Periodontal regeneration has demonstrated significant clinical improvements in intrabony defects far beyond those achieved with debridement alone, with many different regenerative materials, including barrier membranes, grafts, active biologic compounds, and combinations of these. Different surgical approaches have been proposed and tested in combination with the various regenerative materials, but none has demonstrated a clear superiority over the others. Moreover, all of the proposed regenerative approaches have shown a high degree of clinical variability in terms of CAL gain: none has demonstrated the capacity to solve all the different and unique patient/defect presentations. Therefore, to treat a given defect, the regenerative strategy has to be chosen from a panel of options. The adoption of a clinical strategy for optimal application of materials and surgical approach could increase the efficacy of periodontal regeneration and give a clear advantage in terms of improved clinical outcomes. Periodontal regeneration expresses its potential in defects of any depth, from very shallow to very deep, and in extreme conditions can change the prognosis of teeth from hopeless to maintainable units.

Clinical outcomes obtained with periodontal regeneration can be maintained on a long-term basis, provided good oral hygiene and infection control within a stringent recall program are enforced. Current data indicate that, in patients participating in a supportive periodontal care program, 96% of teeth with severe intrabony defects and treated with a periodontal regenerative procedure could be retained for a period of up to 15 years.

Mucogingival Therapy: Periodontal Plastic Surgery

Jan L. Wennström[1] and Giovanni Zucchelli[2]

[1] Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Introduction

Mucogingival therapy is a general term used to describe periodontal treatment involving procedures for correction of defects in morphology, position, and/or amount of soft tissue and underlying bone support at teeth and implants (American Academy of Periodontology 2001).

A more specific term, *mucogingival surgery*, was introduced by Friedman (1957) and was defined as "surgical procedures designed to preserve gingiva, remove aberrant frenulum or muscle attachments, and increase the depth of the vestibule". Frequently, however, the term "mucogingival surgery" was used to describe all surgical procedures that involved both the gingiva and the alveolar mucosa. Consequently, not only were techniques designed (1) to enhance the width of the gingiva and (2) to correct particular soft tissue defects regarded as mucogingival procedures, but (3) certain pocket elimination approaches were also included in this group of periodontal treatment modalities. In 1993, Miller proposed the term *periodontal plastic surgery*, considering that mucogingival surgery had moved beyond the traditional treatment of problems associated with the amount of gingivae and recession type defects to also include correction of ridge form and soft tissue esthetics. Periodontal plastic surgery would accordingly be defined as "surgical procedures performed to prevent or correct anatomic, developmental, traumatic or disease-induced defects of the gingiva, alveolar mucosa or bone" (Proceedings of the 1996 World Workshop in Periodontics 1996). Among treatment procedures that may fall within this definition are various soft and hard tissue procedures aimed at:

- Gingival augmentation
- Root coverage
- Correction of mucosal defects at implants
- Crown lengthening
- Gingival preservation at ectopic tooth eruption
- Removal of aberrant frenulum
- Prevention of ridge collapse associated with tooth extraction
- Augmentation of the edentulous ridge.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

The focus of this chapter is mainly on treatment procedures for corrections of soft tissue defects in relation to the tooth and the edentulous ridge, while hard tissue augmentation procedures are covered in Chapter 50.

Gingival augmentation

The introduction of surgical procedures for gingival augmentation was based on the opinion that the presence of a wide band of keratinized and attached mucosa around the tooth is critical for maintaining gingival health and preventing attachment loss and soft tissue recession (Nabers 1954; Ochsenbein 1960; Friedman & Levine 1964; Hall 1981; Matter 1982). Hence, a discussion of the scientific evidence forming the basis for our current understanding of the role played by the gingiva in the protection of the periodontium proper seems appropriate.

Gingival dimensions and periodontal health

For many years the prevailing concept was that a narrow zone of gingiva (Fig. 46-1) was insufficient (1) to protect the periodontium from injury caused by friction forces encountered during mastication and (2) to dissipate the pull on the gingival margin created by the muscles of the adjacent alveolar mucosa (Friedman 1957; Ochsenbein 1960). Moreover, it was believed that an "inadequate" zone of gingiva would (1) facilitate subgingival plaque formation because of the improper pocket closure resulting from the movability of the marginal tissue (Friedman 1962) and (2) favor attachment loss and soft tissue recession because of less tissue resistance to apical spread of plaque-associated gingival lesions (Stern 1976; Ruben 1979). It was also considered that a narrow gingiva in combination with a shallow vestibular fornix might (1) favor the accumulation of food particles during mastication and (2) impede proper oral hygiene measures (Gottsegen 1954; Rosenberg 1960; Corn 1962; Carranza & Carraro 1970).

Fig. 46-1 Clinical photograph of a mandibular front tooth region. The gingiva on the buccal aspect of tooth 41 (arrow) has a narrow width and shows more pronounced signs of inflammation than adjacent gingival units with a wider zone of gingiva.

The opinions expressed concerning what could be regarded as being an "adequate" or "sufficient" dimension of the gingiva varied. While some authors suggested that <1 mm of gingiva may be sufficient (Bowers 1963), others claimed that the apicocoronal height of keratinized tissue ought to exceed 3 mm (Corn 1962). A third category of authors had a more biologic approach to the question and stated that an adequate amount of gingiva is any dimension that (1) is compatible with gingival health or (2) prevents retraction of the gingival margin during movements of the alveolar mucosa (Friedman 1962; De Trey & Bernimoulin 1980).

One of the first studies in which attempts were made to evaluate the significance of the gingival zone for the maintenance of periodontal health was carried out by Lang and Löe (1972) on dental students who had their teeth professionally cleaned once a day for 6 weeks. All buccal and lingual sites were examined for plaque, gingival conditions, and apicocoronal height of the gingiva. The results showed that despite the fact that the tooth surfaces were free from plaque, all sites with <2 mm of gingiva exhibited persisting clinical signs of inflammation. Based on this observation, the authors suggested that 2 mm of gingiva is an adequate width for maintaining gingival health. Subsequent clinical trials (Grevers 1977; Miyasato *et al*. 1977), however, failed to substantiate this concept of a required minimum dimension of gingiva. In fact, these clinical trials demonstrated that it is possible to maintain clinically healthy marginal tissues even in areas with <1 mm of gingiva.

The question whether a firmly attached portion of gingiva is critical for the protection of the periodontium proper was addressed by Wennström and Lindhe (1983a, b) utilizing the Beagle dog model. In these studies, dentogingival units with different clinical characteristics were experimentally established: (1) units with only a narrow and mobile zone of keratinized tissue and (2) units with a wide, firmly attached gingiva (Fig. 46-2). With mechanical plaque-control measures performed daily, the gingival units could be maintained free from clinical as well as histologic signs of inflammation irrespective of the presence or absence of an attached portion of gingiva. When bacterial plaque was allowed to accumulate (for 40 days), clinical signs of inflammation (redness and swelling) developed that were more pronounced in tooth regions with mobile gingiva (Fig. 46-3a) than in areas with a wide and firmly attached gingival zone (Fig. 46-3b). However, histologic analysis revealed that the size of the inflammatory cell infiltrate and its extension in an apical direction (an assessment which indirectly may be used as an estimate of the apical migration of the bacterial plaque) were similar in the two categories of dentogingival units. The finding that the clinical signs of gingival inflammation did not correspond with the

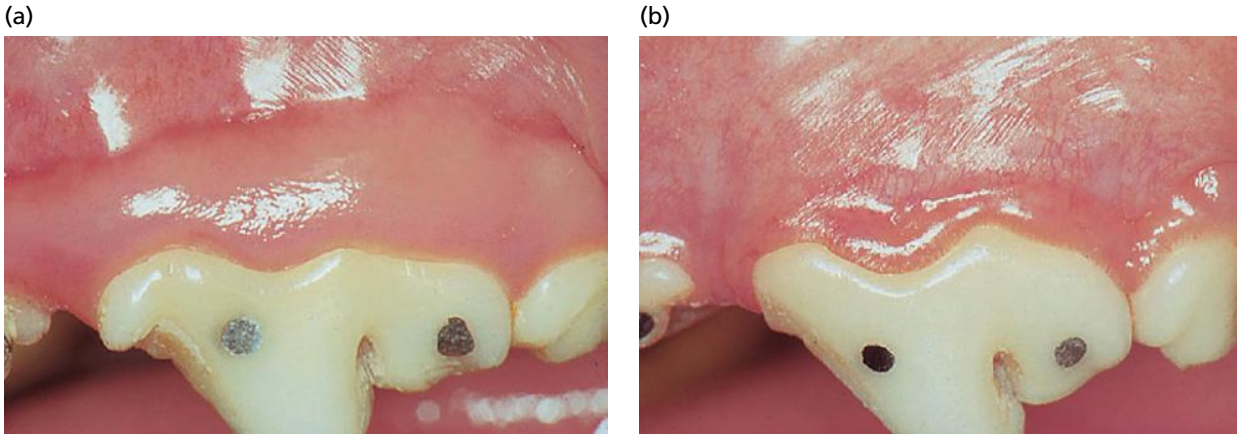

Fig. 46-2 Two teeth in a dog with varying dimensions of the marginal gingiva. (a) Buccal tooth site with a wide zone of attached gingiva. (b) Site with an unattached, narrow band of gingiva.

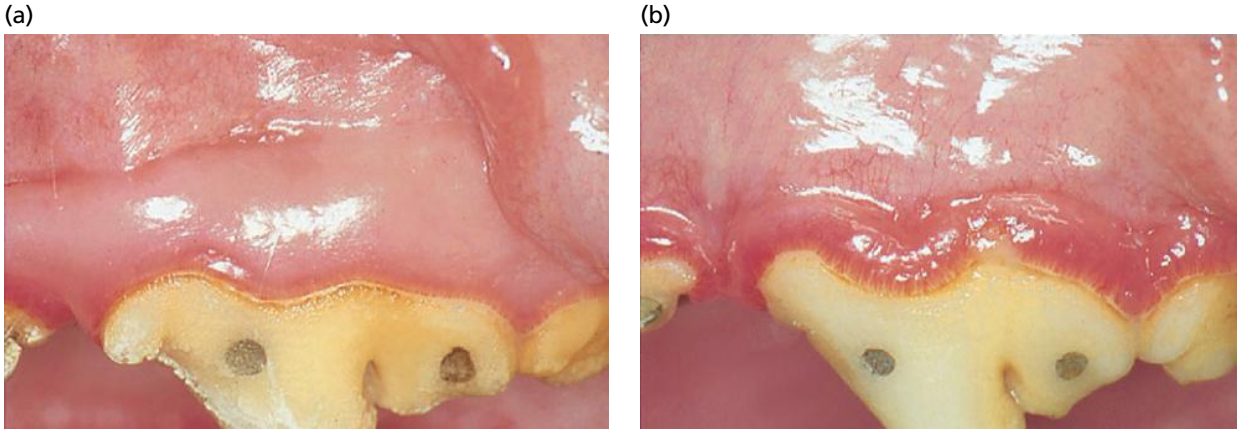

Fig. 46-3 Same teeth as in Fig. 44-2 after 40 days of plaque accumulation. The clinical signs of inflammation are more pronounced at the site with the narrow band of gingiva (b) than at the site with the wide zone of attached gingiva (a).

size of the inflammatory cell infiltrate illustrates the difficulties inherent in the interpretation of data from clinical examinations made in areas with varying gingival widths. This should be kept in mind when interpreting the data from the human study by Lang and Löe (1972) showing that clinically visible signs of inflammation, such as redness and swelling, were more frequent in areas with <2 mm of gingiva than in areas with a wider zone of gingiva.

The necessity for and effectiveness of gingival augmentation in maintaining periodontal attachment was examined by Dorfman *et al*. (1980). Ninety-two patients with bilateral facial tooth surfaces exhibiting minimal keratinized tissue (i.e. <2 mm) had a free gingival graft placed on one side, while the contralateral side served as the untreated control. Prior to and after surgery the patients were subjected to scaling and root planing and instruction in oral hygiene measures. Not surprisingly, the investigators found a significant increase (approximately 4 mm) in the width of keratinized tissue at the grafted sites. This increased width of gingiva, as well as the clinical attachment level, was maintained throughout the 2 years of follow-up. In the control sites, the gingival width was <2 mm and did not vary significantly during the observation period. However, the attachment level was also maintained unchanged in the non-grafted areas. Thus, the resistance to continuous attachment loss was not linked to the height (width) of the gingiva, a conclusion that was further substantiated by subsequent 4- and 6-year follow-up reports of this patient material (Dorfman *et al*. 1982; Kennedy *et al*. 1985).

Further support for the conclusion that a minimal zone of gingiva may not compromise periodontal health is available from a number of other longitudinal clinical studies (e.g. De Trey & Bernimoulin 1980; Hangorsky & Bissada 1980; Lindhe & Nyman 1980; Schoo & van der Velden 1985; Kisch *et al*. 1986; Wennström 1987; Freedman *et al*. 1999). Hence, Hangorsky and Bissada (1980), who evaluated the long-term clinical effect of free soft tissue grafts, concluded that while the free gingival graft is an effective method to widen the zone of the gingiva, there is no indication that this increase has direct influence upon periodontal health.

Conclusion: Gingival health can be maintained independent of its dimensions. Furthermore, there is evidence from both experimental and clinical studies that, in the presence of plaque, areas with a narrow zone of gingiva possess a similar degree of

"resistance" to continuous attachment loss as areas with a wide zone of gingiva. Hence, the traditional dogma of the need for an "adequate" width (in millimeters) of gingiva, or an attached portion of gingiva, for prevention of attachment loss is not scientifically supported.

Marginal tissue recession

Marginal tissue recession, that is displacement of the soft tissue margin apical to the cementoenamel junction (CEJ) with exposure of the root surface, is a common feature in populations with high standards of oral hygiene (e.g. Sangnes & Gjermo 1976; Murtomaa *et al*. 1987; Löe *et al*. 1992; Serino *et al*. 1994), as well as in populations with poor oral hygiene (e.g. Baelum *et al*. 1986; Yoneyama *et al*. 1988; Löe *et al*. 1992; Susin *et al*. 2004). In populations maintaining high standards of oral hygiene, loss of attachment and marginal tissue recession are predominantly found at buccal tooth surfaces (Löe *et al*. 1992; Serino *et al*. 1994), and are frequently associated with the presence of a "wedge-shaped defect in the crevicular area of one or several teeth" (Sangnes & Gjermo 1976). In contrast, all tooth surfaces are usually affected by soft tissue recession in periodontally untreated populations, although the prevalence and severity is more pronounced at single-rooted teeth than at molars (Löe *et al*. 1978; Miller *et al*. 1987; Yoneyama *et al*. 1988; Löe *et al*. 1992).

Tissue trauma caused by vigorous toothbrushing is considered to be a predominant causative factor for the development of recessions, particularly in young individuals. Traumatizing toothbrushing and tooth malposition are the factors most frequently found to be associated with marginal tissue recession (Sangnes 1976; Vekalahti 1989; Checchi *et al*. 1999; Daprile *et al*. 2007). In addition, Khocht *et al*. (1993) showed that the presence of recessions is associated with the use of hard toothbrushes. Other local factors that have been associated with marginal tissue recession are (1) alveolar bone dehiscences (Bernimoulin & Curilivic 1977; Löst 1984), (2) high muscle attachment and frenal pull (Trott & Love 1966), (3) plaque and calculus (van Palenstein Helderman *et al*. 1998; Susin *et al*. 2004), and (4) iatrogenic factors related to restorative and periodontal treatment procedures (Lindhe & Nyman 1980; Valderhaug 1980). At least three different types of marginal tissue recessions may be defined:

1. *Recessions associated with mechanical factors, predominately toothbrushing trauma* (Fig. 46-4). Recessions resulting from improper toothbrushing techniques are often found at sites with clinically healthy gingiva and where the exposed root has a wedge-shaped defect, the surface of which is clean, smooth, and polished.
2. *Recessions associated with localized plaque-induced inflammatory lesions* (Fig. 46-5). Such recessions may be found at teeth that are prominently positioned, that is the alveolar bone is thin or absent (bone dehiscence), and where in addition the gingival tissue is thin (delicate). An inflammatory lesion that develops in response to subgingival plaque occupies the connective tissue adjacent to the dentogingival epithelium. Measurements made by Waerhaug (1952) suggest that the distance between the periphery of microbial plaque on the tooth surface and the lateral and apical extension of the inflammatory cell infiltrate seldom exceeds 1–2 mm. Thus, if the free gingiva is voluminous, the infiltrate will occupy only a small portion of the connective tissue. In a

(a)

(b)

Fig. 46-4 Recessions associated with toothbrushing trauma. The marginal gingiva is clinically healthy and abrasion defects of various extensions can be noted in the exposed roots.

Fig. 46-5 Recession associated with localized plaque-induced inflammatory lesion.

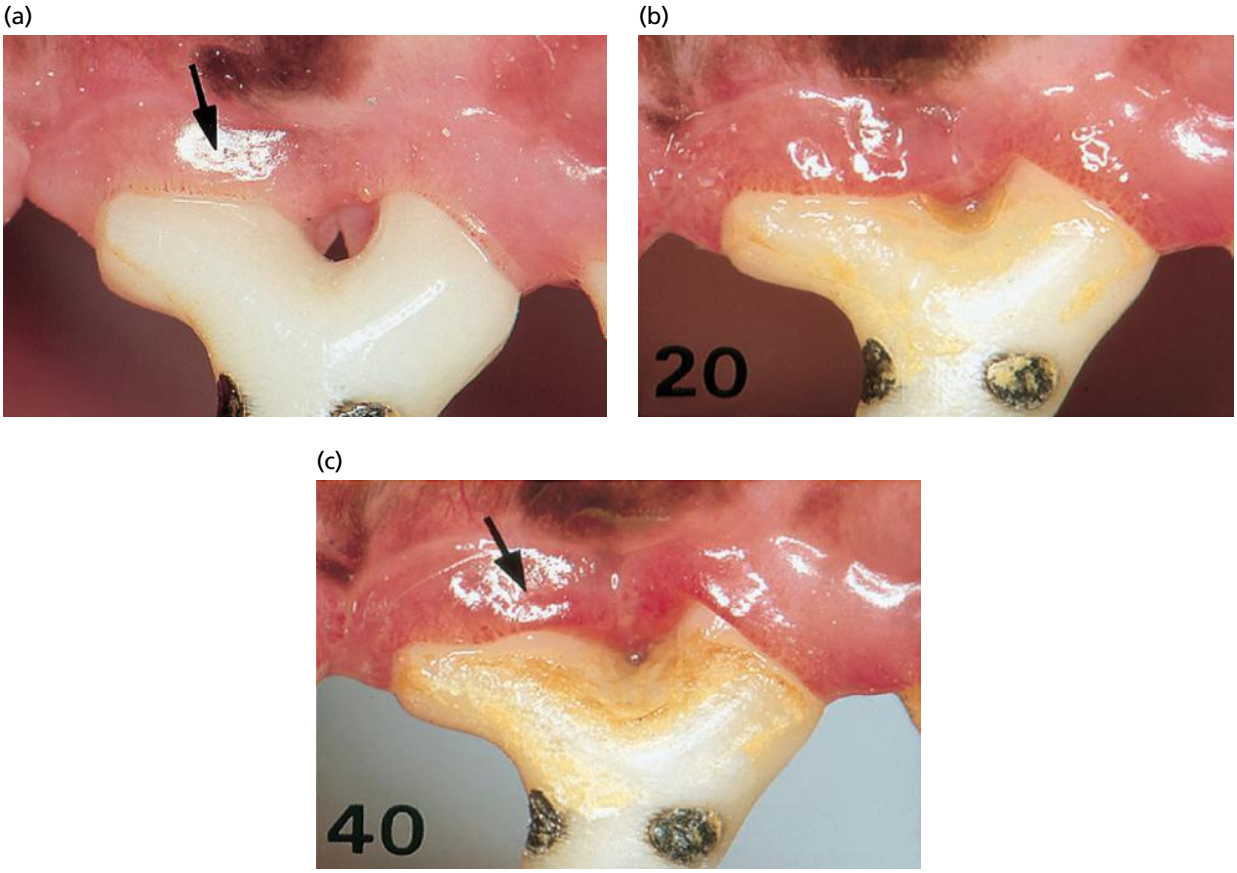

Fig. 46-6 Clinical photographs showing the development of a soft tissue recession as a result of plaque-induced inflammation in a Beagle dog. (a) Note the thin but healthy gingiva (arrow) at the start of the plaque accumulation period. (b) Pronounced clinical signs of inflammation are seen after 20 days. (c) After 40 days of no tooth cleaning, the gingival margin has receded (arrow).

Fig. 46-7 Recessions associated with generalized forms of destructive periodontal disease. Recession of the soft tissue is found not only at the facial aspect of the teeth but also at proximal sites.

thin and delicate gingiva, on the other hand, the entire connective tissue portion may be engaged. Proliferation of epithelial cells from the oral as well as the dentogingival epithelium into the thin and degraded connective tissue may bring about a subsidence of the epithelial surface, which clinically becomes manifest as recession of the tissue margin (Baker & Seymour 1976) (Fig. 46-6).

3. *Recessions associated with generalized forms of destructive periodontal disease* (Fig. 46-7). The loss of periodontal support at proximal sites may result in compensatory remodeling of the support at the buccal/lingual aspect of the teeth, leading to an apical shift of the soft tissue margin (Serino *et al*. 1994). In addition, apical displacement of the soft tissue margin is an inevitable consequence of the resolution of periodontal lesions following treatment, and is independent of a non-surgical or a surgical treatment approach.

Cross-sectional studies showing that a correlation exists between the presence of recession defects and the height (width) of the gingiva (e.g. Stoner & Mazdyasna 1980; Tenenbaum 1982) have often been interpreted as evidence that a narrow zone of gingiva is a contributing factor in the development of soft tissue recessions (Fig. 46-8). It should be realized, however, that data derived from cross-sectional studies can neither prove nor disprove a cause–effect relationship. Consequently, the data reported from such studies may equally well be interpreted to demonstrate that the formation of a recession defect results in a reduced height of the gingiva. If this interpretation is valid, the rationale for increasing the height of the gingiva in an area *apical to an existing defect* as a method to prevent further recession may appear somewhat obscure.

Fig. 46-8 Mandibular tooth segment with multiple buccal recessions illustrating the association proposed between recession depth and gingival height.

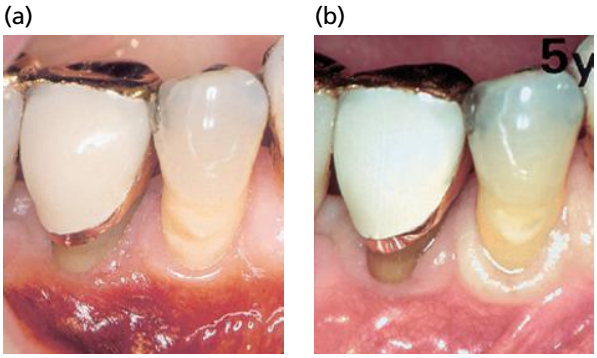

Fig. 46-10 (a) Mandibular canine and first premolar tooth region showing a very narrow zone of gingiva 6 months after surgical therapy. (b) No major change in the position of the soft tissue margin has occurred during a 5-year period despite the lack of attached gingiva.

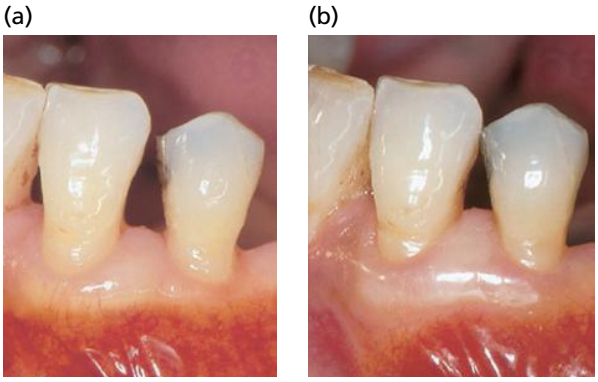

Fig. 46-9 (a) Clinical photograph of a canine and a first premolar in the mandibular jaw with <1 mm of attached portion of gingiva 6 months after surgical treatment. (b) Note the increase of the width of the gingiva at the facial aspect of the teeth and the more coronally positioned gingival margin 5 years later.

In fact, data obtained from prospective, longitudinal studies of patients showing areas with only a minimal zone of gingiva favor the conclusion that a certain quantity of gingiva is not essential for the preclusion of soft tissue recessions. Lindhe and Nyman (1980) examined the alterations of the position of the gingival margin following periodontal surgery in 43 patients with advanced periodontal breakdown. Following active treatment, all patients were recalled once every 3–6 months for maintenance care. The position of the soft tissue margin in relation to the CEJ was assessed on the facial aspect of all teeth after initial healing and after 10–11 years of maintenance. The results showed that both in areas with and without visible keratinized tissue after healing, a small coronal regrowth (≈1 mm) of the soft tissue margin had occurred during the period of maintenance. In other words, no recession was observed in this group of patients maintained on a careful prophylaxis program.

Dorfman *et al*. (1982) reported a 4-year follow-up study including 22 patients with bilateral tooth areas exhibiting gingival recession and lack of firmly attached marginal soft tissue. In conjunction with scaling and root planing, a free gingival graft was placed on one side, while the contralateral control side was treated by scaling and root planing only. All patients were recalled for prophylaxis once every 3–6 months during a 4-year period. The data obtained from the examinations of the non-grafted control areas revealed that no further recession of the soft tissue margin or loss of probing attachment had occurred despite the lack of attached marginal tissue. In fact, there was a slight gain of probing attachment. The authors concluded that recession sites without attached gingiva might not experience further attachment loss and recession if the inflammation is controlled. In a subsequent report, Kennedy *et al*. (1985) presented data on 10 patients who had not participated in the maintenance program for a period of 5 years. In these patients, plaque and clinical signs of inflammation as well as some further recession were noted at the 5-year examination as compared with the data obtained after termination of active treatment. However, except for the clinical signs of inflammation, which were more pronounced in non-grafted sites, no differences were observed between control sites with <1 mm or complete lack of attached gingiva and grafted sites.

The lack of relationship between the height of the gingiva and the development of soft tissue recession is further validated by results from longitudinal clinical studies (Schoo & van der Velden 1985; Kisch *et al*. 1986; Wennström 1987; Freedman *et al*. 1999). The prospective study by Wennström (1987) reported observations made at 26 buccal sites surgically deprived of all keratinized tissue. A baseline examination carried out 6 months after treatment revealed that these sites had regained a zone of gingiva which was, however, not attached or had only a minimal (<1 mm) portion attached to the underlying hard tissues (Figs. 46-9a, 46-10a). Adjacent teeth with a broad zone of attached gingiva were also included in the examinations. In most sites, the position of the soft tissue margin was maintained unchanged over 5 years

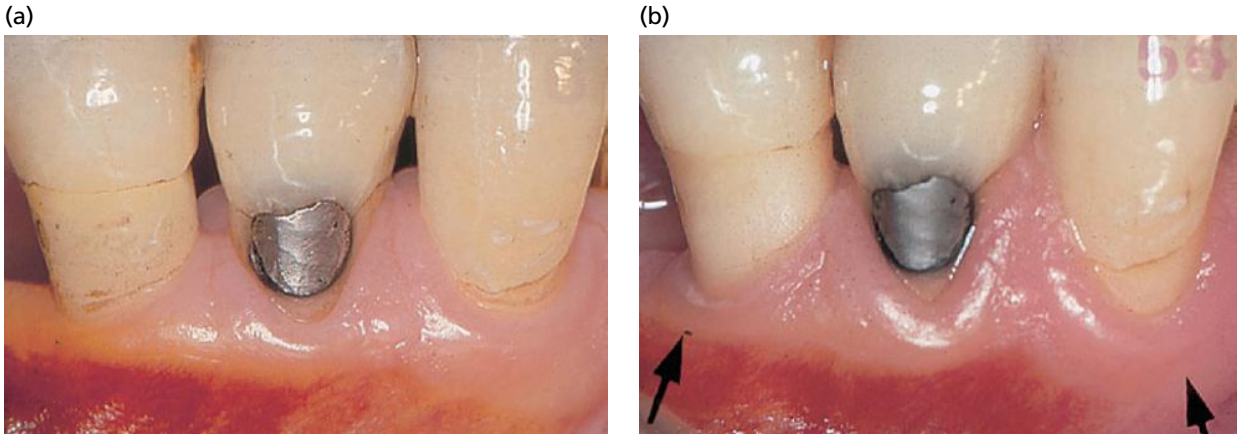

Fig. 46-11 Clinical photographs of the mandibular right canine–premolar tooth region in a patient showing several sites with apical displacement of the soft tissue margin during the 5 years of observation. (a) At the initial examination, the two premolars had <1 mm and the canine >1 mm of attached portion of gingiva. (b) After 5 years, recession and loss of keratinized tissue can be seen on the buccal aspect of the canine, which initially had a broad zone of gingiva (right arrow). The second premolar also showed further apical displacement of the soft tissue margin (left arrow).

(Figs. 44-9b, 44-10b). A further apical displacement of the soft tissue margin had occurred at two of 26 sites with no/a minimal attached portion of gingiva and at three of 12 adjacent control sites with a wide attached zone of gingiva. Since four of these five sites were found in one patient (Fig. 46-11), and all sites were free from clinical signs of inflammation, excessive toothbrushing was considered to be the causative factor, and following correction of the brushing technique no further progression of the recessions was observed. Furthermore, the development of soft tissue recession at the control sites resulted in a decreased gingival width, an observation that supports the concept that a narrow zone of gingiva apical to a localized recession is a consequence rather than a cause of the recession.

Conclusion: Marginal soft tissue recession is a common feature in populations with good as well as poor standards of oral hygiene. There is evidence to suggest that the predominant cause for localized recessions in young individuals is toothbrushing trauma, while periodontal disease may be the primary cause in older adults. Evidence from prospective longitudinal studies shows that the gingival height is not a critical factor for the prevention of marginal tissue recession, but that the development of a recession will result in loss of gingival height.

Marginal tissue recession and orthodontic treatment

Results from clinical and experimental research have documented that most forms of orthodontic therapy are innocuous to the periodontium (see Chapter 58). The clinician may observe, however, that some patients respond to frontal movements of incisors and lateral movements of posterior teeth by gingival recession and loss of attachment (Maynard & Ochsenbein 1975; Coatoam *et al*. 1981; Foushee *et al*. 1985) (Fig. 46-12). Based on the clinical observation that recession may occur during orthodontic therapy involving sites that have an "insufficient" zone of gingiva, it was suggested that a grafting procedure to increase the gingival dimensions should precede the initiation of orthodontic therapy in such areas (Boyd 1978; Hall 1981; Maynard 1987).

Fig. 46-12 Soft tissue recession at tooth 11 observed during the course of active orthodontic treatment.

As discussed previously, the presence of an alveolar bone dehiscence is a prerequisite for the development of a marginal tissue recession, that is a root dehiscence may establish an environment that is conducive for loss of gingival tissue. With respect to orthodontic therapy, this would imply that as long as a tooth is moved exclusively within the alveolar bone, soft tissue recession will not develop (Wennström *et al*. 1987). On the other hand, predisposing alveolar bone dehiscences may be induced by uncontrolled facial expansion of a tooth through the cortical plate, thereby rendering the tooth liable to the development of soft tissue recession. In this context it is interesting to note that experimental studies have shown that labial bone will reform in the area of a dehiscence when the tooth is retracted towards a proper positioning of the root within the alveolar process

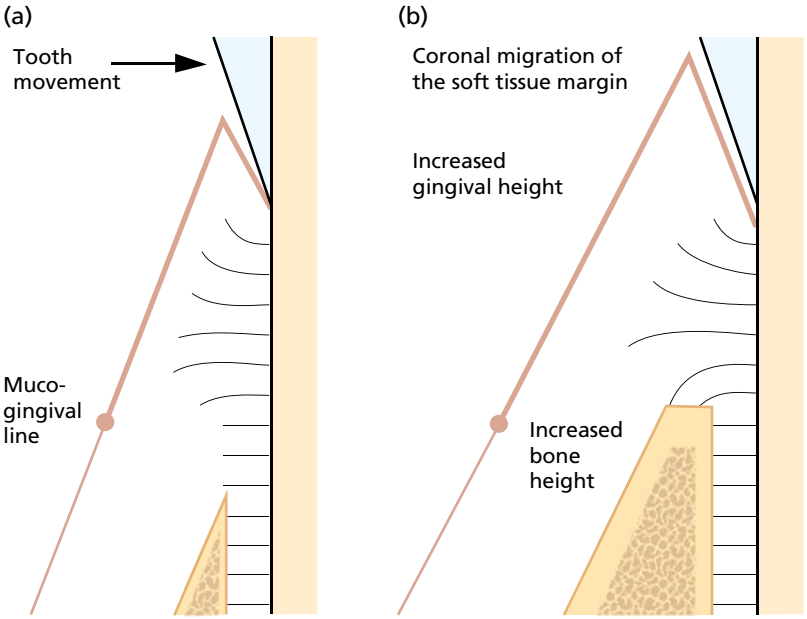

Fig. 46-13 (a) Schematic drawing illustrating alterations occurring in the marginal periodontal tissues following lingual movement of a tooth prominently positioned in the arch and having a bone dehiscence. (b) An increase in bone height and gingival height will be seen as well as a coronal migration of the soft tissue margin following lingual positioning of the tooth.

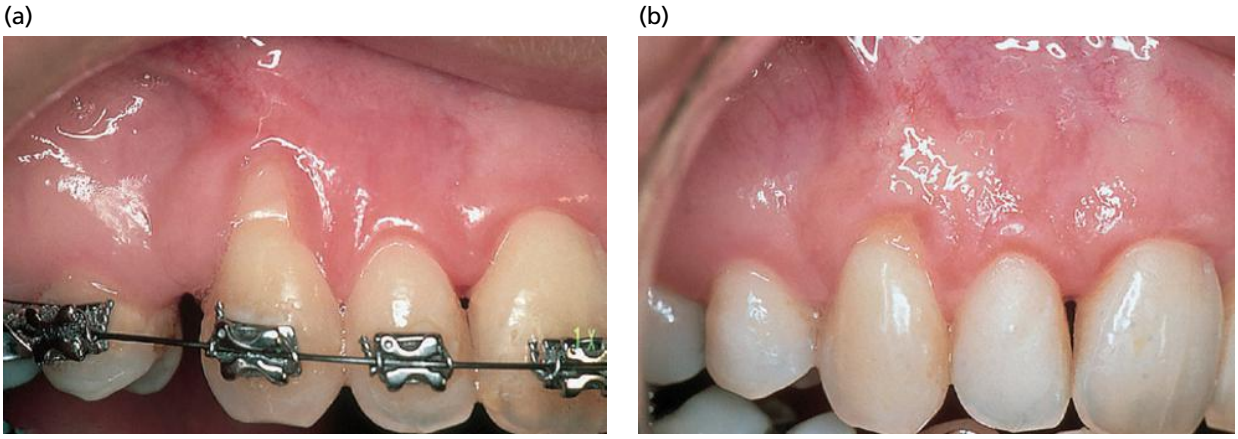

Fig. 46-14 (a) Prominently positioned tooth 13 showing soft tissue recession. (b) Same tooth following the completion of the orthodontic tooth movement. Note the reduction of the recession that has taken place as a consequence of the changed position of the tooth.

(Engelking & Zachrisson 1982; Karring *et al*. 1982) (Fig. 46-13). It is therefore likely that the reduction in recession seen at a previously prominently positioned tooth that has been moved into a more proper position within the alveolar process (Fig. 46-14) is also accompanied by bone formation.

Alterations occurring in gingival dimensions and marginal tissue position in conjunction with orthodontic therapy are related to the *direction of tooth movement*. Facial movement results in reduced facial gingival dimensions, while an increase is observed following lingual movement (Coatoam *et al*. 1981; Andlin-Sobocki & Bodin 1993). Recession of the labial gingival margin and loss of attachment were demonstrated in experimental studies in the monkey following either tipping and extrusion movements or bodily movements of incisors (Batenhorst *et al*. 1974; Steiner *et al*. 1981). However, similarly designed studies carried out in dogs (Karring *et al*. 1982; Nyman *et al*. 1982) and humans (Rateitschak *et al*. 1968) failed to demonstrate that labial tooth movement is accompanied by marginal tissue recession and attachment loss. The conflicting results may be related to differences with respect to, for example, (1) the amount of labial tooth displacement, (2) the presence/absence of plaque and gingival inflammation in the regions subjected to tooth movement, and/or (3) differences in gingival dimensions. Steiner *et al*. (1981) speculated on mechanisms by which gingival tissue could be lost as a result of labial tooth movement and suggested that tension in the marginal tissue created by the forces applied to the teeth could be an important factor. If this hypothesis is valid, obviously the volume (thickness) of the gingival tissue at the pressure side, rather than its apicocoronal height, would determine whether or not marginal tissue recession develops during orthodontic therapy.

Support for this hypothesis is obtained from an experimental study in monkeys (Wennström *et al*. 1987) in which teeth were orthodontically moved into areas with varying thickness and quality of the marginal soft tissue. Following extensive bodily

movement of incisors in a labial direction through the alveolar bone (Fig. 46-15), most teeth showed a small apical displacement of the soft tissue margin but no loss of connective tissue attachment (Fig. 46-16). In other words, the apical displacement of the gingival margin was the result of a reduced height of the free gingiva (Fig. 46-17), which in turn may be related to tension ("stretching") in the soft tissues during the facial tooth movement and reduced buccolingual tissue thickness. Similar to results presented by Foushee *et al*. (1985) from a study in humans, no relationship was found between the initial apicocoronal width (height) of the gingiva and the degree of apical displacement of the soft tissue margin during orthodontic therapy. Thus, the findings do not lend support to the concept of a certain zone of gingiva as

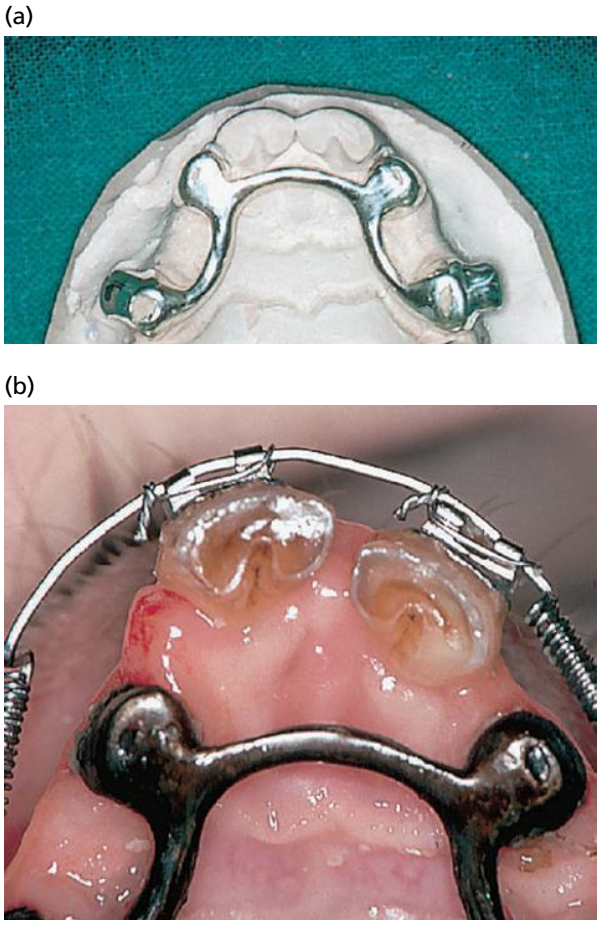

Fig. 46-15 Occlusal view of the maxillary jaw in a monkey showing the position of the central incisors before (a) and after (b) bodily movement in the labial direction. The canines and lateral incisors were joined in an individual fabricated silver splint and used as anchorage teeth.

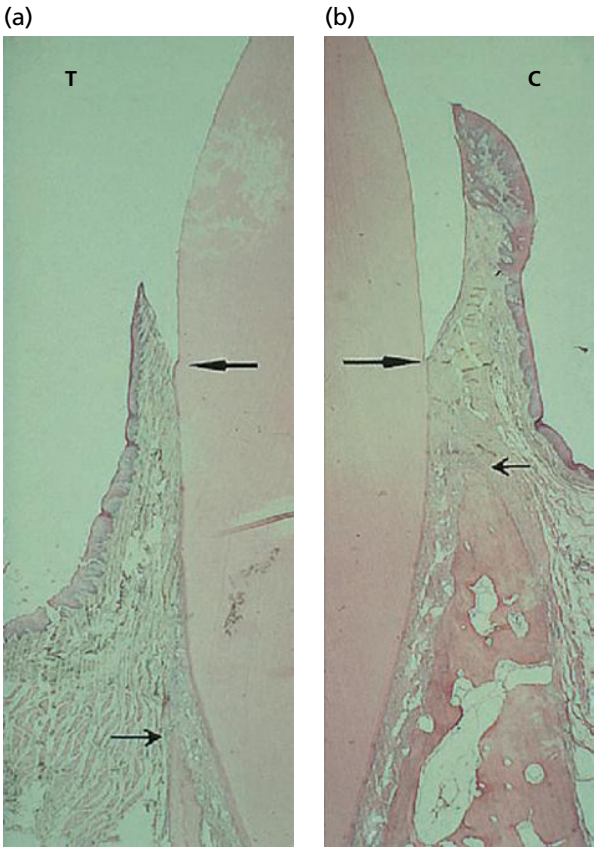

Fig. 46-17 Histologic specimens showing (a) reduced alveolar bone height at an incisor bodily moved in the labial direction and (b) normal alveolar bone height at a non-moved control tooth. Note the maintained level of connective tissue attachment and the reduced height of the free gingiva at the labially displaced incisor (a). Large arrows indicate the position of the cementoenamel junction and small arrows the position of the alveolar bone crest.

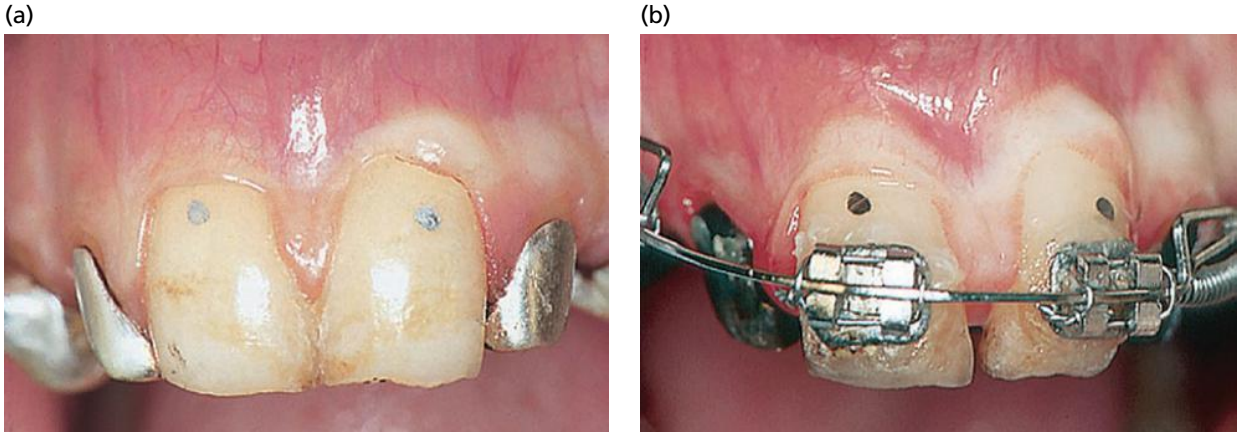

Fig. 46-16 Buccal aspect of the central incisors shown in Fig. 44-15 before (a) and after (b) the labial tooth movement. No obvious change in the location of the gingival margin has occurred despite the pronounced labial displacement of the incisors.

essential for the prevention of recession during orthodontic therapy, but rather corroborate observations reported by Coatoam *et al*. (1981) that the integrity of the periodontium can also be maintained during orthodontic therapy in areas which have only a minimal zone of gingiva.

In the experimental studies by Steiner *et al*. (1981) and Wennström *et al*. (1987), it was observed that teeth experiencing loss of connective tissue attachment when orthodontically moved facially, showed obvious clinical signs of inflammation throughout the experimental period. Since it has been demonstrated that, in the presence of plaque-induced suprabony lesions, orthodontic forces generating bodily tooth movement are not capable of causing accelerated destruction of the connective tissue attachment (Ericsson *et al*. 1978), a decreased buccolingual dimension of the border tissue due to "stretching" of the facial gingiva may have favored the destructive effect of the plaque-associated inflammatory lesion. This assumption is validated by the observations that, in the presence of plaque-induced gingivitis, a thin marginal soft tissue is more susceptible to complete breakdown than a thick one (Baker & Seymour 1976). Furthermore, no difference in attachment loss was observed at plaque-infected teeth that were bodily moved *within the alveolar bone*, irrespective of the type of bordering soft tissue (gingiva or lining mucosa) (Wennström *et al*. 1987). Hence, the *thickness rather than the quality* of the marginal soft tissue on the pressure side of the tooth is the determining factor for the development of the recession. The interpretation is supported by findings of clinical studies in humans analyzing factors of importance for the development of recessions during labial movement of mandibular incisors. Melsen and Allais (2005) found that gingival inflammation and a "thin gingival biotype" were significant predictors for gingival recession, and Yared *et al*. (2006) reported that 93% of the teeth that developed recession had a gingival thickness of <0.5 mm. Hence, the observations made in the studies discussed strongly emphasize the importance of adequate infection control during orthodontic treatment.

Conclusion: The clinical implication of the results from the studies discussed is that labial tooth movement should be preceded by careful examination of the dimensions of the tissues covering the facial aspect of the teeth to be moved. As long as a tooth can be moved within the envelope of the alveolar process, the risk of harmful side effects on the marginal tissue is minimal, irrespective of the dimensions and quality of the soft tissue surrounding the tooth. If, however, the tooth movement is expected to result in the establishment of an alveolar bone dehiscence, the volume (thickness) of the covering soft tissue should be considered as a factor that may influence the development of soft tissue recession during, as well as after, the phase of active orthodontic therapy. A thin gingiva may serve as a *locus minorus resistentia* to developing soft tissue defects in the presence of plaque-induced inflammation or toothbrushing trauma.

Gingival dimensions and restorative therapy

The placement of restoration margins subgingivally may not only create a direct operative trauma to the tissues (Donaldson 1974), but may also facilitate subgingival plaque accumulation, with resultant inflammatory alterations in the adjacent gingiva and recession of the soft tissue margin (Lang 1995; Parma-Benfenati *et al*. 1985; Günay *et al*. 2000). Over a 10-year period, Valderhaug (1980) evaluated longitudinally the soft tissue alterations taking place at facial sites of 286 teeth with subgingivally or supragingivally placed crown margins in 82 patients. The re-examination performed 1 year after insertion of the restorations revealed that the gingivae at teeth with subgingival restoration margins were more commonly inflamed than at those with supragingivally placed borders. Of the 150 teeth which had the facial crown margin located subgingivally at the time of cementation, 40% already showed supragingival exposure of the crown margin after 1 year, and at the 10-year examination as many as 71% had become supragingivally positioned due to recession of the soft tissue margin. Compared to teeth with supragingivally placed crown margins, the amount of recession and clinical attachment loss was greater at sites with subgingivally placed restoration margins.

Stetler and Bissada (1987) evaluated the periodontal conditions at teeth with subgingivally placed restoration margins and varying apicocoronal gingival height and found that teeth having a narrow (<2 mm) band of gingiva showed more pronounced clinical signs of inflammation than restored teeth with a wide gingival zone, but that there was no difference in loss of probing attachment. However, if subgingivally placed restorations favor plaque accumulation and the adjacent gingiva is thin, there may be a potential risk for the development of soft tissue recession. In fact, an experimental study in the Beagle dog (Ericsson & Lindhe 1984), in which metallic strips were inserted subgingivally in areas with varying widths of gingiva, showed that in sites with a thin gingiva, recession was a more likely consequence of the combined tissue trauma caused by the insertion of the strip and subsequent plaque accumulation during a 6-month period than in sites with a thick gingival margin. Accordingly, if recession is to be prevented, either the plaque-control standard has to be improved or the *thickness* of the gingival margin has to be increased. However, an increased gingival dimension *per se* will not prevent the apical propagation of the plaque-associated lesion and the associated loss of periodontal attachment.

The maintenance of stability and function of a load-carrying dental implant is dependent on a

well-functioning soft tissue barrier, established at the transmucosal passage of the implant unit (Berglundh 1993). In this respect, concern has been expressed that the lining mucosa may not provide a sufficient barrier function (Zarb & Schmitt 1990; Warrer *et al*. 1995), and that "keratinized tissue should be created with mucogingival surgical techniques prior to implant placement if not present in adequate amounts" (Meffert *et al*. 1992). With reference to the study by Lang and Löe (1972) on the relationship between width of keratinized mucosa and soft tissue health at teeth, an "adequate" dimension at dental implants was usually defined as ≥2 mm of keratinized mucosa. However, a reported prevalence of implant sites bordered by lining mucosa of 46–74% (e.g. Adell *et al*. 1986; Apse *et al*. 1991; Mericske-Stern *et al*. 1994), but a very high long-term success rate of implant therapy (e.g. Adell *et al*. 1990; Cochran 1996; Lekholm *et al*. 1999), give reasons to question the importance of an "adequate" width of keratinized mucosa for the success of implant therapy.

In a recent systematic review, the question regarding whether or not keratinized mucosa around dental implants is necessary to maintain health and tissue stability was addressed (Wennström & Derks 2012). According to this review, evidence suggests that with good oral hygiene habits, peri-implant soft tissue health can be maintained even when keratinized mucosa is lacking. Soft tissue recession mainly occurred during the early phase of follow-up (6–12 months after prosthesis delivery) and might be more pronounced at sites without keratinized mucosa. On the other hand, there is no evidence for a long-term effect of "inadequate" keratinized mucosa on the development of soft tissue recession, peri-implant bone loss, or implant loss. Also, there is a lack of evidence supporting the concept that grafting procedures aimed at increasing the amount of keratinized mucosa improve the outcomes of implant therapy. However, even if no studies have assessed patient-centered outcomes with regard to oral hygiene performance, one has to consider that some patients might experience pain and discomfort during brushing at implant sites facing the lining mucosa, which in turn may hamper adequate cleaning. In such cases, one might consider a grafting procedure to establish a firmer marginal tissue of keratinized mucosa.

Conclusion: Subgingival placement of the margin of a restoration is likely to result in soft tissue recession over time. Experimental and clinical data suggest that the thickness of the marginal gingiva, but not the apicocoronal width of the gingiva, may influence the magnitude of recession taking place as a result of direct mechanical trauma during tooth preparation and bacterial plaque retention. Evidence suggests that with good oral hygiene, peri-implant soft tissue health can be maintained even when keratinized mucosa is lacking. There is no evidence in support of an "adequate" width of keratinized mucosa as a superior protective soft tissue barrier around dental implants. However, it is recommended to maximize efforts to preserve existing keratinized mucosa during implant treatment procedures.

Indications for gingival augmentation

Scientific data obtained from well-controlled clinical and experimental studies have unequivocally demonstrated that the apicocoronal width of gingiva and the presence of an attached portion of gingiva are not of decisive importance for the maintenance of gingival health and the height of the periodontal tissues. Consequently, the presence of a narrow zone of gingiva *per se* cannot justify surgical intervention (Lang & Karing 1994; Proceedings of the 1996 World Workshop in Periodontics 1996). However, gingival augmentation should be considered in situations where, for example, the patient experiences discomfort during toothbrushing and/or chewing due to interference from a lining mucosa at teeth or implants. Furthermore, when orthodontic tooth movement is planned and the final positioning of the tooth can be expected to result in an alveolar bone dehiscence, an increase of the *thickness* of the covering soft tissue may reduce the risk for development of soft tissue recession. An increase of the *thickness* of the gingiva may also be considered when subgingival restorations are placed in areas with a thin marginal tissue.

Gingival augmentation procedures

Gingival augmentation operations comprise a number of surgical techniques, the majority of which have been developed mainly on an empiric basis. The earliest of these techniques are the "vestibular extension operations", which were designed mainly with the objective of extending the depth of the vestibular sulcus (Bohannan 1962a, b). In recent years, however, pedicle or free soft tissue grafts have become the most commonly used techniques in the management of "insufficient" gingival dimensions, because of higher predictability of the healing result.

Vestibular/gingival extension procedures

The "denudation techniques" included the removal of all soft tissue within an area extending from the gingival margin to a level apical to the mucogingival junction, leaving the alveolar bone completely exposed (Ochsenbein 1960; Corn 1962; Wilderman 1964) (Fig. 46-18). Healing following this type of treatment resulted often in an increased height of the gingival zone, although in some cases only a very limited effect was observed. However, the exposure of alveolar bone produced severe bone resorption with permanent loss of bone height (Wilderman *et al*. 1961; Costich & Ramfjord 1968). In addition, the recession of marginal gingiva in the surgical area often exceeded the gain of gingiva obtained in the

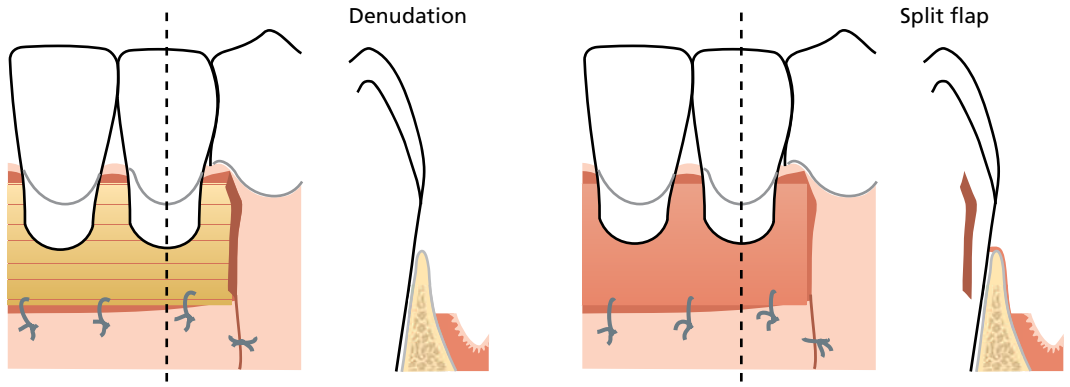

Fig. 46-18 Use of vestibular extension operations for increasing the width of the gingiva involves the production of a wound extending from the gingival margin to a level some millimeters apical to the mucogingival junction. With the "denudation" technique, all soft tissue is removed, leaving the alveolar bone exposed. With the "split-flap" procedure, only the superficial portion of the oral mucosa is removed, leaving the bone covered with connective tissue.

apical portion of the wound (Carranza & Carraro 1963; Carraro *et al*. 1964). Due to these complications and severe postoperative pain for the patient, the use of the "denudation technique" can hardly be justified.

With the "periosteal retention" procedure or "split-flap" procedure (Fig. 46-18), only the superficial portion of the oral mucosa within the wound area was removed, leaving the bone covered by periosteum (Staffileno *et al*. 1962; Wilderman 1963; Pfeifer 1965; Staffileno *et al*. 1966). Although the preservation of the periosteum implies that less severe bone resorption will occur than following the "denudation technique", loss of crestal bone height was also observed following this type of operation unless a relatively thick layer of connective tissue was retained on the bone surface (Costich & Ramfjord 1968). If a thick layer was not secured, the periosteal connective tissue tended to undergo necrosis and the subsequent healing closely resembled that following the "denudation technique" described above.

Other described gingival extension procedures may be considered as modifications of the "denudation" and "split-flap" techniques or combinations of these procedures. The apically repositioned flap procedure (Friedman 1962), for instance, involved the elevation of soft tissue flaps and their displacement during suturing in an apical position, often leaving 3–5 mm of alveolar bone denuded in the coronal part of the surgical area. This resulted in the same risk for extensive bone resorption as with other "denudation techniques". It was proposed by Friedman (1962) that a post-surgical increase of the width of the gingiva can be predicted with the "apically repositioned flap", but several studies indicated that the presurgical width most often was retained or was only slightly increased (Donnenfeld *et al*. 1964; Carranza & Carraro 1970).

The vestibular/gingival extension procedures referred to were based on the assumption that it is the frictional forces encountered during mastication that determine the presence of a keratinized tissue adjacent to the teeth (Orban 1957; Pfeifer 1963). Therefore, it was believed that by the displacement of muscle attachments and the extension of vestibular depth, the regenerating tissue in the surgical area would be subjected to physical impacts and adapt to the same functional requirements as those met by "normal" gingiva (Ivancie 1957; Bradley *et al*. 1959; Pfeifer 1963). Later studies, however, showed that the characteristic features of the gingiva are determined by inherent factors in the tissue rather than being the result of functional adaptation and that the differentiation (keratinization) of the gingival epithelium is controlled by morphogenetic stimuli from the underlying connective tissue (see Chapter 1).

Grafting procedures

The gingival and palatal soft tissues will maintain their original characteristics after transplantation to areas of the alveolar mucosa (see Chapter 1). Hence, the use of transplants offers the potential to predict the post-surgical result. The type of transplants used can be divided into (1) pedicle grafts, which maintain their connection to the donor site after placement at the recipient site (Fig. 46-19), and (2) free grafts that are completely deprived of their connection with the donor area (Fig. 46-20). For gingival augmentation, free grafts from the palate have been used most commonly (Haggerty 1966; Nabers 1966; Sullivan & Atkins 1968a; Hawley & Staffileno 1970; Edel 1974). As an alternative to the use of a mucosal graft from the palate, various allogenic graft materials, for example acellular freeze-dried dermal matrix (ADM) (Wei *et al*. 2000; Harris 2001) and human fibroblast-derived dermal substitute (McGuire & Nunn 2005) may be used, but the increase in the width of keratinized tissue following the use of these grafts may not be as predictable as with the use of autogenous grafts. Based on a systematic review of soft tissue augmentation techniques, Thoma *et al.* (2009) concluded that (1) there is evidence for an increased width of keratinized tissue and attached gingiva following apically repositioned flap/vestibuloplasty; (2) the addition of an autogenous tissue graft significantly increases the width of attached gingiva; and (3) the use of allogenic grafts produces dimensional increases in keratinized

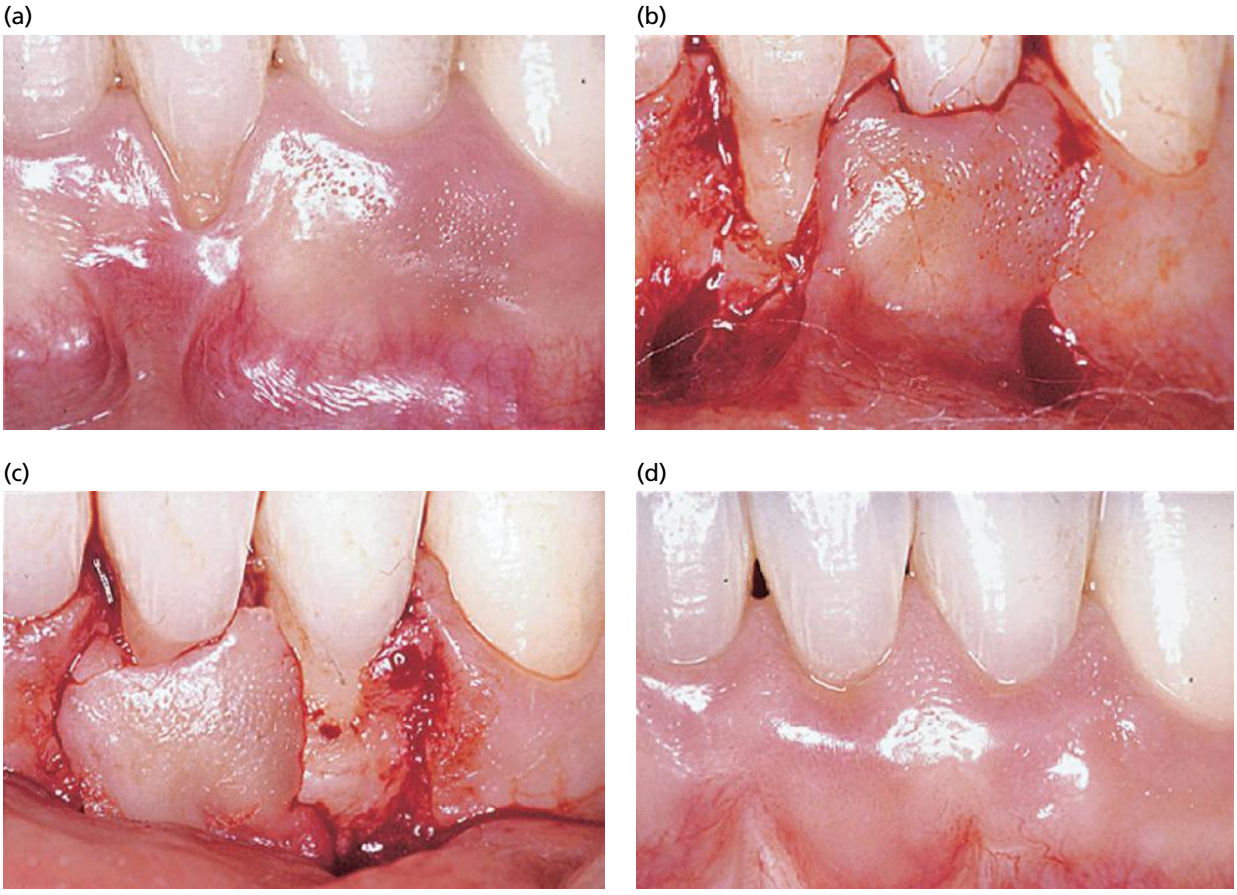

Fig. 46-19 Pedicle graft procedure for gingival augmentation. (a) Lower central incisor with facial soft tissue recession associated with high attachment of a frenulum. (b) Frenulum is released and a split flap of keratinized tissue is dissected from the area of the neighboring tooth. (c) Mobilized soft tissue flap is laterally moved and secured in position at the recipient site. (d) Healing result 1 year post-treatment shows the establishment of a broad zone of keratinized tissue without interfering frenulum.

tissue similar to those produced with autogenous tissue. More recently, a collagen matrix of porcine origin (Mucograft®) was shown to be as effective and predictable as the free autogenous graft in increasing the band of keratinized tissue at teeth and implants, but with significantly lower patient morbidity (Sanz *et al.* 2009; Nevins *et al.* 2011; Lorenzo *et al.* 2012). With the use of the alternative graft materials the preparation of the recipient site is similar to that using an autogenous graft.

Technique

1. The surgical procedure is initiated with the preparation of the recipient site (Fig. 46-20a, b). A periosteal bed free from muscle attachment and of sufficient size is prepared by sharp dissection. The partial-thickness flap is displaced apically and sutured.
2. In order to ensure that a graft of sufficient size and proper contour is removed from the donor area, usually the palatal mucosa in the region of the premolars, it is recommended to produce a foil template over the recipient site. The template is transferred to the donor site where it is outlined by a shallow incision (Fig. 46-20c). A graft with a thickness of approximately 1.5–2 mm is then dissected from the donor area (Fig. 46-20d). It is advocated to place the sutures in the graft before it is cut completely free from the donor area since this may facilitate its transfer to the recipient site.
3. The graft is immediately transferred to the prepared recipient bed and sutured (Fig. 46-20e). In order to immobilize the graft at the recipient site, the sutures must be placed in the periosteum or the adjacent attached gingiva. After suturing, pressure is exerted against the graft for 5 minutes in order to eliminate blood and exudate from between the graft and the recipient bed. The palatal wound is protected with a periodontal dressing. To retain the dressing, a stent usually has to be used.
4. The sutures and periodontal dressing are removed after 1–2 weeks.

For a description of the pedicle graft procedure, see "Root coverage procedures".

Healing following gingival augmentation procedures

Vestibular/gingival extension procedures

Since the specificity of the gingiva is determined by some inherent factor in the tissues, the postoperative results of vestibular extension procedures depend on

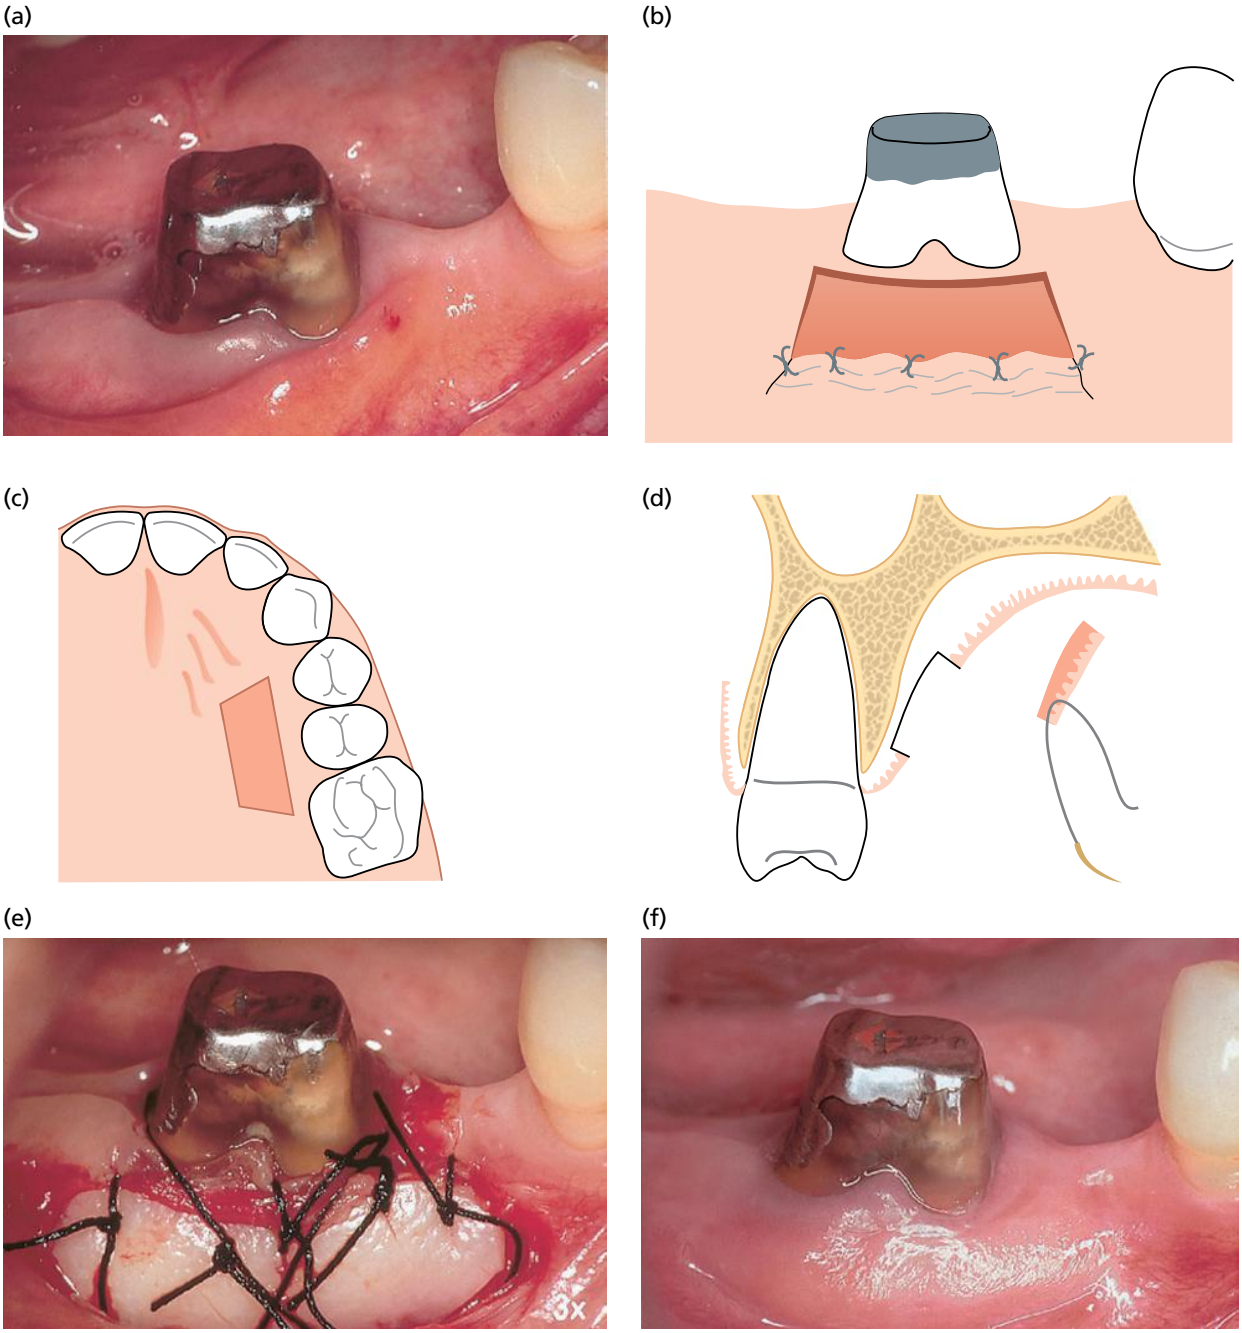

Fig. 46-20 Grafting procedure for gingival augmentation. (a) Lower molar at which the patient experiences discomfort during toothbrushing due to interfering lining mucosa and high attachment of a frenulum. The decision was made to displace the attachment of the frenulum apically and augment the gingival zone through the placement of a free graft. (b) Partial-thickness flap is dissected to prepare a recipient bed. The flap is displaced apically and sutured. (c, d) Graft with a thickness of 1.5–2 mm and of sufficient size and contour (a foil template of the recipient site may be used) is dissected from the palatal mucosa in the region of the premolars. (e) Graft is immediately transferred to the prepared recipient bed and anchored by sutures to secure a close adaptation of the graft to the recipient bed. (f) Periodontal dressing is applied to protect the graft. Following healing, a broad zone of keratinized tissue has been established.

the degree to which the various tissues contribute to the formation of granulation tissue in the wound area (Karring *et al*. 1975). Following the "denudation" or "split-flap technique", the wound area is filled with granulation tissue derived from the periodontal ligament, the tissue of the bone marrow spaces, the retained periosteal connective tissue, and the surrounding gingiva and lining mucosa (Fig. 46-21). The degree of bone resorption induced by the surgical trauma influences the relative amount of granulation tissue that grows into the wound from these various tissue sources. The resorption of crestal bone exposes varying amounts of the periodontal ligament tissue in the marginal area, allowing granulation tissue from the periodontal ligament to fill out the coronal portion of the wound. The greater the bone loss, the greater is the portion of the wound that becomes filled with granulation tissue from the periodontal ligament. This particular tissue possesses the capability to induce keratinization of the covering

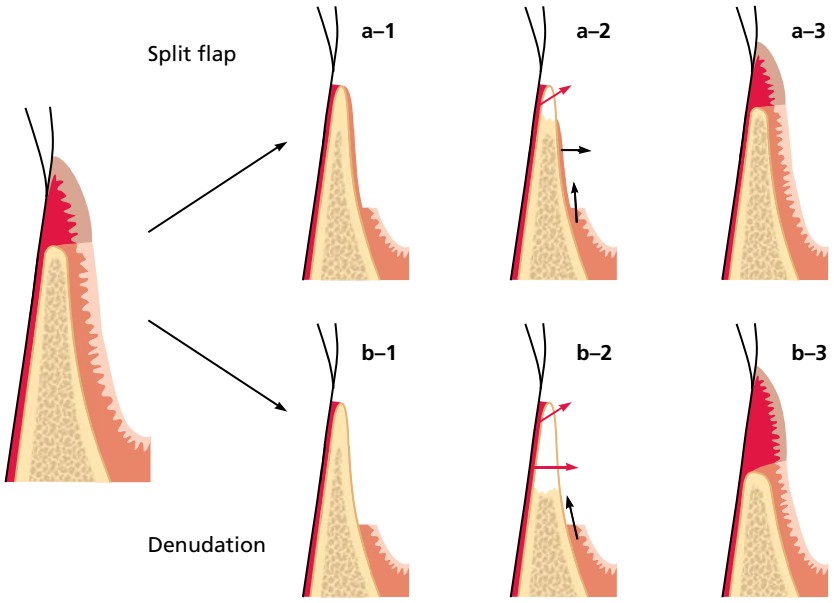

Fig. 46-21 Schematic drawing illustrating different stages of healing following the "split-flap" (a) and "denudation" (b) techniques. Cells from the oral mucosa, bone, and periodontal ligament (arrows) participate in granulation tissue formation. Due to the difference in the degree of bone resorption (a-2, b-2), a larger area of the coronal portion of the wound is filled with granulation tissue from the periodontal ligament following "denudation" than following the "split-flap" technique. Since granulation tissue from the periodontal ligament possesses the ability to induce a keratinized epithelium, "denudation" usually results in a wider zone of keratinized tissue than is the case following the "split-flap" technique (a-3, b-3).

epithelium. This means that the widening of the keratinized tissue following "denudation" and "split-flap" operations is achieved at the expense of a reduced bone height. The "denudation technique" usually results in more bone loss than the "split-flap technique". Therefore, a greater amount of granulation tissue with the capability of inducing a keratinized epithelium develops in the marginal area following the "denudation technique" than following the "split-flap technique". This is in accordance with the clinical observation that the "denudation technique" usually is superior to the "split-flap technique" in terms of increasing the width of keratinized tissue (Bohannan 1962a, b).

