and caregiving for the elderly). In still other cases, community, occupational, and social contexts might be most important (racial health disparities and work-related illnesses). Contextual care is the process by which family physicians help patients to define the meaning of the medical problems and illnesses in their lives. This then allows the patient and physician to develop a collaborative plan that factors patient and family values into a strategy for managing problems involving each of these contexts.

Family physicians are bonded by shared beliefs based on these core principles even though there is substantial variability of how they apply from one community to the next. At the heart of each of these values is a close and enduring relationship between patients and those who care

Telegram: @medical_k

www.konkur.in

for them. Thus, r*elationship-based care* forms the philosophical foundation of the specialty, and understanding care relationships over time is the key to understanding family medicine. Ian McWhinney, considered the father of family medicine in Canada, wrote: "In general (family) practice, we form relationships with patients often before we know what illnesses the patient will have. The commitment, therefore, is to a person whatever may befall them" [27].

Current Challenges and Future Practice

Tomorrow's health care will be shaped by today's events. In selecting what family physicians believe to be the most significant influences on future practice, there is a long list that includes the current focus on evidence-based health care, the medical and societal impact of changing demographics, and some events that are occurring now. The following are the trends the authors believe most likely to influence family medicine in the decade to come.

The Unsustainable Cost of Health Care

Health care in America currently consumes nearly one fifth of the nation's economy with costs per capita that are more than double those of most other countries. Concerns about cost have led most countries to enact measures to restrict them, but the United States has depended largely on market forces to work. For the most part, this has mostly involved attempts to change how health insurance works rather than how the care itself is delivered. While most countries have built systems to make sure everyone has access to health care, universal access is still an unfulfilled promise in America. Without universal access, there will always be a temptation to reduce costs by eliminating people from coverage rather than making the care less expensive. In 2010, the United States enacted the Patient Protection and Affordable Care Act (ACA), the most far-reaching overhaul of America's coverage system since the initiation of Medicare and Medicaid in the 1960s. Its fundamental goal was universal coverage, but it remains controversial with widespread opposition in many parts of the nation. But the ACA is about coverage, not about cost containment, and its full implementation risks further exacerbating the cost problem.

The rising cost of health care has impacted both the private and public sectors of the economy. Businesses struggle to afford health insurance for their workers, with more of these costs being passed to workers themselves. Rising government spending on Medicare and Medicaid has crowded out support of social and educational programs that in some cases have more impact on the health of the public that health care itself. As a result, life expectancy is declining in America for the first time in a century and health disparities based on race, ethnicity, and region of the country are unabated. Still meaningful health reform remains elusive even though the cost problem becomes more severe.

The challenge for family medicine in the coming decade will be to somehow be part of the solution to this problem. The first step in doing so will be to make sure we are not part of the problem.

Commercialization of Medicine

As previously mentioned, American health care has steadily evolved from a collection of small businesses to ever larger corporate delivery systems. While this is often touted as a way to make care more efficient, it can also be viewed as a way to resist cost containment. As government and insurance interests implement measures to lower costs, delivery systems evolve to maintain and expand their market clout. The nation's primary care system lies at the heart of this tension. Family physicians can take the lead in stopping medicine from being converted to a commodity, but more and more practitioners are becoming employees of large health systems. Thus, the nation's family physicians are faced with a choice. On the one hand, family physicians can find security in large health systems and in some cases might succeed in

Telegram: @medical_k

www.konkur.in

helping these systems to evolve in ways that will benefit the public. But there is also the risk that patients will become customers of monopolistic health businesses and that family physicians will help these businesses to resist reform. One way or the other, the nation stands at the precipice of unsustainable health-care spending, and health reform is again at center stage in the national political process.

In 1969 family practice's initial objectives were to combat the fragmentation of health care and protect the centrality of relationship-based care. Today, the family physician's new role is to be the patient's advocate in a system that appears to treat health care as a commodity that is sold to consumers for the highest possible price. Family medicine's future is inexorably tied to the health of the American people whose interests are not always served by more health care; health is the goal, not health care. In a world where patients cannot tell the difference between necessary and unnecessary services, the family physician's role as advisor and partner has never been more essential.

Sustaining Family Medicine as a Desirable Specialty Choice

During family medicine's first decade, as many as 25% of the nation's graduating medical students were choosing family medicine residencies. But student interest fell in the 1980s. In the 1990s, the growth of managed care suggested an increased emphasis on primary care, and student interest again increased. For the past two decades, the portion of American's medical student choosing family medicine has consistently fallen below 12% annually even though the absolute number of medical school graduates and the number of residency programs have increased. The number of medical students choosing careers in family medicine is far fewer that what will be required if all of the American people are to have affordable access to care.

Over the course of history, family physicians have sought to fix its workforce problem by influencing medical school admission policies and by reforming medical school curricula. Successful departments of family medicine exist in most medical schools, but the student interest problem remains refractory to the specialty's best efforts. For many in the discipline, this is viewed as an economic problem that can only be fixed by reform in the physician payment system. To others, blaming forces outside of the discipline itself allows family physicians to avoid the kind of deep reflection required to address this problem. There is considerable truth to both arguments.

Family medicine cannot succeed unless in transforms itself into a field that more medical students will want to enter. Many of them are attracted to family medicine's service orientation and commitment to community-based practice. But family medicine often loses students to other disciplines if they are interested in performing procedures, conducting research, or developing focused areas of practice. Family medicine cannot fix the student interest problem by remaining the same as always, but the specialty also cannot simply try to be all things to all students. Medical students today are no less idealistic than they have ever been, but they are also increasingly not representative of the American people. Medical students are less likely to come from rural communities, communities of color, and poor families than those they will ultimately serve. Fixing the student interest problem remains one of family medicine's greatest challenges and will necessarily require major reforms of the medical education process at the most fundamental level.

Information Technology and the Tension Between Personal Care and Population Health

Over the past decade, the most consequential changes in how health care is actually delivered in America resulted from implementing new information and communication technology. Just as the automobile spelled the end of "horse and buggy" travel and the telephone allowed direct communication with the physician without face to face visits, electronic health records (EHRs) and asynchronous communication by e-mail and text message have profoundly changed the practice of

Telegram: @medical_k

www.konkur.in

medicine. For the first several years after EHRs were adopted, the emphasis was on how to put information into these systems. Physicians who were used to dictating notes in the medical record and writing prescriptions had to learn how to use these electronic systems to order tests, create medical record notes, prescribe medications, and communicate with specialists. Today, family physicians have adapted to these changes and are now faced with the challenge of how to use information that can be extracted from these systems. If information is accurately entered, it is now easy to know things about the practice that could not easily be known before. Family physicians can easily learn how many of their patients with diabetes or hypertension are failing to meet their treatment goals. Family doctors can build registries of unimmunized patients and lists of patients with frequent emergency department use. The ability to access such information has increased the specialty's focus on access to and coordination of services, sometimes at the expense of continuity of care and relationship-based care. Knowing these things raises questions about how to improve them, and these efforts require attention to groups of patients, not just individuals. Thus, a major tension now exists between how best to care for individual people and how to improve the care of the overall population being served.

Today, using asynchronous communication, family physicians communicate with patients by e-mail or text message, and patients have access to nearly limitless information about their health concerns. Patients compare the advice they receive from their family physicians with what they read on the Internet. Sometimes, this improves their understanding, but too often, it confuses them. Electronic information and communication systems are here to stay, and the future of family medicine will depend on how to adapt to them while preserving the specialty's traditional values.

Globalization and Global Health Disparities

The first two decades of the twenty-first century have witnessed dramatic globalization in the world economic marketplace. Goods and jobs are increasingly moving freely across national borders, as is information about lifestyle and economic opportunities. Economic and political unrest in areas such as Africa, the Middle East, and Central America has precipitated the movement of refugees and other immigrants into countries in Europe and North America. At the same time, globalized businesses increasingly work across international borders, and markets are less local than ever before in human history. Health care is not immune from these changes as communities become more ethnically and culturally diverse. In addition, local health-care problems are less likely to remain local as the mobility of the population impacts how disease prevalence affects communities. In the United States, billions of dollars are spent annually for anxiety medication, while in other countries children die of infectious diseases for want of a vaccine or an inexpensive antibiotic. Global disparities in life expectancy and population health are striking, and modern communication technology insures that people know about them. One the one hand, this influences patterns of immigration. On the other hand, it raises problems for the countries to which people move. Recent elections in many countries have underscored the public's unease about open immigration.

The impact of these trends on health care is dramatic. Family physicians in developing countries have far fewer resources with which to work than those in first world countries. Family physicians in Europe and North America are seeing patients who come from much different cultures, speak different languages, and have different health problems that they are used to seeing. Although there is substantial resistance to globalization, it is unlikely that these trends will stop anytime soon. So this has substantial impact on both the day to day work of family physicians and on the process by which they are trained. In such an environment, family physicians have an expanded responsibility. Not only must family physicians care for different patients with different problems; they must also help the communities in which they live to adapt to the changing world.

Telegram: @medical_k

www.konkur.in

Finally, there is the global threat of climate change, a threat that is likely to have dramatic impact on both population health and immigration trends. When the specialty started, the focus was on caring for patients in the context of the individual communities in which family physicians and their patients lived. Information and communication technology have shifted family medicine's focus to the health of those communities themselves. But the future of family medicine will require a more global context for care, and family physicians are only now starting to understand how dramatic this change will be.

Caring for the World

Family medicine has been such a positive influence on health care worldwide that society would have had to invent it for the new millennium, if it did not already exist. Despite past predictions to the contrary, family medicine has survived into the twenty-first century. In fact, it has done much more than survive; it has prospered and has had a powerful impact on health-care delivery and medical education worldwide. Family medicine is a rapidly evolving discipline that brings a much-needed social conscience to medicine and is continuingly reinventing itself as it uses innovative methods to expand its service roles. But a central question remains: is family medicine's goal to fit into the larger health-care community or to fundamentally change it? The quality and availability of health care has measurably improved over the specialty's 50-year history, but this has come at a price. Uncontrolled cost and the growing injustice stemming from population health disparities have brought medicine to a critical juncture. Will health care be devoted to actually improving the health of everyone, or will it be a service business focused on its own economic interests and the care of those who can afford to pay for it. No discipline in medicine has a greater role to play in deciding this question than family medicine. Family medicine must remain the specialty that puts people first – first before profit, first when there are ethical conflicts, first before third-party payers, and first before a single-minded emphasis on disease. Family medicine must resist attempts to commodify relationship-based care if the specialty is to retain the trust of those is serves. Family physicians must care for the world one patient and one community at a time. And all physicians should honor family medicine's remarkable history of achievements and recognize its unlimited potential for future contributions to humankind.

Approach to the Cross-Cultural Clinical Encounter 26
Special Considerations 26

References 27

The need for cultural awareness and cultural sensitivity has never been greater for family physicians. As access to transportation and information sharing broadens to all regions of the globe – and as information is shared nearly instantly – the influence of culture grows and becomes more complex with every passing year. Areas of the United States that saw relatively little change in population for decades have experienced unprecedented change in recent decades.

Although cultural differences are not new, today's family physician has a unique opportunity – and responsibility – to care for the whole person during this period of rapid cultural change. Because cultural groups and their members each have the potential to interpret their world differently, a solid understanding of the underpinnings of culture is necessary to provide safe and effective primary care in today's society.

The Context of Race, Ethnicity, and Culture

The concepts of race, ethnicity, and culture are frequently used interchangeably in clinical settings. Racial distinctions are perhaps most often used as a means of introducing a patient in a clinical presentation. Yet, racial distinctions often have limited clinical utility and, worse, can perpetuate misleading and potentially inaccurate patient stereotypes. Ethnic and cultural factors, by contrast, are less often mentioned in clinical settings even though they can facilitate clinical decision-making to a greater degree.

Race

Physical characteristics (e.g., skin color, facial features, hair type) that are shared by a group of people generally define racial classifications. From these classifications, many make an assumption of a shared genetic heritage that may be intended as useful historic information in clinical settings. Unfortunately, such assumptions are neither useful nor accurate and add little to medical decision-making [1].

Ethnicity

Ethnicity is more useful than the term race in clinical settings. The word *ethnic* is defined in the *Oxford Dictionary* as "the fact or state of belonging to a social group that has a common national or cultural tradition." The word *ethnicity* is derived from the Greek terms *ethnos*, which refers to the people of a nation or tribe, and *nikos*, which means national or nationality. Ethnicity commonly refers to dimensions of race and nationality, as well as concepts included within culture.

Culture

Culture can be described as the social behaviors (e.g., norms, knowledge, skills, and attitudes) of a group of people learned and passed from one generation to the next. Cultural norms are often reinforced by members of the group and can be modified over time. Conclusive statements about culture, therefore, are rarely possible. An individual's affinity to one's culture can be highly variable. This may be determined, for instance, by the amount of time since one's family migrated from one society to another, level of education, or socioeconomic status. In fact, there may be more similarities between two people of the same socioeconomic status who are from different cultures than between two people of the same culture but different socioeconomic status.

Telegram: @medical_k

www.konkur.in

Population Demographic Shifts

The racial and ethnic makeup of the US population is projected to change in coming decades. Nearly 1 in 5 persons in the United States is projected to be foreign born in 2060. By 2044, more than 50% of Americans will belong to a minority group, any group other than non-Hispanic White alone [2]. With this in mind, the traditional Western health care model will be challenged to meet the needs of diverse populations who have differing, at times conflicting, views of health and illness.

Between 2016 and 2060, the Hispanic population is expected to grow from 57.5 million to 111.2 million, an increase of 93%. The Asian population is projected to be the second-fastest growing racial minority group, from 18.3 million in 2016 to 36.8 million in 2060, an increase of 101%. The Black population will grow from 43 million to 60.7 million, an increase of 44%. In contrast, the non-Hispanic White population is projected to diminish by 10%, from 198 million to 179 million [3]. Table 1 illustrates the percentage of the total population each group comprises in 2016 and projection for 2060.

Overall, the U.S. Census National Projections predict a slower growth in population than in the recent past. However, the geriatric population is growing proportionally faster, with 1 in 5 Americans projected to be over age 65 by 2030 [2]. As individuals age, their healthcare needs may be more complex. Primary care professionals will be expected to manage multiple concurrent chronic diseases and understand the unique challenges the older patient faces such as stereotyping, living with rapid technological changes, and learning to access healthcare from multiple settings – from outpatient, inpatient, to long-term care facilities [4].

Table 1 Subgroup percentage of the total population in 2016 and 2060 projections

	2016	2060
Hispanic	18%	28%
Black	13%	15%
Asian	6%	9%
Non-Hispanic White	61%	44%
American Indian and Alaska Native	1%	1%
Other	1%	3%

Health Status of Black or African Americans

Health disparities between Black or African Americans and other racial and ethnic populations are striking. Black Americans experience high rates of infant and perinatal maternal mortality, shorter life expectancy, and overall higher death rates. Cardiovascular disease is the leading cause of death in the United States, and it is disproportionately more common in the Black population. Non-Hispanic Black adults are at least 50% more likely to die of heart disease or stroke prematurely (i.e., before age 75 years) than their non-Hispanic White counterparts [5]. The infant mortality rate for non-Hispanic Black is more than double the rate for non-Hispanic Whites. Rates also vary geographically, which determine the ease of access to high-quality healthcare, education, employment, and other spaces. For instance, the rates of infant mortality are higher in the South and Midwest than in other parts of the country [6]. The prevalence of diabetes among Black adults was nearly twice as large as the prevalence among White adults [7]. These disparities are often due to economic and social conditions that are more common among Black Americans than Whites. For instance, Black adults are more likely to report that they cannot see a doctor due to cost [8].

Health Status of Hispanics

The US Census defines "Hispanic or Latino" as a person of Cuban, Mexican, Puerto Rican, South or Central American, or other Spanish culture or origin regardless of race. Health disparities impacting Hispanics are projected to increase as the proportion of Hispanics in the United States grows. Hispanics have higher rates of obesity than non-Hispanic whites. The prevalence of adult diabetes is higher among Hispanics, non-Hispanic

Telegram: @medical_k

www.konkur.in

Blacks, and those of other or mixed races than among Asians and non-Hispanic Whites. Prevalence is also higher among adults without college degrees and those with lower household incomes [9]. The Centers for Disease Control and Prevention has cited some of the leading causes of death among Hispanics to be heart disease, cancer, unintentional injuries, stroke, and diabetes. There are health disparities among Hispanic subgroups. For instance, Puerto Ricans suffer disproportionately from asthma, HIV/AIDS, and infant mortality. Mexican Americans suffer disproportionately from diabetes [10].

Health Status of American Indians and Alaska Natives

Health disparities within American Indian/ Alaska Native (AI/AN) populations remain among the most underappreciated health disparities in the United States. Further, AI/AN populations are historically marginalized by our healthcare system. Though the Indian Health Service is charged with serving the health needs of these populations, more than half of AI/ANs do not permanently reside on a reservation and therefore have limited or no access to IHS. As a result, AI/AN disparities persist. AI/AN adults aged 50–75 years who reported being up to date with colorectal cancer screening were 11 percentage points lower than the percentage screened among White adults [11]. In 2010, AI/AN and Hispanic adults had the highest age-adjusted mean number of physically unhealthy days in the past 30 days compared with other racial/ethnic populations. During 1999–2010, drug-induced death rates in the 30–39 year age group were highest among AI/AN compared to other racial/ethnic populations [11].

Health Status of Asian-Pacific Americans

Asian and Pacific Islanders (APIs) make up less than 5% of the total population in the United States. This, combined with the fact that as a whole APIs have lower overall death rates for cancer, heart disease, stroke, unintentional injuries (accidents), and diabetes than other racial/ethnic populations, may contribute to the misperception that APIs are somehow immune to the disparities that impact other groups. Closer analysis reveals, however, that disparities also exist among APIs and in many cases to a much greater degree than other subgroups. APIs account for more than 50% of Americans living with chronic hepatitis B. Despite these high rates, many APIs are not tested for hepatitis B. They are frequently unaware of their infection, and many recent immigrants do not have access to medical services that can help save lives [12]. As a result, chronic hepatitis B associated with liver cancer in APIs is one of the most serious health disparities in the United States.

Health Equity

Health equity means that every individual has a fair and just opportunity to be as healthy as possible. The principles of equity focus on removing obstacles that lead to unjust differences in health status due to socioeconomic status, location, income, education, race, or ethnicity [13]. Addressing the social and physical determinants of health is one of the overarching goals of the Department of Health and Human Services' Healthy People 2020 [14]. In addition to access to health services, access to education, safe and affordable housing, and public safety affect population health outcomes. For example, a favorable neighborhood walking environment confers improved cardiovascular health [15]. In a study of data from the Center for Disease Control and Prevention, the overall trend for health justice – a measure of outcomes independent of race, sex, and income – declined from 1993 to 2017 [16]. For instance, non-Asian ethnic minorities experience higher rates of HIV diagnoses than Whites. However, a lower percentage of Blacks diagnosed with HIV are prescribed antiretroviral therapy; and on average, Blacks and Hispanics have a lower percentage of suppressed viral load. It is important to recognize the complexity of these health gaps. In order to achieve health equity, we must identify areas of disparity to change and implement policies, laws, and systems that serve to reduce inequities.

Telegram: @medical_k

www.konkur.in

At the 1966 Second National Convention of the Medical Committee for Human Rights, Dr. Martin Luther King said that "Of all the forms of inequality, injustice in health care is the most shocking and inhumane." We have made some but not nearly enough progress in reducing the barriers to equitable health care. Primary care professionals can work to eliminate this form of inequality wherever and for whomever it affects.

Special Populations

Health Status of LGBT People

Lesbian, gay, bisexual, and transgender (LGBT) individuals encompass all races, ethnicities, religions, and social classes. The "LGBT" acronym is a general term to refer to a group of people that are diverse with regard to their sexual orientation and gender identity [17]. "Sexual orientation" refers to an individual's erotic, physical, and emotional attraction to the same or opposite sex. "Gender identity" refers to personal association to female, male, or other genders (e.g., transgender) and may be compatible or incompatible with sexual assignment determined at birth. Sexual orientation and gender identity questions are not asked on most national or state surveys, making it difficult to estimate the number of LGBT individuals and their health needs. Research suggests that LGBT individuals face health and social disparities linked to social stigma, discrimination, and denial of their civil and human rights. A long-standing history of discrimination against LGBT individuals has contributed to their distrust of the healthcare system. Compared with their heterosexual counterparts, LGBT individuals have been associated with higher rates of psychiatric disorders [18], substance abuse [19, 20], suicide [21], sexually transmitted diseases (STDs) including HIV, and increase incidence of some cancers [17, 22].

Creating a Welcoming Environment

Studies have demonstrated that LGBT individuals and their families survey their surroundings to determine if they are in an accepting environment [17]. In the primary care outpatient setting, modifying patient intake questionnaires to include a range of sexual orientations and gender identities is one example of creating an inclusive environment for LGBT individuals. Other examples include posting nondiscrimination policies in high-traffic areas and providing LGBT-relevant brochures and reading material, asking questions during sexual history taking in a nonjudgmental open-ended manner, and mirroring the terms LGBT individuals use to describe themselves [17]. Care should be taken to ensure confidentiality and to be mindful of assumptions made about gender identity and sexual orientation. Additionally, physicians should have awareness of specific issues involving LGBT youth and elderly to ensure that appropriate referrals, community resources, and support are available to the patient.

LGBT Youth

LGBT youth are more likely to face negative health and life outcomes than their heterosexual counterparts. Many may face unique challenges including rejection from family and friends, bullying at school from classmates and authoritative figures, harassment, and violence [23]. Nearly 30% of this subgroup had attempted suicide at least once in the prior year compared to 6% of heterosexual youth. In 2014, nearly 80% of new HIV diagnoses in youths were from young gay or bisexual men. Positive environments at school and at home can help all youth achieve good grades, physical, and mental health. Creating a safe and supportive environment will help them thrive. A positive school climate has been associated with decreased depression, suicidal feels, substance use, and unexpected school absences [24].

LGBT Elderly

Compared to their younger counterparts, elderly LGBT individuals grew up in an era of discrimination and less acceptance. In the medical world prior to 1973, homosexuality was listed in the Diagnostic and Statistical Manual of Mental Disorders with treatment modalities including electroconvulsive therapy and castration. LGBT elderly are less likely to have children compared to their heterosexual counterparts and thus have less family supports. Prior to the June 2015

Telegram: @medical_k

www.konkur.in

nationwide ruling for legalization of same-sex marriages in the United States, LGBT individuals did not have access to spousal benefits through Social Security and thus may have been impoverished by the death of a partner [17]. LGBT elderly who lose their ability to live independently and are subsequently institutionalized may tend to conceal their sexual orientation [17, 25].

Health Maintenance and Screening

Care should be taken to ensure that routine health maintenance is offered to LGBT patients such as pap smears, mammograms, cancer screening tests, and immunizations. Sexual behaviors such as anal-receptive intercourse and oral intercourse may predispose LGBT individuals to STDs including HIV/AIDS [26]. STD screening should be offered annually and at shorter intervals for high-risk individuals (e.g., multiple partners, drug use in conjunction with intercourse). Consider urethral, rectal, and pharyngeal testing for gonorrhea and *Chlamydia*. Consider screening for anal dysplasia with an anal Papanicolaou test in men who have sex with men (MSM), HIV infected individuals, or any patient with anogenital condylomas [27]. Preexposure prophylaxis against HIV infection may be appropriate for some at-risk individuals who can adhere to daily therapy. Regular screening for obesity, tobacco use, drug and alcohol use, and depression is also recommended.

Health Status of Deaf People

Hearing loss is the second most common disability in the United States, accounting for approximately 10% of Americans [28]. Out of the 8.8 million North Americans who are deaf, it is estimated that between 100,000 and one million belong to the Deaf community [29]. Of note, "Deaf" (uppercase "D") refers to the culture and community of Deaf people, whereas "deaf" (lowercase "d") refers to the lack of hearing [29]. The US Deaf community is a linguistic and sociocultural minority group that is often overlooked as such. It is distinguished by its preferred use of American Sign Language (ASL) and distinct culture. Members of this community were typically deafened during childhood, around age 3, before the acquisition of English language skills. Individuals who were deafened during adulthood are less likely to be members of the Deaf community as they are more likely to have English language proficiency and communicate orally or through speech-reading [29]. Similar to other linguistic and cultural minority groups, studies have shown health disparities in Deaf individuals related to lower socioeconomic status and literacy levels, altered healthcare utilization, communication issues with their physicians, and misinterpretation of medical treatment [27–29]. In an effort to provide culturally competent care, primary care physicians should be mindful of language barriers and differences in sociocultural norms among Deaf people.

Sociocultural Norms

Similar to other cultural minority groups, Deaf individuals tend to socialize among themselves and have differing social norms compared to the majority population. These differences may result in cross-cultural misunderstanding with hearing individuals during social encounters [30]. For instance, communication heavily depends on visual and tactile cues. It is culturally appropriate etiquette for Deaf individuals to describe and distinguish others based on physical features such as weight, nose shape, and hairline. To seek attention, Deaf individuals may touch one another, bang on tables, and wave in someone's visual field. Although these are all acceptable ways to communicate among the Deaf, it may be misunderstood in hearing culture [30]. Another area of cross-cultural misunderstanding is the difference in conversation structure between the Deaf and hearing individuals. English conversations build up to a main point and then conclude, whereas Deaf conversations immediately address the main point and then take a longer time to conclude the conversation [28]. For example, a physician may initiate a conversation by taking time to build a rapport with the patient before eventually discussing the medical issue and treatment plan and then concluding the visit [30]. In Deaf culture, it would be more appropriate for the physician to

Telegram: @medical_k

www.konkur.in

first discuss the main medical issue followed by clarifying the treatment plan and moving to rapport building toward the end [28, 30]. During conversation, a hearing physician should be mindful to not exclude a Deaf individual from conversation as it is considered offensive. Additionally any environmental sounds, such as a knock on the door, should be communicated [28]. For example, if two hearing individuals in the room are having a side conversation, the conversation should be communicated to the Deaf individual.

Language Barriers

In the United States, the preferred language of the Deaf community is ASL; however, unlike other language minority groups, Deaf people are assumed to have fluency in written English and are often expected to communicate via speech-reading and note writing [29]. This can put a Deaf patient at high risk for miscommunication for several reasons. Written and spoken English are often a second language for those who communicate in ASL. Speech-reading is a difficult skill as most English words appear visually ambiguous on the lips. In the context of lower literacy levels among the Deaf, they may not understand specific written words [30]. Furthermore, Deaf people are less likely to repeat themselves than non-English-speaking immigrants [29]. Physicians who are not fluent in ASL should communicate in simple terms, ensure that patients understand medical recommendations, and work with an ASL interpreter to facilitate communication whenever possible [28, 30].

Health Status of Refugee Populations

Family physicians are likely to encounter refugees in the context of a continuity primary care relationship as well as during medical screening examinations conducted as part of the naturalization process into the United States. In either case, an awareness of – and sensitivity to – the unique needs and experiences of refugees can be extremely helpful. Refugees come from diverse ethnic, cultural, religious, socioeconomic, and educational backgrounds [31].

Since 2000, at least 750,000 refugees have resettled in the United States from over 80 different countries, with 30,000 refugees in 2019. Unlike immigrants who generally *choose* to relocate, refugees are forced to relocate and experience emotional trauma, physical trauma, or both when war, famine, or persecution *force* them to flee their countries of origin. Refugees seldom have time to plan, and frequently the move is unplanned and incomplete. There are patterns of experiences shared among refugees which are observed and may offer some understanding for primary care professionals seeking to offer care to the refugees and their families. In general, the mental health and overall wellbeing of this population are strongly tied to their migration history [31].

Common Presenting Problems

Many refugees seek attention for a variety of health problems, most commonly musculoskeletal and pain, mental and social health problems, infectious diseases, and chronic medical conditions. Evaluation of musculoskeletal problems and chronic pain should assess history of physical trauma or physical labor and prior living conditions that may be contributing factors. When presenting with ill-defined pain symptoms, thorough workups rarely yield an organic cause but should nonetheless include assessment for *Helicobacter pylori*, intestinal parasites, vitamin D deficiency, and imaging when appropriate. Not surprisingly, the mental and social health concerns common among refugees can be highly complex and unfamiliar to many family physicians. Depression, anxiety, and posttraumatic stress are more common in refugees than in the general population, as are social isolation, financial problems, and disability, among other concerns (see ▶ Chap. 65, "Care of the Refugee") [32].

Healthcare Issues of Spiritual and Religious Culture

Over the last 20 years, there has been increasing attention to the role of spirituality in multiple areas of healthcare [33]. A Gallup poll in 2017 revealed

Telegram: @medical_k

www.konkur.in

that 87% of Americans believe in God or a universal spirit [34]. Transcending culture, race, and ethnicity, research studies have demonstrated that many seriously ill patients turn to their spiritual beliefs to cope with their illnesses and make important medical decisions [35]. Though studies suggest that most patients would desire integration of spirituality in their medical care, less than 20% of physicians discuss spiritual issues with their patients [33]. In that regard, equally emphasizing the physical, psychosocial, and spiritual facets of humanity is important in the family medicine approach to healing the patient as a whole.

Understanding the difference between "religion" and "spirituality" is essential to having a meaningful conversation with patients about their spirituality. Religion is typically defined as an organized system of beliefs and observances to worship a God or a group of gods, usually embodied within an institution or organization. Spirituality is defined more broadly to describe the search for an ultimate meaning, a deeper sense of values, and relationship with a higher being and may be expressed through religious or nonreligious frameworks. Religious and spiritual practices in particular have been associated with positive health benefits in numerous research studies [35, 36]. Though spirituality generally leads to positive coping, in some instances it can also lead to negative coping, for instance, when an illness or medical crisis is viewed as a punishment from God or when devout prayer does not result in a miraculous cure [35].

As our nation's population grows exponentially, so does the mosaic of religious communities, spiritual beliefs, and practices. Physician demographics across the United States similarly mirror our nation's cultural and religious pluralism. Secular physicians must be mindful to not undermine the spiritual belief system of their patients. Likewise, religious physicians must be mindful to not impose their own belief system onto patients [36]. Though familiarity with diverse spiritual communities and beliefs would be an asset to the clinical encounter, keeping abreast of the wide-ranging nuances is not expected of physicians. It is however important for the beneficent physician to listen, respect these differences, and understand the impact of spirituality on medical decision-making and coping skills in the setting of illness.

Approach to Spirituality in the Clinical Encounter

Spiritual Screening

Obtaining initial spiritual screening is the first step in assessing a patient's spiritual well-being and identifying spiritual distress. Spiritual distress includes "common, normal feelings of vulnerability, sadness, and fear, to problems that become more disabling, such as depression, anxiety, despair, and existential spiritual crises" as defined by the National Comprehensive Cancer Network [37]. Spiritual screening can guide immediate need for spiritual counseling by a trained chaplain or indication for in-depth spiritual assessment. One spiritual screening tool suggested by a consensus panel of the American College of Physicians [35, 36] uses four questions:

1. "Is faith (religion, spirituality) important to you in this illness?"
2. "Has faith been important to you at other times in your life?"
3. "Do you have someone to talk to about religious matters?"
4. "Would you like to explore religious matters with someone?"

Obtaining a Spiritual History

A spiritual history can be performed as part of a social history during an annual physical exam or follow-up visit for new or established patients. A formal spiritual assessment is essential for older patients, hospitalized patients, patients with chronic medical conditions, and those with terminal illnesses to reveal their coping skills, to elucidate their support systems, and to refer to chaplain services [38]. Several spiritual assessment tools are available to assess a patient's beliefs. FICA (Faith and belief, Importance, Community, Address in care), a validated spiritual assessment tool (Table 2) [39], and HOPE spiritual assessment questions (Table 3) [38, 40] use a

		"Are there any specific observances, rituals, or restrictions that your medical team should be aware of?"

comprehensive series of questions to elicit open-ended discussions on spiritual beliefs with patients.

Spiritual Assessment and Plan

After obtaining a spiritual history and evaluating for spiritual distress, clinicians can document their assessment and integrate their findings into a multidisciplinary treatment plan. Medical management and spiritual interventions are influenced by the nuances of a patient's spiritual beliefs. Areas of special consideration may include:

1. Beliefs, rituals, and practices
2. Attitudes to healthcare staff and illness
3. Diet and fasting
4. Washing and toileting
5. Ideas of modesty and dress
6. Birth and death customs
7. Family planning
8. Blood transfusions, transplants, and organ donation
9. Mental health

Anandarajah and Hight suggest four outcomes following the spiritual assessment [40]:

1. No further action other than offering support, acceptance, and compassion.
2. Incorporate spiritual resources into preventive healthcare. Some examples include meditation, yoga, and listening to music.
3. Integrate spirituality as an adjuvant to medical treatment. For example, a patient may request for scriptures to be read prior to a surgical procedure.
4. Modify the treatment plan. For example, a patient with a terminal illness may decide to forego medical treatment and opt for hospice care.

When the spiritual needs of a patient are beyond a physician's competence or there is a request for in-depth spiritual counseling and prayer, physicians should be attentive to their professional boundaries, and a referral should be made to chaplain services. Most chaplains are expertly trained in listening and communication skills and have specialized knowledge on how

Telegram: @medical_k

www.konkur.in

various spiritual paradigms view healthcare. They may provide or arrange for special rituals and rites directly or act as a liaison with a patient's religious leader. If a patient explicitly requests that a physician prays with them, Post and colleagues suggest that it would be acceptable for a physician to listen respectfully however discourage physician-led prayer unless pastoral care is not readily available [36].

Approach to the Cross-Cultural Clinical Encounter

Several general guidelines have been developed to facilitate cross-cultural clinical encounters. The LEARN model developed by Berlin and Fowkes [40] can identify and resolve issues arising from cultural differences and facilitate communication. The LEARN acronym offers a five-step approach to the cross-cultural interview:

1. *Listen*. The first step of the interview is listening and gaining insight into a patient's perception of illness and treatment. This part of the interview creates a milieu for the physician to "join" with the patient. Questions may include "What is your understanding of your illness?" "What is your understanding of the treatment?" "What are your fears?" and "What is your treatment preference?"
2. *Explain*. After gaining an understanding of the patient's concept of the illness, it is the physician's turn to explain his or her perception of the medical condition. It is important that the physician uses a "Western medicine" or biomedical model for his or her explanation of the illness.
3. *Acknowledge*. After the patient and physician have explained their perceptions of the medical condition, the next step is to acknowledge the patient's explanatory model d highlight areas of agreement and resolve areas of conflict.
4. *Recommend*. During this part of the cross-culture interview, it is important for the physician to incorporate the patient's explanatory model and cultural parameters into the biomedical recommendations. This approach is conducive to acceptance of a treatment plan.
5. *Negotiate*. The last stage of negotiation between patient and physician is a key step to the LEARN model. In this stage, the patient and physician work in partnership to negotiate and develop a treatment plan that fits within a culturally competent framework of healing and health.

Special Considerations

Language and Working with Medical Interpreters

More than 60 million Americans speak a language other than English at home, and of those more than 25 million reported proficiency with English as less than "very well" [41]. As a result, this population is less likely to receive preventive care, have regular care, or be satisfied with their care [42], and they are more likely to have complications from medications, have limited understanding of their medical concerns, and have a greater chance of being misunderstood by their care providers [43, 44].

Professional medical interpreters are trained to interpret the spoken word, in contrast to translators who work with written words. Every effort should be made to utilize trained medical interpreters. Using untrained interpreters is more likely to result in errors, violate confidentiality, and increase the risk of poor outcomes [45]. When working with an interpreter, clinicians should view him or her as a collaborator in providing care for the patient. In addition, to work effectively with the interpreter, the clinician should:

1. Allow extra time for the encounter.
2. Meet with the interpreter first to discuss background, build rapport, and set goals.
3. Look at the patient when speaking; address the patient and not the interpreter.
4. Pay additional attention to body language, as it will precede the interpretation of spoken words.
5. Keep sentence structure simple.
6. Be wary of interpretation provided by family members, and remember that in some cultures, it may be taboo for them to discuss certain topics with their loved ones.

Telegram: @medical_k

www.konkur.in

7. Test for understanding, especially when non-professional interpreters are used.
8. Consider a post-encounter discussion with the interpreter to obtain feedback and make corrections if necessary.

Health Literacy

Conveying patient education and medical instructions to patients with limited English proficiency is challenging. For literate patients, printed patient instructions and educational material should be provided in their preferred language. An effective approach to gauging effective communication and health literacy is to actively involve patients in treatment planning and assessing their understanding through "teach-back." This technique has a prospect of better understanding and adherence to a treatment plan [46].

Time

Different cultures frequently perceive the concept of time in different ways. If allowed to go unrecognized, this difference may present a challenge in the cross-cultural encounter. For some patients, being on time may mean arriving within 15 min or within half a day. For some patients, the concept of an appointment may be foreign or unfamiliar. The concept of future time may also vary. Some patients in rural cultures may have difficulty conceptualizing advice to undertake preventive measures or illnesses that may not exist later or may only exist in an abstract way.

Caring for families remains one of the defining characteristics of family medicine. From the change in our discipline's name from general practice to family practice in the 1960s, family-centered care has been central to clinical practice in family medicine. Over the past decade, the role of the family in health care has evolved with the patient's natural support system becoming increasingly important in the era of health-care reform.

Despite rapid societal changes in its structure and function, the family remains the most important relational unit as it tends to individual members' most basic needs for physical and emotional safety, health, and well-being. As such, family members, not health professionals, are the first and most frequent providers of health care. Outside the hospital, health-care professionals give advice and suggestions for acute and chronic illness, but the actual care is decided upon and

usually provided by the patient (self-care) and family members. Additionally, chronic illness requires families to adapt and change roles to provide needed care. The aging of the population has led to a significant increase in the prevalence of chronic illness and disability along with a rise in family caregiving.

In this chapter, the term "family" refers to the patient's natural support system – any person defined by the patient as significant to their well-being and their health care, and "any group of people related either biologically, emotionally, or legally" [1]. This includes all forms of traditional and nontraditional families, such as unmarried couples, blended families, and LGBTQ couples. The relevant family context may include family members who live a distance from the patient or other groups such as all the residents of a community home for the developmentally delayed persons.

Role of the Family in Health and Illness

Humans evolved as highly social beings. As such, our close social relationships have a powerful influence on our physical and emotional health. Close supportive relationships have been shown to account for a 46% increase in survival, equal or greater than traditional biomedical risk factors such smoking, diet, and exercise [2]. For children, the closest and most influential relationship is with his or her parents, and for adults, the relationship with one's spouse or intimate partner has the greatest influence on overall health. Supportive close relationships can promote health by reducing stress and promoting emotional well-being and healthy behaviors. In general, married individuals have better mental and physical health than unmarried people across a wide variety of health conditions, including cardiovascular disease, cancer, and stroke [3]. Negative or hostile close relationships have a damaging effect on health through direct biological or psychophysiologic pathways and harmful health behaviors [4].

Close family relationships have been shown to influence multiple biologic systems, including neurologic, endocrine, cardiovascular, and immunologic systems [5]. Marital stress and conflict has been shown to negatively affect the hypothalamic-pituitary-axis (HPA), leading to abnormal rises in serum cortisol and lower levels of oxytocin. These physiologic changes appear to result in increased levels of chronic inflammation and reduced immunity, both of which are associated with poor disease outcomes. Marital distress is associated with a higher risk of developing metabolic syndrome and diabetes in men and women. Depression and obesity appear to play a mediating role in this connection.

Over one-third of all deaths in the United States can be directly attributable to unhealthy behaviors, particularly smoking, lack of exercise, poor nutrition, and alcohol abuse, and are potentially preventable. These unhealthy behaviors account for much of morbidity or suffering from chronic illnesses, such as heart disease, cancer, diabetes, and stroke. Health habits usually develop, are maintained, and are changed within the context of the family. Unhealthy behaviors or risk factors tend to cluster within families, since family members tend to share similar diets, physical activities, and use or abuse of unhealthy substances, such as smoking or drinking. The World Health Organization [6] characterized the family as "the primary social agent in the promotion of health and well-being."

Despite societal changes, families still tend to eat together, share the same diets, and consume similar amounts of salt, calories, cholesterol, and saturated fats [7]. If one family member changes his or her diet, other family members tend to make similar changes. However, most dietary interventions are directed at individuals with little or no attention to the rest of the family. Obesity is a major public health problem. Over 30% of the population is considered obese (more than 20% over ideal body weight), which contributes to numerous chronic illnesses, including diabetes, hypertension, coronary heart disease, and arthritis. Overeating and obesity can play important homeostatic roles in families. The parents of obese children are less likely to encourage exercise and more likely to encourage their children to eat than other parents. Obesity programs that involve the patient's spouse or the child's family

Telegram: @medical_k

www.konkur.in

have better outcomes, especially with long-term follow-up [8, 9]. The family plays an important role in both the development and the treatment of eating disorders such as anorexia nervosa and bulimia [11].

Smoking causes over 350,000 deaths per year, mostly from heart disease and cancer, and remains the number one public health problem in the United States. Smoking is strongly influenced by the family. Adolescents are five times more likely to start smoking if a parent or older sibling smokes. Smokers tend to marry other smokers, to smoke the same number of cigarettes as their spouse, and to quit at the same time. Smokers married to non- or ex-smokers are more likely to quit and remain abstinent. Support from the smoker's partner or spouse is highly predictive of successful smoking cessation. Specific supportive behaviors such as providing encouragement and positive reinforcement predict successful quitting, while negative behaviors such as nagging or criticism predict failure to quit or relapse. The Agency for Healthcare Research and Quality (AHRQ) recommends family and social support interventions as components of effective smoking cessation [10].

Meta-analyses and systemic reviews have demonstrated that interventions that involve a family member generally have better outcomes than individual interventions across a range of conditions for both adults and children [8, 11]. These interventions can be conceptually divided into those that tend to focus on the illness and provide family psychoeducation on how best to cope with or manage the illness and those that focus more on family relationships and how to improve communication and conflict resolution as a pathway for improved coping with the illness. Overall, Chesla [8] found that the psychoeducational interventions decreased overall mortality when compared to usual care. For adults, the most commonly studied illnesses were dementia, cardiovascular disease, and cancer. For children, the strongest evidence supports family interventions for childhood obesity and Type 1 diabetes. Overall, this research supports the families have a powerful influence on health, and family interventions can improve health outcomes.

Challenges to Family-Centered Care

In the 1990s, there was a surge of interest in the role of the family in family medicine. Several major textbooks and numerous articles on family-centered and family-oriented medical care [1, 12, 13] were published and used in medical schools and family medicine residencies across the country. The Society of Teachers of Family Medicine sponsored a well-attended Family in Family Medicine Conference where the latest approaches to working with families in primary care and teaching family-centered care were presented and discussed. Interest in the family in family medicine seemed to decline in the early 2000s with the end of the Family in Family Medicine Conference and a decline in publications on the family in family medicine. There are many possible reasons for this decline in interest and focus.

Over the past two decades, there has been pressure on family physicians and other primary care physicians to see more patients under the current fee-for-service reimbursement system. Many primary care physicians complain that they have less time with patients and feel like they are on a "hamster wheel" having to work faster and faster. Having less time for individual patients has meant little time for families, whether it is meeting with family members during a routine office visit or a family conference.

In addition, the scope of practice of family physicians has been narrowing. The percentage of family physicians who deliver babies has been steadily declining and currently is around 15%. Furthermore, according to data from the American Board of Family Medicine [14], the number of family physicians who care for children has declined from 77% in 2000 to 67% in 2009. Some of this decline is due to aging of the family medicine workforce and subsequent aging of the patients in their practices, as well as the rising number of pediatricians at a time when the birth rate is flat. As family physicians deliver fewer babies and take care of fewer children, the goal of caring for the entire family recedes.

Telegram: @medical_k

www.konkur.in

The Role of the Family in Health-Care Reform

Despite these challenges, there has been a resurgence of interest in family-centered care, in part due to health-care reform. The health-care system is in the midst of an enormous change, transitioning from a fee-for-service system of reimbursement to a value-based model. With a value-based system of reimbursement, clinicians and health-care systems are paid for the outcomes they achieve, rather than procedures they perform. With these changes, there are new incentives to prevent illness and keep patients and families healthy and out of the hospital. Clinicians can be paid for spending extra time with families and family caregivers to prevent hospitalization and other expensive interventions.

As CEO of the Institute for Healthcare Improvement, Don Berwick, MD, first proposed the concept of the Triple Aim: better patient experience, better health outcomes, and lower costs. The Triple Aim has become the primary goal of health care in the United States. Patient and family-centered care has become a major focus of most health-care institutions. Medicare now bases a portion of its reimbursement on patient and family satisfaction of their care. More hospitals and practices are starting patient and family advisory councils to help guide health-care policies. As our health-care system continues to move from fee-for-service to value-based care where outcomes matter, family involvement and family satisfaction will play an increasingly important role.

Family-Centered Care

Since family physicians meet with individual patients more often than with family members, having a family-centered approach regardless of whether seeing an individual or a family is an important skill. This approach complements a patient-centered approach in which the physician explores the patient's experience of illness. The patient's presenting complaint can be thought of as an entrance or window into understanding the patient in the context of the family since the illness experience inevitably occurs in a family or relational context. By exploring the patient's symptoms and illness in context, the physician can learn more about the patient's family, its relationship to the presenting complaint, and how the family can be used as resource in treatment. A key to being family centered is choosing appropriate questions to learn about the psychosocial and family-related issues without the patient feeling that the physician is intruding, suggesting that the problem is "all in your head," or blaming the patient or the family. In a qualitative study of exemplar family physicians, Cole-Kelly and colleagues examined the core components of a family-centered approach with individual patients [15]. These family physicians used both global family questions, "how's everyone doing at home?" and focused family-oriented questions, "how is your wife doing with that new treatment?" The exemplar physicians frequently inquired about other family members and were able to keep a storehouse of family details that they frequently interspersed in the visits.

A risk of being family centered with an individual patient is getting triangulated between family members – having a patient speak to the physician about another family member in a conspiratorial way that invites side-taking. In Cole-Kelly's study, the exemplar physicians were sensitive to the dangers of inappropriately colluding in a triangulated relationship with the patient and were facile at avoiding those traps. The exemplars seemed to have an appreciation for the importance of understanding the concept of developing a "multipartial alliance" with all family members, rather than becoming triangulated. The exemplars often explored family-oriented material during physical exams or while doing procedures, thus not using extra time for these areas of inquiry. Visits with high family-oriented content occurred 19% of the time, while family-oriented talk was low or absent in 52% of the visits. The visits that had the highest degree of family-oriented content were chronic illness visits and well-baby/child visits.

Asking family-centered questions can metaphorically bring the family into the exam room

Telegram: @medical_k

www.konkur.in

and provide a family context to the presenting problem [16]. Examples of family questions include:

- **Has anyone else in your family had this problem?** This question is often part of obtaining a genogram. It not only reveals whether there is a family history of the problem but how the family has responded to the problem in the past. The treatment used with one member of the family or in a previous generation may be a guide for the patient's approach to his/her illness or may describe how a patient does not want to proceed.
- **What do your family members believe caused, or could treat, the problem?** Family members often have explanatory models that strongly influence the patient's beliefs and behaviors regarding the health problem and how it should be treated. If the physician's treatment plan conflicts with what important family members believe or have recommended, it is unlikely the patient will comply.
- **Who in your family is most concerned about the problem?** Sometimes, another family member may be the one most concerned about the health problem and may be the actual "customer," the one who really wants the patient to receive care. When the patient does seem concerned about the health problem or motivated to follow treatment recommendations, finding out who is most concerned may be helpful in creating an effective treatment plan.
- **Along with your illness (or symptoms), have there been any other recent changes in your family?** This question is a useful way to screen for other additional stressors, health problems, and changes in the patient's family and how it is affecting the patient.
- **How can your family be helpful to you in dealing with this problem?** Discovering how family members can be a resource to the patient should be a key element of all treatment planning.

These questions can be integrated into a routine office visit with an individual patient and provide valuable family information relevant to the problem.

Genograms

Genograms, or family trees, are one key to family-centered care. They are the simplest and most efficient method for understanding the family context of a patient encounter (see Fig. 1), providing a "psychosocial snapshot" of the patient. Genograms also provide crucial information about genetic risks and any family history of serious illnesses. With advances in genetic research, a detailed genogram should be an essential component of every patient's medical evaluation and database [17, 18], ideally integrating genetic and psychosocial information.

Genogram information can be collected at an initial visit with more added during subsequent encounters. The genogram may be quite simple and only include the current household and family history of serious diseases, or it may provide more detailed information about family events and relationships. When possible, the genogram should include family members' names, ages, marital status, significant illnesses, and dates of traumatic events, such as deaths.

Obtaining a genogram can be a particularly effective way to understand the family context and obtain psychosocial information from a somatically focused or somatizing patient. These patients often present with multiple somatic complaints and try to keep the focus of the encounter on their physical symptoms and distress. The problems are challenging, and it is often difficult to obtain family or psychosocial information from them. A genogram representing the family history provides a way to step back from the presenting complaints to obtain a broader view of the patient and his/her symptoms in a manner that is acceptable to the patient.

While there are efforts to create digital genograms and integrate them into the electronic medical records, this is not available for most Electronic Health Records (EHRs). Currently, the best option is to create the genogram on paper, scan it into the EMR, and use a bookmark

Telegram: @medical_k

www.konkur.in

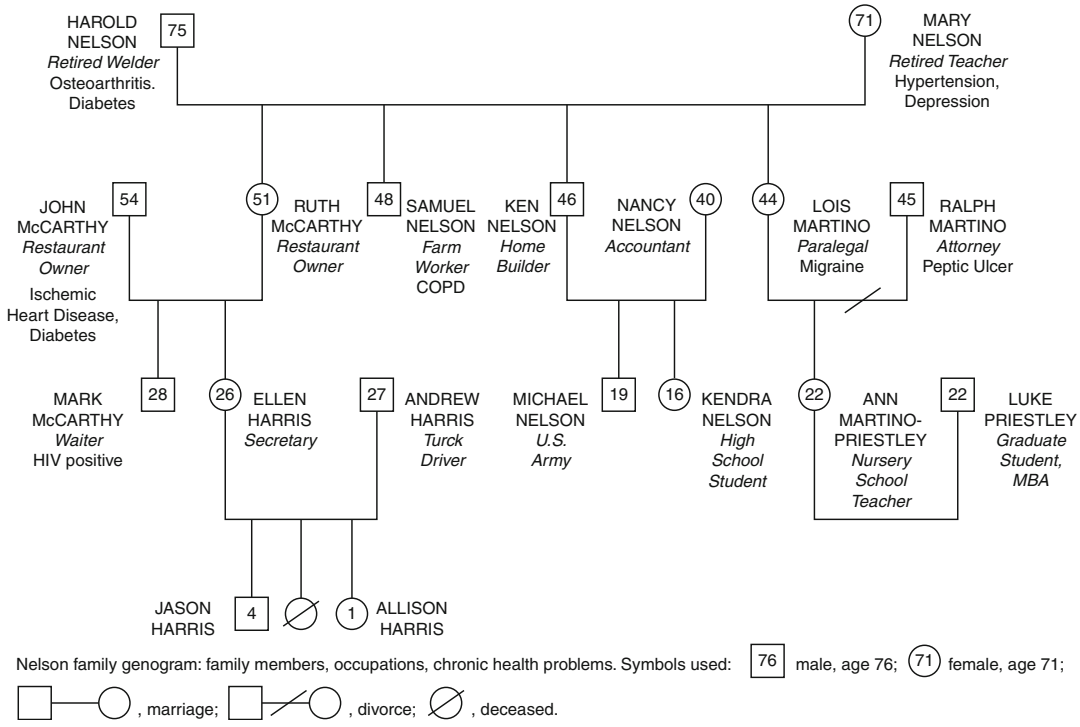

Fig. 1 Genogram

or similar system to easily identify its location. Gone are family folders in which the charts of family members are included in one folder and can be consulted during an office visit. None of the major EHRs have methods for linking the electronic records of family members or even ways to identify related members of a family or household. Clinicians must often rely on household addresses to determine family members.

Meeting with Family Members

Routine visits, in which one or more family members are present, are common and may be initiated by the patient, family members, or clinician. These visits allow clinicians to obtain the family member's perspective on a problem or treatment plan and answer the family member's questions. Family members accompany the patient to office visits in approximately one-third of all visits, and these visits last just a few minutes longer than other visits [19]. In some situations, they may be more efficient and cost effective than a visit with an individual patient since a family member can provide important information about the health problem or the visit may prevent later questions. Family members may serve various roles for the patients, including helping to communicate patient concerns to the doctor, helping patients to remember clinician recommendations, expressing concerns regarding the patient, assisting patients in making decisions, and reporting on the feasibility or acceptability of the treatment plan. Physicians report that the accompanying family members improve their understanding of the patient's problem and the patient's understanding of the diagnosis and treatment.

There are many situations when a family physician may want to invite another family member to the next office visit. Partners and spouses are routinely invited to prenatal visits. Fathers and coparents should be invited to well-child visits, especially when the child has a health or behavior problem. Whenever there is a diagnosis of a serious medical illness or concerns about adherence

Telegram: @medical_k

www.konkur.in

to medical treatments, it is helpful to invite the patient's spouse or other important family members to come for the next visit. Elderly couples are usually highly dependent on each other. It can be particularly effective and efficient to see them together for their routine visits. Each can provide information on how the other one is doing and help with implementation of treatment recommendations. Consulting with family members during a routine visit is advised whenever the health problem is likely to have a significant impact on other family members or when family members can be a resource in the treatment plan.

Principles of Family Interviewing

The principles of interviewing an individual patient also apply to interviewing families, but there are additional complexities. Important Dos and Don'ts of family interviewing include:

DOs
- Greet and shake hands with each family member
- Affirm the importance of each person's contribution
- Recognize and acknowledge any emotions expressed
- Encourage family members to be specific
- Maintain an empathic and noncritical stance with each person
- Emphasize individual and family strengths
- Block persistent interruptions

DON'Ts
- Let anyone monopolize the conversation
- Let family members speak for each other
- Offer advice or interpretations early in a family meeting
- Breach patient confidentiality
- Take sides in a family conflict, unless someone's safety is involved

One must engage and talk with at least one additional person, and there is opportunity for interaction between the patient and family members. In general, the physician must be more active and establish clear leadership in a family interview. This may be as simple as being certain that each participant's voice is heard: "Mrs. Jones, we haven't heard from you about your concerns about your husband's illness. Can you share those?" to directing traffic with a large and vocal family, "Jim, I know that you have some ideas about your mother's care, but I'd like to let your sister finish talking and then we'll hear from you."

When interviewing families, establishing rapport and developing a positive working relationship with each family member is particularly important. In a family systems approach, this is known as "joining." An essential component of joining is making some positive contact with each person present so that each feels valued and connected enough to the physician to participate in the interview. Family members have often been excluded from health-care discussions and decisions, even when they are present. They may not expect to be included in the interview or to be asked to participate in decision-making, even though the conversations at home may be very lively. By making contact with each person, the physician is making clear that everyone is encouraged to participate in the interview.

It is important to join with family members at the beginning of the interview as the physician often has a much more established relationship with the patient. Without this, the family member may either feel left out or as if he or she is merely an observer. One example of this occurs commonly during hospital rounds when there is a family member by the bedside. The usual approach is to either ask family members to leave during the interview or to ignore them. This is both disrespectful and misses the opportunity to use family members as a resource. To avoid this, the physician should greet and shake hands with each family member and find out something about each person, including the family member's relationship with the patient and involvement in the patient's health problems. It may also involve thanking them for their presence and help.

In addition to establishing rapport, the physician can also make use of nonverbal strategies to enhance the relationship with the patient and family members. Just as it is important to be sure

that the physician and an individual patient are in a comfortable sitting position and at eye level with one another, so it is important that other family members are sitting near enough that they can hear what's being said and be easily seen by the physician. This proximity will help the physician make eye contact with each person in the room. Upon entering the room and seeing that one family member is sitting very far from the physician or isolated from other family members, the physician can gently motion the person to come closer to enhance the sense of everyone being included in the patient visit and being an important part of the encounter.

All the principles of good medical interviewing can be extended to family interviewing. It is helpful to encourage each family member to participate and to be as specific as possible, when discussing problems. Individual and family strengths should be emphasized. Emotions that are present in any family member during the interview should be recognized and acknowledged. ("Mr. Canapary, you look upset. Is there anything about your wife's health or her medical care that you are concerned about?") In addition, the physician must take an active role in blocking persistent interruptions and preventing one person from monopolizing the conversation.

Establishing a positive relationship with family members is particularly important and more challenging when there is significant conflict in the family. When this is the case, it is not unusual for a family member to assume that the physician has taken the side of the patient in the conflict. The physician must take extra steps to join with each family member and establish one's neutrality. An exception to this goal is when family violence threatens and then safety must be the first priority.

Similarly, one family member might dominate both the verbal and nonverbal space in the encounter, making it difficult for the other family members to have as much involvement with the patient or physician. For these cases, the physician must "direct traffic," so all voices can be heard.

It is very easy for the physician to unwittingly be pulled into unresolved conflicts between family members. In the case of an ill child, one parent may try to form a relationship with the physician that excludes the other parent. Or, a wife can try to get the physician to side with her, hoping that the physician's alliance will bolster her position against her husband. To avoid getting caught in the middle of a triangle, the physician needs to be facile at reassuring each member of the family that he/she is there to hear each person's story but will remain neutral. Furthermore, the physician can assert that it won't be helpful to the family if he/she takes sides with one member against another. The physician can emphasize the importance of everyone working together as the most beneficial way to enhance the health care of the patient.

Confidentiality

When working with family members, the family physician must maintain confidentiality with the patient. Prior to speaking with a family member, it is important that the physician is clear about what the patient feels can be shared and what, if anything, cannot be. A family member may bring up difficult or awkward concerns, but the physician may only disclose information the patient has approved (unless that patient is incompetent). In most cases, patients will agree that their care plan can be fully discussed with the family members. However, in family meetings involving adolescents or divorced parents, the "rules" for the meeting need to be clearly spelled out. The physician may remind families at the beginning: "John has agreed that I can talk with you about the options for his diabetes treatment. He, of course, will be the one who will make the final decisions, but we both think it will be helpful to have all of your thoughts about what may be best." Such discussions value both the doctor–patient relationship and the patient-family relationships. The positive support of these relationships is only one of the positive outcomes of well-crafted family meetings.

Conclusion

Health-care reform, the aging of the population, the recent pandemic, and advances in medical research will continue to have a dramatic impact on family issues in health care. There are

Telegram: @medical_k

www.konkur.in

increasing demands on families to provide care for each other, especially aged and chronically ill patients, often without adequate services or insurance reimbursements. Family caregiving has led to increasing burden on family members and poor physical and mental health for many caregivers. The role of the family in end-of-life decision-making is only beginning to be addressed. Health-care proxy laws allow patients to identify an individual, usually a close family member, to make medical decisions if the patient is unable to, but little research has been done on how patients make these choices, what they discuss with their designated health-care agent, and whether family members follow the wishes of the patient. Because of the genetic revolution, we have the ability to screen or test for hundreds of genetic disorders, but the impact of this technology on families is just beginning to be examined. Genetic counseling not only needs to address the genetic risks of the individual but the implications for other family members. More family research is needed in each of these areas.

One of the unique and distinguishing characteristics of family medicine is its emphasis on the family. No other medical specialty has a relational or family focus or uses a family-oriented approach. With our changing health-care system, there is increasing recognition of the importance and cost-effectiveness of involving the family in all aspects of medical care. New models of care are being developed that emphasize teamwork, prevention, and collaboration with patients, caregivers, and family members. A family-oriented approach will become an increasingly valued and effective model in the twenty-first century.

Introduction

Stress is a continually growing concern in our society. The impact of stress on mental health and physical illness can be significant and a major factor in healthcare costs in the United States. A large percentage of Americans report feeling moderate-to-high stress levels on a daily basis [1]. When stress extends to include family and social aspects of one's life, complexities can exist beyond just individual coping of a situation or event. Stress has been seen by both patients and physicians as influencing health outcomes.

Family stress can be viewed as a disturbance in the ongoing state of a family system. This disturbance can occur both outside of the system (e.g., war, unemployment, natural disaster) and inside the family system (e.g., death, divorce, chronic illness). This systemic stress creates a change in the family's routine functioning [2]. Normative stressors (e.g., birth of a child, job transition, loss of an older adult) in families are considered to be common and predictable sources of stress. Nonnormative family stressors (e.g., early widowhood, job loss, natural disaster) are uncommon and unexpected and may occur at times other than those expected in the life cycle of the family or its members [3, 4]. How well the family unit copes with these two types of stressors largely impacts both the short-term and long-term adjustments and well-being of both the unit and the individuals in it.

Divorce and abuse have been cited as two of the most stressful events that commonly occur in families [5]. Numerous problematic outcomes and life adjustment problems have been found in individuals following divorce. Divorce has long been linked to physical and emotional health problems in adults. Increases in depression, dysthymia, and alcohol abuse have been reported, based on both the quality of the relationship prior to divorce and financial resources of the family [6, 7]. Additionally, intimate partner violence has long-term health consequences for survivors, even after the abuse has ended. The effects of abuse can lead to negative outcomes such as poorer overall health, lower quality of life, and higher use of healthcare services than the general population [8].

Another type of stress that impacts our patients' health is adverse childhood events (ACEs). These events include abuse of the child as well as household dysfunction such as having a parent with substance abuse disorder, spousal violence in the home, and criminal activity in the home. It is estimated that over 50% of adults have experienced one ACE during childhood [9]. The role that events in childhood play on long-term behaviors, health beliefs, morbidity, and mortality continues to be studied. It has been seen that these events are correlated to increased rates of cancer, ischemic heart disease, chronic lung disease, skeletal fractures, and liver disease [10]. If these events are identified, interventions such as trauma-focused CBT and victim-centered services have been shown to improve protective factors [9].

Family strain has an impact on multiple levels of member's lives. The relationship between parental stress and parenting practices can have strong effects on the behavioral outcomes of children. Parental responses to stress can lead to subsequent internalizing and externalizing behaviors in their children, especially those with serious medical or health conditions, such as diabetes [11]. Stress within families also has significant financial and occupational consequences. Work and family are particularly significant sources of stress, given that a large percentage of adults devote large amounts of time to these two areas of life [12]. The high time demands of work environments have strong impacts on the mental, physical, and relational well-being of the worker and their family members [13]. Families who experience financial strain endure the added challenges of obtaining adequate healthcare and other resources. Other internal and external sources of stress can have major ramifications on the adjustment and well-being of members over time (Table 1).

A chronic illness or a medical issue can prompt the onset of family stress in various ways. For example, caregivers of family members with chronic illness often experience high levels of

Table 1 Examples of internal and external family sources of stress

Internal factors	External factors
Death in the family	Natural disaster
Divorce or separation	Community risks/crime
Financial problems or job loss	Lack of access to care/ insurance coverage
Accident/disability/ illness	Migration/immigration
Miscarriage	Economic recession/ depression
New members in the household	Changes in the workplace
Caregiving	War
Abuse/neglect	Political issues

stress. According to the National Alliance of Caregiving [14], more than half of caregivers in America reported feeling overwhelmed by the amount of care required by an aging or chronically ill family member. Additional life events and stressors can influence a family's ability the cope with a serious or persistent illness. Physicians should view the etiology of family stress from a variety of perspectives and consider its effects on multiple members of the family unit.

Theoretical Frameworks of Stress and Health

Family Systems Theory Framework

For much of the twentieth century, clinical practice of individual symptoms and conditions was largely focused on etiology and considered to be rooted in the psychopathology of the individual. With time, a new systemic paradigm emerged, seeing one's problems as interconnected to other members and relationships in the family system, breaking away from the deterministic, linear, and causal views of individual dysfunction [15]. Bowen [16] further advanced the concept of considering families to be cohesive systems, highlighting the fact that the problems (mental, emotional, or physical) of one individual in a family cannot be understood in isolation from another but rather that the family must be thought of as one emotional unit. Recently, physicians are becoming better informed of the inter-relational and systemic causes of disease and illness, understanding the connections of illness with areas such as family dysfunction, relational stress, mental health issues, parent-child relationships, and spirituality. For families experiencing a member with chronic illness or disability, systems theory not only pertains to the determinants of health within the family system but other relationships with healthcare professionals, insurance providers, and other agencies that may be involved in the patient's care [17].

McDaniel et al. [18] highlighted the following concepts and questions to help physicians apply systems theory into practice with families:

- **The Family as a System: Questions to help identify those in the family.**
  - Who are the members of the patient's family?
  - When it comes to daily support, who does the patient consider as family?
- **Family Stability: Questions to understand the stability of the family.**
  - What does the family do to maintain balance and security for its members?
  - If change occurs too quickly, what will happen to the family's stability?
- **Family Change: Questions to assess the effects of change on the family.**
  - What does the family do to facilitate the needed change?
  - If change does not occur quickly enough, what will happen to the family?
- **The Relational Context of the Symptom: Questions to determine the impact of health concerns on the family.**
  - How do the patient's symptoms influence the family?
  - How does the family influence the patient's symptoms?

Mind-Body-Environment Framework

Antonovsky has been largely credited for being one of the first researchers to explore the physiological response to stress. His work largely focused on the search for health (salutogenesis) rather than pathology (pathogenesis) in individuals enduring situations of extreme trauma. Individuals who have specific dispositions may make individuals more resilient to global stressors on an everyday basis [19]. Antonovsky believed that health, stress, and coping are interrelated factors, and professionals should not focus solely on the factors that cause disease [19]. George Engel [20] gave further attention to biobehavioral health, rejecting the traditional medical model of disease and addressing the importance of exploring the psychosocial dimensions of one's health. According to Engel, areas of one's psychological and social life often have an interchangeable connection to physical health outcomes. The

Telegram: @medical_k

www.konkur.in

boundaries between health and disease, or well and sick, are ambiguous at best. Thus, certain cultural, social, and psychological considerations must be taken into account to define the impact that the stress of illness and disease has on one's life.

Another model of health and stress that has been advanced is the diathesis-stress model [21].

Individuals may be seen to have particular vulnerabilities to stress, given a set of life circumstances both individually and systemically. If the combination of stress and vulnerabilities exceeds a certain threshold, it is more likely that an individual will develop a particular disorder (Fig. 1). The model combines both genetic endowment and environmental factors, along with the reaction to the onset of stressful life events. Certain protective factors (social networks, self-esteem, community) may buffer against the susceptibility to particular stresses that could initiate or exacerbate a given disorder or condition.

These mind-body frameworks are critical for healthcare providers to conceptualize when working with patients and family members. Working from a biopsychosocial model gives physicians an idea of why some individuals view sickness as an "illness," while others may regard these issues as "problems of living." Additionally, physicians can benefit from asking patients and their family members about past stressful events and how they have coped around these events as a unit. Identifying these positive areas of coping around stressful events could provide useful information when establishing treatment goals and in developing suggestions for behavioral and lifestyle changes that patients can make over time.

Health Belief Framework

When individuals make determinations about both short and long term medical decisions, they must often weigh several costs and benefits of their own health. The Health Belief Model theorizes that one's background and personal ideas of their health will impact perceived self-efficacy, which in turn predicts engagement of a certain health behavior [22]. Rooted out of Social Learning Theory [23], the determination of specific health-related actions can be based on sufficient motivation, belief that one will be susceptible to a serious health issues, and the belief that a recommendation would be beneficial to them over time. The model provides a helpful framework of how individual characteristics can influence engagement of certain health behaviors, such as medication adherence, elective surgeries for chronic disease, or vaccinations for influenza.

Developmental Life-Cycle Framework

Families often lack a clear perspective of time when problems or crises occur. Members may be

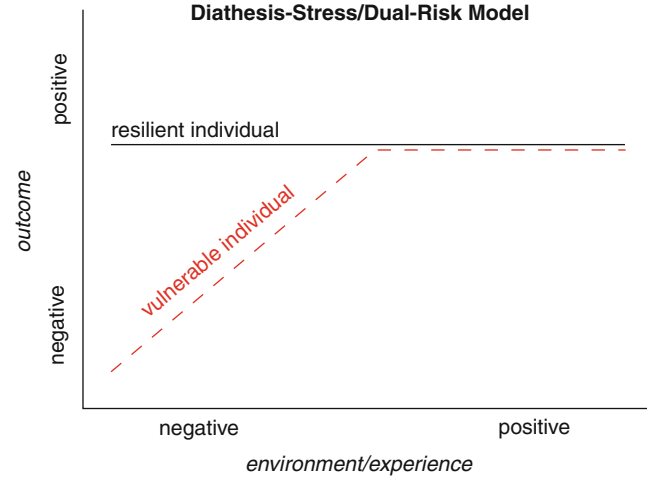

Fig. 1 Diathesis-Stress Model

Telegram: @medical_k

www.konkur.in

stuck in past events, feel immobilized by current situations, or become fearful of possible future events that may occur. From a developmental life cycle framework [24], symptoms and dysfunction in a family system are examined from a systemic perspective. Several stressors have been said to impact the long-term functioning and well-being of members over time. Some stressors derive from family history that is passed down through generations (e.g., secrets, legacies, genetic abilities and disabilities, and religious beliefs and practices). Others are comprised of developmental, unpredictable, and historical events that occur across an individual lifetime (e.g., trauma, chronic illness, accidents, natural disaster, war, and economic circumstances).

Stress may also be transmitted between family members and across generational lines. A family's behavior and response to illness cannot be comprehended apart from its history [25]. A multigenerational assessment of family stress helps to clarify both strengths and vulnerabilities in family members, while identifying "high-risk families" who are often burdened by past unresolved issues. Tracking key events, organizational shifts, and coping strategies around illness can help explain and often predict future coping strategies of the entire system [26].

Having both a developmental and multigenerational lens of patient care broadens the narrative of illness and health-related symptoms across the life span. A useful tool for physicians in the assessment of health and stress in families is the medical genogram (Fig. 2).

Family Response to Crisis Framework

There is wide variation in how families adjust and adapt to a triggering event or crisis. One of the first

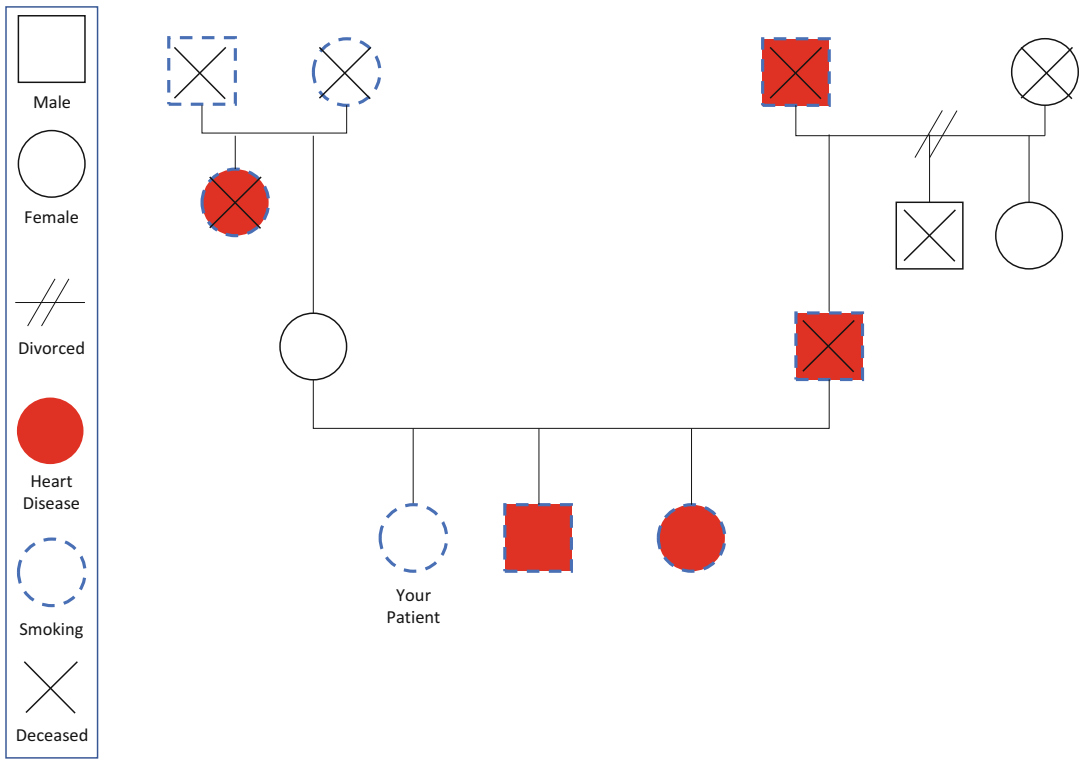

Fig. 2 Medical Genogram: This diagram offers physician a quick way to evaluate health risks, pursue preventative measures or treatment and assess the family history in a more comprehensive and systematic manner. The figure shows how many members of the family have smoked as well as have heart disease. This link could be helpful in further counseling your patient on the importance of quitting smoking

Telegram: @medical_k

www.konkur.in

family stress frameworks to address adjustment and adaptation emerged from Hill's classic work on the family response to war and separation, where he advanced the use of the ABCX family crisis model [27]. Stress is not seen as an inherent characteristic of an event but rather is a function of the family's response to the event and the residual effects over time. Hill hypothesized that when a stressful event or crisis impacts the family unit, the availability of resources and perception of the event will determine the level of stress that the family system will endure. McCubbin and Patterson [28] expanded this model, including a second level of coping and adaptation after a stressor (Fig. 3).

The ABCX model is a useful conceptualization for family physicians when assessing the resources and coping strategies of families after an illness. When families are going through the "crisis period" of an illness, physicians and healthcare professionals can work on normalizing this period of stress and vulnerability in families. This is an important stage that occurs after a patient is diagnosed with a serious or chronic illness and when outside resources and help regarding medical support, medication management, travel, and healthcare access become important factors to consider.

Effects of Stress on Health

Stress can happen inside and outside the family system and it can be normative or nonnormative. The human body is uniquely equipped to handle the demands of an acutely stressful event. The body sets off a series of hormonal responses to prepare the body for action either flight or fight. This response is mediated by the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system (SNS) working together [29]. These acute responses are lifesaving when confronted with a survival situation. In the current modern lifestyle, the need for an acute response to a life-and-death situation is uncommon; nevertheless, when the body perceives stress of any kind, the same systems are activated and the entire body is affected. The response is intended to be short term. When there is no break in the stress or no perceived break in stress, the acute stress response does not resolve. Chronic stress hormone elevation may then result in significant health problems [29].

Acute Stress

The entire body is affected by heightened hormonal and nervous system responses to an acute

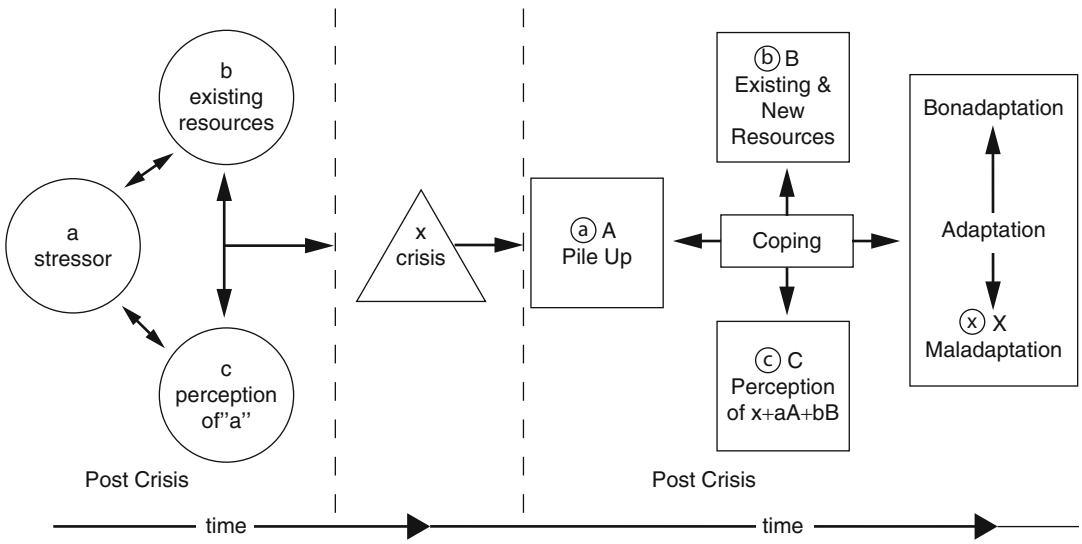

Fig. 3 The Double ABCX Model [28]

Telegram: @medical_k

www.konkur.in

stressful event. The brain and nervous system are significantly impacted. There is an increase in alertness and a sense of anxiety. Short-term memory, concentration, inhibition, and rational thoughts are all suppressed to enhance quick reaction time for the fight-or-flight response. In this state, social and intellectual demands become challenging. The hippocampus is processing long-term memories to discover episodes that might be similar. The brain moves to an increased state of arousal [38]. When activated the adrenals work to release stress hormones. In addition to the hormones that are being produced in the endocrine system, the liver increases blood glucose levels for the energy needed for the fight-or-flight response. The increase state of arousal in the brain results in increase in glucocorticoids as well as norepinephrine. Through the glucocorticoids as well as other neuroendocrine pathways, there is inhibition of the growth hormone pathway, thyroid axis, and reproductive hormones. In the short term, these hormonal changes allow for heightened analgesia, suppression of appetite, and suppression of reproductive axis [29].

The respiratory system responds by increasing respirations to meet the oxygenation demands. This enhances the sense of anxiety and panic that is needed to respond to the flight or fight. The heart and circulation are affected. The heart rate rises and contracts more strongly. Blood pressure rises in response to the acute stress. The blood vessels dilate directed toward large muscles and heart vessels to increase blood flow to those parts of the body that are essential to the fight-or-flight response [29].

As the hormonal and nervous system focuses on the acute needs of the fight-or-flight response, other areas of the body are affected by decreased blood flow. Muscle tension increases as blood supply is diverted to prepare the body for action. The gastrointestinal tract receives less overall blood supply and has a response to the increase in hormones. There is an increase in acid production and sensitivity to heighten hormonal states that can increase epigastric pain and lead to nausea. Lastly in the acute stress state, the reproductive organs are affected. There is decreased blood supply to the genitals [30]. In females, stress hormones interfere with the hormonal regulation of the menstrual cycle. Acute stress can lead to changes in menstrual cycles, menopausal symptoms, and reduced sexual desire.

Once the acute event is resolved, these responses should resolve and return to a resting state. The modern day dilemma is when the perceived acute stress is never resolved, safety is never achieved and the physiologic response changes from an acute state to a chronic exposure to heightened arousal and elevated stress hormone levels. There is growing evidence that these effects exacerbate chronic conditions and may predispose to the development of some chronic conditions such as hypertension or diabetes.

Chronic Stress

The effects of chronic stress can be difficult to study. Studies of the effects of stress can be observed in humans as early as in utero. The effects of chronically elevated cortisol have been observed to result in adverse birth outcomes that include low birth weight, prematurity, and all-cause mortality. In addition, infants born to mothers with elevated cortisol levels also have elevated cortisol, suggesting a lasting effect of stress transferred from mother to child [31].

Chronic stress may have negative effects at any age. A study of post-hip fracture geriatric patients found that those with depression as a marker of chronic stress demonstrated reduced bactericidal functioning of monocytes [32]. There is an increased susceptibility to infections secondary to lower white blood cell counts in response to stress.

Exacerbations of the chronic disease process due to chronic stress are evident in many diseases. Diabetes, for example, is very sensitive to elevated cortisol levels. This leads to insulin resistance and elevated blood sugars [33]. Stress can cause feelings of increased anxiety, which in turn will exacerbate many psychiatric diseases. When left unresolved, stress can lead to chronic anxiety disorders and/or chronic major depression. There is an overall loss of pleasure and accomplishment and the disruption of the serotonin system in the

Telegram: @medical_k

www.konkur.in

brain. Tension headaches, backache, shoulder pain, and chronic pain syndromes can all develop from chronically tense muscles [38].

The increased respiration rate during stress can trigger asthma or COPD exacerbations and worsen respiratory diseases overall. Irritable bowel syndrome has been linked to stress. Those with inflammatory bowel disease can experience increase in flares under stress [30].

Now that we have seen the effects of chronic stress on disease, the question is, can chronic stress cause disease? This is a little harder to make a direct link, but the evidence is growing. In a state of chronic stress, eating habits are affected. When under chronic stress, there is hormonally induced craving for foods high in caloric intact and carbohydrates. Carbohydrate in particular increases tryptophan and can increase serotonin combating the hormonal effects of chronic stress. Chronic exposure to elevated cortisol also boosts abdominal fat and weight gain [29]. There is also a decrease in physical activity after exposure to chronic stress. As depression and anxiety worsen, sleep disorders are exacerbated. Chronic stress may also lead to many negative life choices and leads to an overall increased risk of chronic disease.

Lastly, the evidence that chronic stress has effects on cardiovascular health cannot be ignored. The lifesaving increase in heart rate and blood pressure in an acute stress response loses any benefit when maintained over the long term. It is well established that stress can contribute to the development of atherosclerotic vascular disease, by several mechanisms. There is also evidence to support the possible contribution of an inflammatory response mediated by chronic stress hormones [34]. The coronary arteries are also very sensitive to the stress hormones released during the acute response [29]. The effects go beyond the increase in heart rate and blood pressure. There can be alteration in cardiac rhythms. There is an effect on cholesterol and impaired fat clearance. There is evidence that vessel intima-media thickness increases and there is a release of inflammatory markers into the bloodstream during the stress response (Table 2).

Chronic stress exacerbates many chronic conditions. Chronic stress may lead to negative lifestyle choices that contribute to risk factors for chronic disease. Once acute stress is identified, helping patients manage the acute phase and prevent long-term chronic stress is beneficial to the overall health of all family members.

Counseling Strategies for Patients and Families

By attending to the biopsychosocial framework of health, the patient and family can be helped to minimize the effects of family stress and to

Table 2 The effects of stress by system

System	Acute stress effect	Chronic diseases worsened

develop strategies for coping in the future. Physicians could benefit from utilizing specific counseling skills for psychosocial issues beyond routine screening and assessment at visits. Specific approaches such as behavioral techniques, solution-focused strategies, motivational tools, or educational resources can help both patients and families cope with stress-related issues around illness and health. The following highlight these approaches when working directly with the patient as well as the family system.

Individual Treatment Approaches

Motivational Interviewing

Patients and families are often reluctant to change coping mechanisms in response to stress and crisis management that have been developed over time. When a patient or family member feels "stuck in the situation," it may be due to deficient coping techniques or perhaps their perception of the problem. The ways in which physicians and other professionals can talk with patients and families about health and personal issues can influence their motivation to change certain behaviors. Motivational interviewing (MI) is an effective, evidenced-based approach that delivers these therapeutic benefits to patients, family members, clinicians, and healthcare professionals [34]. MI has been found to have numerous applications to chronic illness and health issues (sexual health, weight loss, medication adherence, diabetes) as well as mental health and family-related issues (depression, OCD, alcohol abuse, anger management, domestic abuse).

Healthcare professionals using motivational interviewing should implement the following key steps [35]:

- Assess the patient and/or family member(s) ambivalence about change
- Recognize change talk when you hear it in conversation (e.g., desire, ability, reasons, need, commitment, taking steps)
- Use open-ended questions and reflective listening skills to get more depth of patients' perspectives
- Meet the patient and/or family member(s) at their stage of change around the particular issue

Solution-Focused Brief Therapy

Pressures of time and schedules often force physicians to have suboptimal encounters with their patients, especially in primary and ambulatory settings. Patients may have limited time to provide in-depth information on their presenting problems and tend to focus solely on complications and symptoms rather than strategies and solutions. Solution-focused brief therapy (SFBT) has become a helpful intervention approach for patients and family members to recognize strengths in order to reduce the intensity of symptoms and identify solutions [36]. Behavioral health professionals and other providers who use this approach ascribe that patients possess the necessary skills needed to improve their lives, but may need help remembering times that they have coped with a particular problem successfully. Solutions are seen as different ways of viewing their lives, that their problems are not to be solved by professionals, but that solutions are mooted and discovered primarily by the patient and/or family [36].

Healthcare professionals using solution-focused brief therapy should implement the following key steps:

- Helping patients and family member(s) recognize the times when stress around the illness, disease, or issue was reduced or did not exist
- Identifying a list of resources and strengths that the family already has available
- Cocreating a treatment plan, where the patient, family, and provider are working together on outlining goals
- Developing small, attainable goals that the patient and family can achieve over time

Cognitive Behavioral Therapy

For some patients, interventions around behavior changes and improved cognitive awareness are warranted to improve health outcomes. Professionals may choose to deliver advice and treatment planning that is more directive and behaviorally oriented in nature. Cognitive behavioral therapy (CBT) is a widely utilized behavioral intervention in medical settings around not just chronic or life-threatening conditions but for self-regulation and stress reduction around mental

Telegram: @medical_k

www.konkur.in

health and family-related stress. Although behavioral approaches can provide effective outcomes for patients and families, this therapy modality has been largely underutilized in primary care. One reason may be the time-limited environments that physicians typically work within [37].

Healthcare professionals using cognitive behavioral therapy should implement the following key steps:

- Support the thoughts, feelings, and emotions of patients and families working through an illness or stressful life event
- Identify certain triggers or barriers that impact negative thoughts and reactions to presenting problems
- Set behavioral goals, where the family can learn to reduce maladaptive behaviors in a time-limited fashion

Mindfulness Based Stress Reduction

When stressful triggers or life events arise, patients need to attend not only to their cognitions and thoughts but also physical symptoms throughout their body. Physicians can reduce the patient's stress or worry of future events and situations but using interventions of awareness and attunement to focus on the "here and now." Mindfulness work is an effective process where one's awareness is on the present moment, paying close attention to the thoughts, feelings, bodily state, and environment around them [38]. In patient and family care visits, this intervention is about teaching individuals how to respond to stressful events more reflectively instead of reflexively. Mindfulness-based stress reduction (MBSR) has integrated meditation work into psychological and family-related issues with patients. Originally, MBSR was a group-based program that helped patients suffering from severe chronic pain and stress-related symptoms, but can be utilized by individuals.

Healthcare professionals using mindfulness should teach patients the following key steps [39]:

- *Body scan*: gradual attention throughout the entire body, focusing on sensations through body regions with periodic breath awareness and relaxation strategies
- *Sitting meditation*: mindful attention of breathing and a state of nonjudgmental awareness of cognitions and thoughts
- *Yoga practice*: breathing exercises, simple stretches, and posture work that is intended to strengthen and relax muscles

Family Treatment Approaches

Family Psychoeducation

Low levels of health literacy can lead to increase individual and family stress. Misunderstanding and miscommunication of health-related information also add to the stress of patients and families dealing with health concerns. Psychoeducational interventions can help educate patients, family members, and caregivers about the specifics of an illness or condition, as well as what areas the family can help provide additional care. This information offers families additional resources to cope around a particular crisis event or diagnosis and provides general problem-solving skills. Particular guidelines [40] can be delivered around illness management, medical adherence, and assistance with daily issues, and expansion of the patient/family member's social network is emphasized. Many psychoeducational interventions given to patients, family members, and other caregiver individuals are not delivered by behavioral health professionals [40].

Healthcare professionals using psychoeducation should implement the following key steps:

- Ask the patient and/or family member(s) what they know about the issue and what professionals have discussed the issue with them
- Deliver basic information in clear and understandable terms for everyone to understand
- Allow for the family to ask follow-up questions or clarify any unfamiliar words, terminology, or medical jargon
- Provide literacy-appropriate health education materials

Intergenerational Approach

Stress in families can be transmitted through multiple generations, where individual family

Telegram: @medical_k

www.konkur.in

members have been unable to cope with life events. Bowen's theory [25] was a way to observe the emotional unit of a family, observing these systems on a continuum, ranging from extremely impaired to high functioning. When anxiety and stress occur in a family system, members will adjust the amount of dependence they have on each other to attempt to resolve the given crisis or situation. This therapeutic approach looks at the family system beyond just symptom reduction, exploring how the family will be able to function in a more healthy fashion around a stressful event such as illness or disability.

Healthcare professionals using an intergenerational approach should include:

- **Level of differentiation in family members**: Members with a well-differentiated "self" can stay calm and clear headed in the face of anxiety and stress. Poorly differentiated members have to rely heavily on these members during times of crisis.
- **Triangulation**: A triangle is a three-person relationship system and the smallest stable relationship system. During times of stress or crisis, two members may pull a third person into their subsystem to resolve a conflict or to mediate tension.
- **Family projection process**: This describes the primary way that parents transmit their emotional turmoil and feelings onto their child. This process can impair the functioning of multiple children and cause onset of clinical symptoms.
- **Emotional cut-off**: This concept describes how individuals manage their unresolved emotional issues with parents, siblings, or family members by completely cutting off ties with the person or group.

Group Treatment Approaches

Dialectical Behavioral Therapy

Patients who have more significant mood or personality disorders often need techniques on how to regulate their emotions more effectively. Dialectical Behavioral Therapy (DBT) is an evidenced-based approach to help individuals increase their emotional and cognitive regulation by learning how to cope with reactive states. DBT has been implemented in several clinical sites where both adults and teens can benefit from a group approach to emotional regulation [41]. Participants in DBT groups practice four domain areas: mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness. Group sessions normally meet once per week to help learn specific skills and apply them around the four domains.

Psychodynamic Group Therapy

Often, patients with similar diagnoses need to have a space to share their inner thoughts and experiences of their condition with others. Those who may be suffering with a similar diagnose such as depression, attention deficit hyperactivity disorder, or bi-polar disorder often benefit from psychodynamic group therapy [42]. The group is led by one or two mental health professionals, where the facilitators help group members learn about some of the dysfunctional patterns of the condition they're experiencing. Each group member takes the role of a mental health healer to their peers, where the group learns about unhealthy patterns of behavior through talk therapy.

Psychoeducational Groups for Families

Psychoeducation is an effective way to inform patients and family members about a particular issue or concern in a clinical setting. Groups offer a combination of cognitive techniques and information so that members will derive considerable growth and understanding of coping with this illness or condition [43]. These groups are led by an experienced therapist who is goal-directed and structured in their technique. Group members take the role of learners around a number of conditions such as depression, diabetes, cancer, or anorexia.

Caregiver Well-Being

Providing care to a loved one often has significant impact on one's life. Between 20 and 44% of caregivers say that providing care is financially, physically, and emotionally difficult on a regular

www.konkur.in

Table 3 Therapist Types. There are several categories and types of therapist. This list presents a summary of the most common [47]

Category	Therapist type	Description
Psychologist		Doctoral degree in psychology, counseling, or education
	Clinical and counseling psychologist	
	Licensed school psychologist	
Social Worker		Master's degree in social work
	Licensed clinical social worker	
	Licensed social worker	
	Licensed independent social worker	
	Academy of certified social worker	
Therapist or Counselor		Masters-level degree in psychology, counseling, marriage, or family therapy
	Licensed professional counselor	
	Creative arts therapist	
	Marriage and family therapists	
	Medical family therapist	
	Licensed clinical alcohol and drug abuse counselor	

basis [44]. Both family and professional caregivers make large sacrifices for loved ones with long-term chronic health condition. With caregiver burnout becoming a public health crisis [45], healthcare providers are often challenged to find resources to help offset the work demands of these individuals. Primary care providers should continue to check-in with caregivers during routine appointments with patients in practice.

Healthcare Team Approach

The physician is situated in a system of care that, when used, can greatly facilitate the care of conditions affecting the health of the patient. Integrative care, a key component of the patient-centered medical home, affords the physician access to expanded resources for assisting patients. Physicians who utilize healthcare professionals in their team can coordinate more effective services and care for patients and families [46]. In the area of coping with family stress, utilizing this team approach can offer additional resources to the patient and their family. There are many options for patients when working with a team. Below is a list of the most common therapist types available and brief descriptions from National Alliance of Mental Illness (Table 3) [47]. Each state has specific licensing requirements for therapists. Please see individual state licensing boards for requirements.

Introduction

What Is Population Health?

The term "population health" is often attributed to David Kindig and Greg Stoddard, who defined it in 2003 as *"the health outcome of a group of individuals, including the distribution of such outcomes within the group."* Since then, definitions have expanded beyond a narrow focus on outcomes. Many definitions now connect health status and health outcomes to better healthcare and chronic disease management. Additionally, population health has also come to mean promoting health behavior change and addressing social determinants of health. Public Health and population health are closely linked but different. The

Centers for Disease Control and Prevention (CDC) makes a distinction between public health and population health, noting public health's emphasis on primary prevention and infectious disease control. This is in contrast with population health, for which they quote George Washington University's Milken Institute – population health provides *"an opportunity for health care systems, agencies and organizations to work together in order to improve the health outcomes of the communities they serve* [1]." Public health focuses on ensuring conditions in which people can be healthy. Population health focuses on health outcomes and the determinants that influence those outcomes [2].

In practical terms, population health is the discipline of working to improve the health of groups of people rather than just individual patients. It takes different forms depending on the target population and the Family Physician's role. A state or county public health director is focused on prevention and other interventions to improve health outcomes across the entire population of a geographic area or jurisdiction. The discipline of community health focuses on neighborhoods or small communities, sometimes focusing on specific high-disparity populations. The managed care medical director may work through provider networks to influence health outcomes of hundreds of thousands of covered lives, while physicians in an Accountable Care Organization (ACO) may share financial risk for the health outcomes of thousands of patients attributed to their practice. At the individual Family Physician level, there is a panel of patients (often multiple panels connected to different payers) whose outcomes require intentional, team-based care management. However, population health from the Family Physician's perspective must take into consideration that which occurs beyond the four Walls of the office space, such as the influence of social, economic, political, and physical environments that affect the health of their patients and families [3].

Why Population Health?

US healthcare in the twenty-first century underperforms relative to the health systems of many other nations. Our costs are higher and our outcomes are worse. Meanwhile, there is increasing consumer demand for a better patient experience. In 2006, the Institute of Medicine's *Crossing the Quality Chasm* report presented six Aims for Improvement, calling for care that is safe, effective, patient-centered, timely, efficient, and equitable.

In 2006, John Whittington and Tom Nolan at the Institute for Healthcare Improvement (IHI) encouraged the move beyond care delivery to focus on outcomes, framed as the Triple Aim – (1) better health outcomes at (2) lower overall cost with (3) a higher quality of care defined from the patient's perspective, that is, a better experience of care for each patient. The Triple Aim concept was eventually woven into the Medicare program and into our national consciousness. In 2014, the Triple Aim was expanded to the Quadruple aim [4], adding wellness of the health care workforce and *"the joy of practice"* as an essential foundation for delivering high quality health care.

Taking these concepts to scale meant reorganizing practices and healthcare systems in order to demonstrate improvements across large groups of patients (practice panels and payer populations). It also meant changing the way providers would be paid, using all the financial force of the US Medicare program to actively promote a shift away from the volume-based, fee-for-service model to value-based models. CMS began promoting value-based models which would reward reductions in hospital admissions (starting with readmissions), emergency visits, and overall cost of care. Other health insurers and large self-insured corporations quickly followed suit. This also importantly meant that the wellness of the health care provider had to be incorporated into models of care that allowed for better efficiency of provider time, use of the electronic health record, tools to assist in quality delivery, promotion of resilience, and attentiveness to work-life balance.

Population Medicine

Individual Providers and Practices

At the level of the individual provider or practice group, the patient panel can be considered your "population" with regard to clinical outcomes and

Telegram: @medical_k

www.konkur.in

costs. For this reason, empanelment is a core element of population medicine at the primary care level. Empanelment is the act of assigning each patient to a primary care provider or team. Empanelment has the dual purpose of assigning responsibility between patient and a specific provider or team, but also establishing a denominator for measuring rates for quality, utilization, and outcome indicators. Effective care teams establish a long term provider-patient bond, continuity of care, and optimal, personalized care, in order to improve management and outcomes of chronic conditions, as well as providing evidence-based preventive care. Payers see this as a path to reducing costs by eliminating duplication of services and managing medical problems in the most appropriate setting. Physicians must know and track their panel size, keeping up with growth, attrition, and risk level, in order to assure that they have the resources necessary to meet the needs of their panel.

Defining the panel starts with identifying patients who have been seen in the practice within a certain time frame, such as within the past two years. The process is then refined with various inclusion or exclusion criteria. The spouse of a patient may identify him/herself as a patient of the practice, even if they have never had a visit, and the practice may choose to include them in their panel if so attributed by the payer. On the other hand, a practice may not want to include in their panel a patient who, for example, was seen once for a sprained ankle, missed several scheduled follow-up appointments, and has no intention of returning to the practice.

Defining the denominator population is essential for calculating outcomes such as hospitalization rates, emergency visit rates, and cost of care per thousand patients (often referred to by insurers as per thousand covered lives). Defining this population is also essential for building a pool for risk stratification and for monitoring outcomes and addressing needs of patients whether or not they choose to come for an office visit.

The team also must establish metrics of performance for managing their panel. Health care providers often prefer quality metrics over which they have a higher-level of control, such as the rate of performing in-office preventive services (e.g., Pap smears and flu shots). However, as the measures move from process to intermediate outcomes, such as rates of blood pressure or glycemic control, clinicians very quickly observe that they are being held accountable for metrics over which they only have partial control. While clinical inertia and the failure to intensify antihypertensive or diabetic regimens may trace back to clinician behaviors, patients are ultimately responsible for their own medication adherence, diet, and exercise. The responsibility and locus of control may shift even further from provider to patient when we consider utilization-based outcomes, such as hospital admissions, bed-days, re-admissions, emergency visits, and total health care costs per patient. Still, in a world of value-not-volume reimbursement, the clinician is responsible, if not financially at-risk, for managing these very outcomes. So, a core concept of outcomes-driven, panel-based care management is that while we cannot *control* patient behaviors or outcomes, we can *influence* those behaviors and outcomes. And while we cannot guarantee a good clinical outcome or lower costs for every individual patient, we can achieve predictably better results on group outcomes spread over a large enough panel of patients.

Chronic disease care management is another core element of the practice of population medicine, influenced strongly by Wagner's chronic care model (Fig. 1).

The foundation of the chronic care model is the dyad of an informed, activated patient and a prepared practice team. The model includes six functional elements: (1) self-management support, (2) delivery system design, (3) decision support, (4) clinical information systems, (5) organization of health care, and (6) community resources and policies [5].

Early iterations of care management were focused on single diseases rather than whole patients and started with disease registries. The paradigm of disease management shifted fairly rapidly to population health management when it became obvious that most patients did not have just one disease at a time. Patients in the diabetes registry often overlapped with those in the hypertension/cardiovascular disease registry, who also overlapped with those in the depression registry.

Telegram: @medical_k

www.konkur.in

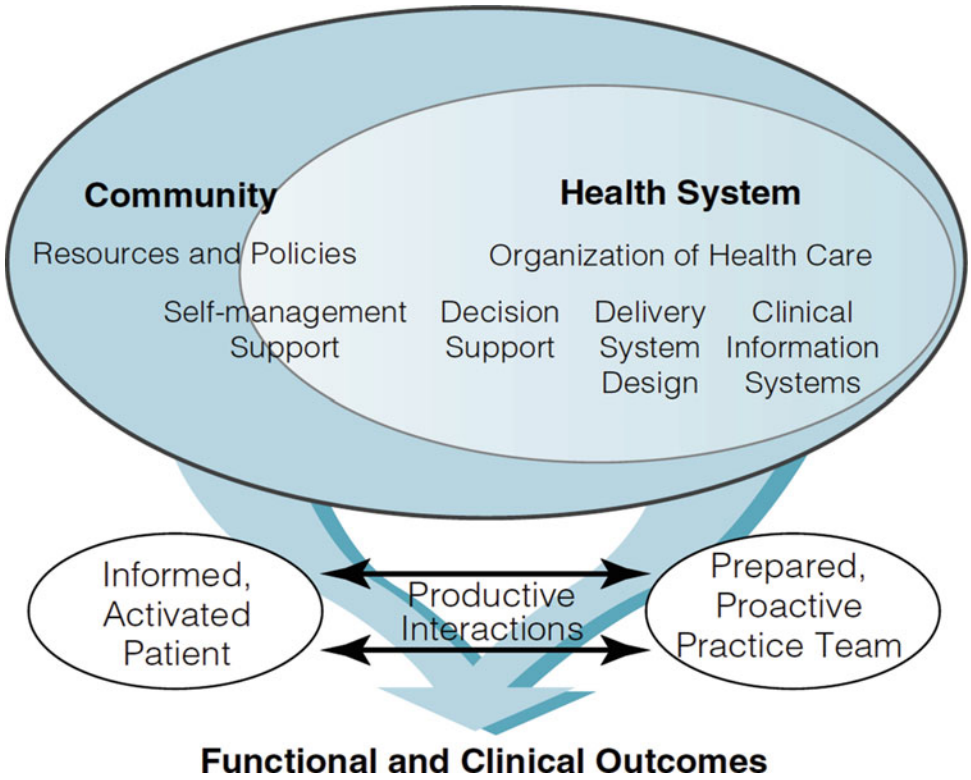

Fig. 1 Wagner [5]. (Used with permission)

In fact, the patients with multiple co-morbidities or multimorbidity turned out to be the patients who most needed to receive the on-going monitoring, care coordination, health education, patient navigation, medication reconciliation, and frequent follow-up contact that could improve clinical outcomes. Thus, disease management rapidly turned into care management at the practice level and into risk-stratified population health management at the levels of health systems and payers.

The core activities of patient empanelment and monitoring clinical metrics and care management are dependent on effectively using an electronic health record not just as a record of day-to-day patient care, but as a relational database that can be queried and produce actionable information in the care of individual patients as well as aggregate reporting on all patients or on subsets of the panel. This was the goal of the 2009 Health Information Technology for Economic and Clinical Health Act (HITECH Act) that mandated and incentivized adoption of electronic health records and established milestones of meaningful use. Querying the EHR data, producing aggregate reports, and creating real-time dashboards that track progress on clinical outcomes for the panel are additional competencies that will be required of every value-based primary care practice [6]. The key is to produce actionable information, to which the practice team can respond both for individual patients and for overall practice performance on panel-based outcomes. This requires dynamic interventions and the rapid-cycle feedback loops known in quality improvement circles as PDSA-cycles (plan-do-study-act).

In this century, primary care panel-based care management which is outcome driven is a team sport. Medical assistants are now engaging in expanded roles, including scribing and algorithm-driven preventive services. Registered nurses engage patients directly in care

Telegram: @medical_k

www.konkur.in

management, health coaching, and health system navigation. Psychologists, social workers, and licensed counselors can add capacity for full behavioral health integration in the practice. Peer counselors are increasingly recognized as having a powerful position on the healthcare team, with neighbor helping neighbor to achieve positive health behavior change and effective self-management. In multicultural settings, these may also be defined as community health workers or *promotoras*.

Some payers have begun specifically paying or rewarding primary care practices for "transforming" into patient-centered medical homes (PCMH). The concept of PCMH very much aligns with the principles of Population Health management. For more detail, please see ► Chap. 134, "Patient-Centered Medical Home".

All of these elements of population health management at the local practice level have been incorporated by Grumbach, Bodenheimer, and others into the comprehensive approach broadly described as *practice transformation*. The core building blocks of practice transformation are shown in Fig. 2 [7].

Population medicine becomes an essential part of a family physician's practice when the business model shifts from a fee-for-service practice to capitated or other value-based contracts. Simple primary care capitation fees pay the physician/practice a recurring payment per member per month (PMPM), regardless of whether or not the patient has a visit or receives other services. The practice takes on some financial risk in the sense that the cost of patient care in the practice must be covered by the monthly capitated revenue, but also gains tremendous freedom in building their team model to best focus on patient outcomes, rather than generating patient volumes. Care that can be managed by phone(telemedicine) or in group visits, for example, no longer requires that a billable service be provided in order to generate revenues.

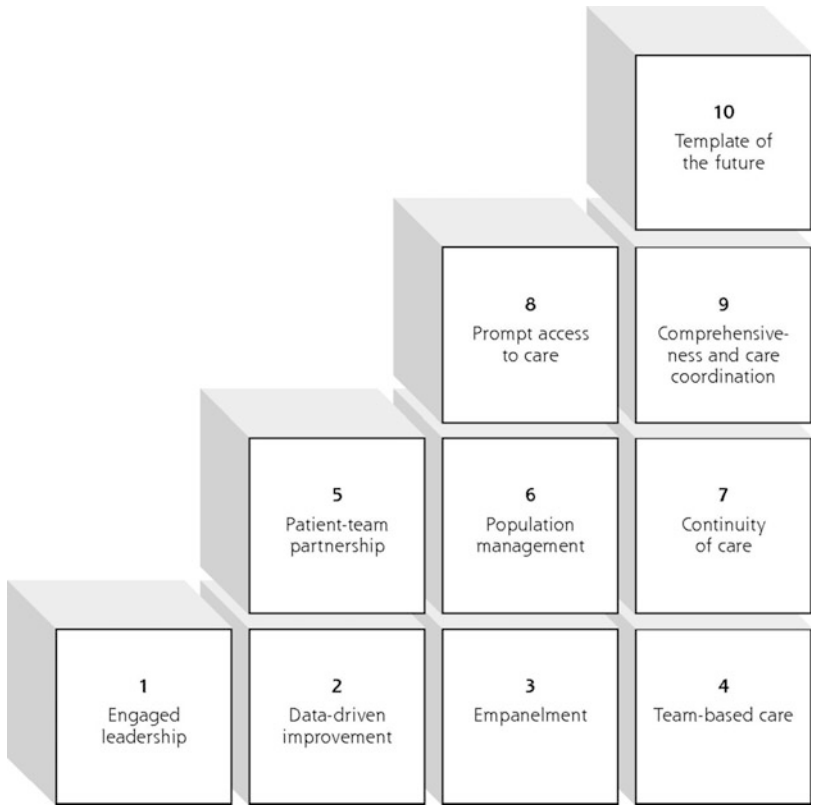

Fig. 2 Chronic Care Model, Brumbach, and Bodenheimer. The core building blocks of practice transformation. Bodenheimer et al. [7]. (Used with permission)

Telegram: @medical_k

www.konkur.in

This re-defines the business model of primary care and requires the primary care practice to know their own costs per empaneled patient rather than just knowing their own charges and collections minus costs per visit. In a sense, negotiating value-based payor contracts means that the practitioner must understand what drives the payer's costs and where the potential savings might come from improving patient outcomes.

Engaging in population medicine can have broad benefits for an entire patient panel and community. Increasing influenza vaccination rates in the practice through standing orders and patient reminders can decrease adverse clinical outcomes and increase "community immunity." At the same time, engaging in population medicine as a business model for primary care practice quickly draws attention to the 80–20 rule, that is, 20% of patients may generate up to 80% of the hospital bed-days and total cost of care. For this reason, payers engaged in population health management will use sophisticated "predictive analytics" to identify which patients are likely to be their high-cost high-utilizers and may seek to engage the primary care practitioner in more intensive care management of these patients. Patients risk-stratified as potentially high-utilizers may require "high touch" strategies to assure their healthcare needs are being met, even if they do not choose to come in for regular visits. Such patients may require various engagement or support strategies, such as emails, texts, or phone calls, weekly telehealth encounters, care navigation, home health services, mental health support, or even social work assistance with housing or transportation issues.

Population Health Management

Health Systems, Provider Networks, and Accountable Care Organizations

The continuum of population health blurs the boundaries between payers, networks, and providers. Increasingly, health care networks and hospital-based health systems engage in value-based care models, which create a distinctly different business model and care model than fee-for-service medicine. One example of population health management at the health system level is the Southcentral Foundation, an Alaska Native-owned, nonprofit health care organization. It emphasizes family-centered, relationship-based care for customer-owners who are at the center of all healthcare decision-making. They practice integrated behavioral and primary care in healthcare teams that also include culturally relevant native healers. The Southcentral system has demonstrated a rigorous ability to focus on outcomes and process measures in continuous data feedback loops to achieve transformational outcomes. A 40% drop in ER visits and a 36% drop in hospital stays represent not only less human suffering events, but also a strong impact on economic cost trends.

Hospital health systems and their network of affiliate physicians may now coalesce into accountable care organizations (ACOs), one form of what CMS refers to as advanced payment models. ACOs accept payments and enter into financial risk sharing agreements, initially with Medicare but often expanding into similar arrangements with Medicaid or with commercial payers. The formation of an ACO demands additional capacities including more sophisticated data management capabilities for feeding back outcomes such as emergency department visits to provider care management teams in real-time, alongside population health data management techniques including defining the denominator population (*attribution*), defining clinical and financial outcome metrics, understanding the utilization and cost variables that drive financial outcomes. Data are also needed on clinical risk factors and comorbidity profiles that drive adverse clinical outcomes (*predictive analytics*), and matching "touch levels" of how often and how frequently the practice calls, visits, or communicates with patients to their level of risk for adverse clinical outcomes, high utilization, and costs.

Predictive analytics not only allow for actuarial projections of utilization and financial risk, but also help to define risk stratification tiers and potentially preventable adverse outcomes. The aim is to determine the financial impact and

Telegram: @medical_k

www.konkur.in

resource utilization that a patient will have on the system.

There are a plethora of risk adjustment models that exist for this purpose [8]. In one study that compared the Acute Physiology and Chronic Health Evaluation, Sequential Organ Failure Assessment score, Charlson co-morbidity index, Model for End-Stage Liver Disease score and Simplified Acute Physiology Score (SAPS), SAPS appeared to perform best for predicting short term mortality. Otherwise, all of the methods seemed to perform similarly [9]. However, comorbidity scores created (and validated) for predicting in-hospital mortality are giving way to often-proprietary risk-scoring tools validated for predicting risk of hospitalization and/or total cost of care, such as the Ambulatory Care Grouper (ACG). Schneeweiss compared six approaches based on demographic and comorbidity profiles to find distinct differences in their accuracy regarding predicting utilization, and each of these methods was enhanced by adding data on numbers of prescribed medications [10].

To some extent, however, managing population health outcomes even at the ACO or health system level still depends on the power of the Family Physician and patient dyad, as well as the primary care team's effectiveness in helping its panel of patients to achieve optimal health outcomes. Combining this front-line connectedness with rapid-cycle data feedback loops that provide real-time information on patient utilization (emergency department visits, failure to refill needed medications, polypharmacy from seeing multiple providers, etc.) can enhance even further the effectiveness of the primary care team.

Population Health

Community Health and Social Determinants

Beyond population medicine or population health management, that is, the effort to manage healthcare delivery and health outcomes for groups of identified patients, is the broader notion of population health. While in population medicine or population health management, the population is typically defined by insurance payer source, health system, medical provider, or sometimes disease state (e.g., mental health carve-outs) [11], community health typically defines its population by geography (e.g., neighborhood or zip code) or by jurisdiction (parish or county) or by a vulnerable subset of a local population (e.g., homeless, migrant farmworkers) or by high-disparity racial sub-groups (e.g., the black or African American community). In the 1940s, two family physicians (Drs. Emily and Sidney Kark) began developing the conceptual framework of Community-Oriented Primary Care in partnership with communities, establishing more than 40 community health centers across South Africa. They describe their model in terms of "community medicine and primary health care as a unified practice," using the primary care practice as a base of operations, but focusing outward on the identification of community needs and the development of potential interventions in partnership with the community, followed by the implementation of interventions and re-assessment of targeted outcomes to dynamically improve the intervention with each iteration (Fig. 3) [12].

Ultimately, we seek to move beyond measuring disease-specific morbidity and mortality and to more generally assess the *health* of the community.

Population health cannot be assessed and fully addressed without taking into consideration the drivers and determinants of health outcomes, social determinants of health and health equity. Williams and others have framed this by saying that *"your zip code is more important than your genetic code in determining health outcomes."* The determinants of health are the conditions in which people live, work, move, breathe, and play that influence overall health. Environment significantly contributes to each individual's health not just at one moment in time, but in all places (whether physical, mental, emotional, social, spiritual, financial, or intellectual) with which one interacts in their socioeconomic and cultural contexts over time.

Many factors impact the health of populations over the course of life. Factors at the individual,

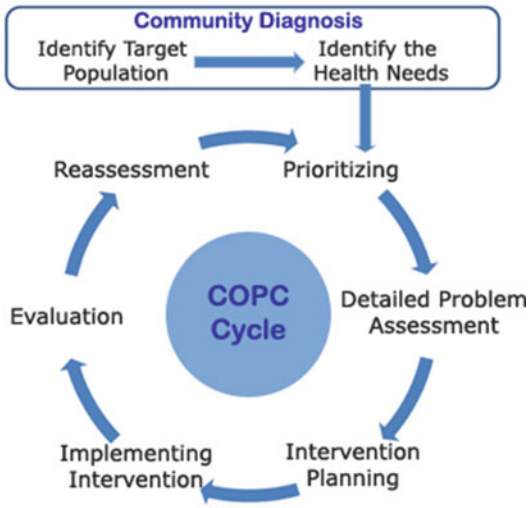

Fig. 3 Community-oriented primary care Model. Integrating Primary Care and Public Health: Learning for the Community-oriented Primary Care Model [12]. (The figure derived from the original version published in 2003 was created by Dr. Joo et al. at Columbia university. Primary Care Online Resources and Education. Prevention – Community Oriented Primary Care [Internet]. Columbia NY: Columbia University [cited 2020 July 11]. Available from: PCORE website. Used with permission)

family, community, systems, and policy level create environments that promote healthy lifestyles and facilitate access to nutritious food, clean water, clean air; primary care including preventive services and behavioral health; quality education from early childhood; good jobs with fair pay; and minimize toxic stress, discrimination, and racism. The opposite is quite true – that if someone is exposed to unhealthy living spaces, stressors early on and over time, that individual is more likely to carry a substantial allostatic load that is associated with endovascular and neurohormonal pathology. They may also be more likely to engage in health risk behaviors, and experience poor health choices early in life with subsequent increased risk of chronic diseases, mental health problems, and premature death [13].

Family physicians recognize that health as not merely the absence of disease, but as wholeness in multiple domains, such that people and communities have the opportunity to live well and thrive. The practice of population medicine and population health calls us to return to a commitment to treating patients in the context of family and community.

The complex causation of health behaviors, health disparities, and adverse health outcomes at the community level requires multidimensional interventions to achieve even simple outcomes. For example, improving rates of initiation of breastfeeding in a community might start with creating a culture of normalization and encouragement of breastfeeding in the workplace and other public areas, offering private areas to breastfeed that are well publicized and accessible, and providing an area to pump and store milk in the workplace. Family physicians can be leaders in incorporating these elements into their practices, while also offering brief breastfeeding education to every pregnant patient at each prenatal visit. At a community level, breastfeeding coaches can be trained and supported, faith communities can provide both messaging and social support, and media (both traditional and social media) can be engaged in broader public campaigns.

To be effective in achieving collective impact requires a re-thinking of our practice role, as well as a new understanding of our communities. Too often, high-disparity neighborhoods have been characterized by deficits or needs-assessments, including degrading terms such as poverty, deprivation-index, or broken-windows index. Community health development models such as asset-based community development (ABCD) require a balanced approach that also sees the strengths and resiliency of communities and works to inventory and build on their resources and assets. This is not work that can be done at a distance. It is foundationally built on trust-based relationships with members of the community who also have trust-based relationships with other members of the community. The person who claims to be a community leader may not indeed "speak for the community." Only relational trust developed over years will be effective across the diversity and within-group heterogeneity that is characteristic of community populations.

Community health centers (CHCs), migrant health centers, and federally qualified health centers (FQHCs) are community-led organizations

Telegram: @medical_k

www.konkur.in

which receive federal grant funding from the Health Resources and Services Administration (DHHS/HRSA). While many serve primarily as a comprehensive, culturally relevant healthcare delivery system for uninsured and underserved patient populations, their origins were in community health development for the purpose of transforming the health of communities themselves.

Public Health

Public health can be defined broadly as all the "public, private, and voluntary **entities**" working together to achieve health of the public in a geographically (or jurisdictionally) defined population. The dependence on an interconnected web of agencies and stakeholders is illustrated in Fig. 4 [14].

However, a subset of public health is a set of highly structured activities conducted through formally defined agencies at various levels from county or parish health departments and state health departments, which are in turn connected with federal activities such as the Centers for Disease Control and Prevention.

While these agencies may differ substantially from one community to another in structure and in the extent to which they provide direct services (versus "assuring" that services are being offered in the community), their role has been summarized in these ten essential functions of public health (Fig. 5) [14].

Some health departments offer primary care, although less so in recent years. More often, direct patient care may be provided in categorical services, tied to specific lines of state or federal funding. These might include family planning and immunization programs, for example.

Public health departments also have a specific focus on communicable diseases – treating and tracking individuals with some historically high-impact infectious diseases such as tuberculosis and syphilis to protect the public. When new conditions emerge, as did HIV/AIDS in the 1980s, or COVID-19 in 2020, public health agencies are on the front lines of identifying cases, surveilling for outbreaks, tracing contacts, and

www.konkur.in

Fig. 5 The 10 Essential Public Health Services. Centers for Disease Control [14]. (Used with permission)

even enforcing isolation for infected patients or quarantine for those exposed.

Public health may be contrasted with population health management by its focus on primary prevention, in areas such as encouraging healthy lifestyle, diet, and exercise. They may specifically engage in obesity prevention, tobacco programs, HIV prevention, and community health education. Public health may also focus on key health status indicators, such as infant mortality, and may direct specific attention to disparities in outcomes. The black-white infant mortality gap, for example, can be measured for public awareness and the development and assessment of interventions by broader community coalitions. This primary prevention focus contrasts with managed care population medicine, which tends to focus on secondary and tertiary prevention for persons with significant health issues and multimorbidity.

Health Policy

It is easy to see the direct connection between the health of the US population and health policy interventions such as the Affordable Care Act (ACA), or the state-level decisions to expand (or not expand) Medicaid coverage to all persons with incomes below 138% of the federal poverty level. Not only did the ACA expand affordable

Telegram: @medical_k

www.konkur.in

health insurance coverage to millions of Americans, it expanded on previous legislation such as the Mental Health Parity Act of 1996 (MHPA), which provided that large group health plans could not impose limits on mental health benefits any greater than those imposed on medical/surgical benefits. This was further extended by the Mental Health Parity and Addiction Equity Act of 2008 (MHPAEA) to cover substance abuse treatment parity.

In the prevention realm, initiatives such as the Vaccines for Children program have an obvious connection to health, but safety legislation such as the 1966 National Traffic and Motor Vehicle Safety Act and the related Highway Safety Act have also had a major health impact, reducing automobile-related fatality rates (which by 1965 had become the leading cause of death for adults under age 40) by over 50%.

Further, our increasing awareness of the social determinants of health leads to a much broader understanding of how policy and legislation can drive health outcomes. Both state and federal policies related to crime and the "war on drugs" led to mass incarceration, disproportionately affecting persons of color despite relative equality in actual use of drugs across racial-ethnic groups. Having a prison record dramatically affects employability and long-term economic opportunities, which are directly tied to a person's opportunity to achieve and maintain optimal health. Homelessness has a profound effect on health, leading some communities to adopt a "housing first" approach to helping the homeless and others to seek larger-scale solutions to affordable housing.

Structural, institutional racism affects individuals in such diverse ways as harsh inequality of public schools across racially defined neighborhoods, which often followed from residential segregation and the redlining of neighborhoods, which is tied to the profound racial wealth gap that far exceeds the more well-publicized problem of income inequality. Examples abound –neighborhoods of color are often centered in food deserts, and food insecurity is closely associated with long-term obesity. Toxic waste sites are geographically situated in low-income communities, as are point sources of industrial air pollution, giving rise to an entire field of advocacy known as environmental justice.

At local and state levels, this understanding has led to a demand for "health in all" policies, starting with a requirement that health impact assessments be undertaken for any new development or project, whether a new highway or new business construction, or new crime legislation. A health-in-all approach to the effects of incarceration as a societal means for addressing issues of substance abuse or mental illness might lead to more aggressive efforts at diversion such as mental health courts or drug courts, as well as an increased devotion of resources to child mental health services as an alternative to the juvenile justice system.

Family Physicians often have the ideal combination of training, knowledge, experience, and front-line observations to be effective advocates for "health-in-all" policies in their own community, as well as at the state and national levels. Discipline is required to advocate for and with members of our community on behalf of our patients, rather than on behalf of our profession.

Even as this chapter is being written, a worldwide pandemic of the novel Coronavirus designated as COVID-19 is overwhelming healthcare delivery systems and dramatically impacting population health outcomes (morbidity and mortality) across the United States and across the world. In this moment, we begin to understand that the health of all people in our nation and in our world is *our* health. We are all interconnected. Individual health outcomes not only add up to aggregated population health indicators, but population health factors can affect our own individual health.

Strategies to Improve Adherence to Prevention Guidance 91
Special Considerations in Underserved Populations 92
Special Considerations in Teaching Practices 92

References 93

Traditionally, there are three tiers of clinical prevention: (a) primary, before disease onset; (b) secondary, after disease onset but before clinical signs or symptoms; and (c) tertiary, after clinical signs and/or symptoms. Examples include immunization (primary), screening (secondary), and post-diagnostic patient education (tertiary, e.g., teaching patients with pedal peripheral neuropathy to check bathwater temperatures with their arms).

Healthy People 2020 Leading Health Indicators

The Healthy People program, led by the US Centers for Disease Control and Prevention (CDC), provides a national blueprint for health that identifies 26 objectives to communicate high-priority issues, four of which apply directly to clinical prevention. Improvement has been mixed: colorectal cancer screening increased from to 59% in 2010 to 65% in 2018, with a target of 71% by 2020 [1], and for childhood immunization, the percentage of children receiving recommended doses of DtaP, polio, MMR, HiB, hepatitis, varicella, and PCV vaccines by ages 19–35 months increased from 68% in 2012 to 70% in 2017 with a target of 80% by 2020 [2]. However, the percentage of adults with hypertension whose blood pressure is under control decreased from 49% in 2009–2012 to 48% in 2013–2016, with a target of 61% by 2020 [3], and diabetes control decreased from 21% in 2008–2012 to 19% in 2013–2016 [4]. More encouraging, 47% of adults ages 50–64 and 68% of adults 65 and older received influenza immunizations in 2018–2019 an increase of 7.1% and 8.5%, respectively, as compared to 2017–2018 [5].

Screening Evidence in Clinical Prevention

Screening is the most prominent example of secondary prevention. In general, screening is appropriate when the following conditions are met: (a) the disease must affect a sizable portion of the population and/or have a high level of severity; (b) the detectable preclinical phase of the disease cannot be so short as to require rapid re-screening since this can become overwhelming in terms of logistics and/or cost; (c) early detection must lead to either a better outcome for the individual being screened or effective prevention of the spread of the disease to others, and these benefits must be more likely when the disease is detected before signs or symptoms appear; and (d) the screening test itself must be safe, acceptable to those targeted for screening, and valid (i.e., sufficiently capable of truly distinguishing between those with and without the disease) [6]. Further, when evaluating a screening program, several types of bias must be avoided. These include lead time bias (e.g., crediting early detection with improved survival when all that has happened is earlier detection); prognostic selection bias (people who choose to be screened may be more likely to take care of themselves and therefore to have a better clinical course than those who do not choose to be screened); and length bias (deaths due to more aggressive disease may occur during the inter-screening interval, meaning that disease detected at screening is less severe) [7]. Randomized, controlled trials are ways to overcome such bias [7].

A number of measurements are available for assessing screening tests. An example is shown in Fig. 1 (a), screening test positive and disease present (true positives), 300; (b), screening test positive and disease absent (false positives), 100;

Telegram: @medical_k

www.konkur.in

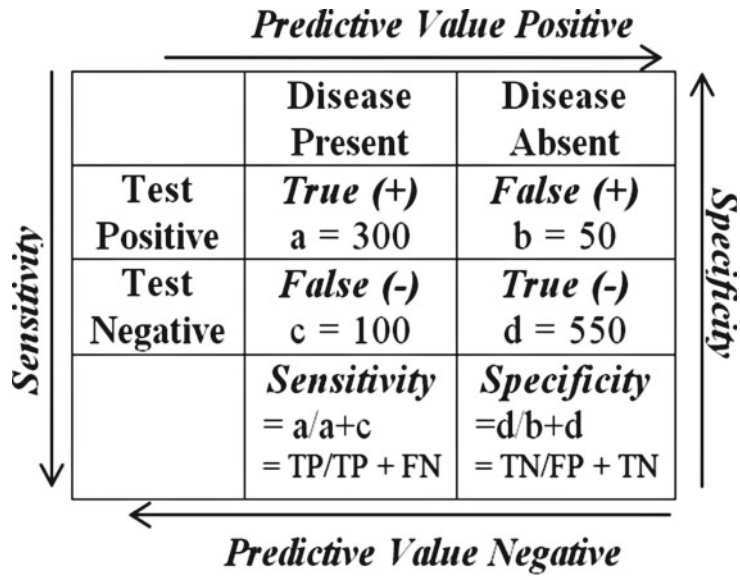

Fig. 1 Sensitivity and specificity of screening tests

As the cutoff criterion decreases, the number of false (-) decrease while false (+) increase, thereby increasing sensitivity and decreasing specificity. In contrast, as the cutoff criterion increases, the number of false positives decrease and the number of false negatives increase, thereby increasing specificity and decreasing sensitivity.

(c), screening test negative and disease present (false negatives), 50; and (d), screening test negative and disease absent (true negatives), 550. In this case, sensitivity, or positivity in disease, is 300/350 or 86%. Tests with high sensitivity have relatively few false-negative results. Specificity, or negativity in health, is 550/650 or 85%. Tests with high specificity have relatively few false-positive results.

While some screening test results are dichotomous ("yes" or "no," as for tuberculin skin tests), many others, such as fasting plasma glucose, are continuous. When screening results are continuous, a cutoff value is often chosen to distinguish a positive test from a negative test. This produces a trade-off between sensitivity and specificity. Specifically, as the cutoff criterion decreases, the number of false negatives decreases, while that of false positives increases, thereby increasing sensitivity and decreasing specificity. In contrast, as the cutoff criterion increases, the number of false positives decreases, and the number of false negatives increases, thereby increasing specificity and decreasing sensitivity. Also, the specificity of a test may be improved (and sensitivity reduced) by requiring a positive result from two tests, while the reverse occurs if a positive result on either of two tests is required. Receiver operating characteristic (ROC) curves – graphs in which sensitivity (y-axis) is plotted against 1-specificity (x-axis) – are also used to estimate the best cut point.

Several other types of information may be obtained. These include:

- Prevalence = (a + c)/(a + b + c + d) = 350/1000 = 35% = proportion of persons being tested who have the disease.
- Accuracy = (a + d)/(a + b + c + d) = 850/1000 = 85%. If the prevalence of the disease being tested differs in two populations

Telegram: @medical_k

www.konkur.in

undergoing screening, the accuracy of the test could be different even if the sensitivity and specificity were the same.

- Predictive value of a positive test (PV+) = a/a + b = 300/400 = 75% = proportion of persons with a positive screening test who have the disease. As the prevalence of disease among those being screened decreases, the PV+ decreases.
- Predictive value of a negative test (PV−) = d/c + d = 550/600 = 92% = proportion of persons with a negative screening test who do not have the disease. As the prevalence of the disease among those being screened decreases, the PV− increases.

PV+ and PV− are both influenced by prevalence. For example, screening for a hematologic disease in a hematologist's office would be expected to produce a higher predictive value than screening with the same test in a primary care clinic. Positive and negative likelihood ratios, in contrast, address similar questions but do not depend on prevalence:

- Positive likelihood ratio = sensitivity/(1-specificity) = 0.86/0.15 = 5.73 = a positive screening test is 5.73 times more likely to occur among those with the disease than among those without the disease.
- Negative likelihood ratio = (1-sensitivity)/specificity = 0.14/0.85 = 0.16 = a negative screening test is 0.16 times more likely among persons with the disease than among persons without the disease.

In all cases, the discomforts and risks associated with screening, including the stress of waiting for diagnostic results and possible adverse effects associated with testing, need to be considered when ordering a screening test.

Health Maintenance

All clinical encounters are opportunities for health promotion and disease prevention, including early identification of risk behaviors and disease, updating immunizations, and providing health guidance. Family medicine encounters, in turn, act in conjunction with preventive interventions provided through schools and other community resources. The United States Preventive Services Task Force (USPSTF) is a leader in providing evidence-based guidance for clinical prevention in primary care. The Task Force is an independent volunteer panel made up of experts from preventive and primary care medicine and nursing. Convened by the Agency for Healthcare Research and Quality (AHRQ), the Task Force gives a letter grade based on the strength of evidence pertaining to the benefits and harms of services that may be offered to people being in the primary care setting and who do not have signs or symptoms of a specific disease or condition. "A" and "B" grades are given to those services for which the Task Force has found good or fair evidence of benefit. As of this writing, preventive services which are generally covered by insurance may be identified at URL: https://www.healthcare.gov/coverage/preventive-care-benefits/. The Task Force does not review all types of preventive services, however. In particular, it defers to the Advisory Committee on Immunization Practices (ACIP) for reviews and updates of the recommended immunization schedule, and it refers users to the Health Resources and Services Administration (HRSA) Discretionary Advisory Committee on Heritable Disorders in Newborns and Children (DACHDNC) for recommendations on screening for heritable diseases in newborns. Primary care physicians should refer to the CDC Vaccines and Immunizations website (http://www.cdc.gov/vaccines/recs/default.htm) for updates and the most current schedules and to the website of the Advisory Committee on Heritable Disorders in Newborns and Children (https://www.hrsa.gov/advisory-committees/heritable-disorders/index.html) for information that is up to date as of the end of Congressional statutory authorization for this committee in September 2019. In the following sections, primary and secondary preventive services as recommended by the Task Force and other organizations according to patient age are described. Additional reviews of prevention for infectious diseases (e.g., post-exposure, travel and occupational prophylaxis, screening for tuberculosis,

Telegram: @medical_k

www.konkur.in

etc.) may be found in other chapters in this volume.

Key Recommendations from the US Preventive Services Task Force (USPSTF) and Advisory Committee on Immunization Practices (ACIP)

Estimates of highest priority in terms of scoring for quality-adjusted life years (QALYs) that could be gained if the clinical preventive service was delivered as recommended (five point maximum) and cost-effectiveness (five point maximum) were the ACIP childhood immunization series (10 points); interventions to prevent initiation of tobacco use including education or brief counseling (10 points); and tobacco use screening, brief cessation counseling, and pharmacotherapy (10 points) [8]. Also scoring highly (eight points) were cervical cancer screening for women ages 21–65 with cytology, colorectal cancer screening of adults ages 50–75 years, and screening and counseling for alcohol misuse [8]. As of 2016, the USPSTF recommended low-dose aspirin use for the primary prevention of cardiovascular disease and colorectal cancer among adults aged 50–59 years who have a 10% or greater 10-year cardiovascular disease risk, are not at increased risk for bleeding, have a life expectancy of at least 10 years, and are willing to take low-dose aspirin daily for at least 10 years [9]. In 2019, the American College of Cardiology and the American Heart Association noted that people between 40 and 70 years of age at high risk of cardiovascular disease (a strong family history of heart attack and uncontrolled blood pressure, cholesterol, or diabetes) and a low risk of bleeding may benefit from low-dose aspirin in addition to those who have a history of heart attack, stroke, coronary stent, or coronary artery bypass surgery and are at low risk of bleeding. In contrast, aspirin was not recommended for healthy people over 70 or under 40 years of age or for people at increased risk of bleeding because of a medical condition or other medication. A healthy diet, exercising, not smoking, and controlling high cholesterol, high blood pressure, and diabetes are among preventive steps to be taken beyond aspirin [10]. USPSTF and ACIP recommendations are constantly evolving and may be accessed at https://www.uspreventiveservicestaskforce.org/Page/Name/home and https://www.cdc.gov/vaccines/acip/recommendations.html, respectively.

Prevention for Infants, Children, and Adolescents (Birth to 18 Years)

Immunization

Birth to 18 Years: The immunization program is one of the most successful examples of effective preventive care in the United States. Through immunization, infants and children can be protected from at least 14 vaccine-preventable diseases before age 2. Low prevalence of most vaccine-preventable diseases has been the result of high coverage (90% and above) for many childhood vaccinations in the last two decades. Yet, while coverage has remained high and stable overall (more than 90% of children ages 19–35 months are getting the recommended vaccines), booster shots and second doses lag for 2-year-olds [11]. Additional efforts by parents and healthcare providers are warranted to maintain and improve the rate of administration of recommended immunizations.

The ACIP recommends the administration of all age-appropriate vaccines during a single visit. If a dose is not administered at the recommended age, however, it should be administered at a subsequent visit. The CDC Vaccines and Immunization website provides the catch-up schedule. The Childhood Vaccine Assessment Tool is also available at https://www2a.cdc.gov/vaccines/childquiz/. Through this link, providers can generate a personal, customized patient immunization schedule.

In addition to *childhood immunizations*, ACIP recommends that *immunizations for adolescents* include one dose of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine; two doses of meningococcal conjugate (MenACWY) vaccine; and three doses of human papillomavirus (HPV) vaccine [12]. Annual

Telegram: @medical_k

www.konkur.in

influenza for all persons aged ≥6 months and "catch-up" vaccinations, such as measles, mumps, and rubella (MMR), hepatitis B, and varicella, are also recommended [12]. See Fig. 2.

Information on travel vaccine requirements and recommendations is available at wwwnc.cdc.gov/travel/. For information regarding vaccination in the setting of a vaccine-preventable disease outbreak, contact your state or local health department.

Federal law mandates that healthcare staff provide a Vaccine Information Statement (VIS) containing both the benefits and risks of a vaccine to a patient, parent, or legal representative prior to the administration of a vaccine. Adverse events associated with vaccines should be reported to the DHHS using the Vaccine Adverse Event Reporting System (VAERS, http://vaers.hhs.gov/index).

Prophylaxis

Newborn: At present, 0.5% erythromycin ophthalmic ointment is the only approved drug for *ocular prophylaxis for gonococcal ophthalmia*

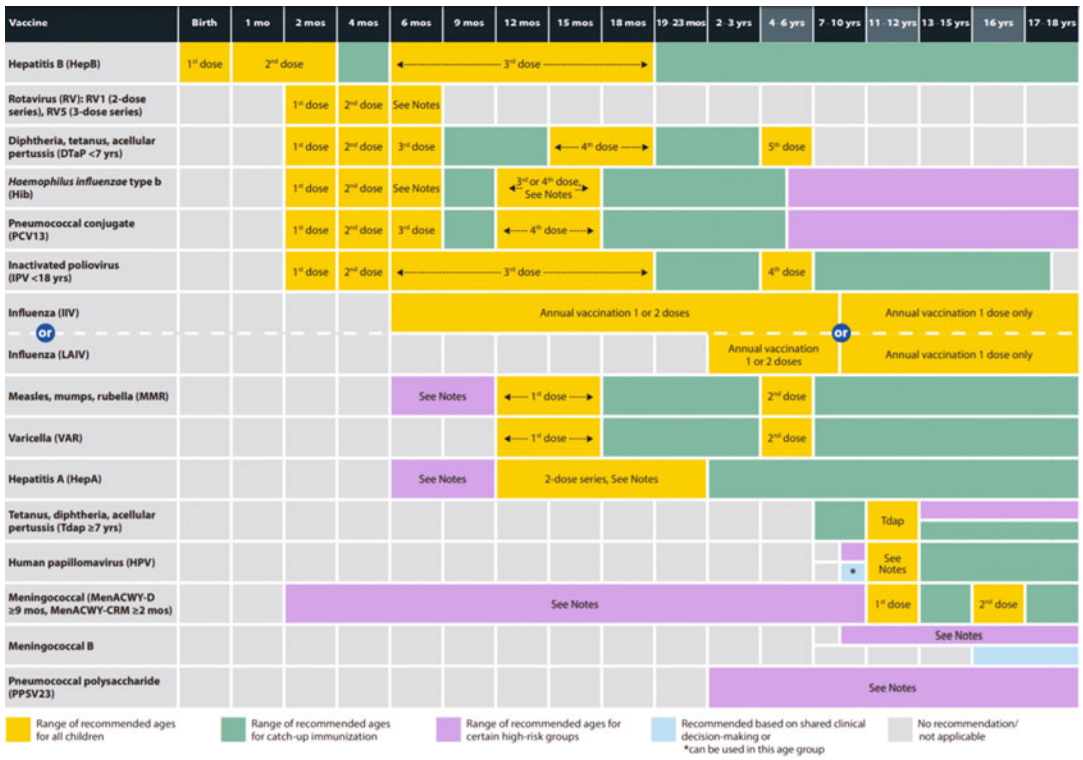

Fig. 2 Recommended immunization schedule for persons aged 0 through 18 years – United States, 2020. Note: The above recommendations must be read along with the footnotes of this schedule. See https://www.cdc.gov/vaccines/schedules/downloads/child/0–18years-child-combined-schedule.pdf. This schedule includes recommendations in effect as of January 1, 2020. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars. School entry and adolescent vaccine age groups are shaded in gray. Always make recommendations by determining needed vaccines based on age; determining appropriate intervals for catch-up, if needed; assessing for medical indications; and reviewing special situations. Administer recommended vaccines if immunization history is incomplete or unknown. Do not restart or add doses to vaccine series for extended intervals between doses. When a vaccine is not administered at the recommended age, administer at a subsequent visit. Vaccination providers should consult the relevant ACIP statement for detailed recommendations, available online at http://www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/index.html. Clinically significant adverse events that follow vaccination should be reported to the VAERS online (http://www.vaers.hhs.gov).

www.konkur.in

neonatorum by the US Food and Drug Administration (FDA). The USPSTF recommends this for all newborns, while the pediatric Red Book states it should be given when gonorrhea is prevalent in the region and prenatal treatment cannot be ensured or where required by law. The Red Book also cautions that efficacy is unlikely to be influenced by a delay of 1 h to facilitate parental bonding but that longer delays have not been studied for efficacy [13].

6 Months to 17 Years: For oral health, the USPSTF recommends applying *fluoride* varnish to the primary teeth of all infants and children starting at the age of primary tooth eruption and prescribing oral fluoride supplementation starting at age 6 months for children whose water supply is deficient in fluoride (<0.6 mg fluoride ion/L [ppm F]). Pediatric sources including the AAP Section on Oral Health add that the fluoride varnish should be repeated every 3–6 months. For high-risk children, an over-the-counter fluoridated mouth wash is recommended starting at 6 years of age if the child can reliably swish and spit. High risk is determined by both maternal/caregiver factors (mother or caregiver who does not have a dentist or who has had active decay in past 12 months) and child attributes (continual bottle/sippy cup use with fluid other than water; frequent snacking; special healthcare needs; and Medicaid eligible) [14].

Counseling and Anticipatory Guidance

Prenatal

Folic acid prophylaxis (400–800 micrograms per day) is recommended for all women who are planning or capable of pregnancy in order to prevent neural tube defects (Table 3).

Birth to 2 Years: This part of the visit allows the family physician to provide culturally and developmentally appropriate information about the patient and is an effective tool to educate parents about maintaining children's health. It is also important to document all counseling efforts. Particular attention should be given to parental concerns such as those related to newborn care, breastfeeding decisions, potential health/environmental risks, and safety. *Breastfeeding* should be encouraged. The benefits of breastfeeding include lower risk of acute otitis media, asthma, eczema, atopic dermatitis, and gastrointestinal tract infection, sudden infant death syndrome, and chronic conditions such as obesity, diabetes, and high blood pressure. The AAP recommends exclusive breastfeeding and/or human milk for infants for the first 6 months of life and continuing at least through the first year in addition to complementary foods, except in rare circumstances such as maternal contraindications or galactosemia. The USPSTF found adequate evidence to indicate that formal breastfeeding education increases rates of initiation, duration, and exclusivity of breastfeeding. Although the USPSTF has not made a recommendation about infant *safe sleep*, sudden infant death syndrome (SIDS) incidence has decreased since the AAP's 1992 recommendation that infants be placed for sleep in a non-prone position. However, recent data show an increase of other causes of sleep-related deaths including suffocation, asphyxia, and entrapment. To address this new evidence, the guidelines have been updated to 19 recommendations for a safe sleep environment for all infants, including back sleeping (supine), a firm sleep surface, breastfeeding, room-sharing without bed-sharing, and avoidance of overheating and exposure to tobacco smoke, alcohol, and illicit drugs [15]. Children are particularly vulnerable to the effects of *secondhand smoke*. It increases the risk for SIDS, asthma, otitis media, and lower respiratory tract infections [16]. The AAFP offers the following recommendations on protecting children from tobacco, nicotine, and tobacco smoke, all of which apply, directly or indirectly, to secondhand smoke:

1. Inquire about tobacco use and tobacco smoke exposure as part of health supervision visits and visits for diseases that may be caused or exacerbated by tobacco smoke exposure.
2. Include tobacco use prevention as part of anticipatory guidance.
3. Address parent/caregiver tobacco dependence as part of pediatric healthcare. (3a) Recommend tobacco dependence treatment of tobacco-dependent parents and caregivers. (3b)

Telegram: @medical_k

www.konkur.in

Implement systems to identify and offer counseling, treatment, treatment recommendations, and/or referral for tobacco-dependent parents.
4. Offer tobacco dependence treatment and/or referral to adolescents who want to stop smoking. (4a) Tobacco dependence pharmacotherapy can be considered for moderate to severely tobacco-dependent adolescents who want to stop smoking.
5. Offer tobacco-dependent individuals quitline referral.
6. Consider potential for neuropsychiatric symptoms with tobacco dependence treatment.
7. Do not recommend electronic nicotine delivery systems for tobacco dependence treatment.
8. If the sources of a child's tobacco smoke exposure cannot be eliminated, provide counseling about strategies to reduce the child's tobacco smoke exposure [17].

Primary prevention with provider counseling to include screening via environmental risk assessments for lead exposure is recommended at 6, 9, 12, 18, 24, and 30 months and at 3, 4, 5, and 6 years of age according the current Bright Futures/Periodicity Schedule, with blood lead level testing to occur if the screen is positive and/or if the child lives in a high prevalence area (e.g., children who are on Medicaid, living in poverty, and living in older housing are considered to be at especially high risk [USPSTF Grade I]). Capillary blood testing should be confirmed by venous blood testing. The physician should inquire about in-home exposures, unsafe renovation practices (houses built before 1978), and potential lead exposures associated with parental occupations and hobbies. Further, the American Academy of Pediatrics (AAP) has stated that, "Evidence continues to accrue that commonly encountered blood lead concentrations, even those below 5 μg/dL (50 ppb), impair cognition; there is no identified threshold or safe level of lead in blood." Evidence-based guidance is available for managing increased lead exposure in children, and reducing sources of lead in the environment, including lead in housing, soil, water, and consumer products, has been shown to be cost-beneficial. Primary prevention should be the focus of policy on childhood lead toxicity [18].

The AAP issues extensive policy statements on the prevention of *drowning*, including 40 recommendations and resources for parents and caregivers and pediatricians [19]. Recommendations have also been issued for exposure to digital media in 2–5-year-olds (summarized in the following section).

3 to 10 Years: Anticipatory guidance and counseling for *lead exposure* should continue through at least 5 years of age. Anticipatory guidance is also warranted during well-child visits in such areas as nutrition, healthy lifestyle practices, and injury prevention. Recommendations for counseling for *lifestyle risk factors* include encouraging a diet high in fruits and vegetables and low in fats; eating a healthy breakfast daily; regularly eating meals as a family; limiting the consumption of sweetened beverages, fast foods, and high-fat snacks; and limiting digital media use (including television). Evidence is sufficient to recommend time limitations on digital media use for children 2–5 years to no more than 1 h per day to allow children ample time to engage in other activities important to their health and development and to establish media viewing habits associated with lower risk of obesity later in life. It is recommended that children below the age of 2 years should not have any exposure to digital media [20]. Personalized plans need to be developed for older children and adolescents. Several recommendations are made, including the need for consistent limits; need to assure time for at least 1 h of physical activity and 12 h of sleep per day; awareness of cyberbullying and cybersexting; awareness that exposure of adolescents through media to alcohol, tobacco use, or sexual behaviors is associated with earlier initiation of these behaviors, in part because peer viewers may see adolescent displays of substance use, sexual behaviors, self-injury, or disordered eating as normative; and awareness that research from both the United States and United Kingdom indicate that major alcohol brands maintain strong presences on Facebook, Twitter, and YouTube [21]. Parents should be encouraged to motivate their children to

Telegram: @medical_k

www.konkur.in

play and to lead by example by participating in an active lifestyle.

Drowning is the main cause of death due to injury among children aged 3–4 years, and anticipatory guidance is important throughout childhood and adolescence [19]. Most deaths of children ages 5–10 years are due to *traffic injuries*, as occupants, pedestrians, bicyclists, or motorcyclists. The USPSTF refers clinicians to the CDC's Community Guide recommendations for actions that they could support within the community, such as laws mandating the use of children's car seats, safety belts, and helmets along with education programs, community-wide information, and enhanced enforcement campaigns (http://www.thecommunityguide.org). The use of child safety seats and safety belts is among the most important preventive measures to reduce motor vehicle-related injuries and deaths. The AAP formerly recommended that infants and toddlers should ride in a rear-facing car seat until they are at least 2 years old, but updated recommendations eliminate the age milestone, offering five recommendations: (1) rear-facing car safety seats as long as possible; (2) forward-facing car safety seats from the time children outgrow rear-facing seats, for most children through at least 4 years of age; (3) belt-positioning booster seats from the time children outgrow forward-facing seats, for most children through at least 8 years of age, and lap and shoulder seat belts for all who have outgrown booster seats; and (5) for all children younger than 13 years to ride in the rear seats of vehicles. The AAP recognizes that every transition is associated with some decrease in protection; therefore, parents should be encouraged to delay these transitions for as long as possible [22].

11 to 18 Years: *Unintentional injuries* (from traffic injuries and other causes as stated above) continue to be major causes of death, and counseling/anticipatory guidance should continue as well. Counseling and interventions to reduce *cardiovascular risk* (e.g., healthy weight, smoking cessation) and reduce involvement in health risk behaviors (e.g., alcohol and drug use, unsafe sexual practices) are also a priority. Anticipatory guidance should be provided about the benefits of regular physical activity (at least 60 min per day) to reduce the risk of developing obesity and chronic diseases, decrease the risk of depression and anxiety, and promote psychological well-being. Children age 10 years and above who have fair skin should be advised about minimizing their exposure to ultraviolet radiation to reduce risk for skin cancer and especially to avoid excess/midday sun exposure, wear protective clothing, and use sunscreen as directed.

Parents should be encouraged to lead by example by providing a healthful food environment and by discouraging the consumption of unhealthy foods outside the home. Family dinners could benefit teens' mental health by creating a conducive environments for open communication between parents and children to mitigate risks of *cyberbullying* and other online challenges [23]. Promoting the healthy and safe use of social media could prevent associated *mental health* and *substance use* problems as well as other risks related to technology use itself (e.g., distraction or sleep problems) in children and adolescents [23]. In addition to counseling about avoiding online behaviors that can have negative consequences, such as "sexting" and sharing of personal information and pictures with strangers, the clinician should confer about strategies to deal with bullying and resources such as creating a *personalized family media use plan* available through recognized organizations such as Bright Futures (https://www.healthychildren.org/English/media/Pages/default.aspx#home).

Sexual risk behaviors among adolescents increase the risk of unintended pregnancy and *sexually transmitted infections* including *HIV.* Young people aged 13–24 accounted for an estimated 21% of all new HIV diagnoses in the United States, and they are the least likely of any age group to be linked to care in a timely manner and have a suppressed viral load [24].

Driven by an increase in e-cigarette use, current tobacco product use has significantly increased among high school and middle school students, hindering the decline in tobacco product use among youths that occurred in previous years. Education and counseling reduce the chances children and teens will start smoking. Interventions include direct counseling with teens individually

Telegram: @medical_k

www.konkur.in

or with families, videos, apps, print materials, activity guides, workbooks, and preprinted prescriptions. While there is insufficient evidence that routine counseling by an individual practitioner to reduce *alcohol* and *illicit drug misuse* in children and adolescents is effective, the AAFP recognizes the importance of counseling aimed at alcohol avoidance by adolescents aged 12–17 years and strict prohibition of driving under the influence of alcohol or impairing agents at any age.

Screening

Comparisons between USPSTF and the American Academy of Pediatrics (AAP) screening recommendations are summarized in Tables 1 and 2.

Newborn: Certain *genetic, endocrine, and metabolic disorders*, as well as *hearing loss* and critical *congenital heart disease* (CCHD), can adversely affect an infant's survival or inhibit a child from achieving full potential. It has been 50 years since the US newborn screening program was first implemented. Universal newborn blood screening *for phenylketonuria (PKU)*, *congenital hypothyroidism (CH)*, and *sickle cell disease* is now mandated in all 50 states. Although State law determines which disorders are included in the screening, the Secretary's Advisory Committee on Heritable Disorders in Newborns and Children (SACHDNC) recommends that states test for a *core panel of 35 congenital disorders and 26 secondary disorders*, including severe combined immunodeficiency (SCID) [25]. The USPSTF recommends that infants who are tested for *PKU* within the first 24 hours after birth should receive a repeat screening test by 2 weeks of age. Screening for *CH* should be done between 2 and 4 days of age or immediately before discharge if this occurs earlier. Confirmatory testing for *sickle cell disease* should occur no later than 2 months of age. Because 50% of children with permanent *congenital hearing loss* have no identifiable risk factors, the USPSTF recommends that universal (as opposed to targeted) screening for hearing loss be completed before 1 month of age. Early detection improves language outcomes. Additional audiologic and medical evaluation before 3 months of age for confirmatory testing is warranted for those who do not pass the newborn screening, and infants with risk indicators should undergo periodic monitoring for 3 years. Although the USPSTF has not made a recommendation for *CCHD screening*, the SACHDNC recommended pulse oximetry after 24 h of age but before discharge for early detection of serious heart defects that could require specialized care within the first year of life.

Birth to 2 Years: Infants should have a follow-up visit within 3–5 days of birth and within 48–72 h after hospital discharge to prevent problems related to *feeding, jaundice,* and *weight loss*. Well-infant and child visits for developmental screening and monitoring should occur at ages 1, 2, 4, 6, 9, 12, 15, 18, and 24 months. The CDC recommends using WHO growth standards (http://www.cdc.gov/growthcharts/who_charts.htm). Screening should encompass length, weight, and head circumference. Dental referral is recommended by the first birthday. The USPSTF found insufficient or inconsistent evidence to recommend for or against the routine use of brief, formal screening instruments in primary care to detect *speech and language delay* in children up to 5 years of age. In contrast, the AAP recommends developmental surveillance to identify infants at risk for developmental delays at every well-child preventive care visit through the age of 5 years. Surveillance consists of asking about parents' concerns, obtaining a developmental history, identifying risk and protective factors, and interacting and making observations of the child. Per AAP recommendations, children with Medicaid are mandated to periodically receive a standardized developmental screening test (e.g., Ages & Stages Questionnaires (ASQ), Infant Development Inventory). *Autism-specific screening* for all children at 18 and either 24 or 30 months is also recommended. Additional screening might be needed by children at high risk for developmental problems due to preterm birth or intrauterine growth restriction.

www.konkur.in

Table 1 Comparison of USPSTF A and B recommendations with corresponding recommendations from the American Academy of Pediatrics

The USPSTF and the AAFP recommend that clinicians discuss these preventive services with eligible patients and offer them as a priority. All these services have received an "A" or a "B" (recommended) grade from the task force		
Recommendation	**USPSTF[a]**	**American Academy of Pediatrics[b]**
Measurements		
Obesity (body mass index)	Screen children and adolescents aged 6 years and older	24 and 30 months, yearly until 21 years of age
Length/height and weight	No recommendation	Newborn, 3–5 days, by 1 month; 2, 4, 6, 9, 12, 18, 24, 30 months; yearly from 3 to 21 years of age
Head circumference	No recommendation	Newborn, 3–5 days, by 1 month; 2, 4, 6, 9, 12, 18, and 24 months
Weight for length	No recommendation	Newborn, 3–5 days, by 1 month; 2, 4, 6, 9, 12, and 18 months
Hypertension	Insufficient evidence	Annually beginning at 3 years of age. Measurement in infants and children with specific risk conditions should be performed at visits before age 3 years
Physical examination	No recommendation	Newborn, 3–5 days, by 1 month; 2, 4, 6, 9, 12, 18, 24, 30 months; yearly from 3 to 21 years of age At each visit, age-appropriate physical examination is essential, with infant totally unclothed and older children undressed and suitably draped
Sensory screening		
Vision	Screen children ages 3 to 5 years at least once to detect amblyopia or its risk factors	Newborn, 3–5 days, by 1 month; 2, 4, 6, 9, 12, 18, 24, 30 months; yearly from 3 to 21 years of age A visual acuity screen is recommended at ages 4 and 5 years, as well as in cooperative 3-year-olds. Instrument-based screening may be used to assess risk at ages 12 and 24 months, in addition to the well visits at 3 through 5 years of age
Hearing loss	Elected not to update 2008 recommendation and noted that the previous evidence review and recommendation may be outdated	Newborn, 3–5 days to 2 months,4, 6, 9, 12, 18, 24, 30 months; yearly from 3 to 10 years, 11–14, 15–17, and 18–21 years of age
Developmental/behavioral health		
Developmental screening	No recommendation	9, 18, and 30 months
Autism spectrum disorder (ASD)	Insufficient evidence to make a recommendation	18 and 24 months
Developmental surveillance	No recommendation	Newborn, 3–5 days, 1 month; 2, 4, 12, 15, 24, and 30 months, 3 years and yearly until 21 years of age
Psychosocial/ behavioral assessment	No recommendation	Newborn, 3–5 days, by 1 month; 2, 4, 6, 9, 12, 18, 24, 30 months; yearly from 3 to 21 years of age Family centered and may include an assessment of child social-emotional health, caregiver depression, and social determinants of health

(continued)

Telegram: @medical_k

www.konkur.in

Table 1 (continued)

Tobacco use in children and adolescents	*Draft recommendation as distributed for receipt of public comments* Primary care-feasible behavioral interventions, including education or brief counseling, to prevent tobacco use in school-aged children and adolescents have a moderate net benefit. Adequate evidence that behavioral counseling interventions, such as face-to-face or telephone interaction with a healthcare provider, print materials, and computer applications, can have a moderate effect	Yearly, beginning at age 11 years[c] Ask and provide counseling about tobacco use and tobacco smoke exposure as part of health supervision visits and visits for diseases that may be caused or exacerbated by tobacco use. Include tobacco use prevention as part of anticipatory guidance. Address parent/caregiver tobacco dependence as part of pediatric healthcare. Offer treatment and/or referral to adolescents who want to stop smoking. Do not recommend electronic nicotine delivery systems for tobacco dependence treatment. Counseling about strategies to reduce the child's tobacco smoke
Unhealthy alcohol use in adolescents	Insufficient evidence to make a recommendation Note: The AAFP recognizes the avoidance of alcohol products by adolescents aged 12–17 years is desirable. However, the effectiveness of the physician's advice and counseling in this area is uncertain	Annually beginning at 11 years of age. Use the CRAFFT to screen for high-risk alcohol and other drug use disorders simultaneously C – have you ever ridden in a *car* driven by someone (including yourself) who was "high" or had been using alcohol or drugs? R – do you ever use alcohol or drugs to *relax*, feel better about yourself, or fit in? A – do you ever use alcohol/drugs while you are by yourself, *alone*? F – do you ever *forget* things you did while using alcohol or drugs? F – do your family or *friends* ever tell you that you should cut down on your drinking or drug use? T – have you gotten into *trouble* while you were using alcohol or drugs?
Illicit drug use	Update in progress	
Depression screening	Adolescents (age 12–18) when systems are in place to ensure accurate diagnosis, effective treatment, and appropriate follow-up	Adolescent patients ages 12 years and older should be screened annually for depression (MDD or depressive disorders) with a formal self-report screening tool either on paper or electronically (universal screening)
Maternal depression screening	All adults including pregnant and postpartum women. Screening should be implemented with adequate systems in place to ensure accurate diagnosis, effective treatment, and appropriate follow-up	Routine screening for postpartum depression should be integrated into well-child visits at 1, 2, 4, and 6 months of age

[a]USPSTF A and B recommendations by date. US Preventive Services Task Force. December 2019. https://www.uspreventiveservicestaskforce.org/Page/Name/uspstf-a-and-b-recommendations/

[b]Note that AAP Bright Futures recommendations are more comprehensive than those of the USPSTF. The above table is an abridgement. Complete AAP recommendations may be found at Bright Futures/AAP Recommendations for preventive pediatric healthcare (Periodicity Schedule). Available at URL: https://www.aap.org/en-us/documents/periodicity_schedule.pdf. Accessed 4 Feb 2020

[c]AAP Section on Tobacco Control. Clinical practice policy to protect children from tobacco, nicotine, and tobacco smoke. Pediatrics 2015. 136(5):1008–1017. https://doi.org/10.1542/peds.2015-3108

The USPSTF found insufficient evidence to recommend universal screening for *iron deficiency anemia (IDA)* in asymptomatic children ages 6–12 months. In contrast, the AAP recommends universal screening for anemia via hemoglobin concentration at approximately 1 year of age.

2 to 10 Years: *Well-child visits* should occur at 24 and 30 months and once every year thereafter. The family physician should ask questions about

Telegram: @medical_k

www.konkur.in

Table 2 Comparison of USPSTF A and B recommendations with corresponding recommendations from the American Academy of Pediatrics for high-risk populations

Procedures	USPSTF	AAP
Newborn blood screening	Referred to discretionary advisory committee on heritable disorders in newborns and children	Screen in the newborn period (confirm initial screen was accomplished, verify results, and follow up, as appropriate. The recommended uniform screening panel (RUSP) **and** screen from 3 to 5 days to 2 months (verify results as soon as possible, and follow up, as appropriate)
Newborn bilirubin	Elected not to update its 2009 recommendation and notes that the previous evidence review and recommendation may be outdated	Confirm initial screening was accomplished, verify results, and follow up, as appropriate. Screen for jaundice and its risk factors before they leave the hospital and conduct a follow-up visit when a baby is 3–5 days old, when bilirubin levels peak. Frequent breastfeeding in the first few days of life also is recommended
Critical congenital heart disease	Part of RUSP (recommended uniform screening panel) (referred)	Newborns using pulse oximetry after 24 h of age, before discharge
Developmental dysplasia of the hip (DDH)	Insufficient evidence to make a recommendation	Hip imaging for female infants born in the breech position and optional hip imaging for boys born in the breech position or girls with a positive family history of DDH
Immunizations	Referred to advisory committee on immunization practices (ACIP) (http://www.cdc.gov/vaccines/schedules/index.html)	Schedules, per the AAP Committee on Infectious Diseases, are available at http://redbook.solutions.aap.org/. Every visit should be an opportunity to update and complete child's immunizations
Anemia	Insufficient evidence to make a recommendation	Assess at 4, 12, 15, 18, 24, and 30 months and yearly beginning at 3 years of age
Lead poisoning	Insufficient evidence to make a recommendation in children 1–5 years of age	Assess at 6, 9, 12, 24 months and at 3, 4, 5, and 6 years. "It is now clear that there is no known threshold below which adverse effects of lead are absent." **12 and 24 month alternative:** Perform risk assessments or screenings as appropriate, based on universal screening requirements for patients with Medicaid or in high-prevalence areas at 12 and 24 months
Tuberculosis	No A or B recommendation for infants or children	Assess at 1, 6, 12, 24 months and yearly from 3 to 21 years
Dyslipidemia	Insufficient evidence to make a recommendation (up to age 20 years)	Asses risk at 2, 4, 6, and 8 years of age. Universal lipid screen between 9 and 11 years of age
Sexually transmitted diseases	Screen for chlamydia and gonorrhea in sexually active women age 24 years and younger	Annually beginning at 11 years of age. Adolescents should be screened for sexually transmitted infections (STIs) per recommendations in the current edition of the AAP Red Book: Report of the Committee on Infectious Diseases

(continued)

Telegram: @medical_k

www.konkur.in

Table 2 (continued)

HIV infection, screening	All adolescents and adults ages 15–65 years and others who are at increased risk for HIV infection and all pregnant women Note: The AAFP's endorses the CDC recommendation to initiate routine screening at age 13 years	Once between the ages of 15 and 18, make every effort to preserve confidentiality of the adolescent. Those at increased risk of HIV infection, including those who are sexually active, participate in injection drug use, or are being tested for other STIs, should be tested for HIV and reassessed annually
Oral health		
Fluoride varnish: dental caries prevention	Apply fluoride varnish to the primary teeth of all infants and children starting at the age of primary tooth eruption	Oral health assessment for all children by age 6 months and a first dental visit by age 1 year
Fluoride supplementation	Oral fluoride supplementation starting at age 6 months for children whose water supply is deficient in fluoride (<0.6 ppm F)	Oral fluoride supplementation and application of fluoride varnish in children at risk for dental caries
Anticipatory guidance		
Anticipatory guidance	No recommendation	Newborn, 3–5 days, by 1 month; 2, 4, 6, 9, 12, 18, 24, 30 months; yearly from 3 to 21 years of age
Skin cancer counseling	Aged 10–24 years who have fair skin High risk: fair skin, freckles, atypical nevi, >50 moles, increased lifetime or intense sun exposure	Sun safety advice during health maintenance visits at least once per year
Suicide risk in adolescents, adults, and older adults	Insufficient evidence to make a recommendation	Recommends to ask questions about mood disorders, sexual orientation, suicidal thoughts, and other risk factors associated with suicide during routine healthcare visits
Child maltreatment	Insufficient evidence to make a recommendation	Use the parent screening tool to screen for risk factors: a Safe Environment for Every Kid (SEEK). http://brightfutures.aap.org/pdfs/Other%203/PSQ_screen.pdf
Counseling about proper use of seatbelts and avoidance of alcohol use to prevent injury	Refers clinicians to the CDC's Community Guide recommendations: laws mandating use, distribution and education programs, community-wide information and enhanced enforcement campaigns. (http://www.thecommunityguide.org)	Counseling and demonstrating the use of child safety seats. Insufficient evidence about counseling for other restraints and to discourage driving under the influence of the alcohol

injury/illness, visits to other healthcare providers, and changes in the family or home and should also address any parental concerns. During these well-child visits, the child's growth and development should be measured, and testing for vision and hearing starting at age 3 years should be performed. A dental home should be established in addition to a medical home, and a preventive visit to the dentist should occur twice per year. During this period, parents often have questions about their child's behavior and social functioning. *Developmental milestones* and observation of parent and child interaction should also be included at every preventive care visit. If needed, intervention by age 3 years can greatly improve a child's development and learning ability. Developmental surveillance in school-aged children can be monitored by asking about school performance to identify the need to test for learning disabilities.