In a clinical study by Wennström (1983), periodontal pockets were eliminated by the use of a "gingivectomy" or a "flap" procedure, both of which involved the complete removal of the keratinized tissue. In the "gingivectomy" procedure, the wounded area was left to heal by second intention, while in the "flap" procedure the alveolar mucosa was repositioned to achieve complete coverage of the surgically exposed alveolar bone (Figs. 46-22a, 46-23a). Irrespective of the surgical technique used, healing resulted in the reformation of keratinized tissue, the width of which, however, was greater following the "gingivectomy" procedure than following the "flap" procedure (Figs. 46-22b, 46-23b). The gingiva was formed because granulation tissue from the periodontal ligament, with the capacity to induce a keratinized epithelium, had proliferated coronally along the root surface. This granulation tissue formation was obviously favored by a more pronounced bone resorption during the healing following the "gingivectomy" procedure.

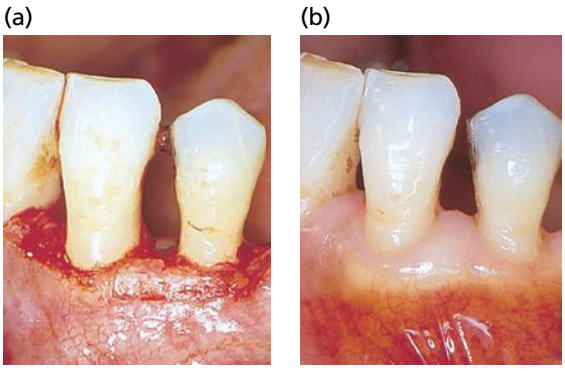

Fig. 46-22 (a) Clinical photograph of the buccal aspect of a canine and a premolar following the removal of the entire zone of gingiva by a gingivectomy procedure. (b) Healing result 9 months after surgery shows regained keratinized tissue.

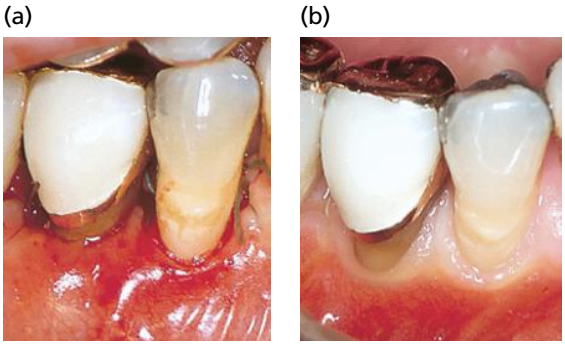

Fig. 46-23 Clinical photographs of a tooth region subjected to excision of the entire zone of gingiva by a flap procedure. (a) Alveolar mucosa has been displaced coronally to achieve complete coverage of the surgically exposed alveolar bone. (b) Healing has resulted in the reformation of a narrow zone of gingiva on the buccal aspect of the teeth, 9 months post surgery.

It can be concluded that the success or failure in extending the width of keratinized tissue by the "denudation" or "split-flap" techniques rests with the origin of the granulation tissue, which is related to the extent of bone loss induced by the surgical trauma. This in turn means that the result with respect to increasing the gingival width by methods involving periosteal exposure or denudation of the alveolar bone is unpredictable. The use of such methods is therefore not justified in periodontal therapy. The procedures discussed merely represent examples of how lack of knowledge about basic biologic principles may lead to the development of inappropriate therapeutic methods.

Grafting procedures

Healing of free soft tissue grafts placed entirely on a connective tissue recipient bed were studied in monkeys by Oliver *et al*. (1968) and Nobuto *et al*. (1988). According to these authors, healing can be divided into three phases (Fig. 46-24):

1. *Initial phase (from 0 to 3 days)*. During these first days of healing, a thin layer of exudate is present between the graft and the recipient bed. During this period the grafted tissue survives with an avascular "plasmatic circulation" from the recipient bed. Therefore, it is essential for the survival of the graft that a close contact is established to the underlying recipient bed at the time of operation. A thick layer of exudate or a blood clot may hamper the "plasmatic circulation" and result in rejection of the graft. The epithelium of the free graft degenerates early in the initial healing phase, and subsequently is desquamated. In placing a graft over a recession, part of the recipient bed will be the avascular root surface. Since the graft is dependent on the nature of its bed for diffusion of plasma and subsequent revascularization, the utilization of free grafts in the treatment of gingival recessions involves a great risk of failure. The area of the graft over the avascular root surface must receive nutrients from the connective tissue bed that surrounds the recession. Thus, the amount of tissue that can be maintained over the root surface is limited by the size of the avascular area.
2. *Revascularization phase (from 2 to 11 days)*. After 4–5 days of healing, anastomoses are established between the blood vessels of the recipient bed and those in the grafted tissue. Thus, the circulation of blood is re-established in the pre-existing blood

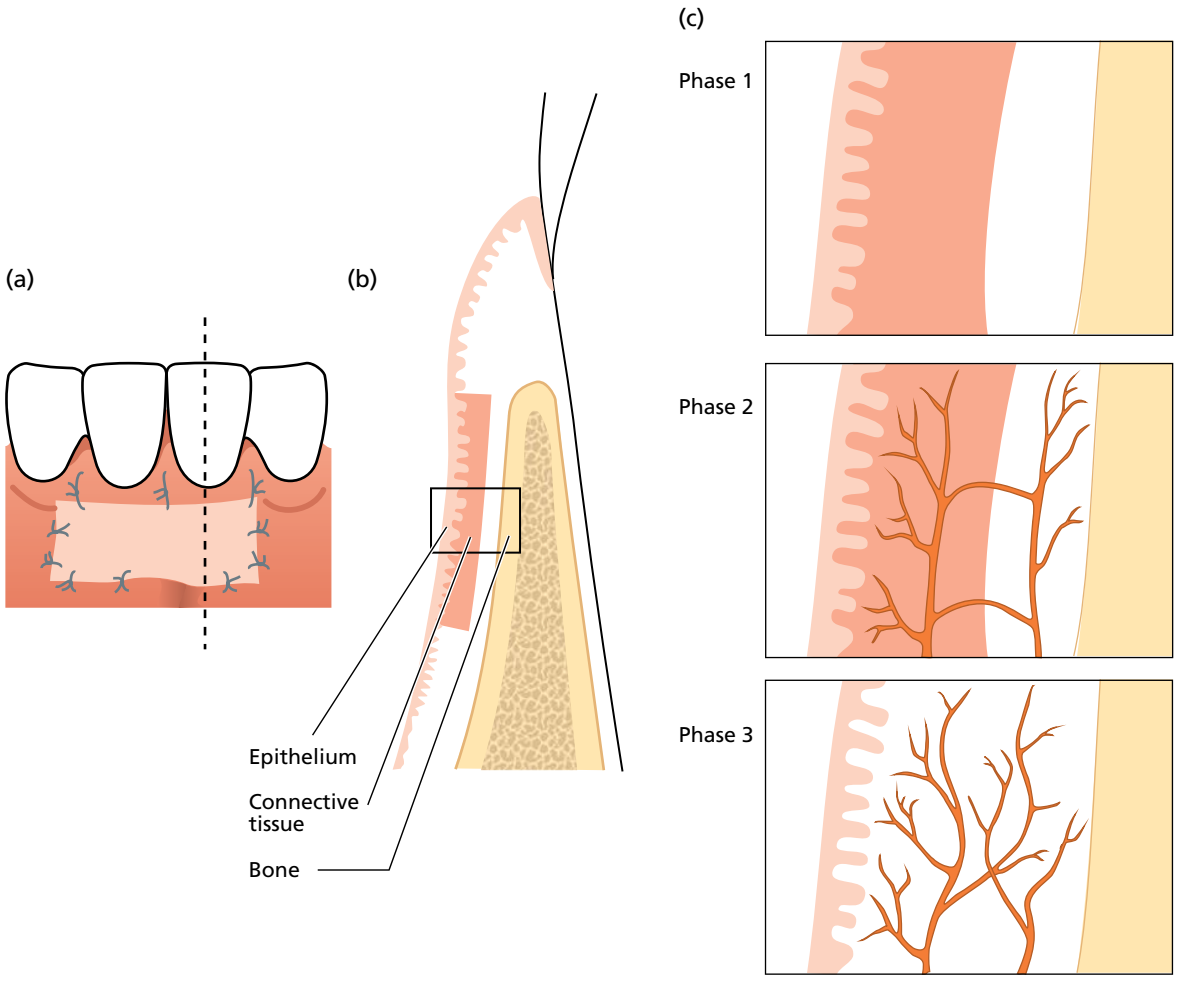

Fig. 46-24 Schematic drawings illustrating healing of a free gingival graft placed entirely on a connective tissue recipient bed (a). (b) Cross-section through the area. The framed areas (c) illustrate the three phases into which the healing process can be divided.

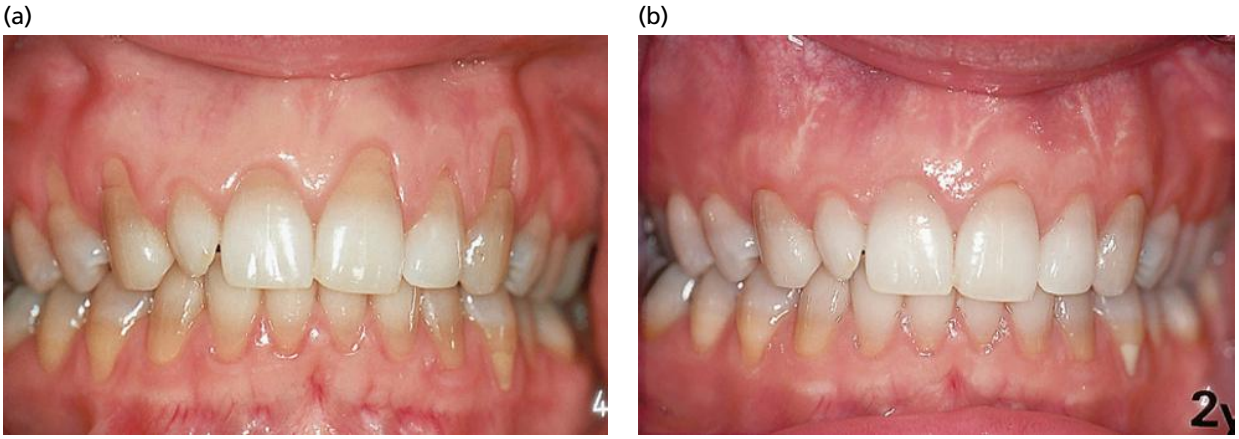

Fig. 46-25 (a) A 25-year-old woman with esthetic concerns due to multiple soft tissue recessions in the maxilla and a high lip line. The gingiva is healthy and several of the exposed root surfaces show abrasion defects, indicating toothbrushing trauma as the causative factor for the development of the recessions. The brushing technique was altered and root coverage was achieved surgically. (b) Two-year post-treatment view.

vessels of the graft. The subsequent time period is characterized by capillary proliferation, which gradually results in a dense network of blood vessels in the graft. At the same time, a fibrous union is established between the graft and the underlying connective tissue bed. The re-epithelialization of the graft occurs mainly by proliferation of epithelium from the adjacent tissues. If a free graft is placed over the denuded root surface, apical migration of epithelium along the tooth-facing surface of the graft may take place at this stage of healing.

3. *Tissue maturation phase (from 11 to 42 days)*. During this period, the number of blood vessels in the transplant is gradually reduced, and after approximately 14 days the vascular system of the graft appears normal. Also, the epithelium gradually matures with the formation of a keratin layer during this stage of healing.

The establishment and maintenance of a "plasmatic circulation" between the recipient bed and the graft during the initial phase of healing is critical in this kind of therapy. Therefore, in order to ensure ideal conditions for healing, blood between the graft and the recipient site must be removed by exerting pressure against the graft following suturing.

Root coverage

The main indications for root coverage procedures are esthetic/cosmetic demands (Fig. 46-25) and root sensitivity. Changing the topography of the marginal soft tissue in order to facilitate plaque control is also a common indication for root coverage procedures (Fig. 46-26).

It should be recalled that the two major causative factors in the development of marginal tissue recession are trauma caused by toothbrushing and plaque-induced periodontal inflammation. The control of these factors will prevent further progression of the

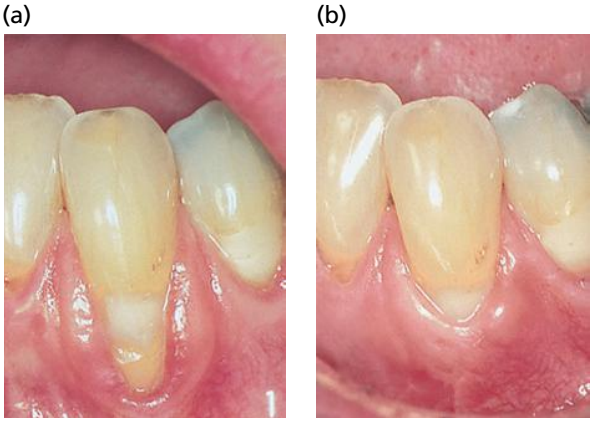

Fig. 46-26 (a) Mandibular canine with a deep recession, which makes self-performed plaque control difficult. (b) To facilitate plaque control, the position of the soft tissue margin was altered surgically.

recession in most cases. This means that in tooth regions with a thin covering of soft tissue, with or without an incipient recession, the patient should be encouraged to carry out effective, but at the same time non-traumatic, plaque-control measures. With respect to toothbrushing, the Bass method (see Chapter 36) should be avoided and the patient should be instructed to use a technique that creates as little apically directed pressure on the soft tissue margin as possible. A soft toothbrush should, of course, be used.

Miller (1985a) described a classification of recession defects taking into consideration the anticipated root coverage that it is possible to obtain with the use of a free gingival graft (Fig. 46-27):

- *Class I*: marginal tissue recession not extending to the mucogingival junction; no loss of interdental bone or soft tissue
- *Class II*: marginal tissue recession extending to or beyond the mucogingival junction; no loss of interdental bone or soft tissue
- *Class III*: marginal tissue recession extending to or beyond the mucogingival junction; loss of

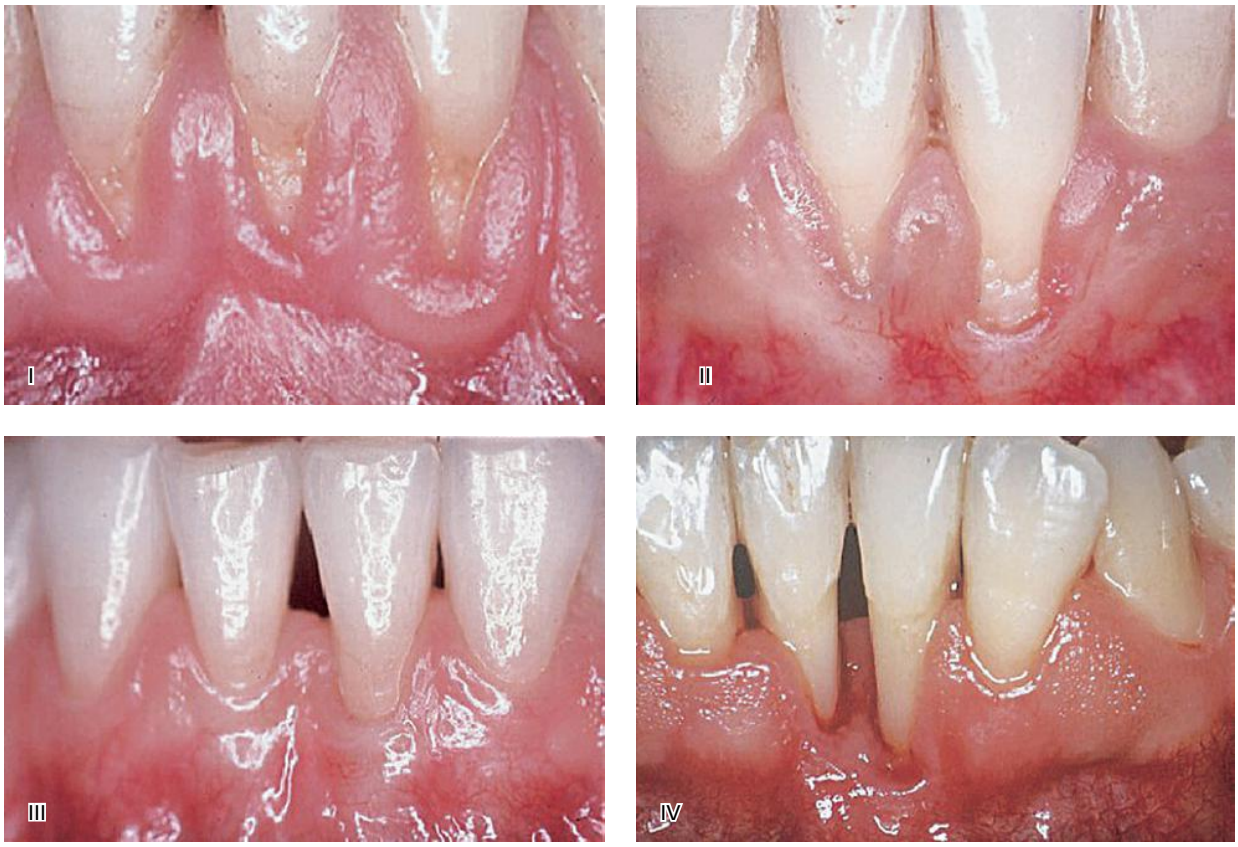

Fig. 46-27 Miller classification of recession defects (see text).

interdental bone/soft tissue or malpositioning of the tooth
- *Class IV*: marginal tissue recession extending to or beyond the mucogingival junction; severe loss of interdental bone/soft tissue or severe malpositioning of the tooth.

While complete root coverage was considered achievable in class I and II defects, only partial coverage could be expected in class III and IV recession defects. While there seems to be no reason to differentiate between class I and II recession defects, the critical clinical variable to assess in order to determine the possible outcome of a root coverage procedure is the level of periodontal tissue support at the proximal sites of the tooth. In line with this interpretation, Cairo *et al.* (2011) suggested a simplified classification of buccal recessions for prediction of the final root coverage outcome, based on clinical assessments of interproximal attachment levels:

- *Recession type 1 (RT1)*: buccal tissue recession with no loss of interproximal attachment
- *Recession type 2 (RT2)*: buccal tissue recession associated with loss of interproximal attachment less than or equal to the buccal attachment loss
- *Recession type 3 (RT3)*: buccal tissue recession associated with loss of interproximal attachment greater than the buccal attachment loss.

A consideration in relation to this classification and the prediction of complete root coverage is that not only is the clinical attachment level at the recession-affected tooth of importance, but also that at the neighboring teeth; in other words, whether or not there is loss of soft tissue height in the proximal site.

Recession defects in children need particular attention. In the growing child, recession defects may be eliminated spontaneously, provided adequate plaque control is established and maintained (Fig. 46-28). Andlin-Sobocki *et al*. (1991) reported from a 3-year prospective study that 25 of 35 recession defects with an initial depth of 0.5–3.0 mm healed spontaneously following improvement of the oral hygiene standard. Furthermore, all but three remaining recessions showed a decrease and no site demonstrated an increase in depth. Hence, reparative surgical treatment of soft tissue recessions in the developing dentition may not be necessary and should preferably be postponed until the growth is completed.

In an orthodontic case showing a recession defect and a thin (delicate) gingiva associated with a prominent, facially positioned tooth (Fig. 46-29a), surgical treatment for root coverage should be postponed until the orthodontic therapy is completed. The recession, as well as the dehiscence, will decrease as a consequence of the lingual movement of the tooth into a more proper position within the alveolar bone (Fig. 46-29b), and, if still indicated, the root coverage

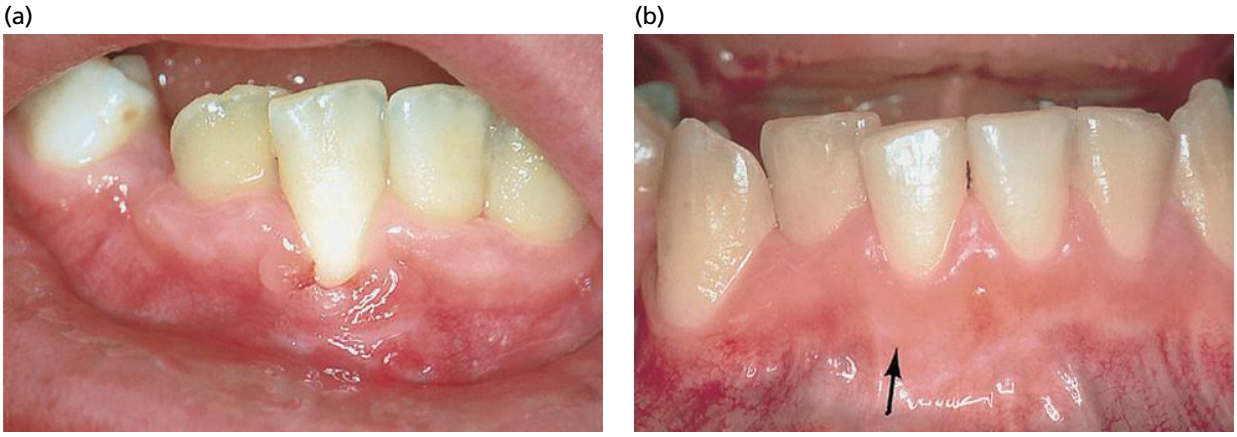

Fig. 46-28 A 9-year-old boy showing recession at tooth 41. (a) Tooth is rotated and buccally positioned. The minimal amount of gingiva found apical to the recession shows pronounced signs of inflammation. The plaque control in the region was improved but surgical intervention was postponed. (b) Same tooth area at the age of 14 years. Note the spontaneous soft tissue repair that has taken place at tooth 41 as a consequence of the improved plaque control and the growth in the alveolar process (arrow).

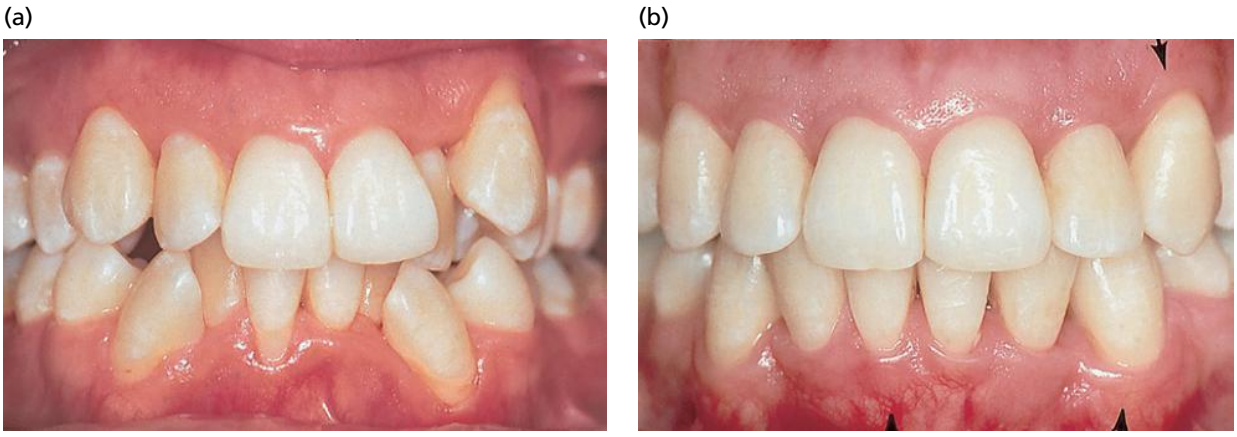

Fig. 46-29 Spontaneous repair of soft tissue recessions following orthodontic tooth movement. (a) A 22-year-old woman showing recessions and thin marginal tissues at prominently positioned teeth, particularly 23, 33, 41, and 43. (b) Following proper alignment of the teeth, the recessions have spontaneously been resolved and an increased gingival height can be noted.

procedure will show higher predictability of complete coverage if performed after rather than before the tooth movement.

Root coverage procedures

Surgical procedures used in the treatment of recession defects may basically be classified as (1) pedicle soft tissue graft procedures and (2) free soft tissue graft procedures.

The *pedicle graft procedures* are, depending on the direction of transfer, grouped as (1) *rotational flap procedures* (e.g. laterally sliding flap, double papilla flap, oblique rotated flap) or (2) *advanced flap procedures* (e.g. coronally repositioned flap, semilunar coronally repositioned flap). The latter procedures do not include rotation or lateral movement of the pedicle graft. Regenerative procedures are also included within the group of pedicle graft procedures, that is rotational and advanced flap procedures involving the placement of a barrier membrane between the graft and the root or the application of enamel matrix proteins.

The autogenous *free soft tissue graft procedures* may be performed as (1) an epithelialized graft or (2) a subepithelial connective tissue graft (non-epithelialized graft), both usually taken from the area of the masticatory mucosa in the palate.

Factors such as depth and width of recession, availability of donor tissue, presence of muscle attachments, and esthetics have to be taken into consideration in the selection of treatment procedure.

Treatment of the exposed root surface

Before root coverage is attempted, the exposed portion of the root should be rendered free from bacterial biofilms. Preferably, this is achieved by the use of a rubber cup and a polishing paste. Controlled clinical trials showed no differences in terms of root coverage or residual probing depth between teeth that had been instrumented (root planed) or polished only (Oles *et al*. 1988; Pini Prato *et al*. 1999). Extensive root planing may therefore only be performed in situations where a reduced root prominence would be considered beneficial for graft survival or tissue

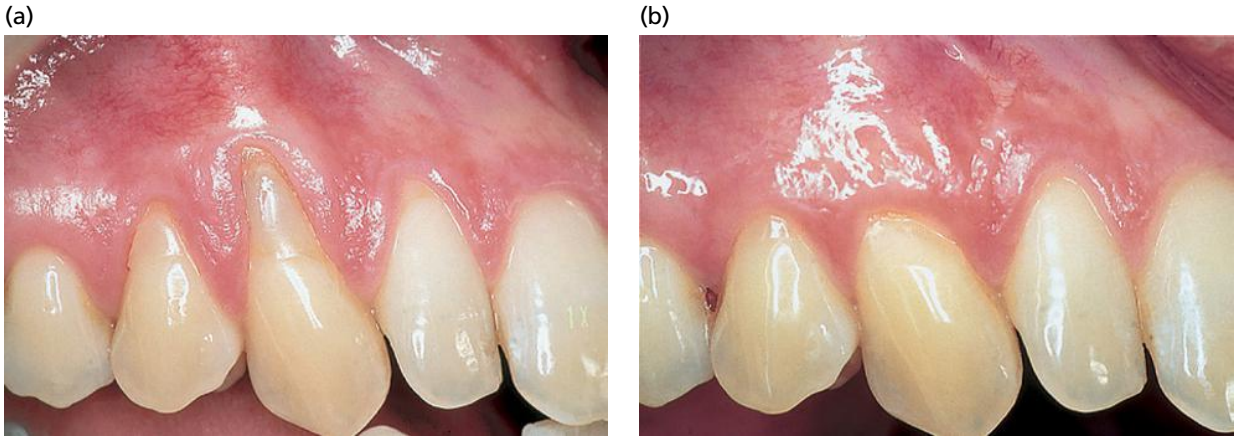

Fig. 46-30 (a) Canine showing pronounced recession and a composite resin restoration in the exposed root. Following removal of the restoration, the exposed root was surgically covered with soft tissue (pedicle graft). (b) Two-year postoperative healing result.

regeneration, or if a shallow root caries lesion is diagnosed. The presence of a filling in the root does not preclude the possibility of root coverage (Fig. 46-30), but preferably the filling should be removed before the root is covered with soft tissue.

The use of root surface demineralization agents has been advocated as important not only for the removal of the smear layer, but also to facilitate the formation of a new fibrous attachment through exposure of collagen fibrils of the dentin matrix and to allow subsequent interdigitation of these fibrils with those in the covering connective tissue. However, controlled clinical trials comparing the clinical outcome of root coverage procedures with and without root conditioning (Ibbott *et al*. 1985; Oles *et al*. 1985; Bertrand & Dunlap 1988; Laney *et al*. 1992; Bouchard *et al*. 1997; Caffesse *et al*. 2000) failed to demonstrate a beneficial effect from the use of acid root biomodification. Gottlow *et al*. (1986) evaluated the healing following treatment of localized gingival recessions with coronally positioned flaps and citric acid root biomodification in a controlled study in dogs. Histologic analysis after 3 months of healing disclosed no differences in the amount of root coverage or new connective tissue attachment between citric acid-treated sites and saline-treated control sites. Although root resorption was a common finding among the citric acid-treated teeth in this dog model, such a finding has not been reported to be common in humans. Based on a systematic review on the efficacy of root surface conditioning, Oliveira and Muncinelli (2012) concluded that there is no evidence that root surface biomodification by, for example, citric acid, EDTA or laser prior to soft tissue root coverage improves the clinical outcome of root coverage procedures.

Pedicle soft tissue graft procedures

Rotational flap procedures

The use of a laterally repositioned flap to cover areas with localized recession was introduced by Grupe and Warren (1956). This technique, which was called *the laterally sliding flap* operation, involved the reflection of a full-thickness flap in a donor area adjacent to the defect and the subsequent lateral displacement of this flap to cover the exposed root surface (see Fig. 46-19). In order to reduce the risk for recession on the donor tooth, Grupe (1966) suggested that the marginal soft tissue should not be included in the flap. Staffileno (1964) and Pfeifer and Heller (1971) advocated the use of a split-thickness flap to minimize the potential risk for development of dehiscence at the donor tooth. Other modifications of the procedure are the *double papilla flap* (Fig. 46-31) (Cohen & Ross 1968), the *oblique rotational flap* (Pennel *et al*. 1965), the *rotation flap* (Patur 1977), and the *transpositioned flap* (Bahat *et al*. 1990).

The technique is as follows:

1. The rotational flap procedure (Fig. 46-32) is initiated with the preparation of the recipient site. A reverse bevel incision is made all along the soft tissue margin of the defect (Fig. 46-32a). After removal of the dissected pocket epithelium, the exposed root surface is thoroughly curetted.
2. At a distance of approximately 3 mm from the wound edge, which delineates the defect at the side opposite the donor area, a superficial incision is performed extending from the gingival margin to a level approximately 3 mm apical to the defect (Fig. 46-32b). Another superficial incision is placed horizontally from this incision to the opposite wound edge. The epithelium together with the outer portion of the connective tissue within the area delineated by these incisions and the wound edges is removed by sharp dissection (Fig. 46-32c). In this way a 3-mm wide recipient bed is created at the one side of the defect, as well as apical to the defect.
3. A tissue flap to cover the recession is then dissected in the adjacent donor area. The preparation of this flap is initiated by a vertical superficial incision placed parallel to the wound edge of the recession and at a distance that exceeds the width of the recipient bed and the exposed root surface by approximately 3 mm (Fig. 46-32c). This incision is

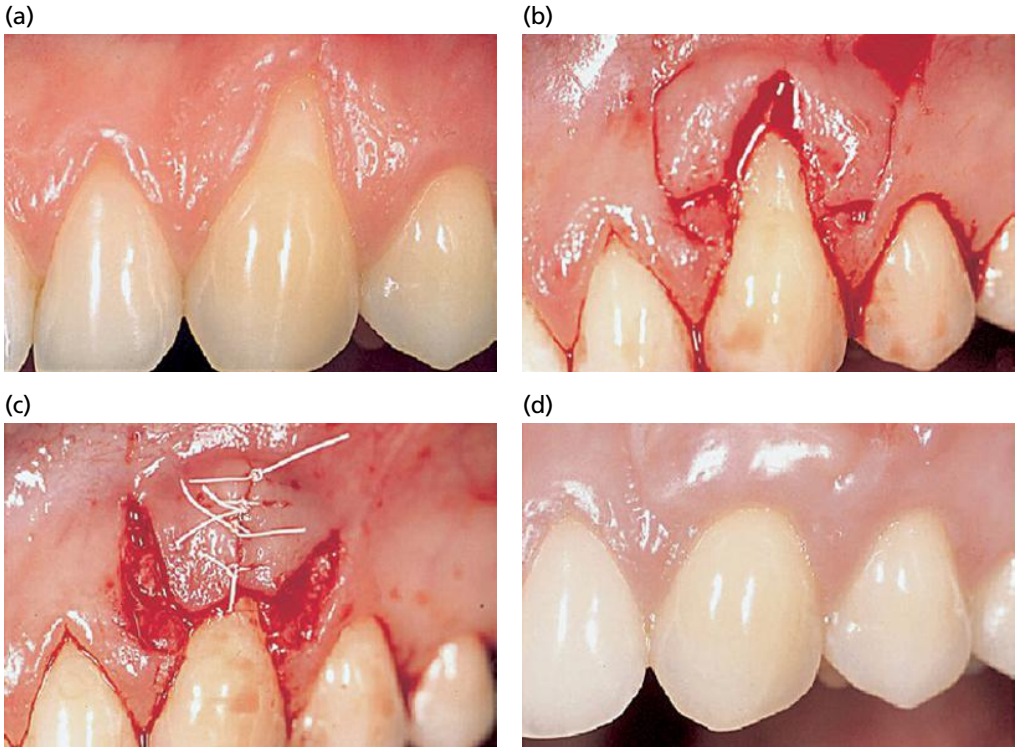

Fig. 46-31 Double papilla flap procedure. (a) Pretreatment view of a maxillary canine with facial soft tissue recession. Using split incisions, soft tissue flaps are mobilized from both sides of the recession (b) and sutured together for coverage of the exposed root (c). The healing result 6-month postoperatively shows complete root coverage (d).

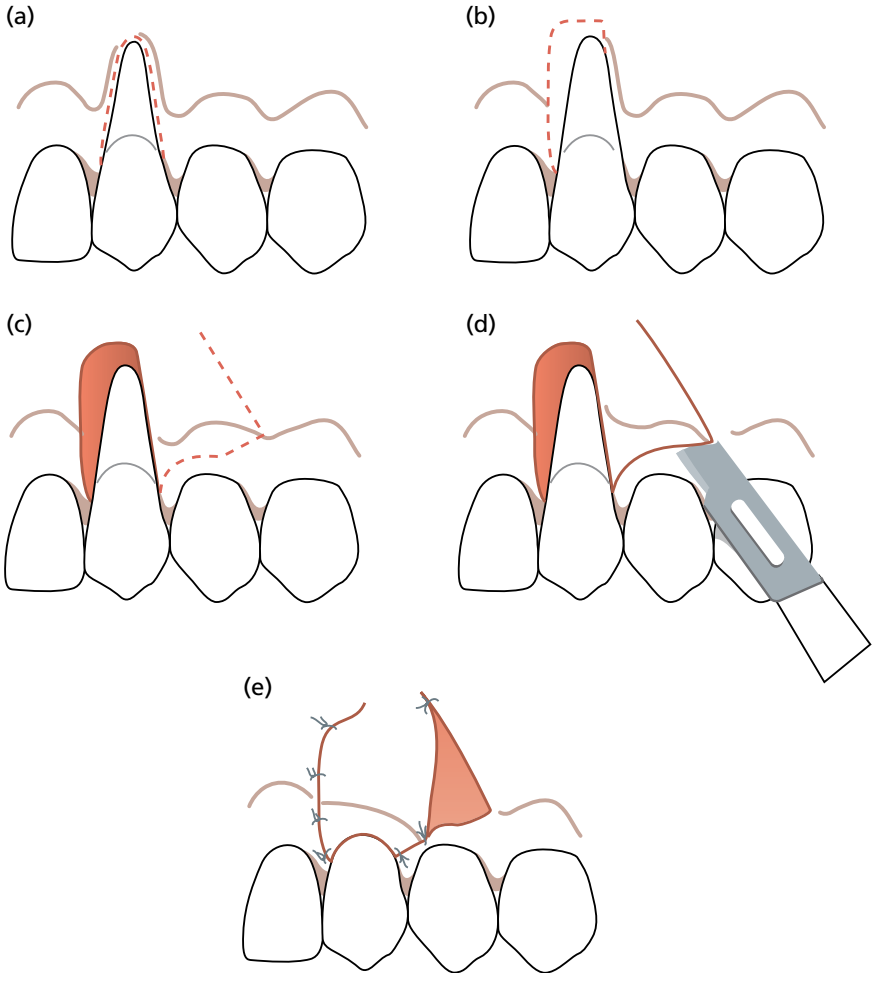

Fig. 46-32 (a–e) Rotational flap procedure. Schematic drawings illustrating the surgical technique for utilizing rotational pedicle grafts to cover localized recession defects (see text for explanation).

extended beyond the apical level of the recipient bed and is terminated within the lining mucosa with an oblique releasing incision directed towards the recession site. An incision connecting the vertical incision and the incision previously made around the recession is placed approximately 3 mm apical to the gingival margin of the donor site.

4. A split-thickness flap is then prepared by sharp dissection within the area delineated by these incisions so that a layer of connective tissue is left covering the bone in the donor area when the flap is displaced laterally over the denuded root surface (Fig. 46-32d). It is important that the oblique releasing incision is made far enough apically that the tissue flap can be placed on the recipient bed without being subjected to tearing forces when adjacent soft tissues are moved. The prepared tissue flap is rotated about 45° when sutured at the recipient bed (Fig. 46-32e).
5. The suturing of the flap should secure a close adaptation of the pedicle graft to the underlying recipient bed. Pressure is applied against the flap for 2–3 minutes in order to further secure a good adaptation. To protect the surgical area during the initial phase of healing, a periodontal dressing may be applied. A light-cured dressing material, for example Barricaid™ (Dentsply International Inc., Milford, DE, USA), is preferably used since this can be applied without dislocating the flap and has, in addition, a favorable esthetic appearance.
6. Following removal of the dressing and the sutures, usually after 10–14 days, the patient is instructed to avoid mechanical tooth cleaning for a further 2 weeks, but to rinse twice daily with a chlorhexidine solution as a method of infection control.

Advanced flaps

Since the lining mucosa is elastic, a mucosal flap raised beyond the mucogingival junction can be stretched in the coronal direction to cover the exposed root surfaces (Harvey 1965; Sumner 1969; Brustein 1979; Allen & Miller 1989; Wennström & Zucchelli 1996; De Sanctis & Zucchelli 2007). The coronally advanced flap can be used for root coverage of a single tooth as well as multiple teeth, provided suitable donor tissue is available. In situations with only shallow recession defects and minimal probing pocket depth labially, the *semilunar coronally repositioned flap* may offer an alternative approach (Harlan 1907; Tarnow 1986). For the treatment of an isolated deep gingival recession affecting a lower incisor, or the mesial root of the first maxillary molar, Zucchelli *et al*. (2004) suggested the use of a *laterally moved, coronally advanced flap*.

The technique for a *coronally advanced flap procedure* is as follows (Fig. 46-33):

1. The coronally advanced flap procedure is initiated with the placement of two apically divergent vertical releasing incisions, extending from a point coronal to the CEJ at the mesial and distal line axis of the tooth and apically into the lining mucosa (Fig. 46-33a).
2. A split-thickness flap is prepared by sharp dissection mesial and distal to the recession and

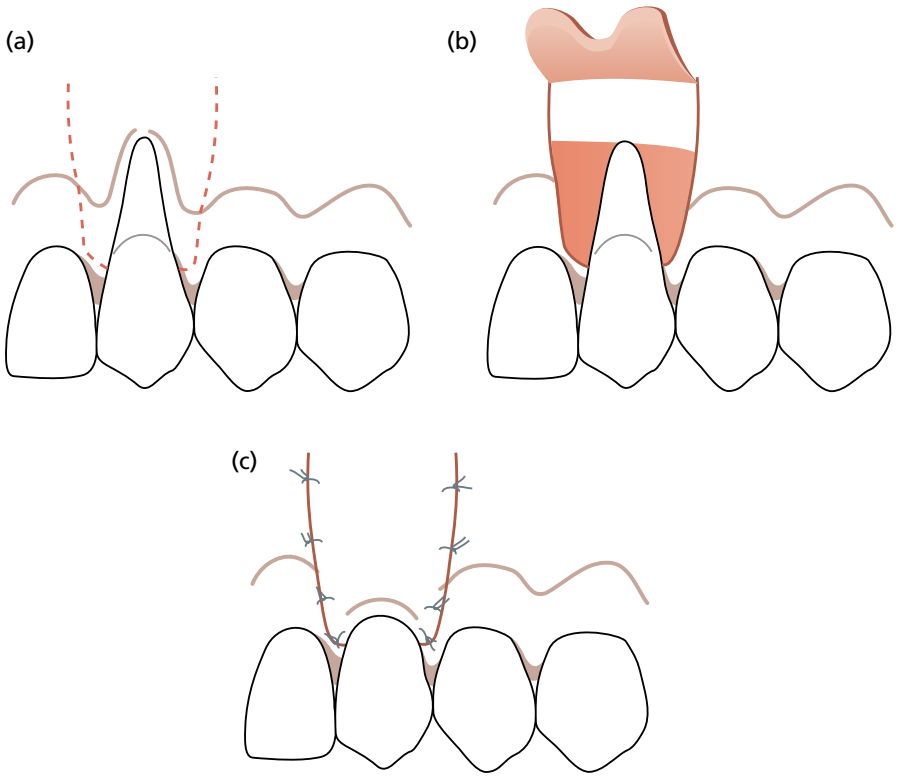

Fig. 46-33 (a–c) Coronally advanced flap procedure. Schematic drawings illustrating the surgical technique for utilizing coronally advanced pedicle grafts to cover localized recession defects (see text for explanation).

connected with an intracrevicular incision. Apical to the receded soft tissue margin on the facial aspect of the tooth, a full-thickness flap is elevated to maintain maximal thickness of the tissue flap to be used for root coverage (Fig. 46-33b). Approximately 3 mm apical to the bone dehiscence, a horizontal incision is made through the periosteum, followed by blunt dissection into the vestibular lining mucosa to release muscle tension. The blunt dissection is extended buccally and laterally to such an extent that the mucosal graft is tension-free when positioned coronally at the level of the CEJ. The facial portion of the interdental papillae is de-epithelialized to allow for a final placement of the flap margin coronal to the CEJ.

3. The tissue flap is coronally advanced, adjusted for optimal fit to the prepared recipient bed, and secured at a level 1-2 mm coronal to the CEJ by suturing the flap to the connective tissue bed in the papilla regions (Fig. 46-33c). Additional lateral sutures are placed to carefully close the wound of the releasing incisions. Mechanical tooth cleaning is avoided during the first 3–4 weeks of healing (rinsing with a chlorhexidine solution is prescribed), and when re-instituted, instructions in the use of a toothbrushing technique creating minimal apically directed trauma to the soft tissue margin is given.

Figure 46-34 illustrates the treatment of a recession defect with the use of the coronally advanced flap procedure. To allow the positioning of the flap margin coronal to the CEJ at the buccal surface, the interdental papillae have to be de-epithelialized before suturing (Fig. 46-35).

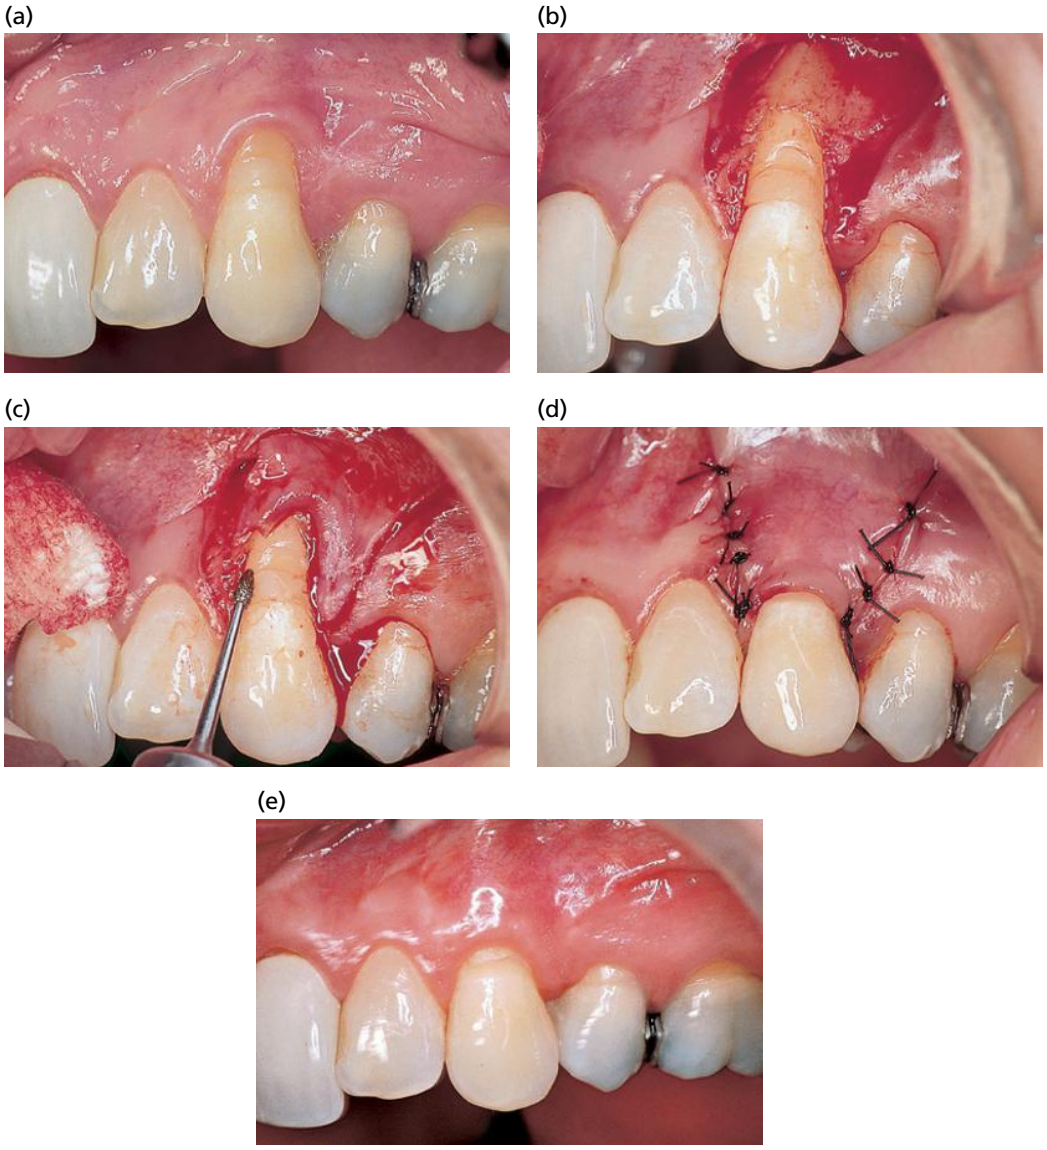

Fig. 46-34 Coronally advanced flap procedure. (a) Deep and wide recession defect on a canine with a composite resin restoration in the exposed root portion. Before preparation of the pedicle graft, the root is polished with pumice and a rubber cup. (b) Split flap has been dissected mesial and distal to the root, and a full-thickness flap apical to the recession. Approximately 4 mm apical to the bone dehiscence, the periosteum has been cut and a blunt dissection performed to facilitate the coronal positioning of the pedicle graft. (c) Composite resin restoration is removed. (d) Close suturing of the pedicle graft to cover the exposed root surface. (e) Healing outcome 1 year postoperatively.

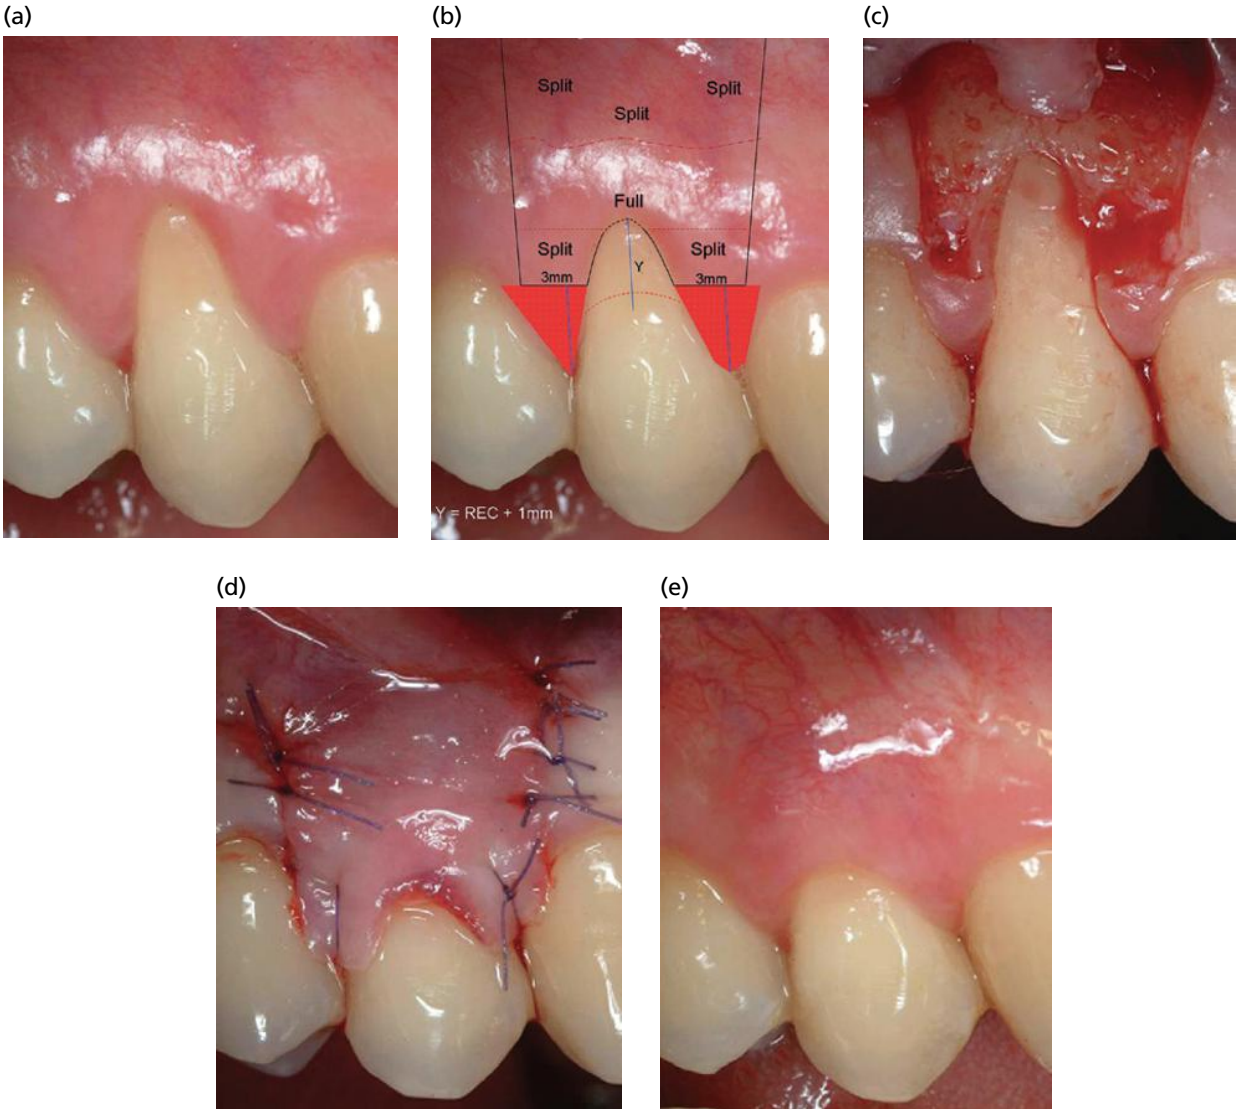

Fig. 46-35 Coronally advanced flap procedure. (a) Recession defect affecting a first premolar. (b) Schematic outline of the flap preparation. (Blue line, amount (in mm) of intended coronal advancement of the flap; dotted red area, de-epithelialized papillae; Split, split-thickness elevation; Full, full-thickness elevation.) (c) Flap elevated. The papilla areas are then de-epithelialized to allow anchorage of the flap coronal to the cementoenamel junction (CEJ). (d) Flap is advanced and anchored at a level coronal to the CEJ with a sling suture. (e) Clinical healing at 1 year.

The technique for a *laterally moved, coronally advanced flap* is as follows (Fig. 46-36):

1. A vertical incision is made approximately 3 mm from the lateral edge of the recession defect at the side opposite the donor area, and parallel to the lateral border of the recession defect. The incision is extended from the level of the CEJ to a point approximately 3 mm apical to the defect. At the marginal end of the vertical incision (at the level of the CEJ), a horizontal incision is made towards the recession defect. A third incision is made parallel to the lateral soft tissue margin of the recession defect on the donor side, from the bottom of the defect to the apical termination of the vertical incision on the recipient side. The area delineated by these incisions is de-epithelialized. In this way a 3-mm wide recipient bed is created lateral as well as apical to the defect.
2. A pedicle graft is harvested from the adjacent tooth site by the use of three incisions: (1) a beveled intrasulcular incision along the lateral edge of the recession defect; (2) a horizontal submarginal incision with a length 6 mm greater than the width of the recession defect; and (3) a beveled oblique vertical incision extending into the alveolar mucosa and parallel to the first incision. The outline of the submarginal incision should preserve 3 mm of marginal soft tissue at the donor tooth, and preferably provide at least 2 mm of keratinized tissue along the entire mesiodistal extension of the flap.
3. The flap is mobilized as a split-thickness flap in its lateral parts, while the center part, which will be placed over the exposed root, is elevated as a full-thickness flap. Apical to the mucogingival line, the elevation is continued as a split-thickness flap until it is possible to passively move the mucosal graft laterally to the recipient site.

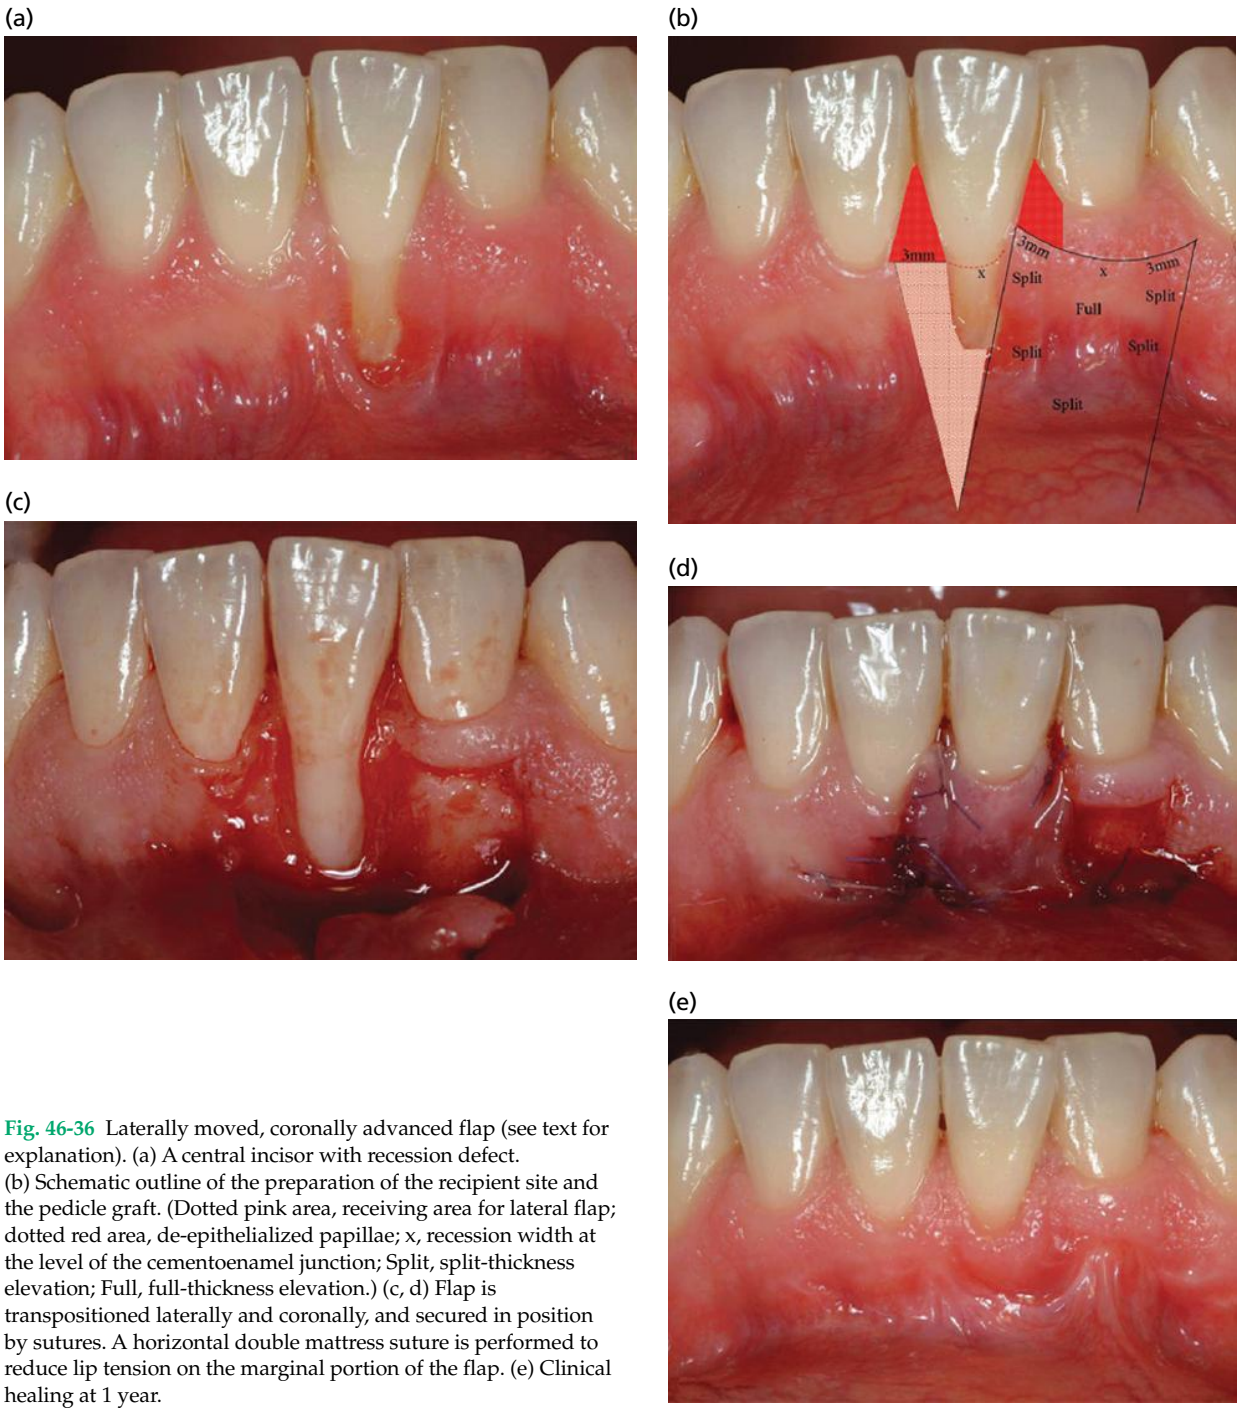

Fig. 46-36 Laterally moved, coronally advanced flap (see text for explanation). (a) A central incisor with recession defect. (b) Schematic outline of the preparation of the recipient site and the pedicle graft. (Dotted pink area, receiving area for lateral flap; dotted red area, de-epithelialized papillae; x, recession width at the level of the cementoenamel junction; Split, split-thickness elevation; Full, full-thickness elevation.) (c, d) Flap is transpositioned laterally and coronally, and secured in position by sutures. A horizontal double mattress suture is performed to reduce lip tension on the marginal portion of the flap. (e) Clinical healing at 1 year.

4. Blunt dissection is performed into the vestibular mucosa to release muscle tension and permit coronal advancement and passive adaptation of the flap to a level coronal to the CEJ.
5. The facial surface of the interdental papillae is de-epithelized to create connective tissue beds to which the laterally moved, coronally advanced flap can be sutured.
6. The suturing of the flap starts with the placement of two interrupted periosteal sutures in the most apical end of the vertical releasing incisions, and continues with a series of interrupted sutures, directed in an apicocoronal direction from the flap to the adjacent wound edge. A horizontal double mattress periosteal suture is placed apical to the vertical incisions to reduce lip tension on the root coverage portion of the flap. The coronal suture is a sling suture, which permits a precise adaptation of the flap against the root surface and the interdental connective tissue beds.

Figure 46-37 illustrates the treatment of a recession defect at a maxillary molar with the use of the *laterally moved, coronally advanced flap* procedure.

Zucchelli and De Sanctis (2000) described a flap design for the treatment of multiple recessions, which

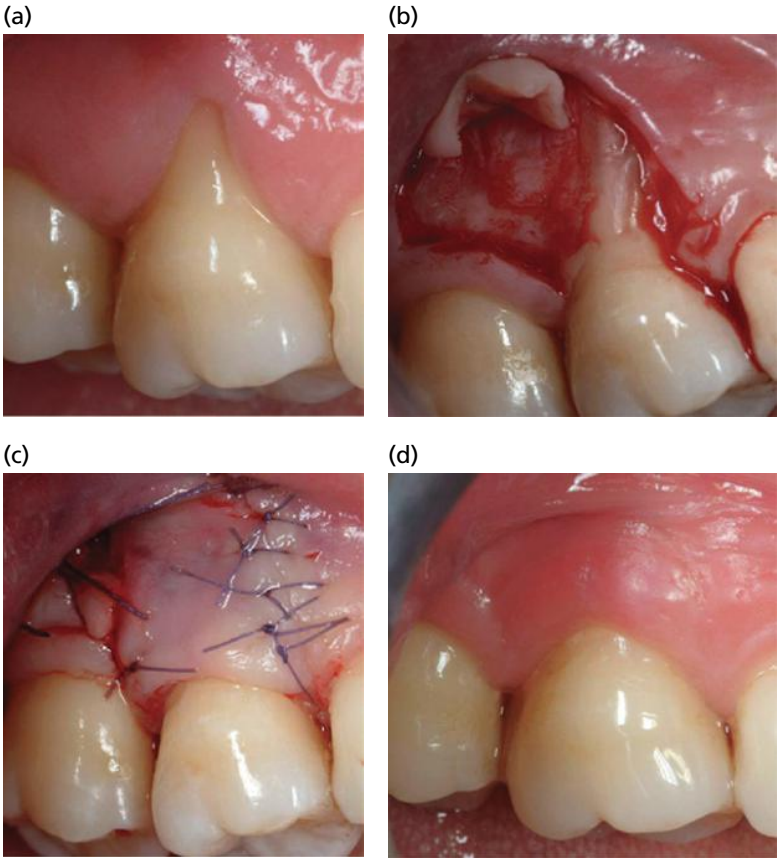

Fig. 46-37 Laterally moved, coronally advanced flap. (a–c) Recession defect at a first maxillary molar treated because of root sensitivity (see text for explanation). (d) Clinical healing at 1 year.

allows for optimal adaptation of the flap following its coronal advancement without placement of vertical releasing incisions. The technique for this *coronally advanced flap procedure for multiple recessions* is as follows (Fig. 46-38):

1. Oblique submarginal incisions are made in the interdental areas and connected with intracrevicular incisions at the recession defects. The incisions are extended to include one tooth on each side of the teeth to be treated to facilitate coronal repositioning of the flap. The oblique incisions over the interdental areas are placed in such a manner that the "surgically created papillae" mesial to the midline of the surgical field are dislocated apically and distally, while the papillae of the flap distal to the midline are shifted to a more apical and mesial position (Fig. 46-38b).
2. Starting at the oblique interdental incisions, a split-thickness flap is dissected (Fig. 46-38c). Apical to the level of the root exposures, a full-thickness flap is raised to provide maximum soft tissue thickness of the flap to be positioned coronally over the roots (Fig. 46-38d).
3. At the most apical portion of the flap, the periosteum is incised and this is followed by dissection into the vestibular lining mucosa to eliminate all muscle tension. The mobilized flap should be able to passively reach a level coronal to the CEJ at each single tooth in the surgical field.
4. The remaining facial portion of the interdental papillae is de-epithelialized to create connective tissue beds to which the flap can be sutured.
5. Sutures are placed to accomplish a precise adaptation of the coronally advanced flap against the teeth and to the interdental connective tissue beds (Fig. 46-38e). In addition, a horizontal double mattress suture may be placed to reduce lip tension on the marginal portion of the flap.

The technique for a *semilunar coronally repositioned flap procedure* is as follows (Fig. 46-39):

1. A semilunar incision is placed apical to the recession and at a distance from the soft tissue margin that should be approximately 3 mm greater than the depth of the recession. The outline of the incision should be parallel to the curvature of the gingival margin (Fig. 46-39a). The incision is extended into the papilla region on each side of the tooth, but care should be taken to maintain a broad base of anchorage to secure a collateral blood supply to the pedicle graft.
2. A split-thickness dissection of the facially located tissue is then made by an intracrevicular incision extending apically to the level of the semilunar incision (Fig. 46-39b). The mid-facial soft tissue graft is coronally repositioned to the level of the CEJ (Fig. 46-39c) and stabilized by light pressure for 5 minutes.
3. No suturing is needed but a light-cured dressing may be applied for wound protection.

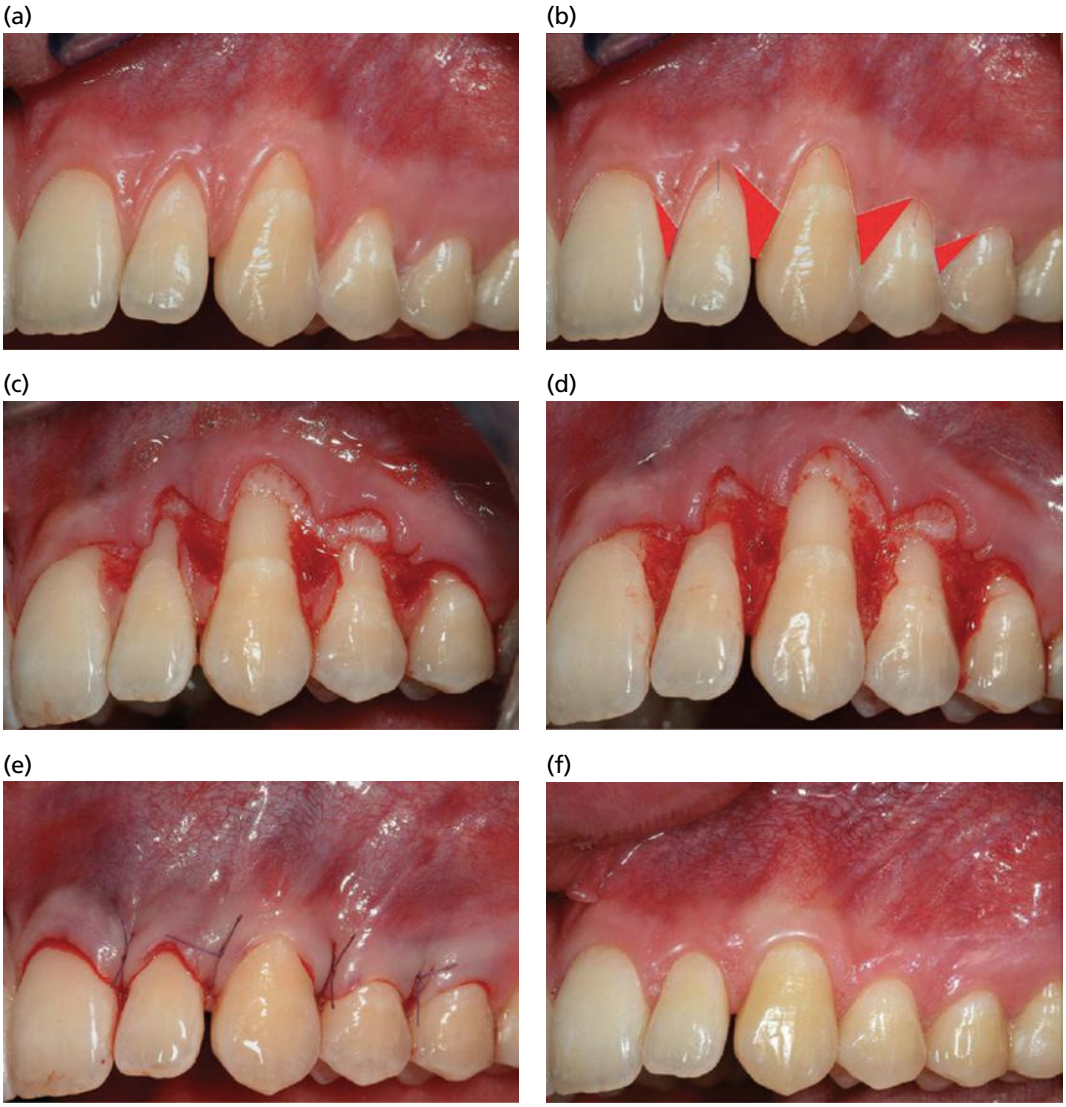

Fig. 46-38 Coronally advanced flap procedure for multiple recessions (see text for explanation). (a–e) Oblique incisions over the interdental areas are placed in such a manner that the "surgically created papillae" mesial to the midline of the surgical field are dislocated apically and distally, while the papillae of the flap distal to the midline are shifted to a more apical and mesial position. (f) One-year post-treatment view.

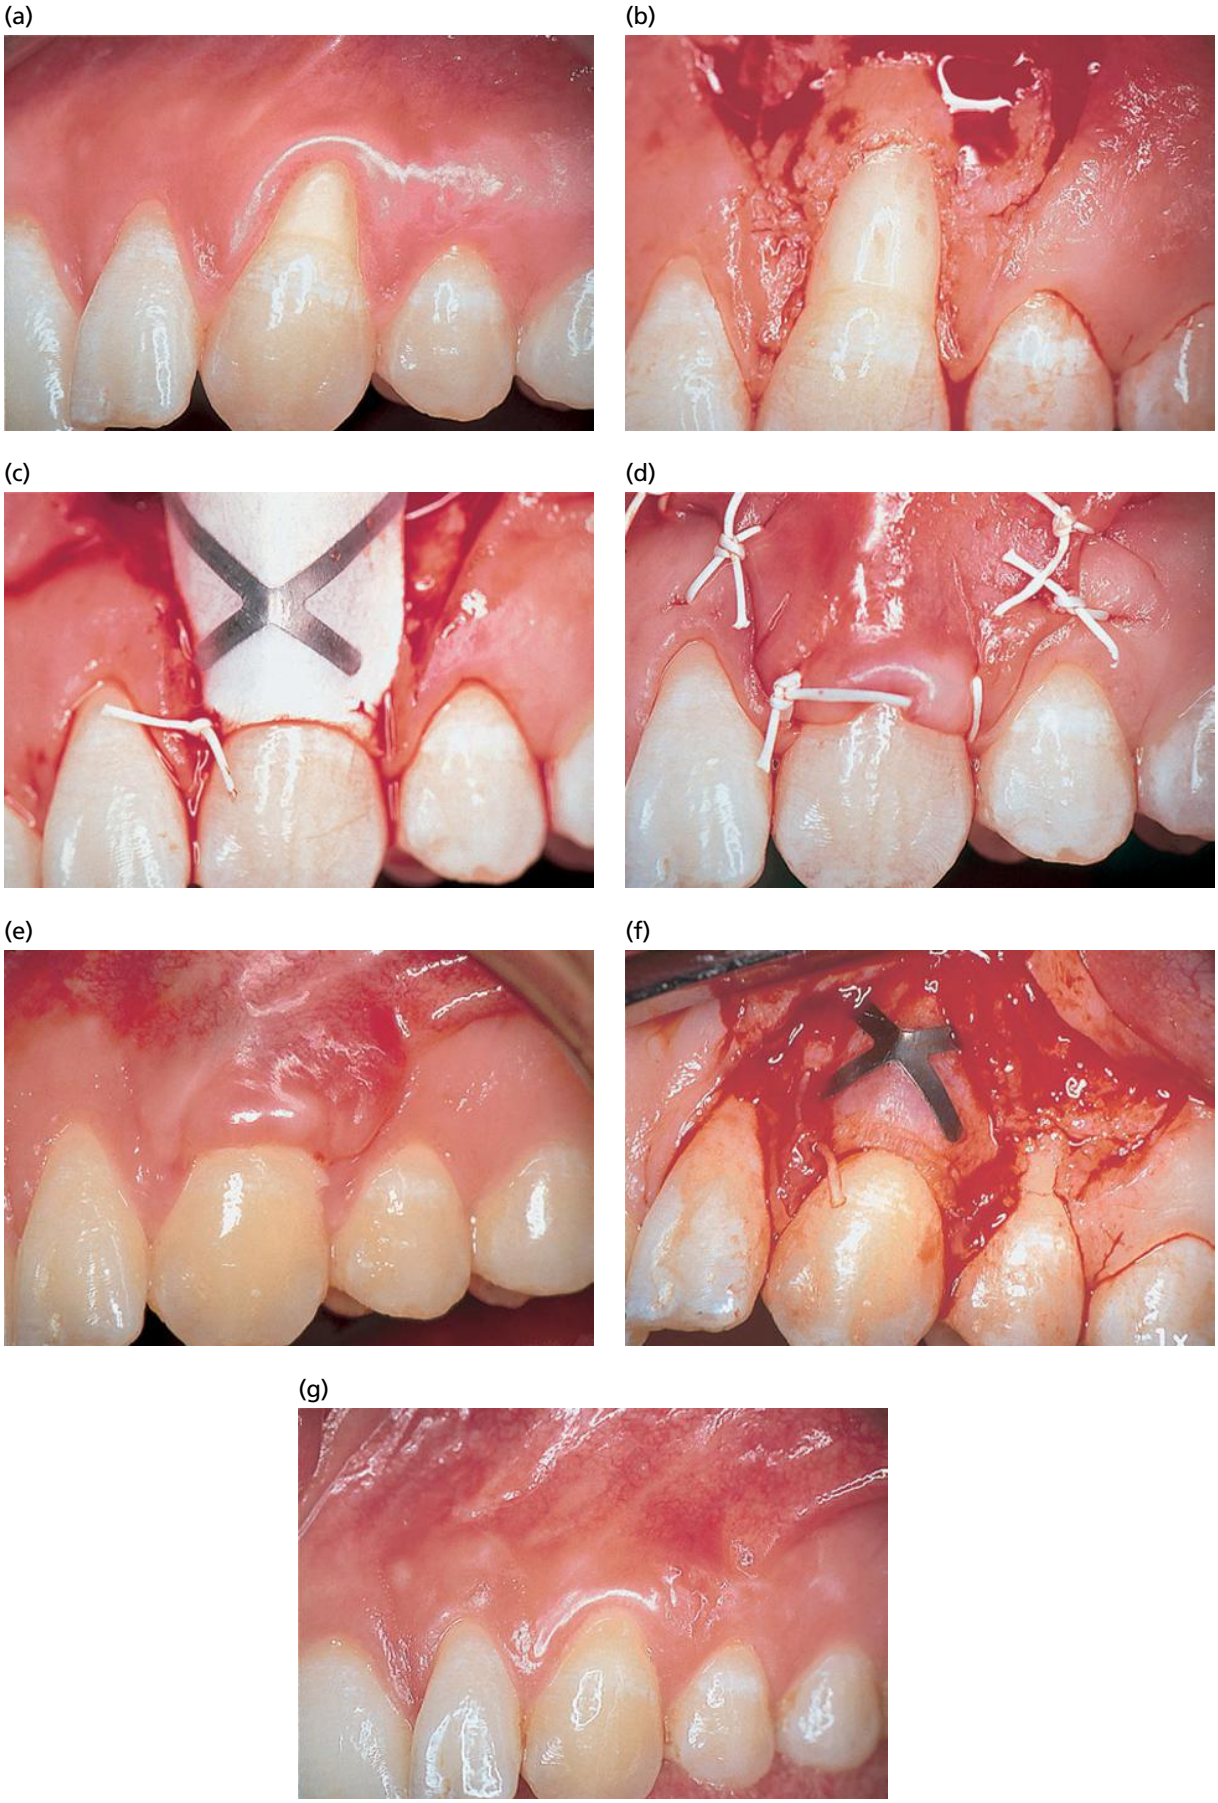

Fig. 46-40 Coronally advanced flap procedure combined with a titanium-reinforced non-biodegradable membrane barrier. (a–f) Recession defect at tooth 23 requiring treatment due to the patient's esthetic demands (see text for explanation). (g) One-year post-operative result.

Pedicle soft tissue graft procedures combined with a barrier membrane

The use of a barrier membrane, according to the principles of guided tissue regeneration (GTR; see Chapter 45), in conjunction with pedicle soft tissue graft procedures was introduced as a treatment modality for root coverage by Pini Prato *et al*. (1992). In order create space for tissue formation between the facial root surface and the membrane, the authors suggested that extensive root planing should be carried out to produce concave root morphology. Specially designed membranes for the treatment of recession-type defects are available, such as non-absorbable titanium-reinforced expanded polytetrafluoroethylene (e-PTFE) membranes (Fig. 46-40c). In addition, a variety of bioresorbable membranes are commercially available, but many of these may not be rigid enough to maintain the required space during healing.

The technique is as follows:

1. The pedicle graft used in the GTR procedure is generated through the preparation of a coronally advanced flap as described above (Fig. 46-40a, b). Depending on the degree of coronal repositioning, the facial portion of the interdental papillae may need to be de-epithelialized to prepare proper recipient beds for the pedicle graft.
2. The root is extensively planed or ground to obtain a concave profile of the root surface, thereby providing space for tissue formation. If a titanium-reinforced membrane is used, the root profile may not need to be changed to establish the required space between the root and the membrane.
3. The membrane barrier to be used is trimmed to cover the exposed root and approximately 3 mm of the bone lateral and apical to the dehiscence (Fig. 46-40c), and anchored to the tooth by a sling suture placed at the level of the CEJ.
4. The mobilized flap is positioned coronally and secured by interdentally placed interrupted sutures (Fig. 46-40d). The membrane should be completely covered by the flap to reduce the risk for bacterial contamination during healing. Additional sutures are placed to close the lateral wound of the releasing incisions.
5. The patient is advised to use a chlorhexidine mouth rinse for infection control and not to use any mechanical cleaning devices for at least 6 weeks in the tooth region subjected to surgery.
6. The use of non-biodegradable membrane barriers requires a second surgery for membrane removal, usually after 5–6 weeks (Fig. 46-40e, f). A partial-thickness trapezoidal flap is raised to expose the membrane. Following its removal, the flap is repositioned at the level of the CEJ to completely cover the newly formed tissue. Mechanical plaque control is re-instituted 4 weeks after membrane removal.

Pedicle soft tissue graft procedures combined with enamel matrix proteins

Abbas *et al*. (2003) described a surgical procedure for periodontal regenerative therapy of recession defects utilizing enamel matrix derivative (EMD) bioactive material (Emdogain®):

1. The surgical technique utilized is the coronally advanced flap as described above (see Fig. 46-33). The interdental papillae should be de-epithelialized to allow for maximum coronal positioning of the tissue flap over the exposed root surface at suturing.
2. Following preparation of the coronally advanced flap, the exposed root surface is conditioned with PrefGel™ (24% EDTA-gel, pH 6.7; Straumann Biologics, Switzerland) for 2 minutes to remove the smear layer.
3. After thorough rinsing with sterile saline, the EMD gel (Emdogain®; Straumann Biologics) is applied to the exposed root surface. The pedicle graft is advanced coronally and secured at a level slightly coronal to the CEJ by suturing the flap to the de-epithelialized papilla regions using non-irritating sutures. The vertical incisions are then closed with two to three sutures. Mechanical tooth cleaning is avoided during the first 3–4 weeks of healing (rinsing with a chlorhexidine solution is prescribed), and when re-instituted, a toothbrushing technique creating minimal apically directed trauma to the soft tissue margin is used.

Free soft tissue graft procedures

A free soft tissue graft of masticatory mucosa is usually selected when there is no acceptable donor tissue present in the area adjacent to the recession defect or when a thicker marginal tissue is desirable. The procedure can be used for the treatment of a single tooth as well as for groups of teeth. The graft used may either be (1) an epithelialized graft or (2) a subepithelial connective tissue graft of palatal masticatory mucosa.

Epithelialized soft tissue graft

The epithelialized free soft tissue graft procedure can be performed either as a two-step surgical technique, where an epithelialized free soft tissue graft is placed apical to the recession and following healing is positioned coronally over the denuded root (Fig. 46-41) (Bernimoulin *et al*. 1975; Guinard & Caffesse 1978), or as a one-step technique by which the graft is placed directly over the root surface (Sullivan & Atkins 1968a, b; Miller 1982) (Fig. 46-42). The latter technique has been the most commonly used.

The principles of utilizing free mucosal grafts were outlined by Sullivan and Atkins (1968a, b) and later modified by Miller (1982):

1. Before any incisions, the exposed root surface is carefully scaled and root planed (Fig. 46-42a). The convexity of the root may be reduced to minimize the mesiodistal avascular recipient bed.

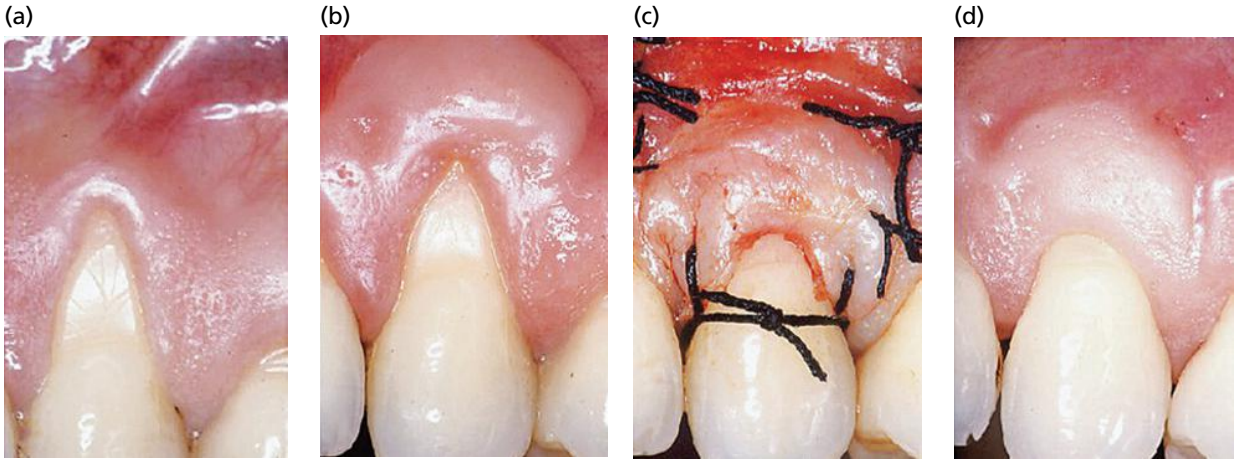

Fig. 46-41 Two-stage epithelialized free soft tissue graft procedure. (a–c) Epithelialized soft tissue graft is placed apical to the recession and allowed to heal. At a second-stage surgery, a coronally advanced flap procedure is performed to achieve coverage of the denuded root. (d) One-year postoperative result.

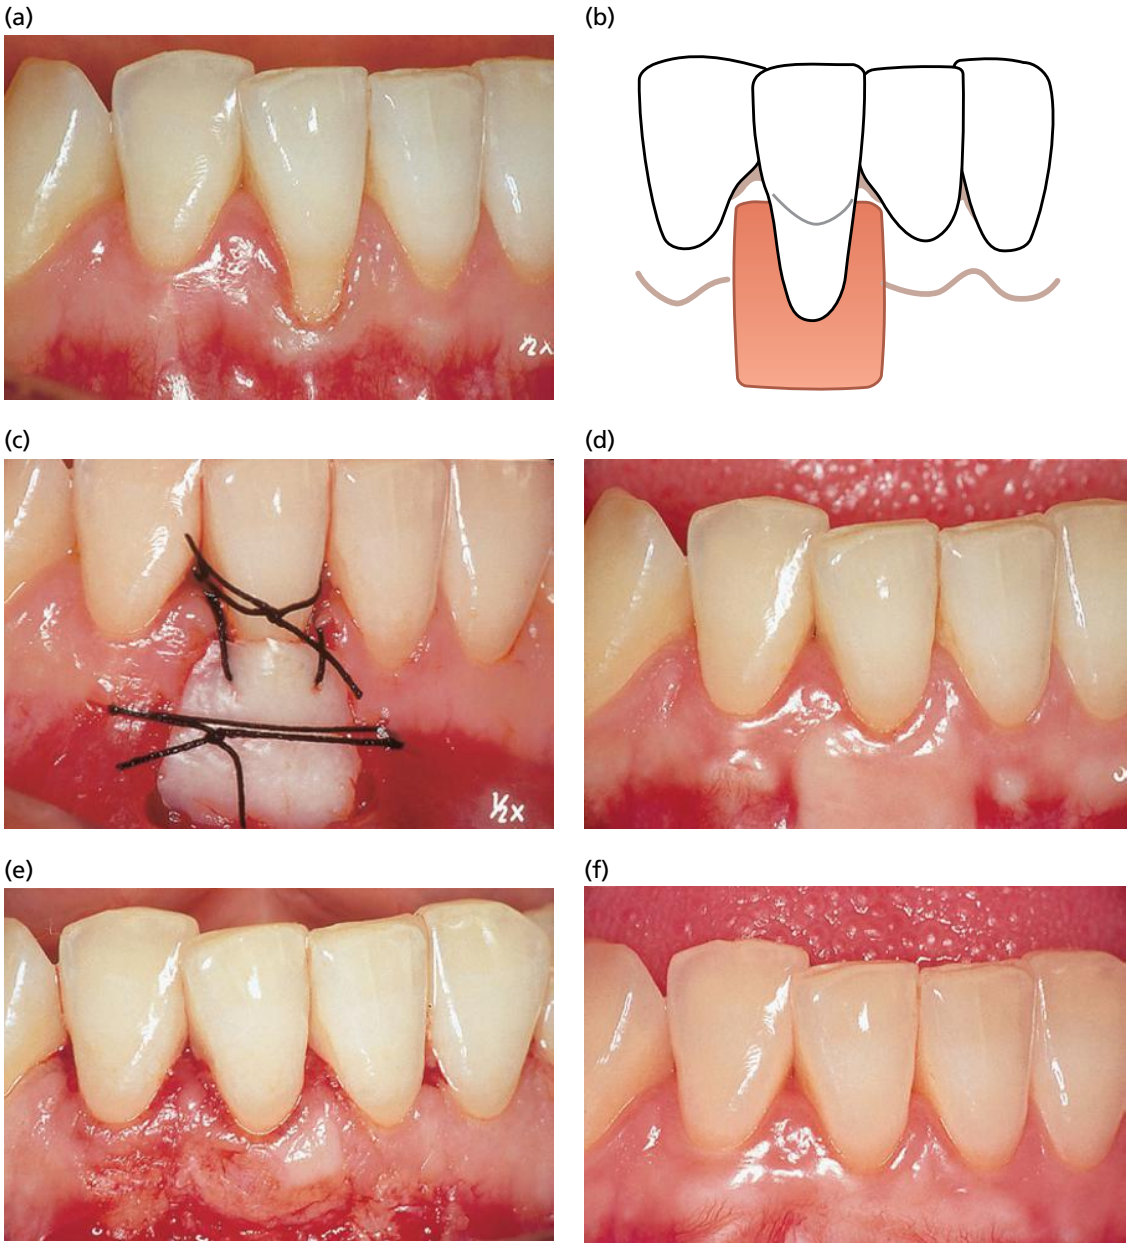

Fig. 46-42 (a–f) Epithelialized free soft tissue graft procedure. A recession defect at a mandibular central incisor treated with the free graft procedure (see text for explanation).

2. As in the treatment with pedicle grafts, the preparation of the *recipient bed* is crucial for the success of the free graft procedure. A 3–4-mm wide recipient connective tissue bed should be prepared apical and lateral to the recession defect (Fig. 46-42b). The area is demarcated by first placing a horizontal incision, at the level of the CEJ, in the interdental tissue on each side of the tooth to be treated. Subsequently, two vertical incisions, extending from the incision line placed in the interdental tissue to a level approximately 4–5 mm apical to the recession, are placed. A horizontal incision is then made connecting the two vertical incisions at their apical termination. Starting from an intracrevicular incision, a split incision is made to sharply dissect the epithelium and the outer portion of the connective tissue within the demarcated area.
3. To ensure that a graft of sufficient size and proper contour is removed from the donor area, a foil template of the recipient site is prepared. This template is transferred to the donor site, the palatal mucosa in the region of the premolars, and the required size of the graft is outlined by a shallow incision. A graft with a thickness of 2–3 mm is then dissected from the donor area (Fig. 46-20c, d). It is advocated to place sutures in the graft before it is cut completely free from the donor area since this may facilitate its transfer to the recipient site. Following the removal of the graft, pressure is applied to the wound area for control of bleeding.
4. The graft is immediately placed on the prepared recipient bed. In order to immobilize the graft at the recipient site, sutures must be anchored in the periosteum or in the adjacent attached gingiva. Adequate numbers of sutures are placed to secure close adaptation of the graft to the underlying connective tissue bed and root surface (Fig. 46-42c). Before the placement of a periodontal dressing, pressure is exerted against the graft for some minutes in order to eliminate blood from between the graft and the recipient bed. Following the control of bleeding, a periodontal dressing is applied to the wound in the donor area in the palate. An acrylic plate may be required to maintain the dressing in place during the healing phase.
5. The sutures and periodontal dressing are usually maintained for 2 weeks. The appearance of a grafted area after 3 months of healing is shown in Fig. 46-42d. A gingivoplasty may be indicated to achieve a satisfactory esthetic appearance of the grafted area (Fig. 46-42e, f).

Connective tissue graft

The techniques utilizing a subepithelial soft tissue graft, that is the connective tissue, involve the placement of the graft directly over the exposed root and the mobilization of a mucosal flap coronally (Fig. 46-43) or laterally (Fig. 46-44) for coverage of the graft (Langer & Langer 1985; Nelson 1987; Harris 1992; Bruno 1994; Zucchelli *et al*. 2003). An alternative technique is to place the base of the connective tissue graft within an "envelope" prepared by an undermining partial-thickness incision from the soft tissue margin, that is part of the graft will rest on the root surface coronal to the soft tissue margin (Fig. 46-45) (Raetzke 1985; Allen 1994). For the treatment of multiple adjacent recessions, a multi-envelope recipient bed ("tunnel") may be prepared (Zabalegui *et al*. 1999). The subepithelial connective tissue graft is harvested from the palate or the retromolar pad by the use of a "trap-door" approach (Fig. 46-46). Compared to the epithelialized graft, the connective tissue graft is preferable due to a less invasive palatal wound and an improved esthetic result. As an alternative to the connective tissue graft, xenogenic collagen matrix (e.g. Mucograft®) may be used (McGuire & Scheyer 2010; Jepsen *et al*. 2013).

The technique for the *connective tissue graft combined with a coronally advanced flap* is as follows (Fig. 46-43):

1. The surgical technique utilized is the coronally advanced flap as described above, but with the difference that the flap is elevated entirely as a split-thickness flap. The interdental papillae should be de-epithelialized to allow for maximum coronal positioning of the tissue flap over the exposed root surface at suturing (Fig. 46-43b).
2. A subepithelial connective tissue graft of masticatory mucosa is harvested on the palatal aspect of the maxillary premolars/first molar (or from the retromolar pad) by the use of a "trap-door" approach (Fig. 46-46). Before incisions are placed, the available thickness of the mucosa is estimated using the tip of the syringe. A horizontal incision, perpendicular to the underlying bone surface, is made approximately 3 mm apical to the soft tissue margin (Fig. 46-46a). The mesiodistal extension of the incision is determined from the graft size required, which is 6 mm longer than the width of the dehiscence measured at the level of the CEJ. To facilitate the removal of the graft, a vertical releasing incision may be made at the mesial termination of the primary incision. An incision is then placed from the line of the first incision and directed apically to perform a split incision of the palatal mucosa (Fig. 46-46b–f). A small periosteal elevator or scalpel is used to release the connective tissue graft from the bone.
3. The graft is immediately transferred to the recipient site and positioned at a distance from the CEJ equal to the height of keratinized tissue originally present apical to the recession defect. The graft is secured in position with two double vertical mattress sutures to adjacent soft tissue lateral to the dehiscence (Fig. 46-43c). A sling suture is placed in the papilla regions to position the margin of the covering advanced flap about 1 mm coronal to the CEJ. Interrupted sutures are used to close the wound along the vertical incisions (Fig. 46-43d).

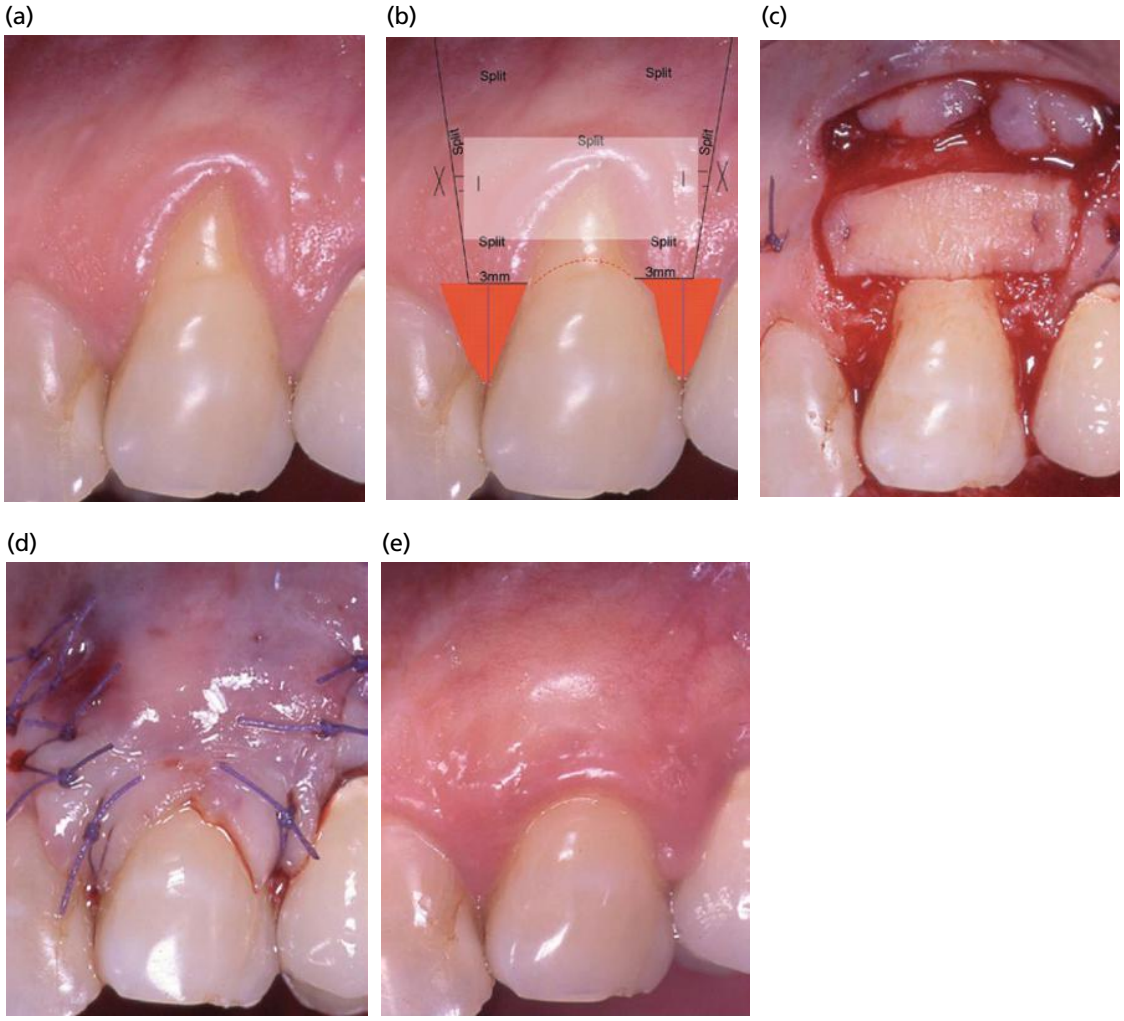

Fig. 46-43 Free connective tissue graft combined with a coronally advanced flap procedure: single recession (see text for explanation). (a, b) Deep gingival recession at a cuspid with minimal height of keratinized tissue apical to the root exposure. (c) Graft has been sutured to leave an area between the cementoenamel junction and the graft available for the marginal keratinized tissue of the flap. (d) Flap has been advanced coronally and sutured. (e) Clinical healing at 1 year.

Figure 46-47 illustrates the procedure applied to a case with multiple recession sites.

The "envelope" technique (Fig. 46-48) is as follows:

1. With the use of the "envelope" technique, the recipient site is prepared by first eliminating the sulcular epithelium by an internal beveled incision (Fig. 46-48a). Second, an "envelope" is prepared apically and laterally to the recession by split incisions (Fig. 46-48b). The depth of the preparation should be 3–5 mm in all directions. In an apical direction, the preparation of the site should extend beyond the mucogingival junction to facilitate the placement of the connective tissue graft and to allow for coronal advancement of the mucosal flap at the time of suturing.
2. A foil template may be used to harvest an appropriately sized connective tissue graft. The graft, which is obtained by the "trap-door" approach described above (Fig. 46-46), is inserted into the prepared "envelope" and positioned to cover the exposed root surface (Fig. 46-48c, d).
3. Sutures are placed to secure the graft in position (Fig. 46-48d). A crossed sling suture may be placed to advance the mucosal flap coronally. Pressure is applied for 5 minutes to adapt the graft closely to the root surface and covering soft tissue.

Figure 46-45 shows the treatment of a recession defect with the "envelope" technique.

The "*tunnel" technique* (Fig. 46-49) is as follows:

1. In case multiple adjacent recessions are to be treated, "envelopes" are prepared for each tooth as described above. However, the lateral split incisions are extended so that the multi-envelopes are connected mesially and distally to form a mucosal tunnel. Care should be taken to avoid detachment of the papillae.
2. The graft is gently positioned inside the tunnel and its mesial and distal extremities are fixed with two interrupted sutures. Sling sutures may be placed to advance the mucosal flap coronally over the exposed portions of the connective tissue graft. Pressure is applied for 5 minutes to closely adapt the graft to the root surface and covering soft tissue.

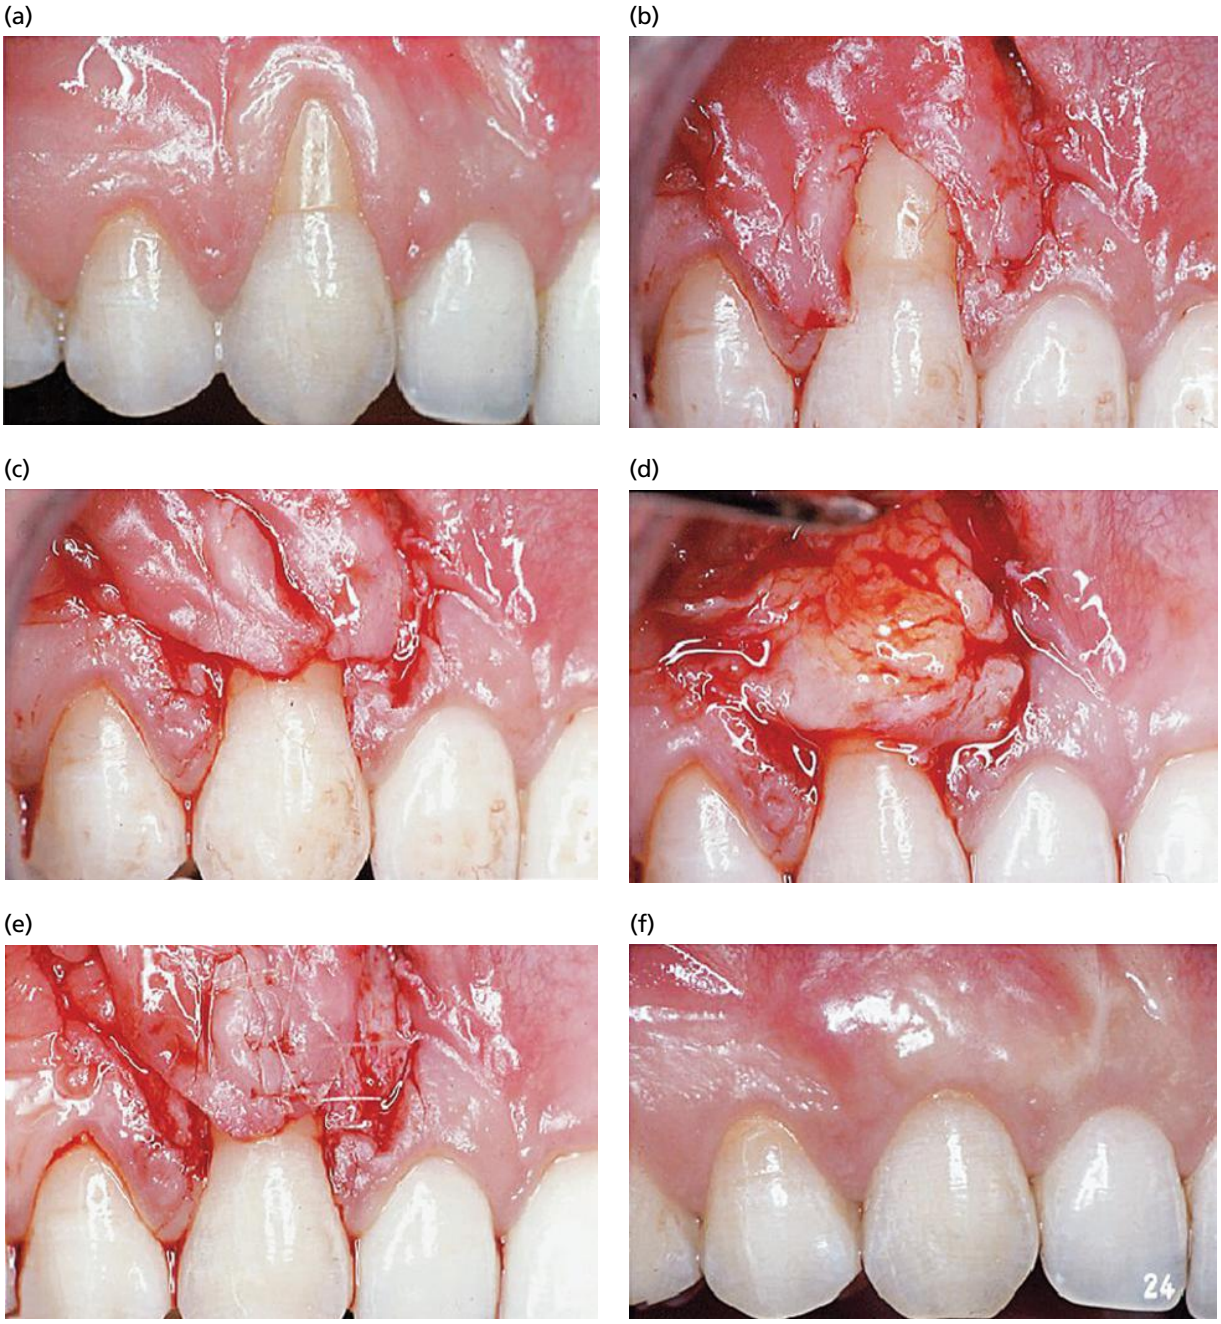

Fig. 46-44 (a–e) Free connective tissue graft combined with a double papilla flap procedure. (f) One-year post-treatment result.

Selection of surgical procedure for root coverage

For each individual case, several factors have to be taken into consideration when selecting the surgical procedure for achieving root coverage, for example jaw, tooth position, recession depth and width, tissue thickness and quality apical and lateral to the recession, esthetic demands, and compliance. From an esthetic point of view, the soft tissue coverage of exposed root surfaces should be in harmony with the adjacent tissue and hence a pedicle graft would be the preference.

For maxillary teeth, the coronally advanced flap may be considered as the basic procedure to be used for single as well as multiple recessions. If the quality of the mucosa apical to the recessions is considered inadequate for root coverage, the procedure is combined with the placement of a connective tissue graft.

In the mandible, the placement of a free connective tissue graft with an "envelope" or a "tunnel" preparation is preferred because of a thin mucosa apical to the recession and often the presence of multiple frenula, that is conditions not suitable for a coronally advanced flap. In case of a localized single recession defect of moderate depth, a rotational flap may be used if keratinized mucosa of sufficient dimensions are available lateral to the recession.

Soft tissue recessions at dental implants are commonly associated with a thin mucosa (Fig. 46-50) and hence the surgical approach to regain soft tissue

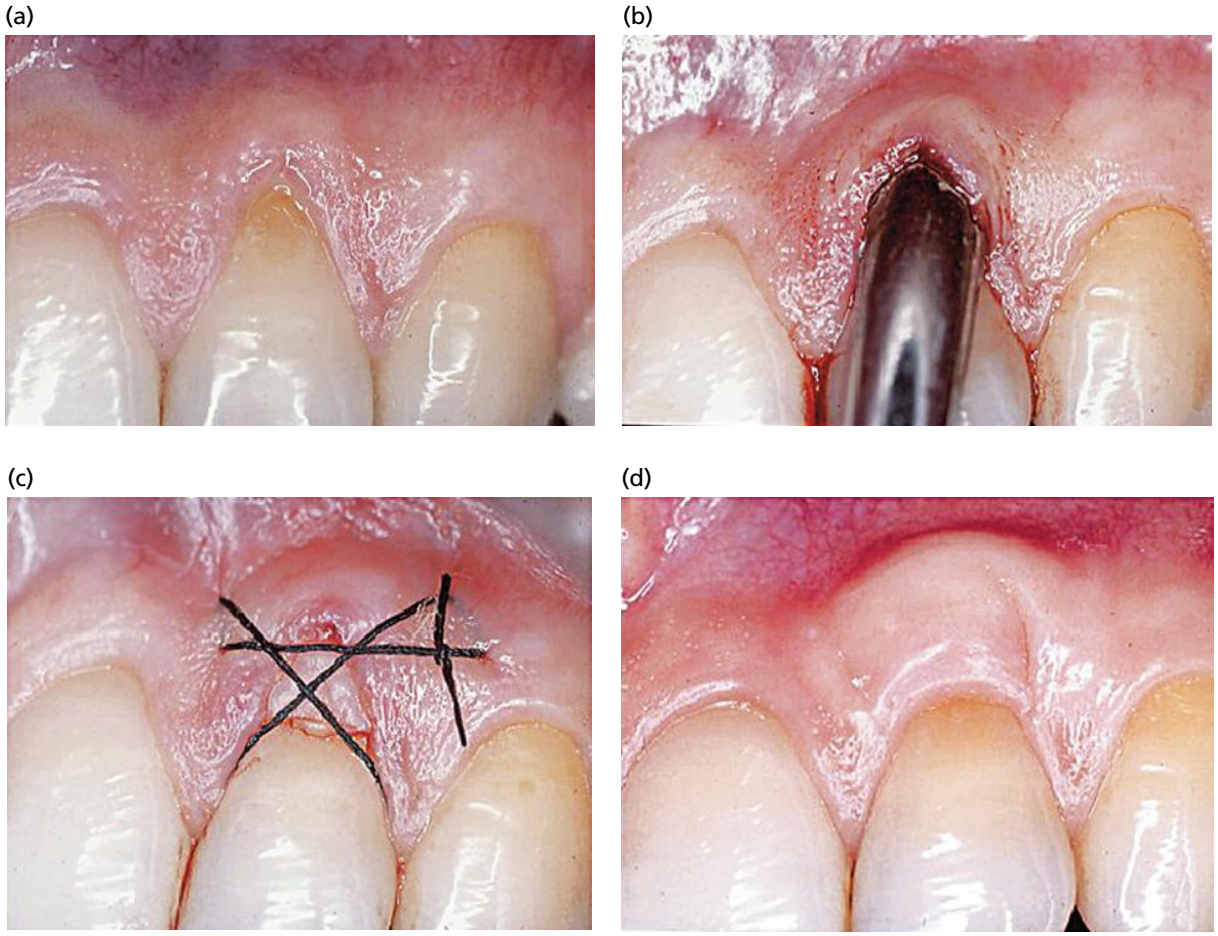

Fig. 46-45 (a–c) Free connective tissue graft procedure: the "envelope technique" (see text for explanation). (d) One-year post-treatment result. (Courtesy of P. Cortellini.)

coverage of the implant unit has to involve a connective tissue graft, either in a combined procedure with a coronally advanced flap or in a two-stage procedure with the placement of the connective tissue graft with an "envelope" procedure, followed by a coronally advanced flap as a second procedure.

Clinical outcome of root coverage procedures

Independent of the modality of surgical procedure used to obtain soft tissue root coverage, shallow residual probing depths, gain in clinical attachment, and increase in gingival height are the common characteristics of treatment outcome. Although the major indications for performing root coverage procedures are esthetic/cosmetic demands and root sensitivity, few studies have used assessments of these criteria as end points of treatment success. Instead, the common outcome variables used are the amount of root coverage achieved, expressed as a percentage of the initial depth of the recession defect, and the proportion of treated sites showing complete root coverage. Whereas complete root coverage may be a successful outcome with respect to root sensitivity, it is not necessarily equivalent to treatment success from an esthetic point of view because, besides root coverage in harmony with adjacent teeth, factors such as tissue thickness, color, and texture influence the appreciation of the esthetic result.

Root coverage

An overall comparison of the treatment outcome of various root coverage procedures is hampered by the fact that there is substantial heterogeneity between studies (Cairo *et al.* 2008; Chambrone *et al.* 2009). The variability in the treatment outcome for the various procedures, both within and between studies, is large, indicating that the procedures are operator sensitive and that various factors influencing the treatment outcome have not been adequately considered. An analysis with regard to initial Miller class I–II recession defects that may be successfully covered following treatment with coronally advanced flaps, based on the data from randomized controlled studies included in recent systematic reviews (Cairo *et al.* 2008; Chambrone *et al.* 2009), shows that on average about 70% root coverage may be expected (range 34–87%). Complete coverage of the recession defect, which is the ultimate goal of the therapy, may be reached in approximately 35% of treated cases (range 15–60%).

Evidence suggests that the treatment outcome can be improved by adjunctive use of connective tissue

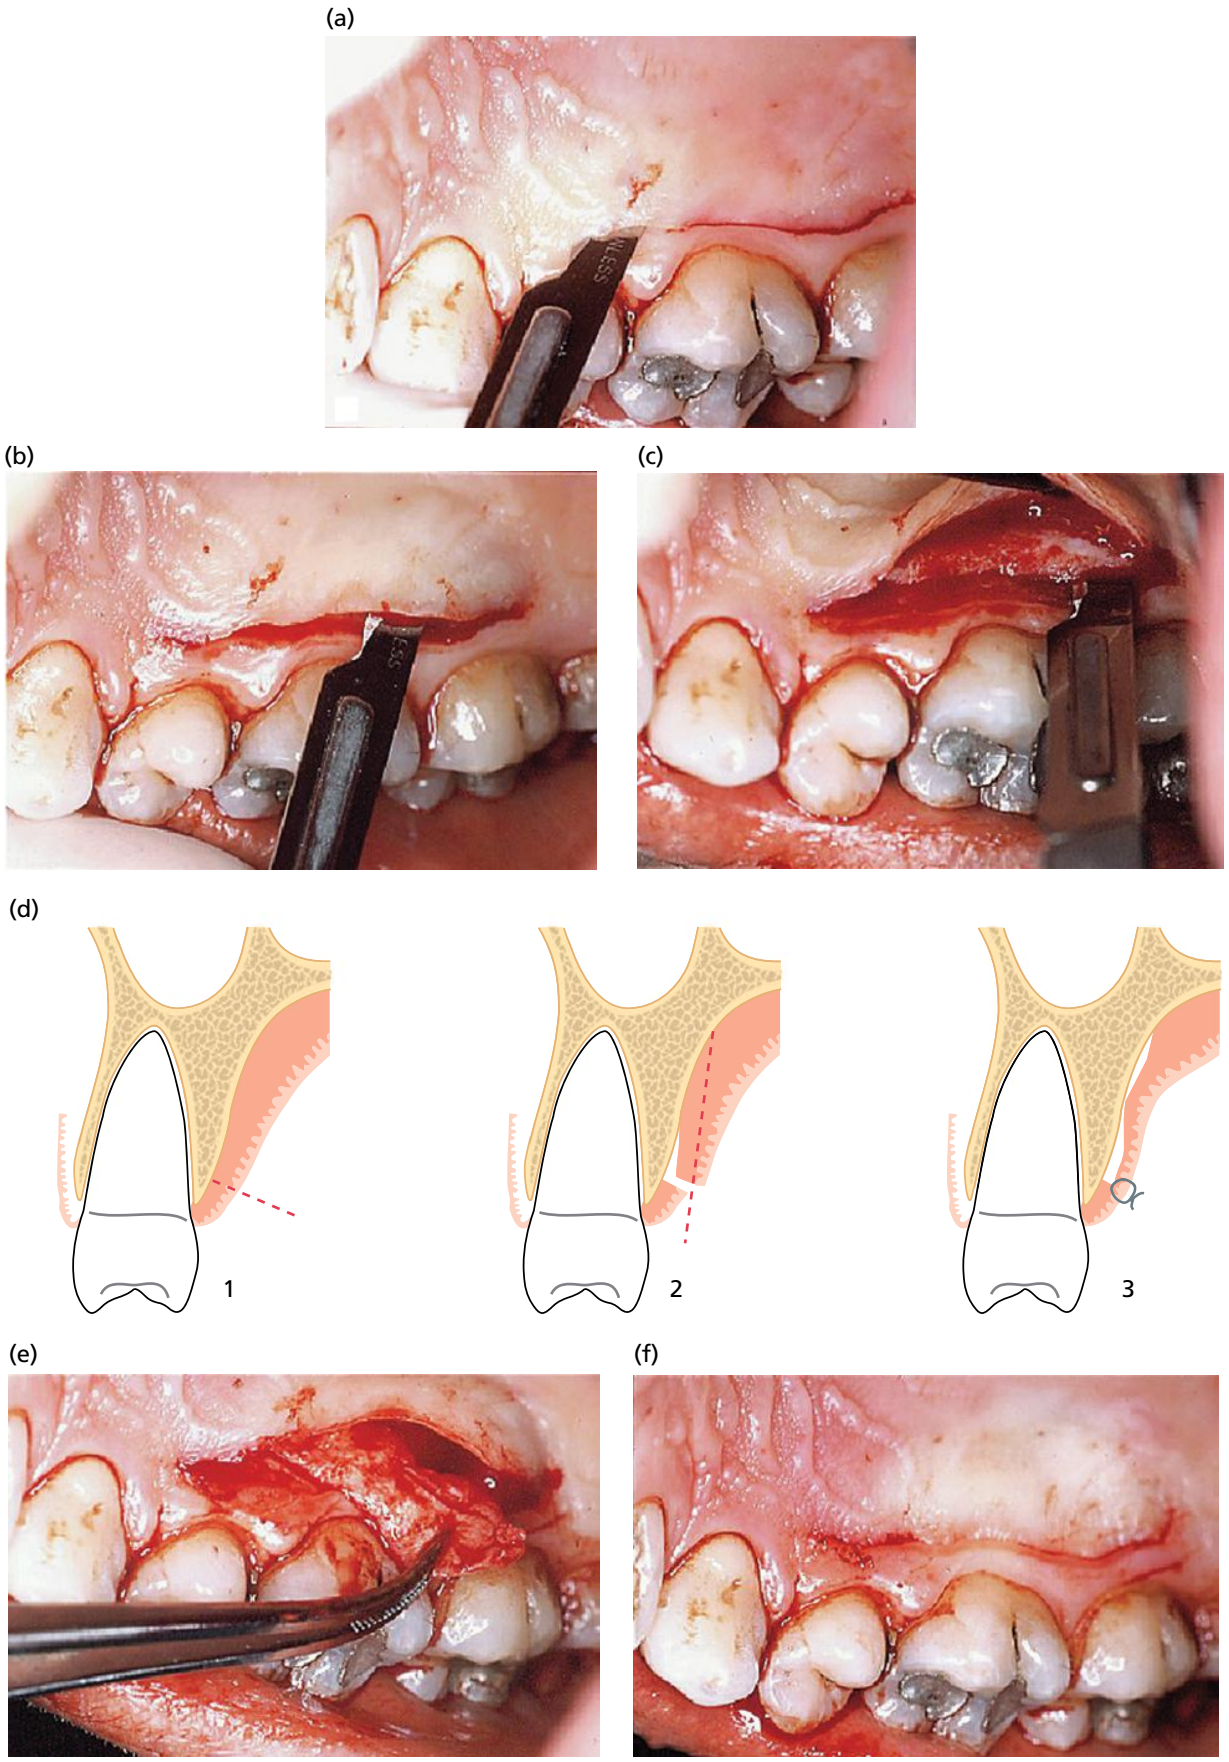

Fig. 46-46 (a–f) "Trap-door" technique for harvesting a free connective tissue graft (see text for explanation).

graft or enamel matrix proteins, with an estimated mean absolute adjunctive effect of 15–25% for complete root coverage and 13–17% for reduction in recession depth (Cairo *et al.* 2008; Chambrone *et al.* 2009; Buti *et al.* 2013). The inclusion of barrier membranes, on the other hand, may not improve the treatment outcome. In fact, based on data from the systematic reviews referred to, the estimated mean absolute effect is –17% for complete root coverage compared to that with a coronally advanced flap alone. The lower mean predictability of complete root coverage achieved with the GTR procedure has been associated with the problem of membrane exposure during healing (Trombelli *et al.* 1995), but whether a bioresorbable or a non-bioresorbable barrier membrane is used does not seem to affect the treatment outcome (Roccuzzo *et al.* 1996).

With regard to the application of soft tissue coverage procedures for the treatment of soft tissue recessions/dehiscenses at dental implants, there is very limited data available in the literature on treatment outcomes. A limited case series by Burkhardt

et al. (2008) showed that complete coverage of the dehiscence was not obtained for any of the treated soft tissue recession defects at dental implants with a depth of 2–5 mm when a combined surgical procedure including connective tissue graft and coronally advanced flap was used. At the 6-month follow-up after surgery, the average gain in soft tissue coverage amounted to 66%.

Factors influencing the degree of root coverage

Patient-related factors. As with other surgical periodontal treatment procedures, poor oral hygiene will negatively influence the success of root coverage procedures (Caffesse *et al*. 1987). Further, a predominant causative factor in the development of gingival recession is toothbrushing trauma, and hence this factor has to be corrected to secure an optimal outcome for any root coverage procedure. Treatment outcome in terms of root coverage is usually less favorable in smokers than in non-smokers (Trombelli & Scabbia 1997; Zucchelli *et al*. 1998; Martins *et al*. 2004; Erley *et al*. 2006; Silva *et al*. 2006), although some studies showed no differences between these groups (Tolmie *et al*. 1991; Harris 1994).

Site related factors Among site-specific factors, the level of interdental periodontal support may be of greatest significance for the outcome of root coverage procedures. From a biologic point of view, complete root coverage is achievable in Miller class I–II recession defects (Fig. 46-51), while when loss of connective tissue attachment and soft tissue height also involves proximal tooth sites (class III–IV recession defects), only partial facial root coverage may be obtainable (Miller 1985b) (Fig. 46-52).

An additional factor shown to influence the degree of attainable root coverage is the dimensions of the recession defect. Less favorable treatment outcome has been reported at sites with wide (>3 mm) and deep (≥5 mm) recessions (Holbrook & Ochsenbein 1983; Pini Prato *et al*. 1992; Trombelli *et al*. 1995). In a study comparing the treatment effect of coronally advanced flap and free connective tissue graft procedures, Wennström and Zucchelli (1996) reported that complete root coverage was observed in only 50% of the defects with an initial depth of ≥5 mm compared to 96% for shallower defects. Pini Prato *et al*. (1992) suggested, based on clinical observations in a controlled clinical trial, that a more favorable result with respect to root coverage might be obtained with the GTR procedure in sites with deep (≥5 mm) recession defects as compared to the coronally advanced flap procedure alone. At the 18-month examination, the average coverage was 77% with and 66% without the inclusion of a membrane barrier. However, data presented from more recent systematic reviews and meta-analyses (Roccuzzo *et al*. 2002; Oates *et al*. 2003) showing that the predictability of root coverage is significantly reduced with the use of barrier membranes, limiting the justification for the use of the GTR procedure in the treatment of recession defects. The pretreatment gingival height apical to the recession defect is not correlated to the amount of root coverage obtained (Romanos *et al*. 1993; Harris 1994).

Technique-related factors Several technique-related factors may influence the treatment outcome of a pedicle graft procedure. In a systematic review including data from 15 studies (Hwang & Wang 2006), a positive correlation was demonstrated between the thickness of the tissue flap and recession reduction. For complete root coverage, the critical threshold thickness was found to be about 1 mm. However, whether a full- or a split-thickness pedicle graft is used for root coverage may not influence the treatment outcome (Espinel & Caffesse 1981).

Elimination of flap tension is considered an important factor for the outcome of the coronally advanced flap procedure. Pini Prato *et al*. (2000a) measured the tension in coronally advanced flaps to compare the

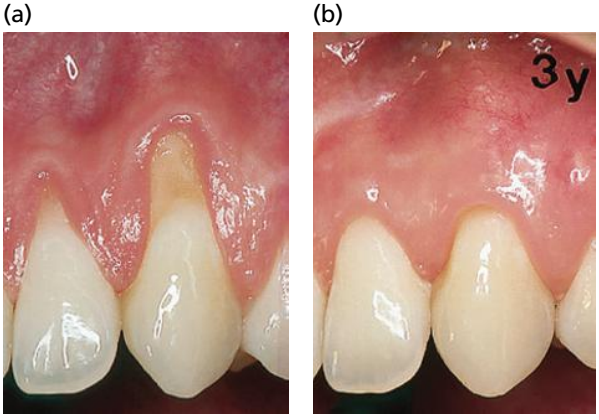

Fig. 46-51 (a) Buccal recession defects but no loss of periodontal support at proximal surfaces. Complete root coverage can be achieved. (b) Three-year follow-up.

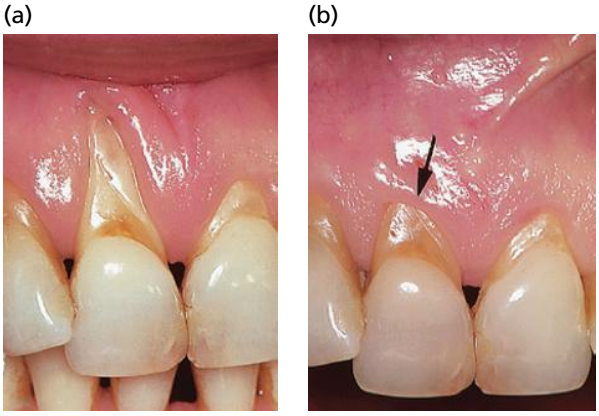

Fig. 46-52 (a) Deep buccal recession at tooth 11. The tooth has loss of support at proximal sites (Miller class III) and complete root coverage is not achievable. Also, neighboring teeth show recessions at all tooth surfaces. (b) Two-year healing result following attempted root coverage at the facial aspect of tooth 11 (arrow). The coronal position of the soft tissue margin is defined by the extension of proximal loss of periodontal support.

amount of root coverage in sites with and without residual flap tension. At sites that had residual tension (mean 6.5 g), the root coverage amounted to 78% 3 months post-surgically and 18% of the treated sites showed complete root coverage. Sites without tension demonstrated mean root coverage of 87% and complete root coverage in 45% of the cases. Furthermore, a statistically significant negative association was shown between the magnitude of residual tension in the flap and the amount of recession reduction.

Although the connective tissue areas lateral to the recession defect are considered important for the retention of the advanced flap when positioned over the root surface, the dimension of the interdental papilla area is not a prognostic factor for the clinical outcome of the root coverage procedure (Saletta *et al*. 2001). As can be expected, the position of the gingival margin relative to the CEJ after suturing affects the probability of complete root coverage following healing. Pini Prato *et al*. (2005) demonstrated that for 100% predictability of complete root coverage in the treatment of Miller class I recessions with a coronally advanced flap procedure, the flap margin has to be positioned at least 2 mm coronal to the CEJ.

With regard to free graft procedures, the thickness of the graft influences their success (Borghetti & Gardella 1990). A thickness of the free graft of about 2 mm is recommended.

Increased gingival height

An increased apicocoronal height of the gingiva is found following all procedures in which pedicle grafts of adjacent gingiva or free grafts from the palate have been placed over the recession defect. It is interesting to note, however, that an increased gingival height is also a common finding following a coronally advanced flap procedure only involving the existing gingiva apical to the recession (Fig. 46-53). This finding may be explained by several events taking place during the healing and maturation of the marginal tissue.

Fig. 46-53 Increased dimension of keratinized tissue 1 year following root coverage with a coronally advanced flap procedure. (a) Before and (b) One-year postoperatively. Arrows indicate the position of the mucogingival line.

Granulation tissue derived from the periodontal ligament tissue will form a connective tissue similar to the one of gingiva and with the potential to induce keratinization of the covering epithelium (Karring *et al*. 1971). A second factor to consider is the tendency of the mucogingival line to regain its "genetically"-defined position following its coronal "dislocation" with the coronally advanced flap procedure used to achieve root coverage. Support for the concept that the mucogingival line will regain its original position over time comes from a study by Ainamo *et al*. (1992). The authors performed an apically repositioned flap procedure in the lower anterior tooth region, which resulted in a 3-mm apical displacement of the mucogingival line. Re-examination after 18 years showed no differences in position of the mucogingival line between sites treated with the apically repositioned flap and contralateral control sites treated with a procedure not interfering with the mucogingival line, indicating that the mucogingival line had regained its original position.

Soft tissue healing against the covered root surface

Treatment of gingival recessions by pedicle grafts or free grafts may be clinically successful, but does the treatment result in a healing characterized by the formation of a connective tissue attachment or an epithelial attachment? Independent of the quality of attachment formed, however, root coverage procedures evidently rarely result in the formation of a deep periodontal pocket.

Healing of pedicle soft tissue grafts

In the areas surrounding the recession defect, that is where the recipient bed consists of bone covered by connective tissue, the pattern of healing is similar to that observed following a traditional flap operation. Cells and blood vessels from the recipient bed as well as from the tissue graft invade the fibrin layer, which is gradually replaced by connective tissue. After 1 week, a fibrous reunion is already established between the graft and the underlying tissue.

Healing in the area where the pedicle graft is in contact with the denuded root surface was studied by Wilderman and Wentz (1965) in dogs. According to these authors, the healing process can be divided into four different stages (Fig. 46-54):

1. *Adaptation stage (from 0 to 4 days).* The laterally repositioned flap is separated from the exposed root surface by a thin fibrin layer. The epithelium covering the transplanted tissue flap starts to proliferate and reaches the tooth surface at the coronal edge of the flap after a few days.
2. *Proliferation stage (from 4 to 21 days).* In the early phase of this stage, the fibrin layer between the root surface and the flap is invaded by connective

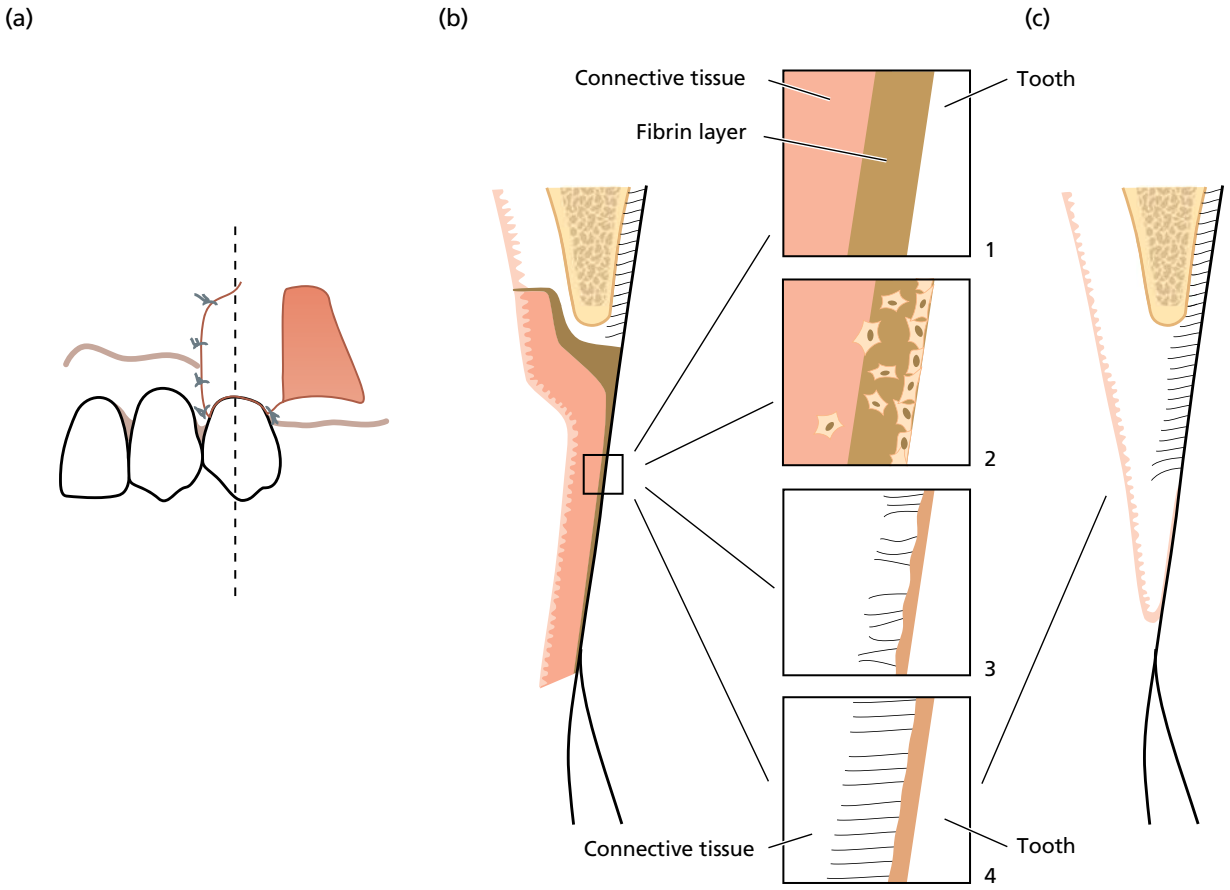

Fig. 46-54 (a) Schematic drawing illustrating healing following treatment of a localized soft tissue recession with a pedicle graft. (b) Cross-section through the area immediately after operation. The framed areas (1–4) illustrate the four stages into which the healing process can be divided. (c) Area after healing. Approximately 50% of the successfully covered defect may show new connective tissue attachment.

tissue proliferating from the subsurface of the flap. In contrast to areas where healing occurs between two connective tissue surfaces, growth of connective tissue into the fibrin layer can only take place from one surface. After 6–10 days, a layer of fibroblasts is seen in apposition to the root surface. These cells are believed to differentiate into cementoblasts at a later stage of healing. At the end of the proliferation stage, thin collagen fibers are formed adjacent to the root surface, but a fibrous union between the connective tissue and the root has not been observed. From the coronal edge of the wound, epithelium proliferates apically along the root surface. According to Wilderman and Wentz (1965), the apical proliferation of epithelium may stop within the coronal half of the defect, although further down-growth of epithelium was also frequently observed.

3. *Attachment stage (from 27 to 28 days).* During this stage of healing, thin collagen fibers become inserted into a layer of new cementum formed at the root surface in the apical portion of the recession.
4. *Maturation stage.* This last stage of healing is characterized by continuous formation of collagen fibers. After 2–3 months, bundles of collagen fibers insert into the cementum layer on the curetted root surface in the apical portion of the recession.

Results of experimental studies in monkeys and dogs on the healing characteristics of the periodontal wound have been interpreted to indicate that gingival connective tissue lacks the ability to form a new connective tissue attachment to the root, but may induce root resorption (see Chapter 28). This finding is of particular interest when considering the rationale for the treatment of recession defects by free or pedicle soft tissue grafts. Since, in these surgical procedures, gingival connective tissue is placed in contact with a denuded root surface, root resorption should be expected to occur. The reason why it is not a common complication following this type of treatment can be explained by two possible events: either cells from the periodontal ligament form a fibrous attachment to the root surface or epithelial cells proliferate apically, forming a root-protective barrier (long junctional epithelium) towards the gingival connective tissue.

Histologic studies to determine whether it is one or the other type of attachment that results following treatment of recessions with pedicle grafts indicate that new connective tissue attachment may form in part of the defect. In the study by Wilderman and Wentz (1965), a connective tissue attachment of around 2 mm and an epithelial attachment of the same height had formed in the soft tissue-covered

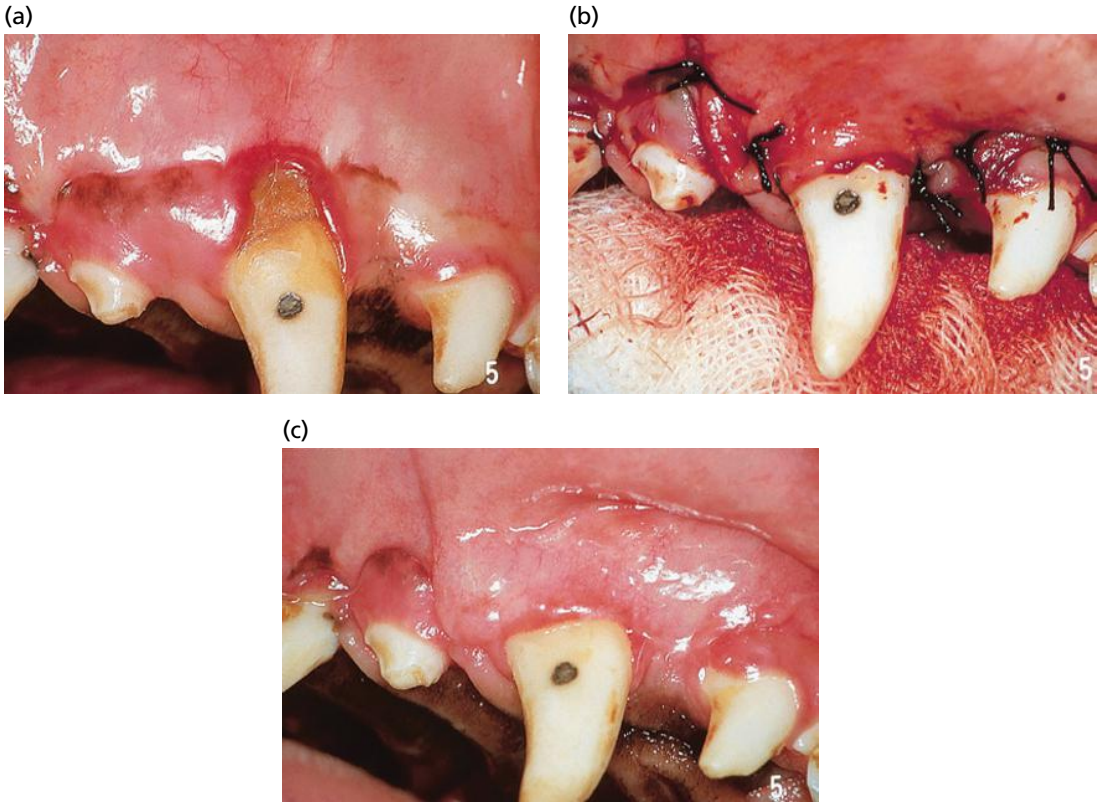

Fig. 46-55 Clinical photographs showing the treatment of an experimentally induced localized recession defect in a dog with a coronally displaced flap. (a) Presurgical appearance of the localized recession defect. (b) Site following flap closure of the defect and (c) following 3 months of healing.

portion of the defect, that is about 50% of the successfully covered defect showed new connective tissue attachment. Gottlow *et al*. (1986) examined the result of healing following treatment of experimentally produced recession type defects with a coronally advanced flap in dogs (Fig. 46-55). The histologic analysis after 3 months of healing disclosed that, on average, 20% of the apicocoronal length of the original defect had been exposed due to recession during healing (i.e. about 80% root coverage was achieved), 40% was covered by epithelium, and 40% demonstrated connective tissue attachment with cementum formation (Fig. 46-56). Determining factors for the type of healing result were the size and the shape of the defect. The possibility of achieving a new connective tissue attachment in the apical portion of the defect seemed to be considerably better in narrow recession defects than in wider ones, most likely because the periodontal ligament at the lateral parts of the defect will serve as a source of granulation tissue from which a new connective tissue attachment can develop.

Healing following pedicle graft procedures has also been histologically studied in monkeys (Caffesse *et al*. 1984; Gottlow *et al*. 1990), and in these studies 38–44% of the successfully covered recession defects demonstrated formation of new connective tissue attachment. The study by Gottlow *et al*. (1990) also showed that the use of a GTR membrane between the root surface and the pedicle graft generated

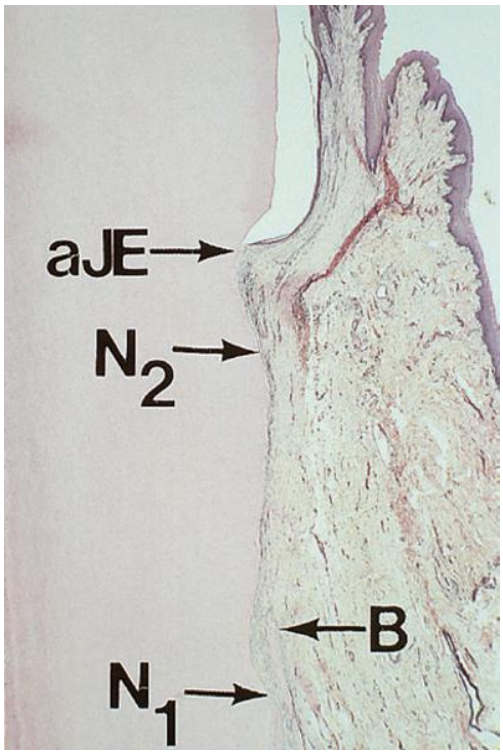

Fig. 46-56 Microphotograph of the healing following a coronally displaced flap in the same dog as in Fig. 44-54. A new connective tissue attachment is formed and extends coronally from the apical border of the notch prepared at the bottom of the bone dehiscence (N_1) to the apical termination of the epithelium (aJE) located within the notch indicating the presurgical level of the soft tissue margin (N_2). (B, alveolar bone crest.)

significantly more new connective tissue attachment (79% of the covered part of the recession defect). A significantly increased amount of cementum formation with inserting collagen fibers was also demonstrated following the utilization of enamel matrix proteins in combination with a coronally advanced flap for treatment of experimentally produced recession defects in dogs (Sallum *et al*. 2004).

Some case reports with human block sections provide further evidence that new connective tissue attachment may be formed following pedicle graft procedures. Histologic evaluation of two teeth treated with a laterally positioned flap revealed that connective tissue attachment was re-established in the apical quarter of the successfully covered portion of the root (Sugarman 1969). Cortellini *et al*. (1993) examined histologically a tooth treated with the GTR procedure and showed that connective tissue faced 74% of the length of the recession defect. New cementum with inserting collagen fibers, that is new connective tissue attachment, covered 48% of the distance between the apical border of the root instrumentation and the soft tissue margin. In addition, histomorphometric assessments of a tooth treated with enamel matrix proteins revealed that new cementum covered 73% of the original defect (Heijl 1997).

Healing of free soft tissue grafts

Survival of a free soft tissue graft placed over a denuded root surface depends on diffusion of plasma and subsequent revascularization from those parts of the graft that are resting on the connective tissue bed surrounding the dehiscence. The establishment of collateral circulation from adjacent vascular borders of the bed allows the healing phenomenon of "bridging" (Sullivan & Atkins 1968a). Hence, the amount of tissue that can be maintained over the root surface is limited by the size of the avascular area (Oliver *et al*. 1968; Sullivan & Atkins 1968). Other factors considered critical for the survival of the tissue graft placed over the root surface are that a sufficient vascular bed is prepared around the dehiscence and that a thick graft is used (Miller 1985b).

Another healing phenomenon frequently observed following free graft procedures is "creeping attachment", that is coronal migration of the soft tissue margin. This occurs as a consequence of tissue maturation over a period of about 1 year post treatment.

There are few histologic evaluations of the nature of the attachment established to the root surface following the use of free grafts for root coverage. Sugarman (1969) reported from a histologic evaluation of a human tooth treated with a free soft tissue graft that new connective tissue attachment was found in the apical quarter of the successfully covered recession defect. Harris (1999) and Majzoub *et al*. (2001), each reporting the histologic outcome of free connective tissue grafts in two cases, found only minimal amounts of new cementum formation in the most apical part of the recession defect and that healing resulted in a long junctional epithelium occupying the interface between the covering soft tissue and the root. Carnio *et al*. (2002) performed a histologic evaluation of four cases of root coverage with a connective tissue graft combined with application of enamel matrix proteins (Emdogain®). They reported that the healing resulted in connective tissue adhesion to the root surface and that the formation of new cementum was observed only in the most apical end of the grafted area.

Thus, the limited histologic information available from humans on the healing of free soft tissue grafts indicates that a healing pattern similar to the one discussed above following pedicle graft procedures may result, namely that connective tissue attachment may be established in the most apical and lateral parts of the recession defect, but that an epithelial attachment is formed along the major portion of the root. Further, the application of enamel matrix proteins may prevent the apical migration of the epithelium, but may not favor the formation of a true connective tissue attachment between the free graft and the root surface.

Interdental papilla reconstruction

There may be several reasons for loss of papilla height and the establishment of "black triangles" between teeth. The most common reason in the adult individual is loss of periodontal support due to plaque-associated lesions. However, abnormal tooth shape, improper contours of prosthetic restorations, and traumatic oral hygiene procedures may also negatively influence the outline of the interdental soft tissues.

Nordland and Tarnow (1998) proposed a classification system regarding the papillary height adjacent to natural teeth, based on three anatomic landmarks: the interdental contact point, the apical extent of the facial CEJ, and the coronal extent of the proximal CEJ (Fig. 46-57):

- *Normal*: the interdental papilla occupies the entire embrasure space apical to the interdental contact point/area
- *Class I*: the tip of the interdental papilla is located between the interdental contact point and the level of the CEJ on the proximal surface of the tooth
- *Class II*: the tip of the interdental papilla is located at or apical to the level of the CEJ on the proximal surface of the tooth but coronal to the level of the CEJ mid-buccally
- *Class III*: the tip of the interdental papilla is located at or apical to the level of the CEJ mid-buccally.