The CDC has recommended growth charts for *monitoring growth* from ages 2 years and older

Telegram: @medical_k

www.konkur.in

(http://www.cdc.gov/growthcharts/clinical_charts.htm), and *body mass index (BMI)* should be calculated at least annually. Overweight and obesity are defined as an age-gender-specific BMI's between the 85th and 95th percentiles and ≥95th percentile, respectively. Screening for obesity in children aged 6 years and older and referral for intensive counseling are recommended by the USPSTF, including interventions for diet and physical activity (Table 1). Interventions that focus on younger children should also incorporate parental involvement as a component.

The USPSTF found insufficient evidence to support screening for *primary hypertension* in asymptomatic children and adolescents (before 18 years of age). Furthermore, although there is good evidence that *dyslipidemia* during childhood increases risks in adulthood, the clinical health benefits shown in adults identified and treated for dyslipidemia have not been studied in children, making the role of screening children uncertain (USPSTF Grade I). In contrast, the National Heart, Lung, and Blood Institute (NHLBI) recommends that children ages 3 years and older have blood pressure measurement at least once at every "healthcare episode." The NHLBI also recommends universal lipid screening between 9 and 11 years of age and selective screening in children and adolescents with a family history of premature coronary heart disease (CHD), a parent with dyslipidemia, or high-risk condition such as diabetes, obesity, or hypertension [26].

11 to 18 Years: Preventable conditions remain the leading causes of morbidity and mortality among adolescents. *Health risk behaviors* (e.g., alcohol and drug use, unsafe sexual practices, etc.) are major contributors to unintentional injuries such as motor vehicle collisions, intentional injuries such as homicide and suicide, and sexual risk behaviors leading to sexually transmitted infections (STIs) and unintended pregnancy. The AAP recommends screening adolescents for high-risk alcohol and other drug use disorders simultaneously beginning at 11 years of age and annually thereafter using the CRAFFT six-item tool (Car, Relax, Alone, Forget, Friends, Trouble) (Table 1).

Obesity has become a major cause of adolescent morbidity. It is a contributor to a dramatic increase in the number of youth with type 2 diabetes mellitus, and it is the strongest risk factor for primary hypertension in children and adolescents. BMI measurement should be standard during health maintenance visits, and patients with excess weight should be referred for counseling and comprehensive weight management programs that include dietary, physical activity, and behavioral counseling.

Sexually active teens should be screened for *STIs* including *chlamydia* and *gonorrhea*. Young women (ages 15–24) account for 44% of reported cases of chlamydial infection and face the most severe consequences of an undiagnosed infection. Because adolescents are a vulnerable population at increased risk of *HIV infection*, assessment for high-risk behaviors and screening for HIV should be standard. The USPSTF advises one-time screening beginning at age 15 years to identify persons who are already HIV-positive, with repeated screening of those who are known to be at risk for HIV infection, those who are actively engaged in risky behaviors, and those who live or receive medical care in a high-prevalence setting (Table 2). Although such testing is generally performed without a separate written informed consent or pretest counseling, providers must anticipate that some patients are poorly equipped to deal with a positive HIV test result and assure that appropriate support is available.

Major depressive disorder (MDD) among adolescents, often undiagnosed and untreated, is a disabling condition that is associated with increased risk of suicide, decreased school performance, poor social functioning, early pregnancy, increased physical illness, and substance abuse. Important risk factors that can be assessed relatively accurately and reliably include parental depression, the presence of comorbid mental health or chronic medical conditions, and a major negative life event in the patient's life. The Patient Health Questionnaire for Adolescents [PHQ-A] and the Beck Depression Inventory for Primary Care Version [BDI-PC] have been used successfully in adolescents to screen for MDD [27].

Telegram: @medical_k

www.konkur.in

Prevention at Ages over 18 Years

Immunization

A recommendation by a patient's healthcare provider for needed vaccines is a strong predictor of patients receiving recommended vaccines. The ACIP annually reviews and updates the "Recommended Immunization Schedule for Adults Ages 19 Years or Older" (Fig. 3). With the exception of the yearly *influenza* vaccination, which is recommended for all adults, recommendations for adults target different populations based on age, health conditions, behavioral risk factors (e.g., injection drug use), occupation, travel, and other indications.

The ACIP recommends beginning *zoster* vaccination at age 50 years with recombinant zoster vaccine (preferred) or 60 years and older with zoster vaccine live. For *pneumococcus bacteria*, all adults 65 years of age or older receive a dose of PCV13 followed 6–12 months later by a dose of PPSV23. If a dose of PPSV23 cannot be given during this time window, it should be administered during the next doctor's visit. PCV13 protects against 13 strains of pneumococcus bacteria, and PPSV23 protects against 23 strains of pneumococcus bacteria. Both vaccines provide protection against meningitis and bacteremia. PCV13 also provides protection against pneumonia. *Hepatitis B vaccine* is recommended for all unvaccinated adults at high risk for HBV infection and diabetic adults <60 years. For patients with diabetes ≥ 60 years, vaccination may be warranted based on likelihood of acquiring hepatitis B and immune response. A single dose of *Tdap* is recommended for all adults aged 19 years and older who have not received Tdap previously regardless of the interval since the last dose of Td. Adults should also receive a Td booster every 10 years. Tdap should be administered to pregnant women during each pregnancy (preferred during 27–36 weeks gestation) regardless of interval since prior Td or Tdap vaccination. Pregnant women who do not have evidence of immunity should receive the first dose of varicella vaccine upon completion or termination of pregnancy and before discharge from the healthcare facility. Vaccination for *varicella*, *zoster*, and *MMR* is contraindicated in pregnancy and immune-compromising conditions (safe in patients with HIV who have CD4 ≥ 200 cells/μL).

Prophylaxis

Folic acid prophylaxis (400 micrograms per day) is recommended through age 45 years to prevent neural tube defects. The USPSTF considers *low-dose aspirin* (81 mg/day) to be of substantial benefit for pregnant women at high risk for preeclampsia (grade B recommendation). Risk factors for preeclampsia include autoimmune disease, hypertension, multiple gestation pregnancy, renal disease, diabetes, and history of preeclampsia (Table 4). Low-dose aspirin therapy can also be considered for those with multiple moderate risk factors. Recommendations for increasing bone strength include *calcium* and *vitamin D supplementation*. The USPSTF also recommends that clinicians engage in shared, informed decision-making with women who are at increased risk for breast cancer about medications to reduce their risk. For women who are at increased risk for breast cancer and at low risk for adverse medication effects, clinicians should offer risk-reducing medications, such as *tamoxifen or raloxifene*.

Counseling and Anticipatory Guidance

Preventive counseling and services are an important component of the health maintenance visit. The family physician should emphasize a shared decision-making approach including unique goals of prevention, life expectancy, comorbidities, potential for harms, and patient values and preferences. Preventive services are more likely to be discussed when patients have an established relationship with an identified clinician. The five leading causes of death – comprising almost two-thirds of all US deaths – are *heart disease*, *cancer*, *stroke*, *lung disease* (*emphysema*, *chronic bronchitis*), and *unintentional injuries* (especially motor vehicle collisions, medication overdoses).

www.konkur.in

Counseling comprises recommendations for healthy lifestyle and intensive behavioral counseling for adults with known risk factors for *coronary heart disease* and *diet-related chronic disease*. The family physician should also advise on the importance of regular physical activity including aerobic, strength, and flexibility training in the prevention of disease and non-traumatic weight-bearing exercise (e.g., walking) for osteoporosis prevention. All patients should be asked about *tobacco* use and provided tobacco cessation interventions. Brief counseling within primary care for smoking cessation increases quit rates and decreases cardiovascular risk. Clinicians have many resources to help patients stop smoking. The CDC has developed a website with many such resources, including information on tobacco quit lines, available in several languages (www.cdc.gov/tobacco/campaign/tips). It is also recommended to assess any history of *alcohol/drug* use. Brief questionnaires (e.g., Alcohol Use Disorders Identification Test (AUDIT)) may help clinicians assess the likelihood of problems or hazardous drinking. Patients should receive behavioral counseling about the effects of alcohol and substance use, including prescription and over-the-counter drugs. Brief interventions in primary care, including feedback, goal setting, and follow-up with short contacts, are effective in reducing alcohol consumption. High-intensity behavioral counseling to prevent *STIs* for adults who are at increased risk of STIs is also recommended. Older adults continue to be sexually active in their later years. In fact, the rate of STIs has more than doubled among middle-aged adults and the elderly over the last decade. The lack of awareness about STIs and their prevention may be contributing to the increasing reported rates. It is important to provide counseling and offer STI testing to those at risk.

Because women may not be aware of *pregnancy* in its earliest stages, patients should be counseled in advance about the adverse effects of obesity, alcohol, illicit drugs, tobacco, and other environmental exposures. If a patient has a BMI $\geq$30, weight loss is recommended before becoming pregnant. Women should be advised that there is no known safe level of alcohol consumption during pregnancy and the harmful effects of alcohol and recreational drug use on fetal development should be stressed. Counseling should emphasize that smoking during pregnancy can cause infant death and is associated with increased risk for premature birth and intrauterine growth retardation. Smoking cessation counseling sessions should be provided, augmented with messages and self-help materials tailored for pregnant smokers as needed.

Screening

The USPSTF recommends screening for four cancer sites – *cervix*, *female breast*, *colorectal*, and *lung.* It does not favor *prostate* cancer screening. Most patients with *cervical cancer* are women younger than 50 years, and most invasive cervical cancers occur in women lacking appropriate screening during the 5 years immediately preceding diagnosis. Cervical cancer screening is not recommended before age 21 regardless of when sexual activity begins. Screening should usually be stopped at age 65 if adequate screening was carried out in the preceding 10 years. Also, if the patient had a total hysterectomy (with complete cervical removal) for benign disease, screening is not necessary. For *breast cancer*, family history and age are key risk factors. The USPSTF recommends biennial mammography for women ages 50–74 years, while the American Cancer Society recommends that annual mammography begins at age 40 and continues so long as the woman is in good health. Women with a family history sug-

Telegram: @medical_k

www.konkur.in

gestive of breast and ovarian cancer syndrome should receive counseling for options which may include genetic testing for BRCA1 and BRCA2 and more intensive screening for breast cancer. The harms resulting from screening for breast cancer include psychological distress, unnecessary imaging tests and biopsies in women without cancer, and inconvenience due to false-positive screening results. Partly because such problems may be accentuated by annual mammography, the USPSTF recommends against annual testing even though models used by the Task Force suggest that annual testing brings a survival advantage. The ACA requires insurers to cover screening mammograms every 1–2 years for women ages 40+ years.

Colorectal cancer (CRC) is the second leading cause of cancer-related deaths and the third most common cancer among American men and women. Early detection and removal of precancerous polyps before CRC develops reduce mortality. Screening is recommended for all adults aged 50–75 years. Although the percentage of US adults aged 50–75 years who were up to date with colorectal cancer screening increased 1.4% points, from 67.4% in 2016 to 68.8% in 2018, screening rates remain far below what would be necessary to decrease incidence and mortality. Strategies to increase screening rates besides clinician recommendation include patient and clinician reminders, decision aids, and organization of office staff to support a program of patient education, monitoring, outreach, and follow-up (e.g., patient navigator, FOBT cards). *Lung cancer* is the leading cause of cancer-related death and the second most common in the US. Prevention of tobacco use, which accounts for nearly 85% of all US lung cancer cases, is the most important intervention to prevent the disease. Although lung cancer screening is not an alternative to smoking cessation, screening high-risk patients aged 55–80 years with low-dose computer tomography (LDCT) is recommended by the USPSTF. Current smokers should be informed of their continuing risk for lung cancer and offered cessation treatments. Screening with LDCT should be viewed only as an adjunct to tobacco cessation interventions. The Task Force does not recommend screening for *prostate cancer* for men in the general US population. Most cases of prostate cancer have a good prognosis, even without treatment, and the lifetime risk of dying from the disease is 2.8%. In addition, the mortality benefits of PSA-based prostate cancer screening are, at best, small and potentially none, while the harms are moderate to substantial potentially due to those associated with overdiagnosis and overtreatment (need for biopsy and impotence or incontinence occurring in at least 50% of men who undergo treatment for a disease that may be indolent).

Overweight, obesity, and *lack of physical activity* are associated with hypertension, diabetes, increased cardiovascular events, and increased all-cause mortality. The USPSTF recommends that clinicians screen their adult patients for obesity and offer or refer them if appropriate to intensive, multicomponent behavioral programs promoting healthy eating, increasing physical activity, or both. In nutrient-sufficient adults, evidence is insufficient to support multivitamin supplementation to prevent cancer and cardiovascular disease. In 2017, the American College of Cardiology and the American Heart Association published new guidelines for hypertension management and defined hypertension as a blood pressure at or above 130/80 mmHg. *Hypertension* affects approximately 45% of adult Americans, and it is a major risk factor for ischemic heart disease, left ventricular hypertrophy, renal failure, stroke, and dementia. Screening for hypertension in adults 18 and over is recommended by the USPSTF. In addition, the Task Force recommends screening for *abnormal blood glucose* as part of cardiovascular risk assessment in adults aged 40–70 years who are overweight or obese. The USPSTF recommends that adults without a history of cardiovascular disease (CVD) (i.e., symptomatic coronary artery disease or ischemic stroke) use a low- to moderate-dose statin for the prevention of CVD events and mortality when all of the following criteria are met: (1) ages 40–75 years; (2) one or more CVD risk factors (i.e., dyslipidemia, diabetes, hypertension, or smoking); and (3) a calculated 10-year risk of a

Telegram: @medical_k

www.konkur.in

cardiovascular event of 10% or greater. Identification of dyslipidemia and calculation of 10-year CVD event risk require universal lipid screening in adults aged 40–75 years.

Combined *syphilis*, *chlamydia*, and *gonorrhea* continue to be serious public health problems in the United States. The USPSTF recommends screening in sexually active women age 24 and younger and in older women at increased risk for infection (history of chlamydial or other STIs, new or multiple sexual partners, inconsistent condom use, and exchanging sex for money or drugs). Recommendations for *HIV* differ regarding age for screening. The USPSTF recommends one-time screening through age 65 years, while the suggested CDC cutoff is 64 years. The American College of Physicians suggests expanding the age range to 75 years due to the growing number of older adults with HIV infection. Screening for *hepatitis B*, *hepatitis C*, and *syphilis* should be offered to all persons at high risk for infection (Table 3). The USPSTF recommends screening all adults for *depression* when staff-assisted depression care supports are in place to assure accurate diagnosis, effective treatment, and follow-up. "Staff-assisted depression care supports" refer to clinical staff (e.g., nurse specialists) who assist the primary care clinician by providing some direct depression care including coordination, case management, or mental health treatment. Several screening tools are available; however, asking two simple questions about mood and anhedonia (Table 4) may be as effective as using more formal instruments. *Intimate partner violence* (*IPV*) and *abuse of elderly and vulnerable adults* often remain undetected. Nearly 25% of women and 14% of men have experienced the most severe types of IPV in their lifetime. Victims of IPV, which refers to physical, sexual, or psychological harm by a current or former partner or spouse, often develop chronic mental health conditions, such as depression, posttraumatic stress disorder, anxiety disorders, substance abuse, and suicidal behavior. Risk factors for IPV include young age, substance abuse, marital difficulties, and economic hardships. Available screening instruments can identify current and past abuse or increased risk for IPV, but for vulnerable adults, the USPSTF found inadequate evidence on the accuracy of screening instruments. Most *abdominal aortic aneurysms (AAA)* ($\geq$3 cm) are asymptomatic until they rupture, and they are also most prevalent in men who have ever smoked. Although the risk for rupture varies greatly by aneurysm size, the associated risk for death is as high as 75–90%. Therefore, considering an effective method for screening and treating appropriate patients before rupture is important. One-time ultrasound screening for AAA in men ages 65–75 years who are current or former smokers is recommended. Selective screening in this age group who have never smoked should be considered if risk factors for AAA are present (e.g., first-degree relative with an AAA, history of other vascular aneurysms, cardiovascular disease, cerebrovascular disease, atherosclerosis, hypercholesterolemia, obesity, or hypertension).

Effectively reducing *bone fractures* among older people involves both preventing falls and increasing bone and muscle strength. Older adults should be asked about recent falls. Fall prevention includes minimizing psychotropic medications and encouraging weight-bearing physical activity and muscle strengthening. The USPSTF recommends routine osteoporosis screening in women aged 65 and older and for those at increased risk most commonly with dual-energy X-ray absorptiometry (DXA) and quantitative ultrasonography. Routine screening for *osteoporosis* is not recommended for young postmenopausal women who do not meet risk factor-based criteria. *Depression in older adults* is often misdiagnosed and undertreated having a significant adverse impact on quality of life, health outcomes, healthcare utilization, morbidity, and mortality. Medicare beneficiaries with chronic diseases and associated depression have significantly higher healthcare costs than those with chronic diseases alone. Also, suicide rates are almost twice as high in the older adult compared with

www.konkur.in

Table 3 USPSTF A and B recommendations for adults

Grade	Recommendations	Description[a]
Screening		
B	Unhealthy alcohol use: screening and behavioral counseling interventions	Screen adults 18 years or older, including pregnant women, and providing persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce unhealthy alcohol use. **NIAAA Single Alcohol Screening Question (SASQ)**: *"How many times in the past year have you had 5 [for men] or 4 [for women and all adults older than 65 years] or more drinks in a day?"* **AUDIT-C alcohol screening:** 1. How often did you have a drink containing alcohol in the past year? 2. How many drinks did you have on a typical day when you were drinking in the past year? 3. How often did you have 6 or more drinks on one occasion in the past year?
B	Depression screening	In the general adult population, including pregnant and postpartum women. Screening should be implemented with adequate systems in place to ensure accurate diagnosis, effective treatment, and appropriate follow-up
A	Blood pressure (BP) Hypertension	Screening for high blood pressure in adults aged 18 and over. The USPSTF recommends obtaining measurements outside of the clinical setting for diagnostic confirmation before starting treatment
A	HIV infection: screening	Persons aged 15–65 years, all pregnant women, and persons who are at increased risk (MSM, IDU, having sex partners who are HIV-infected, unprotected vaginal/anal intercourse, bisexual, exchanging sex for drugs or money
B	Hepatitis B virus infection: screening	Persons at high risk for infection including all foreign born in countries with a high rate of infection, regardless of vaccination history, mainly Asia, sub-Saharan Africa, the Pacific Islands, the Middle East, and Eastern Europe. Also injection drug users; MSM; household contacts and sexual partners of HBsAg-positive persons; patients receiving hemodialysis; and immunosuppressed and HIV-positive persons
A	Syphilis infection: screening	Persons at increased risk for syphilis infection including MSM and engage in high-risk sexual behavior, commercial sex workers, persons who exchange sex for drugs, and those in adult correctional facilities
A	Latent tuberculosis infection (LTBI): screening	Populations at increased risk for LTBI based on increased prevalence of active disease and increased risk of exposure include persons who were born in/former residents of countries with increased tuberculosis prevalence and persons who live in, or have lived in, high-risk congregate settings (e.g., homeless shelters and correctional facilities)
B	Breast and ovarian cancer/ BRCA risk assessment and genetic counseling/testing	Primary care clinicians assess women with a personal or family history of breast, ovarian, tubal, or peritoneal cancer or who have an ancestry associated with breast cancer susceptibility 1 and 2 (BRCA1/2) gene mutations with an appropriate brief familial risk assessment tool. Women with a positive result on the risk assessment tool should receive genetic counseling and, if indicated after counseling, genetic testing

www.konkur.in

Table 3 (continued)

Grade	Recommendations	Description[a]
B	Intimate partner violence screening	In women of reproductive age and provide or refer women who screen positive to ongoing support services
B	Chlamydia and gonorrhea: screening	Sexually active women age ≤24 years and in older women who are at increased risk for infection (prior STIs, HIV, new or multiple sex partners, exchanging sex for money or drugs). Insufficient evidence for screening in men
A	Cervical cancer	Women age 21–29 years with cytology alone every 3 years. For women age 30–65 years every 3 years with cervical cytology alone, every 5 years with high-risk human papillomavirus (hrHPV) testing alone, or every 5 years with hrHPV testing in combination with cytology (cotesting)
B	Hepatitis C: screening	Persons at high risk for infection (past or current injection drug use; blood transfusion before 1992) and 1-time screening for adults born between 1945 and 1965
B	Abnormal blood glucose/ and type 2 diabetes mellitus	As part of cardiovascular risk assessment in adults aged 40–70 years who are overweight or obese. Clinicians should offer or refer patients with abnormal blood glucose to intensive behavioral counseling interventions to promote a healthful diet and physical activity
A	Colorectal cancer (CRC)	Screening in adults ages 50–75 years. The risks and benefits of different screening methods vary
B	Breast cancer screening, mammography	Biennial screening for women 50–74 years. Women 40–49 years should be individualized and take into account patient's risks and values regarding specific benefits (Grade C)
B	Osteoporosis to prevent fractures	Screening with bone measurement testing to prevent osteoporotic fractures in women ≥65 years and in postmenopausal women ≤65 years who are at increased risk of osteoporosis, as determined by a formal clinical risk assessment tool
B	Lung cancer: screening	Annually with LDCT in adults aged 55–80 years who have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years
B	Abdominal aortic aneurysm (AAA), men	One-time screening by ultrasonography in men ages 65–75 years who have ever smoked (≥100 cigarettes). Selectively offer screening for AAA in men ages 65–75 years who have never smoked (C)
Preventive therapies		
A	HIV preexposure prophylaxis	Preexposure prophylaxis (PrEP) with effective antiretroviral therapy to persons who are at high risk of HIV acquisition
B	Breast cancer, prevention medication	Clinicians offer to prescribe risk-reducing medications, such as tamoxifen or raloxifene, for women who are at increased risk for breast cancer and at low risk for adverse medication effects[b]
A	Folic acid for prevention of neural tube defects	All women planning or capable of pregnancy take a daily supplement containing 0.4–0.8 mg (400–800 μg) of folic acid
C	Aspirin use to prevent cardiovascular disease and colorectal cancer	Low-dose aspirin in adults aged 40–59 years who have a 10% or greater 10-year CVD risk and are not at increased risk for bleeding.

(continued)

Telegram: @medical_k

www.konkur.in

Table 3 (continued)

Grade	Recommendations	Description[a]
B	Statin use for the primary prevention of CVD	Adults aged 40–75 years with no history of CVD, 1 or more CVD risk factors, and a calculated 10-year CVD event risk of 10% or greater
B	Falls prevention in community-dwelling older adults	Exercise interventions to prevent falls in community-dwelling adults 65 years or older who are at increased risk for falls
Counseling		
A	Tobacco smoking cessation	Ask all adults about tobacco use, advise them to stop using tobacco, and provide behavioral interventions and US Food and Drug Administration (FDA)-approved pharmacotherapy for cessation to adults who use tobacco
B	Sexually transmitted infections	Intensive behavioral counseling for all sexually active adolescents and for adults who are at increased risk for STIs
B	Weight loss to prevent obesity-related morbidity and mortality in adults	Clinicians should offer or refer adults with a BMI of $\geq$30 kg/m^2 to intensive, multicomponent behavioral interventions
B	Healthful diet and physical activity for CVD prevention in adults with cardiovascular risk factors	Offering or referring adults who are overweight or obese and have additional cardiovascular disease (CVD) risk factors to intensive behavioral counseling interventions to promote a healthful diet and physical activity for CVD prevention
B	Skin cancer prevention	Counseling young adults, adolescents, children, and parents of young children about minimizing exposure to ultraviolet (UV) radiation for persons aged 6 months to 24 years with fair skin types to reduce their risk of skin cancer

the general population, with the rate highest for white men over 85 years of age.

Adhering to Prevention Guidance: Barriers to Care

Barriers to conducting preventive care services may be due to the medical care providers or patients. This section summarizes those barriers and addresses a few techniques to implement in practice to improve patient and provider compliance with preventive care.

Barriers to Provider Adherence

Provider adherence is related, in part, to the challenges of a busy practice, system barriers, or simple human error. Common reasons for provider gaps in preventive care could be due to lack of awareness of guidelines, lack of familiarity with guidelines, lack of agreement, lack of outcome expectancy, and external barriers such as patient and environmental factors [28]. The following sections consider these barriers in more detail.

Time Constraint: Time constraints affect even the most prevention-oriented providers. Patients

Telegram: @medical_k

www.konkur.in

Table 4 USPSTF A and B Recommendations for pregnant women

Recommendations for pregnant women		
B	Preeclampsia: screening	Blood pressure measurements throughout pregnancy
B	Preeclampsia: low-dose aspirin	Low-dose aspirin (81 mg/d) as preventive medication after 12 weeks of gestation in women who are at high risk for preeclampsia
B	Asymptomatic bacteriuria	Urine culture for pregnant women at 12–16 weeks gestation or at their first prenatal visit
A	Hepatitis B virus infection	Pregnant women at their first prenatal visit
A	Human immunodeficiency virus (HIV) infection	All pregnant persons, including those who present in labor or at delivery whose HIV status is unknown
A	Syphilis infection	Early screening for syphilis infection in all pregnant women
A	Rh (D) incompatibility: screening	Rh (D) blood typing and antibody testing at the first visit for pregnancy-related care. Repeated Rh (D) antibody testing for all unsensitized Rh (D)-negative women at 24–28 weeks gestation, unless the biological father is known to be Rh (D)-negative (B)
B	Breastfeeding: counseling	Interventions during pregnancy and after birth to promote and support breastfeeding

presenting for annual well-exams offer the best opportunity to perform indicated preventive services, as patients are then most receptive to prevention, provider time constraints are addressed, and payment is likely to be covered. In compliance with the Affordable Care Act, insurances commonly waive the co-pay and deductible for preventive visits. When patients present with complaints that use up the allotted visit time to assess, diagnose, and treat, it is likely to limit the capacity of the family physician to provide preventive care. The Annual Wellness Visit (AWV) required by the Centers for Medicare & Medicaid Services (CMS) could be utilized as an opportunity to perform preventive services. Furthermore, some services may require time-consuming patient education or counseling. Often practices must reevaluate the delegation of duties and team-based care, shifting some responsibilities to nursing and other staff in order to allow providers to cover the preventive service needs of most patients. For example, estimations show that full adherence to USPSTF recommendations could require 7.3 physician hours out of each working day [29].

Training Needs: Training is a key component of overall practice compliance with the provision of preventive services. It is essential to ensure that the staff is skilled at providing the services required, such as standing orders for vaccination and screenings. In addition, they should be knowledgeable about brief intervention for alcohol and drug use, depression, and lifestyle changes. Barriers include the knowledge base and practice patterns of providers (awareness, familiarity, and agreement with guidelines). Awareness and familiarity with guidelines could be partially addressed through continuing medical education. Other factors may require more extensive training and possibly systematic practice change. Confusion may also stem from updates to guidelines and/or conflicting recommendations from different organizations.

Coding and Billing Difficulties: Though electronic medical record (EMR) systems with billing systems are quickly becoming standard tools with important potential benefits, they are not uniform in their interfaces, features, or data entry requirements. In some instances, EMR may introduce new challenges into daily practice. Receiving reimbursement for preventive services may be difficult. However, it is encouraging that the list of covered preventive services grows more comprehensive annually, particularly in light of the Affordable Care Act (ACA). A similar barrier stems from the disparate coverage provided by states in response to federal mandates. For example, Medicaid coverage of preventive services varies between states, and even as the ACA has included the coverage of key preventive services, many states have not expanded their Medicaid programs.

Telegram: @medical_k

www.konkur.in

Practice Culture: Some providers or practices may be resistant to focusing on preventive services. This resistance can be due to personal prejudices held toward patients (e.g., patients with poor self-care habits or combative attitudes). More importantly, the entire practice may be averse to systematic approaches to implementing preventive services for many reasons, including an orientation toward providing only acute care. In this scenario, the practice-wide goal may be to see as many patients as possible, addressing presenting complaints, with less emphasis on delivering preventive services. This type of practice alignment may even discourage individual attempts to follow prevention guidelines.

Barriers to Patient Adherence

Much like provider compliance, patients may face various barriers that undermine prevention. *Access and Socioeconomic Barriers:* The greatest barrier to patient adherence is a lack of access to preventive services. While cost barriers to regular primary care visits are important, sociodemographically vulnerable groups are also more likely to face other barriers that include transportation, competing time demands, fear, perceptions of risk, and fragmented care [30].

*Health Literacy***:** Health literacy is an important factor impacting patient adherence to preventive care across cultural and socioeconomic groups, and low health literacy, low incomes, and low education are often correlated and low perception of the seriousness of the illness may lead to less preventive health screening [31]. Lifestyle and behavioral health are key components in many of the leading causes of mortality and morbidity in the United States. The prevalence of obesity and type 2 diabetes is example of preventable conditions whose occurrence may indicate a lack of patient knowledge or control over basic lifestyle behaviors. Even when patients are generally knowledgeable about healthy living, they may lack specific knowledge about vaccination, cancer screening, and other preventive services.

Cultural and Demographic Factors: Reviews of preventive service utilization have identified cultural and racial differences when receiving preventive care. However, those differences may be affected by physicians' advice and/or receiving education sessions on preventive screening [32]. Cultural factors may be related to language barriers that affect the rate of receiving preventive care, including cervical cancer screening [33]. Insurance coverage and cost are other essential factors. In some cases, fear, myths, or anecdotes may inhibit a patient from participating in preventive care. Some patients may resist preventive services because they expect a procedure to be uncomfortable. Some may even wish to remain ignorant of any potentially negative test result. Age, lifestyle, obesity, location, previous preventive service, or other medical experiences may all contribute to the likelihood of patient compliance as well [34]. More research is needed to understand the best ways to address these complex factors.

Strategies to Improve Adherence to Prevention Guidance

Addressing *all* patient barriers to preventive care is beyond the scope of this discussion. However, public education, insurance coverage, and a variety of public health campaigns are key features of improving rates of screening and intervention. Preventive services have proven to be cost-effective, cost-saving, and lifesaving in the longer term [35]. Unfortunately, in many cases, the implementation of such services faces practice and provider barriers on the front end. Implementing some of the strategies below may help.

***Training and Time*:** When providers report that they lack training about a new guideline or screening tool, training that targets a particular recommendation may be helpful. This approach requires functional communication between providers and administrators and the will of all parties to solve the problem. Administrators and providers may also proactively collaborate to assess the uptake of new or existing evidence-based guidelines in practice and design improvement programs to facilitate providing the needed

Telegram: @medical_k

www.konkur.in

education and infrastructure to meet goals. However, time constraints can also be addressed in several other ways. Standing orders utilizing nursing staff can effectively shift routine recurring tasks to nursing personnel, such as immunizations and behavioral screenings [36]. Nursing staff effort can be utilized to deliver not only primary preventive services but also secondary and tertiary prevention counseling, case management, care coordination, and even practice management. When well executed, this workflow can improve quality and efficiency [37].

Practice Improvement and Facilitation: Most practices are highly dynamic workplaces, and many experience varying caseloads over time. Even a medium-sized practice may require addressing each of the aforementioned barriers in order to be successful. Practice facilitation, which may include employing or tasking an identified person with the role of helping to get evidence-based guidelines into practice, has been shown effective, and a range of methods are available to initiate this facilitation [38]. Value-based care is making its way into many health markets. Practice facilitation to accommodate value-based care is essential and includes developing registries to track preventive care adherence as well as chronic disease management through care coordination and outreach. Adherence to guidelines and pursuit of high standards of care while maintaining the capacity to meet individual patient needs will be the standard of care in the future [39].

Patient-Centered Medical Home: Perhaps the most widely recognized and comprehensive model for primary care practice improvement is the Patient-Centered Medical Home (PCMH) model. Adopted and developed by the American Academy of Pediatrics, American Academy of Family Physicians, the American College of Physicians, and the American Osteopathic Association, the PCMH principles include a personal physician for each patient; whole-person care, including preventive services; integrated and coordinated care including mental and behavioral health; quality and safety standards including compliance with evidence-based guidelines; and improved patient access [40]. Ideally, transforming a practice into a PCMH involves addressing many of the provider barriers presented herein, while also aiming to support patient compliance. Making the transition to a PCMH can require significant inputs of human and material resources, depending on the starting point of the particular practice. These inputs include staffing changes and hiring, quality improvement assessment processes, regular planning and evaluation meetings, case management and care coordination system development or improvement, practice culture change, health information technology utilization including electronic medical records, integration of mental and behavioral health, and outreach and dialogue with patients to enhance awareness and feedback.

Special Considerations in Underserved Populations

Practices addressing underserved populations, whether in low-income urban or rural areas, tend to see a higher incidence of preventable disease, less access to treatment, lower health literacy, and, in some cases, mistrust of the healthcare system. These patient-level determinants of health demand higher inputs of resources and time to address long-standing patient needs ranging from counseling to numerous tests or procedures in a given visit. Higher needs combined with lower resources result in larger demands on practices. However, at the same time, this offers an opportunity for the practice to achieve a more significant impact and to identify potential areas for further improvement.

Special Considerations in Teaching Practices

Teaching practices require special training and cultural considerations. Resident physicians are often well equipped with knowledge of the most recent prevention guidelines but may lack the experience to effectively recognize opportunities or counsel patients. Moreover, residency practices have higher turnover of physicians due to the nature of training duration, impacting the practices' ability to create effective long-term

Telegram: @medical_k

www.konkur.in

patient-provider relationships. Continuity clinics, in which family medicine physicians track the same patient group through the entire training period, as well as specific training in behavior change modalities and integrative medicine, may help to address these issues.

Lifestyle medicine has become a hot topic within the health care field as of late with courses dedicated to learning lifestyle medicine and more physicians learning how to prescribe lifestyle changes. Lifestyle changes such as diet, smoking cessation, and physical activity are all related to patient's overall health and well-being. This chapter will focus on how to help guide your patients to change their lifestyle and reduce preventable diseases.

Physical Activity

Briefly, exercise can be defined as movement or exercise that requires the body to use energy [1]. Physical activity can be further broken down into subtypes including aerobic activity, muscle-strengthening activity, bone strengthening activity, balance and flexibility activities. Many activities, especially things like walking, running, and weight lifting, for example, cross over several of these subtypes. Striving to include a variety of physical activities may help to optimize fitness.

Benefits of Physical Activity

Physical activity has many immediate and long-term benefits. Some of the notable benefits include improvement in sleep quality, weight loss, neurocognitive benefits, and a sense of general well-being [1]. Longer term benefits include decreases in chronic conditions such as ischemic heart disease, type 2 diabetes mellitus, obesity, and certain cancers, including breast, colon, endometrial, esophageal adenocarcinoma, renal, lung, and certain gastric malignancies [2]. Numerous evidence-based studies demonstrate linkages between physical activity and slowing or stopping disease progression, or even aiding in the reversal of several chronic diseases. For instance, in a randomized trial that compared percutaneous coronary angioplasty with exercise training in 101 patients with stable coronary artery disease, exercise training proved to be superior to percutaneous intervention when comparing both event-free survival and exercise tolerance without symptoms [4]. In patients 65 and older, physical activity has a multitude of benefits, including a decreased rate of falls.

Physical Activity Recommendations

Regarding physical activity, it can be unclear as to what specifically should be recommended to patients. So what counts as exercise and how much exercise is needed to be beneficial? In 2008, the Department of Health and Human Services first issued *Physical Activity Guidelines for Americans* and has since released an updated version 2 of the resource in 2018. The updated resource explains what types and amounts of physical activity yield beneficial results, and highlights ways that health professionals might promote these guidelines.

Current physical activity recommendations include:

- For adults 18 years and older, recommendations include striving for:
  At least 150 min per week of moderate physical activity or at least 75 min of vigorous physical activity per week
  Strength training exercises at least 2 days per week
  Additional benefits can be seen with increased levels of exercise even beyond 300 min of moderate activity or 150 min of vigorous activity per week, but the most substantial benefit occurs in the former category.
- For children and adolescents aged 6–17 years [1, 5]:
  Aim for a goal of 60 min of moderate or vigorous activity each day
  At least 3 days per week of vigorous aerobic activity, bone strengthening and muscle strengthening activities
- For adults age 65 and older, the abovementioned quantity and intensity of physical activity for applies. Of note, special attention should be paid to focusing on multicomponent activities that include elements of balance training as well as muscle building and aerobic activities [1]. Furthermore, while striving toward the standard exercise goals of 150 min of moderate physical activity is ideal, older adults with chronic medical conditions must consider that modifications might need to be made, and he or she should strive to be as physically active as their abilities and conditions allow. For flexibility, static stretches are encouraged, and activities that do not impose excessive orthopedic stress such as walking, stationary bike, or aquatic exercise should be considered [6].

Telegram: @medical_k

www.konkur.in

Exercise Types/Intensity

Now for the next question: "What kinds of exercise count toward these goals?" To help answer this, let us look at the concept of a MET. MET can be defined as "the metabolic equivalent of a task." 1.0 MET is roughly defined as the rate of energy expended by an individual seated at rest. Table 1 illustrates approximate exercise intensities of some activities expressed in METS.

Of note, it is often difficult to explain the concept of METS in a brief clinic visit, and level of exercise is often more easily explained by discussing judgment of intensity of exercise based on how one feels during the activity. For example, one might be performing an activity in the moderate intensity activity level if breathing is quickened but not out of breath or if one is lightly sweating after about 10 min of the activity. Another clue that an activity falls in the moderate intensity category is the ability to continue to talk but not being able to sing while performing the activity. For vigorous intensity activities, some signs include sweating after a few minutes and being able to only say a few words without pausing the activity.

Sedentary Behavior

More recent research specifically highlights the increases in sedentary activity in recent years, along with the health repercussions of sedentary behavior. Sedentary behavior can be defined as waking behaviors with low energy expenditure less than or equal to 1.5 METS. Examples are sitting, reclining, or lying down. Higher rates of sedentary activity increase the risk of cardiovascular disease, type 2 diabetes, certain cancers (colon, endometrium and lung), and all-cause mortality. While reaching the 150 min per week goal of moderate physical activity has been shown to yield the greatest benefits, reducing sedentary behaviors to any degree has notable health benefits – even 5 min at a time. Family physicians have an opportunity to lead by example as well as to make significant community and national health benefits by adhering to personal exercise habits as well as by leading community initiatives.

Physical Activity Assessment and Exercise Prescriptions

Assessing levels of physical activity of patients can be challenging, but there are tools that can make this more straightforward and useful. One easily incorporated tool is the inclusion of a "Physical Activity Vital Sign" (PAVS) in every visit. By asking the following two questions, one can quickly assess whether or not a patient is meeting exercise goals:

1. On average, how many days per week do you engage in moderate to strenuous exercise like a brisk walk?
2. On average, how many minutes do you engage in exercise at this level?

While the PAVS is geared to adult patients, incorporation of similar questions into pediatric and adolescent visits should be considered. With the pediatric population, consider including questions about total screen time per day, as well as exercise both at school and at home and as a group with family.

One important way that practitioners can promote patient adherence to physical activity recommendations is to write exercise prescriptions [7]. Collaboratively working with patients, exercise

Table 1 Examples of physical activity intensity categories [7]

Intensity level	METS	Examples of activities
Light-intensity activities	<3.0 METS	Walking at a leisurely pace (<2 mph), cooking, light household chores
Moderate-intensity activities	3.0–5.9 METS	Walking briskly, moving the lawn, doubles tennis
Vigorous intensity activities	>6.0 METS	Running, carrying a heavy load upstairs, playing soccer or a basketball game

Telegram: @medical_k

www.konkur.in

plans can be individually crafted to maximize benefit and adherence. The aim is to clearly recommend a level of exercise intensity, duration, and frequency, with a gradual increase toward the patient's eventual personal goal. There are several examples of exercise prescriptions available for review online [7]. Also, in the age of technology, there are numerous devices, apps, and websites that can help patients track exercise habits and goals.

Several other tools are available to help assess readiness to change, explore self-efficacy, identify medical contraindications and other aspects of physical activity. Some include the PAAT, PARmed-X, PAR-Q, and RAPA, and are available online. Of particular interest and utility is ACSM's Guidelines for Exercise Testing and Prescription [8]. A useful algorithm based on ACSM guidelines is freely available online in the "Exercise is Medicine – Healthcare Providers' Action Guide." [5]

Nutrition

Nutrition can be defined as the intake, digestion, and absorption of nutrients to provide energy and support metabolic functions of the body. There is a deeper meaning in nutrition, however, as it relates to the overall functioning of the body, mind, and support of overall well-being. Hippocrates stated, "Let food be thy medicine, and medicine be thy food"; this quote recognizes the critical importance of nutrition and dietary choices in determining the structure and function of the body and mind. Often in today's busy world, the power of nutrition has a tendency to be overlooked. Not only can balanced and mindful nutrition provide overall support to optimal functioning but may play a key role in halting or even reversing many common chronic diseases including hypertension, type 2 diabetes mellitus, and certain cancers such as prostate cancer [9, 10].

The concept of energy balance is the difference between energy intake and energy expenditure, with a negative energy balance leading to the body using energy stores (in the form of fat, protein, and glycogen stores) and a positive energy balance leading to storage of excess energy, mostly as adipose tissue [13]. With rates of obesity consistently on the rise, an important focus of appropriate nutrition is the management of obesity and comorbidities associated with it.

Diet Types

With a multitude of nutrition information flooding the media, it is often difficult to ascertain which types of diets or nutrition advice is most evidence based and most beneficial. Here are some of the most current evidence-based diets and nutrition recommendations:

- Mediterranean Diet [14]
  - Places emphasis on monounsaturated fats from olive oil, fruits, vegetable, whole grains, legumes, nuts, fish, and moderate alcohol consumption
  - Limits red meat, refined grains and sugar
  - Has been shown to reduce rates of diabetes mellitus type 2, certain cancers, cognitive decline with age, cardiovascular disease, and overall mortality
- DASH (Dietary Approaches to Stop Hypertension) Diet [15]
  - The DASH diet places emphasis on increasing the amount of fruits, vegetables, whole grains, and low-fat dairy products.
  - Limits saturated fats, cholesterol, refined grains and sugars, and aims for no more than 2400 mg of dietary sodium per day.
  - Studies show a particular improvement in blood pressure with this diet, and when DASH diet is practiced in conjunction with lowered sodium, blood pressure lowering effects in mild hypertension are on par with antihypertensive medication monotherapy [15]. A combination of the DASH diet and low sodium intake reduced systolic pressure on average by 9 mm Hg, with a smaller decrease in diastolic pressure of 4.5 mm Hg.
  - Also has favorable effects on obesity and diabetes mellitus type 2.
- Whole-Food Plant-Based Diet

Telegram: @medical_k

www.konkur.in

  - Focuses on grains, legumes, nuts, seeds, fruits, vegetables, and plant oils.
  - Limits or avoids meats, eggs, processed carbohydrates and sugars.
  - Has been shown to lead to decreased rates of obesity, diabetes mellitus type 2, hypertension, CVD morality, prevent or slow the growth of certain types of cancer such as prostate [10], reduces the risk of dementia [14], and improvements in overall well-being.
  - This category may overlap with vegetarian diet (avoiding meat but eating some animal products such as dairy or eggs), a vegan diet (avoiding all animal products), or a flexitarian diet (predominantly plant-based foods with occasional animal products).

Of note, there are some commonalities among these three presented categories. Using currently available data, the following points seem to be most supported by evidence and can help with deciding which guidelines to promote and how best to counsel patients [15]:

- Plant-based foods should be emphasized over animal-based foods in the diet.
- Focus on whole foods rather than processed foods.
- Water should be the primary beverage consumed.
- Intensive lifestyle modification to increase activity should be recommended to patients at high risk of cardiovascular disease.
- Free sugars should be limited to less than 10% of daily calories.
- Avoid beverages with processed sugars.
- Limit the daily intake of sodium to no more than 2300 mg per day for adults.
- Be mindful of portion sizes.
- Assess for and address barriers to health behavior change.

Obtaining and preparing nutrient dense foods does take work, but finding ways to incorporate a focus on nutrition into daily routines can optimize both physical and mental health and improve overall well-being.

Nutrition Assessment

To best support a patient's nutrition goals, one must first assess the patient's overall nutritional status and dietary routine. One tool to assist with obtaining a base nutrition assessment is the "ABCD's" of the basic nutrition assessment, with an example outline as follows:

A. : Anthropometric data
   - Height, weight, BMI, waist circumference, sometimes body fat percentage

B. : Biochemical data
   - Lab work and other tests

C. : Clinical assessment
   - Medical history
   - Weight history
   - Activity level
   - Physical exam – vital signs, special attention to signs of nutritional deficiency

D. : Dietary assessment
   - Finding out baseline food intake/dietary patterns/schedule/lifestyle will help the physician provide realistic, individualized goals
   - Basic data collection – 24-Hour Food Recall OR
   - Basic data collection – 3-Day Food Record (2 work days and 1 off day)
   - Needs to be specific (type of food/quantity/measured amount/preparation style/liquid intake)
   - Needs to include timing of food/beverage intake

Nutrition Prescriptions

Just as writing exercise prescriptions can help patients reach their physical activity goals, nutrition prescriptions can help patients reach their dietary goals. When writing nutrition prescriptions, it is helpful to adhere to a consistent format. One example is the "SMART" technique, which is outlined with examples below:

- Specific – select a specific food or category of food (i.e., "eat an apple")

Telegram: @medical_k

www.konkur.in

- Measurable – how many/how much (i.e., "eat one medium apple")
- Accountable – who makes food decisions, who buys the food in the home? What setting does the patient eat in? (i.e., How much control does the patient have over their food choices?)
- Realistic/forgiving – What is available to the patient?
- Time bound – How frequent? For how long? (i.e., "eat one medium apple daily for the next one month")

Nutrition prescriptions can be both positive or negative prescriptions. A positive prescription focuses on foods to add to the diet and a negative prescription focuses on which foods to take away from the diet. In general, positive prescriptions tend to achieve better clinical results and outcomes than do negative prescriptions, but both can be helpful. For example, a positive prescription might look like the example above, i.e., "eat one medium apple per day for the next one week." An example of a negative prescription might place a limit on a particular food or might prescribe to avoid a food altogether. For example, a negative prescription might look like: "cheese, ½ cup, no more than once per week for the next 4 weeks" or "avoid all sodas and sugared beverages for the next 4 weeks."

A Note on Vitamins and Supplements

Many patients often ask the question, "which vitamins or supplements should I be taking?" The answer is unfortunately not straightforward, and there is little evidence to support recommendations for most vitamins or supplement to the greater population. One study evaluated some vitamins and supplements to see if they offered any significant improvement on cardiovascular health or mortality, this was inconclusive [16]. Rather than focusing on promotion of particular supplements, it is likely most beneficial to help patients focus on ways that he or she might improve overall diet, as needed nutrients can generally be obtained from a well-balanced whole food diet.

Some current evidence regarding some of the most common vitamins/supplements:

Multivitamins

- Multivitamins alone have not consistently been shown to improve cardiovascular outcomes or improve mortality risk.

Fish oil

- Particularly omega-3 long-chain polyunsaturated fatty acid (LC-PUFA).
- Might have some benefits, including a lowered risk of myocardial infarction and CAD.
- Studies have not shown consistent significant results with regards to improvement in lab markers such as hemoglobin A1C or lipid panels after fish oil supplementation [17].

Folic acid

- Might have some benefit to overall cardiovascular health such as diminished stroke risk.
- Not particularly beneficial in the United States as many foods are already fortified with folic acid, but studies did show greater benefit in countries where food supplementation (mostly grains and processed foods) is not commonplace.
- Supplementation of folate is recommended for women of childbearing age who are pregnant, are planning, or may become pregnant. To prevent neural tube defects in fetuses of women at average risk, a supplement containing 400–800 μg of folic acid daily is recommended per the USPSTF [18].

Vitamin D

- There is inconsistent evidence to support supplementation of vitamin D for improvement of bone health, cardiovascular health, prevention of cancer, all-cause mortality, or improved pregnancy outcomes [19, 20].
- Thus, routine vitamin D supplementation in community dwelling adults is not recommended.
- There is insufficient evidence to recommend screening the general population for vitamin D deficiency.
- Treating asymptomatic adult individuals with identified deficiency has not shown improvements in health.

Telegram: @medical_k

www.konkur.in

- The United States Preventative Services Task Force (USPSTF) recommends against supplemental vitamin D to prevent falls in community-dwelling adults aged 65 years or older [21].
- One population where there are clear indications for vitamin D supplementation are breastfeeding newborns. The AAFP recommends that breastfed infants receive 400 IU of vitamin D supplementation soon after birth until age 1 year. This recommendation applies to both exclusively and partially breastfed infants.

Calcium

- Similar to vitamin D, there is insufficient evidence to show improved outcomes from calcium supplementation, and supplementation should generally be avoided in the adult population.
- Some studies have even suggested a possible increase in stroke risk when taking calcium and vitamin D concurrently, but these data are inconclusive [21].

Vitamin E

- The USPSTF specifically advises against supplementation with vitamin E for primary prevention of cardiovascular disease or the prevention of cancer [16].

Vitamin B12

- Screening people at average risk for vitamin B12 deficiency is not recommended [22].
- Screening should be considered for patients at risk of B12 deficiency including patients who have a history of bariatric surgery, patients on long-term PPI or H2 blockers or Metformin, and those who follow a strict vegan diet.
- Patients who have had bariatric surgery should receive 1 mg of Vitamin B12 PO daily indefinitely.

Motivational Interviewing

Motivational interviewing (MI) was developed by Miller and Rollnick as a method to address intrinsic motivation for changing behaviors by exploring and addressing ambivalence [25]. MI has been applied to various populations and concerns in health care [29]. MI as a counseling style has been used in health care to enhance a person's intrinsic motivation for change and adherence to treatment [26].

MI has been supported empirically and is consistent with theories of intrinsic motivation [27], [28]. Further research has demonstrated that these techniques of MI improve the quality of the clinician-patient interaction. MI can help clinicians integrate evidence-based medicine with patient-centered care and shared decision-making. Family physicians are uniquely placed to integrate these techniques to assist with prevention, health promotion, and wellness [29].

In primary care, MI is often more commonly used in situations where the patient demonstrates ambivalence and the health care provider is assisting with the addressing that uncertainty, e.g., lifestyle choices, adherence to medications, or engagement in treatment recommendations [30]. Motivational interviewing involves four steps: engaging, focusing, evoking, and planning (Fig. 1). These steps are basic building blocks that can be used in any encounter with a patient-centered focus. Engaging is where the clinician works towards building a mutual helping relationship. Focusing is creating a specific guide and plan about change. Evoking is a vital component as this is where eliciting the patient's own reasons

Fig. 1 Four steps of motivational interviewing

Telegram: @medical_k

www.konkur.in

for change are highlighted. Planning is the step in which there is a tangible attainable plan of action made, with an ongoing commitment to changing the identified behavior.

When using MI, it is important to listen carefully with the goal of understanding the person's challenge with making changes. This technique is not about giving advice but rather asking pointed questions to help understand the person's barriers and interest to change. Some example questions may include:

- Why would you want to make this change?
- How might you go about it in order to succeed?
- What are the two best reasons to do it?

By listening intently, the person's readiness to change will also become apparent. The Transtheoretical Model (also called the Stages of Change Model), developed by Prochaska and DiClemente in the late 1970s, focuses on the decision-making of an individual regarding change [31]. The foundation of the Transtheoretical Model (TTM) is the assumption that people do not change behaviors quickly and often it is a process of decision making. This framework highlights that a person will change through a cyclical process and there are various factors that influence one's passage through those stages [31, 32]. This theory has five stages as used in health care (Table 2).

This framework is often not static, a person's readiness to change and individual change processes can be fluid. While there are outcomes specific to the stage, in practice can be often seen is a person vacillating between the stages based on aspects of the task at hand to change. For example, when if a health care provider is working with someone on changing habits for weight loss, a patient may be in the action stage regarding physical activity but be in the contemplation stage with removing fatty foods from their eating habits. By utilizing the techniques of MI and patient-centered communication skills, a health care provider can enhance preventative behaviors for health and well-being.

Stress Management

Stress has been called the most prevalent disease of modern society: an epidemic brought about by the pace of modern life and the pressure to succeed in a climate of increasing job insecurity [33].

In 2018, a large national study in the United Kingdom reported that three-quarters of the study participants had been so stressed in the past year that they had felt overwhelmed or unable to cope. One in three of these people had been left feeling suicidal, and one in six had self-harmed [36].

Social and political factors, that may include finances, the economy, family responsibilities, and relationships, have been reported to be the top causes of stress among Americans. This stress affects every aspect of people's lives. Stress, poor lifestyle choices, and disease symptoms often coexist and may exacerbate each other. Headaches, muscles tension and pain, fatigue, changes in sex drive, stomach upset, and sleep problems are often encountered. Stress can affect the mood

Table 2 Transtheoretical Model (TTM) Stages of Change

Precontemplation	There is no intention to change behavior. The person may acknowledge interest in the desired outcome but does not demonstrate willingness to make the necessary steps
Contemplation	The individual is beginning to consider change at some indeterminate time in the future. The timeframe is sometimes defined as a goal in about the next 6 months
Preparation	The person is planning to change in the immediate future (approximately in the next month). They may engage in change talk and making plans for the change.
Action	Here the individual engages in behavior change. An ongoing state of behavior change.
Maintenance	The person is sustaining the change (often defined as longer than 6 months). At times the behavior is modified as the individual may experience/learn to reframe challenges in continuing with the new behavior.

Telegram: @medical_k

www.konkur.in

with increases in anxiety, restlessness, lack of motivation and focus, feelings of being overwhelmed, irritability, sadness, and depression. It can also affect behaviors such as over- and undereating, angry outbursts, drug and alcohol misuse, social withdrawal, and decreased exercise [35].

It has been shown that simply talking about stress management with patients can help to reduce the effect that it can have on a person's overall health. An easy tool for primary care providers to use to try and identify stress in patients is the prime-MD patient health questionnaire (PHQ) which has been validated to identify mental health disorders [36]. It allows the physician to quickly evaluate a patient's stress, so this can be investigated further if necessary. According to the American Psychological Association, 32% of Americans believe that it is extremely important for health care providers to discuss stress management, but only 17% report that they have discussed stress management with their physicians [35].

Meditation is one technique that has been shown to be effective in decreasing stress in otherwise healthy individuals [37, 38]. Mindfulness meditation has been shown to result in positive changes in the brain and immune function [39]. There is evidence that mindfulness meditation programs may alleviate anxiety, depression, and pain, and they may reduce stress, distress, and improve the quality of life among patients with chronic disease or mental health diseases [40].

It is imperative that primary care physicians not only help to recognize stress in their patient's but also start a conversation about a team-based approach to managing it. Online-based mindfulness strategies have been shown to be modestly effective in reducing overall stress, anxiety, and depression. Given its wide reach, low cost, and easy access, online-based mindfulness strategies are recommended as a part of an overall stress reduction treatment regimen [41]. There are also mindfulness-based stress reduction workbooks with strategies for reducing stress and ways to incorporate mindfulness into daily life that may be very beneficial to both patients and health care practitioners.

Tobacco Cessation

According to the CDC, cigarette smoking is the leading cause of preventable disease and death in the United States, with almost 14% of adults currently smoking cigarettes [42]. Cigarette smoking alone accounts for about one out of every five deaths every year. In addition to the significant health burden that smoking presents, it also has a significant economic burden with more than $300 billion each year lost to smoking-related illness in the form of direct medical care costs and lost productivity dollars. Encouraging smoking cessation can be one of the most beneficial things we can do for our patients and tobacco use should be assessed at all clinical encounters. In fact, most cigarette smokers would like to quit smoking [44]. Some options for encouraging consistent screening are: incorporating a screening question to ask about tobacco product use into the rooming process, or/and including a question in provider note templates to monitor tobacco use every visit as a health "vital sign." Of note, tobacco products such as chewing tobacco and vaporizers or electronic cigarettes also have significant health risks and are included in this discussion as a focus on cessation of all nicotine containing products. Tobacco use is the top preventable cause of death in the United States [45]. Motivational interviewing tools can be extremely helpful with bringing up the topic of tobacco cessation and gauging a patient's readiness for change.

Alcohol Consumption

According to the 2018 National Survey on Drug Use and Health (NSDUH), 70% of people ages 18 or older reported that they drank alcohol in the past year, and 26.45% of people 18 or older reported binge drinking in the past month [45]. When looking at the statistic of 88,000 deaths per year in the United States from an alcohol-related cause, alcohol is the third leading preventable cause of death. From these statistics, it is easy to see that alcohol consumption is something that every primary care physician needs to have a conversation with their patients about, and

Telegram: @medical_k

www.konkur.in

why the USPSTF recommends screening all adults for unhealthy alcohol use. Furthermore, studies have shown that physicians often fail to identify or adequately address patients' drinking habits [47].

Alcohol Use Screening

Recognizing who may be high risk by using validated screening tools is one way to incorporate consistent screening into your patients' care. To adequately assess alcohol use, it is important to understand standard serving sizes of alcoholic beverages and recommended limits of alcohol use. One drink equates to 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of liquor (one shot). The National Institute on Alcohol Abuse and Alcoholism recommends limiting alcohol as follows:

- Men younger than 65 years old:
  - No more than 2 drinks per day
  - *And* no more than 14 drinks per week
- Women of any age and men 65 years and older:
  - No more than 1 drink per day
  - *And* no more than 7 drinks per week

There are numerous tools that a health care provider can use to identify excessive alcohol consumption. The AUDIT screening questionnaire is one example of a helpful screening tool that has been validated to be a good predictor of alcohol-related social and medical problems. It can be used to objectively ask ten questions about alcohol intake to identify patients who may be drinking more than what is recommended. A briefer version of the questionnaire is the AUDIT-C, which includes the first three questions from the full AUDIT questionnaire. Studies have shown the AUDIT-C to be almost as effective as the AUDIT and is often preferred in busy clinical settings due to its brevity [48].

AUDIT-C:

- Question 1: How often did you have a drink containing alcohol in the past year?
  - Never (0 points)
  - Monthly or less (1 point)
  - Two to four times a month (2 points)
  - Two to three times per week (3 points)
  - Four or more times a week (4 points)
- Question 2: How many drinks containing alcohol did you have on a typical day when you were drinking in the past year?
  - 0 to 2 (0 points)
  - 3 or 4 (1 point)
  - 5 or 6 (2 points)
  - 7 to 9 (3 points)
  - 10 or more (4 points)
- Questions 3: How often did you have six or more drinks on one occasion in the past year?
  - Never (0 points)
  - Less than monthly (1 point)
  - Monthly (2 points)
  - Weekly (3 points)
  - Daily or almost daily (4 points)

Scores of $\geq$4 for men or $\geq$3 for women indicate a positive screen. A positive screen indicates an increased risk of alcohol misuse.

When the risk of unhealthy drinking is identified, it is important for the health care provider to counsel the patient and assist with development of a plan to address the issue. A brief alcohol intervention is beneficial, and interestingly, even 5 min of advice has been shown to be as effective as 20 min [49]. During counseling, it can be helpful to engage a patient in behavior change by asking the patient's permission to discuss, then listening to their thoughts and using reflection. Several helpful resources can be found online, one of which being the NIAAA website's publication entitled "Helping Patients Who Drink Too Much." [50] It includes information about screening and managing the care of patients who consume more alcohol than recommended in a primary care setting.

Importance of Well-Being to the Health Care Professional

Of important mention to family medicine practitioners, taking time to prioritize personal health is essential. Optimizing physical activity habits and

Telegram: @medical_k

www.konkur.in

personal nutrition can yield a multitude of personal benefits as well as leading by example to patients and our communities. In addition to optimizing nutrition and exercise, a focus on personal rest and adequate sleep, stress management, and avoiding tobacco and excess alcohol can provide a multitude of personal benefits.

Introduction

The number of travelers crossing borders each year continues to rise. According to the World Tourism Organization, the number of travelers crossing international borders exceeded 1.4 billion in 2020 [1]. Currently, fewer than half of all international travelers seek a travel consultation prior to departure [2]. A basic understanding of traveler's health is necessary to provide travel advice to patients, as family physicians often bridge the gap between knowledge of a patient's health history and travel medicine. In a recent study, primary care providers were second only to the Internet in patient-identified sources of travel health advice [2].

Pre-Trip Consultation

A pre-trip consultation is recommended at least 4 to 6 weeks prior to departure. The components of the consultation are history intake, review of routine vaccinations, travel-related vaccinations, traveler's diarrhea treatment and prophylaxis, malaria prophylaxis, review of personal protective measures, altitude illness prophylaxis, and safety and accident prevention.

History Intake

This includes the traveler's pertinent medical history, current medications, and allergies, which may affect choices for both travel-related medications and vaccinations. Anticipatory guidance for chronic conditions such as diabetes, heart disease, asplenism, and immune compromise may also need to be addressed. Vaccination history is also relevant, as live vaccines must be given either simultaneously or 28 days apart. Several important travel-related questions are also pertinent, including purpose of travel, specific locations that will be visited in the destination country or countries, accommodations, and traveler habits.

Routine Vaccinations

The travel visit also presents an opportunity to catch up on routine vaccinations. These may include pneumococcal vaccination, Tdap, herpes zoster vaccine, and flu shots. Especially important to verify are MMR and varicella immunity, as immunity is pertinent for travel to parts of the world where disease burden for these illnesses is relatively high. A second MMR is recommended for many endemic countries for adults who can only have a single documented vaccination during childhood or later.

Travel-Related Vaccinations

Hepatitis A

Hepatitis A is transmitted through fecal-oral contamination. Its prevalence in developing countries is often high, and vaccination is recommended for all destinations in these areas. The illness rarely causes death but morbidity is significant. Severity of illness is variable between age groups; the illness tends to be more severe in adults.

Hepatitis A is a 2-dose vaccine series, with each dose separated by at least 6 months. It is licensed for use in patients 1 year and older and is safe for use in pregnant women. The first hepatitis A shot imparts >90% immunity and, in healthy travelers under 40 years old, can be given at any time prior to departure [3]. In older or immunocompromised travelers, it is recommended that at least one hepatitis A dose be given at least 2 weeks prior to departure to generate adequate immunity [3]. Once both doses are given, immunity is considered lifelong for hepatitis A and no further boosters are needed.

Hepatitis A vaccine also exists in a 3-dose series called Twinrix, where it is combined with a hepatitis B vaccine. Only persons aged 18 and older are eligible to receive the Twinrix vaccine. The vaccine is administered at 0, 1, and 6 months. It is important to note that immunity imparted with each Twinrix shot is less than the individual hepatitis vaccines administered separately. For adequate immunity (>95%), two doses of Twinrix are recommended prior to travel [7].

In children less than 1 year old, hepatitis A immunoglobulin (Ig) is available; however, this age group tends to have controlled diets which may reduce hepatitis A risk. There are also conflicting recommendations for hepatitis A Ig use for pretravel prophylaxis [3, 7]. The availability and cost of hepatitis A Ig can also be a challenge; therefore, these considerations should be taken into account.

Hepatitis B

Hepatitis B is transmitted through contact with infected blood or bodily fluid products. Several factors increase the risk of hepatitis B. These include volunteer work in which contact with blood or bodily fluids might be encountered (e.g., medical volunteer projects) as well as the potential for sexual contact. An injury or illness while abroad which leads to local medical care may also increase risk of exposure to hepatitis

Telegram: @medical_k

www.konkur.in

B. Traveler risk factors should be assessed prior to administration of hepatitis B vaccination.

Hepatitis B vaccine exists in a 3-shot series spaced at least 0, 1, and 6 months apart. It is licensed for use starting at birth and is safe for use in pregnancy. One dose of hepatitis B imparts approximately 30 to 55% immunity, 2 doses 75% immunity, and 3 doses >95% immunity in adults [4]. At least 2 doses of hepatitis B are recommended prior to travel. It is important to note that the immune response to hepatitis B decreases with age; after age 40, protective immunity from full hepatitis B vaccination decreases to below 90% and to 75% by age 60 [4]. Immune suppression can also decrease the response to hepatitis B vaccination. Therefore, for some at-risk travelers, there may be a benefit in checking hepatitis B antibody titers prior to travel.

A new vaccine, based on a novel adjuvant, known as HepB-CpG was licensed in 2018. It could have application in travel in that it is fully immunizing after 2 doses spaced 4 weeks apart.

Typhoid

Typhoid fever indicates an infection by *Salmonella typhi*, which is spread by fecal-oral transmission. *S. paratyphi* can also cause a similar clinical illness.

There are currently two licensed vaccines in the United States. Typhim Vi is a polysaccharide subunit vaccine, given intramuscularly, with an effectiveness of 55–75%. A booster for ongoing exposure is needed after 2 years. Oral typhoid vaccine consists of a live attenuated strain, Ty21a, which confers similar protection. Unlike the polysaccharide vaccine, however, studies have shown that the oral vaccine does confer some protection against paratyphoid [5]. The manufacturer's instructions are for 1 capsule to be taken an hour before eating every 48 h for 4 doses. The capsules require refrigeration, and revaccination is recommended every 5 years. It can be administered concurrently or at any time in relationship with other live viral vaccines (i.e., yellow fever). However, as antibiotics can impact the vaccine's immunogenicity, it is recommended that no antibiotics be given with, or 3 days before or after, the vaccine. In the case of proguanil, which is one of the active components of the antimalarial atovaquone/proguanil (Malarone ®), a 10-day interval should be maintained between completing the oral typhoid vaccine and starting proguanil. Coadministration with mefloquine is not problematic. As no vaccine confers complete protection, attention to hygiene and eating practices should be emphasized in all travelers.

Yellow Fever

Yellow fever has a widespread distribution in Africa, Panama, and parts of South America. Though classified a hemorrhagic fever, liver and kidney injury is responsible for its morbidity and mortality.

There is a safe and effective vaccine based on an attenuated strain, 17D. Many countries mandate vaccination of travelers. Some countries may even require vaccination of travelers who will transit in airports. Vaccination is restricted to certified vaccination centers. Vaccinees should be provided the International Certificate of Vaccination (yellow card) correctly filled out. Travelers should be told to keep this card with their passport as generally it must be displayed before passport control.

The WHO stated in 2013 that a single yellow fever immunization confers lifelong immunity [6]. While yellow fever vaccine is generally safe, as a live vaccine, it is contraindicated for the immunosuppressed and generally is avoided in pregnant and lactating women. In addition, there are visceral and neurological reactions which occur more frequently at the extremes of age. Therefore, yellow fever is relatively contraindicated less than 9 months of age and absolutely contraindicated below 6 months of age. There is a relative contraindication over age 60 as well, as adverse reactions, though still rare, are increasingly common above this age [7].

Those travelers who have a contraindication to yellow fever vaccination, including age, should be provided an exemption card certifying the medical reason for not receiving the vaccine. The exemption section is included in the International Certificate of Vaccination (yellow card).

Polio

The eradication of polio worldwide has proven to be an elusive goal. At present there are

Telegram: @medical_k

www.konkur.in

10 countries in the world that are considered either polio infected or polio exporting. This list evolves rapidly, but those countries affected and recommendations for polio vaccination are listed and maintained on the CDC website (www.cdc.gov). All travelers to countries with polio should have completed the standard series. In addition to this, adults whose polio vaccinations took place in the remote past should have a single, lifetime polio booster. Long-term (more than 4 weeks) travelers to certain high-risk countries may be required to show proof of vaccination within 1 year for entry and exit. Up-to-date information is available from the WHO [8].

Meningococcus

Infections due to *Neisseria meningitidis* occur worldwide. In the United States, quadrivalent meningococcal vaccine (MCV4) is part of the routine vaccination program. There are two destinations for which vaccination is required or recommended: The *Hajj*, the pilgrimage to Mecca in Saudi Arabia, and the meningitis belt of sub-Saharan Africa. In the meningitis belt in Africa, meningitis can occur at any time but is more frequent during the dry season, from December to June. The serotype of greatest concern is group A.

Vaccination should be considered for all travelers to areas within the meningitis belt if their travel will extend within a month of the December to June window. Quadrivalent conjugated vaccine is the only vaccine presently available for all travelers aged 2 month and older, including those over 55. Boosters are required every 5 years should the traveler remain at risk. Adolescents and preadolescents already vaccinated will not need additional boosters for travel.

Vaccination against type B meningococcus is not needed for travel.

Japanese Encephalitis

Japanese encephalitis (JE) is a mosquito-borne illness prevalent in areas of Asia. Its overall prevalence is 1 case per one million travelers [9]. The risk of contracting the illness includes travel lasting 1 month or greater in rural areas or itineraries in at-risk destinations, which include prolonged and extensive outdoor activities. Symptoms of the disease include change in mental status, fever, and seizures. The fatality rate is 20–30% [9]. Long-term neurological and psychiatric sequelae are seen in 30–50% of survivors [9].

Several brands of Japanese encephalitis vaccine exist in different parts of the world. The current vaccination in use in the United States is IXIARO. IXIARO is a 2-dose vaccination, with doses ideally separated by 28 days, although the second dose can be given one after the first, and ideally at least 1 week prior to travel. The first dose imparts approximately 41% immunity, while the second dose leads to 97% immunity [10]. In addition to use in adults, the IXIARO vaccine has now been approved for use in children aged 2 months to 16 years as of May 2013.

Boosters for JE vaccination are recommended in 1 year for adults, if repeat travel to affected areas is planned. Further booster dosing in the pediatric population is still being actively studied.

Rabies

Rabies unfortunately is almost always a fatal illness. The most common transmission occurs through a bite with an infected animal. Worldwide, the most common source of rabies is infected dogs [11]. Children are particularly prone to rabies exposure while traveling, as they are less likely than adults to exercise caution when coming into contact with animals.

Pretravel vaccination against rabies is recommended for travelers who are visiting locations with high animal rates of rabies and inadequate access to rabies treatment [12]. In many locations in developing countries, access to rabies immunoglobulin (Ig) might not be readily available. Pretravel rabies vaccination would preclude the need for rabies Ig post-exposure in these locales. Vaccination can also be considered for travelers who plan on visiting rabies-endemic locations for extended periods of time (longer than 1 month). Vaccination is often quite expensive and consists of a 3-dose series at days 0, 7, and 21 (or 28). It is licensed for use in persons of all ages and is safe for use in pregnant women.

Post-exposure treatment is 3-pronged [12], consisting of wound care, administration of the

Telegram: @medical_k

www.konkur.in

Table 1 Post-exposure treatment of rabies [12]

Received pre-exposure vaccination?	Wound cleansing needed?	Rabies immunoglobulin administration needed?	Post-exposure immunization schedule
Yes	Yes	No	Days 0 and 3
No	Yes	Yes	Days 0, 3, 7, 14

rabies immunoglobulin (if no pre-exposure vaccination was given), and postexposure vaccination. See Table 1 for postexposure treatment.

Boosters for rabies are generally not recommended for most travelers on subsequent trips where exposure to rabies may be significant [12]. Exceptions to this are travelers who may be working in a veterinary capacity or research capacity with wildlife, where it is recommended that serum antibody titers for rabies be checked prior to revaccination.

Traveler's Diarrhea Prophylaxis

Traveler's diarrhea is a common cause of infectious illness while abroad, affecting an estimated 30–70% of travelers [13]. It is defined as three or more episodes of diarrhea in 24 h with at least 1 of the following associated symptoms: fever, nausea, vomiting, abdominal cramps, tenesmus, or bloody stools. Traveler's diarrhea causes significant morbidity, as it leads to significant disruption in traveler activities and itineraries due to symptoms. While adventure travel and avoidance of precautions put a traveler at higher risk, traveler's diarrhea is also reported on luxury travel itineraries as well.

The most common cause of traveler's diarrhea worldwide is enterotoxigenic *Escherichia coli* [13]. On the rise is enteroaggregative *E. coli* as a pathogen. Other pathogens include *Campylobacter*, *Salmonella*, *Shigella*, viral pathogens, and protozoa such as *Giardia*.

Empiric treatment for traveler's diarrhea is guided by balancing likely pathogens, local resistance patterns, and likely side effects. Ciprofloxacin has been the most common antibiotic used to treat traveler's diarrhea in adults, but concerns about resistance patterns and possible side effects have limited its usefulness. Azithromycin is generally considered the preferred agent. It is given as 500 mg daily for 3 days for adults, and 10 mg/kg per day for 3 days for children. Ciprofloxacin may be used in cases of personal preference or in situations where there are drug compatibility problems due to its hepatic metabolism. Azithromycin is the treatment of choice for both pregnant women and children. Many clinicians prescribe treatment doses of antibiotics for traveler's diarrhea for each traveler to fill in advance and take with them on their trips.

Concurrent treatment of traveler's diarrhea with both loperamide and antibiotics has been shown to decrease traveler's diarrhea symptoms more rapidly than either treatment option alone [14]. A recent meta-analysis of traveler's diarrhea in several communities around the world showed increased likelihood of clinical cure at 24 h and 48 h if combination loperamide/antibiotic therapy is given [14].

Prophylaxis for traveler's diarrhea is a controversial topic. The first-line measure of "boil it, cook it, peel it, or forget it" should be reviewed with all travelers. Drinking water that is bottled or boiled at a rolling boil for 1 min to kill potential pathogens is advisable in all at risk locations. The CDC currently does not recommend traveler's diarrhea prophylaxis [13] due to the development of possible antibiotic resistance. It should be noted, however, that prophylaxis is very effective and can be considered for those with risk factors such as inflammatory bowel disease. Options for prophylaxis include quinolones, which can reduce incidence of diarrhea by up to 90% [13]. Rifaximin is limited by expense but is another option for traveler's diarrhea prophylaxis. Daily bismuth subsalicylate (Pepto-Bismol®), an option that is not available to pregnant women or children due to its aspirin component, reduces incidence of diarrhea around 50% [13], though the patient should be warned of black stools.

Telegram: @medical_k

www.konkur.in

Lactobacillus is also a popular prophylactic option, though studies regarding its use in traveler's diarrhea prophylaxis are inconclusive [13].

Malaria Prophylaxis

The WHO reported for 2018 an estimated 228 million cases of malaria with 405,000 deaths, most of which are in children in sub-Saharan Africa [15]. Malaria in travelers is potentially lethal, but avoidable. In 2016, there were 2078 cases reported in the United States and 7 deaths, almost all in travelers [16].

Historically, four species, *Plasmodium falciparum*, *P. ovale*, *P. malariae*, and *P. vivax*, caused human disease. A fifth species, *Plasmodium knowlesi*, a primate species, now causes significant human disease in Southeast Asia, with a dozen American cases reported in travelers through 2013 [17] as well as many European cases [18]. While all species contribute to human morbidity, the burden of mortality is due to *P. falciparum.* While resistance patterns vary, in general, prophylaxis and treatment that effectively target *P. falciparum* in a given area will be effective against the other forms of malaria as well.

Individuals exposed to malaria on an ongoing basis often develop a partial immunological protection called premunition. This protection allows a low level of chronic infection but generally does not allow the malaria to develop into clinical illness. Anyone who has been outside a malarious area for over 2 years generally has the same risk as a nonimmune individual, though the precise rate of decay of immunity is unclear.

The best measures against malaria are mosquito avoidance, including application of DEET to the skin, bed nets, and clothing, and taking an approved medication for chemical prophylaxis [19]. There are currently several antimalarials recommended for prophylaxis, discussed below.

Mefloquine

Mefloquine has been widely used for several decades. It is somewhat controversial, with common minor side effects such as vivid dreams and disturbed sleep and rare adverse cardiac and psychiatric effects. Avoidance of this drug in patients with known cardiac problems, especially those who take QT interval prolonging medications, is recommended. Those who have or have had a psychiatric diagnosis, including depression, should use another agent. It is helpful to begin mefloquine prophylaxis 2 weeks prior to travel instead of the traditionally prescribed 1 week prior. This both allows for a period of time to evaluate the development of any side effects and achieves a drug-steady state prior to arrival. Mefloquine should continue to be taken 4 weeks after leaving the malarious area. Areas of increasing resistance have made this drug less useful for much of Southeast Asia [20].

Doxycycline

Doxycycline is useful and effective for malaria prophylaxis. It should be started 2 days prior to travel, taken daily and continued daily for 4 weeks after leaving the malarious area. It is contraindicated in children under 8 years of age and in pregnant and lactating women. Dairy products should be avoided for 2–3-h window before and after ingesting doxycycline. Doxycycline is helpful to take with food to reduce nausea. Photosensitivity has been reported but is not as frequent a problem as with tetracycline. Candida infections can be seen, at times even in men. Interference with oral contraceptives does not seem to be the problem it was once thought to be. However, as with other antibiotics, those taking warfarin should have their dose monitored while on doxycycline.

Malarone

Atovaquone/proguanil (Malarone®) is generally regarded as the best tolerated and most effective of available antimalarials for prophylaxis. There are very few side effects. It is taken daily, 2 days prior to, during, and only 7 days after travel in a malarious area, making this the shortest "tail." Its main disadvantage is cost.

Primaquine

Primaquine is indicated for presumptive antirelapse treatment (PART), previously known as "terminal prophylaxis." Terminal prophylaxis

Telegram: @medical_k

www.konkur.in

with primaquine, at a dose of 30 mg [52.6 mg of salt] per day for 14 days [21], is recommended to all who visit areas where *P. vivax* is present. Primaquine is capable of eliminating dormant malarial hypnozoites in the liver, thereby reducing the frequency of relapse. Primaquine triggers a hemolysis in those with G6PD deficiency, so quantitative testing of this enzyme must be performed prior to prescribing this drug. Primaquine should not be prescribed to pregnant women.

Tafenoquine

Tafenoquine, an 8-aminoquinoline like primaquine, was approved in 2018 for prophylaxis of all species of plasmodium, as well for radical cure of vivax [22]. Because of its long half-life, it is possible to give 200 mg daily for 3 days pretravel, then weekly while at risk, and again 1 week after the risk ends. As with primaquine, it is not to be given to those who have not had a quantitative test ruling out G6PD deficiency, or to pregnant women.

Personal Protective Measures

Insect avoidance is an important component of prevention for travelers to the tropics. Medical prophylaxis for malaria works better in combination with avoidance to lessen the parasite exposure. Other protozoal diseases that are transmitted by insects, such as leishmaniasis and trypanosomiasis, have available treatments but are extremely onerous, making prevention strategic. Viral diseases, such as Japanese encephalitis and tick-bourne encephalitis are preventable by vaccination, but the cost and availability of vaccines may discourage their use, especially in short-term travelers. In addition, viral diseases such as dengue, chikungunya, and zika have no treatment or vaccine yet available, so protective measures are the only prevention. Scrub typhus and many other rickettsial diseases may be treated, but are largely preventable.

In areas of risk, permethrin-impregnated bed nets are a major element in malaria prevention. Travelers should take advantage of these when available. Permethrin is also available as a spray-on product for the treatment of clothes [19], which is strategic for many arthropod-borne illnesses, in particular scrub typhus in Asia and tick-bourne typhus in Europe.

DEET (*N*, *N*-diethyl-meta-toluamide) is a repellent with a long history of safe use. Adverse effects are rare. However, it is best to use clothing that covers much of the body so that DEET can be applied sparingly. The American Academy of Pediatrics recommends 10–30% strength for children older than 2 months of age. Picaridin is a product that can be used as well.

Trypanosomiasis is a rare disease in travelers, but there have been reported cases from those going on game drives. Long sleeves and pants and permethrin treatment are helpful strategies for avoidance. In addition, given that tsetse fly traps are purposefully made in royal blue and black colors to attract the flies, these are good clothing colors to avoid during such activities.

Schistosomiasis is one of the most common diseases of returned travelers. There are several species of this fluke, which in its larval stage is an infection of freshwater snails. Travelers to the tropics should be counseled against swimming in freshwater. Wading and even dangling a body part in the water can also transmit the fluke, as well as bathing with untreated lake or river water.

Certain preventive strategies are difficult to apply to those at highest risk: children under the age of 1, pregnant women, and the immunocompromised. For such travelers, it is helpful to encourage thoughtful reflection as to the risks and benefits of travel. In some cases, travel plans can be modified in such a way that the risk can be mitigated.

Altitude Illness Prophylaxis

In several destinations in the world, altitude illness and prevention become a concern. Symptoms of altitude illness include headache, insomnia, nausea, fatigue, and dizziness. Severity of altitude illness can range from acute mountain sickness which is mild to more serious complications such as high-altitude cerebral edema

Telegram: @medical_k

www.konkur.in

(HACE) and high-altitude pulmonary edema (HAPE).

A discussion of altitude prophylaxis is recommended for destinations that involve overnighting above 2,500 m [23]. The most widely accepted preventive measure is slow ascent [23]. Several medications are available for altitude prophylaxis, including acetazolamide and dexamethasone. Recommended dosing for acetazolamide is 125 mg by mouth twice per day, to start 2 days prior to ascent and to continue until the traveler has acclimatized at their maximum altitude (generally 48–72 h) [23]. Acetazolamide can cause side effects such as diuresis and paresthesia and cannot be used in patients with sulfa allergies. Dexamethasone is a second-line prophylactic option, but as it does not aid in acclimation, it can cause rebound symptoms of acute mountain sickness once stopped. Local herbal remedies are also popular and available in high-altitude destinations worldwide, but efficacy in preventing altitude illness is unproven in studies [23]. The most effective treatment for altitude illness is descent.

Safety and Accident Prevention

A significant proportion of the pretravel visit is dedicated toward the discussion of pre-trip immunizations, malaria, and traveler's diarrhea. However, the primary cause of death among travelers is accidents, such as motor vehicle accidents and falls [24]. For this reason, the topic of safety and accident prevention deserves specific mention during the pre-trip consultation. Depending on the destination, standards and safety for driving can vary significantly. There may be political or civil unrest occurring in various destinations that a traveler should be aware of. Registering an international trip with the US State Department and consulting their website may be helpful in trip preparation.

Sexually transmitted diseases are a risk for travelers who might consider having sex while abroad. Assessing for the likelihood of this during the pre-trip consultation is important, and these travelers should be reminded of both the incidence of STDs in their destinations and the use of barrier protection. There can be variability in the quality of condoms purchased abroad.

Finally, trip and evacuation insurance should be considered prior to departure. This might be most useful for those travelers abroad for an extended period of time, especially in remote locations or for travelers who have one or more chronic illnesses.

Emerging Diseases

In the years prior to this edition, the world has dealt with multiple global infections including Zika, MERS-CoV, and COVID-19. Each of these has had impact on travel, whether regional or global, and temporary or long-term. It is not known now what the impact of these viruses or other as yet unidentified viruses will be on travel planning at a future time when the reader reads these words. The best advice is to survey excellent electronic resources such as the CDC's yellow book, the National Health Service UK's "Travel Health Pro" website, and www.promedmail.org, which relies on observers on the ground to give real-time updates of local epidemiological conditions.

Post-Trip Consultation

The goal of the pretravel consultation is the avoidance of illness during and after travel. There will be times when such measures fail. The likelihood of illness is negatively correlated with preventive measures taken. Pathologies frequently encountered in returned travelers include fever, gastrointestinal disease, skin disease, eosinophilia, and latent tuberculosis.

Fever in Returned Traveler

For purposes of this discussion, fever will be defined as an oral temperature $>$ 100.0 °F, although given the cyclical nature of many fevers, subjective reports of fever should be taken seriously. Even remotely completed travel can cause

Telegram: @medical_k

www.konkur.in

illness, but the large proportion of fever cases present within weeks to months of return from travel. One exception is non-*falciparum* malaria, which can incubate for up to a year, and delayed relapse can occur many years later [25].

The most critical subgroups of febrile returned travelers are those with hemorrhagic symptoms. All patients with fever and hemorrhage who have returned within 21 days from travel should be considered to have a viral hemorrhagic fever and placed in isolation (contact, droplet, and aerosol) until proven otherwise. Not all of these diseases are contagious, but until a specific identification has been made, high transmissibility should be assumed.

The next most important task in the care of returned travelers is to identify potential cases of malaria. In many cases, malaria is the most important cause of fever in a returned traveler [26], and the risk of mortality from this pathogen in non-immune patients makes its rapid identification and treatment critical. Malaria can be contracted in any tropical continent and is the most frequent cause of fever in those traveling from Africa. Dengue is the most frequently encountered pathogen from Southeast Asia, and enteric fever (typhoid) is the most frequently encountered fever from the Indian subcontinent [27]. Other important causes of fever include schistosomiasis, leptospirosis, amebic abscess, tuberculosis, and sexually transmissible diseases, including HIV.

Workup for fever should include a careful history, including the itinerary, associated symptoms, and a physical exam emphasizing ENT, pulmonary, GI, neurological, and integumentary systems. A lab workup including a CBC with differential, thin, and thick smears for malaria and blood cultures can also be helpful. For clinical situations such as dengue or chikungunya, specific viral serologies can also be considered.

In practice settings where results are likely to be delayed, empiric treatment with an antimalarial should be strongly considered. Atovaquone/proguanil is widely available as a prophylactic and is effective as a treatment as well. The same can be said for mefloquine. A more ideal medication artemether-lumefantrine (Coartem) is preferred as a treatment and avoids the theoretical problem of using a medication as treatment that may have failed as a prophylactic agent. For severe malaria, of which there are around 300 cases annually in the US, the drug of choice is parenteral artesunate, which had only been available directly from the CDC but has now received FDA authorization and will soon be available for hospital pharmacies to stock [28]. Quinine has a long-track record, but its potential for arrhythmias limits its utility and it is no longer available in parenteral form in the USA.

GI Illness in Returned Traveler

GI illness is one of the most common illnesses in the returned traveler [13]. A history of destination, activities during travel, and onset of symptoms can help distinguish whether or not the illness is travel related. A more in-depth discussion of traveler's diarrhea is reviewed in the pre-trip consultation section of this chapter.

Diarrheal symptoms lasting more than 2 weeks should prompt screening for *Giardia,* amebiasis, and other parasites. Multiple stool samples for O and P testing may need to be submitted to accurately diagnose parasitic infection. Three stool O and P samples on 3 different days is preferred, as 1 sample can miss potential infection dependent on time of collection. In cases where clinical suspicion persists despite negative microscopic results, stool testing for *Giardia* and *Cryptosporidium* antigen is available and is sensitive.

Extended symptoms of diarrhea can also be seen with postinfectious irritable bowel syndrome (IBS), a diagnosis of exclusion in travelers with prolonged diarrheal symptoms more than 30 days after travel [29]. The incidence of postinfectious IBS is variable and ranges from 4% to 31% across all studies [29]. In one study of North American travelers to Mexico, the incidence was 11% of all travelers with diarrhea, with 10% of this number being newly diagnosed cases of IBS [30]. There is no widely accepted strategy for treatment, but options are similar to those recommended for noninfectious IBS including probiotics, antispasmodics, and low doses of tricyclic antidepressants [30].

Telegram: @medical_k

www.konkur.in

A subset of patients who return from travel present with symptoms that they attribute to parasites, with no objective findings to support this belief. In many such patients this belief can become fixed and life-altering. Many will travel from specialist to specialist seeking help. While this phenomenon can be a manifestation of pre-existing psychiatric disorders, it can present in those who are otherwise normal. An approach to delusional parasitosis is to perform limited reasonable rule-out procedures, offer a rational inexpensive empiric treatment, seek to establish a therapeutic relationship, and encourage the patient to accept that like phantom pain, the body sometimes tells the patient that there is a parasite when the parasite never was there, or was successfully treated, and these feelings can be helped by atypical antipsychotics.

Skin Lesions in the Returned Traveler

Skin lesions and rashes are common after return from travel. They may reflect a discrete condition (i.e., cutaneous larva migrans, swimmers itch, or tungiasis) or a systemic illness (i.e., dengue, chikungunya). History of activities during travel and specific locations visited during travel are important in the diagnoses of these conditions.

Eosinophilia

Perhaps the most common laboratory abnormality in a returned traveler is eosinophilia. Rather than focusing on the percentage, and absolute eosinophilia of 500×10^6 or higher should prompt further evaluation. The most common causes of eosinophilia in travelers are schistosomiasis, filariasis, and nematode infections [31], but *Strongyloides stercoralis* is an important consideration and may present decades after a stay in the tropics. Stool for ova and parasites may shed light on certain species of schistosomes and nematodes. Urinalysis should be performed for hematuria and schistosomal ova. Skin exam and a snip test can be helpful with filariasis.

Tuberculosis Screening in the Returned Traveler

In travelers to some destinations, especially developing countries, screening for tuberculosis on return is advised. If the trip itinerary includes a work in healthcare settings or frequent face-to-face contact with persons residing in a TB-endemic location, a PPD screen is recommended 8 weeks after return [32]. In some populations, a PPD may not be appropriate. These would include travelers with a history of BCG vaccine, as immunity is variable and a PPD test in these populations may be positive for decades. For these special populations, an interferon gamma release assay (IGRA)-based test such as QuantiFERON®-TB Gold is preferable for screening [33]. In populations in which there are no special indications for IGRA-based testing, there is no superiority of the IGRA-based test over the PPD test for screening [33]. For travelers who convert either their PPD- or IGRA-based screening to positive, a chest x-ray is recommended to assess for active tuberculosis. Persons with active disease are reportable to the local health department. Persons with latent disease should receive a discussion on the risks and benefits of treatment for latent tuberculosis. The McGill University decision tool is a very useful guide for such discussions [34].

Reentry for Long-Term Travelers: Psychological Concerns

For many return travelers who have been abroad long-term, reentry into life in the United States can be difficult. A variety of emotions can arise on the return, from happiness to anger and sadness. Long-term expatriates can feel isolated and unable to connect with loved ones from home after their experiences abroad. Reverse culture shock can occur as well. Screening for depression, anxiety, and PTSD should be considered for all long-term returned travelers when seen by their primary care providers, especially for those who may have suffered adverse events, or who were required to

Telegram: @medical_k

www.konkur.in

return involuntarily. Counseling is highly recommended for travelers with psychological concerns on reentry.

Preconception and Interconception Care Defined

Preconception care is defined as *a set of interventions that aim to identify and modify biomedical, behavioral, and social risks to a woman's health or pregnancy outcome through prevention and management* [1]. Interconception care is care provided to women beginning with childbirth until the birth of a subsequent child. It is a subset of preconception care that addresses the continuity of risk from one pregnancy to the next [2]. Preconception and interconception care has increasingly been recognized as a crucial component of both women's and infant's health.

Ongoing Problem of Perinatal Morbidity and Mortality

Infant mortality remains a significant problem in the USA. In 2017, the US infant mortality rate was 5.8 per 1000 live births. Despite leading the world in healthcare expenditures, the USA ranks 34th among developed nations in infant mortality [3]. Since 2000, after 40 years of improvement, infant mortality rates continue to be unacceptably high, and maternal morbidity and mortality are *increasing* [4, 5].

The most important causes linked to infant mortality are preterm birth and birth defects (Fig. 1). Birth defects account for 20.4% of all infant deaths and affect 1 in 33 infants born in the USA. Approximately 36.3% of all infant deaths in the USA are attributable to prematurity [6]. After decades of focus on improving prenatal care interventions, the preterm birth rate in the USA remains unacceptably high. Significant racial and ethnic disparities persist. For example, the perinatal infant mortality rate among non-Hispanic black infants is 2.3 times higher than that of white infants [7].

Even more striking is the stark contrast in the maternal mortality rate in the USA compared to other countries in other first world countries (Fig. 2). There is a 350% increase in maternal mortality rates among African American women compared to Anglo and Hispanic women resulting in the development of a number of contemporary initiatives to address these critical public health, access to care, and institutional racism issues [8, 9].

Need to Address Risks Prior to Pregnancy

It is now recognized that many of the modifiable risk factors affecting preterm birth, birth defects, maternal morbidity, and both maternal and infant mortality occur prior to pregnancy. Structural organogenesis of the central nervous system and

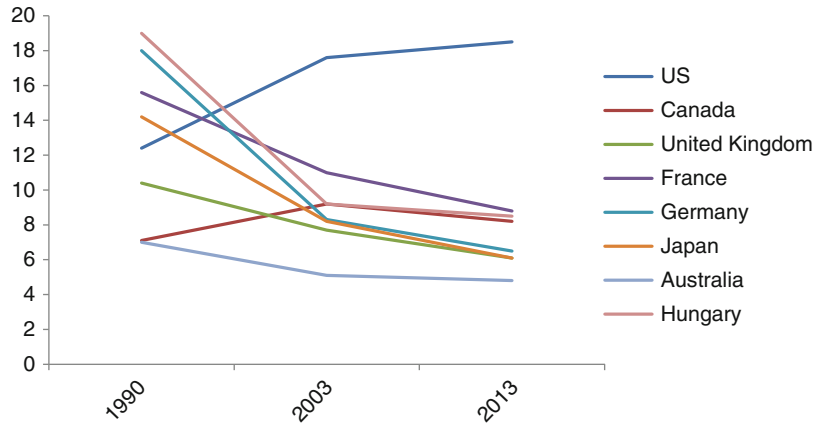

Fig. 2 1990–2017 country comparison maternal mortality (per 100,000 live births). ([5], WHO, UNICEF, UNFPA, World Bank Group, and the United Nations Population Division. Trends in Maternal Mortality: 2000 to 2017. Geneva, World Health Organization, 2019 (Accessed 4/19/20))

heart begins as early as 3 weeks' postconception, and the development of the heart, limbs, and reproductive organs is nearly completed by 8–9 weeks' gestation. As early as the missed menses and by the time a woman enters prenatal care, it is often too late to affect periconception risks [10]. Unfortunately, almost half of all pregnancies in the USA are unintended, thus limiting the ability to "plan" preconception risk reduction [11]. Unintended pregnancy is a risk factor for poor birth outcomes likely through uncontrolled health conditions or maternal behaviors. Additional examples of maternal risk factors that determine birth outcomes are interpregnancy interval, maternal age, exposure to teratogenic medications, exposure to substances, chronic disease control, and preventable congenital anomalies [12] (Table 1).

CDC Recommendations on Preconception Health

In 2006, the CDC released "Recommendations to Improve Preconception Health and Healthcare – United States: A Report of the CDC/ATSDR Preconception Care Work Group and the Select Panel on Preconception Care" [1]. This report included ten recommendations to improve women's health and address the problem of preterm birth, birth defects, and infant mortality through increased focus on preconception care. Recommendation #3: "As a part of primary care visits, provide risk assessment and educational and health promotion counseling to all women of childbearing age to reduce reproductive risks and improve pregnancy outcomes." The select

panel also recommended to (1) encourage each woman and couple to have a reproductive life plan; (2) deliver preconception interventions as follow up to risk screening, focusing on those interventions with high population impact and sufficient evidence of effectiveness; and (3) use the interconception period to provide intensive interventions to women who have had a prior adverse pregnancy outcome (e.g., infant death, low birth weight, preterm birth).

As part of its goal to reduce infant mortality and decrease disparities in reproductive outcomes, the CDC incorporated preconception care into *Healthy People 2020* and launched the Preconception Health and Healthcare (PCHHC) initiative focusing on five areas of engagement: clinical, consumer, public health, policy/finance, and surveillance/research [12]. In 2008, the clinical working group of the PCHHC published a systematic review of the evidence in support of the clinical content of preconception care. More than 30 experts reviewed over 80 topics using the strength of recommendation taxonomy approach consistent with USPSTF. This compendium of evidence has informed the distillation of preconception care into ten focused content areas of risk reduction and intervention to improve future birth outcomes: family planning, nutrition, infectious disease/immunizations, chronic disease management, medication and environmental exposures, substance use, previous pregnancy outcomes, genetic history, mental health, and interpersonal violence [13].

Barriers

Unfortunately, there remain significant barriers to successful implementation of quality preconception health. Women often do not seek reproductive healthcare prior to pregnancy, and a large proportion of women of reproductive age do not have insurance coverage until they are already pregnant [14]. When there is an opportunity in a clinical setting, there is often insufficient time to address preconception health [15]. Other health issues often take priority, and preconception care is usually not the reason for visit. When it comes to interconception care, the focus is more often on the child than on the woman's health [16, 17]. Finally, providers may lack education, guidance, or resources on approaching preconception health issues in the continuum of care [15].

Opportunities in Primary Care

Despite evidence that managing preconception health can help to improve pregnancy outcomes, many women do not receive this care [18]. Nationally, of women aged 18–44, only 46.5% received appropriate contraceptive counseling, 45.3% with risk for infection were tested for chlamydia, 33.2% had preconception counseling. While 80.9% had their blood pressure checked, only 44.9% with obesity were counseled about ways to improve diet, and 55.2% of smokers received counseling to quit [19]. Family physicians and other primary care providers have many opportunities to interact with women of childbearing age and provide this care during well-woman exams, acute care, and chronic disease management visits, as well as when they accompany their children or partners to their visits. "It is not a question of whether you provide preconception care. Rather, it's a question of what kind of preconception care you are providing" (Stanford and Hobbins) [20]. Making preconception health a part of routine primary care could significantly impact the health of women and future pregnancies as well as the health of infants and children.

History

Past Medical History

A thorough past medical history is the cornerstone of comprehensive primary care and equally so in the provision of preconception care. More than 25% of women of childbearing age have a chronic condition such as chronic hypertension, asthma, major depression, etc. (Table 2). It is essential that these chronic conditions be recognized and treated in the preconception period [23, 24]. For example, poorly controlled or undiagnosed diabetes resulting in hyperglycemia in the first

Telegram: @medical_k

www.konkur.in

Table 2 Preconception Care of Common Medical Conditions

Condition	Epidemiology/natural history	Preconception interventions	Contraception strategies	Medication use
Diabetes mellitus (DM) and relationship to gestational diabetes (GDM)	One percent of pregnancies with DM and 7% with GDM. Poorly controlled DM in the first trimester associated with fourfold increase in congenital abnormalities. High rate of recurrence of GDM. Fifty percent GDM develop DM within 5 years	Strict glycemic control of DM in the first trimester reduces the risk of congenital malformation. Lifestyle modification decreases risk of developing DM among women with previous history of GDM	Avoid use of estrogen-containing birth control if patient with DM has concurrent hypertension, renal disease, or thrombophilia	Diabetic medications such as sulfonylureas, metformin, and insulin safe to use in pregnancy
Thyroid conditions	Graves (0.2% prevalence) untreated: poor outcomes Overt hypothyroid (2.5%) Untreated: decreased IQ and increased spontaneous AB and preterm delivery Subclinical hypothyroidism (2–5%) associated with adverse perinatal outcomes	Hypothyroid: levothyroxine should be increased 25% as soon as pregnancy diagnosed Subclinical hypothyroid: RCT evidence for screening and treatment lacking	Overt hypothyroidism and subclinical hypothyroidism are associated with impaired fertility and increased risk of miscarriage	Graves: avoid methimazole in the first trimester; avoid use of propylthiouracil in the second and third trimester Hypothyroid: maintain TSH below 2.5 in the first trimester
Epilepsy	One percent of population; 3–5/1000 births; increased congenital anomalies in women who have seizures and who take antiseizure meds (two to threefold increase)	Discontinue antiseizure meds if seizure-free for 2 years; switch to meds that are less teratogenic before pregnancy such as lamotrigine and levetiracetam	Decreased efficacy of OCs when taking meds that induce liver enzymes, i.e., phenytoin and carbamazepine; use progesterone-only contraceptive methods if using these medications	Consider switching to safest alternative medication – experts do not suggest immediate cessation of therapy due to possible increased risk of seizures; use high-dose folic acid (4 mg/day) 4 weeks before and 12 weeks after conception
Chronic kidney disease (CKD)	Patients with mild CKD (creat 0.9–1.4) have good outcomes. Patients with moderate CKD (1.4–2.5) or severe (>2.5) at risk of developing worsening disease. These patients have increased risk of adverse outcomes if they have HTN	Very important to control blood pressure. Try to avoid pregnancy with moderate to severe CKD	Absolute contraindication to use estrogen OCs with CKD if they have cardiovascular disease and history of VTE and are smokers >35 and patients with liver disease. Use progesterone-only or barrier methods	Avoid use of ACEs, ARBs, and spironolactone in pregnancy

www.konkur.in

Table 2 (continued)

Condition	Epidemiology/natural history	Preconception interventions	Contraception strategies	Medication use
Cardiovascular disease (CVD)	Three percent of women have CVD with a 1% incidence in pregnancy. CVD is the cause of 10–25% of maternal mortality. Conditions that result in NYHA class greater than II or cyanosis at baseline prenatal visit are most predictive of increased risk of perinatal and maternal mortality	Use of warfarin in pregnancy should be avoided; instead, heparin or enoxaparin is used. With prosthetic valves, warfarin may be used in the second and third trimester. Structural heart lesions should be repaired prior to pregnancy. Certain cardiac syndromes have genetic etiology	Important to have thorough cardiac assessment/imaging prior to pregnancy to assist in risk stratification of patients at high risk of morbidity and mortality Avoid COCs for patients with R to L shunts and ischemic disease and for patients with multiple cardiac risk factors. Progestin use is okay	Do not use warfarin in the first trimester. Avoid use of ACE, ARBs, and spironolactone in pregnancy
Hypertension (HTN)	Ten percent of women of childbearing age; women with chronic HTN at increased risk of worsening CKD, preeclampsia, and eclampsia in pregnancy	Preconception treatment of mild-to-moderate HTN results in 250 women needing treatment to prevent one fatal or nonfatal cardiovascular event such as a stroke	Combination OCs may be used in women with mild essential hypertension (140–159/90–99); copper IUD listed as preferred contraception for moderate to severe HTN	ACEs and ARBs are teratogenic and fetotoxic; should be stopped prior to conception
Asthma	Eight percent of pregnant women; 30% of women with asthma have worsening symptoms in pregnancy. Increased maternal and perinatal morbidity and mortality among women with poor control of asthma	Use of systemic steroids in the first trimester associated with threefold increased risk of oral clefts and maternal preeclampsia	Anticholinergic agents are class B and short-acting beta agonists are class C. Budesonide is class B and other inhaled corticosteroids are class C. Maternal smoking cessation is of great importance	Avoid use of systemic steroids in the first trimester. Administer influenza vaccine early in pregnancy
Thrombophilia	Factor V Leiden gene present in 5% of Caucasians; antiphospholipid antibody syndrome most common acquired condition and is more common in blacks Thrombophilias are associated with increased risk of VTE, arterial thrombosis, and severe preeclampsia	Diagnostic testing available for high-risk populations: FH of VTE, personal Hx of VTE; Hx of recurrent pregnancy loss, severe preeclampsia, severe IUGR Consensus expert opinion recommends treatment for many of these conditions in pregnancy; recommend MFM consultation	Genetic counseling and targeted screening indicated for high-risk populations during preconception care Combined OCs not recommended; progestin-only methods, IUDs, and barrier methods preferred	Use heparin or enoxaparin throughout pregnancy. Avoid use of warfarin, especially in the first trimester

www.konkur.in

Table 2 (continued)

Condition	Epidemiology/natural history	Preconception interventions	Contraception strategies	Medication use
Obesity	More than one third of US women are obese which is associated with increased risk of DM, HTN, CVD, OSA, and cancers (breast, uterine, colon) Associated adverse perinatal outcomes include NTD, GDM, HTN, PTD, VTE, IUFD	Important to achieve weight loss prior to conception. Counseling alone or combined with medication can result in modest and sustained weight loss (USPSTF). Bariatric surgery prior to pregnancy is another effective intervention. This surgery is associated with increased fertility rates [21]	Clinicians need to assess obese women for comorbid conditions such as DM, HTN, and OSA and hx of VTE that markedly increase risk to women. With many of these conditions, use of combined OCs is relatively contraindicated. Increased risk of impaired fertility and early pregnancy loss	Bariatric surgery associated with decrease incidence of DM, GDM, HTN, and OSA but increased risk of preterm delivery, SGA, and NICU admissions. Increased risk of nutritional deficiencies with GI bypass surgery, less so with gastric banding [22]
Major depression/ bipolar	Approximately 12% of women in both the preconception and interconception periods have major depression [11]. Victims of intimate partner abuse have a fivefold increase in major depression. Major depression in pregnancy associated with increase in PTD and low birth weight. Bipolar disease associated with increased incidence of postpartum psychosis	Optimizing depression care with medication and psychotherapy associated with improved pregnancy outcomes [20]	Victims of intimate partner abuse have higher incidence of unplanned pregnancy and high-risk sexual behavior. Consider use of long-acting reversible contraception (LARC) for patients who find it difficult to use other daily methods	Patients receiving valproic acid and carbamazepine should be placed on 4 mg of folic acid/day for 4 months prior to conception. Valproic acid should not be used in pregnancy. Avoid use of paroxetine and lithium in the first trimester. Lithium can be used in the second/third trimester

trimester results in a fourfold increase in congenital heart defects and increased risk of pregnancy loss [25].

Previous Obstetrical History

Women who have had three or more spontaneous abortions should undergo additional testing to rule out thrombophilia, thyroid dysfunction, uterine anomalies, and other potential genetic syndromes. Women with a history of a spontaneous preterm delivery are at increased risk of this outcome in the next pregnancy [26]. Women with a prior history of preeclampsia, gestational diabetes, or other poor birth outcomes should have additional evaluation for chronic medical conditions such as diabetes mellitus and essential hypertension and undergo counseling on the importance of preconception and early prenatal care.

Family History

A three-generation family history can identify women who are at increased risk for genetic syndromes such as thrombophilia, coagulopathies, hemoglobinopathies, cystic fibrosis, trisomies, etc. In addition, it is important to obtain ethnicity information about both sides of the family.

Telegram: @medical_k

www.konkur.in

Genetic counselors may be of assistance for patients with positive three-generation family history screening. The carrier frequency for some of these conditions is also increased in selected ethnicities such as African, European, Ashkenazi Jewish, Mediterranean, and Asian descent [27].

Patients identified at increased risk of having a baby affected by one of these syndromes by virtue of a strongly positive family history or belonging to an ethnic group with a higher incidence of these conditions can undergo preconception expanded carrier screening. When one partner is identified to be a carrier, her partner can then undergo this same carrier screening [28].

"Cascade testing" of close relatives is often utilized to identify other family members affected by these conditions [29]. The following site provides summaries of up-to-date genetic conditions and testing recommendations: https://www.acmg.net/ACMG/Medical-Genetics-Practice-Resources/Medical-Genetics-Practice-Resources.aspx.

Social History

Poverty and the constant stressors associated with housing and food insecurity are the norm in many clinical settings. It is important that women living in poverty are given clear instruction and logistical assistance to access available social service resources. These resources vary from community to community, and the clinical team should be actively involved in linking patients to these resources.

Women who are currently experiencing or have a history of intimate partner violence are at marked increase of physical and emotional injury. A national survey in the late 1990s estimated that approximately 4.8 million partner rapes and physical assaults occur in the USA on an annual basis [30]. It is important to screen for exposure to violence routinely in the office setting. The CDC has extensive resources at https://www.cdc.gov/violenceprevention/pdf/ipv/ipvandsvscreening.pdf.

Smoking exerts deleterious effects on the current and future health of women and future pregnancies. Although smoking rates have been declining in the USA since 1990, an estimated 18.7% of non-pregnancy reproductive-aged women were smoking in 2009 [31].

Women using illicit drugs have a higher incidence of medical, psychiatric, psychosocial, and infectious comorbidities. Illicit drug use/abuse is common in rural and urban settings, often putting women at increased risk of significant morbidity and mortality. Ten percent of women of reproductive age report illicit drug use in the past month [12].

Approximately 54% of non-pregnant women of childbearing age consume alcohol and approximately 15.2% binge drink [12]. Women with alcoholism are at marked increased risk for adverse future pregnancy outcomes because alcohol is both a teratogen and fetal toxic agent. There is no known safe level of alcohol ingestion in pregnancy.

Medication History

It is important to review all prescribed and over-the-counter medications and to note which ones could exert teratogenic effects on the developing embryo. About 10–15% of congenital birth defects are thought to be caused by teratogenic exposure. Many anticonvulsant agents, most notably valproic acid and carbamazepine, markedly increase the incidence of neural tube defects. A valuable source for identifying prescriptive and OTC medications that pose risks to the developing embryo can be found at https://mothertobaby.org/fact-sheets-parent/.

Environmental History

Women should be assessed for exposure to major environmental agents including mercury, lead, hydrocarbons, bisphenols (organic compounds with estrogenic properties), and nitrates. These exposures may come from the workplace, hobbies, exposure from well water, contact from plastic containers (#7 plastic containers), or dietary sources (ingestion of large game fish). Clinicians and patients both need to be conversant about these common exposures in the environment [32].

Telegram: @medical_k

www.konkur.in

Physical Examination

The physical exam, in combination with a thorough history, offers the best opportunity to diagnose chronic medical conditions that can adversely impact a woman's current or future health.

Nutritional Status

When conducting the preconception physical examination, the clinician should determine the patient's BMI. Underweight women will have a BMI less than 19.8, while obese women will have a BMI greater than 30. Both of these extremes should trigger more extensive nutritional assessments/screening for eating disorders. Obese women have increased risk of developing hypertension, diabetes, cardiovascular disease, infertility, sleep apnea, and breast/uterine/colon cancer. Health risks of women with low BMIs include nutrient deficiencies, cardiac arrhythmias, osteoporosis, amenorrhea, and infertility [33].

It is important to ask patients about their use of dietary and nutritional supplements. Between 18% and 52% of women of childbearing age consume some kind of OTC dietary supplements. Excessive amounts of the fat-soluble vitamin A (>10,000 IU/day) may be teratogenic and can result in cranial and neural crest defects [21].

The Obesity Epidemic

One third of women are obese. Obesity is associated with an increased risk of type 2 diabetes, hypertension, cardiovascular disease, and other comorbid conditions. Maternal cardiovascular disease is the greatest contributor to maternal mortality. Behavioral, medical, and physical activity therapies aimed at losing 5–10% of total body weight over a 6-month period prior to pregnancy are thought to be realistic.

The provision of long-acting reversible contraception (LARC) to obese women is both safe and effective. The use of emergency contraception and the use of the contraceptive patch are less effective. The use of combined oral contraceptives for obese women is associated with a five- to tenfold increase in venous thromboembolism [22].

Bariatric surgery often leads to greater weight loss. A meta-analysis of 33 studies with 14,880 pregnancies that occurred after bariatric surgery and close to 4 million controls showed an increase for perinatal mortality (OR = 1.38, CI 1/03–1.85), congenital anomalies (1.29, CI 1.04–1.59), preterm birth (OR 1.57, CI 1.38–1.79), and NICU admission (OR 1.41, CI 1.25–1.59). These data suggest the need for specific preconception and prenatal nutritional support and increased fetal surveillance during pregnancies that follow bariatric surgery [34].

Standard Nutritional Recommendations

Women should be counseled on the importance of consuming a healthy, well-balanced diet that is high in fruits and vegetables with a low amount of refined carbohydrates and processed food. Women without a history of a previous pregnancy complicated by a neural tube defect (NTD) should be placed on a multivitamin supplement containing at least 400 mcg of folic acid. This is not only effective in preventing 70% of future neural tube defects but also results in a decreased incidence of limb, cranial facial, and urologic congenital birth defects [35]. Women with a previous history of an infant with a NTD require a much higher amount of daily supplementation with folic acid of 4000 mcg [36].

Vaccine Preventable Infections

Women of reproductive age should be counseled about vaccine preventable infections and offered appropriate immunizations according to the CDC ACIP recommendations [37, 38]. Particularly important for preconception health are hepatitis B, rubella, varicella, annual influenza, and HPV (for those aged 11–26 years).

Telegram: @medical_k

www.konkur.in

Sexually Transmitted Infections (STIs)

It is important for the clinician to develop skills in taking a thorough and sensitive history that identifies a patient's gender identity, sexual orientation, sexual history, and practices. The USPSTF has established screening and counseling recommendations for the following STIs: chlamydia, gonorrhea, hepatitis B, hepatitis C, herpes simplex, syphilis, and HIV. For patients at increased risk of contracting HIV, the use of once-daily treatment with tenofovir/emtricitabine (Truvada) is FDA approved for pre-exposure prophylaxis and is recommended by the USPSTF [39].

Laboratory Evaluation

Women should be screened for diabetes according to current USPSTF guidelines. Screen for anemia for patients with a history of excessive menstrual blood loss, those whose physical exam is suggestive of anemia, or whose family history is positive for hemoglobinopathy.

Strategies for the Prevention of Adverse Birth Outcomes

The traditional approach of addressing maternal risk factors through a single preconception visit has failed to improve birth outcomes. Current recommendations focus on integrating preconception screening, risk reduction, and health promotion into all routine healthcare encounters for women with childbearing potential, regardless of pregnancy intention. Visits for preventive and routine gynecologic care provide natural opportunities for risk reduction, health promotion, and family planning. However, encounters for pregnancy testing, treatment of sexually transmitted infections, and management of chronic medical conditions provide unique opportunities for the delivery of preconception care and counseling. In each setting, advice should be tailored to the needs of patient based on individual attitudes, beliefs, preferences, and stage in the reproductive life span [1].

The Reproductive Life Plan

A key strategy for preconception health promotion is the development a reproductive life plan. Family physicians should encourage all men and women to explore their intention to conceive in the short and long term, taking into consideration their personal values and life goals. Once developed, patients should be educated about how their reproductive life plan impacts their contraceptive and medical decision-making. Because planned pregnancies are associated with improved outcomes for mothers and infants, women should be encouraged to make intentional decisions regarding the number and timing of pregnancies. The CDC has developed resources to assist healthcare providers and patients with developing a reproductive life plan which can be accessed at https://www.cdc.gov/preconception/planning.html.

Reducing Disparities

Family physicians should be aware that women of color are at increased risk for adverse pregnancy outcomes for both mother and baby. The cause appears to be multifactorial, and sociodemographic factors alone do not fully explain racial disparities in birth outcomes [40]. However, a large analysis of 2016 US birth certificate data revealed that the known portion of the disparity in preterm births between non-Hispanic black and white women was driven by sociodemographic and preconception/prenatal health factors [41]. This suggests that preconception interventions targeting these risk factors could potentially reduce racial disparities and improve perinatal outcomes. Other factors likely to contribute to disparities include unequal access to reproductive health services and a lack of comfort among women of color interfacing with the healthcare system. The Black Mamas Matter Alliance (https://blackmamasmatter.org), The National Latina Alliance for Reproductive Health (https://www.latinainstitute.org) and other organizations within the reproductive justice movement advocate at the national level to expand access to contraceptive services, prenatal and pregnancy

Telegram: @medical_k

www.konkur.in

care, and pregnancy termination services for women of color, work to eliminate systematic bias, and increase the voice of women of color within the healthcare system.

Novel Approaches to Preconception Care

In response to the lack of improvement in birth outcomes at the state and national level, many novel strategies for delivering preconception education, screening, and intervention have been developed including the following examples:

- *The Grady Memorial Hospital Interpregnancy Care Program (Atlanta, Georgia)* – In this groundbreaking program, low-income African American women with a history of very low-birth-weight delivery received individualized primary care services, intensive case management, and social support from multidisciplinary teams for 24 months following delivery. A significant reduction in rapid repeat pregnancies and adverse subsequent birth outcomes was achieved with an estimated net cost savings of $2397 per participant. The Grady program has been recognized as a successful model for improving birth outcomes by reducing disparities [42].
- *One Key Question*® (Power to Decide) – This initiative, originally developed by the Oregon Foundation for Reproductive Health, encourages all primary care providers to routinely ask women ages 18–50 "Would you like to become pregnant in the next year?" This question facilitates a conversation between providers and patients in which reproductive needs and preferences are explored [43]. Women are then offered essential preventive services based on identified needs (https://powertodecide.org/one-key-question).
- *The North Carolina Statewide Multivitamin Distribution Program* – This innovative program provided multivitamins with folic acid to low-income, non-pregnant women of childbearing potential to help prevent birth defects. Reported use doubled over a 10-month period among a sample of women receiving multivitamins through this program [44] (http://everywomannc.org/public-health/multivitamin-program/).
- *The IMPLICIT Network* – This collaborative of Eastern US family medicine and pediatric residency programs and community partners has implemented an evidence-based interconception screening and risk reduction intervention for mothers bringing their infants for well-child visits. Quality improvement techniques are used to improve care delivery, and future primary care physicians are trained in best practices (www.fmec.net/implicit.htm). The IMPLICIT ICC Toolkit is accessible at https://www.marchofdimes.org/professionals/implicit-interconception-care-toolkit.aspx.
- *Nurse-Family Partnership* – This program partners low-income, first-time mothers with a registered nurse early in pregnancy. Participating women receive ongoing nurse home visits through their child's second birthday. Nurses help mothers access good preventive and prenatal care, provide parenting support, and encourage self-sufficiency by helping mothers plan future pregnancies, continue their education, and find work (www.nursefamilypartnership.org).
- "*Show Your Love" Campaign* – This social marketing campaign launched by the CDC Preconception Health and Healthcare Initiative encourages women of childbearing age to maintain good health, reduce health risks, and make intentional decisions about pregnancy (https://showyourlovetoday.com).

Preconception Care and the Family

The health of a woman is interdependent with the health and well-being of her family. A woman's health is influenced by her family's medical history, culture, and view of health and illness. Some maternal risks for poor birth outcomes such as poor nutrition, smoking, and depression are associated with adverse effects

Telegram: @medical_k

www.konkur.in

for family members, especially children. The birth of a premature or critically ill newborn has a significant impact on family members. Parents experience stress related to uncertainty of the outcome, increased time away from work, financial burdens, and little time to spend with one another. Older children often experience anxiety due to separation from their parents, disruption of the family schedule, and a limited understanding of the newborn's condition. Family physicians should consider family values, beliefs, and influences (both positive and negative) when delivering preconception care emphasizing the goal of improving the health of all family members.

Preconception Issues for Men

Preconception care for men engages them in achieving planned, healthy pregnancies with their partners. Like women, men should be encouraged to develop a reproductive life plan to guide decisions about reproductive health. The CDC recommends that all men have a preventive care visit prior to conception to promote physiologic and emotional wellness, manage chronic health conditions, and educate men about the importance of avoiding sexually transmitted infections, substances, and toxic exposures. Men should be made aware of factors that can lead to decreased fertility and how to avoid them. Family physicians should also counsel men on the importance of supporting their partner in efforts to adopt a healthy lifestyle, follow treatment plans for chronic conditions, and take responsible steps to ensure planned, appropriately spaced pregnancies [45].

Key Preconception Care Partnerships and Resources

Family physicians should become familiar with the resources and partnerships in their community that provide preconception services for women. Examples include the local Health Department, Healthy Start Programs, Planned Parenthood, and WIC. State chapters of the March of Dimes also support programs that improve preconception health. Many national organizations have developed extensive preconception resources for clinicians:

- Center for Disease Control and Prevention, Preconception Health and Healthcare – Information for Health Professionals – summary of the content of preconception care for women and men, reproductive life planning tools, index of state and local resource, and collection of useful articles (https://www.cdc.gov/preconception).
- The National Preconception Curriculum and Resource Guide for Clinicians developed by the Preconception Health and Healthcare Initiative – includes the National Preconception/Interconception Care Clinical Toolkit, online continuing education modules, and a point of care mobile app (http://beforeandbeyond.org).
- National Healthy Start – HRSA-funded, locally administered programs that connect pregnant women and new mothers in at-risk communities with healthcare and support services through the child's first 2 years of life (www.nationalhealthystart.org).
- National March of Dimes, Resources for Professionals – includes prematurity prevention resources, genetic risk assessment tools, birth outcome statistics (PeriStats), and patient education resources (https://www.marchofdimes.org/professionals/professionals.aspx).
- Power to Decide (formerly The National Campaign to Prevent Teen and Unplanned Pregnancy) – information and resources for women, clinicians, and organizations with a goal of reducing unwanted pregnancy. Resources include the One Key Question™ clinician tool, Bedsider digital patient education resource, #Talking is Power Toolkit aiming to spark meaningful conversations between young people and trusted adults, a repository of contraception access data, and resources that support advocacy.

Pregnancy and childbirth are normal physiological processes for most women. Although an integral part of the fabric of pregnancy and birth is the availability of quality prenatal care to ensure the highest level of safety, modern medicine has sometimes been guilty of using a disease model for the management of pregnancy

and childbirth, resulting in higher rates of complications.

The national US cesarean section rate was 4.5% in 1965 [1], when it was first measured, and steadily increased to the current rate of 32.8% in 2010/2011 [2]. More recent studies reaffirm earlier World Health Organization recommendations about optimal rates of cesarean section. The best outcomes for women and babies appear to occur with cesarean section rates of between 5% and 10%. Rates above 15% seem to do more harm than good [3].

In 1902, J.W. Ballantyne, a Scottish physician, introduced modern prenatal care. In the late nineteenth century, he observed that while much was done for mothers and babies during labor and birth, these activities did little or nothing to reduce the morbidity and mortality of congenital anomalies, multiple births, and fetal diseases. He identified maternal exposures including alcohol, nicotine, and lead and infectious diseases, such as syphilis and tuberculosis, as major fetal hazards and began promoting specific antenatal treatments to reduce their impact on pregnancy outcomes [4].

Beginning in 1907, Dr. Josephine Baker, noting Dr. Ballantyne's methods, began applying these principles to slum dwellers in New York City, among whom infant mortality rates were very high. Services were offered to pregnant women and extended to the postpartum period. Women were seen every 2 weeks in their homes by nurses until 7th month of gestation and then weekly until delivery. At these visits, nurses would inquire about danger signs, check blood pressure, urine, assess fetal heart tones, and provide advice about diet, hygiene, exercise, and preparation for the childs' arrival. This focus on good nutrition and screening for problems during pregnancy dramatically improved outcomes, bringing the maternal and infant morbidity and mortality rates to record lows.

Today, approximately 30% of family physicians provide maternity care. Women living in rural areas and smaller communities often have difficulty accessing maternity care because they reside in places that generally cannot support an obstetrician or a hospital with a labor and delivery suite. Instead they must travel to larger regional medical centers and may delay seeking prenatal care or are seen less frequently during their pregnancies. As a result, the need for family physicians to provide maternity care is particularly important in underserved and rural areas. Because the family physician is the physician for the father, mother, and the child makes them ideal to provide family-centered care.

Family-centered care means providing care in the context of the family. This practice considers, includes, and fosters the development of families with the birth of a child, as new relationships are made, family members taking new responsibilities for each other, the baby, and community. A family physician through family-centered maternity care not only respects the woman's autonomy but also helps guide her into shared decision making in accordance with her goals. This chapter reviews principles and practice of normal pregnancy, labor, and delivery.

Prenatal Care

Ideally, prenatal care starts well before conception. Planning for pregnancy helps to prevent complications and results in optimal maternal and fetal outcomes. Efforts should be made and opportunities utilized with women of childbearing age who present for health maintenance exams to counsel them on a healthy lifestyle, identifying social, behavioral, environmental, and biomedical risks that can affect fertility or pregnancy outcomes. Although many women will seek preconception counseling before attempting to become pregnant, in the USA about 50% pregnancies are unintended [5]. A reproductive health plan should be created and revised with each subsequent visit, taking into consideration contraceptive needs and the timing of pregnancy.

It is recommended that prenatal care should begin as soon as possible after conception, since organogenesis occurs at 3–10 weeks of gestation, but about 30% of women begin prenatal care in second trimester at or around 13 weeks.

Work, home, pets, hobbies, potential toxic exposures, nutrition, hygiene, chronic diseases, teratogenic medications, and substance abuse are

Telegram: @medical_k

www.konkur.in

some of the examples where early intervention can lead to better outcomes.

Traditional prenatal care involves monthly visits until 28 weeks of gestation, then biweekly until 36 weeks, and weekly until the delivery. This schedule may be modified based on risk factors and may be multidisciplinary as required [6].

The supplementation of folate for the prevention of neural tube defects (NTD) is an important intervention and may reduce the risk of NTDs three- to fourfold. Because at least 50% of pregnancies are unplanned, and organogenesis is usually well established before many women realize that they are pregnant, all women of childbearing age who are at average risk of bearing a child with an NTD should be counseled to take 0.4 mg of folate daily. Women at high risk should be counseled to take at least 4 mg of folate. Those at high or intermediate risk include those with a history of previous NTD, pregestational diabetes mellitus, those on anticonvulsants, having a BMI of >35 kg/m^2, and certain ethnic groups, such as Hispanics and Native Americans [7].

Vaccination of women with Tdap during pregnancy (ideally between 27 and 36 weeks gestation) helps to provide some protection to infants from pertussis until they are old enough to be vaccinated themselves. Tdap given to pregnant women stimulates the development of maternal antipertussis antibodies, which pass through the placenta, providing the newborn with protection against pertussis in early life, and will protect the mother from pertussis around the time of delivery, making her less likely to become infected and transmit pertussis to her infant [8].

First Trimester

The first trimester is from week 1 to the end of week 12. Amenorrhea is the cardinal sign of pregnancy in a woman of childbearing age with regular menstrual cycles and should prompt a pregnancy test to confirm this.

Patients may present with morning sickness that may strike any time of the day and can sometimes begin as soon as 3 weeks after conception. This is due to rapidly rising levels of estrogen and progesterone resulting in gastroparesis. Nausea has also been directly related to beta hCG levels and is considered one likely candidate for the emetogenic stimulus arising from the placenta. This nausea may be accompanied by heartburn for the same reason. Eating small frequent meals rather than three large meals and prescribing medications for intractable cases is helpful. It is imperative to ensure that patients have adequate urine output and do not become dehydrated.

Patients may have brief vaginal bleeding or spotting around the time of their usual menstrual cycle likely due to implantation of the embryo in the uterine wall. This may result in confusion on pregnancy dating.

Sore, tender, fuller breasts often occur and are caused by hormones preparing milk ducts to produce milk.

Constipation also occurs – also the result of progesterone causing reduced GI tract motility. Constipation may also occur as a result of iron in the prenatal vitamins. Regular physical activity, hydration, and increased fiber intake usually helps.

Fatigue is also very common during the first trimester and may go on into the second and third trimester. It is thought that progesterone may also have a role in helping to induce sleep. Increased rest and adequate intake of protein may be helpful.

Urinary frequency occurs due to the physical pressure of the urinary bladder on the enlarging uterus. Patients are advised to urinate frequently to help avoid incontinence and urinary tract infections.

Pregnancy causes dilation of blood vessels that tend to cause drops in blood pressure, which may result in postural dizziness and light-headedness. Patients are advised to avoid prolonged standing and to rise slowly after sitting or lying down.

Health Promotion/Counseling

Pregnant women are often more motivated to adapt healthy behaviors during pregnancy. A special effort should be made to counsel and educate women on healthy lifestyles during pregnancy, child birth, and parenting.

Telegram: @medical_k

www.konkur.in

Usually, the first prenatal visit is used for a comprehensive care plan but all prenatal visits should be considered potential counseling opportunities.

1. Patients should be counseled on number and frequency of visits.
2. Maternal weight, blood pressure, uterine growth, fetal activity, and heart rate are monitored.
3. Danger signs: Call the physician with danger signs such as vaginal bleeding, rupture of membranes, decreased fetal activity, and uterine contractions.
4. Seat belts and airbags: Patients should be advised to wear seat belts low across the lap and not to turn off airbags.
5. Nutrition and vitamins: Continue to take prenatal vitamins containing iron and folic acid. Suggestions to improve nausea and vomiting, constipation, and gastroesophageal reflux should be provided if present. Severe nausea and vomiting, ketonuria, and/or electrolyte abnormalities should be investigated to rule out other medical causes, and consider ultrasound to rule out twin or molar pregnancy.
6. Obesity: Obesity is common in pregnant women. They should be counseled on obesity-related complications and may benefit from early screening for gestational diabetes.
7. Gestational weight gain: For the majority of pregnancies, the average weight gain is 25–35 lb (11–16 kg), but a 10–14 lb (4–6 kg) weight gain in an obese female and a 40 lb (18 kg) weight gain in a lean female are also considered normal.
8. Alcohol, cigarettes, and substance abuse: Pregnant women should be strongly advised to quit smoking, alcohol, and any substance abuse to reduce their risk of low birth weight, mental retardation, preterm premature rupture of membranes, preterm labor, and other conditions.
9. Infection precautions: During influenza season, women should receive influenza vaccine regardless of trimester of pregnancy. Tetanus, diphtheria, and acellular pertussis should be administered to the mother in the third trimester of each pregnancy, preferably early in the third trimester.

   Advise mothers to avoid cat feces, such as cleaning out litter boxes, or eating raw or undercooked meat due to the risk of toxoplasmosis.

   If pregnant women are found to lack immunity to varicella or rubella, immunization should be administered immediately after delivery or termination of pregnancy.
10. Work: The effects of physical exertion that include long hours standing, exposure to heat, heavy metals, and hazardous gases should be evaluated and possibly modified on a case-by-case basis. Daycare and health–care workers should be cautioned regarding the risks of exposure to certain infections [9]. Most women should continue to engage in moderate physical activity, keep their heart rate below about 140/min and their body temperature within 1–2° of normal [10].

    Special attention should be paid to oral health. Preventive work or treatments should not be deferred.

    Saunas and hot tubs should be avoided, due to rapid changes in temperature.

    Sexual intercourse to be avoided in cases of undiagnosed vaginal bleeding or ruptured membranes.

Prenatal Screening

Prenatal screening is done for early detection of potential risks to the pregnancy. There are standard screening tests offered to all women, and more specific tests available for women with particular risks. The choice of tests should be evidence based and based also on the genetic history, ethnicity, psychosocial stress [11, 12], history of domestic abuse, and substance abuse.

Common Screening Tests in Pregnancy

First Trimester

Complete blood count

Telegram: @medical_k

www.konkur.in

Blood group and Rh factor
Antibody screen
Urine analysis and culture
RPR
Hepatitis B surface antigen
Rubella IgG
Varicella IgG
Papanicolaou smear
Gonorrhea and Chlamydia culture
"Opt out" HIV screening
Sickle cell screening in appropriate ethnic groups or suspicion
Hemoglobin electrophoresis considered in appropriate ethnic groups or suspicion
Counseling for Tay-Sachs and cystic fibrosis genetic testing
PPD if indicated

Second Trimester
Quadruple screen at 14–18 weeks in which levels of alpha-fetoprotein (AFP), estradiol, beta hCG, and inhibin are measured.
Amniocentesis if indicated
Ultrasonography for fetal age and anatomy

Third Trimester
1 h glucose test to screen for gestational diabetes
Repeat CBC
Repeat antibody screen if appropriate
Group B streptococcal screening at 35–37 weeks
Repeat GC/Chlamydia, RPR, and a check for bacterial vaginosis if indicated
Tdap at 28 weeks

Prenatal screening is discussed with each patient at the initial prenatal visit, and each prenatal test is evaluated to ensure that benefit outweighs the risks and complications.

Nuchal translucency with maternal serum screening markers is used to detect chromosomal abnormalities. Studies in the 1990s showed that decreased levels of pregnancy-associated plasma protein A and increased levels of free beta hCG combined with nuchal translucency (an echo free area at the back of fetal neck on ultrasound) have a comparable detection rate of Down's syndrome at 10–14 weeks to the second trimester quad screen [13–15].

Chorionic villous sampling (CVS) for chromosomal analysis is also offered at 10–14 weeks to all women 35 years or older. It has the advantage that it can detect Down's syndrome earlier than amniocentesis, but carries a slightly higher risk of miscarriage than amniocentesis.

Second Trimester

The second trimester is from the end of the 12th week to the end of the 27th week. There is usually significant improvement in nausea and fatigue.

The extra weight gained in the first 3 months often results in back pain. To ease the pressure, it is advised to practice good posture and use a chair that provides good back support. Sleeping on the side with a pillow tucked between the legs and avoiding excessive lifting may be helpful. It is advised to wear low-heeled, comfortable shoes with good arch support.

About half of pregnant women develop swollen, tender gums around this time. Hormonal changes send more blood to the gums, making them more sensitive and causing them to bleed more easily. Studies suggest that pregnant women with periodontal disease are prone to a number of adverse outcomes that include preterm labor and low birth weight [16].

Much of the breast tenderness experienced during the first trimester resolves. Often, a thin, milky white vaginal discharge (called leukorrhea) occurs in the second trimester of pregnancy. The use of tampons is discouraged. Vaginal discharge may increase. If the discharge is foul-smelling, green or yellow, bloody, or if there is a lot of clear discharge, investigations may be warranted.

Hemorrhoids are common in pregnancy due to increased blood flow and pressure from the gravid uterus.

By the midpoint of pregnancy around 20 weeks women start to feel the first delicate flutters of movement in the abdomen, known as "quickening."

Pregnant women often look as though they are "glowing" because changing hormone levels make the skin on the face appear flushed. An increase in the pigment melanin can also lead to

Telegram: @medical_k

www.konkur.in

brown marks on the face (chloasma, or the "mask of pregnancy") and a dark line (linea nigra) may be seen down the middle of the abdomen. Many of these skin changes typically resolve postpartum.

Thin, reddish-purple lines (striae) may appear on the abdomen, breasts, or thighs. These stretch marks emerge as the skin expands to accommodate the growing belly.

As morning sickness diminishes by the end of the first trimester the appetite returns. Caloric requirements increase by about 300–500 cal a day during the second trimester. Pregnant women should be gaining about 1/2 to 1 pound a week (226–453 g) at this time.

Health Promotion/Counseling

Most women who did not feel so great in the first trimester of pregnancy usually start to feel much better in the second. They gain weight more rapidly this trimester, adding as much as 4 pounds (1.8 kg) a month for the rest of the pregnancy.

Fetal growth, development, and movement accelerate in the second trimester with further development of most of the body organs. Women are advised to wear loose clothing to accommodate the growing belly. A childbirth class is a great way to prepare for labor and birth. Classes range from 1-day intensive workshops to weekly sessions lasting a month or more. The typical class consists of lectures, discussions, and exercises, all led by a trained childbirth instructor and usually covers the signs of labor, the normal progress of labor and birth, techniques for coping with pain, how a partner can help during labor, and when to call the doctor or midwife.

Patients are also counseled and encouraged to breast feed.

Second trimester bleeding should be evaluated carefully. It is not uncommon for women to experience self-limited vaginal bleeding after sexual intercourse. Rh negative patients should receive intramuscular RhoGAM at 28 weeks and after any bleeding or amniocentesis, if done.

Mothers are instructed to report any vaginal bleeding, new onset headaches, blurring of vision, significant edema, right upper quadrant pain, or changes in the frequency or intensity of fetal movement.

Second Trimester Screening

The quad screen – also known as the quadruple marker test is a prenatal test that measures the levels of four substances in a pregnant woman's blood: alpha-fetoprotein (AFP), a protein made by the fetus; human chorionic gonadotropin (HCG), a hormone made by the placenta; estriol, a hormone made by the placenta and the baby's liver; and inhibin A, another hormone made by the placenta. Typically, the quad screen is done between weeks 15 and 20 of pregnancy, in the second trimester, to detect chromosomal abnormalities and NTDs. Cell-free fetal nucleic acid testing in maternal blood is becoming available for various genetic conditions, as is noninvasive testing for fetal Rh in women who are Rh negative. Cell-free fetal DNA gets into the maternal bloodstream via shedding of placental microparticles. These can be detected as early as 7 weeks of gestation, and the level increases as the pregnancy progresses and quickly drops after the baby is born. Cell-free fetal DNA has been used to detect noncompatible RhD factors, X-linked genetic disorders, and single gene disorders. This test carries no risk of miscarriage, but has its limitations.

The results of these screens will help the mother make an informed decision whether or not to proceed to invasive testing for a number of genetic conditions. Amniocentesis is a confirmatory test that is able to sample whole chromosomes. It has slightly lower risk of complications than chorionic villous sampling.

Ultrasound dating is less accurate as the pregnancy progresses but uterus grows in a predictable manner in normal pregnancy. A 12-week uterus fills the pelvis and is a size of a cantaloupe. A 20-week uterus is the level of the umbilicus, and the fundal height usually corresponds in centimeters with the week of gestation measured from the pubic symphysis to the top of uterus. A fetal anatomical survey is done by a detailed ultrasound between 18 and 22 weeks of gestation for detection of physical anomalies.

www.konkur.in

Third Trimester

The third trimester is from 28 weeks onwards. Biweekly visits until 36 weeks and weekly visits until delivery are recommended. The normal duration of pregnancy varies considerably but can be anywhere between 37 and 43 weeks. The fetus really fills out over these next few weeks, storing fat on the body, reaching about 15–17 in. long, and weighing about 4–4½ lb (1.8–2.0 kg) by the 32nd week. The lungs are not fully mature yet, but some rhythmic breathing movements occur. The bones are fully developed but are still soft and pliable. The fetus is storing its own calcium, iron, and phosphorus. The eyelids open after being closed since the end of the first trimester. Around 33–36 weeks, the fetus will descend into the head down position. The fetus is beginning to gain weight more rapidly. The lanugo hair will disappear from the skin, and it is becoming less red and wrinkled. The fetus is now 16–19 in. and weighs anywhere from 5¾ lb to 6¾ lb (2.6–3.0 kg).

At 38 weeks, the fetus is considered full term and will be ready to make its appearance at any time. Mom may notice a different quality of fetal movement, as the fetus is now filling the uterus with little room to move. The fingernails have grown long and small breast buds are present on both sexes. The mother is supplying the fetus with antibodies that will help protect against disease. All organs are developed, with the lungs maturing all the way until the day of delivery. The fetus is about 19–21 in. in length and weighs anywhere from 6¾ lb to 10 lb (3.0–4.5 kg).

RhoGAM may be given to Rh negative moms at 28 weeks if the antibody screen is negative.

Health Promotion/Counseling

The mother at this time is not just carrying an added 20–30 lb (or more) (9.0–13.6 kg), but the expanding uterus rearranges other organs in the body, adding even more strain. To avoid fatigue and increase energy it is often recommended to do small amounts of exercise. A walk, swimming, and prenatal yoga are good options. Taking short breaks at work, putting feet up, eating small, frequent meals and snacks also may help. Persistently low energy levels can be a sign of anemia and should be considered.

An expanding belly can throw off the posture, and the hormone relaxin, which loosens joints in anticipation of delivery, exacerbates the stress on the body.

Doing pelvic tilts, trying an under-the-belly support garment, supporting the back and abdomen with extra padding underneath the back, and keeping a wedge pillow between legs to create equilibrium for the hips can help. Nearly half of all moms-to-be will suffer from heartburn. Avoiding classic heartburn triggers is helpful. These include highly seasoned or acidic foods; greasy, fried, or fatty foods; and caffeine and carbonated drinks, citrus and some dairy foods, such as milk or ice cream. Switching from three meals daily to six easier-to-digest small ones, eating them sitting upright, and avoiding eating too close to bedtime or lying down right after eating also helps.

Over-the-counter remedies like Tums, Rolaids, Mylanta, Maalox, and Zantac are okay to take during pregnancy if lifestyle changes do not help.

The growing uterus puts pressure on the bladder most heavily in the third trimester leading to frequency of urination and sometimes urge incontinence. Trying to urinate on a schedule, such as every hour or two helps prevent this. It is also important to stay properly hydrated and to eat plenty of high-fiber foods to prevent constipation. Edema is caused by fluid retention in the lower half of the body. Varicose veins occur when valves inside blood vessels in the legs become soft or weak, which allows the blood to flow backward, pool, and form painful bulges. Although the swelling normally subsides, but sometimes varicose veins persist after pregnancy so to ease the discomfort of both edema and varicose veins, it is advised to elevate the feet often, switch standing and sitting positions frequently, not to cross legs, lie down whenever possible, preferably on the side, and to wear support hose, which may help soothe the aches and diminish the appearance of varicose veins. It is advised to avoid wearing anything that reduces circulation, like knee-high

Telegram: @medical_k

www.konkur.in

stockings and not to limit fluids to try to minimize puffiness. By 36–38 weeks patients may feel Braxton Hicks ("false") contractions. False contractions tend to be felt in the front of the abdomen only; whereas labor contractions tend to start in the back and come around to the front, sometimes moving from top to bottom of the uterus.

Third Trimester Screening

In women at average risk for gestational diabetes, a 50-g nonfasting 1-h glucose challenge test between 24 and 28 weeks of gestation is done. In contrast, women at high risk for gestational diabetes should be screened using the 50-g glucose challenge test at their first antepartum visit. Women who are at high risk for gestational diabetes include those with personal history of prediabetes, or diabetes in close family member, age more than 25 years, BMI of 30 or higher at the time of conception, history of gestational diabetes in previous pregnancy, and those of Black, Hispanic, American Indian, and Asian ethnicity. Screening cutoffs are 130 mg per dL (7.20 mmol per L; 90% sensitivity) or 140 mg per dL (7.75 mmol per L; 80% sensitivity). The most recent American Diabetes Association (ADA) and ACOG6 guidelines recommend either cutoff. Random or fasting glucose measurements are not recommended for screening because of poor specificity [17].

For women with a positive screening test, the 100-g 3-h oral glucose tolerance test is used to diagnose gestational diabetes. Although most organizations recommend a high-carbohydrate diet for up to 3 days before the test, a recent study showed that test results are not affected by modest variations in carbohydrate intake. Gestational diabetes is diagnosed if two or more plasma glucose measurements meet or exceed the following thresholds: fasting level of 95 mg per dL (5.25 mmol per L), 1-h level of 180 mg per dL (10.00 mmol per L), 2-h level of 155 mg per dL (8.60 mmol per L), or 3-h level of 140 mg per dL (7.8 mmol per L).

Vaginal and rectal swabs are taken at 35–37 weeks of pregnancy to detect group B streptococcus (GBS). GBS colonizes the vagina and gastrointestinal tract of up to 30% of all women and is the leading cause of early onset neonatal group B strep infection. Women who test positive are treated with intrapartum antibiotics to reduce the risk. The lower vagina, perineum, and rectum are cultured between 35 and 37 weeks of gestation and a positive culture is treated intrapartum with intrapartum penicillin G. In women with a high-risk penicillin allergy, clindamycin or erythromycin should only be used if susceptibility testing confirms the organisms' sensitivity. If it is not sensitive, or sensitivity results are not available, intrapartum vancomycin is recommended [18].

A complete blood count (CBC) is also recommended to check anemia at this time due to growing fetal needs.

Gonorrhea, chlamydia, RPR, and bacterial vaginosis are screened again in certain high-risk patient populations in the third trimester, although the cost versus benefit of treating for bacterial vaginosis is unclear. The United States Preventive Services Taskforce (USPSTF) recommends against screening for asymptomatic low-risk pregnant women and concluded with moderate certainty that screening has no net benefit. The results of assessing high-risk asymptomatic pregnant women were conflicting, and as a result the USPSTF concluded that evidence is insufficient to make a recommendation [19].

Fetal Assessment

The previously mentioned "kick counts" that mothers are instructed to perform and the general advice to report decreased fetal movement is the most widely applied method of fetal surveillance. Sensitizing the mother to the importance of detecting a change in fetal movement often provides the first indication of a problem with the pregnancy. Other early indications of a problem include a lack of weight gain and reduced growth velocity as reflected in small fundal height for dates. Assessment of the fetus remote from term is typically intensified as soon as a condition that increases the risk of fetal demise is recognized.

Telegram: @medical_k

www.konkur.in

Fetal heart rate monitoring: Electronic fetal heart monitoring (FHM) or intermittent auscultation is almost universally *performed as the first test* during pregnancy, labor, and delivery to identify the distressed and hypoxic fetus. The data to support improved outcomes with FHM are scarce and conflicting, but the long experience with this testing and the relative lack of availability of other methods to assess fetal condition in utero make FHM the most commonly utilized in the clinical setting.

Although there are many methods used to assess the fetus that include other options for noninvasive testing like Doppler velocimetry, umbilical artery Doppler flow assessment, and other ultrasound assessments, the most commonly utilized assessments include the nonstress test (NST), amniotic fluid volume, and the biophysical profile as well as the contraction stress test.

The NST is a simple low-risk procedure in which fetal heart rate is monitored along with simultaneous monitoring of uterine contractions through external monitors strapped around the abdomen. It is done every week after 32 weeks in many high-risk pregnancies. The fetal heart responds to uterine contractions with tachycardia. Two accelerations of 15 bpm lasting more than 20 s each within a 15 min period are reassuring and is considered reactive NST. This is recommended for women carrying more than one fetus, those with gestational diabetes, or gestational hypertension.

Contraction stress test (CST) is also carried out in high-risk pregnancies. A fetal monitor measures the baby's heart rate in response to contractions stimulated either by oxytocin (Pitocin) or nipple stimulation. Doctors use the measurements to predict how well the baby will cope with the stress of labor. They are also routinely applied for postdate pregnancies, intrauterine growth restriction (IUGR), oligohydramnios, polyhydramnios, decreased fetal movement, gestational diabetes and hypertension, Rh sensitization, or previous unexplained stillbirth. The contractions should occur within 30 min and last 40–60 s with a frequency of three in 10 min. A CST is positive if late decelerations are present with 50% or more of contractions. It is considered inconsistent if decelerations occur in fewer than 50%, and a negative CST has no decelerations.

A biophysical profile (BPP) combines the NST with an assessment of amniotic fluid index, fetal breathing movement, fetal activity, and fetal muscle tone. These parameters are assessed with ultrasound. It gives a reliable indication of fetal well-being. A score of 0–2 is given to each parameter.

A score of 8 or more is reassuring and indicates low risk for still birth. A score of 6 warrants further work up and is considered equivocal. Scores of 0–4 correlate well with a fetal pH of less than 7.2 and is an indication for immediate delivery.

Labor and Delivery

Three Stages of Labor

Labor is described in three stages, and together these stages complete the delivery of the fetus and passage of the placenta.

Stage One

The first stage is the process of reaching full cervical dilatation. This begins with the onset of uterine labor contractions, and it is the longest phase of labor. The first stage is divided into three phases: latent, active, and deceleration.

In the latent phase, the contractions become more frequent, stronger, and gain regularity, and most of the change of the cervix involves thinning, or effacement. The latent phase is most variable from woman to woman and from labor to labor. It may take a few days or be as short as a few hours. Typically, the latent phase lasts for 10–12 h for a woman who has had children. For first pregnancies, it may be closer to 20 h. For many women, the latent phase of labor can be confused with Braxton Hicks contractions. Membranes may spontaneously rupture in the early- to mid-portion of the first stage of labor. If they rupture, the labor process usually speeds up.

The next portion of the first stage of labor is the active phase, which is the phase of the most rapid cervical dilatation. For most women this is from 3 to 4 cm of dilatation until 8–9 cm of dilatation.

Telegram: @medical_k

www.konkur.in

The active phase is the most predictable, lasting an average of 5 h in first-time mothers and 2 h in mothers who have previously delivered.

Finally, there is the deceleration phase, during which the cervical dilation continues, but at a slower pace, until full dilation. In some women, the deceleration phase is not really noticeable, blending into the active phase. This is also a phase of more rapid descent, when the presenting part of the fetus is passing lower into the pelvis and deeper into the birth canal. The deceleration phase is also called transition, and, in mothers with no anesthesia, it is often punctuated by vomiting and uncontrollable shaking. These symptoms can be frightening to watch, but they are a part of normal birth, and they signal that the first stage is almost completed.

Stage Two

The second stage is the delivery of the infant. During the second stage, mom actively pushes out the baby. For first-time mothers, this can take 2–3 h, so it is important to counsel them to save energy and pace themselves. For second babies and beyond, the second stage often lasts less than an hour – and sometimes, only a few minutes.

Stage Three

The third stage of labor is the passage of the placenta, which can be immediate or take up to 30 min. The process may be sped up naturally by breastfeeding (which releases oxytocin) or medically by administering pitocin.

Support during Labor

Emotional and physical support significantly shortens labor and decreases the need for cesarean deliveries, forceps and vacuum extraction, oxytocin augmentation, and analgesia. Doula-supported mothers also rate childbirth as less difficult and painful than do women not supported by a doula. Labor support by fathers does not appear to produce similar obstetrical benefits. A number of studies report early or late psychosocial benefits of doula support. Early benefits include reductions in state anxiety scores, positive feelings about the birth experience, and increased rates of breastfeeding initiation. Later postpartum benefits include decreased symptoms of depression, improved self-esteem, exclusive breastfeeding, and increased sensitivity of the mother to her child's needs. A thorough reorganization of current birth practices is in order to ensure that every woman has access to continuous emotional and physical support during labor [20].

Intrapartum Analgesia

Maternal request is a sufficient medical indication for pain relief during labor. Laboring patients are educated about the different methods of analgesia that are available. Many pharmacological and nonpharmacological methods of labor analgesia have been adopted over the years. Nonpharmacological methods include support from labor attendants, doulas, changes of position, rest, ambulation, or a warm shower. Of the pharmacological methods, regional analgesia has become the most popular method. Short acting narcotics given in the first stage of labor are also commonly used, and may help facilitate dilation of cervix. Possible regional anesthesia techniques include epidural analgesia, spinal analgesia, or a combination of epidural and spinal analgesia. Approximately 60% of laboring women (2.4 million each year) choose regional analgesia for pain relief during labor [21].

Uterine contractions and cervical dilatation result in visceral pain whereas the descent of fetal head and subsequent pressure on the pelvic floor, vagina, and perineum generates somatic pain. Regional analgesia provides partial or complete loss of pain sensations below the T8 to T10 spinal level and is not just helpful in first and second stages of labor but also facilitates patient cooperation during labor and delivery, and if needed, procedures such as forceps or vacuum extraction.

It also allows extension of anesthesia for cesarean delivery if needed. Opioid-induced maternal and fetal respiratory depression can also be avoided. It also helps to control blood pressure in women with preeclampsia by alleviating labor

Telegram: @medical_k

www.konkur.in

pain, and it blunts the hemodynamic effects of uterine contractions and the associated pain response in patients with other medical complications. Possible adverse effects of epidural anesthesia are prolonged first and second stages of labor and the decreased maternal urge and ability to push. However, in spite of these drawbacks epidural anesthesia is extensively and routinely utilized in many hospitals and is requested by many women.

Delivery

Cervical effacement and dilatation is monitored every few hours. Anesthesia options should be reviewed with the patient early so that appropriate plans can be made.

Frequent spontaneous bladder voiding is encouraged. In patients with an epidural, a Foley catheter may be placed. Positioning options for the upcoming second stage of labor should be discussed. Mothers may ambulate and reposition themselves to maximize comfort. They may also eat small amounts of food throughout this stage, unless concern exists for impending difficulty during vaginal delivery and the possible need to convert to a cesarean section.

Delivery is imminent at crowning. Crowning occurs when the fetal head bulges the perineum as the head moves through the birth canal. A feeling of pressure due to distention of the perineum creates a tremendous urge to push for most women. Episiotomy should be avoided unless it appears that the perineum is obstructing progress or emergency delivery is required. If the mother does not instinctively feel when to push, as can occur with heavy anesthesia, she should be instructed to push with contractions.

Preparations for delivery are made when the fetal station is low. Drapes and gowns protect the clinician from the fluid of delivery; sterile preparation is not required. One hand is used to support and maintain the head in the flexed position as it delivers. The other hand is used to support the perineum. This will help control the pace of the delivery of the head. Maternal pushing is often helpful, but too forceful pushing can cause the head to deliver precipitously and can lead to perineal lacerations.

After the head is delivered, the fetal neck is checked for a nuchal cord. Routine suctioning of the nares is no longer recommended by the American Academy of Pediatrics. However, in infants who are likely to require resuscitation, suctioning may be necessary. With both hands on the head, a gentle posterior traction is applied at an angle of 45° to deliver the anterior shoulder followed by gentle anterior traction of the head to deliver the posterior shoulder. Oxytocin is often started at delivery of the anterior shoulder. Continue to support the head with one hand and use other hand to deliver the body. The cord is clamped at two locations, several centimeters apart and cut between the clamps. There has been increasing data over the past few years suggesting benefits for delayed cord clamping. It has been shown to decrease anemia in term infants. Delayed cord clamping is defined as 2–3 min after delivery [22]. The infant is cleaned or placed directly with the mother, assuming a normal appearance and Apgar evaluation. Encouraging skin-to-skin contact between mother and newborn as much as possible is recommended.

Placental separation is evidenced by an increase in the length of umbilical cord, a bolus of blood from the uterus, and migration of superior border of the uterus within the abdomen with an increase in uterine firmness.

Placental delivery is facilitated by applying gentle traction on the umbilical cord with one hand and a gentle counter traction with a vertical pressure just superior to the pubic symphysis with the other hand to prevent inversion of the uterus.

Intravenous oxytocin is administered for the prevention of postpartum hemorrhage. The placenta is examined for its completeness and the uterus is manually explored if the placenta is not intact.

Retained placental fragments increase the risk of postpartum hemorrhage. The mother is examined for cervical, vaginal, or perineal tears. First degree tears or hemostatic abrasions usually do not require suturing.

Introduction

Many acute and chronic medical conditions can expose both the pregnant patient and her developing fetus to risk of poor outcomes. Certain medical conditions can have dire consequences for the mother or fetus if not recognized and treated expeditiously. Family physicians should prioritize preconception counseling, preventative measures, and patient education to minimize the risk of harm to both the pregnant patient and fetus. Commonly encountered medical problems and urgent issues seen less commonly in pregnancy will be discussed in this chapter.

Respiratory Disorders

Asthma

The goal of treatment of asthma in pregnancy is to maintain adequate oxygenation to the developing fetus. The risks of suboptimal control include preeclampsia, gestational diabetes, placental abruption, placenta previa, obstetric hemorrhage, caesarean birth, preterm delivery, and small for gestational age (SGA) infants [1, 2]. Excellent outcomes are achievable with optimal control. Roughly one-third of patients will have worsening severity of asthma during pregnancy. Level of control is typically measured by the patient's forced expiratory volume in the first second of expiration (FEV_1) and peak expiratory flow (PEF). Classification of asthma severity and asthma control should be done in the same manner as the nonpregnant population. The severity of a patient's asthma is directly related to exacerbation and hospitalization rates [2]. For mild, intermittent asthma, controller medication is not indicated. Short-acting β2-agonists as rescue treatment may be used as needed. The cornerstone of treatment for persistent asthma is stepwise titration of inhaled corticosteroids (ICS) and long-acting beta agonists (LABA). Up-titration of the ICS dose may be considered in lieu of adding a LABA in moderate persistent and severe persistent asthma [1]. Budesonide (Pulmicort) has the most robust safety profile to date, though other ICS formulations are considered safe. Avoidance of triggers and control of atopy, rhinitis, and gastroesophageal reflux disease reduces the risk of an exacerbation. Exacerbations are treated in the same manner as the nonpregnant population.

Influenza

Vaccination against influenza is an important part of prenatal care. Influenza during pregnancy increases the risk of maternal and fetal morbidity and mortality. Inactivated influenza vaccines may be safely administered at any point during pregnancy. Live attenuated vaccines, such as the nasal influenza vaccine, are not recommended. Pregnant patients with a history of egg allergy manifesting as hives may safely receive the vaccine. In the event that more serious reactions have occurred due to exposure to eggs, the vaccine may be administered in a medical setting capable of managing anaphylaxis. In the event that a pregnant patient presents within 48 h of onset of influenza-like illness, treatment with oseltamivir (Tamiflu) 75 mg orally twice daily for 5 days or zanamivir (Relenza Diskhaler) two inhalations

Telegram: @medical_k

www.konkur.in

twice daily for 5 days) is recommended [3]. Antiviral treatment may be initiated at >48 h from the onset of symptoms in the event of severe illness. The decision to treat with an antiviral agent should be based on clinical judgment, regardless of the results of influenza testing, due to the possibility of false-negative results. Pregnant patients treated for influenza in the outpatient setting should have close follow-up due to the increased risk of pneumonia following influenza infection.

Cardiovascular Disease

Chronic Hypertension

Chronic hypertension (CHTN) in pregnancy is defined as hypertension diagnosed prior to pregnancy or prior to 20 weeks gestation. Maternal risks of hypertension in pregnancy include cerebrovascular accident, pulmonary edema, renal failure, myocardial infarction, and death. CHTN increases the risk of preeclampsia, gestational diabetes, placental abruption, postpartum hemorrhage, and cesarean delivery, as well. Fetal risks include low birth weight, stillbirth, preterm birth, and congenital anomalies. The American College of Obstetrics and Gynecology (ACOG) defines hypertension as a systolic blood pressure (SBP) measurement of 140 mmHg or greater, or a diastolic blood pressure (DBP) of 90 mmHg or greater, measured on two occasions at least 4 h apart. Severe-range hypertension is defined as either an SBP of 160 mmHg or greater, or a DBP of 110 mmHg or greater, or both. Laboratory evaluation of liver function, kidney function, and a complete blood count should be completed at the time of diagnosis. A random urine protein-to-creatinine ratio may be necessary at baseline as women with CHTN may have proteinuria. Differentiation of CHTN with proteinuria and CHTN with superimposed preeclampsia can be challenging and may require consultation with a maternal-fetal medicine specialist [4].

ACOG recommends initiating medication treatment for CHTN when either the SBP is 160 mmHg or greater, or the DBP is 110 mmHg or greater. For acute-onset severe-range hypertension, treatment should be initiated as soon as possible. Urgent evaluation and treatment of severe-range hypertension on a labor and delivery unit is appropriate. Labetalol, hydralazine, and nifedipine (Procardia) are the most commonly used medications to treat hypertension in pregnancy. Because up to 50% of women with CHTN may develop preeclampsia, pregnant women with CHTN should be started on low-dose aspirin at 81 mg/day at 12–28 weeks gestation, ideally prior to 16 weeks, and this should be continued until delivery. Antenatal surveillance for patients with CHTN may be beneficial, though evidence of the ideal time to initiate testing, the modality of testing and the frequency of testing is lacking. For women with CHTN not requiring medication management and lacking indications for earlier delivery, delivery prior to 38 0/7 weeks is not recommended. For women with CHTN that require medication to control blood pressure and are otherwise without complications, delivery prior to 37 0/7 weeks is not recommended. Because of the increased risk of developing superimposed preeclampsia with advancing gestational age, the risks and benefits of delivery beyond 39 0/7 weeks should be carefully considered and discussed with the patient [4].

Infectious Disease

Urinary Tract Infection

Physiological changes of pregnancy increase the risk of urinary tract infection (UTI). UTIs in pregnancy may present as asymptomatic bacteriuria (ASB) or symptomatic disease with cystitis and/or pyelonephritis. Bacteriuria, including ASB, increases the risk of pyelonephritis and, possibly, preterm birth and decreased birth weight [5]. Pyelonephritis increases the risk of anemia, acute kidney injury, sepsis, pulmonary insufficiency, and acute respiratory distress syndrome in pregnant women [6]. ASB is defined by the Infectious Diseases Society of America (IDSA) as greater than 10^5 colony forming units (CFUs) per milliliter (mL) of the same bacteria on two voided specimens or greater than 10^2 CFUs/mL on one catheterized specimen [5]. The United States Preventive

Telegram: @medical_k

www.konkur.in

Services Task Force (USPSTF) recommends one urine culture between 12 and 16 weeks gestation. The American College of Obstetricians and Gynecologists (ACOG) recommends one urine culture early in pregnancy (Table 1). Neither organization clarifies whether a second urine culture should be collected prior to treatment. Treatment for ASB is only indicated for a positive urine culture with a colony count greater than 10^5 CFUs/mL [5]. ASB with group B streptococcus (GBS) isolated on urine culture should be treated in the same manner. However, GBS bacteriuria at any colony count during pregnancy is an indication for intrapartum GBS prophylaxis [7].

Pregnant women diagnosed with pyelonephritis should be admitted to the hospital for intravenous antibiotics [6]. Empiric treatment for presumed cystitis with classic symptoms is recommended while awaiting culture and sensitivity to direct final treatment. The typical duration of treatment for both ASB and symptomatic cystitis is 4–7 days [6]. Consideration of local antimicrobial resistance and medication safety profiles should guide treatment. Medications such as penicillins, cephalosporins, macrolides, and clindamycin are generally considered safe in pregnancy.

There is mixed evidence on the association of birth defects and exposure to nitrofurantoin (Macrobid, Macrodantin) or sulfonamides during fetal organogenesis. Caution is also advised with use of nitrofurantoin or sulfonamides within 30 days of birth due to a possible increased risk of neonatal jaundice. Both of these medications are contraindicated in women with glucose-6-phosphate dehydrogenase deficiency [8].

Table 1 Infectious disease screening in pregnancy

Recommended test	Timing
HIV	Initial prenatal visit
Hepatitis B	Initial prenatal visit
Syphilis	Initial prenatal visit
Urine culture	Initial prenatal visit (ACOG) 12–16 weeks gestation (USPSTF)
Varicella	Titer at initial visit if no documented history of disease or adequate vaccination
Hepatitis C	Initial prenatal visit if indicated by risk factors
Group B streptococcus	Routinely after 35 weeks gestation or as indicated

HIV

Pregnant women should be tested for HIV as early as possible during each pregnancy (Table 1) [9]. More than 90% of children infected with HIV in childhood acquire the disease in utero, during delivery or through breastfeeding [10]. The risk of mother-to-child transmission (MTCT) can be greatly reduced with combined antiretroviral therapy (cART). In all patients infected with HIV, the objective of cART is to reduce the plasma level of HIV RNA to an undetectable level. In antiretroviral (ARV)-naïve pregnant patients, cART should be started as early as possible. Pregnant women already on a full cART regimen should, in general, continue with their prescribed regimen. Providers should seek consultation or guidance, if necessary, regarding optimal medication regimens that achieve viral suppression while reducing fetal and maternal risk. The United States Department of Health and Human Services' AIDSinfo website (https://aidsinfo.nih.gov/) includes updated guidelines on treatment of HIV in pregnant patients with guidance on choosing an appropriate medication regimen. Also, the National Perinatal HIV Hotline (1-888-448-8765) provides clinical consultations for providers caring for patients with HIV and their children. Patients should be counseled on the importance of daily adherence to their medication regimen. Providers should report patient exposures to antiretroviral therapy to the Antiretroviral Pregnancy Registry (http://www.apregistry.com/). Retesting for HIV in the third trimester, before 36 weeks gestation, is recommended in patients at high risk of acquiring HIV (Table 2). It is recommended that infants exposed to HIV receive antiretroviral medications. Because it is recommended to start antiretroviral therapy as soon as possible after birth, delivery planning should include an evaluation of the delivering hospital's ability to care for HIV-exposed infants [11].

Table 2 Risk factors for HIV and HCV infection in pregnancy

Risk factors for HIV infection	Risk factors for HCV infection
Unprotected anal/vaginal sexual intercourse	History of tattoos/piercings done with unsterilized instruments
History of sexually transmitted infections	History of HIV infection
History of injection drug use/sharing needles	History of injection drug use/sharing needles
Incarceration	History of intranasal drug use
Sex work	Incarceration
Occupational exposure	Occupational exposure
History of blood transfusion prior to 1992	History of blood transfusion prior to 1992

Viral Hepatitis

Hepatitis A

Hepatitis A virus (HAV) produces a self-limited symptomatic or asymptomatic infection that often requires supportive care only. Children are typically asymptomatic when infected but can still transmit the virus [12]. Fecal-oral transmission is facilitated by poor hygiene and substandard sanitation. Detection of immunoglobulin M (IgM) antibodies to HAV are diagnostic of the infection. The vaccine may be given during pregnancy if the patient is at increased risk or desires to be vaccinated [13]. Pregnant patients should be offered postexposure prophylaxis and active vaccination if they report HAV exposure [12].

Hepatitis B

Hepatitis B virus (HBV) is the leading cause of chronic liver disease worldwide [12]. HBV can be transmitted through sexual or parenteral contact. However, up to 50% of HBV infection worldwide is attributable to perinatal transmission. While Hepatitis B virus (HBV) more commonly leads to resolved infection and immunity if acquired in adulthood, 90% of exposed neonates will eventually develop chronic HBV infection in the absence of adequate immunoprophylaxis [14]. The USPSTF recommends that all pregnant women be screened for HBV surface antigen (HBsAg) as early as possible in pregnancy (Table 1) [15]. If HBV screening is negative and the patient is determined to be HBV nonimmune, the HBV vaccine may be given during pregnancy if the patient is at increased risk or desires to be vaccinated [13]. The Society for Maternal-Fetal Medicine (SMFM) recommends HBV viral load testing in the third trimester for pregnant patients with a positive HBsAg test or patients known to be chronic carriers. Tenofovir is recommended for the duration of pregnancy as the first-line antiviral agent if the HBV viral load is greater than 6–8 log 10 copies/mL [14]. HBV immunoglobulin and the HBV vaccine should be administered to all infants born to HBsAg-positive or HBsAg-unknown mothers within 12 h of birth.

Hepatitis C

Hepatitis C virus (HCV) is the leading cause of chronic liver disease in the United States [12]. Mother-to-child transmission (MTCT) is the leading cause of HCV infection in children. The risk of MTCT per pregnancy is 4–7% [16]. The risk of transmission is higher if the mother is co-infected with HIV. MTCT is thought to occur only with detectable HCV RNA during pregnancy [16]. It is recommended that pregnant women at high risk of HCV infection be screened for anti-HCV antibodies during pregnancy (Tables 1 and 2) [12]. Currently, antiviral medications recommended for treatment of HCV are not approved for use in pregnant women. Infants born to mothers infected with HCV should be screened for anti-HCV antibodies after 18 months of age or for HCV RNA after 1 month of age [17].

Cervicitis

Pregnant women with cervicitis should be evaluated for *Neisseria gonorrhoeae* (GC), *Chlamydia trachomatis* (CT), and *Trichomonas vaginalis*. Primary herpes simplex virus (HSV) may also cause cervicitis [18].

Nucleic acid amplification testing (NAAT) on an endocervical swab, a vaginal swab, or a urine

Telegram: @medical_k

www.konkur.in

sample reliably detects GC and CT. If urine sampling is elected, the patient should be instructed on collecting a first-void sample, also known as a "dirty" catch. Trichomonads may be detected on wet-prep microscopy. Because the sensitivity of detecting trichomonads on microscopy is 50%, further testing should be pursued if cervicitis persists in the absence of positive NAAT testing for GC or CT [18]. Confirmatory testing for suspected HSV includes viral detection via viral culture or polymerase chain reaction (PCR), or antibody detection via serological testing [19].

Chlamydia, gonorrhea, and trichomonas infections are managed in the same manner as nonpregnant patients. Although tests-of-cure are not recommended, retesting may be appropriate if there are concerns with reinfection or adherence.

Genital Herpes Simplex

Transmission of herpes simplex virus (HSV) in utero or during birth can lead to poor outcomes in affected neonates. The route of delivery is dependent on the presence of active vaginal or vulvar lesions or prodromal symptoms at the time of labor and delivery. Suppressive therapy with acyclovir (Zovirax) 400 mg three times per day or valacyclovir (Valtrex) 500 mg two times per day, starting at 36 weeks gestation, has been shown to reduce the risk of recurrence of active disease at the time of delivery [19]. Active HSV in a pregnant patient should be managed in the same manner as the nonpregnant population. The Centers for Disease Control's (CDC) 2015 Sexually Transmitted Disease Treatment Guidelines offer guidance on effective medication regimens and may be found here: https://www.cdc.gov/std/tg2015/herpes.htm.

Syphilis

From 2013 to 2017, cases of congenital syphilis in the United States increased by 53.3% [20]. The risks of untreated maternal syphilis include low birth weight, congenital syphilis, preterm birth, stillbirth, and neonatal death [21]. Universal screening of pregnant women for syphilis at the initial prenatal visit is recommended by the USPSTF (Table 1) [22]. Penicillin G is the only known effective antibiotic to treat fetal syphilis and to prevent maternal transmission. For pregnant women with a major penicillin allergy, the CDC recommends penicillin desensitization and subsequent treatment. CDC recommendations on evaluation and treatment of syphilis during pregnancy may be found here: https://www.cdc.gov/std/tg2015/syphilis-pregnancy.htm. Referral to a maternal-fetal medicine specialist is appropriate, especially with advancing gestational age, but referral should not delay treatment.

Varicella Zoster

Varicella zoster virus (VZV) is highly contagious. Immune status against VZV should be verified by either a history of chickenpox, a history of completed vaccination or by serology (Table 1). Varicella pneumonia has been reported to develop in 10–20% of pregnant women who acquire VZV with a mortality rate among patients with pneumonia reported to be 10–40% [23, 24]. While rare, congenital varicella infection can cause fetal skin scarring, chorioretinitis, limb hypoplasia, and microcephaly [23]. In the event of uncomplicated primary VZV infection in a pregnant woman, treatment with acyclovir (Zovirax) 800 mg five times per day for 5–7 days is recommended. Varicella nonimmune patients who report a significant exposure to VZV should receive VZV immunoglobulin within 96 h of exposure [24]. The varicella vaccine is contraindicated in pregnancy.

Tuberculosis

Untreated tuberculosis (TB) in pregnancy increases the risk of preeclampsia, postpartum hemorrhage, spontaneous abortion, preterm birth, and low birth weight infants [25]. Pregnant patients at high risk of infection (Table 3) with TB should be screened with a tuberculin skin test (TST). In patients with HIV or previous BCG

Telegram: @medical_k

www.konkur.in

Table 3 Risk factors and degree of risk for development of tuberculosis

Risk factors	Degree of risk
Close contact with a person with infectious tuberculosis	High
HIV	High
Homelessness	Moderate
Injection drug use	Moderate
Occupational exposure in high risk facilities (hospitals, skilled nursing facilities, correctional facilities, homeless shelters)	Moderate
Immigration from an area of the world with high rates of tuberculosis	Moderate
Diabetes mellitus	Low
Smoking	Low

vaccination, an interferon-gamma release assay (IGRA) may reduce the risk of a false-negative or false-positive TST, respectively [25].

A systematic review of latent tuberculosis infection (LTBI) in pregnancy demonstrated a prevalence of 14–48% among various cohorts in the United States [26]. The CDC recommends treatment for active TB and LTBI as soon as TB is detected. For patients with active TB, the recommended regimen is isoniazid, rifampin, and ethambutol daily for 2 months, then isoniazid and rifampin daily or twice weekly for 7 months, thereafter. For patients with LTBI, isoniazid daily or twice weekly for 9 months and pyridoxine (B6) supplementation is recommended. CDC recommendations for treatment of TB in pregnancy may be found here: https://www.cdc.gov/tb/topic/populations/pregnancy/default.htm.

Endocrine Disorders

Diabetes Mellitus

Pregestational Diabetes

Pregestational diabetes is defined as type 1 or type 2 diabetes diagnosed either prior to conception or early in pregnancy. Because of the significant risks that hyperglycemia imposes on both a pregnant woman and her fetus, more frequent monitoring is often necessary and referral to a maternal-fetal specialist may be appropriate. Women with type 1 or type 2 diabetes who are planning to become pregnant should receive preconception counseling on the importance of euglycemic control to reduce the risk of maternal and fetal complications. At least 400mcg daily of folic acid should also be prescribed due to the increased risk of neural tube defects in the infants of women with diabetes [27].

Throughout pregnancy, there is a physiologic increase in insulin resistance in all pregnant women. Pregnant women with diabetes should be advised to check their blood glucose after fasting and 1 or 2 h postprandial throughout their pregnancy. The following glucose levels should be targeted when considering medication adjustment: less than or equal to 95 mg/dL for the fasting value and less than or equal to 140 mg/dL for the 1-h postprandial value or 120 mg/dL for the 2-h postprandial value. Because of the increased risk of developing preeclampsia, pregnant women with pregestational diabetes should be started on low-dose aspirin at 81 mg/day at 12–28 weeks gestation, ideally prior to 16 weeks, and this should be continued until delivery [27]. Fetal growth should be monitored with fundal height measurement. Periodic ultrasound assessment of growth in the third trimester is a common practice and may be considered, especially if there are concerns for fetal growth restriction or macrosomia. Antenatal surveillance is recommended starting at 32 weeks gestation.

Insulin is the preferred treatment for pregestational diabetes. A 2017 Cochrane review reported insufficient data to recommend any specific insulin regimen over another in pregestational diabetes [28]. The safety of oral antidiabetic medications in the treatment of pregestational diabetes has not been well studied. The decision to prescribe oral antidiabetic medications should be individualized and should include a thorough discussion of the risks and benefits of use [27].

Gestational Diabetes

Screening for gestational diabetes (GDM) is recommended between 24 and 28 weeks gestation. Nearly all obstetricians in the United

Telegram: @medical_k

www.konkur.in

States use the 1-h oral glucose tolerance test (OGTT) as a screening tool [29]. Institutional thresholds for a positive screen vary between 130 mg/dL and 140 mg/dL. A positive 1-h OGTT is typically followed by a confirmatory 3-h OGTT with two or more abnormal values being diagnostic for GDM. Blood sugar testing recommendations and thresholds for treatment are the same as in pregestational diabetes.

Diet and exercise improve glucose levels and medication may not be necessary in GDM [29]. Diet-controlled GDM is classified as A1GDM whereas GDM requiring medication to maintain normal glucose levels is classified as A2GDM. As in pregestational diabetes, insulin is the preferred treatment for poorly controlled GDM. Use of oral antidiabetic medications should be prescribed on an individualized basis in situations where compliance, patient preference, or logistical difficulties complicate adherence to an insulin regimen. ACOG states that metformin and "rarely glyburide" are reasonable alternatives to insulin therapy provided patients are informed of the limitations of safety data and the risk of treatment failure. Antenatal surveillance may be beneficial for patients with poor glucose control and A2GDM. There is no consensus regarding antenatal surveillance for patients with well-controlled A1GDM [29].

Because GDM significantly increases the risk that a woman will develop diabetes later in life, it is recommended that screening with a 75 g, 2-h OGTT be performed at 4–12 weeks postpartum. Thereafter, screening for diabetes every 1–3 years is recommended by the American Diabetes Association and ACOG [29].

Thyroid Disorders

Thyroid stimulating hormone (TSH) values vary during pregnancy due to normal physiologic changes and should be taken into account when interpreting thyroid studies. Notably, an increase in human chorionic gonadotropin (hCG) during the first trimester weakly stimulates TSH receptors on the thyroid gland leading to a slight increase in free T_4 secretion and a subsequent decrease in TSH. TSH values normalize after the first trimester and subsequently increase progressively through the second and third trimesters. The American Thyroid Association has published the following trimester-specific reference ranges for TSH: 0.1–2.5 mIU/L in the first trimester; 0.2–3.0 mIU/L in the second trimester; and 0.3–3.0 mIU/L in the third trimester. A 30% enlargement of the thyroid gland is typical during pregnancy [30]. Significant derangements in free T_4 or T_3 values outside of the reference range are not expected physiological changes of pregnancy and should be correlated with clinical symptoms to evaluate for overt hypothyroidism or hyperthyroidism.

Hypothyroidism

Untreated maternal hypothyroidism is associated with spontaneous abortion, preeclampsia, preterm birth, placental abruption, fetal loss, low birth weight, and impaired neuropsychological development of affected children. Clinical signs and symptoms of hypothyroidism include fatigue, weight gain, constipation, cold intolerance, muscle cramps, dry skin, and hair loss. Hypertension may also be noted. Lab findings of overt hypothyroidism include elevated TSH, decreased free T_4, and, in the case of Hashimoto thyroiditis, the presence of antithyroid peroxidase antibodies. The preferred treatment for hypothyroidism in pregnancy is levothyroxine at an initial dosage of 1–2 mcg/kg daily. TSH should be measured at 4–6 week intervals and levothyroxine adjusted until the TSH value reaches a normal level. There is insufficient evidence to recommend treatment of subclinical hypothyroidism despite some studies showing an association with adverse perinatal outcomes [30].

Hyperthyroidism

Clinical signs and symptoms of overt hyperthyroidism include heat intolerance, diarrhea, tremors, anxiety, excessive sweating, tachycardia, weight loss, goiter, palpitations, insomnia, and hypertension. Untreated hyperthyroidism is associated with low birth weight infants and, possibly, fetal loss [30]. Lab findings of hyperthyroidism include a decreased TSH level and an elevated free T_4 level. Graves' disease accounts for the great majority of cases of overt hyperthyroidism

Telegram: @medical_k

www.konkur.in

and is confirmed by the presence of thyroid-stimulating immunoglobulin (TSI). Historically, propylthiouracil (PTU) has been the treatment of choice for hyperthyroidism in pregnancy due to teratogenic effects of methimazole (Tapazole) during the first trimester. However, in 2009, the U.S. Food and Drug Administration (FDA) issued a safety alert for PTU due to reports of hepatotoxicity. Consequently, the American Thyroid Association and the American Association of Clinical Endocrinologists recommended that PTU be used in the first trimester only and that treatment be switched to methimazole for the remainder of the pregnancy [30, 31]. Due to an increased risk of fetal thyrotoxicosis in pregnancies of women with Graves' disease, referral to a maternal-fetal specialist may be appropriate [30].

Hematologic Disorders

Iron Deficiency Anemia

In pregnancy, anemia is defined as a hemoglobin or hematocrit level below the following trimester-specific thresholds: 11.0 g/dL or 33%, respectively, in the first trimester; 10.5 g/dL or 32%, respectively, in the second trimester; and 11.0 g/dL or 33%, respectively, in the third trimester. The Institute of Medicine recommends that thresholds be lowered by 0.8 g/dL for hemoglobin and 2% for hematocrit in African-American adults [32]. ACOG recommends that all women be screened for anemia during pregnancy. The most common cause of anemia during pregnancy is iron deficiency anemia (IDA). IDA is commonly diagnosed by the presence of low ferritin levels in the setting of a microcytic, hypochromic anemia. IDA in pregnancy is associated with low birth weight, preterm delivery, and perinatal mortality [32].

There is insufficient evidence regarding the optimal dose or formulation of elemental iron for supplementation (Table 4). The British Society of Hematologists suggests 40–80 mg of elemental iron orally once daily at initiation of treatment. Response can be evaluated 2–3 weeks after starting medication and the dose adjusted if necessary. Supplementation should continue until at least 6 weeks postpartum [33]. In patients that do not respond to oral iron, cannot tolerate oral iron, or need rapid correction due to advancing gestation, intravenous iron is an option. A 2019 meta-analysis concluded that IV iron is more efficacious at reaching target hemoglobin levels with greater speed and fewer side effects [34].

Table 4 Different formulations of iron supplementation

Oral iron formulations	IV iron formulations
Ferrous sulfate	Iron dextran
Ferrous gluconate	Iron sucrose
Ferrous fumarate	Ferric carboxymaltose

Gestational Thrombocytopenia

Gestational thrombocytopenia (GT) is defined as a platelet count below 150 x 10^9/L. GT typically does not present before the midpoint of the second trimester and accounts for about 75% of cases of thrombocytopenia in pregnancy. In 1–5% of women, platelet counts in GT are observed to be less than 100 x 10^9/L and rarely less than 75 x 10^9/L [35]. GT generally does not affect the health of the mother or her newborn, though, in rare cases, mild thrombocytopenia can be observed in infants born to mothers with GT [36]. However, because GT is a diagnosis of exclusion, other causes of thrombocytopenia should be considered and referral to a hematologist may be appropriate. After 20 weeks gestation, in the setting of thrombocytopenia, it is essential that preeclampsia, HELLP syndrome, and acute fatty liver of pregnancy are considered as part of the differential diagnosis.

Venous Thromboembolism

Pregnant women and women in the postpartum period are 4–5 times more likely to develop venous thromboembolism (VTE) than non-pregnant women due to increased venous stasis, a hypercoagulable state, compression of the inferior vena cava, alteration of coagulation factors, and decreased mobility [37]. Every pregnant woman should be asked about a personal or family history of thromboembolism and abnormal bleeding or clotting disorders.

Telegram: @medical_k

www.konkur.in

Deep vein thrombosis (DVT) accounts for the majority of VTE events in pregnancy. If DVT is clinically suspected, compression ultrasonography of the proximal veins is recommended as the initial test due to the increased frequency of iliofemoral and iliac vein thromboses when compared to nonpregnant women [37]. Because of the decreased sensitivity and specificity of D-dimer as a screening test in pregnancy, it is not recommended as part of the evaluation of VTE.

Pulmonary embolism (PE) in pregnancy is diagnosed with either ventilation-perfusion (VQ) scanning or computed tomographic angiography (CTA). In general, fetal exposure to radiation from both tests is low, though fetal absorption of radiation is slightly higher with VQ scanning than with CTA. Maternal exposure to radiation, particularly to the breast, is lower with VQ scanning. Guidelines from the American Thoracic Society and the Society of Thoracic Radiology suggest that chest x-ray (CXR) be used as an initial test followed by VQ scanning if the CXR is normal and CTA if the CXR is abnormal [37].

The recommended treatment for VTE in pregnancy is subcutaneous low-molecular-weight heparin at a therapeutic dose, though consultation with cardiology and maternal-fetal medicine is recommended for pregnant women with mechanical heart valves. Oral direct thrombin inhibitors and anti-Xa inhibitors should be avoided in pregnancy. Guidelines from the American College of Chest Physicians on duration of therapy may be found here: https://journal.chestnet.org/article/S0012-3692(15)00335-9/fulltext. ACOG recommends that therapy be continued until at least 6 weeks postpartum irrespective of the clinical scenario [37].

Neurologic Disorders

Epilepsy

Infants born to mothers with epilepsy are at increased risk of congenital malformations. The majority of this risk is conferred by antiepileptic drug (AED) use during pregnancy, though convulsive seizures in the first trimester can increase the risk of malformations, as well [38]. Most women with epilepsy will require continued medication treatment throughout pregnancy. A 2016 Cochrane review of AED monotherapy concluded that valproate has the highest risk of malformations at 10.93%, while levetiracetam and lamotrigine appear to be associated with the lowest levels of risk [39].

Migraine Headache

The frequency and severity of migraine headaches typically decrease during pregnancy. However, treatment may still be necessary for prophylaxis or acute migraine headaches. For prophylaxis, propranolol (Inderal) is generally considered safe in pregnancy, though there are reports of fetal growth restriction associated with fetal propranolol exposure. Valproic acid (Depakote) and topiramate (Topamax) should be avoided in pregnancy [40]. Acetaminophen (Tylenol) and metoclopramide (Reglan) are the only medications considered safe for treatment of acute migraine headaches. While the safety profile of sumatriptan (Imitrex) use in pregnancy is encouraging, its use should be reserved for severe headaches not responsive to other treatments due to an association between use in the second or third trimester and postpartum hemorrhage [41].

Musculoskeletal Disorders

Low Back Pain

More than 70% of pregnant women will experience low back pain at some point during their pregnancy [42]. A 2007 Cochrane review of eight studies concluded that low back pain was reduced with both individual (number needed to treat [NNT] = 2.1) and group physical therapy (NNT = 3.2), and that disability as measured in days of sick leave was reduced by 12% [43]. A 2015 Cochrane review of interventions for low back pain and pelvic pain concluded that land-based exercise interventions of varying duration

Telegram: @medical_k

www.konkur.in

lasting at least 5 weeks significantly reduced low back pain and sick leave [44].

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) in pregnancy is thought to be the result of physiologic changes during pregnancy that result in fluid retention and subsequent median nerve compression [45]. The natural history of pregnancy-associated CTS is variably reported [42, 45]. Evaluation of CTS in pregnancy is the same as in the nonpregnant population, and while there is limited guidance on the indications for electrodiagnostic studies during pregnancy, nerve conduction studies and electromyography are not contraindicated. As in the nonpregnant population, treatment for CTS should be guided by the severity of discomfort and disability, taking into account that the majority of cases resolve within 2–4 weeks of delivery [42].

Psychiatric Disorders

Depression

Up to 23% of pregnant women may experience depression during pregnancy. Some studies have reported an increased risk of low birth weight (LBW) infants, small for gestational age (SGA) infants and preterm delivery when the mother was affected by depressive symptoms. Cognitive behavioral therapy (CBT) and interpersonal therapy (IPT) have been shown to be beneficial for treatment of mild-to-moderate depression in pregnancy [46]. Selective serotonin reuptake inhibitors (SSRIs) are the most commonly prescribed medication in women who have failed to respond to CBT or IPT. Some studies reporting associations between SSRIs and outcomes of offspring such as growth effects, malformations, and neurobehavioral effects have been confounded by lack of adequate controls. Women should, however, be counseled that 15–30% of infants exposed to SSRIs in utero may have increased irritability and restlessness that typically resolves by 2 weeks of age. Also, data showing a possible link between paroxetine and cardiac malformations resulted in the United States Food and Drug Administration classifying paroxetine as a category "D" drug [46]. In pre-conceptional and pregnant women taking paroxetine, the decision to switch to a different medication should be carefully considered and discussed with the patient. Ultimately, severity of depression, the safety profile of psychotropic medications, and gestational age should guide decisions regarding any treatment or the decision to consult with a psychiatrist.

Special Considerations

Substance Use Disorders

ACOG advocates for screening for substance use in pregnancy followed by intervention and referral, if necessary. There are multiple screening tools available: the six-question "Wayne Indirect Drug Use Screener" shows a strong association with toxicology results, and the three-question "Substance Use Risk Profile-Pregnancy" has been validated in pregnancy (Table 5) [47]. Interventions for positive screens include counseling on the effects of substance use during pregnancy, drug treatment services, and coordination of a multidisciplinary treatment team.

Obesity

Obesity in pregnancy confers an array of risks to the well-being of a mother and her fetus. The World Health Organization has defined obesity by a body mass index (BMI) of 30.0 kg/m^2 or greater and further divides obesity into three classes (Table 6). Fetal risks include neural tube defects, hydrocephaly, cardiovascular anomalies, and death. There is also an increased risk of neonatal and infant death in the offspring of obese mothers. Maternal risks include stillbirth, cardiac dysfunction, nonalcoholic fatty liver disease, gestational diabetes mellitus, preeclampsia, cesarean delivery, endometritis, impaired wound healing,

and venous thromboembolism [48]. The risk of complications increases with increasing BMI. Weight loss prior to pregnancy is the most effective intervention to reduce the risk of complications during pregnancy as weight loss or inadequate weight gain may result in poor neonatal outcomes [48]. Recommendations by the National Academy of Medicine (formerly the Institute of Medicine) on weight gain during pregnancy may be found here: https://www.nap.edu/resource/12584/Report-Brief%2D%2D-Weight-Gain-During-Pregnancy.pdf.

In addition to standard prenatal care, ACOG recommends that obese pregnant women be counseled on the limitations of ultrasonography to detect congenital anomalies and that an early screen for gestational diabetes be performed for women with a BMI of 30.0 or greater [48].

Bariatric Surgery and Pregnancy

Periodic evaluation for nutritional deficiency following Roux-en-Y gastric bypass surgery is recommended in the nonpregnant population and should be considered during pregnancy, as well. The most common nutrient deficiencies following gastric bypass involve protein, iron, vitamin B_{12}, folate, vitamin D, and calcium. If initial evaluation is reassuring, surveillance of the blood count, iron, ferritin, calcium, and vitamin D every trimester may be considered [49]. Consideration should also be given to involving the patient's bariatric surgery team in prenatal care as this may be of benefit to maintaining appropriate weight gain during pregnancy [50] and may assist in evaluation of potential complications related to the surgery that become apparent during pregnancy.

Diagnostic Imaging During Pregnancy

Magnetic resonance imaging (MRI) and ultrasonography do not confer risk of radiation exposure and are the preferred imaging techniques in pregnancy. However, the great majority of imaging protocols with computed tomography (CT), x-rays, or nuclear medicine modalities are performed at radiation doses much lower than thresholds associated with fetal harm. Prevention 172
Management 172

References 173

There are a wide range of obstetric complications that may occur during pregnancy. This chapter will focus on six of the most common complications including spontaneous abortion, ectopic pregnancy, hypertensive disorders of pregnancy, placenta previa, and preterm labor.

Spontaneous Abortion

Spontaneous abortion is defined as the involuntary loss of pregnancy prior to 20 weeks of gestation.

Vaginal bleeding in the first trimester of pregnancy is common. It may occur as a result of spontaneous abortion, ectopic pregnancy, gestational trophoblastic disease, or cervical causes. Approximately half the pregnancies complicated by first trimester bleeding result in viable pregnancies.

Epidemiology

Spontaneous abortion or miscarriage occurs in about 15% of clinically identified pregnancies and may occur in up to 50% of pregnancies prior to clinical identification [1].

Etiology

The cause of spontaneous abortion is rarely identified in the individual patient. Research has demonstrated, however, that approximately half of miscarriages occur as a result of trisomy, triploidy, monosomy, or another significant genetic abnormality [2]. Additionally, several environmental factors have been associated with miscarriage including both internal and external factors. Internal factors include advanced maternal age, uterine anomalies, leiomyomata, incompetent cervix, and luteal phase defects that lead to progesterone deficiency. External factors include substance use such as tobacco, alcohol, and cocaine, radiation exposure, infections, and occupational chemical exposure to substances such as arsenic, benzene, ethylene oxide, formaldehyde, or lead.

Diagnosis

Women experiencing a spontaneous abortion typically present with vaginal bleeding and cramping. They may also report a diminution or reversal of early pregnancy symptoms (fatigue, nausea, breast tenderness).

The first steps in evaluation of a patient with suspected miscarriage are to obtain vital signs and establish an estimated gestational age based on last menstrual period. If the estimated gestational age is greater than 9 weeks, an attempt should be made to auscultate fetal heart tones. Examination should then include abdominal, speculum, and pelvic examinations. If adnexal tenderness is identified, ectopic pregnancy should be considered. Non-uterine causes of bleeding can be identified during the speculum examination as can the presence or absence of cervical dilation. The diagnosis of spontaneous abortion can be assisted by use of transvaginal ultrasound. A completed spontaneous abortion will present with an empty uterus with an echogenic endometrial stripe. In a viable gestation, a gestational sac should be visualized between 4 and 5 weeks gestation and must be present with a beta-HCG greater than 1500–2000 mIU/mL. The yolk sac should be visualized between 5 and 6 weeks gestation and must be present with a gestational sac >10 mm, the embryo should be visualized between 5 and 6 weeks gestation and must be present with a gestational sac >18 mm, and cardiac activity should be visualized between 5 and 6 weeks gestation and must be present if the crown-rump length is greater than 5 mm [3]. The presence of a gestational sac with a diameter greater

Telegram: @medical_k

www.konkur.in

than 20 mm without an identifiable embryo or presence of an embryo with a crown-rump length greater than 5 mm without a heartbeat is diagnostic of a pregnancy demise [4].

In patients with unclear course, serial quantitative beta-HCGs and ultrasounds may be beneficial. Between the 4th and 8th week of gestation, beta-HCG levels should double every 48–72 h. Likewise, both the diameter of the gestational sac and the crown-rump length should increase by 1 mm/day. Therefore, repeating labs and an ultrasound in 7–10 days should demonstrate a measurable change in both.

Prevention

Several interventions can lower the risk of spontaneous abortion. These include avoiding smoking, drinking alcohol, and using recreational drugs. Additionally, avoiding exposure to certain viral infections such as rubella can lower the risk. Finally, obesity increases the risk of miscarriage; therefore, patients should be encouraged to achieve a healthy weight prior to pregnancy.

Management

Miscarriage can be managed expectantly, medically, or surgically. Frequently, spontaneous abortions complete without intervention. In women with significant bleeding, pain, or infection, either medical or surgical intervention should be considered [5]. Other women may desire to avoid the watchful waiting that is often required with expectant management. Misoprostol administered either 600 micrograms orally or 600–800 micrograms vaginally can be utilized for medical management of miscarriage. The initial dose can be repeated in 24–48 h if the initial dose is unsuccessful [6]. Surgical management can be performed using either sharp curettage or vacuum aspiration. While complication rates are comparable between the two, vacuum aspiration is faster and causes less pain and bleeding [7].

Ectopic Pregnancy

Ectopic pregnancy is the implantation of an embryo outside of the uterine cavity. The vast majority are located in the fallopian tubes; however, they may rarely occur in the broad ligament, cervix, ovary, or abdominal cavity. Ectopic pregnancy is the second most common cause of maternal mortality.

Epidemiology

Between 2002 and 2007, a study of women enrolled in health plans demonstrated the ectopic pregnancy rate in the United States to be 0.64% [8]. Previous data, which included patients enrolled in Medicaid, demonstrated a rate of 1.9% in 1992 [9]. Both data sets demonstrate an increasing rate of ectopic pregnancy with age. Mortality rates have declined from 1.15 deaths in 100,000 live births to 0.50 deaths per 100,000 live births between 1980–1984 and 2003–2007 [10]. This is a result of increased awareness and improvements in early diagnosis.

Etiology

Any factor that interferes with the fallopian tube's function and ciliary motility increases the risk of ectopic pregnancy. Risk factors can be divided into anatomic and functional. Anatomic risk factors include a history of tubal ectopic pregnancy, infection (e.g., pelvic inflammatory disease), ligation, or surgery. Functional risk factors include hormonal stimulation of ovulation, use of progestin-containing contraceptives, and tobacco use. Risk factors can also be divided based on the strength of their risk for ectopic pregnancy. Factors strongly associated with ectopic pregnancy include previous ectopic pregnancy, history of tubal surgery, and history of DES exposure. Factors moderately associated with ectopic pregnancy include history of sexually transmitted infection, having more than one sexual partner, and cigarette smoking. Finally, factors slightly associated with ectopic pregnancy include prior

Telegram: @medical_k

www.konkur.in

abdominal or pelvic surgery, douching, and sexual intercourse prior to age 18 [11].

Diagnosis

Most patients presenting with an ectopic pregnancy will have abdominal pain, typically lower abdominal and unilateral, and bleeding. Physical examination may help identify a tender adnexal mass, as well as signs of shock (hypotension, tachycardia, altered mental state) or hemoperitoneum (distended abdomen with decreased bowel sounds, referred shoulder pain, and a posterior cul-de-sac which bulges into the vaginal fornix). Serum hCG and progesterone can both contribute to making the diagnosis of anectopic pregnancy. Serum hCG will typically increase early in pregnancy then plateau and possibly fall. If the initial hCG is <1500 mIU/mL, a rise of at least 53% over 48 h is indicative of a viable pregnancy [12].

A recent meta-analysis reviewing 26 cohort studies, including over 9400 women in the first trimester of pregnancy, found that in women with abdominal pain and/or bleeding and an inconclusive ultrasound, a single progesterone test (cutoff between 3.2 and 6 ng/mL) predicts a nonviable pregnancy with pooled sensitivity of 74.6% (95% confidence interval 50.6–89.4%) and specificity of 98.4% (90.9–99.7%) [13].

The gold standard for diagnosis of ectopic pregnancy is the transvaginal ultrasound. At an hCG level between 1500 and 2000 mIU/mL or higher, a gestational sac should be seen in the uterus using transvaginal ultrasound. Identification of an intrauterine pregnancy essentially rules out ectopic pregnancy (heterotopic pregnancy is exceedingly rare). Ectopic pregnancy is very likely if any adnexal mass or significant free pelvic fluid is identified. Finally, ectopic pregnancy is confirmed if a gestational sac with embryo and heartbeat is identified outside of the uterus [14].

Prevention

While there is no specific prevention strategy for ectopic pregnancy, the risk can be minimized by avoiding modifiable risk factors that increase the risk of an ectopic. These include not smoking, avoiding pregnancy before age 18, and taking precautions to prevent sexually transmitted infections.

Management

The management of ectopic pregnancy can be expectant, medical, or surgical. In reliable patients with an hCG <1000 mIU/mL that is declining, expectant management can be considered if there is minimal pain and bleeding and no evidence of rupture, and if a mass is detected, it is <3 cm in diameter, and no fetal heartbeat is detected [15]. Close follow-up is required, and hCG levels should be followed until they are <5 mIU/mL.

Medical management of ectopic pregnancy has utilized the folic acid antagonist, methotrexate. Single-dose methotrexate is administered at 1 mg/kg or 50 mg/m^2. It should be considered in patients with stable vital signs, an hCG of <2000 mIU/mL, a mass < = 3.5 cm in diameter without fetal heartbeat, and no evidence of rupture. Additionally, patients should not have a contraindication to methotrexate administration such as elevated liver enzymes, immunodeficiency, or blood dyscrasias. Serum hCG levels should be checked at days 4 and 7 and then weekly until it is <5 mIU/mL. If the hCG level does not fall between days 4 and 7, a second dose of methotrexate or surgical intervention should be considered [16, 17].

Surgical management of ectopic pregnancy should be considered when the patient is unreliable for follow-up, is unstable, has signs of hemoperitoneum, or has a more advanced ectopic pregnancy. Additionally, surgical intervention should be considered when the diagnosis is unclear or there is a contraindication to either expectant or medical management. Surgical interventions include linear salpingostomy (opening the fallopian tube and removing the ectopic pregnancy) or salpingectomy (removing the fallopian tube) via laparoscopy or laparotomy. Salpingostomy is preferred in patients who wish to maintain fertility [18]. Laparotomy should be limited to patients in whom visualization is

Telegram: @medical_k

www.konkur.in

compromised or hemostasis cannot be achieved utilizing laparoscopy [19].

Hypertensive Disorders of Pregnancy

Hypertensive disorders of pregnancy can be classified into chronic hypertension, gestational hypertension, preeclampsia, and chronic hypertension with superimposed preeclampsia. The term "gestational hypertension" replaces "pregnancy-induced hypertension." The nomenclature of "mild" and "severe" preeclampsia has been abandoned, and preeclampsia is now characterized as being with or without severe features [20]. This distinction helps to emphasize that severe features may develop at any time and that ongoing evaluation is essential in identifying patients with more severe disease.

Epidemiology

Hypertensive disorders of pregnancy affect between 6% and 8% of pregnancies in the United States making them the most common medical complication of pregnancy [21]. The majority of women that develop preeclampsia are nulliparous. In multiparous women, those with multiple gestations, age > 40, history of preeclampsia in prior pregnancy, chronic disease (hypertension, diabetes, and renal disease), elevated BMI, and the presence of the antiphospholipid syndrome increase the risk of developing preeclampsia [22]. Approximately 20% of women with chronic hypertension will develop preeclampsia [20]. Additionally, a family history of preeclampsia, African-American and Latina race, lower socioeconomic class, and women who do not seek or do not have access to prenatal care are at increased risk for developing preeclampsia [20].

Etiology

It has been hypothesized that the pathophysiology of preeclampsia may be the result of a genetic predisposition, an immunologic condition, abnormal implantation of the placenta, endothelial injury to the vascular system, activation of platelets, placental growth factor deficiency, or vasoconstriction as a result of maladaptation of the cardiovascular system. Despite these theories, the exact etiology remains unknown [23].

Diagnosis

Hypertension during pregnancy is defined as a blood pressure of > = 140/90 on two separate occasions 4 h apart or > = 160/110 on a single occasion. Chronic hypertension is defined as hypertension that presents before 20 weeks of gestation or that persists after 6 weeks postpartum. Gestational hypertension is ultimately a provisional diagnosis. It is defined as the presence of hypertension after 20 weeks gestation without the features of preeclampsia defined below. Of those women initially diagnosed with gestational hypertension, approximately 50% will go on to develop preeclampsia [24]. Another proportion will have persistent hypertension after 6 weeks postpartum and be diagnosed with chronic hypertension.

In preeclampsia, hypertension (blood pressure > = 140.90) develops after 20 weeks of gestation and is accompanied by proteinuria. Proteinuria can be identified through a 24 h protein demonstrating > = 300 mg of protein, a protein/creatinine ratio of >0.3 on a random voided urine, or a dipstick of +1 protein on a random voided urine. It is important to note that the presence of edema is no longer a criterion for preeclampsia [20].

Severe features of preeclampsia include two blood pressures of > = 160/110 obtained 4 h apart while the patient is on bed rest, a platelet count <100,000/mL, doubling of AST or ALT, severe right upper quadrant pain without other etiology, creatinine >1.1 mg/dL, doubling of baseline creatinine without evidence of other renal disease, development of pulmonary edema, and cerebral/visual disturbances that did not preexist. Intrauterine growth restriction and proteinuria >5 g in a 24 h urine collection are no longer considered criteria for severe features [20].

Telegram: @medical_k

www.konkur.in

Prevention

A Cochrane review of prophylactically treating women with increased risk of developing preeclampsia with low-dose aspirin demonstrated that the numbers needed to treat to prevent one case of preeclampsia and one fetal death were 69 and 227, respectively [25]. Among women with the highest risk of developing preeclampsia, the number needed to treat to prevent one case of preeclampsia was 18 [25]. Similarly, a Cochrane review of calcium supplementation demonstrated reduced risk of preeclampsia among women at high risk for this condition with low calcium intake [26]. However, routine prophylaxis/supplementation with calcium, magnesium, omega 3 fatty acids, vitamin C, and vitamin E in low-risk patients has not been demonstrated to be effective in lowering the risk of preeclampsia.

Management

For both gestational hypertension and preeclampsia without severe features, patients should be instructed to do daily kick counts to assess for fetal well-being and to self-assess for severe signs or symptoms such as development of a new headache, visual disturbances, chest pain, shortness of breath, persistent nausea and vomiting, or right upper quadrant pain. Patients should be evaluated in the office weekly with blood pressure measurement, platelet count, and liver enzymes. For patients with gestational hypertension, urine should be collected weekly to assess for protein. There is low-quality evidence to support weekly antenatal testing. Additionally, serial ultrasounds should be obtained to assess for growth restriction. Bed rest is no longer recommended [20]. In both gestational hypertension and preeclampsia without severe features, delivery is recommended at 37 weeks gestation [20]. Neither magnesium sulfate during labor nor antihypertensives are recommended.

Once a patient develops preeclampsia with severe features > = 34 weeks gestation, the goal is to stabilize the patient and move toward delivery. If the patient is <= 34 weeks gestation, they should be cared for at a facility that has the required resources to provide care to both the mother and premature fetus. For women who develop preeclampsia with severe features before fetal viability is attained (22–24 weeks depending on location and available resources), once the patient is stabilized delivery should be planned. In women with preeclampsia and severe features <= 34 weeks gestation who are stable, expectant management with close monitoring and appropriate hypertensive control is recommended until the patient is >34 weeks gestation, and then delivery should be planned. In women with preeclampsia with severe features who have reached viability but are <34 weeks gestation and also present with preterm premature rupture of membranes, labor, platelet count <100,000/mL, AST or ALT elevated > twice the upper limit of normal, growth restriction, severe oligohydramnios, new onset or worsening renal dysfunction, or reversed end-flow umbilical Doppler readings, steroids should be administered to promote fetal lung maturity, and an attempt should be made to delay delivery for 48 h to maximize their effectiveness. For patients <34 weeks who present with preeclampsia with severe features and uncontrollable severe hypertension, eclampsia, pulmonary edema, placenta abruption, disseminated intravascular coagulopathy, or Category III fetal heart rate tracing (defined as a sinusoidal pattern or a tracing with absent variability and recurrent late decelerations, variable decelerations, or bradycardia, replaces "non-reassuring" terminology), steroids should be administered to promote fetal lung maturity, but delivery should not be delayed to maximize effectiveness of the steroids. Finally, in women with intrauterine fetal demise, steroid administration is unnecessary, and delivery should be planned [20].

Magnesium sulfate is recommended for patients who present with either preeclampsia with severe features to prevent a seizure or eclampsia to prevent further seizures. The Magpie Trial determined that in women with severe preeclampsia (old nomenclature), 63 women

Telegram: @medical_k

www.konkur.in

needed to be treated with magnesium sulfate to prevent one seizure [27]. Magnesium sulfate should typically be continued until 24 h postpartum or until the patient has demonstrated significant diuresis indicating resolution of vasoconstriction.

Antihypertensive medications are indicated in patients that have blood pressures > = 160/110, although the optimal blood pressure goal is unclear. In acute management, intravenous medications offer a rapid onset and the ability to titrate therapy. Both labetalol and hydralazine have been commonly used. For chronic management of patients with preeclampsia with severe features being expectantly managed, oral medications are preferred. Both oral nifedipine and labetalol have been used in these patients [21].

Placenta Previa

Normal placental implantation occurs at the uterine fundus. Placenta previa, however, occurs when the site of implantation is the lower uterine segment and the placenta overlies or approaches the cervical os. Marginal previa is defined as placenta located within 2 centimeters of the os, whereas complete previa indicates that the placenta covers the os. Morbidity related to placenta previa occurs with maternal hemorrhage, need for cesarean delivery, and risk of abnormal placental implantation (accreta, increta, percreta) which may result in hysterectomy.

Epidemiology

Placenta previa affects approximately 0.4% of pregnancies at term [28]. It typically presents as painless vaginal bleeding in the second or third trimesters which are often triggered by sexual intercourse. Risk factors include chronic hypertension, history of uterine curettage or cesarean delivery (incidence increases to 2.3% after just two cesarean deliveries [29]), cocaine or tobacco use, increasing maternal age, multiparity, and male fetuses [28].

Etiology

The exact etiology of placenta previa is unknown. It has been hypothesized that atrophy or scarring of the endometrium related to prior trauma, surgery (uterine curettage or cesarean), or infection may lead to inadequate or abnormal vascularization of the endometrium in the fundus to allow for implantation [30]. Further research is required to evaluate this hypothesis.

Diagnosis

The diagnosis of placenta previa should be suspected in women who present in either the second or third trimester with painless vaginal bleeding. Additionally, persistent breech or malpresentation at term should raise suspicion. Diagnosis is confirmed with ultrasonography to locate the site of placental implantation. Transvaginal ultrasound is more sensitive and specific than transabdominal ultrasound and has been demonstrated to be safe to perform [31]. In patients in whom abnormal insertion is suspected (accreta, increta, percreta), MRI may be useful in differentiating the level of invasion into the uterine wall.

Prevention

While there is no specific prevention strategy for placenta previa, the risk can be minimized by avoiding modifiable risk factors that increase risk for previa. These include not smoking or using cocaine when considering and during pregnancy and careful consideration of first cesarean in patients who desire additional children.

Management

The management of placenta previa remains somewhat controversial. Most authors recommend expectant management between the time

Telegram: @medical_k

www.konkur.in

of identification of previa and the first (sentinel) bleed as long as they have ready access to a hospital that provides maternity care services [32]. A similar strategy is reasonable for patients after a sentinel bleed following a period of inpatient hospitalization, stabilization, and observation. Patients should be advised to avoid placing any object in the vagina, including intercourse and tampons. In patients with recurrent bleeding, delivery should be considered at 36 weeks gestational age; and in patients without vaginal bleeding, delivery should be considered at 38 weeks gestational age [32].

In women with marginal previa, the mode of delivery should be determined following ultrasound at 36 weeks. If the placental edge is $> =$ 2 cm from the cervical os, an attempt of vaginal delivery should be made. In cases where the placental edge is 1–2 cm from the cervical os, vaginal delivery can be considered; however, facilities should be prepared for the need for emergent cesarean delivery [33].

In women with complete previa, cesarean delivery should be planned for between 36 and 38 weeks gestation, as noted above. Because of the increased risk of placenta accreta, increta, or percreta, the delivery team should be prepared to perform a cesarean hysterectomy [32].

In women with recurrent episodes of bleeding prior to delivery, transfusion should be considered for signs or symptoms of symptomatic anemia. Additionally, because of the risk of severe postpartum hemorrhage and disseminated intravascular coagulopathy during or following delivery, patients should be evaluated for transfusion and the blood bank notified of the potential need to activate massive transfusion protocols.

Preterm Labor and Delivery

Preterm labor is defined as the development of regular uterine contractions that result in cervical change, effacement, and dilation, occurring before 37 weeks of gestation. The greatest risk of preterm labor is resultant preterm delivery.

Epidemiology

In the United States, 11.39% of deliveries in 2013 occurred prior to 37 weeks [34], 40–45% of which are the result of preterm labor without premature rupture of membranes [35]. Between 1990 and 2006, the incidence of preterm delivery increased 20%, largely as a result of an increase in multiple gestations (resulting from increased use of assistive reproductive technology) and late preterm deliveries. Since that time, with an increased focus on decreasing the number of near-term inductions and cesarean deliveries, that rate has fallen to a 15-year low [34, 35]. While efforts persist to decrease the number of preterm deliveries, it will be difficult to eliminate them completely as 30–35% of preterm deliveries are secondary to medically indicated inductions or cesarean deliveries (preeclampsia with severe features, placental abruption, etc.) [35].

Etiology

Common pathways resulting in preterm labor and delivery include immune mediation, inflammation, stress, overdistension of the uterus, uteroplacental hemorrhage, and uteroplacental ischemia [36]. Many risk factors for preterm labor and delivery, which activate these pathways, have been identified and can be divided into preconception, maternal, and fetal factors. These are summarized in Table 1. Unfortunately, nearly 50% of preterm deliveries occur in women without known risk factors for preterm labor or delivery [37]. Of the known risk factors, history of both spontaneous and medically indicated preterm delivery is the most significant distinguishable risk factor for recurrence, increasing the risk by 2.5-fold [38].

Infection is an important cause of preterm labor and delivery and may be responsible for 25–40% of all preterm births. Bacterial vaginosis increases the risk of preterm delivery between 1.5 and 3 times. In women with the TNF-alpha allele 2 gene, the presence of bacterial vaginosis doubles the risk of preterm delivery [36]. Asymptomatic bacteriuria and pyelonephritis have both been

Telegram: @medical_k

www.konkur.in

Table 1 Risk factors for preterm delivery

Preconception	Maternal	Fetal
Body mass index <20 or poor nutrition	Abdominal surgery	Assisted reproductive technology (both singleton and multiple Gestations)
History of LEEP or cone biopsy of the cervix	African-American race	Congenital anomalies
Interpregnancy interval <6 months	Chronic medical conditions (diabetes, Hypertension)	Intrauterine fetal demise
Psychological stress and emotional or Physical abuse	History of preterm delivery	Intrauterine growth restriction
Sexually transmitted illnesses	Infection (bacterial vaginosis, chlamydia, Trichomonas)	Multiple gestation
Smoking	Lack of prenatal care	
Substance abuse (cocaine, amphetamines)	Oligohydramnios	
Uterine anomaly	Periodontal disease	
	Placenta abruption	
	Placenta previa	
	Polyhydramnios	
	Poor social support	
	Short cervix	
	Smoking	
	Strenuous work	
	Uterine contractions	

associated with preterm delivery. Periodontal disease increases the risk by twofold. Sexually transmitted infections including chlamydia, gonorrhea, and syphilis likewise increase the risk of preterm birth. While group B *Streptococcus*, *M. hominis*, and *U. urealyticum* are commonly identified in women with preterm labor, they are not felt to be causal of the preterm labor [35].

Diagnosis

Patients presenting with complaint of preterm contractions should be placed on a tocodynamometer to assess for frequency of uterine contractions. Fetal well-being should be assessed by continuous Doppler and position determined by ultrasound.

In a patient presenting with preterm contractions, assessment should evaluate for status of amniotic membranes (intact or ruptured), presence of infection, and likelihood that contractions will lead to delivery. Evaluation for rupture of membranes is discussed below in the section entitled "Premature Rupture of Membranes." Patients should be evaluated for bacterial vaginosis, gonorrhea and chlamydia, urinary tract infection, and group B *Streptococcus*.

Likelihood of delivery can be assessed via digital cervical examination, terbutaline challenge, fetal fibronectin collection, and measurement of cervical length. Digital cervical examination, while subjective in nature, may be useful if advanced dilation or effacement is noted on examination. A single dose of terbutaline 0.25 mg administered subcutaneously may result in resolution of contractions in patients not in preterm labor. Fetal fibronectin, a placental glycoprotein, is typically absent from vaginal secretions prior to term, and its presence between 24 and

Telegram: @medical_k

www.konkur.in

34 weeks has been associated with preterm delivery. The presence of fetal fibronectin in vaginal secretions collected in the posterior fornix between 24 and 34 weeks has a positive predictive value of 13–30% for delivery in the next 7–10 days. Its absence has a negative predictive value of 99% for delivery in the following 2 weeks [39]. False-positive results may occur if the patient has had intercourse, a digital cervical exam, or transvaginal ultrasound in the past 24 h or is having active bleeding from the cervix or vagina. Transvaginal measurement of cervical length can also be useful in stratifying risk for preterm delivery. In symptomatic women, an initial cervical length of >30 mm excludes the diagnosis of preterm labor, whereas women with a cervical length < 15 mm are at high risk for preterm delivery [40].

Prevention

In women with a history of preterm delivery (spontaneous and not medically indicated), 17-alpha-hydroxyprogesterone caproate (17P) has been demonstrated to reduce the recurrence rate of preterm delivery. It is indicated in women between 16 and 36 weeks gestation who have a history of preterm delivery, who have not demonstrated signs of preterm labor in the current pregnancy, and who are not allergic to the compound. Beginning at 16 weeks, patients should receive 250 mg intramuscularly weekly through 36 weeks or delivery. Studies have demonstrated a decrease in preterm deliveries in women meeting the above criteria who are treated with 17P versus controls (37% vice 55%) as well as an improvement in the health of their infants [41]. Vaginal progesterone has not been shown to be beneficial in this population.

Women with a history of preterm delivery should have their cervical length evaluated by transvaginal ultrasound between 16 and 24 weeks gestation [42]. If the cervical length is found to be <25 mm, cervical cerclage should be offered. Studies have demonstrated a decrease in preterm birth and perinatal morbidity and mortality when cerclage is used in this population [42]. Additionally, in women with history of preterm delivery and a cervical length of <20 mm, vaginal progesterone 100–200 mg administered vaginally on a daily basis has shown to decrease rates of preterm delivery and perinatal morbidity and mortality [43]. Intramuscular progesterone has not been demonstrated to improve outcome in this population.

It is important to note that while published meta-analyses have reported the benefits above with the use of either intramuscular or vaginal progesterone, three recent trials (OPPTIMUM, PROGRESS, and PROLONG) failed to demonstrate similar decreases in preterm labor rates and/or fetal death [44, 45, 46]. As a result, while progesterone remains widely utilized, there is some controversy, in particular for the use of intramuscular progesterone.

Although several studies have examined the treatment of asymptomatic bacterial vaginosis in the prevention of preterm labor and delivery, data remains conflicted. The US Preventive Services Task Force recommends against screening in low-risk women and states that there is insufficient evidence to recommend for or against screening and treatment of women at high risk for preterm labor [47].

Management

Women diagnosed with preterm labor should, when feasible, be transferred to a facility that has the capability to manage a preterm infant. Antenatal corticosteroids should be administered to women between 24 and 34 weeks gestation who present in preterm labor. Either betamethasone 12 mg administered intramuscularly for two doses 12 h apart or dexamethasone 6 mg administered intramuscularly for four doses 6 h apart has been shown to be effective in decreasing perinatal morbidity and mortality [48]. Magnesium sulfate administered intravenously as a 4–6 g bolus followed by a maintenance dose of 1–2 g/h for 24 h in women with preterm labor has been shown to decrease the

Telegram: @medical_k

www.konkur.in

rate of cerebral palsy in their infants [49]. It should be noted that magnesium sulfate is no longer recommended for use as a tocolytic in these patients.

Short-term tocolysis may be considered in women presenting with preterm labor to allow time to transfer to a facility with a higher level of.

care, to allow administration of corticosteroids and magnesium sulfate, and to provide for group B *Streptococcus* prophylaxis. Nifedipine has been shown to decrease the risk of delivery within 48 h and has the advantage of increased latency till birth, improved neonatal outcomes, and decreased maternal side effects compared to other tocolytics [48]. Beta mimetics, such as terbutaline, may also be used to delay delivery. Magnesium sulfate, on the other hand, has not been shown to prolong pregnancy or to improve perinatal morbidity [50].

Group B *Streptococcus* is the leading cause of death secondary to infection in newborns despite widespread implementation of CDC guidelines for its prevention. In women presenting with preterm labor, either ampicillin 2 g intravenously on admission then 1 g every 4 h through delivery or penicillin G 5 million units intravenously on admission then 2.5–3 million units every 4 h through delivery should be administered [51]. Dosing may be discontinued if preterm labor is ruled out or if a negative group B *Streptococcus* culture is obtained. Cefazolin should be used in women with a non-anaphylactic allergy to penicillin. In women with a history of anaphylaxis, clindamycin or vancomycin should be utilized.

Introduction

Labor is a process, and difficulties can arise at any point. This chapter will outline antepartum considerations and focus on the complications that can arise as labor progresses. It is important to keep in mind, however, that there is much overlap in the timing of these questions and problems. The clinician must try to anticipate them early.

Trial of Labor and Vaginal Birth After Cesarean Section

Background

Trial of labor after cesarean delivery (TOLAC) refers to a planned attempt at vaginal delivery by a woman who has previously undergone a cesarean delivery. It is well known that the cesarean section rate has dramatically increased over several decades. Supported by accumulating evidence of relative safety, increased offering of TOLAC represented a countertrend from the 1970s to 1990s, with a resultant decrease in the cesarean rate [1]. However, as more reports of complications such as uterine rupture surfaced, this trend reversed. Among other interested parties, the National Institutes of Health (NIH) in 2010 called on organizations to facilitate access to TOLAC, in an effort to improve perinatal outcomes by reducing complications associated with repeat cesarean sections [1].

Uterine Rupture

The most feared complication of TOLAC is uterine rupture, which can result in significant maternal and fetal morbidity and mortality. Uterine rupture usually involves the previous hysterotomy scar but may extend into the uterine wall or

Telegram: @medical_k

www.konkur.in

beyond. Risk factors include excessive oxytocin administration, dysfunctional labor, history of more than one cesarean, multiparity, short interdelivery interval, and history of nonpregnant uterine perforation [1]. Rates of rupture are difficult to estimate due to a paucity of data, but available literature suggests rates of 4–9% after a classical incision, 0.5–0.9% after a low transverse incision [1], and 1–4% after a low vertical incision [2]. Uterine rupture most frequently presents with fetal heart rate abnormalities. Other symptoms and signs may include abdominal pain, decrease in frequency and/or intensity of contractions, bleeding, or loss of fetal station. Emergent laparotomy may be indicated for any of these findings, as fetal death or adverse neurologic outcomes may occur in as many as 25% of cases of uterine rupture [3].

Approach to the Patient

Decreasing the occurrence of repeat cesareans would be an obvious benefit due to lower rates of hemorrhage, thromboembolism, infection, and surgical complications, as well as a shorter recovery period. However, the endeavor to compare elective repeat cesarean (ERC) with a trial of labor (TOL) in patients with a history of one prior cesarean is complex. The decision of whether to undergo a TOL involves assessing both the chance of successful vaginal birth after cesarean (VBAC) and the risks associated with TOLAC. The calculator most commonly used to stratify this risk is available on the website for the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network (https://mfmunetwork.bsc.gwu.edu/PublicBSC/MFMU/VGBirthCalc/vagbirth.html). Probability for successful VBAC is based on a multivariable logistic regression model which allows for more individualized counseling of pregnant patients with a prior cesarean. It should be noted that while race is a factor in the current calculator, its role is unclear and a model that does not include race or ethnicity is under development.

The decision regarding mode of delivery is ultimately patient-specific, reached after conversation with her provider beginning early in pregnancy. Although there is no consensus, it has been suggested that patients with at least a 60–70% predicted chance of successful VBAC do not have an increased likelihood of morbidity when compared to patients undergoing ERC [1].

Management

The most recent ACOG Practice Bulletin on this issue made a number of recommendations based on "good and consistent scientific evidence" [1]: most patients with one prior low transverse cesarean section should be offered TOLAC; epidural analgesia may be used in patients undergoing TOLAC; misoprostol should not be used for cervical ripening or induction of labor. A number of recommendations were made based on more limited scientific evidence, including that TOLAC is a reasonable option for patients with two prior cesarean deliveries, as well as for patients with an unknown type of uterine scar as long as there is no high clinical suspicion for a classical uterine incision. The bulletin also notes that induction of labor remains an option, although it is critical to recognize that prostaglandin and oxytocin use are key risk factors for complete uterine rupture in both intact and scarred uteri [1, 43]. ACOG recommends a trial of labor even for patients with twins and a history of one low transverse cesarean delivery, as long as the first twin is cephalic [1].

Indications for Cesarean Delivery

Cesarean delivery was once considered the last resort, resulting in maternal death in the majority of cases [4]. It is now generally viewed as safe and increasingly requested and performed without clear indication. It is imperative to understand appropriate indications for cesarean section.

Four indications currently account for up to 90% of cesarean sections: prior cesarean section (~35–40%), labor dystocia (~20–35%), abnormal fetal presentation (~10–20%), and non-reassuring fetal status (~10–25%) [4, 5]. See Table 1 for a helpful categorization of cesarean indications, suggested in *Munro Kerr's Operative Obstetrics*

Telegram: @medical_k

www.konkur.in

Table 1 Indications for cesarean section

Indisputable	Generally accepted[a]	Marginal
Placenta previa	Previous cesarean section	Fear of repeating previous bad outcome
Confirmed fetal compromise or imminent fetal demise (*clear fetal heart rate evidence, umbilical cord prolapse, vasa previa, uterine rupture, severe placenta abruption*)	Breech presentation	Fear of fetal injury
Definite obstruction (*unequivocal cephalopelvic disproportion, soft tissue obstruction, fetal malpresentation*)	Labor dystocia	Fear of maternal pelvic floor injury
	Concern for fetal compromise	
	Maternal medical conditions *(severe preeclampsia, severe cardiovascular disease, super obesity)*	

[a]Within this category, indications may range from relative to absolute

[4]. Frequently, a combination of relative indications, rather than one absolute indication, leads to the decision for cesarean.

Breech Delivery

Background

The Term Breech Trial in 2000 led to a dramatic change in obstetric practice [6]. When compared with planned cesarean delivery, the study demonstrated increased morbidity with planned vaginal breech delivery. Follow-up analyses have suggested short-term benefits in both maternal and neonatal morbidity and mortality from planned cesarean delivery, but the evidence is not yet clear on the persistence of long-term risk for mother or infant [7]. Hesitance to plan vaginal breech deliveries has persisted, and consequently, practitioner experience and comfort with performing this procedure has decreased [8]. ACOG expresses support for shared decision-making between the patient and practitioner that considers both patient wishes and practitioner experience. They note that planned vaginal breech delivery "may be reasonable under hospital-specific guidelines for eligibility and labor management" [8], but only after detailed informed consent that explicitly documents that the risk for neonatal morbidity and mortality may be higher than if a cesarean delivery is planned. Additionally, ACOG recommends first offering external cephalic version as an alternative to cesarean delivery for women desiring vaginal delivery who carry a term singleton breech fetus and have no other contraindications [8].

General Principles

Breech presentation persists in approximately 3–4% of singleton pregnancies at term [5]. There are several types of breech presentation, defined by the relationship of the lower extremities to the buttocks. In frank breech presentation, the hips are flexed and the knees extended, so that the feet are close to the head. In complete breech presentation, one or both of the knees are flexed. In incomplete breech presentation (also referred to as footling breech), one or both knees are not flexed and therefore below the buttocks. As a pregnancy approaches term, the larger mass of the buttocks typically finds its place in the more spacious fundus. Multiple factors increase the risk of breech presentation [5]: amniotic fluid volume abnormalities, high parity, hydro-/anencephaly, previous breech delivery, uterine anomalies, placenta previa, fundal placentation, and pelvic tumors. Risks of vaginal breech delivery include maternal cervical and vaginal trauma; uterine rupture; fetal humerus, clavicle, or femur injuries; brachial plexus injuries; skull fractures; and difficulty delivering the after coming head.

Telegram: @medical_k

www.konkur.in

Management

Because unexpected breech deliveries occur, and because some resource settings make cesarean section impossible, it is important to understand the technique of breech delivery. While multiple sources describe the technique in detail, several points are worth mentioning: episiotomy should be strongly considered; delivery is easier if the fetus is allowed to deliver spontaneously up to the umbilicus, in order to avoid cord compression; delivery must be accomplished promptly once the breech has passed through the introitus [5].

Bleeding Complications During Labor

General Principles

Patients who have placenta abruption, placenta previa, placenta accreta, and vasa previa can present with vaginal bleeding later in pregnancy. It is important to understand the conditions and respond quickly when there is a high index of suspicion. Advances in ultrasonography have improved the early and accurate diagnosis of placenta previa, placenta accreta, and vasa previa allowing the clinician time for preparation.

Placental Abruption

Placental abruption occurs when there is premature separation, either partial or total, of the placenta from the uterine wall prior to birth. Placental abruption occurs in 0.6–1% of pregnancies [9], and the primary risk factor is hypertension. Other risk factors for placental abruption include abdominal trauma, grand multiparity ($\geq$3), uterine anomalies, folate deficiency, short umbilical cord, cigarette smoking, cocaine use, history of abruption, maternal age over 35, obesity, and use of assisted reproductive technology [9, 10]. Most women will experience third trimester bleeding (80%), acute abdominal pain (50%), and/or a non-reassuring fetal heart rate tracing. Ultrasonography does not always detect a clot underneath the placenta; therefore, placental abruption remains a clinical diagnosis and treatment is recommended if there is a high index of suspicion. Close monitoring of mother and baby is necessary. The mother may become hemodynamically unstable and require IV fluids or blood products. When there is a non-reassuring fetal heart rate tracing, an emergency cesarean section may be necessary.

Placenta Previa

Placenta previa occurs when the placenta overlies or is proximate to the cervical os. Placenta previa can be classified as complete if the placenta completely covers the internal os, partial if the placenta partially covers the internal os, marginal if the placenta reaches the internal os but does not cover it, or low-lying placenta if the placenta extends into the lower uterine segment but does not reach the internal os.

Placenta previa may be seen in up to 1.3% of all births [10, 11]. Risk factors include multiparity, previous placenta previa, history of cesarean section, history of dilation and curettage, smoking, pregnancy termination, prior evacuation of retained products of conception, advanced maternal age, multifetal gestation, abnormal fetal lie, and previous intrauterine surgery. The condition is a relatively common finding, often diagnosed incidentally in asymptomatic women by second trimester ultrasounds. Transvaginal ultrasound is the superior method of detection. Once diagnosed, repeat ultrasonography in the third trimester is indicated. If the placenta previa is marginal, they tend to resolve in 95% of cases. Symptomatic women present during their third trimester with painless vaginal bleeding. Placenta previa is associated with antepartum bleeding, the need for hysterectomy, maternal hemorrhage, blood transfusion, septicemia, thrombophlebitis, and an increased risk of preterm birth [10]. Once diagnosed, the initial management is usually conservative as long as there is a reassuring fetal heart rate tracing and the mother is hemodynamically stable, in order to allow for the fetus to progress to as close to term as possible. If bleeding occurs between 24 and 34 weeks of gestation, it is also

Telegram: @medical_k

www.konkur.in

recommended to administer steroids in case preterm delivery is necessary. Planned cesarean section for complete or partial placenta previa is usually performed at 36–37 weeks of gestation [10].

Placenta Accreta

Placenta accreta refers to a placenta that is abnormally adhered to the uterus, invading the myometrium, serosa, or even adjacent organs. This becomes a problem at the time of delivery when the placenta does not separate and may lead to massive hemorrhage. This hemorrhage can cause further complications such as disseminated intravascular coagulopathy, need for hysterectomy, injury to other maternal tissues, renal failure, or death [10]. The incidence of accreta is rising due to the rise in cesarean delivery rates [10] and is estimated to occur in between one in 533–730 deliveries, an eight-fold increase since the 1970s [12]. In addition to prior cesarean delivery, the other major risk factor for placenta accreta is placenta previa; the risk is greatest when both factors are present and the previa overlies the hysterotomy scar [12]. Additional risk factors include prior uterine surgeries, advanced maternal age, multiparity, and in vitro fertilization. It is critical to make the diagnosis of placenta accreta prenatally via sonography or MRI so that proper planning and delivery can occur. Management of placenta accreta involves a planned preterm cesarean section by 34 weeks gestation followed by total abdominal hysterectomy without an attempt to separate the placenta from the uterus to avoid excessive bleeding. As with all planned preterm deliveries at this gestational age, antenatal steroids should be administered prior to delivery. The clinician should be prepared to manage blood loss since women with placenta accreta typically lose 3000–5000 ml of blood at time of delivery [10].

Vasa Previa

Vasa previa is a rare but life-threatening condition that refers to fetal vessels running through the membranes over the cervix and under the fetal presenting part. It is the result of velamentous insertion of the cord into the membranes instead of the safer placenta. Because this can lead to fetal hemorrhage at the time of membrane rupture, it carries a mortality rate greater than 50% [10]. Vasa previa occurs in 1 in 2500 deliveries [10]. Risk factors include a low-lying placenta, placenta with accessory lobes, multiple pregnancies, and pregnancies from in vitro fertilization [10]. Vasa previa can be seen with ultrasonography but is sometimes diagnosed at rupture of membranes when vaginal bleeding is noted along with fetal distress. The diagnosis is confirmed on visual inspection of the placenta after delivery. For vasa previa that is prenatally diagnosed, administration of corticosteroids is recommended at 30–32 weeks with planned cesarean section between 35 and 36 weeks of gestation. Treatment of vasa previa is immediate cesarean section if found at the time of rupture of membranes.

Premature Rupture of Membranes and Preterm Premature Rupture of Membranes

General Principles

Premature rupture of membranes (PROM) at term is defined as rupture of the chorioamniotic membranes more than an hour prior to the onset of labor at 37 weeks of gestation or later. Preterm premature rupture of membranes (PPROM) is defined as the premature rupture of membranes before 37 weeks of gestation. PROM occurs in 8% of pregnancies and PPROM occurs in 2–3% of all pregnancies [13]. About half of PROM patients deliver within 36 h after expectant management only, while half of PPROM patients deliver within 1 week regardless of obstetric management.

Risk factors for PROM include primiparity, prior PROM, preterm labor, first trimester bleeding, and chlamydia infection. Risk factors for PPROM include prior history of PPROM, intraamniotic infection, second or third trimester

Telegram: @medical_k

www.konkur.in

bleeding, cerclage, shortened cervical length, uterine overdistention, smoking, illicit drug use, low socioeconomic status, BMI <20, maternal pulmonary disease, previous LEEP, and nutritional deficiencies [13]. Group B streptococcus (GBS) status is not a risk factor for PROM or PPROM. Both conditions often occur in the absence of any clearly identified risk factors or etiology.

The risk of intra-amniotic infection and postpartum intrauterine infection increases with the duration of membrane rupture. Clinically evident intra-amniotic infection will occur in 15–35% of PPROM patients, and 15–25% will experience postpartum intrauterine infection [13]. Other obstetric complications include placental abruption (2–5% of PPROM patients [13]), umbilical cord compression during labor, and umbilical cord prolapse. The primary risks to the fetus after PPROM are complications of prematurity. Neonatal infection is associated with intra-amniotic infection and positive maternal GBS status in women with term PROM.

Diagnosis

Women will present with a gush or persistent leakage of fluid in both PROM and PPROM. The clinician should perform a speculum exam to inspect for pooling of fluid and do a visual assessment of cervical effacement and dilation. Due to the increased risk of infection, digital cervical examination should be avoided unless clinically indicated by active labor or imminent delivery [13]. The clinician can also perform a nitrazine test to assess for abnormally basic pH of vaginal secretions indicating presence of amniotic fluid, ferning examination, or a commercially available test for amniotic proteins such as AmniSure or ROM Plus. These latter, newer amniotic protein tests are highly sensitive but not specific; the false positive rate falls between 19% and 30%. The United States Food & Drug Administration (FDA) warns that these tests should only be used in combination with other clinical assessments to diagnose rupture of membranes [13].

Treatment

Women presenting with PROM should be induced if labor does not occur near the time of presentation. This is most often accomplished with IV oxytocin, although misoprostol can also be considered as it is equally effective but with greater risk for chorioamnionitis. In the setting of PROM, antibiotics may reduce intra-amniotic and intrauterine infections; however, it has not been shown to improve neonatal outcomes. Thus, the routine use of antibiotics without confirmed maternal infection should be avoided in term patients [13]. Among PPROM patients, a seven-day course of antibiotics (usually IV ampicillin and erythromycin followed by oral amoxicillin and erythromycin) is used to prolong latency and decrease maternal and neonatal morbidity. GBS prophylaxis should be based on prior culture results if available. The treatment of PPROM is dependent on gestational age and assessment of fetal status.

- PPROM at ≥34 weeks of gestation: Induction of labor is recommended, although expectant management may be "reasonably offered" to those between 34 weeks and 36 and 6/7 weeks gestation [13, Level B evidence]. GBS prophylaxis is based on prior culture results or risk factors. A single course of corticosteroids is recommended for women between 34 and 0/7 and 36 and 6/7 weeks gestation who have not previously received an antenatal dose, as long as delivery is expected in no less than 24 h and no more than 7 days.
- PPROM at 24–33 and 6/7 weeks of gestation: Expectant management until 34 weeks if lung maturity is not proven. Treatment with latency antibiotics, corticosteroids, and intrapartum GBS prophylaxis is recommended. Consider the use of magnesium sulfate for fetal neuroprotection if there is a risk of imminent delivery before 32 weeks of gestation.
- PPROM at <24 weeks of gestation (previable): Counsel regarding risks and benefits; including likely neonatal morbidity and mortality. Compare immediate delivery vs. expectant management. Latency antibiotics may be considered at >20 weeks gestation, and corticosteroids may

Telegram: @medical_k

www.konkur.in

be considered at >23 weeks gestation. No GBS prophylaxis necessary. Monitor for signs of infection.

Postterm Pregnancy

General Principles

Postterm pregnancy refers to a pregnancy that is ≥42 and 0/7 weeks of gestation or ≥294 days from first day of the last menstrual period. Early and accurate dating is critical to the diagnosis. In the United States approximately 28% of pregnancies deliver in the 40th and 41st week and 5–7% delivers at over 42 weeks [14]. One risk factor for postterm pregnancy is inaccurate dating. When compared to dating based on LMP, early sonographic dating has been linked to a reduction in prevalence of postterm pregnancy from 6–12% to 2% [15]. Membrane sweeping also decreases the risk of late term and postterm pregnancy [14].

Of the true postterm pregnancies, most have no known etiology. Women at highest risk for postterm pregnancy are those with a previous postterm pregnancy, as the risk is two to three times higher after one prior postterm pregnancy and four times higher after two prior postterm pregnancies [16]. Other risk factors for postterm pregnancy include nulliparity, male fetus, maternal obesity, advanced maternal age, and certain fetal disorders such as anencephaly [14].

Postterm fetuses tend to be larger than term fetuses with a twofold increased risk for macrosomia. This further increases the risk of prolonged labor, shoulder dystocia, meconium-stained amniotic fluid, and cephalopelvic disproportion. These complications increase the risk of birth injury, as well as other sequelae such as failed induction, third or fourth degree lacerations, postpartum hemorrhage, operative delivery, and cesarean section. A postterm pregnancy can also be a cause of emotional distress to the mother. Although the absolute risk of stillbirth remains low, neonatal mortality does increase as the gestational advances beyond 41 weeks, carrying a nearly threefold increased risk of neonatal death between by 43 weeks gestation compared with a 40 week gestation [14]. Other risks to the fetus include neonatal convulsions, meconium aspiration syndrome, low umbilical artery pH, 5-min Apgars less than four, increased rate of NICU admission, and oligohydramnios [14].

Management

In well-dated postterm pregnancies, it is recommended to induce after 42 weeks of gestation regardless of cervical status in order to mitigate perinatal morbidity and mortality [17]. Induction of labor at 41 weeks gestation should be considered and is widely performed. This approach has not resulted in an increased risk of cesarean delivery compared to expectant management. Cervical ripening agents can be utilized in women with unfavorable cervices. The efficacy of antenatal fetal assessment has not been well studied due to ethical implications of assigning patients to the control group. Based on case-control studies, it is reasonable to perform antenatal fetal assessments twice a week beginning at 41 weeks of gestation and these assessment may include nonstress testing, biophysical profile (BPP), or modified BPP (nonstress test plus amniotic fluid volume).

Labor Dystocia

General Principles

The word dystocia means difficult labor [5]. Numerous maternal and fetal complications can result in increased rates of uterine rupture, intrauterine infection, uterine atony following delivery, pathological retraction rings, fistula formation, pelvic floor injury, maternal lower extremity nerve injury, fetal sepsis, and fetal mechanical injuries. Labor dystocia is the most common indication for primary cesarean delivery [18], as well as the underlying factor in at least one-third of all cesarean deliveries [2, 19], and therefore a significant public health concern. The problem is significantly more common in nulliparas than multiparas. Consequently,

Telegram: @medical_k

www.konkur.in

decreasing the incidence of dystocia in nulliparous patients would significantly impact the overall cesarean birth rate [2].

Approach to the Patient

Dystocia has multiple causes, though identifying a specific cause is limited by frequent overlap and lack of definitive diagnostic tools. A common helpful framework divides these causes into problems with *power* (or uterine action), *passenger* (or fetal position in relationship to the maternal pelvis), or *passageway* (or shape and size of the maternal pelvis, i.e., cephalopelvic disproportion). Ineffective uterine action is the most common cause [2, 5], of which there can be various mechanisms (e.g., insufficient strength, incoordination, other events in labor such as [arguably] chorioamnionitis). True cephalopelvic disproportion is likely rare [5] and in practice is diagnosed if labor does not progress normally in the setting of adequate uterine contractions and cephalic presentation. Conceptualizing abnormal labor in this way organizes clinical thought processes and guides interventions.

Diagnosis

No universal set of diagnostic criteria for labor dystocia exists. The labor curves put forth by Friedman in the mid-1900s are increasingly questioned [5], with more recent data suggesting that labor may last longer overall, that the latent phase in particular may last longer, and that labor progress may accelerate as it advances. At the very least, experience since Friedman suggests that labor patterns are contingent on multiple patient variables, including parity, use of regional anesthesia, and fetal presentation [20].

Requiring specific periods of time to pass before diagnosis may not be helpful for each individual labor, but certain conditions should be fulfilled in order to prevent premature decisions [5]. First, dystocia should be diagnosed only after a patient has entered the active phase of labor. Second, every effort should be made to ensure that the patient has been given an adequate trial of labor, which includes adequate contractions over an extended period of time (e.g., 200 Montevideo units per 10 min over 2–4 h). Third, amniotomy should be performed prior to diagnosis [2].

Management/Prevention

The management of labor dystocia follows from the above discussion. As a means of prevention, elective induction should be undertaken with caution. When active labor has been diagnosed, steps should be taken to ensure the adequacy of contractions. Adequacy is determined by Montevideo units, which are most accurately measured by an intrauterine pressure catheter. Especially in the case of nulliparous patients, enhancing the adequacy of contractions will often be accomplished with the use of oxytocin, which is very safe in this group of patients.

Various labor management protocols have arisen since the 1980s, all with the goal of reducing rates of labor dystocia and thereby reducing rates of cesarean delivery. These efforts target nulliparous patients, since rates of dystocia are highest in this group. One such program arose in a large maternity center in Dublin in the 1980s, employing an approach that has come to be known as the "active management of labor" [21]. The protocol achieved remarkable success – one highlight being a low cesarean delivery rate of 4.8%. The overarching lesson from this protocol and others is that the clinician must be vigilant in recognizing and addressing abnormal labor, and then effectively intervene to improve uterine action when necessary.

Infection

Group B Streptococcal Disease

Background

The 1970s witnessed the emergence of group B streptococcus (GBS) as the leading cause of neonatal morbidity and mortality, with reported case-

Telegram: @medical_k

www.konkur.in

fatality rates as high as 50% [22]. Among the 10–30% of mothers colonized with GBS, approximately 50% will transmit the bacteria to their newborn [23]. Guidelines issued in 1996 and 1997 recommended intrapartum antibiotic prophylaxis to prevent neonatal GBS disease [22]. This was followed by guidelines in 2002 recommending universal culture-based screening for GBS colonization in pregnant patients at 35–37 weeks of gestation [22]. These efforts have led to an 80% reduction in the incidence of early-onset neonatal sepsis due to GBS. In 2019, ACOG updated their antepartum screening recommendation, reporting that women from 36 to 37 and 6/7 weeks gestation should undergo screening; patients between 35 and 36 weeks are no longer included. This is to maximize the five-week window of valid culture results to include a gestational age up to 41 weeks. Despite the significant progress in mitigating the risk of neonatal infection, GBS remains the leading cause of neonatal infectious morbidity and mortality [23].

Management/Prevention

Prevention of perinatal GBS disease focuses on early-onset neonatal disease (within the first week of life), as the above efforts have not changed the incidence of late-onset disease [22]. The recommendations for intrapartum management discussed below come from the ACOG Committee Opinion, most recently revised in February 2020 [23].

Intrapartum GBS prophylaxis is always indicated in patients who have had a previous infant with invasive GBS disease, in patients with GBS bacteriuria during the current pregnancy, and in patients with a positive GBS vaginal/rectal culture obtained late in the current pregnancy. In patients whose GBS status is unknown at the time of labor, antibiotic prophylaxis is indicated only in patients with a gestational age less than 37 weeks, rupture of membranes for greater than 18 h, intrapartum fever, or history of GBS positive status in a prior pregnancy. Of note, antibiotic prophylaxis is not indicated for patients with intact membranes undergoing cesarean delivery before the onset of labor, regardless of GBS colonization status. All patients with preterm labor or preterm premature rupture of membranes (PPROM) should be screened for GBS colonization at the time of diagnosis and then treated with appropriate antibiotics for GBS prevention until labor is either ruled out or completed. Ideally, antibiotics should be initiated at least 4 h prior to delivery, though this goal should never delay medically necessary interventions during labor. Penicillin remains the antibiotic of choice, except in the case of severe penicillin allergy in which case cefazolin, clindamycin, or vancomycin would be considered.

Intra-amniotic Infection

General Principles

Intra-amniotic infection (IAI), previously termed "chorioamnionitis," is acute infection and resultant inflammation of one or more of the following: amniotic fluid, placenta, fetus, fetal membranes, or decidua [49]. Most commonly, IAI is caused by polymicrobial bacterial infection ascending from the lower genital tract. IAI complicated 2–5% of pregnancies [24], and may account for half of deliveries prior to 30 weeks and up to 40% of cases of early neonatal sepsis and pneumonia [25].

Risk factors for IAI include prolonged labor, nulliparity, meconium-stained amniotic fluid, longer duration of internal uterine monitoring, the presence of genital tract pathogens such as bacterial vaginosis (BV) and GBS, and a greater number of digital vaginal examinations [25]. Potential maternal complications of IAI include maternal bacteremia, postpartum endometritis, peritonitis, sepsis, and postpartum hemorrhage. Potential fetal complications include death, asphyxia, sepsis, bronchopulmonary dysplasia, cerebral palsy, and long-term neurodevelopmental disability [24, 26]. The majority of fetal and neonatal complications are significantly more common with decreasing gestational age.

Diagnosis

The common diagnostic criteria for IAI are maternal fever > 39 °C alone or maternal fever 38–39 °C with one or more of the following: maternal leukocytosis, fetal tachycardia, or purulent

Telegram: @medical_k

www.konkur.in

cervical drainage [24]. Maternal fever 38–39 °C in the absence of other clinical signs is termed *isolated maternal fever*. In practice the diagnosis is clinical, confirmed by histopathology only after clinical decisions are made. Amniotic fluid culture is the gold standard for clinical diagnosis, but the utility of fluid culture is limited by the time it takes for results.

Treatment

Management of IAI is straightforward. As soon as the diagnosis is made, antibiotics should be initiated, as immediate treatment with antibiotics has been shown to reduce maternal and neonatal complications [26]. For vaginal delivery, the typical antibiotic regiment includes ampicillin and gentamicin. Women with IAI who undergo a cesarean section should receive either clindamycin or metronidazole for anaerobic coverage in addition to ampicillin and gentamicin. The ideal treatment duration is unclear, but typically includes one postpartum dose of the given regimen. Vancomycin or clindamycin can be substituted for ampicillin in penicillin allergic patients. Treating maternal fever with antipyretics is also critical, providing two benefits: avoiding the adverse neonatal outcomes associated with maternal fever and potentially reducing the inclination to perform a cesarean section by resolving the associated fetal tachycardia [26]. Labor should be expedited in the setting of IAI, but cesarean delivery is only indicated for usual obstetric indications.

Meconium-Stained Amniotic Fluid

General Principles

Meconium-stained amniotic fluid (MSAF) presents as greenish- to brown-stained amniotic fluid seen at rupture of membranes. It is the result of the passage of fetal colonic material into the amniotic cavity.

Meconium-stained amniotic fluid occurs in approximately 8–15% of live births [27] and its incidence increases with gestational age. While MSAF occurs in <5% of preterm deliveries, it increases to 7–22% of term deliveries and affects 23–52% of postterm pregnancies [28].

Both prenatal stressors (fetal hypoxia and acidosis) and head or cord compression can cause vagal stimulation and relaxation of the fetal sphincter, leading to MSAF. Exposure of the meconium to the fetus can occur either in utero or at the time of the infant's first breath.

Risk factors for MSAF include postterm gestation, maternal diabetes, maternal tobacco usage, maternal respiratory or cardiovascular disease, preeclampsia, oligohydramnios, intrauterine growth restriction, low score on biophysical profile, and abnormal fetal heart rate tracing.

Meconium aspiration, intra-amniotic infection, and endometritis are all more likely to occur with MSAF [29]. Meconium aspiration syndrome (MAS) is respiratory distress in a newborn that was born through MSAF. MAS develops in 5% of infants delivered through MSAF; 95% of infant with inhaled meconium will clear it spontaneously without complication [29]. MAS is the most serious complication associated with MSAF and can lead to intubation and mechanical ventilation, pneumothorax, seizures, and death [30].

Management

It is thought that MSAF may support bacterial growth by acting as a medium for bacteria, inhibiting the bacteriostatic properties of amniotic fluid, or antagonizing typical host defense systems by diminishing the phagocytic response of neutrophils [31]. It was theorized that prophylactic antibiotics would reduce the rate of adverse events. However, no significant reductions in the incidence of neonatal sepsis, endometritis, or NICU admissions were found. And yet, there was a reduction in the incidence of intra-amniotic infections [31]. Because the rates of neonatal sepsis were similar regardless of antibiotics, there is insufficient evidence at this time to recommend administration of prophylactic antibiotics to laboring mothers with MSAF [31].

Because oligohydramnios can lead to increased cord compression and subsequently the passage of meconium, it has been theorized that amnioinfusion (AI) could be a promising therapy. While AI has been shown to reduce the risk of fetal heart rate deceleration and cesarean section in the presence of oligohydramnios, it has

Telegram: @medical_k

www.konkur.in

not been shown to reduce the risk of moderate or severe MAS, perinatal death, or other major maternal or neonatal disorders in the setting of standard peripartum surveillance [30]. In settings with limited peripartum surveillance, AI did reduce the risk of MAS. Currently, it is not recommended to use prophylactic amnioinfusion to reduce the risk of MAS.

Guidelines on management of the neonate were updated in 2015 and endorsed by the American Academy of Pediatrics, the American Heart Association and ACOG. These guidelines recommend against the former practice of intubation and suction in nonvigorous neonates with MSAF. Instead, infant resuscitation should "follow the same principles for infants with [MSAF] as for those with clear fluid" [32].

Shoulder Dystocia

General Principles

Shoulder dystocia is a relatively rare and usually uncomplicated condition but can become an obstetrical emergency. It occurs at delivery and is characterized by difficulty delivering fetal shoulders with downward traction of the fetal head, requiring additional maneuvers to facilitate extraction. Shoulder dystocia affects 0.2–3% of vaginal deliveries of fetuses in the vertex presentation [33]. It often results when the pubic symphysis obstructs descent of the anterior shoulder or the posterior shoulder is obstructed by the sacral promontory. If descent of the fetal head continues while the anterior or posterior shoulder remains impacted, then stretching of the nerves in the brachial plexus may occur and may result in nerve injury.

Shoulder dystocia cannot be predicted or prevented. The goal is to understand the risk factors and signs of shoulder dystocia and then remain vigilant and quickly responding when it does present. The most well-established risk factors include diabetes, fetal macrosomia (fetal weight $>$ 4000 g), and previous shoulder dystocia, as it may recur in at least 10% of subsequent pregnancies [33]. There is a paucity of literature evaluating labor complications and subsequent dystocia, but mid-pelvic operative vaginal delivery has been associated with increased risk of shoulder dystocia.

Five percent of shoulder dystocias are complicated by neonatal injury, the most common complications being brachial plexus injury and clavicular fracture. Brachial plexus injury occurs in 10–20% [33] of shoulder dystocias. While most cases are transient, and resolve completely, permanent neurologic impairment may result. Clavicular fracture and humerus fractures usually have a benign course and complete recovery. Other more serious and less common complications include pneumothorax, permanent neurological damage due to hypoxia, and death. Maternal complications primarily include postpartum hemorrhage and higher degree perineal lacerations; however, if extraordinary maneuvers such as Zavanelli or symphysiotomy are performed, complications may include uterine rupture, bladder rupture or lacerations, urethral injury rectovaginal fistula, sacroiliac joint dislocation, pubic symphysis separation, neuropathy, and stool incontinence.

Diagnosis

The diagnosis of shoulder dystocia is a clinical diagnosis based on the inability to deliver shoulders after delivery of the head. The physician should be alerted to the potential of shoulder dystocia if they notice the fetal head remains tightly applied to the vulva or retracts (turtle sign) against the perineum.

Management

As soon as a shoulder dystocia is suspected, the physician should respond by alerting the team for the need for additional assistance and preparing the patient. The mother should be alerted to the situation, discouraged from pushing, and moved toward the edge of the bed to better support the maneuvers required. Refer to Table 2 for list of maneuvers used to reduce a shoulder dystocia. When using a maneuver, the clinician should move on to another maneuver if unsuccessful after 20–30 s. In most cases, the physician has

Telegram: @medical_k

Table 2 Maneuvers for managing shoulder dystocia

	Initial maneuvers
McRoberts	Flex the patient's legs against the abdomen Reduces 42% of shoulder dystocias
Suprapubic pressure	Apply moderate suprapubic pressure obliquely to the anterior shoulder to adduct the shoulders into the oblique plane When combined with McRoberts – reduces 50% of shoulder dystocias
Posterior arm	Flex the fetal elbow and sweep the arm across the chest, grasp the hand and extend the arm along the side of the face, deliver the posterior arm Highly effective
Rubin	Place a hand on the posterior surface of posterior (or anterior) shoulder and rotate it anteriorly
Woods corkscrew	Place a hand on the anterior surface of the posterior shoulder and rotate the posterior shoulder 180° May combine with Rubin to increase effectiveness
Gaskin	Place mother in hands and knees and apply downward traction on posterior shoulder or upward traction on anterior shoulder Use in mothers without epidurals that can support their weight
Episiotomy	Perform an episiotomy to allow room for maneuvers, does not itself reduce shoulder dystocia
	Extraordinary maneuvers
Clavicle fracture	Press the anterior clavicle against the ramus of the pubis or pull the anterior clavicle outward to fracture the clavicle
Zavanelli	Return the fetal head to the OA or OP position, flex the fetal head and push it back into the vagina, proceed with cesarean section
Abdominal rescue	If unable to replace the fetal head into the vagina, perform a cesarean section to manually rotate the anterior shoulder into the oblique diameter; proceed with vaginal delivery
Symphysiotomy	Division of anterior fibers of symphyseal ligament – performed by individuals who have knowledge and experience in this procedure

OA occiput anterior, *OP* occiput posterior

up to 5 min to deliver a previously well-oxygenated term infant before there is an increased risk of asphyxial injury. The pH is estimated to fall between 0.01 and 0.04 pH units per minute in the interval between delivery of the fetal head and trunk. No one maneuver has been shown to be superior over another; however, ACOG recommends starting with the McRoberts maneuver as it is a "simple, logical and effective technique" [33]. Practical knowledge of all the maneuvers is important so that the most appropriate maneuver is applied in each clinical situation. Team-based simulation exercises are encouraged to improve communication and enhance familiarity with the various maneuvers.

Prevention

Prophylactic labor induction for the prevention of shoulder dystocia is not routinely recommended in women without diabetes and suspected fetal macrosomia, as it does not prevent shoulder dystocia. Prophylactic cesarean delivery is not routinely recommended unless the estimated fetal weight is >4500 g in women with diabetes or > 5000 g in women without diabetes. Both of these are ACOG level C recommendations.

Assisted Vaginal Delivery

General Principles

Assisted vaginal delivery (or "operative vaginal delivery" when referring specifically to forceps and vacuum) includes forceps delivery, vacuum delivery, and manual rotation of the fetal head. All the maneuvers aim to expedite delivery for maternal or fetal well-being and prevent the need for cesarean birth. Performed with good technique and for appropriate indications, these methods are safe and effective. Overall, rates of assisted vaginal delivery have declined over time, concurrent with an increase in the cesarean rate. However, over several decades the rate of vacuum-assisted vaginal delivery has increased while the rate of forceps delivery has dramatically

Telegram: @medical_k

www.konkur.in

decreased [5]. This shift may owe to the perception that vacuum delivery is less likely to cause maternal pelvic floor injury, which may be true at least in the short term [4].

Approach to the Patient

The indications for forceps and vacuum delivery include conditions that threaten the well-being of the mother or fetus: prolonged second-stage of labor, suspected or potential fetal compromise, and maternal benefit (e.g., maternal exhaustion or cardiac disease) [4, 5, 34]. Prerequisites for both forceps and vacuum application are largely the same [5]: complete dilation of the cervix, ruptured membranes, engagement of the fetal head, vertex presentation, no suspected cephalopelvic disproportion, empty maternal bladder, adequate anesthesia, and precise knowledge of fetal head position. The last prerequisite is worth highlighting, as knowledge of fetal head position is essential for safe and correct application of the assistive device. Contraindications include unknown position of the fetal head and known or suspected fetal bone mineralization or bleeding disorder (Level B evidence) [34].

The current classification system for forceps deliveries, endorsed widely by groups including ACOG, also applies to vacuum deliveries. A central purpose of its implementation was to avoid unsafe application of these techniques, as potential for harm is greater with higher fetal head position and more rotation applied to the head [35]. Outlet forceps delivery occurs with the fetal scalp visible at the introitus, the fetal skull on the pelvic floor, and application of no more than 45° of rotation. Low forceps delivery occurs with the fetal skull at or below +2 station, and midforceps delivery occurs between 0 and + 2 station. High forceps delivery is no longer viewed as being appropriate in any circumstance.

There remains a lack of consensus regarding the relative risks and benefits of forceps versus vacuum delivery. Sequential use of both should be avoided due to increased risk for significant neonatal injury [35]. Potential benefits of forceps are increased likelihood of achieving vaginal delivery [36] and its ability to achieve head rotation. However, forceps have also been associated with a trend toward more cesarean sections, as well as more third and fourth degree tears, vaginal trauma, altered continence, and facial injury [36]. The likely decreased maternal risk is a potential benefit of the vacuum, though cephalohematoma may be more common [36]. In practice, the experience of the operator will often be the primary factor when choosing between forceps and vacuum.

Technique

The technique of forceps and vacuum-assisted delivery is very similar among the numerous specific devices and well described in multiple sources. For occiput anterior presentations, correctly placed forceps travel the occipitomental diameter, with the largest portion of the blades covering the face and the greatest distance between the blades corresponding to the biparietal diameter. Correct placement of the vacuum is also essential, as this allows the fetal head to be flexed to the narrowest diameter in its passage through the pelvis. The center of the vacuum cup should be placed over the flexion point, which is in line with the sagittal suture and approximately 3 cm anterior to the anterior edge of the posterior fontanelle. Assisted delivery should be continued only if clear progress in descent is being achieved. In the case of the vacuum, rotation should not be attempted, pop-offs should be minimized to no more than three, and traction should occur for the shortest amount of time possible.

Manual rotation of the fetal head may be beneficial for occiput posterior or occiput transverse presentations. A decreased rate of operative vaginal delivery has been achieved when employing this technique, without increasing risk [37].

Cord Prolapse

General Principles

Umbilical cord prolapse (UCP) is an obstetrical emergency in which the umbilical cord passes through the cervical os in advance of the fetal presenting part (overt) or alongside the fetal

Telegram: @medical_k

www.konkur.in

presenting part (occult). This can cause cord compression which can lead to fetal hypoxia.

The incidence of UCP has remained stable and affects 1.4–6.2 per 1000 deliveries [38]. In the past UCP carried a high mortality rate; however, with the increased availability of cesarean delivery, the mortality rate has decreased to 10% or less [38].

There are spontaneous and iatrogenic risk factors for UCP. Spontaneous UCP can occur in uncomplicated pregnancies and is related to conditions that prevent the fetus from properly engaging in the pelvis or abnormalities of the umbilical cord itself including: fetal malpresentation (most common), polyhydramnios, preterm delivery, preterm premature rupture of membranes, multiple gestation, fetal anomalies, grand multiparity, cord abnormalities (higher risk of prolapse with a thin cord), birth weight less than 2500 g (although some authors quote <1500 g) [39], and spontaneous rupture of membranes (57% of cases occurred within 5 min of rupture) [40]. Iatrogenic causes include artificial rupture of membranes without an engaged presenting part, attempted rotation of the fetal head, amnioinfusion, external cephalic version in patient with ruptured membranes, placement of an intrauterine pressure catheter or fetal scalp electrode, and placement of a cervical ripening balloon catheter. These risk factors are usually maneuvers performed by the clinician on the labor and delivery floor and do not increase morbidity and mortality due to the availability of a quick response by the clinician.

Diagnosis

UCP is diagnosed clinically by the umbilical cord being palpable or visible in the vagina. The clinician may also notice a severe and sudden drop in the fetal heart tones (FHT) or variable decelerations. It is worth noting that these FHT changes are not always initially seen.

Prevention

Given that membrane rupture, whether spontaneous or artificial, is a risk factor for cord prolapse, it is recommended that care be taken when considering artificial rupture of membranes. If the head is well applied to the cervix, amniotomy may be safely performed. When the fetal head is ballotable, amniotomy should be delayed or performed in a controlled manner to avoid sudden decompression.

Management

Umbilical cord prolapse can quickly compromise the fetus which can lead to disability and death. The primary management of UCP is immediate delivery and is usually done via emergent cesarean section. Until delivery can be performed, the goal is to alleviate pressure on the umbilical cord. This is done by:

- Funic decompression – the clinician places two fingers or the palm on the fetus' presenting part and elevates it.
- Trendelenburg or knee-chest position – place the mother in Trendelenburg position or knee-to-chest position to allow gravity to assist in alleviating pressure on the umbilical cord.
- Foley catheter (first described in 1970 by Vago) – bladder instilled with saline to allow the distended bladder to provide an upward pressure on the fetal presenting part.

The fetus should be continuously monitored until delivery. Neonatal outcomes in cases of UCP are generally good when delivery can be accomplished within 30 min.

Introduction

Childbirth and the postpartum period constitute an exciting yet challenging time for the mother, newborn, and family members. This includes physiological, physical, and psychosocial changes which many new mothers transition through uneventfully. However, this period can also pose overwhelming challenges with associated health issues. Hence, the importance of comprehensive prenatal, intrapartum, and postpartum care along with anticipatory guidance cannot be overemphasized.

Immediate Postpartum Care

The Golden Hour: Maternal-Infant Bonding

The "golden hour" is the immediate 60 min after childbirth. In the past when more babies were born outside the hospital, placing the newborn directly skin to skin on the mother's chest or abdomen was necessary for the infant's survival. It continues to be the practice in many developing countries. In industrialized nations, it had become common practice for infants to be immediately whisked away for "transition" which includes a check of vital signs, maintaining temperature by placing them on the warmer, medications, immunizations, and sometimes a bath. However, it has since been shown that it is in the best interest of the mother-baby dyad that skin-to-skin contact (SSC) be initiated in that time. A Cochrane review of 34 randomized trials involving 2177 mothers and newborns concluded that babies who were immediately exposed to SSC cried less, had better cardiorespiratory function, and had better interactions with their mothers. They also were more likely to breastfeed in the first 1–4 months of life and breastfed longer when compared to babies who were not exposed to SSC. There were no negative effects of SSC found in these trials [1].

Formation of a strong bond between the mother and infant has been shown in multiple studies to enhance the cognitive and neurobehavioral development of the child. Recommendations from early research on maternal-infant bonding include delaying newborn procedures such as medication application, initiating breastfeeding immediately after birth, rooming in, and encouraging parents to interact with their babies [2].

Babywearing, the use of carriers and/or slings of many kinds to secure a baby against a caregiver's body, may be used to help facilitate skin-to-skin contact when done safely [2]. This practice should be encouraged and supported whenever possible.

Immediate Postpartum Contraception

One option that may be offered for the immediate postpartum period is insertion of a long-acting reversible contraceptive (LARC device) [3]. Immediate placement of a LARC has been shown to decrease the risk of short interpregnancy intervals (<18 months from time of delivery to subsequent pregnancy) [3]. Options include the copper or levonogestrel IUD. Subcutaneous placement of an etonogestrel implant is also an option.

Of note, the placement of an IUD immediately postpartum is associated with increased risk of expulsion compared to placement of the device at 6 weeks postpartum. However, consideration may be given to the fact that some patients may have difficulty attending their outpatient postpartum appointments.

Telegram: @medical_k

www.konkur.in

Promotion of Breastfeeding

Part of the benefit of early maternal-infant bonding is the initiation and continuation of breastfeeding. Family physicians, obstetricians, pediatricians, and other members of the medical team all play a significant role in ensuring the success of breastfeeding. Discussion about breastfeeding should begin in the prenatal period. Emphasizing the immediate and long-term benefits of breastfeeding on the mom and baby early in the prenatal period is optimal. The benefits of breastfeeding on the infant and mother have been demonstrated by scientific evidence, hence all major maternal-child health organizations recommend exclusive breastfeeding in the first 6 months of life and continued through 1–2 years of age [4]. Early anticipation of barriers to breastfeeding will help in providing the necessary support for the new mother and her family. During the first several weeks of breastfeeding, infants should be nursed at least 8–12 times in a 24 h period on demand [5]. The Academy of Breastfeeding Medicine recommends creating a breastfeeding-friendly office; understanding the effect of cultural influence on families and communities; and integrating breastfeeding promotion, education, and support throughout the prenatal period [6]. Current evidence suggests that the Baby Friendly Hospital Initiative and the "Ten steps to Successful Breastfeeding" are proven and effective measures to ensure breastfeeding initiation, duration, and exclusivity [7]. Hospitals that are certified as being "baby friendly" have the highest breastfeeding rates [5, 8].

Contraindications to Breastfeeding

There are very few absolute contraindications to breastfeeding or feeding infants expressed breast milk. These include mothers living with HIV, those infected with human T-cell lymphotropic virus (HTLV) or Ebola. In addition, infants should not ingest the breast milk of mothers using illicit drugs. Infants with galactosemia should also not ingest breast milk.

Breastfeeding should be suspended temporarily in women with active brucellosis, those receiving radiopharmaceuticals, and those with active herpes simplex lesions of the breast. Those who should not be in contact with the baby but can feed expressed breast milk include women with active tuberculosis or varicella [9, 10].

Although most medications are compatible with breastfeeding, sources such as Infant Risk (https://www.infantrisk.com/infantrisk-center-apps) and The Drug and Lactation Database (LactMed) (https://www.ncbi.nlm.nih.gov/books/NBK501922/) should be referenced prior to counseling mothers about breastfeeding while taking medications. Breastfeeding is absolutely contraindicated in mothers taking certain medications that include radioactive iodine [11], and antineoplastic drugs such as cisplatin [11].

When counseling women about breastfeeding risks, a discussion of the risks of NOT breastfeeding should also be touched upon. Mothers should be reminded that breastfeeding is the biological norm and preferred method of infant nutrition, as opposed to human milk substitutes (formula) [9].

Important Noncontraindications

It is imperative that family physicians remain knowledgeable about true contraindications to breastfeeding. For example, mothers who are Hepatitis B or Hepatitis C positive may still be able to breastfeed [7]. Patients taking stable doses of methadone may breastfeed as well, regardless of their current methadone dose [12]. Additionally, patients who use marijuana may also breastfeed, as long as it is certain that adulterants are not present in the drug [9]. These decisions should be discussed with the patient so that they understand the true risks being posed to the infant including consideration for the risks is poses to not breastfeed. Additionally, mothers who choose to consume alcohol (up to 8 oz. or wine or 2 beers in a day) while lactating may also continue breastfeeding [12]. They should not be instructed to "pump and dump" and should instead be counseled to breastfeed prior to drinking and

Telegram: @medical_k

www.konkur.in

then wait until at least 2 h after drinking to breastfeed when their blood alcohol level is likely to have diminished.

Similarly, it is not necessary to cease or otherwise interrupt breastfeeding after most radiologic examinations including ultrasounds, chest X-rays, CT scans, or MRIs, including those in which iodinated or gadolinium contrast media are used, as long as no radioisotopes have been used [13]. The most recent guidelines should be referenced prior to making recommendations to lactating patients receiving imaging studies.

Postpartum Complications

Postpartum Hemorrhage

Various definitions for postpartum hemorrhage (PPH) have been proposed. The most commonly used definition is the loss of 500 ml of blood after a vaginal delivery or the loss of 1000 ml after a Cesarean delivery. However, blood loss estimates often underestimate the actual blood loss at a delivery. Another suggested definition is the drop in the hematocrit of 10% or more, but if blood loss is ongoing, the decline in hematocrit may underestimate the actual blood loss [14].

Postpartum hemorrhage has been reported to occur in up to 18% of deliveries, with approximately 3% of births resulting in severe postpartum hemorrhage. PPH is the most common cause of maternal morbidity in developed countries [7]. Complications after PPH include hypotension, difficulty with breastfeeding and caring for the newborn, extreme fatigue, and blood transfusion reactions if a transfusion is required. Hemorrhagic shock after postpartum hemorrhage can lead to Sheehan's syndrome (pituitary necrosis) [7].

There are a number of risk factors for PPH, including a past history of PPH, prolonged labor, augmented labor, overdistended uterus, chorioamnionitis, preeclampsia, and operative delivery [14]. However, many patients who develop PPH have no risk factors, so providers must be alert to this complication at every delivery.

The active management of the third stage of labor (AMTSL) has long been recognized as an effective method for the prevention of PPH. An intravenous infusion of oxytocin (20 units) is widely recommended and is the most important component in the AMTSL. It can be administered as soon as the anterior shoulder is delivered but no later than after placental delivery. Most protocols for the AMTSL have now discontinued immediate cord clamping, since a delay in cord clamping of at least 30–60 s (assuming the newborn does not require resuscitation) has been shown to improve the hematologic status of newborns. Controlled cord traction is often recommended and has been shown to result in a small reduction in blood loss. Routine uterine massage is often performed, but a World Health Organization guideline recommends against this practice, while stipulating that the uterine tone should be routinely assessed [15].

The most common cause of PPH is uterine atony (70%). Trauma is the second-most common cause, at 20%. Trauma can include perineal, vaginal wall, and cervical lacerations; vaginal or vulvar hematomas; uterine inversion; and uterine rupture. Retained placental tissue is the next most common cause, at 10%. The final and least common cause of PPH at a rate of less than 1% is coagulopathy. The coagulopathy may be due to an inherited coagulopathy that was identified before delivery or due to a coagulopathy that develops as a result of a complication of pregnancy or delivery [16].

The initial management of uterine atony involves bimanual uterine massage. If this is not successful, then uterotonic medications should be administered. Oxytocin may already be infusing if it was started as part of the active management of the third stage of labor. If it has not already been initiated, administration of oxytocin 10 units IM or 20–40 units by intravenous infusion should be initiated. If the atony persists, second-line medications include misoprostol (Cytotec), 800–1000 microgram PO, SL, or PR; methylergonovine (Methergine), 0.2 mg IM every 2–4 h; or carboprost (Hemabate), 0.25 mg IM or intramyometrially every 15 min up to 8 doses [16].

Telegram: @medical_k

www.konkur.in

The clinician can evaluate for trauma as a cause of PPH by inspecting the vulva, vagina, and cervix for lacerations and hematomas [16].

The placenta usually delivers within 10 min of delivery of the baby. Visual inspection of the delivered placenta can provide evidence that the placenta delivered intact but does not rule out retained placental tissue. Retained placental tissue is usually easily removed by performing a finger sweep of the uterus with gauze. If placenta accreta, increta, or percreta is present, this can result in difficulty in removal of the placenta and significantly increases the risk for severe postpartum hemorrhage [16].

If a patient has been previously diagnosed with a coagulopathy, measures may already be in place to treat the disorder. If no coagulopathy has been diagnosed in a patient experiencing a PPH and other causes excluded, evaluation of the patient with a complete blood count (CBC), prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen level is indicated [16].

If a patient does not respond to basic measures for the management of PPH, more drastic measures may be required. It is recommended that hospitals have an established protocol that can be activated in cases of severe PPH. This involves a multidisciplinary approach between the physician, nursing personnel, blood bank, and laboratory [15]. Specialty consultation may include an obstetrician, intensivist, and interventional radiologist. Fluid resuscitation is initiated, followed by transfusion of packed red blood cells (PRBCs) and, if necessary, fresh frozen plasma and cryoprecipitate. Placement of a Bakri balloon to provide uterine tamponade should be considered. Other drastic measures include uterine artery embolization, recombinant factor VIIa, placement of B-Lynch sutures, or hysterectomy [14].

Postpartum Gestational Hypertension, Preeclampsia, and Eclampsia

The onset of gestational hypertension, preeclampsia, and eclampsia usually occurs before delivery but can also occur in the postpartum period. Diagnosis, treatment, and management of these conditions are the same as before delivery and are discussed elsewhere. Onset of these conditions can occur up to 6 weeks after delivery [17].

Postpartum Infection

Postpartum patients are at risk for a number of postpartum infections, including endometritis, wound infection, urinary tract infections, mastitis, and pneumonia. Sepsis is diagnosed when the postpartum patient develops systemic symptoms and may progress to septic shock, which has a high rate of morbidity and can also cause maternal death. The presence of fever (100.4 °F (38.0 °C) or greater) after delivery should prompt an evaluation for infection. Evaluation should include a CBC; a catheterized urine specimen for urinalysis and culture; and a physical exam. Further testing such as a blood culture, chest X-ray, wound culture, and CT scan or ultrasound of the abdomen and pelvis will be dictated by the patient's symptoms, lab testing, and physical exam. The value of a culture from the endometrium is limited and not usually indicated [18]. The white blood cell count can be mildly elevated after a normal delivery, so it must be interpreted with caution. Fever can also be caused by medication, so the patient's medications should be reviewed.

Endometritis is the most common cause of postpartum infection. The incidence of postpartum endometritis is approximately 5% after vaginal and 10% after Cesarean delivery [19]. Although preoperative antibiotic prophylaxis reduces the rate of endometritis [20], other risk factors include prolonged labor, prolonged rupture of membranes, intrauterine monitoring, and multiple vaginal examinations. In addition to fever, affected patients often have symptoms of malaise, tachycardia, uterine tenderness, and foul-smelling lochia. Postpartum endometritis is usually polymicrobial, and common causative organisms include Group B *Streptococcus*, *Enterococcus*, gram-positive anaerobes, *Staphylococcus* species, and gram-negative bacilli. Intravenous clindamycin and gentamicin has been shown to have fewer treatment failures than other regimens [21]. Intravenous antibiotics are

Telegram: @medical_k

www.konkur.in

continued until the patient has been afebrile for 24–48 h, the WBC count has normalized, and the patient is otherwise clinically stable [19]. There has not been shown to be any benefit of continuing oral antibiotic therapy after intravenous antibiotic therapy has been discontinued [21].

Postpartum wound infection is diagnosed by redness, swelling, drainage, and/or pain at the site of surgical or traumatic wounds. Risk factors for post-Cesarean wound infection include prolonged labor/prolonged rupture of membranes, chorioamnionitis, obesity, and prolonged surgery [20]. If an abscess is present, this should be opened and drained. A culture should be obtained from any drainage that is present or if an abscess is opened. Causative organisms typically originate from skin flora or by spread from the amniotic cavity (if the patient delivered by "Cesarean" section) [20] and include *Staphylococcus aureus*, *Streptococci*, and gram-negative bacilli.

Urinary tract infections are diagnosed in the same way as general medical patients by the presence of pyuria, usually accompanied by positive nitrate testing on dipstick analysis. Urinary tract infections in the postpartum period are treated as in general medical patients. Similarly, pneumonia is diagnosed with a clinical exam and confirmatory chest X-ray. Treatment is the same as in a general medical patient, with attention to antibiotic selection if the woman is breastfeeding.

Mastitis is diagnosed by physical exam findings of redness, swelling, and tenderness of one breast, usually occurring in the first 3 months postpartum. No blood work or diagnostic testing is needed in uncomplicated cases. Mothers should be encouraged to continue breastfeeding since uncomplicated mastitis does not pose a risk to the infant and continuing milk flow is an important component of treatment [22]. Mastitis is usually caused by *Staphylococcus* aureus, Group A or B Streptococci, or Hemophilus organisms. An oral antibiotic with coverage for *Staphylococcus aureus* is usually employed, typically dicloxacillin, cephalexin, or amoxicillin/clavulanate unless methicillin-resistant *Staphylococcus aureus* is suspected, in which case clindamycin may be considered. Breast abscess may arise as a complication of postpartum mastitis. Treatment involves drainage of the abscess and usually administration of antibiotics. In most cases, breastfeeding may continue.

Postpartum Preventive Care

Immunization

According to the advisory committee on immunization practices, all pregnant women should be immunized with Tdap between 27 and 36 weeks, irrespective of the patient's prior immunization history. Since 2010, there has been a resurgence of pertussis with the highest incidence in 2012. Over 2000 of the cases were among infants, 15 of whom died [23]. Vaccination during pregnancy will prevent hospitalization and death from pertussis. However, if the immunization is not received during pregnancy, it should be provided postpartum [23]. Additionally, MMR should be administered as soon as possible after delivery if the mother was found to be nonimmune to rubella [24]. At the time of this publication, there are no available safety data regarding the risk of the COVID-19 vaccine on lactating patients or their breastfed infants. Shared decision-making should be employed with these patients, to help them decide the best option for them, particularly those at high risk for exposure to COVID-19 and those at high risk for complications should they contract the virus [25].

RhoGAM

The Rh immune globulin (RhoGAM) is given to an Rh-negative mother at 28 weeks of gestation if the Rh status of the baby is unknown, those who give birth to an Rh-positive baby, or any Rh-negative patient after a miscarriage. The purpose is to prevent immune response occurring from alloimmunization which can lead to hemolytic disease of the newborn in subsequent pregnancies. The typical dose is one vial of 300 mcg of RhoGAM within 72 h of delivery if there is no evidence of fetal red blood cells in maternal blood. Otherwise, the quantity of estimated fetomaternal

Telegram: @medical_k

www.konkur.in

hemorrhage determines how many vials of RhoGAM are given [26]. The risk of rhesus alloimmunization can decrease from 1–2% to 0.1% if RhoGAM is given at 28 weeks gestation and postpartum [27, 28]. It is still acceptable to give RhoGAM up to 28 days postpartum if it had not been not given within 72 h of delivery [29].

Postpartum Office Visit

The postpartum period begins an hour after delivery of the placenta though the subsequent 12 weeks (sometimes termed the fourth trimester) [30]. It was popular convention for the postpartum office visit to take place at 6 weeks postpartum. However, in 2018, ACOG published an updated Committee Opinion encouraging for all women to have contact with their maternity care provider either in person or by phone within 3 weeks postpartum, with ongoing support at intervals to be determined by the patient and her physician. In addition, the opinion recommends a comprehensive postpartum visit no later than 12 weeks after delivery. The physician should address issues like breastfeeding, postpartum depression, complications such as urinary incontinence, constipation, sexuality, and contraception. However, for some women, waiting till 6 weeks might be too late [31]. Selected patients may benefit from postpartum office visits as early as 2 weeks after discharge. The discontinuation rate for breastfeeding at 2 weeks is as high as 25%, with many women citing lack of confidence, support, and perceptions of insufficient milk production [32]. Early visits and encouragement from the clinician may play a significant role in rates of breastfeeding continuation. Fifty-five percent of women cited individualized encouragement by their clinician as a reason for continuing breastfeeding until 12 weeks postpartum [33]. Women in the adolescent age group, recent immigrant status, lack of social support, mental health problems, and physician judgment are some indications to consider an earlier visit [31].

In the early postpartum period, issues such as abnormal vaginal bleeding, anemia, perineal pain, constipation, breast pain/engorgement, fever, and contraception should be addressed. Prior to discharge, it is important to evaluate patient's mood, support, and readiness for discharge. A detailed anticipatory guidance regarding postpartum blues and risk for depression is very important [31]. It is the family physician's role to provide support and encouragement for the entire family. Patients should have access to a contact that they can call for support and advice as necessary. At the 3–6 week visit, discussion should surround breastfeeding support, anemia, contraception, libido, and sexuality. Health maintenance, lifestyle modification, and immunization are often addressed after 6 weeks [28]. Physicians provide information and guidance about sexuality in pregnancy and childbirth in fewer than 30% of cases [34]. Sexuality after childbirth can be affected by vaginal dryness, pelvic floor dysfunction, and decreased libido [35]. There is need for education of new parents both before and after childbirth as cultural beliefs and myths continue to play significant roles in sexuality in pregnancy and after childbirth.

Women with a diagnosis of gestational diabetes during pregnancy also require close follow-up in the postpartum period. In the immediate postpartum period, diabetic medications are generally discontinued. Women are often advised to discontinue home blood glucose monitoring. However, they should undergo a 75 g 2-h fasting oral glucose tolerance test or fasting serum glucose check between 4 and 12 weeks postpartum [28, 30].

Postpartum Contraception

If not already completed in the immediate postpartum period, contraception (if desired) should be discussed and offered at the comprehensive postpartum visit. The choice of contraception should be individualized based on a number of factors including breastfeeding, patient's age, parity, previous contraceptive experience, birth spacing, partner's plan, health status, and accessibility. Birth spacing is not just important to mothers but also to their children and to the society in general. The longer the interval between births (especially between 27 and 32 months), the lower the risk of

Telegram: @medical_k

www.konkur.in

major maternal complications such as bleeding, anemia, infection, and even death in subsequent pregnancies [36]. A 3 year interval between births has been shown to decrease neonatal and post-neonatal mortality for the subsequent child [37].

Breastfeeding is a form of contraception. The lactation amenorrhea method (LAM) is an effective mode of contraception up to 6 months in a woman who exclusively breastfeeds and has not resumed menstruation [38]. Once supplemental feeding is introduced or menstrual bleeding starts, an alternative form of contraception becomes necessary [39]. There is much controversy on the safety of contraceptive agents in breastfeeding women, especially regarding milk volume, and the passage of exogenous hormones into breast milk. Many studies have shown decreased milk supply as a major side effect of using combined oral contraception (COC) prior to 6 weeks. It has been found that there is a statistically significant reduction in milk volume among COC users when compared to users of progestin-only contraceptive pills [40].

Postpartum Contraceptive Options

There are a plethora of options available for patients postpartum. Shared decision-making should be employed when helping patients decide which option is right for them. As with any patient considering their contraceptive options, their needs should be discussed in terms of convenience, cost, and medical risk factors. Lactation status should also be a consideration.

The US Medical Eligibility Criteria for Contraception (MEC) [41] provides guidance on which contraceptive methods are most appropriate for a patient in specific situations. Contraceptive options are classified under four categories in the setting of each condition in the US MEC. Category 1 is defined as contraceptives that can be used without restriction in a particular situation, Category 2 denotes that benefits are likely outweigh any theoretical risk, Category 3 denotes theoretical or proven risks that are likely to outweigh benefits, and Category 4 include medications that are considered to pose an unacceptable risk.

Table A1 of the US MEC contains the summary of changes in recommendations made in the 2016 edition. Many of these changes therein pertain to recommendations for use in the postpartum period. Generally speaking, progestin implants, depo-medroxyprogesterone acetate, and progesterone-only pills are classified as Category 2 forms of contraception for breastfeeding patients up to 30 days postpartum. Combined hormonal contraceptives (CHC) (pills, vaginal contraceptives, patches, and the like) are rated as Category 4 in the breastfeeding patient less than 21 days postpartum (those without yet well-established milk supply, and during a time when the risk for VTE is significant), Category 3 for 21–42 days postpartum, and Category 2 thereafter.

The recommendations are different for patients who are not breastfeeding. Progestin implants, depo-medroxyprogesterone acetate, and progesterone-only pills are all rated as Category 1 at any time in the postpartum period for those not breastfeeding. CHCs remain a Category 4 for patients in the 21 days after delivery for non-breastfeeding patients. CHCs are Category 3 in the 21–42 day postpartum period for patients with significant VTE risk factors (such as age >35 or previous VTE), whereas Category 2 in those at average risk for VTE in the 21–42 day postpartum period. CHCs are Category 1 for all patients greater than 42 days postpartum who are not breastfeeding.

Copper IUDs and progestin-containing IUDs are rated as Categories 1 and 2, respectively, within 10 min following delivery in the breastfeeding patient while they are both Category 1 in the nonbreastfeeding patient. For patients who are either breastfeeding or not-breastfeeding, the risks are considered to be similar after 10 min. For patients 10 min to 4 weeks postpartum, IUDs are a Category 2. After 4 weeks IUDs are considered Category 1 for both groups.

Postpartum Depression

Postpartum depression occurs in approximately 13% of all new mothers [42]. Therefore, routine screening for postpartum depression in all mothers is recommended. The Edinburgh

Telegram: @medical_k

www.konkur.in

Postnatal Depression Scale is the most widely used screening tool. Risk factors for postpartum depression include previous postpartum depression, a previous history of depression, poor social support, and psychosocial stressors [43]. Typical symptoms include depressed mood, anhedonia, decreased energy, feelings of guilt, psychomotor retardation, and suicidal ideation. Physicians should measure thyroid-stimulating hormone levels in women with suspected postpartum depression [43]. Psychosocial and psychological interventions including peer support, nondirective counseling, cognitive behavioral therapy, and interpersonal psychotherapy appear to be effective in reducing symptoms of postpartum depression [42]. Selective serotonin reuptake inhibitors have also been shown to be effective in the treatment of postpartum depression [43].

Postpartum Thyroid Dysfunction

The postpartum period is a common time for the development of thyroid dysfunction. The most common postpartum thyroid condition is thyroiditis, affecting approximately 8% of postpartum women [44]. There is currently insufficient evidence to recommend universal screening of all women for postpartum thyroiditis; however, it is recommended that all women with postpartum depression be screened for thyroid disease with a TSH, free T4, and thyroperoxidase antibody testing [45].

The typical clinical course for women who develop thyroiditis is to initially develop transient thyrotoxicosis between 2 and 6 months postpartum. This is usually asymptomatic. Thyrotoxicosis is often followed by hypothyroidism, usually returning to the euthyroid state by the end of the initial postpartum year. Postpartum women with symptomatic thyrotoxicosis should be treated with beta-blockers [44]. Following resolution of the thyrotoxic phase, the TSH should be monitored every 2 months to screen for hypothyroidism. Hypothyroidism may require treatment with levothyroxine. If treatment with levothyroxine is initiated, tapering off of the medication can usually be initiated in 6–12 months, with intermittent monitoring.

Postpartum Venous Thromboembolism

Increased risk for venous thromboembolism continues after pregnancy and actually increases during the postpartum period [46]. In addition, the risk for pulmonary embolism is higher in the postpartum period than during pregnancy [46]. Risk for venous thromboembolism is greatest in the first 3 weeks postpartum, returning to baseline at 12 weeks postpartum [47]. Older age, obesity, smoking, Black race, Cesarean delivery, preeclampsia, maternal hemorrhage, anemia, and postpartum infection are all risks for venous thromboembolism. Diagnosis of postpartum lower extremity venous thromboembolism can be made difficult by the common occurrence of lower extremity edema. However, unilateral leg swelling (particularly left sided), redness, and pain should increase the suspicion for venous thromboembolism. Venous compression Doppler ultrasound is the recommended diagnostic test to evaluate for a lower extremity venous thrombus. Treatment with warfarin is recommended and is safe to use in a breastfeeding mother. Low-molecular-weight heparin can be used as a bridge until the prothrombin time is therapeutic for the requisite period of time. Dyspnea and tachypnea are the most common presenting symptoms of pulmonary embolism. Postpartum pulmonary embolism has a relatively high mortality rate [48].

Health Equity and Standardization of Maternity Care

Racial and ethnic health disparities are pervasive in all areas of medicine. One of the most significant areas for these disparities is in maternity care [49]. Black women are 3 to 4 times more likely to die as a result of circumstances surrounding pregnancy. Health disparities occur along the entire trajectory from preconception to postpartum care.

In the USA, racial and ethnic minorities suffer greater risks of postpartum hemorrhage and puerperal infections than do their White counterparts.

One strategy that has been advanced to combat these disparities is standardization of care. The

Telegram: @medical_k

www.konkur.in

use of tools such as safety bundles, standardized protocols, and standard triggers have been shown to improve care, particularly care that is provided to women of color [49].

recognized and managed many common genetic syndromes such as Trisomy 21, Klinefelter syndrome, Neurofibromatosis, and Huntington's chorea which exist in the population. In the current era of molecular and genomic medicine, there are an ever-increasing set of competencies to adequately assess, interpret, and counsel our patients regarding their genetic contributions to the detection, prevention, and management of disease. Family Physicians have an increasing responsibility to be able to accurately assess genetic familial risk and provide guidance in a vast array of genetic health-care choices including prenatal testing, cancer risk assessment and intervention, medication choices based on genetically determined variations in metabolism, and the exponentially increasing numbers of clinical and direct-to-consumer genetic testing available. The goal is that this genetic data is then integrated into personalized medicine plans for chronic disease prevention.

Despite the existence of medical genetics specialists, and genetic counselors, studies have shown that patients prefer genetic risk assessment and counseling be done by their primary care provider [1]. In addition, as molecular medicine expands away from rare highly penetrant single-gene disorders to the complex interplay of multiple genes, environmental, and lifestyle choices, there will not be an adequate supply of medical geneticists and genetic counselors to meet the growing need or geographic distribution of the population. Therefore, much of the management and prevention of heritable disease will be left to the primary care physician, who is ideally suited for this role [2]. In addition, legal precedent has now been set for negligence claims when providers have failed to identify increased risk for heritable disease, specifically cancer [3].

To address these advancements in genetics, the American Academy of Family Physicians (AAFP) has outlined recommended competencies in medical genetics [4]. In addition, the Genetics in Primary Care Institute [5] developed initially with pediatric primary care in mind has narrowed many of these competencies down to seven key roles for the primary care physician (see below). This chapter will provide the basic tools and references for additional resources to begin integrating these genetic competencies into practice.

Seven Key Roles [5]

1. Evaluate through screening and surveillance: Use family health history for primary prevention of chronic illness and to identify a patient's need for increased surveillance
2. Educate patients and their families: Discuss the importance of screening, early diagnosis, and how genetic tendencies may be present with an acute manifestation of the disease
3. Explain the results: Review and discuss the meaning of screening, test results, and what to expect from genetic consultation and referral
4. Make appropriate referrals: Provide information based on clinical history and ensure adequate follow-up for patients
5. Coordinate care with a subspecialist: Initiate a co-management plan, including treatment and diagnostic testing when indicated
6. Counsel patients and families: Help them understand and adapt to the implications of a genetic diagnosis
7. Provide long-term follow-up and care: Continue to support patients and families and provide primary care through an ongoing relationship within the medical home

Basic Science of Genetics

Terminology

Within normal cellular function, genes are the basic physical unit of inheritance which contains the information to encode a protein. The genes are arranged in discrete units on chromosomes which consist of a long double-stranded DNA molecule [6]. There are approximately 26,000 genes arranged over the 22 pairs of autosomes and one pair of sex chromosomes in the nucleus of a human cell. At conception, each parent contributes one copy of each of their autosomes and one sex chromosome to the subsequent offspring [6]. This collection of genes is known as an individuals' genotype. The chromosomes are then packaged into compressed packages called

Telegram: @medical_k

www.konkur.in

chromatin which allows the DNA material to be condensed into the nucleus. Changes in chromatin structure can affect gene expression and are one mechanism of variation of phenotype without alteration of the genotype, called epigenetic variation. Via the process of gene expression, the cell reads the sequence of DNA three bases at a time and assembles the amino acids together to form proteins. These proteins are then responsible for all cellular functions.

When the normal cellular process is disrupted, mutations or variations in the genetic code develop. These can occur by copying errors during cell division, from exposure to ionizing radiation, chemicals, or viruses. When an error occurs in a germ line cell (sperm or ova), the mutation can be passed on to subsequent offspring. If the mutation occurs in a somatic cell elsewhere in the body, the mutation is not passed on to subsequent generations. Mutations can occur by a single-base pair change, or by deletions, duplications, or rearrangements of small or large sequences of DNA. These alterations in genotype (genetic makeup of a cell) can then manifest in several different phenotypes (observable characteristic or trait). It can result in no effect, called a silent mutation, or in failure to produce a protein, or to produce a modified version of the protein which could impact its function and even excess production of a protein. Some variations may result in a nonviable fetus, others in a genetic syndrome or increased disease risk or susceptibility. The most common variations seen are known as single-nucleotide polymorphisms (SNPs). These are variations of a single-base pair and can be tracked for correlation with disease manifestation, drug response variability, and other phenotypes.

Once genetic variation occurs in the germ line, it can be passed on through several different modes of inheritance. Genetic diseases can be autosomal dominant, meaning that individuals who inherit one mutated copy of a gene will manifest the disease. In this type of inheritance, each affected individual has at least one affected parent, and the disease tends to be seen in each generation of an affected family [7]. De novo mutations may also be seen, where the disease appears initially only in the index case. Autosomal recessive disorders affect individuals who inherit two copies of a mutated gene, one from each parent. The parents are carriers of the mutation since they are heterozygous (possess only one copy of the mutated gene) and are unaffected. Mitochondrial disorders are mutations in the mitochondrial genome which are only inherited from the mother. Mitochondrial diseases affect both males and females and appear in every generation of an affected family. X-linked disorders can be dominant or recessive. X-linked dominant mutations affect females more than males since there is no male-to-male transmission. X-linked recessive mutations, however, affect males more than females since males only need to inherit one copy of the mutated gene from their mother. While most syndromes are single-gene disorders, the expressions of these conditions are often strongly influenced by multiple factors. These may include polygenic risk scores which are combinations of mutations in multiple genes, as well as the impact from epigenetics through chromatin compaction and environmental influences. In addition, many genetic syndromes and diseases have incomplete or variable penetrance, where the genetic trait is not expressed or fully expressed in all individuals carrying the mutation [7]. All of these factors may affect the conditions encountered by the family medicine physician in the clinical setting.

Family History Taking/Genogram

In an ideal office situation, each provider would be able to take a detailed family history of each new patient as they establish care and then periodically review and update this information. With respect to genetic risk assessment, this is best done by creating a pedigree or genogram. The basic pedigree would assess at least three generations and include any relevant medical problems, age of death, and ethnic origins. The advantage of the genogram is the additional overlay of the psychosocial information of the family structure and each individual contribution. The result is a visual aid that may help to detect increased risk for diseases and any associated modifiable risk factors [8].

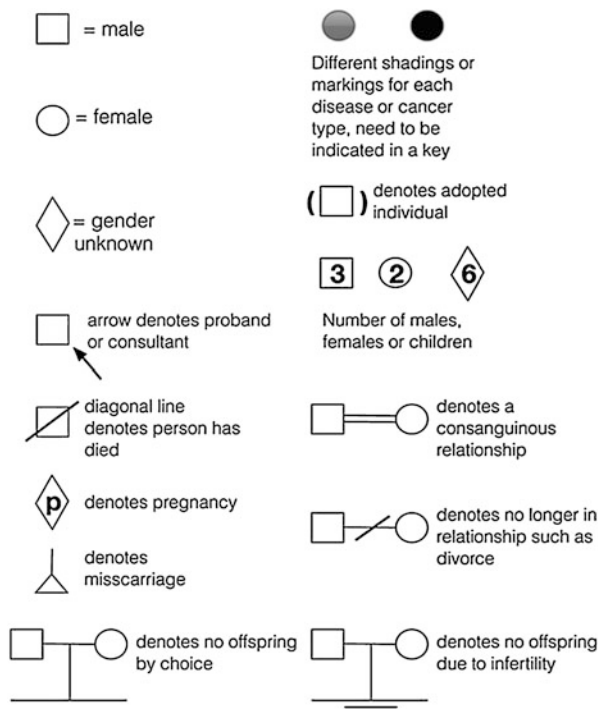
Telegram: @medical_k

www.konkur.in

The pedigree should include the current age of each family member and the age of onset of each disease or diagnosis and the age and cause of death for the patient and the first-, second-, and third-degree relatives on both the patients maternal and paternal lineage [3, 8, 9]. The use of standardized symbols and diagrams allows for rapid recognition of patterns of disease transmission (see Figs. 1 and 2). The identification of two or more individuals on the same side of the pedigree with the same disease, or earlier onset of disease than expected, should raise a red flag for possible genetic pattern of inheritance and increased risk [5]. Identification of consanguinity will also increase the risk due to the higher degree of shared genetic material [8, 9]. Specific ancestral origins are also important to identify due to genetic variation among geographical and ethnic subpopulations. This is especially important in identifying the need for possible prenatal screening. The largest ethnic-specific prenatal panel is the Ashkenazi Jewish genetic panel which tests for carrier status for Bloom syndrome, Canavan disease, cystic fibrosis, familial dysautonomia, Fanconi anemia group C, Gaucher disease, glycogen storage disease Type 1a, maple syrup urine disease, mucolipidosis IV, Niemann-Pick disease, and Tay-Sachs disease [10].

Common Chromosomal and Genetic Disorders

Most patients with common chromosomal and genetic disorders will be diagnosed shortly after birth or early in life. However, all family medicine physicians should be able to recognize common dysmorphic features or raise concern in the presence of multiple physical anomalies or cognitive impairment and coordinate referral to a genetic specialist for diagnosis and management recommendations. There are numerous references available to allow the primary care physician to manage individuals with these known genetic syndromes in the context of their overall health care and the unique medical needs related to their diagnosis. After initial diagnosis, these patients can be effectively managed by the family



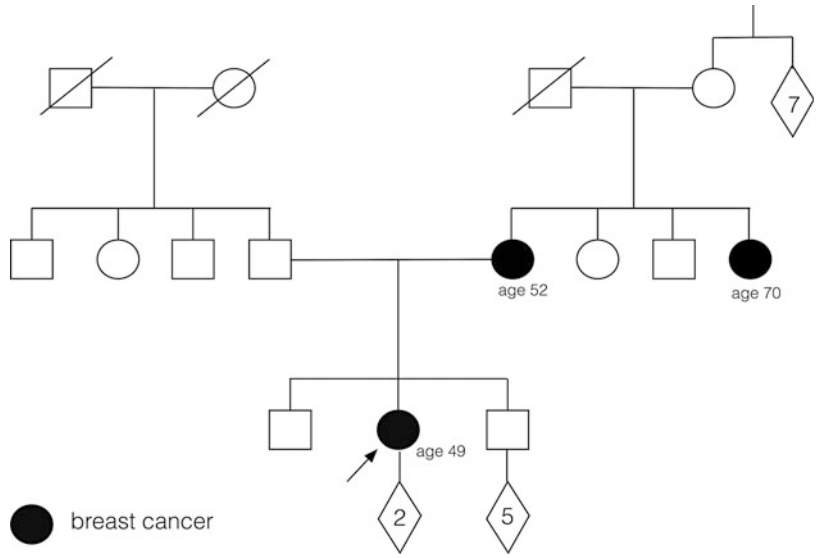


Fig. 1 Standard pedigree symbols

Telegram: @medical_k

www.konkur.in

Fig. 2 Sample pedigree

physician to coordinate any additional interventions, specialty care, and therapies through their primary care medical home (see Table 1).

Some syndromes may not present until adulthood, for example, Klinefelter syndrome may present with a primary infertility evaluation. In these cases, the family medicine physician needs to be prepared to access disease-specific information in order to provide education and emotional support to the newly diagnosed patient, or referral to genetic counseling if available.

Types of Genetic Testing

There are five main classes of genetic testing. These include newborn screening, carrier testing, prenatal testing, diagnostic testing, and predictive testing.

The most widespread form of genetic testing currently in use is newborn screening. These tests are done by tandem mass spectroscopy on a state level to screen for numerous genetic disorders at birth, which allows for early detection and intervention to prevent or minimize disease onset or severity [11].

Carrier testing is done to identify individuals who may carry mutations for specific recessive disorders. These tests are appropriate for those with a family history of a specific genetic disorder, or those from an ethnic group with an increased carrier frequency. The carrier status of an individual or couple is important for reproductive decision-making with regard to their risk of having a child affected with the disorder. In order to pass on the disease, both parents must be carriers of the recessive disorder, and then each pregnancy will have a 25% chance of inheriting both mutations and developing the disorder. One prevalent carrier testing program is for Tay-Sachs disease among people of Ashkenazi Jewish descent where the carrier frequency is 1/27 [12]. Other examples include cystic fibrosis and sickle cell disease.

Pregnancy-related testing includes preconception testing, preimplantation testing, and prenatal testing. Preconception testing is a form of carrier testing done prior to conception. Preimplantation genetic testing is done on embryos generated by IVF for selection and implantation to avoid embryos that are homozygous for a specific genetic condition. Prenatal testing is done to identify genetic changes in the developing fetus when there is a higher risk of genetic or chromosomal disorders due to advanced maternal age or strong family history of a particular condition. These tests are typically performed on cells obtained from amniocentesis or by chorionic villus sampling.

Diagnostic genetic testing is used to confirm a suspected genetic diagnosis in an already affected individual. This type of testing provides a yes or no answer and can diagnose or rule out a specific

Table 1 Common genetic disorders in primary care

Disorder	Inheritance
Achondroplasia	Autosomal dominant
Adult polycystic kidney disease	Autosomal dominant and autosomal recessive
Alpha 1 antitrypsin deficiency	Autosomal codominant
Congenital adrenal hyperplasia	Autosomal recessive
Cystic fibrosis	Autosomal recessive
Down syndrome	Spontaneous chromosomal abnormality
Familial hypercholesterolemia	Autosomal dominant
Fragile X	X-linked dominant
Galactosemia	Autosomal recessive
Gaucher	Autosomal recessive
Hemochromatosis	Autosomal recessive
Hemoglobinopathies	Variable/autosomal recessive/ X-linked
Huntington's chorea	Autosomal dominant
Klinefelter syndrome	Spontaneous chromosomal abnormality
Marfan syndrome	Autosomal dominant
Multiple exostosis	Autosomal dominant
Myotonic dystrophy	Autosomal dominant
Neurofibromatosis	Autosomal dominant
Phenylketonuria	Autosomal recessive
Spinal muscular atrophy	Autosomal recessive
Tay-Sachs	Autosomal recessive
Trisomy 18	Spontaneous chromosomal abnormality
Turner syndrome	Spontaneous chromosomal abnormality

condition as the cause of symptoms. Having a confirmed diagnosis can then help provide anticipatory guidance for the patient in terms of progression and management of their disease.

Predictive testing is used to identify high-risk individuals based on family history, prior to the onset of disease. "Presymptomatic testing" identifies individuals who will go on to demonstrate diseases such as Huntington's chorea. "Predispositional testing" shows that an individual is at higher risk for the development of a certain disease but may not ever develop the disease in one's lifetime, such as breast cancer. The ultimate goal of predictive testing is to prevent or minimize the effects of a genetic disease [7].

Clinical Testing

There are three main types of clinical genetic testing: cytogenetic, molecular, and biochemical testing.

Cytogenetic testing is the examination of whole chromosomes for abnormalities. Whole cells are prepared, and the chromosomes are fixed and stained on slides for analysis. The distinct banding pattern of each chromosome allows for detection of variation. In addition, fluorescent in situ hybridization (FISH) can be used to paint chromosomes or portions of chromosomes with fluorescent molecules to enhance the identification of abnormalities [7].

Biochemical testing uses techniques to evaluate protein activity to assess gene function. These tests measure protein activity and quantity in the collected cell samples. The most prominent example of this is the use of tandem mass spectroscopy in newborn screening [7].

Molecular testing evaluates for DNA sequence changes. Many screening panels have been developed for the most common mutations associated with specific diseases. For example, the CFTR panel screens for the 30 most common mutations in the cystic fibrosis transmembrane conductance regulator gene (CFTR). To further enhance detection, additional techniques such as comparative genomic hybridization (CGH), chromosomal microarray analysis (CMA), and DNA chip analysis are utilized to screen and identify small deletions, duplications, or variations in gene expression when compared to a normal-reference DNA [7].

Direct-to-Consumer Testing

In the last several years, a new industry has blossomed as a result of genetic testing advances in the form of direct-to-consumer testing. In this form of testing, test kits are marketed directly to the patient. This type of free-market medical testing is the center of significant debate regarding the appropriateness of medical data being obtained in the absence of physician interpretation, versus the rights of patients to obtain and manage their own

Telegram: @medical_k

www.konkur.in

private medical data. Although most direct-to-consumer testing is paid "out of pocket," some are attempting to work with the insurance industry to achieve third-party billing for these services. In addition, the FDA is now investigating how direct-to-consumer (DTC) testing should be monitored and approved, as this form of medical industry sets a new precedent. There are currently over 400 companies offering DTC genetic testing on the market [13, 14]. They offer a range of services from ancestral DNA analysis to whole genome chip analysis. It is projected that the global market for this technology will reach $3.4 billion by 2024 [13, 14]. The primary concerns at this time are whether the test results oversimplify complex information, mislead patients by not providing complete informed consent, and whether testing meets clinical validity standards [15]. There is further concern as to whether patients can adequately understand the results and the overall implications of the results on their personal health and that of their family. Patients might overestimate their risk of disease which could cause unnecessary stress, or may misinterpret the results resulting in inappropriately increased screening and/or intervention without the context of a knowledgeable physician or other professional directing their care [15]. Nonetheless, DTC testing may provide an excellent opportunity for collaboration between the primary care physician and the patient when it comes to the interpretation of results and integration of the data into personalized medical management. Recently, the FDA has come out with a statement regarding the requirement of repeating the test in a clinical setting prior to utilization of the report for medical decision-making [16].

Result Interpretation

Before ordering any test in medicine, it is critical to understand the potential results one might receive and the potential impact of these results on both medical decision-making and the psychological and social implications for the patient. Testing should generally be reserved for cases in which the result can lead to changes in care that impact clinical outcomes. It is no different when it comes to genetic testing. Genetic testing results can come back as positive, negative, true negative, uninformative negative (see below), false negative, a variant of unknown significance, or a benign polymorphism. The primary care provider must be able to understand the implications of each of these answers and communicate the results with respect to the genetic question at hand.

A positive result means that a mutation or variation was identified. Depending on the context, this can have several different meanings. For simplicity, this will be discussed in the context of carrier testing vs diagnostic testing. If one is testing to determine carrier status, then a positive result confirms that the individual being tested carries an altered form of that gene. If the variation is associated with a recessive disorder, then this person can potentially pass this mutation on to their children, and if the offspring inherits a second mutated copy from the other, parent would manifest the recessive disorder. If the alteration is a marker representing an increased risk for disease, then the presence of the variation would confirm that the individual is at an increased risk for developing that disease in the future.

If testing is being done to confirm a diagnosis associated with a specific mutation, then a positive test result confirms the diagnosis of that disease and may influence disease treatment.

A negative test result means that a mutation or variation was not identified. If testing carrier status in a family with a known mutation, then this result shows that the tested family member did not inherit that specific mutation and is not at higher risk for the disease or syndrome being tested. This is known as a true negative, and it reduces the risk of a specific disease to that of the general population. If the test is being done in the context of a family with a disease or syndrome with no known associated mutation, then a negative genetic screening test result is an uninformative negative. The uninformative negative does not provide clinically useful data, since it does not distinguish between the absence of the mutation or mutations in the individual and the failure to detect the presumed mutation or mutations leading to the condition of interest. A variant of unknown

Telegram: @medical_k

www.konkur.in

significance (VUS) is a new mutation found in the tested individual that has not been previously proven or linked with a specific disease and uncertainty exists whether or not it is related to the disorder in question. It is hoped that in the future research will reclassify variants of unknown significance as a disease associated mutation, a benign polymorphism, or normal variation within the general population.

Pharmacogenomics

With the rapid advances and decreased costs of genomic testing, the implementation of pharmacogenomics (PGx) as standard of practice in primary care is quickly becoming a reality. Currently there are already FDA prescribing guidelines that include PGx recommendations for nearly 400 medications [17]. Many of these medications represent common medications among the prescribing habits of primary care providers [18–22]. It is imperative that primary care providers become familiar with PGx concepts and the resources available to guide practice management decisions to successfully integrate this technology to improve the health and outcomes of patients.

PGx is the study of how genetic variations impact the inte-individual variability of drug response through pharmacokinetics (metabolism and transport) and pharmacodynamics (receptor targets, signaling cascade) [23]. Genetic variation accounts for 20–95% of the differences observed in a patient's response to medication [24]. With the advances in PGx, the expectation is providers can better predict medication response [23], allowing for tailored prescribing for individual patients as opposed to the classic "one size fits all" model.

In addition to improved medication response, a major contribution from PGx is to reduce adverse drug reactions (ADRs). ADRs have a significant impact on rates of morbidity and mortality with an estimated 100,000 deaths/year [25], hospital admissions, and immense impact on health-care costs [26–30]. ADRs have been reported in nearly 10% of patients in the ambulatory primary care setting [31]. More than half of the drugs with frequently reported ADRs are metabolized by cytochrome p450 drug metabolizing family of enzymes (CYP450) [32, 33]. Some of these drug metabolizing enzymes are highly polymorphic, commonly harboring genetic variations called single-nucleotide polymorphisms (SNPs) which can result in a range of metabolic activity [32]. Identification of these genetic variants in patients allows for informed prescribing of medication and dosage to increase the likelihood of drug efficacy and reduce the likelihood of ADRs [20].

CYP450

Enzymes produced from the CYP450 genes are involved in the metabolism of various molecules and chemicals within cells. There are approximately 60 CYP450 genes in humans. A subset of these genes encodes the enzymes needed for 70–80% of all drug metabolisms. CYP450 enzymes are primarily found in liver cells but are also located in other cells throughout the body. Common variations (SNPs and copy number variants) in CYP450 genes can affect the amount or function of the enzymes they encode and therefore how they activate or breakdown medications. These variations can lead to either rapid, normal, or slow metabolism of a drug. If a CYP450 enzyme metabolizes a drug slowly, the drug will remain in its parent form longer. If this drug is active, less of the drug is needed to get the desired effect. A drug that is metabolized more quickly is broken down faster, and therefore a higher dose may be needed to be effective. If the drug is a prodrug, a parent drug molecule that is inactive on its own, it needs to be metabolized to produce a therapeutic effect. In this situation, the potential clinical impact of reduced or enhanced metabolism is reversed [34]. In the case of two of the common CYP genes, *CYP2C9*, and *CYP2C19*, the common polymorphisms give rise to five distinct phenotypes (see Table 1).

PGx Guidelines

Two organizations in addition to the FDA have been established to help evaluate the emerging

Telegram: @medical_k

www.konkur.in

evidence of PGx linkages and publish evidence-based prescribing recommendations to inform clinical practice. FDA PGx information can be found in drug product labeling describing information on drug exposure and clinical response variability, risk for adverse events, genotype-specific dosing, mechanisms of drug action, polymorphic drug target genes, as well as some specific actions to be taken based on the genomic information. In some cases, PGx statements have reached the highest-level FDA warning, a "boxed warning," and recommendations regarding prescribing of affected medications are offered. A complete list of drugs and their labeling information can be found at the FDA website [35].

The Pharmacogenomic Knowledge Base (PharmGKB; [36]) was created in 2000. This NIH-funded project collects, curates, and disseminates scientific knowledge about the impact of human genetic variation on drug responses. Its clinical-focused subgroup, the Clinical Pharmacogenomics Implementation Consortium (CPIC), was formed in 2009, with the goal to accelerate clinical translation of pharmacogenomic data [37]. CPIC creates peer-reviewed and evidence-based gene/drug clinical practice guidelines for those seeking to adopt PGx testing in clinical practice (see example in Table 1). Published guidelines are freely accessible on their website [38]. The CPIC guidelines include a system for grading levels of evidence linking genotypes to phenotypes, how to assign phenotypes to clinical genotypes, and provide standardized prescribing recommendations based on the genotype/phenotype. Currently, both databases are in a human readable format. The next step is then translating these guidelines into local drug use policies that can be combined with discrete genetic results in the EHR to provide real-time clinical decision support (CDS) to inform treatment decisions at the point-of-care.

Common Clinical Examples

There are many clinically relevant drugs used in the primary care setting that are impacted by PGx. Some of the most well-understood examples at this time include clopidogrel, simvastatin, warfarin, and citalopram as well as the large class of drugs metabolized by *CYP2D6*.

The antiplatelet medication clopidogrel (Plavix®) is a prodrug that requires metabolism to its active form. *CYP2C19* reduced or no function alleles are associated with poor bioactivation of the prodrug, decreased platelet inhibition, and an increased risk of adverse cardiovascular events [39, 40].

CYP2D6 is responsible for metabolizing at least 25% of commonly prescribed drugs, including antidepressants, antipsychotics, analgesics, beta adrenergic blocking agents, antiarrhythmics, and antiemetics. *CYP2D6* poor metabolizers may have toxic levels of the parent drug or failed drug bioactivation such as conversion of codeine to morphine.

Warfarin (Coumadin®) metabolism is an example of how the combined effect from two or more different gene variants can result in changes in both drug pharmacokinetics and pharmacodynamics [41]. Variants identified in *CYP2C9 and CYP4F2* which are responsible for warfarin metabolism [42–45] and *VKORC1* which encodes an enzyme which is needed for effective clotting that is inhibited by warfarin [46], among others, have been shown in combination to explain as much as 35–50% of variation in warfarin drug response [47].

Simvastatin (Zocor®)-induced myopathy has been shown to be associated with variation in the *SLCO1B1* gene which encodes a transporter involved in its hepatic uptake. As high as a 4.5-fold higher odds of myopathy was observed in patients receiving high dose (80 mg) simvastatin who carry just a single at-risk variant [48], resulting in a recommendation for alternative statin or low-dose therapy with simvastatin (20 mg) [49].

PGx Testing

There are currently multiple types of genomic testing technologies on the market. One of the most common and currently least expensive methodologies is a SNP chip array. The SNP chip array

Telegram: @medical_k

www.konkur.in

uses DNA amplification and fragmented genetic target sequences affixed to fluorescent probes to rapidly determine the DNA sequence at specific sites within the genome. In contrast, DNA sequencing reads every DNA base in a targeted region. Next-generation sequencing (NGS) is a newer technology that has dramatically lowered the cost of whole exome sequencing (WES)-coding regions only and even whole genome sequencing (WGS)-coding and noncoding regions. The benefit of chip array is the rapidity of testing, whereas WGS/WES will provide more comprehensive results.

There is an active debate currently in the field as to whether preemptive pharmacogenomic testing versus reactive genotyping is the best method. Because PGx testing is a lifelong result, proponents of preemptive testing argue that given the high incident exposure to medications for which there are PGx recommendations, it will likely be cost-effective to have testing done once in advance of clinical need and for these results to be stored for long-term future use [50]. Prescribing providers can then access gene-drug-specific associations to inform prescribing at the relevant time [51, 52]. One study found that an analysis of over 10,000 patients, preemptive testing revealed a PGx variant in 91% of patients and that 40% of those patients were exposed to at least one of the associated medications in the 3 years following the study [53]. Having this data readily available in the EHR would allow for real time point-of-care prescribing modifications. In addition, the low cost of the large pharmacogenomic panels makes this form of testing less expensive than individual gene testing one at a time [52–54].

Clinical PGx Implementation and a Path Forward

If patients bring genomic test results to the office, providers should assess the source of the test (whether it was an FDA-approved test or if the testing was done in a CLIA lab) and critically review the test information. Specifically, what variants the test assayed and, importantly, what was not tested prior to interpreting results. Further, any clinical recommendations regarding drug therapy should be reconciled with current guidelines such as those provided by CPIC and FDA prior to integrating results into the patient's personal treatment plans. Currently, a recommendation would be to scan and document clinical genomic test results into the EHR in the problem list and black box warnings as allergies, as there is often not yet an existing mechanism to directly import this data. Data from direct to consumer testing must be repeated in a clinical testing lab to validate results prior to use in clinical decision-making.

Table 2: "Poor metabolizer" (PM) refers to combination of no function and/or decreased function alleles; "intermediate" metabolizers" (IM) carry

Table 2 Example CPIC table for antiplatelet therapy recommendations based on CYP2C19 genotype for acute coronary syndrome/percutaneous coronary intervention patients [40, 38]

Phenotype (genotype)	Implications for clopidogrel	Therapeutic recommendations	Classification of recommendations
Ultrarapid metabolizer (UM) (*1/*17, *17/*17) and Normal metabolizer (NM)[a] (*1/*1)	Normal (EM) or increased (UM) platelet inhibition; normal (NM) or decreased (UM) residual platelet aggregation	Clopidogrel: label-recommended dosage and administration	Strong
Intermediate metabolizer (*1/*2, *1/*3, *2/*17)	Reduced platelet inhibition; increased residual platelet aggregation; increased risk for adverse cardiovascular events	Alternative antiplatelet therapy (if no contraindication), e.g., prasugrel, ticagrelor	Moderate
Poor metabolizer (*2/*2, *2/*3, *3/*3)	Significantly reduced platelet inhibition; increased residual platelet aggregation; increased risk for adverse cardiovascular events	Alternative antiplatelet therapy (if no contraindication), e.g., prasugrel, ticagrelor	Strong

[a]Updated nomenclature used (normal metabolizer in place of extensive metabolizer)

Telegram: @medical_k

www.konkur.in

combinations of normal function, decreased function, and/or no function alleles, resulting in decreased enzyme activity; "normal metabolizer" (NM) refers to the "normal" phenotype, usually representing the major proportion of the population; "rapid" metabolizers (RM) have increased enzyme activity through combinations of normal and increased function alleles; and finally, the "ultrarapid" metabolizer (UM) phenotype originates from two increased function alleles or more than two normal function alleles (copy number variation) [55]

Cancer Genetics

Cancer Genetic Risk Assessment

In a recessive or simple "two hit" model of cancer development, one must have a cancer causing mutation on each chromosome in specific genes to develop cancer. However, 5–10% of all cancers are related to an inherited cancer syndrome in which individuals inherit one cancer predisposing mutation in all cells of their body and thus only need to acquire one additional cancer causing "hit" to develop cancer in their lifetime (such as exposure to a mutagenic chemical or virus). However, individuals without this inherited cancer-causing predisposition must acquire both hits in their lifetime to develop cancer. There also exist dominant forms of cancer syndromes in which only a single inherited mutation is adequate for the development of cancer. However, due to variable expression or incomplete penetrance, not all patients with dominant cancer mutations will manifest cancer in their lifetime. More than 50 types of hereditary cancer syndromes have been identified, and most are in genes that control cell growth or repair DNA damage. Family Physicians should be able to recognize the "red flags" that are suggestive of an inherited cancer syndrome and properly counsel patients regarding their risk and options for genetic testing and subsequent screening or treatment to mitigate the potential development of cancer [56]. Some cancers can appear to have an inherited pattern in a pedigree but are caused by nongenetic factors such as living environment, tobacco, diet, or other carcinogen exposures.

Specific red flags within a pedigree include similar types of cancer appearing in multiple generations of the same side of the pedigree, affected individuals younger than 50, male breast cancer, bilateral breast cancer, and cancer diagnosed at an unusually young age. Other red flags include multiple different cancer types occurring independently in the same person, several close relatives with the same type of cancer, the presence of birth defects that are known to be associated with certain inherited cancer syndromes or being from an ethnic group with a high frequency of certain cancer syndromes. To date more than 50 hereditary cancer syndromes have been identified (see Table 3).

If a specific syndrome is suspected, genetic testing can be done to confirm the presence of a mutation. Most experts agree that testing should be recommended if there is a personal or strong family history of an inherited cancer condition and if the test can be adequately interpreted, and the results provide information that will guide medical decision-making. Once this mutation is identified, it can be looked for in relatives of the index case.

Genetic Risk Reduction

Once testing for a potentially deleterious mutation has been confirmed, the patient may be able to take steps to reduce the risk of developing cancer or to begin early or intensive screening for detection. Clinical guidelines include screening at an earlier age for cancer, medication, and prophylactic surgery such as a mastectomy and/or oophorectomy with hereditary breast and ovarian cancer syndrome or colectomy for Lynch syndrome [57]. Other forms of risk reduction might include modifying personal behaviors such as smoking, weight reduction, and abstinence from alcohol.

Epigenetics

Epigenetics is the study of factors that control gene expression, rather than analysis of the DNA code itself [58]. These factors are able to turn gene expression on or off. Epigenetic factors are what help to distinguish cell types in different organs that share all of the same DNA complement, and

Telegram: @medical_k

www.konkur.in

Table 3 Common cancer genetic syndromes

Syndrome	Genes	Related cancer types
Hereditary breast cancer and ovarian cancer syndrome	BRCA1, BRCA2	Female breast, ovarian, and other cancers, including prostate, pancreatic, and male breast cancer
Li-Fraumeni syndrome	TP53	Breast cancer, soft tissue sarcoma, osteosarcoma (bone cancer), leukemia, brain tumors, adrenocortical carcinoma (cancer of the adrenal glands), and other cancers
Cowden syndrome (PTEN hamartoma tumor syndrome)	PTEN	Breast, thyroid, endometrial (uterine lining), and other cancers
Lynch syndrome (hereditary nonpolyposis colorectal cancer)	MSH2, MLH1, MSH6, PMS2, EPCAM	Colorectal, endometrial, ovarian, renal pelvis, pancreatic, small intestine, liver and biliary tract, stomach, brain, and breast cancers
Familial adenomatous polyposis	APC	Colorectal cancer, multiple nonmalignant colon polyps, and both noncancerous (benign) and cancerous tumors in the small intestine, brain, stomach, bone, skin, and other tissues
Retinoblastoma	RB1	Eye cancer (cancer of the retina), pinealoma (cancer of the pineal gland), osteosarcoma, melanoma, and soft tissue sarcoma
Multiple endocrine neoplasia type 1 (Wermer syndrome)	MEN1	Pancreatic endocrine tumors and (usually benign) parathyroid and pituitary gland tumors
Multiple endocrine neoplasia type 2	RET	Medullary thyroid cancer and pheochromocytoma (benign adrenal gland tumor)
Von Hippel-Lindau syndrome	VHL	Kidney cancer and multiple noncancerous tumors, including pheochromocytoma

this is why genetically identical twins are not fully phenotypically identical [58]. This epigenetic modification can be part of normal cellular processes, such as X-inactivation [59].

There are three main methods of epigenetic modulation with interact with each other to modify gene expression, including DNA methylation, histone modification, and RNA-associated silencing [59]. Interaction with the environment including naturally occurring and man-made compounds can modify these epigenetic signals. Therefore, epigenetics can be considered the interface between the environment and the genome [6]. Therefore, environmental factors may play a large role in the disruption in gene expression leading to over or under expression of proteins, both of which can result in phenotypic changes, including disease.

Counseling Considerations

Any person considering genetic testing should be counseled by a trained professional. These may include physicians, genetic counselors, or other health-care providers with additional training in genetic risk assessment and counseling. The counseling should focus on the process of informed consent including the risks, benefits, and limitations of genetic testing in the context of the disease being tested for. Pretest counseling should include which specific tests are most appropriate, the accuracy of the test, the medical implications of a positive or negative result, or of an uninformative result. In addition, the psychosocial implication of genetic test results on the individual being tested as well as relatives who may be implicated by the result and the potential for future inheritance should be considered [60]. Finally, additional discussions regarding confidentiality and insurance discrimination should be addressed. Written informed consent should then be obtained. Though the process of detailed family history taking, it may be determined that testing is not indicated, or that a different family member is the one who should be considered for testing first. Testing should then be followed up by posttest counseling to review the results and develop a management plan accordingly as well as again assessing the

Telegram: @medical_k

www.konkur.in

psychosocial impact of these results [61]. If at any point in this process, the family medicine physician feels that they have exceeded their knowledge or comfort level regarding the condition or conditions, or if the condition involves multiple complex tests, then referral to a genetic counselor or specialist might be considered [61].

In the specific case of pediatric diagnosis, physicians should be prepared to provide education on the etiology, prognosis, genetic mechanism, and recurrence risk of the disorder as well as available treatment options. These children can often be successfully managed between the primary care physician and genetic specialist [5, 62, 63].

Ethics and Privacy Laws

As with many aspects of primary care medicine, genetic medicine frequently encounters sensitive and ethical issues including consanguinity, ethnicity, and patient confidentiality. The potential impact for harm if genetic information were shared without regard is enormous. In addition, the information is not unique to the individual being tested but could possibly impact multiple generations of relatives.

While genetic test results are governed under the same HIPPA laws as all other protected health information, they are not always private. For example, health insurance companies will have access to these results. Genetic privacy and nondiscrimination is therefore of utmost importance. Legal protection in the form the Genetic Information Nondiscrimination Act (GINA) was instituted in 2008 in the United States to protect such information and to prevent discrimination based on genetic test results [13, 64, 65]. GINA prohibits genetic information from being used in health insurance eligibility or to establish premiums or to prevent employment. GINA is not all encompassing and currently does not apply to members of the military and does not apply to other insurance coverage such as life insurance, disability insurance, or long-term care insurance. There are additional laws that vary by state, which may cover these gaps.