In an observational study in humans, Tarnow *et al*. (1992) analyzed the correlation between the presence of interproximal papillae and the vertical distance between the contact point and the interproximal bone crest. When the vertical distance from the contact

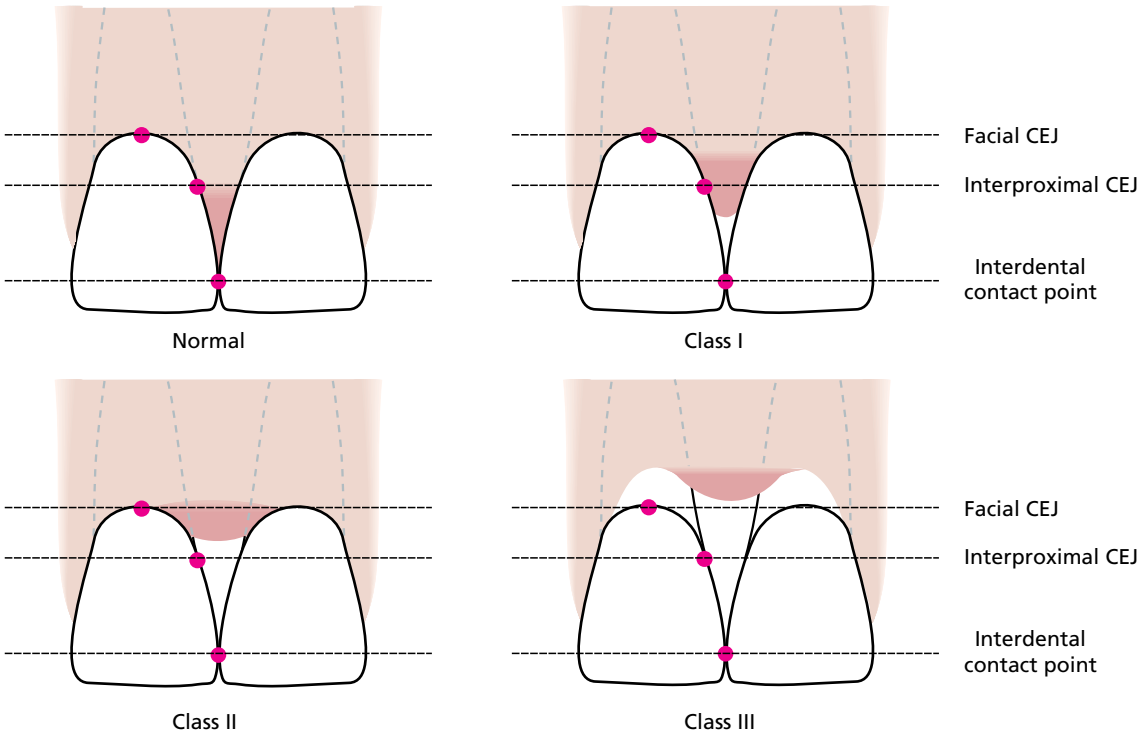

Fig. 46-57 Schematic drawing illustrating the classification system for papilla height. (CEJ, cementoenamel junction.) (Source: Nordland & Tarnow 1998.)

point to the crest of bone was ≤5 mm, the papilla was present almost 100% of the time, whereas if the distance was ≥6 mm only partial papilla fill of the embrasure between the teeth was most commonly found. Considering that a supracrestal connective tissue attachment zone of approximately 1 mm is normally found (Gargiulo 1961), the observation indicates that the biologic height of the interdental papilla may be limited to about 4 mm. This interpretation is supported by the observation that in interdental areas denuded following an apically repositioned flap procedure, an up-growth of around 4 mm of soft tissue had taken place 3 years after surgery (Van der Velden 1982). Hence, before attempts are made to surgically reconstruct an interdental papilla, it is important to carefully assess (1) the vertical distance between the bone crest and the apical point of the contact area between the crowns and (2) the soft tissue height in the interdental area. If the bone crest–contact point distance is ≤5 mm and the papilla height is <4 mm, surgical intervention for increasing the volume of the papilla could be justified in order to solve the problem of an interdental "black triangle". However, if the contact point is located >5 mm from the bone crest, because of loss of periodontal support and/or an inappropriate interdental contact relationship between the crowns, methods to lengthen the contact area apically between the teeth should be selected rather than a surgical attempt to improve the topography of the papilla.

If loss of papilla height is only caused by soft tissue damage from oral hygiene devices, interproximal hygiene procedures must be initially discontinued to allow soft tissue recovery and then successively modified in order to eliminate/minimize traumatic injury to the papillae.

Surgical techniques

Several case reports have been published regarding surgical techniques for the reconstruction of deficient papillae (e.g. Beagle 1992; Han & Takei 1996; Azzi *et al*. 1999). However, the predictability of the various procedures has not been documented and no data are available in the literature providing information on the long-term stability of surgically regained interdental papillae.

Beagle (1992) described a pedicle graft procedure utilizing the soft tissues palatal to the interdental area (Fig. 46-58). A split-thickness flap is dissected on the palatal aspect of the interdental area. The flap is elevated labially, folded, and sutured to create the new papilla at the facial part of the interdental area. A periodontal dressing is applied on the palatal aspect only, in order to support the papilla.

Han and Takei (1996) proposed an approach for papilla reconstruction ("semilunar coronally repositioned papilla") based on the use of a free connective tissue graft (Fig. 46-59). A semilunar incision is placed in the alveolar mucosa facial to the interdental area and a pouch-like preparation is performed into the interdental area. Intrasulcular incisions are made around the mesial and distal half of the two adjacent teeth to free the connective tissue from the root surfaces to allow coronal displacement of the gingival–papillary unit. A connective tissue graft, taken

from the palate, is placed into the pouch to support the coronally positioned interdental tissue.

Azzi *et al*. (1999) described a technique in which an envelope-type flap is prepared for coverage of a connective tissue graft (Fig. 46-60). An intrasulcular incision is made at the tooth surfaces facing the interdental area to be reconstructed. Subsequently, an incision is made across the facial aspect of the interdental area and an envelope-type split-thickness flap is elevated into the proximal site as well as apically to a level beyond the mucogingival line. A connective tissue graft is harvested from the tuberosity area, trimmed to adequate size and shape, and placed under the flaps in the interdental papilla area. The flaps are brought together and sutured with the connective tissue graft underneath.

Crown-lengthening procedures

Excessive gingival display

In most patients, the lower edge of the upper lip assumes a "gum-wing" profile which limits the amount of gingiva that is exposed when a person smiles. Patients who have a high lip line expose a broad zone of gingival tissue and may often express concern about their "gummy smile" (Fig. 46-61). The form of the lips and the position of the lips during speech and smiling cannot be easily changed, but the dentist may, if necessary, modify/control the form of the teeth and interdental papillae as well as the position of the gingival margins and the incisal edges of the teeth. In other words, it is possible by a combination of periodontal and prosthetic treatment measures to improve dentofacial esthetics in this category of patient.

As a base for treatment decisions, a careful analysis of the dentofacial structures and how they may affect esthetics should be performed. It should include the following features:

- Facial symmetry
- Interpupillary line; even or uneven
- Smile line: low, median or high
- Dental midline in relation to facial midline
- Gingival display during speech and during a broad, relaxed smile
- Harmony of gingival margins
- Location of gingival margins in relation to the CEJ
- Periodontal phenotype
- Tooth size and proportions/harmony
- Incisal plane/occlusal plane.

If excessive gingival exposure is due to insufficient length of the clinical crowns, a crown-lengthening procedure is indicated to reduce the amount of gingiva exposed, which in turn will favorably alter the shape and form of the anterior teeth. To select the proper treatment approach for crown lengthening, an analysis of the individual case with regard to crown–root–alveolar bone relationships should also be included.

In the young adult with an intact periodontium, the gingival margin normally resides about 1 mm coronal to the CEJ. However, some patients may have a height of free gingiva that is >1 mm, resulting in a disproportional appearance of the clinical crown. If such a patient complains about his/her "small front teeth" and the periodontium is of a thin phenotype, full exposure of the anatomic crown can be accomplished by a gingivectomy/gingivoplasty procedure (Fig. 46-61).

An assessment should also be made regarding the amount and pattern of pigmentation existing within the gingival tissues, and the patient's desire to maintain or lessen the pigmentation contained within the tissues. The externally beveled path of incision that is usually employed in a gingivectomy procedure will remove the pigmentation and produce pink gingival tissue upon initial healing (Fig. 46-62). The surgically induced color change in the tissues comes about rapidly and markedly affects esthetic values. For this reason, an externally beveled gingivectomy procedure should not be terminated at the midline in patients who have pigmented gingival tissues. It should be extended across the midline to the premolar area to avoid a color mismatch in the esthetic zone of the anterior teeth. The color change may be permanent

Fig. 46-61 Crown-lengthening procedure. (a, b) Pretreatment views. The clinical crowns are considerably shorter than the anatomic crowns. The lateral incisors were congenitally missing and orthodontic treatment had been carried out to move the posterior teeth anteriorly. The canine teeth in the position of the lateral incisors added to the esthetic disharmony. (c) Gingivectomy was performed to expose the anatomic crowns of the teeth. (d) One month post surgery. At this appointment, the canine and first premolar teeth were reshaped and bonded. (e) Tooth form and proportional balance were improved by bonding. (f) At 3 years post treatment, the gingival tissues exhibited no rebound and retained the architectural form sculpted into the tissue at the time of the surgical procedure.

or the pigmentation may slowly return over a period of a year or more. Patients should be informed of the changes in tissue color that will occur and be allowed to make a choice as to the color of the tissue they will have post-surgically. If they wish to maintain their pigmentation, an internally beveled path of incision (internal gingivectomy) should be employed (Fig. 46-63).

If the periodontium is of the thick phenotype and there is a bony ledge at the osseous crest, an apically positioned flap procedure (see Chapter 39) should be performed. This will allow for osseous recontouring (Fig. 46-64).

More extensive bone recontouring is required to solve esthetic problems found in patients who do indeed have short anatomic crowns in the anterior section of the dentition. In this category of patients, prosthetic measures must be used after resective periodontal therapy to increase the apicocoronal dimension of the crowns (Fig. 46-65). Patients who are

Fig. 46-62 (a) Pretreatment view. The patient disliked her "small front teeth" and diastema. Radiographs and probing indicated the gingival tissues were covering the cervical one-third of the crowns. Crestal bone was thin and in normal relationship to the cementoenamel junctions. The patient preferred "pink gums" if she could possibly have them. (b) A long externally beveled path of incision was used to accomplish the gingivectomy. (c) View showing the color changes and pleasing architecture produced in the anterior gingiva at 2 months post surgery. The diastema was partially closed by direct bonding at this time. (d) Post-treatment view showing the enhancement of esthetic values for the patient.

Fig. 46-63 (a) Pretreatment view. This patient disliked her "small front teeth"; she sought consultation to have her teeth made longer by crowning them. Probing and radiographs revealed normal osseous morphology and a wide zone of attached gingiva that covered the cervical one-third of the incisors. It was explained to the patient that a surgical solution was preferred to restorative procedures to make her teeth longer. The patient made a request that the color of her gingival tissues remain unchanged. (b) An internally beveled path of incision was use to effect an "internal gingivectomy" to maintain the pigmentation in the tissues. This created mini flaps in the areas of the papillae. (c) 5-0 gut sutures were used to stabilize the papillae. (d) Crown lengthening that was achieved with maintenance of color harmony can be seen in this view at 3 months post surgery. (Courtesy of E. Saacks.)

Fig. 46-64 (a) Pretreatment view. The patient, a dentist, requested crown lengthening to lessen his "gummy smile" and give him a more masculine appearance. The patient had a wide zone of attached gingiva and thick crestal bone. Palpation indicated bony exostoses. (b) An apically positioned flap and osseous resective surgery, from second premolar to second premolar, were used to lengthen the teeth. The surgery was confined to the labial surfaces. This view shows one-half of the completed surgery. (c) Vertical mattress sutures were utilized to hold the flap apically. (d) Three years post-treatment. Note that the gingival tissues retain the morphology created at the time of surgery.

candidates for this kind of resective therapy can be divided into two categories:

1. *Subjects who have normal occlusal relationships and incisal guidance*. In this category, the incisal line of the front teeth must remain unaltered, but the clinical crowns can be made longer by surgically exposing the root structure and by locating the cervical margins of the restorations apical to the CEJ (Fig. 46-65).
2. *Subjects who have abnormal occlusal relationships with excessive interocclusal space in the posterior dentition when the anterior teeth are in edge-to-edge contact*. In this category, the length of the maxillary front teeth can be reduced without inducing posterior occlusal interferences. In addition, the marginal gingiva can be resected or relocated to an apical position before crown restorations are made.

In some individuals with an excessive display of gingiva, the size and shape of the teeth and the location of the gingival margins may be perfectly normal. The excessive display of gingiva in these cases is often caused by vertical maxillary excess and a long mid-face (Fig. 46-66). Periodontal crown-lengthening procedures will not suffice to solve their problems, but rather the maxilla must be altered by a major maxillofacial surgical procedure. The risk-to-benefit and cost-to-benefit ratios must be thoroughly evaluated before recommending this type of surgical therapy to correct esthetic problems.

Exposure of sound tooth structure

Crown-lengthening procedures may be required to solve problems such as (1) inadequate amount of tooth structure for proper restorative therapy, (2) subgingival location of fracture lines, and (3) subgingival location of carious lesions. The techniques used to accomplish crown lengthening include (1) an apically positioned flap procedure including bone resection and (2) forced tooth eruption with or without fiberotomy.

Apically positioned flap with bone recontouring

The apically positioned flap technique with bone recontouring (resection) may be used to expose sound tooth structure. As a general rule, at least 4 mm of sound tooth structure must be exposed at the time of

Fig. 46-65 Crown lengthening by surgical and prosthetic procedures. (a) Pretreatment view. The patient displayed "short front teeth" and a broad exposure of gum tissue. The full anatomic crown is exposed in this case and the surgically-induced recession will expose root structure. (b) Patient had an unusually wide zone of attached gingiva. The gingival margins were positioned apically by making an internally beveled flap with a submarginal entrance incision as outlined in red ink. The crest of the bone was reduced in height. (c) After the tissues had matured following surgery, individual crowns were prepared for each of the anterior teeth. Crown lengthening was achieved and the patient no longer exposed a broad expanse of gum tissue. (Courtesy of D. Garber.)

surgery. During healing, the supracrestal soft tissues will proliferate coronally to cover 2–3 mm of the root (Herrero *et al*. 1995; Pontoriero & Carnevale 2001; Lanning *et al*. 2003), thereby leaving only 1–2 mm of supragingivally located sound tooth structure. When this technique is used for crown lengthening, it must also be realized that gingival tissues have an inherent tendency to bridge abrupt changes in the contour of the bone crest. Thus, in order to retain the gingival margin at its new and more apical position, bone recontouring must be performed not only at the problem tooth but also at the adjacent teeth to gradually reduce the osseous profile (Fig. 46-67). Consequently, substantial amounts of attachment may have to be sacrificed when crown lengthening is accomplished with an apically positioned flap technique. It is also important to remember that, for esthetic reasons, symmetry of tooth length must be maintained between the right and left sides of the dental arch. This may, in some situations, call for the inclusion of even more teeth in the surgical procedure.

- *Indication:* crown lengthening of multiple teeth in a quadrant or sextant of the dentition.

Fig. 46-66 Patient displays a large expanse of gingival tissue when smiling or speaking. The patient has a long mid-face and vertical maxillary excess. The gingival margins reside 1 mm coronal to the cementoenamel junction and the anatomic and clinical crowns are approximately equal.

- *Contraindication:* surgical crown lengthening of single teeth in the esthetic zone (Fig. 46-68).
- *Technique:* the apically positioned flap technique and methods used for bone recontouring are discussed in Chapter 39.

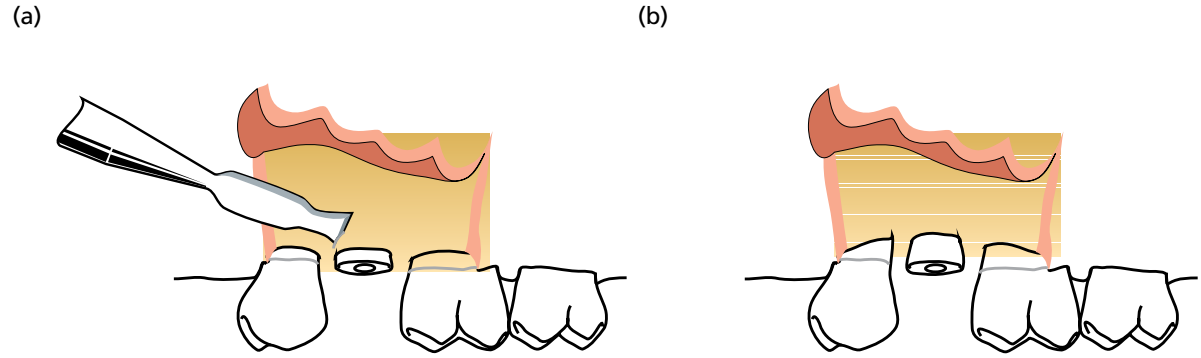

Fig. 46-67 Surgical resective therapy for crown lengthening cannot be confined to the tooth in need of treatment. (a, b) The principles of osseous resection require that bone be removed from the adjacent teeth to create a gradual rise and fall in the profile of the osseous crest. This causes a loss of attachment apparatus and recession of the adjacent teeth as well.

Fig. 46-68 Deformity which interfered with dentofacial esthetics was created at the right central incisor by using a surgical crown lengthening procedure at one single tooth to expose sound tooth structure. The soft tissues cannot follow the abrupt and steep changes in the osseous profile. The crown preparation invaded the zone of normal supracrestal connective tissue. This created a chronic periodontal pocket and adversely affected esthetics. (Courtesy of A. Winnick.)

Forced tooth eruption

Orthodontic tooth movement can be used to erupt teeth in adults (Reitan 1967; Ingber 1974, 1976; Potashnick *et al*. 1982). If moderate eruptive forces are used, the entire attachment apparatus will move in unison with the tooth. The tooth must be extruded a distance equal to or slightly longer than the portion of sound tooth structure that will be exposed in the subsequent surgical treatment. After the tooth has reached the intended position and has been stabilized, a full-thickness flap is elevated and bone recontouring is performed to expose sound root structure. For esthetic reasons it is important that the bone and soft tissue levels at adjacent teeth remain unchanged.

Forced tooth eruption can also be used to level and align gingival margins and the crowns of teeth to obtain esthetic harmony. Instead of using surgical procedures to position the gingival margins of unaffected normal teeth apically to the level of a tooth with recession or orthodontic malalignment, the tooth that is malpositioned or has sustained recession is erupted to the level of the normally positioned teeth. The entire attachment apparatus and dentogingival junction will follow the root of the tooth as it is moved coronally (Fig. 46-69).

- *Indication:* crown lengthening at sites where removal of attachment and bone from adjacent teeth must be avoided. The forced eruption technique can also be used as a method to reducing pocket depth at sites with angular bony defects (Brown 1973; Ingber 1974, 1976). The angular bony defect at the problem tooth can be reduced, while the attachment level at the adjacent tooth surface remains unchanged (Fig. 46-70).
- *Contraindication:* the forced eruption technique requires the use of fixed orthodontic appliances. Thus, in patients who only have a few teeth remaining, an alternative approach for crown lengthening has to be selected.
- *Technique:* orthodontic brackets are bonded to the problem tooth and to adjacent teeth, and are combined with an archwire. Another type of mechanical system can be utilized by placing a heavy gauge bar or wire in grooves prepared in the adjacent teeth and over the problem tooth. A power elastic is tied from the bracket to the archwire (or the bar), which pulls the tooth coronally. If most of the crown structure is lost, root canal therapy is required. A post placed in the root canal is fitted with a power elastic, which is also joined with the archwire. The direction of the tooth movement must be carefully checked to ensure that the problem tooth is not tilted or moved toward the adjacent tooth surfaces.

Forced tooth eruption with fiberotomy

If fiberotomy is performed during the forced tooth eruption procedure, the crestal bone and the gingival margin are retained at their pretreatment locations, and the tooth–gingiva interface at adjacent teeth is unaltered. Fiberotomy is performed using a scalpel at 7–10-day intervals during the forced eruption to sever the supracrestal connective tissue fibers, thereby preventing the crestal bone from following

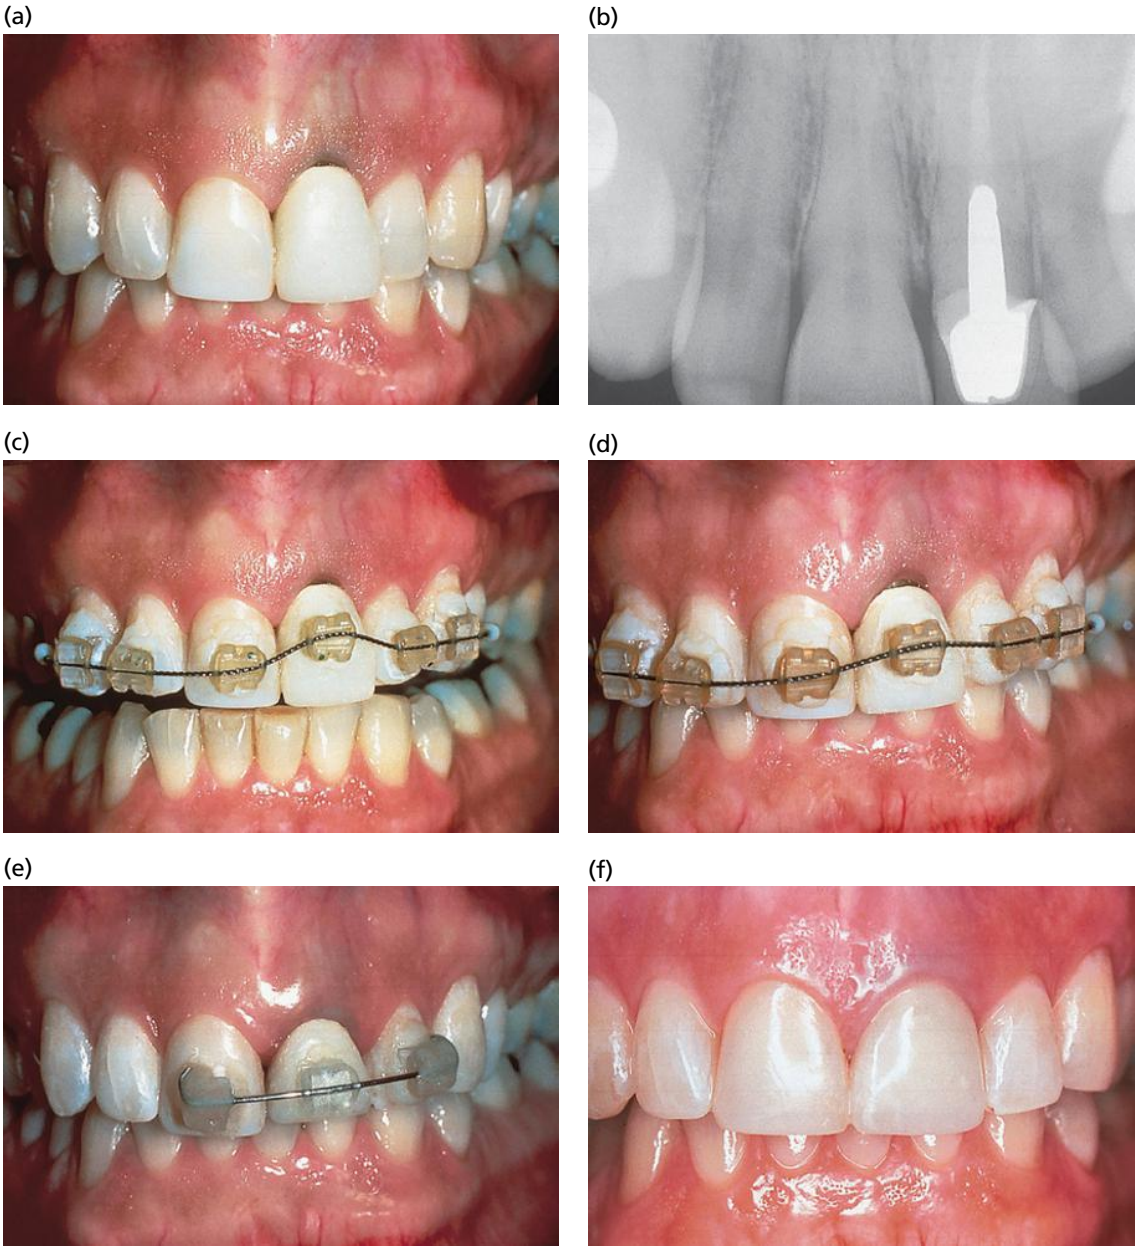

Fig. 46-69 Forced tooth eruption (show method) used to level gingival margins, treat recession on a single tooth, and create esthetic harmony. (a, b) Recession on the left central incisor exposed the root surface darkened from root canal treatment. The uneven gingival margins and dark root surface detracted from an otherwise attractive smile. (c) Nitol wire with an offset bracket was used to slowly extrude the incisor. (d) Occlusal adjustment was made on the lingual side of the crown to create room for the tooth to erupt. This view, after 1 month in tooth movement, shows the gingival tissues moving with the root of the tooth. (e) Sufficient eruption had occurred by 3 months to level the gingival margins. The orthodontic brackets were used for temporary stabilization and a new crown was prepared. (f) New crown masked the show-through of the dark root. The even gingival margins and beautiful crown created esthetic harmony. (Courtesy of J. Ingber.)

the root in a coronal direction. In the case presented in Fig. 46-71, fiberotomy was performed only at the mesial half of the root. Radiographs obtained after 9 weeks demonstrate that crestal bone migration has occurred at the distal but not at the mesial surface of the erupted tooth (Pontoriero *et al*. 1987).

- *Indication:* crown lengthening at sites where it is important to maintain the location of the gingival margin at adjacent teeth unchanged.
- *Contraindication:* fiberotomy should not be used at teeth associated with angular bone defects.
- *Technique:* similar to the technique described for the forced tooth eruption procedure. Fiberotomy is performed once every 7–10 days during the phase of forced tooth eruption.

Ectopic tooth eruption

Surgical intervention is often indicated for teeth erupting ectopically, that is with an eruption position facial to the alveolar process (Fig. 46-72). To create a satisfactory width of the gingiva for the permanent tooth, the tissue entrapped between the erupting tooth and the

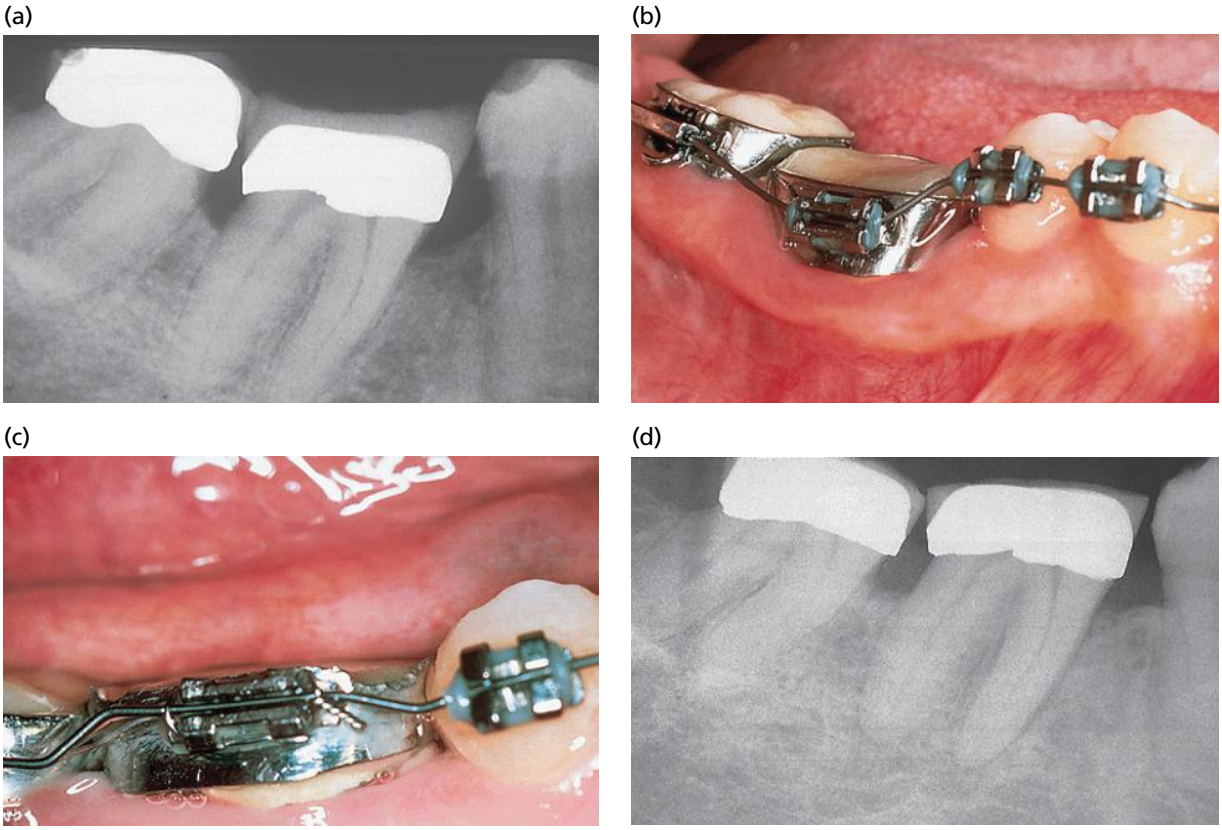

Fig. 46-70 Slow tooth eruption procedure used to level cementoenamel junctions and angular bone crests. (a) Pretreatment radiograph. (b) Nitol wire was used to erupt the molar. (c) Crown was shortened over a period of 4 months by selective grinding. (d) Radiograph taken 8 months after the start of treatment. The angular bone defects were leveled.

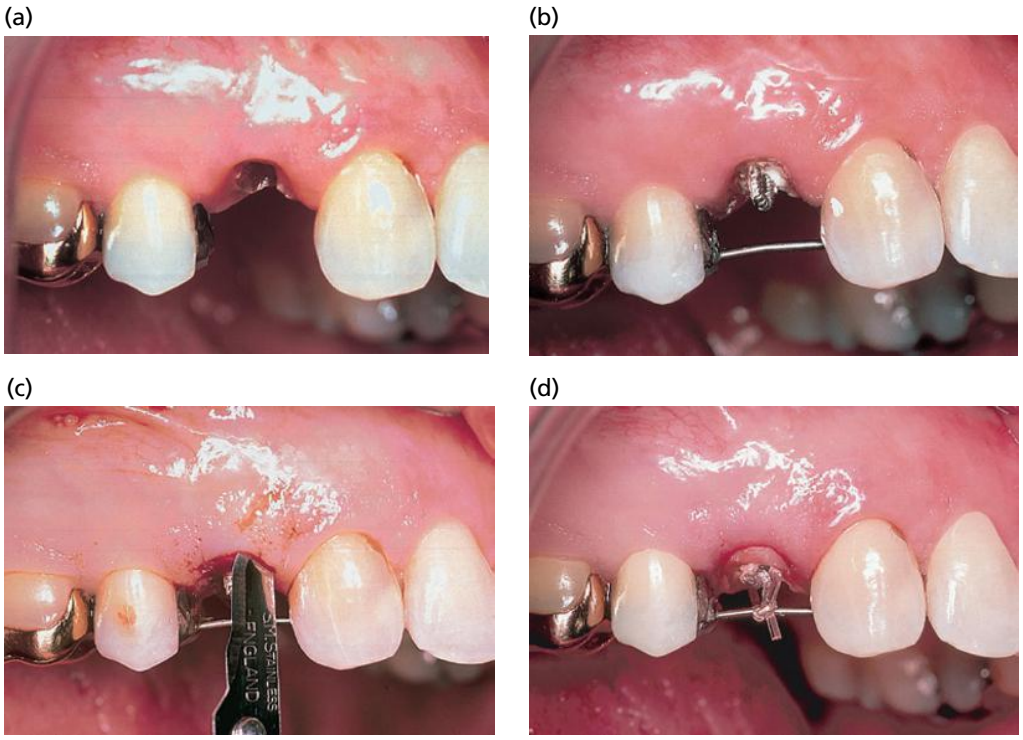

Fig. 46-71 Rapid tooth eruption procedure in conjunction with fiberotomy procedure. (a) Buccal view, the fracture on the first premolar extended subgingivally. (b) Soft tooth structure was excavated and a twisted wire with an occlusal hook was temporarily cemented in the root canal. A bar was placed into the amalgam restoration on the premolar and bonded to the lingual surface of the canine. (c, d) Sulcular fiber resection was performed at the mesial half of the tooth to the level of the bone crest. The distal half remained as a control surface. The fiber resection was repeated once a week during the 3-week eruption phase.

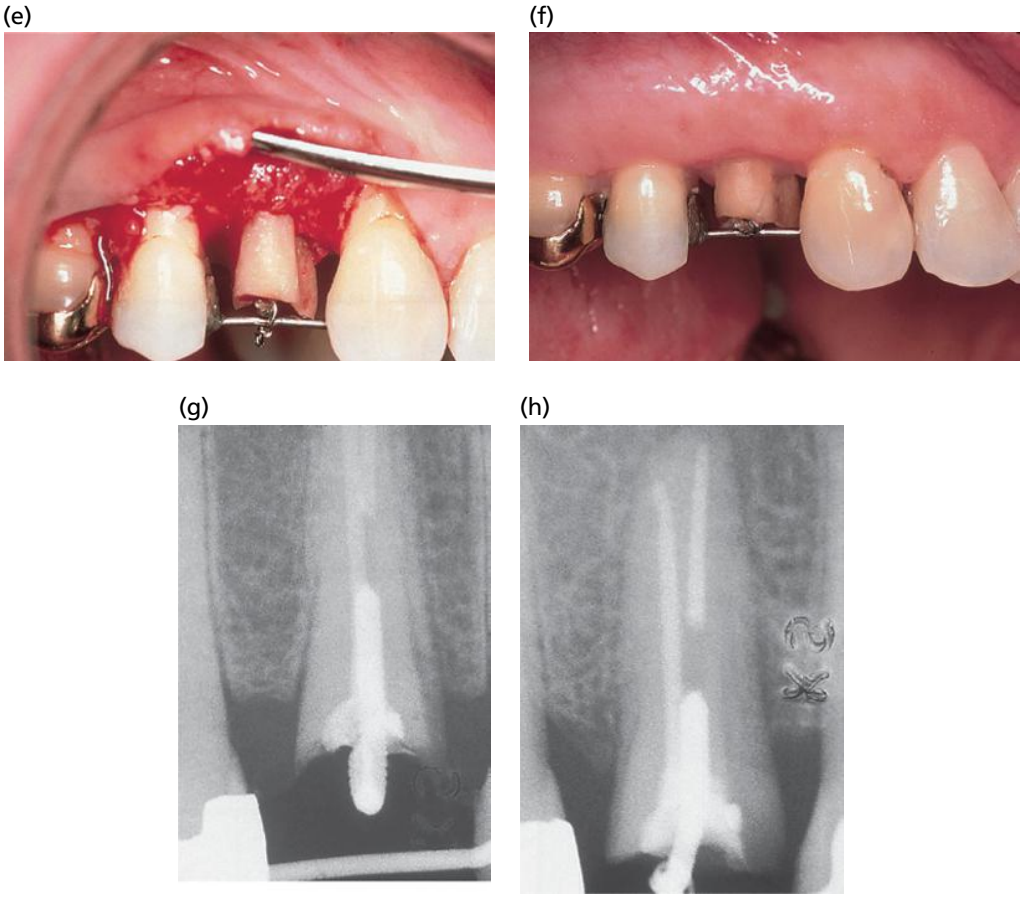

Fig. 46-71 (*Continued*)(e) Tooth was stabilized for 6 weeks, and at that time a full-thickness flap was raised. The bone crest had a "positive" angulation at the distal surface and remained unchanged at the "test" mesial surface. Osseous resection was used to level the bony septum on the distal surface. (f) Ample crown lengthening was obtained and the gingival margins healed to their former shape and location. (g) Pretreatment radiograph enlarged to show the normal shape of the crests of the interdental septae. (h) Enlargement of the post-eruption radiograph (3 weeks of rapid eruption and 6 weeks of stabilization) to show the "positive" angular crest on the "control" distal side and the unchanged crest on the mesial "test" side. (Courtesy of R. Pontoriero)

deciduous tooth is usually utilized as donor tissue (Agudio *et al*. 1985; Pini Prato *et al*. 2000b).

Three different techniques have been described for the interceptive mucogingival treatment of buccally erupting teeth, depending on the distance from the donor site (entrapped gingiva) to the recipient site (area located facially–apically to the erupting permanent tooth) (Agudio *et al*. 1985; Pini Prato *et al*. 2000b):

- *Double pedicle graft* (Fig. 46-73). This flap procedure is indicated when the permanent tooth erupts within the zone of keratinized tissue but close to the mucogingival junction. An intrasulcular incision is performed at the deciduous tooth and extended laterally to the gingival crevice of the adjacent teeth and apically to the erupting permanent tooth. By mobilization of the flap apical to the mucogingival line, the entrapped gingiva can be elevated and transposed for positioning apically to the erupting tooth. Sutures may be placed to secure the position of the gingival tissue facial to the erupting tooth.
- *Apically positioned flap* (Fig. 46-74). When the permanent tooth is erupting apical to the mucogingival junction, vertical releasing incisions have to be placed to allow for apical positioning of the keratinized tissue. Two lateral releasing incisions are made and extended apically beyond the mucogingival junction. An intrasulcular incision is performed at the deciduous tooth and a partial-thickness flap is elevated beyond the ectopically erupting tooth. The mobilized gingival flap is moved apical to the erupting tooth and secured in position by sutures.
- *Free gingival graft* (Fig. 46-75). If the tooth is erupting within the alveolar mucosa distant to the mucogingival junction, a free gingival graft procedure may be selected. The entrapped gingiva is removed by a split incision and used as an epithelialized connective tissue graft. The free gingival graft is placed at a prepared recipient site facial/apical of the erupting tooth. Careful suturing is performed to secure close adaptation of the graft to the underlying connective tissue bed.

All these procedures have been proven to be effective in establishing a facial zone of gingiva following the alignment of teeth erupting in an ectopic position (Pini Prato *et al*. 2000b, c).

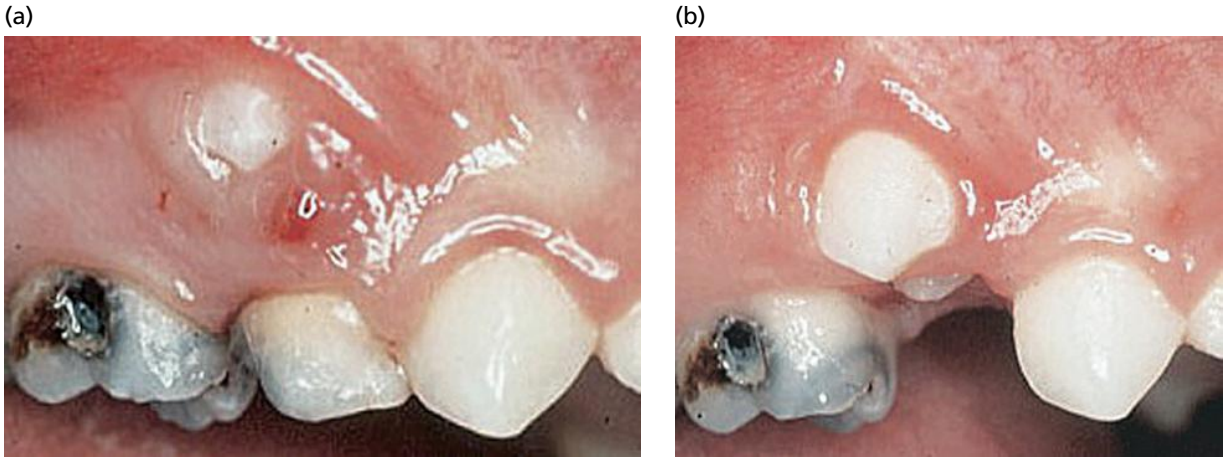

Fig. 46-72 (a, b) Ectopic tooth eruption. The permanent tooth is erupting close to the mucogingival junction.

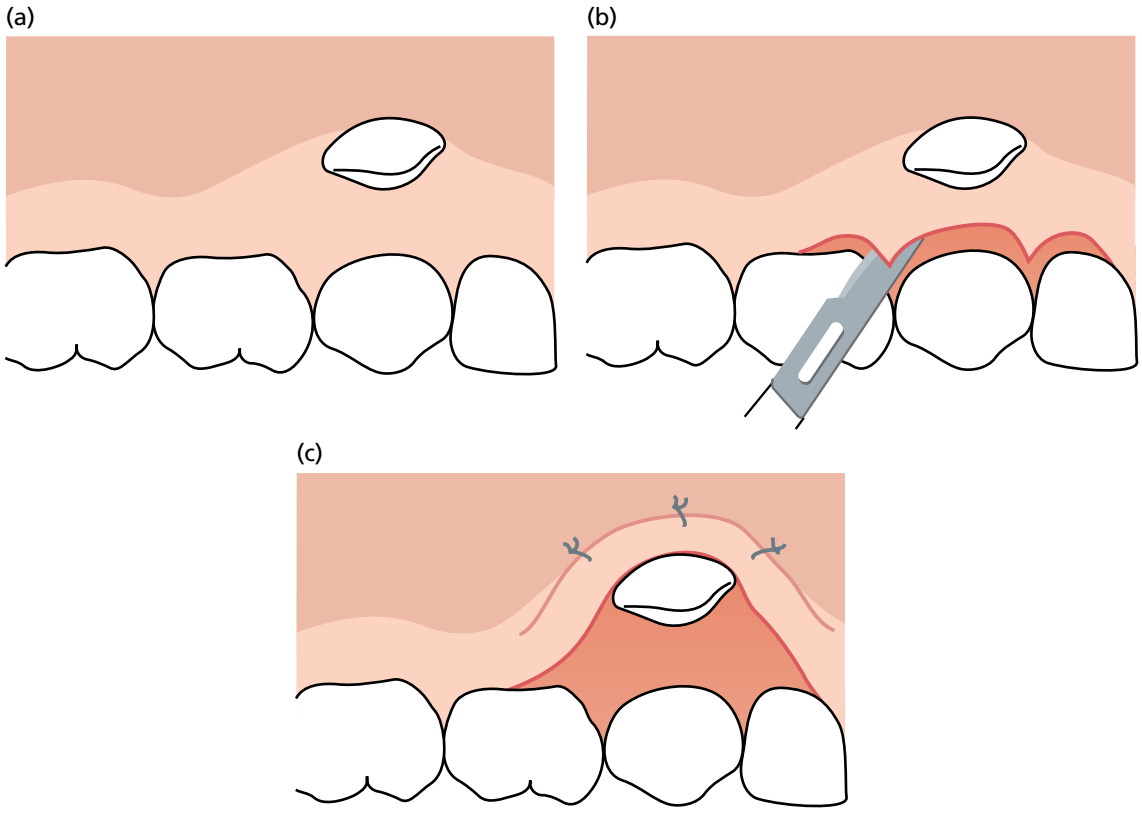

Fig. 46-73 (a–c) Ectopically erupting tooth: double pedicle graft. Schematic drawings illustrating the surgical technique (see text for explanation).

Deformed edentulous ridge

A partially edentulous ridge may retain the general shape of the alveolar process. Such a ridge is traditionally referred to as a normal ridge. Even though this normal ridge has retained the buccolingual and apicocoronal dimensions of the alveolar process, it is not normal in many other respects; the eminences that existed in the bone over the roots are no longer present and the interdental papillae are missing.

The smooth contours of the normal ridge create problems for the restorative dentist. In a fixed bridge the pontics (1) frequently give the impression that they rest on the top of the ridge rather than emerge from within the alveolar process, (2) lack a root eminence, and (3) lack marginal gingivae and interdental papillae. Dark triangles, which almost always interfere with dentofacial esthetics, are present in the embrasure area between the pontics and between the abutments and the pontics. In other words, in the presence of a normal ridge, it may be difficult or impossible to produce a fixed prosthesis which truly restores the esthetics and function of the natural dentition.

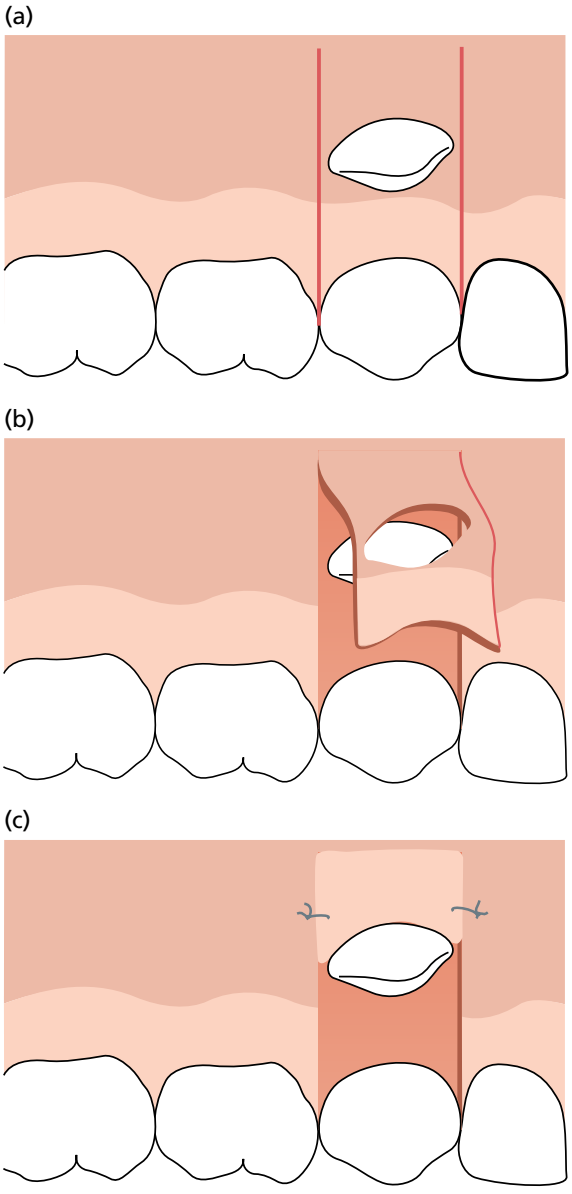

Fig. 46-74 (a–c) Ectopically erupting tooth: apically positioned flap. Schematic drawings illustrating the surgical technique (see text for explanation).

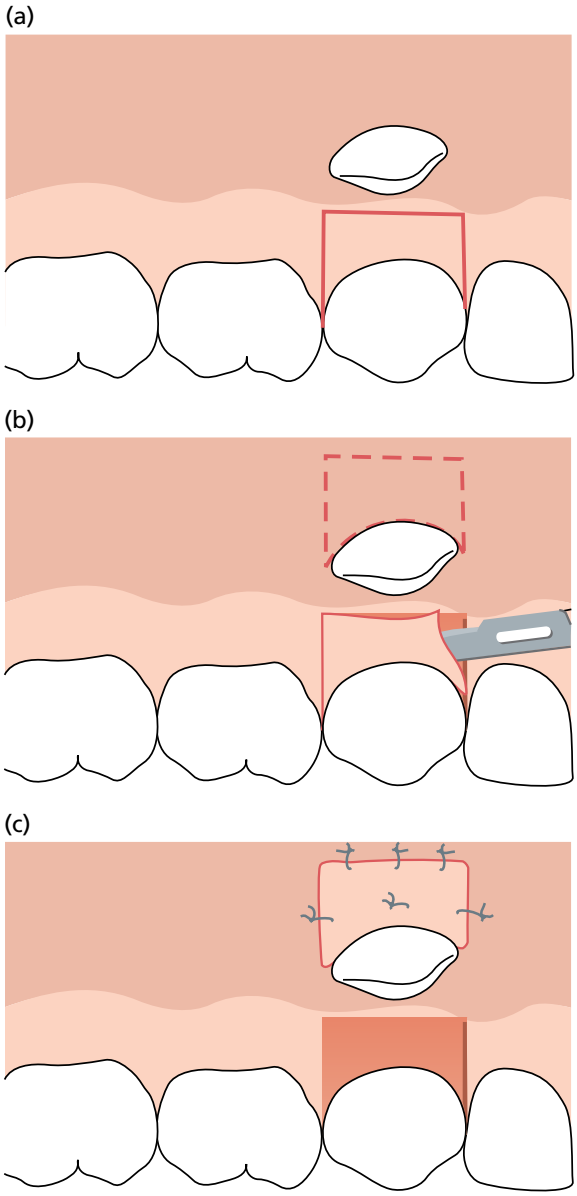

Fig. 46-75 (a–c) Ectopically erupting tooth: free gingival graft. Schematic drawings illustrating the surgical technique (see text for explanation).

Prevention of soft tissue collapse following tooth extraction

Following extraction of a tooth, the topography of the surrounding soft and hard tissues will be altered. The soft tissue margin will collapse and the height of the adjacent papillae will be reduced. This soft tissue collapse may be prevented by immediate post-extraction placement of an ovate pontic to support the soft tissues. Figure 46-76 shows such a situation where a central incisor had to be extracted due to root fracture. With the immediate placement of the pontic, the facial soft tissue margin and the papillae were maintained almost unchanged following the healing of the extraction site. Also, in situations where several adjacent teeth have to be extracted, insertion of ovate pontics may facilitate the preservation of the outline of the soft tissue ridge (Fig. 46-77).

Prevention of ridge collapse due to alveolar bone resorption following tooth extractions must also be considered. Borghetti and Laborde (1996) recommended methods for prevention of bone ridge collapse after tooth extraction in any case of:

- Fracture of the vestibular osseous plate during tooth extraction or due to trauma
- Resorption of the vestibular osseous plate
- Presence of a thin vestibular bone plate.

Procedures proposed for prevention of ridge collapse in conjunction with tooth extractions include (1) flap elevation for complete soft tissue closure of the extraction sites (Borghetti & Glise 2000), (2) placement of connective tissue grafts over the extraction sites (Nevins & Mellonig 1998), (3) placement of bone grafts (Becker *et al*. 1994), and (4) utilization of barrier membranes (Lekovic *et al*. 1997). Procedures for preservation of the bone dimensions following tooth extraction are discussed in Chapter 50.

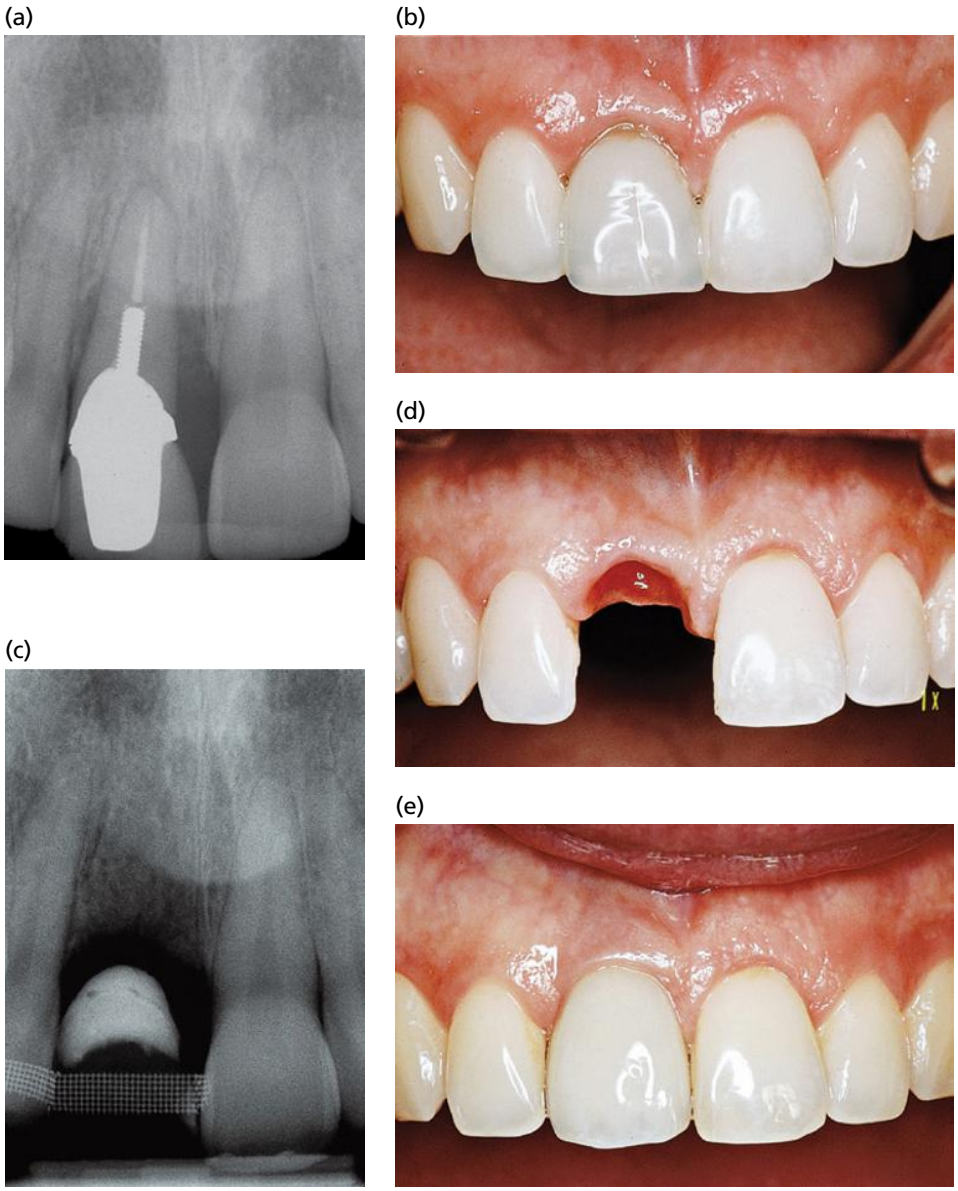

Fig. 46-76 (a) Central incisor that cannot be maintained because of root fracture which also caused pronounced periodontal destruction. (b) Immediately following tooth extraction, an ovate pontic was inserted to support the facial and proximal soft tissues. (c, d) Radiographic and clinical view of the area 6 weeks after tooth extraction. (e) Follow-up 1 year after the placement of the permanent prosthetic reconstruction (single implant).

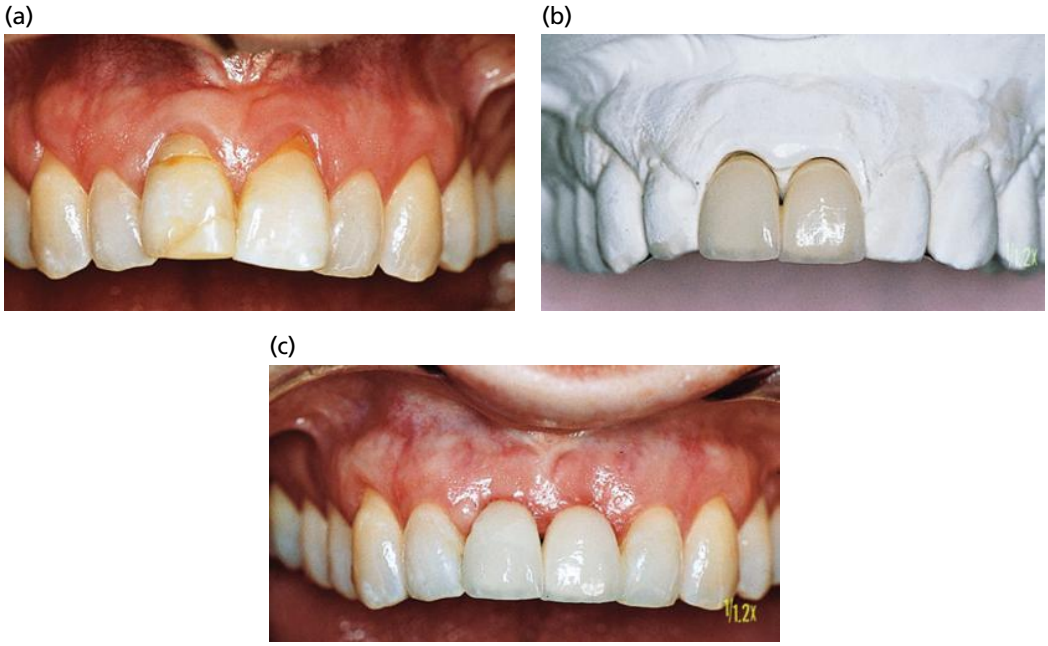

Fig. 46-77 (a) A 26-year-old female patient who had a trauma against the maxillary central incisors. Due to root fracture and endodontic complications, both central incisors had to be extracted. (b) A Rochette bridge with ovate pontics was fabricated as a temporary replacement for the incisors. (c) Clinical view of the front tooth region 8 weeks after tooth extraction and placement of the resin-bonded temporary bridge.

Correction of ridge defects by the use of soft tissue grafts

A deformed ridge may result from tooth extractions, advanced periodontal disease, abscess formations, etc. The deformity that exists in the ridge is directly related to the volume of root structure and associated bone that is missing or has been destroyed. According to Seibert (1983) ridge defects can be divided into three classes:

- *Class I*: loss of buccolingual width but normal apicocoronal height
- *Class II*: loss of apicocoronal height but normal buccolingual width
- *Class III*: a combination of loss of both height and width of the ridge.

Ridge augmentation procedures should be preceded by careful surgical–prosthetic treatment planning with joint consultations involving the surgeon and the restorative dentist in order to attain an optimal esthetic result. The following factors should be determined prior to the initiation of therapy:

- Volume of tissue required to eliminate the ridge deformity
- Type of graft procedure to be used
- Timing of various treatment procedures
- Design of the provisional restoration
- Potential problems with tissue discolorations and matching tissue color.

Ideally, a provisional restoration should be made prior to surgery. The shape of the teeth in the provisional restoration, the axial inclination and emergence profile of the teeth, and embrasure form should be an exact prototype of the final prosthesis that is to be constructed. It is the task of the clinician performing the surgery to augment the tissues to meet the provisional prosthesis in the most exact manner possible. If a gingival flange of pink-colored acrylic is used around single or multiple pontics on a temporary removable partial denture, the flange must be cut away in order to avoid pressure on the graft and give the tissues room to swell during the immediate post-surgical phase of healing. The soft tissue at the surgically-treated recipient site for a graft will undergo considerable swelling during the early phase of healing and the tissues will conform to the tissue-facing surfaces of the bridge or partial denture. The prosthesis is thus used to help in shaping the outline of the augmented ridge to the desired form. The location and shape of interproximal embrasure areas in the provisional bridge will determine where the "papillae" created in the ridge will be located.

Surgical procedures for ridge augmentation

Numerous surgical graft and implant procedures attempting to reconstruct a partially edentulous ridge or ridge defect have been described in the literature over the years. The procedures may be grouped according to the methods used for ridge augmentation as (1) soft tissue augmentation procedures and (2) hard tissue augmentation procedures. In this chapter, only soft tissue augmentation procedures will be addressed, while hard tissue augmentation procedures are covered in Chapter 50. To illustrate the various approaches utilizing soft tissues for ridge augmentation, the following procedures will be discussed:

- Pedicle graft procedure:
  - Roll flap procedure
- Free graft procedures:
  - Pouch graft procedure
  - Interpositional graft procedure
  - Onlay graft procedure.

Studer *et al*. (1997) proposed the use of the pedicle graft procedure for correction of a single-tooth ridge defect with minor horizontal and vertical loss, whereas submerged free connective tissue graft procedures should be selected for larger defects. The onlay full-thickness graft procedure is indicated primarily for ridge augmentation in the presence of additional mucogingival problems such as insufficient gingival width, high frenum, gingival scarring, or tattoo. These recommendations were based on short-term evaluation of the obtained volumetric increase of the edentulous ridge following various augmentation procedures, which demonstrated superior results with the use of submerged connective tissue grafts compared to the use of full-thickness grafts (Studer *et al*. 2000).

"Roll flap procedure"

Surgical concept

The "roll flap procedure" (Abrams 1980) involves the preparation of a de-epithelialized connective tissue pedicle graft, which is subsequently placed in a subepithelial pouch (Fig. 46-78). This procedure is used in the treatment of small-to-moderate class I ridge defects, primarily in cases with a single-tooth space. The technique enables the surgeon to augment tissue apically and labially to the cervical area of a pontic and to give the recipient site the appearance of a normal tooth–gingiva interface. Hence, a buccolingual ridge concavity can be converted into a ridge convexity resembling the eminence produced by the roots of the adjacent teeth (Fig. 46-79).

Technique

A rectangular pedicle of connective tissue is prepared on the palatal side of the defect (Fig. 46-78). The length of the pedicle must match the amount of apicocoronal augmentation that is planned. This, in turn, is related to the amount of root eminence that exists on either side of the defect. If a two- or three-tooth pontic space is treated with the roll technique, two or three separate pedicles are raised. Each of these pedicles will form a new "root–cervical margin".

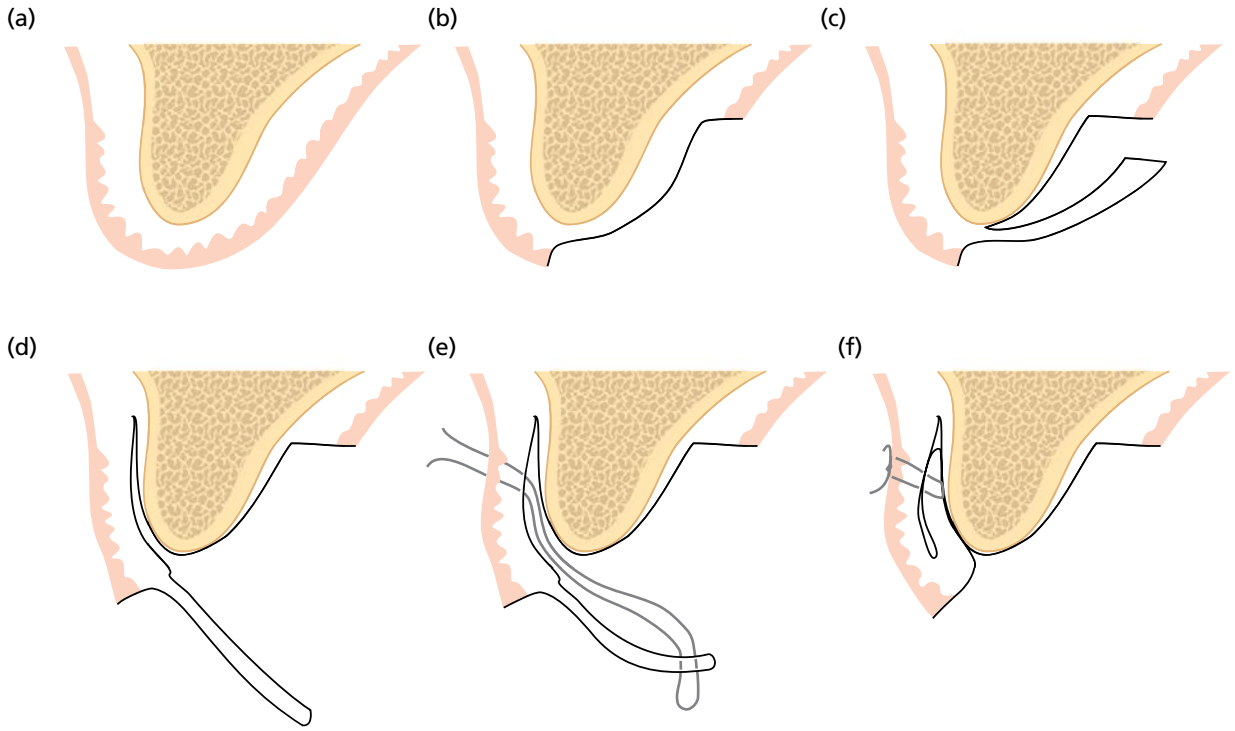

Fig. 46-78 Sequence of steps in the "roll flap procedure". (a) Cross-section of the residual edentulous ridge prior to treatment. (b) Removal of the epithelium. (c) Elevation of the pedicle. (d) Pouch is created. (e) Sutures are placed at the mucogingival junction to catch the tip of the pedicle flap and pull it into place in the pouch. (f) Flap is secured. A convexity in the ridge was created.

Fig. 46-79 "Roll flap procedure". (a) Pretreatment view of a class I ridge defect in the area of the right lateral incisor. Note the marked concavity in the ridge. (b) View shows the surgical site 1 week after surgery and prior to the removal of the sutures. (c) Tissue surface of the pontic was relined with autopolymerizing resin. (d) Final prosthesis in place. Note the illusion of a root eminence and a free gingival margin apical to the lateral incisor pontic tooth. (Courtesy of L. Abrams.)

The epithelium on the palatal surface of the donor site is first removed. A maximum amount of supraperiosteal connective tissue is raised from the palate using sharp dissection. The void that is produced at the donor site will gradually fill in with granulation tissue. Caution must be exercised in dissection of the pedicle flap so that tissue perforation is avoided when the plane of dissection approaches the facial (labial) surface. A pouch is made in the supraperiosteal connective tissue at the facial (labial) surface of the ridge. In order to preserve as much connective tissue and blood supply as possible at the recipient site, the dissection must be made as close as possible to the periosteum of the facial bone.

The pedicle is tucked into the pouch as a try-in procedure. Adjustment of pedicle size should now be made. Once the pedicle fits as desired, it is made ready for the stabilizing suture. The suturing scheme is shown in Fig. 46-78. The suture must be positioned close to the mucobuccal fold. This enables the surgeon to pull the pedicle to the apical portion of the pouch. The suture should not be tied tightly, since it only serves as a positioning and stabilizing device. The use of a resorbable suture material is recommended.

Adjustment of pontic contours

Measures used to adapt the tissue surface of the pontic to the contour of the surgically treated ridge are common to all soft tissue ridge augmentation procedures in patients with fixed bridgework. A light contact is maintained between the pedicle graft and the tissue surface of the pontics. The postoperative swelling will cause the tissue to conform to the shape of the pontic. This enables the clinician to shape the soft tissue into a form that is intended for the augmented site. Autopolymerizing resin is added to the tissue surface of the pontics and is allowed to cure until the resin reaches a dough-like state. The bridge is then seated and pressed into the grafted site. When the resin has set to a firm consistency, the bridge is removed and placed in hot water to complete the process of polymerization (Fig. 46-79). The tissue surface of the pontics and the embrasure areas are then carved to the shape that is intended for the final bridge. The surface of the pontic is polished and the bridge placed using appropriate temporary cement.

Postoperative care

A periodontal dressing is placed over the donor site. No dressing should be placed over the facial (labial) surface of the grafted area where swelling will occur. The dressing at the donor site should be changed at weekly intervals and maintained until wound healing has progressed to a point where the tissue is no longer tender to touch.

Pouch graft procedures

Surgical concept

A subepithelial pouch is prepared in the area of the ridge deformity, into which a free graft of connective tissue is placed and molded to create the desired contour of the ridge. The entrance incision and the plane of dissection may be made in different ways (Kaldahl *et al*. 1982; Seibert 1983; Allen *et al*. 1985; Miller 1986; Cohen 1994):

- *Coronoapically*: the horizontal incision is made on the palatal or lingual side of the defect and the plane of dissection carried in an apical direction (Fig. 46-80)
- *Apicocoronally*: the horizontal incision is made high in the vestibule near the mucobuccal fold and the plane of dissection is carried coronally to the crest of the ridge
- *Laterally*: one or two vertical entrance incisions are started from either side of the defect (Fig. 46-81).

The plane of dissection is made laterally across the span of the deformity.

Indication

The technique is used to correct class I defects. Patients with large-volume defects may have thin palatal tissues, which are insufficient to provide the volume of the donor tissue necessary to fill the deformity. In such cases, various procedures for hard tissue augmentation may be selected (see Chapter 50).

Technique

The pouch is prepared as described above. The mesiodistal entrance incision for the edge of the pouch should be made with a long bevel and must be started well to the palatal (lingual) side of the defect (Fig. 46-80). After the pouch has been filled with graft, the facial tissue will be stretched. The long bevel of the entrance incision permits the palatal edge of the flap to slide toward the facial surface without opening a gap at the incision line. Sometimes, vertical releasing incisions have to be made lateral to the border of the defect.

A suitable donor site is selected in the palate, the tuberosity area, or in an edentulous area and a free graft of connective tissue is excised using a "trapdoor" approach. The graft is immediately transferred to the recipient site and properly positioned. The palatal entrance incision and the releasing incisions are closed with sutures.

Interpositional graft procedure

Surgical concept

Interpositional grafts are not completely submerged and are covered in the manner that a subepithelial connective tissue graft is placed (Fig. 46-82) (Seibert 1991, 1993a, b). Therefore, there is no need to remove the epithelium from the surface of the donor tissue. If augmentation is required not only in the buccolingual but also in the apicocoronal direction, a portion of the graft must be positioned above the surface of the tissue surrounding the recipient site (Fig. 46-83).

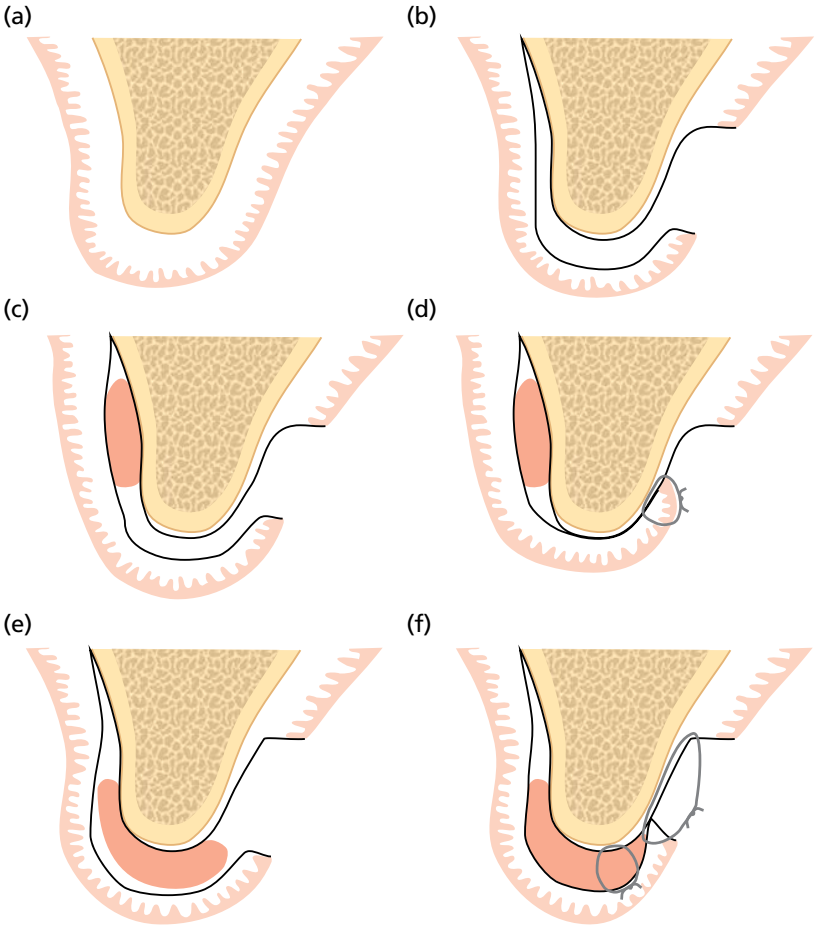

Fig. 46-80 Sequence of steps in the "pouch graft procedure" utilizing a free graft of connective tissue to expand the ridge. (a) Cross-section of the residual edentulous ridge prior to treatment. (b) Horizontal incision to create the pouch is made well to the palatal side of the defect. The incision is started partial-thickness to leave connective tissue to suture to when the flap is closed. The dissection is made supraperiosteal on the labial side of the ridge to (1) ensure an adequate blood supply within the pedicle and (2) permit the flap to expand labially or labially and coronally free of tension. (c, d) Connective tissue graft can be placed as shown for maximal buccolingual augmentation. (e, f) If vertical augmentation is desired, the connective tissue implant can be placed closer to the crest of the ridge. As is shown in (d) and (f), the more the flap is stretched or extended to gain augmentation, the more difficult it is to gain primary flap closure.

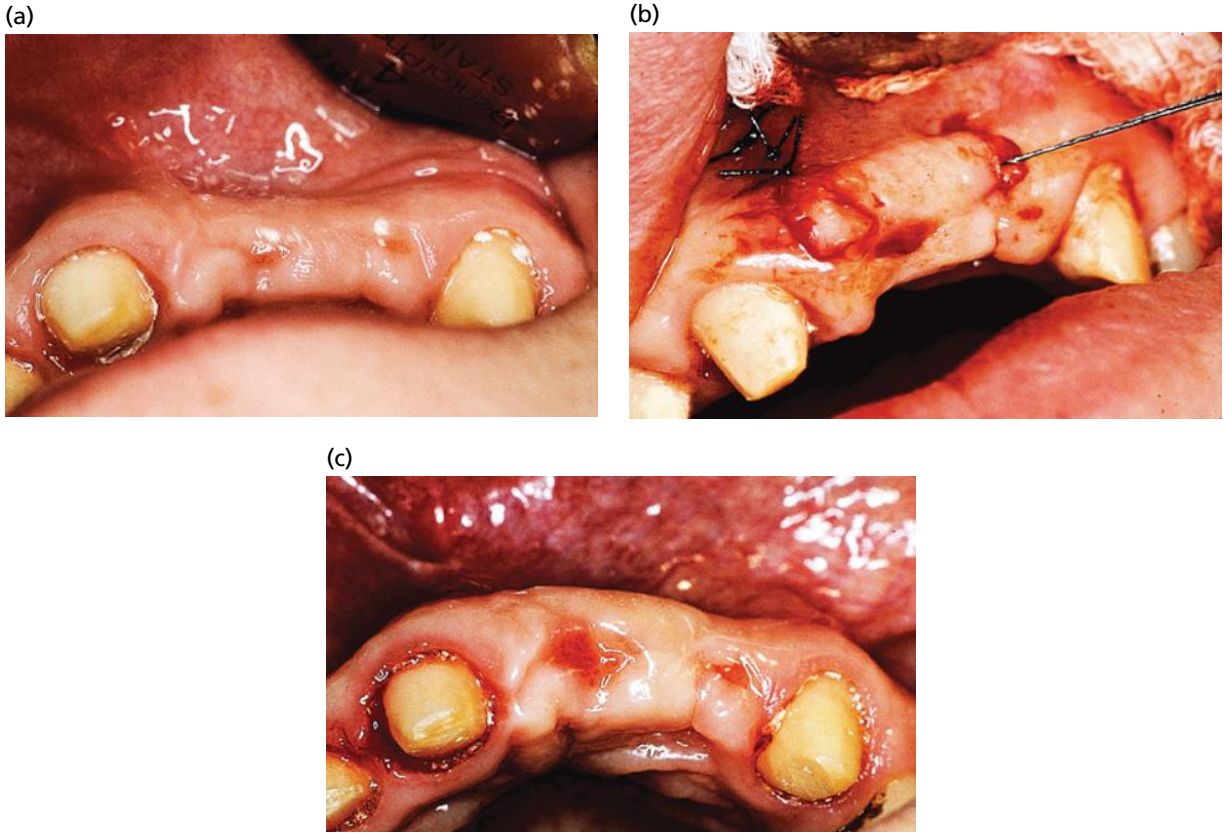

Fig. 46-81 Pouch graft procedure. (a) Pretreatment view of a class I ridge deformity. (b) Placement of the free connective tissue graft in a tunnel prepared by split incision between the two vertical incisions. The graft is brought into position by the use of a suture placed in one end of the free graft. (c) Four months post treatment showing restored facial dimension of the edentulous ridge.

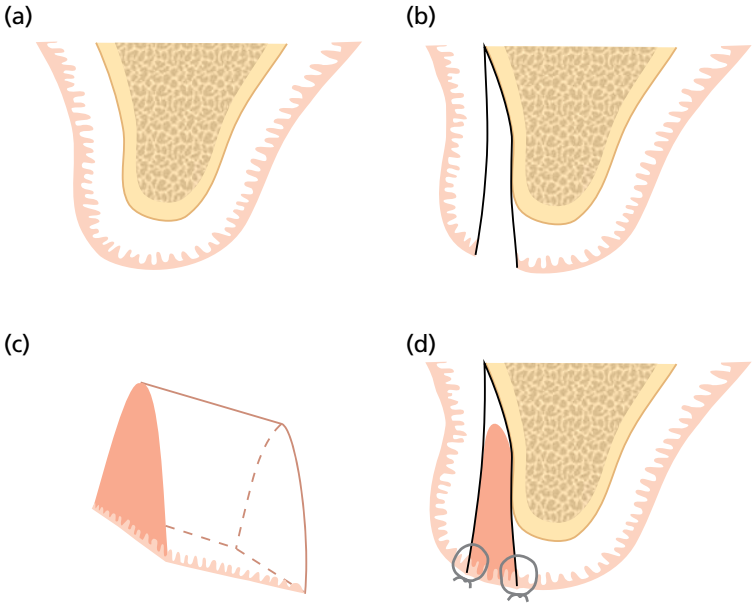

Fig. 46-82 Schematic drawings of the interpositional graft procedure. (a) Cross-section of class I ridge defect. (b) Labial flap (partial-thickness dissection preferred) is used to create the pouch. (c) Wedge-shaped graft is removed from the palate. (d) Epithelial surface of the graft is placed flush with the surface of the tissue surrounding the pouch and sutured around its circumference.

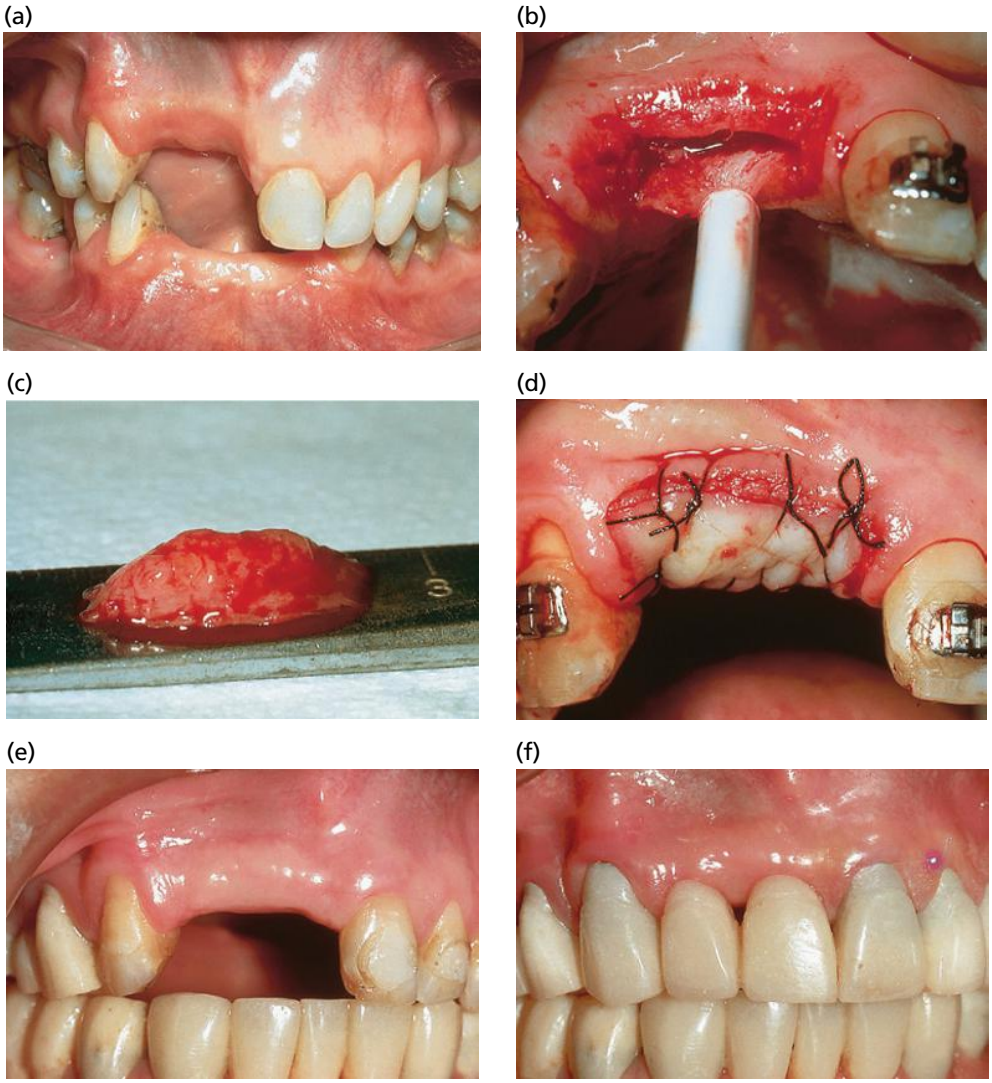

Fig. 46-83 (a) Pretreatment view, class III ridge defect. A two-stage procedure was used to augment the ridge. (b) Pouch was prepared to receive an interpositional graft. Epithelium was removed from the borders of the recipient site to permit some of the graft to be placed above the level of the surrounding tissue in order to gain apicocoronal augmentation. (c) Wedge-shaped graft was 10 mm thick at its center. (d) Interpositional graft was both displacing the labial surface of the pouch in the labial direction as well as adding height to the ridge. (e) Two months post treatment. Additional augmentation was needed apicocoronally. (f) Second-stage onlay graft was used to create a papilla and fill the dark triangle between the pontics.

Fig. 46-83 (*Continued.*) (g) Two months after the first surgical procedure, the ridge was de-epithelialized and cuts were made into the connective tissue prior to placing the second-stage onlay graft into position. (h) Onlay graft was sutured into position. (i) Pontics were adjusted and brought into light contact with the graft. (j) Marked swelling occurred within the graft at 14 days post surgery. (k) Two months following the second surgical procedure, a gingivoplasty was performed to deepen the pontic receptacle sites for the ovate pontics. (l) Post-treatment view 1 year after the final surgical procedure. (Courtesy of J. Seibert and P. Malpeso.)

A certain amount of the grafted connective tissue will thus be exposed in the oral cavity.

Indications

Interpositional graft procedures are used to correct class I as well as small and moderate class II defects.

Technique

An envelope flap, or a split-thickness flap with releasing incisions, is prepared at the facial surface of the defect area. The provisional bridge is placed in position to serve as a reference when estimates are made regarding the amount of tissue that has to be grafted to fill the defect. A periodontal probe may be used to measure the length, width, and depth of the void of the pouch. A suitable donor site is selected in the palate or the tuberosity area, and a free graft of epithelium–connective tissue is excised (Fig. 46-82).

The donor tissue is transferred to the recipient site and placed in position. If gain in ridge height is not intended, the epithelial surface for the graft is placed flush with the surrounding epithelium. The graft is sutured along its entire circumference to the tissues of the recipient site. The provisional bridge is placed in position and the pontics are trimmed and adjusted as discussed above. No dressing is used to cover the recipient site.

If gain also in ridge height is intended, a certain portion of the graft has to be kept above the surface of the surrounding tissue (Fig. 46-83d). Granulation tissue formed during healing will eventually make the border between the graft and the adjacent tissue smooth and properly epithelialized. The swelling, which occurs postoperatively, will assist in sculpting the contour of the ridge.

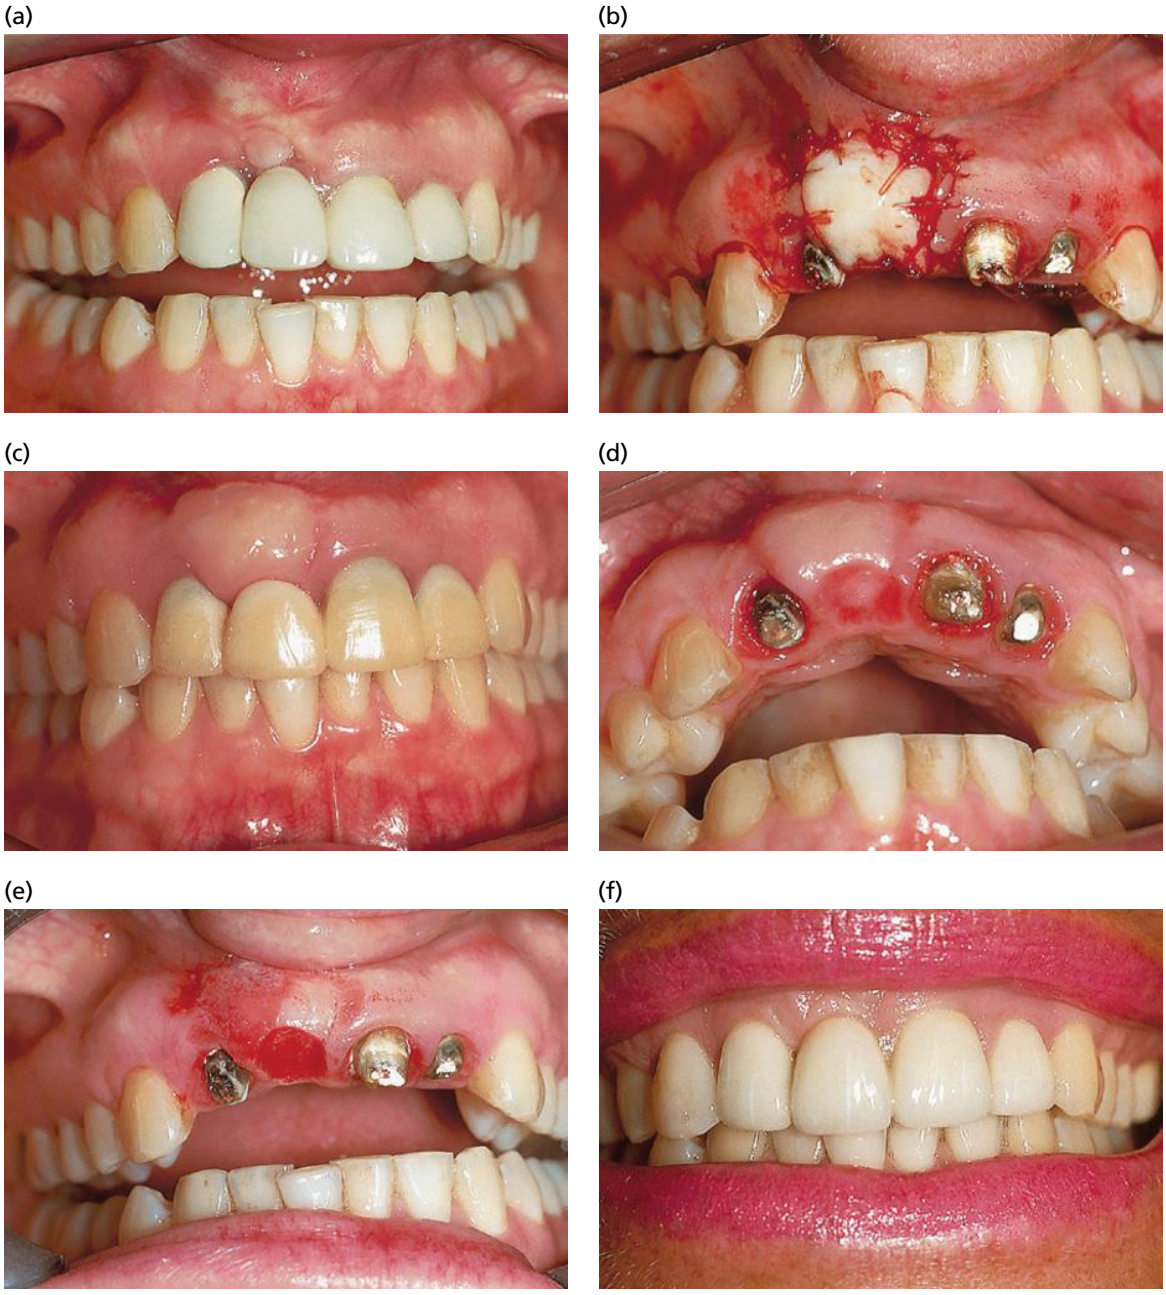

Fig. 46-84 Onlay graft procedure. (a) Pretreatment view. The gingival tissues were distorted from previous attempts at esthetic reconstruction. The patient wished to have a papilla between the right maxillary lateral and central incisor and a natural looking bridge. (b) Pontic area, including the papilla on the mesial of the right lateral incisor, was de-epithelialized and a thick (5-mm) onlay graft was sutured into position. (c) Pontic was shortened at the time of surgery to accommodate the thick graft. At 3 months post surgery, the graft had undergone maximum shrinkage and gingivoplasty could now be done. (d) Incisal view at 3 months post surgery. Note the "papilla" that has been created. The indentation in the ridge was naturally created by the tissue swelling against the pontic tooth. (e) Rotary diamond point gingivoplasty was done to reshape the bulky graft to normal contours, deepen the receptacle site for the ovate pontic, and level the gingival margins. (f) View shows the esthetic harmony that was obtained in the soft tissues and tooth form at 2 years post treatment. (Courtesy of J. Seibert and C. Williams.)

Onlay graft procedures

Surgical concept

The onlay procedure was designed to augment ridge defects in the apicocoronal plane, that is to gain ridge height (Meltzer 1979; Seibert 1983). Onlay grafts are epithelialized free grafts which, following placement, receive their nutrition from the de-epithelialized connective tissue of the recipient site. The amount of apicocoronal augmentation that can be obtained is related to the initial thickness of the graft, the events of the wound healing process, and the amount of graft tissue that survives (Figs. 46-83, 46-84, 46-85). If necessary, the grafting procedure can be repeated at 2-month intervals to gradually increase the ridge height.

Indications

Onlay graft procedures are used in the treatment of large class II and III defects. They are not suitable in areas where the blood supply at the recipient site has

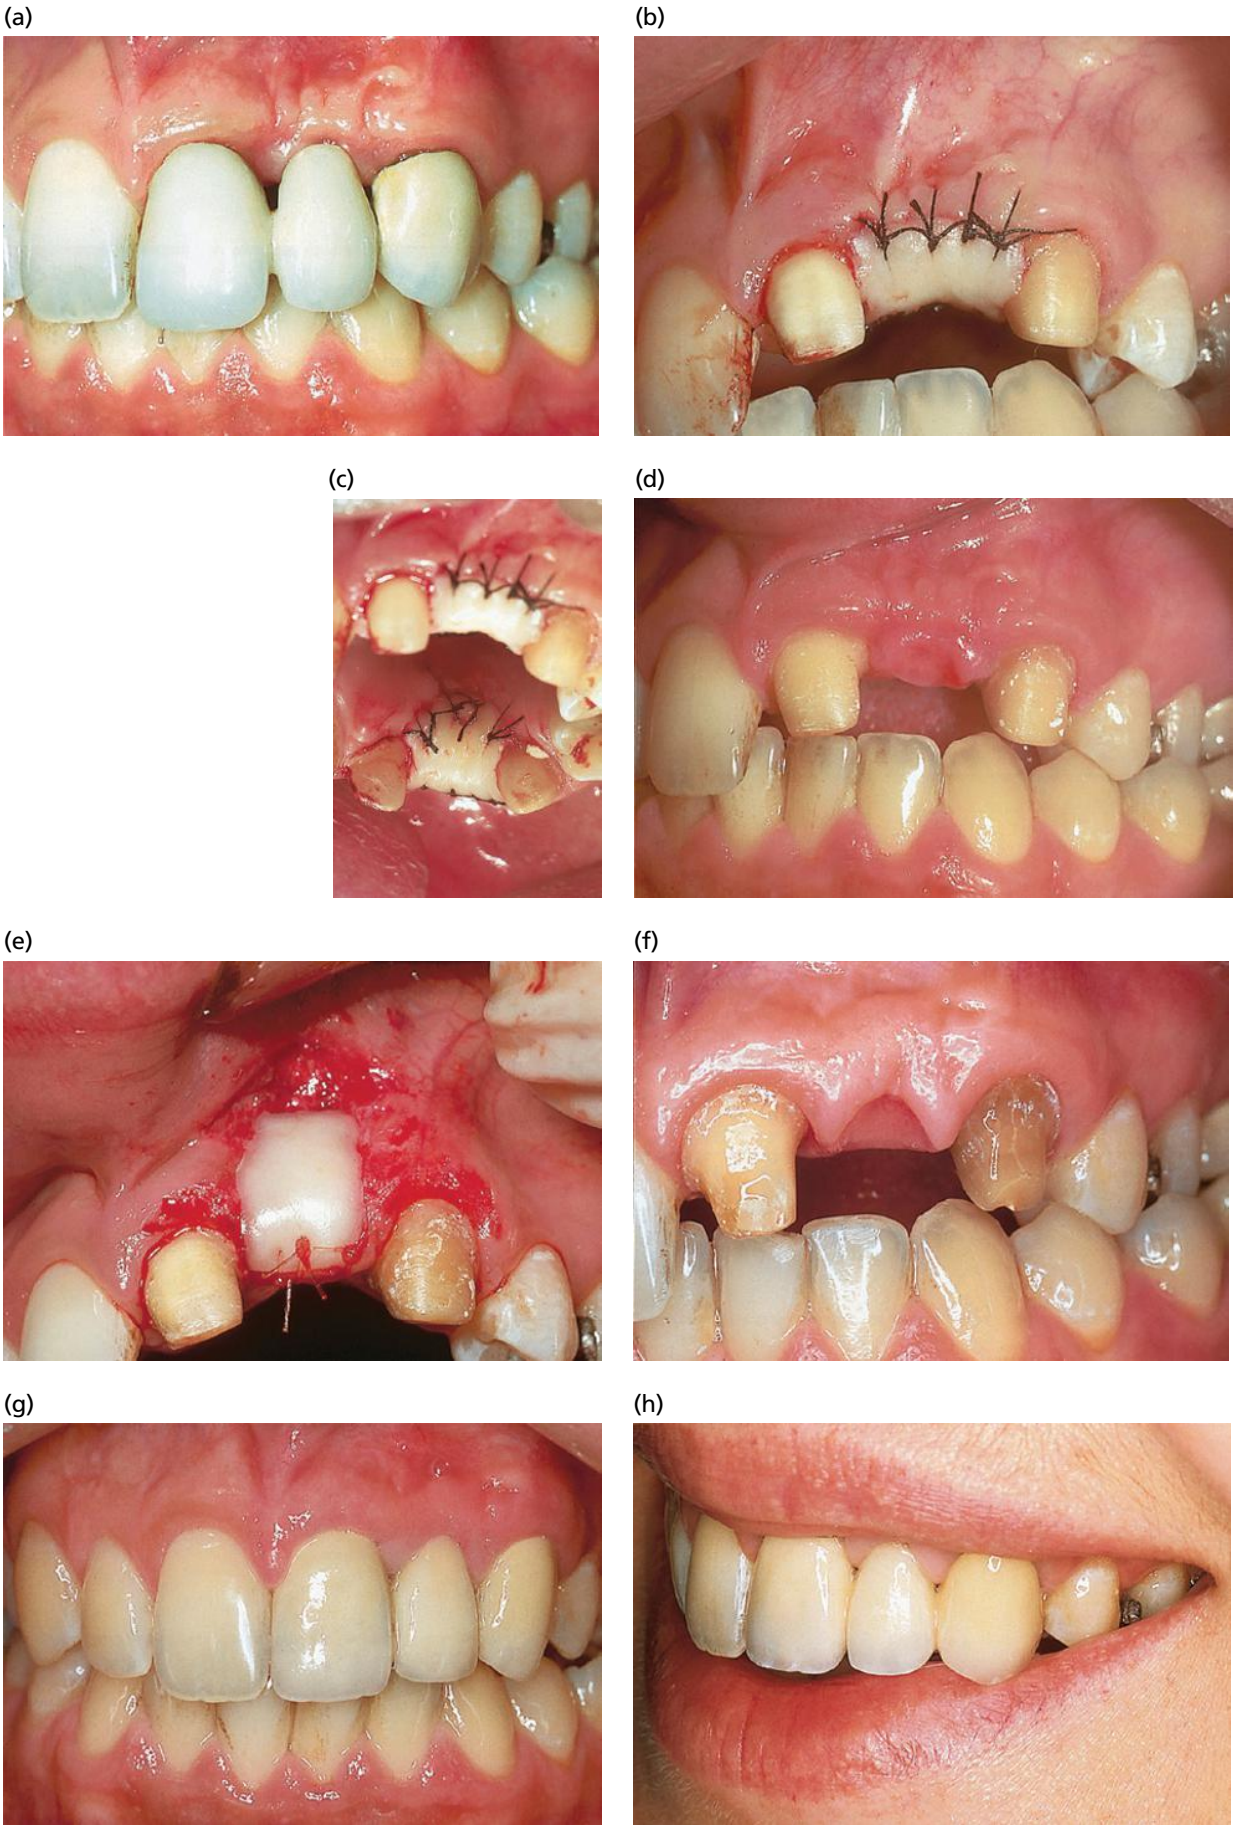

Fig. 46-85 Onlay graft procedures utilized to augment ridge and create papillae. (a) Pretreatment view. The left lateral incisor was extracted after a traumatic injury. The patient detested the dark triangle on the mesial of the pontic, the poor tooth form in the bridge, and the irregular contours in her gingival tissue. (b, c) An onlay graft was used to gain apicocoronal and buccolingual ridge augmentation as well as to develop papillae. Note how the graft was extended to the palatal side of the ridge to gain greater blood supply from a larger connective tissue base. (d, e) At 2 months post surgery, a second-stage veneer graft was used to eliminate the surface irregularities on the surface of the gingiva and gain greater buccolingual augmentation. (f) At 4 months post second-stage surgery, gingivoplasty was done to prepare the area for an ovate form pontic. (g, h) One year post treatment, esthetics have been restored for this patient. (Courtesy of J. Seibert and D. Garber.)

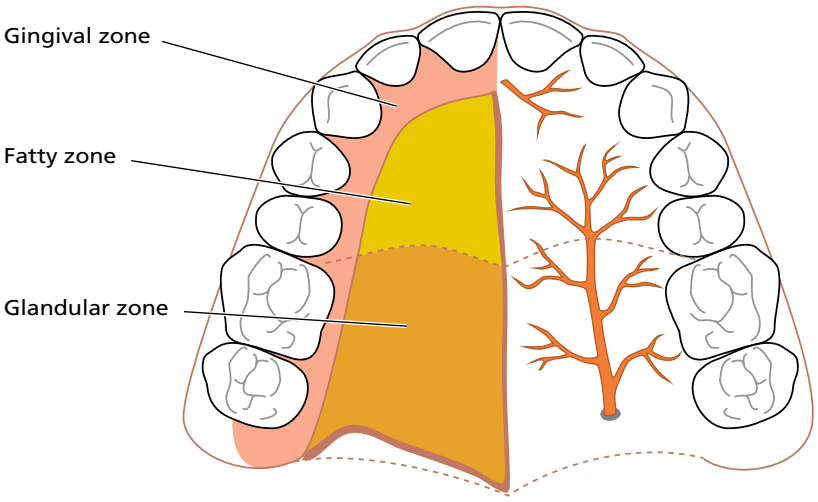

Fig. 46-86 Basic anatomic–histologic zones of the palate. Note the normal location of the greater palatine foramen.

been compromised by scar tissue formation from previous wound healing.

Technique

An attempt must be made to retain as much of the lamina propria of the recipient site as possible. The anesthetic solution should be placed high in the vestibular fornix and in the palate, thus keeping vasoconstriction in the recipient site to a minimum. A scalpel blade is used to remove the epithelium. The scalpel is moved with short, saw-like strokes across the recipient site at a level approximately 1 mm below the outer surface of the epithelium. The least amount of connective tissue possible should be excised. The margins of the recipient site can be prepared with either a butt joint or a beveled margin. The prepared recipient site should be covered with a surgical gauze moistened with isotonic saline while the donor tissue is dissected (Fig. 46-83g–i).

Selection of donor site

Onlay graft procedures, as well as interpositional graft procedures, require large amounts of donor tissue. As a general rule, the palatal vault region of premolars and first molars, midway between the gingival margin and the midline raphae, is the only area in the maxilla that contains the necessary volume of tissue required to augment large ridge defects. During the presurgical planning phase, the tissue of the palate should be probed with a 30-gauge syringe needle to ensure that an acceptable volume of tissue can be obtained at the time of surgery.

The major palatine artery emerges from the posterior palatine foramen located adjacent to the distal surface of the maxillary second molar, midway between the gingival margin and the midline raphae (Fig. 46-86). The artery passes in an anterior direction close to the surface of the palatal bone. It is important therefore that the second and third molar regions are not used as donor sites for large volume grafts.

Planing in graft preparation

As a rule, the graft should be made a few millimeters wider and longer than the dimensions required at the recipient site. The dimensions of the graft are outlined on the palate with the use of a scalpel and light bleeding is provoked to define the surface borders. In order to avoid interference with the palatine artery, the borders of the graft must be planed in such a way that its thinner portions are located high in the palatal vault or in the first molar area. The thicker portions should be harvested from the premolar areas.

Dissection of donor tissue

The base of the graft should be V- or U-shaped to match the shape of the defect in the ridge. The different planes of incision prepared in the palate must therefore converge towards an area under the center or toward one edge of the donor site. It is comparatively easy, with the use of a scalpel, to dissect in an anteroposterior or, from an area high in the palate, in a lateral direction towards the teeth. It is, however, difficult to dissect in an anterior direction from the distal edge of the donor site. There are a variety of blade holders available which permit the scalpel blade to be positioned at different angles to the holder and which enable the surgeon to cut with a back-action. When the donor tissue has been removed, it must be stored in pieces of surgical gauze moistened in isotonic saline at all times.

Treatment of the donor site

Since it is difficult to anchor and maintain a periodontal dressing at the donor site in the palatal vault, an acrylic stent should be fabricated prior to surgery. The stent should be made with wrought wire clasps on each side to add retention and to aid the patient in removing and inserting the device.

The donor site must be inspected carefully for signs of arterial bleeding. If any small vessel bleeding is observed, a circumferential suture must be placed around the vessel distal to the bleeding point. Immediately thereafter, the void at the donor site should be packed with a suitable hemostatic agent

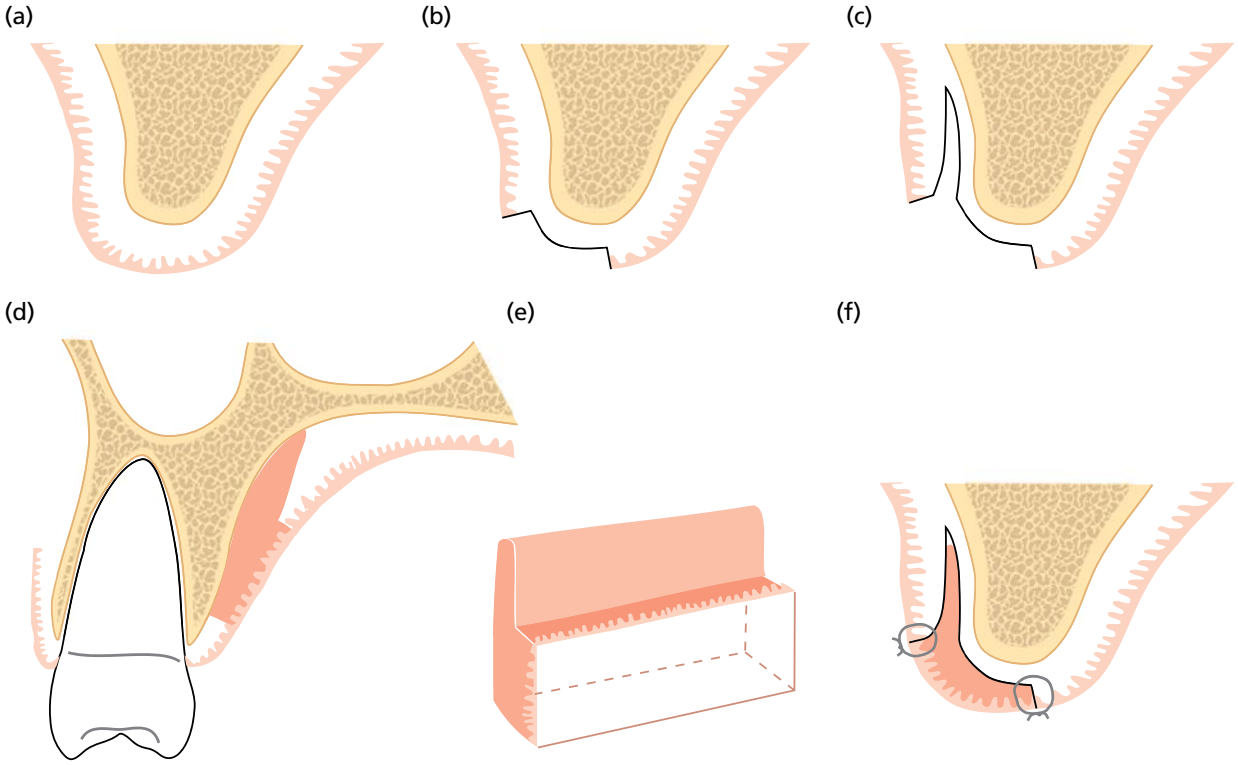

Fig. 46-87 Schematic diagram of the combination onlay–interpositional graft procedure. (a) Cross-section of a class III ridge defect. (b) Epithelium is removed on the labial–crestal side of the ridge to prepare the recipient bed for the onlay segment of the graft. (c) Partial-thickness dissection was then used to create a pouch for the interpositional section of the graft. (d) Dissection for the graft is started at right angles to the surface of the palate. The scalpel blade is then angled to remove a long connective tissue segment for the graft. (e) Three-dimensional view of the onlay section of the graft (including epithelium) and the connective tissue segment for buccolingual augmentation. (f) Graft sutured into position. (Reproduced from Quintessence Pub. Co.)

and the edges of the wound brought closer together with sutures. The stent is then put into position.

Try-in and stabilization of graft

The graft is transferred with tissue forceps to the recipient site for a try-in. The graft is trimmed to the proper shape and adjusted to fit the connective tissue surface of the prepared ridge. A series of parallel cuts may be made deep into the exposed lamina propria of the recipient site to sever large blood vessels (Fig. 46-83g) immediately before suturing. A series of interrupted sutures is placed along the borders of the graft. The dental assistant should stabilize the onlay graft against the surface of the recipient site, while the surgeon completes the placement of sutures.

Wound healing in the recipient site

Considerable postoperative swelling often occurs during the first week after pouch and onlay augmentation procedures. The epithelium of the graft will slough to form a white film on the surface of the graft. Patients should rinse two to four times per day with an antimicrobial mouth wash during the first week after surgery and refrain from mechanical cleaning measures in the area until a new epithelial covering has formed over the graft, which will not occur until a functional capillary circulation has been re-established in the graft (4–7 days after the surgery). The grafted tissue will assume a normal color as the epithelium thickens via stratification. Tissue form is usually stable after 3 months, but further shrinkage may occur over a period of several months. Final restorative measures should therefore not be initiated until after 6 months.

Wound healing in the donor site

Granulation tissue will gradually fill the donor site. Initial healing is usually complete within 3–4 weeks after the removal of a 4–5-mm thick graft. Patients should wear the surgical stent for about 2 weeks to protect the healing wound. The palate returns to its presurgical contour after about 3 months.

Combined onlay–interpositional graft procedures

Class III ridge defects pose a major challenge to the clinician since the ridge has to be augmented in both vertical and horizontal dimensions. The combined onlay–interpositional graft procedure (Fig. 46-87, 46-88) may successfully be used in such a situation (Seibert & Louis 1996). The combined graft procedure may offer the following advantages:

- Submerged connective tissue section of the interpositional graft aids in the revascularization of the onlay section of the graft, thereby gaining a greater percentage take of the overall graft

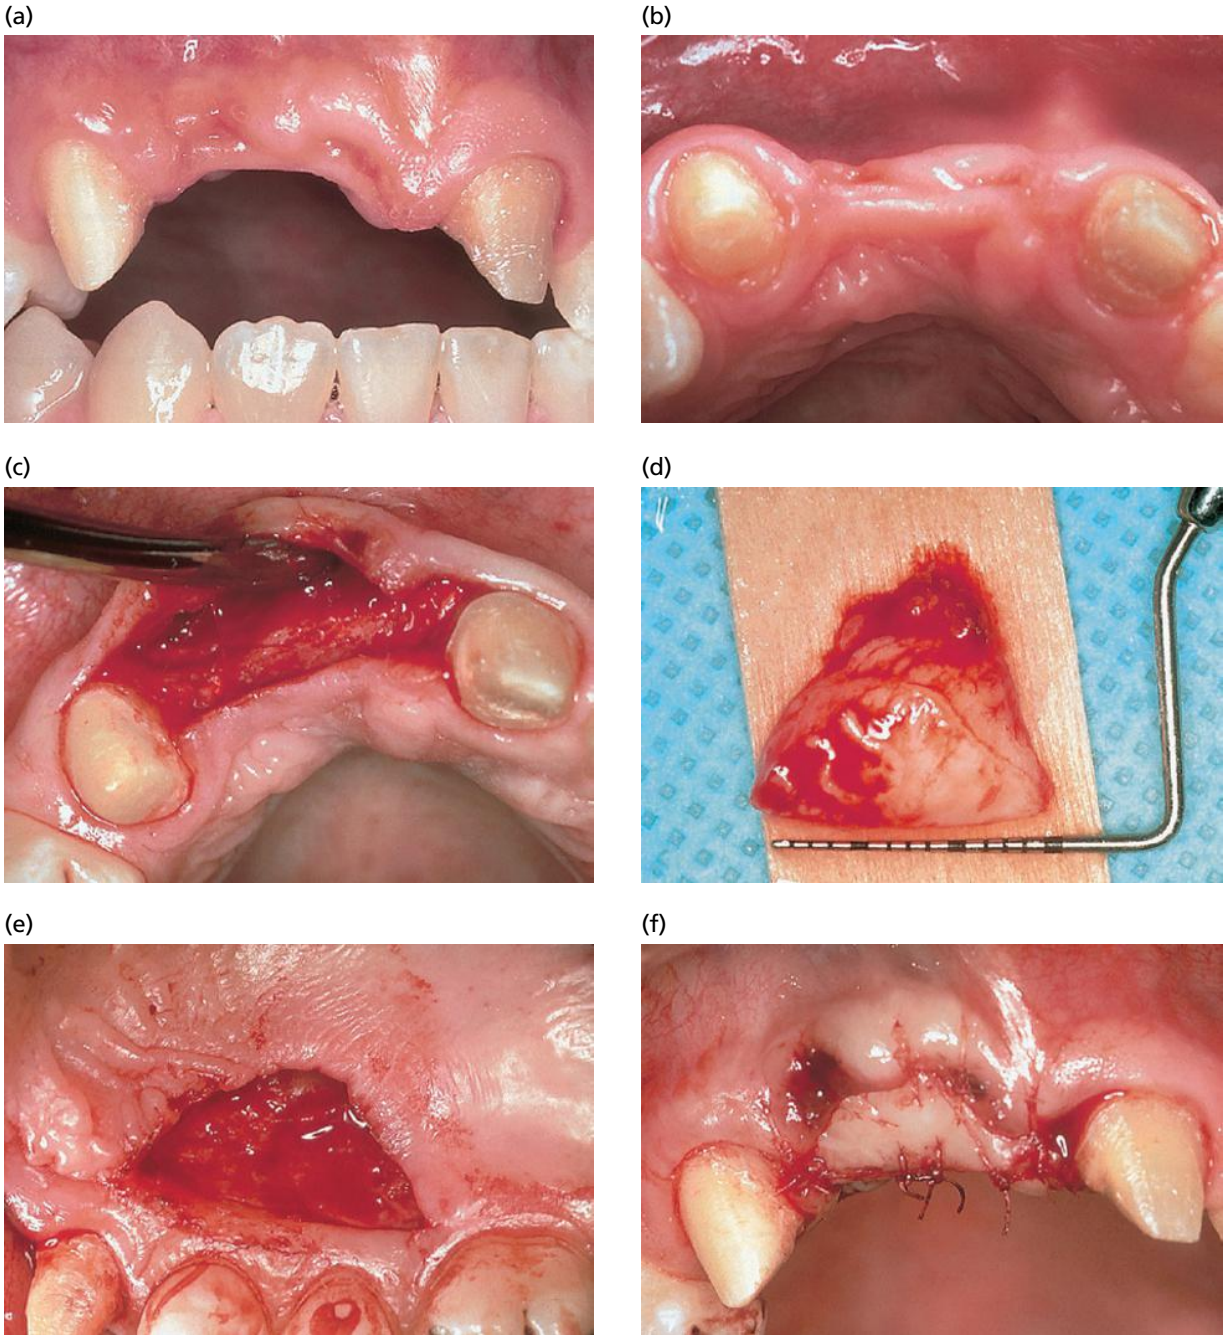

Fig. 46-88 (a, b) Right maxillary lateral and central incisors were lost due to trauma. These views show the horizontal and vertical loss of ridge tissue 10 months after the extractions. (c) Partial-thickness path of incision was extended labially and apically to create a pouch. The amount of space created within the pouch and the degree of relaxation of the flap was then tested with a periosteal elevator. (d) Epithelialized section of the graft can be seen in this view. (e) Premolar area, maxillary right side, was used as a donor area. The area of exposed connective tissue corresponded to the onlay section of the graft. The incisions were extended another 5–7 mm towards the midline on a long bevel to obtain the interpositional segment of the graft. (f) Graft was tucked into the labial pouch and sutured first along its palatal border. The labial flap was then sutured along the epithelial connective border of the graft. The residual labial socket defect in the flap created a soft tissue discontinuity defect along the labial margin of the flap. (g) At 6 weeks post surgery, it can be seen that further augmentation would be required to gain additional soft tissue in both the vertical and horizontal planes. A second-stage procedure was done at this time. (h) An incision 1.5 mm in depth was utilized to de-epithelialize the crestal surface of the ridge. Note that the papillae were not included within the surgical field. The mesial and distal borders of the onlay section of the recipient site were then extended apically to create vertical releasing incisions. The overall recipient site was to be trapezoidal in shape. A labial flap to create the pouch section of the recipient site was made using partial-thickness dissection. (i) The left maxillary premolar area was used as the donor site for the second-stage surgery. (j) This side view clearly shows the epithelialized onlay section of the graft and the de-epithelialized connective tissue section of the graft, as well as tissue thickness. (k) Graft was sutured first along the fixed palatal border to gain initial stabilization. Then the connective tissue interpositional section was sutured along the lateral borders. The flap was then sutured over the interpositional section of the graft at the epithelialized edge of the onlay section of the graft and along the vertical incisions. (l) At 6 weeks post surgery, the provisional prosthesis was modified to bring the tissue surface of the pontics into contact with the healing ridge. (m) At 2 months post surgery, tooth form was further modified on the provisional prosthesis and gingivoplasty was done to sculpt the tissues to their final form and smooth out surface irregularities. (n) Final ceramo-metal prosthesis was inserted 4 months later. The life-like reconstruction of the soft tissues and dentition restored dentofacial esthetics for the patient. (Courtesy of J. Seibert, J. Louis, and D. Hazzouri. Reproduced from Quintessence Pub. Co.)

Fig. 46-88 *Continued*

- Smaller postoperative open wound in the palate donor site
- Faster healing in the palate donor site with less patient discomfort
- Greater latitude or ability to control the degree of buccolingual and apicocoronal augmentation within a single procedure
- Vestibular depth is not decreased and the mucogingival junction is not moved coronally, thereby eliminating the need for follow-up corrective procedures.

Refinement of pontic contours and gingivoplasty soft tissue sculpting procedures

It is desirable, when reconstructing defects within a partially edentulous ridge, to moderately overcorrect the ridge in the area of the deformity. This will compensate for wound contraction and provide the necessary bulk of tissue within the ridge to sculpt the ridge to its final form. Gingivoplasty techniques using rotary coarse diamond stones in an ultraspeed handpiece with copious water spray are used to smooth out incision lines and perfect the fit and shape of the pontic teeth to the crest of the ridge (Figs. 46-84, 46-88). Adjustments are made to shape the cervical contour and emergence profile of the pontic teeth to match those of the contralateral teeth. The tissue-contacting surfaces of the pontic teeth are immediately rebased with autopolymerizing resin and polished. This final tissue sculpting procedure and reshaping of the provisional prosthesis is minor in nature but aids greatly in defining the shape of the papillae and creating the illusion of the presence of a cuff of free gingiva at the pontic–ridge interface.

Microsurgical techniques in dentistry: development of concepts

In general, the main aim of a surgical intervention is no longer just the survival of the patient or one of his/her organs, but the preservation of maximum function and improvement of patient comfort. In many surgical specialties, these demands have been met by a minimally invasive surgical approach.

Microsurgery in general is not an independent discipline, but a technique that can be applied to different surgical disciplines. It is based on the fact that the human hand, with appropriate training, is capable of performing finer movements than the naked eye is able to control. First reports on microsurgery go back to the 19th century when a microscope for use in ophthalmology was developed (Tamai 1993). Later, to correct otosclerotic deafness, the first surgical operation with a microscope was performed in Sweden (Nylén 1924). The microsurgical technique, however, did not attract the interest of surgeons until the 1950s, when the first surgical microscope, OPMI 1, with a co-axial lighting system and the option for a stereoscopic view was invented and commercialized by the Carl Zeiss company.

The microvessel surgery that later revolutionized plastic and transplantation surgery was mainly developed by neurosurgeons (Jacobsen & Suarez 1960; Donaghy & Yasargil 1967). With microsurgically-modified techniques, small vessels of a diameter of <1 mm could be successfully anastomosed on a routine basis (Smith 1964). As a consequence, a completely amputated thumb could be successfully replanted for the first time in 1965 (Komatsu & Tamai 1968). Between 1966 and 1973, a total of 351 fingers were replanted at the Sixth People's Hospital in Shanghai without magnification, resulting in a healing rate of 51% (Zhong-Wei *et al.* 1981). Since 1973, this replantation was performed solely with surgical microscopes and the corresponding success rates increased to 91.5%. These results documented the importance of a fast and successful restoration of the blood circulation in replanted extremities and free tissue grafts. Further achievements of the microsurgical technique in plastic reconstructive surgery included transplantation of toes to replace missing thumbs (Cobbett 1969), interfascicular nerve transplantation (Millesi 1979), microvascular transplantation of toe joints (Buncke & Rose 1979), micro-neurovascular transplantation of the pulp of a toe to restore the sensitivity of the finger tips (Morrison *et al.* 1980), and microvascular transplantation of the nail complex (Foucher 1991). Positive results for microsurgically modified interventions have led to today's routine clinical applications in orthopedics, gynecology, urology, plastic reconstructive, and pediatric surgery.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

After a few early single reports (Bowles 1907; Baumann 1977; Apotheker & Jako 1981), the surgical microscope was introduced in dentistry in the 1990s. Case reports and the application of the microscope were described in the prosthetic (Leknius & Geissberger 1995; Friedman & Landesman 1997, 1998; Mora 1998), endodontic (Carr 1992; Pecora & Andreana 1993; Ruddle 1994; Mounce 1995; Rubinstein 1997), and periodontal literature (Shanelec 1991; Shanelec & Tibbetts 1994; Tibbetts & Shanelec 1994; Shanelec & Tibbetts 1996; Burkhardt & Hürzeler 2000).

Treatment outcomes in endodontics were statistically analyzed in prospective studies following the introduction of microendodontic techniques (Rubinstein & Kim 1999, 2002). Within 1 year after apical microsurgery, 96.8% of cases were considered to be healed. At the re-evaluation 5–7 years after the first postoperative year, a success rate of 91.5% measured by clinical and radiographic parameters was still evident (Rubinstein & Kim 2002). The corresponding percentage of healed cases treated with conventional apical surgery without a surgical microscope was only 44.1% 6 months to 8 years post surgery (Friedman *et al*. 1991). Today, the better outcomes of a microscope-enhanced approach in endodontics is well supported by systematic reviews and meta-analyses (Del Fabbro & Taschieri 2010; Setzer et al. 2012).

Despite the positive results in prospective studies (Cortellini & Tonetti 2001; Rubinstein & Kim 2002; Burkhardt & Lang 2005), the surgical microscope was only slowly accepted in prosthodontics, endodontics (Seldon 2002), and periodontal surgery. Possible reasons for this were the long learning curve, impaired maneuverability of the devices, and high costs for purchasing the instrument.

Concepts in microsurgery

The continuous development of operating microscopes, refinement of surgical instruments, production of improved suture materials, and suitable training laboratories have had a decisive role in the worldwide establishment of the microsurgical technique in many specialties. The three elements, that is *magnification, illumination*, and *instruments*, are called the *microsurgical triad* (Kim *et al*. 2001), the improvement of which is a prerequisite for improved accuracy of surgical interventions. Without any one of these, microsurgery is not possible.

Magnification

Optimal vision is a stringent necessity in periodontal practice. More than 90% of the sensations of the human body are perceived by visual impressions. Vision is a complex process that involves the integration of multiple links between the eye, retina, optic nerve, and brain. An important measure of human eyesight is visual acuity (measured in angular degrees), defined as the ability to perceive two objects separately. The visual acuity is influenced by anatomic and physiologic factors, such as the density of cells packed on the retina and the electrophysiologic processing of the image on the retina. If necessary, it may be improved with corrective lenses.

Another important factor influencing visual acuity is the lighting. The relation between visual acuity and light density is well established: at both low and high light densities, visual acuity decreases. Maximum visual acuity can be achieved at a light density of 1000 cd/m^2 and optimal lighting conditions should be implemented.

Visualization of fine details is enhanced by increasing the image size of the object. This can be done in two ways: (1) moving closer to the objects and (2) magnification. Using the former method, the ability of the lens of the eye to accommodate becomes important and influences the visual capacity. By changing the shape of the lens, the refraction of the optical apparatus increases, allowing it to bring nearer objects into focus. With aging, the ability to focus on near objects is compromised because the lens of the eye loses flexibility (Burton & Bridgeman 1990). This phenomenon is called presbyopia. Presbyopia affects all people in middle age, and becomes especially noticeable when the nearest point at which the eye can focus accurately exceeds the ideal working distances (Burton & Bridgeman 1991). To see small objects accurately, the focal length must be increased. As an example, an older individual reading without glasses must hold the reading matter farther away to see the print, but the longer working distance results in the print being seen in a smaller size. This decrease in image size, resulting from the increased working distance, needs to accommodate the limitations of presbyopia and is especially hindering in clinical practice. In periodontal practice, the tissues to be manipulated are usually very fine and cannot be distinguished easily with normal visual acuity. Therefore, the clinical procedure may only be performed successfully with the use of magnification, which improves precision and, hence, the quality of work.

Optical principles of loupes

In dentistry, two basic types of magnification systems are commonly used: the surgical microscope and loupes. The latter can further be classified into (1) single-lens magnifiers (clip-on, flip-up, jeweler's glasses) and (2) multilens telescopic loupes. Single-lens magnifiers produce the described diopter magnification by adjusting the working distance to a set length. As diopters increase, the working distance decreases. With a set working distance, there is no range and no opportunity for movement, which makes it difficult to maintain focus and, therefore, may cause neck and back strain from poor posture (Basset 1983; Diakkow 1984; Shugars *et al*. 1987). Additionally, diopter magnifiers give poor image quality, which restricts the quality of surgery with them (Kanca & Jordan 1995). These types of glasses cannot be considered to be a true means of magnification.

Fig. 47-1 Compound loupes, inclinable and adjustable in the interpupillary distance (Galilean principle).

(a)

(b)

Fig. 47-2 (a) Prism loupes, sealed to avoid leakage of moisture, front frame mounted and fully adjustable (Prism principle). (b) Sterilizable guards against contact for a safe rotation of the loupe during the surgical intervention.

Telescopic loupes (compound or prism loupes), however, allow good ergonomic posture as well as significant advancements in optical performance (Shanelec 1992). Instead of increasing the thickness of a single lens to increase magnification, compound loupes use multiple lenses with intervening air spaces (Fig. 47-1). These allow adjustment of magnification, working distance, and depth of the field without excessive increase in size or weight. Prism loupes are the most optically advanced type of loupe magnification available (Fig. 47-2). While compound loupes use multiple refracting surfaces with intervening air spaces to adjust optical properties, prism loupes are actually low-power telescopes. They contain Pechan or Schmidt prisms that lengthen the light path through a series of mirror reflections within the loupes (Fig. 47-3). Prism loupes produce better magnification, larger fields of view, wider depths of field, and longer working distances than do other loupes. To guarantee a proper adjustment of loupes, knowledge of some basic definitions and key optical features of loupes is necessary (Fig. 47-4).

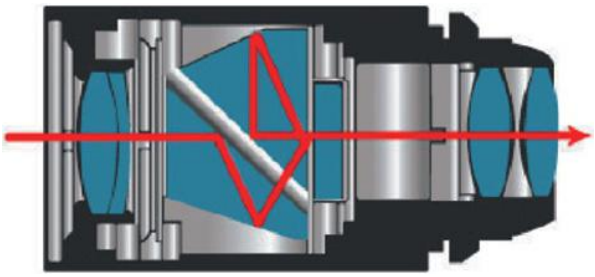

Fig. 47-3 Light path through a prism loupe. Even though the distance the light travels has increased, there is no decrease in brightness or image contrast, even at ×4 or ×5 magnification. This is due to the fact that the light does not travel through air, but rather through the glass of the prism.

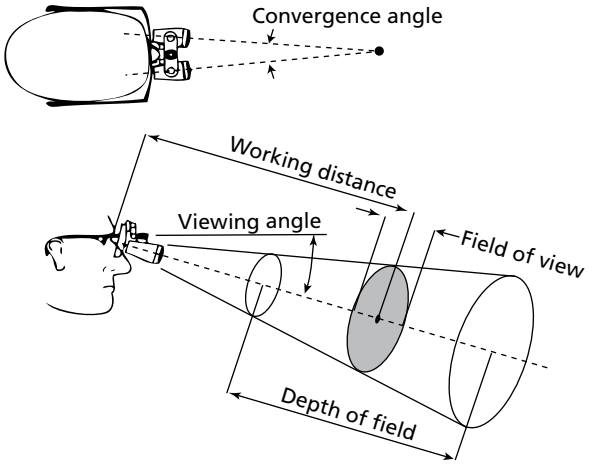

Fig. 47-4 Principal optical features of loupes.

Working distance

The working distance (Fig. 47-4) is the distance between the eye lens and the object in vision. There is no set rule for how much the working distance may be increased. Depending on the height and the resulting arm length of the dentist, the working distance with slightly bent arms usually ranges from 30 to 45 cm. At this distance, postural ergonomics are greatly improved and eye strain reduced due to less eye convergence. The multitude of back, neck, shoulder, and eye problems that dentists suffer when working without using loupes, frequently originate from the need to assume a short working distance to increase visual acuity (Coburn 1984; Strassler 1989). By wearing surgical loupes, the dentist's head can be held in the center of the body's balance over the spine and is stabilized against gravity.

Working range

The working range (depth of field) (Fig. 47-4) is the range within which the object remains in focus. The depth of field of normal vision ranges from working distance to infinity. When moving back from a close working distance, the eyes naturally accommodate and refocus to the new working distance. Normally, eye position and body posture are not frozen in one place for an extended period, but vary constantly. Wearing loupes changes this geometry. Body posture

and position of the extraocular muscles are confined to a range determined by the loupe's characteristics. It is important to understand that each individual's vision is limited to his/her own internal working range, which means that he/she may only be able to maintain focus on an object within a 15-cm range, even though the loupes have a 23-cm depth of field. With any brand of loupe, the depth of field decreases as the magnification increases.

Convergence angle
The convergence angle (Fig. 47-4) is the pivotal angle aligning the two oculars, such that they point at the identical distance and angle. At a defined working distance, the convergence angle varies with interpupillary distance. Wider-set eyes will have more eye convergence at short working distances. Therefore, the convergence angle defines the position of the extraocular muscles and this may result in tension of the internal and external rectus muscles; this may be an important source of eye fatigue.

Field of view
The field of view (Fig. 47-4) is the linear size or angular extent of an object when viewed through the telescopic system. It also varies depending on the design of the optic lens system, the working distance, and the magnification. As with depth of field, when magnification increases, the field of view decreases.

Interpupillary distance
The interpupillary distance (Fig. 47-4) depends on the individual's eye position within the head and is a key adjustment that allows long-term, routine use of loupes. The ideal setting, as with binoculars, creates a single image with a slightly oval-shaped viewing area. If the viewing area is adjusted to a full circle, excess eye muscle strain would inhibit the ability to use the loupes for long periods of time.

Viewing angle
The viewing angle (Fig. 47-4) is defined as the angular position of the optics that allows comfortable working. The shallower the angle, the greater the need to tilt the neck to view the object being worked on. Therefore, loupes for dental clinicians should have a greater angulation than loupes designed for industrial workers. Only slight or no angulation, which results when magnifiers are embedded in the lenses of the eyeglasses, may cause the operator to unduly tilt his/her head to view a particular object. This, again, may lead not only to neck discomfort, but also to pain in the shoulder muscles and possibly to headaches. As the working posture is likely to change over time, the loupes should be adjustable to any posture.

Illumination
Most manufacturers offer collateral lighting systems or suitable fixing options. These systems may be helpful, particularly for higher magnification in the range of ×4 or more. Loupes with a large field of view will have better illumination and brighter images than those with narrower fields of view. Important considerations in the selection of an accessory lighting source are total weight, quality, and brightness of the light, ease of focusing and directing the light within the field of view of the magnifiers, and ease of transport between surgeries (Strassler *et al*. 1998).

It has to be realized that with each surface refraction in a lens, 4% of the transmitted light will be lost due to reflection. In telescopic loupes, this could amount to as much as a 50% reduction in brightness. Antireflective coatings have been developed to counteract this effect by allowing lenses to transmit light more efficiently. The quality of lens coatings varies and should be evaluated when selecting loupes (Shanelec 1992).

Choice of loupes

Before choosing a magnification system, different loupes and appropriate time for a proper adjustment have to be considered. Ill-fitting or improperly adjusted loupes as well as the quality of the optics will influence the performance. For use in periodontal surgery, an adjustable, sealed prism loupe with high-quality, coated lenses offering a magnification between 4× and 4.5×, either headband- or front frame-mounted, with a suitable working distance and a large field of view, seems to be the instrument of choice. The information in Table 47-1 serves as a basic guide to making an appropriate selection.

Optical principles and components of a surgical microscope

The surgical microscope is a complicated system of lenses that allows stereoscopic vision at a magnification of approximately ×4–40 with excellent illumination of the working area. In contrast to loupes, the light beams fall parallel onto the retinas of the observer so that no eye convergence is necessary and the demand on the lateral rectus muscles is minimal (Fig. 47-5). The microscope consists of optical components, lighting unit, and mounting system. To avoid unfavorable vibration of the microscope during use, it should be firmly attached to a wall, ceiling or floor stand. When mounted on the floor, the position of the microscope in the room must allow quick and easy access.

The optical unit includes the following components (Fig. 47-6): (1) magnification changer, (2) objective lenses, (3) binocular tubes, (4) eyepieces, and (5) lighting unit (Burkhardt & Hürzeler 2000).

Magnification changer
The magnification changer or "Galilean" changer consists of one cylinder into which two Galilean telescope systems (consisting of a convex and

Table 47-1 Features to consider in the selection of a magnifying loupe system.

Compound loupes (Galilean)	Magnification range ×2–3.5 Lighter in weight Shorter working distance Shorter loupe barrel
Prism loupes (Keplerian)	Magnification range 3–5× Heavier in weight Longer working distance Longer loupe barrel
Front-frame mounted	Allow up to 90% of peripheral vision Not to be used with prescription glasses Require soft and cushioned nose piece Better weight distribution
Head-band mounted	Restricted peripheral vision Allow use with prescription glasses Better weight distribution Require adjustment more often
Fixed-lens magnifiers	No adjustment options when changing posture Minimum weight
Flip-up capability	Require removable, sterilizable handle Allow switch from magnified to regular vision
Quality of the lenses	Corrected for chromatic and spherical aberration No drop-off in clarity when approaching the edges Sealed system to avoid leakage of moisture Option for disinfection
Adjustment options	Interpupillary distance Viewing angle Vertical adjustment Lock in adjusted position Convergence angle (preset angle may be more user-friendly)
Lens coating	Brighter image More light
Accessories	Transportation box Side and front shields for protection Mounted light source Removable cushions

concave lens) with various magnification factors are built. These systems can be used in either direction depending on the position of the magnification changer. A total of four different magnification levels are available. Straight transfer without any optics yields no magnification. The combination of the magnification changer with varying objective lenses and eyepieces yields increasing magnification when the control is adjusted.

The stepless motor-driven magnification changer must achieve a magnification of ×0.5–2.5 with one optical system, which is operated with either a foot pedal or an electric rotating control, mounted on the

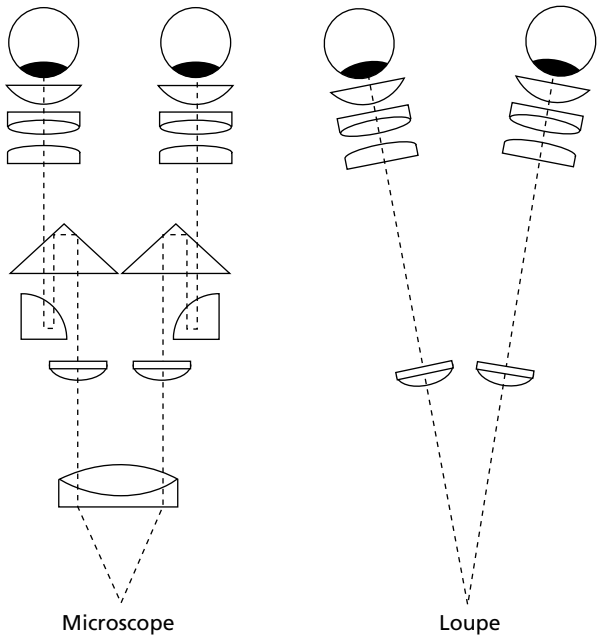

Fig. 47-5 Comparison of vision enhancement with loupes and a microscope. The loupes necessitate eye convergence, while vision is paralleled through the microscope.

microscope. The operator should decide whether to use the manual or motorized magnification changer. If the magnification must be changed frequently, it can be accomplished more quickly with the manual than with the motorized changer, the former not having in-between levels. While the motorized system improves the focus and comfort over the manual system, the former is more expensive.

Objective lenses

As processed by a magnification changer, the image is only projected by a single objective. This simultaneously projects light from its source twice for deflection by the prisms into the operation area (i.e. coaxial lighting). The most frequently used objective is 200 mm (f = 200 mm). The focal length of the objective generally corresponds to the working distance of the object.

Binocular tubes

Depending on the area of use, two different binocular tubes are attached (i.e., straight and inclined tubes). With straight tubes, the view direction is parallel to the microscope axis. Using inclined tubes, an angulation to the microscope axis of 45° is achieved. In dentistry, only inclined, swiveling tubes that permit continuous adjustable viewing are used for ergonomic reasons. The latest configuration consists of a foldable binocular tube with integrated 360° rotation function. This allows a precise increase or decrease of the working distance and adjusts for eye discrepancies between surgeon and assistant, an important aspect for improving ergonomics in periodontal microsurgery (Fig. 47-7). The precise adjustment of the interpupillary distance is the basic prerequisite for stereoscopic vision of the operation area.

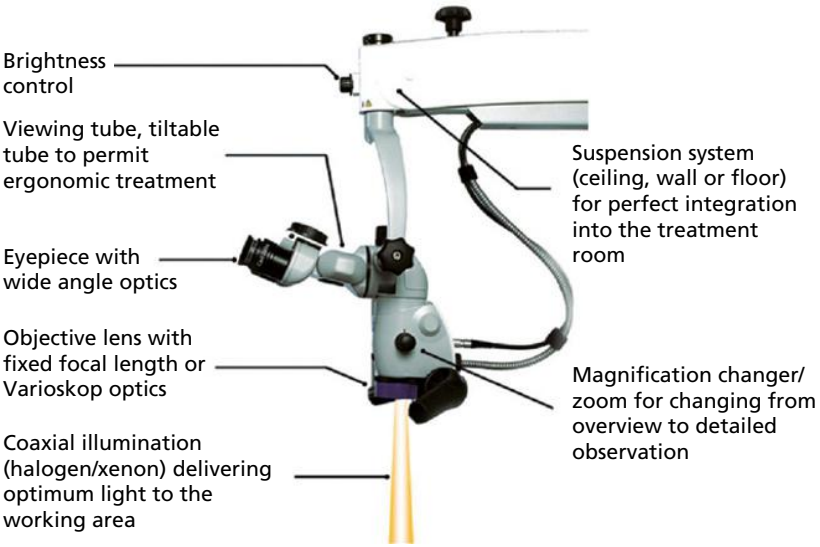

Fig. 47-6 System components of a surgical microscope.

Fig. 47-7 Tiltable and foldable viewing tube allowing an ergonomic posture during clinical work, which is a prerequisite for optimal performance using microsurgical technique.

Eyepieces

The eyepieces magnify the interim image generated in the binocular tubes. Varying magnifications can be achieved (×10, ×12.5, ×16, ×20) using different eyepieces. Eyepiece selection not only determines the magnification, but also the size of the field of view. As with loupe spectacles, an indirect relationship exists between the magnification and the field of view. The 10× eyepiece generally provides a sufficient compromise between magnification and field of view. Modern eyepieces allow a correction facility within −8 to +8 diopters that is a purely spherical correction.

The majority of surgical microscopes are modules that can be equipped with attachments that include integrated video systems, photographic adapters for cameras, units for image storage, color printers, and powerful lighting sources. Prior to purchasing attachments, inexperienced clinicians should research what it is that they need. It is recommended that magnifying loupes are used prior to purchasing a microscope to become accustomed to working under magnification.

Lighting unit

Optimal illumination is necessary with high magnifications. The use of halogen lamps has become popular. These lamps provide a whiter light than lamps using conventional bulbs due to their higher color temperature. As halogen lamps emit a considerable portion of their radiation within the infrared spectrum, microscopes are equipped with cold-light mirrors to keep this radiation from the operation area. An alternative to the halogen light is the xenon lamp that functions for up to ten times longer than the halogen lamp. The light emitted has daylight characteristics with an even whiter color and delivers a brighter, more authentic image with more contrast.

Advantages and disadvantages of loupes and surgical microscopes

A substantial number of periodontists have adopted the use of low magnification in their practices and recognize its great benefits. Most results are based on subjective statements from patients or observations of the attending surgeons. At present, it can only be speculated how significantly the selection of magnification influences the result of the operation. The magnification recommended for surgical interventions ranges from ×2.5 to ×20 (Apotheker & Jako 1981; Shanelec 1992). In periodontal surgery, magnifications of ×4–5 for loupe spectacles and ×10–20 for surgical microscopes appear to be ideal depending on the type of intervention. As the depth of field decreases with increasing magnification, the maximum magnification for a surgical intervention is limited to about ×12–15 when dealing with a localized problem, for example coverage of a single soft tissue recession or interdental wound closure after a guided tissue regeneration of an infrabony defect. A magnification range of ×6–8 seems appropriate for clinical inspections or surgical interventions when the entire quadrant is under operation. Higher magnifications of ×15–25 are more likely required for the visual

examination of clinical details only, such as in endodontic interventions.

Advantages of loupes over the microscope are reduced technique sensitivity, expense, and learning phase. The lighting of the operation field is often insufficient, however, and this may limit the usefulness of magnifications above ×4.5. The surgical microscope guarantees a more ergonomic working posture (Zaugg *et al*. 2004), optimal lighting of the operation area, and freely selectable magnification levels. These advantages are countered by the increased expenses of the equipment and the extended learning phase for the surgeon and his/her assistant. In order to visualize lingual or palatal sites that are difficult to access, the microscope must have sufficient maneuverability. Developments have enabled direct viewing of oral operation aspects. By means of these optical devices, it will most likely be possible to perform all periodontal interventions with the surgical microscope.

Instruments

Technical aspects

Proper instrumentation is fundamental to microsurgical intervention. While various manufacturers provide sets of microsurgical instruments, these are generally conceived for vascular and nerve surgery and, therefore, are inappropriate for use in plastic periodontal surgery. Appropriate sets of steel or titanium instruments for periodontal surgery are available from different manufacturers. A basic set comprises a needle holder, microscissors, microscalpel holder, anatomic and surgical forceps, and a set of various elevators.

As the instruments are primarily manipulated by the thumb, index and middle finger, their handles should be round, yet provide traction so that finely controlled rotating movements can be executed. The rotating movement of the hand from 2 o'clock to 7 o'clock (for right handed persons) is the most precise movement that the human body is able to perform. The instruments should be approximately 18 cm long and lie on the saddle between the operator's thumb and the index finger, and also be slightly top heavy to facilitate accurate handling (Fig. 47-8). In order to avoid an unfavorable metallic glare under the light of the microscope, the instruments often have a colored coating surface. The weight of each instrument should not exceed 15–20 g (0.15–0.20 N) in order to avoid hand and arm muscle fatigue.

The needle holder should be equipped with a precise working lock that should not exceed a locking force of 50 g (0.5 N). High locking forces generate tremor, and low locking forces reduce the ability to sense movement. In order to avoid the thread slipping when tying a knot, the tips of the forceps have flat surfaces or can be finely coated with a diamond grain that improves the security with which the needle holder holds a surgical needle (Abidin *et al*. 1990).

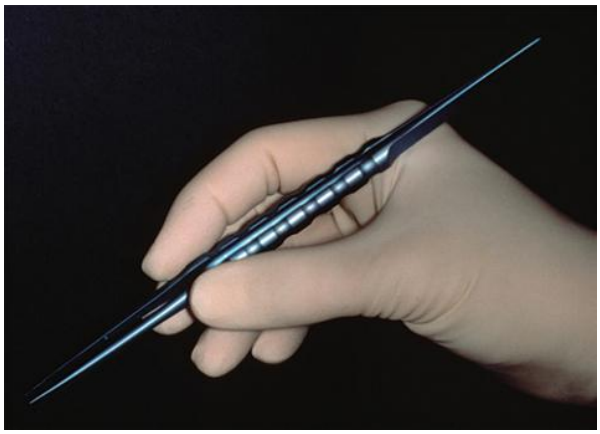

Fig. 47-8 Correct hand position for utilizing microsurgical instruments. Fine rotary movements using a pencil-like grip are needed for precise movements.

The configuration of the needle holder jaw has considerable influence on this security. Teeth on the tungsten carbide inserts provides the greatest resistance to either twisting or rotation of the needle between the needle holder jaws, but this benefit must be weighed against the potential damaging effects of the teeth on suture material. Smooth jaws without teeth cause no demonstrable damage to 6-0 monofilament nylon sutures, whereas needle holder jaws with teeth ($7000/in^2$) markedly reduced the suture breaking strength (Abidin *et al*. 1990). Additionally, the sharp outer edges of the needle holder jaws must be rounded to avoid breakage of fine suture materials (Abidin *et al*. 1989). When the needle holder jaws are closed, no light must pass through the tips.

Locks aid in the execution of controlled rotation movements on instrument handles without pressure. The tips of the forceps should be approximately 1–2 mm apart when the instrument lies in the hand without any pressure.

Various shapes and sizes of microscalpels can be acquired from ophthalmic or plastic surgery instrument sets and supplemented with fine instruments (fine chisels, raspatories, elevators, hooks, and suctions) from conventional surgery.

Microinstruments are stored in a sterile container or tray to protect them against damage. The tips of the instruments must not touch each other during sterilization procedures or transportation. The practice staff should be thoroughly instructed about the cleaning and maintenance of such instruments, as cleansing in a thermo disinfector without instrument fixation can irreparably damage the tip of these very expensive microinstruments.

Suture materials

Suture material and technique are essential factors to consider in microsurgery (Mackensen 1968). Wound closure is a key prerequisite for healing following surgical interventions and is most important for the avoidance of complications (Schreiber *et al*. 1975;

Kamann *et al*. 1997). The most popular technique for wound closure is the use of sutures that stabilize the wound margins sufficiently and ensures a proper closure over a defined period of time. However, the penetration of a needle through the soft tissue in itself causes trauma, and the presence of foreign materials in a wound may significantly enhance the susceptibility to infection (Blomstedt *et al.* 1977; Österberg & Blomstedt 1979). Hence, it is obvious that needle and thread characteristics also influence the wound healing and surgical outcome.