The Future of Genetics in Primary Care

It is likely that, in the near future, Family Physicians will be utilizing genetic tools to identify and prevent many common illnesses such as diabetes, hypertension, Alzheimer's, and chronic obstructive pulmonary disease. How soon this technology becomes integrated into every day practice remains to be seen. In the meantime, it is clear that the Family Physician will need to continue to advance their understanding of the field of genetics and personalized medicine and participate in developing methods of effectively incorporating the technology into daily practice.

Newborn Resuscitation

Term infants who appear well at delivery, have clear amniotic fluid, and good respiratory effort and muscle tone should receive routine newborn care. This includes providing warmth, clearing of the airway as needed, and drying and stimulating of the infant. Ongoing assessment of airway, breathing, circulation, and color should occur as the newborn transitions to extrauterine life. The initial three questions a provider should consider are (1) is this a term newborn, (2) is the tone good, and (3) is breathing or crying present. If the answer is yes to all of these, the infant may remain with the mother for routine care. This initial assessment may occur while the newborn is skin to skin with the mother, during which time any gross abnormalities can generally be observed and ongoing observation by trained staff maintained [1, 2].

If the answer is no to any of the three abovementioned questions, the newborn should be transferred to a radiant warmer to receive one or more of the following interventions in sequence: initial stabilization, ventilation with or without supplemental oxygen, initiation of chest compressions, and administration of epinephrine or volume. All health-care staff involved in the delivery of newborns should be skilled in neonatal resuscitation [1, 2].

The delivery suite should contain equipment appropriately sized to resuscitate newborns of all gestational ages and sizes. This includes a radiant warmer, a source of oxygen with an oxygen blender, instruments for intubation and other airway equipment for suctioning and ventilating, trays for possible umbilical line placement or establishing intravenous access, and drugs such as epinephrine [2].

The initial steps of newborn resuscitation are to maintain normal temperature of the infant by drying well and placing either skin to skin with mother or under a radiant heat source, positioning the infant in a neutral "sniffing" position to open the airway, suctioning the mouth and nose of secretions with a bulb syringe or suction catheter, and providing positive pressure ventilation for newborns with heart rates less than 100 beats/min and apnea or irregular breathing. Most infants respond to these efforts, but if not, further measures include repositioning techniques to overcome mechanical impediments. If the heart rate remains less than 60 beats/min despite intubation and 30 s of effective positive pressure

Telegram: @medical_k

www.konkur.in

ventilation, chest compressions should be initiated. Central access should be obtained via umbilical vessels and emergency drugs administered [1, 2].

Stabilization for Transfer to Higher Level of Care

Once spontaneous circulation returns, treatment involves management of multiorgan dysfunction and provision of a higher level of care in a neonatal intensive care unit (NICU). This may require transport to a tertiary care center. Effective communication with and support of the family should begin early. Goals of management include maintaining adequate ventilation, blood pressure, cerebral perfusion, and cardiac function.

Giving Bad News to Parents After Delivery

One of the most difficult duties of the physician is breaking bad news. The way in which bad news is delivered has a significant impact on the family's grieving process. The physician should provide information in accordance with the patient's needs and desires; assess the recipients' ability to comprehend; determine the family's expectations and readiness to hear the bad news; support the family by employing skills to reduce the emotional impact; and develop a strategy in the form of a plan to move forward. The physician should always be sensitive to the reaction of patients and their families [3].

Common Problems in the Nursery

Respiratory Distress

Respiratory distress may be a transient finding in newborns manifested by tachypnea, grunting, nasal flaring, retractions, and cyanosis. Transient tachypnea of the newborn (TTN) presents within the first hours after birth and shows gradual improvement with most symptoms resolving within 24 h, although TTN may last up to 72 h. Supplemental oxygen may be required. Chest radiographs (CXR) show perihilar streakiness and fluid in the fissures. Persistent or worsening symptoms should prompt an investigation for neonatal sepsis [2].

Respiratory distress syndrome (RDS) due to surfactant deficiency and an inability to maintain alveolar stability is more common in premature newborns or infants born to diabetic mothers. Classic CXR findings include a "ground glass" appearance with air bronchograms. Hypoxia and hypercarbia may be present. The use of antenatal steroids and surfactant administration have decreased the incidence and severity of RDS.

Persistent, severe, or worsening respiratory symptoms, regardless of etiology, should prompt transfer to a higher level of care. Pneumonia, pneumothorax, persistent pulmonary hypertension, and diaphragmatic hernia should be considered in the differential diagnosis of respiratory distress in the newborn.

Late Preterm Infants

Late preterm infants are born at a gestational age between 34 and 36 6/7 weeks. Infants in these gestational ages have increased over recent years, now accounting for more than 70% of all preterm births. Reasons for this increase include a significant increase in inductions of labor and cesarean deliveries and increases in multiple births. Compared to term infants, late preterm infants have higher morbidity and mortality, including a higher prevalence of respiratory distress, temperature instability, hypoglycemia, kernicterus, apnea, seizures, feeding problems, and rehospitalization after discharge. Feeding problems include preterm infants being much more likely than full-term infants to require supplemental intravenous fluids or gavage feeding. Late preterm babies have at least four times the risk of hyperbilirubinemia, compared to term infants. Discharge of late preterm newborns should be delayed until they have demonstrated reliable and appropriate intake with weight gain and absence of hypothermia, hypoglycemia, or

Telegram: @medical_k

www.konkur.in

apnea, and close outpatient follow-up is in place [2].

Small for Gestational Age

Small for gestational age (SGA) newborns are defined by a birth weight (BW) below the tenth percentile for gestational age. SGA newborns may result from constitutional factors such as maternal height, weight, ethnicity, and parity but will eventually reach their appropriate growth potential.

Infants with intrauterine growth restriction are classified as "symmetric" or "asymmetric." Symmetric growth restriction starts early in gestation and results from pathology that might include congenital infections, chromosomal abnormalities, or decreased nutrient supply. The entire body is proportionately small, including weight, length, and head circumference. Asymmetric growth restriction implies a fetus who is undernourished, beginning later in gestation, directing most of its energy to maintain growth of vital organs at the expense of liver, muscle, and fat. In this case, the newborn has relatively normal length and head circumference but reduced body weight, small abdominal circumference, scrawny limbs, and thinned skin [4]. Regardless of etiology, SGA newborns experience increased risks of negative outcomes including hypothermia and hypoglycemia.

Large for Gestational Age

Infants who are born large for gestational age (LGA) have a birth weight greater than the 90th percentile for gestational age. Macrosomia refers to excessive intrauterine growth beyond a specific threshold regardless of gestational age. There is a significant increase in morbidity among neonates above a weight of 4500 g.

The excessive fetal growth appears to result from increased delivery of nutrients to the fetus due to genetic and intrauterine environmental factors. Genetic factors include syndromes and familial traits by which mothers who were LGA are more likely to deliver an LGA infant than mothers who were appropriate for gestational age. Intrauterine environmental factors include maternal obesity, diabetes, or excess gestational weight gain. Complications of LGA infants include increased birth injury such as brachial plexus or clavicular fracture, respiratory distress, hypoglycemia, polycythemia, and perinatal asphyxia [2].

Neonatal Sepsis

Neonatal sepsis occurs in approximately 1–2 cases/1000 births. It is divided into early-onset (<7 days of age) and late-onset sepsis (>7 days of age). Early-onset sepsis tends to occur early, often on the first day of life, with the majority of cases presenting by 12 h of age. Respiratory distress due to pneumonia is the most common presenting sign, but other findings may include low Apgar scores, poor perfusion, or hypotension. Late-onset (7–90 days) sepsis may present in a more subtle manner with poor feeding, lethargy, hypotonia, temperature instability, new or increased oxygen requirement, or apnea. It is associated more commonly with meningitis or other localized infections [5, 6].

The risk of early-onset infection increases if rupture of the maternal membranes occurs more than 24 h prior to delivery and even more significantly with chorioamnionitis. The organisms that most commonly cause early-onset infection include group B streptococcus (GBS, or *Streptococcus agalactiae*), Gram-negative enteric pathogens such as *Escherichia coli*, and *Listeria monocytogenes*. Late-onset sepsis may be caused by these organisms, as well as non-typeable *Haemophilus influenzae*, enterococci, *Staphylococcus aureus*, and coagulase-negative staphylococci [5].

Maternal risk factors for neonatal sepsis include GBS colonization at the time of delivery, chorioamnionitis, intrapartum maternal temperature ≥38 °C, delivery at <37 weeks gestation, and membrane rupture ≥18 h. GBS screening is recommended between 36 and 38 weeks of gestational age via vaginorectal swab culture. Alternatively, nucleic acid amplification testing may be

Telegram: @medical_k

www.konkur.in

performed at the time of delivery if screening was not obtained earlier. Standard GBS screening may have low sensitivity, so the provider should maintain a high index of suspicion for this condition. Intrapartum antibiotic prophylaxis with penicillin G, or ampicillin or cefazolin as alternatives, given intravenously ≥4 h prior to delivery has been shown to be effective in decreasing the incidence of early-onset neonatal sepsis, but not late-onset GBS disease. In cases of penicillin allergy, clindamycin or vancomycin may be used [7].

The clinical diagnosis is difficult because the signs of sepsis are nonspecific and can be seen in other conditions not related to infection [6].

Symptomatic neonates should undergo a full diagnostic evaluation and receive empiric antibiotics. Full evaluation includes complete blood count (CBC) with differential, blood culture, lumbar puncture if clinically stable, and CXR (if respiratory symptoms are present). As appropriate, cultures from tracheal aspirates, C-reactive protein (CRP), and procalcitonin should be obtained. The Centers for Disease Control and Prevention has developed a mobile application to aid in point-of-care evaluation and management for newborn sepsis [8].

Infants being evaluated for late-onset sepsis should receive the studies described for early-onset sepsis, as well as urine cultures and cultures from any other potential foci of infection.

Treatment of infants with presumed early-onset sepsis should include broad-spectrum coverage including ampicillin, plus an aminoglycoside or third-generation cephalosporin such as cefotaxime or ceftazidime. Late-onset sepsis empiric therapy involves coverage for the same organisms for early-onset disease, with the addition of coverage for staphylococci, such as with vancomycin. Initial broad-spectrum coverage should also include cefotaxime or ceftazidime or an aminoglycoside. The blood cultures, inflammatory markers, and clinical course will guide the duration of antibiotic therapy. If cultures are negative after 48 h, antibiotics may be discontinued [5, 6]. Concern for herpes infection should prompt empiric initiation of intravenous acyclovir and appropriate evaluation.

Neonatal Jaundice

Bilirubin is a potent antioxidant and peroxyl scavenger which may be protective against oxygen toxicity in the first days of life for the newborn. Normal homeostasis allows for a balance of bilirubin production, conjugation, and elimination. An immature liver and increased hemolysis in the newborn are factors contributing to increased levels of bilirubin. Jaundice refers to yellow discoloration of the skin, mucous membranes, and sclera, usually associated with total serum bilirubin >5 mg/dL in the newborn period. Although generally benign and transient, hyperbilirubinemia, or excess bilirubin in the blood, can cause severe neurological sequelae by accumulation of toxic amounts of unconjugated bilirubin in the brain leading to kernicterus [9, 10].

In the first week of life, a slight increase in unconjugated bilirubin, derived from normal hemolysis of red blood cells (RBCs) and predominantly bound to albumin, is a normal physiologic process and usually does not merit treatment. Evidence-based guidelines exist to determine levels at which intervention should be considered. Jaundice may be pathologic if presenting within the first 24 h of life [9, 10]. Breastfeeding-associated jaundice, in which breast milk consumption is inadequate, can contribute to early onset of jaundice. In this condition, the lack of adequate intake is the primary contributing factor [10–12]. Interventions to improve breast milk transfer from mother to infant should be undertaken.

Elevated bilirubin may also result from increased hemolysis, decreased conjugation of bilirubin in the liver, decreased excretion of bilirubin, or liver cellular damage. Pathologic forms of hemolysis include ABO incompatibility, Rh isoimmunization, RBC enzyme deficiencies, RBC membrane abnormalities, hemoglobinopathies, or polycythemia. Decreased conjugation of bilirubin may occur due to glucuronyl transferase deficiency disorders like Crigler-Najjar syndrome or Gilbert syndrome. Decreased excretion of bilirubin includes conditions causing abnormal biliary ducts, e.g., extrahepatic biliary atresia, or increased enterohepatic bilirubin recirculation.

Telegram: @medical_k

www.konkur.in

Hepatitis in the newborn may result from congenital infections or inborn errors of metabolism [9, 10].

The principal goal of diagnosis and management of severe hyperbilirubinemia is to prevent acute bilirubin encephalopathy and subsequent kernicterus. Acute encephalopathy results in lethargy, poor feeding, vomiting, high-pitched cry, opisthotonos, seizures, and hypotonia. Kernicterus is an irreversible brain injury characterized by choreoathetoid cerebral palsy, auditory neuropathy, and paralysis of upward gaze [9, 10].

Primary Prevention

Mothers are recommended to initiate breastfeeding within the first hour after birth and continue unrestricted feeding at least 8–12 times a day. Increased frequency of feeding promotes greater excretion of bilirubin in the stool, resulting in decreased hyperbilirubinemia [11, 12].

Secondary Prevention

ABO and Rh (D) blood types and unusual isoimmune antibodies should be tested in all pregnant women. If the maternal blood type is not known, or the mother is either O blood type or Rh factor negative, then ABO, Rh (D), and Coombs testing should be performed on cord blood [10].

Assessment

All jaundiced infants require a full assessment including maternal and family history and clinical examination. This includes screening with transcutaneous bilirubinometry (TcB) or total serum bilirubin (TSB) for all infants, at least prior to discharge. TcB measures bilirubin on the surface of the skin; however, caution must be exercised when used on patients already receiving phototherapy and in newborns with darker colored skin. Any TcB $\geq$75% on the nomogram [10] should have a TSB. Infants with a TcB value $\geq$12 mg/dL, with an onset of jaundice in the first 24 h, or receiving phototherapy should be evaluated only by TSB. Those patients who are undergoing treatment should also only be evaluated with TSB.

Additionally, consideration of maternal and neonatal risk factors must be accounted for which could impact further testing. Maternal risk factors include having a previous baby requiring phototherapy, diabetes, being of Eastern Asian or Mediterranean descent, ABO incompatibility, or a family history of inherited hemolytic disorders. Neonatal risk factors include prematurity, poor oral feeding, hemolytic disease, and birth trauma.

Breast milk jaundice occurs in the second week of life and may take up to 3–4 months to resolve. If there is no evidence of an alternative pathologic etiology, there is no elevation in conjugated bilirubin, and the infant is growing and developing appropriately, no further treatment is needed [12].

Laboratory Assessment

Each bilirubin measurement should be interpreted using the bilirubin nomogram. Using the nomogram to stratify risk helps to identify hyperbilirubinemia requiring treatment [10].

Any infant with jaundice appearing within the first 24 h or with jaundice prolonged in nature should undergo appropriate investigation. These may include a CBC with indices and peripheral smear, reticulocyte count, total and direct bilirubin to evaluate cholestasis, direct antiglobulin or Coombs test, and maternal and infant blood group. Depending on the clinical picture, a serum albumin, sepsis workup, thyroid studies, reducing substances in urine checking for galactosemia, or glucose-6-phosphate dehydrogenase levels may be appropriate.

A direct bilirubin level above 1 mg/dL (when the total bilirubin level is $<$5 mg/dL), or a direct bilirubin level higher than 20% of the total bilirubin level (when TSB is $>$5 mg/dL), constitutes direct (conjugated) hyperbilirubinemia. Direct hyperbilirubinemia is always pathologic and should trigger prompt evaluation.

Treatment

Phototherapy is the most common treatment for most cases of indirect hyperbilirubinemia. It is noninvasive and works by converting unconjugated bilirubin in the skin to a water-soluble form that can be excreted in bile without conjugation. A reduction of 0.5 mg/dL/h in the TSB should be noted when measured 4–6 h after treatment initiation. Overall a decrease in TSB by

Telegram: @medical_k

www.konkur.in

30–40% should occur within the first 24 h. The newborn eyes should be covered with eye patches, and the oral intake should be monitored. Care should be taken to avoid hyper/hypothermia during phototherapy [9, 10].

While most infants with moderate indirect hyperbilirubinemia can be treated effectively with phototherapy, extreme hyperbilirubinemia is a medical emergency, and exchange transfusion should be initiated without delay when bilirubin levels reach treatment thresholds. Exchange transfusion is an invasive procedure involving risks of infection, electrolyte disturbances, thrombocytopenia, fluid overload, coagulopathy, necrotizing enterocolitis (NEC), and thrombosis and should be performed in a neonatal intensive care unit (NICU) [9, 10].

Hypoglycemia

Low blood glucose levels in newborns are a common and usually transient disorder in the neonatal period. Glucose concentration decreases in the immediate postnatal period to as low as 30 mg/dL in many healthy infants at 1–2 h after birth. Glucose levels below 40 mg/dL after the first feeding are considered hypoglycemic. By 3 h, the glucose concentration in normal full-term infants stabilizes at $\geq$45 mg/dL and should be maintained above that threshold unless there is a suspicion for hyperinsulinism, in which case the threshold should be $\geq$65 mg/dL [13, 14].

Certain maternal risk factors, e.g., pre-gestational or gestational diabetes, in addition to medications such as beta-blockers and oral hypoglycemics, increase the risk of neonatal hypoglycemia. Prematurity, intrauterine growth restriction, postmaturity, infection, polycythemia, and hypothermia are also risk factors [13, 14]. Newborns placed skin to skin with their mothers after delivery, and with early initiation of breastfeeding, experience lower rates of hypoglycemia [15]. Hypoglycemic newborns who are asymptomatic may be treated with breastfeeding, with oral feeding with formula or pasteurized donor human milk, or with buccal dextrose gel, while symptomatic infants or those with severe or persistent hypoglycemia may require intravenous glucose support and transfer to a higher level of care.

Metabolic Disorders

Inborn errors of metabolism may present as severe metabolic emergencies resulting in neurologic injury, significant morbidity, and even death. Early recognition, prompt evaluation, and timely management are paramount. Initial symptoms may include vomiting, lethargy, seizures, irregular breathing leading to apnea, and hypothermia. The most common finding in patients subsequently diagnosed as having an inborn error of metabolism is neurologic, followed by gastrointestinal symptoms. After excluding sepsis-like syndromes, or other electrolyte abnormalities such as hypocalcemia, the main metabolic disorders requiring evaluation include urea cycle disorders, fatty acid oxidation defects, and amino acid disorders. All states require newborn screening for certain disorders that are life-threatening or detrimental to long-term health. These disorders are evaluated at an early age because early identification and intervention improve outcomes. Blood is collected by capillary specimen (heel stick) for an initial screen between 24 and 48 h, or before hospital discharge. If the initial screen is collected when the newborn has been feeding orally for less than 24 h, a second screen is required and should be collected between 7 and 14 days of age. State requirements for testing may vary [2]. Most state laboratories offer expanded metabolic screening for a wide variety of metabolic and genetic conditions, and providers should consult their state labs for the most recent information.

Anemia

Anemia is a reduction in RBC number, hematocrit, or hemoglobin concentration to a value >2 standard deviations below the age-specific mean. Anemia in infancy may result from increased erythrocyte destruction, loss of

Telegram: @medical_k

www.konkur.in

RBCs, or inadequate RBC production [16]. The World Health Organization [WHO] [17] recommends delayed umbilical cord clamping (not earlier than 1 min after birth) for improved maternal and infant health and nutrition outcomes, especially iron stores for the newborn. Early cord clamping (less than 1 min after birth) is not recommended unless the neonate is asphyxiated and needs prompt resuscitation. Delayed umbilical cord clamping should not be confused with milking of the cord. The terms are not synonymous. Milking refers to physically expressing blood from the umbilical cord toward the newborn before clamping the cord. Umbilical cord milking in term babies generally is discouraged, as it may increase the risk of polycythemia and hyperbilirubinemia [18].

Initial evaluation of neonatal anemia includes review of perinatal history, physical exam, and assessment of volume status. Labs should include CBC with indices, reticulocyte count, peripheral blood smear, and Coombs test [16]. A Kleihauer-Betke test for fetal cells in the mother's circulation also may be performed. Treatment will be guided by the clinical severity of the anemia and the underlying illness. Transfusions may be required to restore adequate tissue oxygenation and expand circulating blood volume in some cases [16].

Polycythemia

Polycythemia, an abnormal elevation of the circulating RBC mass, is seen frequently in newborns. In newborns, it is defined as a venous hematocrit greater than 65% or a hemoglobin value greater than 22 g/dL, with the normal hematocrit and hemoglobin being 50.3% and 15.9 g/dL, respectively. Although neonatal polycythemia usually represents a normal fetal adaptation to hypoxemia rather than a true hematopoietic defect, the abnormal increase in hematocrit increases the risk of hyperviscosity, microcirculatory hypoperfusion, and multisystem organ dysfunction. Clinical features associated with neonatal polycythemia are generally nonspecific and may include ruddy complexion, irritability, jitteriness, tremors, feeding difficulties, lethargy, apnea, cyanosis, respiratory distress, and seizures. Neurologic signs may also be related to metabolic problems such as hypoglycemia and hypocalcemia [19, 20].

Close attention should be paid to the technique of sample collection while interpreting the test results. Capillary blood samples often show hematocrits that are 5–15% higher than venous samples; therefore, high hematocrit measurements in samples obtained by heel sticks should be confirmed with a free-flowing venous sample.

Polycythemic infants should be evaluated for underlying causes such as intrauterine growth restriction, maternal diabetes, or birth asphyxia. Because clinical manifestations of hyperviscosity can overlap with other conditions, alternative causes for the symptoms should always be carefully excluded. Infants also should be monitored for systemic complications of polycythemia such as thromboses, NEC, hypoglycemia, hypocalcemia, hyperbilirubinemia, and thrombocytopenia. Asymptomatic infants with central hematocrits between 60% and 70% can be monitored closely and aggressively hydrated with adequate enteral intake or intravenous fluids. The hematocrit should be reassessed in 12–24 h, and plasma glucose, TSB, and cardiorespiratory status should be monitored. Patients with polycythemia showing signs or symptoms related to hyperviscosity are frequently treated with plasma exchange therapy. By replacing some of the circulating RBC mass with a crystalloid solution, plasma exchange therapy may reduce blood viscosity and improve end-organ perfusion [19, 20].

Birth Injuries

Birth injuries are defined as a structural destruction or functional deterioration of the body secondary to a traumatic birth. Risk factors include macrosomia and use of instruments, such as forceps or vacuum extraction, during the birth process [21].

Caput succedaneum is a collection of fluid in the superficial scalp that crosses suture lines. It occurs secondary to molding pressure during

Telegram: @medical_k

www.konkur.in

labor and resolves within 4–6 days. Cephalhematoma is a subperiosteal collection of blood that does not cross the suture lines. It is not associated with substantial blood loss and tends to enlarge until about day 3 of life, typically resolving within 3–4 weeks. Subgaleal hemorrhage is a collection of blood between the epicranial aponeurosis and periosteum of the skull. Risk of subgaleal hemorrhage is increased with vacuum-assisted deliveries and can lead to hemorrhagic shock. Clinical findings include tachycardia, a falling hematocrit, and increasing head circumference. Subdural hemorrhage is bleeding between the dura mater and arachnoid layer of the brain that is caused by the rupture of bridging veins. The risk is increased with the use of instruments during delivery. If symptomatic, infants often present with respiratory depression, apnea, and/or seizures.

Facial nerve injury is caused by compression of the facial nerve, often associated with the use of forceps. Most cases resolve within 2–3 weeks. Brachial plexus injuries are the result of damage to the spinal roots C5–T1 that causes paralysis of the upper arm muscles. The most common brachial plexus injury is Erb's palsy, affecting C5 and C6. The arm is adducted with internal rotation, full extension at the elbow, pronation of the forearm, and flexion of the wrist, creating the classic "waiter's tip" posture. The Moro reflex will be asymmetrical. Brachial plexus injuries usually resolve spontaneously, but physical therapy may be considered.

Clavicular fractures are the most common fracture in newborns. Risk factors include macrosomia and shoulder dystocia. It is associated with tactile crepitus over the affected side, with any discomfort resolving within 5–7 days [21].

See Table 1 for an overview of common anomalies encountered in the newborn.

Human Immunodeficiency Virus (HIV) Infection in Newborns and Infants

Effective prevention strategies have reduced the risk of perinatal transmission of HIV infection to less than 1–2% in the United States; however, failures to fully implement these strategies have resulted in vertically transmitted infant HIV infections. All pregnant women should be screened for HIV, and repeat testing at the time of delivery is suggested in high-risk situations or individuals [22, 23].

The predominant route of HIV infection in children is maternal to child transmission including intrauterine, intrapartum, and postnatal, the latter especially through breastfeeding, which is not recommended in the United States, but global recommendations vary. In the absence of anti-retroviral preventive interventions, in nonbreastfeeding populations, 25–30% of infants born to HIV-infected women will become infected. Rates can be as high as 50% for infants with prolonged breastfeeding [22, 23].

In the AIDS Clinical Trials Group 076 trial, zidovudine given during pregnancy, intrapartum, and to the infant after birth was shown to reduce vertical transmission significantly from 26% to 8% in the absence of breastfeeding. Follow-up studies found better efficacy for combination anti-retroviral maternal therapy using at least three drugs from two different classes. This combination therapy has decreased maternal to child transmission to less than 2%. Currently all HIV-exposed infants should receive zidovudine prophylaxis as soon after birth as possible and preferably within 6–12 h of delivery. The usual dose for gestational age $\geq$35 weeks is 4 mg/kg/dose orally twice daily for 6 weeks. Dosing varies for preterm infants (<35 weeks) [22, 23].

Virologic testing (HIV DNA, PCR, or HIV RNA assays) should be performed within the first 14–21 days of life, at age 1–2 months, and then at age 4–6 months for all HIV-exposed infants. Primary care physicians can reference the American Academy of Pediatrics (AAP) Committee on Infectious Diseases [23] guidelines for prevention, evaluation, and management of newborns and infants exposed to HIV. Consultation with a pediatric infectious disease or HIV specialist is recommended whenever possible.

Table 1 Approaches to common neonatal anomalies

Abnormality	Causes	Evaluation/treatment
Head		
Caput succedaneum	Soft tissue swelling of scalp crossing suture lines, occurs with assisted vaginal birth but may occur with spontaneous vaginal or cesarean delivery	Observation
Cephalhematoma	Subperiosteal hemorrhage, does not cross suture lines. More common with assisted vaginal birth	Observation; treat jaundice if develops
Subgaleal hemorrhage/hematoma	Hemorrhage into subgaleal space	Rapid volume resuscitation; monitoring; rare need for surgical evacuation
Macrocephaly (head size >97%)	May be normal; hydrocephalus; genetic and metabolic disorders	Check for neurologic impairment; consider ultrasonography or head magnetic resonance imaging (MRI)
Microcephaly (head size <3%)	Cerebral dysgenesis; prenatal insults; other syndromes; familial	MRI, maternal phenylalanine level, viral studies
Large fontanels	Skeletal disorders; chromosomal anomalies; hypothyroidism; high intracranial pressure	Check for neurologic impairments; obtain thyroid function tests
Small fontanels	Hyperthyroidism; microcephaly; craniosynostosis	Check for neurologic impairments; consider head imaging
Craniotabes (softening of cranial bones giving a "ping-pong ball" sensation)	Prematurity; if local, benign bone demineralization; if generalized, syphilis or osteogenesis imperfecta	Should recalcify and harden over 3 months. If persists, screen for syphilis and check for blue sclera and fractures
Eyes		
Abnormal red reflex ("white pupil")	50% of patients have cataracts, must rule out retinoblastoma	Ophthalmologic evaluation
Nasolacrimal duct obstruction (6% of newborns; overflow tearing or mucopurulent drainage; erythema)	Incomplete canalization of duct with residual membrane near nasal cavity; 96% resolve spontaneously by 1 year	Nasolacrimal massage tid; topical antibiotics for mucopurulent drainage; surgery at 9–12 months, earlier if severe
Ears		
Any significant ear anomaly and preauricular pits/fistulas		Check for hearing impairment
Mouth/palate		
Long philtrum; thin upper lip; small jaw; large tongue	Fetal alcohol syndrome; other genetic syndromes	Check for genetic abnormalities; maternal alcohol use
Epstein's pearls (2–3 mm white papules on the gums or palate)	Keratogenous cysts	Spontaneous resolution in weeks; reassurance
Short lingual frenulum ("tongue-tie")	Normal	Clip if feeding impaired; tip of tongue notches when extruded or cannot touch upper gums
Cleft lip or palate	Isolated variant; some genetic anomalies	Feeding assessment; lip repair usually at 3 months (exact timing varies per patient, surgeon will advise based on individualized plan), palate by 1 year; revision of repair at 4–5 years; speech therapy

(continued)

www.konkur.in

Table 1 (continued)

Abnormality	Causes	Evaluation/treatment
Neck		
Fistulas, sinuses, or cysts midline or anterior to the sternocleidomastoid (SCM); may retract with swallow	Branchial cleft anomalies; thyroglossal duct cysts	Nonemergent surgical referral
Cystic hygroma (soft mass of variable size in the neck or axilla)	Dilated lymphatic spaces (failure of drainage into jugular vein)	Semiurgent surgical referral as lesion can expand rapidly; consider karyotype
Congenital torticollis (tilting of the infant's head due to SCM spasm)	Usually an isolated neurologic defect from traumatic delivery; appears at 2 weeks	Early physical therapy usually successful in 2–3 months; orthopedic referral if persists
Skin		
Umbilical cord granuloma	Vascular, red/pink granulation tissue after cord separation	Apply silver nitrate one to three times protecting surrounding skin; excise if persists
Pustular melanosis	Erythematous maculopapulo-pustular rash of face and trunk, unclear etiology	Observation
Café-au-lait spots (flat, light brown macules; usually <2 cm)	Consider neurofibromatosis if more than four spots larger than 5 mm	No treatment if few in number
Hemangiomas (often raised, red, vascular nodules, deeper lesions appear blue; usually <4 cm; onset during first 3–4 weeks, increases over 6–12 months)	Multiple lesions suggest possible dissemination involving internal organs	Most involute and disappear by 5 years of age; observe without treatment unless involving vital structures (may give propranolol in these cases), ulceration, or infection; evaluate further if multiple
Mongolian spots (gray-blue plaques, up to several centimeters, often lumbosacral, may appear elsewhere)	Hyperpigmentation, seen in up to 70% of nonwhite infants	Benign; most fade over first year; document location since sometimes confused with abuse during infancy
Nevi (variably sized light to dark congenital; brown macules; some others appear later during infancy)	Congenital giant (>20 cm) may undergo malignant degeneration	No treatment needed, although some advise removal of congenital nevi at puberty; refer giant nevi for evaluation
Petechiae (normal only on head or upper body after vaginal births)	Infection or hematologic problem if abnormal	If abnormal, check CBC and look for signs of TORCH syndrome
Port-wine stains (permanent vascular macules)	Possible associated ocular or central nervous system (CNS) abnormalities	Cosmetic problem only, unless other abnormalities found
Subcutaneous fat necrosis (hard, purplish, defined areas on cheeks, back, buttocks, arms, or thighs, appearing during the first week)	Necrosis of fat from trauma or asphyxia	Spontaneous resolution over several weeks; rare complication of fluctuance or ulceration
Abdomen/gastrointestinal		
Mass	Genitourinary (GU) in 50% (either kidney or bladder), can be GI origin as well	Emergent ultrasound (US) of urinary tract
Single umbilical artery	2–4% have other congenital defects, especially cardiac and renal	Careful clinical exam for other defects, consider renal ultrasonography
Delayed passage of meconium (99% of healthy term neonates pass meconium within 24 h)	Small bowel obstruction with bilious vomiting (atresias, malrotations, meconium ileus) or large bowel obstruction (Hirschsprung's, anorectal atresias, meconium plug syndrome)	Anal inspection and rectal exam; if distended, abdominal X-ray and consider contrast enema, rectal biopsy; vomiting, bilious emesis, or distention requires rapid surgical evaluation

(continued)

Telegram: @medical_k

www.konkur.in

Table 1 (continued)

Abnormality	Causes	Evaluation/treatment
Intestinal atresia (bilious vomiting with variable degrees of distention)	If duodenal, resorption of lumen occurred. If jejunoileal, mesenteric vascular injury	Replogle tube to low intermittent suction, lab, abdominal X-ray; contrast enema; surgery
Meconium ileus (distended at birth, X-ray with distended loops and bubbly picture of air/stool in right lower quadrant; absent air/fluid levels)	Abnormal meconium trapping resulting in small bowel obstruction; often associated with cystic fibrosis; may be associated with small for gestational age/intrauterine growth restriction	Abdominal X-ray; consider gastrografin enema (successful in two thirds), otherwise surgery; consider referral to a pediatric pulmonologist, check sweat chloride test or newborn screening result
Meconium plug syndrome (most common distal obstruction)	Inspissated colorectal meconium; diffuse gaseous distention of intestinal loops on X-ray; no air fluid levels	Abdominal X-ray; contrast enema is diagnostic and often therapeutic; search for other causes if symptoms continue
Genitourinary tract		
Ambiguous genitalia (if gonads are palpable, likely to be male)	Virilization of genetic female (esp. congenital 21-hydroxylase deficiency) or undermasculinized male	Obtain blood for chromosomal analysis, may consider buccal smear and 17α-hydroxy-progesterone; withhold diagnosis of sex until karyotype complete
Hypospadias (urethral opening proximal to tip of glans; may be associated chordee: abnormal penile curvature)	Isolated defect unless other GU anomalies present; 10–15% have first-degree relative with hypospadias	Avoid circumcision; repair 6–12 months of age by experienced surgeon; check for cryptorchidism and hernia; siblings at increased risk
Cryptorchidism (failure of testicular descent; 20% bilateral; long-term complications of infertility and cancer if left untreated)	May be normal: seen in 30% of preterm, 4% of term; if bilateral, consider ambiguous genitalia; if hypospadias and bilateral, consider urologic or endocrine problems	Observe for descent by 6 months; if not, treatment by 1 year of age; if bilateral, obtain karyotype; if also hypospadias, do full urologic and endocrine evaluation
Hydrocele (scrotal swelling that transilluminates but does not reduce during the exam)	Persistence of processus vaginalis distally without communication to the abdominal cavity	If no hernia, most spontaneously resolve in 3–12 months; prompt surgical referral if hernia or increasing size; persistence beyond 1 year makes hernia likely
Inguinal hernia (inguinal bulge that extends toward or into the scrotum; larger with crying or straining)	Processus vaginalis persists and communicates with abdominal cavity	If reducible, prompt referral for surgery to avoid incarceration; if irreducible, emergent referral
Testicular torsion	Idiopathic	Emergent evaluation with ultrasonography and surgery
Musculoskeletal		
Syndactyly (fusion of two or more digits)	Sporadic or autosomal dominant	Depending on site, surgery between 6 and 18 months of age
Polydactyly (more than five digits)	Sporadic or autosomal dominant	If no cartilage/bone, remove early, otherwise referral to plastic surgery for evaluation and removal
Metatarsus adductus (forefoot supinated and adducted; may be flexible or rigid; ankle range of motion must be normal)	Hereditary "tendency," but often due to uterine crowding; 10% association with hip dysplasia, requires careful exam	If flexible and overcorrects into abduction, no treatment; if corrects only to neutral, use corrective shoe for 4–6 weeks and reassess; if rigid, needs early casting
Talipes equinovarus (clubfoot; variably rigid foot, calf atrophy, hypoplasia of tibia, fibula, and foot bones)	Multifactorial with autosomal dominant component; 3% risk in sibs and 20–30% for offspring of affected parent	Anteroposterior (AP) and stress dorsiflexion lateral X-ray; early serial casting; if persists, surgery by 6–12 months (90% success rate)

Table 1 (continued)

Abnormality	Causes	Evaluation/treatment
Nervous system		
Spina bifida occulta (spinal defect with cutaneous signs: patch of abnormal hair, dimple, lipoma, hemangioma)	Nonfusion of posterior arches of spine; may be tethering of cord or sinus to spinal space with risk of infection; clinical exam for other defects	Examine for neurologic deficits; US to document defect if cutaneous signs; nonemergent referral to neurosurgeon if dermal sinus or tethering suspected; prompt referral if deficits present

Reprinted by permission from Springer Nature: Problems of the Newborn and Infant by Scott G. Hartman, Alice Taylor (2015)

Guidelines for Early Hospital Discharge of the Newborn

Hospital stays should be long enough to identify early problems and ensure the family is ready to care for the infant at home. Most states recommend and require insurance coverage for a hospital stay up to 48 h for a vaginal delivery and up to 96 h for a cesarean delivery.

Many factors should be included when evaluating a newborn for discharge to home from a maternity facility. These include the following: no significant abnormalities noted on exam, vital signs normal for 12 h prior to discharge, urination and passage of at least one stool, two successful consecutive feeds, no clinically significant hyperbilirubinemia, and adequate follow-up arrangements have been made, either within 24–48 h from hospital discharge or by the 3rd to 5th day of life depending on assessment of risk or need. In addition, the newborn should have been adequately monitored for sepsis; maternal screening labs were within normal limits or addressed; hepatitis B vaccine has been administered (along with hepatitis B immune globulin if the mother is hepatitis B surface antigen positive); newborn metabolic, hearing, and congenital heart screens have been completed; the mother's ability to care for infant was assessed; family and home situation is deemed safe for the infant; follow-up for the infant has been established; and, finally, both the pediatrician and obstetrician agree with the discharge plan [24].

Well-Child Visits

Well-child visits are an important time for the provider to establish relationships with both the family and patient. It is a time for anticipatory guidance, answering parental concerns and delivering patient care, including screenings and immunizations. Each visit also includes an age-appropriate physical exam, growth parameter assessment using the WHO growth standards for infants, nutritional assessment, standardized screening, developmental milestone assessment, and anticipatory guidance. These visits begin 2–3 days after hospital discharge and continue at 1–2 weeks of age and then at 1, 2, 4, 6, 9, and 12 months of age. The full schedule can be found online from the AAP [25], and further information is present in ▶ Chap. 6, "Clinical Prevention."

Nutrition and Feeding

Breastfeeding

The AAP recommends exclusive breastfeeding for about the first 6 months of life as well as continued breastfeeding in addition to complementary solid foods for a minimum of 1 year, or as long thereafter as mother and infant mutually desire to continue breastfeeding [11]. The American Academy of Family Physicians indicates that health outcomes for mothers and babies are best when breastfeeding continues for at least 2 years [26]. The role of the physician is to encourage

Telegram: @medical_k

www.konkur.in

mother and family to pursue breastfeeding the infant if no medical contraindications exist and to provide information on benefits and risks compared to formula feeding.

The benefits of breastfeeding include immunologic protection for the infant, development of optimal intestinal microbiota, and optimization of attachment between mother and infant. Breastfeeding is associated with lower rates of acute otitis media, lower respiratory tract infections, gastrointestinal infections, NEC, sudden infant death syndrome (SIDS), asthma, and obesity in children [11]. Maternal benefits of breastfeeding include reduced risks of type 2 diabetes mellitus and hypertension, as well as breast, ovarian, and endometrial cancers [27].

The primary care physician's role in encouraging exclusive breastfeeding is extremely important and ideally should begin prenatally. Physicians should encourage implementation of optimal maternity care practices to support breastfeeding mothers and newborns in the delivery facility and in office practices. All staff should be trained about breastfeeding so they can provide evidence-based guidance and support. Likelihood of breastfeeding success improves with ensuring immediate skin-to-skin contact and initiation of feeding within the first hour of life. Providers and other health-care staff should observe mothers when breastfeeding and help them modify techniques if difficulties occur. Trained lactation specialists may be helpful in these situations. Newborns should practice rooming-in throughout the hospital stay. Formula should be provided only if medically indicated. Infant formula samples should not be provided at hospital discharge or in the office. Educational materials should not promote commercial infant formula [11].

There are very few absolute contraindications to breastfeeding. These include infants with galactosemia and mothers with active herpes lesions on the breasts, who are HIV or HTLV-1 or HTLV-2 positive, and/or who are using illicit substances. Mothers with untreated tuberculosis should avoid direct contact with the infant but may express milk for feeding until the mother has initiated treatment and has negative sputum cultures [11]. With emerging pathogens, the AAP Committee on Infectious Diseases and the CDC issue guidance regarding the risks and benefits of breastfeeding. All mothers should be up to date on immunizations to confer passive immunity to the infant.

Vitamin D Supplementation

Vitamin D is important for newborns and infants, and a deficiency is associated with rickets and other metabolic problems. Newborns and infants should receive 400 IU of vitamin D each day [28]. Either breastfed infants should be supplemented with 400 IU beginning at hospital discharge [28], or alternatively, maternal intake of 6400 IU of vitamin D daily will raise levels of vitamin D in breast milk to a sufficient level for the infant [29].

Infant Formula

After informing mothers about the benefits of breastfeeding, the families' infant feeding decision should be respected and supported. Providers should avoid appearing judgmental if the mother chooses to feed infant formula. A standard commercially available bovine-based infant formula is most commonly used and tolerated well by most infants. Alternative formulas can be considered in special circumstances. When bottle feeding is chosen, counsel mothers and monitor for the common tendency to overfeed the infant.

Advancing the Infant Diet

For the first 12 months of life, infants should continue to receive human milk or infant formula. Introducing cow's milk earlier increases the risk of iron deficiency anemia and occult gastrointestinal bleeding [30]. At 12 months, infants may continue breastfeeding or replace infant formula with either whole or 2% milk, switching to 1% or skim milk by age 2. Toddler formulas are not recommended.

Telegram: @medical_k

www.konkur.in

Complementary solids may be added to breast milk or formula when the infant (1) exhibits good head control when sitting, (2) is able to sit up with minimal assistance, (3) shows interest in food such as opening the mouth in response to seeing the spoon coming close, and (4) can indicate fullness or refusal by turning the head. Typically, these developmental milestones appear between 4 and 6 months of age. In general, introduction of solids should begin at about 6 months of age from nutritional and developmental standpoints. Families gradually can introduce the older infant to pureed or finely minced foods that the family enjoys. Excessive salt, sugar, and less healthy fats should be avoided.

For infants at high risk of peanut allergy, peanut protein should be introduced before 6 months of age, as it has been shown to reduce the incidence of peanut allergy [31]. Fruit juice should be avoided in infants under the age of 12 months. Between 1 and 3 years of age, the recommendation is no more than 4 oz of juice and only from a cup, not a bottle [32]. Water should be encouraged as the beverage of choice.

Infant Colic

Approximately 10–26% of infants will experience colic. It is described as crying without an etiology for >3 h/day, >3 weeks in duration, beginning before the third week of life. Colic peaks at 6 weeks and tends to resolve by about 3 months of age. The diagnosis is made by taking a good history and performing a complete physical examination. Differentials to consider include constipation, gastroesophageal reflux disease, feeding disorders, acute abdominal pain, occult fracture, and drug withdrawal syndromes [33].

There is no definitive treatment for colic. First-line therapy is parental reassurance and behavioral interventions. Such interventions include sucking, effective swaddling, gentle rocking, and decreased stimulation of the infant. Simethicone is not effective in the treatment of colic. Soy, iron-free, or lactose-free formulas have not been shown to improve colic [33].

Failure to Thrive

Failure to thrive (FTT) occurs when a child receives inadequate nutrition for optimal growth and development, manifested by weight less than third or fifth percentile for age on more than one consecutive occasion, weight dropping down two major percentile lines on the growth chart, weight <80% of the ideal weight for age, and/or the child less than the third or fifth percentile on weight-for-length curves. Infants with intrauterine growth restriction are known to be at risk for subsequent failure to thrive [34]. Three major categories that cause FTT are inadequate intake, malabsorption or excessive gastrointestinal losses, or increased metabolic demand.

Examples of inadequate intake include not enough food being offered, or the child not taking enough food secondary to oral motor dysfunction, developmental delay, or another feeding disorder. Emesis secondary to gastroesophageal reflux or increased intracranial pressure can also result in FTT. Common causes of malabsorption associated with FTT include cystic fibrosis, celiac disease, or food protein intolerance. These may manifest as frequent, loose stools or frank diarrhea. Examples of increased metabolic demand include insulin resistance, congenital infections, certain syndromes (Turner, Down), or chronic diseases (cardiac, renal, endocrine).

Initial workup includes an accurate history of nutritional intake using a 3-day food diary, ideally in consultation with a nutritionist. Laboratory evaluation includes a CBC, complete chemistry panel, celiac screening, stool examination for fats and reducing substances, and a sweat chloride test. In cases of severe malnutrition, the child may need to be admitted to the hospital for evaluation and treatment [34]. All children should be screened for eligibility for nutritional assistance from the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) up to 5 years of age. Pregnant and breastfeeding women also are eligible for WIC benefits.

Fever

Self-limited viral infections are the most common cause of fevers in infant. The younger the infant, the greater concern for the potential of a serious infection with a fever. Infants <3 months of age with no obvious source of fever have an 8.5% risk of having a serious bacterial infection (SBI). Serious bacterial infections include conditions such as sepsis, pneumonia, pyelonephritis, and meningitis that can be life-threatening. The provider must have a reliable system to identify those at risk for a SBI [35].

Neonates (0–28 Days)

A neonate with a rectal temperature of 38 °C or 100.4 °F should be considered a relative emergency and prompt a full evaluation for SBI. Laboratory testing should include CBC with differential, cerebrospinal fluid (CSF), blood, and urine cultures. Admission for empiric intravenous antibiotics is ensured until cultures are negative, or for a full antibiotic course if indicated from laboratory results or patient symptoms.

Ill-Appearing Infants (29–90 Days)

12.8% of ill-appearing febrile young infants may have an SBI. Therefore, these infants should also have CSF, blood, and urine cultures drawn and be admitted for empiric intravenous antibiotics.

Well-Appearing Infants (29–60 Days)

Infants with fever at this age still require laboratory screening for SBI. Generally, evaluation should include a CBC, as well as blood and urine cultures. If the infant is well-appearing, there is low suspicion of an SBI on initial exam, and good outpatient follow-up is available, then it is not necessary to admit these patients.

Infants 61–90 Days Old

If the infant is well-appearing, then the basics of CBC, blood, and urine cultures are obtained with outpatient follow-up. If the infant is ill-appearing and suspicion for SBI is high, then a full evaluation for sepsis and empiric antibiotics with admission to the hospital is warranted.

Infants 3–36 Months Old

For infants with fevers less than 39 °C in this age range, a SBI is less likely. If there are multiple days of high fevers, worsening clinical picture, and no source of infection identified during a careful physical examination, then a CBC is warranted. If it is normal, the infant can be observed closely, but if abnormal, consideration should be given to further workup with blood and urine cultures. Most children with fevers at this age have a viral infection. Otitis media may be seen on examination, especially if symptoms of a preceding upper respiratory tract infection were present.

Sudden Infant Death Syndrome

SIDS, also described as sudden unexpected infant death, is the second leading cause of infant mortality between 1 month and 1 year of age in the United States. SIDS is defined as a sudden, unexpected death before 12 months of age that occurs in a previously healthy infant, in which case the cause of death remains unknown despite a thorough case investigation, including a complete autopsy, death scene investigation, and analysis of clinical history. Each year, 2300 infants die from SIDS in the United States, and the rate peaks between 3 and 5 months of age. Since the "Back to Sleep" campaign was initiated in 1994, the incidence of SIDS has declined between 30% and 50%.

Risk factors include maternal, infant, and environmental factors. Maternal factors include young age, maternal smoking during and after pregnancy, and limited or no prenatal care.

Telegram: @medical_k

www.konkur.in

Infant risk factors include preterm birth and/or low birth weight and male gender. Environmental factors include prone sleeping, sleeping on a soft surface and/or excessive bedding and pillows, co-sleeping, crib bumpers, entrapment when sleeping on couches or chairs, and overheating.

Sleep positioning has been found to be the strongest modifiable risk factor for SIDS, with supine sleeping recommended. Other factors that decrease risk of SIDS include breastfeeding and the use of pacifiers. Apnea monitors are not recommended as they have not been shown to reduce the risk of SIDS. It is important to educate parents in a nonjudgmental way and to reaffirm safe sleep recommendations at every visit during the infant's first year of life. Ideally, the infant should sleep on their own firm sleep surface in the parent room [36, 37].

Brief Resolved Unexplained Event

A brief resolved unexplained event (BRUE) is defined as an event occurring in infants younger than 12 months of age. These episodes previously had been referred to as "Apparent Life Threatening Events" (ALTE). The episodes are described by the observer as brief, resolved, and with a reassuring history, physical exam, and vital signs at the time of clinical evaluation by trained medical providers. "Brief" indicates that the episode lasts less than 1 min, but more often is <20–30 s, and "resolved" refers to the patient being back to baseline after the event.

There are four characteristics that can be described by an observer for a BRUE, and at least one must be described in order to call the event a BRUE: (1) cyanosis or pallor; (2) absent, decreased, or irregular breathing; (3) marked change in tone; and/or (4) altered level of responsiveness. If a patient is found to have an alternate diagnosis, such as reflux or seizures, then a BRUE is not diagnosed. Evaluation and management is focused on the presumed diagnosis.

BRUE cases that are classified as being at lower risk for serious outcomes include infants greater than 60 days old, those born at greater than 32 weeks of gestational age, and those born with no concerning findings during history and exam, such as evidence of abuse or trauma. These infants typically do not need admission. Higher-risk BRUE is defined as any patient that falls outside of the lower-risk definition. Admission should be determined by the provider on an individual basis [37].

Other Common Problems of the Infant

Table 2 provides a brief synopsis of additional common problems of infancy encountered by the primary care physician.

Family and Community Issues

Perinatal Depression

Perinatal depression, also known as perinatal mood disorder, is defined as an episode of major depressed mood and neurovegetative symptoms such as alterations in sleep and appetite during pregnancy or after delivery. It can affect up to 20% of new mothers.

There are many long-lasting and sometimes permanent consequences from untreated depression, such as deterioration of social networks and partner relationships, poor family functioning, increased risk of child abuse and neglect, delayed infant development, and challenges with breastfeeding. Children can develop physical, emotional, cognitive, and social problems.

One assessment used to screen for perinatal depression is the Edinburgh Postnatal Depression Scale. Mothers are comfortable being screened for depression, but a large percentage do not openly speak to health-care professionals about their symptoms. Screening for postpartum depression is recommended during well-child visits at 1, 2, 4, and 6 months, with referral as appropriate for those with positive screens [38].

www.konkur.in

Table 2 Approaches to common problems of the infant. Recommend consulting pediatric formulary (e.g., Harriet Lane Handbook) for current drug doses

HEENT (head, ears, eyes, nose, and throat)
Thrush (pearly white pseudomembranes on the oral mucosa). Causes: transmission from vaginal mucosa during delivery; contaminated fomites (nipples, both breast and bottle; toys; teething rings). Rx: clean fomites (boil bottle nipples, toys); oral nystatin, 200,000–500,000 U q4–6 h until clear for 48 h
Nasolacrimal duct obstruction (see Table 1). Symptoms usually delayed until days to weeks after birth. Rx: nasolacrimal massage three to four times per day with clean hands and cleansing of eyelids with warm water; topical antibiotics (sulfacetamide or gentamicin drops) for secondary conjunctivitis
Strabismus (misalignment of eyes). Screen with corneal light reflex and cover test. Rx: ophthalmology referral for persistent deviation greater than several weeks or any deviation >4 months of age
Hearing loss. Universal screening recommended after delivery by American Academy of Pediatrics Risk factors include family history; congenital infection; craniofacial abnormalities; birth weight < 1500 g; hyperbilirubinemia requiring exchange transfusion; severe depression at birth; bacterial meningitis. Screening: otoacoustic emissions testing or auditory brainstem response. Treatment by 6 months can greatly improve future language development. Infants not passing should have an audiologic evaluation by 3 months (or by 6 weeks if CMV is the potential etiology)
Teething (painful gums secondary to eruption of teeth with irritability, drooling). Fever is not caused by teething. Rx: chewing on soft cloth, teething ring; systemic analgesia
Skin problems
Circumcision. Elective procedure performed only on healthy, stable newborns using a penile block. Contraindicated if any genital abnormalities. Advantages: decreased incidence of phimosis, urinary tract infection, and penile cancer (later in life). Risks: hemorrhage; sepsis; amputation; urethral injury; removal of excessive foreskin with painful scarring
Diaper dermatitis (erythematous, scaly eruptions that may advance to papulovesicular lesions or erosions; may be patchy or confluent; genitocrural folds often spared). Due to reaction to overhydration of skin, friction, and/or prolonged contact with urine, feces, chemicals such as in diapers and soaps. Rx: frequent changing of diapers; exposure to air; bland, protective topical ointment (petrolatum, zinc oxide) after each diaper change; advanced cases may require 1% hydrocortisone ointment
Candidal superinfection (pronounced erythema with sharp margins, satellite lesions, involvement of genitocrural folds). Rx: topical antifungal; treat associated oral candidiasis
Milia (superficial 1–2 mm inclusion cysts). Common on face and gingiva. Requires no Rx
Miliaria (clear or erythematous papulovesicles in response to heat or overdressing; especially in flexural areas). Resolves with cooling
Seborrheic dermatitis (most commonly greasy yellow scaling of scalp or dry white scaling of inguinal regions; may be more extensive). Rx: generally clears spontaneously; may require 1% hydrocortisone cream; mild antiseborrheic shampoos for scalp lesions; mineral oil with gentle brushing after 10 min for thick scalp crusts
Atopic dermatitis (intensely pruritic, dry, scaly, erythematous patches). Acute lesions may weep. Typically involves face, neck, hands, abdomen, and extensor surfaces of extremities. Genetic propensity with frequent subsequent development of allergic rhinitis and asthma. Consider evaluation for food and other allergens. Rx: mainstay is avoidance of irritants (temperature and humidity extremes, foods, chemicals) and drying of the skin (frequent bathing, soaps) with frequent application of lubricants (apply to damp skin after bathing); severe disease usually requires topical steroids; acute lesions may require 1:20 Burrow's solution and antihistamines (diphenhydramine, hydroxyzine)
Heart murmur
Innocent or functional (typically diminished with decreased cardiac output)
Newborn murmur. Onset within first few days of life that resolves by 2–3 weeks of age. Typically soft, short, vibratory, grade I–II/V early systolic murmur located at lower left sternal border that subsides with mild abdominal pressure
Still's murmur. Most common murmur of early childhood. May start in infancy. Typically loudest midway between apex and left sternal border. Musical or vibratory, grade I–III early systolic murmur
Pulmonary outflow ejection murmur. May be heard throughout childhood. Typically soft, short, systolic ejection murmur, grade I–II, and localized to upper left sternal border
Hemic murmur. Heard with increased cardiac output (fever, anemia, stress). Typically grade I–II high-pitched systolic ejection murmur heard best in aortic/pulmonic areas
Pathologic or organic murmurs. Any diastolic murmur. Consider when a systolic murmur has one or more of the following: grade III or louder, persistent through much of systole, presence of a thrill, single second heart sound (most important finding), abnormal quality of second heart sounds (loud, "click"), or a gallop. Other ominous signs:

(continued)

Telegram: @medical_k

www.konkur.in

Table 2 (continued)

congestive heart failure, cyanosis, tachycardia. Evaluation: chest X-ray (CXR), electrocardiogram (ECG), consider arterial blood gas, and if persistent or any distress then cardiology consult
Gastrointestinal
Constipation (intestinal dysfunction in which the bowels are difficult or painful to evacuate). Associated failure to thrive, vomiting, moderate to tense abdominal distention, or blood without anal fissures requires ruling out organic disease (Hirschsprung's, celiac disease, hypothyroidism, structural defects, lead toxicity). Common causes are anal fissures, undernutrition, dehydration, excessive milk intake, and lack of bulk. Less common with breastfeeding. Rarely caused by iron-fortified cereals. Rx: in early infancy increase amount of fluid or add sugars (Maltsupex); later add juices (prune, apple) and other fruits, cereals, and vegetables; may add further artificial fiber (psyllium); severe disease may require use of polyethylene glycol electrolyte solutions (dose varies according to situation) and brief use of milk of magnesia (1–2 tsp.), docusate sodium, and glycerin suppositories and when persistent requires ruling out of organic disease
Gastroesophageal reflux (GERD). Vomiting noted in 95% of infants within the first 6 weeks, resolving in 60% by age 2. Important to distinguish "spitting up" from true GERD. Spitting up is not associated with significant weight loss, breast milk or formula intolerance, or other warning signs. GERD may be associated with growth delay, esophagitis, hemoccult positive stool, chronic cough, and wheezing. Consider cow's milk allergy. Dx: mild cases confirmed by history and therapeutic trial. If more severe, esophageal pH probe and barium fluoroscopic esophagography. Endoscopy if esophagitis is suspected. Rx: elevate head of bed for older infants. Consider thickened feedings with cereal. Refer with persistent severe symptoms
Pyloric stenosis (nonbilious vomiting immediately after feeding becoming progressively more projectile). 4:1 male/female preponderance. Onset 1 week to 5 months after birth (typically 3 weeks). More common in males. May be intermittent. Dx: palpation of pyloric mass (typically 2 cm in length, olive shaped) that may be easier to palpate after vomiting; ultrasound is preferred method to confirm difficult cases (90% sensitivity). Rx: surgery after rehydration
Anemia
Improved nutrition has reduced incidence, but infants remain at significant risk. Additional risk factors: low socioeconomic status, significant maternal anemia, consumption of cow's milk prior to age 6 months, use of human milk substitute that is not iron fortified, low birth weight, prematurity. Effects: fatigue, apathy, impairment of growth, and decreased resistance to infection. Causes: iron deficiency most common (usually sufficient birth stores to prevent occurrence prior to age 4 months), sickle cell disease, thalassemia, lead toxicity. Screening: hemoglobin (Hgb) or hematocrit (Hct) at age 12 months (some recommend only for infants with risk factors). Rx: if microcytic give trial of iron (elemental iron, Feosol, 3–6 mg/kg/day); if not microcytic or unresponsive to iron, consider other causes (family history, environment)
Sleep disturbances
Seventy percent of infants can sleep 5 or more hours of the night by age 3 months. Most 6-month-olds no longer require nighttime feeding. Screening: a sudden change in sleeping pattern should prompt a search for new stresses, physical (infection, esophageal reflux, etc.) or emotional (new surroundings or household members, etc.). Rx: establish realistic parental expectations (consider the natural sleeping patterns of the infant); allow the infant awakening at night to learn how to fall asleep by himself (keep bedtime rituals simple and put the infant in his bed awake; do not respond to infant's first cry; keep interactions during the night short and simple; provide a security object for older infants); slowly change undesirable sleeping patterns (move bedtime hour up and awaken infant earlier in the morning; decrease daytime napping)

Child Care

Many young children spend time in child care. It is recommended that all children and providers be up to date on immunizations to reduce the risk of transmissible infections [25]. On average, children get between 8 and 12 viral infections in the first year of child care. That number typically decreases in the second year due to exposure and subsequent immunity [39]. Parents should interview caregivers to make sure that the values and child-rearing philosophies are consistent with their own and that their child will be in a safe environment.

Family Violence

Family violence is defined as acts of violence that occur among family members such as partners,

Telegram: @medical_k

www.konkur.in

siblings, caregivers, and children. Child maltreatment is more common when the mother's partner is not the child's biological father.

Children who are exposed to violence have a range of physical and behavioral health problems. They have a higher likelihood of school and learning difficulties, drug and alcohol use, engaging in prostitution, committing sexual assault, running away from home, and attempting suicide. Children exposed to violence also are more likely to engage in violent behavior themselves. Family violence is only one type of adverse childhood experience with long-lasting consequences.

Screening questions include (1) has your partner ever injured or threatened to injure your children, (2) are you an equal partner when it comes to making important decisions that affect your family, and (3) what happens when you and your partner have a disagreement [40].

Substance-Exposed Infants

Children of substance-using parents are at increased risk for suffering abuse and neglect. Up to one in five children grows up in a home in which someone abuses drugs or alcohol. Almost 25% of these children do not receive routine health maintenance in the first 2 years of life.

Approximately 32,000 infants born annually in the United States are diagnosed with neonatal abstinence syndrome. This number represents a fivefold increase in recent years and is associated with a significant increase in the cost of health care [41]. Symptoms of prenatal opioid use may manifest in infants as sweating, irritability, increased muscle tone, feeding problems, and seizures as a result of opioid withdrawal. Fetal alcohol exposure can cause prematurity and low birth weight as well as affect growth, cognition, behavior, language, and achievement. Management of substance-exposed neonates should include consultation with neonatal specialists and team-based care and support, as well as referral for appropriate developmental follow-up. The primary care provider may assist families by providing access to resources and should report families to the appropriate authorities if child maltreatment is suspected [42].

Adolescent Parents

Many adolescent mothers have medical and psychosocial risks. Medical complications include poor maternal weight gain, anemia, and pregnancy-induced hypertension. Psychosocial risks include violence during pregnancy, poorer educational outcomes, and future economic difficulties. Factors that improve outcomes for adolescent mothers include actively participating in a program for teenage mothers, remaining in school, and avoiding social isolation [43].

Medical complications of infants born to adolescent mothers include higher incidence of perinatal mortality, low birth weight, preterm birth, developmental disabilities, and poorer developmental outcomes. The role of the primary care physician should be to maintain continuity with the adolescent mothers and care for their children, if possible. They should encourage use of community resources to teach young parents the basic caregiving skills they need and ensure they provide a safe environment for a child. Discussing contraception and prevention of sexually transmitted infections with adolescent parents is also important [43].

Introduction

Infectious diseases are one of the most frequent reasons for pediatric consultations. Although mortality and morbidity from infectious diseases have dramatically declined in recent years, infections among children remain important.

Like many other diseases in children, the complications of the disease such as dehydration might be the primary focus of management rather than treating the causative agent, as many infectious diseases in children are self-limiting.

This chapter will discuss some of the more prevalent infectious diseases in children in addition to some that are less common but should not be missed.

Common Cold

General Principles

Definition/Background

The common cold is an acute, self-limiting viral infection of the upper respiratory tract characterized by variable degrees of sneezing, nasal congestion and rhinorrhea, sore throat, cough, low grade fever, headache, and malaise [1].

Epidemiology

The common cold is the most common infectious disease among children. A healthy child may develop upper respiratory tract infections (URTI) six to eight times per year [2]. Infants and children may experience more prolonged symptoms than adults. Common colds are most commonly caused by rhinovirus, which accounts for about 60% of infections. Other causes include parainfluenza, respiratory syncytial virus, coronavirus, adenovirus, echovirus, coxsackievirus, and parainfluenza virus [3].

Approach to the Patient Diagnosis, History, and Physical Examination

The diagnosis of the common cold is based on symptoms. Symptoms usually peak on day 2–3 of the illness and gradually improve over the next 10–14 days. An associated cough may linger in a minority of children but typically resolves over 3–4 weeks [1, 4]. Fever is uncommon, although temperatures of up to 39 °C may occur in younger children. A red nose with a profuse nasal discharge may be present. The discharge can be clear and watery or mucopurulent (yellow or green). Purulent secretions are more common after the first few days of illness.

Differential Diagnosis

The common cold should be distinguished from allergic rhinitis, isolated pharyngitis, acute bronchitis, influenza, bacterial sinusitis, or pertussis [5].

Treatment

Current guidelines on the treatment and management of respiratory tract infections (RTIs) in children emphasize supportive management. This includes hydration, nasal suction, saline nasal drops, spray, or irrigation. A cool mist humidifier may be helpful. Parents may give acetaminophen to children older than 3 months or ibuprofen to children older than 6 months to treat the discomfort associated with any fever. Over-the counter (OTC) medications such as cough medications or antihistamines are not recommended for young children. As most RTIs are caused by viruses, antibiotics should only be prescribed if an RTI is suspected to be of bacterial origin.

Zinc, vitamin C, and herbal products such as echinacea are advertised to treat or prevent the common cold. There is some evidence that prophylactic use of vitamin C may decrease the duration of the common cold in children. However, with the exception of vitamin C, none of these treatments have been proven to be effective in clinical trials and thus their use is not recommended [6].

Complications of the common cold include acute otitis media, acute bacterial sinusitis, asthma exacerbation, and lower respiratory tract disease. Re-evaluation may be warranted if the symptoms

Telegram: @medical_k

www.konkur.in

worsen (e.g., difficulty breathing or swallowing, high fever) or exceed the expected duration.

Immunizations and Chemoprophylaxis

The Centers for Disease Control and Prevention (CDC) recommends a yearly flu vaccine as the first and most important step in protecting against influenza and its potentially serious complications. All children 6 months and older should receive the influenza vaccine every year before flu activity begins in their community [7].

Prevention

The best methods for preventing transmission of the common cold are frequent hand washing and avoiding touching one's mouth, nose, and eyes. Most children with colds need not be excluded from out-of-home childcare or school because transmission is likely to have occurred before the child became symptomatic [1].

Family and Community Issues

The common cold accounts for approximately 22 million missed days of school and 20 million absences from work, including time away from work to care for ill children.

Common Pediatric Viral Exanthems

General Principles

Definition

An exanthem is a term used to describe skin lesions associated with other systemic manifestations like fever. Exanthems can be caused by infections or allergic reactions to medications or to other agents. Viral infections account for the majority of cases of exanthems in children.

Classification

Pediatric viral exanthems can be classified based on the presentation of the skin lesions, into maculopapular and vesicular rashes. Viral exanthems that manifest with a maculopapular rash include measles, rubella, roseola infantum, and erythema infectiosum. Conversely, varicella and hand-foot-and-mouth disease (HFMD) present with papulovesicular rash.

Diagnosis

History and Physical Examination

Differentiation should be based on the morphologic appearance of the lesions, their distribution and order of appearance, their relation to fever, and the presence of other associated physical findings that can be characteristic and sometimes pathognomonic for a specific viral illness. Diagnosis of pediatric viral exanthems is largely based on the clinical presentation and a good history. Laboratory evaluation is usually not necessary.

Measles

Epidemiology

Measles is a highly contagious disease caused by a paramyxovirus which carries high risk of serious complications and fatalities. Following the introduction of the measles vaccine in 1963 the disease has dramatically declined. However, provisional data from the World Health Organization (WHO) indicates that during the first 6 months of 2019 there have been more measles cases reported worldwide than in any year since 2006 [8].

Patient Approach

Clinical Presentation

Measles virus can be acquired via respiratory droplets from infected individuals. After an incubation period of 1–3 weeks, patients have a two-to-four-day prodromal phase characterized by fever, malaise, cough, coryza, conjunctivitis, and Koplik spots. These spots are pathognomonic for measles infection. They appear as

Telegram: @medical_k

www.konkur.in

small, grayish white papules in the buccal mucosa opposite to the molar teeth and have been described as "grains of salt on a red background." They can last for 12–72 h and start to disappear with the onset of a skin rash. The maculopapular rash first appears in the preauricular area then spreads centrifugally to the rest of the body. The fever usually persists for 3 days after the onset of rash. After 6–7 days the rash starts to disappear in the same order of its appearance. Infection usually results in lifelong immunity, although in rare cases reinfection may occur and present with modified measles having milder clinical manifestations.

Complications

Measles infection can be complicated by a decline in T-cell related immune response leading to an increased risk of infections during and shortly after measles infection. Common complications include gastroenteritis, otitis media, pneumonia, and other respiratory complications. Pneumonia is the most common life-threatening complication. Measles infection can also affect the central nervous system, leading to acute encephalitis, acute disseminated encephalomyelitis (ADEM), and subacute sclerosing panencephalitis (SSPE). Acute encephalitis usually occurs within a few days of the appearance of a rash and is directly due to viral infection. Conversely, ADEM is thought to be a post-infectious autoimmune response. It may also be triggered by other infectious agents, but it carries a higher mortality rate when it follows a measles infection.

SSPE manifests 7–10 years after measles infection and is characterized by progressive neurodegenerative changes. It is thought to be caused by persistent measles virus infection within the central nervous system. Measles-related complications may occur in up to 30% of cases in immunocompetent, and more frequently in immunocompromised patients, pregnant women, individuals with vitamin A deficiency, or in individuals younger than 5 years or older than 20 years [9].

Treatment

In addition to symptomatic treatment, Vitamin A administration once daily for 2 days reduces mortality and morbidity from measles. This is because vitamin A deficiency contributes to a delayed recovery and the high rate of postmeasles complications. In addition, acute vitamin A deficiency and xerophthalmia may be precipitated by measles infection [9]. Ribavirin may be considered for patients with measles-related pneumonia or patients with severe immunosuppression.

Prevention

A two-dose live attenuated measles vaccine is recommended as part of the MMR vaccine given after the child's first birthday. In addition, isolation of infected persons immediately upon making the diagnosis, and until 4 days after the onset of rash can help reduce viral transmission.

Rubella

Rubella is caused by infection by an RNA virus of the Togaviridae family. The infection is also known as "the three-day measles" or "German measles."

Epidemiology

After introduction of the rubella vaccine, there has been a significant drop in its incidence and complications. Sporadic outbreaks have been reported when vaccination rates lag.

Patient Approach

Clinical Presentation

The virus is transmitted via respiratory droplets. After an incubation period of 2–3 weeks, patients start to have mild prodromal symptoms for 1–5 days, such as a sore throat, low-grade fever, myalgias, and symmetrical posterior cervical

Telegram: @medical_k

www.konkur.in

lymphadenopathy, mainly in the postauricular and occipital regions. Then, a maculopapular skin rash starts to appear on the face and rapidly spreads in a craniocaudal manner. This rash typically lasts 3 days (thus the name "three-day measles"). However, nearly 50% of individuals are asymptomatic during infection. Arthritis or arthralgias occur in up to 70% of adolescents, particularly females.

Complications

Complications following rubella infection are infrequent. However, maternal infection during pregnancy can lead to intrauterine fetal death, preterm delivery or congenital rubella syndrome (CRS). The risk of CRS increases if maternal infection occurs early in pregnancy and is less likely if it occurs during the second half of the pregnancy. Infants with CRS can have heart defects, eye defects like congenital cataracts, neurodevelopmental disorders, and bilateral sensorineural hearing impairment.

Encephalitis can rarely follow rubella infection but is more likely to affect adults than young children. Coagulopathy leading to hemorrhagic complications tends to affect infected children more than adults [10].

Treatment and Prevention

Treatment is largely supportive as the disease usually has a mild course, especially among children. Rubella infection can be prevented by administering a live-attenuated rubella vaccine as part of the MMR vaccine given as two doses. Infected individuals are considered infectious from 7 days before the appearance of a rash to 7 days following its disappearance. Therefore, patients should be isolated for more than a week following the onset of a skin rash.

Varicella (Chickenpox)

Varicella is caused by a double stranded-DNA neurotropic virus from the Herpesviridae family. Primary infection can be followed by the dormant presence of the virus in the dorsal root ganglia of the spine which can be reactivated later in life with waning of cell-mediated immunity and manifest as a zoster infection (shingles) with its potentially incapacitating postherpetic neuralgia.

Epidemiology

Varicella occurs worldwide and, in the absence of a vaccination program, affects nearly every person by mid-adulthood. In areas with an implemented varicella vaccine programs, there have been drops in both incidence and complications. Chickenpox is considered highly contagious, with a secondary household attack rates of >90% in susceptible individuals.

Patient Approach

Clinical Presentation

The virus is acquired either via respiratory droplets or by direct contact with vesicular fluids of an affected individual. After an incubation period of 10–21 days, patients start to manifest mild prodromal symptoms like low-grade fever, malaise, and a sore throat, followed by the appearance of pruritic skin lesions within 24 h. Lesions first appear on the trunk or scalp and then spread centrifugally to the extremities. Mucous membranes in the mouth and conjunctivae can be also involved.

Lesions start as a macule that evolves into a papule and then into a vesicle filled with clear fluid, which eventually crusts. New crops of lesions continue to appear in the next few days. Thus, in the same area you can see the coexistence of papules, vesicles, and crusts at the same time, a finding characteristic of varicella. New vesicle formation generally stops within 4 days, and most lesions have fully crusted by day 6 in normal hosts [11]. After the disappearance of the crusts (usually 1–2 weeks later), they are replaced by hypopigmented macules which persist for some time.

Telegram: @medical_k

www.konkur.in

Complications

Varicella infection in immunocompetent children is considered to be a mild and self-limiting disease with a rare occurrence of serious complications. However, infants, adults, adolescents, and immunocompromised individuals are more prone to complications. The most common complication of varicella is bacterial superinfection of the lesions with invasive group A streptococcal or staphylococcal infection in the skin and subcutaneous tissue.

Pneumonia can also be a complication of varicella in adults and immunocompromised individuals. Encephalitis, aseptic meningitis, and transverse myelitis are the main neurologic complications of varicella. In addition, Reye syndrome was a complication observed among children who had been given a salicylate as an antipyretic during the infection. However, after cessation of the use of salicylates in children, it is now rarely seen.

If maternal infection occurs during pregnancy, transplacental transmission of the infection can ensue, leading to congenital varicella syndrome. This can result in low birth weight and multiple congenital abnormalities such as skin scarring, limb hypoplasia, eye abnormalities such as optic nerve atrophy and cataracts, microcephaly and mental retardation.

Treatment

In immunocompetent children, treatment is largely supportive as the infection tends to be self-limited. Acetaminophen is recommended to control fever and calamine lotion or other soothing lotions can be given to control pruritus. However, in adolescents, adults, immunocompromised patients, and children with chronic skin or lung diseases, acyclovir is indicated for 5 days starting within 24 h of rash onset to decrease the severity of symptoms and the disease duration.

Prevention

A live-attenuated vaccine for VZV has been available since 1995. It is administered as two doses at 12–15 months and at 5 years as part of the measles, mumps, rubella, and varicella (MMRV) vaccine or as a separate vaccine. Unvaccinated adolescents and adults who have no history of primary infection are advised to receive two doses of the vaccine separated by at least 28 days.

Patients are typically infectious from 48 h before the appearance of a skin rash until crusting of all the skin lesions, which usually takes place 1 week after the onset of the rash. Therefore, patients should be isolated for at least 1 week following appearance of the exanthem.

Roseola Infantum (Exanthema Subitum or Sixth Disease)

Epidemiology

This is a mild self-limiting disease caused by Human Herpes Virus 6 B (HHV6B) and less frequently by HHV6A and HHV7 viruses. It usually affects infants between 6 and 12 months of age, almost 90% of the cases are children under the age of 2. The virus is usually transmitted to the infant from a healthy asymptomatic carrier individual [12].

Patient Approach

Clinical Presentation

After an incubation period of 10–15 days, infants develop an abrupt high fever that can reach beyond 40 °C. This may last for 3–5 days, without other clear physical findings. The fever is followed by an abrupt defervescence that coincides with the development of the exanthem. During the febrile days, the infant can be active and well-appearing. Sometimes they may be irritable. Other clinical manifestations that have been reported during the febrile period include inflammation of the tympanic membranes, diarrhea, vomiting, bulging fontanelle, and an enanthem in two thirds of cases referred to as Nagayama spots, which are small red papules located on the soft palate and uvula.

Telegram: @medical_k

www.konkur.in

The skin rash that develops after the patient becomes afebrile is macular or maculopapular. It appears first on the trunk and neck and then spreads to the face and extremities. It is usually nonpruritic and lasts for 24–48 h.

Lab Investigations

Because of the lack of specific physical findings during the febrile phase, many infants undergo laboratory evaluation. Findings may include leukocytosis, leukopenia, atypical lymphocytosis, and thrombocytopenia. Pyuria can be observed, which can be confused with a urinary tract infection (UTI). However, urine culture is negative for bacterial growth.

Complications

Complications of roseola are uncommon, and most infants recover spontaneously without sequelae. However, they will continue intermittent shedding of the virus from body secretions for life. In individuals with immunocompromising conditions, reactivation of dormant HHV-6 can lead to encephalitis and cause graft-versus-host disease in liver or bone marrow transplant patients.

Treatment and Prevention

Treatment is supportive and may include antipyretics for the treatment of fever. As the transmission of HHV-6 often involves asymptomatic healthy individuals, prevention is difficult. No vaccine is available.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum (EI) is a mild self-limiting disease caused by Parvovirus B19 infection.

Epidemiology

EI mainly affects school-aged children and usually occurs in epidemics in winter and spring. Males and females are equally affected.

Patient Approach

Clinical Presentation

The virus is transmitted via respiratory droplets. After a 1–2-week incubation period, the child starts to have a nonspecific prodromal phase that manifests as fever, headache, sore throat, rhinorrhea, and arthralgia. Two to four days later, facial malar rash appears with circumoral pallor that gives patients the so-called "slapped-cheek appearance." Three to five days later a macular skin rash starts to appear on the trunk and extremities that lasts for few days and has a lacy-reticulated appearance as it starts to fade. After its resolution, the patient may experience recurrence of the rash in response to certain stimuli such as stress, exercise, and exposure to heat, a phase which can last for several weeks.

Complications

EI is mild self-limiting disease that usually resolves without complications in immunocompetent individuals. Aplastic crisis may occur in children with underlying hematologic abnormalities. Arthropathies are estimated to affect 10% of pediatric patients and up to 60% of adult patients [13].

Treatment and Prevention

Treatment is largely supportive and symptomatic. Isolation of affected individuals is not necessary as the rash is thought to be autoimmune in nature and the patient is no longer infectious when the exanthem appears.

Laryngotracheobronchitis

Definition and Background

Laryngotracheobronchitis, also known as croup, is a common viral infection affecting children under the age of 5 years. It primarily affects children between the age of 6 months and 3 years old. It is uncommonly seen among patients over 6 years of age.

Telegram: @medical_k

www.konkur.in

Epidemiology

Croup affects about 3% of children per year, and it accounts for about 7% of hospitalizations in the United States in children younger than 5 years of age. The main causative agent of croup is the parainfluenza virus (paramyxovirus family), primarily types 1 and 2, which cause 75% of cases. Other viral causes include influenza A and B, measles, adenovirus, and respiratory syncytial virus (RSV) [14]. In some circumstances, superimposed bacterial infections can follow viral croup.

Viruses causing acute infectious croup are spread through either direct inhalation from a cough and/or sneeze, or by contamination of hands from contact with fomites and subsequent touching the mucosa of the eyes, nose, and/or mouth.

Classification

Croup can be classified as mild, moderate, severe or life-threatening, according to the severity of the presenting symptoms (see Table 1). Hypoxemia is a very serious late sign and indicates life threatening croup.

Patient Approach

History

Like most other viral infections, the onset of cough and stridor is usually preceded by coryza and a low grade fever (38–39 °C) that can sometimes exceed 40 °C, and a cough. Within 1–2 days, the characteristic signs of hoarseness, barking cough, and inspiratory stridor develop, often suddenly, along with a variable degree of respiratory distress. Symptoms are perceived as worsening at night, with most emergency room visits occurring between the hours of 10 pm and 4 am. Symptoms typically resolve within 3–7 days but can last up to 2 weeks.

History of barking cough and stridor is usually gradual, with sudden increases in symptoms occurring at night. In cases of sudden onset stridor and cough, there should be consideration of the possibility of foreign body aspiration.

Physical Examination

Once croup is suspected, a physical examination should take place and should be carried out preferably while the child is calm to minimize work of breathing. The examination should start by inspecting the overall appearance of the child.

Regarding vitals, determining the respiratory rate is important, as is documenting temperature, pulse rate, and oxygenation. It is also essential to assess the hydration status of the patient, especially in infants.

Specific examinations of the respiratory system include observation of the use of accessory muscles for respiration, subcostal and intercostal retractions, and nasal flaring. The physical examination is key in the diagnosis and classification of the severity of croup and its subsequent management.

Table 1 Croup severity classification[a]

Item	Mild	Moderate	Severe
General behavior	Normal	Mild intermittent agitation	Drowsiness or severe agitation
Presence of stridor	Only with irritation or activity	Intermittent at rest	Continuous at rest
Signs of respiratory distress	None	Mild increase of accessory muscles, nasal flaring, and increased respiratory rate	Marked use of accessory muscles of respiration Increased or decreased respiratory rate (muscle fatigue)
Hypoxemia			Very late and serious sign indicates life threatening airway obstruction

[a]Adapted from several references and guidelines [17, 18]

Telegram: @medical_k

www.konkur.in

Lab and Imaging

Most of cases of croup do not require blood tests or imaging. However, in cases where the history and physical examination is not clear, or when there is a clinical suspicion of other diagnoses, neck or chest X-ray might be required. If lateral neck X-ray is obtained and the classic appearance, "steeple sign" (due to the narrowing of the subglottic area) may be seen, which supports the diagnosis of croup.

Differential Diagnosis

These include serious causes of acute stridor especially epiglottitis, foreign body inhalation, bacterial tracheitis, bronchiolitis, pneumonia, hyperreactive airway disease, or asthma.

Treatment

A recent Cochrane review concluded that croup score in children with mild to moderate croup does not improve greatly with inhalation of humidified air [15].

Medical treatment of croup depends on the assessment and severity of the case. In all cases parents should be counseled about the course of the disease and the red flags where urgent care should be sought.

In case of mild croup: the child is given oral steroids (one dose of dexamethasone 0.15–0.6 mg/kg or two doses of prednisolone 1 mg/kg, with the second dose given after 24 h of the first) and discharged, if patient is tolerating liquids. In the case of moderate croup; the child is given steroids (the same as for mild croup) and monitored for 4 h. If the child improves then she/he can be discharged. If the child does not show improvement or deteriorates then the patient should be managed as severe croup. In severe croup the child should be given oral or IM/IV dexamethasone of 0.6 mg/kg and be started on epinephrine nebulizers. Epinephrine should be given at the recommended dose of 0.05 mL per kg of racemic epinephrine 2.25% (maximum dose = 0.5 mL) or 0.5 mL/kg of L-epinephrine 1:1,000 via nebulizer (maximum dose = 5 mL). After administration of epinephrine nebulizer, the child should be monitored at least for 4 h, as rebound bronchoconstriction and edema can occur. After 4 h if the symptoms have resolved and the child has no accessory muscle use or stridor at rest, then the child can be discharged. If there is no or only partial improvement, then the child should be admitted to the hospital for further care. If at any point the child becomes hypoxemic then arrangements should be made for the child to be admitted to the pediatric intensive care unit without delay.

Epinephrine works via adrenergic stimulation, which causes constriction of the precapillary arterioles, thereby decreasing capillary hydrostatic pressure. This leads to fluid resorption from the interstitium and improvement in laryngeal mucosal edema [16].

Epiglottitis

Acute epiglottis is a life-threatening condition that should be considered when evaluating children with stridor. The prevalence of acute epiglottitis dramatically declined after the introduction of the *H. influenzae* vaccination. Epiglottitis usually occurs in children 2–7 years of age, with a peak incidence at 3 years of age. The classical presentation is with sudden onset of high fever and the child looks toxic and may be agitated. Respiratory efforts are usually increased with auditable stridor, dyspnea, muffled voice, dysphagia, and drooling. Sitting in a forward leaning (tripod) position with the mouth open and the tongue somewhat protruding might be observed in older children. The classical appearance of the "thumb sign" on lateral neck x-ray can be found in around 95% of cases [19], but once suspected, emergent referral to a higher level of care and preparation for airway management must be initiated without delay.

Acute Gastroenteritis in Children

Definition

Acute gastroenteritis is a clinical syndrome often defined by increased stool frequency (e.g., ≥3 loose or watery stools in 24 h or a number of

Telegram: @medical_k

www.konkur.in

loose/watery bowel movements that exceeds the child's usual number of daily bowel movements by two or more), with or without vomiting, fever, or abdominal pain [20].

Epidemiology

Gastroenteritis is the second leading cause of mortality among children between 1 and 59 months of age [21].

Pathogens causing gastroenteritis can be viral, bacterial, or parasitic; they are usually transmitted via the fecal-oral route. Viruses are the most common pathogens among children younger than 2 years, while bacterial and parasitic infections tend to affect older children and adults.

Rotavirus infection tends to occur in fall and winter. After the introduction of a rotavirus vaccine, norovirus is seen more commonly. Other viral causes of acute gastroenteritis include astrovirus, enteric adenovirus, and sapovirus. In most cases of acute gastroenteritis, diarrhea resolves within 1 week and vomiting within 1–2 days.

Bacterial gastroenteritis can occur following ingestion of poorly cooked meats, eggs, seafood, or unpasteurized milk. Clinically, patients tend to have more pronounced abdominal pain, high fever, and smaller stool volume compared to patients with viral gastroenteritis. In addition, they may have tenesmus and blood or mucus in the stool. Common bacterial causes include Enterotoxigenic *E. coli*, Enteroinvasive *E. coli*, Enterohemorrhagic *E. coli*, Salmonella, Shigella, Campylobacter, and *Clostridioides difficile*.

Differential Diagnosis

Gastroenteritis should be differentiated from other causes of diarrhea or vomiting such as systemic infections (e.g., pneumonia, urinary tract infection, meningitis, and otitis media), other viral infections like influenza and measles, diabetic ketoacidosis, and acute abdominal emergencies such as appendicitis and intussusception.

Clinical Evaluation

History and Physical Examination

History and physical examination should focus on the presence of symptoms of other causes of diarrhea and vomiting, recent contact with individuals with gastroenteritis, especially in the household or day care settings, food exposures, travelling abroad, or recent treatment with antibiotics. Hydration assessment is vital, caregivers should be asked about oral intake especially in the presence of vomiting, increased thirst, and reduced urine output. A more comprehensive evaluation of the hydration status may be elicited by physical examination (Table 2).

Table 2 Clinical features in infants and children with dehydration

Clinical feature	Mild (3–5%)	Moderate (5–10%)	Severe (>10%)
General appearance	Restless	Irritable, restless	Lethargic, unconscious
Tears	Normal	Normal or reduced	Absent
Eyes	Normal	Slightly sunken	Deeply sunken
Mucous membrane	Normal or slightly dry	Dry	Parched
Fluid intake	Thirsty	Thirsty, drinks eagerly	Drinks poorly
Skin turgor	Normal	Reduced (recoils in <2 s)	Reduced (recoils in >2 s), tenting
Capillary refill time	Normal (<2 s)	Delayed (>2 s)	Very delayed (>3 s)
Blood pressure	Normal	Normal to low	Hypotension
Pulse rate	Normal	Tachycardia	Tachycardia or bradycardia
Respiratory rate	Normal	Increased	Deep
Fontanelles	Normal	Depressed	Markedly depressed
Urine output	Normal or slightly reduced	Markedly reduced	Absent for several hours

Telegram: @medical_k

www.konkur.in

Lab Investigations

Stool studies (stool analysis, stool culture, and viral antigen detection) are indicated in cases of prolonged diarrhea beyond 7 days, in the presence of blood or mucus in stool, and in immunocompromised patients. Fecal leukocytes are frequently present in bacterial gastroenteritis. Electrolytes should be assessed in cases of severe dehydration to guide fluid management. In patients with suspected pseudomembranous colitis, a positive stool test for *Clostridioides difficile* toxin confirms the diagnosis.

Treatment

Management of acute gastroenteritis is largely supportive, with fluid management being the cornerstone. The use of antimotility agents in gastroenteritis is not recommended as they can prolong the course of bacterial diarrhea as they delay transit time. The use of adsorbents like smectites, a.k.a. diosmectite (brand names Smecta, Smecdral, Diosecta) can help reduce water loss and therefore can be considered for management of acute gastroenteritis [20]. Diosmectite is available in European countries, Asia, and Africa. Antiemetics are not recommended for routine use in the presence of vomiting as they can have serious adverse effects.

Fluid Management

Management of dehydration can be accomplished over three phases; deficit replacement, maintenance and ongoing losses replacement. The amount and type of fluids to be given during the deficit replacement phase depends on the degree of dehydration.

Oral Rehydration Therapy

Oral rehydration therapy (ORT) reduces childhood mortality from diarrheal disease. ORT is composed of water, glucose, and electrolytes. It can be given by parents or caregivers in both home and hospital settings without the need for intravenous access. ORS should be given in small amounts by spoon or syringe (5 mL every 1–2 min). The WHO and the UNICEF recommend a reduced-osmolarity formulation of ORT to avoid the risk of hypernatremia [22], with the ideal solution having a low osmolarity (210–250 mOsmol/L) and a sodium content of 50–60 mmol/L.

Deficit Replacement

Children manifesting no significant signs of dehydration who are considered to have mild dehydration (<5%) do not require deficit replacement. In patients with moderate (5–10%) dehydration, ORS are administered at a volume of 50–100 mL/kg over 4 h. In children with moderate dehydration, who cannot tolerate oral intake, a bolus of IV isotonic saline given as 10 mL/kg over 30–60 min can be used, followed by ORS to complete the deficit replacement.

Patients with >10% dehydration IV fluids are given initially as rapid infusion of 20–30 mL/kg of isotonic saline over 30 min to restore the circulation, followed by 70 mL/kg of isotonic saline over 2.5 h. As soon as the patient can tolerate oral intake, ORT should be initiated in addition to IVF, since most isotonic intravenous solutions replace water and Na but do not replace glucose, K, or other electrolyte losses. Replacement fluids should be continued under supervision until all the initial signs of dehydration are absent and the patient has urinated. This may require more fluids than initially estimated.

Maintenance Fluids and Ongoing Losses

Once repletion has been completed patients should be started on maintenance fluids given as ORS and feeding should be resumed. In addition, children who manifest no signs of dehydration at presentation can be sent home safely with ORS maintenance treatment. Maintenance fluids are calculated based on patient's weight according to the Holliday-Segar method (100 mL/kg for the initial 10 kg body weight, 50 mL/kg for the second 10 kg of body weight, and 20 mL/kg for the rest of their body weight) given over 24 h. During both the deficit replacement and maintenance phases, ongoing losses by emesis or diarrhea should be estimated as 10 mL/kg for each episode

Telegram: @medical_k

www.konkur.in

of diarrhea and 2 mL/kg for each episode of emesis. These losses should be added to the amount of fluids to be given in the next hour.

Nutrition and Zinc Supplements

Children with acute gastroenteritis should be encouraged to start solid foods as soon as oral intake is tolerated and in infants, breastfeeding or undiluted formula intake continues during the deficit replacement phase as well as during the maintenance phase. During the refeeding process, complex carbohydrates, vegetables, fruits, lean meats, and yogurt are usually tolerated, while fatty foods and foods rich in sugars should be avoided as they can increase diarrhea. The WHO recommends oral zinc sulfate for children under 5 years of age with infectious diarrhea (10 mg/day for children under 6 months and 20 mg/day for children 6 months to 5 years, each for 10–14 days), to reduce the severity and duration of diarrhea and reduce the incidence of subsequent episodes of diarrhea for several months [23].

Antibiotics

Antibiotics are not indicated for most children with acute watery diarrhea, except in patients with suspected cholera, in which case macrolides, fluoroquinolones, and tetracyclines are possible options. Azithromycin, ciprofloxacin, and cefixime can be considered empirically in severe cases of bloody diarrhea while awaiting stool culture results. Antibacterial agents should be avoided when enterohemorrhagic *E. coli* infection is clinically suspected to avoid increasing the risk of hemolytic uremic syndrome. Table 3 summarizes antimicrobial agents for common pathogens causing bloody diarrhea, following the result of stool culture.

Probiotics

Several studies that have been conducted on probiotics in pediatric patients with acute bacterial diarrhea found that probiotics (like *Lactobacillus rhamnosus GG*, *Saccharomyces boulardii*, and *Lactobacillus reuteri*) may be effective in reducing duration and severity of symptoms [24].

Prevention and Vaccination

Acute gastroenteritis can be prevented by meticulous public and personal hygiene especially in childcare facilities. Thorough cooking of meats and poultry are recommended as well as avoidance of unpasteurized milk. Breastfeeding should be encouraged. Breast milk is rich in antibodies and other factors protective against gastroenteritis. Vaccines to prevent rotavirus and hepatitis A infections are recommended. Rotavirus vaccine is an orally administered live virus vaccine that is given in two or three doses depending on the specific vaccine administered.

Kawasaki Disease

Definition/Background

Kawasaki disease (KD) is a systemic vasculitis affecting small- and medium-sized blood vessels and it is considered the leading cause of acquired heart disease in industrialized countries [25].

Epidemiology

The estimated incidence of KD in North America is ≈25 cases per 100,000 children [26]. The highest incidence is reported in Japan where incidence can reach 243.1 per 100,000 population aged 0–4 years. This disease has a ratio of males to females of ≈1.5:1 [27].

History and Physical Examination

Typically, children with KD are less than 5 years old, but older children and rarely adolescents can be affected. KD is characterized by persistent fever for at least 5 days. In the absence of appropriate therapy, fever can continue for 1–3 weeks [28].

Parents might describe redness and painful swelling on the palms and soles of affected children. After 2–3 weeks desquamation of the fingers and toes takes place, which might extend

Table 3 Oral antimicrobial agents for bloody diarrhea in children based on infecting organism

		Drug	Dose and administration	Duration	Notes
Shigella		Azithromycin	12mg/kg day 1 followed by 6 mg/kg daily for days 2–5	5 days	
		Cefixime	8 mg/kg/day QD or BID	5 days	
		TMP-SMX	8–10 mg/kg (based upon TMP component) BID	5 days	If isolated strain is susceptible
Salmonella (nontyphoidal)		TMP-SMX	8–10 mg/kg BID	7–10 days	Their use should be preserved for young infants, infants with high fever and immunocompromised children
		Cefixime	8 mg/kg/day QD or BID	7–10 days	
		Azithromycin	15 mg/kg day 1 followed by 10 mg/kg daily days 2–5	5 days	
Campylobacter		Azithromycin	15 mg/kg day 1 followed by 10 mg/kg daily days 2–5	5 days	Effective if started in the first 3 days of disease onset
Entamoeba trophozoites		Metronidazole	35–50 mg/kg/day TID	7–10 days	
Giardia		Metronidazole	15 mg/kg/day TID	5–7 days	
Clostridioides Difficile	Mild to moderate	Metronidazole	30 mg/kg/day QID	7–14 days	
	Severe or recurrent	Vancomycin	40 mg/kg/day QID	10 days	
		Fidaxomicin	200 mg BID	10 days	For children >6 years

to palms and soles, and a couple of months later Beau's lines (deep transverse grooves across the nails) might be noticed [25, 27].

The morphology of rash in KD may vary. While diffuse maculopapular eruption is most common, scarlatiniform rash, erythroderma, or erythema multiforme-like rashes are also seen. Less frequently urticarial rash can occur [26]. An unusually severe form of psoriasis with plaques and pustular features can rarely occur during or after the acute KD illness [29]. Patients also experience bilateral bulbar nonexudative conjunctival injection which usually begins shortly after the onset of fever and often spares the limbus. Anterior uveitis may be observed by slit-lamp examination during the first week of fever.

Signs and symptoms in the lips and oral cavity include erythema, dryness, fissuring, peeling, cracking, and bleeding of the lips; a "strawberry tongue," with erythema and prominent fungiform papillae; and diffuse erythema of the oropharyngeal mucosa.

Cervical lymphadenopathy is the least common clinical feature. Lymph node swelling is usually unilateral, $\geq$1.5 cm in diameter, and confined to the anterior cervical triangle [30]. In a small subset of patients, lymph node findings may be the most notable and sometimes they are the only initial clinical finding, prompting a clinical diagnosis of bacterial lymphadenitis, and significantly delaying KD diagnosis [30].

There is no specific test for KD. The diagnosis is a clinical one [26].

Telegram: @medical_k

www.konkur.in

Classic KD is diagnosed in the presence of fever for at least 5 days (the day of fever onset is taken as the first day of fever) together with at least four of the five following principal clinical features:

1. Erythema and cracking of lips, strawberry tongue, and/or erythema of oral and pharyngeal mucosa
2. Bilateral bulbar conjunctival injection without exudate
3. Rash: maculopapular, diffuse erythroderma, or erythema multiforme-like
4. Erythema and edema of the hands and feet in acute phase and/or periungual desquamation in subacute phase
5. Cervical lymphadenopathy ($\geq$1.5 cm diameter), usually unilateral

However, patients may not exhibit four or more clinical features at once, rendering diagnosis difficult. For example, some patients may present with fever and meet two or three of the classic criteria. These patients are considered to have incomplete KD [28].

Laboratory and Imaging

As mentioned above, the diagnosis of KD is a clinical one. However, initial laboratory evaluation may be required when the clinical presentation does not meet the full criteria of complete KD and it may include a complete blood count (CBC), electrolyte panel, renal function testing, liver enzymes, albumin, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and urinalysis. Abnormal limits include Albumin 3 g/dL or less, anemia for age, elevated ALT levels, platelets >450,000, WBC count 15,000/mm^3 or greater, and sterile pyuria. Three or more positive laboratory criteria are supportive of a diagnosis of KD.

Echocardiography should be performed to evaluate for coronary artery abnormalities or involvement during the acute stage and it should be repeated at 1–2 weeks and then 5–6 weeks after disease onset. Transthoracic echocardiography is the diagnostic imaging modality of choice to screen for coronary aneurysms. MRI and MRA may be used to image peripheral artery aneurysms.

Cardiac stress testing for reversible ischemia is indicated to assess the existence and functional consequences of coronary artery abnormalities in children with Kawasaki disease and coronary aneurysms.

Treatment

The goal of therapy in the acute phase of KD is to reduce inflammation and arterial damage and to prevent thrombosis in patients with coronary artery abnormalities. The mainstay of initial treatment for both complete and incomplete KD is a single high dose of IVIG together with acetylsalicylic acid (ASA). IVIG should be instituted as early as possible within the first 10 days of illness marked by the onset of fever. Referral to specialized care is warranted once KD is suspected [26, 31].

Medications\Immunizations and Chemoprophylaxis, Referrals, and Counseling

Current long-term management protocols are calibrated to the degree of coronary artery involvement reflecting the known likelihood of severe long-term cardiac complications. Therefore, patients are managed according to risk category [32].

Patient Education and Activation

Since affected children are at risk of complications throughout their lives, parents should be educated to help their children adopt a healthy lifestyle and to avoid cardiovascular risk factors, including obesity, high-fat/high-calorie diets, sedentary lifestyle, alcohol use, and tobacco use, to limit their already high cardiac risk.

Telegram: @medical_k

www.konkur.in

Prevention

There are no known preventive measures for Kawasaki disease. Approximately one patient in every hundred cases may develop a recurrence. Parents should be counseled that there is nothing they could have done to prevent the disease.

Pinworms

Epidemiology

Pinworm infestation is one of the most common parasitic infections seen by family physicians. The infection is caused by a small, thin, white roundworm called *Enterobius vermicularis*. Of all age groups, school aged children are most at risk for pinworm infections, particularly those who live in close, crowded conditions [31].

Transmission

E. vermicularis is transmitted via the fecal oral route. The cycle begins when the gravid adult female worms lay their eggs on the perianal folds. Scratching of the perianal area then leads to autoinfection by transfer of infective eggs to the mouth. Following ingestion, it takes about 1–2 months for the gravid adult female to mature and migrate to the colon where it lays eggs around the anus at night. Each female worm can produce 10,000 or more eggs. Since humans are the only natural host, person-to-person transmission can occur by eating food touched by contaminated hands or by handling contaminated clothes or bed linens or through contact with environmental surfaces that are contaminated with eggs. In addition, eggs may become airborne, inhaled, and swallowed.

Clinical Presentation and Diagnosis

History and Physical Examination

Affected children usually present with complaints of anal itching, also known as pruritus ani, which is most severe at nighttime or in the early morning. Pinworms can also cause vulvar symptoms, such as itching. Children with recurrent episodes of vulvar itching, especially at night, should be examined for pinworms. The worm count might get so high that abdominal pain, nausea, and vomiting develop. Most patients, however, are asymptomatic. Pinworms have also been linked to appendicitis and Eosinophilic enterocolitis. Adult pinworms may be found in normal and inflamed appendices following surgical removal. Urinary tract infections have also been described in young girls with pinworms.

Laboratory and Imaging

The female pinworm (10 mm) can be seen in the perianal region with the naked eye so parents can simply look for the worms in the perianal region 2–3 h after the child wakes from sleep. Alternative techniques such as the "scotch tape test" and analyzing samples from under the fingernails under a microscope can aid in the diagnosis. The "scotch tape test" involves the use of a transparent tape which is applied to the perianal area to collect possible pinworm eggs around the anus first thing in the morning. If a person is infected, the eggs on the tape will be visible under a microscope. The tape method should be conducted on three consecutive mornings right after the infected person wakes up and before he/she bathes or washes the perianal area [31, 33].

Treatment

It is important to simultaneously treat the entire household for pinworms when a decision is made to treat. Anthelmintics, such as mebendazole (100 mg PO as a single dose), pyrantel pamoate (11 mg (base)/kg PO not to exceed 1 g/dose), and albendazole (400 mg PO × 1), are active against *Enterobius vermicularis*. Any of these drugs are given as a single initial dose, and then another single dose of the same drug is given 2 weeks later to prevent re-infection by adult worms that hatch from eggs not killed by the first treatment [31, 33].

Telegram: @medical_k

www.konkur.in

Prevention

Children should be encouraged to wash their hands with soap and warm water after using the toilet and bathe every morning to help reduce the number of eggs on the skin. In institutions, day care centers, and schools, control of pinworm infections can be difficult, but mass drug administration during an outbreak can be successful [31].

General Principles

Behavioral problems in children are both common and underdiagnosed [1, 2]. While some of these conditions have prominent genetic or neurological contributions, it is now widely appreciated that most behavioral problems in children result from maladaptive responses to their environment. Stress, parenting issues, and family environment contribute to behavioral problems [3]. Although many may dismiss childhood behavioral problems as being benign and temporary, studies show that most adult mental health disorders first manifest in childhood, often arising from a preexisting behavioral problem [4]. The family physician plays an essential role in the early detection and treatment of childhood behavioral problems and can reduce both childhood and adult morbidity by detecting these conditions and ensuring early intervention [5].

Attention Deficit Hyperactivity Disorder

Epidemiology

ADHD is the most common childhood neurobehavioral disorder. It is a neurodevelopmental disorder that manifests with symptoms of hyperactivity, inattention, and poor impulse control. US epidemiologic data report that 7–11% of children in the United States are diagnosed with ADHD and the majority of these children are treated with psychostimulants [6]. Data from other countries suggest a similar prevalence internationally.

ADHD is thought to result from delayed maturation of some executive brain functions. Both genetic and environmental causes are thought to contribute to the genesis of the syndrome. The observation of both strong familial clustering and apparent vertical transmission can be the result of both genetic and environmental factors. Functional neuroimaging studies have also shown significant differences between children with ADHD and more typically developing peers [7].

Diagnostic Considerations [8]

The diagnosis of ADHD should be considered in a child presenting with hyperactivity and impulsivity that are not appropriate for their developmental stage. Additionally, the behaviors are pervasive in most environments in which the child functions. These behaviors should also interfere with his or her areas of function, specifically learning, peer relations, and relationships with adults and authority. Most children present with these symptoms during early school years when the demands on their compliance with instructions and attention increase. However, an increasing number of younger children under 4 years of age are being diagnosed with ADHD. Boys are more commonly affected than girls in the hyperactive and combined type, while more girls are affected more often with the predominantly inattentive subgroup

Telegram: @medical_k

www.konkur.in

of ADHD. Establishing the diagnosis depends on fulfilling the DSM-V diagnostic criteria, which in part require the behavior reported to be observed in multiple settings.

The Vanderbilt ADHD Diagnostic Rating Scale can facilitate the diagnosis in the primary care setting. Parent and a teacher forms are available for initial diagnosis and follow-up on treatment effectiveness. The questionnaire is self-administered by the parent and the teacher and includes scoring instructions. The instrument is available on the Internet for use free of charge. It has also been translated and validated in many languages. The use of an instrument has advantages in both documenting the diagnosis and also increasing parental awareness of what behaviors may constitute symptoms of ADHD.

At the time of diagnosis, it is important to consider other conditions that can mimic the presentation of ADHD or coexist with it as a comorbid condition. Common among these are learning disabilities. Difficulty learning and its resultant frustration can result in secondary maladaptive behaviors. Oppositional behavior can present with symptoms similar to ADHD. Oppositional disorder, anxiety, and depression are common comorbidities that are also screened in the Vanderbilt. A low threshold for diagnosis of these conditions in children with ADHD should be maintained. Comorbid conditions often influence the diagnosis and management.

Treatment of ADHD

Both behavioral and pharmacological treatments are effective in the treatment of patients with ADHD [8]. A combination of behavioral and pharmacological interventions often has a beneficially synergistic effect. The choice of approach chosen depends on factors such as the age of the child, the urgency of symptoms, quality, and availability of referral sources and family factors. Family factors include how functional and organized the family is, as well as family's attitudes and preferences toward the use of medications. In younger children, those less than less than 4–5 years of age, behavioral approaches are typically the first-line treatment. However, pharmacological treatments have a faster onset of action and can result in almost immediate symptomatic improvement of the core symptoms of ADHD for older children. Pharmacologic management is most useful in situations where symptoms are severe and causing a lot of disruption.

Pharmacological Treatments

The use of psychostimulants has been shown to be safe and effective in the treatment of ADHD in children [9]. Stimulant medications result in improvement of the core symptoms of ADHD and allow better social functioning. Although psychostimulants do not to "cure" attentional and hyperactivity problems, over the long term, many people develop strategies to better manage these problems as they mature.

Several psychostimulant preparations are available and FDA approved to treat ADHD. Approved nonstimulant options are available and are typically used if there is a poor response to stimulants, concern for diversion or abuse, side effects, or patient preference.

Following are ten general principles for the treatment of ADHD with psychostimulants:

Before you start:

1. A complete history and physical examination with special attention to a history of heart disease, careful blood pressure measurement, and full neurological examination. Laboratory testing is not generally required unless these are indicated by findings on the history and physical examination.
2. Parent and patient should be counseled about the side effects of the medication including appetite suppression. Also this is a good time to make a referral to behavior therapy and/or to counsel the parent on behavioral modifications at home.
3. It is recommended that the parent inform the child's teacher and school nurse that medication is being initiated.

Telegram: @medical_k

www.konkur.in

When you prescribe:

4. Start with an initial low dose and increase gradually as required and tolerated.
5. The morning dose can be taken after breakfast if appetite suppression is a concern.
6. Start with a short acting preparation and move to a long acting preparation if needed once the efficacy and tolerance of the medication is established.
7. Increase the medication dose as needed to control symptoms until the maximum recommended dose is reached or the patient has side effects.
8. Medication administration should be supervised by parents. Parents and patient should be counseled about the potential for abuse and diversion. The exact number of tablets is to be dispensed on a monthly basis. A controlled substance license is required for prescribing psychostimulants. Refills of more than a 1-month supply are generally not allowed.

Follow-up and monitoring

9. Monitor closely at the beginning of treatment. It is advisable to bring the patient and parent in for a follow-up visit in 1 week after starting the medication and after every dose change, to check for tolerance, side effects, blood pressure, and score symptom control. Once a stable dose is achieved, follow-up every 6 months is recommended for monitoring of growth, blood pressure, symptoms, and side effects.
10. Switching to another agent may sometimes be helpful if the maximum dose is achieved without desired clinical improvement or side effects are observed. The second agent should also be started at a low dose and increased gradually.

Management of suboptimal or no response to treatment:

Several issues need to be considered in cases of a lack of response or a suboptimal response. These include:

- Patient is not receiving the medicine: consider whether this is because of lack of organization or because the medication is being diverted.
- Unstructured or chaotic family environment, including domestic violence, homelessness, child maltreatment, or other environmental stressor.
- Wrong diagnosis or unaddressed comorbidity. Common comorbidities include posttraumatic stress disorder, learning disability, anxiety, and severe environmental or psychosocial adversity such as domestic violence, child abuse, or neglect.

Behavioral Treatments for ADHD

Two types of behavioral management are used for patients with ADHD.

1. General behavioral management and environmental modification: this can be very helpful in improving function. For example, establishing a clear and structured routine. Management checklists can be very helpful. One on one attention and behavioral reinforcement by the parents is effective in modifying behavior.
2. Cognitive behavioral therapy can be used in older children and adolescents to internally restructure behaviors. This is generally accomplished through therapy sessions with a psychologist trained in this form of therapy.

Consider referral to a psychiatrist or subspecialty developmental pediatrician:

1. Lack of response to the usual first or second line medications
2. Concern about complex psychiatric or other specific comorbidity

Learning Disabilities, Specific Learning Disorders, and Learning Difficulties

General Principles

"Learning disability" is a legal term used to describe the learning difficulties that result from Specific Learning Disorders (SLD). Learning difficulties and poor academic progress can

Telegram: @medical_k

www.konkur.in

result from many causes [10]. These include inadequate instruction, untreated attentional problems, or physical problems such as vision or hearing problems. Academic achievement in a second language may be difficult for immigrants and refugees who may also have other risk factors for poor academic performance including interrupted schooling and the psychosocial impacts associated with war or displacement.

Specific Learning Disorders (SLD)

These are a group of cognitive disorders that interfere with learning and the use of academic skills, resulting in poor academic performance that is not congruent with the child's cognitive abilities. By definition, these children do not have intellectual disability, global developmental delay, or any other neurological or neurodevelopmental disorder that can account for the learning deficits. SLD are developmental disorders and are present from the onset of formal academic learning, when the child enters school. However, they may not manifest until the demands for learning and academic skills exceeds the child's ability or his or her compensatory mechanisms. These might include excessive effort or high levels of external support.

Three types of SLD are described in the DSM-5 depending on the specific area of impairment. Those are: impairment in reading, impairment in written expression, and impairment in mathematics. Additionally, the degree of deficit varies between individuals. The DSM-5 classifies the severity of SLD from mild to severe depending on the effectiveness of remediations that result in functional learning.

Diagnosis of Specific Learning Disorders

Learning and academic achievement are distributed along a continuum. Therefore, there is no specific cut point that defines a person as having SLD. The diagnosis is made based on arbitrary criteria that depend on established societal norms and expectations.

Learning disorders should be suspected in any child whose academic achievement is below the expected range for age and class. Establishing the diagnosis of SLD requires a comprehensive evaluation that includes:

1. A complete history and physical examination including a complete neurological assessment, developmental and family history.
2. History of the educational difficulty including school reports and formal assessments.
3. Assessment of social functioning.
4. If available, formal psychometric testing that establishes normal cognitive function in addition to a formal educational assessment demonstrating below-average performance on academic achievement skills.
5. Evaluation of comorbidities including attentional deficits or behavioral problems.

If the assessment indicates the possibility of an underlying condition that may contribute to the learning difficulty, it should be investigated accordingly and ruled in or out.

Management of the Child with SLD

1. The first step in the management is counseling the child and family about the condition and what to expect. This is important and can help the child and family adjust to the condition and prevent problems arising from unrealistic expectations for the future.
2. In the United States, children with SLD are eligible for special education resources through the school system based on the Individuals with Disabilities in Education Act. Coordination with the school system is important for optimal outcomes of these children.
3. Utilization of a "strengths based approach" empowers the family and the child to find an area of strength in which the child can succeed while pursuing strengthening of their deficits. Children with SLD have IQs in the normal range by definition and therefore may be able

Telegram: @medical_k

www.konkur.in

to do well in areas that do not depend heavily on (for example) reading or math. These might include sports, art, specific technical skills, and so forth. This approach allows the child to have an opportunity to succeed and perhaps excel in other areas. This in turn helps with self-esteem and emotional health.

4. Children with SLD are at higher risk for secondary behavioral and emotional difficulties. Prevention, early detection, and proper management and referral as needed for these conditions can improve the outcomes of children with SLD.

Disruptive, Impulse Control, and Conduct Disorders

General Principles

Several diagnostic entities that fall under this general heading are described in the DSM-5. These include oppositional defiant disorder, conduct disorder, intermittent explosive disorder, antisocial personality, pyromania, and kleptomania. It has been proposed that these conditions be termed "behavioral addictions." This is in recognition that these disorders appear to share the core features of other kinds of addictions, specifically craving and loss of control. These diagnoses are also linked by the fact that the behaviors result in harm to the sufferer and/or others. Children are diagnosed with these disorders when the observed disruptive behaviors are severe, pervasive, and cause problems or distress [11].

Diagnostic Considerations

Oppositional defiant disorder is persistently hostile, disrespectful, and disobedient behavior usually directed at authority figures, such as parents or teachers. *Conduct disorder* is a pattern of aggression toward others that may include destruction of property and physical violence. In children, *intermittent explosive disorder* may present as severe, repeated tantrums that are out of proportion to the stressor. In older individuals, there is a pattern of brief (usually less than 30 min) angry outbursts that may or may not be accompanied by physical aggression or property destruction. *Antisocial personality* is a habitual disregard for the feelings, safety, or rights of others.

Conditions that are commonly comorbid with these disorders are attention deficit/hyperactivity disorder (ADHD), obsessive compulsive disorder (OCD), anxiety, and depression.

The complete criteria for diagnosing these conditions are found in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) [12].

Treatment

Treatment of these conditions is focused on improving the patient's quality of life, reducing the harms caused by behaviors, and inhibiting the progression of these conditions to more serious forms of disordered behavior as the child becomes older. The treatment of these disorders is dependent on the age of the child, the severity of the symptoms, the degree of insight that the sufferer has into the behaviors in question, and their motivation to improve. Behavioral treatment may be appropriate for young children with milder symptoms. In older motivated individuals with insight, cognitive behavioral therapy is favored. Parent training and family therapy are also important adjuncts to these therapies.

In children who are not good candidates for cognitive behavioral or other behavioral interventions, psychotropic medications have been used. Psychotropics are also used to treat comorbidities that may be present. These include some SSRIs, anticonvulsants, stimulants, and atypical antipsychotics, but discussion of specific treatments are beyond the scope of this chapter.

Anxiety and Specific Phobias

Childhood and adolescence are considered to be a time of heightened risk for the development of anxiety disorders [13]. Studies report that most

Telegram: @medical_k

www.konkur.in

anxiety disorders have their onset in childhood. Anxiety disorders are thought to be the most common mental disorders in childhood. Several specific anxiety syndromes are described in the DSM-5. Separation Anxiety Disorder and Specific Phobias are the two most common entities in childhood. Diagnosing anxiety disorders in primary care may be challenging for several reasons. Younger children may not have achieved the developmental skills that allow them to recognize, verbalize, or process their feelings so they may not be able to describe what they feel. Therefore, the evaluation depends on adult reports which may be biased in a number of ways. Additionally, core symptoms of anxiety differ with age and developmental stage which may add a level of complexity when interpreting criteria for diagnosis and the results of assessment tools.

Risk factors for the development of anxiety in children include a family history of anxiety disorders. Other associations include cold, overprotective, or authoritarian parenting styles.

Screening instruments that help the clinician to detect anxiety include the GAD 7 and SCARED [14].

Diagnostic Considerations

Assessment of children with anxious symptoms requires a detailed history and physical examination. The interview should include the onset and evolution of the anxious symptoms, aggravating and alleviating factors, as well as a family history. In addition, associated symptoms are elicited. Evaluation of the family including parental mental health and home relationships, parenting styles, and economic status are important. Attention to detail and time are needed to make sure the age-appropriate criteria are met for the diagnosis.

Treatment

Referral should be considered if the presumed anxiety symptoms are causing significant disruption of function, especially in younger children. For older children, Cognitive Behavioral Therapy (CBT) has been shown to be effective when administered by a trained therapist [15]. In addition, several serotonin and serotonin norepinephrine reuptake inhibitors have been shown to be effective in treating children with anxiety. Detailed discussion of the pharmacologic treatment for children with anxiety is beyond the scope of this text.

Tics

Tics are a neurobehavioral condition that has its onset before 18 years of age. Tics are defined as sudden, rapid, repetitive, recurrent non-rhythmic movement or vocalizations.

Although tics are involuntary movements, they can often be suppressed voluntarily but only temporarily. The most common types of tics are blinking and throat clearing, but almost any muscle group can be involved.

Tics can occur as part of a specific tic syndrome such as Tourette syndrome, or they can be associated with another CNS disorder. More commonly, they occur in isolation and in the absence of any known medical or neurological disorder. Sometimes, it occurs as a sequela of a streptococcal infection (Pediatric Autoimmune Neuropsychiatric Disorder Associated with Streptococcus (PANDAS); see ▶ Chap. 20, “Selected Problems of Infancy and Childhood”).

Isolated tics are usually transient, but can be chronic. They are common in childhood, with a peak onset at 4–6 years of age. Boys are affected more commonly (M:F ratio of 2–4:1).

Chronic persistent tics are diagnosed when a person has had tics for over a 12-month period even if he or she had remissions (or tic-free periods) during this time.

Children who have tics have a higher risk of comorbid behavioral conditions including ADHD, OCD, and separation anxiety. These conditions often have a greater impact on the patient’s function than tics do.

Adult onset tics are rare. Adult presentations of tics are usually secondary to CNS insults

Telegram: @medical_k

www.konkur.in

or intoxication with a substance and an evaluation to rule out these conditions is warranted. Not uncommonly adults present with mild and undiagnosed tics in childhood that only become clinically significant in adulthood.

Diagnostic Considerations

In addition to a thorough history and physical examination, evaluation for comorbid conditions in children is recommended. These include OCD and other anxiety disorders, ODD and ADHD. In children with an abrupt onset of tics streptococcal throat culture, antistreptolysin-O (ASO) and antiDNAse-B (ADB) serum titers may be considered.

Management of Tics

Counseling patients and parents about the natural history of tics and the benign nature of childhood tics combined with watchful waiting is an acceptable option in individuals who do not experience functional impairment. In more severe cases, especially with children older than 9 years of age, the patient may be referred for behavioral therapy. Comprehensive Behavioral Intervention for Tics (CBIT) combines several behavioral therapeutic approaches to address tics and has been shown to be effective and is considered to be the first line of treatment should treatment be required.

Several medications have been studied for the treatment of tics. Two alpha 2 agonists clonidine and guanfacine have been shown to reduce the tic severity in placebo-controlled trials. In children who have comorbid ADHD, these two medications can also help reduce ADHD symptoms. Other classes of medications have been studied for the treatment of tics. These include antipsychotics, antiepileptics, and botulinum toxin; however, treatment with these agents is associated with a higher risk of adverse effects, so this limits their usefulness in the primary care setting [16].

Thumb Sucking

Thumb sucking and finger sucking is a universal phenomenon among children. Usually, persistent thumb sucking resolves spontaneously between 2 and 4 years of age. Negative effects of thumb sucking include paronychia, koilonychias, and most importantly dental malocclusion. Educating the caregivers in positive and negative reinforcement for this behavior is usually sufficient for treatment. Fingernail lacquer that has a noxious taste can be used ("Thum" Liquid). If the habit is recalcitrant to behavioral interventions and there is concern for the development of dental malocclusion (especially after age 4), referral to a pediatric dentist for consideration of preventive orthodontic devices may be helpful.

Pica

General Principles

Pica is defined as the craving and ingestion of non-food substances. These might include dirt, chalk, or paint chips. It is classified under the section on eating disorders in the DSM-5 and considered along with rumination disorder.

In most situations, pica is a transient condition and subsides with little or no intervention other than active supervision. In some patients, it may be a symptom of nutritional deficiency such as iron or zinc deficiency.

Pica increases the risk of lead or other toxic poisoning, as well as enteric infections involving bacteria or parasites. Pica is more common among children who suffer from intellectual disability. Other conditions reported to be associated with a higher risk of pica include pregnancy, sickle cell anemia, and renal failure [17].

Diagnostic Considerations

The evaluation of children with pica should include screening for iron and zinc deficiency and evaluation for developmental and

Telegram: @medical_k

www.konkur.in

behavioral conditions such as developmental delay, intellectual disability, and autism. Evaluation might include screening for lead poisoning and other conditions based on clinical suspicion.

Management

Behavioral modification strategies that might include distraction, reinforcement, and reward may be helpful and may be all that is needed for resolution of the behavior in most children.

Temper Tantrums

General Principles

Temper tantrums are normal developmental behavior for toddlers, and most are easily manageable. Inadvertent rewarding of the behavior may cause tantrums to escalate and become more disruptive. This happens when the child receives positive or negative attention when he/she throws a tantrum. In most cases, counseling parents to increase nurturing behaviors when the child is exhibiting normal behavior, ignoring minor misbehaviors and tantrums, and teaching them "time out" techniques is usually helpful and effective.

Diagnostic Considerations

Evaluation of the child with difficult-to-manage temper tantrums must include a detailed history including a family history, social history, parenting practices, and an assessment of family dynamics. A mother suffering from depression may not be able to provide responsive parenting and may become overwhelmed with the task of managing her toddler's behaviors. A complete developmental evaluation and physical examination is also essential to rule out developmental delays or atypical development. Referral for further evaluation may be needed in some cases.

Management and Prevention

Positive parenting and a nurturing responsive environment and caregivers are shown to foster the development of healthy emotional regulation in children and can prevent the development of maladaptive behaviors such as temper tantrums [18].

Parenting training and instruction in behavioral modification are usually effective and sufficient for management of this problem. Children suffering from conditions such as autism and global developmental delay have may have particular difficulty in regulating their emotions and a referral for behavioral modification may be helpful in these cases.

Sleep Disturbances

General Principles

Most sleep disturbances in infants and young children are the result of inadvertently reinforcing behaviors that disrupt sleep. These include rocking the baby to sleep or associating sleep with the presence of the adult caregiver, which means that when the child inevitably wakes up in the middle of the night they cannot put themselves back to sleep. They then have to call the parent to help them go back to sleep. In older children and adolescents, the use and exposure to digital screen media has been recently linked to sleep disruption [19].

Management

Management of night awakening depends on the age of the child. In infants the technique of "modified extinction" is effective. It is also acceptable to most parents and is relatively easy to do. The parents are instructed to establish a bedtime routine. Sleep hygiene including a bed time routine that would include regular bedtime, a winding down time, getting ready for bed rituals such as brushing teeth, bathing, and putting pajamas on, followed by quiet activities such as reading a book

Telegram: @medical_k

www.konkur.in

or telling stories or bedtime songs. The child should then be allowed to fall asleep in their bed, on their own. If the child won't sleep and cries when left in the crib, the parent should go back to the room every 5–10 min to reassure the child without picking him up then go back out of the room. This will take longer than the "unmodified extinction" method in which the parent does not go back in the room allowing the child to "cry it out" and eventually fall asleep. Unmodified extinction works faster but is usually more difficult for the parents to comply with.

In toddlers, the child can get out of the bed and go into the parents' room. The parents should take him back to his room promptly every time he does that, and eventually the child will learn to stay in bed. The parents also can use a sticker chart with positive reinforcement as well as strategies to make it less scary for the child to stay in his room such as having a night light, a cuddly toy, or a special blanket.

In older children, the use of screens by children and adolescents can potentially cause sleep disruption especially if used in the evening. The bright light disrupts the natural production of melatonin which helps with sleep. Additionally, stimulating content such as action movies or games may disrupt the normal transition to sleep [20]. Parents should be advised to supervise the content as well as total duration of screen time as well as enforcing turning off all screens including television and cell phones at least 2 h before bedtime [21].

Most family physicians see many musculoskeletal complaints in their office, but they should be aware that children have some conditions that are unique and may not be encountered in adults. This chapter will discuss generalized and regional musculoskeletal conditions, including fracture patterns, gait concerns, and overuse issues encountered among children and adolescents.

Generalized Musculoskeletal Conditions

Common Fracture Patterns

Physeal Fractures

Fractures involving the growth plate of children are called "physeal fractures." These need to be managed with care because they may result in premature closure of the growth plate. Typically, these injuries occur in girls 11–12 years

www.konkur.in

old and boys 13–14 years of age, but more commonly in boys (2:1 ratio), with fractures of the distal radius, distal tibia, and distal fibula being the most common [1]. Physeal fractures are usually diagnosed using plain radiographs, often with the help of comparison x-rays of the non-affected limb. They are generally categorized according to the Salter-Harris classification [2] (Fig. 1). A useful mnemonic is [3]:

- S ("Straight across") – Type I
- A ("Above") – Type II
- L ("Lower" or "BeLow") – Type III
- T ("Two" or "Through") – Type IV
- E ("End") or ER ("ERasure of the growth plate") – Type V

Management will depend upon the location of the fracture, but, generally, all types are managed in consultation with orthopedic specialists. The lower numbered Salter-Harris fractures tend to have fewer complications and better outcomes. A nondisplaced Type I or II fracture is usually immobilized and casted. However, if they are displaced, they will need reduction within 1 week of the injury, followed by immobilization with casting for 3–4 weeks. Salter-Harris Types III–V need prompt orthopedic evaluation because they usually require open reduction. Nonsteroidal anti-inflammatory drugs (NSAIDs) are usually used for pain management, although there are studies that indicate that acetaminophen may be better, as NSAIDs have been shown to be detrimental to bone healing.

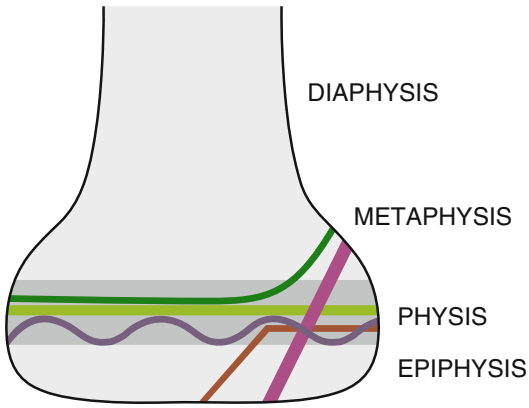

Fig. 1 Salter-Harris classification is defined by the location of the fracture relative to the growth plate (*the gray zone*). Type 1 (*yellow*) is a separation of the growth plate (*STRAIGHT across*). Type 2 (*green*) is a fracture ABOVE the growth plate into the metaphysis. Type 3 (*orange*) is a fracture that extends LOWER than the growth plate into the epiphysis. Type 4 (*pink*) is a fracture that extends THROUGH the epiphysis, physis, and metaphysis. Type 5 (*purple*) is a fracture that ERASES the growth plate due to compression injury. (Image adapted from mnemonic, which was reprinted from Ref. [3], Copyright (1999), with permission from Elsevier)

Buckle Fractures

Buckle fractures are sometimes referred to as "torus fractures." These fractures result from longitudinal compression, such as that which occurs when one falls on an outstretched hand. The bony cortex does not actually break [1]. The most common sites are the distal radius, distal tibia, fibula, and femur. Splinting is usually sufficient as buckle fractures are generally stable. However, they should be followed by an orthopedist. Casting may be done for 3 weeks to ensure healing if the child is likely to be noncompliant with the splint or if he/she is extremely active.

Plastic Deformation Fractures

A plastic deformation fracture occurs when the longitudinal forces overcome a bone's ability to recoil, leading to a bowing deformity. The most common locations are the ulna, radius, and fibula. Simple casting for 4–6 weeks is indicated if the deformation is less than 20° or the child is under 4 years old, as the angulation will self-correct. Reduction and/or surgical intervention may be needed if the deformation is greater than 20° or if the child is over 4 years old [4].

Greenstick Fractures

Greenstick fractures are fractures that do not extend completely through a bent bone, breaking one cortical surface without disrupting the other side. These fractures are considered unstable and have high rates of refracture [5]. The most common location of a greenstick fracture is the forearm. Orthopedics referral is needed, with regular follow-ups. Nondisplaced forearm fractures should be splinted until seen by an orthopedist for casting in a long arm cast for 3–4 weeks,

Telegram: @medical_k

www.konkur.in

followed by short arm casting for another 2–3 weeks [6].

Apophyseal Avulsion Fractures

Common apophyseal injuries, such as Osgood-Schlatter disease, Sinding-Larsen-Johansson syndrome, and Sever's disease, increase the risk of apophyseal avulsion fractures; repeated traction on the fibrocartilage can lead to a portion being pulled off the bone [7]. Most avulsion fractures, such as tibial tuberosity and inferior pole of the patella, result from an acute injury. These fractures need to be immobilized and often warrant an orthopedic referral to evaluate for the need for surgical intervention, to remove or reattach the avulsed bone, especially if there is displacement.

Stress Fractures

Stress fractures are most commonly seen in young athletic or active females but may also affect males. Mean age at the time of injury is around 14 years old. They are caused by overuse, which leads to microfractures. The majority of patients are able to attribute the onset of pain to a recent increase in activity level. On exam, there will be tenderness over the affected bone, with or without surrounding edema. However, if it is difficult to palpate the local area of bone due to overlying tissue, applying stress on the bone that is suspected to be involved may elicit pain, assisting with the diagnosis of a stress fracture. Plain radiographs maybe ordered. However, these usually remain normal until 2 weeks after the onset of pain. If there is a high clinical suspicion with negative radiographs, magnetic resonance imaging (MRI), a bone scan, or a single-photon emission computed tomography (SPECT) scan may be ordered, especially if time is a factor, as when a sports event is looming. Management will depend on the site of fracture. Conservative treatment with ice, acetaminophen, limited weight-bearing, and splinting is done for low-risk sites, whereas fractures in high-risk sites (Table 1) should be evaluated by an orthopedist [8]. Identifying modifiable risk factors (Table 2) when a stress fracture is suspected is extremely important for the management and prevention of another one.

Table 1 Stress fracture sites

Low-risk sites	High-risk sites
Second to fourth metatarsal shafts	Pars interarticularis of lumbar spine
Posteromedial tibial shaft	Femoral head
Proximal humerus	Superior side of femoral neck
Ribs	Patella
Sacrum	Anterior cortex of tibia
Pubic rami	Medial malleolus
	Tarsal navicular
	Proximal fourth and fifth metatarsal
	Great toe sesamoids

Table 2 Risk factors for stress fractures

Modifiable	Nonmodifiable
Low physical activity	Female
Increasing volume and intensity of physical activity	Irregular menses
Low BMI	Older age
Low dietary calcium intake	Prior stress fracture
Poor biomechanics	Family history of osteopenia or osteoporosis

Apophyseal Injuries (Apophysitis)

Apophysitis of the Hip

An apophyseal injury of the hip occurs in active adolescents, usually athletes in track, soccer, or gymnastics [9]. The injury can involve the anterior superior and anterior inferior iliac spines, iliac crest, or ischial tuberosity (Fig. 2). Typically, the patient will present with a dull pain in the hip that is associated with activity, with or without a history of trauma. On examination, there may be some localized tenderness. If ecchymosis is present, an avulsion fracture should be suspected. Radiographs of the hip and pelvis are not necessary; however, they are usually obtained to rule out other causes of hip pain. Treatment is based on severity of symptoms but must include avoidance of the aggravating activity, stretching the affected area, ice, and NSAIDs. If limping is predominant, limitations on weight bearing can be made. Children and adolescents should be enrolled in a rehabilitation program. Return to play should only be advised once full range of motion is achieved without pain, which may take anywhere from 4 to 6 weeks [9].

Telegram: @medical_k

www.konkur.in

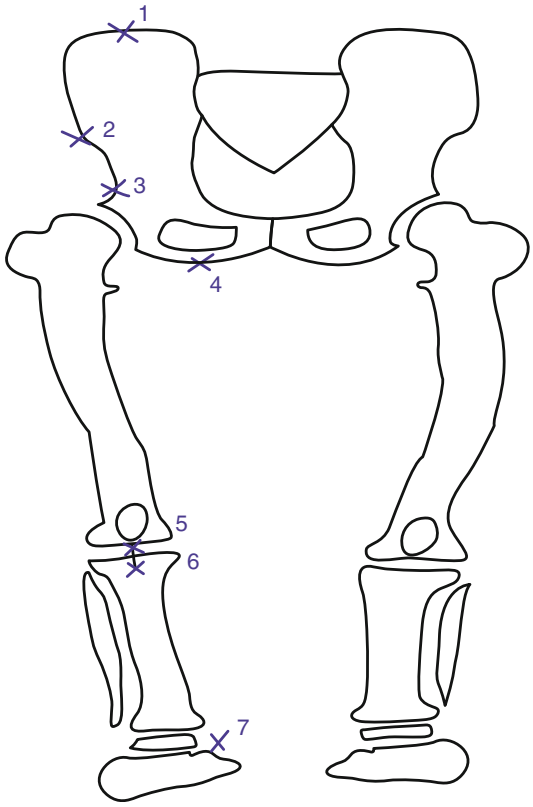

Fig. 2 Apophysitis locations. (*1*) Iliac crest; (*2*) anterior superior iliac spine; (*3*) anterior inferior iliac spine; (*4*) ischial tuberosity; (*5*) inferior pole of patella (Sinding-Larsen-Johansson); (*6*) tibial tuberosity (Osgood-Schlatter disease); (*7*) calcaneus (Sever's disease)

Sinding-Larsen-Johansson Syndrome

Sinding-Larsen-Johansson syndrome is an apophyseal injury, a type of osteochondrosis that occurs at the inferior pole of the patella (Fig. 2) after repeated microtrauma [10], usually in boys between the ages of 10 and 12 years old. They may complain of pain that is worse when walking up or down stairs or jumping. Usually, the only abnormal finding upon examination of the knee is tenderness and swelling at the inferior patellar pole. Fragmentation may be seen on anteroposterior (AP) and lateral plain radiographs. Treatment is geared toward pain control with NSAIDs, decreasing the inflammation with ice, and quadriceps rehabilitation. Resolution of symptoms may take 3–18 months [11].

Osgood-Schlatter Disease

Osgood-Schlatter disease is a common cause of gradual-onset anterior knee pain in children aged 9–13 years old. It is a traction apophysitis of the proximal tibial tubercle at the insertion of the patellar tendon. It can lead to limping, usually during growth spurts. Children often describe the pain as worsening with activities such as running, climbing, or jumping, but improving with rest. There is often tenderness to palpation over the tibial tubercle (Fig. 2) and reproduction of pain with resisted knee extension. Sometimes, a prominence may be palpated over the tibial tubercle. Radiographs, AP, and lateral views are usually not necessary but are done to exclude other conditions, especially if the pain worsens at night, which is not typical of Osgood-Schlatter's. The symptoms often resolve once the growth plate has closed. Until then, treatment includes ice, pain control with NSAIDs, and physical therapy [12]. If pain persists, referral to orthopedics may be considered for potential injection of 12.5% dextrose [13] or even surgical removal of the bony prominence. Referral to orthopedics is needed if the patient is unable to lift his/her heel off the table without bending the knee; this suggests an issue with the extensor mechanism, which may require surgery [14].

Sever's Disease

Sever's disease is considered an irritation of the calcaneal apophysis (Fig. 2), usually presenting in active adolescents (9–11 year olds), on average presenting earlier on girls (6 years old in girls vs. 8 years old in boys). These patients usually participate in sports which require a lot of running, and it may take 3–4 years to fully resolve [15].

Patients will often complain of unilateral or bilateral heel pain related to activity. Examination reveals tenderness of the calcaneal apophysis with weakened dorsiflexion, and gastrocnemius-soleus flexibility can be decreased. Imaging may be done to rule out other conditions, such as a unicameral bone cyst, if symptoms present unilaterally [14]. Management includes rehabilitation exercises and

Telegram: @medical_k

www.konkur.in

pain management with NSAIDs to help decrease the inflammation. The patient should be advised not to take any pain medication before activities so as not to mask the pain. Return to activities should only be done once pain subsides. Use of a ¼ in. heel lift with icing for 20 min per day can also provide relief [14]. Should symptoms persist after 4–8 weeks of treatment, casting for 3–4 weeks may be considered [9].

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) occurs when subchondral bone and cartilage separate from the underlying bone. The most common locations of OCD are the knee and ankle, but it can also occur at the elbow, talus, and distal humerus. The patient will generally describe vague pain associated with swelling, clicking, and sometimes locking that gets worse with activity. On examination, there is tenderness over the lesion. When OCD occurs in the knee, the Wilson test may be positive, and there may be an antalgic gait [14]. The Wilson test is performed by having the patient lie supine and extend the knee from a 90° angle while internally rotating the tibia. It is considered positive when there is knee pain as the knee is extended with the tibia internally rotated; however, there is no pain when the same maneuver is performed with the tibia externally rotated. The medial femoral condyle will be tender to direct palpation when the knee is flexed to 90°. Plain radiographs should be obtained. If suspected in the knee, tunnel and lateral views should be included. MRI can be useful to visualize articular cartilage integrity. When the cartilage is intact, management can consist of modifying activity or placing the patient on crutches for 6–8 weeks [16]. Surgery might be needed to avoid early onset of degenerative joint disease if the child is already skeletally mature or if the articular cartilage has some damage. Orthopedic referral is indicated if the lesion is larger than 2 centimeters (cm) because such lesions can lead to complications, including early-onset degenerative joint disease [14].

Growing Pains

Growing pains are the most common cause of episodic musculoskeletal pain in children. These nonarticular leg pains occur at night in healthy active children 3–12 years of age, with a peak of 6 years. These leg pains are often felt in the calf but may also be felt in the foot, ankle, knee, or thigh. The pain episodes may last from minutes to hours. They are usually bilateral and are more common in boys and among children with laxity of the ligaments. The pain may be more likely to occur if the child has been particularly physically active during the day. The etiology is unknown, but it may be an overuse syndrome. There are no associated systemic symptoms such as weight loss, fevers, or fatigue [14]. The diagnosis is based on the clinical picture and a normal physical exam. If there are atypical symptoms, such as unilateral leg pain, further studies such as CT, MRI, x-rays, bone scan, or lab work should be obtained to rule out pathology. The differential diagnoses of growing pains include fractures, osteomyelitis, malignancy, metabolic systemic disease, and osteonecrosis; these should be excluded before a diagnosis of growing pains is made [14]. Treatment of growing pains consists of comforting the child, local massage, and analgesics. In a recent study, there was reduction of pain after vitamin D supplementation [17].

Regional Musculoskeletal Conditions

Neck and Back Problems

Spondylolysis and Spondylolisthesis

"Spondylolysis" is defined as the separation of the vertebral pars interarticularis, most commonly at L5, which may be unilateral or bilateral. About 25% of cases progress to spondylolisthesis, which is the bilateral defect that allows the vertebral body to slip anteriorly. There are several risk factors for spondylolysis, including occult spina bifida at S1, Scheuermann's kyphosis, and a family history of spondylolysis. These conditions are common among adolescent athletes with repetitive flexion and extension movements of the back,

Telegram: @medical_k

www.konkur.in

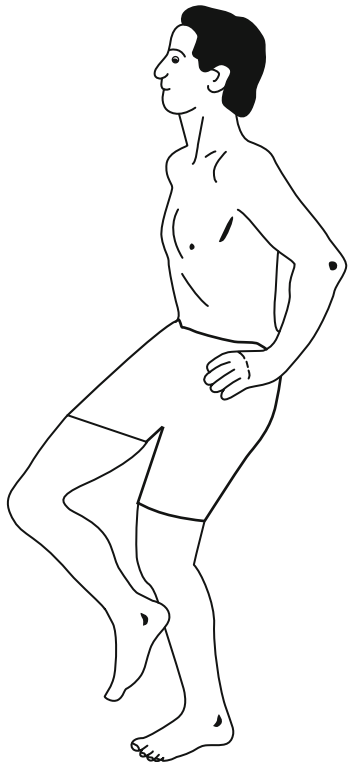

Fig. 3 The stork test: Ask the patient to lean backward while standing on one leg; considered positive if the back pain is reproduced on the same side the patient is standing on

causing an achy back pain that radiates into the buttock and posterior thighs. Symptoms improve with rest, but higher-grade slips can present with neurologic manifestations, such as urinary incontinence [14].

A positive Stork test suggests spondylolysis (Fig. 3). It is performed by asking the patient to hyperextend his/her back while standing on one leg; a positive test reproduces the back pain [18]. Palpation of the spinous processes can reveal a prominent process, suggesting significant spondylolisthesis. Observation of the gait may reveal high-grade spondylolisthesis in some patients, as they may walk with their hips and knees flexed (the Phalen-Dickson sign [19]). Plain radiographs with AP, weight-bearing lateral, and oblique views of the lumbosacral spine may help reveal the "Scotty dog" sign (Fig. 4), which is associated with spondylolysis [1]. If not well-visualized, additional imaging may be needed. If neurologic symptoms are present, obtaining an MRI is often helpful.

Symptomatic spondylolysis should be managed with activity restriction, possibly with thoracolumbosacral orthosis (TLSO) for pain management, and aggressive physical therapy. Treatment of spondylolisthesis will depend on the grading of slippage; however, early cases can

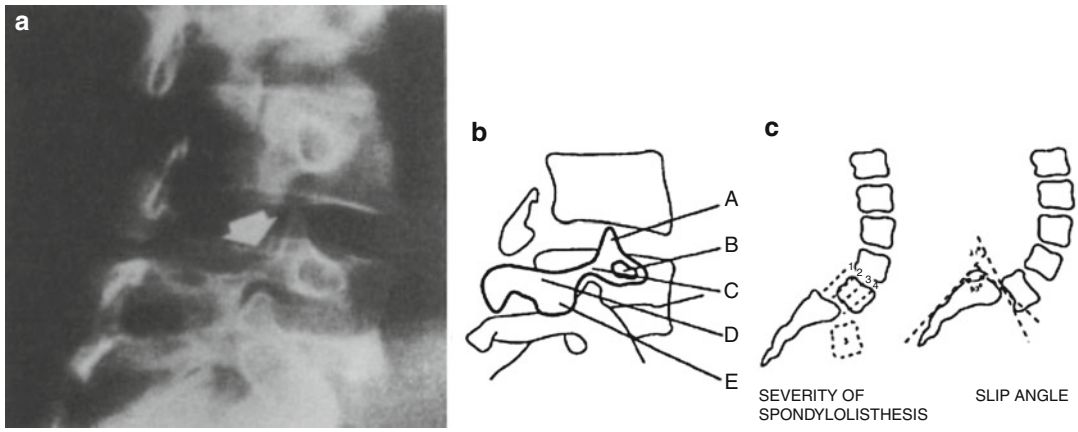

Fig. 4 Spondylolysis and spondylolisthesis (*right*). Telegram: @medical_k

www.konkur.in

be managed like spondylolysis. Those with greater than 50% slippage and who are skeletally mature are candidates for spinal fusion. However, if there are neurologic signs, neural decompression may be needed in addition to spinal fusion [14]. Urgent additional imaging and intervention should be ordered if the following are present: <4 years old, fevers, weight loss, worsening pain, nocturnal pain, history of trauma, malignancy, or tuberculosis [21].

Idiopathic Scoliosis

Idiopathic scoliosis is defined as an abnormal lateral curve of the spine. This is further divided into subcategories based on the age of the child at diagnosis: infantile (0–3 years), juvenile (4–9 years), and adolescent (≥10 years). These children may present after a school screening, which is currently not supported by the US Preventive Services Task Force (USPSTF), or due to obvious asymmetry of the back, noted by others. It is important to establish when the asymmetry was first noticed, any associated symptoms, and signs of puberty. The Adam's forward bend test is commonly used to assess the rotational component of scoliosis, in combination with a scoliometer. The test is done by standing behind the patient, asking the patient to bend forward to reach for his/her toes, and then assessing for any asymmetry. When clinically suspected, scoliosis films (standing posteroanterior [PA] and lateral films of the entire spine) are needed to assess for the Cobb angle and skeletal maturity, via the Risser scale (Fig. 5) [23]. Lateral bending films are sometimes obtained for preoperative evaluation.

When there is low risk for progression in adolescent idiopathic scoliosis, the primary care physician can manage and follow with repeat scoliosis radiographs every 6–9 months. Orthopedic referral is indicated when there is any of the following [24]:

- More than 7° of trunk rotation
- A premenarcheal girl, or a boy between 12 and 14 years old, with a Cobb angle of 20–29°
- A Cobb angle of 30° or more in any patient
- Any patient with a progression of 5° or more of the Cobb angle

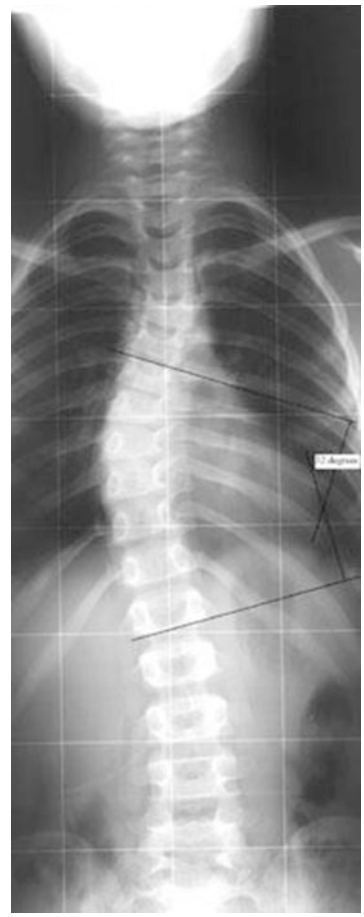

Fig. 5 Measurement of the scoliosis angle. Horizontal lines are drawn parallel to the end plates of the neutral vertebrae at the end of the curve. Where perpendicular lines intersect, the angle of scoliosis is measured. In this case, the angle of Cobb measures 32°. ([22]. With kind permission from Springer Science and Business Media)

Management of these patients will vary between bracing and surgical intervention. If surgery is performed, activity is usually restricted for several months after surgery.

Scheuermann Disease

Scheuermann disease or juvenile kyphosis is the anterior wedging of at least 5° in three adjacent thoracic vertebral bodies, usually found during early adolescence. It is associated with spondylolysis. It presents with subacute pain that worsens after activity and at the end of the day without a clear precipitating event. Upon

Telegram: @medical_k

www.konkur.in

examination of the child, a sharp angulation of the thoracic or thoracolumbar spine is observed, especially as the child bends forward. Some may call these patients "hunchbacked." Radiographs of the spine while standing, especially lateral views, are important for diagnosis. If the angulation is less than 60°, conservative management is usually tried, with hyperextension rehabilitation. However, for curves greater than 60°, bracing is often employed for as long as the vertebral end plates are not fused [25].

Elbow Problems

Osteochondrosis of the Elbow

Osteochondrosis of the elbow is also referred to as "Panner's disease." It is generally found in the dominant arm of young males between the ages of 7 and 12 years old and is the most common cause of lateral elbow pain in children less than 10 years old [26]. The full etiology is unknown, but it is most likely due to insufficient blood supply to the chondroepiphysis during a compressive force. This, in combination with active ossification of this age group, leads to local avascular necrosis and subsequent recalcification of the capitellum. They may complain of sudden onset lateral elbow pain that is reproducible on palpation. There may be decreased range of motion with extension. Plain radiographs, with AP and lateral views, may show an irregular joint surface with fragmentation of the capitellum. Panner's disease is managed by cessation of activities that place stress on the joint until imaging, and physical exam shows evidence of full healing, usually in about 6–12 weeks.

Radial Head Subluxation

Subluxation of the radial head is a common injury in preschool children aged 1–4 years old. It is commonly called a "pulled elbow" or "nursemaid's elbow" because it occurs from traction on the forearm while pronated and with the elbow extended. The child will have been observed not using the affected arm as usual. For an unknown reason, it is more common in the left arm [27]. On examination, the child is often observed holding the affected arm closely to the body, with the elbow extended. Tenderness is often present over the anterolateral aspect of the radial head. Plain radiographs with AP and lateral views are often obtained to exclude other causes or more serious bony injuries; still, the diagnosis can be made by history and physical exam alone. Management is reduction by either one of two methods: hyperpronation or supination with flexion [28].

In the hyperpronation method, the examiner supports the elbow and places steady pressure on the radial head while gripping the distal forearm with the opposite hand and hyperpronating the forearm. The supination with flexion method is also performed by supporting the arm at the elbow and applying pressure on the radial head, but the opposite hand maintains traction on the forearm; in one smooth motion, the elbow is fully supinated and flexed. The child will usually resume normal activity with the arm within 5–10 min after reduction. Patients whose elbows cannot be reduced initially should be examined for possible fracture. Reduction may be tried for up to two times; however, if the arm remains immovable, radiographic image is warranted [29]. Orthopedic referral is indicated after several failed attempts at reduction, at which point obtaining radiographs and placing the arm in a sling are recommended until evaluation by a specialist.

Gait Abnormalities

Normal Gait and Alignment

In order to recognize abnormal gait, it is important to be able to identify the natural progression of alignment and gait in children. From birth, the legs are slightly in varus (10–15°) and will gradually straighten to the neutral position at around 12–18 months of age. The legs then become valgus, with a peak of around 3–4 years old. By 11 years old, the valgus alignment improves to 5–7° [14]. Normal gait has two phases: stance and swing. These phases should be symmetrical when

Telegram: @medical_k

www.konkur.in

comparing the lower extremities, with the stance taking up 60% of the time of the entire gait [1].

Metatarsus Adductus

Intoeing is commonly secondary to metatarsus adductus, which is seen more in first children and is the most common cause of congenital foot deformity [30]. It is thought to be due to excessive uterine molding from the primigravid uterus. Although the children rarely have symptoms, parents tend to be concerned and may bring them in for a checkup. Examination may show an intoeing gait, often bilateral, and deep medial creases on the feet. Careful evaluation is extremely important since treatment is based on severity. To determine severity, the examiner should use the heel bisector method (Fig. 6), which entails drawing a line that divides the heel in half and continuing the line to see where it lands in relation to the toes [14]. Normally, the line will fall between the second and third toes. In mild cases, the line will fall in the middle of the third toe. In moderate cases, the line will be between the third and fourth toes. In severe cases, it will fall between the fourth and fifth toes. Imaging is usually not necessary but is done to exclude other causes in toddlers or older children who have persistent symptoms.

The majority of metatarsus adductus cases will self-resolve, but some may need treatment. Mild cases that can be passively corrected should be kept under observation. Stretching exercises should be performed by the parents at each diaper change for moderate cases that can be passively corrected by regularly moving the foot into a neutral position. The exercise entails applying laterally directed pressure on the first metatarsal head for 10 s. The parent should be instructed to perform it five times a day on each foot [31]. Severe cases that are rigid may be treated with serial casting for 6–8 weeks, with good outcomes, if started before 8 months old.

Tibial Torsion

Internal tibial torsion is a common cause of intoeing in toddlers and may be associated with metatarsus adductus and genu varum. The thigh-foot angle (TFA) should be estimated by measuring the angle between the longitudinal axis of the femur and the foot (Fig. 7). A TFA greater than 20° is excessive but will normally correct without any intervention at around 5 years of age [32]. Only when the torsion is severe (TFA more than 85°) should surgical intervention be considered.

(From Bracker and Achar [20]. With kind permission from Springer Science and Business Media)

Femoral Anteversion

Children greater than 4 years old will commonly have intoeing secondary to femoral anteversion. Sitting in the classic "W" position [33] with their knees together and feet on either side can contribute to the femoral anteversion. While walking, the child's legs appear as if they were internally rotated; when running the legs will flip outward ("egg-beater" or "windmill" pattern). The hip will exhibit increased internal rotation with range of motion testing. Radiographs are usually unnecessary. Most cases require nothing more than observation, given that 85% will spontaneously resolve usually by 11 years of age [34].

Genu Varus

"Genu varus," also known as "bow-leggedness," is a common concern among parents because of the way it affects the appearance of the child's legs. Genu varus may cause children to walk with intoeing or have frequent falls. Depending upon the age of the child, genu varus could be completely benign, as all children are naturally born bowlegged. Genu varus may persist until the child is about 2 years of age. During this period, the recommended management is simply observation and reassurance. Pathologic causes include conditions such as Blount disease, nutritional rickets, trauma, metabolic bone disease, or even a neoplasm. Physical examination is useful in helping to distinguish pathologic versus physiologic etiologies. Asymmetric bowing with a lateral thrust upon walking is suggestive of a pathologic cause [35]. Radiographs of the entire lower extremity are known as teleograms and should be obtained while standing if suspecting a nonphysiologic cause. If a pathologic cause is found, it is recommended that the child be referred to an orthopedist or the specialist for the underlying etiology. The follow-up for an otherwise physiologic genu varus in a child should be every 4–6 months to ensure resolution.

Blount's Disease

Blount's disease is a pathologic cause of genu varus that is differentiated from physiologic bowing on physical exam and radiographs. Risk factors include African American lineage, early walking, and obesity. These children will present with an asymmetric angular alignment of the lower extremities and walk with a lateral thrust [35]. The teleograms will show the bowing deformity of the proximal tibia and medial beaking, with a downward slope of the proximal tibial

Telegram: @medical_k

www.konkur.in

metaphysis. There are two subtypes of Blount's disease: infantile and adolescent. The infantile type is usually diagnosed before the age of 4 years old and is bilateral, whereas the adolescent type can be unilateral or bilateral. The infantile type can be managed with braces to decrease the compressive forces and has a better prognosis if treatment begins before 3 years of age. If the varus deformity does not correct with bracing, then a referral to an orthopedist is warranted. In contrast, the adolescent form is more appropriately managed by an orthopedist because surgery with hemiepiphysiodesis or tibial osteotomy is the mainstay of treatment.

Genu Valgus

"Knock-kneedness," or "genu valgum," can also often present to a primary care clinician's office due to parental concern with the appearance of a child's legs and the clumsiness associated with this condition. Occasionally, the child may complain of pain in the knee or foot. Like genu varus, genu valgum is part of the normal progression of development, usually seen between the ages of 2 and 5 years old. When there are no other concerns of a potentially pathologic etiology such as trauma, a systemic condition, or a neoplasm, observation and reassurance is recommended. Worsening genu valgum after 4 years of age should raise suspicion regarding a pathologic cause. Clues found upon physical examination that make a pathologic cause more likely include [35]:

- Unilateral genu valgum
- Height that is below the third percentile
- Greater than 8 cm between the medial malleoli when the knees are extended, patellae pointed straight, and femoral condyles that are touching
- A medial thrust on ambulation

Similar to genu varus, when a pathologic cause is suspected, it is appropriate to obtain teleograms. The parents should be reassured if physiologic genu valgum is suspected, as it generally self-corrects when the patient is between 4 and 7 years of age. However, obese children should be followed regularly since they run a higher risk of developing worsening genu valgum [14]. Referral to orthopedics should be done for pathologic cases as they can lead to long-term consequences such as meniscal tears and higher rates of osteoarthritis.

Hip Problems

Developmental Dysplasia of the Hip

Formerly termed "congenital hip dysplasia," developmental dysplasia of the hip (DDH) refers to the abnormal development of the acetabulum and the proximal femur, which may occur as the child is developing and not always congenitally, hence the change in terminology. DDH may present at birth, with an abnormal gait as a toddler or activity-related hip pain in adolescents. Every newborn and child should be evaluated routinely for this condition until the child is walking normally.

The newborn hip exam should be performed on an infant who is not wearing clothes or diapers and should include the Barlow and Ortolani maneuvers. The Barlow maneuver is considered positive if there is a palpable clunk, while the hip is adducted with gentle posteriorly directed pressure, which signifies that the hip is dislocatable. The Ortolani maneuver should follow the Barlow maneuver and is considered positive if a palpable click is felt when abducting the hip while lifting the trochanter anteriorly, which assumes that the hip is reducible. Classically, Barlow and Ortolani maneuvers were performed together because when both are positive, diagnostic specificity increases to 99%; however, a recent reevaluation of examination techniques suggests that Ortolani's test is more important [36]. In children over 3 months of age, DDH is highly suspected if passive abduction of the hip is less than 45° [37]. Additional maneuvers include the Galeazzi and Klisic tests, which can help in detecting DDH in older children. The Galeazzi test is performed by having the patient assume the supine position with hips and knees flexed so that the feet are side by side and flat on a surface; the position of the knees are observed. The test is considered

Telegram: @medical_k

www.konkur.in

positive if the knee of the affected side is lower than the other. The Klisic test is performed by imagining a line between the anterior-superior iliac spine and greater trochanter to see where it falls in relationship to the umbilicus; if the line falls below the umbilicus, the test is considered positive. Children who have a positive Trendelenburg pelvic tilt test may also have DDH.

In the first 6 weeks of life, many newborns may have "clunks" due to normal physiologic laxity that may raise suspicion for DDH. Ultrasound screening for DDH is typically performed for infants younger than 4–6 months, however, should usually be postponed until at least 3–4 weeks of life to allow the normal laxity to resolve [38]. Older children and adolescents may be screened with plain radiographs. Confirmed cases should be referred to orthopedics. Treatment may involve utilizing a Pavlik harness and proceeding to surgery if it fails or if the patient is older than 18–24 months.

Transient Synovitis

Hip pain in a child aged 3–8 years old after a recent upper respiratory infection should raise suspicion for transient synovitis. Males are twice as likely to suffer from this condition than are females. Generally, the child will appear well but will have limited range of motion of the hip. If fever is present, it is often low grade. Basic laboratories including a complete blood count (CBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) should be obtained. The Kocher criteria [39] (refuses to bear weight on affected side, fever $\geq$101.3 F, ESR $\geq$40 mm/h, and WBC $>$12,000 cells/microL) are very useful in helping to guide the clinician. The likelihood of the presence of septic arthritis rises with each criterion met, and the presence of all four criteria makes the diagnosis of septic arthritis almost certain. Ultrasonography or MRI can be performed to identify if a joint effusion is present. If septic arthritis is not suspected, patients can be observed closely. If any signs or symptoms suggesting septic arthritis arise subsequently, then joint aspiration is recommended. Transient synovitis is managed conservatively with NSAIDs. Most patients make a full recovery within 1 week [40]. The child may return to activity as he or she tolerates it.

Septic Hip

As in adults, septic arthritis can be very damaging to the joint and therefore should not be missed. When septic arthritis occurs in the hip of a child, typically he or she will be ill-appearing and often febrile ($>$101 °F). The child may refuse to weight-bear or move the affected limb due to severe pain. Obtaining blood to check white blood cell count, ESR, and CRP is important. A high score using the Kocher criteria suggests septic arthritis [39] and typically the CRP is higher than 2 mg/dL. To confirm the diagnosis, an ultrasound-guided hip aspiration should be done with synovial fluid and blood cultures. Ideally, these should be done before starting antibiotics. Intravenous antibiotics should not be delayed, however, if the hip aspiration cannot be done in a timely fashion. Coverage should include the most common pathogens including *Staphylococcus aureus*, *H. influenzae* type B, and *Streptococcus pneumoniae*. Some patients may require repeated drainage of the hip joint so that blood flow is not compromised by the increased intraarticular pressure.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) must not be missed in children presenting with non-radiating, aching pain in the hip, groin, or upper thigh. There is usually no trauma associated with SCFE, but the pain worsens with activity and can cause patients to limp or even be unable to bear weight. SCFE is commonly found in obese, adolescent males ($>$95th percentile for weight). Examination will show a limited range of motion [14]. Often, the gait is altered. If the SCFE is unilateral, the patient may walk with a Trendelenburg gait; if involvement is bilateral, a waddling gait may be observed [41]. Plain radiographs of the hip with AP and lateral views should be obtained to confirm the diagnosis (Fig. 8). Upon diagnosis, immediate orthopedics referral is warranted because complications of SCFE include osteonecrosis of the femoral head and femoroacetabular impingement.

www.konkur.in

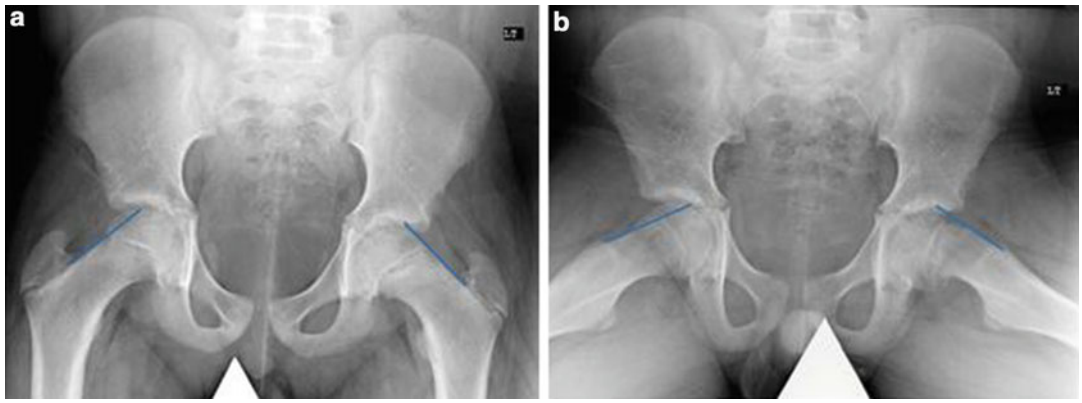

Fig. 8 Slipped capital femoral epiphysis. Image (**a**) is the anteroposterior (*AP*) view. Image (**b**) is the frog leg lateral view. The *blue line* on the AP (Klein's line) drawn along the femoral neck demonstrates the relative varus of the femoral epiphysis. A similar line drawn on the lateral demonstrates the relative posterior displacement of the left femoral epiphysis compared to the normal right hip. (From Lee [42]. With kind permission from Springer Science and Business Media)

Legg-Calve-Perthes Disease

Legg-Calve-Perthes disease (LCPD) is avascular necrosis of the proximal femoral head that typically presents in boys between the ages of 4 and 8 years old. Parents will often bring them in after the patients have been limping for about 3 weeks. The child may complain of groin pain radiating to the proximal thigh. Observation of gait may reveal an abductor lurch, while evaluation of range of motion will show a decrease in hip abduction and internal rotation. Although early LCPD may not show up on plain radiographs, they should still be done with AP and frog leg views. If radiographs are normal and clinical suspicion remains high, an MRI should be ordered. The frog leg views may show a crescent sign (Fig. 9), which is a late sign of LCPD.

Fig. 9 Perthes disease lucent crescent (*arrowhead*) of the outer femoral head on a frog-leg view in an 8-year-old boy. (From Oestreich and Crawford [43]. With kind permission from Springer Science and Business Media)

Although most cases are unilateral, LCPD can be bilateral. If found to be bilateral and symmetrical on imaging, additional workup is required with imaging of the hands, knees, and spine to rule out epiphyseal dysplasia [14]. Children should be made non-weight bearing, and orthopedic referral should be made for any child older than 6 years, or children younger than six, who have significant involvement of the femoral head. Early stages of LCPD can be managed with activity restriction, pain control, and close follow-up to monitor range of motion. Physical therapy may be prescribed to maintain range of motion. Containment treatment can be done for those with poor prognosis (i.e., children greater than 6 years of age at onset) [44]. Containment treatment involves various methods of keeping the femoral head within the socket to allow remodeling of the femoral head as it heals.

www.konkur.in

Foot Problems

Toe Walking

Toe walking can be a parental concern, although the children are usually asymptomatic. In idiopathic cases, the child will start walking on time but will walk on his/her toes. This condition usually resolves itself in 3–6 months. However, if upon examination passive dorsiflexion is less than 10°, an Achilles tendon contracture might be present. An Achilles tendon contracture is treated with serial short leg casting over 6 weeks, with each cast increasing the amount of dorsiflexion of the foot and ankle. Rehabilitation is also appropriate for those with mild contractures. Imaging is usually only performed if the history is unclear or if there is a question raised upon examination. An orthopedic surgery referral should be initiated if there is suspicion of a fixed heel cord (Achilles contracture) or if toe walking is unilateral, as this almost always has a pathological etiology [14].

Talipes Calcaneovalgus

Positional calcaneovalgus feet or talipes calcaneovalgus is very common among newborns, secondary to the uterine positioning [1]. After birth, the foot appears hyperdorsiflexed and abducted, appearing as though it is flipped and resting on the lower anterior leg. Imaging is not necessary unless the case is questionable, in which case obtaining simulated weight-bearing radiographs is appropriate. The majority of cases will self-resolve, but casting may be necessary if the foot and ankle cannot be plantar flexed past the neutral position.

Talipes Equinovarus

Talipes equinovarus, also known as "clubfoot," occurs when one or both feet appear overly plantarflexed and inverted. It can be caused by many etiologies and can be categorized into congenital, syndromic, and positional. Parents usually raise concerns due to the appearance of the foot; however, early on, children are asymptomatic. If left untreated, talipes equinovarus can lead to difficulty wearing normal shoes, pain, and a gait disturbance. Physical examination may demonstrate high arches, forefoot adduction, heel varus, and ankle equinus. It is important to assess the rigidity of the foot. Imaging with weight-bearing AP and lateral views is obtained in older children but not necessary in infants. Children with talipes equinovarus are usually managed by orthopedists with the Ponseti method, which entails long leg casting and subsequent bracing [45].

Pes Cavus

"Pes cavus" refers to abnormally high-arched feet which can be due to neurologic disease, residual clubfoot deformity, or idiopathic causes. Children with pes cavus will have difficulty wearing shoes and complain of pain in the forefoot. Examination should include an evaluation of the alignment of the ankle, heel, midfoot, and toes. In many cases, there will be calluses under the metatarsal heads. When pes cavus is suspected, AP and lateral films should be obtained to evaluate the alignment by passing a line from the axis of the talus to the first metatarsal, which will show an increased angle. All children with pes cavus should be referred to orthopedists; however, while awaiting their visit, arch supports and shoe modifications may be helpful [14]. Rehabilitation can also be prescribed to strengthen the foot muscles and to promote range of motion. When these measures fail, surgery may be a consideration.

Flexible Versus Rigid Flatfoot

Parents are often concerned if their child's foot is flat also known as pes planus. There are different types of flatfoot, and it is important to determine if the condition is flexible or rigid flatfoot, because the management can vary. Flexible flatfoot is rarely symptomatic; if it is, the patient will usually complain of an inability to keep up with his or her peers or feel discomfort in the medial hindfoot related to activity. Performing the Jack test is a quick and easy way to make the differentiation: the child is asked to stand on his/her toes and the clinician observes whether the foot's arch is restored [14]. If it is, then it is considered flexible; if it is not, then it is rigid. In children who have symptoms, it is appropriate to obtain plain

Telegram: @medical_k

www.konkur.in

Table 3 Orthotics for pes planus (flatfoot) [46, 47]

University of California Biomechanics Laboratory (UCBL) orthosis	Provides longitudinal arch support by encompassing heel and hindfoot
Heel cup	Provides calcaneal support

radiographs (AP, lateral, and oblique views) to rule out other causes.

Management of flexible flatfoot can be done by the primary care clinician as most cases improve on their own; therefore, reassurance is key. However, if symptoms persist, shoe inserts can be prescribed to give arch support (Table 3). Rigid flatfoot usually requires some intervention, whether it be orthoses, serial casting, or even surgery. Management of rigid flatfoot should be geared toward its cause and may even require orthopedic referral.

Tarsal Coalition

Tarsal coalition is one cause of rigid flatfoot. It is due to abnormal connections between two tarsal bones. Symptoms usually start late in childhood and can be related to a change in activity. Parents may observe that the child is walking with a limp. Upon examination, rigid flatfoot is found with restricted hindfoot motion. Radiographs including AP, lateral, and oblique views are first-line imaging and should be obtained to confirm the coalitions. If they are not well visualized, a computed tomography (CT) scan is the gold standard and may be ordered to confirm the diagnosis. Management depends upon the severity of symptoms. If there are minimal symptoms, observation is appropriate; mild to moderate symptoms may require a short leg walking cast for 4–6 weeks [14]. Cases that are persistent after nonsurgical treatment may require surgical intervention to remove the coalition.

Freiberg Disease

Osteonecrosis of the metatarsal head is called Freiberg disease, which typically presents in adolescent girls. It is due to ischemia that most commonly affects the second metatarsal head but may also affect the third or the fourth metatarsal head [48]. The patient may describe a feeling a dull, aching pain in the forefoot that is worsened with activity and can be related to a trauma. There will be tenderness and edema of the metatarsal head with pain on dorsiflexion. Although plain radiographs can show fragmentation of the metatarsal head with flattening, this usually does not appear until 2–3 weeks after the onset of symptoms. Management depends on the severity of symptoms. For mild symptoms, rest and modification of activities may be sufficient. However, if the pain becomes particularly bothersome, short-term casting to allow for non-weight bearing on the affected metatarsals may be needed. In persistent cases, surgery may be done to remove loose bodies or realign the bone [14].

Kohler Disease

Similar to Freiberg disease, Kohler disease is osteonecrosis, but of the navicular bone. In most cases, it is unilateral and presents more commonly in males between the ages of 4 and 8 years old. Patients may present with foot pain and limping. On examination, there is tenderness and swelling at the medial arch. Observing the child's gait may reveal a limp, with the affected foot turned out more than the other while walking. Plain radiographs show a smaller navicular. Patients tend to do well without treatment, as the condition can spontaneously resolve. Those with more pain can be treated with a short-term walking cast for 4–8 weeks [49].

Developmental Surveillance

The first year of life is marked by the highest rate of growth and development. The brain doubles in size in the first year of life and increases in size by another 15% in the second year. Developmental skills are acquired at a very high rate in infancy so that even minor disruptions in development at this stage can have serious long-term implications [1]. The goal of developmental surveillance in infancy is early identification of any deviations or disruptions to the normal growth and developmental trajectories. Identification should then lead to developmental and medical evaluation. Early intervention in children has been shown to improve functional outcomes for children with developmental delays [2].

The American Academy of Pediatrics recommends that developmental surveillance be incorporated into every well-child visit through the fifth year of life [3]. Developmental surveillance includes identifying risk factors for developmental delay, eliciting parental concerns, the clinical assessment of developmental milestones, and the administration of screening instruments.

Common risk factors for developmental delay include genetic diseases, congenital malformations, and prenatal factors such as congenital infections and exposure to drugs. Environmental factors include maternal depression, nutritional deficiencies, and toxic stress. A family history of genetic syndromes or developmental delay is important in assessing the risk for developmental delays (Table 1).

Eliciting parental concerns is important, because the parent has intimate knowledge of the child and has the opportunity to observe him or her over time. Additionally, research indicates that parental assessment or concerns about their child's development are generally accurate [4, 5]. Additionally, asking the parents for their concerns strengthens the therapeutic alliance with the parents and engages them in monitoring the development of the child.

The classification of "streams of development" remains helpful as a framework for understanding and evaluating development in infancy and early childhood. The streams of development include the domains of gross motor, fine motor, social, and language development. A fifth dimension of intellectual and cognitive development is sometimes added to assess global function and intelligence.

Neurodevelopment generally follows a predictable course. For example, motor development tends to progress in a cephalocaudal and proximal to distal fashion. However, individual variations are common.

Clinical assessment of development involves eliciting the acquisition of milestones in each stream of development at the appropriate age.

Motor milestones are generally easily observable during the visit such as neck control, sitting, standing, or walking [6]. Fine motor milestones such as object manipulation can also be observed during the exam. Verbal and social skills may be more difficult to elicit from the child during the brief visit in the unfamiliar environment of the doctor's office, and the clinician may have to rely on parental report for those milestones (Table 2). A complete assessment of development should also include an assessment of growth as well as a general physical and neurological assessment to detect any associated abnormality or risk factors.

The use of developmental screening instruments improves the accuracy of detection of developmental delays significantly, and their use is recommended periodically [7]. Several validated developmental screening instruments are available. The American Academy of

Table 1 Risk factors for developmental delay

Genetic and chromosomal abnormalities	Chromosomal defects: Down syndrome, fragile X syndrome, Klinefelter's syndrome, Noonan syndrome, Williams syndrome, Angelman syndrome, Rett syndrome, Prader-Willi syndrome
	Inborn errors of metabolism, mitochondrial diseases, lipid storage diseases, etc.
	Muscular dystrophy syndromes
Congenital malformations	Lissencephaly, holoprosencephaly, thyroid agenesis, etc.
Intrauterine	Drugs and toxins: Alcohol, illicit drugs, teratogens
Exposures	Congenital infections: (TORCH)
	Malnutrition (IUGR), placental insufficiency
Perinatal and postnatal	Prematurity
Conditions	Birth asphyxia or birth trauma
	Neonatal infections especially CNS infections
	Emotional deprivation
	Experiential deprivation
	Sensory deprivations: Hearing or visual impairment
	Malnutrition, iron deficiency
	Exposure to toxins: Lead poisoning
	Severe congenital heart disease requiring surgery

Table 2 Normal developmental milestones

Age	Gross motor	Fine motor	Social emotional	Language
2 weeks		Coordinated and effective sucking	Soothed by maternal voice	Startles to voice
		Hands fisted near face		
2 months	Lifts head off bed in supine position	Hands fisted	Social smile	Coos in response to social
4 months	Lifts chest off the table	Unfisted	Laughs aloud with	Vocalizes when alone
	No head lag when pulled to sit			
6 months	Tripod sit	Transfers object from hand to hand	Babbles, gestures for up	Babbles interactively
	Leads with head when pulled to sit			
	Rolls over in both directions			
9 months	Crawls on hands and knees	Inferior pincer grasp	Searches for family: Where is mama?	Mama, dada, nonspecific
12 months	Walks awkwardly	Mature pincer grasp	Proto-imperative pointing (points to a subjects he/she wants)	Mama, dada plus 3 words
15 months	Walks well		Proto-declarative pointing: (points to share experiences with parent)	Uses 3–5 words, names 1 object
	Recovers to standing from stooping			Mature jargoning
18 months	Runs awkwardly	Feeds self with a spoon	Points to 3 body parts	Uses 10–25 words
	Throws a ball walks upstairs with hands held			Names one picture on demand
24 months	Runs well	Follows a 2-step command	Parallel play	50 words or more, 2-word sentences, 50% intelligibility, knows own name
	Kicks a ball			
	Throws a ball overhand			
30 months	Jumps in place	Imitates horizontal line	Imitates adult activities	Knows pronouns (refers to self as I) and prepositions (up, in, out)
	Kicks ball throws ball overhand	Takes clothes off		
36 months	Rides a 3 wheeler	Copies circle	Starts sharing	200+ words, 75% intelligibility, 3-word sentences uses plurals names body parts
	Catches ball	Feeds self with a spoon	Knows name and gender	

Pediatrics recommends the administration of a standardized developmental screening instrument at 9, 18, and 30 months and the administration of an autism screening tool at 18 and 24 months. The USTSPF recently stated that there is insufficient evidence to support recommendations for or against screening for autism or speech and language disorders [6].

It is important to realize that some variability exists between children due to child or environment-related variables. However, significant delays should raise suspicion especially in the presence of risk factors and should prompt an evaluation or close monitoring. Table 3 provides a list of red flags that should raise alarm and prompt a workup.

Telegram: @medical_k

www.konkur.in

Table 3 Developmental red flags

Rolling over before 3 months	Indicates increased tone
Not walking by 18 months	Muscle weakness
No words by 18 months	Speech delay: hearing impairment, cognitive delay, ASD, etc.
Hand laterality before 12–18 months	Weakness of the other side
Not sitting by 7 months	Muscle weakness
Isolated fine motor delay	Visual impairment

If developmental delay is suspected based on the above evaluation, further assessment will be necessary to determine the cause. However, this evaluation should not delay the referral for rehabilitative services such as speech therapy, which are often helpful regardless of the cause of the delay.

In the USA, under the Individuals with Disabilities Education Act (IDEA), children from birth to 3 years can receive services with a general diagnosis of developmental delay. The management of children with developmental delays often requires a multidisciplinary approach. Children with severe developmental delays are prone to a host of complicating conditions such as seizure disorders, feeding difficulties, respiratory complications, and musculoskeletal complications. Care coordination is extremely important in the optimal management of these children.

Support is also needed for families who care for children with developmental delays to help manage the added physical and emotional burden and manage the needs of other typically developing children in the family.

Approach to the Infant or Child with Motor Delay

The approach to the evaluation of a child with motor delay depends on whether there are associated delays in one or more of the other streams of development. Global developmental delay (GDD) is diagnosed when delay is present in two or more streams of development.

Pure motor delay, in which the child has significant delay in achieving the motor milestones, can result from defects in the central nervous system, the neuromuscular junction, or in the muscles.

The evaluation of children with motor delay starts with the history, where special attention should be paid to perinatal history including pregnancy exposures and complications, delivery complications, prematurity, and postnatal course including neonatal illness and NICU admissions. Family history of neuromuscular disease or deaths in the neonatal period or infancy should be sought.

Prematurity is a common risk factor for developmental delays, with 11–12% of babies in the US born prematurely [8]. Therefore, premature babies require close developmental surveillance.

A complete and thorough physical examination with special attention to dysmorphic features, growth parameters, hepatosplenomegaly, and head circumference should be done. A full neurological evaluation including special attention to muscle tone and reflexes is critical for the diagnosis. Motor delay associated with dysmorphic features, growth delay, or delay in other milestones should raise the suspicion of a genetic syndrome, chromosomal defect, or a metabolic disorder. Increased muscle tone usually points to a CNS abnormality and is the hallmark of cerebral palsy. When a CNS cause is suspected, and a clear history leading to the diagnosis of cerebral palsy is not available, neuroimaging should be considered.

Severe hypotonia present at birth should raise the suspicion of congenital neuromuscular diseases such as Werdnig-Hoffmann Syndrome. Later-onset progressive hypotonia is a hallmark of muscular dystrophy.

It is important to remember that delays in achieving motor milestones can sometimes be caused by medical problems. Examples might include a delay in walking caused

Telegram: @medical_k

www.konkur.in

by developmental dysplasia of the hip, nutritional deficiencies such as rickets, or hypothyroidism [9].

Decreased muscle tone in the presence of motor delay points either to a systemic condition or to a defect in the muscles or neuromuscular junction. Metabolic conditions such as hypothyroidism as well as a number of the inborn errors of metabolism are associated with hypotonia and motor delay; however, most of these metabolic conditions are associated with delays in the other streams of development as well as other organ system dysfunction which may manifest as hepatitis, hepatomegaly, or seizures. Inherited diseases of the neuromuscular junction such as Werdnig-Hoffman disease causes severe hypotonia and motor delays and is usually fatal without invasive respiratory support. Muscular dystrophies have a later age of onset depending on the specific syndrome and are associated with progressive deterioration of muscle function. These disorders are distinguished from CNS and neuromuscular disorders by the presence of a high creatine kinase (CK) levels in the blood [10].

Red flags in the evaluation of motor delay that are indications for urgent referral to a pediatric neurologist include high CK levels indicating muscular dystrophy and the presence of muscular fasciculation indicating spinal muscular dystrophy. Loss of motor milestones is always abnormal and generally indicates a degenerative brain disorder. Patients in these categories are at risk of rapid deterioration of muscle tone that may threaten their vital functions such as swallowing and respiration.

Management of children with motor delay depends on the diagnosis. Children with motor delay regardless of the cause, however, usually will benefit from physical and occupational therapy, which aims to maximize function and prevent secondary developmental losses as a result of the original insult. Mobility and physical competence are essential for the exploratory behavior necessary for the development of other motor, social, and cognitive skills. Studies have documented that improved physical capacity results in significant improvements in language and problem-solving skills [11].

Speech Development and Speech Delay

Language development starting in the second half of the first year is largely dependent on the volume and quality of auditory input and the quality of the social environment. A positive social response to an infant's vocalizations is critical for the continuation of attempts to talk. Additionally, intact motor skills are necessary for the production of speech in infants.

Cognitive delay regardless of the cause is associated with speech delay. Cognitive delay can be one of the manifestations of a chromosomal aberration such as Down syndrome. Newer chromosomal and genetic testing is identifying chromosomal abnormalities associated with cognitive delays such as the 22q11.2 deletion syndrome [12].

However, in many situations the cause of the delay is never identified.

Speech delay is also a common presenting feature of autism spectrum disorder (ASD) and may or may not be associated with cognitive delay.

It is estimated that 40% of children with ASD have cognitive delays; however, even among those with normal cognition, speech and language development of children with ASD is often atypical.

Whether or not another diagnosis is present, early speech delay is associated with later language and reading disorders and the development of behavioral problems in late childhood and adolescence [13].

Evaluation of speech delay starts with a general evaluation to rule out risk factors including the presence of congenital or genetic syndromes. Family history of cognitive delay, ASD, or speech delay must also be sought. Physical examination including a thorough neurologic and assessment of the other streams of development may help to identify conditions that may increase the risk for speech delay. Early hearing evaluation should always be pursued in a child with speech delay. In addition, an assessment of the social environment including the nature of caregiver interactions with the infant is another critical part of the evaluation of speech delay.

Telegram: @medical_k

www.konkur.in

In children where speech delay is associated with communication and social interaction deficits, ASD should be considered and placed high on the differential diagnosis.

As with other forms of developmental delay, intervention in the form of speech therapy should not be delayed pending the establishment of the diagnosis. Children who have ASD and other associated deficits may benefit from special behavioral therapy. The diagnosis and management of ASD is discussed in ▶ Chap. 37, "Developmental Disability Across the Lifespan."

Recent research on language development indicates that language development in children can be enhanced by a rich and interactive linguistic environment beginning at birth. This includes responsive verbal interaction and reading to children. Promotion of early literacy by encouraging parents to interact verbally with their children and to read to their children regularly starting in the first year of life has been shown to be an effective strategy to improve language development. Additionally, there are convincing data that exposure to screen media in early childhood can result in delays in language and social development [14]. The American Academy of Pediatrics recommends that primary care physicians counsel parents to completely eliminate exposure to screen media in the first 2 years of life and to limit exposure to less than 2 hours thereafter.

Cognitive Impairment

Cognitive impairment is classified as mild, moderate, severe, and profound. The causes of cognitive impairment include genetic, metabolic, prenatal exposure to toxins or infections, and postnatal CNS insults. The more severe types of cognitive delay are more likely to have an identifiable etiology, whereas mild delays are more commonly idiopathic. In most children with moderate to severe cognitive impairment, other developmental delays are evident, allowing detection in infancy and early childhood. On the other hand, it is not uncommon for a child with borderline or mild intellectual disability to escape detection until after they enter school.

Children with mild to moderate cognitive delay often present with school underperformance. In addition to a thorough history and physical examination as outlined above, the workup of a child with isolated cognitive impairment should include genetic testing [15].

Evaluation of children with mild to moderate cognitive delay not associated with other diagnoses usually requires psychometric testing, which can be done through the school system.

Cognitive impairment is also associated with increased risk for behavior problems, including difficult to manage temper tantrums and disruptive behavior.

In the USA, children with cognitive delay qualify for special education services through the IDEA act. Referral for early childhood intervention services should be made early in the course of diagnosis, while further evaluation proceeds.

Oral Health

Dental caries has been called a "hidden epidemic." The Family Physician is often the first point of care for infants and children and their families and can be important in helping to provide oral preventive care and counseling during the most critical period for the development of dental disease. Disparities in the incidence of dental caries and access to dental care are more pronounced in the USA than those for general health. Six groups of children who are at high risk for dental caries have been identified [16]:

1. Children with special healthcare needs
2. Children of mothers with a high incidence of caries
3. Children with demonstrable caries, plaque, demineralization, or staining
4. Children who sleep with a bottle or are breastfed through the night
5. Later order offspring
6. Children in families of low-socioeconomic status

The American Academy of Pediatrics recommends that primary care providers be trained in

Telegram: @medical_k

www.konkur.in

Table 4 Anticipatory guidance for prevention of dental caries

Preventive strategies	Counseling points
Dietary counseling	Exclusive breast feeding for 6 months
	Continue breast feeding until 1 year or more
	Discourage bottle in bed
	Wean bottle by 1 year
	Avoid sugary drinks
	Limit 100% juice to 4–6 oz./day
	Only water between meals
	Model healthy eating habits
Oral hygiene	Model oral hygiene and consistent brushing
	Brushing twice daily with a smear of fluoride toothpaste
	Supervise brushing until age 8
Fluoride	Drink fluoridated tap water
	Use fluoride toothpaste
	Apply fluoride varnish 2–4 times per year starting with the eruption of the first tooth
Establish a dental home	Refer to a dentist by the first birthday
Dental injury prevention	Cover furniture corners
	Proper use of car safety seats
	Awareness of electrical cord risk for mouth injuries
	Use mouth guards in contact sports

performing oral health assessments on all children beginning at 6 months of age to identify known risk factors for early childhood dental caries and also to provide anticipatory guidance and dental referral by 1 year of age (Table 4).

Pediatric Autoimmune Neuropsychiatric Disorders Associated with Group A Streptococcal Infections (PANDAS)

The first neuropsychiatric syndrome linked to group A streptococcal (GAS) infection was Sydenham's chorea, associated with rheumatic fever [17]. More recently, other neuropsychiatric manifestations have been described in association with GAS [18].

Table 5 Criteria for diagnosing PANDAS

1. Presence of a tic disorder or OCD.
2. Prepubertal age of onset [3–12].
3. Temporal association between symptom exacerbation and streptococcal infection.
4. Abrupt onset of symptoms and episodic course of symptom severity.
5. Presence of neurologic abnormalities during periods of symptom exacerbation.

PANDAS describe a subgroup of children who present with acute-onset obsessive-compulsive disorder (OCD) or tic disorders that follows an episode of Group A streptococcal infection. Additionally, children may have an acute episodic exacerbation of a preexisting OCD or tic disorder following GAS infections. In many situations, the neuropsychiatric symptoms resolve promptly after the successful treatment of GAS infection. The association is proposed to be immune mediated, although an etiologic association between GAS infection and neuropsychiatric symptoms has not been proven. Proposed criteria for diagnosis [19] are listed in Table 5.

This phenomenon is strictly limited to the pediatric age group, which is necessary to make the diagnosis. Some authorities recommend testing for GAS in any child presenting with acute neuropsychiatric symptoms such as tics or OCD, or with episodic exacerbations of existing OCD or tic symptoms. Appropriate treatment of GAS is discussed elsewhere. Treatment with immune modulating drugs is not recommended outside of research settings. Symptoms of OCD and tic disorder should follow standard treatment guidelines. The response to therapy is similar in patients with and without associated GAS infection.

Although antibiotic prophylaxis is effective and recommended for the prevention of Sydenham's chorea, it is not recommended in the prevention of PANDAS pending studies that explore the pathophysiology of its relationship with GAS and studies of treatment outcomes.

Lead Poisoning

Lead is a heavy metal that does not occur naturally in the body and has no physiological role. Lead is toxic to all living cells, and the accumulation of lead can lead to dysfunction in almost all organ systems in the body. Children have an increased risk of lead poisoning because of their mouthing behavior and increased rates of lead absorption, especially when iron deficiency coexists, which is common in early childhood. Children are also particularly vulnerable to leads' toxic effects. Most importantly, the developing brain is highly susceptible to the toxic effect of lead. Quite low levels of lead exposure have been found to cause permanent and irreversible learning and behavioral problems.

Although lead poisoning has decreased in the USA since the 1970s following the elimination of lead from gasoline, paint, and the canning of food, certain pediatric population groups remain at high risk for lead poisoning. For those children, the CDC recommends routine screening at 12 and 24 months and at any time until 5 years of age if they have not been tested before [20]. These high-risk groups include:

1. All children who live in areas with 27% of housing built before 1950.
2. Populations in which the percentage of 1- and 2-year-olds with elevated blood lead levels is 12% or greater.
3. Children who receive services from public assistance programs for the poor such as Medicaid or the supplemental food program for women, infants, and children (WIC).
4. Children who screen positive by parental questionnaire.

Blood lead levels above 5 mcg/dl should initially be confirmed with a venous sample. If confirmed, it should prompt a home visit by the health department to inspect the home, day care, or any other place that the child spends time. The discovery of any source of lead should lead to proper treatment and abatement of the source, followed by re-evaluations of the blood level of the child to ensure that the levels decline. Other children living in the same household should also be tested.

Blood lead levels above 45 mcg/dl should be treated with chelation [21]. There are several compounds used to treat lead poisoning and different regimen recommendations depending on the severity of the intoxication. Because of the side effect profile of chelation drugs and the lack of experience among many clinicians in the use of these agents, the services of a toxicologist with expertise in chelation is helpful in the management of these patients [22].

Health Care of the Adolescent

21

W. Suzanne Eidson-Ton

The care of adolescent patients is similar to care for any other patient in many ways. However, adolescence is a period of rapid change as teenagers' transition from childhood to adulthood, with all of the concomitant physical, intellectual, psychological, and sexual changes. It can be quite a chaotic time for both teens and their families. For family physicians, the primary role is often to help smooth this transition by helping families and their teenagers understand all of the changes happening, supporting teens in safe and healthy risk taking, and encouraging the gradual differentiation that is occurring.

Ideally, all visits with teenagers will include time with the family together, time with the adolescent alone, and time with the parent/guardian(s) alone. Especially in new patient adolescent visits, it is very important to establish the extent of confidentiality to which teenagers have a right, and the limits of that confidentiality. It is also important for teens to understand what services they may consent to and receive without their parent/guardian(s)' knowledge or consent. This will vary from state to state, but will usually include some reproductive health services and perhaps limited mental health and drug/alcohol services. It is important to know local laws regarding consent of minors, so that one can appropriately counsel and treat adolescent patients and their families. An overview of minor consent laws by state in the USA can be found at: https://www.guttmacher.org/state-policy/explore/overview-minors-consent-law.

Regarding confidentiality, it is best practice to start a new patient visit with both the teen and her/his parent/guardian(s). It is important to begin the visit by letting the family know that they will be seen all together first in order to discuss everyone's concerns. It is also recommended to let them know early in the visit that the teen will then be seen alone, explaining that he/she has a legal right to confidentiality about anything s/he discloses unless they tell the physician that s/he plans to hurt him/herself, someone else, or that someone is hurting them. (Please note that the author is using a variety of pronouns to be as inclusive as possible.) As mandated reporters, family physicians must report suspected child abuse to the appropriate authorities (Child Protective Services – CPS) and must treat suicidal or homicidal intent as would be done with any other patient. Otherwise, whatever the teen discloses to the physician must be kept in confidence. This does not mean, however, that secrets should be encouraged between teens and their parent/guardian(s). In fact, in many situations, it is helpful to encourage teens to talk with their parent/guardian(s) about the things they have shared, and the physician can offer to be present during the discussion, if the teen thinks that would be helpful.

Some early adolescents may be quite intimidated to meet with a provider alone, but this is an important pattern and precedent to set, so that they and their parent/guardian(s) understand that this will happen at every visit. For very emotionally immature adolescents, the physician may meet with them very briefly, only to determine if there is anything else that requires discussion and to screen for abuse. There are always, of course, exceptions to the rule. For example, developmental delayed adolescents who spend all of their time with trusted adults may not need extensive time alone with the physician; however, it is best practice to check in with them alone if possible and appropriate.

Example of Interacting with an Early Adolescent

Particularly as teenagers gain emotional maturity, it is important for them to understand that their healthcare provider respects them as individuals and understands that they have autonomy in many decision-making aspects of their lives. This will help establish a trusted therapeutic relationship with the teen and allow for better use of motivational interviewing for risk reduction when necessary. One easy way to show respect is to greet the teen first upon entering the room and then asking her/him to introduce those accompanying him/her (if one does not already know them). This may not be as effective with emotionally immature teens, but as they get older, it can be very helpful. See box for sample introduction and confidentiality discussion with a new teen patient.

> Provider: Hello, you must be Mary Smith. It is nice to meet you. I am Dr. Jones. Mary (shyly) – age 14: Hi. Provider: Mary, can you please introduce me to this woman with you today? Mary: Oh, that's my mom. Provider: Thank you. Mrs. Smith, I presume? Mother: Yes. But you can call me Jane. Provider: Wonderful to meet you, Jane. I am Dr. Jones (shaking hands). Before we get started, I would like to explain to you both how we operate with teen visits. I will talk with you both, first, and hear about both of your concerns, and then I will meet with Mary alone for a bit, just to talk. For the physical exam, Mary, you may decide if you want your mother in the room. Mary: Oh, yes, please. Provider: Alright, no problem. I do want you to both know that, legally, at her age, Mary does have a right to confidentiality. So, I won't tell anyone else what Mary tells me without her permission. The only exceptions are if Mary tells me that she plans to hurt herself or someone else, or if she tells me that someone is hurting her. In those situations, I am obligated to notify other appropriate people or authorities. Do either of you have any questions?

History taking for an adolescent patient is similar to that of any other patient, particularly when the parent/guardian(s) are in the room. It is best to direct questions to the teen whenever possible and then obtain details and clarifications from the parent/guardian(s) as necessary. One can start by asking the teen if they have any concerns s/he would like to address, and then, subsequently, asking the parent/guardian(s) what they would like to address in the visit. As with any well child visit, the provider should ask about diet, exercise, screen time (including TV, computers, cell phones, video games, etc.), developmental issues (level in school, grades), and safety concerns (bike helmets, water safety, seatbelts). Regarding physical development, genetically female children should be asked about breast development and menses. All teens should be asked about pubertal hair growth. The immunization record should be reviewed for any needed boosters or updates. Once the patient's concerns and the parent/guardian(s)' concerns have been heard and understood and the past medical, surgical, medication, allergy, and family histories have been obtained, the parent/guardian(s) should be asked to step out of the room while the physician speaks with the patient alone. If there is some hesitancy or concern from the parent/guardian(s), one can explain that this is a routine part of visits with all adolescents and is recommended by all major medical associations. The parent/ guardian(s) may be further reassured that the goal of this is not to be secretive,

Telegram: @medical_k

www.konkur.in

but to help teenagers begin to take some responsibility for their health and their relationship with their health care provider. In almost all cases, these explanations are enough to ease parent/guardian(s)' mind. If the parent/guardian(s) are very resistant, and the teenager is relatively young, one may rarely elect to forgo the individual meeting with the teen, but should ask the family to prepare for this at their next visit. You can find a CDC handout for parents explaining the importance of individual time with the teen at this website: https://www.cdc.gov/healthyyouth/healthservices/pdf/OneonOnetime_FactSheet.pdf

Prior to the individual time with a teenager, it is a good idea to remind the adolescent about his/her right to confidentiality and the limits to that confidentiality. The primary issues to address during the individual meetings are psychosocial health issues. These include body image, mental health, sexual development and health, safety concerns, and substance use. It is important to touch on each of these issues at each visit, as teens are not seen in the office often, unless there is a problem or they need a sports or school physical. Further, adolescents are rapidly changing and answers will most certainly change from visit to visit. There are several acronyms that have been developed to help providers remember all of the areas to address. The best known is probably the HEADSSS assessment [1]. H stands for home, E is for education, A is for activity, D is for diet (body image), drugs, alcohol and tobacco, the first S is for safety, the second S stands for sex and sexuality, and finally, S for Suicide (depression). This acronym covers most important topics and is easy to remember. However, although it, in general, proceeds from least intimate to most intimate topic, home can be a sensitive topic for some teens, and school may be a safer way to start. Also, for the most part, HEADSSS focuses on risk factors, rather than acknowledging the teen patient's strengths. An alternative acronym that the author prefers [2] is shown in the side bar with letter explanation and sample questions. As is evident, this acronym begins with strengths, which is a wonderful way to begin a conversation with any patient, and the information obtained can be particularly useful if necessary to counsel the teen about risk reduction related to the other questions. Another difference in this acronym is the word *Emotion* rather than *Suicide*, which is much more neutral, and can prompt physicians to ask patients questions about rating their life and other less loaded questions first.

Psychosocial History (SSHADESS) **S – *Strengths*:** What are your strengths? What are you good at? What would your friends say that they like about you? **S – *School*:** What grade are you in? At which school? What do you like/dislike about school? Favorite subject? Friends at school? Do you feel safe at school? Any problems with bullying? Is there a trusted adult you can talk with at school? What do you plan to do after you graduate (or leave school)? **H – *Home*:** Do you feel safe at home? Do you have your own or share a room? Is there a trusted adult you can talk with at home? Is there a gun in your home? **A – *Activity*:** What do you do after school and on the weekends? How much screen time do you have? Are you involved in sports or other regular exercise? What do you do to have fun with your friends? **D – *Diet/body image*:** What do you like to eat? How often do you eat? Do you eat breakfast? How often do you eat meals with your family? Do you think that your body is about the right size, or would you like to gain or lose weight? How do you feel about your developing body? Do you see yourself as a boy or girl, both or neither? & ***Drugs/alcohol/tobacco*:** Do you know anyone who smokes or vapes? Do you smoke or vape? (Ask similar questions for alcohol and drugs.) *For teens who do use alcohol or drugs*, quantify amount and ask: Where do you use? With whom? **D – *Drugs/alcohol/tobacco (continued)*:** Do you ever drive after using or ride with someone who has used? **E – *Emotion*:** How do you feel on most days? If you would rate your life on a scale of 1–10, what number would you give your life? Why? (If less than 10), How could it be better? (If depression or low self-esteem red flags), Do you ever feel

Telegram: @medical_k

www.konkur.in

like hurting yourself? [Consider using a validated depression screening tool as the USPTF recommends screening for Major Depressive Disorder in all adolescents.] **S – *Safety*:** (Already partially addressed under school and home.) May talk about bike helmets, neighborhood safety, gang activity, seatbelts, never riding with impaired drivers, etc. **S – *Sexuality and Sex*:** This topic depends heavily on the sexual and emotional maturity of the teen. However, be aware that even young teens are known to sometimes be involved in sexual activity with their peers or be victims of sexual abuse. (Younger ~10–14): Do you find that you are attracted to any of your peers? If yes, are they boys or girls, both or neither? Do you have a boyfriend, girlfriend or significant other? Do you ever touch physically? Does anyone ever force you to do something that you do not want to do? As below, if appropriate. (Older ~15–21): Have you ever had sex? Do you currently? What is the gender of your partner(s)? Do you have intercourse? Oral, anal, vaginal? Barrier protection? Contraception? Do you feel safe with your partner(s)?

While the above illustrates a list of sample questions one can use, the goal is to have a conversation with teenage patients. The questions help the physician to open up the conversation. The objective of the physician should be to understand your patient's thoughts and feelings about all of these topics, in order to support them in their healthy choices and/or normalcy (most teens want to be "normal"); to help them problem solve around issues such as safety; or to motivate them to make safer, healthier choices, if they are at risk. Risk taking and experimentation during adolescence is a normal developmental process [3]. Unfortunately, reckless risk taking is a major cause of accidental death or injury in adolescents [4]. Healthcare providers can help teens understand how and be motivated to take risks in the safest possible ways. In addition to providing contraception to those teens at risk for unwanted pregnancy, healthcare providers should discuss prevention of sexually transmitted infections, including offering pre-exposure prophylaxis (PreP) to those adolescents at high risk for acquiring HIV. Physicians should also encourage adolescent patients to discuss these issues with other trusted adults as much as possible.

In addition to the questions presented, it is important to assess conflict resolution strategies for teens in their relationships, both in their families, as well as in any romantic relationships. These questions should be asked of all teens to screen for possible intimate partner violence (IPV) but also to counsel teens of all genders on healthy conflict resolution strategies. Possible questions for these issues are below.

> *What happens when there are disagreements at home? Do you feel safe in your relationships with adults and peers? Do you feel safe with your boy/girlfriend/significant other? (if appropriate) What happens when you and your girl/boyfriend/significant other argue or disagree? Do you ever feel controlled by your boy/girlfriend/significant other?*

Finally, when working with teens and their families, it is important to be aware that many adolescents may be LGBTQIA+ (lesbian, gay, bisexual, transgender, questioning [their sexuality or gender]/queer, intersex or asexual). For this reason, it is important to ask all questions around sex and sexuality with gender neutral terminology. Family physicians can help adolescents and their families understand that there is nothing wrong or abnormal about being LGBTQIA+. Unfortunately, LGBTQIA+ teens have higher rates of risky behavior, higher rates of being bullied or physically assaulted, and higher rates of depression and suicide, with transgender teens having the highest rates among all of these groups [5–9]. Acceptance and support from their family is one of the strongest protective factors for LGBTQIA+ teens, so encouraging family discussion and understanding (as much as is safe and possible) is ideal. Information for families struggling with these issues can be found at The Family Acceptance Project website: http://familyproject.sfsu.edu/home. A brief on-line training module for healthcare providers of LGBTQIA+

adolescents can be found at http://www.lgbthealtheducation.org/wp-content/uploads/Module-4-Caring-for-LGBTQ-Youth.pdf. Other resources for caring for LGBTQA youth can be found at https://prh.org/arshep-ppts/#lgbtq-essentials.

The physical exam in adolescence need not be more invasive than the physical exam performed in other well child exams in the absence of problems or specific issues. It is still important to monitor growth, and particularly to calculate the BMI (body mass index) in order to screen for overweight or obesity issues. Obesity is a growing public health problem in children and adolescents. In 2015–2016, 20.6% of 12–19 year olds were found to be obese [10]. There is no evidence that screening adolescents for scoliosis in the absence of symptoms or problems is effective, and therefore, routine screening is not recommended [4].

The physical examination of adolescents should generally include visual inspection of the breasts and genital region for Tanner staging and observation of any abnormalities, and these aspects of the exam should be chaperoned (either by the parent/guardian or another health center staff, per the wishes of the patient). However, there is no reason to do a more invasive genital exam unless needed for diagnosis of abnormal symptoms. The USPSTF (US Services Preventive Task Force) recommends against testicular exam for screening for cancer in adolescents. Similarly, all major organizations including the USPSTF, ACOG (American College of Obstetrics and Gynecology), and the ASCCP (American Society for Colposcopy and Cervical Pathology) recommend beginning cervical cancer screening no earlier than 21 years of age, regardless of sexual history. It is important to screen sexually active teens for syphilis and HIV and for gonorrhea and chlamydia, but this can be done with urine PCR testing for genital exposure, throat swab for oral exposure, or a self-collected rectal swab for anal exposure, so there is no need for a pelvic exam unless symptoms are present, or suspicion of another problem exists [4].

Physical sexual development is generally categorized using Tanner staging. Tanner Stage 1 is the preadolescent stage. For Tanner stages, see charts below (adapted from 11). The data presented here are reported averages, but there is a wide range of "normal" and some evidence that female adolescents in the USA and other developed nations are reaching these stages at earlier ages than previously, possibly related to more available calories [12] (Tables 1 and 2).

After the physical exam, if the parent/guardian(s) are not already present, the physician can usually have them join the adolescent for the summary and closure of the visit. Prior to inviting the parent/guardian back, the physician should answer any questions the teen has and remind the patient about confidentiality and the services that they can seek without parental permission. As with other well child exams, there are several preventive and anticipatory guidance issues to consider. Regarding immunizations, the CDC (Centers for Disease Control) recommends a Tdap (tetanus, diphtheria and pertussis) booster, the first dose of meningococcal conjugate vaccine, and the HPV (human papilloma virus) vaccine series for all girls and boys at age 11–

Table 1 Tanner stages for genetic females

	Average age (years)	Breast	Pubic hair	Other
Stage II	10–11	Bud (thelarche)	Long, soft, light hair near labia	Peak growth velocity follows
Stage III	12–13	Further growth of areola and tissue, no separation	More hair and more darkly colored	Menarche may occur late in this stage
Stage IV	14–15	Areola/nipple complex separates from breast tissue – secondary mound	Hair become coarse	Menarche usually occurs in this stage
Stage V	16–17	Larger breast with single contour	Full adult distribution	Menarche may occur here

Adapted from Ref. [11]

Table 2 Tanner stages for genetic males

	Average age (years)	Testes	Penis	Pubic hair	Other
Stage II	11–12	Testes enlarge and scrotal sac darkens	Minimal- no growth	Long, soft hair	–
Stage III	12–13	Further growth	Growth, especially in diameter	More hair and more curly	–
Stage IV	15	Further growth	Continued growth	Hair become coarser	Some axillary and facial hair
Stage V	16–17	Adult in size	Adult in size	Full adult distribution	

Adapted from Ref. [11]

12 years. A booster of the meningococcal vaccine is recommended at age of 16 years. In addition, the influenza vaccine should be administered annually. Immunocompromised teens require a different vaccination schedule. See details at https://www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html.

Regarding immunizations, HPV vaccine requires particular attention. The current immunization rates have improved over the last few years, but remain relatively low for both sexes. In 2017, 64.5% of girls received one dose but only 43.7% received the full series. The rates were even lower for boys, at 57.1% and 34.4%, respectively [13]. In order to increase the rates in HPV vaccination, and decrease the rates of cervical and other HPV-related cancers (including oropharyngeal, anal, vulvar, and penile cancers), primary care providers must be more effective at offering and counseling families about the vaccine. Many parent/guardian(s) believe that there is no need to vaccinate their children against a sexually transmitted disease since they are not sexually active. While physicians may educate parent/guardian(s) that vaccination should be done before exposure for maximal effectiveness, parent/guardian(s) may believe that this will increase sexual promiscuity in their teenagers. A study, however, demonstrated that there was no increase rate of sexually transmitted infections in a large group of adolescent girls after HPV vaccination [14].

Anticipatory guidance for parent/guardian(s) during the teen years is very important, but often skipped in adolescent visits. A thorough discussion of diet recommendations, exercise, and limiting screen time is warranted, particularly for teens with or at risk for obesity. There are many web-based resources for nutrition and activity in adolescence; several are available through the CDC website at http://www.cdc.gov/healthyyouth/npao/index.htm or at http://www.nutrition.gov/life-stages/adolescents/tweens-and-teens (this one has handouts for teens and parents/guardians). See Table 3 below for basic details of the American Heart Association recommended diet for teenagers [15].

In addition to a healthy diet, adolescents should participate in moderate to vigorous exercise for at least 60 min daily. The 2017 National Youth Risk Behavior Survey found that fewer than 27% of high school students were meeting these physical activity recommendations [16], so it is important for physicians to discuss physical activity with teen patients and their families. Finally, regarding screen time, the American Academy of Pediatrics recommends less than 2 h of media per day for all children. While the recommendation is that all screen time be reduced, a recent study found that only TV watching was associated with increased risk of diabetes in an at risk population of adolescents [17]. In general, however, the fewer hours spent in front of any screen, the more physically active a child will be. A healthy lifestyle, including a nutritious diet and regular exercise not only benefits adolescent physical health, but there is evidence that it is important for optimal cognitive function and emotional wellbeing as well [18, 19]. Parent/guardian(s) and teens should understand the relationship between diet, physical activity, and screen time and physical and mental health.

Table 3 Nutritional needs of adolescents

	Girls – early adolescence	Girls – late adolescence	Boys – early adolescence	Boys – late adolescence
Calories (kcal)	1600	1800	1800	2200
Fat (% kcal)	25–35	25–35	25–35	25–35
Lean meats (oz)	5	5	5	6
Vegetables (cups)	2	2.5	2.5	3
Fruits (cups)	1	2	1.5	2.5
Grains (oz)	5	6	6	7
Fat free milk/dairy (cups)	3	3	3	3

Adapted from Ref. [15]

While counseling regarding lifestyle factors affecting obesity is very important, physicians cannot ignore the social determinants of health that affect obesity rates. Obesity is more common in low income households, and obesity rates correlate with levels of poverty. A recent article using GPS with adolescents found a complex relationship between teen's neighborhoods and their food consumption, but one clear association was a relationship between distance to convenience stores and teen fruit/vegetable consumption [20]. In addition to assisting individual adolescents and their families, physicians can work at the local and community level to address such disparities in access to healthy food and safe places to exercise and play.

Parenting strategies and discipline are topics that should be discussed with the parent/guardian(s) of adolescents whenever possible. Many parents continue to use the parenting skills they used when their children were younger. However, given that the adolescent stage of development is concerned with identity development and differentiation, these parenting strategies are often no longer very successful. The Center of Children on Families at the Brookings Institute has found that adolescents with parent/guardian(s) with certain parenting styles tend to be more successful as adults. (See below for parenting styles [21].) Adolescents with parent/guardian(s) who parent in an Authoritative style have lower risk taking behavior and higher school achievement [21]. For parent/guardian (s) with difficulties around these issues, a separate counseling appointment is sometimes necessary. The physician can also speak with parent/guardian(s) without the adolescent present if they feel more comfortable speaking about their concerns when alone. The main objective of counseling parent/guardian (s) should be to improve their authoritative parenting skills. Important authoritative parenting skills include age appropriate parental monitoring, appropriate discipline and communication of family values, as well as warmth and regard. Self-efficacy in their parenting is also important. There are many resources for parent/guardian (s) to improve their parenting skills of adolescents, particularly those of communicating with their children. An example of a helpful websites is:

A Parent's Guide to Surviving the Teen Years at kidshealth.org/parent/growth/growing/adolescence.html.

Parenting Styles **Authoritative:** High emotional support with consistent discipline ("positive parenting") **Authoritarian:** Discipline but with low emotional support ("dominating") **Indulgent:** High emotional support without discipline ("permissive") **Uninvolved:** Low discipline and low emotional support ("disengaged")

In order to be supportive of their adolescent children, parent/guardian(s) need to understand that the major developmental task of adolescence is individuation towards independence. They can be most effective when they

Telegram: @medical_k

www.konkur.in

communicate well and guide their children in making good choices. One simple suggestion is have parent/guardian(s) consider how they would react to their teens' situations if they were their coach rather than their parent. COACH is also an acronym parents can use. (See below.) It is very important that parent/guardian(s) know that adolescents are still greatly influenced by their parent/guardian (s) when making decisions, even if it seems that the opinions of their peers matter more [21].

COACH to Improve Parenting

C: Create Confidence
O: Observe
A: Advise
C: Calmly let them experience life
H: Help them debrief after experiences

In summary, in order to be most effective in the healthcare of adolescent patients, it is necessary to have therapeutic relationships with both the adolescent patient and her/his parent/guardian(s). Family physicians who care for all individuals in the family unit are uniquely suited to establish these relationships. Addressing adolescent health needs in a respectful and confidential way is a must, but supporting parent/guardian (s) in their relationships with their teenage children and the authoritative skills that are most effective is also necessary for optimal health outcomes for youth.

General Principles

Definition/Background

The population of the world is aging due to decreasing fertility and mortality rates. By 2030 one in five Americans will be above the age of 65. In the USA, the fastest-growing segment of all age groups are those aged 85 and above. Seniors disproportionately use all aspects of health services. Clinicians treating this population face the challenge not only of treating chronically ill adults but also in helping to delay or prevent the onset of chronic disease. This chapter provides information on issues that are common to this population and are valuable to the family physician who cares for these patients.

Selected Clinical Issues

Frailty

Pathophysiology

As our population ages, addressing frailty will become an essential aspect of elderly care. Frailty, defined as a chronic progressive condition with a spectrum of varying severity and heterogeneity, is a geriatric syndrome of weakness, weight loss, and low activity associated with adverse health outcomes especially in response to a stressful environment [1, 2].

www.konkur.in

The overall prevalence of frailty in community-dwelling older adults aged 65 years and over in the USA ranges from 15%. Globally numbers range between 3.5% and 25%. This subset of the older population responds poorly to external stressors and lacks the ability to bounce back from acute illness. This in turn increases their risk of dependency. The prevalence of frailty is higher among women and African Americans. Primary frailty is due to intrinsic physiological dysregulation that has reached beyond a threshold of normal recovery. Research in recent years has shown that this results from physiological, genetic, cellular, and molecular changes in the body of the frail elder. These result in increased risk of poor outcomes, namely, falls, disability, dependence, and death (Fig. 1).

Secondary frailty is the result of complex interactions between multiple comorbidities and physiological changes during stress and aging. Among elderly people above 65 years of age, 75% suffer from three or more chronic conditions. Chronic conditions, including coronary artery disease, congestive heart failure, hypertension, peripheral vascular disease, chronic obstructive pulmonary disease, arthritis, cancer, diabetes, and HIV/AIDS, all increase the risk of disability and frailty. In both primary and secondary frailty, changes in the body occur, leading to decreased muscle mass (sarcopenia), loss of muscle strength, slowed motor performance (such as walking speed), decreased physical activity, worsened exercise tolerance (low energy or fatigue), and inadequate nutritional intake.

Diagnosis

In the clinical setting, the presence of frailty can be assessed by identifying at-risk elders through a detailed history, physical examination, and Comprehensive Geriatric Assessment. There are many validated tools available to use in clinical settings to screen for frail elders [3, 4] (See Table 1). There are two prominent models that form the basis of assessment tools. Frailty Phenotype tools are based on the five phenotypic criteria, and frailty index tools estimate the accumulation of deficits that occur due to aging process [5]. The first manifestation of frailty tends to be weakness, slowed walking speed, and/or decreased physical activity. Walking speed has been shown to predict

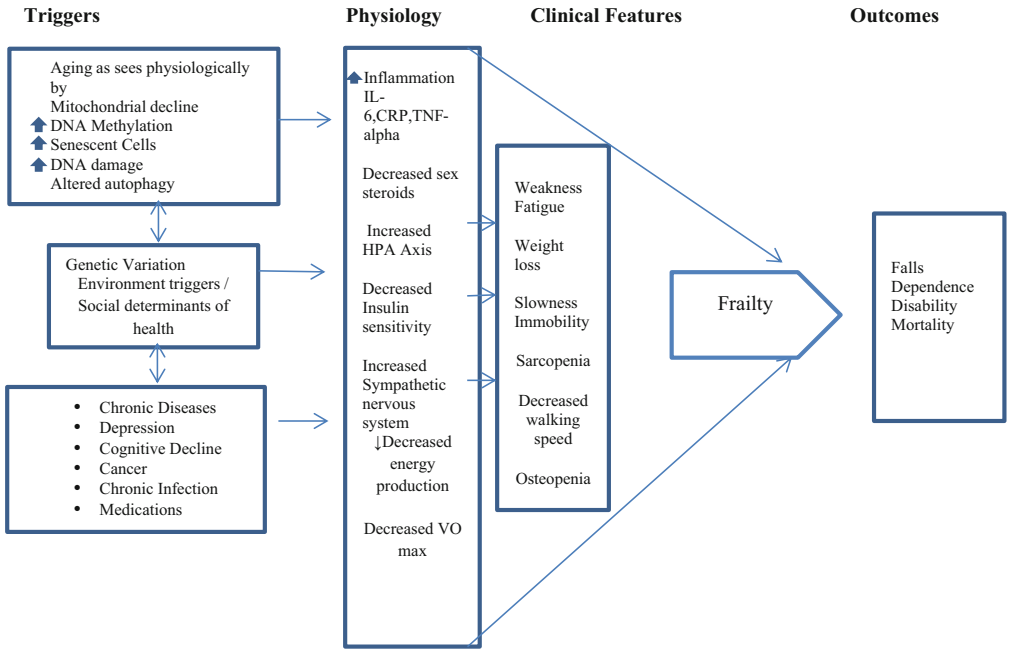

Fig. 1 Model for frailty

Table 1 Frailty assessment tools

Frailty assessment tool	Content
Frailty Phenotype [6]	Uses signs and symptoms to assess by predefined criteria – Frail if three of five criteria present
Clinical Frailty Scale [7]	Uses physical and functional indicators – 7 point scale to quantify degree of frailty
Vulnerable Elders Survey [8]	Thirteen questions, considers age, self-rated health, limitations in physical function, and functional disabilities- identifies at-risk community dwellers for health deterioration
Groningen Frailty Indicator [9]	The GFI is a validated, 15-item questionnaire with a score range from zero to fifteen that assesses the physical, cognitive, social, and psychological domains. A GFI score of four or greater is considered the cutoff point for frailty
Edmonton Frail Scale [10]	Multidimensional assessment instrument that includes the timed-up-and go test and a test for cognitive impairment
SHARE-FI Frailty Instrument [11]	Measures five items including grip scale – Has a web-based calculator
Tilburg Frailty Indicator [12]	Has two parts, part A measures life course determinants and multi-morbidity, and part B measures physical, social, and psychological domains of frailty
Comprehensive Geriatric Assessment [13]	Standard CGA-good correlation with clinical frailty scale
Frailty index (deficit accumulation index) [14]	The frailty index is composed by a long checklist of clinical conditions and diseases. Score is based on total accumulated deficits
FRAIL Scale [15]	Easy to remember F = fatigue, R = resistance (unable to climb one flight of stairs), A = ambulation (inability to walk one block), I = more than 5 illness, L = loss of weight (5%)

mortality and mobility disability and is a good screening marker. Frail elders meet three or more of five phenotypic criteria: weakness as measured by low grip strength (based on gender and body mass index), slowness by slowed walking speed (takes greater than 6–7 s to walk 15 ft), low level of physical activity (expends less than 270 kcal/ week for females and less than 383 kcal/ week for males based on activity scale), low energy or self-reported exhaustion, and unintentional weight loss (more than 10 lb. in a year) [1, 2]. Disability is measured by impairment in activities of daily living (ADL) and instrumental activities of daily living (IADL) (Table 2), and comorbidity is defined by the presence of two or more diseases. Frailty is a distinct entity and so can sometimes exist without the presence of disability or chronic comorbidities. Currently efforts are underway to identify biomarkers to identify frailty.

Management

Frailty is managed by a team-based, multi-disciplinary approach targeting biological, socio-behavioral, and environmental stressors and is associated with improved outcomes especially with respect to polypharmacy, falls, functional status, decreased nursing home admission, and mortality [16]. Preventing and minimizing immobility and maintaining physical activity and muscle mass are critical in older adults at risk of frailty. Resistance, or strengthening exercise supplemented by aerobic exercise and balance training [17] (e.g., tai chi) and nutritional support, particularly protein supplementation, appears to be important to both the prevention and management of frailty. Decreasing the stress of environments such as hospitals by reducing iatrogenic adverse events and polypharmacy during acute illness is also important. The role of micronutrient supplementation and hormone replacement therapy is not clear [18]. Addressing depression and various physical comorbidities is important to frailty management [19, 20]. Prescribing various appetite stimulants and anabolic agents to undernourished older adults needs further investigation. Recent studies with nutritional interventions like specific nutritional supplement formula; daily food fortification with protein supplement; nutritional education and counseling; and supplementation of micronutrients, including vitamin D,

Table 2 Definitions of ADLs and IADLs

Activities of daily living (ADLs)	Instrumental activities of daily living (IADLs)
Ability to perform basic self-care tasks: *Dressing* – Ability to dress oneself appropriately *Eating* – Ability to self-feed *Ambulating* – Ability to move in one's environment *Toileting* – Ability to use toilet facilities *Hygiene* – Ability to clean oneself, including hair and teeth	Ability to use instruments and interact with the environment to perform tasks necessary for independent function: *Shopping* – Ability to obtain necessary terns for care (food, clothing, hygiene needs) *Housekeeping* – Ability to keep environment clean *Accounting* – Ability to manage money and simple finances *Food preparation* – Ability to prepare foods for eating *Transportation* – Ability to use modes of transportation to get necessary items

omega-3 fatty acids, and multivitamins have reported mixed results. The management approach should consider issues that are particular to each individual, including interactions among conditions, and treatments, the patient's own preferences, goals, and prognosis as well as the feasibility of each management decision and its implementation [18].

Although frail elderly patients as a group have higher rates of morbidity and mortality, it is important to recognize that many frail elders will live for a number of years at a functional level. Key considerations for prevention of frailty include monitoring physiologic reserve, performing regular exercise to prevent chronic muscle loss, preventing acute illness (vaccinations), increasing physiologic reserve before anticipated loss (prehabilitation), and removing obstacles for smooth recovery (comprehensive geriatric evaluations).Understanding any functional losses that frail elderly may have sustained and pairing their needs with an appropriate level of services is important to maintain their quality of life. Early referral to palliative services when indicated may prolong survival and improve quality of life.

Constipation

Constipation is one of the most common gastrointestinal disorders seen in elderly. In adults older than 60 years, the prevalence is 33%, whereas the overall prevalence among adults of all ages is about 16%. Physicians typically define chronic constipation as infrequent bowel movements, usually less than three per week, for at least three of the prior 12 months. Patients may complain of a myriad of symptoms including hard stools, feeling of incomplete evacuation, abdominal discomfort, bloating and distension, excessive straining, sense of anorectal blockage during defecation, and the need for manual maneuvers and the use of laxatives [21, 22].

Types and Risk Factors

Constipation may occur in isolation or due to specific disorders. Primary constipation can be divided into three main types based on colon transit time and ROME 3 symptom criteria: normal transit, outlet dysfunction or defecatory disorder, and slow transit constipation [21]. There can be overlap of these primary types of constipation. The self-reported prevalence of secondary constipation increases with age and occurs more commonly in females than males. Less exercise, a sedentary lifestyle, diseases that create immobility, and the use of a variety of medications are the most significant risk factors in the elderly for secondary constipation (Tables 3 and 4).

Evaluation

Evaluation of constipation begins with a detailed history and physical examination, including a visual survey of perianal area, a digital rectal examination, and a detailed medication review. This initial assessment will help to identify secondary causes of constipation . Further diagnostic tests are directed toward symptoms and history and physical exam findings to rule out organic causes. Primary constipation is usually diagnosed after initial workup identifies no obvious etiology. The presence of any concerning symptoms such as bleeding per rectum, weight loss, and abnormal

Autonomic neuropathies	Hypokalemia
Depression	Systemic sclerosis
Stroke	Obstructing colonic lesions like cancer
	Dehydration

Table 4 Medications associated with constipation

Anticholinergics – Tricyclic antidepressants
Anticonvulsants
Antihypertensives – Calcium channel blockers diuretics
Anti-Parkinsonsian drugs
Opiates
5-HT $_3$-antagonists
Nonsteroidal anti-inflammatories
Chronic laxative abuse
Bismuth, iron, lithium, iron, aluminum antacids

test results like anemia should prompt urgent direct visualization of colon. Colon transit study or manometric evaluations may be indicated in refractory cases of constipation [22].

Management of Constipation

Nonpharmacological Management

Most elderly will improve by increasing physical activity, fluid intake, increasing fiber slowly to 25–30 g in their diet, and the cessation of any offending medications. It is important to remind individuals to respond to the urge to defecate after drinking warm, caffeinated beverages in the morning and to develop a daily routine for toileting. Foods high in soluble fibers such as grains, bran, nuts, beans, vegetables, or fresh fruits will help by adding bulk to the stool.

Pharmacological Management

When lifestyle, dietary changes, and nonpharmacological interventions are insufficient to ameliorate symptoms, a variety of over-the-counter and prescription medications are available to treat constipation. A stepwise approach with initial bulking agents and an osmotic laxative should be considered before adding stimulants (Table 5). Bulking agents cause increases in stool volume, a decrease in colon transit time, and an improvement in stooling consistency. Osmotically active agents are nonabsorbed agents whose main side effects are increased bloating and gas. Stimulants alter colonic motility and can alter fluid and electrolyte transport into the stool. They should be restricted in their use to two to three times a week to prevent overstimulation and atony of the bowel. The last resort for severe constipation is the addition of rectal suppositories and/or enemas to stimulate colon evacuation. In elderly with cardiac and renal problems, use of phosphate enemas more than the recommended dose (one enema in 24 h) can lead to electrolyte abnormalities, dehydration, and rarely death. Lubricants are avoided in elderly as they can cause lipoid pneumonia if aspirated as well as anal leakage.

Newer agents like chloride channel activators (lubiprostone) and guanylate cyclase C activator (linaclotide) act at the receptor level in the gut and increase intestinal fluid, accelerated stool transit, and relaxation of the smooth muscle and may be indicated in select cases of chronic constipation. Serotonin 5-HT4 receptor agonists (e.g.,

Telegram: @medical_k

www.konkur.in

Table 5 Drug therapy for constipation

Drug groups and specific medications	Common doses	Comments
Bulk agents		Effective at 12–72 h, inexpensive, causes gas and bloating
Bran Methylcellulose (Citrucel) Psyllium (Metamucil, Konsyl) Barley malt extract Calcium polycarbophil (FiberCon)	1 cup/day 1–4 tbsp./day 1–4 tbsp./day 12–32 g bid 1 tab qd-qid	
Lubricants		
Mineral oil	Contraindicated in elderly	
Osmotic/ hyperosmolar agents		Effective in 24–48 h, nonabsorbable, treats moderate to severe constipation PEG effective in 1 h
Lactulose (Cephulac) Sorbitol (70%) Polyethylene glycol (Metamucil)	15–30 ml qd-bid 15–30 ml qd-bid 6–25 g once per day	
Stimulants		Most effective, most work within 1 h, senna takes 8–12 h, long-term uses of anthraquinones causes melanosis coli, GI cramping
Anthraquinones-senna (Senokot) Bisacodyl (Dulcolax) Glycerin	Two tablets once daily to four tablets twice daily 10 mg suppositories or 5–10 mg by mouth up to three times/week Suppository; up to once daily	Rectal irritation
Saline laxative		Effective in 1–3 h, Magnesium toxicity
Magnesium (milk of magnesia)	15–30 ml once or twice daily	
Enemas		Effective within 30 min, last resort in healthy patients; used frequently in combinations with stimulants in patients who are demented, hospitalized, or on chronic narcotics Mechanical trauma, electrolyte problems
Tap water Phosphate enema (Fleet) Soap suds enema Mineral oil retention enema	500 ml per rectum 1 unit per rectum 1500 ml per rectum 200–250 ml per rectum	
Secretagogues		Opioid-induced constipation diarrhea, nausea headache
Lubiprostone (Amitiza) Linaclotide (Linzess)	24 mcg BID 145 mcg once daily	
Serotonin 5-HT4 receptor Agonists (prucalopride)	2–4 mg once daily	Approved by FDA, also available in Canada and Europe

Telegram: @medical_k

www.konkur.in

prucalopride) act by increasing intestinal motility and are available in Europe and Canada [23].

Sleep-Related Disorders in Elderly

Older adults consider quality sleep an essential part of good health [24]. More than half the elderly have sleep complaints. There is a common misconception that sleep disruption is an expected phenomenon of aging. Higher prevalence of sleep disruption is noted in the elderly as it is related to coexistent physical and psychosocial conditions and not solely due to physiological changes. It appears that there is bidirectional relationship between sleep disorders and multiple comorbidities and psychiatric disorders [25]. The most common sleep complaints among older adults are difficulty falling asleep, nighttime awakening, early morning awakening, and daytime sleepiness. Certain sleep disorders do increase in prevalence with age, such as sleep-related breathing disorders (i.e., sleep apnea) [26], periodic limb movement disorder [27], restless legs syndrome, and circadian rhythm sleep disorders. At least one-half of community-dwelling older adults use OTC and/or prescription sleeping medications [28].

Compared with younger adults, older adults generally take longer to fall asleep and have more nighttime wakefulness and more daytime napping. This is due to intrinsic age-dependent changes and interactions between circadian arousing processes and the homeostatic sleep drive. An earlier bedtime and earlier wake time are also common due to advanced circadian rhythms and reduced amplitude of circadian rhythm. Older adults also have less N3, or slow-wave, sleep (which is the deeper stage of sleep) than younger adults and increases in light stages of sleep [29].

Sleep-related disorders can be identified by routinely asking simple screening questions related to sleep habits, snoring, sleep quality, leg movements in sleep, and daytime sleepiness or fatigue. Assessment of coexisting medical problems and medications that affect sleep should be considered. Polysomnography may be indicated when sleep apnea, periodic sleep disorders, or narcolepsy is suspected. Wrist actigraphy can be used in identifying circadian rhythm disorders and in nursing home residents, in whom traditional sleep monitoring can be difficult to obtain [20].

Management of sleep-related disorders is guided by the specific diagnosis and any associated medical comorbidities. Sleep hygiene measures can help with milder insomnia. The strongest evidence currently supports cognitive-behavioral therapy for chronic insomnia which generally combines stimulus control, sleep restriction, and cognitive restructuring [20]. Short-term hypnotic therapy can be considered, but long-term use has been associated with increases in adverse events like falls [30], cognitive impairment, and impaired driving [31, 32]. Obstructive sleep apnea (OSA) is a treatable condition that is associated with cardiovascular disease, including hypertension, stroke, myocardial ischemia, arrhythmias, cardiovascular events, and all-cause mortality [33]. OSA is also associated with motor vehicle crashes, and there is some evidence suggesting a link to cognitive impairment [34]. Older patients whose sleep apnea is associated with congestive heart failure or respiratory disease should be referred to a sleep specialist.

Social and Functional Issues

The vast majority of Medicare beneficiaries have one or more chronic conditions and geriatric syndromes, which are defined as unique, multifactorial health conditions in elderly that increase their risk of dependency and disability. Our healthcare system is organized in such a way that most sites of care such as the hospital, outpatient clinic, and nursing homes work in silos and there is not much incentive to improve care coordination [35]. Therefore, innovative cost-effective models that consider comprehensive geriatric evaluations and those that improve the quality of care and safety of the elderly should be developed and financed by current healthcare system [36] (Fig. 2).

In acute care settings, systematic approaches using multicomponent multidisciplinary

Telegram: @medical_k

www.konkur.in

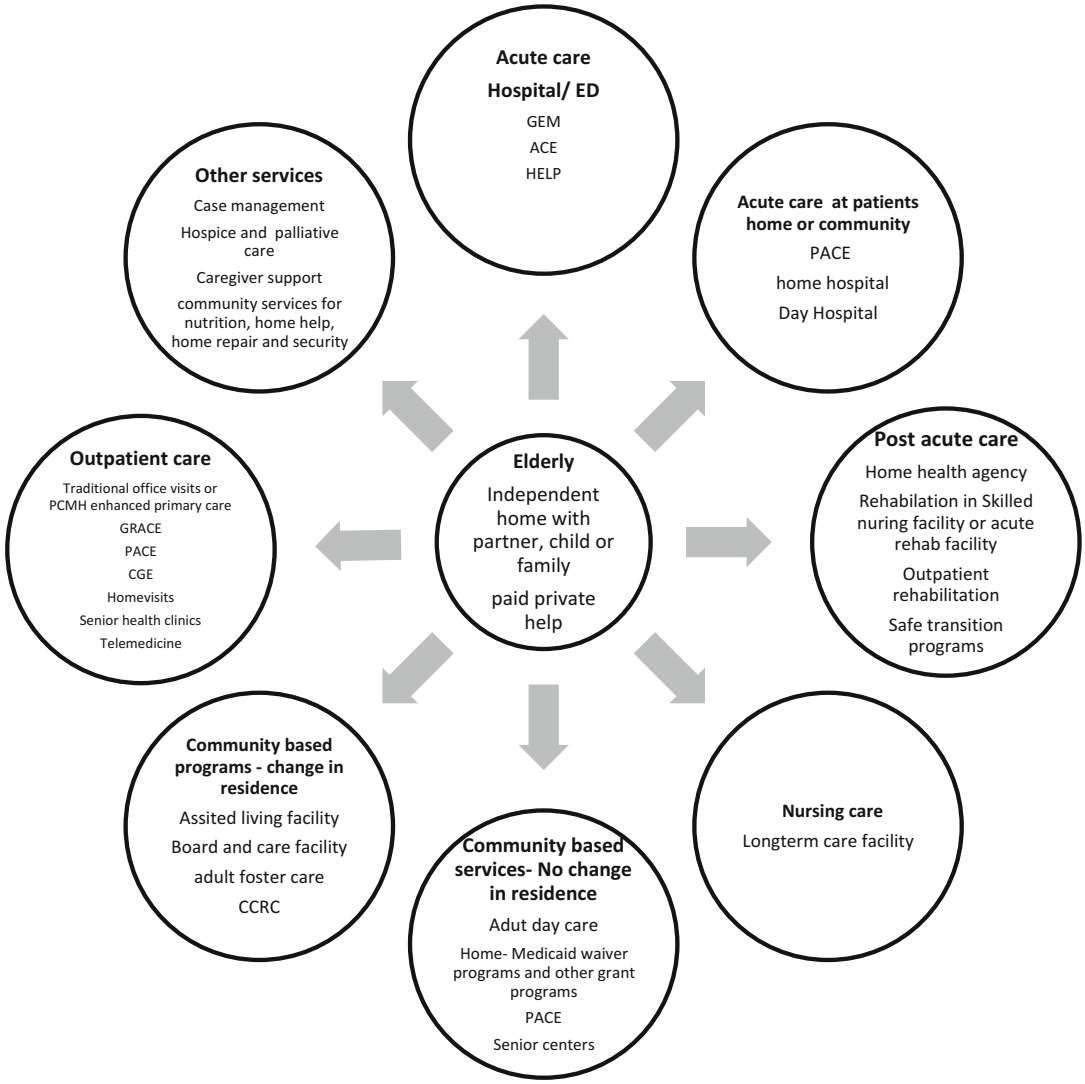

Fig. 2 Services available for elderly across various healthcare settings. *GEM* geriatric evaluation and management, *ACE* acute care of elderly, *HELP* hospital elder life program

interventions decrease morbidity in hospital and improve functional outcomes [37–39]. In some situations hospital at home provides safe, economic, and effective alternatives to inpatient care in the community [20, 36]. Targeted interventions that improve care transitions before and after discharge, the use of home health services, caregiver support, case management, and comprehensive discharge planning that includes follow-up, medication reconciliation, and education have all been shown to reduce inhospital readmission and improve clinical and functional outcomes [36, 40].

Program of All-Inclusive Care for the Elderly (PACE) [41, 42] is a model of care that provides inpatient, outpatient, and long-term services to frail community-dwelling adults requiring more rigorous c, typically only available in a nursing home setting. Interdisciplinary teams provide care across the continuum, thereby catering to complex medical and social needs of these elderly individuals.

Telegram: @medical_k

www.konkur.in

Outpatient comprehensive geriatric assessment (CGA) [37] and geriatric evaluation and management (GEM) [36] are supplemental services designed to identify all of a person's health conditions affecting their physical, cognitive, functional, and social capabilities and also to help with development of comprehensive treatment plan. Geriatric Resources for Assessment and Care of Elders (GRACE) is a patient centered medical home-based model with enhanced geriatric care which provides home-based CGA by an interdisciplinary team, who coordinate complex healthcare needs with the patient's primary care provider and community liaison [40, 42].

Community-Based Assistive Services and Living Arrangements

The population of older adults is characterized by heterogeneity across measures of health status, functioning, and socioeconomic position. The options available to a particular individual are dependent on many variables including the seniors' specific needs, their caregiver support in terms of family and friends, their financial and insurance status, available assistive services, and living arrangements. For the physician, an important goal is to assist the patient in finding appropriate services and living arrangements (Fig. 2) [20, 43].

Assistive Services

Informal support for seniors comes from family and friends. Formal support services are part of every community. There are a variety of formal assistive services designed to support seniors who are living in noninstitutionalized settings. Support services come from both governmental organizations and private organizations. Information and referral services are available to find the types of services that people need (Table 6).

Alternative Living Arrangements

Many seniors find themselves in need of living arrangements other than the single family home/apartment because of failing health. There are a variety of options, depending on the level of services needed.

Independent living facilities – Independent living facilities (ILFs) are for the senior who needs minimal services but prefers to have them centralized. Such housing usually is an apartment or a bungalow that is associated with a facility providing services in a centralized location. Usually ILFs provide for a congregate meal service, exercise facility, group activities, and a group transportation system. Many of these facilities provide for an easy transition to a more intensive assisted living mode.

Board and care facilities – The board and care facilities are also called group homes or residential care facilities. These are living arrangements in which a number of unrelated seniors live together providing for a reduced cost of services and greater care supervision. The residents can have their own room, or share a room, and have access to a cooperative living room, dining room, and kitchen. There is nonprofessional staff support at these facilities that does the housecleaning and meal preparation and can assist residents in the taking of medication. These facilities are frequently licensed by the state.

Assisted living facilities – Assisted living facilities are growing in popularity. They are also known as personal homes, residential homes, and domiciliary care. An assisted living facility offers an independent living arrangement with 24 h support from licensed professional staff. Medication administration and management can be directed by either nonskilled or nursing staff depending on state license requirements. They have fewer regulations and are mostly funded by private long-term care insurance. Costs are not reimbursed by Medicare except in a few states. Usually people share living rooms, dining rooms, and recreational facilities but live in their own apartment-like room. This living arrangement is intended to provide seniors with increasing help from staff as they age while they remain in the same environments.

Continuing care retirement communities (*CCRCs*) – CCRCs are all-inclusive facilities that provide the levels of care necessary for the aging individual. They require substantial

Telegram: @medical_k

www.konkur.in

Table 6 Formal community-based support services for seniors

Community-based services	Description
Senior centers	Central location for group activities for seniors such as games, crafts, health fairs, etc.; usually has a congregate meal program
Adult day care	Provides daytime supervised activities for seniors in a group setting; some can accommodate patients with dementia. Nonskilled custodial care to custodial car not covered by Medicare
Day hospitals	Provides daytime supervised activities for seniors in a group setting plus medical services (usually multidisciplinary rehabilitation services or nursing services for parenteral medication). Covered by Medicare like home health services
Nutrition programs	Provides meals to seniors; can be at congregate sites such as day care or senior centers; can be home delivered program such as meals-on-wheels
Housekeeping services	Provides simple housekeeping services such as house cleaning, washing, shopping, or food preparation
Home repair services	Provides necessary home repair services such as installation of safety equipment (bath railing, locks), repair of steps or simple plumbing or electrical needs
Security services	Provides for easy contact to emergency services; commonly a necklace or button that contacts local emergency room
Telephone contact services	Provides for a daily telephone call to ensure that the individual is in no need
Transportation services	Provides transportation for seniors into the community; sometimes limited to appointments for healthcare needs
Case management	Provides a coordinator of care for a senior who can assist in financial and social service needs
Respite care	Provides for short-term care for a senior so that a live-in caregiver can have a break (respite) from care

financial resources that are typically funded through upfront "entry fees" and a fixed monthly expense, or a variable monthly expense depending on the level of services needed. Most provide for independent living, assisted living, and more supervised living including a skilled nursing facility. Financing is mostly private, but some facilities may have Medicare- or Medicaid-funded beds for skilled care.

How to Help Seniors Understand Medicare

Medicare Structure

Medicare is federal health insurance that is administered by the Center of Medicare and Medicaid Services (CMS) for people 65 or older, people under 65 with certain disabilities, and people of any age with end-stage renal disease (ESRD) requiring dialysis or a kidney transplant. It was enacted into law in 1965 and is currently the nation's largest source of payment for medical care, insuring almost 54 million beneficiaries.

Medicare comprises four benefits. Medicare Part A covers hospital, skilled nursing home, home health, and hospice services. Medicare Part B covers physicians, nurse practitioners, social workers, psychologists, therapists, laboratory tests, and durable medical equipment. Medicare Part D covers some of the cost of prescription medications. Medicare Part C provides the benefits offered under Medicare Parts A and B through Medicare Advantage (MA) plans, which are managed care plans. Most MA plans also offer Medicare Part D benefits. Medigap supplemental insurance plans are available that cover Medicare Part A and Part B deductibles and coinsurance costs [44]. Medicaid is a joint federal and state program that provides health insurance (including long-term custodial care in nursing homes) to people of all ages who have low incomes and limited savings [45].

The Affordable Care Act (ACA) of 2010 laid out several changes to the financing, coverage, and costs of healthcare for older adults. Some of the major changes include creation of the Center for Medicare and Medicaid Innovation (CMI),

which has been charged with testing and implementing new care and payment models such as the Accountable Care Organization and the Patient-Centered Medical Home, partial closure of the coverage gap in the Medicare Part D, extended coverage for preventive care services, and expansion of Medicaid (32/50 states as of September 2017) in which many more Medicare beneficiaries will be qualified as dually eligible, eliminating many of their out-of-pocket expenditures.

Although Medicare spending is on a slower upward trajectory now than in past decades, the aging of the population, growth in Medicare enrollment due to the baby boom generation reaching the age of eligibility, and increases in per capita healthcare costs are leading to growth in overall Medicare spending. At the same time, recent legislative changes, including repeal of the ACA's individual mandate, have worsened the short-term outlook for the Medicare Part A trust fund and have led to projections of higher Medicare spending in the future.

Medicare Finances

In 2018, Medicare accounted for 15% of the federal budget and 20% of national healthcare spending, 30% on prescription drugs, 23% on physician services, and 25% of hospital payments. 85% of the funding comes from people younger than 65 years old through taxes and interest on the Medicare trust fund. Only 15% comes from monthly premiums, deductibles, and co-payments. Total Medicare benefit payments for 2018 were 731billion dollars [45]. Approximately 85% of patients with Medicare have some form of supplemental insurance to help pay for deductible costs, co-payments, and uncovered expenses (especially prescription drug costs). Fifteen percent of patients have Medicaid supplemental insurance, 35% have an employer-sponsored plan, 25% have purchased a private supplemental plan (so-called Medigap policy), and 10% have supplemental plans through a variety of public (state and federal) programs. In 2013, the average Medicare beneficiary spent $ 5503 out of pocket. This Table 7 includes premiums for Medicare and other types of supplemental insurance and costs incurred for medical and long-term care services [46, 47].

Covered Services

Medicare is an extensive insurance plan with coverage extending from hospital to home and from physicians to therapists. Its coverage is complex and subject to a variety of deductibles and co-payments (Table 7). Neither Part A nor Part B of the Medicare program covers routine dental or foot care, hearing aids, eyeglasses, orthopedic shoes, cosmetic surgery, acupuncture, custodial nursing home care, or care in foreign countries. The preventive services that are 100% covered are yearly wellness visits, a fecal occult blood test, pap smear, Herpes zoster vaccination, screening mammogram, blood tests for diabetes, cardiovascular disease, influenza and pneumococcal vaccinations, glaucoma screening, sigmoidoscopy or colonoscopy or barium enema, measurement of bone mass, hepatitis B vaccination, and medical nutrition therapy for diabetes and kidney disease [44].

Assessing Older Drivers

Currently, motor vehicle injuries are the leading cause of injury-related deaths among 65- to 74-year-olds and are the second leading cause (after falls) among those aged 75 to 84 years. Older adult drivers have the highest fatality rate per crash and per mile driven among all age groups except for those below 29 years. Driving is a cornerstone issue for many seniors as it provides access to shopping, medical services, food, and socialization. The inability to drive may increase the risk of social isolation and negatively affects well-being.

Inquiry about driving should be routine part of history taking. The initial screen should include review of medications and an assessment of any medical illness that might affect driving ability. A collateral history from family members about unsafe driving behaviors or traffic violations may be required. Those at risk should have driving-related factors assessed. These include vision, cognition, and somatosensory skills.

Table 8 Potential or mild functional losses associated with increased driving risks

Cognitive loss	Visual-spatial losses more important than memory in early disease Slowed central processing of information ("slowed reaction time") MOCA (Montreal Cognitive Assessment) $\leq$18; Mini-Mental Status Examination (MMSE) $\leq$ 24; Trail Making Test $\geq$180secs, Maze Test $\geq$60secs
Motor loss	Loss of grip strength and wrist function Limitations in rotation of neck Limitation in upper and lower extremity motion/strength Rapid walk or get up and go test $\geq$9 secs
Sensory loss	Visual loss – Visual fields, central acuity, night vision, and increased glare Hearing loss – Especially bilateral hearing loss Patients with combined visual and hearing loss at highest risk
Loss of consciousness	Any seizure disorder Medical diseases (cerebrovascular, cardiac arrhythmias, diabetes, medication use, alcohol use) that have caused loss of consciousness within last year

Table 8 lists the most commonly cited causes of potential or mild functional losses correlated with driving impairment. Licensing, and testing, and mandatory medical reporting requirements vary from state to state in the USA. Physicians often play a key role in identification and referral of potentially unsafe drivers [48].

Once the physician has determined that the individual elder is at risk, then a discussion should ensue with the patient and their family about reasons for restricting driving and possible evaluation and remediation through driving rehabilitation services or adult driving classes [49]. In many states, the Department of Motor Vehicles has a driving competency assessment program that requires seniors to take written and performance tests to determine continued licensure. In states where this is unavailable, it is important to consider assisting the patient and family with alternate modes of transportation and available services to help compensate for the loss of driving independence. Ongoing assessment at follow-up is crucial to identify depression, isolation of the patient, and caregiver stress.

Urinary Incontinence

A standardized definition of urinary incontinence (UI) by the International Continence Society states that UI is the complaint of involuntary loss of urine, which is objectively demonstrable and is a social or hygienic problem [1]. Based on population studies, the prevalence of UI ranges from 9.9% to 36.1%, and prevalence is often twofold higher in older women versus older men [2]. UI is underreported, with an estimated 50% of patients not seeking help. This may be due to embarrassment or the belief that UI is a normal part of aging. There are significant clinical, psychosocial, and financial impacts associated with UI, including depression, anxiety, sexual dysfunction, work impairment, social isolation, dependence on caregivers, and reductions in quality of life [3].

In the elderly, bladder capacity and force of contractility decrease as a result of the aging process while the post-void residual (PVR) volume may increase [4]. There also may be uninhibited bladder contractions. These physiological changes do not cause UI but are predisposing factors for UI. There also are age-associated changes in vasopressin and atrial natriuretic hormone that lead to the elderly excreting most of their fluids later in the day and at night, resulting in one to two episodes of nocturia [5].

Types of Urinary Incontinence

When evaluating a patient with UI, a key initial step is determining if the condition is due to a transient or an established cause. A transient cause should be sought because treatment will usually restore continence.

Transient Urinary Incontinence

Transient causes of UI probably account for 33% of cases in the community-dwelling elderly, around 50% of cases of hospitalized elderly patients, and a significant number of patients in long-term care [1]. For acute-onset cases of UI, there often is a treatable cause. The mnemonic "DIAPPERS" is used to recall possible causes of transient UI [6]:

- *D*elirium
- *I*nfection – urinary (symptomatic)
- *A*trophic urethritis/vaginitis
- *P*harmaceutical/ *p*rostate
- *P*sychological, especially depression
- *E*ndocrine (or excess fluid intake/output)
- *R*estricted mobility
- *S*tool impaction

Telegram: @medical_k

www.konkur.in

If a treatable cause is found, action should be taken to remedy the problem.

Established Urinary Incontinence

With established UI, no reversible cause is identified, and the incontinence is chronic. There are five major types of established UI to consider. These are urge, stress, overflow, functional, and mixed incontinence.

Urge incontinence (overactive bladder) is the most frequent type of established UI in older adults [5]. Symptoms include a sudden, uncontrollable need to void. Urge incontinence can result in the loss of large or small amounts of urine, often on the way to the washroom. There also may be symptoms of frequency, nocturia, and enuresis associated with urge incontinence. Urge incontinence is the result of abnormal detrusor muscle contractions.

Stress incontinence is losses of small volumes of urine with increases in intra-abdominal pressure (e.g., sneezing, coughing, lifting). There are two key types of stress incontinence: anatomic stress incontinence and intrinsic sphincteric deficiency. Anatomic stress incontinence is caused by anatomical changes resulting in bladder and bladder neck hypermobility. These changes often are associated with vaginal childbirth or postmenopausal status. Anatomic stress incontinence is commonly seen in older women in ambulatory clinic settings and long-term care [5]. Risk factors include pelvic prolapse, cystocele, or urethrocele. Intrinsic sphincteric deficiency, the second type of stress incontinence, is caused by functional damage to the urethral sphincter mechanism. This may be the result of prior pelvic or bladder surgery, radiation, or trauma.

Overflow incontinence is the third major type of incontinence. Overflow incontinence is thought to be the second commonest type of established UI in older men. With overflow incontinence, the bladder cannot empty properly and becomes overdistended. Presenting symptoms include dribbling, weak urinary stream, intermittency, hesitancy, straining, frequency, and nocturia resulting in the loss of continual, small volumes of urine. The most common cause of overflow incontinence in men is bladder outlet obstruction from prostatic enlargement (e.g., benign prostatic hyperplasia or prostate cancer). In women, cystoceles or uterine prolapse can less commonly cause obstruction incontinence. Urethral or bladder neck stricture or stone also may cause overflow incontinence in women. A second cause of overflow incontinence in both sexes is detrusor hypocontractility which may be from a neurogenic or non-neurogenic cause. With age, the detrusor may become fibrotic and replaced by connective tissue leading to impaired contractility. Neurogenic causes include neuropathy from diabetes mellitus, pernicious anemia, alcoholism, and mechanical damage to the spinal nerves from a herniated disc, spinal stenosis, and/or a tumor.

Functional incontinence, the fourth type of UI, occurs in patients with normal genitourinary functioning. It may result from a decline in physical or cognitive functioning or may be the result of psychiatric illness. These changes affect the person's ability to void independently.

Mixed incontinence, the final type of UI, typically is a combination of urge and stress incontinence. As such, mixed incontinence shares both the causes and symptoms of both stress incontinence and urge incontinence.

Evaluation of Urinary Incontinence

All patients with UI must be evaluated for any transient-reversible causes. This should include a history, physical examination, and urinalysis. The history will cover the UI symptoms including duration, frequency, timing, precipitants, and the amount of urine lost. Associated symptoms such as frequency, urgency, nocturia, dysuria, hesitancy, straining, poor stream, and hematuria should be ascertained. In order to exclude potentially serious underlying conditions, patients with UI should be asked about onset of incontinence, abdominal or pelvic pain, hematuria, lower extremity weakness, changes in gait, cardiopulmonary and neurologic symptoms, weight changes, and/or mental status changes. Alcohol and caffeine intake also should be noted. Additional history should be obtained regarding

Telegram: @medical_k

www.konkur.in

sensation of prolapse, prior surgery, urinary tract infection symptoms, parity and mode of delivery, vaginal symptoms, bowel habit, and history of constipation. A structured medication review also should occur. The effect of UI on quality of life should be determined. In frail older adults, asking about functional status, mood changes, mobility changes, changes in cognitive status, and medication changes is especially important [7].

The physical examination includes abdominal, neurologic, and genitourinary tract examinations. The bladder must be palpated. The family physician should assess both cognitive function and nerve roots S2–3 during the neurologic examination. In men, the genitalia should be examined to look for abnormalities of the foreskin, glans penis, and perineal skin. A rectal examination should be performed, testing for perineal sensation, sphincter tone, fecal impaction, and prostatic enlargement. In women, a pelvic examination should be undertaken to assess perineal skin and muscle tone and to determine if there is pelvic prolapse or a pelvic mass. The cough stress test should be performed to assess if there is urine loss with a full bladder [8]. Examination also should include a post-void residual (PVR).

The type of UI should be identified. If the cause of UI is still unclear, a daily voiding diary may help to clarify the type and severity of the UI. Referral to a specialist should be considered in these cases. Referral to a continence specialist or further investigation with urodynamics could be considered if the diagnosis is uncertain or if treatment has not been successful. If there is persistent hematuria without infection, the patient may require cystoscopy. Referral to a specialist could be considered if surgery is being contemplated to clearly identify the underlying type of UI (e.g., transurethral resection of the prostate or gynecological surgery).

Treatment of Urinary Incontinence

There are three main approaches to treatment of UI: behavioral, pharmacological, and surgical [5]. Behavioral techniques include toilet assistance, bladder education/retraining, pelvic floor muscle exercises, biofeedback, and electrical stimulation. Toilet assistance can include scheduled toileting or prompted voiding. Bladder education involves delayed and timed voiding, urge suppression, and fluid/diet alterations. Bladder training may be useful for urge and stress UI. Prompted voiding often is used in frail or cognitively impaired patients. For stress incontinence, pelvic floor muscle exercises or Kegel exercises are useful. Vaginal cones (weights that are inserted into the vaginal vault and held in place) also can be used to strengthen the pelvic floor muscles. Patients should consume six to eight cups of fluid per day and limit caffeine and alcohol intake. Non-pharmacologic treatments for overflow incontinence include intermittent catheterization, indwelling urethral or suprapubic catheters, external collection systems, and protective undergarments. Chronic indwelling catheters increase frequency of symptomatic UTI and can contribute to urinary tract infections or sepsis. As such, they should be viewed as a last resort when all else has failed or when there is accompanying local skin breakdown.

In terms of pharmacological therapy, anticholinergic or antimuscarinic agents help relax the bladder and increase bladder capacity. These agents are used for incontinence with detrusor overactivity (e.g., urge incontinence). Medications available for urge UI include oxybutynin (Ditropan), tolterodine (Detrol), fesoterodine (Toviaz), solifenacin (Vesicare), darifenacin (Enablex), propiverine (Mictonorm), and trospium (Sanctura). Mirabegron (Myrbetriq) is a relatively newer drug in the class of beta-3 adrenergic agonists which also is used as an alternative to antimuscarinics to treat urge incontinence. A recent systematic review found that mirabegron had similar efficacy to the common antimuscarinics with less cholinergic side effects [9]. Before starting any of these medications, ensure a normal post-void residual (PVR) volume as urinary retention may occur. Systematic reviews of randomized trials have found that antimuscarinics compared with placebo have a modest benefit over placebo in reducing urgency UI. In the largest systematic review to date [10],

Telegram: @medical_k

www.konkur.in

which included 96 randomized trials, fewer than 200 women per 1000 treated with medications achieved continence. Similar efficacy was demonstrated for all antimuscarinic agents (darifenacin [Enablex], fesoterodine [Toviaz], oxybutynin [Ditropan], solifenacin [Vesicare], tolterodine [Detrol], and trospium [Sanctura]). The role of topical estrogen replacement therapy in UI treatment in women remains unclear. That is, there is widespread anecdotal evidence that topical estrogen replacement therapy is effective in treating UI in postmenopausal women, but the literature is contradictory. Vaginal pessary is another nonsurgical treatment often used in elderly women for prolapse. The local pressure effect of these can cause erosions so they should be used with estrogen therapy [11]. In men with overflow incontinence, two classes of medication have been shown to decrease symptoms: alpha-adrenergic antagonists and 5-alpha reductase inhibitors. The alpha-adrenergic antagonists include terazosin (Hytrin), tamsulosin (Flomax), prazosin (Minipress), or doxazosin (Cardura). Patients on alpha-adrenergic antagonists must be monitored for orthostatic hypotension, dizziness, peripheral edema, tachycardia, nasal congestion, impotence, and first-dose syncope. The 5-alpha reductase inhibitors finasteride (Propecia, Proscar) and dutasteride (Avodart) also can be quite helpful.

Nocturnal polyuria also can contribute to incontinence at night and there is some variation in the amount of urine produced at night by age. However, if more than one-third of the daily urine production occurs at night, that is considered to be abnormal. There are many causes of nocturnal polyuria including abnormality of vasopressin secretion (low), secondary to medications (like diuretics and beta-blockers), increased fluid, caffeine, or alcohol intake, third spacing of fluid, and sleep apnea. In the case of third spacing of fluid due to causes such as congestive heart failure and venous stasis, consideration could be made to give diuretics in the late afternoon. For those patients who have abnormal vasopressin secretion, a trial of desmopressin could be considered to attempt to increase to time to first nocturnal void [12]. Surgery can be used for various clinical scenarios of UI. Retropubic suspension and sling can be used for stress incontinence. If overflow incontinence is due to obstruction (e.g., benign prostatic hyperplasia), surgery may be required (e.g., transurethral resection of the prostate).

Falls

Falls are the leading cause of fatal and nonfatal injuries among the elderly in the United States. In 2015 alone, falls cost approximately $50 billion in direct medical costs [13]. The incidence of falls increases with age from 30% to 40% per year in patients over 65 years living in the community to 50% for those over 80. In those over 70 years of age, 41% of falls result in minor injury with 6% resulting in major injury. Five percent of falls in older patients will lead to hospitalization.

All community-dwelling seniors should be screened annually for falls by asking the following question: "In the past year, have you had a fall (including a slip or trip where you lost your balance and ended up on a lower level)?" If the answer is "yes" to more than one slip, trip, or fall, an injurious fall, or balance and mobility problems, conduct a multifactorial falls risk assessment. The reason the assessment is multifactorial is because falls in older adults often are not due to a single cause. A fall history and their circumstances should be completed including date, time of day, location, circumstances (e.g., what the patient was doing at the time of a fall, patient's perception as to the cause, associated symptoms preceding the fall such as chest pain, shortness of breath, palpitations, dizziness), and circumstances after the fall (e.g., loss of consciousness, injuries, post-fall interventions, severity of the fall, duration of any changes in activities of daily living [ADL]/mobility status, and in the patient's confidence in walking and/or fear of falling). Some find the "SPLATT" [14] mnemonic useful:

- *S*ymptoms
- *P*revious falls
- *L*ocation
- *A*ctivity
- *T*ime
- *T*rauma

Telegram: @medical_k

www.konkur.in

History also should include medications currently taken, the use of alcohol, the presence of acute and chronic medical conditions, function (e.g., assessment of basic and instrumental activities of daily living-IADLs), mobility, and lower urinary tract symptoms (LUTS) (e.g., urinary urgency, frequency, nocturia, and urge incontinence). Certain LUTS (i.e., urge incontinence, mixed incontinence, overactive bladder, nocturia) increase the risk of falls among older individuals by up to twofold. A comprehensive medication review by a physician, nurse practitioner, or pharmacist should be conducted on all elderly patients who have had multiple falls or an injurious fall. All medications, their doses, and frequency of use should be reviewed at least annually [15]. The 2019 Updated American Geriatrics Society Beers Criteria for Potentially Inappropriate Medication Use in Older Adults noted that the following medications may exacerbate a history of falls or fractures: antiepileptics, antipsychotics, benzodiazepines, nonbenzodiazepine hypnotics, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors (SNRIs), selective serotonin reuptake inhibitors (SSRIs), and opioids [16]. Moderate risk medications that are more weakly associated with falls include anticonvulsants and cardiovascular agents (e.g., antihypertensives, antiarrhythmic medications, beta-blockers, peripheral vasodilators, and nitrates).

The physical examination should cover the following: A neurologic examination including mental status, lower extremity strength (e.g., Can the patient stand from sitting without using their arms?), vision, vestibular function (e.g., detection of movement-provoked dizziness by first shaking the head side to side and then nodding it up and down, a head impulse test if trained to do it and there are no contraindications such as severe cervical arthritis), lower extremity sensation and reflexes, a search for extrapyramidal signs (e.g., tremor, rigidity, akinesia, and postural instability), and coordination. A musculoskeletal examination focusing on the lower extremities (e.g., joints, range of motion, pain, deformities) and feet/footwear (e.g., foot problems such as plantar fasciitis, hallux valgus, bunions, ingrown toenails, onychogryphosis, and multiple foot problems) are associated with an increased risk of falling. In-home falls have been associated with being barefoot or wearing socks without shoes and/or proper-gripped slippers. A cardiovascular examination should include assessment of heart rate and rhythm, orthostatic pulse, and postural blood pressure (supine and standing). A blood pressure drop of 20 mm Hg or 10 mm Hg is considered clinically significant. Regular eye assessments should be encouraged. Assessment for osteoporosis including asking about prior osteoporotic fractures and any past bone mineral density tests should be done. Inquiry about historical heights and measurement of current height also should be done, with a historical height loss of greater than 6 cm suggesting the presence of vertebral fractures. Measurement of the occiput-to-wall distance should be done, with an occiput-to-wall distance of greater than 5 cm indicative of the presence of kyphosis which may be the result of vertebral fractures. An assessment of rib to pelvis distance should be conducted, with two or less fingerbreadths suggestive of the presence of vertebral fractures [17]. Screening tools such as the Timed Up and Go test [18] can be used to predict the risk of falls. Once an older adult has been identified as having decreased lower extremity strength or impaired balance, based on either simple observation or outcomes from fall risk screening tools, referral to a physiotherapist is recommended for a detailed assessment of the physical factors which may be contributing to fall risk.

There are a number of interventions that can reduce the risk of falls in seniors. In elderly patients with impaired vision, interventions include good lighting, use of contrasting paints or carpet to mark the edge of stairs, and advising on the avoidance of wearing bifocals while walking. Treatment of orthostatic hypotension also is an important consideration with treatment dependent on the most likely cause. History taking should focus on the type of dizziness: Vertigo (a false sense of motion often described as a spinning or whirling sensation), disequilibrium (feeling off-balance or wobbly), or presyncope (a feeling of lightheadedness or feelings of blacking out or fainting). For many elderly patients, categorization of dizziness may be difficult in

Telegram: @medical_k

www.konkur.in

that the patient may have multiple types of dizziness. Common causes of vertigo include benign paroxysmal positional vertigo (BPPV), vestibular neuritis, and Meniere's disease. Orthostatic (postural) hypotension is a possible cause of presyncope. There are multiple possible causes of disequilibrium such as stroke, Parkinson's disease, sensory impairments (e.g., peripheral neuropathy), and adverse effects of medications. Management is directed at the cause. In general, elderly individuals should wear shoes with low heels and firm slip-resistant soles both inside and outside the home.

Treatment of osteoporosis also is important. Ensuring adequate intake of calcium through dietary sources and supplementation with vitamin D 800–2000 IU is recommended. Depending on the severity, medication treatment of osteoporosis with bisphosphonates, RANK ligand inhibitor (denosumab), selective estrogen receptor modulators (raloxifene), parathyroid hormone (teriparatide), or hormone replacement therapy may be warranted. Hip protectors (devices that absorb and shunt the energy of the impact of a fall away from the greater trochanter) have a role in preventing hip fractures among those at high risk of falls if the patient is willing to wear them. High-risk older adults in long-term care facilities may benefit from their use, but their utility in preventing hip fractures among the elderly in the community is not proven [19]. Physiotherapy is recommended for older patients with lower extremity weakness and/or impaired gait and balance. For the elderly patient living alone or left alone for long periods, an emergency response system should be considered. A home safety checklist for assessment of environmental risks can be used by elderly patients and/or their families. Referral to an occupational therapist may be made for high-risk elderly patients [20].

In summary, the most efficacious interventions reported for elderly patients who are at high risk for falls include adaptation or modification of the home environment, discontinuing or tapering psychoactive medications, discontinuing or tapering of other medications (e.g., anticholinergics, benzodiazepines, hypnotic sedatives, and antihypertensives), minimizing postural hypotension, management of foot problems and footwear, and exercise, especially balance, strength, and gait training. See Fig. 1 for an algorithm in the prevention of falls in older persons living in the community from the American Geriatrics Society and British Geriatrics Society [21].

Orthostatic Hypotension

Orthostatic hypotension (OH) is defined as a "sustained reduction of systolic blood pressure of at least 20 mmHg or diastolic blood pressure of 10 mmHg within 3 min of standing or head-up tilt to at least 60° on a tilt table" ([22], p. 46). It is estimated to be present in up to 70% of institutionalized elderly and 6% of community-dwelling elders [22]. Measuring the blood pressure after sitting (not lying) will miss some cases of OH. However, there is some controversy regarding how long to wait after standing before measuring blood pressure (BP). Generally, the standing BP is measured at 1 min (for screening purposes, a single 1-min reading is usually sufficient) and 3 min after standing.

The recommended approach is to diagnose the underlying cause of OH and manage it. An important step is to review medications and discontinue or reduce medications that may be contributing to the problem. Ensure adequate fluid intake. Modify salt restriction where appropriate. Use compensatory strategies (e.g., elevate head of the bed, rise slowly, dorsiflex feet before getting up). Use pressure gradient stockings (preferably thigh high) where appropriate. Consider pharmacological therapy (e.g., fludrocortisone [Florinef], midodrine [Orvaten, ProAmatine], pyridostigmine [Mestinon]) if the above strategies are unsuccessful and there are no contraindications. See the Finding Balance website for resources targeted for both older adults and medical practitioners (https://findingbalancealberta.ca/).

Polypharmacy

There are varied definitions of polypharmacy, from using inappropriate prescriptions to using five or more prescriptions. Depending on the

Telegram: @medical_k

www.konkur.in

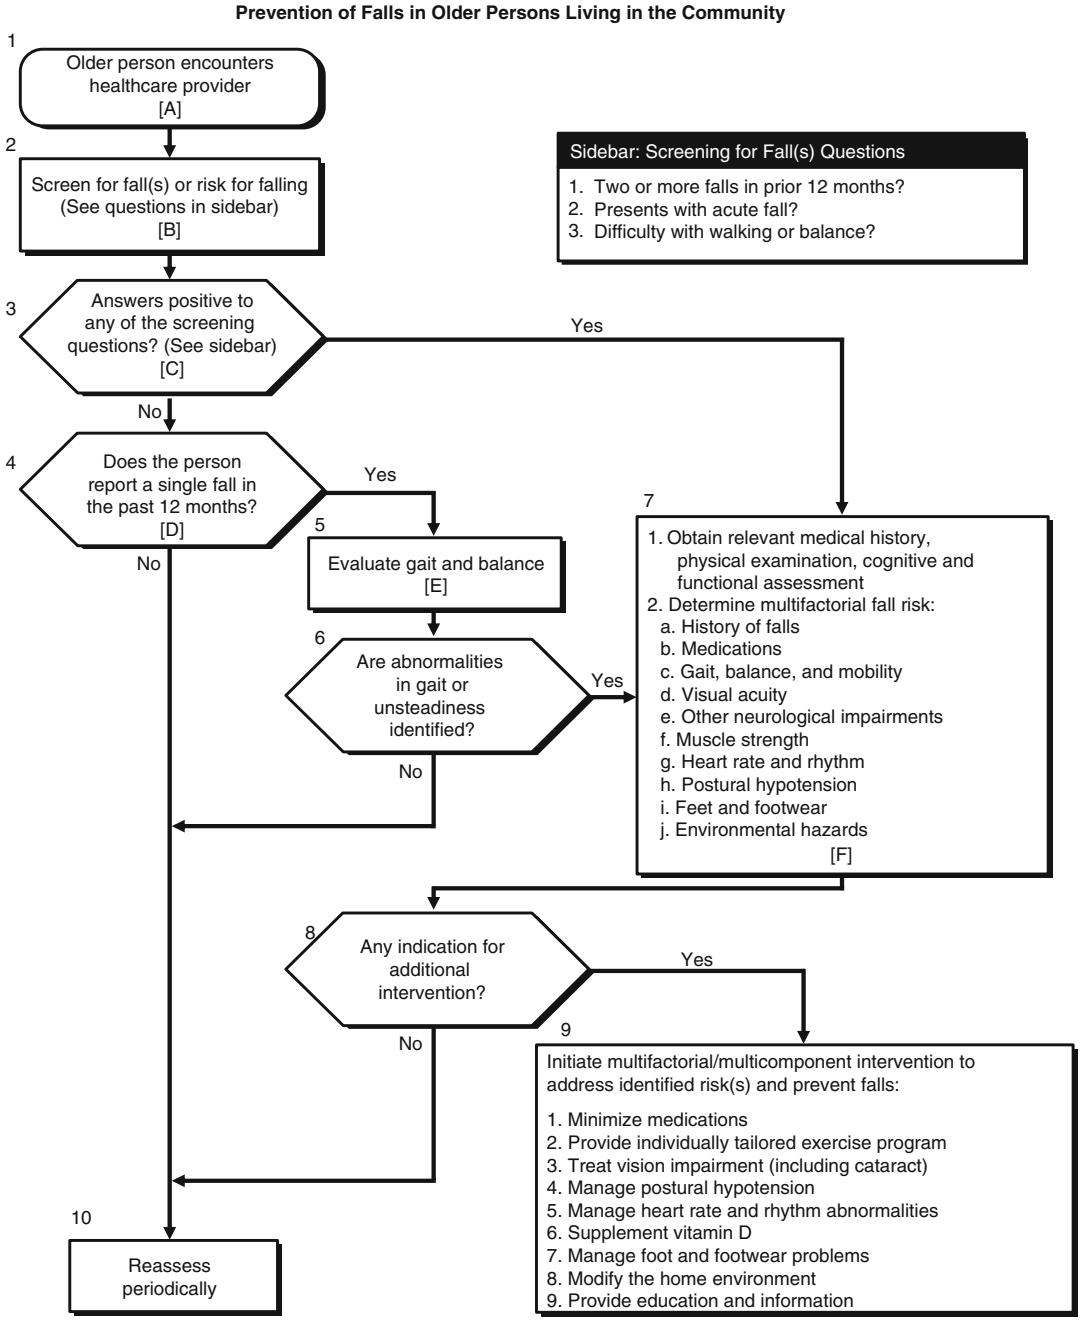

Fig. 1 Prevention of falls in older persons living in the community. This is an algorithm for screening and assessment of falls in older persons, developed by the Panel on Prevention of Falls in Older Persons of the American Geriatrics Society and British Geriatrics Society (Originally published in 2012; with kind permission of © John Wiley and Sons 2011. All Rights Reserved)

definition, the incidence of polypharmacy varies from 5% to 78%. It is estimated that the worldwide costs of polypharmacy is $18 billion US [23]. Inappropriate drug prescribing may lead to avoidable adverse drug events (ADEs). ADEs should be considered to be the cause for any new

Telegram: @medical_k

www.konkur.in

symptom in an older adult until proven otherwise. ADEs occur two to three times as frequently in older persons. Patients taking fewer than three drugs have a 1–2% risk of ADEs whereas those taking more than six drugs have a 13% risk of ADEs. Thirty percent of admissions to hospital are because of adverse drug events. ADEs increase hospital length of stay, costs, and mortality. The annual costs of drug-related morbidity in the USA are estimated to be $528 billion in 2016 [24]. Drug-related hospitalizations cause 2.4–6.5% of all medical admissions in the United States in the general population. ADEs are increased in the elderly due to age-related changes in pharmacokinetics and pharmacodynamics, increased comorbidities, polypharmacy, and nonadherence. Drug trials frequently exclude older adults. As a result, approved drug doses may not be appropriate for the elderly population.

An example of prescribing guidelines for the elderly is the Beers criteria. The American Geriatric Society is the steward of the Beers criteria and produces updates on a 3-year cycle. Medications or classes are identified and divided into three categories: potentially inappropriate medications or classes to avoid, medications to avoid with certain diseases/syndromes, and medications to be used with caution in older adults [16]. Another clinically useful prescriber guideline for older patients is the Screening Tool of Older Persons' Prescriptions (STOPP) criteria [25].

Drug categories to avoid in the elderly, regardless of the consensus criteria used, include the following [26]:

1. Anticholinergics (e.g., tertiary tricyclic antidepressants, gastrointestinal antispasmodics, antimuscarinics, antipsychotics, first-generation antihistamines).
2. Sedatives/hypnotics (e.g., barbiturates, long- and short-acting benzodiazepines) should not be prescribed for chronic usage.
3. Anti-inflammatories (avoid chronic usage).
4. Opiate-related analgesics (e.g., pentazocine [Talwin], meperidine [Demerol]).
5. Antiarrhythmics class Ia, Ic, and III (e.g., disopyramide [Norpace] with anticholinergic, negatively inotropic side effects; amiodarone [Cordarone, Nexterone, Pacerone]; digoxin [Lanoxin, Lanoxicaps] > 0.125 mg/day).
6. Cardiovascular (e.g., alpha blockers, alpha agonists, immediate-release nifedipine [Adalat, Afeditab, Nifediac, Nifedical, Procardia], spironolactone [Aldactone] > 25 mg/d with risk of hyperkalemia).
7. Anti-infective (e.g., nitrofurantoin [Furadantin, Macrobid, Macrodantin] with reduced creatinine clearance/pulmonary toxicity).
8. Endocrine (e.g., desiccated thyroid/cardiac, testosterone/cancer risk, sliding scale/hypoglycemia, megestrol [Megace]/deep venous thrombosis, oral hypoglycemic agents/glyburide [DiaBeta, Micronase] with low blood sugars).

Strategies for Appropriate Prescribing

There are several recommended strategies for appropriate prescribing in the elderly [27, 28]. The strategies are as follows:

1. Maintain an up-to-date drug list with indications for all prescriptions, over-the-counter drugs, and herbal supplements.
   a. Consider non-pharmacological options.
   b. Regularly review the need for the drug and stop the drug, if possible.

Medication reconciliation is crucial for transitions of care. It is a process that identifies medication discrepancies, informs prescribing decisions, and prevents medication errors. The process has three steps: verification (medication use history, accurate list), clarification (medications and doses are accurate), and reconciliation (identify any discrepancies between what is ordered and the patient list, making changes to orders, documenting changes, communicating updated list to the next provider). This medication reconciliation process decreases medication errors by 70% and ADEs by 15%.

Structured Medication Review (SMR) [29] is a regularly scheduled discussion between a patient and their doctor/pharmacist/nurse to

Telegram: @medical_k

www.konkur.in

review ALL medications to address how each medication is working, how each medication is taken, and patient concerns. A SMR should be done when the patient asks for a review, if they are on >5 meds or have >3 comorbidities, they have received medications from more than one physician, and/or there has been a medication change in the last 12 months.

2. Know the actions, adverse effects, and toxicity profiles of medications prescribed; avoid and be vigilant of high-risk drugs as identified by the 2019 Beers criteria [16].
3. Start new medications at a low dose and titrate up based on tolerability and response; give a time-limited trial for new medications to determine if the medication is working ("start low and go slow"). Remember to discontinue trialed medications if they prove not to be beneficial.
4. Prioritize medication prescribing – consider the patient's life expectancy/prognosis/quality of life and time to benefit, and modify treatment for the elderly according to life expectancy [30].
5. Avoid using one drug to treat the side effects of another (e.g., prescribing cascade). Consider adverse drug effects as a potential cause for any new symptom.
6. Attempt to use a single drug to treat two of more conditions (e.g., mirtazapine [Remeron] for depression and weight loss in the elderly).
7. Avoid using multiple drugs from the same class or with similar actions.
8. Educate the patient/caregiver about each medication.
9. Know the patient's cognitive function, health literacy, access to care, and financial status/cultural factors/preferences.
10. Provide written information and engage in medication reconciliation ("teach me back" strategy).
11. Arrange a home visit to review medications with a transitional team member if needed.
12. Educate prescribers/MD.
13. Maintain the simplest medication regimen regarding number of medications, routes, and frequency of administration (If possible, once or twice daily dosing is best).
14. Communicate with other prescribers (teamwork between physicians and pharmacists leads to best outcomes); encourage one prescriber to be responsible primarily for monitoring of prescription information to be clearly communicated in a timely manner.
15. Use systems that support optimal prescribing behavior.
    a. Drug utilization reviews.
    b. Automated drug alerts providing information on potential drug interactions or dose problems.
    c. Smartphone reference guides for drug–drug interaction tools.
    d. Pharmacist-led interventions for medication review.
    e. Pharmacist-led interventions and multidisciplinary care (e.g., involving a geriatrician) have been found to be effective in improving appropriate prescribing.

Underutilization (Underprescribing)

Underprescribing of medications also is a significant issue in the older adult population. One study defined underuse of a medication as "the omission of a drug when there is a clear indication and no contraindication" [33, p1096]. It has been found that up to 50% of older adults in a long-term care facility had not been prescribed some recommended therapy [32]. Part of the problem related to underprescribing in the older adult population is due to published guidelines on treatment and management of medical conditions. The vast majority of, if not all, guidelines on drug prescribing are directed at single disease entities while older adults have multiple comorbidities and sometimes one treatment guideline will contradict another. Pain and osteoporosis are two commonly undertreated problems in the elderly. Careful review of the comorbidities and a history of the older adult are necessary to uncover any medications that are omitted but could provide health benefit.

Telegram: @medical_k

www.konkur.in

Pain Management

Pain management is an important issue in the elderly in that pain impacts function and quality of life. Chronic pain is reported by 20–50% of patients in primary care [33]. Assessment of pain in the elderly patient can be difficult especially if there is cognitive impairment or dementia. In addition, acute pain syndromes (e.g., myocardial infarction, acute abdomen) may present atypically in the frail elderly.

WHO Analgesic Ladder

Pharmacologic approaches are the cornerstone of treatment of acute and chronic pain. The World Health Organization (WHO) analgesic ladder was designed to guide treatment of cancer related pain and organizes drug therapy into three steps: (1) nonopioid drugs (aspirin, acetaminophen [Tylenol], nonsteroidal anti-inflammatory drugs [NSAIDs], COX-2 inhibitors), (2) low-dose opioids, and (3) higher-dose opioids [34]. This ladder was widely disseminated and built a standard of practice around pain control not just for cancer patients but also for patient with acute or chronic pain. The recommendation is for treatment to begin with nonopioids, with opioid drugs added as necessary. It is important to realize that when acetaminophen-opioid combinations are used (e.g., acetaminophen with codeine [Tylenol no. 3] or acetaminophen with oxycodone [Percocet]), patients should receive no more than 4 g of acetaminophen per day. NSAIDs and aspirin should be avoided in the elderly if possible due to frequent side effects. When possible, choose oral medications over other more invasive modes of delivery. When pain is localized to specific joints, consider topical NSAIDs as an alternative to systemic NSAIDS. Patients, including the elderly, who have pain most of the day, should receive their drugs (e.g., acetaminophen) regularly and not on an "as needed" basis.

Opioids

The decision to start opioids may be considered for noncancer pain in those with moderate to severe chronic pain that is adversely affecting function and quality of life. The decision to use opioids needs careful consideration. Patients should be stabilized on short-acting opioids before switching to equianalgesic doses of long-acting opioids. Opioid side effects include nausea and vomiting, constipation, pruritus, and CNS effects. A bowel routine should be initiated in all patients taking opioids, with an osmotic laxative such as polyethylene glycol the recommended first-line treatment. For those experiencing sedation, a dose reduction of 25% or opioid rotation may help. An opioid equianalgesic table should be used (see Table 1). In rotating to an opioid other than methadone (Dolophine) or fentanyl (Sublimaze), the equianalgesic dose should be reduced by 25–50%, for methadone 75–90%, and for fentanyl equal dose. As of July 2012, the US Drug and Food Administration introduced a Risk Evaluation and Mitigation Strategy (REMS) for all extended-release hydromorphone (Dilaudid), morphine (Avinza, Kadian, Oramorph, Roxanol), oxycodone (Oxecta, Oxyfast, Roxicodone), oxymorphone (Opana), tapentadol (Nucynta), fentanyl (Sublimaze), and methadone (Dolophine) The REMS involves provider training, patient counseling, and distribution of a medication guide for patients with each dispensing. For more information, see the REMS website: http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm111350.htm.

Table 1 Opioid equianalgesic table [35]

Drug	Intramuscular dose (mg)	Oral dose (mg)
Morphine (Avinza, Kadian, Oramorph, Roxanol)	10	30
Hydromorphone (Dilaudid)	1.5	7.5
Codeine	130	200
Oxycodone (Oxecta, Oxyfast, Roxicodone)	15	20
Oxymorphone (Opana)	1	15
Methadone (Dolophine)	10	20

Neuropathic Agents

For neuropathic pain, gabapentin (Gralise, Neurontin), pregabalin (Lyrica), or tricyclic antidepressants (TCAs) should be considered as first-

Telegram: @medical_k

www.konkur.in

line treatment. Serotonin-norepinephrine uptake inhibitors (SNRIs) should be considered first or second line. Gabapentin (Gralise, Neurontin) is effective for postherpetic neuralgia and diabetic neuropathy. The drug is started at a low dose and slowly titrated up to effect. Pregabalin (Lyrica) may achieve faster pain control as less time is needed to titrate to a full dose. Other anticonvulsants including topiramate (Topamax), lamotrigine (Lamictal), levetiracetam (Keppra), phenytoin (Dilantin, Phenytek), sodium valproate (Depakote), zonisamide (Zonegran), tiagabine (Gabitril), and clonazepam (Klonopin) have been considered for neuropathic pain treatment, but the research shows there is poor evidence of benefit. An exception would be carbamazepine (Carbatrol, Equetro, Tegretol) for trigeminal neuralgia. Tricyclic antidepressants (TCAs) (e.g., amitriptyline [Elavil], nortriptyline [Pamelor]) may be used for neuropathic pain though their anticholinergic side effects must be considered. Venlafaxine (Effexor) has evidence for use in diabetic neuropathy and polyneuropathies, but not for postherpetic neuralgia. Duloxetine (Cymbalta) has evidence of effectiveness in diabetic neuropathy, fibromyalgia, low back pain, and osteoarthritis.

Since the experience of pain comprises both physical and psychological components, it has been shown that combination therapies are more effective than single therapies [36]. Other adjunctive therapies to be considered in a multifaceted approach are behavioral medicine (e.g., cognitive behavioral therapy, biofeedback, relaxation therapy, and psychotherapy), exercise, acupuncture, physical and occupational therapy, chiropractic, ultrasound, and electrical neuromodulation (e.g., transcutaneous electrical nerve stimulation, spinal cord stimulation), heat/cold, nerve blocks, Botox, and steroid injections.

Nutrition

Nutrition is of vital importance to patients of all ages. It can be particularly important for the elderly as they require fewer calories, but not fewer nutrients, to maintain their weight and health. Approximately 15% of older outpatients and more than 50% of older inpatients are malnourished, with up to 71% of elderly patients at nutritional risk. Dehydration is common among the elderly. This is partly because the sense of thirst diminishes with age. However, there are a variety of other factors contributing to dehydration in the senior population, including voluntary limitation of oral intake due to urinary urgency or frequency or limited access to hydration due to impaired mobility or cognition.

Weight loss in older adults is a concern. Weight loss is usually a combination of inadequate dietary intake, decreased appetite, muscle atrophy, and inflammatory effects of disease. Malignancy is the second most common cause of weight loss in the senior population (16%), with depression being the commonest cause (18%). Physiological factors include a decrease in the acuity of taste and smell with aging, which lessens the enjoyment of eating.

Inadequate dietary intake can include social factors such as poverty, isolation, and difficulty obtaining groceries. Medical factors include poor dentition or poorly fitting dentures which may lead to chewing difficulties. Swallowing disorders are more common in older persons and gastrointestinal motility declines with age. Other risk factors for malnutrition include certain medications (e.g., opioids and diuretics) and illnesses (e.g., dementia). Conditions such as pressure ulcers, chronic infections, malabsorption, malignancy, endocrine disorders, end-organ disease (e.g., congestive heart failure, end-stage renal disease, chronic obstructive pulmonary disease, hepatic failure), rheumatological disorders, and alcoholism can increase metabolic demands and result in malnutrition. “MEALS ON WHEELS” is a useful mnemonic for the causes of weight loss in the older adult [37]:

- ***M***edications (e.g., digoxin, theophylline, serotonin reuptake inhibitors, antibiotics)
- ***E***motional (e.g., depression, anxiety)
- ***A***lcoholism, elder abuse
- ***L***ate-life paranoia or bereavement
- ***S***wallowing problems
- ***O***ral factors (tooth loss, xerostomia)

Telegram: @medical_k

www.konkur.in

- ***N***osocomial infections (e.g., tuberculosis, pneumonia)
- ***W***andering and other dementia-related factors
- ***H***yperthyroidism, *h*ypercalcemia, *h*ypoadrenalism
- ***E***nteral problems (e.g., esophageal stricture, gluten enteropathy)
- ***E***ating problems
- ***L***ow-salt, *l*ow-cholesterol, and other therapeutic diets
- ***S***ocial isolation, *s*tones (chronic cholecystitis)

Weight loss is of concern in seniors given its associated mortality in this population. Clinically significant weight loss can be as low as 5% over 3 years. If there is 2% or greater decrease of body weight in 1 month, 5% or greater decrease in 3 months, or 10% or greater in 6 months, this should prompt clinical investigation and workup [37]. There are many screening tools that can be used to assess for malnutrition in the elderly patient. One simple test in the highest quartile for sensitivity (>83%) and specificity (>90%) is the Malnutrition Screening Tool (MST). It asks two short questions: "Have you been eating poorly because of decreased appetite?" and "Have you lost weight recently without trying?" Older adults are less able to adapt to underfeeding, experience less frequent hunger, and are less likely to regain lost weight. This results in chronic, persistent weight changes.

Decreased appetite (anorexia) in the elderly is related to the physiologic factors identified above. Cachexia is a more complex metabolic syndrome related to illnesses that result in loss of muscle with or without fat mass. The illnesses could include cancer, end-stage renal disease, chronic pulmonary disease, congestive heart failure, and/or AIDS. Cachexia is different than starvation, sarcopenia, psychiatric, gastrointestinal, or endocrinological causes of weight loss. With cachexia, there is inflammation and catabolism, often making cachexia resistant to intervention. Sarcopenia is loss of muscle mass, strength, and function that is unrelated to underlying illness. Sarcopenia is present in over 50% of adults 80 years of age and older. It is caused by endocrine changes (e.g., decreased testosterone and estrogen), cytokine changes, decreased physical activity, chronic disease, inflammation, insulin resistance, and nutritional deficiencies (particularly low protein intake).

Nutritional Assessment

Nutritional assessment is important in the senior population. Weight loss can be identified via serial weight measurements. A dietary referral can be made to get a more formal dietary intake assessment. A complete history (including any new medications, diagnoses, or social issues) and physical examination are recommended on a regular basis. Anthropometric measures such as weight, height, body mass index (BMI), and skinfold thickness can be helpful for the initial assessment. Laboratory tests, including a complete blood count (CBC), electrolytes, creatinine, glucose, thyroid-stimulating hormone (TSH), serum albumin, liver function studies (LFTs), and cholesterol levels, may be obtained. Transferrin and prealbumin levels are more sensitive measures of short-term undernutrition. Erythrocyte sedimentation rate (ESR)/C-reactive protein (CRP) should be done if cachexia is suspected. Chest/abdominal X-rays and abdominal ultrasound may be considered. The strongest predictors of malignancy as a cause for the weight loss are age >80 years; white blood cell count >12,000/mm ^{3}; albumin <3.5 g/dl; alkaline phosphatase >300 IU/L; and lactate dehydrogenase >500 IU/L. In patients with significant ongoing weight loss, a CT chest/abdomen/pelvis should be considered, bearing in mind comorbidities and frailty status. If early satiety is present, gastroscopy should be considered. Referral to a dietitian for assessment and intervention is recommended when the body mass index (BMI) is less than 22 for those patients age 65 years and older and if there is an unplanned weight loss of >2% in 1 month or >10% in 6 months.

Other indicators that place senior patients at nutritional risk and require monitoring or community services include poor appetite; changes in dental health or difficulty in biting and/or chewing; difficulty accessing groceries or making meals due to access, finances, or mental illness; or

Telegram: @medical_k

www.konkur.in

concerns with meal patterns including routine skipping of meals or lack of variety in food intake.

Treatment of Nutritional Deficiencies

An important step in addressing nutritional deficiencies in seniors is identification and treatment of the cause of those deficiencies. Consider removing any dietary restrictions (e.g., restrictions for those on a cardiac diet or diabetic diet). Inquire if shopping and meal preparation are being accommodated and if assistance with feeding is required. Ensure that recommended foods fit the patients' ethnic or religious preferences. Increase nutrient density of foods. Protein content can be increased with milk, whey powder, egg whites, or tofu. Fat content can be increased by adding olive oil to sauces, vegetables, grain, or pasta. If these fail to increase weight, snacks should be added. Consider liquid nutritional supplementation. These have been shown to increase weight (more so in patients at home or in long-term care) and to improve mortality, except in those living at home. When there is refusal or inability to swallow, enteral tube feeding with a small-bore nasogastric tube (NGT) or percutaneous enteral gastrostomy (PEG)/jejunostomy (PEJ) tube may be considered. The decision on which of these methods to use depends on patient preference, suspected length of time the feedings will be necessary, and patient tolerance. Feeding can occur in a continuous fashion or with intermittent bolus feeds. There is an increased risk of aspiration with both NGT and PEG feeding. Total parenteral nutrition (TPN) is indicated in the elderly patient when there is an inability to use the gut to meet nutritional needs. Complications associated with TPN are more likely to occur in the elderly population. In patients with advanced dementia, there is limited evidence for benefit with enteral feeding.

Appetite stimulants may play a role in addressing nutritional deficiencies. In seniors with cancer, megestrol acetate and steroids have been used. In older patients treated with megestrol acetate (Megace), observation for complications such as congestive heart failure and deep vein thrombosis is needed. Dronabinol (Marinol) has been shown to increase appetite in patients with AIDS. Mirtazapine (Remeron) could be considered to increase appetite and induce weight gain in patients with depression.

Pressure Ulcers

Pressure ulcers are defined as ischemic soft-tissue injuries that result from pressure over bony prominences (e.g., sacrum, calcaneus, ischium). Pressure ulcers are a significant problem for older adults with comorbidities, as well as for those in long-term care and critically ill patients. Patients with spinal cord injuries or stroke are at particular risk for the development of pressure ulcers. Pressure ulcers are associated with pain, reduced quality of life, and increases in morbidity and length of stay in hospital. The best treatment for pressure sores is prevention, but even under the best conditions, prevention is not always possible.

Assessment and Staging of Pressure Ulcers

Pressure ulcers should be assessed for stage, size, exudates, necrotic tissue, sinus tracts, and granulation. The National Pressure Ulcer Advisory Panel is the most common system of staging ulcers, with staging as follows:

- Stage 1 – Localized, non-blanching erythema.
- Stage 2 – Partial thickness loss of dermis.
- Stage 3 – Full-thickness skin loss and fat may be visible.
- Stage 4 – Full-thickness skin and tissue loss with exposed bone, tendon, or muscle.
- Unstageable – Obscured full-thickness skin and tissue loss.

Treatment of Pressure Ulcers

Historically, the standard of care for prevention of pressure ulcers has been focused on positioning and regular turning of bed or chair-bound seniors

Telegram: @medical_k

www.konkur.in

at least every 2 h. However, the evidence for this practice is quite poor with the few randomized controlled trials being underpowered and at high risk of bias [38]. One study has shown no difference in the development of pressure ulcers in a population of bed-bound seniors post hip fracture with 2 h repositioning versus patient turned less often. More studies are required to determine the optimal frequency of repositioning. Once a pressure ulcer has developed, positioning and support surfaces need to be reviewed and changed as needed. Wound care with debridement of any necrotic tissue is necessary. Negative-pressure wound therapy may be considered. The wound should be monitored on a daily basis including the ulcer itself, the dressing, and the area around the ulcer. Monitoring for the presence of pain and complications such as infection is needed. Older adults with pressure ulcers commonly are in a catabolic state and need protein and calorie optimization. While vitamin C and zinc are commonly prescribed to promote wound healing, there has been no conclusive research supporting this treatment. Pressure-relieving support surfaces also are utilized to promote wound healing. These include non-powered surfaces like foam; overlays of foam, air, or water; and powered mattresses. There is moderate quality evidence for ulcer prevention through the use of alternative foam mattresses but low-quality evidence for the use of alternating pressure mattress, sheepskin, gel pads in surgery, and suspension beds in the intensive care unit (ICU) [39]. Attention to pain control and comfort is important.

Dressings

Stage 1 pressure ulcers can be dressed with transparent films for protection. Stage 2 pressure ulcers require an occlusive or semipermeable dressing to maintain a moist environment. The treatment of Stage 3 and 4 pressure ulcers depends on the amount of exudate, desiccation, necrotic tissue, or infection. If there is heavy exudate, an absorptive dressing (e.g., alginates, foams, and hydrofibers) is required. For desiccated wounds, saline-moistened gauze, transparent films, hydrocolloids, and hydrogels are needed. Debridement of all necrotic tissue is important. This can be achieved via sharp debridement with scalpel or scissors, mechanical via wet-to-dry dressings, enzymatic using collagenase/fibrinolysin or deoxyribonuclease, or autolytic via semiocclusive (transparent) or occlusive dressings (hydrocolloids or hydrogels). Most pressure ulcers will heal with treatment. Using the above measures, over 70% of Stage 2, 50% of Stage 3, and 30% of Stage 4 pressure ulcers are healed at 6 months [40]. However, surgery is sometimes required using skin grafts, skin flaps, musculocutaneous flaps, and free flaps.

Transitions of Care

As people grow older, they often struggle to achieve a balance between maintaining independence and accepting help. Most older adults would like to live at home for as long as possible. However, caregivers may find that they are overwhelmed and exhausted with providing care to an older family member. As such, it also is important that caregivers receive support to ensure they can continue to provide care while also maintaining their own well-being.

Determining Support Needs

Elderly patients living at home often have challenges in day-to-day routines including personal care such as bathing or more difficult tasks like transportation, grocery shopping, managing money, and/or house maintenance. The elderly patient and family should be advised to seek out supports and resources before they are needed or before the situation becomes urgent. Information about supports and resources may be in a variety of formats – online, telephone, and referral-based as well as in- person. The availability of some supports and resources may depend on where the older person lives. Aspects that elderly patients should consider in determining needs:

Telegram: @medical_k

www.konkur.in

1. Preferences: What is important to me? What do I value?
2. Support network: What help can my family and friends provide?
3. Eligibility: What services am I eligible for?
4. Availability: What services are available in my community?
5. Finances: What can I afford?
6. Timing: How much time do I have to make a decision?

Community Supports

Community supports that allow patients to maximize their potential and function in their home environment for as long as possible are available in many communities. Community supports occur in many settings, such as faith-based programs, community-driven programs (e.g., leagues or groups), local programs (e.g., Seniors' Associations, Meals on Wheels), advocacy groups, and through national programs (e.g., Alzheimer Society). Some community supports may include services that are available with or without cost (e.g., equipment, homemaking services, transportation).

Healthcare Resources

Healthcare resources are typically more formal and structured than community supports. They usually require a referral and may include a cost. These types of resources include the following: home care, in-home professional health services, day programs, day hospitals, mental health services, respite services, rehabilitation services, equipment assessments, and publicly funded housing supports.

Levels of Care

When older adults can no longer manage to live in their own homes, various levels of care are available. Levels of care often are based on the type and amount of care needed. It is never too early to discuss alternative types of housing and to begin planning for the future. The Continuing Care system provides various types and levels of care for older adults that support their independence and quality of life. In Canada, for example, there are three settings in which the Continuing Care system provides accommodation, healthcare, and personal services. These settings are Home Living, Supportive Living, and Facility Living. Careful assessment is important because a less restrictive environment may be a better solution and because patients and families often are not aware of these options. Family physicians should evaluate patients thoroughly, focusing on their functional abilities and identifying what areas they require help with. A mental status examination is important, as patients may appear relatively intact on casual questioning but actually suffer from severe cognitive impairment.

Home Living

Home living services provide home-based care for the elderly who live in their own home, apartment, or another independent setting. Home living can provide in-home professional support services such as nursing and rehabilitation, personal support services, and equipment. Examples of personal support services include medication assistance, bathing, or grooming assistance.

Supportive Living

Supportive living combines accommodation services with other supports and care. Supportive living settings vary by size and types of services provided. It can include meals, housekeeping, and social activities. Residents pay a fee to cover the cost of accommodation and needed services. Residents also can receive professional and personal support services through home living (home care). These support services can be provided by private for-profit, private nonprofit, or public operators. Examples include seniors' lodges, group/personal care homes, private supportive living, and designated supportive living. Designated supportive living settings have additional health and personal care services which are funded publicly.

Telegram: @medical_k

www.konkur.in

Facility Living

Facility living includes long-term care facilities such as nursing homes and auxiliary hospitals. Care and accommodation services are provided for people with complex health needs who are unable to remain at home or in a supportive living setting. In facility living, residents pay an accommodation fee to cover the costs of providing accommodations and services such as meals, housekeeping, and building maintenance. Health services in facility living are publicly funded.

Older Drivers

On a per capita basis, elderly drivers' fatal crash rates begin to increase at 70 years of age. Factors contributing to the higher crash rates of elderly drivers include impairments in functional abilities to drive (e.g., sensory, motor, cognitive) as a result of age-related changes in driving skills, the presence of one or more medical conditions, and/or the drugs used to treat those conditions. Evidence implicates the role of medical conditions more so than age-related changes [41]. In particular, drivers with cardiovascular disease, pulmonary disease, diabetes, psychiatric disorders, visual disturbances, musculoskeletal disorders, neurological conditions, and cognitive impairment were at greatest risk for at-fault crashes in a large population-based study [41]. The higher crash and fatality rates of older drivers have prompted calls for tighter legislation for older drivers, particularly at the time of license renewal. It also has resulted in the need for a test or tests to evaluate the driving competence of elderly drivers.

Evaluating Older Drivers

The medical community often is called upon to provide an assessment of "fitness to drive." To assist with this process, a number of medical associations have developed medical fitness to drive guidelines (e.g., the Canadian Medical Association's Determining Medical Fitness to Operate Motor Vehicles: A Guide for Physician – 9.1 Edition [42] and The American Medical Association Physician's Guide to Assessing and Counseling Older Drivers [43]). Medical history should cover history of coronary artery disease, stroke, movement disorders, seizures, diabetes, sleep disorders, arthritis, and the presence of illness such as dementia. Prescription and over-the-counter medication use should be documented. Research has shown that benzodiazepines increase motor vehicular crashes (MVCs) by fivefold, antidepressants 1.8 times, and opioids 1.5 times. Alcohol and other substance use should be ascertained in any assessment of fitness to drive.

Driving history should cover how often the senior drives, MVCs or traffic violations in the last year, and getting lost while driving. If a caregiver is present, they can be asked if they have accompanied the patient as a passenger recently and whether they have any concerns about the patient's driving.

A physical examination should be done to look at mobility (gait and balance), function, vision, and cognition. The neck, shoulders, and wrists should be examined for range of movement. Common tests for assessment of "cognitive fitness to drive" include the Mini-Mental State Exam (MMSE), Trails A and B, and clock drawing. However, none of these tests is very predictive although the American Academy of Neurology suggests an MMSE score of $\leq$24 identifies patients at risk of unsafe driving. The SIMARD MD is a paper and pencil test developed to assist healthcare professionals in identifying cognitively impaired drivers with good predictive properties on identifying those failing and passing an on-road test and those who are indeterminate and in need of further assessment [44]. Many pen and paper cognitive tests rely on proficiency of the English language and may be a significant disadvantage to those for whom English is not their first language. One of the advantages of the SIMARD MD is that this test is available in nine languages (Arabic, Chinese, English, French, Hindi, Punjabi, Spanish, Tagalog, and Vietnamese), with the tests available at no cost. When assessing patients from diverse backgrounds, using cognitive screening tools available in other languages

Telegram: @medical_k

www.konkur.in

or concentration on functional testing should be considered.

Mandatory reporting of moderate to severe dementia is required in some US states and 7 of the 10 provinces and all 3 territories in Canada. On-road testing may pick up more unsafe drivers than cognitive testing. However, unless they are specifically adapted for drivers with cognitive impairment, regular road tests (e.g., on-road assessments designed to test "basic" driving skills) may fail to detect safety issues in this population of drivers due to overlearned skills [45].

The primary care physician is an essential partner in assessing driving competency. While many families have concerns, they often do not feel able to discuss it with their family member. In the interests of maintaining the family physician-patient relationship and if the patient has already been referred to geriatrics for cognitive assessment, assessment of and discussions related to fitness to drive may be done by the specialist. If drivers have a physical disability, vehicle adaptations could be made to address this disability (e.g., peripheral neuropathy [foot drop]). In addition, alternate transportation services for seniors (e.g., modes of transportation that exist outside of public transportation programs and include both for-profit and not-for-profit services delivered via private vehicles, buses, handibuses, handivans, minivans) are available in many urban and rural, and to a lesser extent in remote areas. These alternate transportation services enable many older adults to meeting their medical, essential, and social/recreational needs, as well as reducing the risk of social isolation in older adults who voluntarily or involuntarily stop driving [46].

Breaking bad news and driving cessation support programs have been developed and can be useful for patients and their families [47].

General Principles

Dementia is a common problem seen by family physicians. There is no disease-modifying agent currently available for treating progressive dementias such as Alzheimer's. Cognitive-enhancing medications can be offered on a trial basis but have very limited benefit. Recent studies support the benefits of vigorous exercise in delaying the onset or slowing the progression of most dementias [1]. Management should focus initially on patient and family education and early discussion of goals of care. Physicians should look to evidence-based guidelines to help provide high-value interventions for the prevention and management of common complications of dementia. These include depression, delirium, agitation, falls, adverse medication effects, and burdensome, distressing interventions near the end of life. Advanced dementia can be devastating for both the patient and family. Support from a trusted family physician during this difficult time can be invaluable.

Approach to Care: Older adults should undergo routine cognitive screening in venues such as the *Medicare Wellness Visit*. Screening can be done through a number of available tools including the *Mini-Cog* (3-item 5-min recall and clock draw) [2]. If the initial screening is abnormal, a more detailed, quantifiable test such as the *Montreal Cognitive Assessment* (MoCA) or the Mini-Mental Status Exam (MMSE) should be considered. These are more widely accepted as reliable for tracking disease progression and statistical responses to treatment. Evaluation for reversible causes of cognitive impairment should also be done (Table 1). If this is negative, it is highly probable that the patient suffers from one of the common nonreversible dementias. A consultation should be considered if the diagnosis is in doubt.

Definition/Epidemiology

Estimates of dementia prevalence vary widely due to imprecise diagnosis and documentation. Average estimates are about 4% for people aged 55–65, 10% aged 65–75, 20% aged 75–85, 30% aged 85–90, and 40% aged >90. In 2020 there were approximately 5.8 million people in the USA with dementia. This number is expected to increase to 13.8 million by 2050 [4].

The 2013 revision of the Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-5) introduced *neurocognitive disorder* (NCD) to replace the preferred term for dementia. The main rationale was the perceived stigma attached to the diagnosis of dementia, especially in younger persons. It recognizes that the term dementia is still appropriate for the use in settings where it is customary [5].

The diagnostic criteria for dementia are [5]:

1. Cognitive impairment involving at least one of the following domains: memory, language, complex attention, executive function, perceptual (visual-spatial) motor function, and cognitive behavior.
2. This must represent a decline from a prior level of function.

Table 1 Reversible dementia/cognitive impairment

Drugs	Any medication with anticholinergic, sedating, or other CNS effects should be suspect. Renal impairment will magnify side effects. Effects may be additive so polypharmacy should be addressed even if there is not a single "smoking gun" medication. See "Beers List" for further details [3]
Eyes/ears	Lack of sensory input over time will hasten cognitive decline. Severe hearing or visual impairment can lead to an incorrect diagnosis of dementia if a hurried clinician does not adjust their assessment appropriately
Metabolic	Thyroid disease and B_{12} deficiency should be ruled out. Renal function, CBC, and liver function tests are also recommended
ETOH	Alcohol abuse can cause short-term memory impairment and other neurologic deficits. Deficits may improve at least partially with cessation
Normal pressure hydrocephalus	This usually presents with gait instability and possibly urinary incontinence before dementia becomes apparent. The gait is usually wide based with steps close to the floor ("magnetic") and normal arm swing. This differs from a parkinsonian gait with limited arm swing due to bradykinesia and rigidity
Tumor/trauma	Tumors or trauma, including subacute or chronic subdural hematoma, may present with cognitive impairment. There are usually additional neurologic signs
Infections	Testing for *neurosyphilis* is no longer routinely recommended for all dementia patients. It should be considered if presentation is atypical with early neuropsychiatric symptoms or if HIV positive. HIV dementia is common in late-stage disease
Affect/depression	Depression can result in low scores on cognitive tests due to lack of engagement (*Pseudodementia*). Long-standing depression can cause true cognitive impairment due to diminished social and mental stimulation
Sleep apnea	This is now recognized as potentially contributing to cognitive decline, although it is usually a minor factor

Telegram: @medical_k

www.konkur.in

3. Reversible causes of cognitive impairment including delirium have been ruled out.
4. There is loss of independence due to impaired functional status in activities of daily living (ADLs) or independent activities of daily living (IADLs).

If criteria 1–3 are present but independent functioning is preserved, even with the help of compensatory strategies by the patient, the diagnosis is *mild cognitive impairment* (MCI), not dementia. About 30% of people with MCI will progress to dementia within 5 years. MCI can be amnestic (memory impaired) or non-amnestic. The progression to dementia is highest in research settings if patients have amnestic MCI with biomarkers suggestive of Alzheimer's pathology (see below) [6].

DSM-5 has added additional specifications for the likely etiology of the dementia (Table 2).

Table 2 Common dementias and their characteristics

Progressive (neurodegenerative) dementias: The underlying pathology inevitably progresses, although at varying rates. A terminal stage will be reached unless death from another cause supervenes. There is significant overlap among AD, LBD, and VaD	
Alzheimer's disease **(AD)** (65–70%)	Characterized by insidious onset with short-term memory decline as the earliest deficit in most people. Language and visual-spatial changes may be the initial deficit in about 5%. Pathologic changes begin years before clinical features develop. There is overlap with Lewy body dementia (LBD) and vascular dementia (VaD), especially in older age groups
Lewy body dementia **(LBD)** (15–20%)	Characterized by visual hallucinations and spontaneous fluctuations in mental status. REM sleep disorder (vivid dreams physically acted out) may be the earliest sign. Most people will develop parkinsonian features eventually, which may be subtle If cognitive impairment develops after the onset of Parkinson's disease, it is known as **Parkinson's disease with dementia (PDD)**
Frontotemporal dementia **(FTD)** (5%)	Age of onset is generally earlier than AD and LBD, often in the 40s or 50s. There also appears to be a hereditary component more frequently. There are three subgroups. The most common is FTD-behavioral variant (Pick's disease) which affects personality and behavior early in the course when memory may be well preserved. Less common are semantic dementia and primary progressive aphasia which affect speech and language initially
Prion disease (<1%)	Rapidly progressive with changes in behavior, coordination, and vision in most. Caused by communicable proteins in CNS, though most cases arise spontaneously. Dx is by CSF 14-3-3 protein levels. Creutzfeldt-Jakob disease (CJD) is the most common form. Incidence about 1/1 million/yr
Secondary dementias: (may be stabilizable)	
Vascular (VaD) (15–20%), usually a cofactor rather than the primary etiology	Deficits vary depending on location and extent of the stroke(s). More likely to be the primary etiology in the oldest age group (>90) It is important not to confuse expressive aphasia or dysarthria with dementia if nonverbal communication is preserved
Alcohol (<5% as primary factor)	Short-term memory deficits most prominent in chronic overuse. Ataxia also is common. Dementia may partially improve after alcohol cessation
Brain injury from isolated trauma (TBI) or hypoxia (<1%)	Multiple presentations depending on extent or site of brain injury. Cognitive deficits may be subtle if injury or hypoxia was relatively mild. Usually is not progressive
Chronic traumatic encephalopathy (<1%)	Due to repeated trauma such as concussions in athletic injuries. May have changes similar to FTD, with personality changes a prominent early feature and tau proteins on pathologic study. May have insidious onset and progression

Telegram: @medical_k

www.konkur.in

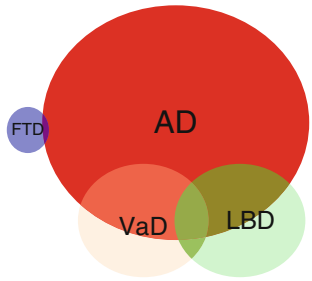

Fig. 1 Prevalence and overlap of common dementias. **Alzheimer's disease (AD) = 65–70%. Lewy body dementia (LBD) = 15–20%. Vascular dementia (VaD) = 15–20%. Frontotemporal dementia (FTD) = 5%**

There is significant overlap of the most common dementia etiologies (Fig. 1).

It is now recognized that Alzheimer's pathology develops years before clinical symptoms of MCI or subsequent dementia. This pathology includes beta-amyloid deposits outside of neurons, tau protein tangles within neurons, and hippocampal shrinking. The National Institutes of Health (NIH) working group on Alzheimer's has therefore proposed the revision of Alzheimer's disease diagnosis and staging. Three stages are identified: preclinical, MCI, and clinical disease [6].

Biomarkers which are usually abnormal in all three stages of AD include *amyloid PET scans*, structural MRI, and CSF proteins. They are now being used in research of therapies designed to impact the pathological processes. Medicare has approved the preauthorized use of *biomarkers* for the evaluation of dementia when the diagnosis is in doubt and it is felt that a precise diagnosis is clinically important. This group would typically include younger patients or those with atypical or rapidly progressive symptoms [7].

Approach to the Patient

History and Physical Examination

A focused history and physical should be performed if cognitive impairment is suspected based on abnormal screening tests or symptoms reported by the patient or family. Key areas are:

History of Present Illness: Time course regarding onset/progression of cognitive change or other symptoms is critical. Insidious onset and slow progression of symptoms are characteristic of AD, LBD, and FTD. A family member is usually needed to provide a reliable report of this. More abrupt onset is of concern for stroke or other secondary or reversible causes of cognitive impairment (see Tables 1 and 2).

Family History: A positive family history of FTD increases the likelihood of FTD as the etiology, especially if behavior/personality changes are presenting symptoms. About 20% of FTD is inherited through an autosomal dominant gene [8]. FH of AD or LBD/PDD confers a more modest increased risk. Age is by far the highest risk factor for these.

Medical History: This should include history of stroke, Parkinson's, depression, syphilis, HIV, *Down's syndrome* (which frequently leads to AD), or other neuropsychiatric disorders.

Medications: A careful medication review will often reveal additive CNS side effects from multiple medications.

Social History: Screening for alcohol abuse is important. Risk factors for cardiovascular disease such as smoking, poor diet, and lack of exercise are also associated with increased risk for MCI and dementia. *Social isolation* increases the risk for dementia.

Speech/Affect/Memory: Fluent speech with socially appropriate, normal affect but impaired short-term memory is suggestive of MCI or early AD. Blunted speech which may be socially inappropriate at times should raise concern for FTD. LBD/PDD may have more blunted speech or more difficult with retrieving long-term memory facts than AD with better short-term memory in early and middle stages. Flat affect or lack of engagement during the assessment may indicate depression (pseudodementia).

Gait/Motor/Sensory: These should be normal in early-middle stage AD. PDD will have clear parkinsonian features as by definition these develop before the dementia. Parkinsonian features usually develop at some point in LBD but may be subtle. *Gait* changes with a

Telegram: @medical_k

www.konkur.in

wide-based, shuffling ("magnetic") gait with good arm swing are suggestive of NPH. The arm swing in Parkinson's is usually diminished due to rigidity or bradykinesia. *Neurosyphilis* signs may include diminished proprioception with high-stepped gait or weakness (tabes dorsalis) or small pupils that don't react (Argyll Robertson pupils). Upward gaze palsy in a patient with parkinsonism is diagnostic of progressive supranuclear palsy, a Parkinson's plus syndrome that usually leads to dementia.

Lab/Imaging

Basic labs to rule out non-neurodegenerative etiologies of cognitive impairment should be done, including CBC, liver and renal function, TSH, and B12. A onetime head CT/MRI can be considered, especially if there are early changes in behavior, speech, vision, or motor functions which could suggest a non--Alzheimer's etiology. In contrast, a patient of advanced age with only short-term memory decline can usually be safely managed without additional imaging.

Treatment

Prevention and Early Detection

The best evidence for preventing or delaying onset of mild cognitive impairment and subsequent dementia supports healthy diets, exercise, and good cardiovascular health [1, 9, 10]. Vigorous exercise has also been shown to increase hippocampal volume in short-term studies. Hippocampal shrinkage is one of the prominent biomarkers for early Alzheimer's. The likely mechanism is increased levels of *BDNF (brain-derived neurotrophic factor*) through exercise [10]. This reinforces the key role of family physicians in promoting healthy lifestyles for patients of all ages to reduce risk for a wide range of serious diseases. There are no medications shown to reduce risk of developing MCI or preventing its progression to dementia [1].

Medications

Cognitive Enhancers: The most commonly used medications are cholinesterase inhibitors (CIs). These include donepezil, rivastigmine, and galantamine. They have at most modest benefit on symptoms with no disease-modifying activity. There is no effect on delaying the progression of MCI to dementia or prevention of the most devastating aspects of end-stage disease [1]. A targeted literature review of CIs and memantine was used for the 2008 American Academy of Family Physicians (AAFP) and American College of Physicians (ACP) clinical guidelines. It concluded that the average change in cognitive score (on MMSE or other tests) with *donepezil* was "statistically significant but not clinically important" ([11], p. 372). There may be a small subset of patients with clinically significant improvement. There was no significant difference between the CIs [11]. It reached the same conclusion about lack of clinically important improvement on cognitive testing for memantine ([10], p. 375). More effective cognitive enhancers have not been introduced since 2008. There is evidence for modest improvement in behaviors and functional status in some studies. The clinical significance of this is also not clear [11]. CIs are used primarily for AD and LBD. They have no benefit in FTD, and they may even increase agitation [8].

Current guidelines suggest that these medications can be offered on an individualized trial basis if the patient/family desires it after discussion of their limited benefits, potential side effects, cost, and the patient's overall prognosis [11]. If the patient and/or family desire a trial, they should be reassessed after several months. If there is no apparent benefit per patient or family and improvement or stabilization on an MMSE or other test is not verified, discontinuation should be considered.

Common side effects of *donepezil* and other CIs are GI related, including dyspepsia and poor appetite. There is also an increased risk of syncope [3]. A common conundrum involves a patient

Telegram: @medical_k

www.konkur.in

with dementia on a CI with poor appetite and weight loss. Is it due to the medication or disease progression? A trial of medication discontinuation should be considered.

Memantine is FDA indicated for moderate to severe dementia. Adding this to donepezil or other CIs has been a common practice. Adding memantine to donepezil did not improve effectiveness in the largest study to date [12]. Common side effects of memantine include headache, confusion, and hallucinations. Like the side effects of CIs, these may be difficult to differentiate from disease progression. A trial of discontinuation should be considered if these occur. Vitamin E has been used, but studies of its benefit have been inconclusive [13].

Antipsychotics: These should be used rarely in dementia due to concerns about serious side effects such as sedation, falls, confusion, and limited evidence for efficacy [3]. There is now an FDA black box warning of an increased risk of death among those using antipsychotics for dementia-related behavioral disturbances. However, they can be helpful in patients having severe distress from delusional agitation or psychosis that does not improve with other interventions. They should be used with extreme caution in patients with LBD/PDD, who frequently have severe neuroleptic sensitivity due to their dopamine deficiency from Parkinson's.

Antidepressants: Selective serotonin reuptake inhibitors (SSRIs) have better evidence for treating "agitation" than antipsychotics [14]. Depression is common in all patients with incurable serious health problems which may explain some of their effectiveness. They also have antianxiety effects. *Citalopram* has the best evidence for efficacy [14]. There is a theoretical concern for QT prolongation with citalopram, so the FDA recommends that doses above 20 mg a day not be used in the elderly. Sertraline is an alternative if QT prolongation is a concern. *Trazodone* has been shown to help with sleep cycle disturbance [15]. Tricyclic antidepressants should be avoided in most patients due to higher rates of sedating and anticholinergic side effects.

Anxiolytics: *Benzodiazepines* should be used with extreme caution due to increased confusion and fall risk [3]. A short-acting medication such as lorazepam can be useful in limited settings such as before personal care for patients who become severely distressed or physically combative during bathing or dressing in spite of non-pharmacological interventions. It is also helpful for restlessness and anxiety at the end of life. *Buspirone* is non-sedating and a much safer alternative to benzodiazepines in nonterminal patients. It has been shown to be effective in treating behavioral disturbances in dementia [16].

Hypnotics: *Melatonin* is the body's natural sleep hormone and should be first-line therapy. Effects are not as dramatic as with sedating medications, but there is a much better safety profile and no risk of dependence. It is more effective given nightly, 1–2 h before sleep, rather than as needed. Trazodone is generally the next-line treatment if needed. Zolpidem and similar hypnotics have adverse effects in the elderly similar to benzodiazepines and should be avoided. Antihistamines including diphenhydramine have similar risks, as well as more adverse anticholinergic effects [3].

Behavioral/Psychological Issues

Disruptive or distressing behaviors eventually develop in most patients with dementia. The most challenging issues for many families and other caregivers are wandering, agitation, incontinence, and disrupted sleep patterns. There are behavioral and environmental interventions which can be very helpful (Table 3). Medications should be a last resort.

Anticipatory guidance by their physician early in the disease process can help families prepare to access community and other resources which will help improve care and reduce caregiver stress. Families often benefit from counseling to help deal with grief about losing the loved one they knew before dementia changed them so much. Spiritual and psychosocial support is available to patients and families in all hospice programs.

Telegram: @medical_k

www.konkur.in

Table 3 Management of *behavioral issues in dementia*

1. **"Agitation"** should prompt a search for an *unmet need* (such as pain, need for toileting, constipation, thirst, hunger, urinary retention, fear, or loneliness) before considering treatment with medications. Fear of bathing, showering, or being undressed by a "stranger" is especially common. Allowing the patient to have as much control as possible over how and when this will be done is helpful Psychotropic medications should be reserved for delusional agitation not amenable to behavioral strategies and which causes severe distress or potential physical harm to the patient or caregiver. Buspirone is a safer alternative with proven effectiveness [16]
2. **Wandering** behaviors will occur at some point in most patients. Environmental modifications to allow safe walking in an enclosed area and daily vigorous exercise are the most effective interventions. Safe return bracelets are recommended for all ambulatory patients. Medications are of no benefit Searching for a dead spouse or other relative is common and should be redirected to a positive conversation about that person. Trying to convince the patient that their spouse or parent has died is usually counterproductive
3. **Incontinence**: Most patients with dementia have *functional incontinence* due to loss of cognitive awareness about needing to use or find the bathroom. Treatment should be scheduled toileting, with adult briefs as a backup measure. Overactive bladder medications do not address the root cause. They also have potentially serious anticholinergic side effects
4. **Sleep:** Nighttime awakening and wandering are stressful for caregivers and often prompt a request for sedating medications which should be avoided due to adverse side effects (see "Beers List"). Melatonin is safe and usually has modest benefit in establishing a more regular sleep cycle. Avoiding daytime naps, vigorous exercise, and not going to bed early are the most effective interventions. Families should be educated about the normal decline in hours of sleep needed with aging (average of 6–7 h a day for people >80)
5. Support groups are a valuable resource for family education and support in dealing with challenging behaviors and other dementia care issues. Early referral to the local *Alzheimer's Association* or other support groups should be strongly considered

End-Stage Dementia

Recent research has demonstrated that progressive dementias have a disease trajectory that is similar to other terminal illnesses such as advanced cancer [17]. Prior discussion of the goals of care by the family physician is instrumental in avoiding non-beneficial and potentially uncomfortable and emotionally distressing interventions in hospitals or other settings as the disease progresses [18, 19]. Difficult decisions about life support or hospital transfers are often faced in a nursing home or hospital. Whenever possible, the family physician should try to provide care or support in those settings directly as attending physician or via a social visit or phone call. Specific management issues are detailed in Table 4.

Summary

Family physicians will see increasing numbers of patients with dementia as our population ages. They are well suited to evaluate and manage the majority of patients with dementia. Referral to subspecialists for ongoing care has not been shown to improve outcomes [22]. It should be considered in atypical cases where the diagnosis is in doubt.

Routine cognitive screening is a required component of Medicare Wellness Visits. This will help family physicians improve early detection and prompt evaluation for reversible causes. Most cases unfortunately will not be reversible. Efforts should then focus on family education and preventing complications of dementia. Avoiding adverse medication effects and promoting exercise to help reduce *falls* and disruptive behaviors are effective low-cost interventions.

A cornerstone of family medicine is the universal promotion of healthy diets and exercise for disease prevention. These, along with cognitive stimulation, are currently the most effective interventions for delaying the onset and progression of most dementias. The use of imaging or other biomarkers to detect early or preclinical dementia may become important in the future if disease-modifying medical therapies become available.

www.konkur.in

Table 4 Management of end-stage dementia. End-stage dementia is characterized by loss of interest in food, difficulty in recognizing family members, and increased susceptibility to aspiration pneumonia and other infections. It is now generally recognized as a terminal disease process [17]

1. Early discussion of goals of care	All adults should be encouraged to prepare an *advance directive* while mentally competent. It should include their wishes about care if a terminal illness develops. This should include wishes about life support including tube feedings if advanced dementia develops. This will prevent family distress when facing these decisions without knowing their loved one's wishes [18] Education about the ultimately terminal course of neurodegenerative dementias such as Alzheimer's should be included in this discussion. Many forms are available to facilitate this, such as Five Wishes. Goals of care should routinely be reviewed in Medicare Wellness Visits or other venues if not yet established
2. Nutrition	*Feeding tubes* have not been found to be of benefit in advanced dementia and do not prevent aspiration [20]. Impaired swallowing signals a very poor prognosis, and focus should shift to pleasure feedings and other comfort measures. Sweets and cold, soft foods such as ice cream are usually best appreciated and tolerated at this stage Orders such as NPO (nothing by mouth) should be avoided as this may lead to a misperception by families that we are "starving" the patient. "Pleasure feeds as tolerated" is a preferred alternative. Mouth swabs with fluid of choice should be offered in the final stage. This can be especially comforting for family members Education should focus on the fact that not eating is part of the natural course of the disease and the body responds by shutting down bodily functions including the thirst center. The body begins producing endorphins (natural opioids) to help transition to a comfortable death
3. Hospitalizations	Hospitalizations of nursing home patients with advanced dementia for pneumonia or other complications are common and have not been shown to improve outcomes. They are associated with worsening confusion and debility while in the hospital. Treatment at the nursing facility after discussing the risk/benefits of hospital transfer with the family is generally recommended
4. Hospice/palliative care	*Hospice* care improves pain and other comfortable dying measures in end-stage dementia [21]. Patients meet hospice criteria when life expectancy is <6 months as evidenced by loss of interest in food with weight loss, recurrent infections, skin breakdown, multiple falls, severely diminished speech and understanding, or other dementia complications

Early discussion of patient and family goals of care regarding their wishes if dementia progresses is critical to avoiding unwanted burdensome care in end-stage disease. Hospice or other comfort-focused care support is strongly recommended when this stage is reached to help reduce patient and family suffering.

General Principles

Definition and Background

Elder abuse is generally defined as the maltreatment of individuals over the age of 60 [1]. The World Health Organization (WHO) recognizes elder abuse as "a single, or repeated act, or lack of appropriate action, occurring within any relationship where there is an expectation of trust which causes harm or distress to an older person" [2]. Instances of abuse toward older adults perpetrated by a stranger (e.g., theft, fraud) are therefore not considered elder abuse [3]. Elder abuse can be of various forms: physical; psychological/emotional, sexual; financial and material abuse; abandonment; neglect; and serious loss of dignity and respect [4].

The American share of the older population over 65 is expected to increase from 16.6% in 2020 to 22.4% by 2050 [5]. Similarly, the global share of older people is projected to increase from 9.3% in 2020 to 15.6% in 2050 [5]. In parallel,

www.konkur.in

aging of the global population will likely result in an increased prevalence of elder abuse around the world [1, 3, 6]. Global prevalence rates of overall elder abuse were reported to be 10–15.6% and 34% for self-report and third-party reports, respectively [7, 8]. Geographical differences were seen in those prevalence estimates with the highest rates in Asia at 20.2%, moderate numbers in Europe at 15.4%, and a lower reported prevalence in the Americas at 11.7% [1, 8]. However, these estimates may be inaccurate due to the lack of clear definitions, reporting guidelines, and reliance on self-reports from those who are able to participate in surveys. This may exclude vulnerable patients who are at greater risk for mistreatment [1]. Thus, a busy family physician caring for older adults is likely to encounter victims of elder abuse on a regular basis.

Disturbingly, only 1 in 23 cases of elder abuse were reported to Adult Protective Services (APS) agencies and fewer than 2% of reports and neglect came from physicians, suggesting that physicians may lack training, experience, education, and adequate guidelines for the assessment and management of abuse [9, 10].

Elder abuse causes fear, depression, stress, isolation, sleep disorders, disability, and increases the risk for suicide and death. Victims of abuse have a mortality rate three times higher than non-victims [3, 9, 11].

Despite growing awareness and concern regarding elder abuse, the US Preventive Services Task Force (USPSTF) concluded in 2018 that the current evidence was insufficient to assess the balance of benefits and harms of screening for abuse and neglect in all older or vulnerable adults. Further, The USPSTF found no valid reliable screening tools in the primary care setting to identify abuse of older or vulnerable adults without recognizable signs and symptoms of abuse [12]. The American Medical Association, on the other hand, encourages physicians to inquire about abuse routinely. The National Center on Elder Abuse suggested that primary care settings may provide a valuable opportunity for elder abuse screening as elders are frequently seen for common conditions associated with aging [13, 14]. Despite the discordance in screening guidelines, physicians might be confronted with situations that arouse suspicions of abuse [15].