Characteristics of the needle

The needle consists of a swage, body, and tip, and can differ in terms of material, length, size, tip configuration, body diameter, and nature of the connection between needle and thread. In *atraumatic* sutures, the thread is firmly connected to the needle through a press-fit swage or fixed in a laser-drilled whole. There is no difference concerning stability between the two attachment modalities (Von Fraunhofer & Johnson 1992). The body of the needle should be flattened to prevent twisting or rotation in the needle holder. The needle tips differ widely depending on the specialty in which they are used. Tips of cutting needles are appropriate for coarse tissues or atraumatic penetrations. In order to minimize tissue trauma in periodontal microsurgery, the sharpest needles, namely reverse cutting needles with precision tips or spatula needles with micro tips (Fig. 47-9), are preferred (Thacker *et al*. 1989).

The shape of the needle can be straight or bent to various degrees. For periodontal microsurgery, the 3/8″ circular needle generally ensures optimum results. A wide range of lengths, as measured along the needle curvature from the tip to the proximal end of the needle lock, are available. For papillary sutures in the posterior area, needle lengths of 13–15 mm are appropriate. The same task in the front aspect requires needle lengths of 10–12 mm, and for closing a buccal releasing incision, needle lengths of 5–8 mm are adequate. To guarantee perpendicular penetration through the soft tissues, which prevents tearing, an asymptotic curved needle is advantageous in areas where narrow penetrations are required (e.g. margins of gingivae, basis of papillae). To fulfil these prerequisites for ideal wound closure, at least two different sutures are used in most surgical interventions. Table 47-2 serves as a basic guide to the selection of the appropriate suture material.

Characteristics of the thread

The thread may be classified in either *resorbable* or *non-resorbable* materials. Within these two categories, the materials can be further divided into *monofilament* and *polyfilament* threads. The bacterial load of the oral cavity also demands attention when choosing the suture material. Generally, in the oral cavity the wound healing processes are uneventful, thereby reducing the risk of infection introduced by contamination of the thread. As polyfilament threads are characterized by a high capillarity, monofilament threads are preferred (Mouzas & Yeadon 1975). *Pseudomonofilaments* are coated polyfilament threads that aim to reduce mechanical tissue trauma. During suturing, their coating breaks and the properties of the pseudomonofilament thread then correspond to those of polyfilament threads (Macht & Krizek 1978). However, fragments of the coating may invade the surrounding tissues and elicit a foreign body reaction (Chu & Williams 1984).

Resorbable sutures

Resorbable threads may be categorized as *natural* or *synthetic*. Natural threads (i.e. surgical gut) are produced from the intestinal mucosa of sheep or cattle. The twisted and polished thread loses stability within 6–14 days due to enzymatic breakdown (Meyer & Antonini 1989). Histologic examinations have confirmed inflammatory tissue reactions with a distinct infiltrate when using these threads. For this reason, use of natural resorbable threads is generally obsolete (Bergenholtz & Isaksson 1967; Helpap *et al*. 1973; Levin 1980; Salthouse 1980).

Synthetic threads have the advantage of constant physical and biologic properties (Hansen 1986). They are made from polyamides, polyolefines or polyesters that disintegrate on hydration

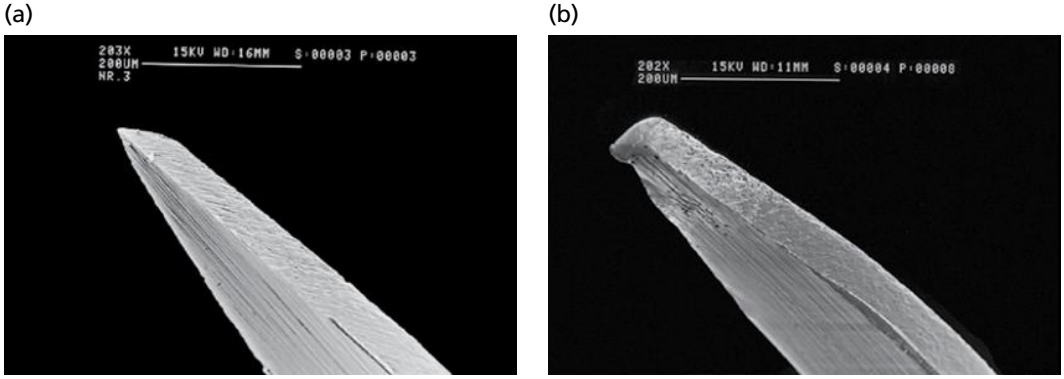

Fig. 47-9 (a) Intact sharp spatula needle. (b) Damaged needle tip after sticking it into the enamel surface.

Table 47-2 Ideal needle-thread combinations (non-resorbable) for use in periodontal microsurgery.

Indications	Suture strength	Needle characteristics	Thread materials	Product name
Buccal releasing incisions	7-0	3/8 curvature, cutting needle with precision tip, needle length of 7.6 mm	Polypropylene	Prolene®
	7-0	Asymptotic curved needle, cutting needle tip, round body, needle length of 8.9 mm	Polypropylene	Prolene®
	9-0	3/8 curvature needle, spatula needle, needle length of 5.2 mm	Polyamide	Ethilon®
Interdental sutures, front area	6-0	3/8 curvature, cutting needle with precision tip, needle length of 11.2 mm	Polypropylene	Prolene®
	7-0	3/8 curvature, cutting needle with precision tip, needle length of 11.2 mm	Polyamide	Ethilon®
Interdental sutures, premolar area	6-0	3/8 curvature, cutting needle with precision tip, needle length of 12.9 mm	Polyamide	Ethilon®
	6-0	3/8 curvature, cutting needle with precision tip, needle length of 12.9 mm	Polypropylene	Prolene®
Interdental suture, molar area	6-0	3/8 curvature, cutting needle, needle length 16.2 mm	Polyamide	Ethilon®
Crestal incisions	7-0	3/8 curvature, cutting needle with precision tip, needle length 11.2 mm	Polyamide	Ethilon®
	6-0	3/8 curvature, cutting needle with precision tip, needle length 12.9 mm	Polypropylene	Prolene®
Papilla basis incisions	7-0	Asymptotic curved needle, cutting needle tip, round body, needle length 8.9 mm	Polypropylene	Prolene®
	9-0	½ curvature, cutting needle with micro tip, needle length 8.0 mm	Polyamide	Ethilon®

into alcohol and acid. Polyester threads are mechanically stable and, based on their different hydrolytic properties, loose their firmness over different but constant times. A 50% reduction of breaking resistance can be expected after 2–3 weeks for polyglycolic acid and polyglactin threads, 4 weeks for polyglyconate, and 5 weeks for polydioxanone threads. The threads are available in twisted, polyfilament forms and monofilament forms when finer sutures are required. The capillary effect is limited and hardly exists for polyglactin sutures (Blomstedt & Österberg 1982).

Non-resorbable sutures

A commonly used material for fine monofilament threads (0.1–0.01 mm) that shows adequate tissue properties is polyamide. Tissue reactions seldom occur, except when errors occur in the polymerization process (Nockemann 1981). Polyolefines are inert materials that remain in the tissues and are not subjected to hydrolytic degradation (Salthouse 1980; Yu & Cavaliere 1983). Materials with excellent tissue properties are polypropylene and its newest further development, polyhexafluoropropylene. After suturing, the thread is encapsulated in connective tissues and maintains its stability for a longer period. Threads that are 5-0 and thicker are relatively stiff and, for that reason, may impact patient's comfort.

A substance with similar biologic, but improved handling, properties is polytetrafluoroethylene. Due to its porous surface structure, the monofilament threads should only be used in conjunction with measures to restrict bacterially loaded oral cavity.

Intraoral tissue reactions around suture materials

The initial tissue reaction after suturing is the result of trauma.If a resorbable suture remains *in situ* for >2 weeks after wound closure, an acute inflammatory reaction may continue. This phenomenon is caused by bacteria entering the stitch canal and penetrating along the thread (Chu & Williams 1984; Selvig *et al*. 1998). The reaction culminates on the third postoperative day (Selvig *et al*. 1998). It is comparable for resorbable and non-resorbable suture threads (Postlethwait *et al*. 1975). Histologically, this early response is characterized by three zones of tissue alteration (Selvig *et al*. 1998): (1) an intensive cellular exudation in the immediate vicinity of the entry of the stitch canal, followed by (2) a concentric area, harboring damaged cells as well as intact tissue fragments, and (3) a wide zone of inflammatory cells in the surrounding connective tissues.

A bacteriostatic effect of glycolic acid during the resorption process of polyglactin threads (Lilly *et al*. 1972) could not be established (Thiede *et al*. 1980), and the resorption of the polyglycolic thread was inhibited by the acid environment caused by the infection (Postlethwait & Smith 1975). Such studies confirm the increased risk for bacterial migration along the thread in the humid and bacterially-loaded oral cavity. Experimental and clinical data indicate that most wound infections begin around suture material left within the wound (Edlich *et al*. 1974; Varma *et al*. 1974). Polyfilament threads additionally facilitate the bacterial migration, and bacteria can also penetrate the inner compartment of the thread, which impairs the immunologic response of the host (Blomstedt *et al*. 1977; Haaf & Breuninger 1988). This is just one reason why monofilament, non-resorbable sutures are preferred and they should be removed at the earliest biologically acceptable time (Gutmann & Harrison 1991). The infectious potential can further be reduced by using an anti-infective therapy based on daily rinsing with or topical application of chlorhexidine (Leknes *et al*. 2005).

Another promising option to reduce the bacterial migration along the suture is coating it with a bacteriostatic substance. Vicryl® Plus (Ethicon®, Norderstedt, Germany) is a resorbable suture material coated with triclosan that inhibits bacterial growth for up to 6 days by damaging the membrane of the bacterial cells (Rothenburger *et al*. 2002; Storch *et al*. 2002).

Training concepts: Surgeons and assistants

The benefits of the operating microscope in periodontal surgery seem to be obvious. What then are the reasons for the delay in taking advantage of periodontal surgery under the microscope? The main reason is that most surgeons do not adjust to the surgical microscope and those who have been using microscopes successfully, have not made adequate in-depth practical recommendations to help other periodontal surgeons overcome their initial problems. Working under magnification changes the clinical settings as the visual direction during the surgical intervention does not meet the working ends of the instruments and the field of view has a smaller diameter. Additionally, the small size of the tissue structures and sutures threads requires movement to be guided by visual rather than tactile control. This altered clinical situation requires adjustment from the surgeon.

The three most common errors in the use of the surgical microscope are: (1) using magnification that is too high, (2) inadequate task sharing between surgeon and assistant, and (3) lack of practice.

High magnification

There is a tendency to use magnification which is too high. As described above, one of the fundamental optical principles is the higher the magnification, the narrower the field of vision and the smaller its depth. This concept is important because high magnification makes surgery more difficult, especially when it involves considerable movement. In these circumstances, low magnification of ×4–7 should be used. On the other hand, higher magnification of ×10–15 may be useful when dissecting within a small area and less movement is required, for example in papilla preservation techniques. In general, the magnification should be that which allows the surgeon to operate with ease and without increasing his/her usual operating time required for a particular surgical procedure. Surgical time does not have to be increased once the surgeon has adapted fully to the microscope. The more experienced and skilled the surgeon is with the microscope, the higher the magnification he/she can use with ease.

It may take 6 months or more for surgeons to become familiar with a magnification of 10×, which usually is the maximum used in plastic periodontal surgery. A point of diminishing return will eventually be reached where the advantages of magnification are outweighed by the disadvantages of a narrower field of vision.

Task sharing between surgeon and assistant (teamwork)

In microendodontics during root canal treatment, the whole procedure is performed with a minimum change in position changes by the operating persons. Focusing can easily be achieved by moving the mirror towards or away from the objective lenses. In periodontal surgery, both hands are used to hold the instruments and changes in position are more frequently required, which increase the demands on the operating team and require an ideal cooperation between surgeon and assistant.

In all surgeries, at least two operating persons are involved: a surgeon and an assistant, who assists the surgeon in the most rudimentary tasks of the operation. Among the tasks undertaken by the assistant, those that he/she performs for almost all operations and requiring varying levels of skill, should be considered: flap retraction, suction, rinsing and cutting the sutures. To guarantee a continuous work flow during the surgical intervention, a second assistant who organizes the instruments is frequently desirable.

In periodontal microsurgery, where inherently the surgeon has very little access, retraction is vital. The retraction should be done from different positions and must be devoid of all tremor or movement. This is an exceptionally strenuous task as the assistant is expected to maintain the same posture for a period of time which can extend to 1 hour. Fatigue experienced by the assistant will increase the chances of tremor as time goes by.

For optimal working conditions, the assistant also needs to view the operation under magnification. An assistant wearing loupes is also able to use open

peripheral vision to arrange the instruments and to check the patient's facial expression during the operation. On the other hand, the surgeon and assistant will only have the same view if co-observer tubes are used; the assistant is then able to point the suction tube to the right place and keeping the view clear; this is also an issue during suturing when the air intake of the suction tube can easily suck the fine threads.

Lack of practice

When working under high magnification, the surgeon has to adjust to the narrow field of vision with a new coordination between eye and hand. This adjustment comes only after much regular practice with simple surgical procedures. The practice unit consists of a microscope, microinstruments, and different suitable models. At the start of training, a two-dimensional model, such as a rubber dam, is appropriate for learning how to manipulate the instruments, pick up the needles, and tie knots. After the initial training, practicing on three-dimensional models (fruit, eggs, chickens) helps the surgeon become accustomed to the restricted depth of the field.

Another aim of training is to reduce tremor. Its physiologic basis is uncertain, but it is important to be aware of the causes in order to prevent it. An important factor is body posture, which must be natural, with the spinal column straight and the forearms and hands fully supported. An adjustable chair, preferably on wheels, is recommended for the surgeon who should place him/herself in the most comfortable position. Tremor varies between individuals and even in the same individual under different conditions. In some people, the intake of coffee, tea or alcohol may increase tremor; in others, emotions, physical exercises or the carrying of heavy weights can cause it.

After completion of an appropriate training during which instrument handling has become automatized, the surgeon can be said to have adjusted to the new conditions and will then be able to fully concentrate on the surgical procedure in clinical practice without requiring additional time.

Clinical indications and limitations

The clinical benefits of a microsurgical approach in periodontal practice have mainly been evaluated from case reports (Shanelec & Tibbetts 1994; Michaelides 1996; Shanelec & Tibbets 1996; de Campos *et al*. 2006) and case cohort studies (Cortellini & Tonetti 2001; Wachtel *et al*. 2003; Francetti *et al.* 2004). The procedures described were surgical coverage of buccal root recessions and flap closure after regenerative interventions. Both of these interventions have in common the manipulation during surgery of delicate soft tissue structures, which could be refined by selecting a less traumatic surgical approach. All of the studies confirmed the beneficial effects of the microsurgical approach. When covering a root recession, vascularization of the injured tissues becomes critical as there is no blood supply from the underlying root surface. Frequently, the coverage is performed by a connective tissue graft from the palate, which has different vascular characteristics compared to the supracrestal gingiva and is the only tissue, naturally created and specifically designed, that can survive and function over avascular root surfaces. As graft survival depends upon early plasmatic diffusion (Oliver *et al*. 1968; Nobutu *et al*. 1988), firm and stable flap or graft adaptation is of crucial importance to minimize the coagulum and facilitate the ingrowth of new vessels. A minimally traumatic approach allows a more precise flap preparation and suturing with a reduction in tissue and vessel injuries, resulting in faster and more complete anastomosis of new capillary buds from the recipient bed with the existing, but severed, vessels of the graft or the flap. There is strong evidence supporting the hypothesis that the mechanical properties of the extracellular matrices are important for capillary morphogenesis, while factors like pH (acidic condition), ionic strength, and other biochemical parameters primarily stimulate the proliferation and migration of endothelial cells (Nehls & Herrmann 1996).

The interdental gingiva is also a delicate tissue with a limited vascular network. As the gingival plexus does not extend interproximally, the central part of the interdental soft tissue is only supplied by vessels from the periodontal ligament space and arterioles that emerge from the crest of the interdental septa (Folke & Stallard 1967; Nuki & Hock 1974). These anatomic factors influence the wound healing capacity of the tissues after surgical dissection and the small size of the structures (i.e. papilla or col) complicates the precise adaptation of the flap margins. Therefore, wound dehiscences, resulting in healing at secondary intention, are a common finding after suturing the papilla in papilla preservation techniques (Tonetti *et al.* 2004). Using microsurgery to form a modified or simplified papilla preservation flap, primary wound closure could be noted in 92.3% of all treated sites 6 weeks after the intervention (Cortellini & Tonetti 2001).

Historical comparisons with studies performed by the same authors without the use of an operating microscope showed a clear advantage for the use of a microsurgical approach. Complete primary wound closure was observed in only 67% of the cases treated with a simplified preservation flap (Cortellini *et al*. 1999b), and in 73% of the cases treated with a modified papilla preservation flap (Cortellini *et al*. 1999a). These results clearly demonstrated the improvement in tissue preservation and handling using a minimally invasive approach to achieve primary closure of the interdental space (Fig. 47-10).

A cohort study evaluating a flap design for regeneration with enamel matrix derivatives [*minimally invasive surgical technique* (MIST)] combined with the microsurgical technique, confirmed the previous positive results with primary wound closure of the interdental tissues in all of the treated sites 6 weeks postoperatively (Cortellini & Tonetti 2007) (Fig. 47-11).

Subjective observations of clinicians have found there is a less traumatic approach in periodontal surgery when magnification aids and fine suture materials are used. These ensure passive wound closure in most surgical interventions. This speculation was substantiated by an *in vitro* experiment evaluating the tearing characteristics in mucosal tissue samples subjected to applied tension forces with sutures of different sizes and needles of different characteristics (Burkhardt *et al.* 2006). The pig jaw mucosal tissue samples were attached to a test-tearing apparatus of a Swiss textile company and the tension tearing diagrams were traced for 3-0, 5-0, 6-0, and 7-0 sutures with forces of up to 20 N. While the 3-0 sutures almost exclusively led to tissue breakage at an average of 13.4 N, the 7-0 sutures broke before tissues were torn in every instance at a mean applied force of 3.6 N. With 5-0 and 6-0 sutures, both events occurred randomly at a mean force of 10 N. This indicates that a clinician will influence the amount of damage to the tissue depending on his/her selection of a thick or thin suture material. Considering this fact, it may be speculated that wound dehiscence may be prevented and a passive flap adaptation may be improved by the choice of thinner sutures; this inevitably requires magnification if its benefits are to be fully appreciated.

Fig. 47-10 Primary closure of the buccal papilla after a crown lengthening procedure. Modified mattress suture (according to Laurell) with 7-0 polyamide thread (black) and two single knot closures with 8-0 polypropylene thread (blue).

Wound healing in periodontal and peri-implant defects following flap surgery is conceptually a more complex processes than wound healing in most other sites in the body due to fact that the wound is constituted of several interfaces of tissues that differ fundamentally in composition. While connective tissue flaps opposing vascular surfaces are more resistant to mechanical forces, blood clot adhesion to avascular surfaces like dentin, enamel, ceramic or titanium, seems to be impaired and this, therefore, leaves the wound interfaces more susceptible to tearing (Wikesjö & Nilvéus 1990; Wikesjö *et al*. 1991; Werfully *et al*. 2002). It is evident that control of flap tension requires careful attention and has to be controlled in situations where mechanical stability of the flap is required.

The role of flap tension in primary wound closure was recently investigated in humans (Burkhardt & Lang 2010). Sixty patients scheduled for single implant installation were recruited. Before suturing, the tensile forces on the flap were recorded with an electronic tension device. After 1 week, the wounds were inspected with regards to complete closure. While only a few (10%) wound dehiscences resulted for flaps subjected to minimal initial tension of 0.01–0.1 N, flaps subjected to higher closing forces (>0.1 N) yielded significantly increased percentages of wound

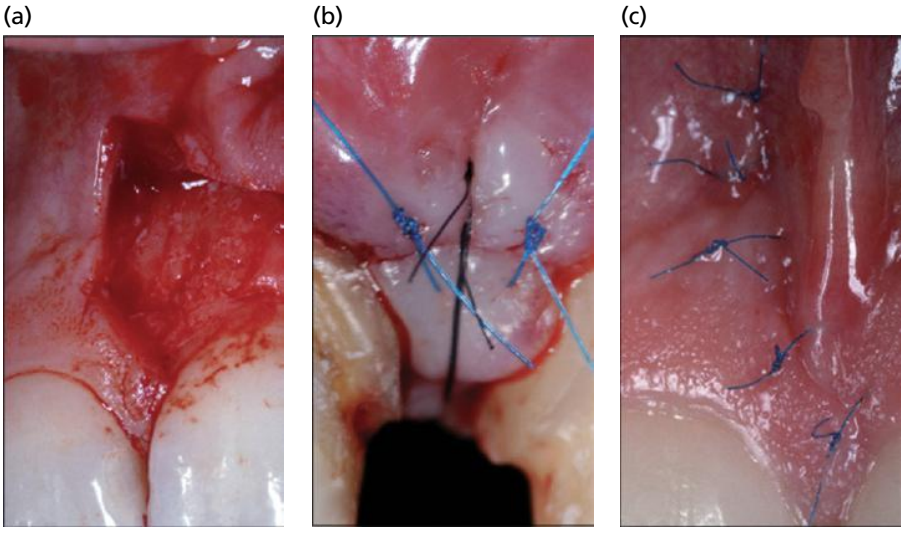

Fig. 47-11 Minimally invasive surgical technique (Cortellini & Tonetti 2007). (a) Suturing with 8-0 polypropylene thread (blue). (b) Clinical appearance 7 days postoperatively. (c) Clinical appearance of the releasing incision 4 days postoperatively.

dehiscences (>40%). This study also revealed that flaps with a thickness of >1 mm demonstrated significantly lower proportions of flap dehiscences at higher closing forces (>15 g) than thinner flaps (≤1 mm). This study supports the need to control closing forces at the wound margins. In order to minimize tissue trauma, the use of finer suture diameters and magnification aids may be helpful owing to the fact that thinner sutures (6-0, 7-0, 8-0) tend to break rather than tear tissue (Burkhardt *et al*. 2006).

Opponents of periodontal microsurgery often mention the adverse effect of a prolonged intervention time when working with microscopes. It has been shown that the incidence and severity of complications and pain following periodontal surgery correlate closely with the duration of the surgical procedure (Curtis *et al*. 1985). It can be speculated that an extended operation time may counter the beneficial treatment effect of minimally invasive techniques. However, studies comparing micro- and macrosurgical approaches do not support this concern (Burkhardt & Lang 2005).

Considering all these facts, there are no clinical contraindications for the use of magnification in periodontal surgery. From a user's point of view, a few aspects in the oral cavity are difficult to access with an operating microscope. In these circumstances and in surgical interventions which require a frequent change of position, the use of loupes may be preferable.

Comparison to conventional mucogingival interventions

Today's *plastic periodontal surgery,* evolving from *mucogingival surgery*, includes all surgical procedures performed to prevent or correct anatomic, developmental, traumatic or disease-induced defects of the gingiva, alveolar mucosa or bone (Proceedings of the 1996 World Workshop on Periodontics 1996). To verify the beneficial effects of a microsurgical approach, the results with a conventional technique in all the different indications have to be evaluated first. The variables to be used as descriptors of the therapeutic end point of success may vary, depending on the specific goal of the mucogingival therapy. Some results, such as volume changes after ridge augmentation procedures, are clinically difficult to assess due to a lack of a defined end point and therefore are documented in the literature by qualitative measurements only. Plastic surgical interventions with clearly defined landmarks for measurement, and thus well investigated in the literature, are guided tissue regeneration procedures (Needleman *et al*. 2006) and coverage of buccal root recessions (Roccuzzo *et al*. 2002; Clauser *et al*. 2003; Oates *et al*. 2003; Pagliaro *et al*. 2003; Cairo *et al*. 2008). While the former results in a reduction in probing measures, improved attachment gain, and less increase in gingival recession compared to open flap debridement, the latter yields a significant reduction in recession depth and also improvement in clinical attachment level measures. However, there is a marked variability between the studies, indicating the influence of case selection, materials used, applied techniques, and surgeon's dexterity. As a result, it is difficult to draw general conclusions because the factors affecting the outcomes are unclear from the literature and may include study conduct issues such as bias. Among these factors, the dexterity of the surgeon ranks high and seems to strongly influence the results. Dexterity is a complicated, proprioceptive reflex involving the eye, hand, and brain, and therefore is difficult to assess in clinical settings. To eliminate its influence and to estimate the magnitude of the real benefits of a microsurgical approach, micro- and macro-surgical techniques need to be compared in controlled studies.

Concerning the coverage of mucosal recessions, a comparison between the two approaches (micro- and macro-surgery) was performed in a randomized controlled clinical trial (Burkhardt & Lang 2005). The study population consisted of 10 patients with bilateral class I and class II recessions at maxillary canines. In a split-mouth design, the defects were randomly selected for recession coverage with either a microsurgical (test) or macrosurgical (control) approach. Immediately after the surgical procedures and after 3 and 7 days of healing, fluorescent angiograms were performed to evaluate graft vascularization. The results at the test sites revealed vascularization in 8.9 ± 1.9% immediately after the procedure. After 3 days and after 7 days, this had risen to 53.3 ± 10.5% and 84.8 ± 13.5%, respectively. The corresponding results at control sites were 7.95 ± 1.8%, 44.5 ± 5.7%, and 64.0 ± 12.3%, respectively (Fig. 47-12). All the differences between test and control sites were statistically significant. In addition, clinical parameters were assessed before the surgical intervention, and 1, 3, 6, and 12 months postoperatively. Mean recession coverages of 99.4±1.7% for the test and 90.8±12.1% for the control sites were seen after the first month of healing. Again, this difference was statistically significant. The percentage of root coverage at both test and control sites remained stable during the first year at 98% and 90%, respectively.

This clinical study clearly demonstrated that mucogingival surgical procedures designed for the coverage of exposed root surfaces and performed using a microsurgical approach, improved the treatment outcomes substantially and to a clinically relevant level when compared with the clinical performance under routine and macroscopic conditions. However, the choice of micro- and macro-surgical approaches must consider not only treatment outcomes, but also logistics, cost, and patient-centered parameters. Future comparative studies will provide the evidence as to whether or not the use of the surgical microscope will further increase surgical effectiveness and thus become an indispensable part of periodontal surgical practice.

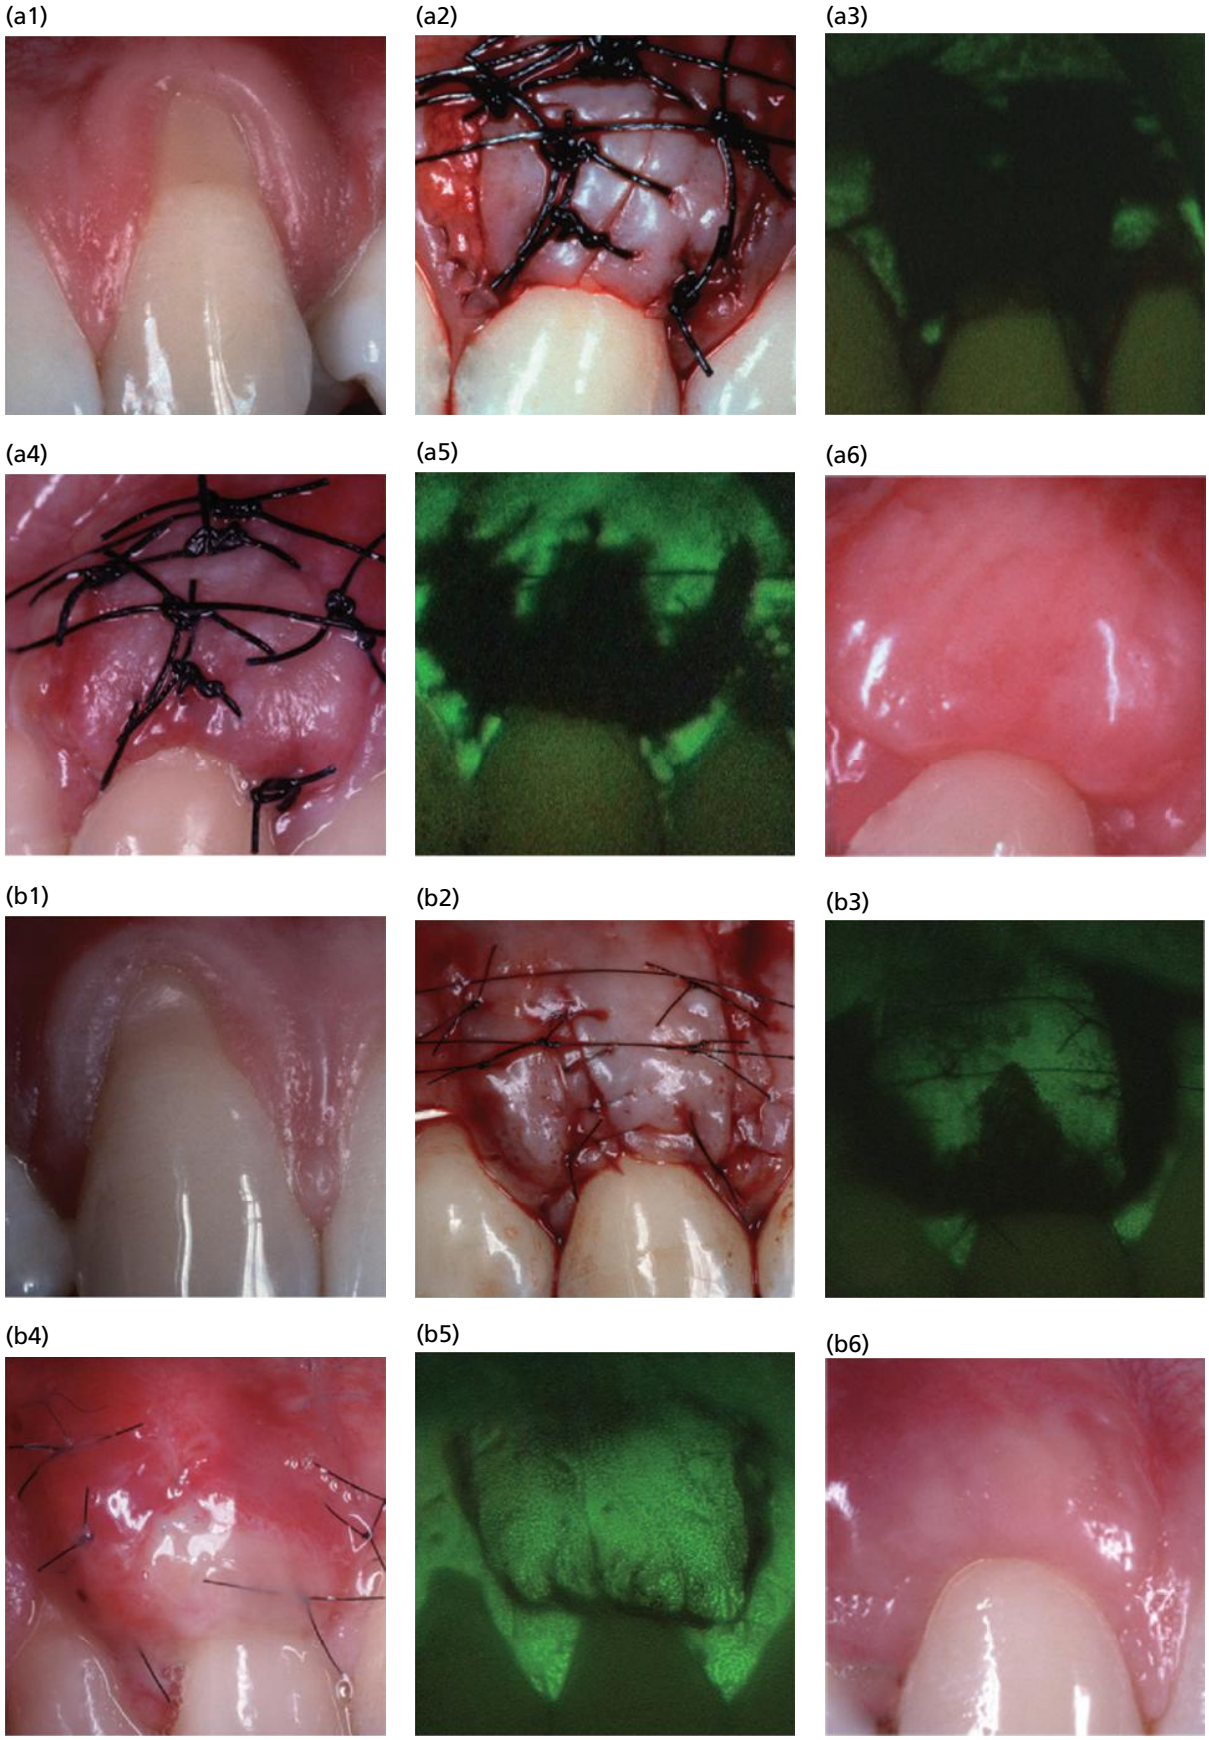

Fig. 47-12 Recession coverage: comparison of macro- and micro-surgery (Burkhardt & Lang 2005). (a) Macrosurgical recession coverage. (a1) preoperative clinical photograph; (a2) immediately after the surgical intervention; (a3) angiographic evaluation immediately after the intervention; (a4) healing after 7 days; (a5) angiographic evaluation after 7 days; (a6) clinical photograph at 3 months (visible contours of incision lines). (b) Microsurgical recession coverage: (b1) preoperative clinical photograph; (b2) immediately after the surgical intervention; (b3) angiographic evaluation immediately after the intervention: (b4) healing after 7 days; (b5) angiographic evaluation after 7 days; (b6) clinical situation after 3 months (no traces of the intervention visible).

Chapter 48

Piezoelectric Surgery for Precise and Selective Bone Cutting

Stefan Stübinger[1] and Niklaus P. Lang[2,3]

[1]Center for Applied Biotechnology and Molecular Medicine (CABMM), Vetsuisse Faculty, University of Zurich, Zurich, Switzerland

[3]Center for Dental Medicine, University of Zurich, Zurich, Switzerland

Background and physical principles

The oscillating sound pressure wave of ultrasound is above the upper human audible level (30–20 KHz). The use of ultrasonics has now largely established itself in periodontology (Flemming *et al*. 1998; Lea *et al*. 2003) and endodontics (Walmsley *et al*. 1992). The first results of ultrasound-assisted periodontal therapy date back to 1955 (Zinner 1955). High-frequency sound waves were used for mechanical debridement of dental hard tissues (Catuna 1953). Clinically, clear advantages for ultrasonic waves in calculus removal were seen compared to conventional scaling (Johnson & Wilson 1957). Certain beneficial effects were also demonstrated for removal of root canal fillings and fractured instruments from root canals using ultrasonic waves (Walmsley *et al*. 1990).

By converting electrical energy into ultrasonic waves, usually by magnetostriction or piezoelectricity, ultrasound can be used for thermal, mechanical, and chemical applications. Whereas magnetostriction alters the physical dimensions of a material in a magnetic field, piezoelectricity is based on the so-called piezo effect. French physicists Jean and Marie Curie first mentioned this effect in 1880 (Hoigne *et al*. 2006). They described the development of an electric current on the surface of certain crystals and many substances when subjected to mechanical strain. The reversion of this effect, which occurs when crystals are deformed under an electric current, was discovered a while later.

An alternating voltage applied to a polarized crystalline piezo-ceramic causes expansion in the direction of polarity and, perpendicular to it, contraction of the material. This vibrating movement and behavior of the crystals lead to oscillation at a specific frequency and amplitude (Stübinger *et al*. 2005). The transmission and reflection of this oscillating beam can be used in medical imaging, and its detection and measurement from tissues inside the human body gives useful information. The specific acoustic impedance of the permeated tissues causes beam diversification at their boundaries through a complex interaction of absorption, reflection, refraction, diffusion, and diffraction (Bains *et al*. 2008).

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Technical characteristics of piezoelectric bone surgery

The use of piezoelectric physical process was effectively applied in dentistry for ablation and abrasion of hard tissue by Catuna (1953). A few years later, the use of traditional ultrasonic vibration technology for cutting mineralized tissue was studied in animals (Mazorow 1960; McFall 1961; Horton *et al*. 1975, 1981).

Horton *et al.* (1981) demonstrated that ultrasound-based osteoplastic surgery safely and precisely removed hard tissue with little intraoperative interference from bleeding. The same group also demonstrated histologically that ultrasonic osteotomy of buccal alveolar process defects in dogs showed a favorable healing tendency in comparison to when this was performed with a low-speed rotary cutting bur. Even though the osteotomy sites cut with a rotary bur revealed the smoothest bone surface, bone healing after ultrasonic osteotomy was enhanced.

However, all these studies using magnetostrictive ultrasonic instruments did not result in any clinical applications due to the limits of the technology. In order to overcome these technological limits, Vercellotti *et al*. (2001a) conducted research to develop a new clinically effective ultrasonic and sonic piezoelectric bone-cutting instrument in animals, called Piezosurgery®. In 2000, the first human clinical study introducing the Piezoelectric Bone Surgery procedure was published (Vercellotti 2000). This well-accepted and revolutionary surgical method was introduced in a split ridge split case report in which the edentulous ridge was so narrow that it had previously not been possible to cut it using other cutting instruments and at the same time maintain its integrity.

Today piezosurgery represents an innovative bone-cutting technique based on the use of microvibrations at a specific ultrasonic frequency modulated by sonic waves (Fig. 48-1). After a short learning curve, the cutting effectiveness of piezosurgery is comparable to that of other bone-cutting instruments, but in addition it offers greater control in the handling of small and delicate bone fragments.

The piezoelectric cutting action is the result of bone micronization produced by mechanical shock waves that vibrate in a linear manner at a sonic and ultrasonic frequency (from 30 to 30 000 Hz). The reduced vibration amplitude (20–80 µm) of the cutting tips is the main reason for the most interesting surgical characteristics: selective cutting action, precision, intraoperative control, and safety. The selective cutting action is a result of the limited amplitude of the mechanical microvibrations: at these amplitudes only mineralized tissue can be cut and damage to soft tissue is avoided because of their elasticity. The ultrasonic technology to cut soft tissues requires higher frequencies >50 kHz (Labanca *et al.* 2008).

Moreover, the mechanical micro-movements at a frequency of about 24–30 kHz generates a cavitation effect in the irrigation solution, which reduces intraoperative overheating and bleeding, thus increasing surgical visibility and safety, and facilitating healing mechanisms.

Fig. 48-1 Mectron Piezosurgery® device.

Application of piezosurgery

While the piezoelectric device commonly has a similar design to that of conventional surgical hand pieces, due to the different cutting principle with this device, the surgeon still needs to be trained in its operation. While Salami *et al*. (2010) found that especially well-trained otologic surgeons do not need any defined learning period before successfully performing straight osteotomy lines using piezosurgery, they still concluded that, "an audited training period should exist for all surgeons who undertake the piezoelectric device for the first time".

For ultrasonic osteotomy, the optimal rake angle between the piezoelectric device and the orthogonal preparation axis is 0–10° (Khambay & Walmsley 2000). Outside this angle range, both cutting performance and precision fall off in quality. In contrast to rotating burs, increasing the manual pressure exerted on the piezoelectric device does not accelerate the cutting speed. Rather, with increased manual pressure the cutting tip is no longer able to operate freely and its vibration is massively constrained, resulting in overheating. Furthermore, increased manual pressure will diminish haptic sensitivity and fragile bone as well as soft tissue structures are commonly iatrogenically damaged as a result. Thus, great care needs to be taken when applying contact pressure. Periodic interruptions will slow the cutting vibrations and are particularly recommended when performing comprehensive and deep cuts (Robiony *et al*. 2004). Such intervals also give the surgeon the opportunity to refine the most appropriate osteotomy design with superior levels of precision and tissue protection.

In terms of both dexterity and tactile sensitivity, piezosurgery offers certain advantages. In micrometric osteotomy, easy handling with increased maneuverability is achieved with reduced contact pressure and macro-vibrations. Reduced contact pressure supports this effect. Thereby, not only is accidental trauma to adjacent soft tissue structures reduced, but also the invasiveness of the surgical procedure can be minimized. There is no need to supplement the applied force to balance the rotation or oscillation of the instrument so as to avoid tissue damage from lack of control. In contrast, a bone bur rotating at a speed of about 20 000 rpm applies approximately 320 shock waves/minute, and generates macrovibrations that reduce precision and intraoperative control. In fact, during the cutting action, the surgeon must exert a pressure on the hand piece in the order of several kilograms. Together with the small and sophisticated cutting tips, ultrasonic microvibrations reduce the chipping effects at the osteotomy rims. Spalling of brittle mineralized hard tissue structures is marginal and only occurs in exceptional cases of forced insert tilting or lever movements by the surgeon.

Thus, delicate handling and practical experience are vital to maximizing the advantages of piezosurgery. Only then can very precise cuts be made in anatomically difficult-to-reach areas or previously inaccessible locations. In this regard, the acoustic feedback from the cutting process allows the most suitable operating pressure to be defined for the treatment of cortical or cancellous bone structures.

Bone quality as well as the physical characteristics of the working tip have a tremendous influence on the mode, shape, and magnitude of the oscillation. Claire *et al*. (2013) explored the effect of the oscillation patterns of a universal OP3 piezosurgery tip on morphologic cutting characteristics. Qualitatively, cutting of cortical bone produced a narrow defect with a clear bony demarcation of the cut as compared to cancellous bone. Physical loads of up to 100 g on the working tip were found to be ideal for cortical bone; a 200-g load significantly decreased tip oscillation. This effect with increasing load was not seen for spongious bone. The lower limit of the load must also be carefully considered, as when too low the tip starts to slide across the surface of the bone and as a result the sharpness of the incision will be lost and osteotomy margins will be irregular (Romeo *et al*. 2009).

Clinical and biologic advantages of piezosurgery

Execution of osteotomies with marginal tissue damage and low blood loss promotes optimal healing conditions in the postoperative phase. The associated reduction of pain and swelling will improve patient comfort. Furthermore, the constant and adjustable irrigation cooling gives a clear intraoperative view, allowing precise removal of blood and cutting debris. Ultrasound-induced cavitational bubble activity in the liquid irrigation solution additionally facilitates visibility around the osteotomy site (Fig. 48-2).

Fig. 48-2 Cavitation effect of saline solution gives good intraoperative visibility.

Beyond the technical precision of piezosurgery, however, biologic outcomes, including prevention of bone necrosis and thermal or mechanical injury to adjacent tissues, are of utmost importance. Especially in the wake of the trend toward less invasive surgery with advanced precision and less accidental damage, piezosurgery offers a safe technique that avoids overheating and tissue trauma. Surgical stress has a great influence on the viability of cells and the regeneration processes following trauma. For this reason, any manipulation of bone should be as atraumatic as possible to stimulate a fast and unimpeded healing.

In a series of different *in vitro* and *in vivo* studies, several authors have demonstrated that piezoelectric bone cutting does not impair bone remodeling or cell viability. Chiriac *et al*. (2005) analyzed the morphology, viability, and differentiation of cells growing out of the bone chips generated by piezoelectric surgery or use of a conventional rotating drill. The bone chips were mainly from cortical donor sites. The authors demonstrated that autogenous bone chips harvested from both piezoelectric surgery and use of a conventional drill contained vital cells that differentiated into osteoblasts *in vitro*. Overall, they did not find any significant differences between the viability of the chips harvested using the two methods.

von See *et al*. (2010) performed further analyses on the viability of endochondral (femoral) and membranous (mandibular) bone cells harvested from piezoelectric surgery, compared to those harvested with a rotating drill or a scraper. Morphometric evaluation showed a smooth surface after the use of the drilling device or the piezoelectric device. In contrast, small cracks and an irregular bone surface were seen following use of the scraper method. Overall, endochondral and membranous osteoblast proliferation did not show any differences between the harvesting methods; however, cell count showed significantly more osteoblast-like cells in specimens harvested with a scraper or piezoelectric device than with a bur. Therefore, the osteogenic potential of autogenous

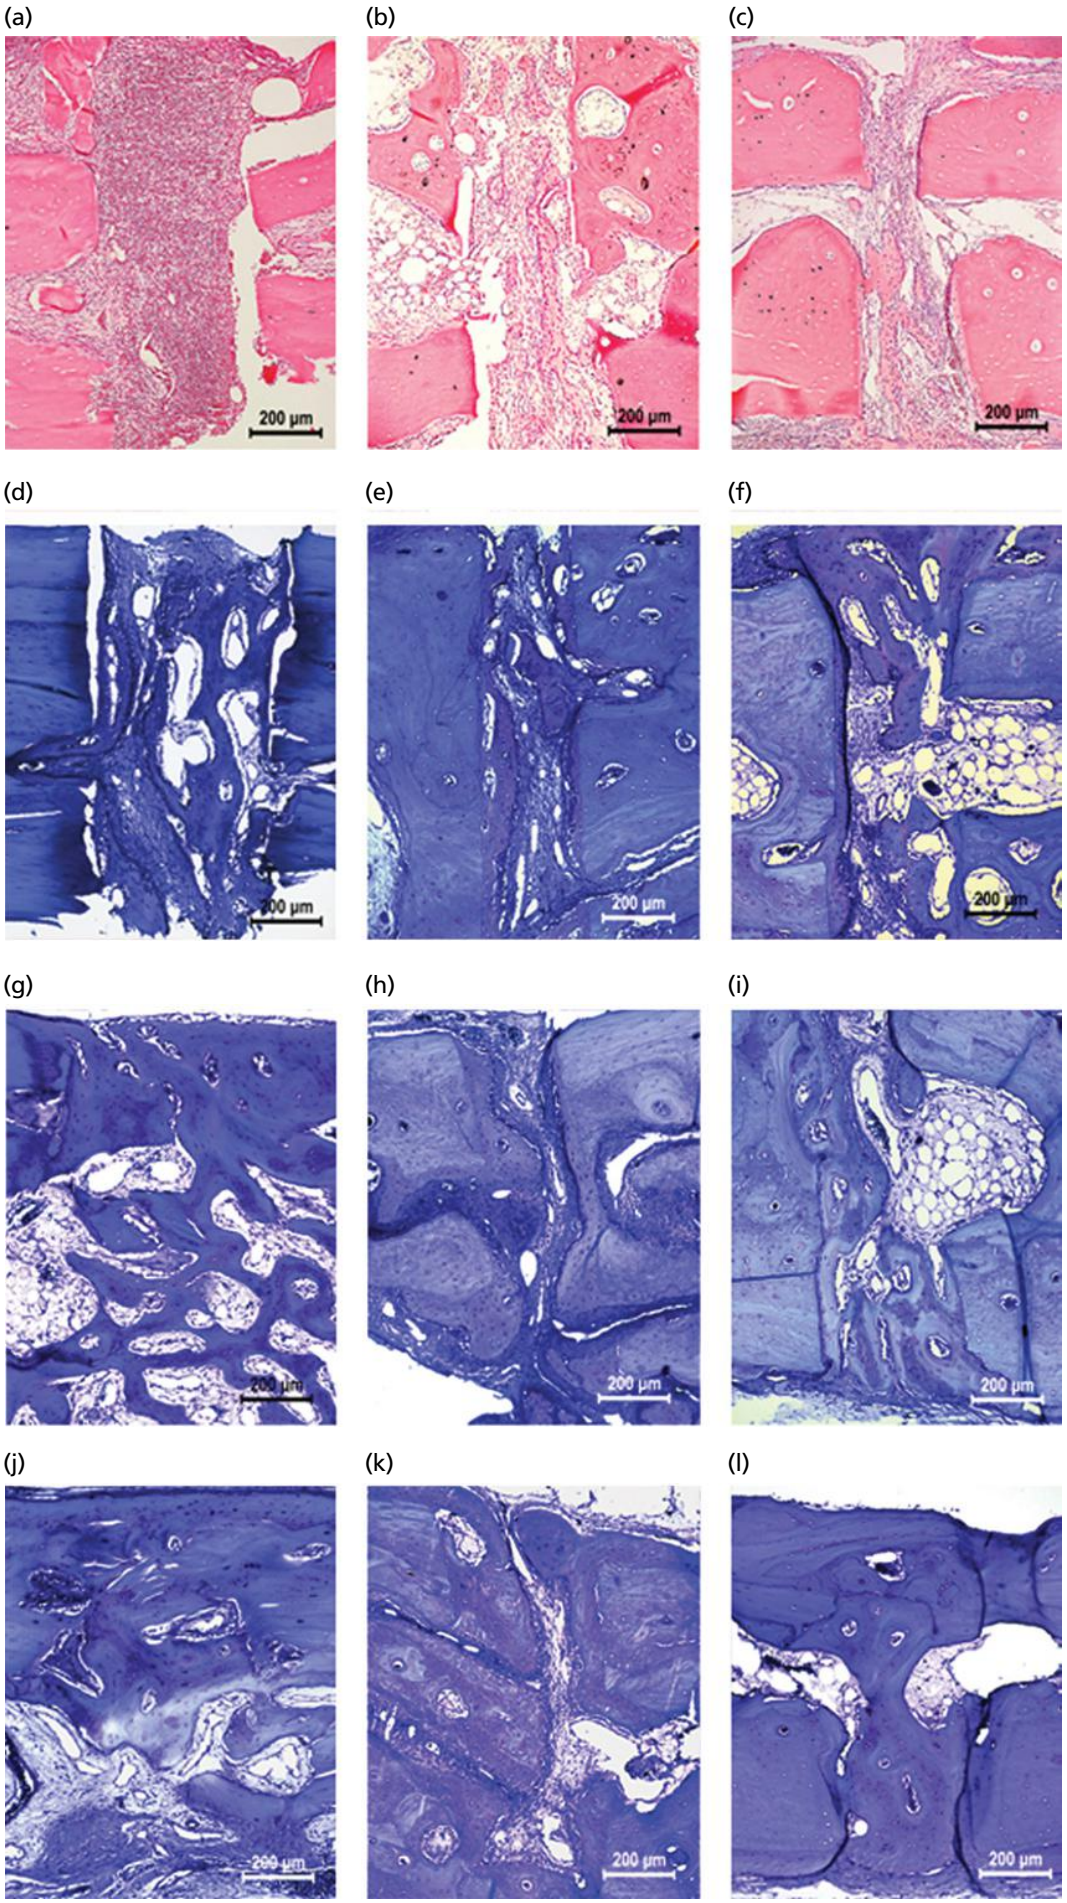

Fig. 48-3 Summary of histologic results following osteotomies performed with piezosurgery (a, d, g, j), a novel saw blade (b, e, h, k), or a conventional saw blade (c, f, i, l). (a–c) Specimens after 1 week were stained with hematoxylin and eosins to clearly identify the soft tissue structures and matrix in the early healing phase. (d–f) Specimens after 2 weeks, (g–i) 3 weeks, and (j–l) 5 weeks were stained with toluidine blue to evaluate new bone formation and bone remodeling. All three osteotomy techniques showed characteristic gap healing with bridging of the osteotomy site with immature and woven bone in the initial healing stage. After 5 weeks, all techniques revealed an advanced remodeling with lamellar structures (Reproduced with permission of Springer.).

bone harvested by piezosurgery appears promising for any regenerative procedure.

Concerning heat generation in close vicinity to the osteotomy gap and the corresponding biologic tissue reactions, Heinemann *et al.* (2012) compared different sonic and ultrasonic systems with conventional rotary burs in fresh porcine jaw segments. Even though histologic investigations indicated intact osteocytes adjacent to the osteotomy rims with all three instruments, piezosurgery showed the highest temperature rise (18.17° C). In contrast to sonic surgery, the walls of the funnel-shaped piezoelectric osteotomy sites showed a conspicuous stained defect zone of about 30 µm at the lateral aspect. Additionally, a clear undulation of the trabecular bone structure could be observed. In a further cadaver study in sheep mandibles, Metzger *et al*. (2006) found that the "pneumatic hammer"-effect of the piezoelectric device produced a significantly rougher surface with loosened bone edges and a defect zone of about 170 µm, in comparison to a conventional rotary bur.

Vercellotti *et al.* (2005) evaluated histologically the reparative potential and osseous response following resective periodontal piezoelectric ostectomy and osteoplasty in a dog model. After elevation of full-thickness mucoperiosteal flaps and soft tissue degranulation, about 4 mm of bone was removed from around each tooth by applying randomly either piezosurgery, a carbide bur, or a diamond bur. Whereas in the early (14 days) as well in the late (56 days) wound healing phase, both bur groups revealed a certain histologically detectable bone loss, the group subjected to piezoelectric bone surgery demonstrated a slight mean gain in bone level at both time points. Based on their results, the authors suggested that piezosurgery might be highly beneficial for the physiologic restructuring of the osseous architecture of the alveolar crest after resective periodontal therapy.

In a further experiment in rabbit skulls, Ma *et al*. (2013) compared bone healing following osteotomies performed with either piezosurgery or with two different oscillating saw blades. After 1 week, the osteotomy gap in the piezoelectric group showed a large number of inflammatory cells, a high degree of vascularized tissue structures (72.8%), and provisional matrix (21.8%). In some cases, small and scattered islands of the start of centripetal osteoid formation could be observed near the osteotomy rims. After 2 weeks, the gap was mostly filled with a mixture of immature woven bony structures, and the amount of new osteoid and mineralized bone tissue had increased. After 5 weeks, the osteotomy gaps had almost completely filled with newly formed bone with a high degree of mineralization. Consolidation of the osteotomy gap was in many cases almost complete and in some cases new bone structures revealed a lamellar orientation (Fig. 48-3). The same group demonstrated similar results with piezoelectric osteotomy in a sheep tibia model (Stübinger *et al*. 2010a). Three months after piezoelectric osteotomy, advanced bone remodeling with the distinct formation of lamellar bone was seen. The original mid-shaft osteotomy line marked the border for healing with early-stage longitudinal alignment of remodeled lamellar bone.

Fig. 48-4 IM2 insert to obtain pilot osteotomy with the ultrasonic implant site preparation technique (UISP).

Piezoelectric implant site preparation

In addition to conventional osteotomy, piezosurgery can also be used for implant site preparation (Vercellotti *et al*. 2014). This application, however, calls for special surgical tips with an adapted shape and geometry to allow a symmetrical implant hole to be drilled with minimal thermal and mechanical damage to the bone (Fig. 48-4).

Preti *et al.* (2007) analyzed neo-osteogenesis and inflammatory reactions after implant site preparation using either piezosurgery or a conventional drill. The authors evaluated the levels of bone morphogenetic protein-4 (BMP-4), transforming growth factor-beta 2 (TGF-ß2), tumor necrosis factor-alpha (TNF-α), and interleukin-1 beta (IL-1ß) and IL-10. Notably in the early phase (7–14 days), piezoelectric implant sites revealed more newly formed bone with larger amounts of osteoblasts. Except for IL-1ß and TNF-α, levels of BMP-4, TGF-ß2, and IL-10 were increased in the piezoelectric group at this time period. Overall, piezoelectric bone surgery was more effective in stimulating peri-implant osteogenesis with a clear reduction in pro-inflammatory cytokines. Similar good biologic and biomechanical results for piezoelectric implant site preparation have been reported in a pelvic sheep model (Stübinger *et al.* 2010b).

Clinical applications of piezoelectric surgery

The results of several experimental and clinical studies investigating bone healing and biologic behavior of hard and soft tissue structures following piezoelectric osteotomy provide a sound clinical basis for the clinical application of piezoelectric surgery. However, in spite of the proven and obvious advantages of piezosurgery, individualized patient medical care and the experience of the surgeon are of vital importance

in determining the surgical outcome and overall acceptance by the patients.

One of strongest criticisms of piezosurgery is the time-consuming nature of the technique. As the surgeon cannot accelerate piezoelectric cutting by advanced manual customization, which usually is a practicable scheme for conventional drilling devices, the overall efficiency is dependent on the preselected power settings. Therefore, when removing large amounts of bone, the combined use of piezosurgery with conventional high-speed drills is an approved and advocated approach.

Nonetheless, the intraoperative safety of piezosurgery makes it the preferred technique in all types of bone surgery. The use of autologous bone to correct and reconstruct bony defects is still a widely preferred and approved method to replace lost bone volume. Harvesting of bone fragments *en bloc* as well as particulate bone has certain advantages in different clinical indications. However, the regenerative capability of harvested bone fractions and the harvesting technique demand specific surgical and technical requirements if a successful treatment outcome is to be guaranteed (Berengo *et al.* 2006; Bacci *et al.* 2011). Whereas conventional rotating or oscillating devices allow easy and fast harvesting of block grafts, their use in harvesting bone chips is more limited. For collecting an adequate amount of particulate bone, scrapers show superior performance, but osteotomy of complete bone structures is not possible with these instruments. Piezosurgery overcomes these limitations as custom-designed cutting tips allow an individualized surgical approach depending on the situation. Shape, width, and thickness of piezosurgical tips are optimized for typical and common intraoral applications using adjusted power settings. For this reason, piezoelectric technology is used widely in routine dental surgery (Fig. 48-5).

Piezosurgery had gained a wide acceptance in implant dentistry for maxillary sinus elevation, bone grafting, lateralization of the inferior alveolar nerve, alveolar ridge expansion, and orthodontic microsurgical osteotomies.

Sinus floor elevation

In oral surgery, and particularly in implant dentistry, the need for micrometric, selective cutting makes piezosurgery an ideal and less invasive method, especially for maxillary sinus elevation. The technique of maxillary sinus floor elevation is used to rehabilitate the edentulous posterior maxilla with implant-borne prostheses when there is insufficient bone volume due to the reduced height of the residual edentulous ridge. The clinical success of implants placed in the bone-grafted maxillary sinus is similar to that reported for implants placed in pristine bone (Pjetursson *et al.* 2008). An essential condition for this is that the surgical technique is performed correctly at each step. The most frequent complication in standard sinus lift surgery using conventional drilling devices is perforation of the Schneiderian membrane, which can occur both during the access osteotomy and during elevation maneuvers. Bone grafting performed in the presence of a perforation is, most of the time, responsible for an inflammatory complication during the healing period, which may require re-intervention. To reduce the risk of perforation, Vercellotti *et al.* (2001b) studied a new surgical protocol using piezoelectric surgery. The study sample showed a clear reduction in the rate of membrane perforation (5%). Even though this was a pilot study in a small number of patients, its results can be regarded as promising. To avoid any accidental, iatrogenic tearing or perforation of the Schneiderian membrane, specific blunt cutting tips secure an effective osteotomy with preservation of the underlying delicate sinus soft tissue structures (Fig. 48-6).

Even though most studies report clinically favorable results using piezosurgery for the access osteotomy and loosening the membrane, some studies have shown no clear surgical benefit for the piezosurgical approach (Rickert *et al.* 2013). The latter, however, should not deter surgeons from routinely using piezosurgery for maxillary sinus elevation (Fig. 48-7).

The lateral window technique is probably the most established and approved application of piezosurgery, although other approaches, including from

Fig. 48-5 OT8R insert cutting action to simplify the bony block osteotomy and reduce soft tissue damage.

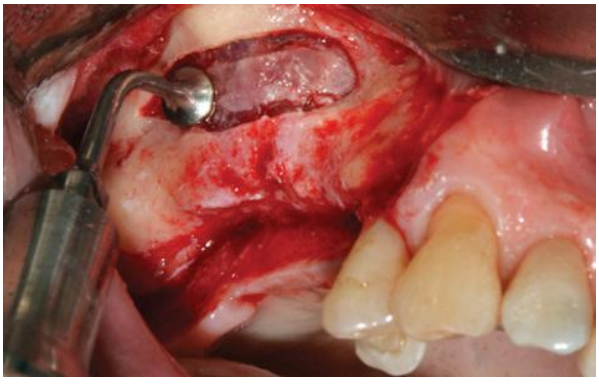

Fig. 48-6 EL1 insert for sinus membrane separation following use of the safe piezoeletric bony window osteotomy technique.

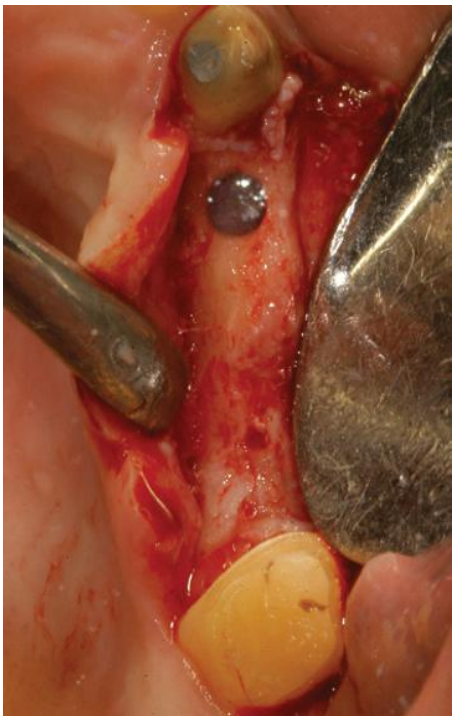

Fig. 48-7 Sinus lift crestal approach using the piezosurgery OT9 tip to preserve the Schneiderian membrane.

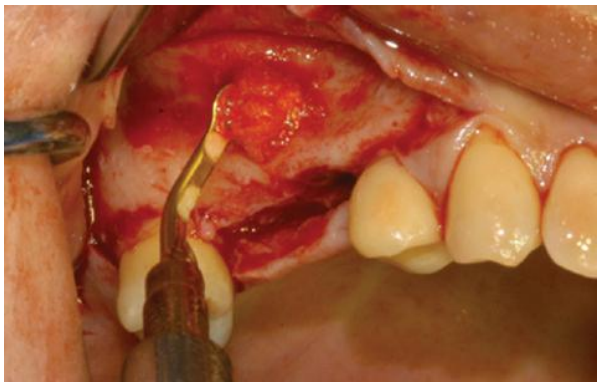

Fig. 48-8 Lateral sinus wall osteoplasty using the OP3 insert to reduce the bony wall thickness for a safer antrostomy technique and simultaneous bone chip harvesting.

the crestal and palatal sides, have been described (Stübinger *et al.* 2009; Baldi *et al.* 2011; Cassetta *et al.* 2012). Notably, the thin and precise cutting with piezosurgery allows proper repositioning of the lateral window lid into the former defect site (Sohn *et al.* 2010). This surgical procedure facilitates graft stabilization when particulate augmentation techniques are used to fill the sinus cavity. Use of a shielding membrane can then in many cases be regarded as facultative or even dispensable. A further advantage of piezosurgery is that, as well as opening the bony window, particulate bone can be simultaneously harvested from the adjacent surface of the edentulous ridge in a scraping–pulling fashion (Stacchi *et al.* 2013). The autologous bone material can then be used either alone or in combination with various biomaterials (Fig. 48-8). With slight variations in the overall osteotomy design, numerous authors have highlighted and supported the effectiveness and success of piezoelectric sinus grafting (Wallace *et al.* 2007; Cortes *et al.* 2012; Wallace *et al.* 2012).

Bone grafting

Rehabilitation of fully and partially edentulous patients by means of endosseous implants has proven to be a predictable treatment option with convincing long-term results (Adell *et al.* 1990; Blanes *et al.* 2007). Yet, a major precondition for the success and sustainability of dental implants is the availability of enough and adequate residual bone volumes. Several techniques for ridge augmentation have been promoted to overcome the problem of insufficient bone volume at the implantation site. In this regard, autogenous bone grafts from the chin or ramus region for bony reconstruction of intraoral defects have proved to be a safe and reliable method due to their osteogenic properties, good long-term stability, and minor resorption. For all interventions, including harvesting, where thin and fragile bony structures are susceptible to fracture as a result of the application pressure or vibration, an accurate and atraumatic osteotomy is a major prerequisite. Piezosurgery offers a potentially safe bone processing technique in such cases, with its high precision allowing individual geometries to be cut. Especially in esthetically demanding zones, the former contour can be preserved or ideally reconstructed using customized bone blocks harvested with customized piezoelectric cut designs (Majewski 2012). With custom-built cutting tips, it is possible to perform osteotomies in difficult-to-access anatomic areas, with minimal trauma to surrounding soft tissue structures. This enables the surgeon to safely harvest bone grafts from, for example, the ramus region or the zygomaticomaxillary region (Stübinger *et al.* 2006). Furthermore, the thorough and comprehensive osteotomy lines achieved reduces the use of hammers and chisels for loosening the bone fragments, thus reducing patient discomfort and the accidental risk of harming underlying vital tissues like the inferior alveolar nerve. Thus, piezosurgery gives the surgeon unprecedented opportunities to harvest intraoral autologous bone grafts with high precision and safety.

Lateralization of the inferior alveolar nerve

Avoidance of iatrogenic damage is of utmost importance and demands not only great skills from the surgeon, but also a minimally invasive osteotomy technique. This is particularly important to avoid damage to the inferior alveolar nerve during surgical removal of impacted molars, spacious tumors or cysts, as well as during implant placement into severely vertically atrophic alveolar ridges. Generally, the inferior alveolar nerve is at risk of harm during

conventional removal of deeply impacted third molars in 1–22% of cases (Degerliyurt *et al.* 2009). The close proximity of the nerve to the impacted teeth together with the reduced manual control over rotating or oscillating instruments makes it difficult for the surgeon to safely preserve this vital structure.

The same problem confronts the surgeon during a lateralization procedure for implant placement. Lateralization of the inferior alveolar nerve is often performed as an alternative to the augmentation technique (Metzger *et al.* 2006). Especially in the posterior areas, conventional instruments limit the visibility and surgical control necessary to distinguish between hard and soft tissue structures. This often leads to surgical damage to the nervous structures. The precise and selective piezoelectric cut with an additional cavitation effect affords much greater safety (Bovi 2005). By creating a replaceable cortical lateral bone lid over the neurovascular bundle, the surgeon obtains free and clear access to the nerve. The bone window is easily relocated to its former position and this protects the nerve structures following nerve retraction, transposition, and subsequent implant placement. Even if there is unintentional contact with the nerve, the negative side effects are much lower than when a conventional rotating or oscillating instruments comes into contact with the nerve (Salami *et al.* 2008).

Edentulous ridge splitting

Split-crest techniques avoid the need for bone augmentation of atrophic edentulous ridges with autologous bone grafts from intra- or extra-oral donor sites. Thereby, the disadvantage of requiring a second surgical donor site can be overcome. During a bone-splitting procedure, the compromised edentulous ridge is cut crestally and the lingual plate is separated from the buccal plate. The dental implant is inserted in the resulting expanded space.

Clinically, edentulous ridge-splitting techniques have been proven to be especially successful for the trabecular bone of the maxilla (Fig. 48-9). The high elasticity and flexibility of cancellous bone structures in the upper jaw allow an effective and fast osteotomy with atraumatic ridge expansion (Amato *et al.* 2012). In the cortical mandible, bone splitting is much more challenging, as mechanical trauma as well as the shape and design of the cutting tools often fracture the thin and fragile bone segments. In contrast, bone sectioning with piezoelectric devices ensuring micrometric osteotomies with no macrovibrations allows easy handling with an increased maneuverability even in delicate cases. Piezosurgery is ideally suited to providing a stable and sound placement and integration of dental implants in these conditions. Thus, even though edentulous ridge splitting using conventional instruments has proven to be a successful treatment regimen (Simion *et al.* 1992; Scipioni *et al.* 1999), the application of piezoelectric osteotomy has improved and refined the surgical procedure.

Fig. 48-10 Piezoelectric corticotomy for monocortical tooth dislocation and ligament distraction.

Orthodontic microsurgery

The precise and selective cutting with minimal pressure and vibration also advocate ultrasound-based osteotomy for selective alveolar decortication associated with alveolar augmentation in accelerated orthodontic treatment (Wilcko *et al.* 2001). Rapid achievement of a functionally and esthetically stable occlusion plays a vital role in modern orthodontic therapy. Monocortical tooth dislocation with dentoalveolar compensation is a common procedure in orthognathic surgery to correct dental malpositions, and several orthodontic approaches to correcting tooth malpositions or inclinations are available (Lai *et al.* 2008; Wilmes *et al.* 2009). However, certain features, such as hard and soft tissue dehiscences, fenestration defects, root resorptions, and gingival recession, detract from a favorable treatment outcome. A possible surgical alternative that reduces the required orthodontic forces as well as treatment time is interdental or vestibular corticotomy combined with orthodontic treatment (Ahn *et al.* 2012). With the increased precision of piezoelectric osteotomy,

microsurgical orthodontic therapy has emerged as a promising and reliable treatment concept (Vercellotti & Podesta 2007; Bertossi *et al*. 2011). With simple vertical interdental incisions and minimal soft tissue manipulation, individual teeth can be loosened and separated from each other with vertical and basal monocortical osteotomies (Fig. 48-10). Alveolar augmentation with bone blocks or bone chips can be simultaneously performed. The different designs and shapes of cutting tips offer a wide range of osteotomy patterns for an ideal repositioning and stabilization of bone–tooth blocks.

Conclusion

The advantages of piezosurgery allow numerous modifications of proven surgical procedures, but also novel surgical techniques for common and standard surgical interventions in oral and maxillofacial surgery. Clinical application of piezosurgery has enhanced the handling of delicate structures. Regarding osteotomies of thin and fragile bones, the application of ultrasound is superior to that of other mechanical instruments, because it is easy to handle, provides efficient bone ablation, and minimizes accidental harm to adjacent soft tissue structures.

Chapter 49

Timing of Implant Placement

Christoph H.F. Hämmerle,[1] Maurício Araújo,[2] and Jan Lindhe[3]

Introduction

Restorative therapy performed on implant(s) placed in a fully healed and non-compromised alveolar process has high clinical success and survival rates (Pjetursson *et al.* 2004). Currently, however, implants are also being placed in (1) sites with ridge defects of various dimensions, (2) fresh extraction sockets, (3) the area of the maxillary sinus, etc. Although some of these clinical procedures were first described many years ago, their application has only relatively recently become common. Accordingly, one issue of primary interest in current clinical and animal research in implant dentistry includes the study of tissue alterations that occur following tooth loss and the proper timing thereafter for implant placement.

In the optimal case, the clinician will have time to plan for the restorative therapy (including the use of implants) prior to the extraction of one or several teeth. In this planning, a decision must be made whether the implant(s) should be placed immediately after the tooth extraction(s) or if a certain number of weeks (or months) of healing of the soft and hard tissues of the alveolar process should be allowed prior to implant installation. The decision regarding the timing for implant placement, in relation to tooth extraction, must be based on a proper understanding of the structural changes that occur in the alveolar process following the loss of the tooth (teeth). Such adaptive processes are described in Chapter 3.

The removal of single or multiple teeth will result in a series of alterations within the edentulous segment of the alveolar process. Hence, during socket healing, the hard tissue walls of the alveolus will resorb, the center of the socket will become filled with cancellous bone, and the overall volume of the site will become markedly reduced. In particular, the buccal wall of the edentulous site will be diminished not only in the buccolingual/palatal direction but also with respect to its apicocoronal dimension (Pietrokovski & Massler 1967; Schropp *et al.* 2003). In addition to hard tissue alterations, the soft tissue in the extraction site will undergo marked adaptive changes. Immediately following tooth extraction, there is a lack of mucosa and the socket entrance is thus open. During the first weeks following the removal of a tooth, cell proliferation within the mucosa will result in an increase of its connective tissue volume. Eventually, the soft tissue wound will become epithelialized and a keratinized mucosa will cover the extraction site. The contour of the mucosa will subsequently adapt to follow the changes that occur in the external profile of the hard tissue of the alveolar process. Thus, the contraction of the ridge is the net result of bone loss as well as loss of connective

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

tissue. Figure 49-1 illustrates the tissue alterations described above. It is obvious that no ideal time point exists following the removal of a tooth, when the extraction site has (1) maximum bone fill in the socket and (2) voluminous mature covering mucosa.

A consensus report was published in 2004 describing issues related to the timing of implant placement in extraction sockets (Hämmerle *et al.* 2004). Attempts had previously been made to identify the advantages and disadvantages of early, delayed, and late implant placements. Hämmerle and co-workers considered it necessary, however, to develop a new concept (classification) that incorporated the growing knowledge in this field of implant dentistry. This new classification took into consideration data describing structural alterations that occur following tooth extraction as well as knowledge derived from clinical observations.