This chapter discusses the definitions of abuse, risk factors for abuse associated with both the elderly and their caregivers, barriers that elderly patients and their physicians face when dealing with abuse issues, assessment of suspected elderly abuse victims, reporting guidelines, and prevention strategies.

Categories of Abuse

The Centers for Disease Control and Prevention (CDC) and a diverse group of elder abuse experts collaboratively produced version 1.0 of uniform definitions and recommended core data elements of the major types of elder abuse as follows [4, 9]:

Physical abuse: The intentional use of physical force that results in acute or chronic illness, bodily injury, physical pain, functional impairment, distress, or death. This includes pushing, slapping, kicking, spitting, hitting, misusing medications, force feeding, and using restraints. These physical acts may cause bruising, cuts, lacerations, sprains, hair loss, missing teeth, fractures, burns, and other traumatic injuries.

Sexual abuse: Forced and/or unwanted sexual interaction (touching and non-touching acts) of any kind with an older adult. It includes rape, unwanted touching, sexual advances, or innuendo. Victims may suffer from trauma around the anus, vagina, breasts, and mouth.

Emotional/psychological abuse: Verbal or nonverbal behavior that results in the infliction of anguish, mental pain, fear, or distress. It includes humiliation/disrespect, threats, harassment, isolation, or coercive control. Threats to institutionalize or withhold medication, nutrition, or hydration are also included in this category. Victims often display feelings of depression, withdrawal, and apathy.

Financial abuse/exploitation: The illegal, unauthorized, or improper use of an older individual's resources. This includes, but is not limited to, depriving an older individual of rightful access to, information about, or use of personal benefits, resources, belongings, or assets. It consists of overpayment for goods or services; unexplained

Telegram: @medical_k

www.konkur.in

changes in power of attorney, wills, or legal documents; missing checks or money; or missing belongings.

Neglect: Failure to protect an elder from harm or the failure to meet needs for essential medical care, nutrition, hydration, hygiene, clothing, basic activities of daily living or shelter, which results in a serious risk of compromised health and/or safety, relative to age, health status, and cultural norms. Neglect may be intentional or unintentional, and it might also occur within retirement homes, assisted living facilities, nursing homes, and hospitals [15] .

Self-neglect: Is frequently omitted or reported separately in statistical summaries. It has been described as "the behavior of an elderly person that threatens his/her own health and safety." It is not unique to seniors and it might be reflective of problems that fall outside the realm of elder abuse [15].

There is some disagreement in the literature as to the most common form of elder abuse. Nonetheless, recent meta-analyses have shown that emotional abuse was the most common, followed by financial abuse, neglect, and then physical abuse [1, 7, 8]. Sexual abuse was the least often reported, likely due to failure to screen for or lack of disclosure by victims [1, 7, 8]. Cultural or regional differences might have been found in incidence and reporting of the abuse subtypes due to differences in cultural norms that in turn could influence abuse perception and outcomes. However, a possible association between elder abuse, culture, and ethnicity is inconsistent across the literature [16].

Risk Factors

Evidence supports a multifactorial etiology of elder abuse involving victim vulnerability and perpetrator risk factors, and factors related to their relationship and the environment [1, 3, 17].

Victim vulnerability factors: Dependency, poor physical health, cognitive impairment, low socioeconomic status, gender, age, and race/ethnicity are some of the most commonly cited vulnerability factors [1, 18]. Dependency can be functional, financial, social, or emotional in nature [3]. Physical and cognitive disability have been associated with a greater risk of elder abuse as they impair their ability to seek help, impair decision-making capabilities, and limit autonomy [19]. Patients with dementia are more likely to be victims of financial exploitation [9, 20]. Women are more likely to be victims of abuse as they have a longer lifespan that might increase their risk of dependence and cognitive impairment in old age [1, 7, 18]. Elder abuse is also more common in minority older adults compared to whites [21]. In particular, older lesbian, gay, bisexual, and trans (LGBT) people are more likely to have known vulnerability factors, such as loneliness, lower likelihood to be partnered and to have children, which puts them at higher risk of abuse compared to their heterosexual peers [22].

Perpetrator risk factors: Perpetrators are most likely to be adult children or spouses, and they are more likely to be males, to have a history of substance abuse, to have mental or physical health problems, to be socially isolated, to have financial problems with dependence on the victim, and to be experiencing major stress especially caregiver burnout and poor coping skills [1, 15, 18].

Relating to the relationship: A conflictual relationship between the victim and the perpetrator has been consistently identified as a vulnerability factor for elder abuse [3].

Relating to the environment: Lack of social support, living with a larger number of household members other than a spouse, and living in a facility rather than in the community are associated with higher rates of abuse [1, 3].

A good screening history by the family physician is needed to uncover a possibility of a neuropsychiatric disease in the victim, and to reveal a potential perpetrator especially if the caregiver becomes exhausted and overwhelmed over time.

Challenges to Identification

Patient-Related Challenges

Victims of elder abuse usually face many obstacles when disclosing abuse because it is being perpetrated primarily behind closed doors and by family members. Some patients have physical or

Telegram: @medical_k

www.konkur.in

cognitive barriers or are socially isolated which not only renders them at risk of abuse but also makes their recognition challenging [23]. Other barriers to seeking help include fear of consequences for self and the perpetrator, especially if it is a close family member; victims might be afraid of retaliation or worsening of the abuse and their relationship with their family, of being abandoned, isolated, or institutionalized [24]. They also might be physically frail or have socioeconomic dependency on the perpetrator in addition to feelings of shame and embarrassment, self-blame, low self-esteem, helplessness, and the stigma associated with seeking help [9]. Also, they may have doubts about the capacity and adequacy of services to help them, a lack of trust in professionals, and accessibility were some other barriers reported [23, 24].

Physician-Related Challenges

The challenges doctors face in detecting elder abuse are mainly due to lack of awareness about elder abuse and its prevalence [25]. Many physicians may not be able to detect the signs of elder abuse, much less how to screen for it, and especially ascribing the subtle signs of abuse to the vicissitudes of "normal" aging [26]. Ageism acts as a type of prejudice that both justifies abusive behavior against older people and leads to overlooking the consequences it has on them. It impedes the prevention and early identification of elder abuse [26, 27]. Fear of legal and ethical consequences are not to be disregarded especially when the victim is not willing to share information with the authorities [25, 28]. Training family physicians to screen for risk factors contributes to early detection and intervention and thus prevents further abuse [9].

Assessment

History and Physical Examination

Family physicians may have well-established relationships with older adults and their families that allow them to recognize potential abuse provided that they maintain a high level of suspicion. They should work with multidisciplinary teams to ensure thorough assessment, intervention, and follow-up of elderly patients [29].

During the consultation, it is helpful to interview the patient and caregiver together and separately to detect disparities offering clues to the diagnosis [30]. Interviewing the victim alone helps mitigate the fear of retaliation and shame that might otherwise hinder disclosure [10]. If a language barrier exists, a professional translator should be used rather than the caregivers or family members [30].

A complete history is the key; it should start with open-ended questions such as "Can you tell me what happened?" and further questions should be neutral and nonjudgmental to encourage patients and caregivers to provide detailed information [10]. The history should focus on current health status, living arrangements, emotional stressors, social support, medication review, and financial status [30]. All vulnerability and risk factors for abuse should, also, be inquired about as well as the patient's functional status, cognition, care needs, and safety of the home environment [10, 30]. Screening for depression and social isolation should not be overlooked [31].

Behavioral signs that may offer clues that suggest elder abuse include poor eye contact, anxiety, low self-esteem, and helplessness [30]. A caregiver who often interrupts the patient to answer questions for him or her or appears reluctant to leave the patient alone might be a potential perpetrator [30, 32]. Nonetheless, interruptions during history taking may be compensatory for the patient's cognitive impairment and do not always indicate abuse [10]. Moreover, physicians should be able to differentiate signs of injuries from disease processes and normal aging. These include allergic reactions, osteoporotic fractures, vaginal bleeding due to atrophy, and anorexia caused by mental illness [10, 19].

The physical examination should be comprehensive, with the patient completely undressed in order to perform a full dermatological evaluation including fingernails and toenails [30]. The clinical manifestations of elder abuse are difficult to

Telegram: @medical_k

www.konkur.in

identify and vary by type of abuse. However, general signs suggestive of abuse and neglect might include signs of dehydration and malnutrition, poor hygiene and physical care, and signs of psychological distress [19].

Patterns of injury such as ligature marks, multiple burns and bruises, of different sizes and ages, found on the abdomen, neck, posterior legs, or medial arms, as well as the presence of unusual or unexplained fractures are suggestive of physical abuse, whereas sexually transmitted infections, unexplained vaginal/rectal bleeding or pain in the oral or anal–genital regions are suggestive of sexual assault that mandates forensic examination [10, 16]. Mobility assessment helps ascertain the actual cause of injuries from reported falls, while cognitive assessment using the Mini-Cog test helps screen for a possible dementia [10, 19, 33].

The comprehensiveness of the physical examination should be coupled with a meticulous documentation of all findings including the patient's statements, behavior, appearance, and body charts or clinical photographs of the location and morphology of injuries [10, 29].

Radiographs should be obtained when possible if fractures are suspected along with a CT scan if the patient has suffered a head injury. If clinical findings suggest malnutrition, then laboratory testing (e.g., complete blood count, blood urea nitrogen, creatinine, total protein, and albumin levels) should be requested to document consistent findings [19]. Serum drug levels help uncover possible poisoning, under treatment or inappropriate use of medications [10].

Management and Reporting Guidelines

Despite the presence of several tools that have been validated for elder abuse evaluation and management, there is currently no gold standard tool [14, 32]. The Elder Abuse Suspicion Index (EASI) was validated in a primary care setting to screen for abuse in cognitively intact patients. The EASI has five patient-answered items, plus one physician question with a marginal sensitivity of 0.47 and a specificity of 0.75 [14, 15, 34]. Figure 1 shows a suggested algorithm for the management of suspected elder abuse.

A positive screen for elder abuse does not unequivocally indicate abuse, but it mandates referral for complete multidisciplinary functional assessments that may include home visits by local social workers, concerned family or friends, or Adult Protective Services (APS) authorities [1, 10]. Importantly, clinicians do not have to prove that elder mistreatment has occurred; they need only document a reasonable cause to suspect that it has [29]. After that, physicians need to ensure safety of the victim and report the case. Reporting is not federally mandated but is regulated by state governments; nearly all states have enacted mandatory reporting laws whereas pertinent statutes may vary [29]. Failure to report, however, can be considered negligence and is potentially punishable by fines, imprisonment, or loss of license [19]. Providing educational material for patients and families that includes a description of the warning signs of caregiver stress and available community supportive services is also an effective reporting approach. Even when law enforcement becomes involved, family physicians still bear significant responsibility for follow-up medical care of patients [10].

Online resources available to assist physicians with elder abuse include Eldercare Locator (https://eldercare.acl.gov/Public/Index.aspx), the Administration on Aging, American Medical Association, and the National Centre on Elder Abuse [10, 14].

Prevention

Elder abuse is a complex, multifaceted problem, and preventive strategies should be applied at many levels including public education and awareness. Early multidisciplinary intervention and education on resources and community support can be implemented to preserve elders' emotional well-being [9, 35, 36]. Home care clinicians can play an important role in prevention through astute observation of patients, their behaviors, and environment which alerts clinicians to potential abuse [9].

Telegram: @medical_k

www.konkur.in

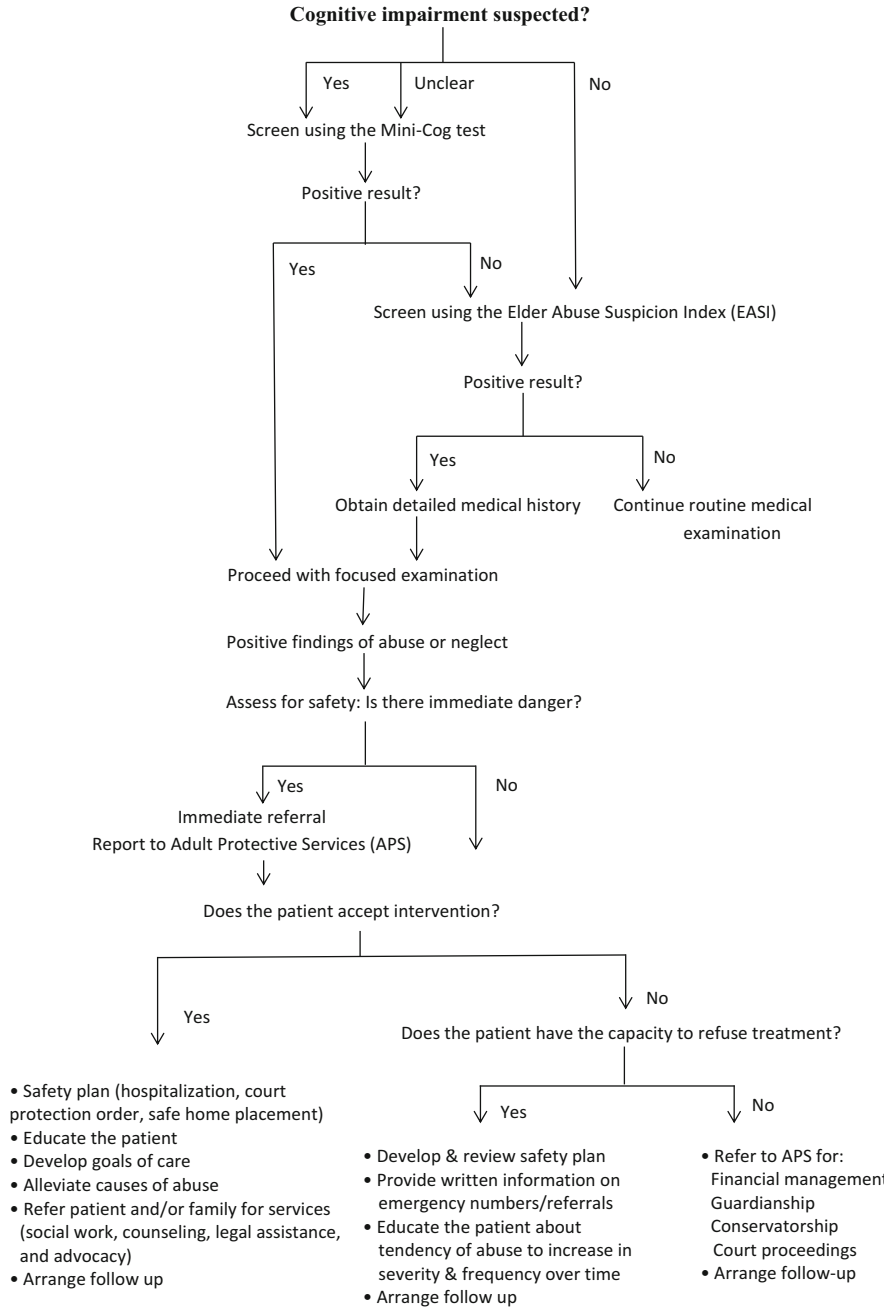

Fig. 1 Management of suspected elder abuse (Adapted from Refs. [10] and [29])

Conclusion

Family physicians may have well-established relationships with older adults and their families that allow them to recognize potential abuse and neglect [29]. They are likely to encounter elder abuse in their practice, hence early identification and intervention are essential to avoid catastrophic events and to save lives.

It is estimated that the number of people over 65 will surpass the estimated number of children under 18 for the first time in 2030 worldwide [1]. A deficit in the number of geriatricians will make treating older adults part of any primary care physician's practice.

When caring for older adults, assessment of functional ability is critical. Function gives the physician a picture of the interaction between medical conditions, physical aging, cognition, and overall health in the setting of the patient's environment. Function is a predictor of mortality, a reflection of a patient's level of independence, and often corresponds to their quality of life [2]. Knowing a person's baseline functional abilities also allows the physician to recognize when there is a change in their condition. However, physicians often do not recognize the importance of functional disabilities in their patients. At times, disease management is less important than maximizing patient function. In the same way, understanding a patient's functional status is the only way to assess the patient's resource needs and appropriate level of care.

Functional Impairment of Older Adults

Sensory Impairment

Older patients commonly have decreased sensory awareness, commonly evidenced by vision and hearing loss. Hearing loss is most common in

www.konkur.in

the high-frequency range and is usually bilateral. Hearing loss can lead to isolation, depression, and avoidance of social events.

The whisper test is an accurate and simple office screen for hearing loss [3]. Standing behind the patient at arm's length (about 2 feet), have the patient cover the untested ear, fully exhale (to control for the loudness of the whisper), and whisper a combination of three numbers and letters (e.g., K-4-2). Then ask the patient to repeat the set. If unable to repeat correctly, a second set is whispered. If unable to repeat at least three of the possible six numbers or letters, the test is considered positive for impairment. If the patient fails the whisper test screening or if the patient acknowledges hearing loss, the next step is evaluation for occluding cerumen. If present, one should retest after removal. If the screen is failed again, the provider should offer referral to audiology for definitive diagnosis and treatment.

Visual impairment can be assessed by asking questions regarding driving, reading, and assessing for falls. When examining visual acuity, make sure to use the patient's corrective lenses. Using a Snellen chart (far vision) or Rosenbaum card (near vision), those scoring worse than 20/40 is the cutoff for visual impairment [4]. A quick medication review looking for drugs that can be associated with blurry vision (such as amiodarone, sildenafil, tamoxifen, and anticholinergics) should be performed. Remember that patients over 65 should get a full eye exam biennially (yearly for those with diabetes) for early detection of conditions causing visual impairment.

Nutrition

Poor nutrition in the elderly is often overlooked by physicians unless they maintain a high index of suspicion for this condition. If available, weight and height should be compared to the year before. Unintentional weight loss of >5% in 6 months or a low BMI should trigger a nutritional assessment. A careful history can often indicate why a patient is losing weight. Mechanical causes, like ill-fitting dentures or a dry mouth, as well as social causes, like eating alone or not being able to leave the house to get groceries or being unable to cook meals, may provide insight into a patient's concerning nutritional status. Also, ask about economic barriers in securing food and the use of community services such as Meals on Wheels, senior centers, or church-delivered food. The use of the two-question screening tool "Hunger Vital Sign" helps flag those with food insecurities. Ask if within the past 12 months the patient worried whether food would run out before they got money to buy more or if the food they bought just didn't last and they didn't have money to get more. A positive answer to either of these questions indicates food insecurity. Making a connection to the local agency on aging usually provides meal resources that can be relayed to patients. Looking into the Supplemental Nutrition Assistance Program (SNAP), formerly called Food Stamp Program, can also help those with lower income. Requirements vary by state. Reviewing for medications and conditions that can lead to weight loss, including digoxin, cholinesterase inhibitors, SSRIs, amiodarone, and topiramate, and screening for depression are important. Nonpharmacologic treatments for weight loss in older adults include removing specific (often unpalatable and sometimes unaffordable) diets (low sodium, low fat); adding between meal snacks; increasing calorie density of foods; arranging for shopping trips, cooking times, and feeding assistance if needed; and attending group meals to avoid social isolation. No medications are FDA-approved to promote weight gain in older adults.

Mobility

In older individuals, causes of falls are often multifactorial. Asking about falls (if yes, how many), fear of falling, and feelings of unsteadiness, as well as assessing for associated symptoms like dizziness or presyncope or pain that impairs mobility, can help the clinician uncover the more obvious causes. Asking about the use of assistive devices, canes, walkers, and wheelchairs is also

Telegram: @medical_k

www.konkur.in

important. Checking medication lists and potential culprits like tricyclic antidepressants, benzodiazepines, sedatives, opiates, anticonvulsants, antipsychotics, antiarrhythmic, antihypertensive, and diuretics as well as using screening tools like STEADI [5], which includes the Timed Up and Go, can help guide appropriate interventions for fall prevention.

Mood

Recognizing and diagnosing late-life depression can be difficult. Complaints like lack of energy or other somatic symptoms like poor sleep, gastrointestinal complaints, and fatigue are common. Oftentimes patients will neglect to mention these to their providers. Screen all patients for depression with the Patient Health Questionnaire-2 [6]. It includes the following two questions:

- In the past 2 weeks, have you had little interest or pleasure in doing things?
- In the past 2 weeks, have you often been bothered by feeling down, depressed, or hopeless?

A positive screen is followed up with a more in-depth assessment, usually a Patient Health Questionnaire-9 or the 15-item Geriatric Depression Scale [7]. Always consider that depression may be a primary condition or associated with comorbid illnesses such as dementia. In the absence of suspicion for a specific condition, checking thyroid levels, B12, electrolytes, liver and kidney function tests, complete blood count, and a urinalysis is a reasonable workup for secondary causes. Patients suffering from subsyndromal depression (those with symptoms that do not meet full DSM criteria) deserve special mention. These patients should be monitored carefully, since the disease can present itself at any time and then require management. Treatment options include cognitive behavioral therapy, problem adaptive therapy for those with mild dementia, SSRIs, and SNRIs. Avoid paroxetine and fluoxetine in the elderly, as these are more anticholinergic.

Sleep

The idea that older adults require more sleep than young adults is a common misconception. It is perfectly acceptable for an older adult to sleep 5–7 h or as much as 12 h without concern, as sleep patterns naturally change as we age. Asking about bedtime routines and latency time before falling asleep (it takes longer for older adults to fall asleep), as well as nocturia and presence of naps, will often provide clues to the underlying causes of sleep problems. Screening and evaluation for appropriate treatment for sleep apnea should also be performed if this is a possibility. Sleep hygiene strategies (Table 1) can be emphasized as first-line treatment. If medications are prescribed, using the lowest effective dose and combining with behavioral treatment are preferred. Be aware these medications increase the risk of falls and hip fractures. Over-the-counter antihistamines should never be used to treat insomnia in older adults. Consider using SSRIs or buspirone for those with anxiety at bedtime. If a medication is required for sleep, short-term use or intermittent use is preferred.

Table 1 Sleep hygiene strategies

Sleep hygiene strategies
1. No caffeine or other stimulants after lunch
2. Alcohol in moderation and none after dinner
3. No smoking in the evening
4. Exercise (not excessive and not just before retiring) and get sunshine during the day
5. Have a pure carbohydrate snack (cake, cookie, candy) 15–20 min before heading to bed
6. Use bed (and bedroom) only for sleeping
7. Go to bed only when sleepy. Do not set a regular time for going to bed in the evening; go to bed only when you are tired and sleepy
8. If still awake after 30 min, get up, go to another room, engage in interesting or useful activity until sleepy again, and then return to bed. If still unable to sleep in 30 min, repeat as often as necessary
9. Get up at the same hour every morning
10. Avoid daytime or early evening naps
11. Keep the bedroom cool, quiet, and dark in the evening and night

Continence

Urinary incontinence can be evaluated by asking about changes in bladder habits, specifically problems with leakage, frequency, or urgency. In older adults, it is most often multifactorial, but eliciting the primary component if possible (urge, stress, overflow) may be helpful to determine specific evaluation and treatment. Red flags like hematuria and pelvic pain should be referred for urological evaluation after excluding urinary tract infection. Patients with frequency and urgency but without urinary incontinence should be treated for overactive bladder. The use of tools like the International Prostate Symptom Score [8] can quickly help with diagnosing prostatic obstruction problems, which are often present in older men. Examining functional status (including mobility); assessing for bladder distension, cord compression symptoms, presence of edema, and prostate consistency in men; and checking for phimosis, paraphimosis, or balanitis and for atrophic vaginitis and rectocele or cystocele or prolapse in women will be helpful in determining a cause. Assessing mental status, which is particularly important for planning appropriate treatments, will also prove beneficial. Testing includes review of a "bladder diary" where the patient records time and volume of continent and incontinent voids, as well as jotting down oral intake. Measuring post-void residuals (preferably with a bladder scanner instead of a catheterization) and a basic urinalysis are the usual first steps of evaluation. Next steps usually include urodynamic studies if the diagnosis remains unclear. Treatment strategies include ensuring adequate access to toileting, including commodes or urinals, prompted voiding in those with cognitive impairment (asking if a patient needs to void, taking them to the bathroom starting at 2–3 h intervals, and praising when continent and responding to toileting), using adaptive clothing, optimizing treatments for heart failure, controlling chronic cough, and reducing or eliminating medications that can contribute to incontinence. Decreasing consumption of caffeine and diuretic beverages and avoiding extreme fluid intake, as well as limiting fluids after supper to decrease episodes of nocturia, treating constipation, and encouraging patients to quit smoking (which produces a chronic cough), may also be beneficial. Urge, stress, and mixed urinary incontinence are also treated with behavioral therapy, particularly bladder training.

Bladder Training Instructions

1. Start by going to the toilet and trying to pass urine every 2 h while you are awake.
2. Try to pass urine whether or not you feel the need to. You must try to pass urine even if you have just been incontinent.
3. If you get a strong urge to go to the bathroom before your scheduled time:

   stop and don't run to the bathroom, stand still or sit down if you can, and relax. Take a deep breath and let it out slowly. Concentrate on making the urge decrease or even go away, in any way that you can (imagine the pressure becoming less and less).
4. Keep on this schedule until you can go 2 days without an episode of urine leakage. Then, increase the time between scheduled trips to the toilet by 1 h. When you once again are able to go 2 days without an episode, extend the time between trips again.
5. Keep this up until you can go 4 h between trips to the toilet or until you are comfortable. This may take several weeks.
6. Don't get discouraged. Bladder training takes time and effort, but it is an effective way to get rid of incontinence without medicines or surgery.

Similarly, changes in bowel habit can be difficult problems for an elder to bring up but extremely important to their perception of health. Constipation, which is usually defined as fewer than two to three bowel movements a week, straining at defecation, hard feces, or feelings of incomplete evacuation should first prompt a medication review (see Table 2) and then a search for conditions that cause constipation (see Table 2). Stopping all constipating medications, if possible, followed by increasing dietary fiber to around 20 g/day and increasing fluids to 1.5 L/day and physical activity are first steps to management of constipation. Adding an osmotic agent like

Telegram: @medical_k

	Stroke

polyethylene glycol, followed in order by a stimulant laxative, like senna or bisacodyl, should be the next step. Docusate is not routinely used in older adults, as there is no good evidence that it is effective in that population.

Passage of three or more watery stools in a day meets the criteria for diarrhea. As always, review the medication list for potential culprits like antibiotics, laxatives, metformin, and cholinesterase inhibitors. Also check for fecal impaction and consideration of disorders like IBS, malabsorption, IBD, and infections. Lactose intolerance is also a common cause of diarrhea in older adults. If patients appear acutely ill or dehydrated, hospitalization and further testing as guided by history and physical exam are preferred, but those that do not appear seriously ill or do not have blood in their feces may wait 48 h to see if symptoms resolve. First-line treatments in the management of diarrhea in older adults include loperamide and bismuth subsalicylate.

Patients reporting diarrhea should also be questioned about fecal incontinence. This is another condition which is often multifactorial. The most common causes, aside from those mentioned above for diarrhea, include overflow from colonic distension by excessive feces causing continuous soiling, dementia, and anorectal incontinence due to a weak external sphincter (commonly seen post-surgery or in multiparity). Red flags like hematochezia or unexplained weight loss should prompt a referral to gastroenterology.

On physical exam, focusing on palpating the abdomen for colonic distension or masses and inspecting the anus for fissures, hemorrhoids, rectal prolapse, or rectocele may help determine the cause. Basic lab work includes checking thyroid levels and a metabolic panel and may include radiographs and/or endoscopy.

Cognition

There is insufficient evidence at the current time to recommend for or against dementia screening in older adults. Many patients recognize early cognitive deficits such as recall of names or item placement. Minor problems in these domains may indicate a higher than average risk for progression to dementia, but the deficits may remain stable or may resolve. It is not until they start having memory problems that affect their day-to-day activities that we can make a diagnosis of dementia. Screening with the Mini-Cog is simple. If a patient fails, obtaining a Montreal Cognitive Assessment, St. Louis University Mental Status test, or a Mini-Mental Status Exam is the next appropriate step. This, together with a history (from the patient and often from family or caregivers), physical and neurological exam gives us a better picture of the situation at hand. It is important to assess both basic activities of daily living (ADLs), which are skills necessary to get ready for the day, and instrumental activities of daily living (IADLs), which require more complex mental processes such as executive function and judgment. (Table 3). Several tools are available for use as an aid in assessing ADLs and IADLs such as the Katz index for ADLs [9] and the Lawton scale for IADLs [10]. Difficulty in IADLs may precede a decline in cognitive screening tests in persons with a developing dementia. Such a decline should prompt more thorough cognitive testing.

Concerns about driving should be addressed, including if the patient has had any driving-related problems, recent accidents, moving violations, passenger complaints, or problems with getting

Telegram: @medical_k

www.konkur.in

Table 3 Activities of daily living and instrumental activities of daily living

Activities of daily living	Instrumental activities of daily living

lost in familiar areas. Any of these are red flags and may indicate a need for further examination and formal driving evaluation. Safety concerns should be discussed honestly with the patient and family, particularly if the patient lacks insight into the deficits. Suggesting a driving evaluation by an occupational therapist (OT) is a good next step for cases in which it is not clear if they should be completely off the road. While an initial OT consultation is generally a Medicare-covered service, on-the-road testing is not and costs at least $300–500 depending on location. Take into account the fact that recommending that a patient stop driving can lead to decreased activity and increased depressive symptoms.

Lab testing when cognitive decline is a concern includes a complete blood count, thyroid studies, homocysteine level, methylmalonic acid, electrolytes, liver and kidney function, HIV, and serologic testing for syphilis. Brain imaging is rarely useful but may be pursued in the appropriate setting. The primary goal of treatment is to improve quality of life and maximize functional performance by enhancing cognition, mood, and behavior.

Geriatric Syndromes

When a medical condition does not fit into a distinct organ-based disease category and is present in older adults, it is termed a geriatric syndrome. The causes of these syndromes are usually multifactorial. Examples include cognitive impairment, delirium, incontinence, malnutrition, falls, pressure ulcers, sleep disorders, sensory deficits, fatigue, and dizziness. These conditions have a major impact on quality of life for older adults and are a common cause of disability. There is a strong association between the presence of geriatric syndromes and dependency in activities of daily living [11].

The hallmark geriatric syndrome is frailty, which is defined as increased vulnerability to adverse outcomes after exposure to a stressful event. Frail older adults are less able to adapt to stressors such as acute illness or trauma than younger or non-frail older adults. This increased vulnerability contributes to a higher risk of adverse outcomes, including death. Older age itself does not define frailty; instead, multiple frailty screening tools have been developed and utilized for risk assessments. Frailty tools are increasingly used to identify patients at highest risk of adverse outcomes. Common frailty models include the Physical Frailty Phenotype scale [12], the Frailty index, and the FRAIL scale [13].

End of Life and Goals of Care

It is never too early to begin advance care planning and a discussion about goals of care. Choices need to be made about what outcomes are important to patients, and this is often more useful when the patient is able to provide input and the cognitive capacity to express these wishes. These discussions should include determination of surrogate decision-makers (appointing a durable power of attorney to serve as a surrogate in the event of personal incapacity) and also clarifying and articulating patients' values over time. Advance directives are useful to help guide therapy if a patient is unable to speak for himself. Tools like Do Not Resuscitate orders, Physician Orders for Life Sustaining Treatment (POLST), and Living Wills are useful for reference and possibly to fill out when having these conversations. Specifically mentioning what the patient's wishes are in regard to resuscitation procedures, mechanical ventilation, chemo and radiation therapy, dialysis, blood products, and pacemakers can help guide decision-making in difficult times.

Telegram: @medical_k

www.konkur.in

When a serious life-threatening disease appears and end of life is near, robust measures are taken to optimize the quality of life by anticipating, preventing, and treating suffering. These measures, also known as palliative cares, have been shown to improve patient the quality of life remaining and outcomes and should be recommended without reservation.

Hospice care is palliative care provided by an interprofessional team for patients who no longer seek disease-modifying treatments, but instead prefer to allow the disease to take its normal trajectory. In the United States, a patient must have a prognosis of less than 6 months to live in order to qualify for this service.

Both palliative care and hospice care manage common end-of-life symptoms like pain, delirium, anorexia and cachexia, anxiety and depression, bowel obstruction, constipation, cough, dysphagia, dyspnea, excessive secretions, nausea, vomiting, skin failure, and fatigue.

Introduction

Child maltreatment is a public health emergency that impacts the physical, emotional and cognitive development of affected children. The impact is not limited to childhood, as significant adverse events during childhood affect adult health with an increased burden of disease and risk of early death [1]. The Centers for Disease Control and Prevention (CDC) defines child maltreatment as any act or series of acts of commission or omission by a parent or other caregiver that results in harm, potential for harm or threat of harm to a child [2]. Maltreatment can be classified into abuse or neglect, and the majority are victims of neglect. However, at least 15% of reports contain two or more maltreatment types [3]. The economic burden of child maltreatment was estimated at $428 billion in 2015 [4].

In 2018, there were more than 3.5 million reported cases of child maltreatment in the United States, with 678,000 victims confirmed. Of these victims, there were an estimated 1770 fatalities [3]. The CDC estimates that one in seven children have experienced child abuse and/or neglect in the past year and this is likely underreported [5]. The highest rate of victimization occurs in the first year of life. While girls are victimized at a higher rate than boys, the fatality rate for boys is higher. Child maltreatment occurs in families of all backgrounds. However there exists a racial disparity in both victimization and fatalities, with American Indian, Alaskan Native and African American children subject to child abuse and neglect at higher rates than Caucasian and Hispanic children [3]. While the association between child physical abuse and poverty is strong [6], clinicians should be careful to avoid premature judgment of the parent or caregiver based on their appearance, ethnicity, or socioeconomic status.

Prevention

Child maltreatment is preventable by enhancing support to families, addressing social and cultural norms and intervening to lessen harms or prevent future risk to children [5]. Children younger than three, those with disabilities, chronic illness or mental health issues are at increased risk for maltreatment. Parents with a personal history of child maltreatment, substance abuse or mental illness are at increased risk for abusing or neglecting their own children. Low income, low level of education, young age of parents, non-biological caregivers in the home and family stress have all been associated with increased risk (Table 1). Other significant risk factors include under resourced communities, violence in the community, presence of intimate partner violence in the home and social isolation [7]. Inadequate parenting skills are an important component of risk and can be mitigated by education that focuses on child-parent relationships, age-appropriate rules that reinforce good behavior, and monitoring in a supportive environment.

The role of the family physician in recognizing risk and protective factors is essential in establishing the groundwork to provide effective anticipatory guidance for families to reduce the incidence and impact of child abuse and neglect. Protective factors include strong parenting skills, a child with a robust ability to self-regulate behavior and emotional reactions, problem-solving skills and a positive school environment. It is imperative that the tenets of trauma-informed

Table 1 Risk factors for child maltreatment

Parent or caregiver	Child
Sudden series of major life stressors	Impaired parent-infant bonding
Domestic violence in home	Young age, less than 3 years
Mental illness	Chronic illness, developmental delay or special needs
Substance abuse	Infant in care of non-biological caregiver
Lack of understanding of child behavior and emotional skills	Foster child
Attribution of malicious intent for age-appropriate behavior	Behavioral challenges

Telegram: @medical_k

www.konkur.in

care form the basis for patient care and approaching sensitive topics [8]. Physicians must approach each patient and family with kindness and compassion and provide adequate time for each person to narrate their concerns without pressure. Uncovering personal or family trauma offers an opportunity for deeper understanding of the struggles that might increase risk for maltreatment. The goal is to enhance relationships and improve caregiver capacity, expanding the ability for a parent or family to respond to stress in a supportive manner.

Neglect

Neglect is the failure of a parent or caregiver to provide for a child's basic needs and represents approximately 60% of reported maltreatment cases reported to child protective services [6]. In its most subtle form, this includes a lack of supervision and implementation of childproofing safeguards which increase the risk for accidental ingestions and unintentional injuries. Age-appropriate anticipatory guidance must be provided at each developmental stage, so parents and caregivers are prepared for the associated risks. Discussing the child's environment can uncover unforeseen hazards and provide an opportunity for education that nurtures parenting skills and mitigates hazard. Reviewing standardized handouts with the parent or caregiver such as the American Academy of Pediatrics' comprehensive Bright Futures handouts or The Injury Prevention Program (TIPP) Safety Sheets is an efficient way to incorporate anticipatory guidance into the outpatient well child visit. Individualizing parent or caregiver education is important, as there may be health literacy challenges that impede thorough understanding. Other forms of neglect include failure to provide for educational needs, failure to provide adequate food or shelter and medical neglect.

Medical Neglect

Medical neglect may present as a parent or caregiver not accessing medical care for a child when needed, not providing treatments that are deemed medically necessary or withholding medical treatment in the face of a life-threatening condition [9, 10]. Children without adequate medical care may present with untreated chronic conditions, lack of immunizations or injuries that have not healed properly.

Educational Neglect

Neglect of educational needs may be difficult to identify. Children who are frequently absent or do not attend school may not be recognized if the school district is under-resourced or overwhelmed, especially when facing situations such as natural disasters or a public health crisis. Children with special educational needs require extra support at home and school, and often fall behind when those resources are not provided. Some parents may find it difficult to advocate for their child and physicians may be a source of support or strength in providing suggestions for how and to whom they should voice concerns. Specific questions during a medical encounter about school performance, academic challenges, or behavioral issues may help to identify a child with educational needs so that the appropriate community resources can be provided.

Pediatric Undernutrition

In more serious forms of neglect, a child may exhibit growth failure and/or developmental delay due to insufficient caloric intake and inadequate nurturing. Pediatric undernutrition, formerly referred to as failure to thrive, is a clinical diagnosis typically defined as weight less than the fifth percentile or having declined down across two lines on the weight curve. Weight will decrease first as the body tries to preserve linear growth and head circumference, but these two measures will eventually falter when limited access to adequate calories is prolonged. While undernutrition includes both organic and non-organic causes, psychosocial factors account for about half of growth failure in infancy [11]. When undernutrition reaches a critical point, immune

Telegram: @medical_k

www.konkur.in

function may be impaired, putting the infant at risk for frequent, chronic or severe infections. The undernourished infant can become irritable or less engaging, which may disincentivize the parent or caregiver from caring for the child as attentively – further compounding the growth failure [11].

When a clinician is concerned about poor growth trends or failure to meet age-appropriate developmental milestones, a careful evaluation of growth patterns over time and a review of past medical history of the child including age of acquisition of developmental milestones, history of traumatic events or family stressors, detailed family medical and social history and knowledge of cultural norms should be considered. It is helpful to perform a comprehensive review of systems, with emphasis on gastrointestinal, genitourinary, neurological, cardiopulmonary, and endocrine systems. When reviewing the feeding history, physicians should pay attention to specific and concrete details of intake and output as detailed (Table 2). For organic causes of pediatric undernutrition, the central nervous system, musculoskeletal, cardiopulmonary, genetic, renal, and endocrine systems may be involved. Most of these disorders can be identified by characteristic physical features during the physical exam. The remainder typically reveal themselves on screening laboratory tests. If a psychiatric disease is identified during evaluation, attention to past trauma or abuse may help the patient on their road to recovery.

Early identification and effective intervention in cases of pediatric undernutrition result in better outcomes for the child and the family. Chronic undernutrition leads to cognitive impairments and developmental delay due to impaired brain growth and inadequate stimulation. This may not be fully reversible. Even once appropriate nutritional intake is resumed, the child may have residual difficulties such as behavioral problems in later childhood. Effective intervention should seek to assist the primary caregiver or parent, in a nonjudgmental and supportive manner, to understand the child's growth difficulties, nutritional needs, and obtain access to unmet medical, mental health, or social services to help achieve appropriate catch-up growth. A multidisciplinary team including a primary care physician, pediatric dietician, social worker, mental health professionals and others may be helpful to achieve such success [12].

Physical Abuse

Physical child abuse is defined as the intentional use of physical force against a child that results in physical injury. Physical abuse represents an estimated 19% of reported child abuse cases [11]. This can present in many ways, including contusions, fractures, burns, head trauma and other injuries. The evaluation of any suspicious injury requires careful assessment of the entire body for additional injuries, as well as those in various stages of healing. It is important to query the mechanism of injury and to further evaluate those situations in which the history and physical exam are inconsistent. The developmental stage of the child must also be considered when evaluating injuries, as this can provide information relevant to mechanism and likelihood of injury. Review of medical records for a history of frequent injuries may provide additional information that will aid in identification of child abuse. Table 3 outlines red flags for physical abuse of a child.

Table 2 Infant feeding history

Feeds offered	Type, volume, calories
Timing and context	Who is doing the feeding? Frequency, location in home, method, noise level, storage and preparation
Method	Breast – Time, frequency, latch, position, production, maternal fluid/diet intake Bottle – Type of formula, preparation, volume
Infant behavior	Interest, refusal, fussiness, sleepiness
Parental dietary beliefs	Concerns, fears, cultural considerations, source of information/support
Output	Voiding volume/frequency, stool volume/frequency, stool appearance

Table 3 Red flags for physical child abuse

Current condition	Behavioral cues	Past medical history	Physical exam
Lack of history or unwitnessed injury	Delay in seeking care	Repetitive accidents or injuries	Fractures
Vague or incomplete story of injury	Parent-child interactions are strained, hostile or lack empathy	Poor adherence with appointments, delayed vaccines	Bruises to the head or neck, covered by clothing
History incompatible with severity of injury	Parent report of behavioral difficulties, crying prior to injury	Parent report of irritability, feeding or behavioral challenges	Burns
Story changes over time or conflicting account of injury	Parent labels child as clumsy or bad	Evidence that care is sought at multiple facilities over time	Multiple scars suggestive of prior injuries

When physical abuse is suspected, a comprehensive physical exam should be completed as soon as possible. While most physicians will not function as a forensic investigator, a complete history and physical are very important for ongoing evaluation and documentation of child abuse [13]. The physical examination should include vital signs, growth parameters including head circumference in infants, general appearance, a complete examination of the body surface examination, palpation of each bone and a complete examination that is focused on identification of injury and sequelae of prior injuries.

In children of all ages, it is important to consider the possibility of intraabdominal injury in those with substantial or suspicious soft tissue injuries. Useful laboratory evaluations include hepatic transaminases, complete blood count, coagulation studies and urinalysis. Sometimes a toxicology screen may be useful if an overdose or poisoning is suspected.

Patterns of Injury

When evaluating bruises and burns, the clinician should look for patterns that can provide clues to how the injury was sustained and document findings objectively [14]. Bruises are the most common presentation of physical abuse, and the pattern of the contusion often provides clues about the mechanism of injury (Table 4). For example, a bruise that has the appearance of a handprint might indicate a hard slap, while linear welts may indicate the child was struck with a belt. A small round burn might indicate intentional infliction with a lit cigarette. Burns that spare the space between toes and the palms of hands might indicate an intentional scalding.

Fractures

Significant contusions require further evaluation for fracture underlying the bruise. Because children under the age of two have more elasticity of connective tissue and bones, fractures cannot be excluded without radiography thus a skeletal survey may be indicated [15]. Children older than 5 years can usually provide a sufficient history of pain so screening imaging is not mandatory, but should be considered based on clinical findings. Between 2 and 5 years of age a clinician should consider other indicators of physical abuse and perform imaging if abuse is strongly suspected. The contents of the skeletal survey include individual films of the arms and hands, legs and feet, thorax, pelvis, spine and skull. Fractures that are highly specific for child abuse are those of the posterior ribs, sternum, scapula, spinous processes and metaphyseal fractures. Multiple fractures, those in various stages of healing, digital fractures and complex skull fractures are also suspicious for physical child abuse.

Abusive Head Trauma

Abusive head trauma is a leading cause of death in children under 5 years of age, with infants comprising 18% of cases [16]. Prevention education to

Table 4 Injury patterns

Observation	Possible etiology
Round bruises in a fingertip pattern	Grabbing or gripping
3–4 small round bruises in linear pattern	Hit with a closed fist
Parallel, linear bruises with central sparing	Slapped
Circumferential bruises around body part	Ligature mark
Bruises adjacent to mouth	Gagged
Bruising or abrasions in arching pattern	Human bite
Bruising/abrasion in shape of object	Hit with object/implement
Petechiae of head/neck, subconjunctival hemorrhage	Strangulation

avoid shaken baby syndrome is essential for all parents and caregivers as it results in the death of about one in four babies affected. Shaken baby syndrome is a constellation of findings that include subdural hematomas, retinal hemorrhages, and posterior rib and metaphyseal fractures [13]. Many victims suffer from repeated episodes of abuse and the injuries can be severe with long-lasting impact such as macrocephaly due to posttraumatic hydrocephalus, chronic subdural hematoma or acute brain swelling and microcephaly secondary to posttraumatic cerebral atrophy. Other injuries include skull fractures, scalp hematoma, periorbital ecchymosis and subconjunctival hemorrhage [13]. These injuries may be difficult to detect, especially in small children, and may present as acute confusion, vomiting, lethargy, visual problems, hearing loss, idiopathic developmental delay, learning disabilities, behavioral problems, attention deficit and hyperactivity disorder, or a plateau in cognitive or physical development. Follow-up studies on victims of abusive head trauma indicate that one-third of victims have good neurological outcomes, one-third have moderate disability and the remaining third have severe disabilities [11]. Physical findings as seemingly innocuous as a ruptured tympanic membrane, but without evidence of recent infection, should raise suspicion for abuse.

Sexual Abuse

Sexual abuse of children is common, and those with disabilities, mental illness or chronic conditions are at greater risk. The CDC estimates that one in four girls and one in thirteen boys experience child sexual abuse [17], and that 91% of perpetrators are someone the child or the family knows [18]. Nine percent of reported child abuse cases involve sexual abuse [11]. When approaching a child or family when sexual abuse is suspected, it is important to recognize that any sexual activity where consent is not or cannot be given meets the definition for sexual abuse [19]. This includes any completed or attempted sexual act, sexual contact or exploitation of a child by an adult or caregiver [2]. Contact sexual abuse includes penetration, attempted penetration and sexual touching of any type. Noncontact sexual abuse includes acts of exposure, filming of a child in a sex act, sexual harassment or prostitution of a child.

The consequences of child sexual abuse may be extensive, potentially resulting in both physical and mental health consequences. While genital injuries are common, especially in young children they often heal quickly resulting in a lack of grossly identifiable injury pattern on physical examination. If extensive, these injuries can result in tears that require surgical repair, fistulas and incontinence. Sexually transmitted infections can result in infertility issues and chronic illnesses such as human immunodeficiency virus or hepatitis. Mental health sequelae include depression and posttraumatic stress disorder, as well as increased risks of substance abuse and suicidality. Children who have been sexually abused are more likely to engage in risky sexual behaviors, both in adolescence and adulthood, increasing their risk for sexually transmitted infections and unplanned pregnancies. They are also at increased risk for future violence and re-victimization.

Telegram: @medical_k

www.konkur.in

Sex Trafficking

Trafficking of children for sexual activities is increasingly reported in the United States and should be considered in a child or adolescent with an unusually high number of sexual partners or one who has knowledge of sexual acts that seem inappropriate for age and developmental stage. The Polaris Project reports a 19% increase in the identification of victims of all types of human trafficking from 2018 to 2019. Seventy-eight of those individuals for whom their age is known were determined to be minors at the time the trafficking began [20]. A disproportionate number of these victims are female, although male victims are also at risk, as are members of gender minority groups. Children are unable to legally provide consent for sex, so any commercial sex acts in which they are induced to participate are considered trafficking by United States federal law [19]. This includes prostitution, escort services, online advertisements to recruit buyers and pornographic photography or videography of a child.

Health services are a major point of contact for accessing assistance for victims of human trafficking [21]. A thorough and non-judgmental history is imperative that includes a confidential interview. As with other forms of abuse when one person is controlling another, queries should not be posed in the presence of the person who accompanies the child due to the risk of increased violence following the encounter. Common indicators for sex trafficking in the healthcare setting include an inconsistent or scripted history, a discrepancy between history and observations, severe trauma, malnutrition, or branding via tattoos or other means. Behavioral indicators include signs that the child is anxious or fearful. They may also display a depressed mood or self-harm behaviors. Substance abuse is common in victims of child sex trafficking and may be precede or follow the initiation of trafficking or sexual abuse. If a child appears much younger than stated age, it is prudent to check the Federal Bureau of Investigations missing persons database [22]. History should include queries about recruitment, threats and the extent of sexual activities the child was induced to participate or perform. If the child and clinician do not speak the same language, a trusted and reliable interpreter who is not connected to the suspected trafficking/abuse situation must be engaged. The physical examination should be targeted to address the child's specific concerns and should include evaluation for genital injury and sexually transmitted infections. Several protocols for the identification of human trafficking have been developed [23], but all begin with a trauma-informed approach to questions, assurance of confidentiality, patient comfort and assessment of safety.

Emotional Abuse

Emotional or psychological abuse is often harder to identify yet may cause more long-term consequences than physical abuse. Children who suffer emotional abuse such as rejection or withholding of love, belittling, humiliation or threats may present as an anxious or withdrawn child. School absences and a drop in school performance may be apparent in emotionally abused children [10]. While non-specific, the patterns of behavior that should alert the clinician to the possibility of emotional abuse include social withdrawal, anger or aggression, disordered eating, developmental delay or history of running away from home. Long-term exposure to emotional abuse may put a child at risk for depression and other mental health concerns.

Witness to Abuse

Children who witness violence are also prone to negative outcomes. This includes children exposed to intimate partner violence between parents or caregivers and witnessing death – especially if that person is a loved one. In some states, witnessing domestic violence in the home is considered child abuse and is reportable to child protective services. These traumatic childhood events often result in behavioral problems such as risky sexual behavior, violence toward peers, perpetration of sexual assault, and increased risk of becoming a runaway. Children who witness violence are more likely to

Telegram: @medical_k

www.konkur.in

develop mental health issues such as depression, anxiety disorders and substance abuse, and have a higher rate of suicide than their peers. Approximately 40% of children who witness intimate partner violence between their parents or caregivers are victims of physical abuse themselves [24].

Bullying

Childhood bullying is a common experience for children and adolescents, and an estimated 20% of children have been bullied at school [25]. Bullying is an unwanted, aggressive attack or intimidation that is intended to cause fear, distress or harm to the victim. Bullying can impact school performance and attendance and can increase the risk for self-harm, anxiety, depression, sleep disturbance, and feelings of isolation [26]. While there are no evidence-based screening tools specific to the identification of bullying, physicians can consider the use of the HEEADSSS tool as a screen to assess risk [27]. The American Academy of Pediatrics suggests clinicians introduce the concept of bullying to parents during the 6-year-old well child visit. Queries about school safety, academic performance, and relationships with other students and teachers will help to uncover problems with bullying at school [26].

Cyberbullying is becoming more prevalent with the widespread use of social media. The CDC estimates that 16% of children have been the victim of cyberbullying within the past year [25]. It may be difficult to identify since children may worry that their online activity will be restricted, thereby removing a source of social support [28]. Girls and sexual minorities are more likely to be victimized, and there are increasing reports of suicidality due to cyberbullying [29]. The Cyberbullying Research Center has developed a guide for healthcare providers [30].

Medical Child Abuse

While less common than other types of maltreatment, children are vulnerable to medical child abuse. Medical child abuse is defined as a child receiving unnecessary or potentially harmful medical care at the instigation of a parent or caregiver [9]. Factitious disorder imposed on another, formerly known as Munchausen syndrome by proxy, is a form of mental illness in which a caregiver seeks medical attention on behalf of a child who is not actually ill [31]. The Cleveland Clinic estimates one in twenty-five hundred child abuse cases are due to factitious disorder imposed on another [32]. It has been proposed that this number is likely an underestimate, since less severe cases of medical child abuse are unrecognized. In this rare form of abuse the parent or caregiver is willing to have the child undergo unnecessary testing, take medications, or induce illness or injury in the child to gain sympathy and attention. The onset of the child's illness is often gradual then escalates over time [31]. Diagnosis of medical child abuse is challenging as many parents or caregivers seek care from multiple clinicians. Clinicians can be misled into thinking the child actually has an illness, leading to further testing and referrals to subspecialists which perpetuates the abuse. When medical child abuse suspected, it is critical to access all historic medical records. An accurate diagnosis requires that the clinician maintain a healthy skepticism under certain circumstances. The prognosis of the child's physical, psychological, and social wellbeing can be poor if appropriate action is not taken [31].

Identification and Referral

Failure to consider child maltreatment as a possibility is a common barrier to identification [33]. Missed diagnosis of intentional injury, or failure to appreciate a pattern of repetitive injuries, is especially common when physicians are working with families who have sporadic or inconsistent access to healthcare. Family physicians may fear alienating parents or caregivers and may be wary of the stigma associated with child protective services involvement [34]. However, the process of identification and initial evaluation is well within the scope of practice of the family physician [35]. The healthcare provider who recognizes known or suspected child abuse serves as a link to

Telegram: @medical_k

www.konkur.in

the child welfare system and other community resources that can provide enhancement of recovery and promote resilience through identification of protective factors and elimination of risk factors. Validation of any disclosure, with reassurance that it isn't the clinician's response.

Referral to a child protective team for further evaluation of child abuse or neglect can be initiated by the family physician or child protective investigator, and the details included in the initial documentation of suspected or confirmed maltreatment are an important component of a formal investigation. The multi-disciplinary child protective team can provide several services including forensic interview and examination, psychological evaluation, child and family assessments and expert court testimony if needed. They frequently provide additional training for physicians who frequently encounter child maltreatment and those interested in participating in the child protection team.

Documentation and Reporting

Careful documentation of suspected or known child maltreatment is essential. This begins with a detailed description of the historical information that lays the foundation for the concern of abuse, neglect or exploitation, and includes a detailed description of disclosure when given. That information should be quoted exactly as provided by the child or parent/guardian, with the use of quotation marks where appropriate to document the specific utterances of those involved. Examination must be carefully recorded, including a detailed description of all injuries or signs of sexual abuse such as vaginal discharge or genital injuries. The physician should include photographs and/or drawings when appropriate. A brief safety assessment should be conducted to discern risk for both immediate and impending danger to the child [36]. Identification of protective factors offers an opportunity for families to enhance a child's response to stressful events or environments, augment parenting skills and well-being, and improve opportunities for connections and school-based interventions for children exposed to domestic violence [36].

Referrals to other care providers or community resources should be included in the documentation of the encounter, including a follow-up plan for ongoing care and evaluation. This record not only validates the concern, but also provides a resource for child protective services, court system and law enforcement when needed (Fig. 1). In some circumstances, a referral to a child advocacy center where a forensic evaluation can be completed is necessary. In most circumstances, it is not the role of the family physician to serve as an investigator for child abuse, but rather to link to services that are available and report as required by law. These issues are complex, and the information presented here should be augmented by knowledge of state laws and local resources.

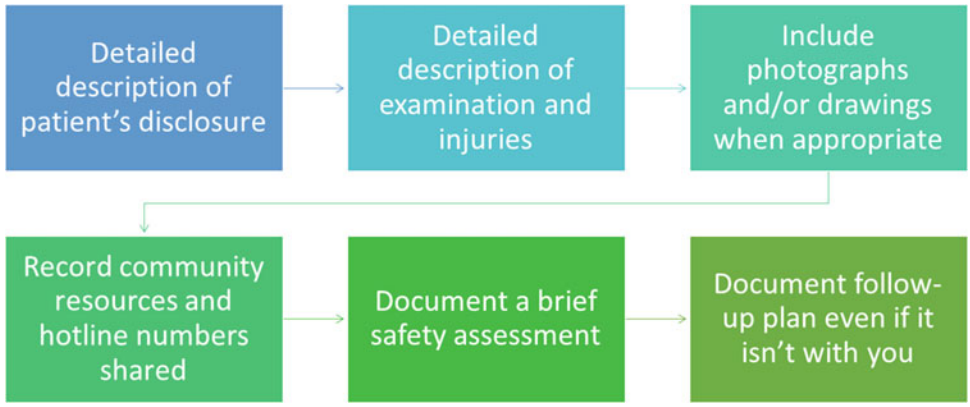

Fig. 1 Essential components of documentation for child maltreatment

Telegram: @medical_k

www.konkur.in

In the United States, The Federal Child Abuse Prevention and Treatment Act [19] requires that each State have provisions or procedures for requiring certain individuals to report known or suspected instances of child abuse and neglect. In most states and territories, physicians are mandatory reporters for child maltreatment, although in eighteen States and Puerto Rico, any person who suspects child abuse or neglect is required to report [37]. The specific laws, including the degree to which the reporting is protected as privileged communication, varies by state.

Summary

Child maltreatment is common, and physicians are mandatory reporters for suspected and known abuse, neglect, and exploitation. The American Academy of Pediatrics recommends clinician involvement in preventing child maltreatment and provides guidance on risk factors, protective factors, and clinical management [33]. The United States Preventive Services Task Force (USPSTF) concluded in 2018 that current evidence is insufficient to assess the balance of benefits and harms of primary care interventions to prevent child maltreatment, primarily due to the lack of clear benefit [38]. In 2019, the American Academy of Family Physicians supported the USPSTF recommendation regarding interventions to prevent child maltreatment, but reaffirmed in a policy statement that family physicians should be able to recognize the signs and symptoms of child abuse, be aware of community resources and reporting laws, and that they provide anticipatory guidance about child development, stressful stages, and appropriate techniques for discipline [35] (Table 5). Caring for victims of child maltreatment requires a multidisciplinary approach that should center on patient-identified needs including attention to education, psychological health of the child and family well-being.

Table 5 Interventions to prevent child maltreatment

Perform assessment of parental or caregiver well-being
Offer age-appropriate anticipatory guidance
Ensure parental access to material resources and food security
Improve stability of family unit
Provide tools to mitigate stressors within the family
Assess awareness of parental exposure to childhood trauma and abuse
Offer education for current and future developmental milestones
Assess and strengthen child's support system outside of family unit
Query exposure to violence
Provide education about substance use
Provide education about dating violence and sexual activity

Intimate partner violence (IPV) is a serious but preventable form of violence that affects millions of Americans. Intimate partner violence, as defined by the CDC, is physical, sexual, or psychological harm by a current or former partner or spouse. It can occur among heterosexual or same-sex couples and in teen and elderly couples and does not require cohabitation or sexual intimacy [1].

Background

IPV is, at its core, about control and power. It is not merely tempers flaring and out-of-control behaviors perpetrated by individuals with anger management issues; it is an attempt by one member of a relationship to establish and systematically maintain control and power over the other.

Prevalence

While previous estimates of IPV have been inconsistent due to differing IPV definitions, survey strategies, and limited numbers of respondents, the large-scale National Intimate Partner and Sexual Violence Survey sought to clearly define IPV as well as capture a broad range of IPV behaviors. This has yielded some of the most comprehensive epidemiologic data on IPV to date. They identified four major subtypes of IPV:

1. Physical violence
2. Sexual violence
3. Stalking
4. Psychological aggression

According to this study, 36.4% or approximately 43.6 million American women have experienced physical violence, sexual violence, or stalking at some point in their lifetime. Among men, lifetime prevalence is 33.6% [1]. While the vast majority of male victims experienced primarily physical violence, the types of abuse suffered by females were distributed more evenly among physical violence, sexual violence, and stalking. Additionally, women experience more severe forms of IPV than men and are thus more likely to be severely injured, sexually assaulted, or murdered [2]. Also, about a third of all American women and men have been the victim of psychological aggression or emotional abuse by an intimate partner during their lifetime [1].

Intimate partner violence occurs across age, ethnicity, gender, and economic lines and among both heterosexual and homosexual couples. Nonetheless, there are both individual and social factors that affect the prevalence of IPV. Young age and low income have been found to be consistent demographic factors linked to men abusing their partners. Additional individual risk factors for becoming an abuser include low academic achievement, delinquency in adolescence, heavy alcohol use, depression, personality disorders, and witnessing or experiencing violence as a child [3].

There are also community risk factors for IPV. While IPV may be present in all socioeconomic groups, women living in poverty are disproportionately affected [3]. Poverty likely exerts multifactorial pressures on individuals and marriages, leading to frustration, hopelessness, marital discord, and higher IPV rates. How a community responds to IPV also affects its prevalence. Communities that punish abusers and those who offer victims sanctuary and support have the lowest rates of IPV. Cultural and societal factors may furthermore give rise to higher levels of violence among intimate partners. Women are more likely to be beaten by their husbands in societies where men have economic and decision-making control in the household, where divorce is uncommon, and where women commonly do not work outside of the home, and in places where individuals commonly use violence to resolve conflict [3].

Cycle of Abuse

In an abusive relationship, the partner being abused tends to fall into something known as the cycle of abuse. This cycle includes three phases, a tension-building phase, an abusive or explosion phase, and the apology phase, commonly known as the "honeymoon" period. Once initiated, the cycle repeats over and over again convincing

Telegram: @medical_k

www.konkur.in

the victim to stay in the relationship because the abuser apologizes, makes amends, and promises never to repeat the abusive behavior again. The victim is hopeful the abuser is capable of change, but the honeymoon period ends, tension builds, and more abuse occurs. Over time this cycle recurs faster and violence escalates.

Subtypes of IPV

Physical Violence

A range of violent behaviors are included in physical IPV. Acts of violence may include slapping, shoving, hair pulling, hitting, restraining, burning, choking, or harming with knife or gun. One in three American women has experienced some form of physical violence by an intimate partner in her lifetime [1]. Physical violence often escalates over time, placing the victim at an increasing risk for injury and death the longer she remains in a violent relationship.

Sexual Violence

Sexual violence may include rape (forced penetration or being made to penetrate someone else), sexual coercion, any kind of unwanted sexual contact. Nearly one out of five American women reports a completed or attempted rape by an intimate partner in her lifetime, and half have experienced any form of sexual violence by an intimate partner [1]. Sexually abused individuals report feelings of extreme guilt and embarrassment thus making it very difficult for them to disclose the abuse.

Stalking

Victimization by stalking may take many forms but can be defined as a pattern of harassing or threatening tactics used by a perpetrator that both is unwanted and causes fear or safety concerns for the victim. A perpetrator can stalk a victim in person, showing up at the victim's home, school, or workplace when unwanted. They may follow them, watch from a distance, track them using GPS, and even sneak into the victim's home, leaving frightening or threatening items or messages behind. Stalkers also commonly use phone calls, texts, emails, or messages via social media to send the victim unwanted or disturbing messages. Approximately 16% of women and 6% of men in the United States report that they have experienced stalking in their lifetime to the point of feeling very fearful or worried that he or she or a loved one would be harmed or killed [1].

Psychological Aggression

Acts of psychological aggression are varied, but all aim to exert control, erode the victim's self-esteem, instill fear, and garner power for the abuser over his or her partner. The most commonly reported behaviors include name-calling and use of insulting language, humiliation, angry behaviors that seem dangerous, and being kept track of by demanding to know one's whereabouts. In all, about a third of women and men report psychological abuse by an intimate partner during their lifetime [1]. Abusers may isolate their partners, not allowing the victim to leave home, drive, or use the telephone, keeping them from family or friends. They may make threats of violence toward the victim, their children, pets, or other family members. Abusers can destroy precious keepsakes, steal money, and hide medicine. When particularly desperate to maintain control in the relationship, especially when victims announce they are leaving, abusers may even threaten suicide, hoping to capitalize on their partner's guilt and convince them to stay.

Consequences of IPV

According to the World Health Organization, which has studied the pandemic of IPV in many countries worldwide, violence in a relationship has profound effects that extend far beyond the health and happiness of the victim. It has been tied to a large number of diverse negative health outcomes, some immediate and some long term.

Physical effects of IPV include cuts, bruises, and sprains that may result from hitting, punching, pushing, or thrown items. Broken bones, deep lacerations, organ damage, and permanent physical disability may result from more severe

Telegram: @medical_k

www.konkur.in

beatings or use of weapons [3]. While many victims present to a hospital emergency room for care of these injuries, others are forced to delay treatment or are denied treatment altogether.

In addition to the immediate physical injuries of IPV, there are many other associated health consequences with long-term effects. An IPV perpetrator may undermine his partner's ability to control her reproductive choices in order to maintain a position of power. Forced sex, unwillingness to use contraception, and interference with access to reproductive health services have been documented in many relationships with IPV. Thus, IPV is associated with unwanted pregnancy, sexually transmitted infections, miscarriages, repeat abortions, and poor pregnancy outcomes [4]. Chronic pain syndromes like fibromyalgia, neurological disorders including migraines, and gastrointestinal disorders are also increased [5].

Victims of IPV often develop long-term mental health problems as a result of the chronic trauma they endure. Individuals who are abused by their partners are more likely to suffer from depression, anxiety, phobias, sleep problems, eating disorders, psychosomatic disorders, substance abuse, and posttraumatic stress disorder (PTSD) [3]. Abused women are also at heightened risk for suicide and suicide attempts [3].

Homicide by an intimate partner is the most serious form of IPV. In most cases, the man in a relationship exhibits possessive, jealous behavior and obsesses over his partner. Tension and conflict build over time culminating in a major event that leads the man to act. The triggering event is often the woman's announcement that she is leaving. The time immediately after a woman leaves an abusive partner is the most dangerous for her and her children [6].

From 1980 through 2008, intimate partners committed 14% of all homicides in the United States. The total estimated number of intimate partner homicide victims was 2,340. In fact, 45% of all women and 5% of men who were murdered died at the hands of an intimate partner. Minorities are at higher risk with black women being more than four times more likely than white women to be killed by a current or former partner [7].

In one study, 82% of the men who killed their intimate partners were known to the authorities, either police or medical or mental health officials. Female victims of murder had almost always used a health-care agency in the months just prior to their deaths. These frequent contacts with helping agencies by both victims and perpetrators represent real opportunities for intervention and prevention of IPV homicide [8].

Even more disturbing are cases of familicide in which the abuser murders his intimate partner, their children, and then commits suicide. Thankfully, these cases are rare but nonetheless usually garner widespread media coverage. In almost all of these cases, the killer is a white, non-Hispanic man, has access to a gun, and has previous history of abuse [9].

Special Populations and Considerations

LGBTQ Couples

Lesbian, gay, bisexual, transsexual, and queer (LGBTQ) abuse victims have unique concerns and needs that are often misunderstood or ignored. Research indicates that individuals who self-identify as lesbian, gay, or bisexual have an equal or often higher prevalence of IPV compared to self-identified heterosexuals, with bisexual women being disproportionally impacted. Bisexual women reported significantly higher rates of physical violence, sexual violence, and stalking by an intimate partner (61% lifetime prevalence) than did their heterosexual or lesbian counterparts (35% and 44%, respectively) [10]. The same study found that 26% of gay men and 37% of bisexual men experienced IPV during their lifetime.

Transgendered individuals are at even higher risk for IPV. Approximately, 2/3 of all transgendered people report violence at home with more male-to-females (67%) than female-to-males (38%) reporting abuse. Most transgendered victims were particularly unlikely to report violence to police due to fear of revictimization [11].

Telegram: @medical_k

www.konkur.in

This fear of poly-victimization commonly exists across LGBTQ populations and refers to scenarios in which individuals are first abused by their intimate partners and later suffer more abuse at the hands of insensitive or homo-/trans-phobic law enforcement agents or health-care providers. This can compound their experience of trauma, can cause reluctance to seek out any kind of help, and requires the need for additional services to provide thorough support.

Abusive partners may employ tactics unique to the LGBTQ community. They may threaten to "out" their partner which may cause a profound impact on the victim's relationships with family, friends, or employers. Abusers may further block access to hormones or interfere with a transgendered individual's surgical treatments [11].

LGBTQ victims face additional challenges if they decide to reach out for help. As previously noted, they may meet resistance, ridicule, or frank discrimination from available helping agents. Even well-intentioned service providers may be incompetent regarding LGBTQ-specific language and culture. Many domestic violence shelters and services have been set up to exclusively aid and protect the stereotypical female victim from her male partner. Thus, there are many shelters where lesbian or trans-women are not welcome and even fewer shelters that can assist male victims.

Pregnant Women

Just as perpetrators may exert control over matters of contraception and sexual health, they may also seek to control the outcome of a pregnancy. Some women are forced to have abortions, while others who might desire termination are denied access by their partners. Between 3% and 9% of women experience abuse during pregnancy. Pregnant women who are young, single, members of a minority race or ethnicity, and living in poverty are at higher risk with IPV rates skyrocketing to nearly 50% during pregnancy [12].

Patterns of IPV for women may change when they are pregnant. Approximately 1/3 report pregnancy being a relatively protected period with less abuse, while the remaining 2/3 report either no change or an escalation of abuse [13].

IPV can lead to devastating consequences for both the mother and the developing infant. Many IPV victims face ongoing challenges in obtaining adequate care. In fact, victims of IPV are 30% more likely than their nonabused counterparts to receive inadequate prenatal care [14], missing more appointments, and experiencing late entry to care.

Aside from reduced medical care during pregnancy, abused women are more likely to have poor nutrition and inadequate weight gain. Certainly, concomitant maladaptive coping behaviors such as smoking and use of alcohol and illicit substances play a role in poor maternal health. These factors may lead to low birth weight and preterm labor, both of which are well-established risk factors for infant morbidity and mortality [12]. Also, the stress of experiencing abuse during pregnancy may alter a woman's hypothalamic-pituitary-adrenal axis. Animal models show that such stress in the perinatal period leads to heightened secretion of hormones, including corticotropin-releasing hormone, which may trigger preterm labor and can restrict uteroplacental perfusion [15, 16].

The most devastating consequences of IPV in pregnancy are fetal death and maternal homicide and suicide. IPV may contribute to spontaneous abortions and fetal loss as a result of blunt physical or severe sexual trauma to the mother by an abusive partner. Among pregnant women, 54.3% of suicides and 45.3% of homicides were associated with IPV [12].

Children

While child abuse is a topic covered in a separate chapter in this text, it is important to note that minors often suffer consequences when IPV is present in the home. Certainly, there can be an overlap of IPV and child abuse co-occurring with the abuser victimizing both partner and children. However, even when no direct physical harm befalls the children in the home, there is evidence that interparental violence leads to immediate and

Telegram: @medical_k

www.konkur.in

long-lasting negative outcomes for children witnessing it. As the level of verbal and physical violence escalates for a mother, her children suffer more conduct problems, more emotional problems, and develop lower levels of social functioning [17, 18]. It is also important to note that during adolescence, many children start to form their own intimate partner relationships. Without intervention and help, these children may start to accept and apply the same violent patterns they have learned at home in these relationships [19].

Teens

Teen dating violence is a widespread issue with 8% of high school students who dated someone in the past year reporting being hit, shoved, or physically hurt by a boyfriend or girlfriend [20]. Teens often think that certain behaviors like teasing, name-calling, and even physical fighting are playful, acceptable parts of a normal relationship. Over time, these behaviors may escalate to more serious forms of physical and sexual abuse and stalking. Among adult IPV victims, 22% of women and 17% of men report their first abusive relationships occurred during their teen years [1]. Programs aimed at the education of teens to promote healthy dating relationships may be a key to reducing violence in adulthood.

HIV

IPV can increase a woman's risk for acquiring human immunodeficiency virus (HIV). Higher rates of HIV in IPV victims may be due to forced sex with an infected partner or compromised negotiation of safe sex practices [21]. Additionally, IPV victims, constantly under threat of further abuse and in a state of chronic stress, often resort to maladaptive behaviors that further increase their risk for HIV [22, 23]. They report higher rates of intravenous drug use, treatment for other sexually transmitted infections, prostitution, and anal sex, all of which are known HIV risk factors [23]. Furthermore, among HIV-positive patients, associations have been found between IPV, poor HAART adherence, and faster CD4 cell count decline due to chronic stress and depression. This leads to disease progression and increased morbidity and mortality [24].

Immigrants

Immigrant women are more likely to be socially isolated and living in poverty, both risk factors for abuse. Unfortunately, there are numerous factors among immigrants that make it especially difficult to seek or obtain help. Identified barriers include threats of deportation by the abuser, language differences, worries about discriminatory or insensitive treatment, and a lack of familiarity with legal rights and the US social system [25, 26]. It is also recognized that some cultures have very strict and highly paternalistic views on marriage and gender roles. While health-care providers need to be culturally sensitive, violence and abuse are not excused by these cultural norms and need to be addressed for the safety and protection of all victims. Providers or community advocates who speak the victim's language and have an understanding of the victim's cultural practices are most adept at successfully uncovering IPV and offering appropriate services and support.

Disabled Persons

Acts of domestic and sexual violence are committed at higher rates against disabled individuals with twice as many disabled women experiencing nonconsensual sex by an intimate partner [11]. It is also important to note that the intersection of violence and disability may be glaringly apparent with some acquiring their disability as a result of IPV and then returning to live with and depend upon the abuser for aid [11]. Abusers are more likely to commit controlling acts upon partners with disabilities, such as limiting access to services and health care, withholding help with basic ADLs, and forced isolation. People with disabilities may lack access to shelters that are equipped to manage their medical as well as social needs.

Telegram: @medical_k

www.konkur.in

Deaf individuals or those with limited speech capabilities may face challenges in basic communication, while those with limited mobility may be unable to travel to places of aid due to environmental barriers such as lack of wheelchair ramps or elevators.

Public Health and Economic Burden

IPV is a clear public health and economic issue and the Affordable Care Act identifies IPV screening as a national health priority, alongside diabetes, HPV and cervical cancer, HIV, and other sexually transmitted infections [27].

With regard to business and economics, IPV reduces work productivity and leads to absenteeism. Nearly a quarter of employed women report that IPV has affected their work performance at some point in their careers [28]. There are also unfortunate instances in which domestic violence and stalking issues migrate out of the home and to a victim's place of employment. Companies must provide resources and support to these victims and take measures to ensure a safe work environment for all employees. Human resources staff should be trained to recognize potential signs of IPV, respond with support and advocacy, and, when appropriate, engage with law enforcement.

Even though IPV is generally thought of as a social and medical issue, it is possible to attach a true dollar cost to IPV in the United States. In a 1995 study, IPV against women alone cost $5.8 billion annually. Updated to 2003 dollars, costs would total over $8.3 billion per year [29]. A more recent 2018 study estimated the cost to be growing and would total $3.6 trillion dollars in lifetime medical costs and lost productivity [30].

Prevention

Although this type of violence exists in most countries and communities worldwide, interestingly there are some societies where IPV is virtually absent [3]. These societies can give advocates and victims hope that with proper organization of social relations, education, and programming, IPV can be successfully minimized.

The CDC asserts that IPV is preventable. Therefore, emphasis is being placed on interventions that prevent violence before it occurs. Many prevention programs target our nation's youth. Several are specifically aimed at promoting healthy dating relationships among adolescents and teens. These initiatives seem promising in that they address issues of respect, gender roles, and conflict resolution while promoting self-esteem and self-advocacy. Other programs target bystanders and witnesses of IPV, encouraging a more proactive role to support victims of violence [31]. Education of first responders is also necessary.

Screening

In order for any health screening initiative to be successful, physicians must recognize the importance of screening and make it a routine part of history taking. A meta-analysis of IPV screening practices showed that across medical specialties, screening rates were problematic. Only 1.3–12% of patients reported being screened for IPV by their primary care physicians. And for obstetricians and gynecologists, among the most active in advocating for IPV victims, only 10% of patients reported having been screened [32].

Most commonly, physicians stated that they did not screen because they either had a poor understanding of IPV, in general, they feared offending patients, they did not have adequate time to perform a screening, or they felt that there were inadequate resources and interventions for victims if IPV was uncovered [32].

Starting in 2013, the United States Preventive Services Task Force (USPSTF) recommended that clinicians screen women of childbearing age for IPV and provide or refer women who screened positive to intervention services. This recommendation is given a Grade B rating [5].

Physicians reluctant to screen based on time constraints should feel reassured that the screening tool most recommended by the USPSTF is quick

Telegram: @medical_k

www.konkur.in

and efficient to administer. With just four questions, the HITS instrument has high levels of sensitivity and specificity. It may be administered by the clinician verbally or by the patient in written form, and with the HITS acronym, it is simple to recall (**H**urts, **I**nsults, **T**hreaten, **S**cream) (Fig. 1).

Even with a convenient screening tool, a challenge worth noting in performing IPV screening of any kind is that patients are not likely to divulge violence in the presence of their abuser. Unfortunately, the batterer, in an effort to maintain control over the victim and to protect him- or herself from legal repercussions of abuse, often accompanies the victim to the emergency room and to primary care visits. He or she may hover and refuse to leave the patient alone and may insist on answering questions for the patient. These factors reinforce the necessity for taking the history in private, and astute physicians may need to employ some subterfuge in order to get the patient alone. Asking for a urine sample, for instance, is a simple way to separate the couple. While the abuser may think his partner may be just going to the restroom, the physician may instead bring the patient to another exam room to gather a more thorough violence history in private.

It is important to note that most patients will not spontaneously divulge IPV in their current or former relationships, yet want physicians to ask them about the topic in a supportive and confidential manner [34]. Incorporating an IPV history into routine history taking can identify IPV and build rapport between patient and physician. A sensitive and specific inquiry into IPV communicates to the patient that such issues are important to the provider. Even if a victim initially denies abuse, choosing to remain silent at the first inquiry, a seed of trust and support is planted, and he or she may open up at a future visit.

The HITS tool is a screening tool. It is not diagnostic, and should a patient screen positive, more detailed follow-up questioning is critical to better understand the full scope of abuse and immediate risk to the patient. When asking about IPV, providers need to provide a secure sense of confidentiality, offer support and make it clear that abuse is never the victim's fault, give judgment-free counsel, and offer to follow up. Like most items in the medical history, questions should begin open-ended (e.g., "tell me more about your home life" or "describe your relationship with your significant other") and then transition to more closed-ended, specific inquiries ("does your partner hit or push you?" or "have you been forced to have sex against your will?"). Because victims often do not

HITS Tool for Intimate Partner Violence Screening: Please read each of the following activities and fill in circle that best indicates the frequency with which you partner acts in the way depicted.

How often does your partner?	Never	Rarely	Sometimes	Fairly often	Frequently
1. Physically hurt you	O	O	O	O	O
2. Insult or talk down to you	O	O	O	O	O
3. Threaten you with harm	O	O	O	O	O
4. Scream or curse at you	O	O	O	O	O
Scoring	1	2	3	4	5

Each item is scored from 1-5. Thus, scores for this inventory range from 4-20.

A score of greater than 10 is considered positive.

www.konkur.in

talk about abuse unless specifically asked, clinicians should expect that open-ended questions may not always be high yield. If that is the case, the provider should be prepared to lead the conversation with a series of direct, closed-ended questions. Simple yes or no questions are far easier for reluctant patients to answer than having to verbalize all of the details of their abuse unprompted.

Management

As previously mentioned, physicians are often unaware of and disillusioned by possible interventions for IPV victims. In most American communities, there are services in place for abused individuals and their families, though services may vary and can be more difficult to access in some communities.

Resources

For help with assisting IPV victims, the National Domestic Violence Hotline is a good place to start. IPV victims, or health-care providers on their behalf, can call the 24-h hotline (800-799-SAFE (7233)) for help and support or visit the website (http://www.thehotline.org) for a listing of agencies nearby. It is also helpful to have a printed list of local agencies that the patient can discreetly take with her. Most local agencies are able to support victims in various ways. They may offer safe shelter, emotional support and counseling for all family members, free legal advice and advocacy, and access to local law enforcement if legal recourse is desired. Physicians should be able to either refer to such an agency or help give direct assistance if no convenient local agency exists. Health-care providers should not be forceful when making referrals or suggestions; rather, they need to allow their patients to decide how and when to proceed.

Safety Plans

While referrals and follow-up are necessary for long-term care and support, health-care providers must also suggest a safety plan for the victim to put into place immediately. Safety plans typically involve making preparations to escape acute danger and flee to a place of safety. Patients should be encouraged to pack a bag containing a few days of clothing for themselves and, when applicable, their children. The bag should also contain spare keys, copies of important legal documents (passports, birth certificates, and other identification), some money, and any necessary medication. Physicians should ask IPV victims to consider where they might go should they need to flee. Retreating to the home of a known family member or close friend may make it easy for the abuser to find the victim, so a relatively secret or unexpected location tends to be a safer option. If the victim has children old enough to understand, the safety plan should be discussed with them. They may also benefit from a secret safety word that could be used in front of the abuser to signify the need to leave and retreat to safety.

Documentation

Once recognized, IPV must be documented in the patient's chart. The victim may feel uneasy about the private details of her/his life being recorded, so it is important to reassure her/him that the records are confidential and may only be accessed with permission. Proper and thorough documentation of IPV is crucial as the medical record may need to be referenced to receive certain services or be utilized in legal proceedings. Historical components should be written precisely and chronologically. Statements in the medical record should be objective and, as much as possible, done using the patient's own words. Avoid medical jargon and, in paper charts, write with clear penmanship. Describe the patient's behavior and any injuries observed in detail. It is advisable to use drawings or photographs when possible and with permission to clarify the exact location and type of injuries present. Placing a coin or ruler next to an injury helps to notate size and scale in photographs, and, when possible, the patient's face should be visible. When able, take all photographs before treatments are administered.

www.konkur.in

Reporting

Reporting of IPV is not as standardized and simple to understand as child abuse, for example, in which general mandatory reporting laws exist nationwide. Unlike a child or a disabled person who is unable to speak for and make decisions for him- or herself, mandatory reporting of IPV is problematic in many ways and thus is not a law in the majority of states. Mandatory IPV reporting undermines a victim's autonomy, interferes with confidentiality, and harms the rapport and trust built between the patient and physician.

Another reason that most states do not have mandatory reporting of IPV is that it has not been shown to improve outcomes. Calling the police or local agencies has been shown not to help but rather puts victims at increased danger due to retribution by their abuser.

IPV reporting laws vary from state to state, but generally fall into four categories:

1. States that require reporting of injuries caused by weapons
2. States that mandate reporting for injuries caused in violation of criminal laws, as a result of violence, or through nonaccidental means
3. States that specifically address reporting in domestic violence cases
4. States that have no general mandatory reporting laws

In addition to understanding your state-specific laws, certain IPV situations might require unique considerations. For instance, teen dating violence might meet criteria for mandated reporting under child abuse or statutory rape laws. IPV of a physically or mentally impaired adult or elder might also meet mandatory reporting requirements. IPV of a LGBTQ individual might be appropriately deemed a hate crime.

Even with an understanding of state laws, healthcare providers often recognize that implementation and policies can vary locally. Providers need to have knowledge of local reporting mandates and should consider contacting local IPV coalitions and law enforcement agencies to fully understand how the laws are specifically implemented in their particular municipalities [35].

Introduction

Sexual assault is an act of violence and aggression and represents a complex problem with medical, psychological, and legal aspects. Because definitions vary among states, the term sexual assault is sometimes used interchangeably with rape. The Federal Bureau of Investigation's definition of rape recognizes that victims of rape and perpetrators may be of either gender and includes oral and anal penetration as well as penetration with an

www.konkur.in

object. This definition also includes instances in which the victim is incapable of giving consent because of temporary or permanent mental or physical incapacity (including due to the influence of drugs or alcohol) or because of age. Physical resistance is not required on the part of the victim to demonstrate lack of consent [1, 2].

Occurrence

In a nationally representative survey of adults, nearly 1 in 5 (18.3%) women and 1 in 71 men (1.4%) reported experiencing rape at some time in their lives. There is a lifetime prevalence of rape of 13% for women and 6% of men. 42.2% of female rape victims were first raped before age 18 years. Among female rape victims, perpetrators were reported to be intimate partners (51.1%), family members (12.5%), acquaintances (40.8%), and strangers (13.8%). Among adult women surveyed in 2010, 26.9% of American Indian/Alaska Natives, 22% of non-Hispanic blacks, 18.8% of non-Hispanic whites, 14.6% of Hispanics, and 35.5% of multiracial women experienced an attempted or a completed rape at some time in their lives. Among male rape victims, perpetrators were reported to be acquaintances (52.4%) and strangers (15.1%) [3].

Impact

The potential short-term and long-term health effects of sexual violence are well established. Potential short-term effects include injury, sexually transmitted diseases, and pregnancy. Long-term effects include somatic complaints, psychiatric disorders, and such health risk behaviors as substance abuse, suicidal ideation, and chronic physical health problems.

Studies also report impaired physical, sexual, and psychosocial functioning, decreased quality of life, increased risk for re-victimization, and problems with access and use of health-care services [4]. Female victims of sexual assault are more likely to engage in risky health behaviors such as hazardous alcohol use and use of sexual behavior to regulate negative affect [5].

Female Victims

Women aged 16–24 years are four times more likely to be assaulted than women of any other age [6]. Among college women, sexual assault is a significant public health problem. 11–20% report that they experienced completed sexual assault perpetrated by threat or force, or the incident occurred when they were incapable of consenting. Female victims in underrepresented minority groups may experience more PTSD symptomatology and may be more likely to believe that their community blames them for the assault [7]. Because the incidence of sexual violence in some racial and ethnic minority populations is higher than many white populations, it is important to understand the role played by health and community disparities when planning emergency care interventions and for preventing adverse health outcomes [4].

Female veterans experience high rates of sexual assault during their service in the military. They are eligible to receive lifetime care at any Veterans Health administration facility for health problems related to military sexual assault [8].

Male Victims

Prevalence rates of male sexual assault are difficult to calculate, as few victims report their assault to the police or medical services [9]. It is estimated that 1 in 71 or 1.4% of men report experiencing rape at some point in their lives [3]. While sexual assault of males occurs less frequently than females, it is not limited to all male populations such as jails or prisons. While most perpetrators of male sexual assault are male, women are perpetrators too. A comparison of data between male and female victims shows that both groups are assaulted by strangers at the same rate, but males are more likely to have more than one assailant. A higher proportion of victims are identified as gay, bisexual, or having consensual sex with men.

Telegram: @medical_k

www.konkur.in

Many assaults of men involve anal rape. Men are more likely to be assaulted by acquaintances. The motivations of their assailants include sexual gratification, conflicted feelings about sexual orientation, humiliation of the victim, and exercising power and control [10].

Intimate Partner Violence

An intimate partner is a current or former spouse, an opposite or same sex cohabitating partner, or a boyfriend, girlfriend, or date. Intimate partner violence entails physical, sexual, or psychological harm by a current or intimate partner, and it affects millions of people per year. Intimate partner violence is commonly associated with sexual assault. Sexual assault that occurs within an intimate partner relationship has been shown to result in an increase in PTSD symptomatology [11]. It is commonly believed that sexual assault is more traumatic when committed by an unknown assailant; however, sexual assault in marriage or dating relationships has been found to be equally detrimental to women's physical and mental health [12, 13].

The Family Physicians' Role

In 2011, the American College of Obstetricians and Gynecologists recommended that health-care providers routinely screen all women for a history of sexual assault, paying particular attention to those who report pelvic pain, dysmenorrhea, or sexual dysfunction. Prevention of long-term physical and mental consequences can be prevented by early identification of victims [1].

The physician conducting an evidentiary evaluation of a sexual assault victim must comply with state and local statutory or policy requirements involving the use of evidence gathering kits. If a sexual assault victim communicates with the physician's office, she/he should be encouraged to immediately go to a medical facility, not to bathe, change her clothing douche, urinate, defecate, wash out her mouth, clean her fingernails, smoke, eat, or drink [1, 14].

The time limits for evidence collection depend on the jurisdiction and range from 72 to 120 h. The evaluation and treatment of sexual assault victims are time-intensive and should optimally be provided by a team that includes an emergency physician or other medical provider overseeing care and treating injuries, a trained sexual assault examiner, and a social worker or rape crisis counselor who has expertise in acute reactions to rape and can assist in offering support, describing options, and explaining the hospital process. Physicians should understand that it is not their responsibility to determine whether a sexual assault has occurred since such a determination will be made through the legal system [15].

Care of the Victim

When a history of sexual assault is obtained, the clinician may expect that recounting of the incident and various health-care procedures such as pelvic or rectal exams may trigger anxiety reactions [1]. A carefully recorded history should be obtained from the victim. The history should include general medical history, sexual history, and OB/GYN conditions, including current pregnancy or risk of pregnancy. The health-care provider should document the victim's emotional condition.

General body trauma is more frequent than genital trauma in up to two thirds of rape victims who present to the ED [15, 16]. Injuries may include blunt or penetrating injuries to the head, face, torso, or extremities as well as defensive injuries such as lacerations, abrasions, or bruises.

The collection of evidence is a multistep process that can take several hours and is optimally performed by specially trained personnel. The purpose is to collect and record evidence including DNA to support the victim's report of the assault. Evidence collection requires the patient's consent at each step, and the examiner should explain each step of the process to the victim. A detailed examination of the entire body should be performed with injuries being photographed or drawn accompanied by a written description and location of each. Sheets in which the victim is

Telegram: @medical_k

www.konkur.in

transported should be preserved and folded. Before a Foley catheter is placed, evidence that may contain DNA can be collected from the vagina or penis. Standardized evidence collection kits contain forms for documentation to assist examiners.

Because a meticulous pelvic examination is required, anesthesia may be required to enable patient cooperation. With witnesses present (and named in the record), inspect the perineum and vulva for abrasions, ecchymoses, and lacerations. Over 90% of victims will have trauma at one or more of four locations: posterior fourchette, labia minora, hymen, and fossa navicularis. Tears occur most frequently on the posterior fourchette and fossa. Abrasions are usually seen on the labia and ecchymoses are most often seen on the hymen.

An alternate light source (ultraviolet illumination) should be used to check the patient and her clothing for semen. Positive areas should be blotted with saline-moistened filter paper, labeled, and packaged separately. Pubic hair should be combed, and both the comb and material obtained should be packaged together. Pubic hair cuttings should be obtained, as well as scrapings from under the fingernails.

Each specimen should be packaged separately and labeled with source, patient's name, and date. All assembled items should be sealed individually and then sealed together in a large container to verify that they were unaltered during transfer to the law enforcement agency. The person who accepts the evidence should sign for the material, and this transfer should become part of the chart. In brief, the record should reflect the chain of evidence.

The vaginal speculum should be moistened with saline only, and careful inspection of the vagina should be performed. Saline-moistened cotton swabs may be used to obtain fluid from the vaginal pool and the endocervix and placed in labeled, corked sterile glass tubes for culture for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. The same fluid should be applied to glass slides and air-dried but not fixed. Next, deposit 2 mL of saline in the vaginal vault, and with aspiration, search for motile sperm (often motile even 4–6 h after ejaculation). If the mouth or anus was penetrated, similar specimens should be obtained. Blood should be drawn for VDRL and blood type. HIV as well as hepatitis (B and C) testing at this time and later should be offered. Proper labeling of all samples is essential [17].

A pregnancy test is advisable if the patient may have become pregnant during the assault. The risk of pregnancy after rape is approximately 5%. Emergency contraception (EC) should be provided. Progestin only EC (1.5 mg of levonorgestrel) administered as a one-time dose within 120 h after unprotected intercourse has been shown to be 98.5% effective in preventing pregnancy. The best efficacy is within 72 h of the sexual assault [15].

There are long-term health consequences that are associated with sexual assault such as increases in somatic symptoms, diminished levels of function, alterations in perceptions of health, and decreased quality of life. Some women may present with complaints of chronic pelvic pain, dysmenorrhea, or sexual dysfunction without disclosing a history of sexual assault [1].

STI Prevention

All patients should be offered prophylaxis for STIs [18] (Table 1). The most common sexually transmitted infections reported in sexual assault victims include trichomoniasis, gonorrhea, and *Chlamydia trachomatis* [19]. The HIV status of assailants is usually unknown and tends to be of great concern to the victim. And although it is infrequent, cases of HIV transmission following sexual assault have been described [20, 21]. Genital or rectal trauma, multiple traumatic sites involving lacerations, or deep abrasions and the presence of preexisting genital infection or ulcers in the victim increase the risk of HIV transmission [22]. Health-care providers should carefully consider several factors when deciding to recommend the initiation of postexposure prophylaxis (PEP) after sexual assault, such as whether or not a significant exposure has occurred during the assault, knowledge of the HIV status of the alleged assailant, and whether the victim is willing to complete the PEP regimen. Clinicians should

Telegram: @medical_k

www.konkur.in

Table 1 STI prophylaxis after sexual assault

Cefixime 400 mg orally in a single dose
or
Ceftriaxone 250 mg IM in a single dose
plus
Azithromycin 1 g orally in a single dose
or
Doxycycline 100 mg orally twice a day for 7 days
Plus
Metronidazole 2 g orally in a single dose
Postexposure hepatitis B vaccine (without HBIG) – at the time of the initial exam, at 1–2 months and at 4–6 months after the first dose
If the survivor appears to be at risk for HIV transmission (start within 72 h of assault) – lab work prior to start: pregnancy test, HIV test, CBC, and CMP
Tenofovir 300 mg orally daily + emtricitabine 200 mg PO daily
Plus
Raltegravir 400 mg orally twice daily
or
Dolutegravir 50 mg PO daily for 28 days

recommend HIV PEP when significant exposure may have occurred. PEP should also be offered in cases of bites that result in visible bleeding. PEP should be started as soon as possible, ideally within 2 h of the assault. Some guidelines restrict initiation of PEP to 36 h after the exposure as it is noted that there is diminished efficacy of the regimen by delaying its initiation. The patient's HIV status should be tested within 72 h of the initial assault and then repeated at 3 months and 6 months. The health-care provider should provide HIV risk reduction and primary prevention counseling whether or not PEP was initiated [23]. HBIG should be administered if the assailant is known to be hepatitis B positive; otherwise, active immunization alone for hepatitis B may be considered.

Emotional Reactions and Psychological Sequelae

After the assault, a rape trauma syndrome often occurs. The initial or disorganization phase may last days to weeks. The victim may experience physical reactions such as generalized pain, eating and sleeping disturbances, and emotional reactions such as anger, fear, anxiety, guilt humiliation, embarrassment, self-blame, and mood swings. The second or delayed phase is characterized by flashbacks, nightmares, and phobias as well as somatic and gynecologic symptoms. This phase often occurs in the weeks and months after the event [1, 24].

Longitudinal data indicate that sexual assault survivors are at increased lifetime risk for posttraumatic stress disorder (PTSD) 30%, major depression (30%), and contemplation of suicide (33%) or an actual attempt (13%). Risk factors for PTSD after rape include previous depression, alcohol abuse, and increase severity of injury during the assault [15, 25]. Health-care providers should enlist the input of social workers or rape crisis counselors to help evaluate the patient's immediate and future emotional needs and formulate a plan for safety after the patient is discharged home.

Follow-Up

Sexual assault victims should be referred for both medical follow-up (testing for pregnancy, HIV, and hepatitis) and psychological or psychiatric support. Rape crisis centers can provide ongoing support, free confidential counseling, and legal services. Some states require mandatory reporting of rape (with identifying information either included or removed) or weapon-related injuries in a competent adult. All jurisdictions require reporting the assault of a child or an elderly or disabled person.

Prevention

Prevention of sexual assault is a societal issue. Programs that are effective address public attitudes about relationships and sexuality and teach conflict resolution skills. Teaching women life skills may decrease their vulnerability to sexual assault or re-victimization. Support and safety programs, transportation policies and procedures, campus and community safety programs, and

Telegram: @medical_k

www.konkur.in

crime prevention programs have all been shown to decrease the incidence of sexual assault.

Recognizing that a sexual assault has occurred and providing the victim effective care represents primary prevention of re-victimization and secondary prevention for the victim. Prosecution rates are improved when care is provided by victims' advocates, as well as by physicians, and other health-care professionals particularly nurses who have been trained in programs such as Sexual Assault Nurse Examiners can provide accurate collection and documentation of forensic evidence [26, 27].

Conclusion

Sexual assault is an act of aggression by the powerful on the less powerful. Although both women and men can be sexually assaulted, women are at greatest risk. Family physicians must be prepared to recognize and treat victims of sexual assault. Treatment of the woman who has been sexually assaulted should address legal, medical, and psychosocial aspects of care and should be coordinated with law enforcement, victims' advocates, psychological support, and other trained medical personnel [25, 27, 28].

General Principles

Definition/Background

Because mental illness is so common and may cause as much or more disability than many chronic medical illnesses, psychological assessment is integral to the evaluation of each patient in the Family Medicine paradigm.

Most perturbations in the psychological state of patients presenting to the attention of the family

physician are, like most physical illnesses, transient or minimal and not likely to significantly impact health. Sometimes these issues can be more pervasive; many of these are related to the patients' social and existential milieu. Finally, there are patients who display symptom clusters of a quality, severity, and chronicity most consistent with classically described psychiatric conditions. Differentiating between these groups of patients may be difficult. Symptoms may fluctuate significantly over time, so at times they meet criteria for a diagnosis of a psychiatric disorder, and at other times, they do not. Longitudinal follow-up may be helpful to assess the importance of symptoms in a given patients' life.

While contemporary psychiatric classifications of illness represent the pinnacle of our current understanding of the neurobiological basis of many psychiatric conditions, they often do not comport with the patients' own lived experience, do not fit easily into the realities of the primary care setting, and may not be very successful in bringing about satisfactory patient-centered outcomes [1–3]. Assumptions that the psychiatric populations seen in primary care and tertiary care are identical may result in a "category fallacy" when using standard criterion-based diagnosis systems used in subspecialty care [4]. While it is important for the physician to try to focus on the assessment of behaviors that are observable, measureable, and therefore reproducible, this unavoidably reductionist approach excludes or discounts many factors that might be important to the patient and may risk medicalizing normal human experience.

It has been suggested that an alternate, pragmatic system of classification of patients with mental health problems be developed to better categorize the range of disorders seen in primary care [5].

Regarding the treatment of mental health issues, it is increasingly recognized that measures and outcomes that are important to clinicians and health systems may not always be the yardsticks that are meaningful to patients. In-depth studies of patient outcomes have identified that some aspects of the organization of mental health practice may actually interfere with a patients' ability to fully recover from mental illness. Individuals with chronic mental health issues often end up living in "virtual institutions" where all aspects of their identity are directly linked to the mental illness through their social network and housing, for example. Ultimately, mental illness, and its associated dysfunction, becomes inextricably linked to their sense of self, which can be a barrier to improvement [6].

With this fact in mind, many health systems worldwide are rethinking and overhauling their approaches to the management of psychiatric illness. The "recovery" movement recognizes that many individuals with chronic mental illness will never achieve "normality." Instead, aiming for reintegration of these patients into society in order that they might attain a meaningful and fulfilling life becomes an important focus.

When encountering a possible mental health problem, the family physician often faces a series of very challenging tasks. The multidimensionality of undifferentiated patient presentations often makes the assessment of these patients highly complex. In addition, the ability of the physician to articulate the problem in a way that makes sense to the patient and then to negotiate a narrative that provides an opportunity to use the resources available to develop solutions to the patients' problems is one of the keys to providing the highest quality mental health care in the primary care setting. An overreliance on reductionistic models, based on rigid criteria, may not be helpful in many cases and may be associated with high rates of nonadherence, ineffective treatment, and premature termination of care [7].

Epidemiology

Mental health problems are very common. National surveys estimate that in 2012, 4% of adults in the United States suffered from a mental illness that significantly affected day-to-day living, and in that same year, 18.6% of all adults suffered from some kind of mental disorder classifiable according to the DSM [8]. Data from both the United States and international sources reveal that the majority of patients with a mental health problem never come to medical attention, instead seeking care through informal channels that may

Telegram: @medical_k

www.konkur.in

include friends, family, and alternative practitioners. Of those who do seek medical attention, only a fraction are seen by professionals specializing in mental health care [9, 10]. This means that most people with mental health issues who go to a doctor present to the primary care physician and will never interact with a mental health professional. Additionally, many patients who do ultimately receive mental health treatment from a subspecialist subsequently drop out of care [11]. Overall, it is estimated that at least 90% of medical mental health-care worldwide is delivered by primary care physicians [5].

High levels of morbidity and mortality are observed among patients with serious mental health issues, and these are a particular cause of concern for the family physician. Several studies have documented significant reductions in life expectancy among patients with chronic mental illness. This excess mortality is thought to be due to the behavioral clustering associated with these conditions that include smoking, substance abuse, poor diet, and lack of exercise [12–14]. Other data suggest that disruptions in neurohormonal systems caused by mental illness may also contribute to morbidity [15]. In addition, long-term effects of certain psychiatric medications may increase risks of obesity, metabolic syndrome, and its attendant conditions [16]. The monitoring, prevention, and treatment of these conditions are often overlooked in caring for these patients. A review of interventions to reduce health-risk behaviors and medical conditions among patients with schizophrenia and bipolar disorders found that there was good evidence to support behavioral interventions for weight loss, and the use of varenicline and bupropion for smoking cessation [17]. However, only a few studies have been carried out in patients with psychiatric illness, particularly in primary care settings, and more work is needed to explore the effectiveness of interventions for prevention in these populations [18].

Approach to the Patient

Patients presenting to primary care with mental health problems typically differ in important ways from the ones seeking help from subspecialty psychiatric care. In the subspecialty psychiatric setting, virtually all patients have accepted a psychiatric dimension to their illness and so volunteer emotional symptoms as a matter of course. In contrast, in the primary care setting, patients are much less likely to relate affective or behavioral symptoms, instead focusing on a combination of somatic complaints and social factors. Very often, they do not perceive the emotional and psychiatric aspects of their condition. The willingness of individuals to consider a psychiatric dimension of their illness varies widely and may be influenced by among other things, the feelings of disempowerment and stigma associated with mental illness [19]. In addition, cultural, social, or personality characteristics particular to individuals or groups of patients may discourage recognition or acceptance of a psychiatric diagnosis. Also, the illness itself may interfere with insight. This may result in unconscious or conscious attempts to rationalize, discount, conceal, or disguise symptoms that they may perceive to be "psychiatric" in nature. Failure of the physician to ferret out the condition then provides the patient with "evidence" that the problem is a (more acceptable) physical one. It is not unusual to encounter patients who are so resistant to the idea of a psychiatric component to their illness that they demand further extensive testing to detect unlikely physical illnesses, refuse, or (more commonly) fail to adhere to treatment, or simply find a different, and hopefully more malleable practitioner.

This dynamic highlights the central role that establishing trust and the development of a common understanding between physician and patient has in improving rates of treatment of mental health problems [20]. Trust is usually developed through ongoing and bidirectional communication that gives coherence to the patients' own experience, allows them to develop an acceptable context in which to place their illness and ideally to develop a narrative of coping or healing.

Among those who are reluctant to consider a mental health explanation for their symptoms, rolling with the patients' resistance, "planting a seed," and allowing them to consider the issue at leisure will often result in their being much more amenable to consideration of an emotional or psychiatric dimension of their condition in future visits.

Telegram: @medical_k

www.konkur.in

One approach that has been quite successful for this author, when faced by resistance in the face of a likely psychiatric diagnosis is to tell the patient, for example, "I'm not certain what is causing this condition" and provide a differential diagnosis that includes both possible physical causes and psychiatric condition(s). "What I would like you to do is over the next week or two is to have you monitor and record your symptoms and also record what is going on during the day, including any issues that result in stress to see whether they affect your symptoms."

Diagnosis

Screening for mental health problems is frequently carried out in the primary care setting in high-income Western countries. Using standardized instruments for the diagnosis of depression, for example, improves the detection rate of this condition; in the absence of screening, only about 50% of cases are detected [21]. Screening may also allow patients another avenue by which psychological discomfort can be articulated and brought to the attention of the physician. However, controversy exists regarding the costs and benefits of screening for many mental health conditions in primary care and may depend on whether resources are available to ensure that the problem can be treated effectively if it is discovered [22]. However, little evidence is available to assess the efficacy or acceptability of this kind of screening in many cultures.

The detection of mental health issues in the primary care setting depends largely on characteristics of both the patient and the physician. Although the well-documented lack of detection and treatment of mental health issues in primary care is widely assumed to result solely from a knowledge deficit on the part of physicians, the widespread ineffectiveness of educational interventions suggests that there are a number of more important issues that result in the outcomes observed [5]. In most general medical settings, there are a number of barriers that may interfere in making a diagnosis of a mental health condition. These include the poor fit of psychiatric classification systems in primary care as mentioned above, variations in the training or other characteristics of the physician, the undifferentiated nature of many mental health presentations, patient characteristics, and systems barriers.

Since most current workflows in primary care are not designed to deliver mental health care in a way that differs paradigmatically from the care of most physical disorders, the system in which the physician works is often the major barrier to addressing and treating these problems. Time pressure is one of the most commonly cited of these. It is well recognized that the number of complaints presented by a patient in the primary care setting is directly proportional to the nonrecognition of mental health problems. One solution which is becoming more popular is the development of "colocated mental health services" in which detection of a mental health problem results in the patient being comanaged with a mental health professional who has the time and specialized training to focus solely on the mental health issue that is suspected or identified.

The availability of appropriate triage options or medications is another barrier. Many physicians may correctly surmise that there is little to be gained by making the diagnosis of a stigmatizing psychiatric condition if it is unlikely that the patient is going to receive successful treatment for it, or if the perceived social costs to the patient of making a diagnosis will outweigh the benefit of treatment [23]. In some countries, psychiatric medications may not be available in the primary care setting, and cost may be another limiting factor in many settings. Lack of availability of counseling services also may be a problem. Other barriers to the treatment of mental health problems in primary care have been recognized, including one study that found an association between lower rates of recognition of a mental health problem and the use of electronic health records [24].

These systemic barriers may lead some physicians to avoid "the can of worms" posed by a potential mental health issue. This may lead them to implicitly collude with the patient by accepting the validity of the patients' somatized

Telegram: @medical_k

www.konkur.in

"ticket of admission" to the doctor, and, instead of addressing it, to ignore it or to defer addressing the problem.

History

A unique characteristic of primary care is the longitudinal relationship shared by the physician, patient, the family, and ideally the community. This has a number of advantages that include the ability to observe symptoms at intervals, the time to develop trust and a shared understanding and narrative about the condition, and the ability to contextualize both the diagnosis and treatment. A longitudinal relationship also may have the disadvantage of "foreknowledge" that may result in the clinician discounting apparently new discordant information or observations that arise during the course of a familiar relationship.

Review of the patients' past medical record, when it is available, is often very helpful. It is quite common for patients with undiagnosed behavioral problems to make frequent visits to various practitioners and care settings with vague or recurrent mild or undiagnosed illnesses. However, it should be noted that at least one study has found that the majority of patients with undiagnosed physical symptoms presenting to primary care do not have a mental disorder [25]. A thorough evaluation of the record may reveal a previous clinicians' recorded suspicion of a mental health problem, though follow-up may not have occurred. Alternatively, prescribing patterns of previous physicians – such as the frequent prescription of benzodiazepines – may suggest that they had considered the possibility of a mental health condition that they may not have directly addressed or recorded.

Patients presenting to the physician with a previously diagnosed mental health condition are also commonly seen. Not infrequently, patient records are unavailable or may be inadequate. While many patients may have a good understanding of their illness and can recount their history and treatments, others may suffer from enough impairment or deficient communication skills that it is difficult to get a good idea of the patients' past history and what previous treatments have been attempted. Others may minimize or conceal their history to avoid memories of a painful chapter in their lives or to avoid a possible negative judgment by the physician. At times, it is only after a trusting relationship has developed that the history of a mental health problem emerges.

A careful history around current and past use of substances is warranted. Substance abuse is often comorbid with other mental health issues and may be even more difficult to uncover than the associated psychiatric condition. Comorbidity of mental health and substance use disorders complicates the course and worsens the prognosis of both disorders [26]. Patients with a past history of substance abuse are prone to relapse in the face of exacerbations in their mental health condition.

Mental health conditions are often brought to the attention of the physician by family members or other concerned individuals in the patients' social environment. The role of collateral informants is often invaluable in determining prior functioning, premorbid personality traits, and family history. These may provide critical clues to the diagnosis and an assessment of the problems' severity. Further, friends or family members may help to negotiate appropriate treatments with the patient. Finally, understanding the support and social capital that the patient enjoys may be important in assessing prognosis.

Physical Examination

Findings on the general physical examination are very important. Psychiatric symptoms can be due to many conditions – ranging from the side effects of over-the-counter supplements to genetic, metabolic, neurologic, immunologic, and malignant disorders. Even after the diagnosis of a primary psychiatric disorder is made, the physician must keep an open mind about the presence of an underlying physical illness. A slowly progressive occult illness may initially manifest with a mental health problem and remain hidden for some time despite negative initial evaluations for organic disease. The old adage that even people who

Telegram: @medical_k

www.konkur.in

somaticize develop a "serious" physical illness eventually must also be kept in mind.

Dress, mannerisms, affect, and hygiene may all provide clues to the patients' illness, background, or the image that they want to project to the examiner. Subtle abnormalities in cognition or mental status might point to the diagnosis of a neurological condition such as frontotemporal dementia or psychosis. Many chronic illnesses, such as Parkinson's chronic lung disease and patients with cardiovascular or cerebrovascular disease, are associated with very high rates of mental health diagnoses, particularly depression. The clinician should maintain a high index of suspicion for comorbidity in these patients. The association of neuroleptic medications with development of the metabolic syndrome may lead to obesity, hypertension, and acanthosis nigricans. Other stigmata such as tardive dyskinesia, jaundice, gingival hypertrophy, petechiae, or pallor due to the adverse effects of medications may be apparent on physical examination.

Laboratory and Imaging

It is always correct to acknowledge that any investigations should be guided by the results of the history and physical exam. When making a diagnosis of a psychiatric condition in a patient with an unrevealing history and physical examination, this author will often obtain baseline laboratory testing to include a complete blood count, comprehensive metabolic panel, and thyroid-stimulating hormone, in order to screen for occult conditions which may be difficult to detect with less invasive measures.

Many patients with serious mental illness may have a long history of chronic medical conditions, abuse, and social adversity; the physician should be alert for associated illnesses, such as sexually transmitted or blood borne infections, and chronic infections such as tuberculosis. Additionally, routine health maintenance measures, such as lipid measurements and mammograms, while sometimes requiring additional diligence to ensure that these are adhered to by the patient, should not be neglected. In addition, patients taking certain medications chronically for psychiatric problems may require periodic laboratory testing to detect toxicity, and the family physician should be familiar with routine testing recommendations for these medications.

Differential Diagnosis

As mentioned above, the differential diagnosis of psychiatric conditions is vast; psychiatric symptoms may be a manifestation of virtually every category of illness including malignancies, rheumatological conditions, toxic ingestions, infections, injuries, and endocrinopathies.

Particularly common issues in primary care that should be specifically considered include occult substance abuse, sleep apnea, and social difficulties such as abuse or family stress. The family physician must maintain a reasonable level of suspicion for an underlying physical or social condition while maintaining equanimity in the face of some level of uncertainty.

Treatment

In the past few years, the development of various evidence-based clinical guidelines for the treatment of mental health issues have both provided guidance to primary care physicians and have also tended to constrain their roles to the making of diagnoses, providing prescriptions for medication and referral to specialty services. Often, little acknowledgment is given to evidence indicating that individual patient characteristics may be more important than protocol-driven factors in the delivery of this care [27].

Increasingly, treatment strategies focusing on long-term recovery from mental illness, with less emphasis on pathology, deficits, and medication in the treatment of these conditions are gaining ground. It is recognized that the recovery from mental illness is a highly personal and subjective experience and that clinician-centered outcomes, such as an enumeration of symptoms, might be less important in defining outcomes. The longitudinal relationship that physician and patient enjoy

Telegram: @medical_k

www.konkur.in

can be used to develop a meaningful narrative of the illness, out of which many possible and sometimes unexpected solutions can arise. In this paradigm of treatment, professional knowledge and resources that can include medications, social support, meaningful work, and relationships can be used as tools to facilitate the process of recovery and achieve the ultimate goal of the attainment of a life that has value and meaning to the patient.

Medications\Immunizations and Chemoprophylaxis

Many patients with mental illness will require ongoing treatment with psychotropic medications in order to maximize their social and occupational functioning. These medications, while central to treatment, can result in side effects, which may range from trivial to life-threatening. Side effects are a major cause of discontinuation of medications, and nonadherence is common [28]. Particularly among patients who are on multiple medications at high doses, the family physician must maintain vigilance for drug interactions and other adverse reactions to medications. The cost and availability of various medications may be another significant barrier to medication adherence. Community health workers or agencies may help to ensure that barriers are minimized so that interventions are not compromised.

Attention to immunization status is important, particularly among patients who are institutionalized, chronically malnourished (such as those who misuse substances) or are frankly immune compromised.

Referrals

The standard model for the treatment of difficult mental health problems in the primary care setting has been to refer the patient to a psychologist, counselor, or psychiatrist, in much the same way that any other specialty referral is made. There are several disadvantages to this approach. Chief among them is the fact that in the primary care, patients often do not follow-up with these appointments [29]. Another disadvantage is frequent suboptimal coordination and communication between providers. Discontinuities in treatments, opinions, or approaches can easily become a new source of anxiety and difficulty for the patient who may suffer from several mental and physical problems that require ongoing services for both sets of conditions. In an attempt to remediate some of these issues, the "collaborative care" model of mental health care has been piloted in a number of settings. In this model, behavioral practitioners, who may be nurse specialists, counselors, social workers, psychologists, or psychiatrists, work in a team with the physician. When a determination is made that additional and focused mental health attention is required, the physician may make a direct "warm" handoff of the patient to another mental health provider, thereby "breaking the ice" and giving the patient assurance that the carers are communicating and that the physician has confidence in the team. Close communication among members of the group, sometimes in the presence of the patient, ensures that the approach to care is as cohesive and seamless as possible. While this approach has been demonstrated to be effective for patients with depression, anxiety, and perhaps bipolar disorders in the outpatient setting, there is no evidence that it is effective in patients with schizophrenia [30, 31]. In addition, issues around the optimal implementation of these models and their cost-effectiveness are still unclear [32].

Community Mental Health Agencies

With the movement away from hospitalization and institutionalization occurring worldwide, there is an increasing need for patients to be cared for in the community. The services these agencies, organizations, or teams provide can differ but can include domiciliary and supervised care, halfway houses, day care facilities, support groups for patients and caregivers, and sheltered work. The advantages of community agencies include focused attention to the social and economic reintegration of individuals with psychiatric disorders into the community. A recent review

Telegram: @medical_k

www.konkur.in

suggested that there are improvements in social functioning, quality of life, and psychiatric symptoms among patients with severe mental illness who were deinstitutionalized, although these changes were modest [33].

Counseling

The delivery of counseling for mental health issues by family physicians is a time-tested strategy in primary care, providing good short-term outcomes, although long-term efficacy is less clear [34]. Advantages of the delivery of counseling by the physician in the office setting include the ability to deliver interventions in a timely and strategic manner and without necessarily having to make a potentially stigmatizing diagnosis. In recent years, a number of approaches and brief interventions have been developed that can be successfully implemented by the family physician in a time-limited encounter. These include motivational counseling, journaling, and solution-focused therapy.

Although the presence of dedicated mental health providers in the clinical setting may be very helpful in the provision of counseling to patients with mental health issues, mental health counseling that is explicitly labeled as such may be associated with stigma among patients [35]; one study showed a discrepancy among the numbers of patients who reported their willingness to receive counseling from a dedicated mental health provider versus those who actually sought and received counseling at a 1-year follow-up [36]. Another reported a significant discrepancy between provider and patient as to whether mental health counseling had been delivered [37]. Counseling for mental health issues was also significantly less likely to be delivered to African American patients in the primary care setting, although other types of counseling were delivered at equal rates in different ethnic groups [38]. Although these findings taken together may be indicative of various barriers to the delivery of mental health counseling in primary care, it could also be a manifestation of the effects of implicit negotiations between patient and physician regarding patient acceptance of various interventions.

Patient Education and Activation

Psychoeducation is a critical part of management of psychiatric disorders and, in many cases, is the only intervention required for many of the mental health conditions encountered in primary care. Education, normalization, and reassurance by the physician allow for patient and family self-regulation.

Prevention

Mental illness, like many physical illnesses, has multiple contributing causes which are poorly understood. It is clear that both heredity and environmental factors, most notably adverse childhood experiences influence the development of both physical and mental illness in adulthood [39, 40]. Various interventions to reduce exposure to adverse experiences in childhood, such as parent training programs, have been demonstrated to result in improved mental health outcomes in children. The impact of social determinants of health on the development of mental illness is increasingly recognized [41]. These factors include poverty, suboptimal housing, and poor education.

Family and Community Issues

The importance of the role of family and community in the perceptions and treatment of patients with mental health problems cannot be understated. Culture fundamentally influences the ways in which mental health problems are perceived, as well as framing the relative risks and benefits of diagnosis and treatment.

The involvement of family and other sources of informal support are often very important to recovery and should be specifically explored by the physician with the patient. These sources of

Telegram: @medical_k

www.konkur.in

support should be engaged as early as possible in the treatment process.

Summary 432

References 433

Anxiety disorders are characterized by an excessive fear response; these disorders are extremely prevalent among the general population and have a 2:1 female predilection [1]. Functional impairment is common with these disorders and, along with depression, are among the leading causes of disability and work related absences. As such, it is postulated that the economic burden of anxiety disorders is greater than any other psychiatric disorder, due to the high prevalence and cost of medical and psychiatric treatment [2]. The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), defines fear as "the emotional response to real or perceived imminent threat" and anxiety as "anticipation of future threat." Fear typically induces surges of autonomic arousal and thoughts of immediate danger and escape, whereas anxiety typically manifests as muscular tension and avoidant behaviors. If the anxiety creates maladaptive behaviors, physical manifestations, or mental symptoms then it becomes problematic. The anxiety disorders listed in the DSM-5 tend to be highly comorbid with other psychiatric conditions [1]. Anxiety disorders discussed in this chapter are the following: separation anxiety disorder, selective mutism, specific phobia, social anxiety disorder, panic disorder, agoraphobia, and general anxiety disorder. Other anxiety disorders that do not fall under the previously mentioned disorders will briefly be discussed. In addition, obsessive-compulsive, trauma- and stress-induced related disorders will be discussed due to their relevance to anxiety. Anxiety disorders covered in this chapter are presented in Table 1 with associated ages of onset.

The DSM-5 requires a minimum of 6-month duration of symptoms that are not attributable to another medical condition and mental disorder or induced by a substance or medication to meet diagnostic criteria for anxiety disorders. An exception is noted in symptom duration for children with separation anxiety disorder and selective mutism, with a required duration of 4 weeks and 1 month, respectively. Many anxiety disorders develop in early childhood and typically persist into adulthood if not adequately treated. These disorders differ from developmentally normative fear or anxiety in magnitude of reaction or persistence beyond developmentally appropriate periods. A thorough grasp of a proper differential diagnosis and treatment of anxiety disorders can be daunting; however, it may be easier to conceptualize various anxiety disorders from the perspective of the developmental spectrum, using age of onset to help guide a differential [1, 3, 4].

Separation Anxiety Disorder

Separation anxiety disorder is the most common anxiety disorder in children under 12 years of age [1]. Approximately 90% of cases have onset before the age of 13 and the prevalence (3–4% in children) decreases as patients age [5]. Genetics and parental anxiety disorders are risk factors for developing separation anxiety disorder [6]. Primary symptoms include severe distress or anxiety from actual or possible separation from the home or attachment figure. The inappropriate fear is characterized by anxiety of potential harm toward the attachment figure or worry about events that could cause separation from the attachment figure. Separation can trigger symptoms such as crying, yelling, vomiting, and trembling. Symptoms must last for at least 4 weeks in children or 6 months in adolescence. Persistent reluctance to separate from home may lead to poor academic performance or inability to perform tasks of daily living. Repeated nightmares about separation and physical complaints of headache, nausea, or abdominal pain are common when impending separation is anticipated. The Adult Separation Anxiety Questionnaire consists of 27 questions and can be used to aid in the diagnosis of adult separation anxiety [7].

www.konkur.in

Table 1 Summary of DSM-V Anxiety Differential by Age of Onset [1]

Disorder	Age at onset
Separation anxiety disorder	Preschool–adolescence
Selective mutism	Less than 5 years
Reactive attachment disorder	9 months–5 years
Disinhibited social engagement disorder	2 years–adolescence
Specific phobia	Early childhood age <10 years
Social anxiety disorder (social phobia)	Adolescence
Panic disorder	Early adulthood
Agoraphobia	Early adulthood
Generalized anxiety disorder	Early adulthood
Substance−/medication-induced anxiety disorder	Variable
Anxiety disorder due to another medical cause	Variable
Other specified anxiety disorders	Variable
Unspecified anxiety disorder	Variable
Obsessive-compulsive and related disorders	Late adolescence–early adulthood
Post-traumatic stress disorder	Early childhood–adulthood
Acute stress disorder	Early childhood–adulthood
Adjustment disorders	Early childhood–adulthood

Treatment can include antidepressants in severe cases, but typically symptoms of separation anxiety disorder tend to resolve over time. Parents of children with separation anxiety disorder may make significant lifestyle accommodations to relieve symptoms, that is, changing work routines, sleeping patterns [1, 8]. Negative consequences include sadness, social withdrawal, or constant demand for attention. Independent activities also may be affected (i.e., school avoidance, fear of sleeping alone, leaving for college) and should be explored. Other social stressors to consider include school bullying, bereavement, or exposure to a recent traumatic event. This disorder is often comorbid with generalized anxiety disorder, specific phobia, posttraumatic stress disorder (PTSD), social anxiety disorder, agoraphobia, OCD, and personality disorders.

Selective Mutism

Selective mutism usually presents before the age of 5 years and is characterized by a consistent failure to initiate speech in specific social situations where there is an expectation for speaking (e.g., school) even though the individual speaks in other situations [1]. Point prevalence is between 0.03 and 1% [1]. Occasionally, a diagnosis of selective mutism may be delayed until a child enters school and more attention is placed on social interactions. Diagnosis relies on input from parents and the child's teachers. The disturbance must be present for at least 1 month, but not the first month of school, and is not due to lack of knowledge of, or comfort with, the spoken language required. Communication disorders or intellectual disabilities should be considered in the differential diagnosis. Social anxiety disorder is a common comorbidity and should be identified and treated if present [1, 9].

Specific Phobias

Specific phobias involve the manifestation of marked fear, anxiety, or avoidance in the context of specific objects or situations [1]. Persons with specific phobias typically have more than one phobia. Common phobias include fear of heights, situations, or animals among others. Symptoms of specific phobias generally develop before the age of 10 after a traumatic event, but not all phobias have a specific trigger. Symptoms that persist into adulthood tend to be persistent and are unlikely to remit. Specific phobia, though low in prevalence,

Telegram: @medical_k

www.konkur.in

remains a commonly experienced disorder in late life. Persons with specific phobias should be referred to mental health professionals for treatment. The most common treatment is desensitization procedures starting with relaxation followed by graded exposure to the phobia.

Social Anxiety Disorder (Social Phobia)

Social anxiety disorder (social phobia) is characterized by marked fear, anxiety, or avoidance of social situations where possible scrutiny and assessment by others may occur. The average age of onset for social anxiety in the United States is 13 years. Common fears are humiliation, embarrassment, and failure. Typically, patients have anxiety anticipating public speaking and interviews. Avoidance of social situations may hinder new job, education, or promotion opportunities. Patients with social anxiety have an increased school dropout rate. Lack of employment is a strong predictor for social anxiety disorder. Depression is a common comorbidity in social anxiety disorder and may be related to the use of substances to help mitigate social fears [1].

First line treatment involves validation and reassurance from the provider. If necessary, low dose propranolol can be used as needed 30–60 min prior to social functions to relieve anticipatory anxiety [4]. Antidepressants can also be used if the anxiety is not limited to specific scenarios. If a patient requires further treatment, referral to a mental health care professional may be helpful.

Panic Disorder

Panic disorder is characterized by recurrent unexpected panic attacks that have an onset within minutes [1, 10]. It has a lifetime prevalence of 4.7%, average onset of 20–24 years, and occurs more frequently in females [5]. Typically, there is no "trigger" to the panic attack. Attacks are described as occurring suddenly. Patients are unable to control the panic attack with willpower alone. Diagnosis requires an abrupt onset, within minutes, of 4 or more symptoms. Manifested symptoms include tachycardia, diaphoresis, tremor, shortness of breath, sensation of choking, chest pain or discomfort, nausea, abdominal distress, dizziness, lightheadedness, chills or a sensation of heat, paresthesia, derealization or depersonalization, fear of losing control or dying. Culture-specific symptoms may occur (e.g., tinnitus, screaming, crying) but they do not count as DSM diagnostic criteria. The panic attack must then be followed by 1 or more months of at least one of the following: continued anxiety about additional panic attacks or maladaptive change in behavior related to the attack. The diagnosis must not be related to substance abuse or another medical condition. Panic disorder may lead to fear of leaving home (agoraphobia) in some cases. Panic disorder is frequently comorbid with other anxiety disorders, depression, and bipolar disorder. Panic disorder is associated with high levels of social, occupational, and physical disability. Individuals with panic attacks or a diagnosis of panic disorder in the past 12 months have a higher risk of suicide [1].

Agoraphobia

Agoraphobia is defined as fear or anxiety about being in open spaces (e.g., public venues), standing in line or in a crowd, using public transportation, or being alone outside the home [1]. Agoraphobia is associated with panic disorder. It is differentiated from other anxiety disorders since sufferers specifically fear that help may not be readily available in the event of a panic attack. The onset of agoraphobia is typically early adulthood, as is the case with panic disorder. The situational fear encompasses thoughts of being unable to escape or of being embarrassed due to manifestations of their anxiety. The course is typically persistent and chronic, with only 10% of cases remitting spontaneously. Approximately one third of affected adults are homebound and unable to work. Common comorbidities include other anxiety disorders, depressive disorders, PTSD, and alcohol use disorder.

Telegram: @medical_k

www.konkur.in

Generalized Anxiety Disorder

Generalized anxiety disorder (GAD) is characterized by excessive and persistent worry that is difficult to control, causes significant distress or impairment, and occurs most days for at least 6 months [1]. The worry is attributable to multiple events or activities and has three of the following symptoms: restlessness, easily fatigued, difficulty concentrating, irritability, increased muscle tension, sleep disturbance. It is one of the most common mental disorders in the primary care setting [11]. GAD is twice as common in women as it is in men and is the most common anxiety disorder among the elderly population [12, 13]. The typical age of onset is early adulthood. Lifetime prevalence in the United States is estimated to be between 5.1 and 11.9% [5, 14]. GAD often presents with comorbid substance abuse, PTSD, and obsessive-compulsive disorder (OCD). Additionally, major depressive disorder that is comorbid with GAD portends a more severe and prolonged course of illness and a greater functional impairment [14]. GAD is also common among patients with chronic pain and with unexplained chronic physical illness [1, 3]. Differentials include OCD, panic disorder, somatoform disorders, paranoid psychotic disorders, eating disorders, and various personality disorders. Negative outcomes that may be exacerbated by untreated GAD include increased blood pressure and coronary artery disease.

Other Anxiety Disorders

This group of disorders includes the following: substance- or medication-induced anxiety disorder, anxiety disorder due to another medical cause, other specified anxiety disorders, and unspecified anxiety disorder [1]. Substance- or medication-induced anxiety disorder presents with symptoms of panic and anxiety that developed during or immediately following intoxication or withdrawal of a substance or medication. Anxiety disorder due to another medical condition is explained by the physiological effect of the underlying medical condition (e.g., hyperthyroidism, arrhythmia, asthma, seizure disorders).

Other specified anxiety disorders and unspecified anxiety disorders do not fit into the criteria for one of the aforementioned anxiety disorders.

Obsessive-Compulsive and Related Disorders

This group of disorders includes obsessive-compulsive disorder (OCD), body dysmorphic disorder, hoarding disorder, trichotillomania (hair-pulling disorder), excoriation (skin-picking) disorder, substance- or medication-induced OCD, OCD due to another medical condition, and unspecified OCD. The age of onset is typically late adolescence or early adulthood, but can present in late childhood as well. The presence of recurring intrusive and persistent thoughts (obsessions) and repetitive behaviors or mental acts (compulsions) are a hallmark of this collection of disorders. The specifics of OCD vary by individual, but there are common themes which include contamination obsessions and cleaning compulsions; symmetry obsessions with repeating, ordering, and counting compulsions; religious, aggressive, or sexual obsessions and related compulsions; and harm obsessions and related compulsions [1, 15].

Body dysmorphic disorder is characterized by a perceived flaw in physical appearance that is minor or absent. Repetitive acts of checking the mirror, excessive grooming, and reassurance-seeking behaviors are common [1].

Hoarding disorder is described as significant difficulty with discarding possessions, irrespective of value, resulting in an intense need to save items. Symptoms include accumulation of items that congest and clutter living spaces to the point that their intended use is compromised [1, 7].

Trichotillomania (hair-pulling) disorder involves recurrent hair pulling with resultant hair loss, despite repeated attempts to stop the behavior. Excoriation (skin-picking) disorder involves recurrent picking of the skin despite repeated

Telegram: @medical_k

www.konkur.in

attempts to cease. These two disorders are usually preceded by feelings of anxiety or boredom [1, 7, 16].

Substance- or medication-induced OCD involves symptoms related to intoxication or withdrawal of a substance or medication. Symptoms resulting from OCD due to another medical condition are specifically associated with that medical condition. Other specified OCDs and unspecified OCD have atypical presentations and uncertain etiologies which do not meet criteria for diagnoses listed above [17].

Trauma- and Stressor-Related Disorders

Reactive Attachment Disorder

Reactive attachment disorder typically presents between the ages of 9 months and 5 years and is characterized by noticeably inappropriate or disturbed attachment behaviors [1]. Children must be at a developmental age of at least 9 months for diagnosis as the child must be able to make selective attachments. The exact disorder prevalence is unknown due to difficulty in case identification but it is uncommon. Children with reactive attachment disorder rarely or minimally turn preferentially to an attachment figure for comfort, support, or nurturance. Behaviors absent in the individual are an absence of expected comfort seeking and lack of response to comforting behaviors. When distressed, children with the disorder show no consistent effort to obtain comfort, support, nurturance, or protection from caregivers. Children with reactive attachment disorder have diminished or absent positive emotions when comforted by caregivers. Unexplainable negative emotions can occur such as episodes of fear sadness, or irritability. This disorder is commonly comorbid with social neglect (e.g., malnutrition) and developmental delay [1]. Differentials include autism spectrum disorder, intellectual disability, and depressive disorders. Adolescent patients presenting with similar symptoms to reactive attachment disorder likely have a separate psychiatric disorder as it is unknown whether it occurs in older children [18].

Disinhibited Social Engagement Disorder

Disinhibited social engagement disorder is characterized by culturally inappropriate and overly familiar behavior with relative strangers [1]. The inappropriate behavior may be verbal or physical and include willingness to venture away to unfamiliar settings or follow an unfamiliar adult without hesitation. Children with the disorder often have patterns of neglect that are presumed to be responsible for the abnormal behavior. As with reactive attachment disorder, children must be at least 9 months of age for diagnosis. The disorder usually presents at 2 years of age to adolescence. It is persistent if it lasts for longer than 12 months. The disorder is rare, occurring in only 20% of children with a history of severe neglect and raised in foster care or in institutions. Differential includes attention-deficit/hyperactivity disorder, but patients with disinhibited social engagement disorder do not demonstrate hyperactivity or inattention. Children may have comorbid cognitive delays, language delays, or stereotypies.

Post-Traumatic Stress Disorder (PTSD)

The hallmark of PTSD is the development of specific symptoms when exposed to one or more traumatic events involving actual or threatened death, serious injury, or sexual violation [1]. Older data suggest approximately 60.7% of men and 51.2% of women in the USA report at least one traumatic event in their lifetime [19]. Lifetime morbidity risk for PTSD is estimated to be 10.1% of the population [20]. The prevalence of PTSD is highest in those with increased risk of traumatic exposure, such as veterans, police, firefighters, emergency medical personnel, and victims of violent crime or rape. Symptoms of PTSD vary in clinical presentations and may involve dysfunction in five domains: intrusive thoughts, mood changes, dissociative

Telegram: @medical_k

www.konkur.in

reactions, avoidance, and marked alterations in arousal. Symptoms can begin within 3 months after exposure to a traumatic event; however, symptoms can also present much later before full criteria for a diagnosis of PTSD are met. Several diagnostic scales are available. Similar conditions that do not meet all the requirements for PTSD are acute stress disorder and adjustment disorder [1]. Examples of comorbid conditions with PTSD include depression, substance use disorders, and somatic symptoms. Psychotherapy is the preferred treatment option, and consideration should be given to refer these patients to a mental health provider for treatment. Second-line therapy includes antidepressants which are discussed in more detail below.

Screening Tools for Anxiety Disorders

The Hamilton Anxiety Rating Scale (HAM-A) (Fig. 1) and the Generalized Anxiety Disorder 7-item Scale (GAD-7) (Fig. 2) are two tests that are used to screen for possible anxiety in the clinical setting (Figs. 1 and 2, respectively). The HAM-A includes 14 items which measure psychic and somatic symptoms of anxiety. Each item is scored from 0 (not present) to 4 (severe), with a total score range of 0–56. Less than 17 indicates mild severity, 18–24 mild to moderate severity, and 25–30 moderate to severe. The HAM-A is most useful for gauging the response of anxiety to treatment [19]. It has been criticized, however, for its lack of discrimination between anxiety and depressive symptoms [20]. The GAD-7 has been identified as a useful tool with validity for identification of probable cases of generalized anxiety disorder [21, 22].

Both the GAD-7 or HAM-A can be used to monitor symptoms objectively at follow-up in practice; however, neither of these scales have been validated for monitoring purposes in trial data [23]. If the scales are being used for follow-up, a patient must complete the same scale they used in diagnoses. An adequate threshold for successful treatment is at least a 50% reduction from baseline symptoms, with the overall goal being remission, which is rare.

Panic disorder can be screened with either the Panic Disorder Screener (PADIS), a point-based scale, or the PHQ-Panic Screener, yes or no answers [24, 25]. Screening for panic disorder is similar to GAD. The PADIS has a 77% sensitivity and 84% specificity, whereas the PHQ-Panic Screener has a 57% sensitivity and 91% specificity. Both scales can also be used to measure patient treatment progress at follow-up, but the same scale should be used for comparison.

Treatment

The recommended first-line treatment for anxiety and related disorders is listed in Table 2. In general, the greatest therapeutic benefit is derived from combined pharmacotherapy and psychological therapy [15, 26]. Achieving true remission is rare in these disorders. Goal-directed therapy should be emphasized [26]. Anxiety is thought to be mediated by serotonin abnormalities; therefore, medications with some serotonin activity are used for treatment [32]. Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) treat a broad spectrum of symptoms and have efficacy for common comorbidities, making them excellent first-line options [15, 26]. Screening for suicidal ideation, homicidal ideation, and previous manic episodes must be negative and documented before initiation of SSRIs or SNRIs as these medications can worsen those symptoms. Patients should also be counseled on potential drowsiness. Pharmacotherapy is started at the lowest dose possible and titrated up slowly to minimize adverse effects and determine the lowest effective dose [27].

The most common adverse effects with SSRIs are sexual dysfunction, drowsiness, sleepiness, weight gain (1 to 6 pounds), dry mouth, insomnia, fatigue, nausea, dizziness, lightheadedness, and tremor [33, 34]. Sexual dysfunction includes decreased desire, arousal, and orgasm and occurs in approximately 60% of patients but resolves spontaneously in one fifth of patients at 6 months [35]. Most patients (~70%) have sexual dysfunction symptoms alleviated after a 50% dose decrease, otherwise switching to a non-SSRI can

Hamilton Anxiety Rating Scale (HAM-A) [19]

Below is a list of phrases that describe certain feeling that people have. Rate the patients by finding the answer which best describes the extent to which he/she has these conditions. Select one of the five responses for each of the fourteen questions.

0 = Not present, 1 = Mild, 2 = Moderate, 3 = Severe, 4 = Very severe.

1	**Anxious mood**	0	1	2	3	4	8	**Somatic (sensory)**	0	1	2	3	4
	Worries, anticipation of the worst, fearful anticipation, irritability.							Tinnitus, blurring of vision, hot and cold flushes, feelings of weakness, pricking sensation.					
2	**Tension**	0	1	2	3	4	9	**Cardiovascular symptoms**	0	1	2	3	4
	Feelings of tension, fatigability, startle response, moved to tears easily, trembling, feelings of restlessness, inability to relax.							Tachycardia, palpitations, pain in chest, throbbing of vessels, fainting feelings, missing beat.					
3	**Fears**	0	1	2	3	4	10	**Respiratory symptoms**	0	1	2	3	4
	Of dark, of strangers, of being left alone, of animals, of traffic, of crowds.							Pressure or constriction in chest, choking feelings, sighing, dyspnea.					
4	**Insomnia**	0	1	2	3	4	11	**Gastrointestinal symptoms**	0	1	2	3	4
	Difficulty in falling asleep, broken sleep, unsatisfying sleep and fatigue on waking, dreams, nightmares, night terrors.							Difficulty in swallowing, wind abdominal pain, burning sensations, abdominal fullness, nausea, vomiting, borborygmi, looseness of bowels, loss of weight, constipation.					
5	**Intellectual**	0	1	2	3	4	12	**Genitourinary symptoms**	0	1	2	3	4
	Difficulty in concentration, poor memory.							Frequency of micturition, urgency of micturition, amenorrhea, menorrhagia, development of frigidity, premature ejaculation, loss of libido, impotence.					
6	**Depressed mood**	0	1	2	3	4	13	**Autonomic symptoms**	0	1	2	3	4
	Loss of interest, lack of pleasure in hobbies, depression, early waking, diurnal swing.							Dry mouth, flushing, pallor, tendency to sweat, giddiness, tension headache, raising of hair.					
7	**Somatic (muscular)**	0	1	2	3	4	14	**Behavior at interview**	0	1	2	3	4
	Pains and aches, twitching, stiffness, myoclonic jerks, grinding of teeth, unsteady voice, increased muscular tone.							Fidgeting, restlessness or pacing, tremor of hands, furrowed brow, strained face, sighing or rapid respiration, facial pallor, swallowing, etc.					

Fig. 1 Hamilton Anxiety Rating Scale (HAM-A)

help. Nausea occurs in 60% of patients, sertraline is the greatest offender [36]. Of the SSRIs, fluoxetine causes the most insomnia and agitation and generally should be avoided in treating anxiety conditions. Rare adverse effects of SSRIs include bleeding (1 bleed per 8000 prescriptions), serotonin syndrome, extrapyramidal symptoms (fluoxetine is the worst offender), and syndrome of inappropriate antidiuretic hormone secretion [37]. No recommendations are available to prevent serotonin syndrome, but it is good practice to limit the number of serotonin acting agents. The physician should be cognizant of possible early serotonin syndrome with new onset tremors, mydriasis, hyperactive bowel sounds, diaphoresis, skin color changes, and

If you checked off any problems, how difficult have these made it for you to do your work, take care of things at home, or get along with other people?

Not difficult at all	
Somewhat difficult	
Very difficult	
Extremely difficult	

Fig. 2 Generalized Anxiety Disorder 7-item (GAD-7) scale

lower extremity hyperreflexia when a patient is taking an SSRI or SNRI [38].

Most of the adverse effects with SSRIs are the same with SNRIs; however, sexual dysfunction is less frequently reported. Supine diastolic blood pressure (DBP) should be regularly monitored for patients taking SNRIs. Venlafaxine at higher doses can increase supine DBP by 10 to 15 mg DBP in 13% of patients. Generally systolic blood pressure is minimally affected. Duloxetine is associated with less hypertension (~2 mmHg DBP increase) than venlafaxine, does not cause weight gain, and also has an indication for neuropathic pain which may of benefit in selected patients.

No universal approach for switching or discontinuing antidepressants exists. However, good practice suggests SSRIs and SNRIs can be directly interchanged at equivalent doses [39]. Discontinuation of SSRIs and SNRIs should be performed over at least 4 weeks as abrupt cessation can cause flu-like and neurologic symptoms. Paroxetine and venlafaxine require longer tapers (25% reduction every 4 to 6 weeks) due to their comparatively shorter half-lives.

Other antianxiety medications include the tricyclic antidepressant doxepin and buspirone. Both have limited efficacy and should be limited as second line options after SSRIs and SNRIs have been trialed at appropriate doses and duration (4 to 6 weeks at the maximum dose). Benzodiazepines are inappropriate maintenance therapy for anxiety disorders [40]. Keeping

Table 2 First-line treatment of anxiety and related disorders [4, 15–17, 26–31]

Diagnosis	Treatment(s)	Comments
Anxiety disorders		
Separation anxiety disorder	SSRI 1. Fluoxetine (Prozac) up to 40 mg/day[a]. 2. Paroxetine (Paxil) up to 50 mg/day[b]. Psychotherapy 1. CBT[c]	Currently, no FDA-approved medications for separation anxiety; however a trial of SSRI is considered reasonable
Selective mutism	SSRI 1. Fluoxetine (Prozac) up to 60 mg/day Psychotherapy 1. CBT[c]	
Specific phobias	Psychotherapy 1. Exposure therapy[d]	
Social anxiety disorder	SSRI 1. Paroxetine (Paxil). 2. Sertraline (Zoloft). SNRI 1. Venlafaxine (Effexor) Psychotherapy 1. Exposure therapy[d]	
Panic disorder	Psychotherapy 1. CBT[c] SSRI 1. Fluoxetine (Prozac). 2. Paroxetine (Paxil). 3. Sertraline (Zoloft). SNRI 1. Venlafaxine (Effexor)	
Agoraphobia	Psychotherapy 1. Exposure therapy[d]	
Generalized anxiety disorder	SSRI 1. Escitalopram (Lexapro). 2. Paroxetine (Paxil). SNRI 1. Duloxetine (Cymbalta). 2. Venlafaxine (Effexor).	
Obsessive-compulsive and related disorders		
Obsessive compulsive disorder	SSRI 1. Fluoxetine (Prozac). 2. Sertraline (Zoloft). 3. Paroxetine (Paxil). Psychotherapy 1. CBT[c]	Higher doses of SSRI treatment are often needed in some cases
Body dysmorphic disorder	Psychotherapy 1. CBT[c]	
Hoarding disorder	SSRI 1. Paroxetine (Paxil) TCA 1. Clomipramine	No specific pharmacotherapy can be recommended strongly at present; however, a trial of an SSRI is considered reasonable
Trichotillomania	SSRI 1. Fluoxetine (Prozac) Antipsychotics 1. Aripiprazole (Abilify). 2. Quetiapine (Seroquel).

Diagnosis	Treatment(s)	Comments
	Supplements 1. N-acetylcysteine (dosing range, 1200–2400 mg/day) Psychotherapy 1. HRT[e]	
Excoriation disorder	SSRI 1. Fluoxetine (Prozac)	
Trauma-and stressor-related disorders		
Post-traumatic Stress disorder	SSRI 1. Paroxetine (Paxil) 2. Sertraline (Zoloft) Psychotherapy 1. Exposure therapy	

[a]Ages 7–17 years
[b]Ages 8–18 years
[c]CBTcognitive behavioral therapy. Emphasizes the relationship between cognitions (thoughts), somatic experiences (physical complaints), and behavior in anxiety-provoking situations
[d]Exposure therapy. Utilizes repeated exposure to feared stimuli and memories surrounding a traumatic event and aims to help the patient to experience a decrease in fear and an increase in mastery of anxiety symptoms by incorporating mental processing, psychoeducation, and breathing relaxation exercises
[e]HRT habit reversal therapy. A CBT approach that consists of awareness training and stimulus control

benzodiazepines on an as-needed basis for routine anxiety-provoking situations can reinforce the fear response and should be avoided. However, single dose benzodiazepines may be appropriate for some patients in specific scenarios (e.g., air travel, surgery). If a benzodiazepine must be used for severe cases, clonazepam is preferred as it has a slower onset of action and longer half-life, thus reducing the phenomenon of rebound anxiety, which is sometimes seen with other agents.

Over-the-counter herbal remedies may be considered as adjunctive therapy. The most common agents include valerian (Valeriana officinalis), kava (Piper methysticum), passionflower, St. John's wort (Hypericum perforatum), and Rhodiola rosea. While efficacy and robust safety data are lacking, the risk benefit ratio should be discussed with patients.. Due to the concern of potential liver toxicity with the use of kava, a double-blind, randomized, placebo-controlled study showed kava to be well tolerated, except for a small increase in headaches, and was moderately effective for GAD [28]. St. John's Wort is commonly used by patients but may have significant interactions with medications including antiretrovirals, immunosuppresants, antineoplastics, anticoagulants, oral contraceptives, and hormone replacement medications.

Treatment for panic disorder includes patient counseling on panic disorder, and specific assurances that the panic attacks are not dangerous despite symptoms [41]. Referral should be made to mental health care providers for cognitive behavioral therapy. Benzodiazepines may be used briefly, but should be tapered rapidly as the effect of antidepressants ramp up.

Complementary and Alternative Methods

Yoga

Yoga is an ancient Asian practice that has become increasingly popular in Western culture. It incorporates meditation and postures and connects individuals with mindful breathing. It is meant to improve the symbiotic relationship between mind, body, and soul. It has been used for centuries to calm the mind, which is an essential part of the

Telegram: @medical_k

www.konkur.in

practice. There are various forms of practice, but all serve to have the same basic teachings that focus on poses, breathing techniques, and meditation. Several review articles looking at randomized and nonrandomized trials have concluded that practicing yoga can reduce anxiety and overall stress levels [42, 43].

A systematic review of 17 peer-reviewed articles published from 2011 to 2013 concluded that yoga is a promising modality for stress management. Twelve of the 17 articles reviewed were randomized control trials. The number of subjects ranged from 20 to 205. The outcome measures, length of treatment, and type of yoga varied greatly among the studies [44]. This systematic review did not address any particular anxiety disorder diagnosis.

Exercise

Physical activity may provide psychological benefits of improvement in skills, body image, and physical fitness that can enhance self-esteem [45]. Aerobic exercise provides psychological benefits of self-mastery, goal attainment, and socialization.

Data suggests aerobic exercise is effective in the treatment of those with diagnosed anxiety disorder or clinically elevated anxiety levels on a validated rating scale [46]. High-intensity exercise seems to have greater anxiety relief effects than low-intensity. Additional studies suggest that exercise is more effective than control in reducing anxiety symptoms [47].

Acupuncture

Traditional Eastern Medicine encompasses several modalities, including acupuncture. The practice has become more common in Western society, usually in conjunction with allopathic and osteopathic practices. Acupuncture uses specific points in the body that are all connected to one's individual "Qi" or life energy. The insertion of needles into these points alters the "flow" which can serve to aid a particular ailment related to that point. Although acupuncture has been studied in the use of chronic pain, when it comes to treatment of anxiety disorders, there is still very little evidence for efficacy. Concerns that frequently arise are if there is a consensus on which points are directly related to anxiety, the type of acupuncture used (needling vs cupping), duration and frequency of treatments, and appropriate control groups [48].

Mindfulness

The term mindfulness originates from the ancient Indo-Aryan Pali word "sati" meaning having awareness, attention, and remembering [49]. The notion of mindfulness is thought to reach back to Buddhist concepts, but has developed into a more modern definition of moment-to-moment awareness of one's experience without judgment [49]. Mindfulness-based stress reduction (MBSR) and mindfulness-based cognitive therapy (MBCT) merge Eastern practices of mindfulness with Western cognitive-behavioral practice [50]. Review of randomized control trials comparing mindfulness treatments including MBSR and MBCT with active control conditions has shown mindfulness-based interventions to be effective in treating a number of conditions including depression, anxiety, and chronic pain [50].

Daily situations in which this can be practiced include while driving a car, washing dishes, or in a more defined setting such as meditation sessions. More recently, online mindfulness-based interventions (MBIs) have become available and are an option for those who may be unable to participate in face-to-face settings. A meta-analysis of the effects of online MBIs suggests evidence of efficacy for programs that improve mental health outcomes, with smaller effects on anxiety and depression with a more notable effect on stress [51].

Summary

Anxiety disorders, obsessive-compulsive and related disorders, and trauma- and stressor-related disorders account for significant morbidity and mortality. Specifically, the anxiety disorders

Telegram: @medical_k

www.konkur.in

account for the majority of cost burden due to their high prevalence and the increasing cost of appropriate therapies. Timely and accurate diagnoses followed by appropriate treatment are of the utmost importance due to the pervasive nature of these disorders and their effects. Most disorders are best treated with combined therapies: for example, CBT or exposure therapy coupled with pharmacotherapy. Alternative herbal therapies lack significant efficacy data but are often considered safe for use and may be considered if interactions are avoided. Regular physical exercise is an effective intervention that has multiple beneficial effects on overall health. While strong evidence may be lacking for yoga and acupuncture, data seems to indicate a positive effect on the course of anxiety disorders, and they should be considered as adjuncts to treatment for patients who are open to them. Mindfulness techniques appear to have the most robust support from current evidence, which is not surprising given the degree of overlap with the well-established practice of CBT.

Depressive and bipolar disorders are medical conditions which are often first diagnosed and treated in primary care settings [1, 2]. Hence, family physicians are in a frontline position to provide optimal care for patients who suffer from these disorders. This chapter will provide succinct and practical information on the diagnosis and most effective pharmacologic and nonpharmacologic treatments of these disorders in a primary care setting. Newer therapies, such as deep brain stimulation, as well as consideration of special populations, will also be discussed.

Epidemiology

Mood disorders, such as major depressive disorder, persistent depressive disorder (PDD; formerly dysthymic disorder), and bipolar disorders are quite common [3]. The lifetime prevalence of having any type of mood disorder is 20%. In 2012, it was estimated that 10.4 million adults aged 18 or older in the USA had at least one major depressive episode resulting in severe impairment in the past year. This represented 4.5% of all US adults (see Fig. 1).

In general, mood disorders are more common in women, in those with a family history of psychiatric illness, and in those individuals who have comorbid medical disorders. The majority of patients with mood disorders first present to nonpsychiatrists, such as family physicians, often complaining of somatic, rather than mood symptoms (e.g., pain, GI upset, headache, etc.).

Risk and Prognostic Factors

While the exact causes of depressive and bipolar disorders remain unclear, risk factors have been identified for the development of depressive disorders and classified into three major categories. These are temperamental, environmental, and genetic/physiological. Within these areas, neuroticism (negative affectivity), adverse childhood events, and a family history of depression are some of the strongest risk factors [4]. First-degree relatives of people with major depression (MD) have an increased risk of MD. The variance in liability to MD is accounted for by additive genetic effects and environmental influences specific to an individual [4].

A family history is also one of the strongest risk factors for bipolar disorders, and there is an average tenfold increased risk among first-degree adult relatives of individuals with bipolar I or bipolar II disorders [5]. Twin studies are generally consistent in observing greater concordance among monozygotic twins than dizygotic twins, which may provide evidence that susceptibility genes contribute to the familiality of bipolar disorder [6].

Bipolar I disorders are also more common in countries with a higher socioeconomic status and among separated, divorced, and widowed individuals than married or single individuals, although the direction of this association remains unclear [4].

Psychological theories propose the idea that individuals with these disorders are more likely to engage in more "depressogenic" cognitive styles and more cognitive distortions in response to stressors than do nondepressed individuals. In addition, newer theories are evolving which examine the role of inflammatory markers resulting from oxidative stress and the negative impact of poor nutrition on the development and maintenance of these disorders, as well as other genetic, physiologic, and environmental precursors of depressive and bipolar disorders.

Diagnostic Criteria

Depressive Disorders

The *Diagnostic and Statistical Manual* of the American Psychiatric Association Fifth Edition (DSM5) divides mood disorders into two categories: depressive disorders and bipolar and related disorders [4]. A major depressive disorder is diagnosed if the patient has experienced depressed mood or loss of interest and at least four additional symptoms (see Fig. 2) for at least 2 weeks and has never experienced a manic, hypomanic, or mixed episode.

In children and adolescents, the mood may be irritable rather than sad. Once the diagnosis has been made, specifiers which note severity, course, and specific aspects of the depressive episode (including psychotic features, anxious distress, peripartum onset, and others) are also noted. As with all DSM-5 disorders, symptoms cannot be due to another psychiatric disorder, physiological effects of a substance, or another medical illness and must cause clinically significant distress or impairment in important areas of functioning.

In *persistent depressive disorder*, formerly "dysthymic disorder," the essential feature is a depressed mood that occurs for most of the day, for more days than not, for at least 2 years (at least 1 year for children and adolescents). This disorder represents a consolidation of DSM-IV-defined chronic major depressive disorder and dysthymic disorder in the DSM-5. Major depression may precede persistent depressive disorder, and major depressive episodes may occur concomitantly during persistent depressive disorder. Individuals whose symptoms meet major depressive disorder

Telegram: @medical_k

www.konkur.in

DSM-5 Criteria for Major Depressive Disorder and Persistent Depressive Disorder (Dysthymia)

MAJOR DEPRESSIVE DISORDER

5 or more symptoms must have been present in the same 2-week period and represent a change in previous functioning (at least 1 of the symptoms is depressed mood or loss of interest):

1. Depressed mood most of the day, nearly every day (observed or subjective)
2. Markedly diminished interest or pleasure
3. Significant weight loss or weight gain or change in appetite
4. Sleep disturbance (insomnia or hypersomnia)
5. Psychomotor retardation or agitation nearly every day (observed)
6. Fatigue or loss of energy nearly every day
7. Feelings of worthlessness or inappropriate/excessive guilt
8. Impaired ability to think or concentrate or indecisiveness
9. Recurrent thoughts of death, suicidal ideation, or a suicide attempt or specific plan for committing suicide.

- *Mood can be irritable in children and adolescents*
- *Has never had a manic or hypomanic episode in the past*

PERSISTENT DEPRESSIVE DISORDER (DYSTHYMIA)

Depressed mood most of the day nearly every day, for more days than not, for at least 2 years (observed or subjective). During this 2-year period, the individual has never been without the symptoms for more than 2 months at a time.

Presence, while depressed, of 2 or more of the following symptoms during the same period:

1. Poor appetite or overeating
2. Insomnia or hypersomnia
3. Low energy or fatigue
4. Low self-esteem
5. Poor concentration or indecisiveness
6. Feelings of hopelessness

- *Mood can be irritable and duration must be 1 year or longer in children and adolescents)*
- *Has never had a manic or hypomanic episode in the past*

A useful mnemonic to aid in diagnosis is SIG:ECAPSS ("prescribe energy capsules"). These stand for Sleep changes (insomnia or hypersomnia), Interest (loss of), Guilt (or worthlessness), Energy (fatigue), Concentration (impaired), Appetite (decreased or increased), Psychomotor (retardation or agitation), Suicidal ideation (and plan or intent) and Sex (decreased libido).

Fig. 2 DSM-5 criteria for major depressive disorder and persistent depressive disorder (dysthymia)

criteria for 2 years should also be given a diagnosis of persistent depressive disorder in addition to major depressive disorder, a diagnosis often termed, "double depression."

In primary care, a large number of patients present with somatic, rather than mood, symptoms. It is important that the family physician ask patients who present with insomnia and

Telegram: @medical_k

www.konkur.in

fatigue about accompanying depressive symptoms. In addition, depression is often comorbid with, or can result from, other medical conditions or due to the side effects of medications. In the DSM-5, subthreshold depressive symptoms which meet many but not all the criteria for a depressive disorder can also occur and is now termed "unspecified" rather than "not otherwise specified." Once depression is suspected, it is of critical importance to also assess whether or not the patient has experienced a manic, hypomanic, or mixed episode in the past, as treatment for unipolar and bipolar depression differs significantly.

In addition to taking a detailed history and using SIGECAPS as a mnemonic, there are short assessment instruments readily available online at no cost. One of these, the Brief Patient Health Questionnaire (PHQ-9) [7], is widely available and has a sensitivity of 88% and a specificity of 88% for major depression. PHQ-9 scores of 5, 10, 15, and 20 represented mild, moderate, moderately severe, and severe depression, respectively [7]. This brief assessment has been translated into many different languages and is available here: http://phqscreeners.com/pdfs/02_PHQ-9/English.pdf.

Scoring instructions for the PHQ-9 are available at http://www.phqscreeners.com/instructions/instructions.pdf.

It should be noted that the PHQ-9 is only a screening test for depression. If positive, the clinician should then conduct a careful diagnostic interview, using DSM-5 criteria, to make a diagnosis of a depressive disorder.

The most recent (2016) US Preventive Services Task Force (USPSFTF) guidelines recommend screening adults (18 and older), including pregnant and postpartum women, for depression when adequate systems are in place to ensure accurate diagnosis, effective treatment and follow-up (please see https://www.uspreventiveservicestaskforce.org/uspstf/recommendation/depression-in-adults-screening). "'Staff-assisted depression care supports' refer to clinical staff that assist the primary care clinician by providing some direct depression care, such as care support or coordination, case management, or mental health treatment." Per the USPSTF report, "the lowest effective level of staff-assisted depression care supports consisted of a screening nurse who advised resident physicians of positive screening results and provided a protocol that facilitated referral to behavioral treatment." (Please see http://www.uspreventiveservicestaskforce.org/Page/Document/RecommendationStatementFinal/depression-in-adults-screening.)

Bipolar and Related Disorders

Bipolar disorders are often underdiagnosed in primary care. In the DSM-5, three distinct types of bipolar disorders are recognized: bipolar I disorder, bipolar II disorder, and cyclothymic disorder. As with the depressive disorders, categories for the diagnosis of substance-induced mood disorders, bipolar, and related disorder due to another medical condition and unspecified bipolar and related disorders are also available in the DSM-5.

Bipolar I Disorder

Bipolar I disorder is the most severe form of this illness. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder, even though this manic episode may have been preceded by and may be followed by hypomanic or major depressive episodes. While the overwhelming majority of those with bipolar I disorder also have episodes of major depression, only the presence of a manic episode is needed to make this diagnosis.

DSM-5 criteria for a manic episode include:

A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week and present most of the day, nearly every day (any duration if hospitalization is necessary). During this period, three (or more) of the following symptoms (four if the mood is irritable) are present:

1. Inflated self-esteem or grandiosity
2. Decreased need for sleep
3. More talkative than usual or pressure to keep on talking

Telegram: @medical_k

www.konkur.in

4. Flight of ideas or racing thoughts
5. Distractibility
6. Increase in goal-directed activity (or psychomotor agitation)
7. Excessive involvement in activities that have a high potential for painful consequences (spending money, sexual indiscretions, substance abuse, etc.)

These symptoms must represent an unequivocal change in functioning and cannot be due to another psychiatric illness, physiological effects of a substance, or another medical condition and must cause significant distress and impairment in functioning.

Note: A useful mnemonic to aid in the diagnosis of a manic episode is DIGFAST (see Fig. 3).

Once the diagnosis of bipolar I disorder has been made, specifiers for the current or most recent episode (manic, hypomanic, depressed, or unspecified), as well as severity (mild, moderate, severe, psychotic, remission), are also recorded. Additional specifiers are then noted if applicable (rapid cycling, anxious distress, mixed features, psychotic features, and others).

Bipolar II Disorder

Bipolar II disorder consists of a pattern of recurring mood episodes consisting of one or more major depressive episodes and at least one hypomanic episode:DSM-5 Hypomanic Episode. For a diagnosis of bipolar II disorder, a patient must meet the criteria for a current or past hypomanic episode and a current or past major depressive episode.

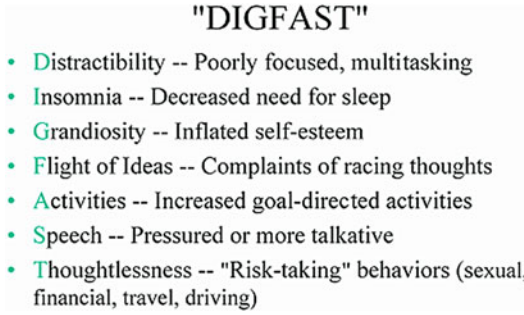

Fig. 3 DIGFAST

A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 4 consecutive days and present most of the day, nearly every day. During this period, three (or more) of the following symptoms (four if the mood is irritable) are present:

1. Inflated self-esteem or grandiosity
2. Decreased need for sleep
3. More talkative than usual or pressure to keep on talking
4. Flight of ideas or racing thoughts
5. Distractibility
6. Increase in goal-directed activity (or psychomotor agitation)
7. Excessive involvement in activities that have a high potential for painful consequences (spending money, sexual indiscretions, substance abuse, etc.)

These symptoms must represent an unequivocal change in functioning and cannot be due to another psychiatric illness, physiological effects of a substance, or another medical condition and must cause significant distress and impairment in functioning. Please see previous section for criteria for major depressive episode.

In order to make this diagnosis, the major depressive episodes must last at least 2 weeks, with symptoms present more days than not, and the hypomanic episodes must last at least 4 days. As with bipolar I disorder, the patient may not perceive their elevated mood as problematic; however, others (family members, co-workers) may be quite distressed by the individual's unstable behavior. Patients with bipolar II disorder often first present with major depression, which again underscores the importance of asking about a previous history of manic or hypomanic episodes. A mnemonic which can be used to help to differentiate unipolar from bipolar depression is WHIPLASHED (see Fig. 4).

Cyclothymic Disorder

A diagnosis of cyclothymic disorder is given when a patient has numerous episodes of hypomanic and depressive symptoms over the course

Telegram: @medical_k

www.konkur.in

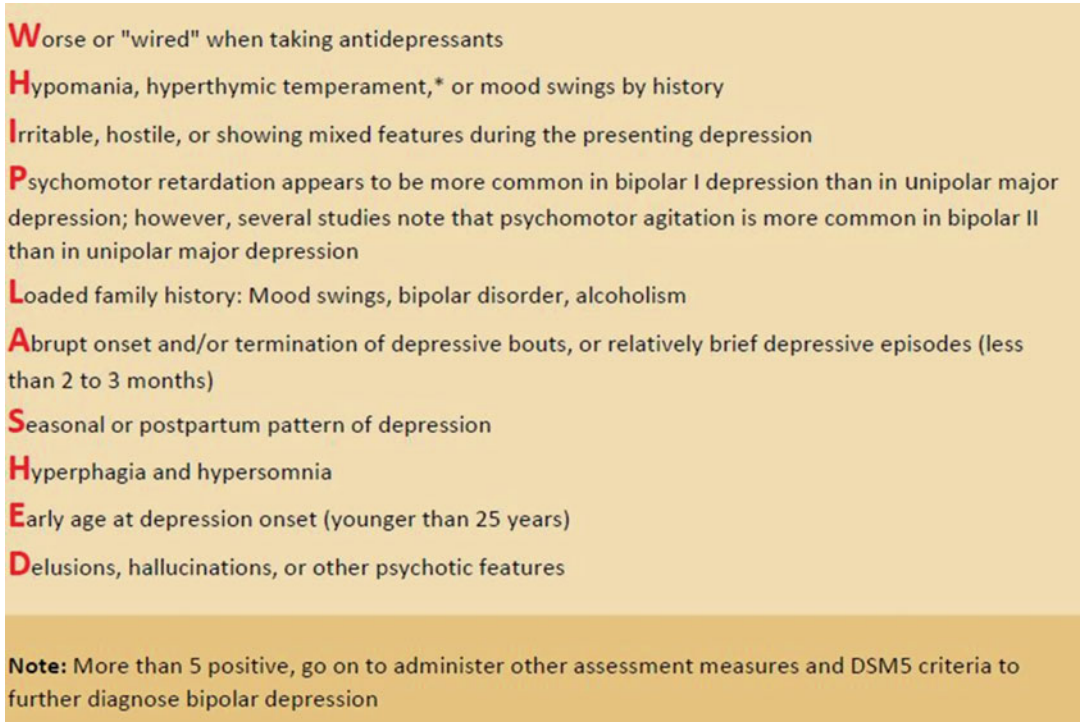

Fig. 4 WHIPLASHED screen for bipolar depression [8]

of at least 2 years (or 1 year in children and adolescents) which do not meet the full criteria for a diagnosis of a bipolar or depressive disorder but cause a significant impairment in functioning. Cyclothymic disorder is a bipolar spectrum disorder which usually begins in adolescence or early adulthood. There is a 15–50% risk that an individual with this disorder will subsequently develop bipolar I or bipolar II disorder [4]. This diagnosis might be considered for those patients whose clinical symptoms cause concern yet who do not demonstrate a positive screen on assessment measures.

The authors highly recommend using the *The Pocket Guide to the DSM-5 Diagnostic Exam* to aid in diagnosing depressive and bipolar and related disorders in your patients: http://www.appi.org/Book/Subscription/JournalSubscription/id-3310/The_Pocket_Guide_to_the_DSM-5%C2%AE_Diagnostic_Exam.

In addition, many other excellent screening tools for these disorders can be found online at no cost at: http://www.integration.samhsa.gov/clinical-practice/screening-tools.

Suicide

Tragically, depressive and bipolar disorders often lead to suicide, making them potentially fatal illnesses if left untreated. One large analysis of 40 separate postmortem studies found that 45% of those who died by suicide had seen a primary care provider within the month before their death, and 77% had such contact within the past year [9]. Older adults who died by suicide were even more likely to have had recent contact with a primary care provider. Hence, it is extremely important to ask depressed and bipolar patients about suicidal intent. It should be noted that asking about suicidal ideation does *not* increase the risk of suicide. The SAD PERSONS screen assesses risk factors for suicide (S = Sex-male, A = age > 60, D = depression, P = previous

Telegram: @medical_k

www.konkur.in

attempt, E = ethanol/other drug abuse, R = rational thinking (loss of), S = suicide in family, O = organized plan/access, N = no support, S = sickness (chronic pain/disease)). The Columbia Suicide Severity Rating Scale is another excellent resource: http://www.integration.samhsa.gov/clinical-practice/Columbia_Suicide_Severity_Rating_Scale.pdf.

Newer approaches for assessing suicide risk are also rapidly emerging, such as a mobile application for Apple and Android devices, "Suicide Safe," from the Substance Abuse and Mental Health Services Administration (SAMHSA) website http://store.samhsa.gov/apps/suicidesafe/ and a blood test which may predict suicidal behaviors by examining certain combined epigenetic and genetic biomarkers [10] among others.

Differential Diagnosis

Detection and treatment of mood symptoms depends on properly identifying the potential etiology underlying the presenting complaint. Non-psychiatric conditions that can give rise to mood symptoms include environmental triggers, neurologic disorders, other psychiatric disorders, and medical comorbidity. Potential medical causes are diverse ranging from cardiovascular disorders to nutritional deficiencies. Psychosocial stressors may contribute to the acute onset of mood symptoms with major life changes or bereavement causing adjustment difficulties. Cognitive disorders, such as the neurodegenerative disorders, may present early in their course with noticeable alterations in mood. Excluding organic causes of depression to a reasonable degree of certainty is always the first step in making a diagnosis.

Substance use, personality, anxiety, and the somatoform disorders can all have an impairing mood component as a hallmark of their pathology. Treatment would include addressing the specific concerns in these populations such as assisting with the withdrawal syndrome, detoxification, and maintenance of abstinence in the patient with a substance use disorder.

Bereavement may present with symptoms consistent with depression. The DSM-5 removed the bereavement exclusion from its criteria, as many individuals may develop depression after a loss. Studies suggest that if treated promptly, symptom presence would be shorter. For this reason, if symptoms of a full, major depressive episode are present following bereavement, clinical judgment should be exercised to determine if the patient requires treatment. A preponderance of data support treating those meeting criteria for a major depressive disorder during the period of 2–12 weeks following bereavement [11].

Treatment Principles

The primary goal for the treatment of depression in the primary care setting is complete remission of depressive symptoms. The primary care clinician must allow an adequate trial of each medication before determining if the patient has failed that particular medication. An adequate trial includes sufficient length of time for the medications to demonstrate a response, which can be as early as 1–2 weeks in eventual responders to greater than 4 weeks in some individuals [12]. Obtaining measurements of response with the use of screening instruments to monitor response and progression toward remission may be beneficial in enhancing the quality of care and clinical outcome for patients. The PHQ-9, mentioned earlier in this chapter, and the Hamilton Rating Scale for Depression (HAM-D) are examples of a self-rated and a clinician-rated scale, respectively.

The primary care physician will be able to provide successful care to a bipolar patient depending on various elements such as illness severity, comorbidities, personal experience, ancillary support from the institution where the physician is practicing, and complexity of the case. Primary care physicians need to decide which level of care will be required; for example, would acute or long-term treatment be provided by them, or would a psychiatrist need to be involved through a referral or collaborative care?

Telegram: @medical_k

www.konkur.in

For most patients, acute and maintenance treatment will require pharmacological management. The objective of providing acute treatment is to reduce symptoms with adequate safety, making sure the medication is well tolerated. Monotherapy is commonly the first line of treatment, but many times, combination therapy will be required to manage the symptoms of bipolar disorder.

A word should be said about new trends in pharmacogenetic testing to ascertain response to antidepressant treatment. The following is a summary from an excellent article by Zeier and colleagues on this topic [12]:

> Substantial investigations of genomic sequencing have been devoted to identifying gene-drug interactions affecting response to antidepressant treatment. Individual responses to antidepressants, as well as the unpredictability of adverse side effects, leave clinicians with a prescribing strategy that often relies on trial and error. There are available pharmacogenetic testing products that are marketed to physicians. These tools use algorithms to integrate multiple genetic variants and assemble the results into an easily interpretable report to guide prescribing of antidepressants and other psychotropic medications. At present, there is insufficient data to support the widespread use of these pharmacogenetic tests in clinical practice. In some clinical situations, the technology may be informative, particularly in predicting side effects [12].

Treatment

Biologic Therapies

Depressive Disorders

Many pharmacologic agents are used to treat depressive symptoms including selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs). The clinician must make several decisions before recommending a specific antidepressant. Which medication will target the depressive symptoms with fewest side effects will need to be determined. Access to the medications (insurance formularies), their cost, and the ease of dosing will play an important part in the implementation of a treatment protocol.

Selective Serotonin Reuptake Inhibitors

The SSRIs (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline, and vortioxetine) are first-line agents in the treatment of major depressive disorder. Well-tolerated by many, these medications are widely prescribed for many psychiatric disorders. Physicians who have experienced using these medications will anticipate and use potential side effects to their advantage such as using a sedating medication with a patient with complaints of insomnia [13]. See Table 1 for further useful information on this topic.

The interactions of SSRIs with other medications will be important for the treating clinician to monitor on a continual basis. Constant surveillance is important for patient safety, as well as education about the signs/symptoms of toxicity secondary to their use of an antidepressant [14].

Serotonin-Norepinephrine Reuptake Inhibitors

The SNRI medications (desvenlafaxine, duloxetine, levomilnacipran, and venlafaxine) are used to treat depressive symptoms in refractory cases, as part of an augmentation strategy with an SSRI. They are also used as monotherapy if patients have a partial or nonresponse to an SSRI. Many clinicians believe that the SNRIs can be helpful in patients with comorbid anxiety and pain syndromes.

Tricyclic Antidepressants and Monoamine Oxidase Inhibitors

The TCAs (amitriptyline, desipramine, doxepin, imipramine, nortriptyline, and protriptyline) and MAOIs (isocarboxazid, phenelzine, selegiline, tranylcypromine) are still widely used because of the wealth of data on their use, low cost, and effectiveness. Their higher incidence of side effects when compared to newer agents and their higher lethality in overdose have relegated these agents to a second-line use in most treatment plans when first-line medications have failed [15].

Other Antidepressants

Antidepressants with different mechanisms of action from the SSRIs/SNRIs (bupropion, mirtazapine, trazodone, and vilazodone) are also widely prescribed. Bupropion is often used to augment other antidepressants or as monotherapy to offset sexual side effects that may be experienced during treatment for depression. Mirtazapine is often prescribed as an adjunct, or monotherapy, for patients with insomnia and/or anorexia. Trazodone is another agent that is widely used for insomnia, even more so than for its antidepressive qualities [15]. The S-enantiomer of ketamine, esketamine, was recently approved for treatment-resistant depression [16]. A list of medications currently approved for treating major depressive disorder is below (Table 2).

Augmentation

Partial response to pharmacotherapy is common in many patients. When a patient has an initial response to an antidepressant medication, with the dosage and treatment length being optimized, a plateauing effect may take place with stagnation in further improvement. Instead of switching to another medication in the same class, the physician may consider augmentation strategy. Augmentation of antidepressants, with other agents, has demonstrated efficacy in several circumstances, including being added to a regimen when a patient has partial response to treatment, the patient is unable to tolerate higher doses of the base antidepressant, or if switching to a different medication is not practical. Several medications are used in augmentation strategies for the treatment of depressive symptoms including mood stabilizers (i.e., lithium), atypical antipsychotics (i.e., aripiprazole), triiodothyronine, stimulants (i.e., modafinil), and hormone replacement (i.e., testosterone in men) [17].

Alternative/Complementary Options

Knowing about the use of alternative treatments by patients is of paramount importance to the treating physician. Understanding the potential interactions with other recommended therapies may guide the treatment plan. Data for the efficacy of substances such as St. John's wort, high-dose folate, omega-3 fatty acids, and S-adenosyl methionine (SAMe) are limited. Therefore, they cannot be recommended as first-line options [18]. Therapeutic massage, physical exercise, meditation, and acupuncture/acupressure are also widely used with good effect but limited evidence [18].

Bipolar and Related Disorders

Management of bipolar disorder varies according to the current presentation of the patient, and it should be tailored to either acute or maintenance

Table 2 FDA-approved medications for major depressive disorders [17]

Medication	Dose range	Half-life	Considerations
Amitriptyline (TCA)	10–300 mg	10–28 h	Substrate for CYP450 2D6, 1A2
Bupropion (other)	75–450 mg, depends on formulation	4–10 h parent; active metabolite 20–27 h	Multiple formulations: Immediate release (IR), sustained release (SR), extended release (XL). Inhibits CYP450 2D6
Citalopram (SSRI)	10–40 mg, 10–20 mg if >60yo	23–45 h	Weak inhibitor of CYP450 2D6
Desipramine (TCA)	10–300 mg	24 h	Substrate for CYP450 2D6, 1A2
Desvenlafaxine (SNRI)	50–400 mg	9–13 h	Minimally metabolized by CYP450 3A4
Doxepin (TCA)	1–6 mg	8–24 h	Substrate for CYP450 2D6
Duloxetine (SNRI)	20–60 mg	12 h	Substrate for CYP450 2D6, 1A2
Escitalopram (SSRI)	5–20 mg	27–32 h	No significant CYP450 interactions
Fluoxetine (SSRI)	10–80 mg	2–3 days for parent drug, active metabolite 2 weeks	Inhibits CYP450 2D6, 3A4
Imipramine (TCA)	10–300 mg		Substrate for CYP450 2D6, 1A2
Isocarboxazid (MAOI)	10–40 mg	Up to 21 days	Significant interactions with other drugs that block serotonin reuptake
Levomilnacipran (SNRI)	20–120 mg	12 h	Substrate for CYP450 3A4
Mirtazapine (other)	7.5–45 mg	20–40 h	No significant CYP450 interactions
Nortriptyline (TCA)	10–150 mg	36 h	Substrate for CYP450 2D6
Paroxetine (SSRI)	10–60 mg	24 h	Inhibits CYP450 2D6
Phenelzine (MAOI)	15–90 mg	Up to 21 days	Significant interactions with other drugs that block serotonin reuptake
Protriptyline (TCA)	10–60 mg	74 h	Substrate for CYP450 2D6
Selegiline (MAOI)	6–12 mg/24 h	18–25 h	Transdermal patch used for depression
Sertraline (SSRI)	25–200 mg	22–36 h parent drug; 62–104 h for metabolite	Inhibits CYP450 2D6, 3A4
Tranylcypromine (MAOI)	10–40 mg	Clinical action up to 21 days	Significant interactions with other drugs that block serotonin reuptake
Trazodone (other)	50–600 mg	Biphasic half-life: 1st phase 3–6 h, 2nd phase 5–9 h	Substrate for CYP450 3A4
Venlafaxine (SSRI)	(IR) 37.5–375 mg; (XR) 37.5–225 mg	3–7 h parent drug; 9–13 h for metabolite	Immediate release, extended release formulations
Vilazodone (other)	10–40 mg	25 h	Substrate for CYP450 3A4
Vortioxetine (SSRI)	5–20 mg	66 h	Substrate for CYP450 2D6

Table 3 FDA-approved treatments for bipolar disorder [19, 20]

Acute mania	Acute bipolar depression	Bipolar maintenance
Lithium	Olanzapine/fluoxetine	Lithium
Chlorpromazine	Quetiapine, XR	Lamotrigine
Valproic acid, ER	Lurasidone[a]	Olanzapine
Olanzapine[a]	Cariprazine	Aripiprazole[a]
Risperidone[a]		Quetiapine, XR (adjunct)
Quetiapine, XR[a]		Risperidone long-acting injection[a]
Ziprasidone		Ziprasidone (adjunct)
Aripiprazole[a]		
Carbamazepine, ECR		
Asenapine[a]		
Cariprazine		

[a]Adjunctive and monotherapy. ER, ERC, XR: extended release formulations

treatment. Both phases of the illness may entail depressive or manic symptoms, and this will determine the appropriate intervention to choose (please refer to list below) (Table 3).

Acute Treatment

Mania. The goal of treatment of a manic episode is to achieve rapid relief of symptoms resulting in full remission in a safe setting. Most often, hospitalization during a manic episode is required in order to maximize patient safety. Pharmacologic therapy is the cornerstone of treatment for a manic episode, and monotherapy can be implemented using mood stabilizers or antipsychotic agents. The FDA-approved mood stabilizers include lithium, valproic acid, and carbamazepine. Lithium should be titrated slowly to prevent toxicity and is associated with moderate improvement of symptoms in 40–80% of patients after 2–3 weeks of treatment [21]. Valproic acid and carbamazepine have similar efficacy in decreasing symptoms as lithium but have a more rapid onset of action. Over 50% of patients treated with these two medications experience improvement in their manic symptoms.

Of the first-generation antipsychotics, only chlorpromazine has been FDA approved to treat acute mania. Due to frequent side effects, second-generation antipsychotics are used more often. Of the second-generation antipsychotics, risperidone, quetiapine, ziprasidone, aripiprazole, and asenapine have been approved for use as monotherapy in acute mania. All of them, except for ziprasidone, have also been approved for use as adjunctive treatments to mood stabilizers. Attention should be directed to the development of akathisia, somnolence, weight gain, and other extrapyramidal symptoms such as tardive dyskinesia when using these agents.

Depression. Only four agents have been approved for the treatment of bipolar depression. These include olanzapine + fluoxetine combination, quetiapine and quetiapine XR, lurasidone, and cariprazine. Of these, only quetiapine is approved to treat acute depression in patients suffering from bipolar II [22] and, along with cariprazine, is approved as monotherapy to treat manic episodes.

Although the use of antidepressant medications may seem the appropriate choice for treating depression in patients with bipolar disorder, there is scarce evidence for their use in the literature, with randomized controlled trials showing that antidepressants are not better than placebo in this situation [23], and they may precipitate mania or hypomania if used as monotherapy.

Mixed States. When patients meet criteria for mixed features, valproic acid is a good choice for treatment. Lithium has not shown benefit with this presentation or during rapid cycling and should be avoided.

Maintenance Treatment

Depression

In terms of unipolar depression, a general rule of thumb is that once a patient has been asymptomatic for 6 months to a year, continue to treat for 12 months for those who have had one episode of

Telegram: @medical_k

www.konkur.in

major depression, 2–3 years for those patients with two episodes of major depression, and consider lifetime maintenance treatment with antidepressants for individuals who have experienced three or more major depressive episodes in their lives.

Bipolar Disorder

For bipolar disorders, after an acute episode has been controlled, maintenance treatment should be implemented to prevent recurrence of symptoms, and the current recommendation is to continue lifelong treatment. Only two mood stabilizers are approved as monotherapy for maintenance in bipolar disorder: lithium and lamotrigine. Lamotrigine has been shown to prevent recurrence of depressive symptoms but has been linked to Stevens-Johnson syndrome. Monitoring for the development of a rash is advised. Lithium has proven to decrease the incidence of suicide but has been linked to many side effects, including renal and thyroid problems and teratogenicity. Lithium blood levels should be monitored carefully, and close attention should be given to medication interactions, as it has a very narrow therapeutic index.

While no medications have been approved to treat cyclothymic disorder, mood stabilizers may be considered on a case-by-case basis.

In addition to mood stabilizers, 5 second-generation antipsychotics have also received approval for treatment: olanzapine monotherapy, aripiprazole monotherapy and adjunctive treatment, quetiapine adjunctive treatment, risperidone long-acting injectable monotherapy and adjunctive treatment, and ziprasidone as adjunctive treatment. It is important to mention that if the primary care physician does not have experience or does not feel comfortable using any of these medications for the treatment of bipolar disorder, they should defer the care of the patient to a more experienced provider.

Psychological Therapies

In the past 40 years, 400 randomized controlled trials have investigated the beneficial effects of psychotherapies for adult depression. These modalities include cognitive-behavioral and interpersonal therapies and newer approaches, such as acceptance and commitment therapy and cognitive bias modification. It appears all of these therapies are equally effective, and a growing number of studies are focused on scaling up of psychological services, including the training of lay counselors, telephone-based psychotherapies, and Internet-based counseling [24]. It should be noted that medication therapy may not be the optimal choice for many patients with depression. Specifically, for patients with mild to moderate symptoms who do not exhibit severe impairments in overall functioning, psychotherapy may be more efficacious than pharmacologic treatment and should be considered as a first-line recommendation.

For individuals with bipolar disorders, psychoeducation focusing on the recognition of early warning signs of relapse appears to be an effective adjunct to medication management. Cognitive-behavioral therapy, family-focused therapy, and interpersonal therapy have also been found to be particularly efficacious when used as adjuncts to pharmacotherapy to improve both symptoms and overall function [22].

Physician-Administered Counseling Strategies

Family physicians are in an excellent position to teach patients selected cognitive-behavioral interventions, such as cognitive restructuring. This can be accomplished by simply teaching patients that their distorted, negative, reactive thoughts create distressful feelings (such as depression and anxiety) which, in turn, lead to increased pain and other uncomfortable somatic symptoms and subsequently to unhealthy and maladaptive behaviors. Cognitive restructuring consists of asking the patient, "What can you tell yourself. . .or what would the wise, rational, nonreactive part of you tell you to make you feel less distressed (e.g., angry, sad, anxious, etc.)?" [25]. The patient may be given "homework" to practice changing thoughts to change feelings and then asked about their success or struggles in doing this exercise at each visit. Other counseling techniques which family physicians can successfully implement in an office-based setting with depressed and bipolar patients include brief mindfulness and diaphragmatic breathing exercises [25].

Telegram: @medical_k

www.konkur.in

Other Non-pharmacological Interventions

Electroconvulsive therapy (ECT) is a well-documented and effective treatment for major depressive and bipolar disorder. It remains the gold standard of treatment for refractory depressive disorders and should be considered a first-line treatment for major depressive disorder presenting with catatonia, severe suicidality, severe psychosis or agitation, peripartum depression, and situations where a rapid response to treatment is required. For bipolar disorder, benefit has been demonstrated in studies of patients in both manic and depressive states of their illness [26].

Deep brain stimulation (DBS) is a newer intervention designed to reduce depressive symptoms but is limited to specific clinical settings and will benefit from more data on its efficacy [27]. Vagal nerve stimulation (VNS) is usually reserved for treatment-refractory cases but has no positive RCTs proving its efficacy [14]. Repetitive transcranial magnetic stimulation (rTMS) was approved by the FDA in 2008 to treat major depressive disorder in patients who failed one, but no more than two standard antidepressant trials. rTMS involves creating a powerful electrical current near the scalp delivered by repetitive pulses (microseconds) of an MRI-strength (close to 1.5 Tesla) magnetic field from a coil placed over the scalp. Sessions usually last 20–40 min, 5 days a week, typically for 6 weeks. This procedure is carried out while the patient is awake, resting in a specially equipped chair. More research is needed to test the efficacy and safety of this procedure in patients with bipolar disorder.

Light therapy is effective for the treatment of seasonal affective disorders [18].

Social Treatments

As discussed throughout, depressive and bipolar disorders can have a catastrophic impact on interpersonal, occupational, and physical functioning. However, patients should be made aware that these illnesses can be treated to remission and that their family physician will be there to support them throughout. It is important to involve social work as needed and to inquire about other support networks. By its nature, depression – whether unipolar or bipolar – is an extremely isolating illness, and every attempt should be made to engage patients in available resources, such as local or online support groups, twelve-step programs (e.g., Emotions Anonymous: http://www.emotionsanonymous.org/), and organizations such as the Depression and Bipolar Support Alliance http://www.dbsalliance.org/site/PageServer?pagename=home.

Opiate Use in Depressed Patients

The use of opiates is commonly seen in patients with chronic pain. There has been a well-established relationship between chronic pain, depression, and long-term use of opiates. Even with the use of antidepressants, many of these patients will not achieve adequate response to treatment because of their use of opioids. The use of buprenorphine, an opioid partial agonist, has been an effective tool in the primary care setting for medication-assisted treatment (MAT) by physicians who have completed training and who have met the certification requirements to prescribe this medication. Studies are still ongoing which use buprenorphine as adjunctive treatment to depression, as this medication has been shown to improve mood and satiate cravings for opiate use [28].

Special Populations

Children and Adolescents

A conservative approach is usually best with individual, group, or family therapy being the first treatment modality, adding in pharmacotherapy for the treatment-resistant or severe cases. It is recommended that when treating children and teens with depression and bipolar disorder, a child psychiatrist should be consulted early on; however, if this is not possible, caution with prescribing in these populations should be observed, as many psychotropic medications are not FDA

Telegram: @medical_k

www.konkur.in

approved for use in children. Children and adolescents differ in their pharmacokinetics from adults and require special consideration when diagnosing and treating mood disorders. Children can present with more irritability and somatic complaints than concerns about their depressed mood. Children tend to have a faster elimination rate for medications because of their greater liver/kidney parenchyma to body size, increased body water, and decreased amount of adipose tissue [29]. This faster rate of clearance means that a steady state is reached sooner, but the medications may require more frequent dosing to maintain the steady state. In addition, when prescribing antidepressants for children/teens, parents/caregivers should be given medication guides which discuss the potential warning signs of these medications. These guides are available at: http://www.fda.gov/drugs/drugsafety/informationbydrugclass/ucm096273.htm.

Older Adults

Older individuals may have confounding manifestations of other medical conditions that may resemble depression, including fatigue, decreased energy, decreased appetite, or psychomotor retardation. For this reason, a careful look should be taken to each individual case to discern between those symptoms caused by depression and those caused by a medical problem. A depression screening form especially tailored for older adults is the Geriatric Depression Scale (GDS) which may be more accurate for this population. It is important to note that depression is not a normal part of aging and it should be treated accordingly. Older adults that are diagnosed with depression at a later age for the first time should be treated at least for 2 years before treatment tapering is considered, in order to decrease the risk of recurrence.

It is important, when assessing older adults, to understand that medical and neurological comorbidities may confound recognition of the clinical features of bipolar disorder as well. It has been reported that elderly persons with bipolar disorder suffer from more medical illnesses than those without bipolar disorder [30]. These include cardiovascular disease, hypertension, type II diabetes, and obesity. Treatment considerations include minimizing or avoiding the use of medications that have anticholinergic properties, as these may affect the elderly individual by causing dry mouth, blurry vision, constipation, urinary retention, hypotension, tachycardia, cognitive impairment, and delirium. For depression and bipolar disorder, medications are generally started at half the dose that would be recommended for a younger adult and should be increased more slowly by half the recommended dose.

Pregnant and Lactating Women

The antenatal and postnatal periods are particularly vulnerable times for depression to impact the functioning of the mother. Untreated/undertreated antenatal depression is associated with a plethora of adverse outcomes including premature delivery, low infant birth weight, higher risk for developmental delay in the child, and decreased likelihood of breastfeeding initiation [31]. Postpartum depression is associated with impairment in the mother-infant attachment. Treatment is guided by risk versus benefit, with detection of depression as early as possible in the pregnancy. The decision of which antidepressant to recommend to the pregnant patient will depend on many factors including previous response to treatment and severity of illness. Like most of the antidepressants, sertraline has a “C” classification for safety in pregnancy and may be continued during breastfeeding. Sertraline and paroxetine are the preferred first-line choices for lactating women secondary to their safety profile when compared to the other antidepressants [32]. Paroxetine has a “D” classification for safety in pregnancy and should be avoided in the first trimester.

General Principles

Definition/Background

Suicide is the intentional ending of one's own life that is oftentimes the end result of another pathologic process such as substance abuse, mood disorders, or psychosis. Suicidality itself may be divided into a continuum of seriousness ranging from thoughts of death to passive and then active

suicidal ideations which range from formulation of a plan, to suicide attempts, and finally to completed suicide [1]. A related though somewhat separate entity is chronic suicidality often seen in the context of personality disorders [2, 3].

Epidemiology

In 2017, suicide was the 10th leading cause of death in the United States, accounting for the loss of more than 47,000 lives. In the 10–44 age group, it was second only to unintentional injury as a cause of mortality. Suicide drops out of the top 10 causes of death only in the group of people 65 and older, though the absolute number remains high [4].

Suicide rates vary by age, race, and gender. Teens and those in the fourth decade of life are the most likely to die by suicide. Females are twice as likely to attempt suicide, while males are four times more likely to be successful in an attempt. White Americans attempt suicide at 10 times the rate of African-Americans or Pacific Islanders, while Native Americans have roughly twice the rate of other minority groups [5]. Groups that perceive themselves to be socially isolated, such as sexual minorities, are also at increased risk [6].

Approach to the Patient

Assessment of suicide risk is a clinical decision that can only be made after a comprehensive evaluation. In 2014, the United States Preventive Services Task Force reiterated their previous I-statement regarding routine screening for suicide risk in the primary care setting, given insufficient evidence to evaluate benefit versus harm. However, this recommendation is only for the screening of asymptomatic persons [7]. Nearly half of the patients who die by suicide have seen a healthcare clinician in the preceding month [8]. Physicians should therefore remain alert for suicidal ideation among their patients, particularly among those with risk factors that are discussed below.

Diagnosis

History

Historical information may be divided into risk factors that increase the likelihood of a suicide attempt, while protective factors decrease the relative risk.

Risk Factors

Risk factors for suicide include biological, environmental, psychiatric, and social factors, though there is considerable overlap between categories. A general list of risk factors may be found in Table 1. Several risk factors deserve particular attention because of their significance. Despite psychiatric treatment, patients who have made a previous suicide attempt are at significantly increased risk for the remainder of their lives. In the year following an attempt, these patients are 100 times more likely to die by suicide than members of the general population [9]. Psychiatric disorders, especially depression with anhedonia and/or anxiety, bipolar disorder

Table 1 Risk factors for suicide [10, 12]

Biological and cultural
Male gender
Caucasian, Native American, Native Alaskan
Late adolescence, or age >60 years
Family history of suicide
Major illness or chronic disease, including chronic pain
Environmental
Recent loss of loved one
Access to means (such as firearms)
Exposure to suicide
Unemployment, or other financial stressors
Social stressors including isolation, recent humiliation, or debt
Psychiatric
Depression esp. with comorbid anxiety disorders
Bipolar disorder, esp. mixed episodes
Personality disorder
Schizophrenia, esp. with command hallucinations
Hopelessness, anhedonia
Other psychoses
Substance use disorder
Previous suicide attempt
Social
Social isolation
Never married, widowed, or divorced

Telegram: @medical_k

www.konkur.in

with a mixed episode, and personality disorders, also confer a significantly increased risk [10]. Finally, any patient with a known or suspected substance use disorder should receive special attention during episodes of depression, stress, or following stated suicidal ideation [11]. Substances are believed to contribute to suicide risk either by enabling actions the victim may otherwise be unable or too afraid to take or by their effects of impairing judgment, increasing impulsivity, and worsening depressive symptoms.

Protective Factors

There are a variety of protective factors that decrease the likelihood of suicidal behavior. These include access to healthcare, the availability of psychological treatment, a sense of being connected to family and community, being married, and cultural and religious beliefs that oppose suicide. Each of these factors provides a reason for continued living and offers hope that the symptoms of depression will improve.

Laboratory and Imaging

Laboratory and imaging orders may be considered to diagnose or exclude possible medical conditions that could be contributing to the presenting complaint of suicidal ideation. For example, obtaining a urine drug screen and blood ethanol level may be helpful in determining further risk for suicide due to impaired judgment, confirm or refute elements of the differential diagnosis such as substance dependence, and provide guidance on treatment options [13].

Special Testing

There are no validated clinical decision-making tools to assess suicide risk as the interplay of the various risk and protective factors is complex [14]. Many physicians fear inquiring about suicidal thoughts, even among patients who are known to be at high risk. This is due, at least in part, to a belief that by asking the physician may actually cause the patient to consider suicide; in fact studies have shown the opposite to be true. Patients are not more likely to make a suicide attempt if asked about ideation. In fact, many are actually relieved that their physician has inquired about a topic that they may have been too afraid to broach [15]. Direct inquiry about suicidal thoughts has also been associated with improved identification of those at risk for suicide [16]. Physicians should be alert for patients at risk for suicide and should not hesitate to discuss suicidal thoughts with their patients.

Treatment

Behavioral

When evaluating a patient who is experiencing suicidal ideation, the primary care physician must determine where the patient is on a spectrum of risk for completing suicide. According to the US Preventive Service Task Force recommendation statement, the assessment for risk of suicide is complicated by the fact that individual risk factors alone provide little predictive value about whether or not an individual will complete suicide [7, 17]. Furthermore, there is a paucity of data on what specific components should be included in a risk assessment in order to reliably predict suicide [17]. Therefore, a two-step process to guide physicians in evaluating patients who are at risk for suicide has been developed: the suicide risk assessment and the suicide risk formulation [13].

In a suicide risk assessment, information is gathered from the patient that may include general medical history, history of suicide attempts, any current or previous mental health diagnoses or treatment, family history, current symptoms, observed behaviors, information from family and associates, mental health screening tools, and the medical record. The use of alcohol, illicit substances, prescription medication abuse, and other psychosocial stressors (such as potential loss or recent loss of employment, divorce, recent diagnosis of terminal illness) should also be assessed. The assessment of suicidal ideation may include

Telegram: @medical_k

www.konkur.in

inquiries into the specificity of plan, lethality of the plan, and access to means. Additionally, a review of protective factors (i.e., resources available to the patient that tend to be protective against suicide), such as social support, religious beliefs, dependent children, willingness to seek help, is important. This information then can be synthesized for the suicide risk formulation [13, 14, 18]. The more information that is gathered in the suicide risk assessment, the better the physician will be able to estimate the patient's level of risk [14]. While there are no standard assessment questions, some questions physicians can consider within the suicide risk assessment are whether the patient has had recent or current thoughts of self-harm or death, if there is a plan to engage in self-harm, do they have access to method(s), is there intention to follow through with the plan, if there have been past attempts, if there is a family mental health history, and what has kept them from engaging in self-harm [19, 20].

There is no particular guideline to help physicians prepare the suicide risk formulation, but rather the physician considers the additive interaction of all of the risk factors for a particular patient. Regarding risk level, the physician can consider whether a patient is at acute or chronic risk. Within the acute and chronic categories, the physician must then determine whether the risk is low, intermediate, or high [2] (see Table 2).

Following placement into a risk category, the physician can develop an appropriate treatment plan. For patients at high risk, treatment may be inpatient hospitalization for stabilization. Clinicians should have a plan in place for notification of emergency transport in an efficient manner, thereby reducing unnecessary patient waiting time or leaving against medical advice. The patient should be directly monitored until emergency services arrive. If the patient refuses inpatient hospitalization, involuntary admission or commitment may be required [2]. Laws for involuntary commitment differ among states and jurisdictions.

Patients who are assessed to be in the acute but intermediate-risk category may be more challenging when developing a treatment plan. These patients may be offered inpatient hospitalization for monitoring and medication stabilization. However, they may refuse inpatient treatment as an option and may not be suitable to involuntary hospitalization due to the lack of current intent to engage in self-harm, have certain protective factors, and/or are able and willing to comply with an outpatient treatment plan. The outpatient treatment plan for these patients should be comprehensive and include a suicide safety plan, close follow-up with the specific goal of reassessment of suicidal ideation, and provision of emergency resources, such as the suicide crisis hotline, restricted access to means of self-harm, and inclusion of family/friends if possible (see Table 3). The suicide safety plan should be given to the patient and/or family members, if present, in order to ensure that the patient can refer back to

Table 2 Risk categories for suicide [2, 18]

Acute	
High risk	May include ideation with intent and/or serious risk factors that impair judgment
Intermediate risk	May have ideation and a collection of risk factors but lacks current intent
Low risk	No plan, intent, or behaviors indicating preparation for suicide
	May have had ideation but there are also protective factors present
Chronic	
High risk	Chronic mental health concerns that are uncontrolled
	Absent protective factors
	Unpredictable social stressors (relationship problems, job losses, lower socioeconomic status)
Intermediate risk	Have chronic mental health or health conditions that vacillate in stability but have protective factors and/or coping skills
Low risk	Have a history of mental health concerns but have protective factors/coping resources

Telegram: @medical_k

www.konkur.in

Table 3 Suicide safety plan components [21]

A list of coping skills/strategies that one can use to decrease symptoms. For example, the patient could generate a list of calming activities or hobbies that are enjoyable and accessible, make a list of reasons for not engaging in self-harm, and/or make a list of positive qualities, etc.	Warning signs that symptoms are worsening or symptoms to monitor such as an increase in suicidal thoughts, depressive symptoms, progression to making a plan for how to commit self-harm, increased isolation, substance use
List of resources such as crisis hotlines	Elicit any other resources that the patient might feel are helpful
Removal of items that may be used to cause self-harm	A list of social support resources (friends or family)

the steps they need to take should their symptoms worsen and require intensive intervention. A referral to psychiatry and/or therapy services might be advantageous for the patient as these specialties have access to resources and treatment options that may be unavailable to primary care physicians [2, 21].

Patients who are considered at lower risk may be described as individuals who have suicidal ideation without a plan or intent and have protective factors, and there is confidence that the patient will seek services if their symptoms increase.

There are patients who are at chronic risk for suicide due to persistent mental and/or medical illness, personality disorders, impulsivity, and engagement in substance abuse or dependence, those who have persistent psychosocial stressors, and/or those who have poor coping and problem solving skills. Treatment strategies for patients who are at higher and intermediate chronic risk include ensuring that they maintain follow-up in specialty care, are compliant with their current treatment plan, and have access to a specified suicide safety plan. Patients who are at low chronic risk may have adequate coping skills, social support, and other resources. These patients may benefit from preventive strategies such as monitoring their psychosocial environment for stressors and reiterating the availability of resources if needed [2].

Medication

The treatment plan for suicidal ideation may include initiation of medication with additional safety planning and plans for follow-up. Specialty services such as therapy and/or psychiatry consultation may also be offered [2]. If a selective serotonin reuptake inhibitor (SSRI) is initiated, the Food and Drug Administration (FDA) issued a black box warning that these medications may increase the presence of suicidal thoughts or actions during initiation of these medications in children and adults ages 18–25. However, it is important to remember that depression and other serious psychiatric illnesses are the strongest risk factors for suicide. Careful consideration of the benefit-risk ratio, detailed counseling, and close monitoring and follow-up of any patient thought to be at risk for suicide are central to management. Furthermore, other medications that hold potential for overdose or toxicity should be limited or monitored.

Prevention

Identification

Given the irreversible nature of completed suicide, prevention is of utmost importance; identification of patients at risk prior to an attempt is key. Primary care physicians must be alert for patients at risk for suicide. Those who commit suicide are likely to have been evaluated by a primary care clinician in the 30 days preceding death [8]. However, the benefit of screening for suicide risk in primary care populations is uncertain [7].

Multiple barriers exist to the disclosure of suicidal intent. These include fear of stigmatization and invasion of privacy by strangers. Truthful disclosure is encouraged by maintaining a comfortable longitudinal relationship with a

Telegram: @medical_k

www.konkur.in

provider. In the absence of previously established rapport, suicide risk assessment (either via clinical assessment or screening tool) should be done in a manner that is personal, employing both a caring attitude and genuine concern. Routine assessment by ancillary staff should be avoided as this may be perceived as impersonal and disrespectful, possibly resulting in failure to disclose suicidal thoughts to staff or clinicians [22].

Though disclosure of suicidal intent has historically relied upon an interaction between a clinician and a patient, technological advances may allow digital phenotyping to identify at-risk individuals in the future [23]. Similarly, utilizing electronic health record data combined with self-report questionnaires could allow prediction of a suicide attempt as well [24].

General Considerations

In addition to identification of at-risk patients, several other strategies may be employed to prevent suicide and suicide attempts. Educating primary care physicians has been shown to decrease rates of suicide, and though evidence is less robust, gatekeeper training may also play a role in reduction of suicide [25]. Restricting access to lethal methods through detoxification of domestic gas, decreasing pesticide absorption as well as the restriction of their sale, and limiting access to certain medications (including packaging changes) have been effective in reducing suicide rates [25, 26]. In the United States, stricter firearms legislation, specifically, has been shown to decrease incidence of both pediatric and adult suicides; however, evidence of benefit is conflicting when implemented in other countries. Furthermore, installing barriers at common jumping sites has also been shown to reduce death by suicide [25]. Education of the general public is an important component of suicide prevention, serving to promote early identification and management of mental health conditions and to destigmatize mental illness [26]. Community-based programs that integrate these principles, as well as promoting a system-wide approach to suicide prevention and supporting the implementation of comprehensive policy changes, have been successful in reducing suicide rates [27, 28]. Furthermore, family-based interventions, specifically for suicidal adolescents, decrease suicidal ideation and risk [25], and risk for older adults may be mitigated by depression screening in combination with community follow-up [29]. School-based interventions can additionally impact suicidal ideation and attempts [30]. Media engagement in suicide prevention efforts can be accomplished through responsible reporting [26, 31]. The media can serve as a vehicle for public education on a large scale. However, imprudent media reporting also can potentially worsen suicide risk by inadvertently glamorizing suicide and by publicizing suicide hot spots that may attract vulnerable persons [25, 31]. However, the effectiveness of public awareness campaigns is uncertain [25].

Therapeutic Considerations

Several psychiatric disorders, including depression, are associated with an increased likelihood of suicide [10] (see Table 1). (To this end, the USPSTF recommends screening adolescents and adults for major depressive disorder (MDD) when adequate support systems and follow-up care are available [7].) Failure to optimize treatment of conditions such as depression contributes to many suicide attempts [26], and initiation of pharmacologic therapy with SSRIs or tricyclic antidepressants has been shown to reduce rates of attempted suicide [25].

Psychotherapy for suicide attempters including cognitive therapy and interpersonal psychotherapy plays a role in reducing suicide attempts [32, 33]. In adolescents, cognitive therapy is also effective in reducing suicidal ideation and behavior [25]. An additional psychotherapeutic modality, dialectical behavioral therapy, has also been shown to reduce suicide attempts, improve treatment adherence, and reduce utilization of healthcare resources in patients with borderline personality disorder [34]. Finally, electroconvulsive therapy, often a therapeutic last resort, quickly resolves suicidal thoughts; therefore, it has been proposed

Telegram: @medical_k

www.konkur.in

that this modality might be preemptively used more often [25].

Inpatient Considerations

Attempted and completed suicide by inpatients can be limited by several interventions. Ensuring a safe environment that is free of potential means as well as adequate and supportive supervision reduces suicide risk [35, 36]. The disruptive effect of impending environmental changes or transitions – e.g., discharge, staffing changes, and variation in personnel schedules – must also be minimized by ensuring quality staff communication [35].

Follow-Up Care

Post discharge follow-up contact plays an important role in decreasing suicide risk [37]. After a failed suicide attempt, ensuring timely and frequent follow-up care (especially after ER evaluation or hospital discharge) can extend the amount of time between discharge and a repeat suicide attempt, thus allowing possible intervention and prevention of adverse events [38] (see Fig. 1). In fact, suicide risk remains markedly elevated for years after an attempt; therefore, long-term prevention efforts must extend beyond the immediate post discharge time period [39]. Particularly for adolescents hospitalized for suicidality, utilizing technology-enhanced interventions after hospital discharge may play a role in decreasing suicide attempts [40].

Emerging Environmental and Other Considerations

Emerging evidence supports several non-traditional suicide risk factors. Altitude has been proposed as a potential risk factor for suicide, presumably due to metabolic stress as a result of hypoxia [41]. Among elderly patients, lack of quality sleep seems to confer an elevated risk of suicide regardless of the presence of a mood disorder [42]. Chronic medical conditions, such as pain, could confer an increased risk of suicide. In fact, chronic pain, irrespective of type, is an independent risk factor for suicide and is associated

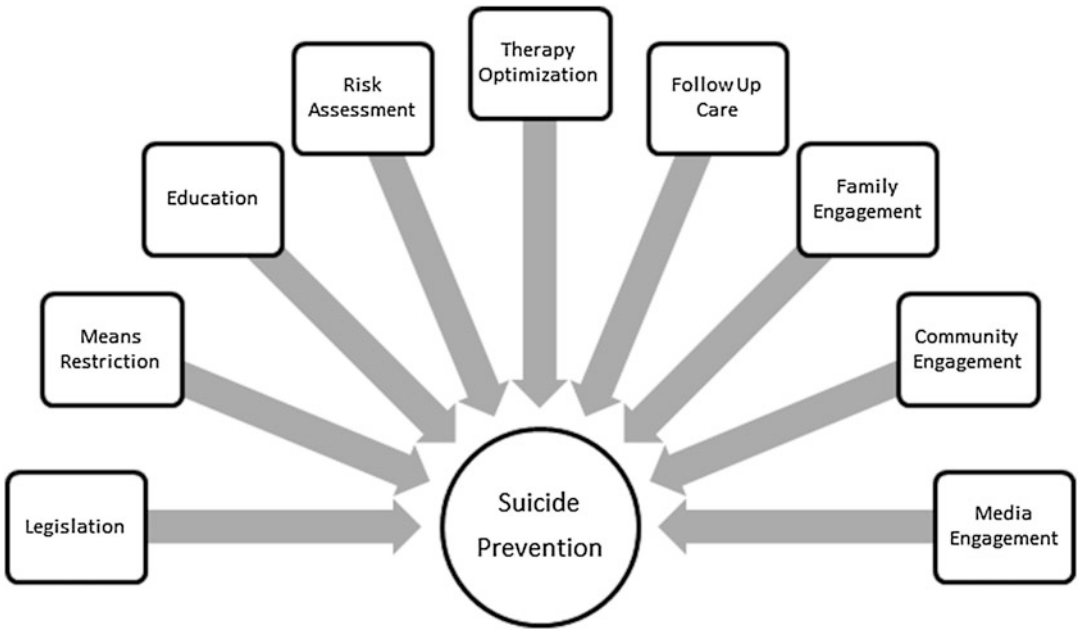

Fig. 1 Components of suicide prevention [20–22, 24, 25, 34]

Telegram: @medical_k

www.konkur.in

with a doubling of risk of suicidal thoughts as well as suicide completions [43]. Moreover, glucocorticoid therapy appears to increase the risk of attempted or completed suicide as well as utilization of hypnotic medications [44, 45]. Tobacco dependence and posttraumatic stress disorder (PTSD) are also emerging as risk factors for suicide [46]. Recent prison release seems to be associated with increased suicide risk especially in the presence of comorbid mental illness or substance abuse [47]. Future approaches aimed at mitigating suicide risk may include strategies to modify these risk factors.

Family and Community Issues

Child survivors of parental suicide are at increased risk of suicidal ideation and hospitalization for suicide attempts [34]. These children are also at risk for hospitalization related to depressive and anxiety disorders as well as other psychiatric symptoms and social maladjustment [48]. Children exposed to adverse experiences (e.g., domestic violence, divorce, a depressed or suicidal household member, or physical, sexual, or emotional abuse) are at increased risk of attempted suicide [49]. Of note, multilayered suicide prevention programs decrease the risk of moderate to severe family violence as well as overall risk for completed suicide [27, 28]. Finally, the lifetime economic burden of suicide is great, costing in billions of dollars due to medical costs and lost productivity [50].

General Principles

Introduction

Somatization is a term used to describe psychological or emotional distress manifesting in the form of physical symptoms. These complaints can be frequently seen in the primary care setting. Patients will often undergo significant medical testing to rule out organic causes. This testing can lead to unnecessary costs and potential harm.

The *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. (DSM-5) defines Somatic

Symptom and Related Disorders as the presence of physical symptoms and or excessive concern regarding medical illness or symptoms [1]. This is a change from the 4th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-4), which previously categorized these disorders as Somatoform Disorders. Another change from DSM-4 to the DSM-5 is the recognition that somatic symptoms can be present with other medical and psychiatric diagnoses. DSM-5 recognizes Somatic Symptom and Related Disorders as Somatic Symptom Disorder, Conversion Disorder, Illness Anxiety Disorder, Factitious Disorder, and Psychological Factors affecting another medical condition. Somatization that does not fit into these categories is classified as "other specified and unspecified somatic symptom and related disorders."

Epidemiology

Among patients who present to the primary care setting with physical complaints almost 25% of them have no objective evidence of a physical disease process [2]. Additionally, many patients display and perceive symptoms that can be judged to be out of proportion to the degree of illness present, or perceive symptoms that cannot be explained. Frequently, their attention to these symptoms may be excessive or even disabling.

Etiology of Somatization

Somatization disorders should be conceptualized in the setting of the biopsychosocial model which includes biological factors, psychological factors, and social factors.

Biological Factors

Unfortunately, not much is understood about the biology of somatic symptom and related disorders. Many patients with somatic symptoms often have comorbid anxiety and depressive disorders and utilize the health care system at a higher rate than those without a psychiatric diagnosis [2]. It is known that stress causes changes in the function of the hypothalamic- pituitary axis, but more studies are needed to understand the pathophysiology behind stress and somatic symptom disorders [3].

Environmental and Social Factors

Somatization can be affected by early childhood experiences, cultural beliefs, and psychological factors. Adverse childhood experiences have a significant impact on patients' personality and lifelong health outcomes with about 61% of adults reporting that they experienced at least one adverse childhood experience [4]. Adverse childhood experiences include violence, abuse, neglect, witnessing violence in the home, and growing up in a household with mental health or substance abuse problems. Alternatively, it has been hypothesized that some families have learned to communicate their needs to one another through the language of illness and suffering.

Approach to the Patient

The nature of uncertainty in somatic-related disorders brings anxiety to both the family physician and patient [5]. This anxiety can lead to difficult encounters in which both the patient and family physician experience frustration. It is important for the family physician to be mindful of their bias and perceptions of this disorder which could affect their behaviors toward the patient. The patient struggling with a somatic-related disorder is not feigning illness and there is generally no gain or incentive [5]. In patients with somatic symptom disorder, the patient's suffering is real. It has been noted that even in patients suffering from illness with a clear organic pathology, the experience of suffering is poorly correlated with the extent of tissue damage or degree of functional impairment [6].

There is a group of patients who present with prominent anxiety. They often display an increased focus on bodily signals which leads to

Telegram: @medical_k

www.konkur.in

misinterpretation of harmless signals as alarming and leads to increasing anxiety. Others present as sad and apathetic which can complicate the differentiation between major depression and sadness due to the impact of somatic symptoms. When patients present as passive, they often feel no control over their life and experience a sense of helplessness. Finally, patients may also present as distressed or puzzling to the family physician [7].

The family physician can offer to help the patient to develop the skills to cope with the symptoms and not focus simply on looking for a "cure." Coping will help patients to improve their functioning and quality of life. Patients will also benefit from receiving an explanation that is compatible with the concepts they hold about their own health. In other words, how does the patient think about their health? What do they think is going on? Is there something that makes it better? Empowering the patient to think about and articulate the answers to these questions may increase the patient's level of perceived control over their condition.

Diagnosis

Patients with somatic symptom disorders will usually present to their primary care physician rather than to a mental health professional. This may make the diagnosis of somatic symptom disorder even more difficult, since the default paradigm of the medical system tends to be based on the "ruling out" of various "serious" pathological conditions, rather than actively detecting and diagnosing somatic symptom disorders. Ideally, the diagnosis is made early and is based on the presence of positive symptoms and signs rather than the absence of medical explanations for somatic symptoms. The history of this condition is characterized by the presence of positive symptoms and signs for at least 6 months. Positive symptoms of somatic symptom and related disorders are disproportionate and excessive thoughts about the seriousness of symptoms, persistently high levels of anxiety about health or symptoms, and excessive time and energy devoted to the symptoms or health concerns [2].

Labs and imaging should be limited to only what is medically necessary to prevent unnecessary harm. Increased diagnostic testing can lead to increased false-positive results which can then lead to unnecessary procedures. There is some evidence that increased testing may have complex effects on patient experiences and may lead to increased patient anxiety [8].

Differential Diagnosis

Somatic symptom and related disorders are often comorbid with other psychiatric diagnoses as described above. This can make the differential diagnoses broad. In order to narrow down the differential, it is helpful to determine if the physical symptoms seem to have a psychiatric etiology by considering the following:

To what extent are the signs and symptoms intentionally produced?
Do the symptoms follow traumatic or stressful life events?
To what extent are the symptoms related to a psychiatric diagnosis such as anxiety or depression?
Is there a secondary gain?

Treatment

The management of somatic symptom disorder can be frustrating for the family physician. While these patients are often viewed as challenging, by cultivating the relationship those challenges can be mitigated. When symptoms are seen as medically unexplained, relationship-building strategies are a key tool in the family physician's toolbox. The management of somatic symptom disorders requires a multifaceted approach tailored to the individual patient. To choose the correct treatment plan, primary care clinicians should keep in mind psychological, social, and cultural factors that influence somatic symptoms.

It is recommended that the family physician implement the following strategies: schedule

Telegram: @medical_k

www.konkur.in

regular appointments, establish a strong therapeutic alliance, acknowledge, and legitimize the patient's symptoms, and limit diagnostic testing or referrals to specialists [9, 10] (Table 1).

Recommendations need to be used in a flexible manner as patients may have different presentations of their symptoms.

Physicians who explicitly display sensitivity to the intensity of patients' suffering facilitate the resolution of mild Medically Unexplained Symptoms (MUS). A person who is predisposed to worry in general not only about health concerns may be labeled a "somatizer" if the clinician minimizes or fails to recognize and nonverbal cues to the emotions regarding the patient's worry [11]. If the clinician does not acknowledge the patient's concerns, it can lead to an increase in patient anxiety when they feel they are not being heard. It is imperative to develop awareness of one's reactions to patients, as physicians who feel discouraged and frustrated will struggle to express genuine empathy for the patient's distress and stay present in the relationship.

As demonstrated in the previous section, the approach to the patient is vital to the treatment in primary care. When assisting patients to cope and manage their distress, utilizing non-judgmental and empathetic statements is at the forefront. Communication is a key technique that must be learned for challenging encounters, particularly when there are medically unexplained symptoms. Once the patient perceives the physician is not "on their side," management will be impacted. Some examples of wording that can be used are seen in Table 2.

Education about the symptoms and treatment, commitment to working to help the patient find a way to manage their distress, identifying goals, and negotiation of treatment goals are the main components of the process in the visits. These are techniques that are part of the treatment process. In randomized studies, treatment groups showed clear improvements in physical disability, overall mental health, and decreased use of narcotics and benzodiazepines when these components were incorporated into the visits, compared with controls [5].

Psychotherapy

Psychotherapy is an established treatment modality in patients with somatic symptoms and related disorders, but it has limitations. Various forms of psychotherapy have been recommended for a somatoform disorder such as cognitive behavioral therapy and mindfulness-based therapy. Patients who are considered for referral should be assessed for suitability for psychotherapy [12]. Further,

Table 1 Approach to the patient with somatic symptom and related disorders

Recommendations for patient approach	Purpose and goal
Schedule regular appointments	Regulates the visits to the Emergency Department and excessive calls as well as avoiding the need to have symptoms to get an appointment
Establish a strong therapeutic alliance	Listen to the patient and have empathy for their suffering
Acknowledging and legitimizing patient's symptoms	Validate their experience and verbalize that what they are feeling is real while educating them about the mind and body connection
Limit diagnostics	Limit diagnostics that can be further damaging to a patient's health
Referral to specialist	When referring ensure that there is a specific question that needs to be answered versus a general referral

Table 2 Speaking to patients with medically unexplained symptoms

"Although it is not completely understood there are some interventions we can try that can help you deal with the symptoms better"	"I can see how frustrating not having an answer is for you"
"You are worried that there is something serious going on with your health"	"What are you most worried about"

Telegram: @medical_k

www.konkur.in

some patients with these concerns may never follow through with seeing a therapist because they do not agree that their distress is primarily generated by psychological factors.

Cognitive Behavioral Therapy

Cognitive behavior therapy (CBT) has been found to be an effective treatment of somatoform disorders [12, 13]. It focuses on cognitive distortions, unrealistic beliefs, worry, and behaviors that reinforce health anxiety and somatic symptoms. Maladaptive behavioral patterns (avoidance behavior) along with the socio-occupational and interpersonal impairments are also addressed [12, 13]. Benefits of cognitive behavior therapy include reduced frequency and intensity of symptoms and cost of care and improved patient functioning [12, 13].

Mindfulness-Based Therapy

Mindfulness-based therapy (MBT) has been used effectively to treat a variety of physical and psychological disorders, including depression, anxiety; as well as treating somatization disorders, including fibromyalgia, chronic fatigue syndrome, and irritable bowel syndrome.

Mindfulness-based therapies are superior to waitlisted controls in reducing pain, depression, anxiety, symptom severity, and improving quality of life [14].

A memory aid for the approach to and treatment of patients with somatic issues has been proposed. The CARE MD (Consultation/cognitive behavior therapy, Assessment, Regular visits, Empathy, Medical/psychiatric interface, Do no harm) mnemonic was developed to help primary care clinicians recall the elements of working effectively with patients who have somatic symptom disorder [15] (Table 3).

Pharmacotherapy

SSRIs or tricyclic antidepressants have been shown to be effective in alleviating symptoms in patients with somatic symptoms [9, 16].

In a meta-analysis of 94 trials, antidepressants provided substantial benefit. Amitriptyline was the most studied tricyclic and provided benefits for at least one of the following outcomes: pain, morning stiffness, global improvement, sleep, fatigue, tender point score (based on the number and severity of tender points), and functional symptoms [17].

Antidepressants can be initiated to treat psychiatric comorbidities, such as anxiety and depression, which may help in managing the overall emotional distress the person experiences. It does not, however, directly treat the distorted thinking process that is often underlying in persons with this disorder. For this reason, it is important to include psychotherapeutic interventions in the treatment of patients.

Table 3 CARE MD primary care approach

Step	Description
Consultation	Consult and/or collaborate with mental health
Assessment	Evaluate for other medical and psychiatric disorders
Regular visits	Schedule short/frequent follow-up to reduce overuse of medical care (e.g., inappropriate emergency department visits, excessive calls) and avoid the need for the generation of symptoms to get an appointment; stress coping rather than cure
Empathy	Spend most of the time listening to the patient and acknowledge that what he or she is feeling is real
Medical-psychiatric relationship	Emphasize the mind-body connection; avoid comments such as "there is nothing medically wrong with you"
Do no harm	Limit diagnostic testing and referrals to subspecialists; reassure the patient that serious medical diseases have been ruled out

Telegram: @medical_k

www.konkur.in

Cultural Considerations to Treatment Planning

While there are a vast array of cultural worldviews that influence a patient's response to health and illness, some important considerations include the ways in which the patient perceives or defines the problem, how it is expressed (somatically, behaviorally, or affectively) who should be consulted for the condition that is encountered (e.g., medical workers, lay or religious healers, support networks), as the patient or communities' own preferred treatment options.

Variables such as age, gender, race, education, ethnicity, socioeconomic status, language, sexual orientation, religion/spiritual beliefs, geographic location, and physical abilities all influence a person's culture and identity. Help-seeking behaviors may be impacted by these variables and also influence the ways in which distress is expressed by individuals. In many groups, physical symptoms may be perceived to be more acceptable than expressions of psychological or emotional distress. Therefore the expression of emotional discomfort as a somatic symptom – or the "idiom of distress" by a particular patient may be immediately clear to someone familiar with the patient's background and worldview, while another physician may have more difficulty recognizing the patient's physical symptoms as possible manifestations of psychological distress. Recognizing somatic symptoms in context, appropriately addressing symptoms that may represent serious illness, and retaining open lines of communication and trust with patients suffering from somatic symptom disorder coming from different backgrounds and conditions are the most challenging tasks faced by family physicians in everyday practice. A sound understanding of the underlying dynamics and approaches to these conditions will reduce the complexity and uncertainty that often accompany these conditions.

General Principles

Definition/Background

The diverse psychiatric disorders discussed in this chapter are unified by the fact that patients will generally not present to their family physician self-reporting their disorder, as many lack insight into the cause of their symptoms. With eating disorders, the family physician may be tipped off to the diagnosis by concerned family members or by physical signs and symptoms of the condition. Patients with personality disorders may elicit strong reactions from the physician and staff and may behave in ways that seem to contradict the achievement of good health. Within each group of disorders, there are specific diagnostic criteria described by the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [1, 2]. In either case, the specific psychiatric diagnosis may not be as important as is gaining general insights into the psychopathology and developing strategies to engage the patient as an active participant in their care.

Eating Disorders

Eating disorders encompass a range of abnormal thoughts and behaviors surrounding food, eating, and weight control. In anorexia nervosa and bulimia nervosa, distorted body image and sometimes an extreme fear of body fat are at the core of the condition. Binge-eating disorder is associated with shame, obesity, and increased risk of metabolic syndrome. Pica, rumination disorder, and avoidant/restrictive food intake disorder are not associated with disturbed self-image but may cause significant medical complications. The prevalence of any eating disorder in the general population varies throughout the world but is thought to be about 1%. They appear to be more prevalent in high-income, developed countries, but there are insufficient epidemiological studies from low- and middle-income countries [3]. There can be significant overlap among symptoms of eating disorders, and in some cases, patients do not meet criteria for a single diagnosis.

Diagnosing an eating disorder can be challenging. Patients who seek help on their own often complain of the physical sequelae of low body weight and malnutrition, such as fatigue and constipation, or the psychological symptoms associated with starvation such as depression and anxiety. For the family physician, recognizing aberrant behaviors and thoughts and treating resulting medical complications holistically can assist the patient to get the comprehensive care that is needed for effective treatment.

Anorexia Nervosa

Anorexia nervosa (AN) is a disease that most commonly manifests in adolescence or early adulthood. While it has been traditionally associated with girls and young women in high-pressure, high-achieving families and societies, it is important to recognize that all ethnicities, children, boys, and older women and men can also be affected. The hallmarks of AN are persistent and inadequate energy intake to provide metabolic needs, intense fear of gaining weight or becoming fat, and disturbed self-perception of weight and shape. The DSM-5 recognizes subtypes including restrictive, where weight loss is achieved through dieting, fasting, and/or excessive exercise, and a binge-eating/purging type, where the person

Telegram: @medical_k

www.konkur.in

abuses laxatives, diuretics, or enemas to counteract any weight gain from binge-eating. It is also important to understand that variations exist: women with type 1 diabetes are at increased risk for eating disorders and may withhold insulin to achieve weight loss [4], and there are case reports of patients who develop anorexia after gastric bypass surgery [5]. The lifetime prevalence of anorexia is 0.5% in US women. Some cultural groups, including Latino and African Americans, may express less "fat phobia." Asians may relate their decreased food intake to gastrointestinal disturbances. Anorexia is 10 times more common in females than males [6], and the age of onset is typically late adolescence.

Diagnosis

The DSM-5 has amended the requirements for diagnosing anorexia nervosa. It removed the requirement for amenorrhea and the need to be less than 85% of expected weight. The new weight loss definition requires weight below a minimally normal level for age, sex, developmental trajectory (for children and adolescents), and physical health. The Centers for Disease Control and Prevention (CDC) and World Health Organization use body mass index (BMI) less than 18.5 kg/m^2 to define low body weight in adults, and WHO uses BMI less than 17 kg/m^2 for "moderate or severe thinness." Using a BMI-for-age percentage can be helpful for children and adolescents, with BMI-for-age less than the fifth percentile to suggest underweight. The DSM-5 cautions, however, that children above that cutoff can be affected by low weight if their growth is impaired.

Patients with anorexia rarely complain of weight loss. A hallmark of the disorder is distorted self-view and continued belief in either general obesity or fat target areas on the body. Extreme malnutrition causes physiological symptoms which may be distressing enough to bring the patient to medical attention, including amenorrhea, fatigue, constipation, early satiety or bloating, palpitations, fainting, and sometimes depression or anxiety. Starvation also impairs cognitive function which further impairs insight into the disorder.

On physical exam, in addition to significant emaciation, patients may show significant abnormalities in vital signs, including hypothermia, hypotension, and bradycardia. Skin may be dry, with thinning hair and sometimes lanugo. Peripheral edema may be present when the patient stops laxative or diuretic abuse or starts to regain weight. Laboratory abnormalities are also due to chronic starvation (see Table 1).

Behavioral changes may be reported by family members, as the patient may either lack insight or feel secretive about eating and or purging activities. The degree of functional impairment varies, as some are able to continue school, professional, and social activities. More severe cases may be significantly less able to function. The differential diagnosis includes other disordered eating patterns associated with major depression, substance abuse, or schizophrenia such as avoidant/restrictive eating, but these conditions are distinguished from anorexia by the lack of fear of gaining weight. Medical conditions predisposing to poor oral intake include gastrointestinal disorders, occult malignancies, or HIV disease.

Treatment

The type and intensity of treatment for anorexia depends on the severity of weight loss and medical complications. Those with extremely low weight, comorbid medical conditions, or significant laboratory and physical abnormalities need to be hospitalized for close monitoring as refeeding is started. The medical goals of treatment include replacing electrolytes and monitoring the refeeding process. Refeeding syndrome is a serious complication which can lead to significant fluid and electrolyte shifts that can predispose to heart failure and sudden cardiac death. Preventing refeeding syndrome requires a structured refeeding plan with careful increases in calories and protein as well as monitoring of electrolytes. Comprehensive eating disorder centers use a variety of protocols, but many include nasogastric

Table 1 Physical and laboratory abnormalities in anorexia nervosa

Physical signs	Notes
Marked weight loss	Weigh patient in hospital gown; do not allow her/him to look at scale
Hypothermia	Temp <96% F may indicate need for admission
Hypotension, orthostasis	SBP < 90, positive orthostasis, consider admission
Sinus bradycardia	<50 BPM day, <45 BPM night, consider admission
Murmur	Mitral valve prolapse can develop with starvation
Dry, brittle hair and nails	Chronic malnutrition
Lanugo	Chronic starvation and hypothermia
Peripheral edema	Heart muscle wasting, response to refeeding
Abdominal bloating	Can occur with any refeeding
Lab and ECG abnormalities	
Sinus bradycardia, prolonged QTc	Combination predisposes to ventricular arrhythmias and sudden cardiac death
↓ glucose, potassium, calcium, magnesium, phosphorous	Particularly dangerous in the setting of prolonged QTc
↑ blood urea nitrogen (BUN), creatinine	Dehydration, prolonged activation of renin-angiotensin-aldosterone system
↑ alanine aminotransferase (ALT), aspartate aminotransferase (AST)	Steatosis from prolonged or severe starvation
↓ triiodothyronine (T3), ↑thyroxine (T4)/T3 ratio Normal TSH	Starvation-induced euthyroid sick syndrome; self-corrects with weight gain

References [7, 8]

feeding until the patient is willing and able to eat sufficiently.

Psychiatric treatment for anorexia includes comprehensive refeeding, as the starved brain may lack the ability to develop insight about dysfunctional weight perceptions. Psychotherapeutic treatment of anorexia is crucial. The Maudsley method is a family-based therapy that is effective in teens with anorexia, especially within the first 3 years of illness. Individual cognitive behavioral therapy (CBT) and group therapies are also widely used. Selective serotonin reuptake inhibitors can be used to treat comorbid depression and anxiety, but have not been shown to improve weight gain or prevent remission [7, 9].

Prognosis

Most patients with anorexia nervosa experience full or partial resolution of their condition within 5 years of diagnosis, but up to 20% may experience chronicity [10]. The crude mortality rate is 5% per decade and often due to medical complications or suicide [1].

Bulimia Nervosa

Similar to anorexia, those with bulimia nervosa (BN) have negative feelings about their bodies and a distorted relationship with food. Unlike anorexia, patients with bulimia tend to be normal to overweight and consequently may not come to medical attention as dramatically. The hallmarks of the disorder include binge-eating with compensatory purging behaviors to avoid weight gain. Bulimia primarily affects young women and is more common than anorexia, with a prevalence in the United States of 2–3%. It occurs with similar frequency in many other high-income countries. The underlying risk factors are similar to

Telegram: @medical_k

www.konkur.in

anorexia, but there is a higher burden of comorbidity with anxiety, depression, and borderline personality disorder [1, 6, 7].

Diagnosis

The DSM-V defines binge-eating as episodes of unnaturally large food intake that is accompanied by a feeling of loss of control about eating. This must occur at least weekly over 3 months to meet criteria. Purging through induced vomiting; inappropriate use of diuretics, emetics, or laxatives or excessive exercise are also key to the diagnosis. Binging and purging behaviors may vary over time; some patients may continue to binge without subsequent purging, leading to crossover to binge-eating disorder. While some with anorexia exhibit binge-purge behavior, the diagnoses can be easily distinguished as anorexia requires the patient to have a low BMI.

Medical complications can include menstrual irregularities or amenorrhea. Diuretic or laxative abuse can lead to significant electrolyte disturbances, especially hypokalemia, and consistent laxative abuse can lead to dependence on them for bowel movements. Tooth enamel erosion from repeated exposure to gastric acid is sometimes visible on the lingual surface of the teeth. Rare complications include esophageal tears, gastric rupture, and cardiac arrhythmias. Patients are often ashamed of the binging and purging and may try to hide their behaviors. In between binging episodes, patients may restrict or "diet" to avoid further weight gain.

Treatment

The severity of electrolyte or GI abnormalities dictates the intensity of medical treatment. Patients with severe electrolyte disturbances require hospitalization for electrolyte monitoring and repletion, although they generally correct rapidly once purging has stopped. Treatment of laxative-induced constipation is managed with a combination of reassurance that bowel function will return and judicious use of an osmotic laxative (see Table 2). Cognitive behavioral therapy is the mainstay for treating bulimia. Adjunctive medication, especially high-dose fluoxetine (60 mg daily), seems to be effective in reducing binge-eating and purging. If fluoxetine is not successful, it is reasonable to try other SSRIs as second line pharmacotherapy [11].

Table 2 Abnormalities in bulimia nervosa

Physical exam signs	Notes
Normal or overweight, with fluctuations	From binging and purging
Dental enamel erosion, gum disease	Recurrent vomiting
Parotid gland enlargement	Recurrent vomiting
Calluses on knuckles, hands	Damage from teeth from recurrent self-induced vomiting
Edema	From activation of renin-angiotensin-aldosterone system from chronic laxative or diuretic abuse
Lab abnormalities	
↓ potassium, chloride, magnesium, metabolic alkalosis	From recurrent vomiting or laxative or diuretic abuse
↑ BUN, creatinine, ↑ creatine kinase (CPK)	Prolonged hypokalemia and reduced kidney perfusion from chronic hypovolemia

References from [7, 8]

Prognosis

The remission rate is 80% for bulimia, but an increased crude mortality rate of 2% per decade persists. Death is often due to suicide or, rarely, from medical complications.

Binge-Eating Disorder

Binge-eating is characterized by the same secretive, uncontrolled eating seen in bulimia, but without the accompanying purging. Those with binge-eating disorder report either a specific or generalized lack of control over what they eat that results in large amounts of food consumed quickly in the absence of physical hunger. As

Telegram: @medical_k

www.konkur.in

opposed to bulimia, where dieting often precedes binging, binge-eaters will diet after a binge. Binge-eating often results in overweight or obesity and leads to greater physical and psychosocial impairment than BMI-matched controls. Binge-eating disorder occurs in 0.8% of men and 1.6% of women in the general US population, although the prevalence is much higher among those seeking weight loss treatment. Therapies adapted from bulimia treatment include modified cognitive behavioral therapy and dialectical behavioral therapy. Additionally, some selective serotonin reuptake inhibitors may be beneficial, and topiramate (although limited by side effects) seems an effective addition to CBT for decreasing binge-eating and weight [11, 12].

Personality Disorders

Patients with personality disorders have habitual thoughts, emotions, and patterns of behaving that are maladaptive and result in impaired social functioning. These traits may be present from childhood, though they solidify in adolescence or early adulthood and tend to be stable throughout life. Personality disorders often coexist with other psychiatric and substance abuse disorders, complicating treatment of both. Personality disorders are common, with a community prevalence of 4–13% for any personality disorder, but are even more prevalent in medical settings, with estimates that 30–45% of psychiatric outpatients and about 24% of primary care patients could meet criteria for any personality disorder [13–15].

There are 10 distinct personality disorders described in the DSM-V, but a significant proportion of patients may exhibit traits of more than one disorder. As patients often lack insight into the source of their continued crises or instability, appropriate diagnosis can require repeated evaluations over time and input from others close to the patient. Given the potential for continuity and long-term doctor-patient relationships, family physicians may well see these patients more than any other specialty, including psychiatry. As patients with personality disorders can be challenging, it is important to develop strategies to recognize personality disorders and traits in order to provide the best care and minimize physician and staff frustration and burnout.

While personality disorders tend to be set from early adulthood, patients may generally function well and not come to clinical attention until later in life, often when support systems are lost. Personality disorders are distinguished from other psychiatric disorders by the fact that the fixed thought and behavior patterns occur persistently and not only in the context of a psychotic or mood disorder. Conversely, it is important to recognize that while patients may have personality traits that may be suggestive of a disorder, the threshold for diagnosis may not be reached unless those maladaptive responses cause impairment or distress.

Research is ongoing about other models of conceptualizing and categorizing personality disorders, but the DSM-V maintained its previous organizational structure for personality disorders, categorizing the disorders into clusters: A (paranoid, schizoid, schizotypal), B (antisocial, borderline, histrionic, narcissistic), and C (avoidant, dependent, obsessive-compulsive) [2].

There is growing evidence that despite the traditional view of the fixed nature of these disorders, some patients may improve symptomatically over time. The fundamental treatment for personality disorders is therapy. Cognitive behavioral therapy (CBT) and dialectical behavioral therapy (DBT) are commonly employed. CBT uses cognitive restructuring, skills training, and behavior modification to help improve functioning. DBT is a form of CBT that is widely used in borderline personality disorder and in others with suicidality and incorporates individual and group therapy. It recognizes the patient's underlying extreme reactions to events and helps the patient accept the underlying predisposition and learn skills to help overcome destructive thoughts and behaviors. Treatment of some personality disorders, such as borderline personality disorder, has been studied more thoroughly than others. There are no FDA-approved medications for treating personality disorders, but there is some evidence for

Telegram: @medical_k

www.konkur.in

off-label use for specific associated symptoms such as impulsivity, aggression, or anxiety [16].

Cluster A Personality Disorders

Patients with cluster A personality disorders often appear eccentric and odd. As children and adolescents, they may have been loners who had poor peer relationships and may have been teased for exhibiting odd behaviors and not following social norms. Those with cluster A disorders may be less likely than the general public to establish primary care, as they are essentially mistrustful.

Paranoid Personality Disorder

Patients with paranoid personality disorder have a basic and pervasive mistrust of others that is characterized by suspicions of exploitation and doubts of trustworthiness and fidelity in friends, family members, and coworkers. These characteristics can make patients difficult to get along with and make close relationships difficult. Their response to perceived threats can make them litigious and also prone to fanatical worldviews. Prevalence in the general population is likely between 2% and 4% but may be lower in primary care populations as these patients may not seek care. Some case reports indicate improvement in functioning with CBT [17].

Schizoid Personality Disorder

Those with schizoid personality disorder often appear aloof and impervious to the needs of human interaction. They almost always choose solitary hobbies and jobs and may not have any close relationships beyond first-degree relatives. National surveys suggest a prevalence of 3–5% of the general public but it is uncommon in clinical settings; patients may not see their personality traits as distressing and consequently do not seek treatment. Schizoid personality disorder is more common in families with schizophrenia, suggesting the possibility of a genetic influence.

Schizotypal Personality Disorder

Patients with schizotypal personality disorder come across as odd. They share the fundamental discomfort with intimacy with schizoid personality disorder but in addition may be eccentric and have distorted thoughts – "magical thinking" – that influences behavior and is outside of the cultural norm. They tend to be anxious in social situations and may have few close relationships. Patients with schizotypal personality disorder may seek treatment for anxiety or depression rather than for the disorder itself. The reported prevalence of about 4% is higher in the general public than it is in psychiatric or primary care settings (up to 2%). There is some evidence that low-dose atypical antipsychotic medications can improve executive function and reduce negative symptoms [16].

Cluster B

Cluster B disorders are characterized by manipulative and impulsive behavior, although the motivations for these behaviors is different; those with antisocial personality disorder manipulate others for power or acquisition, while those with borderline personality disorder will manipulate for attention and nurturing.

Antisocial Personality Disorder

Antisocial personality disorder (or psychopathy) is characterized by a pervasive disregard for the rights of others and is manifested by repeated illegal behavior, deceitfulness, impulsivity, aggressiveness, consistent irresponsibility, and lack of remorse. While the diagnosis cannot be made until age 18, evidence of conduct disorder starting by age 15 is part of the criteria. While the overall prevalence of this disorder is low – 0.6–

Telegram: @medical_k

www.konkur.in

3% – not surprisingly, the rate is much higher among those in the criminal justice system, where just under 50% of prisoners worldwide meet criteria [18]. The condition is also commonly associated with other psychiatric conditions and can complicate the treatment of the same. Evidence-based pharmacologic research is limited to therapies for impulsive aggression that suggest benefit from lithium and phenytoin [16].

Borderline Personality Disorder

Borderline personality disorder appears to be relatively uncommon in the general population – about 2% – but comprise 6% of primary care visits, 10% of those in outpatient mental health clinics and 20% of inpatient psychiatric patients [19]. The fundamental criteria of this disorder include pervasive instability of interpersonal relationships and self-image, resulting in significant impulsivity, including suicidality and self-mutilation . Those with borderline personality disorder constantly guard against real or imagined abandonment, and this fear drives intense and unstable relationships and a sense of constant crisis. Patients with borderline personality disorder may initially idealize certain providers or partners, only to suddenly "flip" or "split" and devalue them when the perceived support is not sufficient. This "splitting" is frequently the first concrete sign of this personality disorder noted by providers. There is significant overlap with other psychiatric disorders, including mood disorders, eating disorders (especially bulimia), and substance abuse.

Borderline personality disorder is the most studied personality disorder, with extensive evidence about therapy and psychopharmacologic treatments. CBT and DBT can be effective; evidence-based guidelines recommend selective serotonin reuptake inhibitors for impulsive aggression and have found some benefit from aripiprazole, mood stabilizers, and anticonvulsants, especially topiramate, on multiple symptoms. However, studies show minimal effect on overall disease severity and many of these medications require monitoring and they can have significant side effects [20].

Histrionic Personality Disorder

Histrionic personality disorder manifests by patients who are excessively emotional and attention-seeking. They will use speech, dress, or sexual provocativeness or other means to maintain the center of attention. This resulting drama can impair job and relationships as they are needy for but cannot truly achieve intimacy. The prevalence is <2% in the general population, but may be higher in primary care settings because of heightened medical concerns.

Narcissistic Personality Disorder

Narcissistic personality disorder is also uncommon – 0.8% up to 6% depending on the criteria used, but may be over represented in clinical populations. People with this disorder can be grandiose, with a sense of entitlement, belief that they are special and should only associate with other special or high-level people, and may lack empathy and be extremely sensitive to any criticism or defeat.

Cluster C

Cluster C personality disorders are all characterized by anxiety that is manifested in different ways. The avoidant, dependent, and obsessive-compulsive personality disorders may coexist with mood disorders which may drive patients to seek medical attention for anxiety, depression, or somatic complaints.

Avoidant Personality Disorder

Those with avoidant personality disorder have an inordinate fear of criticism, disapproval, or rejection that manifests as social inhibition and feelings of inadequacy. They can appear as very shy, quiet, and timid and may avoid new social or job-related experiences because of fear of ridicule. The reported prevalence is about 2% in the general public. Treatment is not well studied, but

Telegram: @medical_k

www.konkur.in

small studies show improved functioning with both group and individual CBT [17].

Dependent Personality Disorder

Dependent personality disorder is characterized by a pervasive need to be cared for, paired with an inordinate fear of separation. Patients with this disorder have difficulty functioning independently, which can lead to problems at work and lead to submissive behaviors in relationships, including an unwillingness or inability to leave abusive relationships. In the primary care office, these patients may take a lot of time to feel cared for or seem unable to follow through with self-care recommendations. This disorder is uncommon, estimated at about 0.5% in the general population.

Obsessive-Compulsive Personality Disorder

Those with obsessive-compulsive personality disorder are motivated by a pervasive need for control, which is manifested by preoccupation with order, perfectionism, and inflexibility. The self-imposed high standards can cause significant anxiety and dysfunction. This disorder is distinguished from obsessive-compulsive disorder (OCD) because it lacks the presence of compulsive behaviors. These patients may live below their economic means and may be prone to hoarding. The prevalence is thought to be between 2% and 8% of the general population, making it one of the most common of the personality disorders. Multiple psychotherapeutic treatments have shown benefit, and SSRIs may be effective in treating accompanying anxiety.

Table 3 Strategies for effective engagement and management of patients with personality disorders in primary care

Cluster traits	Manifestations in primary care encounter	Strategies
Cluster A traits		
Mistrust of others	Expect critical comments, litigious threats	Allow patients to vent frustrations without confirming or confronting paranoid beliefs
Difficult to engage in therapeutic relationship	May discount recommendations	Provide consistent, professional attitude without becoming too informal
Odd thoughts and behaviors	May have unusual health beliefs	Expect and tolerate eccentric beliefs and behaviors
Excessive social anxiety	May not get more comfortable with physician relationship over time	Provide clear explanations without becoming overly friendly, warm, or humorous
Cluster B traits		
Manipulative	May be drug-seeking or have frequent disability claims	Be empathetic, but set clear limits despite angry outbursts from patients; recognize the physician's need to "do something" in response to demands
Heightened emotional responses	Suicidal threats, gestures	Set safety goals and communicate to other team members
Somatization	Frequent office visits or calls for medical concerns	May do well with regularly scheduled and somewhat frequent follow-up to minimize emergency calls and crises
Cluster C traits		
Hypersensitive to criticism, shame, or rejection	May seem evasive with direct questions	Validate patient's concerns and encourage patient to report symptoms
Fear of losing control	May perseverate on details and miss big picture	Provide thorough and detailed evaluations, but do not highlight uncertainties in treatment or prognosis
Fear of separation	May be in abusive relationships	Provide reassurance, frequent scheduled follow-up

Management in the Family Medicine Practice

As patients may exhibit traits from multiple personality disorders, lack insight into the source of their distress, and not be willing to accept a diagnosis, managing patients with personality disorders can be challenging. It may take a long and trusting doctor-patient bond for a patient to accept a referral to behavioral health. In the meantime, there are strategies the family physician can use when working with personality-disordered patients (see Table 3).

General Principles and Background

Small amounts of stress (emotional strain) are beneficial and healthy and help individuals to perform better, whether at work, in relationships, or in physical activities. Excess stress can lead to both mental and physical illness. Individuals perceive stress differently: the same demands asked of one person may cause great stress and in another hardly any. As young adults make their way through new experiences in work and relationships, they experience stress and have to learn how to navigate through it effectively. Some persons who experience high levels of stress will go on to develop persistent anxiety symptoms. Other individuals may have anxiety that does not seem related to external stressors. Sometimes a prominent familial component is present. It is often unclear whether this is a genetic predisposition or learned behavior.

www.konkur.in

Anxiety can be defined as chronic and persistent worry, which is multifocal, excessive, and difficult to control [1]. Anxiety disorders (AD) are the most common psychiatric disorder of adults, affecting as many as 30% of adolescents and adults at some point in their life [2]. They are the sixth leading cause of disability in both high- and low-income countries with the highest rates between ages 15 and 34 [3]. Anxiety disorders often have their onset in childhood and adolescence. Some anxiety disorders are more common in childhood (e.g., separation anxiety) than adulthood (e.g., generalized anxiety disorder). Developmentally, as demands to perform increase, whether in school, work, or relationships, more opportunities arise for fears to occur based on prior experiences. It is crucial that the family physician be able to recognize and assist young adult (YA) patients experiencing excessive levels of stress or AD.

Child abuse, physical punishment in childhood, a parental history of mental disorders, low socioeconomic status, and harsh or overprotective parenting styles are all associated with an increased risk of anxiety disorders [4]. In addition, social stressors include experiences of ethnic or racial discrimination, bullying, and social rejection which can result in increased stress and anxiety [5]. Another, more recent phenomenon that appears to be linked to stress and anxiety in YA is exposure to social media [6].

The Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) classifies anxiety disorders into three types. It separates primary anxiety disorders from obsessive-compulsive disorders and trauma- and stress-related disorders. Several types of primary anxiety disorders exist, including general anxiety disorder (GAD), panic disorder (PD), social anxiety disorder (SAD), specific phobias, agoraphobia, separation anxiety, and others. Young adults tend to experience specific phobias, social anxiety, panic disorder, and general anxiety disorder most often. The criteria for GAD based on the DSM-5 are as outlined below:

DSM-5 Criteria for Diagnosis of General Anxiety Disorder

- Excessive anxiety and worry about various events have occurred more days than not for at least 6 months.
- Difficulty controlling the worrying.
- Anxiety and worrying are associated with at least three of the following six symptoms: restlessness or being "on edge," being easily fatigued, difficulty with concentration, irritability, muscle tension, and sleep disturbance.
- The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in important areas of functioning (e.g., work, relationships).
- The disturbance is not due to physiologic effects of a substance or medical condition.
- The disturbance is not better accounted for by another mental disorder.

(Adapted from the American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5), 2013.)

Epidemiology

According to the National Institute of Mental Health, as many as 32% of adolescents have experienced an anxiety disorder in the last year [2]. Estimates of lifetime prevalence rates of anxiety disorders range from 13 to 33%. According to the World Health Organization, while approximately half of cases of anxiety disorder are recognized, only 1/3 are offered treatment. In one study only 20% of patients with anxiety sought help from health care, and in those who did seek help, about 25% received no treatment at all [7]. Research shows that the annual and lifetime prevalence of AD among females are 1.5–2 times as high as that of males. Patients who are nonheterosexual and gender nonconforming have a higher prevalence of all mental health problems and should be screened regularly [8]. Unemployment and chronic illness are both associated with increased risk for anxiety disorders. A growing body of literature is developing on the effects of social media in creating stress in adolescents and young adults; there is clearly a correlation between mental health problems and media use. A recent systematic review reported that social media use correlated with anxiety, depression, and psychological distress [9]. However on the other hand, social networking may also improve

Telegram: @medical_k

www.konkur.in

social support and interpersonal connectedness, which can decrease stress in YA [10].

Etiology

Persistent or disproportionate anxiety is thought to involve a dysregulation of the normal physiologic response to stressors. It is hypothesized that in disabling anxiety, people experience deficits in the extinction of fear. Human survival depends on an immediate response to a potentially injurious stimulus that leads to self-preservation. In patients with an exaggerated response to stress, minor stressors lead to an overreaction that is inappropriate to the situation and causes dysfunction in a particular situation (as in PD) or in general life functions (as in GAD). Functional MRIs in individuals with anxiety show that the areas of the brain that are most involved include the limbic tract, specifically the amygdala and the insula, as well as their connections to the prefrontal cortex [5].

Genetic predisposition for AD exists, and a good family psychiatric history is essential in all patients with possible AD. Risk in first-degree relatives of patients with an anxiety disorder is estimated to be 4–6 times higher that controls. Specific genes have been associated with PD, SAD, and GAD, but they are clearly complex and multifactorial in nature [11].

Clinical Presentation

Anxiety disorders often present to the clinician with somatic symptoms that patients do not recognize as being stress related. Common symptoms include but are not limited to the following: abdominal pain, headaches, sleep problems, chest pain, chronic back pain, episodes of tachycardia, sweating, chest tightness or difficulty breathing, shaking, and light-headedness or dizziness. Many patients have problems with concentration and present to the physician seeking treatment for attentional disorders. Many patients with AD have already used substances in an attempt to treat their disorder, most commonly alcohol and marijuana, but also sleep aids such as diphenhydramine and melatonin, and sometimes prescription drugs that might include anxiolytics. There is also a strong link between sleep deprivation and anxiety [12].

Not uncommonly patients with AD have comorbid diagnoses that most often include SUD or major depression (MD). It is important to rule out substance use disorders (SUD) when making a diagnosis of an AD in patients. Research has demonstrated that anxiety in adolescents is associated with the development of SUD in later life, and also, patients with AD are more likely to develop a SUD than those without [13].

Panic attacks (PD) are isolated episodes of a constellation of symptoms that may be precipitated by a known/expected event (going to school, public speaking, being in a crowd) or may come on suddenly without warning (see the DSM-5 criteria for PD below). Many who experience them feel as if they might die and are worried that they are having a heart attack or "going crazy." Often persons with panic attacks feel chest pain, dizziness, dread, and profuse sweating. Sometimes they have shaking and paresthesias. Very often, especially with the first attack, they end up in the Emergency Department. Although normal testing can be reassuring in the short term, the medicalization of anxiety may paradoxically result in an escalation of concern and worry.

Patients suffering from comorbid panic disorder and major depression are also at higher risk of self harm [14].

DSM-5 Criteria for Panic Disorder

(A) Recurrent unexpected panic attacks. This includes a surge of intense discomfort that peaks within minutes and includes four or more of the following symptoms: palpitations, sweating, trembling/shaking, shortness of breath, choking, chest pain, nausea or abdominal pain, dizziness, chills or heat sensations, paresthesias, derealization or depersonalization, fear of losing control or going crazy, and fear of dying.

(B) At least one of the attacks has been followed by 1 month of one or both of the following:
   1. Persistent concern or worry about additional attacks or their consequences.
   2. A significant behavior change related to the attacks (designed to avoid precipitating an attack).

Telegram: @medical_k

www.konkur.in

(C) The attack is not related to the effects of a substance or another medical condition.
(D) The disturbance is not better explained by another mental disorder.

(Adapted from the American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5), 2013.)

Differential Diagnosis

The differential diagnosis of both GAD and PD is important to consider in all patients. A thorough history and physical exam are crucial to eliminate other causes of symptoms: arrhythmias, orthostatic hypotension, thyroid disease, asthma or other pulmonary diseases, and epilepsy should be included in the differential. Screening tests to consider based on a positive history or exam might include thyroid-stimulating hormone or an electrocardiogram. An exhaustive battery of tests is unnecessary and counterproductive in most cases, as it often leaves patients feeling as if the physician has simply "given up" on finding a "real diagnosis." If the physician strongly suspects GAD or PD, it is important to state this directly at the initial visit and let the patient know that other testing is being done simply to solidify the diagnosis.

Table 1 Generalized Anxiety Disorder 7-item scale

Over the last 2 weeks, how often have you been bothered by the following problems?	Not at all	Several days	>50% days	Nearly every day
1. Feeling nervous, anxious, or on edge	0	1	2	3
2. Not being able to stop or control worrying	0	1	2	3
3. Worrying too much about different things	0	1	2	3
4. Trouble relaxing	0	1	2	3
5. Being so restless that it's hard to sit still	0	1	2	3
6. Becoming easily annoyed or irritable	0	1	2	3
7. Feeling afraid as if something awful might happen	0	1	2	3

GAD-7 Questions from Spitzer et al. [15]

Evaluation for Anxiety Disorders

Evaluation of patients for anxiety disorders should be done in a standardized fashion. The most common simple office based screening tool for evaluation of anxiety in adults is the General Anxiety Disorder-7 (GAD-7) Screen (Table 1). This is a short, seven-question tool that has been well validated for identifying problematic anxiety in adults. It can be used as an initial screening tool in patients suspected of having an anxiety disorder. These tools are simple for patients to fill out, available in multiple languages, and easy to access and evaluate.

Comorbid problems with chronic health, mental health conditions, and SUD are common in patients with AD, both as results of the condition and as precursors. Up to 35% of people with GAD self-medicate with drugs. The clinician needs to screen carefully for substance use disorders, using tools such as the CAGE or CRAFFT questions or with the assistance of behavioral health staff [16].

Treatment Options

The two primary treatment options that have proven most effective for treating anxiety in YA are cognitive behavioral therapy (CBT) and specific medications. Combining the two therapies yields greater efficacy. Mindfulness-based stress reduction (MBSR) therapy is a newer treatment

Telegram: @medical_k

www.konkur.in

modality that shows great response in some patients, especially with general stress management but also in anxiety disorders.

Cognitive Behavioral Therapy

Data on CBT show that its effectiveness is significant, but varies depending on the type of anxiety being treated [17]. Patients who are treated with CBT should be counseled that they will be making an investment in their long-term health that will benefit their mental health for the rest of their life. Usually they are asked to invest 8–12 sessions in learning valuable ways to identify potential stress-inducing situations, modify their thinking about situations, and subsequently work to change reactions that happen in response to stressors. This type of therapy can be done by different specialists in behavioral health (BH), including psychiatrists, psychologists, licensed mental healthcare providers, and some social workers with specific training in CBT. In the past 10 years, more options for CBT delivered electronically have been studied, and some are proving to be equally effective [18]. They are especially useful when working with patients in areas where there is limited access to behavioral health specialists. Many electronic applications ("apps") have been created over the past decade that are designed to assist in management of stress and anxiety, many of them using CBT or mindfulness-based stress reduction (MBSR) (see below).

Medications

Many medications have shown effectiveness in treating anxiety. The most commonly used medication in anxiety treatment are the selective serotonin reuptake inhibitors (SSRIs) and the serotonin and norepinephrine reuptake inhibitors (SNRIs). This group of medications has been well studied and proven effective in treating anxiety disorders in multiple trials with very good results and is the mainstay for treating anxiety. The drawback to using these medications are that they are slow to act. Patients need to be instructed that it will take weeks or even months for medications to become effective. This is quite difficult for someone already experiencing what they consider to be unbearable stress. Medications are usually started at the very lowest end of dosing and increased every 2–4 weeks until (1) symptoms are improved, (2) undesirable side effects are encountered, or (3) the maximum dose is reached, and patient still has no response to the medication.

Medication side effects are common and should be addressed as well. Many of the SSRIs/SNRI' have an effect on libido. This can make them less desirable for YA. Gastrointestinal distress may occur common in the first week or so but usually improves with time. Some persons experience insomnia on the medications and that is why they are usually dosed in the morning. However, other patients may experience drowsiness, so changing the dose to evening might be necessary. It is also essential to ensure that patients have an "emergency plan" in place for severe episodes of anxiety or depression. This should include who they would call or talk to and a backup such as the suicide hotline. Counseling all young adults to keep the suicide hotline number in their cell phone just in case they (or a friend) need it is important. (See Table 2 for the most commonly prescribed medications for anxiety and their dosing recommendations.)

Other Commonly Used Medications for Treatment of Chronic Anxiety

Benzodiazepines show great effectiveness in the treatment of anxiety symptoms, but due to their potential for abuse and dependence, they should rarely be used for anything but short-term treatment. They are considered second- or third-line treatment and should be avoided in patients with a history of alcohol or other SUD. When used appropriately, they can offer relief until long-term control with other medications and therapy is achieved. They are helpful in managing patients with situational anxiety, such as fear with a medical procedure or fear of flying. They are also sedating and have some amnestic properties and should never be used when working or driving.

Telegram: @medical_k

www.konkur.in

Table 2 Medications commonly used in the treatment of anxiety

Medication	Class	Trade name	Starting dose	Maximum daily dose	Side effects/other
Fluoxetine	SSRI	Prozac	10 mg QAM	80 mg	Often activating
Sertraline	SSRI	Zoloft	25 mg QAM	200 mg	Drowsiness, GI distress
Paroxetine	SSRI	Paxil	10 mg QAM	60 mg	Contraindicated in minors
Escitalopram	SSRI	Lexapro	10 mg QAM	20 mg	Sweating
Citalopram	SSRI	Celexa	20 mg QAM	60 mg	Sweating
Duloxetine	SNRI	Cymbalta	30 mg QAM	120 mg	Nausea, dry mouth
Venlafaxine	SNRI	Effexor	37.5 mg QAM	225 mg	Paresthesias
Buspirone	Azapirone	Buspar	10 mg BID	60 mg	Sweating, insomnia
Quetiapine	Antipsychotic	Seroquel	25 mg daily	300 mg	Sedating
Hydroxyzine	Antihistamine	Atarax, Vistaril	25 mg Q6°	100 mg Q6°	Sedating, for acute use

Buspirone is an azapirone anxiolytic and is effective in some patients with GAD.

Beta-blockers such as propranolol are useful in prevention of performance anxiety (such as test-taking, giving speeches, etc.), but are not useful in other types of AD. Tricyclic antidepressants also have been used successfully in treating AD, but their safety profile is less desirable, so are used less often. Anxiety is not considered a primary indication for these drugs. When using them a good cardiac history is essential as they can prolong QT interval and are more lethal if overdosed or taken by a child. Bupropion has not shown strong evidence of effectiveness in treating anxiety. Drugs that stimulate gamma-aminobutyric acid receptors (GABAergic drugs) also have been shown to have some effectiveness in treating anxiety (pregabalin, gabapentin). Prazosin has shown some efficacy in treating post-traumatic stress disorder in patients but is not useful in AD alone. Hydroxyzine is FDA approved for the treatment of anxiety and may be an option if other medications are not good options. None of these drugs have anxiety as a primary indication for their use.

When initiating treatment, the provider should generally start low and advance dosing slowly. Patients with AD are often very sensitive to medications, so should start at a lower dose. The dose can be increased every 2–4 weeks depending on tolerance. However, they are often not effective until a relatively high dose is reached. It is usually recommended that patients continue on medication for a minimum of 6–12 months of positive response before considering discontinuation of the medication. The dose should be tapered gradually over weeks to months. Relapse, unfortunately, can be common, both with treatment with CBT and medications, and may be as high as 40%. Use of alcohol should be discouraged in patients on medication for anxiety, as it may result in dangerous interactions.

Alternative Therapies for Anxiety and Stress in Young Adults

Many other treatments have been evaluated for anxiety. Most recently, MBSR has been shown to have some effectiveness in anxiety treatment and can be recommended as having moderate effectiveness [19]. Mindfulness is defined as the practice of "paying attention in a particular way: on purpose, in the present moment, and nonjudgmentally" [20]. It is a form of behavioral therapy that has its origins in Buddhism and meditation. It has become the focus of anxiety and stress treatment by many BH specialists. Many web-based apps focus on MBSR and are widely utilized by YA. Their ease of accessibility is attractive to YA patients.

Telegram: @medical_k

www.konkur.in

Endorphins released by exercise might be also helpful in alleviating stress and anxiety in young adults. Exercise has been studied as treatment for anxiety and stress, and early data seem to show that it is a good adjunctive therapy to treating both, though less effective than medications [21]. The clear health benefits of exercise make it a reasonable suggestion for stress relief in many patients if they are willing to invest the time.

Most studies done on other modalities for treatment of anxiety (including yoga, hypnosis, music, pet therapy, reiki, acupuncture, and massage therapy) do not show significant effects or are too small or of too poor quality to yield significant results. However, they do not have any adverse side effects, and many are helpful for overall mobility and fitness. The most commonly used herbal medications to treat anxiety include kava, lavender, and valerian. They are not FDA-regulated products and need to be scrutinized for authenticity and potency. They should be used very cautiously and can cause toxicity if used inappropriately or concomitantly with prescribed medications.

In recent practice, many providers are faced with young adults experiencing AD who are coming forward with requests to have their pets approved as "therapy pets." There is some data that show benefit in overall health and mood from a relationship with a pet. More literature exists about companion animals relieving loneliness than other mental illnesses, but there is some data suggesting that they do improve stress in young adults [22]. When approached about the idea of having a pet as therapy, patients should be reminded that their mental health is their responsibility, and they should be using proven methods to treat themselves. If a pet helps to ameliorate their loneliness and get them some exercise, that may be a benefit. But they should not expect getting a pet to make their anxiety disappear, and in some cases the added responsibility of caring for a pet can add to stress.

Marijuana use has become popular in YA patients as a means of decreasing stress and anxiety. All patients with anxiety should be screened for its use. As it is becoming legalized in many states, we can anticipate its use more often. Good clinical trials are lacking on its effectiveness, and its use by adolescents and YA should be discouraged as it is known to have negative effects on the developing brain [23]. We do not fully know the effects of combining marijuana with other drugs commonly used to treat depression. Cannabidiol (CBD), the nonpsychoactive component of marijuana, has some preliminary studies that suggest that it may be helpful in treating anxiety, but they are limited at this time [24].

can be included in their communities and lead meaningful lives. Developmental disability is not a disease, illness, prognosis, or set of specific cognitive or physical traits. Rather, it is a social construct, defined in the Developmental Disabilities Assistance and Bill of Rights Act of 2000 as a severe, chronic disability that manifests during the developmental period of life, and is expected to continue indefinitely. It results in substantial functional limitations in three or more areas of major life function including self-care, receptive and expressive language, learning, mobility, self-direction, capacity for independent living, and economic self-sufficiency. It is a disability that requires special interdisciplinary services and supports and lifelong, individually planned and coordinated care [1]. Developmental disabilities can result from genetics, injury, or intrauterine, perinatal, or postnatal environmental conditions. Developmental disabilities include diagnoses such as autism, cerebral palsy, epilepsy, traumatic brain injury, and intellectual disability.

Most people with developmental disabilities, even those who share the same diagnosis, have a wide range of strengths and challenges. Individual assessment, treatment, education, and support plans are required. Most individuals with developmental disabilities have complex combinations of developmental, behavioral, medical, and psychiatric conditions. The degree of disability experienced by an individual is dependent on their function as well as on the accommodations in their social and physical environment. For example, a person with an intellectual disability and mobility problem may struggle in a group where technical jargon is used, but participate well if the facilitator makes sure the room is wheelchair accessible and people use plain language. Disability can also evolve over time and can be impacted by treatments and chronic disease. Disability can be reduced by how well risks for secondary conditions are identified and managed, the variety and quality of the opportunities the person is offered, the skills they develop, and how well the person is included, served, and supported by their community.

Role of the Family Physician in Team-Based Care

Family Medicine's holistic view of health is the best approach to maximizing the potential of people with developmental disabilities. Developmental disabilities typically have primary or secondary impact on multiple organ systems and include sensory, movement, cognitive, and physical aspects. Sometimes, medical treatments or procedures can improve outcomes. Other times, focusing on building motor, communication, cognitive, or adaptive skills is a more productive approach. Interventions to educate and support families to include people with developmental disabilities in their community can also improve quality of life and health. Like all patients, people with developmental disabilities need support to make healthy lifestyle choices and need preventive screening and care. Family physicians do not need to be experts in all aspects of care for people with complex disabilities. They can provide routine care and take a lead in coordinating interdisciplinary teams of speech, physical, and occupational therapists, specialists, nurses, dentists, special educators, case coordinators, recreational and vocational therapists, direct support professionals, family and friends who provide treatment, care, and support.

Improving Outcomes with Prenatal Counseling and Care

Genetic Counseling and Testing

With increasing accuracy, prenatal genetic screening and diagnostic testing can identify genetic risks and traits. Diagnostic tests such as amniocentesis and chorionic villus sampling can also expose pregnancies to risks such as pregnancy loss, interventions, discrimination on the basis of the results, maternal anxiety, and false positive or negative results.

Prenatal testing, per se, does not provide women with any information on what it might be like to raise a child with a disability. It provides no information regarding where, in the wide range of

Telegram: @medical_k

www.konkur.in

possible phenotypic outcomes, their child might fall. Genetic tests can't tell parents what services, supports, and resources are available to help them; what a child's strengths will be; what they will contribute to their family or community; or what treatments are available now or will be in the future. When counseling women, it is important to provide accurate and unbiased information on all of these issues so they can make informed choices about their pregnancy. Women may use the information to decide to pursue a termination; ensure they deliver at a hospital with an appropriate level of care; or to prepare themselves to welcome their child into a nurturing environment. However, in many situations, prenatal testing raises more questions than it can answer.

How information is presented to families during prenatal genetic counseling can impact the decisions they make regarding the pregnancy, how well they bond with their child, and how quickly they access services and social support for themselves. Even if their child does not have a disability, it can impact how they support and welcome children with disabilities from other families into their communities [2]. Accurate, balanced, and up-to-date information about common genetic conditions for expectant parents and health care providers is available from Lettercase which is a program of the National Center for Prenatal and Postnatal Resources [3].

Manage Environmental Risks and Health-Related Behaviors

Some developmental disabilities can be prevented by better managing environmental risks and health-related behaviors. Contaminated food and water supplies, infectious diseases, environmental toxins from household products, fires, industrial pollutants, poor nutrition, medications, smoking, alcohol, and drugs, and exposure to domestic or community violence can increase the incidence and prevalence of developmental disabilities. To reduce their patient's risk, family physicians can encourage immunizations, stay abreast of local environmental health issues, take a leadership role in helping their communities adapt to climate change, and participate in public health screenings and interventions which target social determinants of health.

Both younger and older maternal age are associated with increased risks for birth defects. Births to teenage mothers have been decreasing since the 1990s but are still high compared to other industrialized countries. Older maternal age is strongly associated with chromosomal birth defects which can lead to developmental disabilities [4].

Population-Based Developmental Screening for Children

Population-based screening for children for developmental disabilities refers to screening all children who present for primary care as opposed to those who have specific risk factors or when a concern is expressed. The American Academy of Pediatrics recommends conducting developmental surveillance at every health supervision visit and conducting general developmental screening using evidence-based tools at 9, 18, and 30 months. They also recommend autism-specific screening at ages 18 and 24 months [5]. The United States Preventive Services Task Force concluded that there is insufficient evidence to assess the balance of benefits and harms of screening for autism spectrum disorder between ages 18 and 30 months, or for screening for speech or language delay in children aged 5 years or younger [6, 7]. The most common screening tools are parent questionnaires such as the Ages and Stages Questionnaire, Parent's Evaluation of Developmental Status, and the Modified Checklist of Autism in Toddlers (MCHAT) [8].

Assessment

Diagnostic Evaluations

All people who are identified by population based screening; who self-identify as someone with a suspected disability; or whose parents or teachers express concern about development should receive a comprehensive developmental

Telegram: @medical_k

www.konkur.in

assessment in all areas of need. A careful prenatal, birth, and developmental history should be obtained, and if relevant, an educational and vocational history. School records and ancillary information from friends and family can help. Developmental pediatrician or genetics evaluations can be helpful if the etiology of the disability is unclear, a syndrome is suspected, or a genetic diagnosis would change the clinical management. For example, people with Down Syndrome should be monitored for conditions that include hematologic abnormalities, hypothyroidism, hearing loss, cardiac and celiac disease, and atlantoaxial instability [9]. Families may request diagnostic testing to make informed reproductive decisions or to facilitate social connections with other people with similar conditions.

Functional Evaluations

Functional evaluations should include assessments of vision, hearing, and sensory integration, neuromotor function including gait, seizure threshold, and mental health and behavior. Any difficulties with swallow, feeding, skin integrity, continence, and elimination should be assessed. Psychoeducational or neuropsychological testing may be considered. Assessment should also include questions about basic and instrumental activities of daily living. Patients often function much better at home where they may have home modifications or adaptive equipment than they do in the exam room. Alternatively, they may need prescriptions for home modifications or adaptive equipment to improve their function. For example, a patient who use a wheelchair and elevator for mobility in a doctor's office may crawl or use grab bars to walk or climb stairs at home. A person who has difficulty remaining calm in a clinic due to sensory overstimulation may be calm and regulated at home. Home and telehealth visits can provide a fuller picture of a patient's functional strengths and challenges. Observing someone's function in their natural environment may suggest ways in which the environment in their home or community may be improved.

Communication Evaluations

Communication is essential for developing and maintaining relationships, patient care, and self-direction. Everybody communicates. Most people have multiple ways in which they express themselves such as speech, body language, facial expressions, vocalizations, pointing, writing, typing, and picture icons. Find a way. Don't give up. It may take time. Behavior can be a form of communication. However, not all behavior is communication. Some behavior is impulsive, stereotyped, frozen due to seizure activity or difficulty with initiation, or out of a person's conscious control such as a tic. People who have significant motor dyspraxia, which is common in cerebral palsy and autism, may have normal cognition with significant difficulty with speech and other forms of expressive communication.

Speech is a complex motor planning function which requires the coordination of breath and dozens of facial muscles. It utilizes different parts of the brain than other language functions such as reading, encoding and retrieving memories, vision, and hearing. No assumptions can be made about a person's cognition based upon their inability to produce clear speech. Cognition can't be assessed accurately in people who do not have a fluent form of expressive communication. When working with nonspeaking patients, ask how to best to support their communication. Give time for them to respond without interrupting, even if their response is delayed or slow. Presume that your patient understands or can learn. Speak to your patient in a normal tone, volume, and speed unless directed to make accommodations. If you are uncertain how much a patient is understanding, make sure they can see and hear you and you are using their preferred language. Speak to them directly rather than to their supporters. Ask permission to get additional information from others. Give them the same information you normally would provide to any patient. Provide information in a variety of formats such as verbally, visually, and through demonstrations or practice. Nonspeaking people should receive assessments to determine the best augmentative and alternative communication strategies [10].

Psychoeducational or Neuropsychological Assessments

Children ages 3–21 are entitled to a free, appropriate education in the least restrictive setting [11]. Many people with developmental disabilities, including those with intellectual disabilities, are pursuing higher education or are employed. Psychoeducational and neuropsychiatric testing can help identify and build on strengths and suggest adaptations and modifications to enhance learning. Educational and vocational outcomes are better when people are included in general education classrooms and workplaces [12, 13].

Effective Communication with Families

Tips for Breaking Diagnostic News

To help families hear news about a new major diagnosis in a constructive way, start by conveying in your body language, tone, and words that you genuinely like your patient. For example, you can put a small child on your knee or cuddle them in your arms, give them a warm smile or a tickle, and compliment the family's parenting. Be straightforward about the results of tests or evaluations. Avoid language or tone that implies that being disabled is bad or tragic. Most people with disabilities rate their quality of life similarly to nondisabled people. Expressing pessimism about quality of life or suggesting that living with a disability is suffering can lead to decisions which limit life sustaining care or opportunities and can easily become a self-fulfilling prophesy. Life expectancy and outcomes continue to improve for people with disabilities and encourage patients to connect to disability organizations which can provide patients with positive role models. Share your patient's hopes, your uncertainty, and the range of likely medical issues and outcomes. Assure the family that you will be there for them to help their child maximize their potential and help to connect them to support no matter what happens on their journey.

Practical Problem-Solving

Some families go through a grieving process where they mourn the child they thought they were going to raise and adjust to parenting a child with a disability. If parents express grief and disappointment, encourage them to get counseling so they have an appropriate time and space to work through their feelings without negatively impacting their child by expressing those feelings in front of them. Redirect the conversation to practical problem-solving and next steps.

Caregiver Assessment and Support

People with disabilities have a right to maximize their potential. So do their caregivers. Both are important. Most families find caring for a child with a disability to be very rewarding. However, if caregivers are feeling isolated, overwhelmed, burnt out, or resentful of their role, in a separate visit, assess their needs. Win-win solutions are usually possible. If caregivers feel they are not able to pursue their own goals, a meeting with a social worker or developmental services care coordinator may be necessary to develop a more sustainable service and support plan for the family. All caregivers need respite, and some caregivers may need to transfer some of their responsibilities to someone else.

Early Intervention

Children ages 0–3 are entitled to assessment and early intervention services. Every state and territory in the United States has a free or reduced cost program to provide services and supports to help babies and toddlers learn new skills and increase their success. The services may include speech, physical, behavioral therapy, infant stimulation, and respite care. It may also include durable medical equipment, adaptive equipment such as wheelchairs and voice output devices for those who are unable to produce speech [14].

Prevention and Treatment of Co-occurring and Secondary Conditions

Developmental disability is not a disease, but people with disabilities have high rates of co-occurring chronic medical conditions such as seizure disorders, arthritis, occult fractures, and psychiatric conditions. Due to sensory, cognitive, and communication challenges, illness may present in atypical ways. As a result, it may not be recognized until later in the disease process. Illness often presents as a change in function or behavior. Careful documentation of a patient's baseline behavior and function will aide in recognizing changes which indicate disease. A proactive approach to identifying undiagnosed or undertreated conditions is necessary. People with developmental disabilities should have more frequent routine visits to document baseline exam and screen for changes.

Secondary conditions are not a part of a person's disability but result from poor management of risk factors. They include things like pressure sores, aspiration pneumonia, bowel obstructions, injuries and falls, and urinary tract infections. Pressure sores can result from poorly fitted wheelchairs, pressure points on mattresses, lack of sufficient personal assistance to reposition, or skin breakdown from incontinence and poor hygiene. Aspiration pneumonia can result from unrecognized dysphagia, inappropriate food textures, positioning, or rushing when feeding. Bowel obstruction and urinary tract infections can result from poorly managed constipation. Injuries can be avoided with proper mobility devices or personal assistance, helmets or hip padding for people with generalized seizure disorders, and careful training and procedures for lifting during transfers and transportation.

Abuse and Neglect/Trauma

People with developmental disabilities are at high risk of all types of abuse including physical, emotional, sexual, and financial. They are also at risk for all types of human trafficking including child sex trafficking which is the fastest growing type of crime in the United States [15]. Family physicians should have a high index of suspicion and fulfill obligations to report any suspected mistreatment. Provide information to patients about healthy sexuality.

Trauma-informed principles should be used. Avoid physical restraint of teenagers and adults. This is often traumatizing and can lead to injuries of both patients and staff. If necessary, use sedation for medical procedures. It is not unusual for providers to ignore or downplay the agency of a disabled individual when a medical procedure is required. Providers may be tempted to accept proxy consent from a parent or conservator for physical restraint for a medical procedure. This practice is ethically questionable, at best. In all but the most urgent situations, if a patient is unable to consent, use patience and sedation if necessary. Along the same lines, consent is always required in order to touch patients or their adaptive equipment. Provide patients with information about sexual health. Respect and encourage patients to set boundaries about how and by whom they are touched [16].

Transition to Adulthood

Transition is a process, not an event. Transitions involve people, activities, and locations. The major things that provide stability in our lives are our home, major relationships, and activities such as school or work. Try not to make major changes in more than one of these at once. Start preparing children early to take increasing control of their relationships with their health care providers, personal assistants, and education. Supported decision-making is an alternative to guardianship which allows people with disabilities to retain their legal capacity to direct their lives, even if they need support from people they trust to make decisions. Encourage families to prepare children with disabilities to direct their own lives. To assist with preparing for adult life, children with disabilities should have opportunities to communicate with health professionals and service providers directly. Educate people with developmental disabilities about their conditions.

Telegram: @medical_k

www.konkur.in

They should be included in meetings where information about them will be discussed or decisions that impact them are made. Provide them with opportunities to make decisions. If transitions to new health care providers will be needed, try to stagger changes as much as possible to maximize continuity [17].

Aging with a Developmental Disability

The service needs of people with developmental disabilities may become more intense as they age, and families may not be able to provide the same level of support. While children get regular assessments through the school system, adults may need referrals or help to get functional assessments as their service needs evolve. Ideally, changing service needs should not lead to loss of home and the important relationships people with disabilities form with members of their household. Skilled nursing supports, additional personal assistance, home modifications or adaptive equipment, and when medically appropriate, access to palliative care and hospice should be made available to enable people with developmental disabilities to age in place.

Allergic Rhinitis

General Principles

Definition and Background

Allergic rhinitis is a disease characterized by clear nasal discharge, nasal itching, sneezing, and airflow obstruction, due to IgE-mediated inflammatory reaction in sensitized persons. Fatigue and malaise may occur concomitantly, leading to common labels such as "hay fever" or simply "allergies." Allergens most commonly implicated in allergic rhinitis include plant pollens, dust mites (*Dermatophagoides*), pet (cat, dog) dander, and house pests like cockroaches. Coexisting conditions include asthma, allergic conjunctivitis, atopic dermatitis, and obstructive sleep disorders. Allergic rhinitis, asthma, and atopic dermatitis are sometimes referred to as the "atopic triad." Despite being a very common disorder, allergic rhinitis remains undertreated worldwide [1].

Epidemiology

Allergic rhinitis is a highly prevalent condition that affects 15–50% of the population [2]. Disease onset starts after infancy, rising in early childhood, peaking in adolescence, and decreasing gradually in older age groups [3].

Risk factors include exposure to smoking, family history of allergic diseases, indoor and outside air pollution (living in an urban or industrial area), furry pets, carpeted floor, cockroaches, and antibiotic use [2, 4].

Due to its high prevalence, allergic rhinitis is a leading cause of productivity loss at work and school. The direct costs in the United States alone exceed US$11 billion per year, a majority

www.konkur.in

of which are drug prescriptions [5]. Allergic rhinitis is perhaps the cause of greater loss of productivity than any other disease.

Classification

Allergic rhinitis can be classified as intermittent or persistent. Allergic rhinitis is considered intermittent if exposure or symptoms occur less than 4 days per week or less than 4 weeks per year. If exposure or symptoms exceed these durations, the term persistent allergic rhinitis is applied. This distinction between intermittent and persistent helps guides treatment selection.

Clinical severity of allergic rhinitis is graded into two levels: (1) mild and (2) moderate-to-severe. The moderate-to-severe level is associated with asthma as well as sensitization to dust mite, pollen, and cat dander [6]. The use of previous classification into seasonal and perennial subtypes is now discouraged as these clinical descriptions are overlapping.

Disease coding into subcategories by specifying the triggering allergen aids in accurate diagnosis and treatment. Thus, allergic rhinitis may be coded as due to pollen, food, animal (cat or dog) hair and dander, and other allergen or, if allergen remains unknown, as unspecified. In patients with coexisting bronchial asthma, listing asthma as the primary diagnosis is recommended.

Approach to the Patient

The diagnostic approach to the patient with suspected allergic rhinitis relies on careful medical interviewing with additional supporting information from physical examination and allergen testing. In patients who report identifiable triggers or have seasonal symptoms and exhibit a clinical response to antihistamines or nasal steroid sprays, the diagnosis of allergic rhinitis is straightforward. More commonly, patients may not have a clearly identifiable trigger. Coexisting allergic disorders such as atopic dermatitis and asthma as well as a family history of these or allergic rhinitis itself increase the likelihood of allergic rhinitis.

Diagnosis

History

The chief symptoms of allergic rhinitis are nasal congestion, watery nasal discharge, nasal itchiness, and sneezing. Associated symptoms include posterior discharge of nasal secretions (postnasal drip), sniffling, and itching in eyes. Patients may be able to identify triggering allergens that provoke episodes of rhinitis, such as exposure to pet dander from cats or dogs. Others may indicate certain seasons coinciding with pollen production; however, year-round pollen production can lead to persistent symptoms.

Patients may report problems caused by posterior nasal discharge (postnasal drip). These troublesome symptoms include spasmodic cough, frequent throat clearing, coughing spells when speaking, and a sensation of choking. Allergic rhinitis affects sleep quality leading to insomnia, restless sleep, disordered breathing, nocturnal enuresis, snoring, as well as daytime sleepiness [7]. Hyposmia can occur with longstanding allergic rhinitis.

Physical Examination

Findings suggestive of allergic rhinitis include clear nasal discharge and pale discoloration of the nasal mucosa. Nasal turbinates may appear swollen and boggy with a pale bluish or pink appearance. Nasal septal perforation may occur due to inappropriate technique in using nasal steroid sprays or less common causes, such as Wegener's granulomatosis. Eyes may show conjunctival hyperemia with watery discharge. Children may exhibit darkening of periocular areas with mild puffiness termed "allergic shiners," attributed to congestion in the veins of the eyelid. Repeated upward rubbing of the nose may produce a horizontal skin crease over the nose. Physical examination may uncover coexisting asthma and atopic dermatitis.

Laboratory and Imaging

Plain radiographs of the sinuses are not recommended. Radiological imaging does not provide any specific diagnostic information relevant to

Telegram: @medical_k

www.konkur.in

allergic rhinitis. Imaging of the nasal sinuses and adjoining structures via computed tomography (CT) or magnetic resonance imaging (MRI) may be indicated when complicated chronic sinusitis with extension of infection, nasal polyposis, or a neoplasm is suspected.

Special Testing

Allergy to an antigen is a clinical diagnosis. Proof of allergen sensitivity is not needed to start empiric treatment in patients with a likely diagnosis of allergic rhinitis. A positive skin or blood test, without symptoms of allergy, does not necessarily denote that the patient has an allergy to that antigen. Allergen sensitization testing is indicated when the response to 2–4 weeks of moderate intensity anti-allergy treatment is inadequate; when the diagnosis is unclear to guide therapeutic adjustments; or when knowledge of the specific allergens involved could alter treatment recommendations. Selection of specific antigens during testing should be guided by patient's history, rather than obtaining an indiscriminate battery of tests.

Either laboratory blood testing or office-based skin testing can provide proof of sensitization to specific allergens. Both methods are considered to have similar accuracy; however, skin testing may have higher sensitivity. Furthermore, each of these two alternatives has certain benefits over each other. With blood testing, there is no risk of anaphylaxis, skin conditions such as atopic dermatitis and dermatographism can be ignored, patients can continue taking antihistamines, and skill and special equipment needed to perform skin testing are not needed. On the other hand, skin testing yields results promptly and is also less expensive than blood testing. In spite of the forgoing discussion, as discussed above, a majority of patients with allergic rhinitis can be diagnosed and managed without allergen testing.

In skin testing, allergens are introduced into the patient's skin either using the prick (puncture) or, less commonly, intradermal injection and observed for wheal and flare formation in 15–20 min. Intradermal technique is more sensitive and is often used to follow up on negative skin prick testing. Other skin testing methods such as scratch testing are less reliable and are no longer recommended. As skin testing involves introducing antigens that stimulate mast cells to release histamines and other proinflammatory cytokines via IgE binding, allergic adverse reactions including anaphylaxis are potential concerns. Skin testing is therefore contraindicated in patients with severe or uncontrolled asthma as well as any severe illness such as unstable cardiovascular conditions. Current medications should be carefully documented as medications such as antihistamines and tricyclic antidepressants may suppress the skin reaction. Finally, the standardization of allergen extracts and skin testing techniques is essential to ensure reliable results.

Blood testing involves ascertaining the serum for the presence of IgE to a set of specific allergens using an immunoassay. As enzyme-linked immunoassays are more commonly employed, the term "RAST" used to refer to radioactive-labeled assays is becoming obsolete. Sampling nasal mucosal fluid for IgE or other inflammatory markers is not recommended in routine clinical practice. Serum testing for total IgE level and for non-IgE antibodies such as IgG is not helpful in the diagnosis of allergic rhinitis.

Differential Diagnosis

Upper respiratory viral infections such as acute rhinopharyngitis may produce similar symptoms especially rhinorrhea and sneezing but often have additional features such as fever, malaise, muscle aches, and a shorter duration. Recurrent viral infections especially in children should be differentiated from seasonal allergic rhinitis episodes by careful history taking enquiring about the presence of environmental triggers and sick contacts.

Chronic sinusitis, more accurately referred to as chronic rhinosinusitis and a potential consequence of allergic rhinitis, is characterized by thick mucopurulent nasal secretions, unilateral (or sometimes bilateral) nasal discharge, sinus tenderness, and a duration of more than 2 weeks.

Since allergic rhinitis is sometimes difficult to distinguish from nonallergic rhinitis (e.g., vasomotor rhinitis or rhinitis medicamentosa), diagnostic

Telegram: @medical_k

www.konkur.in

uncertainty may remain in many patients. The proportion of nonallergic rhinitis may be as high as 50% of all cases with chronic intermittent rhinitis. However, the exact demarcation between allergic and nonallergic rhinitis remains controversial. Even among patients with allergic rhinitis, inflammatory responses in the nasal mucosa can be experimentally induced by nonspecific stimuli. This observation has led to claims that nonallergic rhinitis may only be a tendency to mucosal hyperresponsiveness rather than a specific disease entity. A careful history may uncover irritant stimuli responsible for nonallergic rhinitis such as smoke, chemicals, temperature changes, and odors.

Unusual symptoms such as unilateral rhinorrhea, persistent anosmia, recurrent epistaxis, unilateral nasal blockage, or headache indicate a more concerning cause such as granulomatous diseases, chronic rhinosinusitis, nasopharyngeal tumors, or a cerebrospinal fluid (CSF) leak.

Treatment

Behavioral and Family Issues

Physicians underestimate the impact of allergic rhinitis on their patients' lives [8]. Reduced cognitive function affecting school and work, impaired decision-making ability, and decreased self-esteem have been reported. Increased rates of learning disorders, attention, and conduct deficits impair children with allergic rhinitis in particular when obstructive sleep disorder and asthma are coexistent.

Environmental Measures

Reducing allergens in the home environment by removal of pets such as cats and dogs and house pests, for example, cockroaches, reduces the levels of the allergens but may have a limited effect on patient symptoms. Complete eradication of the allergen is usually not possible, and even reduction in levels is transient – replenishing within a few days – thereby raising issues of long-term feasibility. Intensive use of multiple methods is somewhat more effective but often impractical. Measures such as frequent washing of pets, HEPA air filtration systems, impermeable vinyl bed covers, acaricides (insecticide sprays against house dust mites), frequent washing of floors, removal of upholstered furniture, and washing bedsheets in hot water at more than 55 °C can reduce allergen levels temporarily but are associated with only transient or no improvement in symptoms.

Medications

Approach to Pharmacologic Treatment and Combination Medication Use

Intranasal corticosteroid sprays are the most effective treatment; however, many patients prefer oral medications (Table 1). Drug combinations are more effective than single drug therapy, but

Table 1 Treatment options for allergic rhinitis

Drug class	Drugs	Efficacy	Main adverse effects and cautions
Oral antihistamines, second generation	Cetirizine, loratadine, desloratadine, fexofenadine	Mild to moderate	Mucosal dryness, sedation
Intranasal steroids	Fluticasone, triamcinolone, budesonide	Moderate	Nasal dryness, epistaxis
Intranasal antihistamines	Azelastine, olopatadine	Mild to moderate	Bitter taste, epistaxis, sedation, burning sensation
Oral decongestants	Pseudoephedrine, phenylephrine	Mild	Agitation, gastrointestinal disturbances, insomnia
Intranasal decongestants	Oxymetazoline	Mild to moderate	Rebound nasal congestion, rhinitis medicamentosa
Oral leukotriene antagonists	Montelukast	Mild	
Immunotherapy	Specific subcutaneous/sublingual allergens	Moderate	Allergic reactions including anaphylaxis

Telegram: @medical_k

www.konkur.in

adding oral antihistamines to nasal corticosteroids does not confer benefit [9]. Leukotriene inhibitors and intranasal antihistamines are less effective than nasal corticosteroid sprays [10]. Intranasal antihistamines have the fastest onset of action (within minutes), while intranasal corticosteroids take a few hours to a few days.

Second-generation antihistamines are recommended for daily use based on high-quality evidence, although intermittent usage can be helpful in seasonal symptoms. Switching to a different antihistamine may sometimes work in patients who are refractory to the initial agent. The choice between oral and nasal antihistamine should be decided on patient preferences since efficacy appears to be similar.

Effectiveness and compliance with standard drug treatment is often modest, and one-third to two-thirds of children and adults have limited or no response. Such cases should be considered for allergen immunotherapy.

Oral Antihistamines

H_1 antihistamines, although only moderately effective, are most commonly used as the first line of treatment in allergic rhinitis primarily because of rapid onset of action, over-the-counter availability, and low cost. Additional benefits include once-daily oral dosing and sustained control with daily intake. These well-established medications have proven efficacy in clinical trials for the relief of rhinorrhea, sneezing, nasal itching, and nasal discharge. Additionally, these agents reduce ocular itching and watery discharge in case of concomitant allergic conjunctivitis. However, antihistamines are less effective than intranasal steroids in the treatment of allergic rhinitis.

Antihistamines are classified into first-generation agents, such as diphenhydramine, chlorpheniramine, and hydroxyzine, and second-generation drugs, for example, loratadine, desloratadine, fexofenadine, and cetirizine, which tend to be nonsedating. Both groups are considered to have similar efficacy in allergic rhinitis. First-generation agents are prone to anticholinergic (muscarinic receptors) adverse effects such as drowsiness and dry mouth. Cetirizine has been shown to be a safe and effective first-line antihistamine in allergic rhinitis [11]. Nasal mucosal dryness can become unpleasant at higher doses. Sedation can affect the ability to drive safely or work in high-risk situations such as at industrial sites. Work performance can be impaired even without drowsiness. In the elderly, cognitive impairment, delirium, blurry vision, dry mouth, constipation, and urinary retention are potential concerns with antihistamine use. Antihistamines should be avoided in children younger than 2 years of age [12].

Intranasal Corticosteroids

Intranasal steroids such as fluticasone, triamcinolone, and budesonide nasal sprays are the most effective treatments available for allergic rhinitis, yet their effectiveness is only moderate, and patients may need additional medications. Different agents in this class of medications appear to have similar efficacy, and the choice may depend on patient experience based on side effects such as aftertaste and odor. These drugs may take 1 week or more to show clinical improvement, and, as in inhalers for asthma, patient counseling about technique of application is important. Patients should be advised to flex the neck forward, keep the spray pointing posteriorly and slightly away from the nasal septum (facilitated by holding the canister in the contralateral hand), and pinch the other nostril while inhaling. Vigorous nasal inhalation and rinsing of nostrils should be avoided immediately afterward. Intranasal steroids are known to help relieve the symptoms of concomitant allergic conjunctivitis and to improve asthma control.

Adverse effects of intranasal corticosteroids include nasal dryness and epistaxis. There appears to be no long-term effects on nasal mucosa, hypothalamic-pituitary axis, bone growth in children, and the ocular lens.

Intranasal Antihistamines

Nasal antihistamines such as azelastine and olopatadine show effectiveness in reducing nasal congestion but may be associated with bitter taste, epistaxis, drowsiness, headache, and burning sensation in the nasal mucosa. A combination

Telegram: @medical_k

www.konkur.in

intranasal spray containing an antihistamine as well as a corticosteroid is superior to intranasal corticosteroid alone [10].

Oral Decongestants

Oral decongestants such as pseudoephedrine are available in combination with antihistamines, typically denoted by the suffix "-D" in the trade name. They improve the modest relief of nasal blockage by antihistamines, but the combination may be associated with excessive mucosal dryness.

Nasal Decongestants

Topical decongestants such as oxymetazoline nasal sprays are effective in reducing nasal stuffiness with an initial dose, an effect that decreases rapidly with continued use within a few days. Concern for rebound nasal congestion, termed rhinitis medicamentosa, with long-term use has led to recommendations for intermittent usage limited to 3 days at a time.

Oral Leukotriene Antagonists

Oral leukotriene receptor antagonists such as montelukast are not recommended as the primary treatment choice in allergic rhinitis due to limited efficacy. Among patients with coexisting asthma, these agents may be more appropriate. Leukotriene inhibitors show enhanced efficacy in allergic rhinitis when they are co-administered with an oral antihistamine.

Immunotherapy

Allergy immunotherapy consists of subcutaneous or sublingual exposure to gradually increasing doses of one or more antigens over 3–5 years. Immunotherapy is efficacious and cost-effective compared to standard drug treatment, and its effects last beyond the treatment course [5]. Apart from the inconvenience of twice weekly injections, allergic reactions including anaphylaxis remain a potential concern. The sublingual route appears to be safer and easier for patients as therapy can be administered at home. Along with improvement in concurrent asthma and allergic conjunctivitis, immunotherapy prevents development of new onset asthma and other allergies.

Referrals

Consultation with an allergy specialist is recommended for patients with allergic rhinitis who are not well controlled after a 2–4-week trial of pharmacologic treatment with combination medications and those with severe disease. In patients with inferior turbinate hypertrophy and inadequate response to medical therapy, referral to an ENT surgeon for surgery may be helpful. Acupuncture may be considered in selected patients based on patient preference [13].

Counseling and Patient Education

Real-world evidence indicates that patients are usually non-adherent to treatment [10]. Most patients self-medicate and use medications as needed when their symptoms return. The vast majority of patients (including allergy specialists with allergic rhinitis) do not follow the physician's recommendations [10].

Patients should be counseled about the potential adverse effects of antihistamines including sedation and impaired decision-making. Patient counseling about appropriate technique, delayed onset of symptom relief, and the importance of regular daily use are critical in ensuring effectiveness of inhaled intranasal steroids.

Prevention

Although some patients report benefit, there is inconsistent evidence for daily nasal rinsing, wearing a face mask outdoors, staying indoors especially in the early morning and after sunset, avoiding lawn mowing and leaf clearing, planting insect-pollinated flowers rather than wind-pollinated ones, drying clothes indoors, shampooing hair to remove pollen, keeping windows closed, or relocating to another geographic area during high pollen season.

The use of impermeable mattress covers from birth onward does not prevent sensitization to dust mites in infants.

www.konkur.in

Family and Community Issues

Public health awareness campaigns about allergic rhinitis appear worthwhile given its high prevalence, the availability of low-cost treatment options, as well as the very high burden on school and work productivity.

Definition

Anaphylaxis is an acute, severe, potentially life-threatening, multisystem syndrome [1]. It is characterized by the release of mast cell- and basophil-derived mediators into the circulation

A. C. Gitu (✉) · A. Skiff

[2]. It manifests as rapidly progressing airway, breathing, or circulatory problem and is usually, although not always, associated with skin and mucosal changes [3].

Biphasic anaphylaxis is recurrence of signs and symptoms occurring 1–72 h after resolution of the initial episode [2].

Epidemiology

Lifetime cumulative prevalence of anaphylaxis is reported as 5.1% in the general US population, when the criteria for diagnosis are defined as involvement of 2 or more systems, together with respiratory or cardiovascular involvement. The prevalence falls to 1.6% if a hospital visit and a threat to the patient's life are added to the above criteria [4]. The reported incidence of anaphylaxis in studies done after 2005 is approximately 50 episodes per 100,000 person-years, but estimates may be susceptible to ascertainment bias [5]. The frequency of anaphylaxis varies by geographic region (higher in areas with less sunlight), demographic group (higher in children age 0–4 years than in adults), cause (food-induced in younger people vs drug-induced and Hymenoptera in older patients), and gender (more frequent in males until 10–15 years, females more after age 15) [5].

An increase in frequency of anaphylaxis over time has been reported in the literature. However, it is debated whether this is due to increased diagnosis or due to a true increase in the frequency of the disease. At least 30% of patients who have survived an episode of anaphylaxis will experience one or more recurrences [5].

The incidence of fatal anaphylaxis ranges from 0.12 to 1.06 deaths per million person-years, while the prevalence of deaths in patients diagnosed with severe anaphylaxis is 0.3%–2% [5]. Drugs, insect stings, and food are the three leading causes of fatal anaphylaxis, with drugs being the trigger in 50% or more of cases. In several studies, food-induced anaphylaxis was more frequently fatal in younger patients (5–35 years) whereby insect- and drug-induced anaphylaxis was more frequently fatal in the older population (>35–40 years) [5]. Older age signals a greater risk of fatal anaphylaxis, potentially due to the reduced capacity to tolerate the effects of hypoxia, hypotension, and arrhythmia.

Pathogenesis

An important mechanism in many cases of anaphylaxis is that of IgE binding and cross-linking of the high affinity IgE receptor (FcεRI) on the surface of mast cells and basophils. Anaphylaxis also involves multiple other cell types such as neutrophils, monocytes, macrophages, and platelets as well as signaling through complement components, cysteinyl leukotrienes, platelet activating factor, IL-6, IL-10, and TNF-receptor 1 [2].

The understanding of anaphylaxis has evolved through the use of precision medicine to more of a mechanistic description of phenotypes with underlying endotypes supported by diagnostic biomarkers [6]. As shown in Fig. 1, these phenotypes are defined by clinical presentation into type I-like reactions, cytokine storm-like reactions, and mixed reactions. Several studies have also identified complement-mediated activation of basophils and mast cells as the underlying mechanism in some cases of severe anaphylaxis [6].

The endotypes underlying these phenotypes include IgE- and non-IgE mediated processes, direct mast cell and basophil activation, cytokine release, mixed reactions, and complement activation. Biomarkers that are involved in these processes include histamine, tryptase, and other mediators, as well as cytokines such as tumor necrosis factor alpha (TNF-α), interleukin 6 (IL-6), and interleukin-1 beta (IL-1β) [6]. In type I reactions and selected cases of cytokine-release and mixed reactions, desensitization is indicated. However, use of desensitization is not indicated in direct mast cell/basophil release due to complement activation [6].

Triggers

Anaphylactic triggers can provoke a response through IgE- and non-IgE mediated mechanisms (see Fig. 2). The more rapidly anaphylaxis

Telegram: @medical_k

www.konkur.in

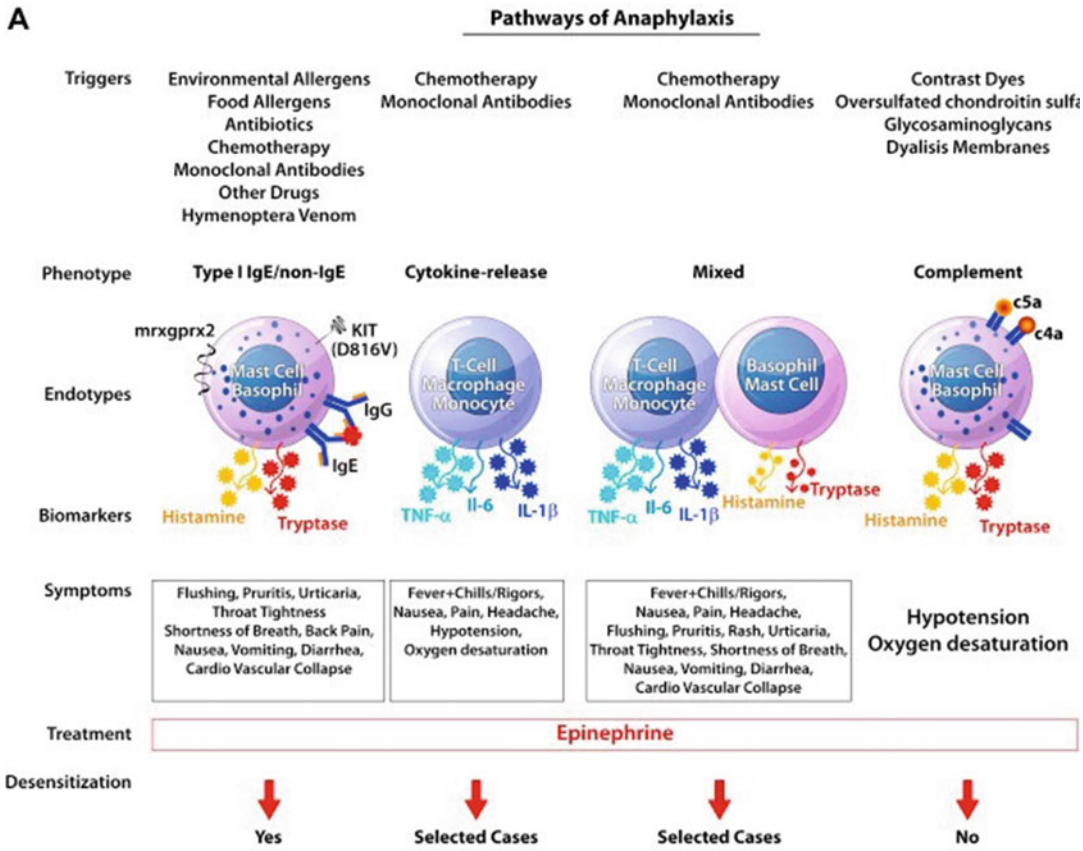

Fig. 1 Modified from [6] Used with permission

develops, the more likely the reaction is to be severe and potentially life threatening [7]. Prompt recognition of signs and symptoms of anaphylaxis is critical, and epinephrine should be administered as soon as anaphylaxis is suspected.

Food

Food is the leading cause of anaphylaxis presenting to United States emergency departments and is estimated to affect up to 8% to 11% of the US population [2]. Foods most commonly responsible for anaphylaxis include peanuts, tree nuts, shellfish, fish, milk, and egg, although any food can produce a reaction [8]. Allergy testing to foods should be considered for anyone who has experienced an anaphylactic event [8]. Patients at high-risk for fatal food-induced anaphylaxis include adolescents, patients with a prior history of a reaction, patients allergic to peanuts or tree nuts, patients with a history of asthma, and those presenting with the absence of cutaneous symptoms [8]. Special care must be taken by patients, parents, and caretakers to investigate the ingredients and contents of foods to prevent trigger-food ingestion by a patient with a known food allergy. They should also pay close attention to food advisory labeling (e.g., "may contain") which has become more prevalent. This avoidance strategy is the cornerstone of prevention for food-induced anaphylaxis.

Medications

Medications rival food as the most common cause of anaphylaxis [8]. The most common implicated classes are antibiotics, especially

Telegram: @medical_k

www.konkur.in

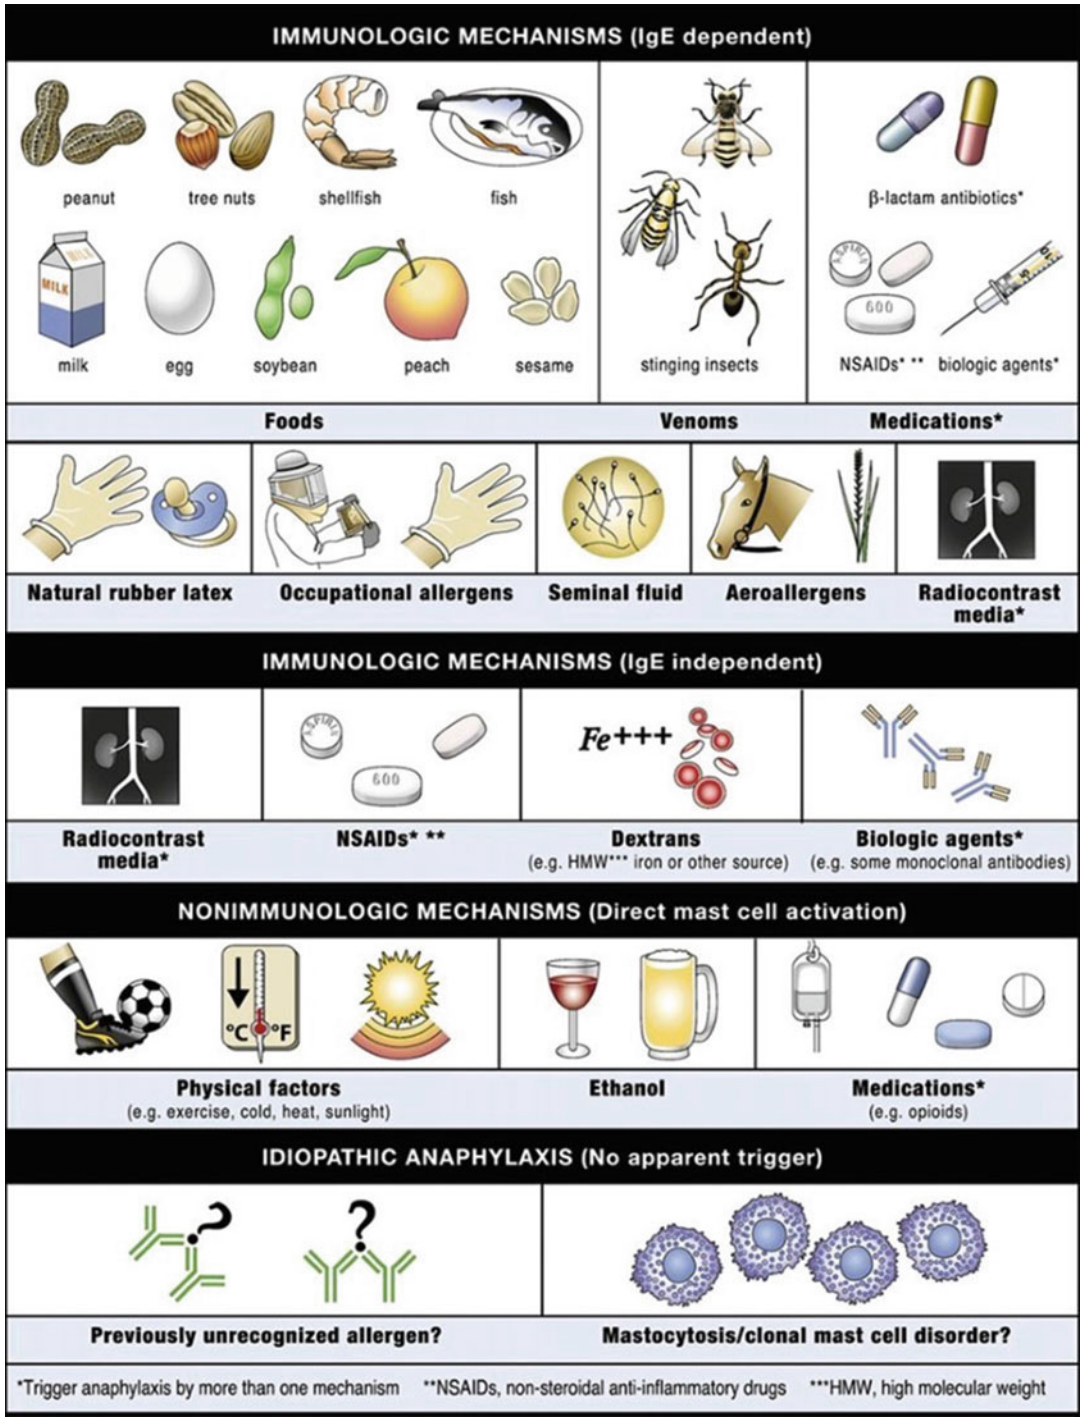

Fig. 2 Anaphylaxis mechanisms and triggers. (Adapted with permission from Elsevier [10])

β-lactam antibiotics, and nonsteroidal anti-inflammatory drugs (NSAIDS). Approximately 10% of the US population has reported allergies to penicillin. Higher rates have been reported by older patients and those that are hospitalized. However, the risk of clinically significant

Telegram: @medical_k

www.konkur.in

IgE-mediated or T lymphocyte-mediated penicillin hypersensitivity is less than 5%. IgE-mediated penicillin allergy diminishes over time, with 80% of patients becoming tolerant after 10 years [9].

In patients with penicillin allergy, cross-reactivity with cephalosporins occurs in approximately 2% of cases. However, in the subset of patients with a history of anaphylaxis after penicillin administration, around 40% have shown cross-reactivity with a cephalosporin, but this is almost exclusively with the aminocephalosporins (e.g., cefaclor, cephalexin, cefadroxil) that have similar chemical side chains or R_1 groups [9].

For patients with medium to high risk penicillin allergy histories, penicillin skin testing and referral to an allergist/immunology specialist for evaluation should be considered. Negative penicillin skin testing results carry a predictive value exceeding 95%. This approaches 100% when combined with an oral amoxicillin challenge [9].

NSAIDS are another common cause of anaphylaxis. True anaphylactic reactions appear to be specific to each NSAID. The majority of those who have experienced an anaphylactic reaction to one NSAID can tolerate a structurally unrelated NSAID [8].

Venoms

Anaphylaxis from insect stings differs clinically in children and adults. Cutaneous symptoms are the most common overall, affecting 80%; they are the sole manifestation in 15% of adults but in more than 60% of affected children [10]. Systemic reactions are reported by up to 3% of adults and 1% of children. Patients with anaphylactic reactions to an insect sting should be referred for skin testing to venom if the insect was a flying hymenoptera (e.g., bees and wasps) and to whole-body extract if the insect was a fire ant [8]. Venom immunotherapy for flying hymenoptera is 90–98% effective in preventing further anaphylactic reactions. Any patient experiencing anaphylaxis to a hymenoptera sting should have a baseline serum tryptase drawn to rule out systemic mastocytosis [8].

In addition to allergy referral, patients should be counseled on avoidance of the offending insect and prescribed an auto-injectable epinephrine with counseling on proper use.

Anesthesia/Perioperative

The precise incidence of anaphylaxis related to anesthesia is unknown. Clinical experience suggests that it is more commonly seen with general anesthesia (with an incidence of 1:10,000 to 1:20,000) than with local or spinal anesthesia [8]. The most frequent causes in the perioperative period are neuromuscular blocking agents and antibiotics [8]. However, other agents have also been implicated, such as barbiturates, opioids, blood products, and latex [8]. Management of anaphylaxis in the perioperative period is similar to anaphylaxis in other situations.

Exercise

Exercise-induced anaphylaxis (EIA) and food-dependent EIA (FDEIA) are rare but potentially life-threatening syndromes in which the association with exercise is the key defining characteristic [8]. The range of physical activity that triggers the syndrome is broad and EIA is not fully reproducible. In FDEIA, the combination of ingesting sensitizing food and exercise is required to induce symptoms [8]. Anaphylaxis occurs within a few hours of specific food ingestion and exercise, with wheat and omega-5 gliadin as the predominant triggers [6]. However, other grains, nuts, and seafood have also been reported [8].

The management of EIA must be tailored depending on the severity of symptoms, presence of co-triggers, and the patient's desire to continue to exercise. Patients must carry two epinephrine auto-injectors while exercising and stop exercising immediately at the onset of symptoms. Prophylactic treatment with corticosteroids and antihistamines is not consistently effective and often fails to prevent attacks [8].

Telegram: @medical_k

www.konkur.in

Diagnosis

The diagnosis of anaphylaxis should be made clinically. The National Institute of Allergy and Infectious Diseases proposed clinical criteria that have a sensitivity of 95% and specificity of 71% in an emergency department setting [1, 2]. Diagnosis and treatment of anaphylaxis must occur rapidly and should not be delayed for confirmatory testing, which has poor sensitivity [11].

Clinical Criteria [1]

1. Acute onset of illness with involvement of the skin, mucosal tissue, or both (e.g., generalized hives, pruritus or flushing, swollen lips, tongue, or uvula) and at least one of the following:
   (a) Respiratory compromise (e.g., dyspnea, bronchospasm, stridor, hypoxemia).
   (b) Reduced blood pressure or symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence).
2. Two or more of the following that occur rapidly after exposure to a likely allergen (for that patient):
   (a) Skin/mucosal involvement.
   (b) Respiratory compromise.
   (c) Reduced blood pressure.
   (d) Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting).
3. Reduced blood pressure (BP) after exposure to a known allergen.
   (a) Infants and children: low systolic BP (age specific) or greater than 30% decrease in systolic BP.
   (b) Adults: systolic BP of less than 90 mm Hg or greater than 30% decrease from that person's baseline.

History

An extensive history from the patient, family member, or witness should be obtained (See below) [8]. Infants, teenagers, pregnant women, and the elderly are at higher risk for serious reactions [11]. Other risk factors for severe anaphylaxis include asthma, atopy, and cardiovascular disease and potentially mast cell disorders, beta-blocker, or angiorctensin-converting enzyme inhibitor use [12].

Essential History to Obtain in the Evaluation of a Patient with an Anaphylaxis Episode

- Detailed history of ingestants (foods/medications) taken within 6 h before the event.
- Activity in which the patient was engaged at the time of the event.
- Location of the event (home, school, work, indoors/outdoors).
- Exposure to heat or cold.
- Any related bite or sting.
- Time of day or night.
- Duration of the event.
- Recurrence of symptoms after initial resolution.
- Exact nature of symptoms (e.g., if cutaneous, determine whether flush, pruritis, urticaria, or angioedema).
- In a woman, the relation between the event and her menstrual cycle.
- Was medical care given and what treatments were administered.
- How long before recovery occurred and was there a recurrence of symptoms after a symptom-free period.

Physical Exam

The evaluation should initially focus on patient stability and vital sign assessment, but then examination should shift to potentially involved organ systems. This should include lung and cardiac auscultation, assessment of tissue perfusion, abdominal exam, skin exam, cognitive assessment, and inspection of the throat and mucous membranes. The frequency of clinical manifestations is depicted in Table 1 [8].

Ancillary Studies

Treatment with epinephrine for a suspected case of anaphylaxis should not be delayed for laboratory studies. However, certain tests may be

considered in working up the differential diagnoses of anaphylaxis [11].

1. Serum tryptase –levels peak 60–90 min after the onset of symptoms and persist for 6 h.
2. Plasma histamine –levels begin to rise within 5–10 min and remain elevated for less than 60 min.
3. Plasma-free metanephrine and/or urinary vanillymandelic acid may be used if a paradoxical response to a pheochromocytoma is suspected.
4. Serum serotonin can help rule out carcinoid tumor.

Differential Diagnosis

The differential diagnosis of anaphylaxis is summarized in Table 2 [13]. Specific signs and symptoms of anaphylaxis may be seen in other disorders such as urticaria/angioedema and asthma [7].

Management of Anaphylaxis

The treatment of anaphylaxis begins with a rapid assessment and maintenance of airway, breathing, and circulation [1]. When any of the criteria of anaphylaxis are fulfilled, or if there is any other reason to suspect that a patient is experiencing anaphylaxis, epinephrine should be administered immediately. Other resuscitative therapies should also be instituted as needed, including supplemental oxygen for patients with hypoxemia or respiratory symptoms, and intravenous fluids for patients with hypotension [1].

Primary Treatment

Epinephrine is the first-line treatment for anaphylaxis and should be administered as soon as a diagnosis of anaphylaxis is suspected into the anterolateral thigh in a dose of 0.01 mg/kg to a maximum of 0.5 mg in adults and 0.3 mg in children [1, 2]. The dose should be repeated every 5–10 min as needed for refractory symptoms.

Auto-injectors are commercially available in 0.3 mL (0.3 mg) and 0.15 mL (0.15 mg) doses. Per the package insert, the 0.3 mg dose is intended for patients who weigh more than 30 kg and the 0.15 mg dose is intended for patients who weigh 15–30 kg [14]. There have been no published dose-response studies documenting the optimal dose of epinephrine. The 2015 Anaphylaxis Practice Parameter Update recommends that it would seem advisable to consider prescribing an

Excess endogenous histamine	Nonallergic angioedema
Mastocytosis/clonal mast disorders[e]	Hereditary angioedema types I, II, and III
Basophilic leukemia	ACE inhibitor-associated angioedema
	Systematic capillary leak syndrome
	Red man syndrome (vancomycin)
	Pheochromocytoma (paradoxical response)

Adapted with permission from Elsevier [10]

[a]Acute asthma symptoms, acute generalized urticarial, or myocardial infarction symptoms can also occur *during* an anaphylactic episode

[b]Histamine poisoning from fish, for examples, tuna that has been stored at an elevated temperature; usually, more than one person eating the fish is affected

[c]Pollen-food allergy syndrome (oral allergy syndrome) is elicited by fruits and vegetables containing various plant proteins that cross-react with airborne allergens. Typical symptoms include itching, tingling, and angioedema of the lips, tongue, palate, throat, and ears after eating raw, but not cooked, fruits and vegetables

[d]Distributive shock may be due to anaphylaxis or to spinal cord injury

[e]In mastocytosis and clonal mast cell disorders, there is an increased risk of anaphylaxis; also, anaphylaxis may be the first manifestation of the disease

epinephrine auto-injector in children who weigh less than 15 kg (33 pounds) [8].

As a nonselective adrenergic agonist, epinephrine works rapidly to increase peripheral vascular resistance through vasoconstriction, to increase cardiac output, to reverse bronchoconstriction and mucosal edema, and to stabilize mast cells and basophils.

Antihistamines (H_1-and H_2-antagonists) are considered second-line treatment for anaphylaxis, given their slow onset of action and inability to stabilize or prevent mast cell degranulation or to target additional mediators of anaphylaxis. Unlike epinephrine, antihistamines will not effectively treat cardiovascular and respiratory symptoms such as hypotension or bronchospasm. Antihistamines are useful for the symptomatic treatment of cutaneous symptoms such as urticaria and pruritus.

Although glucocorticoids are frequently used as an adjunctive therapy for anaphylaxis, evidence is lacking to support clinical benefit, and they should not be administered in place of epinephrine in the treatment of acute anaphylaxis [2].

Secondary Treatment

After the treatment of an anaphylactic reaction, an observation period should be considered for all patients for at least 1 h after signs and symptoms have resolved because the reaction might recur as the effect of epinephrine wears off [1]. The recurrence of biphasic reactions occurs in 3–18% of

Telegram: @medical_k

www.konkur.in

anaphylactic reactions [15]. There are no reliable clinical predictors to help identify patients at increased risk for a biphasic reaction, but severity of initial symptoms and/or the administration of >1 dose of epinephrine have been suggested as a guide to determining a patient's risk for developing biphasic anaphylaxis. Additional risk factors include wide pulse pressure, unknown anaphylaxis trigger, cutaneous signs and symptoms, and drug trigger in those younger than 18 years [2].

A reasonable length of time to consider observing the postanaphylactic patient is 4–6 h in most patients, with prolonged observation times or hospital admission for patients with severe or refractory symptoms. More caution should be used in patients with reactive airway disease because most fatalities associated with anaphylaxis occur in these patients [1].

Glucocorticoids and antihistamines are not recommended as an intervention to prevent biphasic anaphylaxis, but may be considered for the secondary treatment of anaphylaxis. In particular, antihistamines are effective therapy for the many cutaneous signs and symptoms associated with anaphylaxis including pruritus, flushing, and urticaria [16].

Discharge Plan

After diagnosis and treatment of anaphylaxis, all patients should be kept under observation until symptoms have fully resolved. They should receive education on anaphylaxis and risk of recurrence, trigger avoidance, self-injectable epinephrine education, referral to an allergist, and be educated about thresholds for further care.

Emphasis on early treatment, specifically the self-administration of epinephrine, is essential. The patient's medical history should be updated to include an electronic flag or sticker regarding their history of anaphylaxis and the trigger(s). The patient can also be instructed to wear and/or carry identification denoting the condition and can also be instructed to have telephone numbers for paramedic rescue squads and ambulance services on hand. A written action plan can be helpful in this regard.

Before discharge, consider measuring allergen-specific IgE levels in serum for assessment of sensitization to relevant allergens ascertained from the history of the anaphylactic episode.

Follow-up Plan

Follow-up with an allergist/immunology specialist is required, particularly for patients in whom the trigger is not known. Allergy/immunology specialists play a uniquely important role in preparing the patient for self-treatment in the community, confirmation of the trigger of an anaphylactic episode, education regarding allergen avoidance, and immune modulation.

Prevention

Patient education is the most important strategy to prevent recurrent anaphylaxis. The first step is that of identification of and avoidance of triggers whenever possible.

Pharmacologic prophylaxis with antihistamines and/or glucocorticoids should be administered to prevent index hypersensitivity reactions to certain chemotherapeutic agents and in patients receiving allergen immunotherapy. Such prophylaxis is not recommended for patients with prior radiocontrast hypersensitivity reactions when re-administration of a low or iso-osmolar, nonionic radio-contrast media agent is required [2].

Immunotherapy may be used, particularly for allergens that are difficult to avoid. Subcutaneous venom immunotherapy protects up to 90% of adults and 98% of children against anaphylaxis from future stings. When necessary, desensitization using a published protocol may be conducted to prevent medication-triggered anaphylaxis [17].

For patients with frequent episodes of unknown or idiopathic anaphylaxis: consider glucocorticoid and nonsedating H_1-antihistamine prophylaxis for 2–3 months; consider measurement of a baseline tryptase level to identify mastocytosis/clonal mast cell disorders [17].

Confirmation of Anaphylaxis Triggers

This is usually performed by an allergy/immunology specialist, who perform skin tests and measure specific IgE levels in the patient's serum. These tests do not distinguish between sensitization associated with increased risk of anaphylaxis, which is relatively uncommon, and asymptomatic sensitization, which is widespread; therefore, the allergens selected for testing should be relevant to the history of the anaphylactic episode [17] (Fig. 3).

General Principles

Background

The Epstein-Barr virus (EBV) is a member of the Herpesviridae virus family. Humans are the primary reservoir for EBV that targets B-lymphocytes and nasopharyngeal epithelial cells [1]. EBV has a latency phase where, following a primary infection, it infects epithelial cells, enters the circulating B lymphocyte, and persist for the life in a latent

state [2]. It is the most common causative agent of infectious mononucleosis (IM) [3]. Oral route is the primary method of transmission, attributing to the moniker "the kissing disease." There is also evidence of mutation in EBV being linked to certain types of cancers in humans [4].

Epidemiology

EBV, with more than 90% seroprevalence, is one of the most common viral infections in the world. In developing countries and people living in lower socioeconomic groups, most EBV transmission occurs in infancy and early childhood with the primary infection being asymptomatic. In the industrialized countries and members of the higher socioeconomic groups, EBV causes IM primarily among adolescents and young adults, The annual incidence of IM in the United States is estimated to be 0.5%, with the estimated annual IM incidence rates for young adults, which varies widely, ranging from about 0.2% to 0.8% for ages between 15 and 19 years [5]. This variation could be due to differences in populations studied, true geographic or epidemiologic variation, or variations due to sample size. There is no gender predisposition, yearly cycle, or seasonal variation in IM [6].

Classification

At present, EBV isolates worldwide can be grouped into Type 1 and Type 2, a classification based on variations in the virus' genetic sequence, with Type 1 EBV most prevalent worldwide and Type 2 EBV more common in parts of Africa [7]. This genome variation is important as it may contribute to some of the diseases associated with EBV.

Approach to the Patient

EBV-induced IM should be suspected when an adolescent or young adult complains of sore throat, fever, and malaise and also has pharyngitis and lymphadenopathy. An algorithmic approach can be used [8], especially when considering IM-like illnesses in the differential diagnosis to ensure that conditions warranting specific therapy are distinguished from others requiring only supportive care [9].

Diagnosis

History

The natural history of IM is highly variable, owing to differences in patient populations, criteria used for diagnosis, and methods used for description, and majority of the patients recover without apparent sequelae [6]. EBV has an incubation period of approximately 30–50 days, and whether an individual develops IM depends on the timing of exposure to the virus. Children often present with nonspecific or no symptoms. Young adults tend to present with sore throat, fever, fatigue, and malaise. An older age at infection is generally considered a risk factor for severe EBV primary infection [10]. Cough, rash, arthralgias, myalgias, nausea, and somnolence are unusual symptoms, present in $<10\%$ of patients [11].