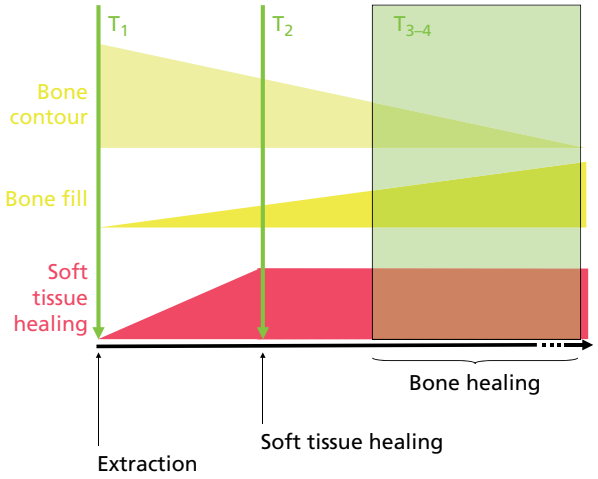

Fig. 49-1 Schematic drawing depicting the changes in the soft and hard tissues following tooth extraction over time. $T_{1–4}$ represent the four different time points for implant placement.

The classification presented in Table 49-1 was introduced in the consensus report. Important aspects included:

- In clinical practice, the decision to place an implant following tooth extraction is usually determined by some soft and hard tissue characteristics of the healing socket. Healing does not necessarily follow rigid time frames, and may vary according to site and patient factors.
- To avoid temporal-based descriptions, this new classification used numerical descriptors – types 1, 2, 3, and 4 – that reflect the conditions of the hard and soft tissues:
  - Type 1 placement: the implant is placed immediately following the extraction of a tooth
  - Type 2 placement: the implant is placed in a site where the soft tissues have healed and a mucosa is covering the socket entrance
  - Type 3 placement: the implant is placed in an extraction site at which substantial amounts of new bone have formed in the socket
  - Type 4 placement: the implant is placed in a fully healed ridge.
- It was further recognized that there is a clear separation between hard tissue healing and soft tissue healing within and around the extraction socket.

This classification has since been refined (Chen *et al.* 2009).

Advantages and disadvantages of the various timings are shown in Table 49-1.

Two methods for flap closure at implant sites have been described. One approach requires primary

Table 49-1 Classification of types 1–4 implant placements, and advantages and disadvantages of each type.

Classification	Definition	Advantages	Disadvantages
Type 1	Implant placement as part of the same surgical procedure as and immediately following tooth extraction	Reduced number of surgical procedures Reduced overall treatment time Optimal availability of existing bone	Site morphology may complicate optimal placement and anchorage Thin tissue biotype may compromise optimal outcome Potential lack of keratinized mucosa for flap adaptation Adjunctive surgical procedures may be required Technique-sensitive procedure
Type 2	Complete soft tissue coverage of the socket (typically 4–8 weeks)	Increased soft tissue area and volume facilitates soft tissue flap management Allows resolution of local pathology to be assessed	Site morphology may complicate optimal placement and anchorage Increased treatment time Varying amounts of resorption of the socket walls Adjunctive surgical procedures may be required Technique-sensitive procedure
Type 3	Substantial clinical and/or radiographic bone fill of the socket (typically 12–16 weeks)	Substantial bone fill of the socket facilitates implant placement Mature soft tissues facilitate flap management	Increased treatment time Adjunctive surgical procedures may be required Varying amounts of resorption of the socket walls
Type 4	Healed site (typically >16 weeks)	Clinically healed ridge Mature soft tissues facilitate flap management	Increased treatment time Adjunctive surgical procedures may be required Large variation in available bone volume

would closure, whereas the other one allows for a transmucosal position of the implant or the healing cap. No differences regarding survival rates and interproximal bone levels were found when these two methods were compared in a split-mouth design (Ericsson *et al.* 1997; Astrand *et al.* 2002; Cecchinato *et al.* 2004). These studies did not, however, analyze in detail the differences between submerged or transmucosal healing in sites of high esthetic importance. Hence, not only the width of the gap but also the width of the alveolar process is a parameter to be considered during treatment planning.

A recent review analyzed the clinical outcomes of implants placed according to the timing scheme described above (Chen & Buser 2009). Based on the analysis of 91 studies, it was found that bone augmentation procedures were more effective in type 1, 2, and 3 placements than in type 4 placement. Furthermore, it appeared that recession of the facial mucosal margin was more frequent when implants were placed according to the type 1 timing.

Type 1 placement as part of the same surgical procedure as and immediately following tooth extraction

Ridge alterations in conjunction with implant placement

It has become common practice to insert implants immediately after the removal of teeth that were scheduled for extraction for various reasons. Over the years, many claims have been made regarding the advantages of immediate implant placement (Chen *et al.* 2004). These advantages include easier definition of the implant position, reduced number of visits to the dental office, reduced overall treatment time and costs, preservation of bone at the site of implantation, optimal soft tissue esthetics, and enhanced patient acceptance (Werbitt & Goldberg 1992; Barzilay 1993; Schwartz-Arad & Chaushu 1997b; Mayfield 1999; Hämmerle *et al.* 2004).

It was proposed that placement of an implant in a fresh extraction socket may stimulate bone tissue formation and osseointegration, and hence counteract the adaptive alterations that occur following tooth extraction. In other words, type 1 implant installation may allow the preservation of bone tissue of the socket and the surrounding jaw. It was in fact recommended (e.g. Denissen *et al.* 1993; Watzek *et al.* 1995; for review see Chen, *et al.* 2004) that implant installation should be performed directly following tooth extraction as a means to avoid bone atrophy.

Clinical studies in humans (Botticelli *et al.* 2004; Covani *et al.* 2004) and experiments in dogs (Araújo & Lindhe 2005; Araújo *et al.* 2006a, b) have examined the influence of implant installation in the fresh extraction socket on bone modeling and remodeling in the surgical site.

Botticelli *et al.* (2004) examined hard tissue alterations that occurred in the alveolar process during a 4-month period of healing following implant placement in fresh extraction sockets. Eighteen subjects (21 extraction sites) with moderate chronic periodontitis were studied. The treatment planning of all 18 subjects called for extraction of single teeth, and restoration by means of implants in the incisor, canine, and premolar regions of the dentition. Following sulcus incisions, full-thickness mucosal flaps were raised and the tooth was carefully mobilized and removed with forceps. The site was prepared for implant installation with pilot and twist drills. The apical portion of the socket was pre-tapped. A non-cutting solid-screw implant (Straumann®, Basel, Switzerland) with a rough surface topography was installed. The implant was positioned in such a way that the marginal level of its rough surface portion was located apical to the marginal level of the buccal and lingual/palatal walls of the socket (Fig. 49-2a). After implant installation (1) the distance between the implant and the inner and outer surface of the buccal and/or lingual bone plates and (2) the width of the marginal gap that was present between the implant and the buccal, lingual, mesial, and distal bone walls were determined with the use of sliding calipers. The soft tissue flaps were replaced and the implants were "semi-submerged" during healing (Fig. 49-2b). After 4 months of healing, a surgical re-entry procedure was performed (Fig. 49-2c). The clinical measurements were repeated so that alterations

Fig. 49-2 Clinical views of (a) implant position in the fresh extraction socket; (b) flaps replaced and sutured; (c) implant site after 4 months of healing (buccal view).

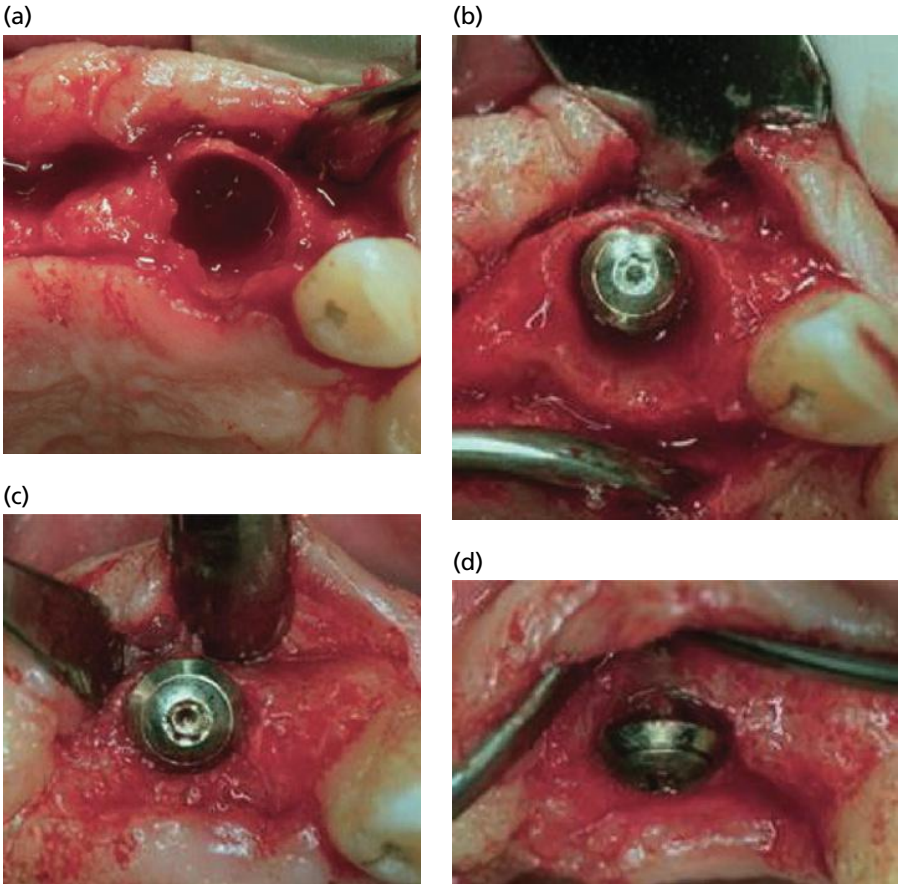

Fig. 49-3 Clinical views of (a) alveolar socket of a maxillary canine; (b) implant position in the fresh extraction socket; (c) implant site after 4 months of healing (occlusal view); (d) implant site after 4 months of healing (buccal view). Note the very thin bone covering the buccal aspect.

that had occurred during healing regarding (1) the thickness and height of the buccal and lingual/palatal socket walls and (2) the width of the marginal gap could be calculated.

Figure 49-3a shows an extraction socket immediately after the removal of a maxillary canine tooth. At re-entry it was realized that the marginal gap had completely resolved. Furthermore, the thickness of the buccal as well as the palatal bone walls had markedly reduced (Fig. 49-3c, d). In Fig. 49-3d, the implant surface can be seen through the very thin remaining buccal bone wall.

Another site from this clinical study is shown in Fig. 49-4. The first maxillary premolar (tooth 14) was removed (Fig. 49-4a) and one implant was placed in the palatal socket of the fresh extraction site. A second implant was placed in the healed edentulous ridge and in position 15 (Fig. 49-4b). At re-entry, it was observed that (1) the marginal gap had completely resolved and (2) the distance between the implant and the outer surface of the buccal bone plate had markedly reduced (Fig. 49-4c).

Botticelli *et al.* (2004) reported that during the 4 months of healing following tooth extraction and implant installation practically all marginal gaps had resolved. At the time of implant placement, the mean distance (18 subjects, 21 sites) between the implant and the outer surface of the buccal bone wall was 3.4 mm, while the matching dimension on the lingual/palatal aspect was 3.0 mm. At re-entry after 4 months, the corresponding dimensions were 1.5 mm (buccal) and 2.2 mm (lingual). In other words, the reduction of the buccal dimension was 1.9 mm (56%), while the equivalent reduction of the lingual dimension was 0.8 mm (27%). The findings by Botticelli *et al.* (2004) strongly indicate that implant placement in a fresh extraction socket may, in fact, not prevent the physiologic modeling/remodeling that occurs in the ridge following tooth removal.

In a recent randomized controlled clinical study, parallel-walled and conical implants were placed immediately into 93 extraction sockets of maxillary non-molar teeth (Sanz *et al.* 2010). Detailed clinical measurements taken at implant placement and 16 weeks thereafter assessed the changes in the relationship between the bone of the socket and the implant surface. A pronounced reduction of the buccal bone dimension occurred over this time period. A smaller reduction of external bone dimension was observed at the lingual aspect. No differences were found between the parallel-walled and conical implants with respect to reduction of the ridge contour. In contrast to the reduction of the external dimensions of the ridge, the gaps between the walls of the socket and the implant surface at the time of placement had partially been filled with newly formed bone at the 16-week follow-up examination (Huynh-Ba *et al.* 2010; Sanz *et al.* 2010).

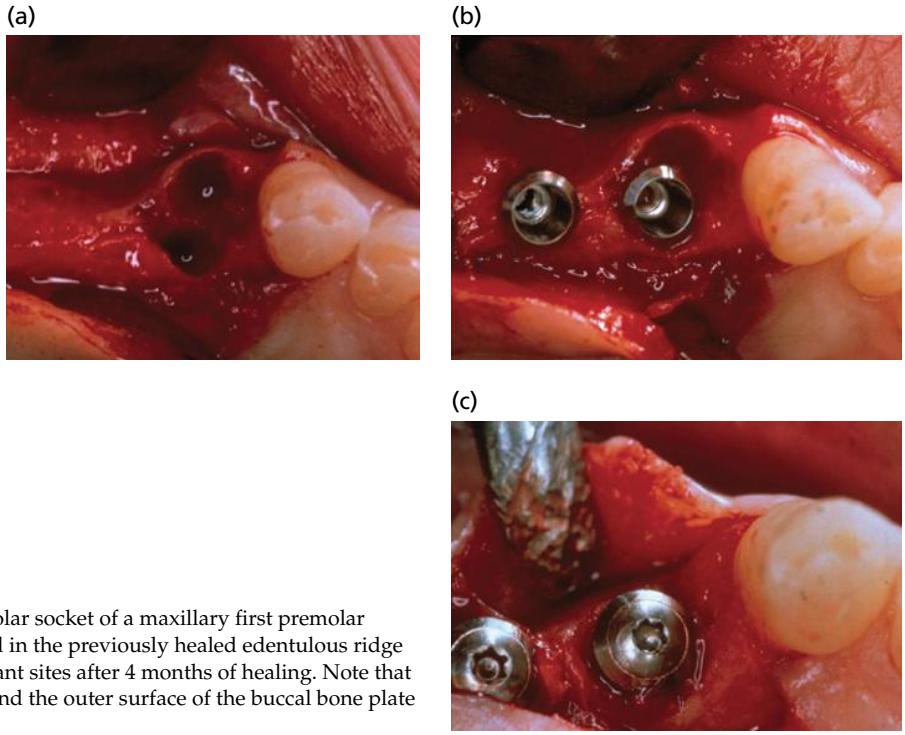

Fig. 49-4 Clinical views of (a) alveolar socket of a maxillary first premolar (occlusal view); (b) implants placed in the previously healed edentulous ridge and in the alveolar socket; (c) implant sites after 4 months of healing. Note that the distance between the implant and the outer surface of the buccal bone plate was markedly reduced.

In a subsequent paper analyzing the same patient groups, it was found that the bone fill of the gap between the implant and the bone walls of the socket as well as the maintenance of the buccal bone height were more favorable at premolar as compared to canine and incisor sites (Ferrus *et al.* 2010; Tomasi *et al.* 2010). Furthermore, the thickness of the buccal bone wall and the dimension of the gap described above favorably influenced the amount of bone fill during the 4-month healing period. A 3-year follow-up examination reported minimal implant failures and stable soft and hard tissue conditions in both groups of implants (Sanz *et al.* 2014).

In order to study the bone modeling/remodeling that occurs in the fresh extraction site following implant placement in more detail, Araújo and Lindhe (2005) used histologic means to determine the magnitude of the dimensional alterations that occurred in the alveolar process following the placement of implants in fresh extraction sockets in the Beagle dog. Buccal and lingual full-thickness flaps were elevated in both quadrants of the mandible. The distal roots of the third and fourth premolars were removed (Fig. 49-5a). In the right jaw quadrants, implants (solid screw, Straumann®) with a rough surface were placed in the sockets so that the marginal border of the rough surface was below the buccal and lingual bone margin (Fig. 49-5b). The flaps were replaced to allow a "semi-submerged" healing (Fig. 49-5c). In the left jaws, the corresponding sockets were left without implantation and the extraction sockets were fully submerged under the mobilized flaps (Fig. 49-5d). After 3 months, the mucosa at the experimental sites in the right and left jaw quadrants appeared to be properly healed (Fig. 49-6). The animals were sacrificed and tissue blocks containing the implant sites and the edentulous socket sites were dissected and prepared for histologic examination. Figure 49-7 shows a buccolingual section of one edentulous site after 3 months of healing. Newly formed bone covers the entrance of the socket. The lamellar bone of the buccal cortical plate is located about 2.2 mm apical to its lingual counterpart. Figure 49-8a presents a similar section from an implant site in the same dog. The marginal termination of the buccal bone plate is located about 2.4 mm apical to the lingual crest. In other words, the placement of an implant in the fresh extraction socket failed to influence the process of modeling that occurred in the hard tissue walls of the socket following tooth removal. Thus, after 3 months of healing the amount of reduction of the height of the buccal bone wall (in comparison to the lingual bone alteration) was similar at the implant sites and the edentulous sites. At 3 months, the vertical discrepancy between the buccal and lingual bone margins was >2 mm in both categories of sites (edentulous sites 2.2 mm, implant sites 2.4 mm).

In a follow-up experiment in the dog, Araújo *et al.* (2006a) studied whether osseointegration, once established following implant placement in a fresh extraction socket, could be lost as a result of continued tissue modeling of the bone walls during healing. As was the case in their previous study (Araújo & Lindhe 2005), the distal roots of the third and fourth premolars in both quadrants of the mandible were removed following flap elevation. Implants were installed in the fresh extraction sockets, and initial stability of all implants was secured. The flaps were

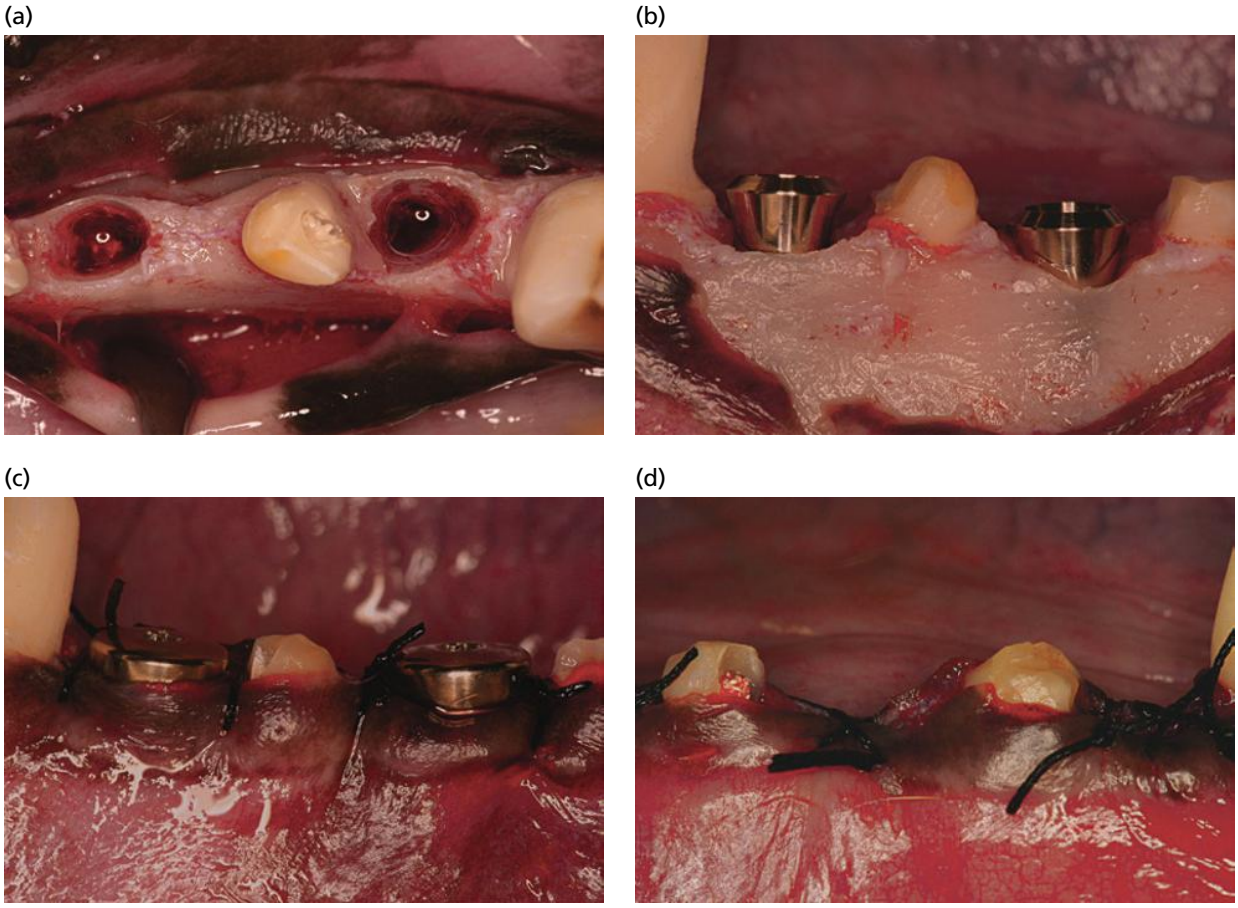

Fig. 49-5 (a) Mandibular premolar site (in a dog experiment) from which the distal root of the fourth premolar was removed. (b) In the test side of the mandible, the implant was placed in the socket in such a way that the rough surface marginal limit was flush with the bone crest. (c) Mucosal, full-thickness flaps were replaced and sutured to allow a "semi-submerged" healing. (d) On the contralateral side of the mandible, the sockets were left without implantation.

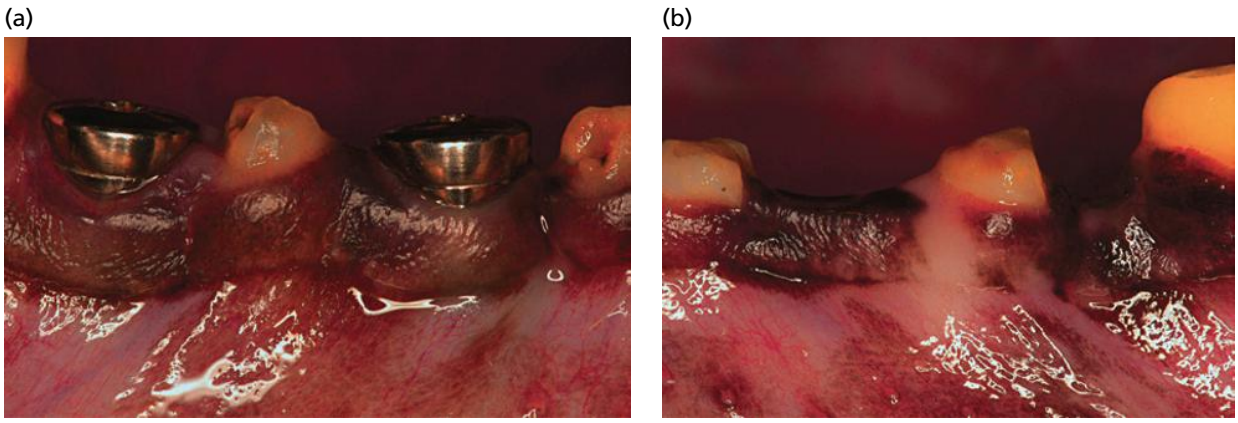

Fig. 49-6 (a) Implant and (b) edentulous sites after 6 months of healing.

replaced and "semi-submerged" healing of the implant sites was allowed. Immediately following flap closure, biopsies were obtained from two dogs, while in five dogs healing periods of 1 month and 3 months were permitted prior to biopsy. Figure 49-9a shows a buccolingual aspect of an extraction site immediately after implant installation. Contact was established between the pitch on the surface of the implant body and the walls of the socket. A coagulum resided in the void between the contact regions (Fig. 49-9b) and also in the marginal gap. In sections taken after 4 weeks of healing, it was observed that this void had become filled with woven bone that made contact with the rough surface part of the implant (Fig. 49-10). In this 4-week interval, (1) the buccal and lingual bone walls had undergone marked surface resorption, and (2) the height of the thin buccal hard tissue wall had been reduced. In the interval between 4 weeks and 12 weeks of healing, the buccal bone crest shifted further in an apical

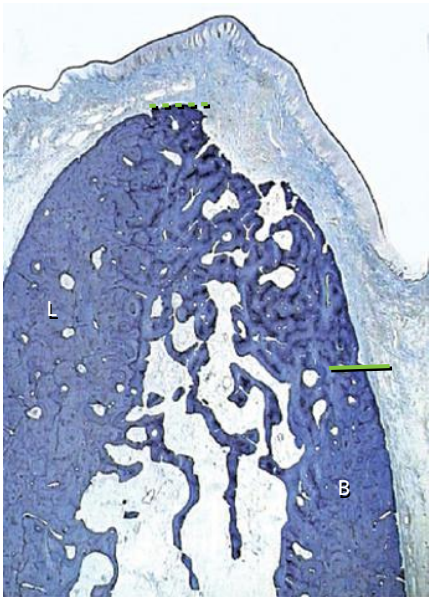

Fig. 49-7 Buccolingual section of the edentulous site. Note that the remaining buccal crest (continuous line) is located far below the lingual counterpart (dotted line). (B, buccal aspect; L, lingual aspect.)

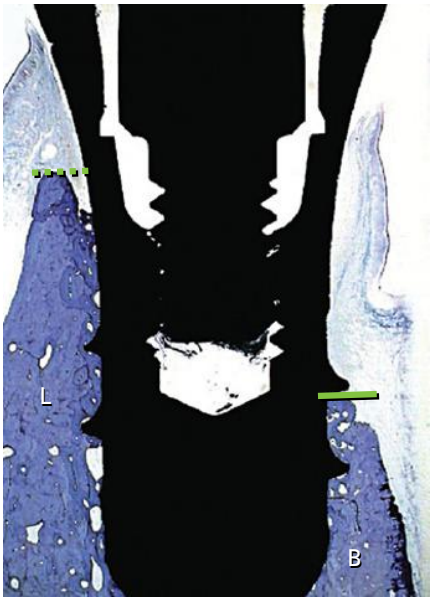

Fig. 49-8 Buccolingual section of the implant site. Note that the remaining buccal crest (continuous line) is located far below the lingual counterpart (dotted line). (B, buccal aspect; L, lingual aspect.)

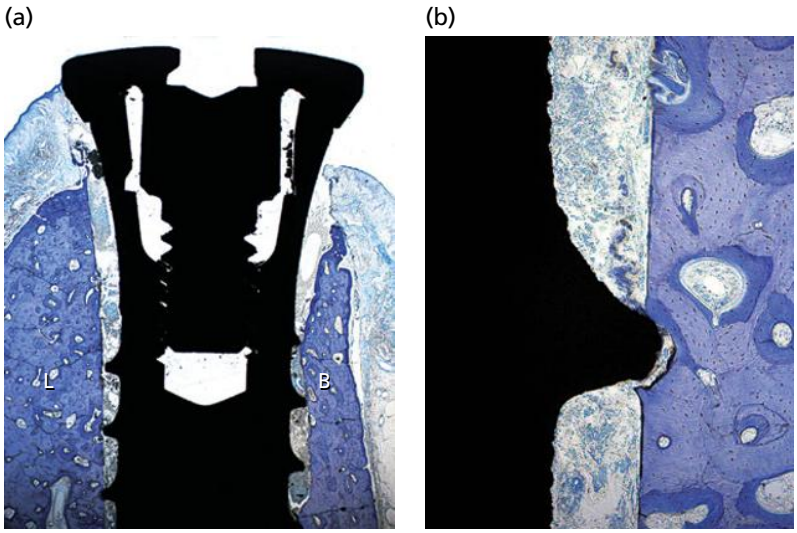

Fig. 49-9 (a) Buccolingual section of an extraction site immediately after implant installation. (b) Contact was established between the pitch on the surface of the implant body and the walls of the socket. (B, buccal aspect; L, lingual aspect.)

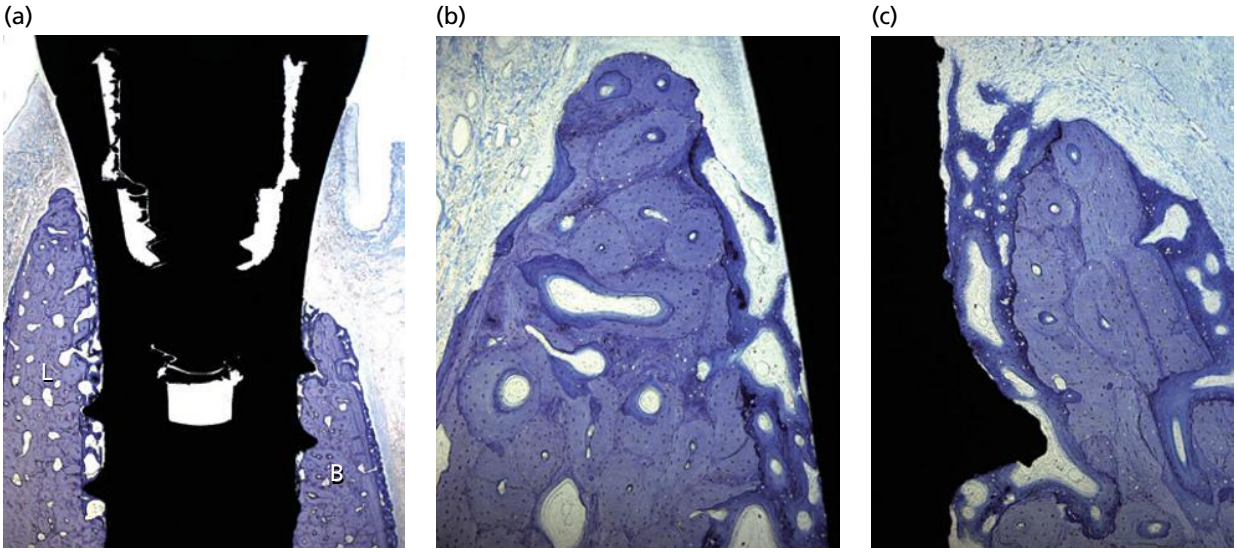

Fig. 49-10 (a) Buccolingual section 4 weeks after implant installation. The void between the implant surface and the bone wall was completely filled with newly formed bone in both lingual (b) and buccal (c) aspects. (B, buccal aspect; L, lingual aspect.)

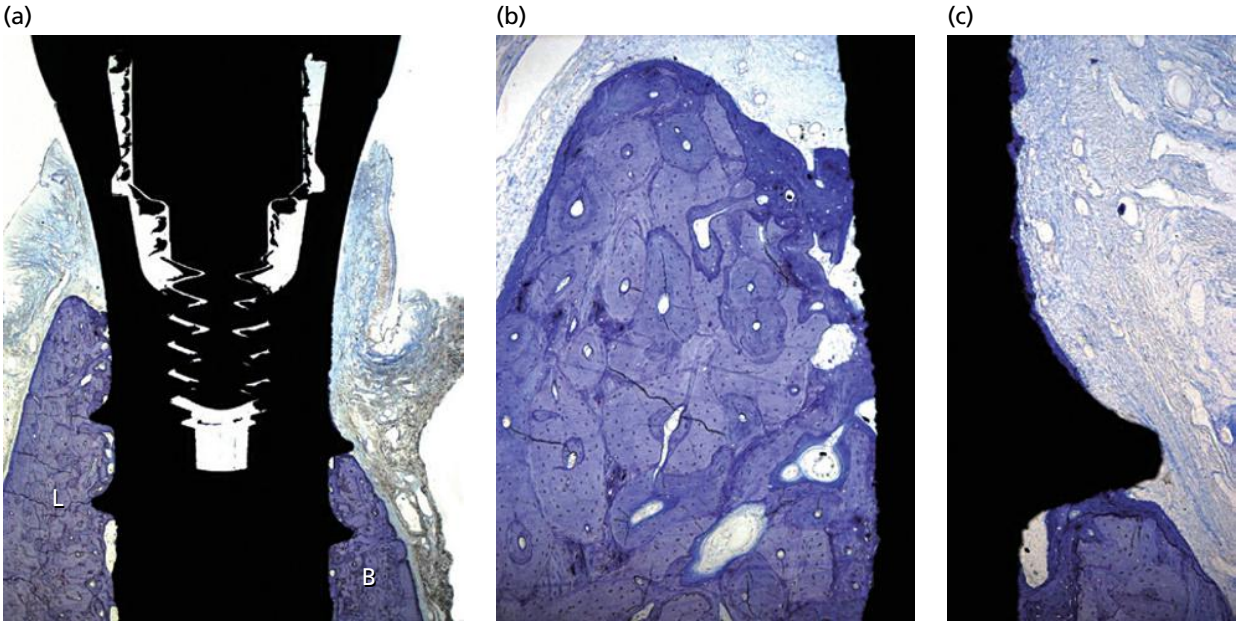

Fig. 49-11 (a) Buccolingual section 12 weeks after implant installation. Note that the buccal bone crest shifted in an apical direction and fragments of it can be seen on the denuded implant surface (c). The lingual bone crest, however, remained stable (b). (B, buccal aspect; L, lingual aspect.)

direction (Fig. 49-11). The woven bone at the buccal aspect that in the 4-week sample made contact with the implant in the marginal gap region had modeled and only fragments of this bone remained (Fig. 49-11c). At the end of the study, the buccal bone crest was located >2 mm apical to the marginal border of the rough implant surface.

These findings demonstrate that the bone (woven bone)-to-implant contact that was established during the early phase of socket healing following implant installation was in part lost when the buccal bone wall underwent continued atrophy. It is obvious, therefore, that the alveolar process following tooth extraction (loss) will adapt to the altered functional demands by atrophy and that an implant, in this respect, is unable to substitute for the tooth. The clinical problem with type 1 placement is that the bone loss will frequently cause the buccal portion of the implant to gradually lose its hard tissue coverage, and that the metal surface may become visible through a thin peri-implant mucosa and cause esthetic concerns (Fig. 49-12).

The question now arises whether it is possible to overcome this problem. This issue was studied in a Beagle dog experiment by Araújo *et al.* (2006b). The distal root of the third mandibular premolar and the distal root of the first mandibular molar were removed and implants placed in the fresh extraction sockets. The third premolar socket in this dog model is comparatively small, and hence the implant inserted (Straumann® Standard Implant, diameter 4.1 mm) occupied most of the hard tissue wound (Fig. 49-13). During healing, resorption of the buccal bone wall occurred (Fig. 49-14) and >2 mm of the marginal portion of the implant became exposed to peri-implant mucosa.

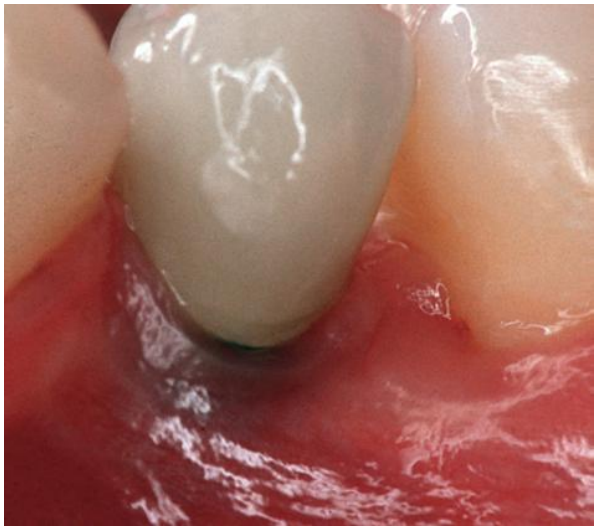

Fig. 49-12 Clinical view of an implant lacking the buccal bone. Note that the metal surface had become visible through the thin mucosa.

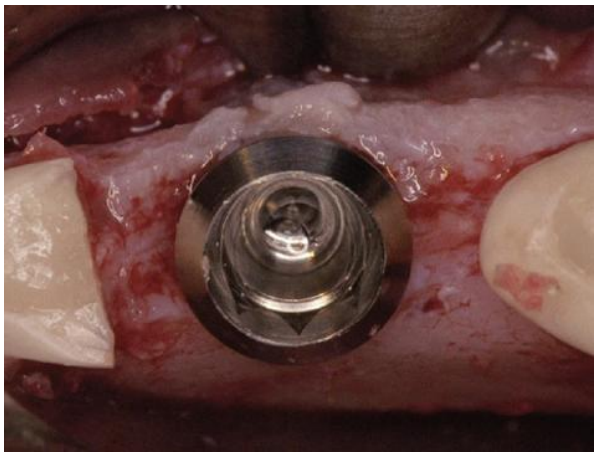

Fig. 49-13 Implant installation in the narrow, third premolar alveolar socket.

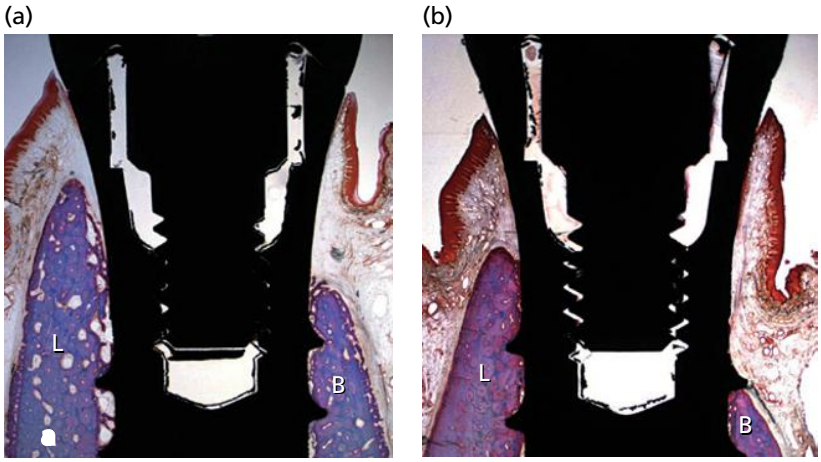

Fig. 49-14 Buccolingual section of the healed premolar sites (a) 4 and (b) 12 weeks after implant installation. (B, buccal aspect; L, lingual aspect.)

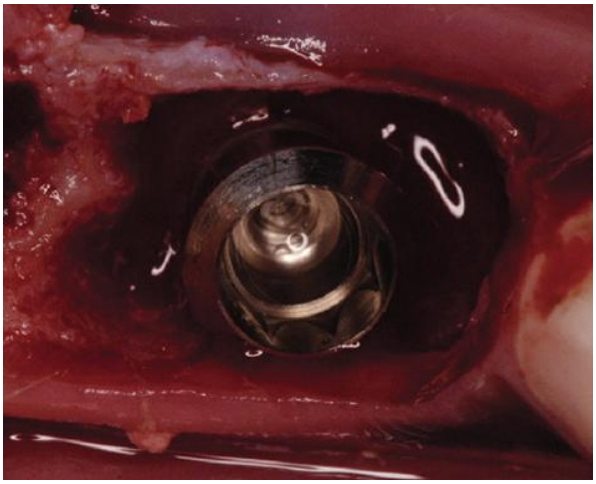

Fig. 49-15 Implant installation in the wide, first molar alveolar socket.

The molar socket, on the other hand, is very large (Fig. 49-15) and hence after implant (Straumann® Standard Implant, diameter 4.1 mm) placement, a >1-mm wide marginal gap occurred between the metal body and the bone walls (Fig. 49-16b). Primary stability of the implant was achieved through contacts between the metal body and the bone in the apical (periapical) portions of the socket. During the early phase of healing, this gap in the molar site became filled with woven bone. In the interval during which the buccal bone wall underwent programmed atrophy, the newly formed bone in the gap region maintained osseointegration and continued to cover all surfaces of the implant (Fig. 49-16a, b).

Conclusion: The data reported illustrate an important biologic principle. Atrophy of the edentulous ridge will occur following tooth loss. This contraction of the ridge cannot be prevented by placing an implant in the fresh extraction socket. The atrophy includes a marked reduction of the width and height of both the buccal and lingual bone plates; in particular, the buccal bone plate will undergo marked change. To some extent the problem with buccal bone resorption can be overcome by placing the implant deeper into the fresh socket and in the lingual/palatal portion of the socket.

As a consequence of the above-described healing, bone regeneration procedures may be required to improve or retain bone volume and the buccal contour at a fresh extraction site. Such bone augmentation is sometimes mandatory in the esthetic area.

Stability of implant

Another issue with type 1 (and also type 2) placement is the anchorage of the implant to obtain primary stability in a position in the jaw that will enable the subsequent restoration to meet high demands regarding esthetics and function. In most cases of type 1 placement, the implants are fixed in native bone apical to the alveolus (Fig. 49-17). Additional retention may be achieved by anchoring the implant in the bony structures of the alveolar walls or interradicular septa.

Another critical issue with type 1 placement is related to how to deal with the presence of periapical pathology at the tooth to be extracted. In a controlled clinical trial, it was observed that primary stability of some implants in a type 1 procedure could not be achieved (Siegenthaler *et al.* 2007). In this study, implants were inserted to replace teeth either exhibiting periapical pathology (test) or presenting healthy periapical conditions (control) (Siegenthaler *et al.* 2007). Apart from the finding that in four implant sites in the test group and one in the control group no implants could be placed due to an unfavorable bone morphology that precluded primary implant stability, no differences were found between the test and the control groups. At 5-year follow-up of the same group of patients, 100% implant survival was recorded in both groups. Furthermore, low levels of marginal bone loss and favorable clinical parameters with no statistically significant difference between the implants in the test and control groups were observed.

Data from a recent study analyzing 418 sites where implants were immediately placed into

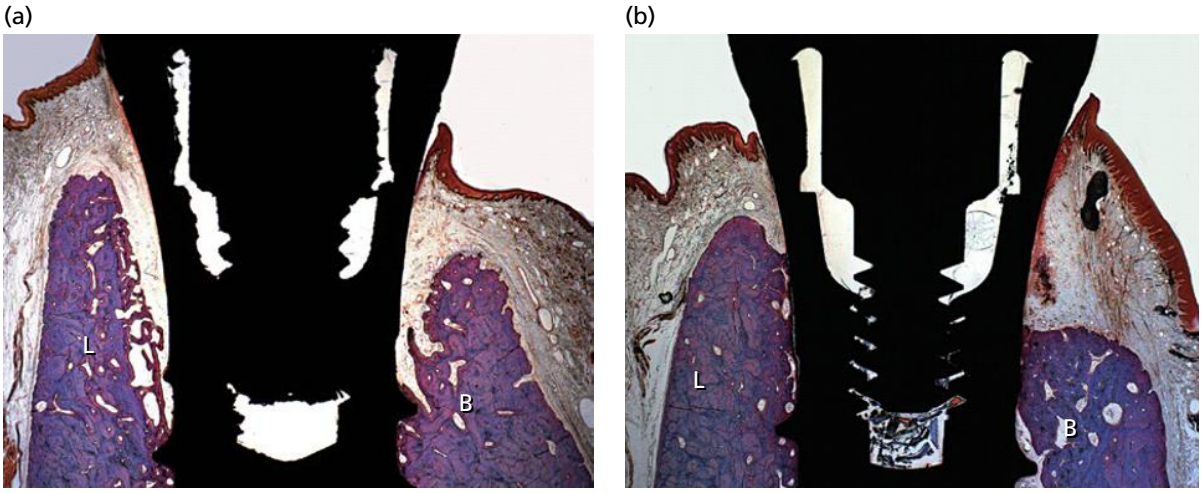

Fig. 49-16 Buccolingual section of the healed molars sites (a) 4 and (b) 12 weeks after implant installation. (B, buccal aspect; L, lingual aspect.)

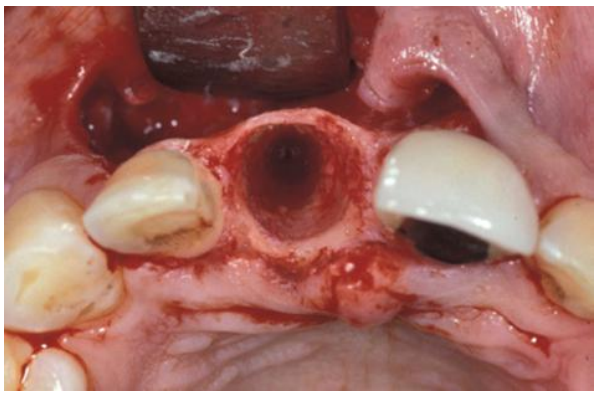

Fig. 49-17 Type 1 implant placement provides optimal availability of existing bone contours. Note the presence of a thin buccal bone plate. Anchorage of an implant can be achieved by engaging the bone apical to the apex of the extracted tooth and the palatal wall of the socket.

extraction sockets with periapical pathology revealed 97.8% survival after a mean follow-up of >5 years (Fugazzotto 2012).

A recent systematic review analyzed data from eight human trials with implants immediately placed into extraction sockets in the presence of periapical pathology (Waasdorp *et al.* 2010). Treatment regimens consistently included thorough debridement of the site prior to implant placement. Bone defects present were normally treated with guided bone regeneration (GBR) procedures. In the majority of cases, an antibiotic regimen was prescribed. Clinical and radiographic results revealed survival and success rates similar those for implants placed in non-infected sites. In contrast, studies have reported a higher occurrence of periapical lesions at implants, when the tooth replaced by the implant had exhibited periapical pathology, or when the tooth next to the implant site exhibited periapical pathology (Lefever *et al.* 2013).

Hence, it appears that the presence of periapical pathology at the tooth to be extracted may represent a higher risk for periapical problems at implants immediately placed into the extraction socket. An important body of evidence, however, suggests that by applying a meticulous treatment regimen, implants placed into the site where teeth with periapical pathology have been extracted, can be maintained with high survival and success rates over time.

How to deal with teeth exhibiting marginal periodontal pathology is another important clinical question regarding type 1 implant placement. In a recent study, implants were immediately placed to replace two groups of teeth (Crespi *et al.* 2010). In one group, the marginal periodontium showed signs of infection, but in the other group the marginal periodontium was clinically healthy. Four years after implant placement, no significant differences between the two groups were found regarding implant survival, marginal bone levels, and peri-implant soft tissue parameters. Hence, properly performed immediate implant placement may lead to successful outcomes when replacing teeth affected by marginal periodontitis.

Type 2 placement: Completed soft tissue coverage of the tooth socket

There are several reasons why the type 2 approach is often recommended. At this stage of healing, the socket entrance is covered with a mucosa. The soft tissue is (1) comparatively mature, (2) has proper volume, and (3) can be easily managed during flap elevation and replacement procedures. Furthermore, the type 2 timing permits an assessment of the resolution of periapical lesions that may have been associated with the extracted tooth. The disadvantages inherent in the type 2 approach include (1) resorption of the socket walls and (2) an extended treatment time (see Table 49-1).

Following tooth extraction, the socket becomes filled with a coagulum that is then replaced with granulation tissue within a few weeks. In the normal case, it takes about 4–8 weeks before the soft tissue

Fig. 49-18 Soft tissues have completely healed over the extraction socket 8 weeks after tooth removal (type 2).

(granulation tissue, provisional connective tissue; see Chapter 3) fills the socket and its surface becomes covered with epithelium (Amler 1969; Zitzmann, *et al.* 1999; Hämmerle & Lang 2001; Nemcovsky & Artzi 2002). The maturation of the soft tissue (further deposition and orientation of collagen fibers) that can facilitate flap management may require an even longer healing time.

The larger amount of soft tissue that is present at the site of implant placement when the type 2 approach is used allows for precise management of the mucosal flap and hence optimal soft tissue healing (Fig. 49-18). This advantage with the type 2 timing must be matched against the hard tissue reduction and the change of the ridge contour that results from the resorption of the socket walls and of the buccal bone plate. It must be noted that at some extraction sites the mucosa may remain adherent via scar tissue to the underlying bone or to the provisional connective tissue of the socket. In such cases, it may be difficult to separate the soft tissue from the bone and to mobilize the flap. In such a situation, the trauma caused in conjunction with flap elevation may rupture the soft tissue and compromise healing. This in turn may result in soft tissue dehiscence, local infection, and inflammation (Zitzmann *et al.* 1997).

As shown in Fig. 49-1, the initial gain in mucosa (area and volume) is later followed by an overall loss of soft tissue volume. This is evidenced by the fact that the volume of the alveolar process – including the bone as well as the mucosal compartments – markedly decreases during the first 12 months following tooth extraction (Schropp *et al.* 2003).

During the 4–8 weeks between tooth extraction and type 2 implant placement, only small amounts of new bone (woven bone) will form in the socket. This means that the risk of not achieving primary implant stability is similar in type 1 and type 2 approaches. Thus, in sites where the available bone height apical to the tip of the root is <3 mm, it is frequently impossible to obtain primary implant stability in the bone beyond the apex of the extracted tooth. When, in addition, a wide alveolus is precluding the engagement of its bony walls, the type 3 approach may be favored.

Type 3 placement: Substantial bone fill has occurred in the extraction socket

The type 3 time frame is chosen for implant installation at sites where, for various reasons, bone fill is required within the extraction socket. Newly formed woven bone will occupy the socket area after healing periods extending from 10 to 16 weeks (Evian *et al.* 1982). In this period, however, the walls of the socket are frequently completely resorbed and replaced with woven bone. The entrance to the socket is closed with a cap of woven bone that is in the process of remodeling. The mucosa that covers the extraction site is (1) residing on a mineralized ridge, and (2) mature and easier to manage during surgical flap elevation and replacement procedures.

The type 3 approach often allows the clinician to place the implant in a position that facilitates the prosthetic phase of the treatment. The disadvantages with this approach encompass (1) a prolonged treatment time, (2) additional resorption and diminution of the ridge, including a substantial change of its contour, and (3) a concomitant loss of soft tissue volume.

Type 4 placement: Alveolar process is healed following tooth loss

In the type 4 approach, the implant is placed in a fully healed ridge. Such a ridge can be found after 4 months, but more likely after 6–12 months of healing following tooth extraction (loss). After 6–12 months of healing following tooth extraction, the clinician will find a ridge that is lined by a mature, often well-keratinized mucosa that resides on dense cortical bone. Beneath the cortical bone plate, cancellous bone occupies a varying portion of the alveolar process (see Chapter 3).

In a study of human volunteers it was observed that the rate of formation of new bone within the extraction site started to decrease after 3–4 months of healing. At this stage, the newly formed bone and the remaining bone of the socket walls entered into a phase of remodeling (Evian *et al.* 1982). Concomitant with the remodeling of this centrally located bone tissue, extra-alveolar resorptive processes leading to

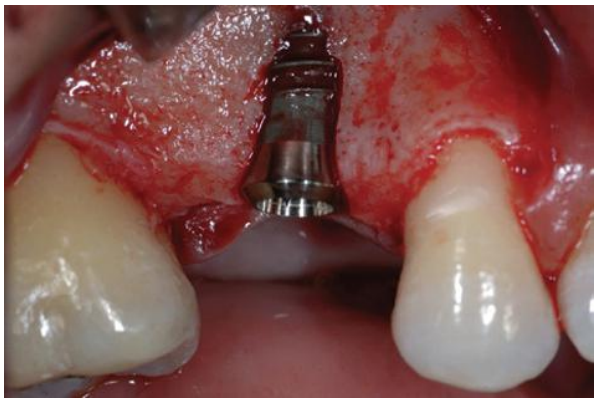

Fig. 49-19 Buccal dehiscence defect is present at an implant placed into a ridge, which has undergone substantial buccal bone resorption since tooth extraction several months ago (type 4).

a further contraction of the ridge and change of its contour continued for at least 12 months (Schropp *et al.* 2003).

The advantage of type 4 installation is that healing is more or less complete and only minor additional change of the ridge may occur. The disadvantages include (1) increased treatment time and (2) further reduction of the overall volume of the ridge and change of its external contour. This pronounced additional loss of ridge volume may at times require complicated bone augmentation procedures (Fig. 49-19). As a consequence, type 4 placement is avoided in most cases when the tooth (teeth) to be replaced is (are) present at the time of examination and treatment planning.

Clinical concepts

When implants are to be placed in the edentulous portion of the ridge, factors in addition to the tissue changes over time must be considered. Thus, in the treatment planning phase, aspects such as the (1) overall objective of the treatment, (2) location of the tooth within the oral cavity – in the esthetic or non-esthetic zone, and (3) anatomy of the bone and the soft tissue at the site(s) to be treated, must be evaluated.

Aim of therapy

Dental implants are most commonly used to restore health and function. During the surgical phase of therapy, therefore, ideal conditions must be established for successful bone and soft tissue integration with the implant. In a growing number of cases, however, treatment must also satisfy patient demands regarding the esthetic outcome. In such cases, the overall surgical and prosthetic treatment protocol may become more demanding, since factors other than osseointegration and soft tissue integration may play an important role.

Restoration of health and function

In cases where the restoration of health and function constitutes the primary goal of the treatment, the location and volume of available hard and soft tissues are the important factors to consider. In such cases, the type 1 approach is usually selected (Wichmann 1990).

The replacement of a single-rooted tooth with an implant in a fully healed ridge will, in most cases, ensure proper primary stability with the implant in a correct position. In addition, the soft tissues are sufficient in volume and area. The mucosal flap can be adapted to the neck (or the healing cap) of the implant (one-stage protocol). When primary wound closure is intended (two-stage protocol), mobilization of the soft tissue will allow tension-free adaptation and connection of the flap margins.

When an implant is placed in the unhealed site of a multirooted tooth, the surgical procedure becomes more demanding. Often, the ideal position for the implant is in the area of the inter-radicular septum. If the septa are delicate, anchorage for primary implant stability may be difficult to achieve (Fig. 49-20). In addition, in molar sites there is often only a small amount of soft tissue present. This may create a problem with respect to wound closure with a mobilized, tension-free flap. In some molar sites, primary wound closure may not be possible following implant installation.

The presence of marginal defects (gaps) between the implant and the fully healed ridge following type 4 placement was regarded in the past as a significant problem that could compromise osseointegration. However, studies in humans and animals have demonstrated that in such a horizontal marginal defect (gap) of ≤2 mm, new bone formation as well as defect resolution and osseointegration of the implant (with a rough titanium surface) will occur (Wilson *et al.* 1998; Botticelli *et al.* 2004; Cornelini *et al.* 2005).

Esthetic importance and tissue biotype

The replacement of missing teeth with implants in the esthetic zone is a demanding procedure. Deficiencies in the bone architecture and in the soft tissue volume and architecture may compromise the esthetic outcome of treatment (Grunder 2000). Hence, when an implant is to be placed in the esthetic zone, not only the anatomy of the hard tissues but also the texture and the appearance of the soft tissues must be considered.

In a recent systematic review including patients with intact facial bone walls and a thick soft tissue biotype, a limited risk for advanced mid-facial soft tissue recession was reported (Cosyn *et al.* 2012). Furthermore, it was stated that the literature was scarce regarding the effect of different parameters on mid-facial soft tissue recession, like thin or thick tissue biotype, flapless or flap surgery, and immediate or late provisionalization. In another study of a specific treatment protocol that included type 1 implant

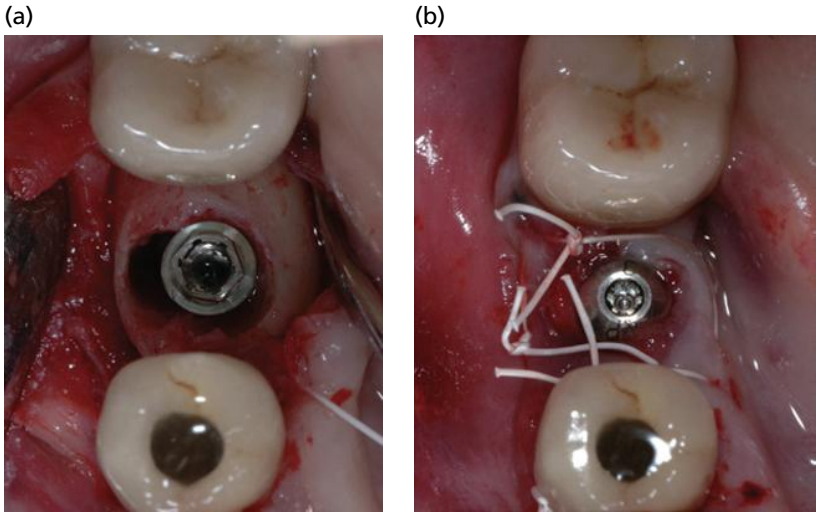

Fig. 49-20 (a) Immediate implant placement (type 1) in a mandibular premolar extraction socket. Note the buccal bone deficiency, where bone will be augmented by guided bone regeneration. (b) Same site as in (a) following adaptation of the flap around the neck of the implant, obtaining a transmucosal mode of healing.

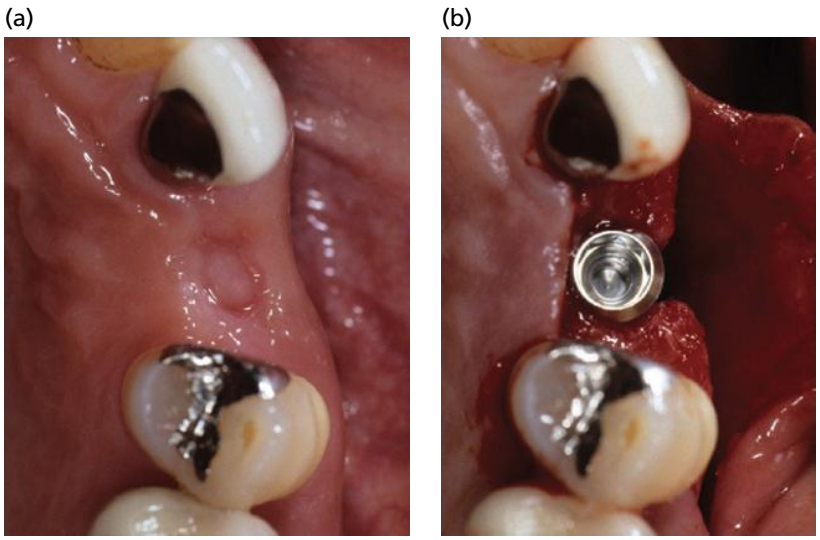

Fig. 49-21 (a) Single-tooth gap 8 weeks following tooth extraction. The soft tissues have completely healed over the extraction socket. (b) Same site as in (a). An implant has been placed in the edentulous gap. The resulting buccal dehiscence defect will be augmented with bone by applying guided bone regeneration.

placement, flapless surgery, and immediate provisionalization, Cabello *et al.* (2013) reported good esthetic outcomes with only small changes in the height of the interproximal papillae and the level of the mid-facial mucosal margin.

Type 2 installation is often preferred when implants are placed in the esthetic zone (Fig. 49-21). The key advantage of type 2 (as opposed to type 1) installation is the increased amount of soft tissue that will have formed during the first weeks of healing following tooth extraction. It must be emphasized, however, that no randomized controlled studies comparing the treatment outcomes in type 1 or type 2 placements have so far been reported.

Apart from obtaining soft tissue coverage of the previous entrance to the alveolus, type 2 installation has also been claimed to reduce facial soft tissue recession compared to type 1 implant placement. In a comparative study assessing esthetic outcomes of immediate and conventional implant placement, no treatment was favored over any other with respect to overall esthetic results (Raes *et al.* 2011). Interestingly, conventional implant placement was associated with more mid-facial recession than immediate implant placement. In a clinical study of implants placed in fresh extraction sockets (Botticelli *et al.* 2004), during healing, they became clinically osseointegrated within the borders of the previous extraction socket. However, significant loss of buccal bone height (contour) also occurred. In esthetically critical situations, this loss of contour may lead to a compromised outcome. Hence, not infrequently, tissue augmentation procedures must be performed in the esthetic zone.

In this context, it is important to realize that when a two-stage implant placement protocol is used, the labial mucosa will recede following abutment connection surgery. Mean values of recession between 0.5 mm and 1.5 mm, but with large variations, have been reported in several clinical studies (Grunder 2000; Oates *et al.* 2002; Ekfeldt *et al.* 2003). These findings additionally stress the necessity for a careful treatment approach when implants are placed in the esthetic zone. The biotype (see Chapter 4) of the soft and hard tissues may play a role in the esthetic outcome of implant therapy. Characteristics of soft and hard tissues at teeth were described and classified into two biotypes: the flat thick or the pronounced scalloped, thin biotype (Olsson & Lindhe 1991; Olsson

Fig. 49-22 Patient exhibiting a thin tissue biotype as characterized by a thin free gingiva, a narrow zone of keratinized and attached mucosa, shallow probing depths, and a pronounced "scalloped" contour of the gingival margin, including recessions at some maxillary anterior teeth. Tooth 11 is scheduled for extraction and replacement by an implant using a type 2 or 3 approach.

et al. 1993; Weisgold *et al.* 1997). The thin tissues in the latter type include a thin free gingiva, a narrow zone of attached mucosa, and a pronounced "scalloped" contour of the gingival margin. In addition, the scalloped thin biotype is associated with a delicate bone housing. In a recent study it was found that buccal tissue recession at single-tooth implants was more pronounced in patients exhibiting a thin biotype compared to patients with a thick biotype (Evans & Chen 2008). Based on these findings and on clinical experience, it was proposed that patients exhibiting a pronounced scalloped biotype should be treated with a type 2, 3, or 4 rather than a type 1 implant installation approach (Fig. 49-22). Currently, the paucity of data from well-controlled clinical studies precludes clear statements regarding the effect of the different types of implant placement on the stability and the height of the soft tissues at the implant sites.

Success of treatment and long-term outcomes

Numerous clinical studies have demonstrated that type 1 implant placement is a successful and predictable clinical method (Lang *et al.* 1994; Schwartz-Arad & Chaushu 1997a; Hämmerle *et al.* 1998; Covani *et al.* 2004). In addition, success and survival rates for type 1 implants have been reported to be of the same magnitude as those for implants placed in healed ridges (Gelb 1993; Grunder 2000; Gomez-Roman *et al.* 2001; Gotfredsen 2004; Schwartz-Arad *et al.* 2004). Histologic studies in animals confirmed the viability of type 1 placement. Unloaded titanium implants placed in extraction sockets showed a high degree of osseointegration (Anneroth *et al.* 1985), that is similar to that for implants placed in healed sites. Furthermore, a few studies analyzing survival rates for type 2 and 3 placements have shown survival rates similar to those reported for type 1 and 4 placements (Watzek *et al.* 1995; Nir-Hadar *et al.* 1998; Polizzi *et al.* 2000).

Conclusion

In situations where teeth are to be replaced with implants, various factors govern the decision regarding the optimal time point for implantation following tooth extraction. Of special importance are the overall objective of the treatment, the location of the tooth within the oral cavity, the anatomy of the bone and the soft tissue at the site, and the adaptive changes of the alveolar process following tooth extraction. The decision regarding the timing for implant placement needs to be based on a thorough understanding of the structural changes that occur in the alveolar process following tooth extraction, with and without implant placement, as presented in this chapter.

Introduction: Principles in alveolar bone regeneration

The alveolar process is sensitive to a variety of environmental and physiologic factors that influence its ability to function and maintain its integrity. Before implant therapy became available, the physiology and healing patterns of the edentulous ridge after a tooth was extracted were often neglected or not dealt with properly (Amler *et al*. 1960; Amler 1969). Today, implant placement in severe cases of alveolar resorption is a well-understood and recognized challenge that significantly impacts the success of implant therapy. Although alveolar bone loss can be congenital, the result of trauma, pathology, and chronic/acute infection, or a consequence of periodontal disease, the loss of mechanical function following a tooth extraction is the most widely experienced scenario that leads to this clinical deficiency. In fact, after a tooth is extracted, approximately 25% of the bone volume has been reported to be lost after the first year. Over time, this deterioration may progress and is often reported to be responsible for a 40–60% loss of alveolar volume during the first 3 years after a tooth is lost. The resulting ridge deficiency is primarily the result of the gradual loss of the horizontal dimension accompanied by a rapid loss of bone height (Carlsson *et al*. 1967). Therefore, clinicians have suggested protocols to minimize ridge resorption or correct clinically unfavorable deficiencies (Tarnow & Eskow 1995; Sclar 2004; Seo *et al*. 2004) (Fig. 50-1).

Successful ridge augmentation procedures consider basic biologic and physical principles of bone to enhance the regenerative potential of the host. The placement of bone grafting materials to favor healing in osseous defects or to augment atrophic edentulous ridges to allow dental implant installation has been evaluated in a number of experimental and clinical studies, and has become a gold standard treatment in implant dentistry (Fig. 50-2).

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Advanced bone grafting protocols have evolved to allow predictable implant placement in severe ridge deficiencies that would have otherwise prevented implant therapy.

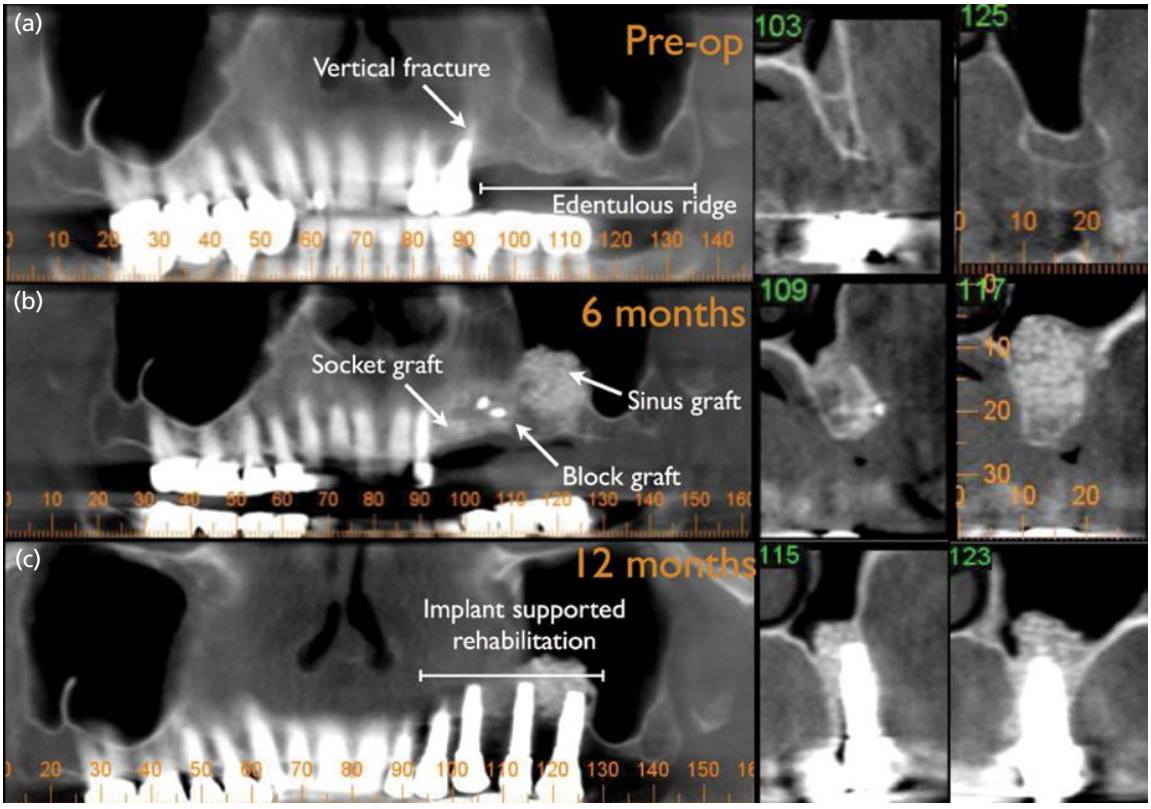

Fig. 50-2 Availability of diverse bone grafting materials. This has significantly contributed to the development of successful ridge augmentation techniques. (a) Baseline radiographic image highlights the edentulous deficient ridge. (b) Six months after the required grafting procedures. (c) Twelve months after surgery and implant-supported rehabilitation.

It has been found that the osteogenic environment that maximizes the bone regenerative potential of traditional advanced grafting procedures is often affected by local as well as systemic factors. In some cases, the incorporation of the bone graft in the recipient site may be partially or completely impaired, and in turn there may be bone resorption and bone loss associated with the donor grafting material. As a consequence, much of the intended volume is lost, and frequently, the defects heal with fibrous connective tissue instead of bone. The surgical principles that favor bone regenerative therapies have been discussed and have helped to create awareness of the physical and biologic factors that are determinants of adequate healing (Wang & Boyapati 2006). The molecular wound healing events following tooth extraction and eventual consolidation and bone repair of the residual ridge occur through an orderly sequence of expression of osteogenic factors associated with angiogenesis, cell survival, matrix synthesis, and maturation (Lin *et al.* 2011). Some of the most important modifiable factors to consider and assist in proper wound management are discussed below.

Promoting primary wound closure

Primary closure is primordial for bone regeneration because it provides an undisturbed environment for healing (Gelb 1993; Becker & Becker 1996; Fugazzotto 1999; Goldstein *et al*. 2002). Ideal flap closure should be relatively passive and tension-free. In this way, the risk of membrane exposure, wound contraction, collagen formation and remodeling, re-epithelialization, and patient discomfort are decreased. In order to ensure primary closure, the presence of adequate soft tissue should be assessed prior to surgery. It may be recommended to augment the soft tissues prior to bone augmentation in cases where the soft tissue is lacking.

Enhancing cell proliferation and differentiation

Proper cell proliferation and differentiation not only provides blood, oxygen, and nutrients to the tissues, but also acts as a source of angiogenic and osteogenic cells. Sources of osteogenic cells include the periosteum, endosteum, and undifferentiated pluripotent mesenchymal cells. The bone marrow is an excellent source of these mesenchymal cells, which can differentiate into osteoblasts and osteoclasts. In order to increase important early healing events, perforations of the cortical plate have been recommended to facilitate the migration of cells to the healing site (Buser *et al.* 1995). This is a process referred to in the literature as the regional acceleratory phenomenon (RAP). These perforations act as a mechanical or non-infective stimulus that increases blood perfusion to the healing site. Therefore, important growth factors are released, allowing the tissue to heal faster than the normal unperturbed regeneration process (Frost 1983; Shih & Norrdin 1985).

Currently, a number of biologically active products are available clinically to overcome common intrinsic wound healing limitations by enhancing cell proliferation and differentiation, and by allowing a more rapid and predictable bone anabolic signaling process between the graft and the host tissue.

Protecting initial wound stability and integrity

One factor that affects wound healing is stability of the blood clot, and the barrier membrane helps stabilize the blood clot (Wang *et al*. 2004). This is important because the clot contains a multitude of cytokines [e.g. interleukin-1 (IL-1), IL-8, tumor necrosis factor], growth factors [e.g. platelet-derived growth factor (PDGF), insulin-like growth factor-1 (IGF-1), fibroblast growth factor-2 (FGF-2)], and signaling molecules that aid in recruiting cells to promote healing. Moreover, the blood clot is important for the formation of granulation tissue and subsequent formation of bone (Schenk *et al.* 1994).

Additionally, to allow proliferation of bone-forming cells, a physical space is necessary (Oh *et al.* 2003). This is typically achieved through the use of membranes that exclude epithelial and connective tissue cells, or a proper scaffold. As will be discussed later, membrane collapse is problematic as it compromises the space available for the osteogenic cells. Hence, the use of titanium-reinforced membranes helps in space maintenance, especially in cases of severe bone loss (Jovanovic *et al.* 1995), compared to the collapse reported with collagen membranes alone (Oh *et al*. 2003).

This chapter discusses the growing evidence in the area of bone augmentation procedures that are frequently employed by clinicians to augment the deficient residual ridges prior to implant therapy.

Treatment objectives

The rationale behind any crestal bone augmentation procedure is to establish sufficient bone availability for safe and predictable dental implant therapy, as well as for attaining adequate bone thickness around the installed implant. Spray *et al*. (2000) evaluated the influence of bone thickness on the marginal bone response at second-stage uncovering surgeries, and reported that as the bone thickness approached 1.8–2 mm, bone loss (i.e. implant dehiscence) decreased significantly. Although the "adequate" bone thickness may vary depending on the macroscopic and microscopic implant configurations, as well as the clinical indication, it is generally agreed that at least 2 mm of bone on the buccal side of the implant are needed to achieve long-term stability of peri-implant health and good esthetics.

This rationale is further justified by the growing evidence for biologic complications around functional implants. The prevalence of these peri-implant

diseases affecting the implant-supporting bone (peri-implantitis) ranges between 28% and 56% of patients and between 12% and 43% of implants (Zitzmann & Berglundh 2008). Among the potential risk factors for peri-implantitis, rough implant surfaces exposed to the oral environment are at a higher risk of accumulating bacterial plaque biofilms and hence the development of mucosal inflammation (Renvert *et al*. 2011). Schwarz *et al*. (2012) evaluated the influence of residual marginal dehiscence bone defects after guided bone regeneration (GBR) on the long-term stability of peri-implant health, and reported that implants exhibiting residual defect heights of >1 mm were at higher risk of presenting mucosal clinical attachment loss, marginal recession, and deepened probing pocket depths 4 years after treatment. Therefore, the implant surgeon should ensure that there is enough bone to fully cover the implant surface and in case of limited availability, carry out a bone augmentation procedure.