Physical Examination

Pharyngitis, fever, and lymphadenopathy constitute the classic triad of presenting signs, occurring in over 80% of patients with IM. Splenomegaly may not be detectable upon physical examination, but ultrasound assessment of splenic size during acute IM has shown that all patients develop splenomegaly of varying degrees [12]. Splenic rupture should be suspected in a patient presenting with classic IM, abdominal pain, and anemia. Other clinical findings may include pharyngeal inflammation and palatal petechiae, seen more commonly in adolescents. Jaundice and hepatomegaly tend to occur more frequently in older adults [13]. Patients with IM, who were presumed to have strep throat and given a penicillin derivative such as amoxicillin for treatment, may also present with a typical copper-colored maculopapular rash. This is thought to be due to transient penicillin

Telegram: @medical_k

www.konkur.in

hypersensitivity induced by immune dysregulation during the acute stage of infection [14].

Rarely, patients with primary EBV infection may develop chronic multisystem disease with two clinical patterns. The first and more common is recovery from the initial disease but persistent lingering or recurring symptoms that develop months to years later, and the second pattern is a continuous "mono-like" illness that may last indefinitely [14].

Acute EBV infection has been associated with complications such as meningitis, encephalitis, Guillain-Barre syndrome, aplastic and autoimmune hemolytic anemia, myocarditis, pneumonitis, and nephritis [15]. Other conditions, such as lymphoproliferative disorders, connective tissue diseases, and certain malignancies are concerning as long-term complications, especially in immunocompromised individuals [9].

Laboratory and Imaging

The diagnosis of IM depends on presence of the typical symptoms and a positive heterophile "monospot" antibody test. When positive in the presence of IM symptoms, the heterophile test has an approximate sensitivity of 85% and specificity of 94% [6]. However, the heterophile tests have several limitations. Nearly 10% of patients with IM are consistently heterophile-negative [8]. Furthermore, the test may be falsely negative in approximately 40% of children 4 years of age or younger who do not develop heterophile antibodies following primary EBV infection. Other infections like toxoplasmosis and cytomegalovirus (CMV), certain malignancies, and autoimmune diseases have also been linked with positive heterophile antibody tests. Finally, heterophile antibodies can persist for a year or more and therefore are not always diagnostic of an acute EBV infection [14].

If the heterophile test is negative, a complete blood count (CBC) with differential can be done. A finding of marked lymphocytosis (over 50% of all lymphocytes) with atypical cells comprising at least 10% of all leukocytes would suggest heterophile-negative EBV-induced IM according to the Hoagland criteria [9].

Chronic EBV infection can be characterized by the antibody profile of negative viral capsid antigen (VCA) IgM indices, very high VCA IgG indices, and modestly elevated Epstein-Barr virus nuclear antigen (EBNA) -1 IgG levels [14].

Special Testing

If EBV is strongly suspected but heterophile antibody testing is negative, EBV-specific antibodies VCA IgM, VCA IgG, and EBNA-1 IgG can be obtained for confirmation of infection [14]. Other modalities such as immunoblotting and serial quantitative measurements of EBV DNA in the blood can also be considered.

Differential Diagnosis

Table 1 includes the differentials diagnosis of IM [9]. Diagnostic testing is particularly important if the patient is pregnant since conditions such as CMV, human immunodeficiency virus (HIV), and toxoplasma infections can cause infection and negative fetal outcomes.

Treatment

Behavioral

Parents can be advised against kissing children on the mouth to limit oral shedding of the virus and to keep toys, particularly in daycare spaces, clean to prevent transmission. Physical activity of any intensity within the first 3 weeks of illness may increase risk of splenic rupture and therefore should be restricted [13].

Medications\Immunizations and Chemoprophylaxis

Treatment is generally supportive for IM. Glucocorticoids can decrease the severity of sore throat associated with IM within the first 12 h of treatment, but neither these medications nor antivirals

Telegram: @medical_k

www.konkur.in

Table 1 Differential diagnosis for infectious mononucleosis

Diagnosis	Distinguishing features
Streptococcal pharyngitis	Abrupt onset of sore throat during peak incidence (winter and early spring) months Exudative pharyngitis, absence of splenomegaly or hepatomegaly Positive rapid strep or throat culture
CMV	Contact with children, especially younger than 2 years of age Anicteric hepatitis Usually heterophile antibody negative
Toxoplasmosis	History of ingesting undercooked meat, exposure to cats or cat droppings Nontender lymphadenopathy Usually heterophile antibody negative
HIV/Acquired Immuno-Deficiency Syndrome (AIDS)	Intravenous drug use, unprotected sexual intercourse, or other HIV exposure risks Mucocutaneous lesions, rash, diarrhea, weight loss, nontender lymphadenopathy Adults with HIV/AIDS are more likely to have a concurrent infection from EBV
Adenovirus	Nonspecific upper respiratory symptoms including cough Less systemic lymphadenopathy Heterophile antibody negative
Leukemia	CBC abnormalities including very high or low white blood cell count, low hemoglobin with signs of hemolysis, and low platelets
Drug side-effect	Minocycline, carbamazepine, phenytoin, isoniazid

such as acyclovir have been shown in studies to decrease the severity or length of illness of IM [13].

Three prophylactic EBV vaccine candidates have been tested in humans [14]. Two were based on the major surface glycoprotein gp350 of EBV that allows the virus to attach to human B-lymphocytes and cause infection. The third prophylactic EBV vaccine candidate was an adjuvant EBNA-3A peptide designed to control expansion of EBV-infected B cells by general CD8 T-cell immunity to EBNAs. At this time, the clinical application of vaccines is limited to prevention of complications associated with EBV rather than reducing rates of primary EBV infection [16].

Referrals

In cases of airway obstruction, an otolaryngology consultation may be urgently warranted. Referrals to other specialists may be necessary depending on complications.

Counseling

Majority of the patients with EBV infection recover without sequelae and develop lifelong immunity to controlling the latent virus [17]. IM is mostly self-limiting and recovery is common in 2–4 weeks.

Patient Education and Activation

Measures such as frequent handwashing and limiting shared items, such as toothbrushes and eating utensils, can help maintain good hygiene in general. Patients should be advised to maintain adequate hydration, rest, and good nutrition. They should also be educated on potential complications and the course of the illness, and given clear instructions for follow-up and return to physical activity [17].

Prevention

Due to the very high worldwide prevalence of EBV antibodies in adults, it is nearly impossible to avoid exposure to EBV. The role of antivirals (e.g., acyclovir, valacyclovir, ganciclovir, and

Telegram: @medical_k

www.konkur.in

valganciclovir) in prevention of posttransplant EBV disease is uncertain [14].

Family and Community Issues

Further investigation into asymptomatic primary infection in adolescents and young adults is warranted.

Definition/Background

Respiratory viruses are ubiquitous organisms that can cause a wide spectrum of clinical manifestations in patients of all ages ranging from mild or even asymptomatic upper respiratory tract infections to fatal illnesses with multiorgan failure [1]. Viral infections of the respiratory tract are also common in all age groups and are the leading cause of mortality in children under 5 years of age in developing countries [2]. They pose a significant symptom burden for individuals and a high financial burden to society – mostly due to loss of productivity, healthcare costs, and school absenteeism [3]. Advances in diagnostic testing and improved ability to detect pathogens have demonstrated that viral pathogens are important causal pathogens of respiratory tract infection even in immunocompetent patients. As the number of elderly adults and those with chronic medical conditions increases, the burden of viral respiratory infections has also increased [4].

Additionally, viral respiratory infections play an important role as a trigger for exacerbations of chronic respiratory diseases, such as asthma, or chronic obstructive pulmonary disease (COPD) [3].

Epidemiology

In the United States, 25 million people visit their family doctors every year with uncomplicated upper respiratory infections [1]. The epidemiology of respiratory tract infection is changing due in part to the aging of the US population and the success of childhood vaccination programs [4].

The incidence and impact of these viral infections tend to be greatest at the extremes of life: in infancy and in the elderly. Up to 70% of children and 30% of adults with respiratory viral infection may develop lower respiratory symptoms. The virus is often the sole pathogen identified [5]. In addition, respiratory viruses frequently initiate a cascade of events that ultimately leads to bacterial infection [1]. Most respiratory virus infections occur in the fall and winter months, but viruses such as human adenovirus, and potentially SARS-COV-2, do not show a seasonal variation in spread [6].

Etiology

Some of the more common viral causes of respiratory tract infection include human adenovirus, influenza virus types A and B, human metapneumovirus, parainfluenza virus, respiratory

Telegram: @medical_k

www.konkur.in

syncytial virus(RSV), rhinovirus (most common), and coronavirus [7, 8]. All of them are RNA viruses, except for adenovirus, which is a DNA virus.

Transmission

Respiratory viruses are readily transmitted from person-to-person through direct contact with infected persons and aerosolization of infective droplets during coughing and sneezing or, indirectly, by hand transfer of contaminated secretions or transfer from contaminated objects or surfaces to the nasal or conjunctival epithelium of susceptible persons (see Table 1) [9, 10].

Pathogenesis

The pathogenesis of viral respiratory tract infections is not fully understood but appears to involve a delicate balance between virus infection and clearance by the host. Inoculation occurs through the upper respiratory tract, primarily the eyes and nose, and most viruses multiply locally in the respiratory epithelium of the large and small airways without causing systemic infection. Depending on the virus, this may result in inflammation, increased mucosal secretions, and leukocyte infiltration as well as changes in ciliary and mucus-producing functions. Both upper and lower ciliated airway cells can be destroyed and the epithelium denuded, with clearance mechanisms and phagocytic cell function compromised. This damage creates susceptibility to superinfection by bacteria. Host immune responses also appear to play an important role in pathogenesis. For example, certain viruses appear to interact with the immune system in ways that trigger immediate hypersensitivity reactions, which may lead to virus-induced wheezing and asthma.

A variety of responses involving interferon and cytotoxic T-cell responses with release of cytokines and chemokines are associated with elimination of the virus and subsequent recovery. Various degrees of cytokine release occur, with the most severe of these representing the entity known as a "cytokine storm" [9].

Laboratory Testing

Most respiratory viral infections are diagnosed clinically [11]. Testing may also be indicated for certain viral infections when management decisions or infection control will be impacted by the result (e.g., influenza and COVID-19).

Table 1 Common routes of transmission for respiratory viruses. Adapted from [10]. Used with permission

Transmission route	Particles involved and particle characteristics	Characteristics/definition of transmission
Contact		Self-inoculation of mucous membranes by contaminated hands
Direct	Deposited on persons	Virus transfer from one infected person to another
Indirect	Deposited on objects	Virus transfer through contaminated intermediate objects (fomites)
Airborne		
Droplet	Droplets (>5 μm) Remain only briefly in air (<17 min) Dispersed over short distances (<1 m)	Short-range transmission Direct inoculation of naïve person through coughing/sneezing/breathing of infected person Deposition mainly on mucous membranes and upper respiratory tract
Aerosol	Aerosols, droplet nuclei (<5 μm) Remain in air for prolonged periods Dispersed over long distances (>1 m)	Long-range transmission Inhalation of aerosols in respirable size range Deposition along the respiratory tract, including the lower airways

Telegram: @medical_k

www.konkur.in

Nasopharyngeal specimens are often used in routine clinical practice and in many surveillance studies [12].

Testing Methods [9]

- Viral cultures
  - Highly specific but with low sensitivity
  - Labor, resource, and time intensive
- Direct antigen detection tests
  - Immunofluorescence or immunoassay
  - Moderate specificity and sensitivity
  - Rapid and amenable to point-of-care testing
- Nucleic amplification tests
  - Polymerase chain reaction (PCR) and other nucleic acid amplification assays
  - Highly sensitive and specific
  - The new reference standard in respiratory virus testing
- Serology
  - Generally not helpful in the acute clinical setting
  - Often used in research and epidemiological studies
- Multiplex testing platforms
  - Testing for multiple respiratory pathogens from a single specimen
  - Becoming more routinely used in hospitals and emergency rooms

Common Cold

Definition/Background

The common cold is a conventional term for a mild upper respiratory illness, the hallmark symptoms of which are nasal stuffiness and discharge, sneezing, sore throat, and cough [13].

Common colds are defined as upper respiratory tract infections that affect predominantly the nasal part of the respiratory mucosa. Because upper respiratory tract infections can affect any part of the mucosa, it is often arbitrary whether an upper respiratory tract infection is called a "cold" or "sore throat" ("pharyngitis" or "tonsillitis"), "sinusitis," "acute otitis media," or "bronchitis." Sometimes all areas (simultaneously or at different times) are affected during the same illness [14].

Although the term tends to imply that there is a single cause for the illness, the common cold is actually a heterogeneous group of diseases caused by numerous viruses that belong to several different families [13].

Etiology/Spread

The viral causes of the common cold are rhinoviruses (30–50%), coronaviruses (10–15%), influenza viruses (5–15%), RSV (5%), and adenoviruses, enteroviruses, and human metapneumovirus (all <5%) [13]. For many colds, no infecting organism can be identified [14].

Transmission of common cold infections is primarily through direct contact rather than droplet spread [14].

Prognosis

Common colds are usually short lived, lasting a few days, with a few lingering symptoms lasting longer. Symptoms peak within 1–3 days and generally clear by 1 week, although cough often persists. Although they cause no mortality or serious morbidity, common colds are responsible for considerable discomfort, lost work, and medical costs.

Epidemiology

The occurrence of the common cold shows clear seasonality. In temperate regions of the world, the frequency of respiratory infections increases rapidly and remains high in the winter months, decreasing as the weather warms again in spring. In tropical areas, most colds arise during the rainy season. The incidence of upper respiratory infections is inversely proportional to age. On average, young children have 6–8 and adults 2–4 colds per year. During the first years of life, boys seem to

Telegram: @medical_k

www.konkur.in

have more respiratory infections than girls, but this difference is reversed later in life. Day-care attendance is a major risk factor for respiratory illnesses in children, and the frequency of colds increases with the number of children in the group. However, frequent infections in the preschool years may lower the frequency of the common cold during school years. Psychological stress is associated with susceptibility to the common cold in a dose-dependent manner. Finally, some reports indicate that heavy physical training increases the risk of respiratory infections, whereas moderate physical activity may decrease risk [13].

Clinical Manifestations

Rhinovirus infections typically start with a sore throat, which is soon accompanied by nasal stuffiness and discharge, sneezing, and cough. The soreness of the throat usually resolves quickly, while the initial watery rhinorrhea turns thicker and more purulent. The purulence of the nasal discharge is generally not associated with changes in the nasopharyngeal bacterial flora and is not thought to indicate a simultaneous bacterial infection of the nasal mucosa. Fever is an infrequent finding during rhinovirus infections in adults, but it is fairly common in children with upper respiratory infections of any cause. Other symptoms associated with the cold syndrome include hoarseness, headache, malaise, and lethargy. Myalgia is an occasional complaint in patients with colds, although it is a more typical feature of influenza infection.

Diagnosis

Diagnosis is made clinically and testing is rarely necessary.

Treatment

Because the symptoms of the common cold are universally self-limited, treatment is aimed at reducing the duration and severity of illness. Informing patients about the natural course of the common cold can help manage expectations, limit antibiotic use, and avoid unnecessary over-the-counter purchases [15]. Antibiotics have no role in the treatment of acute viral upper respiratory infections in children or adults and should not be prescribed [16, 17].

Treatments with proven effectiveness, and those proven to be ineffective or even harmful, are listed in Table 2.

The Food and Drug Administration has issued an advisory that over-the-counter cold medications containing a decongestant or antihistamine should not be used to treat children younger than 4 years because of lack of benefit and low but

Table 2 Treatments for the common cold [14, 15]

Adults		Children	
Effective	**Ineffective**	**Effective**	**Ineffective**
OTC NSAIDs	Antihistamine monotherapy	Intranasal ipratropium	Antibiotics
Zinc	Increased fluid intake	Analgesics	Antihistamines
Nasal decongestants	Codeine	Honey	Antitussives
Intranasal ipratropium	Echinacea	Acetylcysteine	Echinacea
	Intranasal corticosteroids	Nasal saline irrigation	Intranasal corticosteroids
	Pelargonium sidoides (African geranium)	Ointment containing camphor, menthol, and eucalyptus oils	
	Steam	Vitamin C – initiated prior to the onset of symptoms	
	Vitamin C, D, or E		

Telegram: @medical_k

www.konkur.in

significant mortality rates associated with their use in this population [18, 19]. The only safe and effective treatments for children are analgesics, acetylcysteine, honey (for children older than 12 months of age), nasal saline irrigation, intranasal ipratropium, and menthol rub [15].

Complications [13]

Although the common cold is usually a self-limited illness of short duration, the viral infection is sometimes accompanied by a bacterial complication. In children, the most common bacterial complication is acute otitis media, which occurs in about 20% of children with viral upper respiratory infections. Other common bacterial complications of viral upper respiratory infections include sinusitis and pneumonia. Sinusitis has been estimated to occur as a complication in 0.5–2% of colds. Pneumonia associated with a viral upper respiratory infection is often a bacterial complication of the predisposing viral illness, but it can also be an extension of the viral illness to the lung.

Acute viral respiratory infections are also associated with acute exacerbations of asthma and COPD. In immunocompromised patients, RSV is usually the most common cause of severe viral respiratory illness, but rhinovirus infections have also been associated with severe and even fatal lower respiratory tract disease.

Laryngitis

Definition/Background

Laryngitis is defined as inflammation of the larynx which can be infectious or non-infectious. Acute laryngitis usually lasts less than 3–4 weeks and is most commonly caused by the same viruses as the common cold described earlier in this chapter.

Approach to the Patient

Symptoms of laryngitis typically include dysphonia (hoarseness of voice or change in voice pitch) and/or pain in the anterior neck typically coinciding with other symptoms of an upper respiratory infection. Acutely, it is important to differentiate between other possible causes of laryngitis such as bacterial or fungal infection, allergic rhinitis, acid reflux, voice misuse and overuse, toxic inhalation or ingestion, postnasal drainage, or trauma [20].

Treatment

There are no clinical criteria that help to distinguish clearly between viral and bacterial causes of laryngitis. The routine use of antibiotics in acute laryngitis does not improve clinical outcomes, however [21]. Treatment is typically supportive including voice rest, avoidance of irritants, humidification, local lubrication, and systemic hydration. Despite widespread use, corticosteroids are not routinely recommended in patients with hoarseness, except in children with croup [22]. Direct visualization of the vocal cords by laryngoscopy should be considered for symptoms lasting >3 weeks or for patients with stridor, recent surgery, recent intubation, radiation therapy to the neck, or weight loss.

Influenza

Definition/Background

Influenza is an acute respiratory illness caused by the influenza virus which is a single stranded RNA virus from the *Orthomyxoviridae* family. Human influenza virus subtypes A and B cause the epidemics of human disease, while influenza virus type C causes a mild respiratory illness similar to the common cold. Influenza viruses have genetic properties that can create "antigenic shifts" which have the potential to cause pandemics of human illness due to lack of preexisting immunity [23]. In temperate climates, seasonal epidemics occur annually in the winter months (see Fig. 1), while in tropical climates influenza cases occur intermittently throughout the year. Worldwide, it is estimated that influenza causes 290,000–650,000 deaths each year [24].

Telegram: @medical_k

www.konkur.in

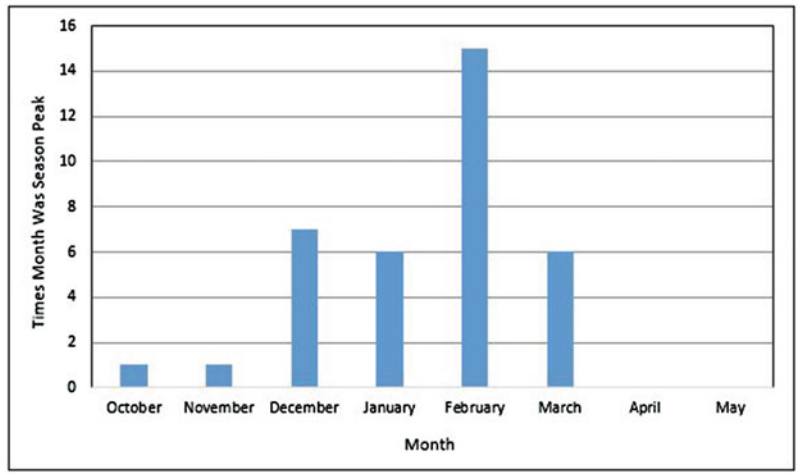

Fig. 1 Peak month of flu activity in the United States: 1982–1983 through 2017–2018 [25]

Clinical Manifestations

Infection of the respiratory tract by influenza virus commonly causes fever, cough, sore throat, nasal congestion or rhinorrhea, headache, muscle aches (myalgias), and malaise. Diarrhea and/or vomiting may be present, especially in children. Complicated infection can lead to lower respiratory tract disease, central nervous system involvement (e.g., encephalopathy, encephalitis), severe dehydration, or secondary complications such as organ failure and septic shock [26]. Symptoms typically begin abruptly after a 1–4-day incubation period and typically last about 3–7 days, but cough and fatigue may persist beyond 2 weeks [27]. Influenza infection can also exacerbate other underlying chronic diseases such as asthma, COPD, and congestive heart failure.

Treatment

Treatment for influenza infection is largely supportive, and the same principles typically apply to the common cold as described previously in this chapter. Antivirals can reduce symptom duration by 0.5–1 day in an average adult, but may reduce mortality, especially in high-risk patients (severe illness, patients <2 years old or >65 years old, patients who are pregnant, residents of long-term care facilities, patients with other chronic medical conditions or immunosuppression). The greatest benefit for antiviral treatment has been demonstrated when given as soon as possible, especially in the first 48 h after symptom onset. Treatment with antivirals is recommended for up to 5 days after the onset of illness in hospitalized patients to reduce morbidity and mortality. There are currently three different classes of antiviral medications: neuraminidase inhibitors, cap-dependent endonuclease inhibitors, and adamantanes (see Table 3). Currently the neuraminidase inhibitors and the novel cap-dependent endonuclease inhibitors are active against circulating influenza A and B strains and are approved by the Food and Drug Administration (FDA). The adamantanes are not recommended for treatment because they are only active against influenza A and there are currently very high rates of resistance among circulating influenza A strains [28].

Prevention

In addition to basic infection mitigation measures for infections of the respiratory tract (discussed later), vaccination is a major strategy for prevention and control of influenza. Vaccine composition is adjusted each year based on the predicted strains for the upcoming flu season and is coordinated by the World Health Organization. Current recommendations call for annual vaccinations in all patients 6 months of age and older with any of the licensed, age-appropriate vaccines including the inactivated influenza vaccine, recombinant

Telegram: @medical_k

www.konkur.in

Table 3 Drugs available for the treatment of influenza in the United States [28]

Drug name	Method	Age	Mechanism of action	Activity against influenza strains	FDA approval	Notes
Oseltamivir phosphate (Tamiflu)	Pill or liquid suspension	>14 days	Neuraminidase inhibitor	A and B	Yes	Early treatment of hospitalized patients has been reported to reduce morbidity and mortality in children and adults
Zanamivir (Relenza)	Inhaled	>7 years	Neuraminidase inhibitor	A and B	Yes	Contraindicated in patients with asthma or COPD
Peramivir (Rapivab)	Intravenous	>2 years	Neuraminidase inhibitor	A and B	Yes	
Baloxavir marboxil (Xofluza)	Pill	>12 years	Cap-dependent endonuclease inhibitor	A and B	Yes	Not recommended in pregnancy, breastfeeding, complicated illness, or hospitalized patients due to lack of data
Amantadine	Pill	Not recommended	Adamantane	A only	No	High levels of resistance to adamantanes among currently circulating influenza A viruses
Rimantadine	Pill	Not recommended	Adamantane	A only	No	High levels of resistance to adamantanes among currently circulating influenza A viruses

influenza vaccine, or live attenuated influenza vaccine [29]. The number needed to vaccinate in order to prevent a case of influenza varies according to the "match" between the vaccine and circulating virus strains. Fewer than 1% of vaccine recipients experience fever after vaccination, and other risks of harm are much lower [30]. Overall there is significant benefit for vaccination compared to potential harm, and while yearly efficacy can fluctuate, universal vaccination is strongly encouraged to improve herd immunity to influenza, thus protecting high-risk individuals.

Antivirals are not generally recommended for chemoprophylaxis due to increasing antiviral resistance, and annual influenza vaccination is the preferred method of prevention. Oseltamivir and zanamivir can be considered for chemoprophylaxis for prevention in patients with severe immune deficiencies or who are at high risk of influenza complications who have been exposed to a person with influenza in the first 2 weeks following vaccination or who cannot receive influenza vaccination due to a contraindication [28].

Acute Bronchitis

Definition/Background

Acute bronchitis is a self-limited infection of the epithelial cells of the bronchi characterized by the presence of cough, with or without sputum

Telegram: @medical_k

www.konkur.in

production. The majority (>90%) of cases of uncomplicated acute bronchitis are due to a viral infection, most commonly influenza A and B, parainfluenza, RSV, coronavirus, adenovirus, rhinovirus, and human metapneumovirus. A minority of cases may be caused by non-viral organisms such as *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Bordetella pertussis*, *Legionella*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, or *Moraxella catarrhalis*. Acute bronchitis can also be caused by inhalation of irritants such as cigarette smoke, ammonia, and other noxious substances. Acute bronchitis is one of the most common diagnoses encountered by family physicians with approximately 100 million office visits per year. This number is equivalent to about 10% of outpatient visits in the United States [31].

Approach to the Patient

The symptoms of acute bronchitis overlap with other clinical syndromes of upper and lower respiratory tract infections and typically include cough for at least 5 days (with or without sputum production), dyspnea, low-grade fever, headache, wheezing, rhonchi, or other signs of obstruction. Symptoms generally last for 2–3 weeks, but the cough may persist for up to 8 weeks in some cases [32]. Despite widespread belief that purulent sputum indicates bacterial infection, sputum color does not appear to be predictive of bacterial infection in patients with acute cough with otherwise healthy lungs [33]. In the absence of abnormal vital signs, history, or physical exam findings that may be consistent with pneumonia, a chest radiograph is not necessary in most cases.

Treatment

As in other upper respiratory infections, treatment is generally targeted toward symptoms and balanced against risks of side effects. Routine use of antibiotics is not recommended for uncomplicated acute bronchitis as they have limited efficacy and significant adverse effects [34]. Inhaled albuterol can be useful in patients with asthma or COPD but may not reduce cough in children or adults without underlying lung disease [35].

Coronavirus Infections

Human Coronavirus Types [7]

Coronaviruses are RNA viruses named for the crown-like spikes on their surface.

Common human coronaviruses (causing mild respiratory infections)

1. Alpha coronaviruses
   a. 229E
   b. NL63
2. Beta coronavirus
   a. OC43
   b. HKU1

Other Human Coronaviruses (Causing More Severe Respiratory Disease)

3. MERS-CoV (the beta coronavirus that causes Middle East respiratory syndrome or MERS)
4. SARS-CoV-1 (the beta coronavirus that causes severe acute respiratory syndrome or SARS)
5. SARS-CoV-2 (the novel coronavirus that causes coronavirus disease 2019 or COVID-19)

COVID-19

Definition/Background

After the first reported cases in Wuhan province, China, in December 2019, COVID-19 has become a global pandemic with over ten million confirmed cases and over 500,000 deaths by the end of June 2020 [36].

Clinical Presentation

Patients infected with SARS-CoV-2 may remain asymptomatic or develop mild, moderate, or severe illness. Mild symptoms include cough, fever, malaise, gastrointestinal symptoms, and anosmia [37]. Severe illness usually begins approximately 1 week after the onset of symptoms. Dyspnea is the most common initial

Telegram: @medical_k

www.konkur.in

symptom of severe disease and is often accompanied by hypoxemia [38]. Patients with mild disease usually recover at home, while those with moderate or severe symptoms require hospitalization for observation and supportive care [38]. Hypercoagulability also seems to be an important pathophysiological mechanism that may lead to damage in a number of end organs.

There are few proven therapies for COVID-19, but various agents and techniques are under investigation as of this writing. Infection control and prevention efforts center on personal protective equipment for healthcare workers, universal masking, social distancing, vaccination, as well as testing and tracing [37].

The median incubation period, from exposure to symptom onset, is approximately 4–5 days, and 97.5% of patients who are symptomatic will have symptoms within 11.5 days after infection.

Risk factors for complications of COVID-19 include older age (e.g., >65 years), cardiovascular disease, chronic lung disease, hypertension, diabetes, and obesity.

New and Emergent Respiratory Infections [39]

Besides COVID-19, other respiratory diseases caused by viral agents have included severe acute respiratory syndrome virus (SARS), Middle East respiratory syndrome virus (MERS), and pandemic influenza caused by a novel H1N1 strain [39].

Common themes in emerging infections include zoonotic hosts and changes in human behavior, including increased international travel and/or modification of the physical environment [39].

SARS

Etiology, Epidemiology, and Clinical Presentation

Severe acute respiratory virus (SARS) is a rapidly fatal pulmonary infection caused by the SARS coronavirus (SARS-CoV). The first documented outbreak occurred primarily in China from 2002 to 2004 with regional outbreaks in North America and Europe attributed to human-to-human transmission from infected international travelers. A total of 8096 cases from 29 countries, including 774 fatalities, were identified during the course of the outbreak (case fatality rate: 9.6%) [39]. There have not been any known cases of SARS reported worldwide since 2004.

MERS

Etiology, Epidemiology, and Clinical Presentation

Middle East respiratory syndrome (MERS) was first identified during September 2012 in a Saudi Arabian patient with respiratory failure. In comparison to the rapid spread and subsequent quiescence of SARS-CoV, MERS-CoV has continued to circulate and produce sporadic outbreaks both within the Arabian Peninsula and in countries where infected patients have traveled. There have been 2266 confirmed cases of MERS and 804 fatalities (case fatality: 35.5%).

The clinical presentation varies from asymptomatic infection to severe disease with respiratory failure. In general, older patients and those with chronic comorbid conditions (diabetes, heart disease) are at greatest risk for progression to respiratory failure.

Pandemic Influenza 2009

Etiology, Epidemiology, and Clinical Presentation

In contrast to the emergence of COVID-19, MERS, and SARS, the 2009 H1N1 influenza pandemic was a re-emergence of a pathogen most commonly responsible for seasonal infections, but with demonstrated pandemic potential. The virus (H1N1pdm09) first emerged in Mexico during the spring of 2009. The virus contains gene segments from human, porcine, and avian influenza strains. Since its introduction in human populations, the 2009 strain has become a commonly circulating strain and is now routinely incorporated into the seasonal vaccine.

Telegram: @medical_k

www.konkur.in

The full clinical spectrum of pandemic influenza infection differs little from seasonal influenza. However, during the 2009 pandemic, patients infected with the pandemic strain were younger, were less likely to have underlying conditions, more frequently required ventilatory support or ICU care, and had relatively frequent extrapulmonary complications. In those cases progressing to severe disease, acute onset hypoxemia and acute respiratory distress were frequent. In addition, patients with severe influenza requiring hospitalization were at increased risk of developing secondary bacterial pneumonia, acute kidney injury, and requirements for mechanical ventilation.

Prevention

Respiratory viral infections are predominantly transmitted through infected droplets. Following general hygienic practices helps to decrease transmission. These include regular hand hygiene, minimizing contact with sick individuals, and avoiding the sharing of personal items. Following "cough etiquette," including covering the nose and mouth with a tissue while coughing, proper disposal of tissue, and prompt hand washing, is also shown to decrease spread of respiratory infections [40]. Currently, an effective vaccine is available only for influenza. Other measures of prevention include antivirals for high-risk patients exposed to influenza and use of palivizumab, a monoclonal antibody, in high-risk individuals to prevent respiratory syncytial virus (RSV) infections. New evidence has been growing to support universal mask-wearing and physical distancing and avoidance of large social gatherings during times of high levels of community viral transmission such as an epidemic or pandemic. During times of critical supply shortages, higher levels of personal protective equipment including gowns, gloves, surgical masks, and respirators should be reserved for healthcare workers and other medical first responders. The general public (with the exception of children under the age of 2, anyone who has trouble breathing, or anyone is unable to remove a mask without assistance) should use cloth face coverings to help reduce the spread of disease from symptomatic and asymptomatic carriers [41].

Family and Community Issues

Antibiotic resistance in the healthcare setting is a growing threat to public health, and, as of 2019, 2.8 million people become infected and 35,000 people die each year from antibiotic-resistant infections [42]. In part, antibiotic-resistant infections stem from the prescribing of antibiotics when they are not needed, as in the case of viral respiratory tract infections.

Many strategies can help to reduce inappropriate antibiotic use including patient information handouts, use of procalcitonin levels, point-of-care C-reactive protein testing, print-based or computer decision support strategies, delayed antibiotic prescription, the use of diagnostic labels that reinforce the benign nature of the condition (e.g., "chest cold"), and helping to reframe patient expectations relating to length of illness [43]. Ultimately, good physician-patient communication and patient education can help combat this growing threat to public health. By acknowledging the suffering and discomfort caused by viral infections, the family physician is able to partner with the patient, proactively treat their symptoms, and offer them support without exposing them to further risk through inappropriate antibiotic use.

Sinusitis

Sinusitis is defined by inflammation of the mucosa of the paranasal sinuses. In addition to the sinuses, the inflammation almost always involves the nasal cavity, and thus the term *rhinosinusitis* is often used interchangeably with *sinusitis* [1]. For the remainder of this chapter, the term *rhinosinusitis* will be used. Rhinosinusitis is further separated into three classifications based on duration and recurrence of symptoms [2].

Acute rhinosinusitis: signs and symptoms lasting less than 4 weeks

Recurrent acute rhinosinusitis: four episodes lasting less than 4 weeks with complete resolution of symptoms in between episodes

Subacute rhinosinusitis: signs and symptoms lasting 4–12 weeks

Chronic rhinosinusitis: signs and symptoms lasting 12 weeks or longer

Epidemiology

Rhinosinusitis is an extremely common condition, with about one out of eight adults being diagnosed in the United States each year, resulting in nearly 30 million diagnoses [3]. Women are more frequently affected by rhinosinusitis than men, and adults older than 45 years old are at higher risk [3]. Southern regions of the United States are also disproportionately affected compared to other regions such as the Northeast and West [3]. Chronic rhinosinusitis has an enormous economic burden: direct costs for chronic rhinosinusitis management have been estimated at around $13 billion per year in the United States, while indirect costs related to chronic sinusitis-related loss in work productivity have been estimated to be over $20 billion per year [4].

Risk Factors

Rhinosinusitis is more common in individuals with allergic rhinitis and/or asthma [5]. Other risk factors include anatomic abnormalities such as polyps or a deviated septum, in addition to systemic conditions such as cystic fibrosis or other conditions associated with immunodeficiencies [6]. Other risk factors include air travel and smoking or exposure to second-hand smoke.

Microbiology

The most common causes of acute rhinosinusitis are viral in etiology. Common pathogens include rhinovirus, influenza, and parainfluenza virus species. Secondary bacterial infection is uncommon. It is estimated that only 0.5–2% of cases progress to acute bacterial rhinosinusitis [7]. Common bacterial causes of rhinosinusitis include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* [7]. Rarely, fungal infection can lead to acute rhinosinusitis; these cases occur almost exclusively in immunosuppressed individuals, such as people living with HIV, patients undergoing chemotherapy, or those with uncontrolled diabetes mellitus.

Clinical Presentation

Rhinosinusitis classically presents with flu-like symptoms, including nasal congestion, mucopurulent nasal discharge, headache, and facial or sinus pain and/or pressure that worsens when bending forward [8]. Other symptoms might include fever, cough, dental pain, hyposmia or anosmia, and ear pressure or fullness.

Both acute viral rhinosinusitis and acute bacterial rhinosinusitis present similarly, and there are no reliable clinical criteria that distinguish between etiologies reliably [7]. However, acute viral rhinosinusitis and acute bacterial rhinosinusitis tend to have different clinical courses:

In acute viral rhinosinusitis, symptoms typically peak in severity between days 3 and 6, and either symptomatically improve or completely resolve within 7–10 days [2]. Fever, if present, will generally present and resolve within the first 24–48 h of the illness, after which respiratory symptoms become more prominent [7]. Viral rhinosinusitis can present with purulent discharge, which is generally a sign of nasal/sinus mucosa inflammation. Typically, nasal discharge initially presents clear, becomes purulent, then becomes clear again.

In acute bacterial rhinosinusitis, symptoms tend to last longer than 10 days [2, 7]. Often, there is a biphasic pattern of illness ("double worsening"), in which there are worsening symptoms after an initial period of improvement. However, individual symptoms cannot be accurately used to distinguish between bacterial or viral rhinosinusitis. Rather, the full clinical picture

Telegram: @medical_k

www.konkur.in

and temporal pattern must be considered altogether when making a formal diagnosis [2].

Diagnosis

The diagnosis of rhinosinusitis is based on clinical signs and symptoms. Per guidelines from the American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS), acute rhinosinusitis can be diagnosed when patients present with: less than 4 weeks of purulent nasal discharge **and** severe nasal obstruction, facial pain/pressure/fullness, or both [7]. The clinical diagnosis of acute bacterial rhinosinusitis is made when symptoms persist for more than 10 days without improvement, or with worsening of symptoms within 10 days after initial improvement ("double worsening").

Patients with acute bacterial rhinosinusitis associated with signs or symptoms suggestive of ophthalmologic, neurologic, or surrounding soft tissue involvement are diagnosed as having **complicated acute bacterial rhinosinusitis** and require urgent evaluation and treatment. Concerning signs and symptoms include:

- Periorbital edema or erythema
- Vision changes (double vision, blurry vision)
- Proptosis
- Altered mental status
- Meningeal signs (neck stiffness, Kernig's and Brudzinski's sign)
- Pain with eye movement

Physical Exam

Physical exam findings may include warmth and/or tenderness over the cheekbones, and clear or purulent discharge within the nose or posterior pharynx [2]. Facial pain or pressure with percussion of the sinuses may also be present, though the sensitivity and specificity of these findings have not been established and are not diagnostic alone [9]. Anterior rhinoscopy may also show nasal mucosa erythema and edema, narrowing of the middle meatus, turbinate hypertrophy, and nasal discharge.

Diagnostic Imaging and Laboratory Studies

Rhinosinusitis is typically a clinical diagnosis, though imaging may be useful in particular settings. If there is suspected intraorbital or intracranial complications, immunocompromised states, or severe and/or recurrent disease, computed tomography (CT) scan of the head and paranasal sinuses with contrast should be considered [10] and may also be used to exclude a diagnosis of rhinosinusitis. However, CT findings may not correlate with overall severity of symptoms. Plain radiographs are **not** useful due to their poor sensitivity and specificity [11]. Nasal endoscopy can be used for better visualization of nasal purulence than an anterior nasal exam. However, it is not essential for diagnosis and is often impractical in the primary care setting [12]. Microbiological testing of sinus aspirates or endoscopic cultures can be collected to distinguish between infectious etiologies, but these are seldom used outside of tertiary settings [12].

Treatment

Initial Management

Acute viral rhinosinusitis should be treated symptomatically, including the use of analgesics, antipyretics, topical intranasal glucocorticoids, hydration, and nasal irrigation with saline [8]. Over-the-counter analgesics and antipyretics such as nonsteroidal anti-inflammatory drugs and acetaminophen are usually sufficient for pain and fever relief [2, 7].

Topical intranasal glucocorticoids have been shown to significantly improve pain and nasal congestion when compared to placebo [13]. Higher doses of intranasal glucocorticoid are more effective in reducing symptoms without serious adverse effects [13]. Minor adverse events may include epistaxis, nasal itching, and headache. While the adjunctive use of oral glucocorticoids can provide slight improvements in symptoms for patients who are prescribed antibiotics [14], the side effects and risks of systemic glucocorticoid use make it a less preferred option

Telegram: @medical_k

www.konkur.in

for patients diagnosed with acute bacterial sinusitis [8] or chronic rhinosinusitis with or without nasal polyps [15].

Nasal saline irrigation may provide some symptomatic relief such as reduced nasal secretion and obstruction, as well as reduced use of decongestant medication, though the evidence is not extremely robust [16]. However, it is a relatively safe therapy (provided the irrigants are sterile or bottled water) with minor adverse effects, such as nasal burning and irritation [16]. It should also be borne in mind that those needing to limit their sodium intake may not be able to use this method.

Oral decongestants have not been shown to be efficacious at reducing symptoms of rhinosinusitis [2] and are commonly associated with adverse effects (nervousness, irritability, headache, nausea). Intranasal decongestants may improve nasal congestive symptoms in some patients [2] but should be used cautiously and for no more than three consecutive days to avoid rebound congestion [17].

Antihistamines can provide symptomatic relief due to its drying effects, particularly for patients with underlying allergic rhinitis [18]. However, there is no evidence for significant efficacy in acute rhinosinusitis [2]. In addition, antihistamines, particularly the first-generation formulations, have been associated with adverse effects such as anticholinergic effects (e.g., dry mouth and eyes, constipation, blurred vision, drowsiness) and should be avoided in certain populations such as the elderly [7].

Mucolytics thin mucus and may improve nasal drainage. However, there is no evidence to support their use in rhinosinusitis [2].

Antimicrobial Therapy

The decision to use antibiotic therapy should be based on a shared consensus between the physician and the patient once a diagnosis of bacterial rhinosinusitis has been made. Antibiotic therapy has been shown to have significant clinical improvement at 7–16 days compared to placebo, but the difference is small [19]. Thus, the potential benefits of antibiotic therapy must be considered against potential adverse effects, including allergic reactions and development of drug-resistant bacteria.

Empiric treatment of acute bacterial rhinosinusitis in patients without a penicillin allergy is most often amoxicillin-clavulanate at a dose of 875 mg of amoxicillin and 125 mg of clavulanate orally two times daily for 5–10 days [2, 7]. The addition of clavulanate improves coverage for resistant strains of *Haemophilus influenzae* and *Moraxella catarrhalis.* For patients allergic to penicillin, the options include doxycycline (100 mg orally twice a day or 200 mg daily for 5–10 days), clindamycin (300 mg orally three times a day for 10 days), cefexime (400 mg orally once a day for 10 days), levofloxacin (500 mg orally once a day for 5–10 days), or moxifloxacin (400 mg orally once a day for 5–10 days) [2, 7].

Patients who have failed initial antibiotic treatment should be started on a different antibiotic than their initial therapy.

It is important to note that the Food and Drug Administration has advised that the use of fluoroquinolones (levofloxacin, moxifloxacin) be considered after other alternatives have been considered due to their potentially serious side effects (that include tendon rupture, joint and muscle pain, confusion, and hallucinations) that may outweigh their benefits [20].

Chronic Rhinosinusitis

Chronic rhinosinusitis is a condition that is caused by persistent inflammation of the nasal and sinus mucosa. The understanding of this condition is still evolving. Infectious, environmental, and host factors are all thought to play a role in its genesis. As the name implies, the condition is generally managed rather than cured in most patients; thus, treatment options are usually limited to reduction of symptoms and improving overall quality of life. In cases where acute rhinosinusitis does not improve despite appropriate medical therapy options, or in cases where recurrent episodes of rhinosinusitis are problematic, otolaryngology referral may be warranted [2].

Tonsillitis and Pharyngitis

Tonsillitis is defined as inflammation of the tonsils, whereas pharyngitis is defined as inflammation of the pharynx. However, while the subjective complaint of sore throat is often clinically diagnosed as

Telegram: @medical_k

www.konkur.in

pharyngitis, there is no firm distinction between sore throat caused by tonsillitis and sore throat caused by pharyngitis [21]. Moreover, inflammation of either the tonsils or pharynx often leads to inflammation and swelling of multiple contiguous anatomic structure, including the adenoids and nasopharynx, to create the perception of odynophagia [22]. Therefore, for the remainder of this chapter, throat pain and discomfort will be referred to as *tonsillopharyngitis*.

Epidemiology

Acute tonsillopharyngitis accounts for approximately 14 million ambulatory care visits annually [23], as well as 6% of children's visits to pediatricians and family physicians [24]. The incidence of acute tonsillopharyngitis is most frequent in childhood before the age of 18 [31] and peaks during the winter and early spring [25]. The economic cost of group A streptococcal pharyngitis specifically in school-aged children has been estimated to range from $224 to $539 million per year [26].

Etiologies

Infectious

The most common causes of tonsillopharyngitis are respiratory viruses, including rhinovirus, influenza virus, parainfluenza virus, coronavirus, adenovirus, and respiratory syncytial virus [27]. Other viruses such as enteroviruses (coxsackievirus, echovirus), herpes simplex virus, and Epstein-Barr virus can also cause pharyngitis [27].

Bacteria may also cause acute tonsillopharyngitis, of which the most common cause is Group A β-hemolytic *Streptococcus* (GAS), accounting for 5–15% of adult cases of pharyngitis [28], and 15–30% of pediatric cases of pharyngitis [27]. Other bacterial causes include group C β-hemolytic *Streptococcus* (GCS), *Corynebacterium diphtheriae*, *Yersinia enterocolitica*, *Francisella tularensis*, and *Mycoplasma pneumoniae* [27]. *Neisseria gonorrhoeae* can also be a cause of acute pharyngitis, particularly in sexually active adolescents.

Fungal causes of tonsillopharyngitis are less common, though *Candida* species can cause thrush, which can lead to sore throat.

Inflammatory

Inflammatory causes of tonsillopharyngitis include chemical irritation, postnasal drip, allergic rhinitis, foreign body, mechanical trauma and injury (e.g., intubation), vocal cord granuloma, laryngopharyngeal reflux, and Kawasaki disease [29].

Clinical Presentation of GAS Tonsillopharyngitis

GAS tonsillopharyngitis classically presents with sudden onset of a sore throat and may be accompanied by headache, fever, abdominal pain, and nausea and vomiting [30]. Physical exam findings may include tonsillopharyngeal inflammation and patchy exudates, palatal petechiae, tender cervical lymphadenopathy, and a scarlatiniform rash [30].

Laboratory Diagnosis

There is considerable overlap between the clinical presentations of streptococcal and viral tonsillopharyngitis, and although scoring systems have been implemented to aid in identifying patients at low risk for streptococcal infection [31], laboratory confirmation is usually required for a definitive diagnosis. Thus, guidelines from the Infectious Disease Society of America (IDSA) recommend laboratory testing for GAS tonsillopharyngitis with rapid antigen detection test (RADT) and/or culture, **unless** clinical features suggesting viral infection are present (conjunctivitis, cough, rhinorrhea, oral ulcers, hoarseness) [30]. A negative RADT warrants a backup throat culture, as the sensitivity of RADT ranges from 70% to 90% compared to throat culture of 90–95%. However, a backup throat culture is not necessary with a positive RADT, since it has a high degree of specificity (95%) [30].

Complications of GAS Tonsillopharyngitis

Suppurative Complications

Suppurative complications arise when GAS invades deeper adjacent tissues, resulting in infection and abscess formation. Peritonsillar abscesses are a potential complication of tonsillitis. This condition is one of the most common head and neck deep space infections, with an incidence of around 1 in 10,000 annually [32], most commonly seen in teenagers and young adults [33]. The abscess forms between the tonsil, the superior constrictor muscle, and the palatopharyngeal muscle [34]. Peritonsillar abscesses classically present with fever, odynophagia, erythema, trismus, deviation of the uvula, unilateral otalgia, drooling, and a muffled "hot potato" voice [34]. Significant odynophagia or impaired swallowing may result in dehydration. The diagnosis of peritonsillar abscess is primarily clinical, though CT scans and intra-oral ultrasounds can be used in certain circumstances, such as trismus limiting physical exam or in an uncooperative child [34]. Severe complications may occur if there is significant airway obstruction or further spread to adjacent regions (retropharyngeal abscess) [34]. Suspected spread of infection should be further assessed with MRI or CT with contrast.

Retropharyngeal abscesses are a potential complication of tonsillopharyngitis and most commonly occur in children between the ages of 2 and 4 years [45]. The most common clinical presentation includes neck pain, fever, odynophagia, and dysphagia following an upper respiratory infection [35]. Neck swelling may also be present, and depending on the degree of airway obstruction, there can also be a muffled "hot potato" voice, drooling, stridor, or tripod positioning. Initial management should be focused on maintaining the airway, as well as immediate consultation with an otolaryngologist, or if one is not immediately available, a person capable in obtaining and managing a difficult airway. Once the patient has been stabilized, a CT scan of the neck may be warranted for further evaluation [36].

Other potential suppurative complications of GAS tonsillopharyngitis include cervical lymphadenitis, acute otitis media, and impetigo [37].

Nonsuppurative Complications

Nonsuppurative complications of GAS tonsillopharyngitis are typically the results of post-infectious autoimmunity and include acute rheumatic fever, poststreptococcal reactive arthritis, Scarlet fever, acute glomerulonephritis, and pediatric autoimmune neuropsychiatric disorder associated with group A streptococci (PANDAS) [38].

Treatment of GAS Tonsillopharyngitis

Antibiotic therapy is the primary method of treatment for GAS tonsillopharyngitis. Penicillin or amoxicillin are considered first-line treatment options for GAS tonsillopharyngitis in most patients due to their efficacy, safety, narrow spectrum of activity, and low cost [39]. For patients without penicillin allergy, treatment options include either penicillin V orally (250 mg twice or three times daily for 10 days in children, 250 mg four times daily or 500 mg twice daily for 10 days in adolescents or adults) or amoxicillin orally (50 mg/kg once daily, maximum of 1000 mg/day for 10 days) [39]. For patients with penicillin allergy, treatment options include cephalexin orally (20 mg/kg/dose twice daily, maximum of 500 mg/dose for 10 days), cefadroxil orally (30 mg/kg once daily, maximum of 1 g/day) for 10 days, clindamycin orally (7 mg/kg/dose three times daily, maximum of 300 mg/dose) for 10 days, azithromycin orally (12 mg/kg once daily, maximum of 500 mg/day) for 5 days, or clarithromycin orally (7.5 mg/kg/dose twice daily, maximum of 250 mg/dose) for 10 days [39]. Research has not suggested one antibiotic regimen is superior to another [40].

Adjunctive treatment of GAS tonsillopharyngitis with nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen can be used supportively to relieve pain and fever, though aspirin should be avoided in children [39].

Telegram: @medical_k

www.konkur.in

Treatment of peritonsillar abscess primarily consists of incision and drainage alongside antibiotic coverage for both aerobic and anaerobic bacteria [41]. Empiric antibiotic therapy includes ampicillin-sulbactam intravenously (50 mg/kg/dose, maximum 3 g/dose every 6 h in children; 3 g every 6 h in adults) or clindamycin intravenously (13 mg/kg/dose, maximum 900 mg/dose every 8 h in children; 600 mg every 6–8 h in adults) [42]. Tonsillectomy is indicated in patients with peritonsillar abscess unresolved by incision and drainage, recurrent peritonsillar abscess, symptoms of sleep apnea, or multiple episodes of recurrent tonsillitis [41].

Treatment of retropharyngeal abscess primarily consists of antibiotic therapy against gram-positive aerobes and anaerobes [43]. Larger abscesses (>2.5 cm) or failure to respond to antibiotic therapy often warrants surgical incision and drainage [44].

Chronic Carriers and Asymptomatic Contacts

Chronic carriers may have GAS in their pharynx but do not have an immunologic response to the organism [45]. During winter and spring time in temperate climates, as many as 20% of school-aged children may be asymptomatic GAS carriers [46]. In these patients, testing and treatment with antibiotic therapy is generally not warranted, as carriers are unlikely to spread GAS, and even more unlikely to develop suppurative or non-suppurative complications [46, 47]. However, there are certain indications to treating asymptomatic carriers of GAS: any personal or family history of rheumatic fever, during outbreaks of acute rheumatic fever, or acute poststreptococcal glomerulonephritis, during outbreaks of GAS in closed/semi-closed communities (college campus, schools, military barracks, prisons, etc.), families with repeated episodes of GAS among family members, significant amount of anxiety about GAS among family members despite education and reassurance, or cases in which tonsillectomy is being considered due to chronic GAS carrier state [45].

Tonsillectomy

Tonsillectomy is the second-most common outpatient procedures performed on children in the United States [48]: the most recent report found that 289,000 tonsillectomies were performed in 2010 in children <15 years old [49]. Current guidelines outlined by the American Academy of Otolaryngology-Head and Neck Surgery Foundation recommend tonsillectomy in patients with at least seven episodes of recurrent tonsillopharyngitis in the past year, at least five episodes per year for 2 years, or at least three episodes per year for 3 years with documentation for each episode of tonsillopharyngitis with at least one of the following features: temperature >38.3 °C (101 °F), cervical lymphadenopathy, tonsillar exudate, or a positive test for GAS [50]. For patients who do not meet any of these criteria, watchful waiting is recommended [50].

General Principles

Definition/Background

Sexually transmitted infections (STIs) are of great healthcare and economic burden to the United States. In fact, most sexually active men and women will contract an STI at least once in their lifetime [1]. According to 2008 US estimates, STIs resulted in 16 billion dollars of direct medical costs [2]. Additionally, 19.7 million new infections occurred, with 50% occurring in individuals 15–24 years of age [3]. Overall, human papillomavirus (HPV) is the most common sexually transmitted infection. Other common infections include chlamydia, gonorrhea, hepatitis B virus, herpes simplex virus type 2 (HSV-2), human immunodeficiency virus (HIV), syphilis, and trichomoniasis [1]. Chlamydia, gonorrhea, and syphilis infection rates continue to increase in numbers over the years although this may be related to improve screening practices [4]. Family physicians have a responsibility to improve prevention, detection, and treatment of STIs in order to decrease transmission and prevent subsequent morbidity and mortality.

Chlamydial Infection

Chlamydia is a sexually transmitted infection caused by *Chlamydia trachomatis*, which can infect the cervix, urethra, rectum, lung, and eye. Chlamydia is a frequent cause of pelvic inflammatory disease (PID), infertility, chronic pelvic pain, and ectopic pregnancy and may facilitate the transmission of HIV in women. In men, chlamydia commonly leads to epididymitis and orchitis [5]. Chlamydia continues to be the most commonly reported STI in the United States since 1994, with approximately 1.8 million cases in 2018. Females have higher rates of infection

Telegram: @medical_k

www.konkur.in

and, in both genders, the highest rates of infections occur in the 15–24-year age group [4].

Screening

The CDC recommends that all sexually active women younger than 25, and older women with risk factors, such as multiple or new sexual partners, be screened annually. In addition, all pregnant women younger than 25, and older women with risk factors should be screened early in pregnancy and then rescreened during the third trimester. The CDC recommends annual screening for men who have sex with men (MSM) [6]. There is insufficient evidence to recommend routine screening in sexually active men who have sex with women [7].

Clinical Presentation

Female patients may complain of vaginal discharge, bleeding, or dysuria; however, most chlamydia infections are asymptomatic. Physical exam may reveal mucopurulent or purulent discharge with or without a friable cervix; however, a normal exam does not exclude infection. Male patients are also predominantly asymptomatic, with only 2–4% of infected men reporting symptoms such as penile discharge, pruritus, or dysuria. Male and female patients who have receptive anal intercourse may present with rectal pain, discharge, or bleeding [5]. Additionally, male and female patients who engage in orogenital sex may have pharyngeal infection, but symptoms are rare [8].

Diagnosis

In women, diagnostic testing can be performed through endocervical samples, provider or patient-collected vaginal samples, or urine specimens. In men, specimens from a urethral swab or urine sample are sufficient. Pharyngeal and rectal specimens can also be taken for cell culture when appropriate. Nucleic acid amplification testing (NAAT) is the most sensitive testing available and can be used on almost all specimens; however, research is still in progress to confirm the efficacy of NAAT in pharyngeal and rectal swabs. NAAT, cell culture, direct immunofluorescence, EIA, and nucleic acid hybridization can all be used on endocervical and urethral samples. All documented chlamydia infections must be reported to the CDC.

Treatment

Patients should be treated for chlamydia immediately after diagnosis of chlamydia or gonorrhea for presumed coinfection with chlamydia. Patients should be instructed to abstain from sex for 7 days after completion of therapy and until sexual partner(s) have also been treated adequately. Ideally, the antibiotics should be available to the patient at the physician's office, and the first dose should be directly observed. Patients who are likely to fail to comply with a 7-day course of treatment should receive single-dose treatment. All patients who test positive for chlamydia should also be evaluated for other sexually transmitted infections such as gonorrhea, syphilis, and HIV and instructed on the need for repeat testing for chlamydia in 3 months to identify reinfection. Repeat testing for chlamydia earlier than 3 weeks after treatment is not recommended because of the persistence of nonviable antigen leading to falsely positive results [7] (Table 1).

Table 1 Treatment of Chlamydia Trachomatis

Preferred regimen	Dosage	Instructions	Duration
Azithromycin	1 g	By mouth in a single dose	1 day
Doxycycline	100 mg	By mouth twice daily	7 days
Alternative regimen			
Erythromycin ethyl succinate	800 mg	By mouth four times daily	7 days
Levofloxacin	500 mg	By mouth once daily	7 days
Ofloxacin	300 mg	By mouth twice daily	7 days

Telegram: @medical_k

www.konkur.in

Pregnancy

Pregnant women with chlamydia can be treated safely with azithromycin or the alternative erythromycin dosing if needed. Additionally, infected pregnant patients should be retested 3 weeks after treatment for a test of cure. She should also undergo repeat testing in 3 months and again in the third trimester of pregnancy if risk factors are present [7].

Sexual Partners

Ideally, the patient's sexual partner should undergo clinical evaluation, testing, and counseling regarding STIs in addition to antibiotic therapy. However, in certain circumstances, the family physician may consider implementing Expedited Partner Therapy (EPT). EPT is the clinical practice of treating sexual partners with prescriptions or medications without requiring a clinical examination or testing. This is particularly useful when sexual partners will not obtain appropriate medical care for any reason. The option to use EPT is legal in most states within the United States; however, a family physician must check their own state law prior to engaging in EPT. Additionally, EPT should only be utilized in very selective cases in the MSM population due to the risk of concurrent undiagnosed HIV and should never be used in partners who may be at risk for severe infections [9].

Gonorrhea

Gonorrhea infection is caused by the bacteria *Neisseria gonorrhoeae*, a Gram-negative diplococcus. Gonorrhea can cause urogenital, anorectal, pharyngeal, and conjunctival infections [4]. Like chlamydia, it can lead to PID and its complications and increase the risk of transmission of HIV in women [10]. Additionally, *N. gonorrhoeae* can cause disseminated gonococcal infections and, rarely, endocarditis and meningitis [4]. Even more concerning, gonorrhea is becoming resistant to fluoroquinolones and cefixime, limiting options for treatments [11, 12]. There were 583,405 cases of gonorrhea reported in the United States in 2018, making it the second most common reported STI [4]. There is a higher number of cases in men than women. This infection occurs most commonly in persons between the ages of 15 and 24 years.

Screening

The CDC recommends that all sexually active women under 25 years of age and sexually active women 25 and older with risk factors, such as multiple or new sexual partners, be screened annually [4]. In addition, all pregnant women under 25 years of age or 25 and older with risk factors should be screened at least once in pregnancy. The CDC recommends annual screening for men who have sex with men (MSM) but makes no recommendation regarding men who have sex with women [7].

Clinical Presentation

Like chlamydia, gonorrhea is often asymptomatic in women. Women may present with vaginal discharge, dysuria, pelvic pain, or frequent heavy menses. Physical exam may reveal mucopurulent discharge, cervicitis, or adnexal or cervical tenderness. Unlike chlamydia, 90% of men with gonorrhea exhibit symptoms including dysuria, penile discharge, or epididymitis. A rectal infection can be asymptomatic or result in anal pruritus, rectal pain, mucopurulent discharge, and tenesmus. A pharyngeal infection from oral sex can cause pharyngeal symptoms. Disseminated gonococcal infection affects 0.4–3% of patients with gonorrhea. Patients may present with asymmetric joint pain and swelling along with a skin rash. In rare cases, untreated disease progression causes perihepatitis, meningitis, or endocarditis [10].

Diagnosis

Neisseria gonorrhoeae can be detected by culture and nucleic acid hybridization tests (NAAT) with

Telegram: @medical_k

www.konkur.in

female endocervical and male urethral swab specimens. NAATs can be used to detect infection in the above samples as well as provider or self-collected vaginal swabs and urine specimens. NAATs are not FDA approved for use in the rectum, pharynx, and conjunctiva; however, some NAATs are used in certain specialty laboratories due to their superior sensitivity over culture. In cases of suspected treatment failure, a culture must be performed to determine bacterial sensitivities. All documented gonorrheal infections must be reported to the CDC [7].

Treatment

Patients should be treated for gonorrhea immediately after diagnosis and also screened for chlamydia, syphilis, and HIV. Patients should be instructed to abstain from sex until completion of treatment and resolution of symptoms in both the patient and their sexual partner(s). The antibiotics should be available to the patient at the physician's office, and the first dose should be directly observed. All patients who test positive for gonorrhea should be treated for possible coinfection with chlamydia. Infected individuals should also be evaluated for other sexually transmitted infections such as HIV and syphilis and instructed on the need for repeat testing for gonorrhea in 3 months to identify reinfection. If there is concern for treatment failure, a culture must be checked in order to confirm antibiotic susceptibility. If treatment failure is discovered, the case should be discussed with the local health department [7].

Because of emerging antibiotic resistance, the preferred treatment option for patients infected with gonorrhea is ceftriaxone 500 mg intramuscularly in one dose with the addition of azithromycin 1 g orally in a single dose. If the patient is allergic to azithromycin, he or she can take doxycycline 100 mg by mouth twice daily for 7 days as an alternative. If ceftriaxone cannot be used, there are two alternative options: cefixime 400 mg orally in one dose with either azithromycin 1 g orally in one dose or doxycycline 100 mg orally twice daily for 7 days or azithromycin 2 g orally alone in a single dose (although this is not preferred due to increasing drug resistance). These dosing regimens also include treatment for likely coinfection with chlamydia [7].

Penicillin/Cephalosporin Allergy

For a patient that has an allergy to cephalosporins or an EgE-mediated penicillin allergy, data on alternative therapeutic options are limited. Options include dual treatment with a single dose of oral gemifloxacin 320 mg plus a single dose of oral azithromycin 2 grams. In these cases, it is best to consult with an infectious disease specialist [7, 12].

Pregnancy

Infected pregnant women should be treated with the recommended or alternative dosing of a cephalosporin as well as concurrent treatment with azithromycin for presumptive coinfection with chlamydia. If the patient cannot tolerate a cephalosporin, consultation with an infectious disease specialist is recommended [7].

Sexual Partners

The patient's last sexual partner or any partners within 60 days prior to symptoms must be empirically treated for gonorrhea and chlamydia. Partners should undergo clinical evaluation, testing, and counseling regarding STIs in addition to treatment; however, they may be eligible for EPT [9]. Since the preferred treatment requires an intramuscular injection of ceftriaxone, partners can be treated with an alternative therapy of cefixime 400 mg and azithromycin 1 g [9]. Similar to chlamydia, EPT should only be utilized in very selective cases. EPT should not be used in populations at high risk for HIV such as MSM with gonorrhea and should never be used in partners who are exhibiting signs of more severe infection [7].

www.konkur.in

Trichomoniasis

Trichomoniasis, caused by the protozoan *Trichomonas vaginalis*, is the most common nonviral sexually transmitted infection in the world [13]. An estimated 3.7 million people in the United States are infected but only 30% develop symptoms of infection [7]. Although asymptomatic, trichomonas can result in infertility, pelvic inflammatory disease, and adverse birth outcomes in infected pregnant women. In addition like gonorrhea and chlamydia, trichomoniasis increases the sexual transmission of HIV, at least doubling the risk of acquiring HIV infection [13].

Screening

The CDC recommends screening for trichomonas in women with risk factors such as history of new or multiple partners, sexually transmitted infections, exchanging sex for payment, or injecting drugs or women receiving care at STI clinics or correctional facilities [6].

Clinical Presentation

Often, men infected with trichomonas exhibit no symptoms; however, they may present with nongonococcal urethritis. Women may complain of malodorous yellow-green vaginal discharge with associated vulvar irritation; however, most remain asymptomatic [7].

Diagnosis

For women, trichomoniasis may be diagnosed through direct microscopy of a wet prep of vaginal secretions; however, this is only 50–60% sensitive. NAAT is highly sensitive and can be run on vaginal, endocervical, or urine specimens from women and urethral swabs or urine from men. Two point-of-care vaginal swab tests are available: OSOM Trichomonas Rapid Test uses immunochromatographic technology and Affirm VP III uses DNA hybridization, both with sensitivities of >83%. *T. vaginalis* can also be detected through culture of vaginal secretions, liquid-based pap cytology, and NAAT or PCR of vaginal, endocervical, or urine specimens although this is no longer the gold standard. In men, urethral swab, urine, or semen can be cultured; however, NAATs as discussed above can be used to detect *T. vaginalis* in men with superior sensitivity [7].

Treatment

Patients who test positive for trichomonas should be tested for other sexually transmitted infections including HIV. Trichomonas is treated with metronidazole 2 g by mouth in a single dose or tinidazole 2 g by mouth in a single dose. An alternative treatment is to give metronidazole 500 mg by mouth twice daily for 7 days. Topical metronidazole is not an acceptable option, as it does not reach appropriate therapeutic levels. Patients should be instructed to abstain from sex until completion of treatment and resolution of symptoms in both the patient and their sexual partner(s). Although retesting for trichomonas 3 months after treatment can be considered in women, there are no guidelines recommending this. If *T. vaginalis* persists despite treatment with metronidazole and it is not due to reinfection, it should be considered to be resistant, which happens in 4–10% of cases in vaginal trichomoniasis. If a patient fails metronidazole 2-g single-dose treatment, the patient can be treated with metronidazole 500 mg orally twice daily for 7 days. If patients fail this treatment, they should be given tinidazole or metronidazole at 2 g orally daily for 7 days. Failure to respond to these treatments may require specialty consultation.

In addition, patients with a critical allergy to nitroimidazoles, which include both metronidazole and tinidazole, must undergo desensitization [7].

Pregnancy

Vaginal trichomoniasis has been associated with adverse pregnancy outcomes, particularly premature rupture of membranes, preterm delivery, and

Telegram: @medical_k

www.konkur.in

low birth weight. Women can be treated with 2 g metronidazole in a single dose at any stage of pregnancy. Unfortunately, treatment with metronidazole has not been shown to reduce adverse birth outcomes, and, in fact, some limited data shows a possibility of increased prematurity or low birth weight after treatment with metronidazole [14, 15]. Treatment should be offered to prevent respiratory or genital infection of the newborn as well as further transmission to sexual partners; however, therapy can be deferred until after 37 weeks of gestation in asymptomatic women [7].

Sexual Partners

As with gonorrhea and chlamydia, the patient's sexual partner should undergo clinical evaluation, testing, and counseling regarding STIs in addition to treatment; Expedited Partner Therapy can be considered if necessary [9].

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is characterized by inflammation of the upper genital tract in the female, which can include endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. It was previously one of the most common gynecologic reasons for inpatient hospital admission in the United States, but improved outpatient and emergency room treatment has decreased the need for hospital admission [16].

Multiple organisms have been implicated in PID, often including *N. gonorrhea* and *C. trachomatis*. More recently, other organisms are also involved including *G. vaginalis*, *H. influenzae*, enteric Gram-negative rods, *S. agalactiae*, cytomegalovirus, *M. hominis*, *U. urealyticum*, and possibly *M. genitalium* most likely beginning with an ascending infection originating in the cervix and creating the opportunity for entry of other organisms [7, 16]. It is important to recognize PID in its early stages to avoid complications such as tubo-ovarian abscess, pelvic peritonitis, and long-term sequelae [7]. About 20% of women with PID become infertile, 40% develop chronic pain, and 1% of those who do conceive have an ectopic pregnancy [16].

Clinical Presentation

Women may present with a wide range of symptoms ranging from no symptoms to vaginal bleeding or discharge to pelvic pain [6, 16].

Diagnosis

The diagnosis is typically made clinically. On exam, the patient should have at least cervical motion tenderness, uterine tenderness, or adnexal tenderness. Leukorrhea, vaginal discharge, cervical exudate, cervical friability, temperature $> 101\ ^{\circ}F$ ($38.3\ ^{\circ}C$), and elevated ESR or CRP are often seen. Known gonorrhea or chlamydia infection may also assist in making the diagnosis. However, because of the potentially severe consequences of untreated PID, these criteria are not required to make a clinical diagnosis. Sometimes, symptoms can present subtly, and the condition can have an indolent course. In cases requiring more invasive testing, PID may be diagnosed through ultrasound or MRI imaging showing thickened and fluid-filled Fallopian tubes or a tubo-ovarian complex, histopathology demonstrating endometritis, or laparoscopy showing abnormalities consistent with PID. Of note, negative cervical cultures do not exclude PID, as cultures may not be positive with upper reproductive tract disease [7].

Treatment

All women diagnosed with PID should be tested for gonorrhea and chlamydia as well as HIV. Women with PID can be treated in the outpatient setting unless they have signs of severe infection including nausea, vomiting, or high fever, are pregnant, cannot tolerate or have failed oral antibiotic therapy, have a tubo-ovarian abscess, or need observation to rule out a possible surgical

Telegram: @medical_k

www.konkur.in

emergency. Those who require hospitalization should receive parenteral antibiotic therapy for 24–48 h after clinical improvement. Those with a tubo-ovarian abscess should be observed for at least 24 h. Options for parenteral treatment are listed in Table 2 [7].

Parenteral Treatment

All other patients can be treated in an outpatient setting with similar efficacy. If a patient fails to improve after 72 h, they should be reevaluated to reconfirm PID as the cause of their symptoms and then treated with parenteral antibiotics. Options for outpatient treatment are listed in Table 3 [7].

Table 2 Parenteral Treatment of Pelvic Inflammatory Disease

Recommended regimen	Subsequent oral therapy	Tubo-ovarian abscess present
Cefotetan 2 g IV every 12 h *or* Cefoxitin 2 g IV every 6 h *and* Doxycycline 100 mg PO/IV every 12 h	Doxycycline 100 mg every 12 h for a total of 14 days	Add oral clindamycin 450 mg every 6 h for a total of 14 days *or* Metronidazole 500 mg every 12 h for a total of 14 days
Clindamycin 900 mg IV every 8 h *and* Gentamicin at 2 mg/kg of body weight in an IV or IM loading dose, followed by 1.5 mg/kg every 8 h	Doxycycline 100 mg orally twice daily for a total of 14 days *or* Clindamycin 450 mg four times daily for a total of 14 days	Choose clindamycin over doxycycline for subsequent oral therapy: Clindamycin 450 mg four times daily for a total of 14 days
Alternative therapy		
Ampicillin/sulbactam 3 g IV every 6 h *and* Doxycycline 100 mg orally or IV every 12 h	Doxycycline 100 mg orally twice daily for a total of 14 days	Add oral clindamycin 450 mg every 6 h for a total of 14 days *or* Metronidazole 500 mg every 12 h for a total of 14 days

See Ref. [7]

Outpatient Treatment Options

Patients who are treated for PID should also be tested for HIV. If a patient tests positive for gonorrhea or chlamydia, he or she should be retested 3–6 months after treatment.

Penicillin Allergy

If a patient has a severe penicillin allergy and cannot take a cephalosporin, the patient can be treated with parenteral therapy or given a course of fluoroquinolone Table 4, particularly if community prevalence and individual risk for gonorrhea is low and follow-up is likely. This is not ideal given the emergence of quinolone-resistant *Neisseria gonorrhoeae*. Patients should be cultured for gonorrhea prior to treatment in order to

determine susceptibilities. If the isolate is quinolone-resistant or susceptibilities are not available, consult with an infectious disease specialist [7].

Sexual Partners

The patient's last sexual partner or any partners within 60 days prior to symptoms must be tested and also empirically treated for gonorrhea and chlamydia [7].

Syphilis

Syphilis is caused by the spirochete *Treponema pallidum*. Rates of syphilis dropped to their nadir in 2000; however, rates have been increasing since then. In 2018, a total of 35,063 cases of primary and secondary syphilis were reported to the CDC, with 86% of these cases occurring in men. Of males who are affected, most are men who have sex with men and men who have sex with both men and women [4, 17].

Screening

The CDC recommends screening of all pregnant women at their first prenatal visit and then retesting in the early third trimester and at delivery if at high risk. Additionally, the CDC recommends testing at least annually for sexually active MSM and every 3–6 months in high risk MSM [6].

Clinical Presentation

Primary Syphilis

A patient infected with syphilis may present with a painless chancre at the site of inoculation anywhere from 10 to 90 days after infection. The chancre typically progresses from a macule to a papule to an ulcer with a clean base, and multiple lesions may occur. These lesions will resolve without treatment in 3–6 weeks. The patient may also demonstrate regional bilateral rubbery and painless lymphadenopathy [17].

Secondary Syphilis

The lesions of secondary syphilis occur several weeks after the primary chancre appears and may persist for weeks to months. There may be overlap between primary and secondary stages. Patients most commonly present with non-pruritic maculopapular skin rash involving the palms and soles; flat patches of mucocutaneous lesions in the oropharynx, larynx, and genitals; and lymphadenopathy. Patients may also demonstrate condyloma lata, which are heaped-up, wartlike papules in warm intertriginous areas. Infection can involve the liver and kidney with occasional splenomegaly. Alopecia, typically in a patchy "moth-eaten" pattern, may be seen [17].

Tertiary Syphilis

Although progression to tertiary syphilis remains rare, failure to consider the diagnosis is common. Late syphilis can occur within 1–20 years of infection and is characterized by gummatous syphilis, cardiovascular problems, or CNS disease. Gummas are granulomatous lesions that destroy mucosa, soft tissue, cartilage, bone, eye,

Telegram: @medical_k

www.konkur.in

and viscera. Cardiovascular complications include ascending aortic aneurysm, aortic insufficiency, or coronary ostial stenosis [17].

Neurosyphilis

Neurosyphilis occurs when *T. pallidum* spreads to the central nervous system, can occur at any stage of syphilis, and may be asymptomatic. Neurosyphilis can be divided into early and late stages. Early neurosyphilis can occur months to a few years after infection, presenting with acute syphilitic meningitis or meningovascular syphilis. Late neurosyphilis occurs decades after infection and may present as general paresis or tabes dorsalis. Ocular involvement can occur at any stage of neurosyphilis [17].

Latent Syphilis

Latent syphilis occurs when the host suppresses the infection so that no clinical signs or symptoms are apparent and serology is positive for syphilis. This can occur at any point within the primary and secondary stages of syphilis. Latent syphilis is categorized as early latent syphilis, late latent syphilis, or latent syphilis of unknown duration. Early latent infection denotes syphilis infection of less than 1-year duration. In order to classify a patient as having early latent syphilis, certain criteria must be met to assure that infection occurred within the past 1 year. If there has been previous serologic testing within the past year, there must be either seroconversion from previously negative results or a fourfold increase in titer. Additionally, latent syphilis can be categorized as early if the patient exhibited unequivocal symptoms of primary or secondary syphilis within the past year and initiated sexual contact with a confirmed infectious case of syphilis within the past year or the only possible sexual exposure occurred within the past year. Late latent syphilis, on the other hand, is infection that has been present for greater than 1 year. If there is uncertainty about the duration of latent syphilis, it is classified as latent syphilis of unknown duration, and treatment guidelines for late latent syphilis should be followed. Syphilis is much less sexually transmissible in the latent phase [17].

Diagnosis

Definitive diagnosis of syphilis is through darkfield examination of lesion exudate or tissue for *T. pallidum*. Presumptive diagnosis is also possible through the use of serologic testing; however, serologic testing may not be positive in early stages of primary syphilis. Additionally, both nontreponemal and treponemal tests must be used in conjunction in order to avoid false-positive results. Although the CDC recommends initial testing beginning with nontreponemal tests such as Venereal Disease Research Laboratory (VDRL) or RPR, some labs implement initial testing through treponemal tests. Because of the high rate of false positives, particularly in those with autoimmune conditions, older age, and injection drug users, positive nontreponemal tests must be confirmed with treponemal tests such as fluorescent treponemal antibody absorbed (FTA-ABS) tests, *T. pallidum* passive particle agglutination (TP-PA) assay, various EIAs, and chemiluminescence immunoassays. Nontreponemal tests are reported quantitatively which allows for identification of disease activity, reinfection, and response to treatment through trends in titers, which may eventually decline to become nonreactive over time. In contrast, treponemal tests should not be used to evaluate disease activity or treatment response, as the test will likely remain reactive regardless of treatment. Serologic testing cannot be used to reliably distinguish between stages of syphilis. All positive tests must be reported to local or state health departments [7].

Treatment

Primary and Secondary Syphilis

All stages of syphilis are preferentially treated with parenteral penicillin G. Primary and secondary syphilis in nonpregnant adults is treated with a one-time dose of benzathine penicillin G 2.4 million units intramuscularly. Within 24 h after treatment, patients may experience the Jarisch–Herxheimer reaction, an acute febrile illness with

Telegram: @medical_k

www.konkur.in

associated headache, myalgia, fever, or other symptoms, which can be treated symptomatically with fever and pain reducers as needed. In addition, all patients with syphilis should be tested for HIV infection. To assure appropriate treatment, patients need to have repeat evaluation and serology 6 and 12 months following treatment to assure a fourfold decrease in nontreponemal titer. In patients with an inadequate treatment response, the clinician should consider additional clinical and serologic follow-up, retreatment with weekly penicillin G 2.4 million units intramuscularly for 3 weeks, retesting for HIV, and CSF analysis [7].

If a patient is penicillin allergic and not pregnant, treatment with doxycycline 100 mg orally twice daily for 14 days or tetracycline 500 mg four times daily for 14 days is appropriate. Ceftriaxone 1 g daily IM or IV for 10–14 days may be an effective treatment for early syphilis. Azithromycin in a single 2 g oral dose is effective for treating early syphilis; however, due to resistance patterns, it should only be used when penicillin or doxycycline treatment is not feasible [7].

Tertiary Syphilis

Tertiary syphilis should be treated with benzathine penicillin G 2.4 million units intramuscularly given at 1-week intervals for a total of three doses. Before treatment, patients affected with tertiary syphilis should undergo a CSF examination. Guidelines for further follow-up of these patients vary; infectious disease consultation might be considered in these cases [7].

Neurosyphilis

Neurosyphilis is treated with aqueous crystalline penicillin G 3–4 million units IV every 4 h or 18–24 million units daily through continuous infusion for 10–14 days. There is also an alternative regimen of procaine penicillin 2.4 million units IM once daily with probenecid 400 mg orally four times daily for 10–14 days. After completion of this initial 10–14 days of treatment, patients may also receive additional benzathine penicillin 2.4 million units IM once per week for up to 3 weeks. All patients with neurosyphilis must be tested for HIV. Follow-up CSF studies to document a decrease in leukocytes must be completed at 6-month intervals to assure treatment response. The CSF cell count and protein should be normal after 2 years. If a patient is penicillin allergic, ceftriaxone 2 g IV or IM daily for 10–14 days is administered. If the patient cannot receive ceftriaxone due to cross-reactivity or other reasons, the patient must be desensitized [7].

Latent Syphilis

Early latent syphilis should be treated with benzathine penicillin G 2.4 million units intramuscularly in a single dose. Late latent syphilis or latent syphilis of unknown duration should be treated with benzathine penicillin G 2.4 million units intramuscularly given at 1-week intervals for a total of three doses. The management of a patient who misses one of the weekly doses of benzathine penicillin is unclear; however, current guidelines suggest that 10–14 days between benzathine penicillin doses may be acceptable. If intervals are longer than 14 days, the entire course of therapy must be restarted. Additionally, if the patient is pregnant and misses any of the three doses of penicillin, she must restart the entire course of therapy in order to reduce the possibility of transmitting syphilis to the fetus. If a nonpregnant patient with early latent syphilis is penicillin allergic, the patient may be treated with doxycycline 100 mg orally twice daily for 14 days or tetracycline 500 mg four times daily for 14 days. If the nonpregnant penicillin-allergic patient has late latent syphilis or latent syphilis of unknown duration, the patient should be treated with doxycycline 100 mg orally twice daily or tetracycline 500 mg orally four times daily for 28 days. Quantitative nontreponemal serologic tests should be repeated at 6, 12, and 24 months. If the titers increase fourfold, a high titer ($>$1:32) fails to decline at least fourfold in this time period, or if clinical signs of syphilis emerge, the patients must undergo CSF examination and be retreated for latent syphilis [7].

Pregnancy

In order to prevent congenital syphilis in the fetus, all pregnant patients must be treated with

Telegram: @medical_k

www.konkur.in

penicillin as indicated above based on her stage of syphilis. If a pregnant patient is penicillin allergic, she must be desensitized and treated with the appropriate dosing regimen of penicillin.

Sexual Partners

Any sexual partner of a patient diagnosed with syphilis should be evaluated clinically and serologically. Because early stages of primary syphilis may be seronegative, partners of patients with syphilis who were exposed within 90 days preceding the diagnosis of primary, secondary, early latent, or latent syphilis of unknown duration with a high nontreponemal titer ($\geq$1:32) should be treated presumptively. If it has been greater than 90 days since exposure through sexual contact with a patient diagnosed with primary, secondary, early latent, or latent syphilis of unknown duration with a high nontreponemal titer ($\geq$1:32), the partner should be presumptively treated if serologic testing is not immediately available and follow-up is uncertain. In all other cases, the patient can be treated based on clinical and serologic findings. For the purposes of treatment of partners only, latent syphilis of unknown duration can be assumed to be early latent disease if titers are high. Long-term sex partners of patients with latent syphilis can be evaluated clinically and serologically for syphilis and treated based on their results [7].

Genital Warts

Genital warts affect 1% of all sexually active men and women in the United States. Human papillomavirus or HPV causes genital warts, and 90% of genital warts are caused by HPV 6 or 11 [18]. Genital warts are transmitted through vaginal, anal, and oral contact and can be transmitted even if there are no visible warts [7]. Genital warts are highly contagious, as approximately 2/3 of sexual partners will develop clinical genital warts within 9 months of sexual contact [19].

Clinical Presentation

While genital warts are typically asymptomatic, patients may complain of pain or pruritus at the sites of the warts. Genital warts appear as flat papular lesions or pedunculated cauliflower-like growths on the anogenital mucosa [18].

Diagnosis

Diagnosis of genital warts is clinical, but a biopsy can be taken for definitive diagnosis if the patient is immunocompromised; if the lesions are atypical, pigmented, indurated, fixed, bleeding, or ulcerated; or if they worsen or fail to improve with standard treatment [7].

Treatment

Genital warts are treated for resolution of symptoms or for cosmetic concerns. While treatment is not definitive, it will often result in wart-free periods. Additionally, although treatment of warts has been shown to reduce HPV viral load, no studies have demonstrated that this reduces transmission to uninfected partners [7]. When left untreated, warts may resolve, remain the same in appearance, or increase in size and number [7].

There are multiple topical treatment modalities for genital warts; these can be divided into patient-applied (Table 5) and provider-applied (Table 6), listed below. Clinicians can determine which method is most beneficial based on wart size, location, patient preference, and cost. Most genital warts respond within 3 months of therapy. Follow-up visits facilitate the assessment of the response to treatment. Side effects of treatment include hypo- or hyperpigmentation, scarring, chronic pain, and rarely systemic effects [7].

Topical Condyloma Treatments: Patient Applied

See Ref. [7]

Telegram: @medical_k

www.konkur.in

Table 5 Patient Applied Treatment for Condyloma [7]

Treatment	Instructions	Reapplication/ duration	Side effect	Special considerations	Safety in pregnancy
Podofilox 0.5% solution or gel	Apply twice daily for 3 days followed by 4 treatment-free days	Repeat as needed for up to 4 cycles	Mild to moderate pain or local irritation	Wart area must be less than 10 cm^2, and volume of podofilox used must be 0.5 mL or less per day	Contraindicated
Imiquimod 3.75% or 5% cream	Once daily at bedtime three times a week; washed off 6–10 h after application	Treatment for maximum of 16 weeks	Redness, irritation, induration, ulceration/ erosion, and vesicles		Uncertain
Sinecatechin 15% ointment	Apply 0.5 cm strand of ointment to each wart three times daily	Treatment for maximum of 16 weeks	Erythema, pruritus/ burning, pain, ulceration, edema, induration, and vesicular rash	Avoid sexual contact while ointment is applied Not recommended for HIV-infected persons, immunocompromised persons, or persons with clinical genital herpes	Uncertain

Table 6 Physician Applied Treatment for Condyloma [7]

Treatment	Application instructions	Interval	Special considerations	Side effect	Safety in pregnancy
Cryotherapy with liquid nitrogen	May be used with topical or injected local anesthesia as needed	Every 1–2 weeks		Immediate pain, subsequent necrosis, and blistering	Safe
Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80–90%	Apply a small amount to wart; allow to dry fully (denoted by white frosting) before patient sits or stands	Every week as needed	Neutralize with soap or sodium bicarbonate if pain is intense. Use powdered talc, sodium bicarbonate, or liquid soap preparations if excess is applied		Unknown
Surgical removal by trained provider	Local anesthesia, electrocautery, or tangential excision with fine scissors or scalpel, laser, or curettage		Surgical therapy is most beneficial for patients who have a large number or area of genital warts		Safe

Topical Condyloma Treatments: Provider Applied

See Ref. [7]

Alternative regimens include podophyllin resin, intralesional interferon, photodynamic therapy, and topical cidofovir. These treatment options presently have insufficient data and more side effects. Cervical warts must be biopsied to exclude high-grade squamous intraepithelial lesion, and there are other treatment

recommendations for warts located in the urethral meatus, vagina, and anus [7].

Pregnancy

Pregnant patients with genital warts have limited options for treatment. Pregnant patients with genital warts can proceed through typical prenatal care and delivery; however, cesarean may be required for genital warts which may obstruct the pelvic outlet or cause excessive bleeding during vaginal delivery. Pregnant patients should be informed that rarely the HPV subtypes 6 and 11 associated with genital warts could be passed on to offspring, causing respiratory papillomatosis. It is uncertain exactly how the virus is transmitted from the mother; therefore, there are currently no recommendations to prevent transmission [7].

Prevention

As with all sexually transmitted infections, HPV infection and genital warts can be prevented through abstinence or limitation of the number of sexual partners. Condoms are not fully protective against HPV because all genital areas are not completely covered by a condom. The quadrivalent human papillomavirus vaccine is active against most subtypes of HPV that cause genital warts in men and women [7].

Genital Herpes

Herpes simplex virus (HSV) 1 or 2 causes genital herpes, although most recurrent genital infections are caused by HSV-2. More than 50 million people in the United States suffer from HSV-2. Once contracted, HSV is a chronic lifelong illness with varying number of reoccurrences and intermittent viral shedding [7]. HSV infection increases the risk of HIV acquisition two- to fourfold due to the presence of open ulcerations in the mucosa. Rarely, HSV can result in disseminated infection, pneumonitis, hepatitis, blindness, encephalitis, and aseptic meningitis. The chronicity of HSV often causes psychological distress and stigma [20].

Screening

General screening for genital herpes is not recommended [7].

Clinical Presentation

Most patients have no or only mild symptoms. 87% of infected individuals are unaware of being infected. Patients may notice one or more vesicles on the mucosa of the genitals, rectum, or mouth, which eventually ulcerate. These ulcerations may take 2–4 weeks to heal. Incubation after exposure ranges from 2 to 12 days; the primary outbreak is usually longer with more systemic symptoms of malaise, fever, and lymphadenopathy. Subsequent outbreaks may be preceded by hours to days of a prodromal tingling or shooting pains in the legs, hips, and buttocks before appearance of lesions [20].

Diagnosis

If a patient has a genital ulcer or mucocutaneous lesion, cell culture or polymerase chain reaction assay (PCR) should be taken from a vesicle. PCR assays are the most sensitive and can be used to determine the presence of HSV1 or HSV2. Because viral shedding is intermittent, a negative culture or PCR does not exclude a diagnosis of HSV infection. A patient's serum can also be tested for type-specific serum antibodies to HSV 1 or 2. Positive HSV-1 serum antibodies may be caused by a previous oral infection that often occurs in childhood, but it can also indicate genital HSV. Patients with HSV-2 are more likely to have recurrences and have increased occurrences of asymptomatic viral shedding. Serum antibody testing is useful if a patient has suspected HSV due to symptoms but has a negative PCR or culture. It can also be instructive if the patient has a clinical diagnosis of genital

Telegram: @medical_k

www.konkur.in

herpes but no history of laboratory confirmation. Finally, it provides useful information for patients that have a sexual partner with known HSV. Screening of the general population for HSV-1 and 2 is not recommended [7].

Treatment

Antiviral therapy can be given for suppression or treatment of individual episodes. There is no treatment available to completely eradicate latent virus or alter the course of recurrences after medication is discontinued [7].

A patient's first clinical episode of genital herpes should be treated with antiviral therapy due to the severity and length of symptoms. Patients may have severe genital ulcers and systemic or neurologic involvement. Treatment options for immune-competent individuals include acyclovir 400 mg orally three times daily, acyclovir 200 mg orally five times daily, famciclovir 250 mg orally three times daily, or valacyclovir 1 g orally twice daily, all with a duration of 7–10 days. Longer courses could be considered if needed for incomplete healing [7].

Suppressive therapy reduces the frequency of outbreaks by 70–80% and decreases transmission of HSV-2 to noninfected sexual partners. There are several options for suppressive therapy in immunocompetent individuals including acyclovir 400 mg orally twice daily, famciclovir 250 mg orally twice daily, valacyclovir 500 mg orally once daily, or valacyclovir 1 g orally once daily; however, famciclovir may be less effective for the suppression of viral shedding [7]. Additionally, if a patient has 10 or more outbreaks per year, valacyclovir at the 500 mg dosing may be less effective. Because the frequency of outbreaks tends to diminish over time, the provider and patient should consider reevaluating the need for suppressive therapy yearly.

Patients who choose episodic therapy should be instructed to initiate therapy within 24 h of the first lesion or during the outbreak prodrome and given an ample supply of medication for convenient immediate therapy. Patients can take acyclovir 400 mg orally three times daily for 5 days or acyclovir 800 mg orally twice daily for 5 days or acyclovir 800 mg orally three times daily for 2 days or famciclovir 125 mg twice daily for 5 days, famciclovir 1,000 mg orally twice daily for 1 day, famciclovir 500 mg once followed by 250 mg twice daily for 2 days, valacyclovir 500 mg orally twice daily for 3 days, or valacyclovir 1 g orally once daily for 5 days [7].

Rarely, patients develop severe disease which requires hospitalization and parenteral therapy with acyclovir 5–10 mg/kg IV every 8 h for 2–7 days or until clinical improvement is observed. The patient should then continue oral antiviral therapy to complete at least 10 days of total therapy [7].

Pregnancy

Pregnant women infected with herpes risk transmitting infection to the fetus, particularly if primary infection occurs later in pregnancy or active infection is present during labor. If a woman newly contracts genital herpes late in pregnancy, she should be managed in consultation with an infectious disease and maternal-fetal-medicine specialist [7]. Herpes infection requires multiple measures to decrease this risk, as newborn infection can be fatal. Patients with known genital herpes are given antiviral suppressive therapy starting at 36 weeks of gestation and are delivered via cesarean if active lesions or prodromal symptoms are present during labor [20].

Sexual Partners

Sexual partners of patients with HSV should be evaluated and counseled. If sexual partners are asymptomatic, physicians can offer type-specific serologic testing for HSV infection to determine HSV status [7].

Telegram: @medical_k

www.konkur.in

STD Prevention

As a family physician, prevention of sexually transmitted infectious is critical not only through screening, early diagnosis, and treatment of infected patients and their partners but also through primary prevention by addressing behavior change. The family physician must always take a thorough sexual history and provide information on risk reduction in a compassionate and nonjudgmental manner. Patients can reduce risk of infection through abstinence, limiting the number of sexual partners, correct use of barrier methods such as male and female condoms, and vaccination when available. Additional information is available through the curriculum provided by the CDC on STD/HIV National Network of Prevention Training Centers (http://nnptc.org) [7].

Summary of HIV for Family Physicians 575
References 576

Natural History

The illness was first described on June 5, 1981, with the landmark *Morbidity and Mortality Weekly Report* (MMWR) www.cdc.gov/MMWR describing five cases of *Pneumocystis carinii* (now named *Pneumocystis jirovecii*) in Los Angeles, California. It is interesting to note that the MMWR writers note "all the above observations suggest the possibility of a cellular-immune dysfunction related to common exposure that predisposes individuals to opportunistic infections" well before the HIV was identified and named. In 1983, scientists discovered the virus that causes AIDS. The virus was at first named the human T-cell lymphotropic virus type III/lymphadenopathy-associated virus, and this name was later changed to HIV (human immunodeficiency virus). Of the retrovirus family, evidence of infection in humans has now been found as early as the 1920s from human remains and lab specimens in central Africa [1]. Two genetic strains of HIV have been identified, type 1 and type 2. HIV type 1 is the cause of 95% of all infections worldwide.

HIV is spread from person to person through blood, semen, vaginal secretions, and breast milk. Sweat, urine, tears, and saliva are not considered infectious.

Sexual intercourse and needle sharing account for the vast majority of cases, with a smaller number of infants infected at birth or through breast milk. Rare accidental transmission via needle stick or blood exposure remains an occupational hazard as well.

The majority of cases in the United States are from man-to-man (men who have sex with men, MSM) transmission. Worldwide, sexual contact is the most common mode of transmission, though it is thought that parenteral sources such as injection drug use account for about 20% of cases. Risk reduction can be achieved with "safer sex" (barriers or behaviors precluding semen or blood exposure), condom use, clean needles, and universal precautions for healthcare workers.

New data suggests that reduction of an infected person's viral load to an undetectable level renders HIV transmission to theoretically zero, and recently pre-exposure prophylaxis (PrEP) for the prevention of infection of a person at risk (e.g., an uninfected person intimate with an infected partner) has been approved by the US Public Health Service Task Force www.USPHTF Clinical Practice Guidelines 2014. The United States Department of Health and Human Services (HHS) has new initiatives as of November 2019 to improve access and awareness for PrEP under the program named "Ready Set, PrEP" with access to medications at no charge to those without insurance medication benefit [2].

The HIV, upon transmission and breach of host defenses, infects the host CD4 cells (helper/inducer lymphocytes) of the immune system, and by enzymatic insertion into the CD4 replication genome replicates HIV, then destroying the CD4 cell. When enough CD4 cells have been destroyed, host defenses are severely weakened, and eventually the infected person becomes ill developing infections, malnutrition, and malignancies. Without treatment, the average time from infection to the development of an AIDS-defining illness is approximately 10 years, although this interval may vary greatly [3].

Screening and Diagnosis

An estimated 154,000 persons in the United States have HIV infection and are not aware they are infected [4]. In the United States, females, blacks, Hispanic/Latinos, and older individuals are more likely to experience delays in diagnosis. The public health implications of this are enormous: studies demonstrate that patients who are aware of their infection take much more care not to transmit the virus to others [5]. Worldwide, more than 30 million people are infected [6]. More than 75% of all people infected with HIV are in sub-Saharan Africa, and AIDS is the leading

Telegram: @medical_k

www.konkur.in

cause of death for people between the ages of 15 and 59. Also, more than 60% of people living with HIV in low-resource settings are unaware of their status.

HIV Testing

Both patient and the public health are served by HIV discovery, and the newest recommendations by the USPSTF recommend one time screening of all adults from ages 15 to 65 unless they decline (opt out) testing. Pregnant women should be tested as early as possible in each pregnancy, and for those at higher risk, should be tested in the third trimester as well [7]. High-risk individuals, for example, injection drug users, MSM, people who trade sex for money or drugs, and sexual partners of those with HIV, should be tested at least yearly. In addition, testing should be considered in patients presenting with signs of immunodeficiency, weight loss, malignancies, and herpes zoster. In lower-resource settings where there is high prevalence of HIV, the WHO recommends universal screening in clinical settings and community-based screening where possible.

In the United States, direct to consumer in-home HIV testing is available utilizing saliva and is becoming more widely available in other countries [8]. Although the current home-based tests may vary in sensitivity and specificity and lack the option for direct patient counseling and assessment, research suggests that a variety of options for testing and reporting of results is important to remove some of the many barriers that currently exist to testing for the virus [9].

In June of 2014, the Centers for Disease Control and Prevention (CDC) updated testing recommendations, in which laboratories conducting initial testing for HIV should use an FDA-approved antigen/antibody combination immunoassay that detects HIV-1 and HIV-2 antibodies and HIV-1 p24 antigen to screen (a so-called fourth-generation assay). The p24 antigen is typically detectable by 1–2 weeks after transmission of the virus. If that testing is indeterminate, HIV nucleic acid testing (NAT) or quantitative HIV viral load testing is employed. Western blot confirmation is no longer recommended [10].

Symptoms by HIV Stage

Acute HIV Infection

Acute infection represents a burst of viral replication and is marked by fatigue, fever, myalgia, and arthralgia, often with sore throat and swollen lymph nodes. Acute infection resembles acute mononucleosis. Symptoms occur typically 1–4 weeks after transmission and, because of the relatively nonspecific presentation, are often overlooked and the disease goes undiagnosed. At this time, the HIV viral load is very high, but antibodies are typically not yet present, leading to an important diagnostic pearl: if suspected, acute HIV is best confirmed by obtaining HIV RNA (PCR "viral load") testing at this stage. Seroconversion, or the development of positive HIV antibodies, occurs within 4 weeks to 6 months after exposure and very rarely longer than 6 months after exposure.

Asymptomatic HIV Infection

After the acute HIV infection, patients usually enter a period of time lasting 7–10 years with minimal or no symptoms. The viral load declines to a low-level "set point" and the CD4 count slowly declines. The public health is in danger here: an infected person may have no knowledge or symptoms of his/her infection and intimate partners are at risk.

AIDS

The viral load rises, CD4 count drops, symptoms start to appear: at first, rashes "red itchy bump disease" thrush, lymphadenopathy, fatigue, night sweats, weight loss, herpes zoster, recurrent vaginal yeast infections, and unexplained diarrhea are common. When CD4 counts drop below 200 cells/mm^3 (normal range 400–2000 cells/mm^3) or if diagnosed with severe infection or malignancy (candidiasis of lungs or esophagus, invasive cervical cancer, cryptococcosis, cryptosporidiosis, tuberculosis, *Mycobacterium avium*, *Pneumocystis*

Telegram: @medical_k

www.konkur.in

jirovecii, progressive multifocal leukoencephalopathy, salmonella septicemia, toxoplasmosis, cytomegalovirus, chronic or severe herpes simplex, histoplasmosis, isosporiasis, Kaposi's sarcoma, lymphoma, wasting syndrome, or HIV-related encephalopathy), "AIDS" is now diagnosed. While useful in the past in determining severity of disease and for determination of disability, this designation is less useful today, but serves as a reminder of the importance of specific prophylaxis against *Pneumocystis jirovecii*, *Mycobacterium avium*, and toxoplasmosis in persons with advanced immune decline.

Conditions commonly seen in primary care that might raise suspicion for HIV in an individual not thought to be at risk otherwise might include recurrent community-acquired pneumonia, multidermatome herpes zoster or herpes zoster in a young individual, generalized lymphadenopathy, otherwise unexplained peripheral neuropathy, recurrent or severe herpes simplex, or extensive molluscum contagiosum. Patients with persistent fevers or cytopenias of unknown etiology should also be strongly considered for HIV testing.

Medical Management

Pre-exposure Prophylaxis (PrEP)

Both the CDC and the World Health Organization (WHO) recommend the daily use of pre-exposure prophylaxis (PrEP) for those individuals at higher than average risk for acquisition of HIV, along with other methods of risk reduction. This includes groups such as MSM, people in discordant relationships (where only one partner has HIV), and injection drug users at risk. PrEP has been shown to be highly efficacious in preventing virus transmission among those who are adherent to therapy [11]. Currently two Tenofovir products are offered for PrEP protection, with a host of others in the pipeline, including injectable forms. Tenofovir DF with emtricitabine (Truvada) was first approved, followed by Tenofovir Alafenamide with emtricitabine (Descovy) approved in October of 2019.

General guidelines for the use of PrEP include exclusion of acute or chronic HIV infection before beginning therapy, repeating HIV testing at least every 3 months during therapy, obtaining baseline renal function testing, and rechecking renal function at least every 6 months. In Addition, hepatitis status should be checked, as current PrEP therapy would be inadequate treatment and could possibly promote hepatitis resistance or a flare of hepatitis activity. Of note, STI diagnoses are common in PrEP users, and USPHS guidelines recommend STI testing (including triple screening of throat, urethra, and rectum for chlamydia and gonorrhea) at 3 or 6 month intervals for PrEP users [12].

Acute or Suspected Exposure (Post Exposure Prophylaxis [PEP])

In primary care, it is not uncommon to encounter patients who have had an actual or suspected exposure to HIV. These exposures may be encountered in an occupational environment (such as a needle stick) or otherwise be potentially exposed through body fluid contact such as may occur with unprotected sex, sexual assault, or the use of shared needles or injection equipment. Levels of risk for transmission are variable and in the United States can be assessed by calling the National Clinician's Post Exposure Prophylaxis Hotline 24 h a day at 888-448-4911. While post exposure prophylaxis is generally safe, toxicity, sometimes severe, can occur which may include toxic epidermal necrolysis and severe hepatitis. Therefore, it is important to weigh the risks and benefits of post exposure prophylaxis with each patient. Also, in cases where prophylaxis is unsuccessful, the selection of resistant strains of HIV may make treating the infection problematic. Therefore, PEP use should be avoided in people who have ongoing or repeated HIV exposures [13].

Post exposure prophylaxis should be started within 72 h of exposure and continued for 28 days. Optimally, a three-drug regimen is chosen to take into account factors such as efficacy, pill burden, and dosing frequency as well as cost. CDC and WHO recommendations are for three drugs, although WHO also states that two-drug regimens, while not optimal, are acceptable [14].

Telegram: @medical_k

www.konkur.in

Evaluation of Patients with HIV

After diagnosis and upon entry into care, every patient should have: a complete medical history, physical examination, and laboratory evaluation, along with counsel about transmission, self-care, intimate partner care, and the public health. A baseline evaluation, as recommended by the Health and Human Services Panel on Antiretroviral Guidelines for Adults and Adolescents, includes HIV antibody testing; CD4 T-cell count; plasma HIV RNA (viral load); CBC; chemistry profile; transaminase levels; BUN/Cr; urinalysis; serology for hepatitis A, B, and C viruses; glucose; lipids; and HIV genotypic resistance testing. In addition, some authorities recommend HLA-B 5701 to screen for abacavir sensitivity; a tropism test (for future consideration of a CCR5 antagonist); chlamydia, gonorrhea, and syphilis testing; PPD/QuantiFERON/chest X-ray testing for TB (a PPD is considered positive for those living with HIV when induration measures 5 mm rather than the usual 10 mm); toxoplasmosis antibody testing; CMV and varicella serology; cervical pap smear (at 6-month intervals initially, then yearly after two negative smears); and an anal/rectal pap smear (to screen for HPV-related squamous cell carcinoma of the anus) [15] (Table 1).

Pregnancy testing is important for women of child-bearing age, along with a discussion of contraception and avoidance of HIV treatment regimens that may be teratogenic [16].

A patient-centered multidisciplinary approach is often necessary: HIV is a complex illness with enormous emotional and physical implications. Patients still fear job loss, insurance and medical cost, shunning and isolation, along with the fears surrounding illness and death or a foreshortened life. Coinfections, substance use, housing concerns, and mental illness may also be present, and patients often are best served by a team and sometimes an advocate. Family physicians can be the advocate and team leader: continuity of care is good medicine against the fear of abandonment and shunning, and comprehensive care is critical to long-term health.

Immunizations include annual influenza vaccination, pneumococcal vaccination, hepatitis A and B vaccination for those who are vulnerable, latent or active TB treatment, and treatment for hepatitis B and/or C for those found to be coinfected. Meningococcal vaccine is also recommended. Live vaccinations are generally contraindicated: these include oral poliomyelitis, herpes zoster, varicella, measles, mumps, and rubella (at least until the immune system is restored). Human papillomavirus (HPV) vaccination, though not studied in persons living with HIV, is recommended and now has an expanded age range, from age 9, and can be given in some circumstances to age 45 [17].

The CD4 count and HIV viral load are repeated at 1 month after initiation of highly active antiretroviral therapy (HAART), after therapy changes, then at 3–6 months, and later annually at follow-up visits for those found to have achieved:

- A consistently suppressed viral load (ideally fewer than 20 copies or "undetectable")
- A stable protective CD4 count (more than 300 cells/mm^3)
- No active illnesses

HAART

Despite the very rare suggestion of "cures" in the past, and two documented cases of cure after marrow eradication and stem cell transplant, control of HIV is the goal for now [18]. Very quickly after medical suppression of viral replication ceases, most patients experience a rapid return of detectable and increasing viral loads, then the inevitable destruction of CD4 cells and return to illness. Viral reservoirs are postulated, perhaps in the central nervous system, spleen, or marrow, that permit the virus to remain in dormancy during treatment, only to rapidly reappear "when the coast is clear."

The CDC now recommends that ALL patients infected with HIV, independent of viral load or CD4 count at diagnosis, are treated with highly active antiretroviral therapy (HAART), with the goal being an undetectable viral load and normal range CD4 count. Linkage into care and

Table 1 Testing for HIV-positive patients

Test	Frequency
HIV serology – confirmatory	Initial visit
CD4 count	Initially, then at 3–6 months. If stable (see text) once yearly
Viral load	Initially, then every 3 months when on treatment. If stable (see text) once yearly
HIV resistance genotype	Initially and after treatment failure prior to change in treatment regimen
Complete blood count	Initially, then every 3–6 months
Lipid panel and serum glucose	Initially, then every 3–6 months
Chemistry panel	Initial visit, then every 6–12 months
Toxoplasma serology	Initially and if CD4 falls below 100 cells/mm^3
CMV and VZV serology	Initial visit
Syphilis serology	Initially, then yearly
Chlamydia and gonorrhea urine NAAT	Initially and every 3 months to yearly depending on risk
G-6-PD screening	Initial visit
PPD	Initially, then yearly if negative
Hepatitis serologies (A, B, and C)	Initial visit
Pap smear	Initially in 6 months and yearly if negative *x*2
HLA-B∗5701	If consideration is being given to the use of abacavir
Co-receptor tropism assay	If consideration is being given to the use of a CCR5 antagonist

adherence to medications can be difficult and uneven, but clarification of treatment regimens and once-daily combination medications provide some promise for achieving this goal. Medications break viral replication through the use of replication enzyme inhibitors. The classes include:

- Nucleoside reverse transcriptase inhibitors (e.g., zidovudine, lamivudine)
- Protease inhibitors (e.g., tipranavir, ritonavir)
- Non-nucleoside reverse transcriptase inhibitors (e.g., efavirenz, nevirapine)
- Integrase strand transfer inhibitors (e.g., raltegravir, dolutegravir)
- Fusion inhibitors (enfuvirtide)
- CCR5 antagonists (maraviroc)

Fixed dose once-daily combination products are currently available. All treatment recommendations include medications from more than one enzyme group, to provide added protection against development of viral resistance and resurgence. Novel treatments include fixed dose combinations including only two antiretroviral classes: efficacy studies support these choices for some patients (dolutegravir/rilpivirine and dolutegravir/lamivudine) [19]. In addition, monthly injectable cabotegravir/rilpivirine holds promise as another opportunity for treatment [20]. Full treatment guidelines can be found at www.aidsinfo.nih.gov/guidelines and telephone guidance from the National HIV Consultation Service of the Department of Family and Community Medicine at San Francisco General Hospital at (800):933–3413.

Generic medication is now available in some of the enzyme inhibitor classes, costs are becoming more approachable, and AIDS Drug Assistance Programs (ADAP or Ryan White programs) and manufacturer patient assistance programs can help to provide medication access. Clinical research trials may appeal to some, and monitoring and medications are provided for those who consent to participate.

CD4 count monitoring and HIV viral loads after treatment has begun may suggest nonadherence or the development of resistance. If a formerly undetectable viral load begins to rise and then becomes undetectable again, viral emergence from reservoirs may be to blame or a period of nonadherence may be the cause. Protracted and

Telegram: @medical_k

www.konkur.in

continuing viral load elevation suggests nonadherence or the development of viral resistance, repeating a genotype resistance assay and switching to a different HAART regimen, is in order, along with a determination of the cause of nonadherence if possible, and a remedy. Despite the enormous risk of nonadherence, daily lifetime treatment is difficult and easily sabotaged. Depression, substance use, relationship stresses, homelessness, mental illness, transportation, insurance, and medication access can make adherence difficult for patients and medical caregivers alike.

Management of the Immunocompromised Patient

Prophylaxis

If the CD4 counts fall below 200 cells/mm^3, prophylaxis against *Pneumocystis jirovecii* (also abbreviated as PCP, referring to the former name of *Pneumocystis carinii*) with daily trimethoprim-sulfamethoxazole (TMP-SMX 1 DS tab daily) is recommended. For the sulfa allergic, dapsone and pentamidine can be considered. TMP-SMX has the added benefit for prophylaxis against toxoplasmosis. Below a count of 50 CD4 lymphocytes/mm^3, azithromycin is recommended for prophylaxis against *Mycobacterium avium* complex (MAC).

HIV Wasting and Fatigue

Muscle loss, weight loss, fatigue, and fevers/night sweats commonly affect those living with HIV. Causes can include sepsis, infection, malignancy, malnutrition, malabsorption, vitamin D deficiency, and low testosterone. Thorough investigation including cultures, imaging, and lab work is required. Lipodystrophy, with adipose abdomens, and "buffalo hump," with facial wasting and lower extremity wasting is a hallmark of HIV and in some cases may be caused by antiretroviral therapy [21].

Skin and Mucosa

Often the first signs of HIV are evident on the skin. From common "red itchy bump disease" seborrhea, candida, and intertrigo to malignancies such as basal cell skin cancers, squamous cell cancers, melanomas, and Kaposi's sarcoma, aggressive culture, consultation, and biopsy are wise. Rapid expansion of molluscum contagiosum reflects declining immune defenses, as does the appearance of varicella zoster. Onychomycosis of finger and toenails may also be seen [22]. More commonly cellulitis, MRSA skin infections, felons, herpes infections, and hairy leukoplakia may make an appearance.

Eyes

In patients with CD4 counts of less than 50–100 cells/μL, 6–12 monthly ophthalmology exams are recommended by a provider skilled in HIV eye manifestations, which may include cytomegalovirus infection and risk of blindness [23].

Pulmonary

From the beginning of awareness about HIV, lungs have been an early and frequent host to disease. Tuberculosis treatment is a major and worrisome worldwide focus of HIV care. Pneumocystis heralds immune decline, and the lungs can also be host to Kaposi's sarcoma, Mycobacterium avium (and others), and numerous other forms of pneumonia. Pneumocystis usually requires bronchoscopy for definitive diagnosis, but is inferred by the characteristic pattern on chest X-ray ("snowstorm" infiltrate) insidious dyspnea, and elevated LDH. In the age of HAART, it is increasingly recognized that conditions such as COPD, lung cancer, pulmonary hypertension, and bacterial lung infections may be increased among patients living with HIV [24].

Telegram: @medical_k

www.konkur.in

Cardiac

With the advances in HIV care, patients are living longer, increasing their likelihood of cardiac disease. Many antiretroviral medications cause lipid disorders: along with tobacco use, viral cardiomyopathies, and inflammatory effects, cardiac disease has become a major threat to long-term health in this population [25].

Blood and Lymph

Lymphoma is one of the AIDS diagnostic illnesses and is seen in a high proportion of persons with advanced HIV disease. Anemia from medication, malnutrition, or toxicity to marrow is common (note that macrocytosis can be a surrogate marker of adherence, appearing as a side effect of zidovudine therapy). Thrombocytopenia and leukopenia commonly occur, perhaps as a direct effect of HIV infection, but requiring investigation as to their cause. Generalized lymph node enlargement is often evident in early HIV infection and may persist throughout the course of illness. Differential diagnosis of lymphadenopathy includes malignancy, infection, and reactive changes [26].

GI Tract and Liver

Lactic acidosis can result from antiretroviral treatment for HIV, presenting as fatigue, myalgia, nausea, and abdominal pain [27]. Pancreatitis is seen frequently in patients with HIV, both due to the infection and as a side effect of treatment [28]. Coinfection with hepatitis B and/or C infection requires coordinated management and, often, consultation. The liver is subject to inflammation as a side effect of antiretroviral therapy and infection from mycobacteria, fungi, and malignancy.

Renal

Renal impairment is an emerging concern, in large measure because of the nephrotoxicity of some HIV medications. Nonsteroidal anti-inflammatories can be problematic, along with the effects of hypertension, diabetes, and some antibiotic therapies. Specialized centers have now begun kidney transplantation in some cases of persons living with HIV and advanced kidney disease [29].

Musculoskeletal

Both HIV and antiretroviral treatment are thought to contribute to higher rates of osteopenia in patients living with HIV. Some authorities recommend screening for osteopenia in all males with HIV over 50, all postmenopausal women with HIV, and all patients with suspected fragility fractures [30]. Avascular necrosis of bone is not uncommonly seen [31].

Neurologic System/CNS

Central nervous system disorders can include Toxoplasmosis, Cryptococcus, CNS lymphoma, and progressive multifocal leukoencephalopathy (JC virus). AIDS dementia is a major concern, presumably from direct HIV infection of the brain. This manifests as impaired decision-making, forgetfulness, confusion, and motor disorders. Both PML and AIDS dementia have some reversal potentially with HAART [32].

HIV in Children

The number of HIV-infected children in the United States declined by two-thirds from 1992 to 1997 according to the CDC. In one of the great public health interventions of our times, and based upon the landmark study in 1994 by the Pediatric AIDS Clinical Trials Group (ACTG 076), zidovudine (AZT) given to HIV-infected women in the second or third trimester and continued during labor remarkably reduced rates of perinatal transmission of HIV. Further updates reducing maternal-infant transmission (MIT) have refined this to even lower levels of transmission [33]. In high-income countries, mothers should abstain from breastfeeding and instead provide formula, as HIV may be transmitted to their infants in up to 40% of cases. In low-

Telegram: @medical_k

www.konkur.in

and some middle-income countries, where the health risks of waterborne disease and costs of formula are prohibitive, exclusive breastfeeding for the first 6 months of life is recommended by the WHO and UNICEF [34].

All pregnant women should be screened for HIV as early as possible in each pregnancy. Women with HIV who take antiretroviral medication during pregnancy as recommended can reduce the risk of transmitting HIV to their babies to less than 1%. HIV disproportionately affects African American babies in the United States. Cesarean delivery is indicated if maternal HIV viral load is >1000 copies/mm^3 of blood. HIV may also be transmitted through breast milk, creating concern in those parts of the world where safe and reliable alternatives to breastfeeding may not exist. Small numbers of children have been infected through contaminated blood or blood products prior to screening of the blood supply in 1985 and through sexual or physical abuse by HIV-infected adults.

HIV infection is often difficult to diagnose in infants and children: symptoms may not be present, and antibodies present in the child's blood may be maternal in origin for the first 18 months. HIV PCR/viral load testing on an infant or child is more reliable, and serial testing may be indicated.

Signs and symptoms may include failure to thrive, delayed developmental milestones, neurologic complications, frequent infections, severe and recurrent candida infections, and respiratory infections. In low-resourced parts of the world, AIDS orphans are a grim reminder of the impact of HIV infection on families and communities [35].

Treatment protocols for children and infants, using liquid formulations and weight-based dosing, can be found at www.aidsinfo.nih.gov/pediatricguidelines.

HIV in Women

Greater challenges may exist for women living with HIV: caring for family, access to medical care and treatment, social stigma, and gender-specific concerns are identified. Early research tended to exclude women from clinical trials, so less is known. HIV can cause higher incidence of cervical dysplasia, invasive cervical cancer, recurrent herpes infections, yeast infections, and HPV. More frequent pap screening is recommended, and support systems and advocacy are recognized as needs in many communities. Minority women are disproportionally affected by HIV, and for some, employment, insurance, and responsibilities of children create unique challenges [36].

HIV and Aging

About half of older people with HIV have been infected for 1 year or less. The rates of HIV in patients older than 50 years are 12 times higher for African Americans and 5 times higher for Hispanics compared with whites. Older people may be at risk because healthcare providers may not test for HIV in older folks, older people may lack awareness of their risk, many older people are newly single, and many have limited knowledge about safer sex. Of interest, older patients are found to have better medication adherence to HAART and respond well to antiretroviral treatment. Some illnesses impacted by aging patients living with HIV include dementia, depression, diabetes, hyperlipidemia, cardiac disease, infection, and medication interactions. Social isolation and stigma can be difficult in older adults, contributing to depression, substance use, and increased mortality [37].

Summary of HIV for Family Physicians

Though complex, our role is vitally important, with immense satisfaction in both the individual relationships with our patients affected with HIV and in the health of our communities. The whole person care delivered for persons living with HIV in family medicine offices and patient-centered medical homes can help earn trust, which is vital for adherence and long-term health. In addition, many family physicians care for "people at the margins" the homeless, incarcerated, transgender, migrants, and patients living in rural areas: each

Telegram: @medical_k

www.konkur.in

requires dexterity in order to achieve care goals and to support trust building.

General Principles

Public Health and Economic Burden

Sepsis remains the primary cause of death from infection despite advances in vaccines, antibiotics, and acute care [1]. It is estimated to affect over 30 million people annually worldwide of which more than five million die [2, 3]. Although the majority of sepsis cases and sepsis related deaths are estimated to occur in low and middle-income countries, its impact remains significant globally transcending geographical location and socioeconomic status [4]. For instance, in the United States (US), sepsis affects over one million people and accounts for approximately 270,000 deaths annually [3, 5].

Sepsis treatment uses significant resources globally. The median of the mean hospital-wide cost of sepsis per patient is estimated at $32,421 [3]. In USA, sepsis is the most common cause of in-hospital deaths and costs more than $24 billion annually [6]. The economic burden of sepsis and its overall impact on morbidity and mortality as well as health and well-being of affected patients and their families is significant [7]. Fortunately,

www.konkur.in

timely targeted interventions improve outcomes in sepsis [1, 5, 6]. Prompt interventions at access points into the health care system play a crucial role in mitigating the negative outcomes of sepsis. It is likely that patients will present to ambulatory settings (primary care physician office, urgent care facility, etc.) earlier in the course of their infection. This underscores the importance of increased family physician awareness of sepsis and sepsis-related issues.

Definitions and Classification

Bacteremia is the presence of viable bacteria in circulating blood. Bacteremia is usually associated with a symptomatic infection and is demonstrable by bacterial growth from an aseptically collected blood culture specimen [8]. However, bacteremia often occurs transiently without any clinical consequences.

Sepsis was previously defined as a known or suspected infection with systemic manifestations of infection [9]. Most of the manifestations previously required to diagnose sepsis are no longer necessary for diagnosis [1, 5]. The most recent definitions were revised in 2016. The Society of Critical Care Medicine (SCCM) and the European Society of Intensive Care Medicine (ESICM) concluded that sepsis should be defined as life-threatening organ dysfunction caused by a dysregulated host response to infection rather than increasingly severe manifestations of uncontrolled bacterial infection **[**1**,** 10**]**.

Septic shock was previously defined as sepsis-induced hypotension not responsive to adequate fluid resuscitation[11]. The 2016 task force revision now defines septic shock as sepsis with persisting hypotension requiring vasopressors to maintain mean arterial pressure (MAP) $\geq$65 mm Hg and having a serum lactate level $>$2 mmol/L (18 mg/dL) despite adequate volume resuscitation [1, 12]. Patients in this subset of sepsis have particularly profound circulatory, cellular, and metabolic abnormalities that are associated with a greater risk of mortality than with sepsis alone [1]. Septic shock is associated with hospital mortality rates as high as 80% [13].

Approach to the Patient

Clinical presentation: Early identification and appropriate evidence-based medical care are key to increasing the chance of survival and improving overall outcomes in sepsis [1, 5–7, 14]. An aging population with more chronic illnesses, greater use of invasive procedures, immunosuppressive drugs, chemotherapy, transplantation, and increasing microbial resistance to antibiotics all contribute to increasing rates of sepsis. Bacterial (mainly gram-positive) infection is the most common cause of sepsis. Sepsis from fungal, viral, or parasitic infections can occur [5, 15]. The case-fatality rate of sepsis depends on the setting, microbe, and severity of disease. Mortality can be as high as 30% for sepsis and 80% for septic shock [13].

The most common sites of infection are the respiratory, genitourinary, and gastrointestinal systems, as well as the skin and soft tissue [16]. These sites account for over 80% of all cases of sepsis [17]. Fever is often the first obvious manifestation of sepsis [16]. However, biological and clinical heterogeneity in affected individuals such as age, baseline medical status, concurrent injuries (including surgery), medications, anatomical source and type of infecting organism add to the complexity of manifestations as well as the resultant morbidity severity and mortality [1, 18]. Therefore, clinical suspicion is key to an appropriate and timely diagnosis. In the elderly, for example, anorexia, withdrawal, agitation, disorientation, and confusion may be early signs of sepsis [16, 19]. In neonates, exaggerated physiologic jaundice, tachypnea, poor feeding, and reduced tone may be the only manifestations of sepsis.

History taking focused on the chief complaint with a pertinent review of systems is often adequate for initial triage. However, some patient with sepsis may present with nonspecific constitutional symptoms.

Physical Examination A complete physical examination is indicated. This is important because sepsis from an infection in less obvious areas such as the pelvis or perineum may occur. However, a thorough physical examination

Telegram: @medical_k

www.konkur.in

should not delay early initiation of life-saving care.

Diagnosis

The **Sequential [Sepsis-related] Organ Failure Assessment (SOFA)** score (Table 1) is currently the main tool used to assess sepsis associated organ dysfunction. An advantage of SOFA is that it grades abnormality by organ system and accounts for clinical interventions. SOFA can be scored retrospectively (either manually or by automated systems) from clinical and laboratory measures often performed routinely as part of acute patient management [1]. SOFA is helpful in sequential assessment of the severity of organ dysfunction in patients who are critically ill from sepsis. It uses measurements of major organ function to calculate a severity score [20]. SOFA calculators are freely available online and they can be readily utilized for patient care wherever there is internet access.

Organ dysfunction can be identified as an acute change in total SOFA score $\geq$2 points consequent to the infection. Of the sequentially calculated scores, the mean and the highest SOFA scores are most predictive of mortality. Scores that increase by about 30% are associated with a mortality of at least 50% [21].

Parameters that are used in calculating the SOFA severity score are as listed below [20, 22].

- Ratio of arterial oxygen tension to the fraction of inspired oxygen (PaO_2/FiO_2)
- The mean arterial pressure or the amount of vasopressor medication necessary to achieve or maintain optimal mean arterial pressure (MAP)
- Bilirubin level
- Platelet concentration
- Glasgow coma score
- Serum creatinine level or urine output

QuickSOFA (qSOFA) is a bedside clinical score that helps with rapid identification of patients that are more likely to have poor outcomes. It can be used in ambulatory, emergency, or non-ICU in-patient settings [1, 10]. The presence of at least 2 qSOFA clinical criteria (Table 2) predicts poor outcomes [24].

The qSOFA is however statistically inferior compared with SOFA for encounters in the ICU and has a statistically lower content validity as a measure of multiorgan dysfunction. Thus, the task force recommended use of a SOFA score of 2 points or more in encounters with infection as criteria for sepsis and use of qSOFA in non-ICU settings to consider the possibility of sepsis [1, 25, 26].

Laboratory Workup and Imaging

There is no gold standard diagnostic test for sepsis [10], rather sepsis is a syndrome of physiologic, pathologic, and biochemical abnormalities induced by infection [1]. Additionally, although bacterial infections are the most common cause of sepsis, viral, fungal, or parasitic infections are also known causes of sepsis.

Routine laboratory workup for sepsis includes two sets of blood cultures (drawn before starting antibiotics if possible). Urinalysis, lactate level, complete blood count (CBC), comprehensive metabolic panel (CMP), clotting profile, urine culture, and cultures from other suspected sites (wound, respiratory secretions, CSF, or other body fluids) are important as well. Other laboratory tests and imaging studies should be individualized based on history and physical examination findings.

Lactate levels have been strongly correlated with morbidity and mortality [27, 28]. Lactate level is an independent prognostic predictor of mortality for patients with sepsis. It has superior discriminative power to qSOFA and shows discriminative ability similar to that of SOFA [29].

Differential Diagnosis

Various conditions can mimic sepsis. Although the differential is very broad, common causes of systemic inflammatory response syndrome

(SIRS) listed below are differential diagnoses of sepsis.

Systemic inflammatory response syndrome (SIRS) is a condition in which an uncontrolled inflammatory response occurs in response to an insult. It can occur even in the absence of probable or documented infection [1, 5, 30, 31]. They may simply reflect an appropriate host response. SIRS may present in a range of conditions (see list below) in many hospitalized patients including

those who never develop infection and never incur adverse outcomes [1, 30].

Some causes of systemic inflammatory response syndrome (SIRS) [31]:

- Anaphylaxis
- Sterile inflammation, for example, vasculitis, acute pancreatitis
- Hypovolemia, for example, acute blood loss
- Trauma
- Respiratory diseases, for example, in acute respiratory failure, chemical aspiration
- Ischemia, for example, in acute myocardial infarction, acute mesenteric ischemia
- Diabetic ketoacidosis
- Adrenal insufficiency
- Transfusion reaction
- Burns
- Autoimmune disorder
- Substance abuse or intoxication
- Drug overdose
- Inborn errors of metabolism

In the face of manifestations of SIRS, exclusion of sepsis is often a challenge as microbiological investigations are often negative for various reasons. These include antibiotic administration prior to sample collection, or technical issues related to blood culture. Only 30–50% of patients diagnosed with sepsis have positive blood cultures [2]. Negative or inconclusive blood cultures do not exclude the possibility of sepsis in patients when there is a high index of suspicion of this condition. Thus, in the clinical setting, the diagnosis of sepsis is often empirical or made retrospectively.

Treatment

Aggressive and timely management of patients with sepsis is paramount. Expeditious transfer to an inpatient setting should occur. Sepsis should generally warrant greater levels of monitoring and intervention, including possible admission to critical care or high-dependency facility [1]. Intravenous fluid resuscitation can be started in the ambulatory setting. Blood culture collection should not cause delay in necessary care at any point. Empiric antibiotics should be started after blood culture sample collection and in any case within 1 h of arrival at the hospital or emergency room. The antibiotic choice can be based on the patient's history (e.g., recent antibiotics used), clinical context (community vs. health setting-acquired infection), most likely pathogens, local susceptibility patterns, and cost-effectiveness. Fluid resuscitation should be initiated and continued upon arrival to the emergency room or hospital. If septic shock is present, vasopressor therapy should be initiated.

If a localized source of infection is detected, intervention (such as abscess drainage) should be undertaken as soon as possible within the first 12 h after the diagnosis is made [9].

The Surviving Sepsis Campaign (SSC) care bundle (see list below) is a selected set of elements of care distilled from evidence-based practice guidelines. Using the bundle simplifies complex processes of care of patients with severe sepsis and has demonstrated marked improvements in survival rates after sepsis [9, 32, 33].

Hour-1 Surviving Sepsis Campaign Bundle of Care is to be completed within 1 h from time zero. "Time zero" or "time of presentation" is defined as the time of triage in the emergency department or, if referred from another care location, from the earliest chart annotation consistent with all elements of sepsis or septic shock ascertained through chart review [33].

Hour-1 Surviving Sepsis Campaign care bundles components are listed below [33]

1. Measure lactate level
2. Obtain blood cultures prior to administration of antibiotics
3. Administer broad spectrum antibiotics

Telegram: @medical_k

www.konkur.in

4. Administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L
5. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) ≥65 mmHg

Prevention

Infection prevention efforts, including those targeting both community-acquired and healthcare-associated infections, can reduce sepsis incidence [34, 35]. Intentional public health education efforts to raise public and clinician awareness of sepsis and its sequelae will likely help with prevention, early diagnosis, and prompt interventions. Patients at increased risk of sepsis should be appropriately vaccinated against pneumococci, *Haemophilus influenzae* type b, meningococci, and the influenza virus. The Centers for Disease Control (CDC) strategies for preventing infections include promotion of vaccination for diseases like pneumococcus and meningitis, smoking cessation programs to prevent community-acquired pneumonia, and strategies to prevent healthcare-associated infections. Early identification and appropriate treatment of infection in all patients especially those at increased risk of sepsis reduces chances of progression to bacteremia and sepsis. Good nutrition and lifestyle choices (including regular exercise) boost the body's natural defense system and ability to fight infection. Hand hygiene and good general hygiene practices reduce the rate of infection transmission. Antibiotic stewardship reduces the prevalence of bacterial resistance in the community.

Family and Community Issues

Sepsis survivorship is a substantial and underrecognized public health problem with major implications for patients, families, and the healthcare system. Sepsis survivors often develop physical, cognitive, and affective deficits in the months and years after discharge. These new deficits are relatively more severe among patients who were in good health prior to hospitalization for sepsis [36]. Declines in the level of functioning impact many areas of a patient's life ranging from the ability to perform activities of daily living (ADL) to executive functioning [7, 37]. This may affect the structure and functioning of the family unit. Additional issues include caregiver fatigue, marital stress, and other psychosocial, medical, economic, and legal issues. It is important for family physicians to maintain vigilance for possible sequelae of sepsis among patients and their families beginning at the discharge planning phase of care. An understanding of immediate and long-term outcomes helps with managing expectations and setting goals of care especially when assessing options for short- or long-term care.

Toxoplasmosis

Toxoplasmosis is an infection with a worldwide distribution, affecting immunocompetent and immunodeficient hosts, as well as pregnant women and newborn babies.

Etiology and Epidemiology

Toxoplasma gondii is an extremely successful protozoal parasite, which infects almost all mammalian species including humans. Approximately 30% of the human population is chronically infected with *T. gondii.* The severity of congenital infection is inversely proportional to gestational age at the time of infection. The transmission rate to the fetus is 10–15% in the first trimester, 22–40% in the second, and 68% in the third trimester [1].

Toxoplasma gondii exists in four different stages: oocyst, which is the product of the parasite cycle in the cat's intestine. Subsequently, they are excreted in cat feces. In the soil, they transform into the infectious form, the tachyzoite, which penetrates all nucleated cells and replicates rapidly, causing tissue destruction. This stage is responsible for the clinical manifestation of the disease. The body's immune response transforms these tachyzoites into slowly replicating bradyzoites. This tissue cyst can be found in the brain, heart, and skeletal muscle.

A single cat can pass more than 100 million nonsporulated oocysts, which become infective within 1–5 days after defecation. Freezing, chemical, or physical treatment (such as chlorine or ozone treatment) does not destroy sporulated oocysts; only heating >55 °C reliably destroys them [2].

There are four means of acquiring toxoplasmosis in humans: ingestion of infectious oocysts from the environment (soil contaminated with feline feces), ingestion of tissue cysts from an infected animal, contaminated fruits/vegetables, and contaminated water. Vertical transmission from an infected mother to her fetus is possible. The final route of acquisition is via blood transfusion or solid organ transplantation from an infected donor [3].

Ingestion of raw or undercooked food (including beef, goat, lamb, or pork) or drinking unpasteurized goat milk is responsible for the majority of toxoplasmosis cases in the USA and Europe. In other parts of the world, infection with toxoplasma is more likely due to environmental exposure. Once an individual is infected, the

Telegram: @medical_k

www.konkur.in

organism lies dormant in eye, muscle, or brain tissue and is not eliminated [4].

Clinical Features

Toxoplasma infections are divided into four categories: toxoplasmosis in the immunocompetent host, toxoplasmosis in the immunocompromised host, toxoplasmosis in pregnancy, and congenital toxoplasmosis.

Acquired Toxoplasmosis Infection in the Immunocompetent Host: Infection in this group is asymptomatic in 80–90% of patients. On the other hand, if symptoms develop, the most common manifestation is bilateral, symmetric cervical adenopathy. Associated symptoms are fever, chills, sweat, headaches, myalgia, pharyngitis, hepatomegaly, and splenomegaly (mononucleosis-like symptoms). This is a benign self-limiting course and may last from a few weeks to months. Acute toxoplasmosis may be mistaken for acute Epstein-Barr virus (EBV) or as *Cytomegalovirus* infection (CMV), especially since atypical lymphocytes can be seen in toxoplasmosis infection. There is an association between *T. gondii* and mental health illness, mostly schizophrenia and generalized anxiety disorder [5, 6, 7]. Human immunodeficiency virus (HIV) also should be included as part of the initial evaluation. Other differential diagnoses might include syphilis, sarcoidosis, Hodgkin's disease, and lymphomas.

Toxoplasma gondii has the ability to disseminate through the bloodstream and can cross vascular barriers such as the ocular area, causing ocular toxoplasmosis (posterior uveitis or necrotizing retinochoroiditis). These lesions commonly "heal" within 2–4 months after infection, leaving a hyperpigmented scar, a result of retinal pigment epithelium disruption. Acute retinal lesions may be associated with adjacent old scars indicating recurrent attacks.

Toxoplasmosis Infection in the Immunocompromised Host: In immunocompromised individuals, especially patients with acquired immunodeficiency syndrome (AIDS), usually when the CD4 lymphocyte count is below 100 cells/microL, the parasite can reactivate and cause disease. All patients with HIV should be screened for *Toxoplasma gondii* infection. The most common site of reactivation is the central nervous system (CNS), and the next is the retina. Toxoplasma infection is the most common CNS opportunistic infection in AIDS patients.

Cerebral Toxoplasmosis: Cerebral toxoplasmosis usually presents with clinical symptomatology such as fever, neurological deficit, confusion, and headaches. Laboratory evaluation includes serologic evaluation with immunoglobulin G (IgG). The majority of patients with cerebral toxoplasmosis are positive for IgG antibodies. Radiologic evaluation includes brain imaging (CT or MRI). Ring-enhancing brain lesions are often associated with edema, with predilection for the basal ganglia. While brain biopsy is the definitive test to confirm the infection, the morbidity associated with this procedure means that the diagnosis is usually made on the basis of the clinical picture, serology, and imaging findings. Cerebrospinal fluid (CSF) may demonstrate elevated protein and mononuclear pleocytosis. The differential diagnosis includes CNS lymphoma, cryptococcosis, mycobacterial infection, or bacterial abscess.

Chorioretinitis: Chorioretinitis usually presents with eye pain and visual deficit. An ophthalmologic evaluation reveals posterior uveitis, retinal lesions, and vitreous inflammation.

Toxoplasmosis in Pregnancy: Women of childbearing age may acquire toxoplasmosis, resulting in primary maternal infection. Fetal infection may occur from transmission of the parasite from mother to fetus before the development of a protective immunologic response in the mother.

During acute infection, the mother is usually asymptomatic, but when symptoms develop, they are vague: fever, malaise, myalgia, fatigue, and headaches. Lymphadenopathy is usually present. Pregnant women who have mono-like symptoms but are EBV serology negative should be tested for toxoplasmosis, cytomegalovirus, and, if at risk, for HIV.

Infections during pregnancy are most reliably diagnosed by blood samples at least 2 weeks apart using toxoplasma-specific IgG or IgM. A maternal primary toxoplasma infection poses serious

Telegram: @medical_k

www.konkur.in

risk to the fetus, but a reactivation of primary toxoplasmosis does not (congenital toxoplasmosis secondary to reinfection is rare). The majority of fetuses exposed to acute toxoplasmosis infection in the first trimester die in utero or develop severe neurological or ophthalmological sequelae. Fetuses infected in the second or third trimester tend to develop milder or subclinical findings at birth.

Congenital Toxoplasmosis: Neonates with congenitally acquired toxoplasmosis may have few, if any, manifestations on their physical exams and remain asymptomatic. The classic triad of intracranial calcifications, hydrocephalus, and chorioretinitis occurs in few of the infected newborns. If there is a high index of suspicion, then laboratory and radiologic evaluations are needed to diagnose congenital toxoplasmosis – ophthalmologic evaluation, seeking retinal scarring (focal necrotizing retinitis). CSF shows pleocytosis with mononuclear cells and elevated protein. Toxoplasma-specific IgM or isolation of *T. gondii* from the CSF can be attempted. Ultrasound of the head may reveal calcifications in brain parenchyma, but head CT is more sensitive in visualizing these lesions.

Differential diagnosis in the neonatal period includes other congenitally acquired diseases that include rubella, CMV, syphilis, and herpes infection.

Laboratory Diagnosis

The use of serologic tests to search for anti-*Toxoplasma gondii* is a primary method of diagnosis. The tests most commonly used in routine laboratories for the detection of anti-*Toxoplasma gondii* IgG are the double sandwich enzyme-linked immunosorbent assay (ELISA), the indirect fluorescent-antibody assay (IFA), the indirect hemagglutination assay, and the direct agglutination test and for anti- *Toxoplasma gondii* IgM, double sandwich ELISA, immunosorbent agglutination assay (ISAGA), and IFA.

The Toxoplasma Serology Laboratory at the Palo Alto Medical Foundation (USA) www.pamf.org/serology/clinicianguide.html offers advice to clinicians about ordering and interpretation of test.

IgG antibodies: usually appear between 1 and 2 weeks after acquiring the infection, peak within 1–2 months, and usually persist for life. A positive test confirms that an infection has occurred but does not indicate how long ago occurred. A number of tests looking for "avidity" to toxoplasma IgG antibodies have been introduced: antibody avidity to a specific antigen is lower in patients with recent infection and higher avidity in older infection. The dissociation test can distinguish low-avidity test antibodies (seen in recently acquired infection) from high-avidity antibodies (seen in infections >4 months old). Although there is a consensus that a high-avidity index can rule out acute infection, the interpretation of a low-avidity index is less clear [8].

IgM antibodies: may appear earlier and decline more rapidly than IgG antibodies. False positives may result in cross-reactivity with rheumatoid factor (RF) and antinuclear antibodies (ANA). A major problem with a positive IgM test is the lack of specificity. A positive IgM is not an accurate marker of acute infection; it may persist for at least 12 years after acute infection. Also, another complication is the fact that several methods have a high frequency of false-positive results. Due to difficulties establishing an acute diagnosis in the immunocompromised, pregnant, or neonatal individual, it is suggested to follow up with infectious diseases or maternal-fetal specialist. An algorithm from the Centers for Disease Control and Prevention (CDC) for the immunodiagnosis of toxoplasmosis is shown below (Table 1).

IgA antibodies: may be detected in serum of congenitally infected neonates or in an acutely infected adults. This antibody can also remain positive for several months or even a year. This test is more useful in diagnosing congenitally acquired toxoplasmosis in the fetus and newborn.

IgE antibodies: can be used to diagnose toxoplasmosis in acutely infected newborn (congenital toxoplasmosis), children with congenital toxoplasma chorioretinitis, or adults. The duration of persistence of this antibody is less than IgM or IgA and may be useful in identifying recently acquired infection.

Telegram: @medical_k

www.konkur.in

Table 1 Interpretation of immunodiagnosis of toxoplasmosis

IgG result	IgM result	Report/interpretation for humans
Negative	Negative	No serological evidence of infection with *Toxoplasma*
Negative	Equivocal	Possible early acute infection or false-positive IgM reaction. Obtain a new specimen for IgG and IgM testing. If results for the second specimen remain the same, the patient is probably not infected with *Toxoplasma*
Negative	Positive	Possible acute infection or false-positive IgM result. Obtain a new specimen for IgG and IgM testing. If results for the second specimen remain the same, the IgM reaction is probably a false-positive
Equivocal	Negative	Indeterminate: Obtain a new specimen for testing or retest this specimen for IgG in a different assay
Equivocal	Equivocal	Indeterminate: Obtain a new specimen for both IgG and IgM testing
Equivocal	Positive	Possible acute infection with *Toxoplasma*. Obtain a new specimen for IgG and IgM testing. If results for the second specimen remain the same or if the IgG becomes positive, both specimens should be sent to a reference laboratory with experience in diagnosis of toxoplasmosis for further testing
Positive	Negative	Infected with *Toxoplasma* for more than 1 year
Positive	Equivocal	Infected with *Toxoplasma* for probably more than 1 year or false-positive IgM reaction. Obtain a new specimen for IgM testing. If results with the second specimen remain the same, both specimens should be sent to a reference laboratory with experience in the diagnosis of toxoplasmosis for further testing
Positive	Positive	Possible recent infection within the last 12 months or false-positive IgM reaction. Send the specimen to a reference laboratory with experience in the diagnosis of toxoplasmosis for further testing

http://www.cdc.gov/parasites/toxoplasmosis/

Polymerase chain reaction (PCR): has been used to detect *T. gondii* in various biological specimens such as CSF, vitreous/aqueous fluids, bronchoalveolar lavage (BAL) fluids, blood, and other tissues. PCR in blood samples appears to be a sensitive method for diagnosis of disseminated and cerebral toxoplasmosis [9].

When an individual gets exposed to *T. gondii*, any antibody test will be able to determine the presence or absence of the infection. A more difficult task is to determine whether an individual has acquired the infection recently or in the past. A true-negative IgM test effectively rules out a recent infection, but a positive IgM serology test might not be a representative of a recent infection; therefore, confirmatory tests should be performed.

Acute infection is suggested when there is a greater than fourfold rise in the IgG antibody in serum run in parallel or when there is a seroconversion of IgG and IgM antibodies from negative to positive. A single titer either IgG or IgM is insufficient to make a diagnosis of acute toxoplasmosis, so a confirmatory test is strongly suggested to rule out acute infection.

IgA antibodies are superior and more sensitive than IgM in the peripheral blood of newborn babies. It is strongly suggested to repeat another IgA at least 2 weeks apart to verify that no maternal contamination has occurred. Maternally acquired IgG antibodies should disappear between 6 and 12 months of life.

Treatment

In immunocompetent hosts: treatment is not necessary unless symptoms are severe or they persist for several weeks. Usually a lower dosage is used than with immunocompromised hosts. Therapy is used for about 2–4 weeks. Treatment consists of pyrimethamine (100 mg loading dose, then 25–50 mg daily) in association with sulfadiazine (2–4 g/day orally three times a day). All patients receiving pyrimethamine need to receive leucovorin calcium (folinic acid 10–25 mg/day). Other alternatives are pyrimethamine with clindamycin (300 mg orally four times a day), pyrimethamine with azithromycin (500 mg orally

Telegram: @medical_k

www.konkur.in

daily), pyrimethamine with atovaquone (750 mg twice a day), and trimethoprim (10 mg/kg/day) with sulfamethoxazole (50 mg/kg day) T-S twice daily.

In immunosuppressed hosts: Higher doses are required for 6 weeks. After this therapy, dosage is reduced for chronic management (this regimen is for patients who respond well to therapy). For patients who deteriorate clinically in the first 48 h of initial therapy, or develop elevated intracranial pressure, or CNS midline shift, dexamethasone (4 mg every 6 h) should be used. Monitoring patients at this time should not be based on IgG serology but with clinical, neurological, and radiological modalities. If the patient does not improve in 10–14 days after therapy is started, then consideration for an alternative diagnosis needs to be made. Treatment consists of pyrimethamine (200 mg loading dose, then 50–75 mg daily), as well as leucovorin (10–25 mg daily), in association with sulfadiazine (1 g orally four time daily); initially therapy is for 6 weeks. Alternative therapy might include T-S (5 mg/kg of trimethoprim or 25 mg/kg of sulfamethoxazole) twice daily, pyrimethamine with azithromycin (1 g orally daily), pyrimethamine with atovaquone (1.5 g twice daily), and sulfamethoxazole with atovaquone. For severe inflammatory processes, dexamethasone may be considered in a dose of 4 mg orally every 6 h. The use of medication for primary prophylaxis is when the CD4 falls below 100 cell/ml.

In ocular toxoplasmosis, most ophthalmologists elect not to treat due to the fact that these lesions are old inactive ones or scars. If decision to treat is done by an experienced ophthalmologist, then pyrimethamine with sulfadiazine in association to leucovorin for 4–6 weeks is adequate. Consideration for use of a steroid is made on a case-by-case basis.

During pregnancy: If toxoplasma is identified by serology due to maternal symptomatology, then treatment is justified. Prenatal treatment reduces serious neurological sequelae of congenital toxoplasmosis but does not affect ocular disease, vision, or mother-to-child transmission. Conventional therapy is with spiramycin (1 g orally every 8 h) alone; another alternative is pyrimethamine with sulfadiazine (P-S) in association with leucovorin. P-S is no more effective than spiramycin. There is no evidence that early treatment reduces risk of intracranial lesions or chorioretinitis. Also, there is no evidence that prenatal treatment reduces the risk of chorioretinitis. There is clear evidence that there is a reduction in serious neurological sequelae [9]. Alternative regimens include using pyrimethamine (50 mg daily) with sulfadiazine (3 g /day twice daily) for 3 weeks and then alternating with spiramycin (1 g orally daily) for another 3 weeks until baby is delivered. Leucovorin is added when P-S regimen is used.

Neonates: Infants with congenital infection should be treated with P-S and leucovorin for 21 days and then followed by either azithromycin or spiramycin for 4–6 weeks. Alternating P-S with macrolides should be continued for a minimum of 6 months, although generally is continued for 1 year. If neonate has elevated protein in the CSF or has chorioretinitis, then prednisone (1 mg/kg/day) may be added. Healthy newborns delivered to mothers with elevated antibody titers should be treated with a macrolide alone, until serologic evidence for the diagnosis of T. Gondii is definite [10].

Trichinellosis

Trichinellosis cases are much less common now than in the past. However, every year, approximately 20 cases are reported to Centers for Disease Control and Prevention (CDC) [11].

Etiology and Epidemiology

Trichinella spiralis, an intestinal nematode, is a common cause of trichinellosis. At present, 12 taxa including eight species and four genotypes (T6, 8, 9, 12) are recognized in the genus *Trichinella*. These taxa are divided into those that encapsulate in host muscle tissue and those do not encapsulate (T. *pseudospiralis*, *T. papuae*, and *T. zimbabwensis*). Among these, only six species and one genotype have been detected in humans.

Telegram: @medical_k

www.konkur.in

T. spiralis has a worldwide distribution, and pigs, rodents, and carnivores (e.g., fox, wild boar) are common hosts. *T. nativa* is common in arctic bears and walruses. *T. murelli* is common in carnivores in the USA and South Canada. *T. britovi* is common in carnivores and swine in Europe, Asia, and Africa. *T. papuae* is common in crocodiles and pig in Australia and Southeast Asia. *T. pseudospiralis* is common in swine, carnivorous birds, and animals in Europe [12].

In the USA, most swine are fed grain. Only a small proportion of swine are fed garbage. Those that are fed garbage may become infected with *T. spiralis*. Viable larvae in inadequately cooked meats particularly pork and wild game meats are ingested, passed into small intestine, and attached to the intestinal mucosal villi; once there, they develop into adult worms that mate and produce more larvae, which seed the skeletal muscles via the blood and lymphatic stream.

Clinical Features

Infection can be divided into an intestinal (enteral) and muscular (parenteral) phase. Clinical infection may range from asymptomatic/subclinical to severe disease based on the larvae ingestion. Most infections are subclinical (< 70 larvae). After ingestion, larvae migrate from intestinal mucosa to blood vessels, where they spread through the body, reaching striated skeletal muscle [13]. Infection with a heavy load (75–150 larvae) may lead to clinical features of the enteric phase including diarrhea (most common), abdominal discomfort, and vomiting. The parenteral phase usually begins 1–6 weeks after ingestion of the larvae and may present with fever (54%), myalgia (70%), facial or periorbital edema (28%), headache, fatigue, and weakness [14]. Conjunctivitis, subungual hemorrhages (vasculitis), and maculopapular rash may be also observed [15]. The differential diagnosis of trichinellosis includes influenza, dermatomyositis, and viral gastroenteritis.

A history of recent consumption of raw or undercooked meat should raise suspicion for the diagnosis of trichinosis.

Laboratory Diagnosis

Eosinophilia is often seen about the second week of illness and may reach very high levels. Serum creatinine phosphokinase and lactate dehydrogenase levels may be elevated when muscles are involved.

Organism-specific antibodies are generally detectable by 3 weeks after infection. Specific antibodies are usually measured by ELISA or immunofluorescence, further confirmed with the Western blot. If the diagnosis is still in doubt, muscle biopsy may be obtained from a tender, swollen muscle to detect larvae.

Treatment

The mainstay treatment for trichinosis is anthelmintic, salicylates, and bed rest. The main anthelmintic drugs used against trichinellosis are albendazole (15 mg/kg/day in two doses for 10–15 days) or mebendazole (200–400 mg orally three times a day for 3 days, then 400–500 mg three times a day for 10 days – not available in the USA). These drugs are contraindicated in pregnancy and in children less than 2 years of age. Treatment is effective if given in early stages of infection. Jarisch-Herxheimer-like reactions have been reported with these drugs in severe infestations due to massive release of antigenic substances. Prednisone (30–60 mg/day for 10–15 days) may be used in severely ill patients. Heating meat in a microwave oven, curing, drying, and smoking meat are not effective methods to inactivate Trichinella larvae [13].

Prevention

The mainstay of prevention of trichinosis is the proper cooking of meats. Although *Trichinella* larvae can be killed at 55 °C, meats should be cooked to reach a core temperature of 71 °C for at least 1 min until there is no trace of pink fluid or flesh. Exposure to freezing temperatures of −15 °C or lower for 3 weeks also sterilizes pork infected with *T. spiralis*.

Lyme Disease

Etiology and Epidemiology

Lyme disease (LD) is the most commonly reported tick-borne disease in the United States and Europe. It was initially diagnosed in the town of Lyme, Connecticut in 1977, after an unusual cluster of what appeared to be juvenile rheumatoid arthritis. LD is caused by the spirochete *Borrelia burgdorferi* (Bb) and rarely, *Borrelia mayonii* in the United States; *Borrelia afzelii* and *Borrelia garinii* are the most common in Europe and Asia. Borrelia is a Gram negative spirochete bacterium. Bb is transmitted by the deer tick *Ixodes scapularis* (blacklegged tick) in the East, mid-Atlantic, and Upper Midwest and by the *Ixodes pacificus* in the West Coast of the USA. *Ixodes ricinus* is the major European vector. These vector ticks are forest dwellers, spending most of their time hiding in the leaf litter of the forest floor, where humidity is high and the risk of desiccation is low. Thus, Lyme disease is associated with heavily forested areas of the northern hemisphere.

Most cases of LD in the USA occur in southern New England, southeast New York, New Jersey, eastern Pennsylvania, eastern Maryland, Delaware, and parts of Minnesota and Michigan. The *I. scapularis* tick has a 2-year, three-stage life cycle: The larvae emerge from eggs laid in spring, hatch in early autumn, take their first meal, and become infected with spirochetes. Larvae molt into nymphs and during the next spring and summer takes their second meal (most likely to transmit infection). In late summer, they transform into adult forms, and they take their third meal (also infectious). They then reproduce, thus repeating the life cycle again. Approximately 30% of nymphal and up to 50% of adult female I. scapularis are infected in some areas [16]. Most humans are infected through the bites of nymphs and they are tiny (less than 2 mm) and difficult to see. Adult ticks can also transmit Lyme disease bacteria, but they are much larger and are more likely to be discovered and removed before they have had time to transmit the bacteria (Fig. 1).

Several factors are associated with the risk of transmission of Bb from ticks to humans. The tick must be infected; a critical factor is the duration of tick attachment, the tick feeds, and becomes engorged, discharging its saliva into the bite wound. The bacteria live in the midgut of the tick, which needs to be engorged with blood before migrate to the salivary gland and the saliva, then the organism is injected into the host [17]. The proportion of infected ticks varies greatly both in geographic area and the stage of the tick in its life cycle. How long the tick is attached (36–48 h) and whether or not it is engorged are two of the most important factors to consider when assessing the risk of transmission to humans.

Clinical Presentation

Lyme disease is classified into three different stages: early localized disease, early disseminated disease, and late disseminated disease. It is diagnosed in patients who have been previously exposed to an infected tick and who subsequently develop the typical signs and symptoms associated with LD affecting the skin, central nervous system (CNS), musculoskeletal system, and cardiac system.

Early localized disease will manifest as erythema migrans (EM), which appears at the site of the tick bite, usually within 7 to 14 days after the bite (range 3–30 days). It is classically reported as a single lesion, uniform erythematous, and oval to circular rash with a median of 16 cm (5–70 cm), and it expands for several days to weeks to form a large annular erythematous lesion. The lesion is usually asymptomatic but may be pruritic and has associated symptoms such as fever, malaise, headaches, lymphadenopathy, and myalgia. The EM lesion is pathognomonic of Lyme disease and it occurs in approximately 80% of patients. It is important to note that a skin lesion indistinguishable from EM occurs in Southern tick-associated rash illness (STARI), and it is found in the southeast and south central regions of the United States.

Early disseminated disease usually occurs weeks to several months after the tick bite and may be the first manifestation of Lyme disease. The patient presents with multiple EM lesions; these lesions are smaller but morphologically similar to the initial lesion (EM). Another skin manifestation, called Borrelia lymphocytoma, a bluish-red nodule appearing usually on the earlobe or nipples within months or years of an infection can be seen in LD reported from Europe [18]. After the initial stage, the spirochete disseminates systemically via lymphatic system or bloodstream, it affects extracutaneous sites such as joints, CNS, and cardiovascular system. Common manifestations of early disseminated disease are migratory arthralgia (arthritis is usually a manifestation of late disease), which is reported in 60% of untreated patients. Neurologic involvement may include lymphocytic meningitis and cranial neuropathy – usually unilateral facial nerve palsy. Motor or painful sensory radiculoneuropathy known as Bannwarth's syndrome is more common in Europe. Lyme disease should be in the differential diagnosis in the etiology of Bell's palsy in endemic areas. Cardiac involvement, such as atrioventricular nodal block or myopericarditis, is less common.

Late disseminated disease occurs months to years after the tick bite. The patient presents either as chronic arthritis (monoarticular or oligoarticular) or neurological symptoms (encephalomyelitis or peripheral neuropathy). Approximately 60% of untreated patients develop intermittent arthritis and 10% develop persistent monoarthritis usually affecting the knee [19]. Other late manifestation including Acrodermatitis chronica atrophicans, a chronic sclerosing dermatitis, develops in patients infected with *B. afzelii* an uncommon manifestation in Europe. It is usually located in the lower extremities and progresses slowly. The initial inflammatory phase is characteristic with a bluish-red discoloration of the skin located in the distal parts of extremities, which then progresses to the atrophic phase, with epidermal thinning.

Post-Lyme symptomatology is characterized by symptoms and complaints for more than 6 months after adequate treatment. Musculoskeletal or radicular pain, dysesthesias, neurocognitive symptoms, sleep abnormalities, and fatigue have all been reported. No additional antimicrobial therapy is effective at this stage, but symptomatic management is recommended.

Serologic testing is an important tool for the diagnosis of Lyme disease. The Centers for Disease Control and Prevention (CDC) recommends serologic evaluation as the preferred initial diagnostic test. Serologic testing should be performed in patients who meet **all** of the following criteria: A recent history of having resided in or traveled to an area endemic for Lyme disease, risk factor for exposure to ticks, and having **s**ymptoms consistent with early disseminated disease or late Lyme disease (e.g., meningitis, radiculopathy, mononeuritis, cranial nerve palsy, arthritis, and carditis). Serologic testing should **not** be performed for screening of asymptomatic patients living in endemic areas or patients with nonspecific symptoms only, due to greater chance of false-positive test results than true positive test results.

A two-tiered protocol using an enzyme-linked immunosorbent assay (ELISA) is initially followed by a more specific Western blot to confirm the diagnosis when the assay is positive or equivocal. If the ELISA test is negative, an immunoblot is not necessary. The ELISA test provides quantitative estimate of antibodies against

Telegram: @medical_k

www.konkur.in

Bb. The immunoblot produces information about specific proteins against Bb that are present (band). In order for a Western blot to be considered positive, it requires to have either two bands for IgM or five bands for IgG. Urine antigen testing is not recommended [20]. IgM antibodies usually appear 2–4 weeks after infection, peak at 8–10 weeks after infection, and gradually disappear, but in some patients, these may persist for several years. IgG antibodies appear after 6 weeks postinfection, peak after 4–6 months, and still are detectable after several years. A diagnosis of Lyme disease should not be based solely on a positive serology (IgM), but on epidemiological data, as well as physical examination, since IgM and IgG may persist for years after effective treatment of LD.

Polymerase chain reaction (PCR) test can be done in synovial fluid and cerebrospinal fluid in patients with untreated Lyme arthritis and meningoencephalitis [21]. FDA does not approve urine and blood specimens for PCR testing due to limitations [22]. False-negative PCR results can occur due to the presence of inhibitors of the DNA polymerase, such as hemoglobin or hyaluronic acid. The accuracy of PCR is highly dependent upon the care used in sample collection and storage and the technique used in the assay.

Culture remains the diagnostic standard. Although it is not routinely available, it is useful in biopsy samples of EM lesions or plasma in multiple EM lesions. This is due to the fact that EM appears 3–30 days after the tick bite, while Bb antibodies appear 2–4 weeks after the bite. Individuals with EM may have negative serology but positive spirochetes in the blood.

Treatment

Early localized disease characterized by EM is best treated with an oral antibiotic. Adults should receive doxycycline (100 mg twice a day), or amoxicillin (500 mg three times a day), or cefuroxime (500 mg twice a day), or azithromycin (500 mg daily). Children older than 8 years of age can receive doxycycline (4 mg/kg/day twice a day, maximum dose 100 mg twice a day), and younger children should receive amoxicillin (50 mg/kg/day in three doses, maximum 500 mg per dose) or cefuroxime (30 mg/kg/day in two doses, maximum 500 mg per dose) or azithromycin (10 mg/kg/day, maximum 500 mg per dose). Doxycycline is contraindicated in pregnancy and breastfeeding and in children younger than 8 years old. All of the above treatments should be for 14 days.

Early Disseminated Disease: Multiple EM, localized cranial nerve palsy, or carditis without heart block can also be treated with oral antibiotics. Parenteral ceftriaxone (2 g IV daily) in adults or children (50 mg/kg/day) is used for treatment of Lyme meningitis, myocarditis, and heart block in symptomatic individuals requiring hospitalization. Once symptomatology improves, then oral therapy is completed. Therapy is for 14–28 days.

Late disease such as arthritis, without neurologic involvement, can be treated with oral antibiotics as used for EM, but treatment should be prolonged for up to 28 days. Patients with neurologic symptoms including encephalitis, encephalomyelitis, or peripheral neuropathy with or without arthritis should be treated with parenteral antibiotics as in early-disseminated disease for 14–28 days.

A Jarisch-Herxheimer reaction may develop after therapy is initiated (fever, sweating, myositis). In this case, the medications are generally continued, and nonsteroidal anti-inflammatory drugs are often beneficial.

Post-Lyme disease symptoms are difficult to treat. Randomized controlled trials of repeat antimicrobial therapy in such patients have **not** shown a sustained benefit of prolonged antimicrobial therapy. The most common reason for lack of response to appropriate antimicrobial therapy used to treat LD is misdiagnosis (the patient does not have Lyme infection). The knee synovitis of Lyme disease may persist for months after antibiotic therapy possibly due to the triggering of an autoimmune process [23, 24]. Nonspecific symptoms (fatigue, arthralgia, or neurological maladies) may persist for several weeks even with successful treatment and should be treated with nonsteroidal anti-inflammatory medications.

Ebola and Marburg Virus

Etiology and Epidemiology

Ebola (EBV) and Marburg viruses (MARV) are the members of family *Filoviridae*, causing Ebola virus disease and Marburg disease in humans and primates. The genus Ebolavirus consists of five species: Zaire, Sudan, Bundibugyo, Tai Forest, and Reston. They are named according to the location of the first outbreak recorded by this strain. The outbreak caused by the Zaire species in Central Arica has the highest case fatality rate (80–90%). The same virus was the causative agent of the 2014–2016 epidemic in West Africa; in which, there were nearly 29,000 total cases (suspected, probable or confirmed) and case fatality rate was approximately 40%. Since then, the Zaire species has been responsible for three epidemics in the Democratic Republic of the Congo in 2017 and 2018. MARV consists of a single species: Lake Victoria MARV (Fig. 2).

Ebola and Marburg viruses are single-stranded RNA viruses. In the past, those were classified as "hemorrhagic fever viruses" based on their clinical manifestations which include bleeding and shock. But only a small percentage of patients developed significant bleeding, which usually occur in terminal phase of illness. Therefore, the term "hemorrhagic fever" is no longer used. The filoviruses were first recognized in 1967, when the inadvertent importation of infected monkeys from Uganda resulted in outbreak of illness among vaccine plant workers in Marburg, Germany. MARV is often introduced into human by people who enter cave and mines. EBV may be introduced by hunting or processing meat. Bats can act as host and are reservoir for filoviruses. The transmission pathway from bats to humans and the possible role of bats in the initiation of Ebola outbreaks have not been identified so far.

The virus spreads through direct contact (such as through broken skin or mucous membranes in the eyes, nose, or mouth) with blood or body fluids (urine, saliva, sweat, feces, vomit, breast milk, and semen) of a person who is sick with or has died from Ebola Virus Disease, and can remain in certain bodily fluids-including semen, even if the patient no longer have symptoms of severe illness. Ebola virus can be transmitted via contaminated objects (such as needles and syringes), infected fruit bats, or nonhuman primates (such as apes and monkeys).