Diagnosis and treatment planning

Patient

In general, there are no specific contraindications for ridge augmentation procedures provided the patient can withstand a conventional oral surgical procedure. For bone augmentation procedures as well as for other types of oral implant operations, there are some relative contraindications that need to be taken into consideration, mainly medical conditions that might impair normal bone healing. For example, in patients with diabetes, there is evidence that implant success rates are similar to those in healthy patients, provided there is appropriate glycemic control. Experimental studies, however, have provided histologic evidence of impaired healing in implants placed in diabetic animals when compared to healthy controls, although osseointegration was achieved in both groups (Colombo *et al*. 2011; Schlegel *et al*. 2013). Recently, the effect of experimental diabetes and metabolic control on the potential for *de novo* bone formation following GBR was investigated in the rat mandible (Retzepi *et al*. 2010). These authors did not observe statistically significant differences in the amount of vertical bone regeneration when uncontrolled diabetic, insulin-controlled diabetic, and healthy animals were compared. The uncontrolled diabetes group, however, showed an increased rate of infectious complications and a less predictable outcome. When metabolic control of the systemic condition was achieved, the detrimental effects on healing were reversed.

Smoking has also been found to negatively affect the long-term prognosis of osseointegration (Bain & Moy 1993). Clinical studies have reported that smokers present not only higher rates of implant failure when compared with non-smokers (De Bruyn & Collaert 1994; Lambert *et al*. 2000), but also a greater number of complications around successfully integrated implants (Roos-Jansaker *et al*. 2006), such as a higher incidence of peri-implant mucositis and peri-implantitis (Heitz-Mayfield 2008). Although there is ample evidence on the negative effects of tobacco smoking on the clinical outcomes of periodontal regenerative therapies, such as guided tissue regeneration (GTR) (Patel *et al*. 2012), few studies have directly evaluated its effect on GBR. A meta-analysis, based on six studies, evaluated the effects of smoking on dental implants placed on augmented bone and reported an odds ratio (OR) of 3.61 (95% CI 2.26–5.77) for implant failures (Strietzel *et al*. 2007). In this systematic review, the impact of smoking on the outcomes of different bone regeneration techniques (horizontal and/or vertical augmentation) was assessed in four retrospective studies: three studies reported more failures and complications in smokers compared with non-smokers. Moreover, the amount of bone augmentation in smokers was inferior when compared with that in non-smokers. Similarly, a recent clinical case series evaluated the outcomes of a GBR procedure combining autogenous bone and an expanded polytetrafluoroethylene (ePTFE) membrane (Lindfors *et al*. 2010). In the group of non-smokers, the augmentation procedure was successful in 95% of the cases, whereas in smokers it was successful in only 63% of the cases. Moreover, signs of soft tissue inflammation were present in ten (37%) of the augmentation sites, and this occurred more often in smokers (75%) than in non-smokers (21%).

These patient-related factors are not absolute contraindications for bone augmentation procedures, but they should be taken into consideration during diagnosis and treatment planning. When a bone augmentation procedure is indicated, the patient's systemic status should be optimized.

Defect classification

Bone availability is the main prerequisite for safe and predictable implant placement. There are, however, many clinical situations where bone quantity is limited and therefore, bone augmentation procedures are indicated. In order to decide on the appropriate bone augmentation strategy, the available bone crest must be carefully evaluated with careful clinical examination and three-dimensional (3D) radiography (see Figs. 50-1, 50-2) of the bone morphology.

According to Seibert (1983), alveolar crest defects are classified into three categories (Fig. 50-3):

- *Class 1 defects*: when the bone deficiency is predominantly in the horizontal dimension
- *Class 2 defects*: when the bone deficiency is predominantly in the vertical dimension
- *Class 3 defects*: when the bone deficiency affects both the vertical and horizontal dimensions.

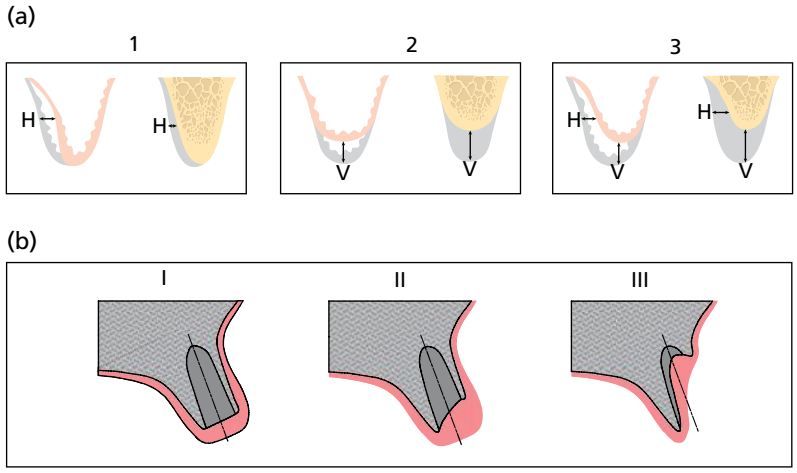

Fig. 50-3 (a) Alveolar crest defects, Seibert classification. (b) Extraction sockets defect, Hämmerle & Jung classification.

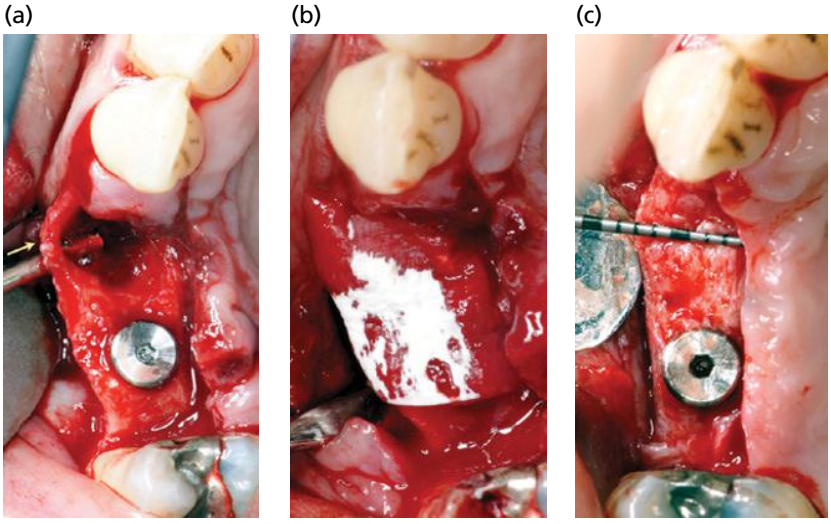

Fig. 50-4 (a, b) Socket preservation (deproteinized bovine bone mineral + non–cross-linked collagen membrane) in position 13 due to fenestration (arrow) of the buccal bone wall of the socket (class II defect, Hämmerle & Jung) and immediate implant (no graft) in position 14. (c) Re-entry surgery at 4 month. Outcome of the socket preservation procedure. Note the bone remodeling at the implant site.

Depending on the amount of available bone and the defect type, the treatment strategy may consider implant placement and a concomitant bone augmentation procedure (one-step GBR procedure) or bone augmentation and delayed implant placement once the bone volume has been augmented (two-step GBR procedure). The one-step procedure is indicated in class 1 defects when there is enough vertical bone for placing an implant with appropriate primary stability and the bone regenerative procedure is intended for horizontal bone augmentation. In class 2 and 3 defects, depending on the amount of vertical augmentation needed, the delayed approach is usually indicated (Fig. 50-4).

Bone augmentation procedures could also be considered when placing implants in fresh extraction sockets. In most of these clinical situations, the morphology of the socket does not match the implant diameter and, depending on the resulting bone defect, a different bone augmentation procedure might be indicated.

Hämmerle and Jung (2008) (Fig. 50-3) have classified these defects in fresh extraction sockets as:

- *Class I*: extraction socket that has intact bone walls after tooth extraction
- *Class II*: extraction socket that has a marginal dehiscence/fenestration of the buccal bone wall after tooth extraction
- *Class III*: extraction socket that has a large dehiscence of the buccal bone wall after tooth extraction.

A one-step GBR procedure is usually indicated for class I and II defects, while in large class III defects the delayed approach might be indicated.

When placing implants in extraction sockets, timing of the bone augmentation procedure is also very important since, depending on the time elapsed from tooth extraction, different soft tissue conditions may be encountered. For details regarding the different implant treatment strategies in extraction sockets, see Chapter 49.

Bone augmentation therapies

In the mid-1980s, the GTR principle was applied in periodontal regeneration, based on the early studies of Melcher (1976), who developed the concept of using barrier membranes to "guide" the biologic process of wound healing. These early experimental studies demonstrated that the exclusion of soft tissue invasion of the defect by means of a barrier membrane, allowed the cells with regenerative potential to migrate to the site (derived from the periodontal ligament or bone marrow) and promoted periodontal regeneration (Nyman *et al*. 1982). Based on the same biologic principle, the GBR treatment concept was mechanical exclusion of the soft tissues from filling the osseous defect, thus allowing the cells with osteogenic cells to colonize the wound (Dahlin *et al*. 1988). The key prognostic factor in GBR was enough space under the barrier membrane to allow for bone regeneration of the crestal defect. Depending on the morphology of the defect, this space could be maintained with either a particulated graft or a block graft. Different biomaterials, natural and/or synthetic, have been developed, investigated, and used as grafts for bone augmentation procedures.

The following sections describe the biologic principles of GBR using different preclinical models and also the biomaterials that have been most frequently investigated and used as graft materials.

Biologic principles of guided bone regeneration

Seibert and Nyman (1990) demonstrated successful reconstruction of surgically-created, buccolingual defects in the edentulous ridge of dogs after 90 days of healing, with newly formed bone filling the space created beneath e-PTFE (Gore-Tex®) non-resorbable barrier membranes. Furthermore, Smukler *et al*. (1995) reported that the application of barrier membranes in class III ridge defects led to a mean vertical augmentation of 3.31 mm (Buser *et al.* 1995), and demonstrated that this regenerated bone could successfully integrate dental implants when these were placed 6 months after the GBR procedure.

The sequence and pattern of bone regeneration in GBR procedures has been investigated in experimental studies. Schenk *et al.* (1994) investigated surgically-created, membrane-protected defects in the edentulous ridge in dogs. The histologic analysis showed a sequence of events starting with the organization of a blood clot that filled the protected space beneath the membrane. A connective tissue matrix rich in new vascular structures replaced this blood clot and later, deposition of woven bone started from the surrounding bony walls and concentrically filled the defect. This woven bone was later replaced by parallel-fibered lamellar bone, resulting in a new cortical structure at the periphery of the defects. This pattern of intramembranous bone growth shown in GBR was described also in the healing of an alveolar socket after tooth extraction (Cardaropoli *et al*. 2003).

Dahlin *et al.* (1989) were the first to provide evidence to support the effectiveness of GBR around implants. e-PTFE membranes were applied around exposed implant threads inserted in rabbit tibiae and peri-implant bone formation was observed provided enough space was secured under the membrane. Becker *et al*. (1990) also assessed the potential of GBR in treating exposed threads of implants placed in dog mandibles. They reported a mean increase of 1.37 mm in bone height for the GBR-treated test sites, versus 0.23 mm for the sham-operated controls.

Vertical bone augmentation using this principle was also demonstrated by Jovanovic *et al*. (1995) who reported regeneration of the mandibular process when applying e-PTFE membranes around supracrestally placed implants in dogs. The new bone formed supracrestally amounted to 1.82 mm (SD 1.04) and 1.9 mm (SD 0.3) when using titanium-reinforced and standard e-PTFE membranes, respectively. GBR was also studied histologically in monkeys with e-PTFE membranes placed around dental implants inserted immediately into fresh extraction sockets (Warrer *et al*. 1991): bone regeneration was seen around the implant circumference in GBR-treated sites, compared with a lack of bone contact in non–GBR-treated control sites. Similar experimental studies in dogs also showed successful bone regeneration using e-PTFE membranes in implants immediately placed in fresh extraction sockets (Becker *et al*. 1991; Gotfredsen *et al*. 1993).

Regenerative materials

Barrier membranes

Different types of barrier membranes have been tested for GBR. These membranes must fulfil specific criteria for promoting bone regeneration of the edentulous ridge, such as biocompatibility, cell occlusion properties, integration by the host tissue, and space-making capacity. Their specific composition falls into two broad categories: non-resorbable and resorbable. e-PTFE has been the most frequently used material for *non-resorbable membranes* in both periodontal and bone regeneration clinical applications. e-PTFE membranes are flexible with an external porous structure allowing for tissue integration and an internal occlusive layer providing the barrier mechanism. They are composed of a chemically stable and biologically inert polymer that resists microbiologic and enzymatic degradation and does not elicit any immunologic reactions. To enhance the space-making capacity of these devices, a titanium scaffold is applied between the two ePTFE layers, adding stiffness and reinforcing the membrane structure. These non-degradable barrier membranes require a second surgical intervention to remove them. This disadvantage, together with the high occurrence of postoperative complications, mainly from early membrane

exposure, has limited their clinical use and has led to the development and broader use of resorbable membranes.

Bioresorbable membranes must ensure that the tissue reactions during the process of membrane resorption or biodegradation are minimal and do not affect the outcome of bone regeneration (Hardwick *et al*. 1995). Several bioresorbable materials have been tested with varying success in bone regeneration applications. Bioresorbable membranes are either natural (xenogeneic collagen type I or III) or made of synthetic polymers, including polyurethane, polyglactin 910, polylactic acid, polyglycolic acid, polyorthoester, polyethylene glycol, and different combinations of polylactic and polyglycolic acid (Sandberg *et al*. 1993; Zellin *et al*. 1995; Brunel *et al*. 1998; Jung *et al*. 2006). When inserted into an aqueous environment, such as a biologic system, the biodegradable polymers undergo enzymatic degradation by hydrolysis. The natural collagen membranes undergo resorption by enzymatic degradation. This membrane degradation process depends on many factors, such as membrane composition, pH, temperature, degree of polymer crystallization, cross-linking in collagen membranes, and membrane volume (Warrer *et al.* 1992; Hämmerle & Jung 2003). The duration of the barrier function is, therefore, variable and the resorption process may interfere with the wound healing and bone regenerative outcome.

Several experimental studies have compared the potential of these barrier membranes for promoting bone regeneration. When non-resorbable e-PTFE membranes were compared with synthetic bioresorbable membranes made of poly D,L-lactide-co-trimethylencarbonate, significantly more bone was formed around implants covered with e-PTFE membranes, although both test and control implants exhibited new direct bone-to-implant contact (Hurzeler *et al.* 1997). These differences are mainly due to the lack of stiffness and space-making capacity of bioresorbable membranes, which when placed directly over the implant threads, tend to collapse and occlude the space available for bone regeneration. This problem is usually overcome by using a scaffold or graft material under the membrane that provides the space for tissue in-growth and subsequent bone formation. Experimental studies comparing non-resorbable and collagen resorbable membranes, with and without the use of a scaffold, have shown similar bone regenerative outcomes for the non-resorbable membranes and the collagen resorbable membranes used with a scaffold (Hurzeler *et al*. 1998).

For collagen membranes, the biodegradation and concomitant tissue integration depends on the degree of collagen cross-linking. A comparative study evaluated different collagen membranes: (1) BioGide (BG) (non–cross-linked porcine type I and III collagens, bilayered) (Geistlich Biomaterials, Wolhusen, Switzerland); (2) BioMend (BM) (glutaraldehyde cross-linked bovine type I collagen) Sulzer Medica, Colla-Tec Inc., Plainsboro, NJ, USA); (3) BioMendExtend (BME) (glutaraldehyde cross-linked bovine type I collagen) (Sulzer Medica); (4) Ossix (OS) (enzymatic cross-linked bovine type I collagen) (3i, Colbar R&D Ltd, Ramat Hush-aron, Israel); (5) TutoDents (TD) (non–cross-linked bovine type I collagen, bilayered) (Tutogen, Carlsbad, CA, USA); (6) VN(1); (7) VN(2); and (8) VN(3) (1, 3, 4 × chemical cross-linked porcine type I and III collagens, bilayered, respectively) (Geistlich Biomaterials) (Rothamel *et al*. 2004). The non–cross-linked porcine-derived collagen types I and III exhibited good tissue integration (without observable foreign body reactions), rapid neoangiogenesis, and almost complete biodegradation 4 weeks after implantation. The vascularization and biodegradation of chemical and enzymatically cross-linked collagen membranes, however, were slower and the resorption rate was directly related to the degree of cross-linking.

The choice of membrane material usually depends on the amount of bone regeneration needed, mainly in the vertical dimension. e-PTFE barrier membranes have demonstrated more favorable results when compared with resorbable devices, mainly due to their better space-making capacity, longer barrier function, and lack of a resorption process that may negatively affect bone formation (Hämmerle & Jung 2003). Nevertheless, a high rate of soft tissue dehiscence was observed with the use of ePTFE membranes. When this complication occurs, early contamination of the exposed membrane usually jeopardizes the regenerative outcome. A meta-analysis evaluating the influence of membrane exposure on the outcomes of regenerative procedures reported that new bone formation was six-fold greater when no soft tissue dehiscence occurred (Machtei 2001).

As already mentioned, these frequent complications and the need for a second surgery to remove the membrane with non-resorbable membranes make resorbable membranes the current gold standard, provided they are used with an adequate space-making graft material. The choice of non–cross-linked resorbable collagen membranes should be based on their advantages in terms of earlier neoangiogenesis, lack of inflammatory response, and fast biodegradation/integration within the host tissue.

Bone grafts and bone substitutes

Bone grafts

Autogenous bone grafts (autografts) have historically been the gold standard in bone regeneration therapies since they have well-documented osteoconductive, osteoinductive, and osteogenic properties (Yukna 1993). In alveolar bone augmentation surgeries, autogenous bone is used either as a particulate or a block graft. Particulate bone grafts are normally harvested from intraoral sites and used in combination with barrier membranes following the principles of

GBR. These bone chips have the disadvantages that their availability is limited within the oral cavity and, as they lack a rigid and supportive structure, they do not provide the space-making capacity necessary for the treatment of class II and III defects. In these cases, rigid titanium-reinforced ePTFE barrier membranes or other space maintenance strategies, such as tenting screws or microimplants, have been used in conjunction with particulate bone autografts. Another drawback with the use of autografts is their fast resorption rate, which requires early implant placement to assure functional loading to the regenerated bone, thus preventing its resorption.

Monocortical block autografts may be harvested from intra- or extra-oral sites. Common intraoral donor sites are the mandibular chin or the ascending ramus area, whereas common extraoral donor sites are the iliac crest or the calota. They may be used in combination with barrier membranes or alone, and they require fixation to the recipient crestal site with mini-screws to avoid micro-movements during healing. These grafts, due to their excellent space maintenance capacity, are indicated in large crestal defects in which there is a need for vertical bone augmentation. Their main disadvantage is the morbidity associated with their harvesting, mainly from the chin area. As with particulate autografts, their resorption rate is high, although when combined with a barrier membrane or with bone particulate xenografts, resorption is slowed.

Bone substitutes

In order to avoid the morbidity associated with the harvesting of autogenous bone grafts, allografts, xenografts, and alloplasts have been indicated and tested.

Allografts are bone grafts harvested from cadaver donors and processed by freezing or demineralization and freezing. These grafts are then sterilized and supplied by specially licensed tissue banks as bone particles or large blocks. Demineralized freeze-dried bone allografts (DFDBAs) have shown osteoconductive as well as osteoinductive properties due to the release of bone morphogenetic proteins (BMPs) during the demineralization process. There is some concern, however, regarding their absolute non-infectivity, although there have been no reported cases of disease transmission from DFDBAs used for dental purposes among over 1 million cases over 25 years (Yukna 1993). These allografts are usually used in combination with barrier membranes following the principles of GBR.

Xenografts are graft biomaterials of animal origin, mainly bovine and equine. These graft materials are deproteinized in order to completely remove the organic component and thus avoid any immunogenic reaction. This chemical or low heat process preserves the original bone architecture and the inorganic mineral composition, which assures the osteoconductive properties of the biomaterial. Inorganic bovine bone grafts are usually particulate and utilized according to the principles of GBR in combination with resorbable collagen membranes. Different preclinical and clinical studies have demonstrated their safety and efficacy as bone substitutes for both periodontal and peri-implant augmentation procedures (Baldini *et al*. 2011). Recently, highly purified porcine collagen type I has been added to xenografts to enhance their clinical handling by improving the cohesion between the mineral granules.

Alloplasts are synthetic bone substitutes that include different combinations of calcium phosphates fabricated under different sintering conditions, which yields different physical properties and resorption rates. The combination of hydroxyapatite and beta-tricalcium phosphate (β-TCP) provides a scaffolding function (hydroxyapatite) as well as osteoconductive properties (β-TCP). These biomaterials are usually resorbable and delivered as granules. They should be always used in combination with barrier membranes.

Choice of material

This choice should be based on the clinical indication. For small bone defects requiring mainly horizontal bone augmentation, the use of xenografts and alloplasts has demonstrated excellent results. When the objective is to preserve the socket walls after tooth extraction, experimental studies have evaluated the histologic healing when the sockets are filled with different graft materials. The use of autogenous bone chips alone does not counteract the physiologic process of bone remodeling that occurs at the socket bone walls after tooth extraction (Araújo & Lindhe 2011). Indeed, the healing process at these sites filled with autografts showed characteristics similar to those of the sockets without any filling. In contrast, the use of xenografts with a much slower resorption rate demonstrated significantly better preservation of the socket walls than the non-grafted sites. Histologically, these xenograft granules were integrated and fully surrounded by newly formed bone (Araújo & Lindhe 2009). In a similar experimental model, a β-TCP alloplast demonstrated limited bone promotion properties, with the graft particles being encapsulated with connective tissue (Araújo *et al.* 2010).

In crestal defects requiring horizontal augmentation, particulate bone grafts should be utilized in combination with barrier membranes. Experimental studies testing different graft materials [biphasic hydroxyapatite + β-TCP (BCG)] or collagen-coated deproteinized bovine bone mineral (DBBM) (BOC) showed that both biomaterials increased bone fill and the percentage of osseointegrated bone–graft particles, and it was concluded that both BCG and BOC provide an osteoconductive scaffold to support GBR procedures at dehiscence-type defects (Schwarz *et al.* 2007).

In large crestal defects for which the aim is both horizontal and vertical bone augmentation, the use of

monocortical autogenous corticocancellous block grafts is recommended. In experimental studies comparing the use of these block grafts with and without a barrier membrane, a significant buccocrestal resorption and limited bone augmentation were demonstrated in the non–membrane-protected group, thus demonstrating the clear indication for always protecting the block graft with a resorbable barrier device (von Arx *et al.* 2001).

Evidence-based results for ridge augmentation procedures

These procedures have been used in five main clinical applications: ridge preservation, bone regeneration in fresh extraction sockets, horizontal bone augmentation, ridge splitting/expansion, and vertical ridge augmentation.

Ridge preservation

Important structural changes of the edentulous ridge take place after tooth extraction and eventually lead to dimensional changes of the alveolar crest. A recent systematic review assessed the hard and soft tissue changes occurring 6 months after tooth extraction in humans and demonstrated a horizontal bone loss of 29–63% and vertical bone loss of 11–22% from the dimensions of the alveolar bone crest at the time of extraction (Tan *et al*. 2012). With the goal of preventing these physiologic hard and soft tissue changes, different bone augmentation techniques have been proposed to preserve the alveolar architecture after tooth extraction. In general, these ridge preservation techniques have been defined as: "Any therapeutic approach carried out immediately after tooth extraction aimed to preserve the alveolar socket architecture and to provide the maximum bone availability for implant placement" (Vignoletti *et al*. 2012).

These ridge preservation approaches have utilized GBR principles using the following regenerative technologies:

- Resorbable and non-resorbable barrier membranes alone
- Resorbable barrier membranes in combination with bone substitutes
- Bone substitutes alone
- Bone substitutes in combination with soft tissue grafts.

Furthermore, different surgical techniques have been proposed, such as flap/flapless approaches allowing for primary/secondary healing.

Results from a systematic review evaluating the efficacy of these socket preservation therapies concluded that these techniques may reduce the bone dimensional changes that occur after tooth extraction, although some degree of vertical and horizontal bone loss can still be expected (Ten Heggeler *et al.* 2011). These results are consistent with those from another recent systematic review that compared the outcomes of socket preservation therapies with the spontaneous healing of the post-extraction socket (Vignoletti *et al.* 2012). A statistically significant greater reduction in bone height and width for the control groups compared to the test groups treated with socket preservation therapies was demonstrated: weighted mean differences between test and control groups were 1.47 mm and 1.84 mm, respectively. Furthermore, in an attempt to assess the influence of the different factors that may influence this outcome, a subgroup analysis with meta-regression was performed. The potential factors included in the meta-regression were: (1) the socket site, that is the integrity/non-integrity of the socket bone walls and presence/absence of adjacent teeth; (2) the surgical protocol, that is flapped/flapless surgery or primary flap closure/secondary intention healing; and (3) the biomaterial used, that is membrane/no membrane or type of graft material. The conclusions from the subgroup analysis were:

- Use of membranes gave better results than for use of grafts alone in terms of horizontal bone changes.
- A slight tendency towards less bone loss in the horizontal direction was observed when the sockets healed by primary intention.
- Flapped surgical procedures demonstrated significantly less horizontal bone resorption of the socket, when compared to flapless surgeries.

Based on this evidence, it is not possible to indicate which type of surgical procedure or biomaterial is most suitable for socket preservation, but the use of barrier membranes and a flapped surgical procedure should be suggested.

Bone regeneration in fresh extraction sockets

According to the classification proposed at the Third ITI Consensus Conference (Hämmerle *et al*. 2004), immediate and early implant placement (type 1 and 2) protocols have been indicated as the most suitable for implant placement following tooth extraction. The type 1 protocol (immediate implant placement) was first presented in 1976 by Schulte and Heimke (1976). The several advantages inherent to placing the implant immediately after tooth extraction have led to a growth in popularity of this protocol in the last decade and this has attracted the interest of clinicians and investigators (Fig. 50-5).

Based on preclinical and human studies, it is well accepted that implant placement into a fresh extraction socket does not counteract the physiologic bone remodeling in the alveolar bone crest. Results from human trials have demonstrated that both vertical and horizontal dimensional changes of the alveolar

crest may be expected. Botticelli *et al*. (2004) demonstrated a horizontal resorption of approximately 56% and 30% of the original dimension of the buccal and lingual bone walls of the sockets, respectively, when placing single-tooth immediate implants in the anterior region of the maxilla. These results are consistent with data from a similar study demonstrating 36% and 14% hard tissue resorption at the buccal and palatal bone walls, respectively. Furthermore, the vertical bone resorption of the buccal bone crest was also investigated and amounted to a mean value of 1 mm (SD 2) (Sanz *et al*. 2010). These changes in the horizontal and vertical dimension were mainly influenced by the thickness of the buccal bone plate (>1 mm) and the gap that occurs between the implant surface and the buccal socket wall. Hence, implants placed into sockets with a <1-mm buccal thickness/gap are at higher risk of presenting a dehiscence defect that exposes the implant surface to the oral environment and a greater overall horizontal resorption of the alveolar crest.

This type 1 immediate implant surgical protocol combined with other treatment concepts has also been proposed:

- Immediate implant placement with a graft and/or barrier membranes and/or a soft tissue graft (Fig. 50-6)
- Immediate implant placement with immediate loading.

A recent systematic review has estimated survival and success rates of implants and the implant-supported prostheses; the prevalence of biologic, technical, and esthetic complications; and the magnitude of soft and hard tissue changes following implant placement immediately into fresh extraction sockets (Lang *et al*. 2012). On the basis of 46 included clinical trials, the 2-year survival rate of implants placed into extraction sockets was 98.4% (97.3–99%). Unfortunately, only limited long-term data were available for the occurrence of biologic complications. In terms of esthetic results, it was reported that about 20% of patients who underwent immediate implant placement suffered from suboptimal esthetic outcomes due to buccal soft tissue recession in studies with observation periods of 3 years or more. Gingival biotypes and a buccolingual position of the implants were the most relevant factors for buccal soft tissue levels.

The effect of regenerative therapies combined with type 1 immediate implant placement has been evaluated in a multicenter prospective clinical study (De Angelis *et al.* 2011). In this study, patients received a resorbable membrane alone or in conjunction with a bone substitute, and were followed up to 1 year after implant loading. The authors reported an more favorable outcome when using a membrane in conjuction with the bone substitute. However, they disclosed that single post-extractive implants might be at a higher risk for implant complications.

Although a high survival rate for type 1 immediate implants has been reported in the literature, long-term outcomes based on peri-implant health and esthetics are still not available. Based on the available evidence, important risk factors for unpredictable esthetic outcomes are the thickness of the buccal bone plate, gingival biotype, and buccolingual positioning of the implant. Although many authors advocate the use of horizontal bone augmentation techniques (GBR) in conjunction with immediate implant placement, the evidence for this additional treatment is unclear from controlled clinical trials.

To overcome some of these surgical/clinical limitations of the immediate implant protocol, the type 2 or early implant placement protocol has been advocated. This surgical protocol consists of performing the extraction and thoroughly cleaning the extraction socket, then waiting 4–6 weeks before placing the implant, which allows for soft tissue coverage and full healing of the extraction wound. The rationale for this surgical approach lies in the elimination of any infectious tissue, mostly in situations where the reason for the extraction was periapical or very deep periodontal pathology, and at the same time having enough soft tissue to allow for primary intention healing during the implant therapy through a tension-free flap closure without altering the mucogingival line. This is particularly important since, in many clinical situations, the cause of extraction is deep periodontal or periapical pathology where the availability of bone is limited and bone augmentation will be required in conjunction with the implant placement. The importance of early implant placement lies in the availability of the socket walls, since 4 weeks after extraction the socket walls will be preserved and this facilitates the placement of the implant and the required bone augmentation. Moreover, the recent evidence for a usually very thin (1 mm) maxillary buccal bone wall (Huynh-Ba *et al*. 2010; Januario *et al*. 2011) makes the requirement for bone augmentation almost the norm whenever implants are placed in critically esthetic areas in the anterior maxilla, in spite of having enough vertical bone availability. The type 2 implant placement protocol is therefore very appropriate in this indication. Not only is the bone height and width of the ridge mostly preserved, but there is also enough keratinized mucosa to allow for a successful bone augmentation procedure during the implant placement; the results of augmentation techniques depend on a tension-free primary wound closure (Buser *et al*. 2008).

The efficacy of this surgical protocol has been recently studied in a systematic review comparing it to the standard type 3 or delayed protocol (implant placement at least 3 months after tooth extraction). This reported the pooled mean difference between the type 2 versus type 3 protocols to be a 13.11% reduction of defect bone height and a 19.85% reduction of defect bone width in favor of the type 2 protocol (Sanz *et al.* 2012). In terms of esthetic outcomes, based on two studies (Schropp *et al.* 2004; Schropp & Isidor 2008), at 2-year follow-up patients were significantly more satisfied with the early placement protocol, both in terms of the appearance of the restoration and the overall experience with treatment. These differences, however, were lost at the 5-year follow-up.

Horizontal ridge augmentation

Horizontal ridge augmentation can be performed using particulate or block grafts with or without barrier membranes (Fig. 50-7). The use of particulate grafts together with barrier membranes (GBR) is especially indicated in conjunction with the placement of an implant in class I defects, when there is enough bone width to allow good implant primary stability. In severe class I defects, a delayed bone regeneration approach (staged) is indicated and a block graft is often advocated to assure enough space maintenance to allow significant horizontal augmentation. Both GBR and block grafts have been demonstrated to be a successful and predictable treatment modality to augment a horizontally deficient ridge (Fig. 50-7, 50-8). (Fiorellini & Nevins 2003; Schwartz-Arad & Levin 2005; Schwartz-Arad *et al*. 2005). According to Donos *et al*. (2008), the implant survival rate for staged GBR was 99–100%, while that for one-stage ridge augmentation was 87–95%, but this systematic review was hindered by a lack of randomized clinical controlled trials and heterogeneity of the available studies, thus restricting the number of studies included in the systematic review.

Different authors have published case series utilizing bone grafts for horizontal bone augmentation and have concluded that it is a reliable procedure. In 15 partially edentulous patients, 18 alveolar ridges were augmented with ramus or symphysis block grafts. The mean horizontal ridge augmentation was 6.5 ± 0.33 mm. At implant placement surgery, the graft had resorbed to 5.0 ± 0.23 mm, which is a reduction of 23.5%, but it was still sufficient for implant placement (Cordaro *et al*. 2002). Raghoebar *et al*. (2000) performed horizontal ridge augmentation on the edentulous mandibles of seven patients using autogenous block grafts. The bone width increased from 1.3 ± 0.3 mm to 5.6 ± 0.6 mm. Although after 3 months of healing, at implant placement, there had been a slight resorption of the bone width by 0.5 ± 0.3 mm, it was still sufficient for implant placement. In a controlled

(d) Histologic evaluation of the regenerated bone shows significant osteoconductivity and incorporation of the allograft block particles with new/vital bone. Use of block grafts to overcome severe horizontal ridge deficiencies have proven very predictable.

clinical study, 30 patients with inadequate bone width were assigned to two different groups: (1) GBR + e-PTFE + autograft and (2) autogenous onlay grafts only: 2.7 mm of horizontal bone gain was attained in the GBR group compared to 4.0 mm in the onlay graft group. The authors also found that the graft resorption was greater in the GBR group compared to the block graft group (40% vs 25%) (Chiapasco *et al*. 1999).

The use of autografts is currently somewhat limited due to the morbidity associated with their harvesting and their high resorption rate (mainly when used as bone chips). The use of bone substitutes, mainly of xenogeneic origin, together with resorbable membranes (collagen), has demonstrated good results in one-stage or delayed horizontal bone augmentation techniques with minimal patient morbidity and few postoperative complications. Moreover, these xenogeneic grafts have a very slow resorption rate, which assures their long-term stability. In a prospective case series, 12 patients with 15 implant sites receiving horizontal ridge augmentation using DBBM with or without barrier membrane were followed for 9–10 months before placement of dental implants (Hämmerle *et al*. 2008). The mean crestal bone width was significantly increased from 3.2 mm at baseline to 6.9 mm, demonstrating the effectiveness of using boned substitutes for horizontal ridge augmentation

Ridge splitting/expansion

Another technique used in the maxilla to augment bone width through bone condensation is ridge splitting or ridge expansion osteotomy. Summers (1994a, b) first used this technique, osteocondensation, to augment bone width and elevate sinus floors in an attempt to avoid the lateral window sinus lift. This technique is preferably used in the maxilla because this bone is frequently type III or IV, which is more amendable to osteocondensation compared to type I or II bone. Chisels and osteotomes are used to produce longitudinal greenstick fractures in the bone and create osteotomy sites without the need for drilling. This preserves the compromised bone volume. The bone is compressed to the lateral surfaces with the use of osteotomes of increasing diameters, thus increasing its strength and density. The advantage of this technique is that it allows for the ideal implant diameter to be placed in the restoratively driven position. In addition, the cancellous bone and marrow are exposed to grafting of the site, which improves revascularization and healing (Engelke *et al*. 1997). Summers (1994b) proposed the use of this technique if the alveolar bone is at least 3 mm wide on the basis of the assumption that this is the minimum width for cancellous bone found between the cortical plates. However, in a more recent study on cadavers, Katranji *et al*. (2007) found that the buccal plates in the edentulous maxilla and mandible had a mean cortical thickness of 1.0–2.1 mm. Therefore, it may be prudent to use this technique when the lateral ridge width is 4–5 mm as at this width there is some cancellous bone between the cortical plates. This procedure is accompanied by simultaneous implant placement.

Ridge splitting and/or expansion are frequently described together because of their common treatment outcome: increase in lateral bone width. Ridge splitting is essentially the fracture of the buccal cortical plate and its displacement laterally to accommodate implant placement. The spaces created between the cortical plates and the implants are subsequently filled with particulate bone graft materials (Scipioni *et al*. 1994; Engelke *et al*. 1997). Ridge expansion involves the creation of an osteotomy site with the initial implant drill and expansion of the site with osteotomes or the implant fixture. According to Donos *et al*. (2008), the implant survival rate ranged from 86.2% to 100%, while the success rate for the split osteotomy in achieving adequate ridge width for implant placement ranged from 87.5% to 97.8%.

Vertical ridge augmentation

In general, there is a lack of randomized controlled clinical trials evaluating the efficacy of these surgical techniques. Moreover, the available studies are very heterogeneous and with relatively small sample sizes, which limits the ability to draw valid conclusions. From the limited information available, it appears that vertical augmentation is a highly technique-sensitive procedure which may give successful treatment outcomes, like adequate gain in vertical bone height and successful implant placement (Fig. 50-9).

A recent systematic review evaluated clinical outcomes of vertical bone augmentation to enable dental implant placement (Rocchietta *et al.* 2008). The review evaluated clinical, histologic, and long-term outcomes of implants placed in vertically regenerated bone and identified three main groups of vertical bone augmentation techniques: (1) GBR (seven studies), (2) onlay bone-block grafting (five studies), and (3) distraction osteogenesis (13 studies). The lack of clinical trials, the heterogeneity of the studies, and the small sample sizes limited the ability to perform any meta-analysis, although the authors reported that there was clinical and histologic evidence corroborating that vertical ridge augmentation may be achieved successfully. Nevertheless, a broad range of technique-related complications were highlighted. For GBR, the reported complication rates were 0–45.5% and complications were mainly related to membrane exposure. For distraction osteogenesis, complication rates were higher (10–75.7%), and complications included fractures or infection of the distractor, neurologic alterations, fractures of the distracted or basal bone, and lingual or palatal inclination of the distracted bone. Minor complications were reported after onlay block bone grafting and these were related to the morbidity from harvesting the block and graft shrinkage. These results are consistent with data

from an earlier systematic review that evaluated the outcomes of horizontal and vertical augmentation procedures (Esposito *et al*. 2009). From this review it was concluded that no specific technique was superior and the complexity of these techniques and the high frequency of complications was highlighted.

There are several published case series demonstrating the possibility of attaining a significant vertical bone augmentation, but also highlighting the technical difficulties and the high number of postoperative complications of this technique. In a small clinical study, six partially edentulous patients were recruited and 14 implants were placed leaving the coronal third exposed circumferentially. Autogenous bone grafts covered with titanium-reinforced e-PFTE membranes were used to cover the implants and the flaps were raised to allow for a submerged healing. An average of 4.95 mm of bone height was gained after 12 months in areas where the membranes were not exposed (Tinti *et al*. 1996). In a similar study, Simion *et al*. (1994) placed implants protruding 4–7 mm above the bone crest in five patients. e-PTFE membranes were used to cover the exposed implant threads. At 9 months, the histologic assessment showed bone formation up to 3–4 mm above the previous bone crest and the implant fixture was osseointegrated with the new bone. In a multicenter long-term study, Simion *et al*. (2001) evaluated the survival rate of implants placed at the time of the vertical ridge augmentation. The 123 implants with 2–7 mm of exposed implant thread were assigned to three groups: titanium-reinforced e-PTFE, allograft, and autograft. The overall implant success rate was 97.5% in the group with e-PTFE membranes, and this was the group demonstrating the least amount of bone loss.

Distraction osteogenesis was initially used in orthopedics, and more recently adapted to augment deficient edentulous ridges. The technique involves three stages: (1) latency, (2) distraction, and (3) consolidation (Cano *et al*. 2006) (Fig. 50-10). In the latency phase, once the osteotomy has been performed, undisturbed healing takes place over 1 week. This is followed by the activation of the distractor, which is placed into the prepared site during surgery, with a daily controlled force that aims to separate the bone segments at a rate of 0.5–1 mm/day. Distraction is usually performed over a period of 30 days and significant bone gain can be attained (4–7 mm) (Gaggl *et al*. 2000). In the consolidation phase, a callus forms in the space between the bone segments and subsequently remodels into mature bone. This technique has the advantage of not requiring a donor site and the significant bone gain obtained can be in the vertical, horizontal, or both directions. However, distraction osteogenesis has frequent complications, sometimes of a severe nature, such as fracture of the mandible or the moveable segment. Increased patient discomfort during the activation of the device and the incorrect direction of the distractor leading to excessive bone on the lingual side are also frequent complications; the latter leads to inadequate bone formation (Saulacic *et al*. 2009).

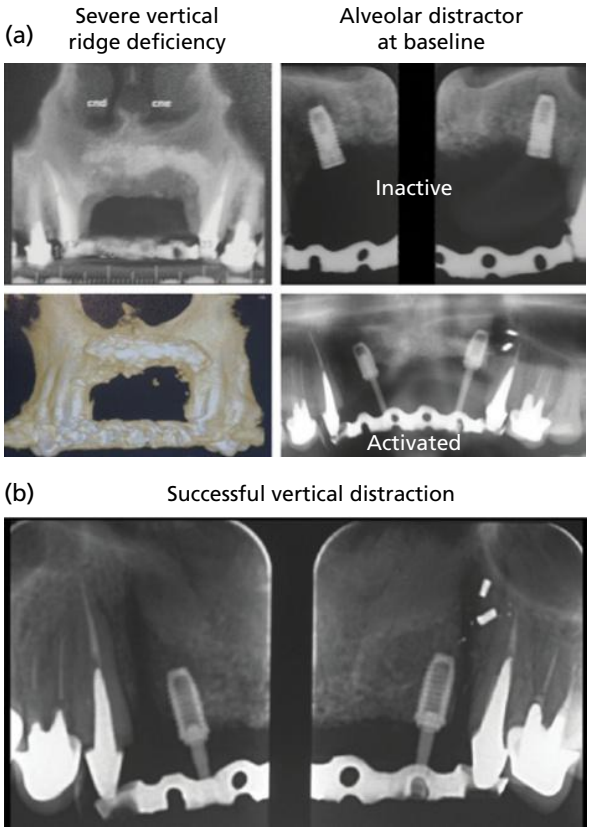

Fig. 50-10 Distraction osteogenesis. Stabilization of the ridge using a unidirectional vector distractor and successful vertical ridge compensation in the anterior maxilla. (Courtesy of T. Valcanaia.)

Taking into consideration the difficulties in performing these techniques, the frequent complications, and the heterogeneity and lack of quality of the available scientific evidence, their use should not be generalized, but rather limited to very experienced operators.

Emerging technologies

Growth factors

Wound healing approaches using growth factors to increase bone volume have significantly advanced the field of periodontal regenerative medicine. A major focus of periodontal research has been the impact of tissue growth factor on bone and tissue regeneration (Giannobile 1996; Anusaksathien & Giannobile 2002; Nakashima & Reddi 2003; Raja *et al*. 2009). Advances in molecular cloning have made available unlimited quantities of recombinant growth factors for applications in tissue engineering. Recombinant growth factors known to promote skin and bone wound healing, such as PDGF (Rutherford *et al*. 1992; Giannobile *et al*. 1994; Camelo *et al*. 2003; Ojima *et al*. 2003; Nevins *et al*. 2005; Judith *et al*. 2010), insulin-like growth factors (IGFs) (Lynch *et al*. 1991; Giannobile *et al*. 1994; 1996; Howell *et al*. 1997), fibroblast growth factors (FGFs) (Terranova *et al*. 1989; Sigurdsson *et al*. 1995; Giannobile *et al*. 1998; Takayama *et al*. 2001; Murakami *et al*. 2003), and BMPs (Gao *et al*. 1995; Wikesjo *et al*. 2004; Huang *et al*. 2005), have been used in preclinical and clinical trials for the treatment of large ridge and alveolar deficiencies (Jung *et al*. 2003; Fiorellini *et al*. 2005; Nevins *et al*. 2005). Currently, two recombinant proteins are clinically used to enhance and promote edentulous ridge regeneration, BMP-2 and PDGF-BB.

Biologic effects of PDGF

PDGF is a member of a multifunctional polypeptide family that binds to two cell membrane tyrosine kinase receptors (PDGF-Rα and PDGF-Rβ) and subsequently exerts its biologic effects on cell proliferation, migration, extracellular matrix synthesis, and antiapoptosis (Kaplan *et al*. 1979; Seppa *et al*. 1982; Heldin *et al*. 1989; Rosenkranz & Kazlauskas 1999). PDGF-α and -β receptors are expressed in regenerating periodontal soft and hard tissues (Parkar *et al*. 2001). In addition, PDGF initiates cell chemotaxis (Nishimura & Terranova 1996), mitogenesis (Oates *et al*. 1993), matrix synthesis (Haase *et al*. 1998), and attachment (Zaman *et al*. 1999). More importantly, *in vivo* application of PDGF alone or in combination with (IGF-1 enhances mineralized tissue repair (Lynch *et al*. 1989, 1991; Rutherford *et al*. 1992; Giannobile *et al*. 1994, 1996). PDGF has been shown to have a significant regenerative impact on periodontal ligament cells as well as on osteoblasts (Matsuda *et al*. 1992; Oates *et al*. 1993; Marcopoulou *et al*. 2003; Ojima *et al*. 2003).

Biologic effects of BMPs

BMPs are multifunctional polypeptides belonging to the TGF-β superfamily of proteins (Wozney *et al*. 1988). The human genome encodes at least 20 BMPs (Reddi 1998). BMPs bind to type I and II receptors that function as serine–threonine kinases. The type I receptor protein kinase phosphorylates intracellular signaling substrates called Smads (*Sma* gene in *Caenorhabditis elegans* and *Mad* gene in *Drosophila*). The phosphorylated BMP-signaling Smads enter the nucleus and initiate the production of other bone-related matrix proteins, leading to bone morphogenesis. The most remarkable feature of BMPs is their ability to induce ectopic bone formation (Urist 1965). BMPs are not only powerful regulators of cartilage and bone formation during embryonic development and regeneration in postnatal life, but also participate in the development and repair of other organs such as the brain, kidney, and nerves (Reddi 2001).

Studies have demonstrated the expression of BMPs during tooth development and periodontal repair, including alveolar bone (Aberg *et al*. 1997; Amar *et al*. 1997). Investigations in animal models have shown the potential repair of alveolar bony defects using rhBMP-12 (Wikesjo *et al*. 2004) or rhBMP-2 (Lutolf *et al*. 2003; Wikesjo *et al*. 2003). In a clinical trial, rhBMP-2 delivered by a bioresorbable collagen sponge revealed significant bone formation in a human buccal wall defect model following tooth

extraction when compared to the collagen sponge alone (Fiorellini *et al*. 2005). Furthermore, BMP-7, also known as osteogenic protein-1, stimulates bone regeneration around teeth and endosseous dental implants, and in maxillary sinus floor augmentation procedures (Rutherford *et al*. 1992; Giannobile *et al*. 1998; van den Bergh *et al*. 2000).

Cell therapy

The cell is central to new tissue growth and differentiation. In cell-based regenerative medicine, cells are delivered to a defective site with the goal of improving the regeneration process (Mao *et al*. 2006). Cell delivery approaches are used to accelerate edentulous ridge regeneration through two primary mechanisms: (1) use of cells as carriers to deliver growth or cellular signals; and (2) provision of cells which are able to differentiate into multiple cell types to promote regeneration. The use of cells as vehicles to deliver growth factors can stimulate an endogenous regeneration process (Discher *et al.* 2009). This strategy has been intensively investigated in both soft and hard periodontal tissue regeneration. Stem cell research has soared in the past few years and the effects of these cells on healing and regenerative potential have been extensively studied.

Mesenchymal stem cells (MSCs) are self-renewable and can differentiate into a variety of cell types that form mesenchymal and connective tissues (Pittenger *et al.* 1999; Mao *et al*. 2006). Bone marrow stromal cells are the most widely investigated MSCs because they are easily accessible. These cells were initially isolated and described over 50 years ago based on their ability to adhere to plastic substrates of cell culture plates (Becker *et al*. 1963). Since then, this simple protocol has been widely used to isolate MSCs from many tissues, such as adipose tissue, muscle, liver, pancreas, and cartilage (Ward *et al*. 2010). MSCs have a tremendous potential in regenerative medicine owing to their multipotency and capability to form a variety of tissues. Regarding periodontal tissue engineering, both extraoral and intraoral stem cells can be harvested and then subjected to enrichment and expansion techniques. Within this context, multiple sources of stem cells have been evaluated for the treatment and regeneration of the edentulous ridge (Huang *et al*. 2009). There is strong potential for the use of MSC sources from outside the oral cavity for transplantation to the oral and craniofacial complex (Noth *et al.* 2010; Ward *et al*. 2010).

Bone marrow stromal cells have also been shown to promote bone healing and dental implant osseointegration (Bueno & Glowacki 2009). In a series of studies, Yamada *et al*. (2004) used a combination of platelet-rich plasma as an autologous scaffold with *in vitro*-expanded bone marrow stromal cells to increase osteogenesis in dental implant surgery. This "autogenous injectable bone treatment" resulted in higher marginal bone levels, better bone–implant contact, and increased bone density compared to controls. Recently, cells harvested from the bone marrow were driven down MSC pathways via a single-pass perfusion process to promote bone regeneration in tooth extraction socket and sinus floor augmentation procedures (Kaigler *et al*. 2010).

Just as periodontal ligament is essential for osteogenesis and cementogenesis during development and remodeling, cells derived from this tissue are necessary for the appropriate healing response to injury (Shimono *et al*. 2003). Transplantation of periodontal ligament cells has shown the potential to regenerate alveolar bone *in vivo* (Nakahara *et al.* 2004).

Besides stem cell delivery, other cell-based therapy strategies have been developed based on the concept that transplanted cells will promote regeneration by secreting growth factors via autocrine and paracrine pathways. Allogenic foreskin fibroblasts have been shown to be safe and able to promote keratinized gingiva formation at gingival recession defects (Nevins *et al*. 2005). A tissue-engineered living cellular construct composed of viable neonatal keratinocytes and fibroblasts was reported to achieve a comparable clinical outcome to that with a gingival graft (McGuire *et al*. 2008), with strong potential to promote tissue neogenesis through the stimulation of angiogenic signals (Morelli *et al*. 2011).

These investigations support the use of this approach to deliver important cues to drive the regenerative process, and illustrate the significant potential of cell-based therapy to form a variety of periodontal tissues.

Scaffolding matrices to deliver cells and genes

Scaffolding matrices are used in tissue engineering to provide an environment where space is created and maintained over a period of time for cellular growth and tissue in-growth. These matrices serve as 3D template structures to physically support and facilitate periodontal tissue regeneration when combined with cell- or gene-based tissue engineering. Over the past two decades, scaffolds have been extensively developed, studied, and utilized. Several fundamental requirements of scaffold design have been proposed (Murphy & Mooney 1999). When applied to tissue engineering, scaffolds should (1) provide a 3D architecture that supports a desired volume, shape, and mechanical strength; (2) have a high porosity and surface-to-volume ratio with a well-interconnected open-pore structure to promote high seeding density and embrace bioactive molecules; (3) be biocompatible; and (4) degrade at a controlled rate and pattern that allows sufficient support until tissue defects are fully resolved.

Transplantation of cells can be carried out via tissue-engineered scaffolds (Murphy & Mooney 1999) that provide adhesion and anchorage for interacting stem cells in order to control the presentation of adhesion sites, thereby improving cell survival and participation (Alsberg *et al*. 2003; Davis *et al*. 2005). Through similar cell therapy approaches, extensive reconstructions are becoming more predictable, as demonstrated by the

regeneration of a mandible formed in a patient by using a metal and polymer scaffold seeded with stem cells and BMPs (Warnke *et al*. 2004).

Bioactive molecules, such as growth factors, may also be encapsulated into nano-/micro-particles that are embedded in matrices to aid their sustained release, thereby enhancing stimuli for tissue formation. Other approaches using scaffolds include mimicking stem cell niches to regulate daughter cell proliferation, differentiation, and dispersion into surrounding tissue or attracting useful cells to a desired anatomic site (Discher *et al*. 2009).

Scaffold fabrication technologies as applied to periodontal tissue engineering include conventional prefabricated scaffolds, such as particulated, solid form; injectable scaffolds that are adapted or administered into a periodontal defect; and novel image-based designs that result in a 3D printed scaffold that is customized to fit into a defect .

Prefabricated scaffolding matrices

Conventional scaffolds used to regenerate tissue *in vivo* are prefabricated, and many techniques have been described that produce both natural and synthetic polymeric scaffolds. Naturally-derived scaffolds include autografts, allografts, and xenografts. Alloplasts and other polymers are synthetically engineered materials consisting of bioactive molecules that serve a function similar to that of natural scaffolds.

Naturally-derived scaffolds

There are many naturally-derived scaffolds used for tissue engineering applications. Freeze-dried bone allograft (FDBA) is a mineralized bone graft that has been suggested to promote osteoinductive and osteoconductive bone regeneration, although reports of its regenerative effectiveness have been mixed (Altiere *et al*. 1979; Dragoo & Kaldahl 1983; Goldberg & Stevenson 1987). Variability in preparations of the allograft, and its regenerative potential and osteoinductive ability are seen between different bone banks (Shigeyama *et al*. 1995; Schwartz *et al*. 1996). Nonetheless, FDBA appears to be a practical material for regeneration of periodontal attachment apparatus. Xenogenic grafts show physical and chemical similarities to human bone matrix, and they have been successful in various periodontal and implant-related bone repair cell delivery applications (Nevins *et al*. 2006). DBBM has osteoconductive properties (Hämmerle *et al*. 1998).

Synthetic biomimetic polymer scaffolds

Synthetic polymers have been studied extensively as gene therapy delivery systems since it is easier to modify their properties, such as by controlling their macrostructure and degradation time, compared to naturally derived scaffolds (Jang *et al*. 2004). Furthermore, the release mechanism and exposure duration of bioactive molecules, such as growth factors, can be controlled (Ramseier *et al*. 2006). By acting as a localized gene depot, synthetic polymer scaffolds have the ability to maintain the therapeutic level of encoded proteins, which limits unwanted immune responses and potential side effects (Ghali *et al*. 2008).

Polymers such as poly(lactic-co-glycolic acid) (PLGA) have drawn much attention for their excellent properties for encapsulation of genes (Mundargi *et al*. 2008). PLGA microspheres have been used to deliver antibiotics, as an occlusive membrane for GTR, as a growth factor carrier for periodontal regeneration, and for cementum and complex tooth structure engineering (Williams *et al*. 2001; Kurtis *et al*. 2002; Young *et al*. 2002; Jin *et al*. 2003; Cetiner *et al*. 2004; Moioli *et al*. 2006). However, while microsphere systems have demonstrated promising results, new microtechnology approaches today are focusing on nano-sized particles (Agarwal & Mallapragada 2008). Nanotechnology has been attracting much attention for therapeutic agent and gene delivery, and a number of studies and reviews have delineated its contribution and capability to meet challenges of current regeneration therapy (Agarwal & Mallapragada 2008; Mundargi *et al*. 2008; Sanvicens & Marco 2008).

The nanoscaled fibrillar structure of collagen shows promising effects on cellular biologic activities, and suggests potential as a synthetic polymer scaffold that mimics the nanofibrous structure of collagen (Woo *et al*. 2007). Furthermore, a recent study has developed macroporous polymer scaffolds with varying pore wall architecture in order to enhance the environment for induction of cellular activity and provide guidance for 3D regeneration (Wei & Ma 2009). Therefore, a delivery scaffold can provide a suitable environment for targeted cells and tissues, as well as controlling the dynamic release of entrapped biologics. Periodontal therapy based on these systems, however, remains in its infancy.

The use of hyaluronic acid (HA) in the dental field has been demonstrated to restore periodontal defects and to carry and deliver growth factors such as BMP and FGF-2 (Wikesjo *et al*. 2003). A recent *in vitro* study has shown an HA and collagen (Col) combination scaffold to be a suitable environment for the growth of human periodontal ligament cells and therefore its potential in periodontal tissue engineering (Wang *et al*. 2009).

Inorganic calcium phosphate-based materials have also been used as delivery systems. Materials such as β-TCP are synthetic scaffolds that can be used to repair osseous defects around teeth or dental implants by acting as a bone substitute or as a carrier for growth factor delivery (Gille *et al*. 2002).

Hydrogels, formed by the cross-linking or self-assembly of a variety of natural or synthetic hydrophilic polymers to produce structures that contain >90% water, are obtained from natural materials such as collagen chitosan, dextran, alginate or fibrin. They are favorable for tissue engineering due to their innate ability to interact with cells while undergoing controlled degradation (De Laporte & Shea 2007; Moioli *et al*. 2007; Agarwal & Mallapragada 2008). Vector release from hydrogels is dependent upon the physical structure and

degradation of the hydrogel, and its interactions with the vector (De Laporte & Shea 2007).

Computer-based applications in scaffold design and fabrication

Computer-based applications in tissue engineering are some of the most recent developments in scaffold design and fabrication for cell and gene delivery (He *et al*. 2010). This type of technology, image-based design, has been used to define virtual 3D models for surgical planning by utilizing data from computed tomography (CT) and magnetic resonance imaging (MRI). Specifically, in tissue engineering, CT or MRI data are used to define the 3D anatomic geometry of a defect and then to create a template for a scaffold at a global anatomic level. This 3D printed scaffold, since it is produced from the 3D model, will precisely fill the defect space. Furthermore, the architecture of the scaffold can be defined to design the heterogeneous internal structure in such a way that creates region-specific variations in porous microstructures and scaffold surface topography, thereby altering the material and biologic properties in specific regions of the scaffold, such as modulus, permeability, and cell orientation (Hollister *et al*. 2002).

Future perspective

Tissue engineering is making an important impact on bone regeneration therapy. The use of cell and gene therapy to enhance and direct periodontal wound healing into a more predictable regenerative path is being exploited in bioengineering efforts aimed at developing a therapeutic system to promote bone repair (Rios *et al*. 2011). Various novel delivery scaffolding systems are being extensively studied and fabricated, and are demonstrating capabilities to meet the challenges of current regeneration therapy. However, numerous challenges remain. A major obstacle is how to maximize the utility of cells/genes delivered to a passive or permissive environment where there is context for the type of cell needed, but in which very few biologic signals are given to encourage normal cell function (Ramseier *et al*. 2005). Other obstacles, such as identifying cell sources and clinically relevant cell numbers, the integration of new cells into existing tissue matrices, and the achievement of functional properties of tissue equivalents using an expanded repertoire of biomaterials, also need to be confronted in the field of tissue engineering. Practical and regulatory requirements will also need to be met before the technologies of cell and gene transfer can be applied in the clinical arena.

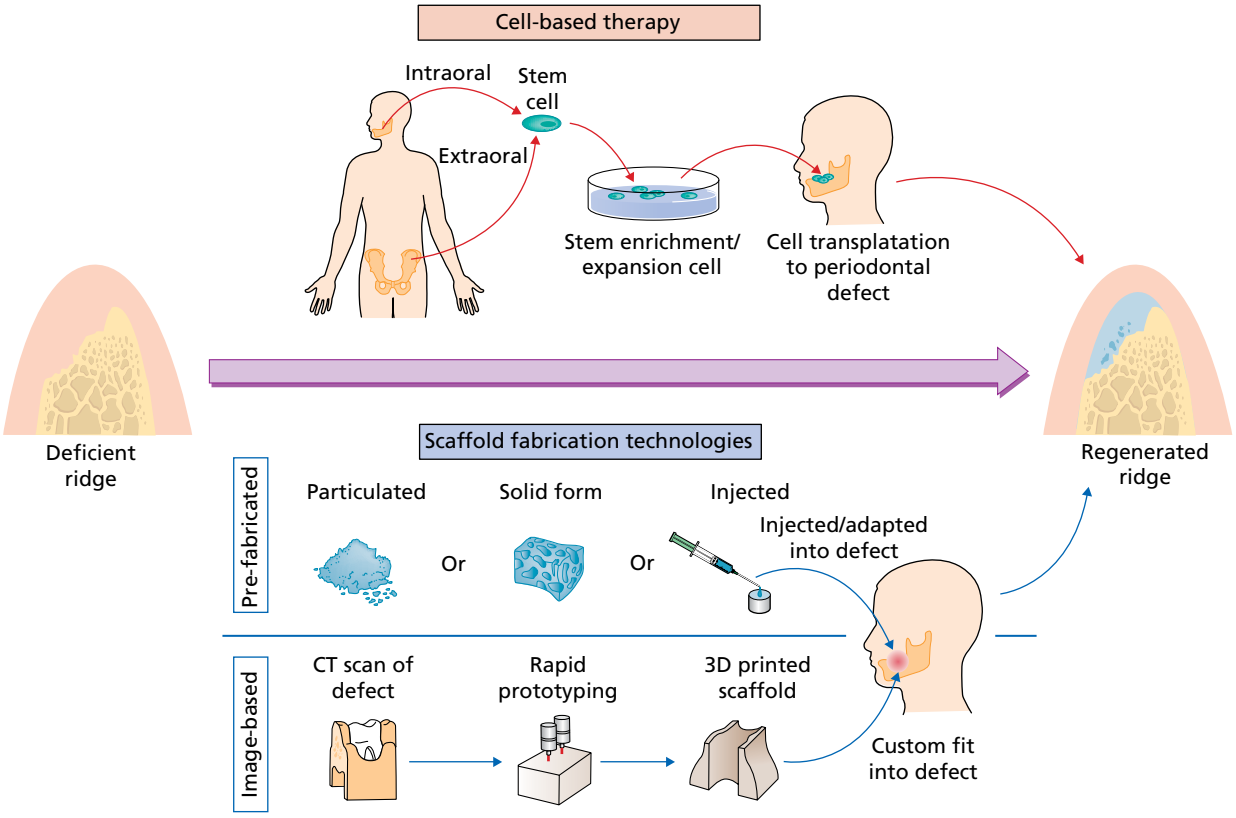

Fig. 50-11 New emerging technology for the treatment of edentulous ridge deficiencies. Research advances enable the integration of cell therapy and novel scaffold fabrication technologies. This promising modality could enhance predictable rapid tissue regeneration and ultimately the outcome of implant therapy. Extraoral and intraoral stem cells represent a viable and accessible source from which to harvest and expand multipotent colonies. Adequate cell density could be reached *in vitro* in a controlled environment and made readily available. Prefabricated and image-based scaffolds are becoming an essential component in regenerative medicine. A defined supporting structure allows the localization and guidance of the appropriate cells and proteins, and the establishment of a mechanically competent environment.

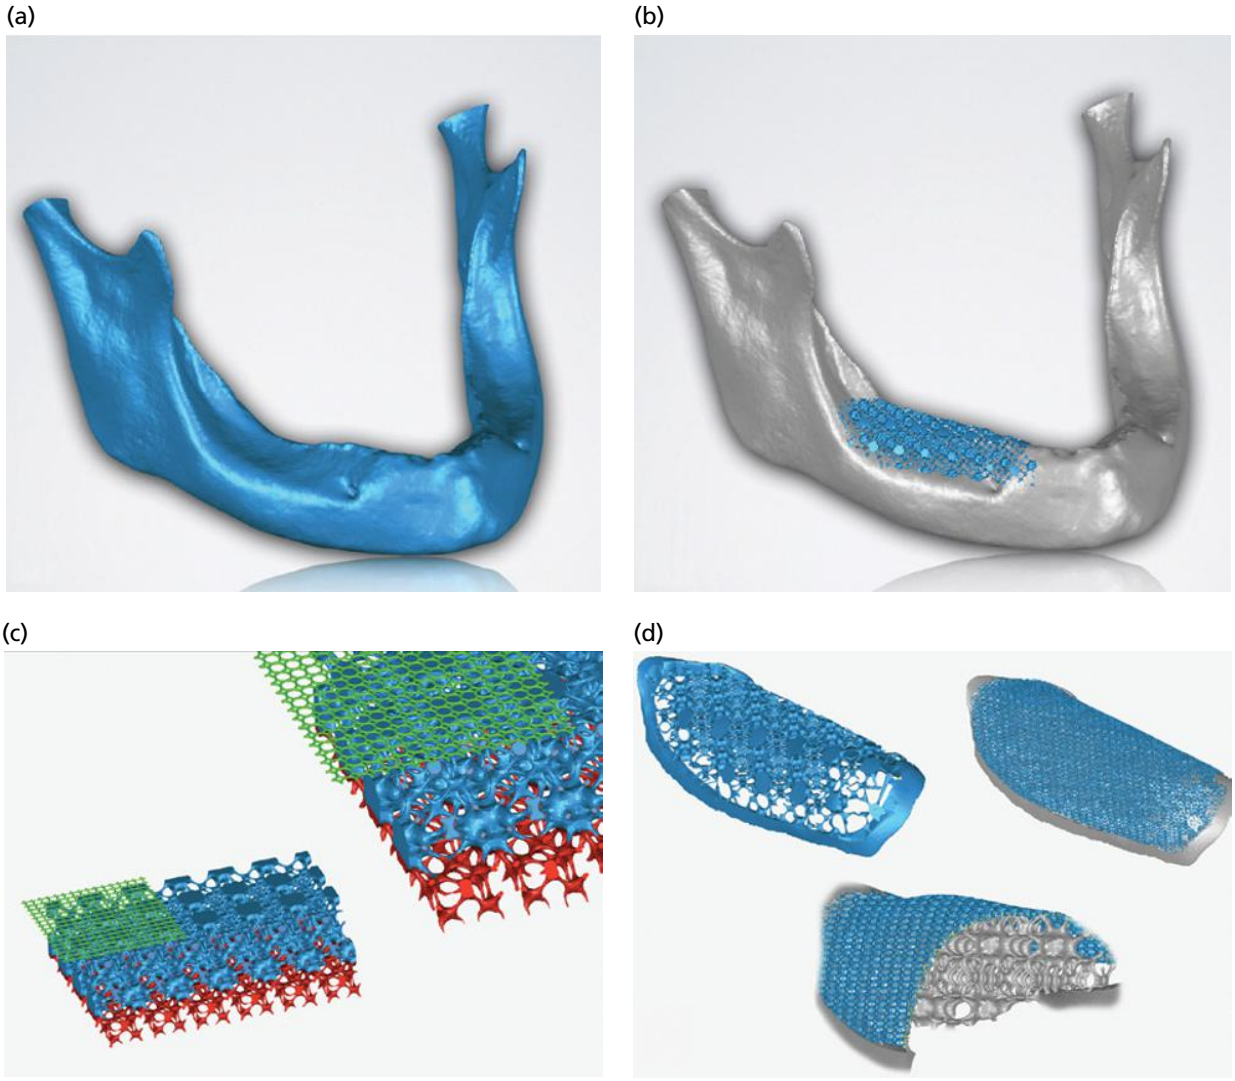

Fig. 50-12 (a) Volume rendering of cone-beam computed tomography (CBCT) scan of an edentulous ridge deficiency. CT provides a reliable digitized image dataset that is adequate for the assessment of mineralized tissue defects. (b) Custom-fit scaffold design. (c) Multilayer design. Based on 3D image data, a scaffold structure is designed using a computer-aided design (CAD) system. Scaffold topography could be used to enhance or modulate cell/tissue incorporation. (d) Enhanced scaffold topography. (Courtesy of I. Rudek.)

Collectively, the cell-based, scaffold, and gene therapy methods interface and complement each other to enhance the potential to restore tissue function and structure in a predictable manner (Figs. 50-11, 50-12). It is expected that in the future that there will be greater usage of bioactive molecules such as BMPs and PDGF to accelerate and enhance the healing potential of the defects, bringing about faster, easier, and predictable treatment outcomes. The success and the future of periodontal regenerative therapy will need to be supported by understanding of and ability to recognize clinical situations that will benefit from one or an integration of these new emerging technologies.

Conclusion

In general, ridge augmentation procedures have become increasingly predictable. The correct selection and application of the available techniques and biomaterials are key determinants of implant survival/success rates. Currently, research in the field of advanced bone grafting is directed at overcoming the technical and biologic limitations that continue to challenge implant dentistry. The use of novel scaffolding biomaterials, bioactive molecules, and advanced surgical techniques offers potential in the creation of increased bone volume and predictability in the treatment of challenging bone defects. Only through further research and development in the area of scaffold fabrication, along with cell-based and gene therapy, can tissue engineering continue to advance.

Chapter 51

Elevation of the Maxillary Sinus Floor

Bjarni E. Pjetursson[1] and Niklaus P. Lang[1,2]

[1] Department of Periodontology, School of Dental Medicine, University of Berne, Berne, Switzerland
[2] Center of Dental Medicine, University of Zurich, Zurich, Switzerland

Introduction

Elevation of the maxillary sinus floor was first reported by Boyne in the 1960s. Fifteen years later, Boyne and James (1980) reported on the elevation of the maxillary sinus floor in patients with large, pneumatized sinus cavities as a preparation for the placement of blade implants. The authors described a two-stage procedure: the maxillary sinus was grafted using autogenous particulate iliac bone in the first stage of surgery, and in the second stage of surgery after approximately 3 months, the blade implants were placed and later used to support fixed or removable reconstructions (Boyne & James 1980).

As implant dentistry developed, it became more evident that the posterior maxillary region was often limited for standard implant placement, since the residual vertical bone height was reduced (Fig. 51-1). An elevation of the maxillary sinus floor was an option in solving this problem. Several surgical techniques have been presented for entering the sinus cavity, elevating the sinus membrane, and placing bone grafts.

A transalveolar approach for sinus floor elevation with subsequent placement of implants was first suggested (Tatum 1986). Utilizing this approach, a "socket former" for the selected implant size was used to prepare the implant site. A "green-stick fracture" of the sinus floor was accomplished by hand tapping the "socket former" in a vertical direction. After preparation of the implant site, a root-formed implant was placed and allowed to heal in a submerged way.

Summers (1994) later described another transalveolar approach, using tapered osteotomes with increasing diameters (Fig. 51-2). Bone was conserved by this osteotome technique because drilling was not performed. Adjacent bone was compressed by pushing and tapping as the sinus membrane was elevated. Then, autogenous, allogenic or xenogenic bone grafts were added to increase the volume below the elevated sinus membrane. A follow-up of 173 press-fit submerged implants, placed using this technique, reported a success rate of 96% at 18 months after loading (Rosen *et al*. 1999).

Today, two main procedures of sinus floor elevation for dental implant placement are in use: (1) a

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Fig. 51-1 Radiograph of a posterior maxilla, showing reduced residual bone height which will not allow standard implant placement.

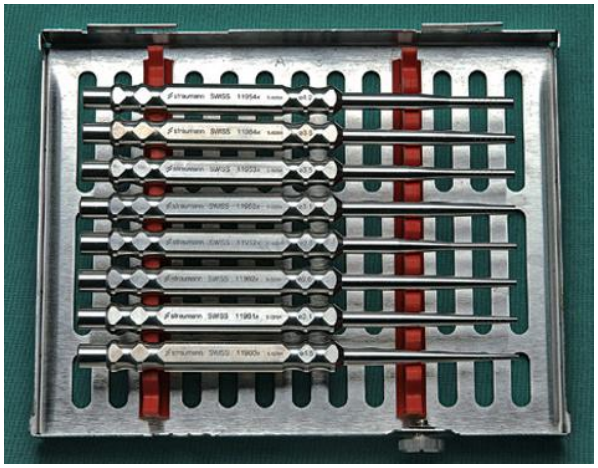

Fig. 51-2 Set of tapered osteotomes with different diameters to compress and push the residual bone from the implant preparation into the sinus cavity and to elevate the sinus membrane (introduced by Summers in 1994).

two-stage technique using the lateral window approach, and (2) a one-stage technique using a lateral or a transalveolar approach. The decision to use the one- or the two-stage technique is based on the amount of residual bone available and the possibility of achieving primary stability for the inserted implants.

Treatment options in the posterior maxilla

Implant placement in the posterior maxilla remains a challenge. Reduced bone volume due to alveolar bone resorption and pneumatization of the sinus cavity makes it more difficult to place implants to support a dental prosthesis.

Several treatment options have been used in the posterior maxilla to overcome the problem of inadequate bone quantity. The most conservative treatment option is placement of short implants to avoid entering the sinus cavity. For placement of short implants, there is still a need for at least 6 mm of residual bone height, however. Another way of

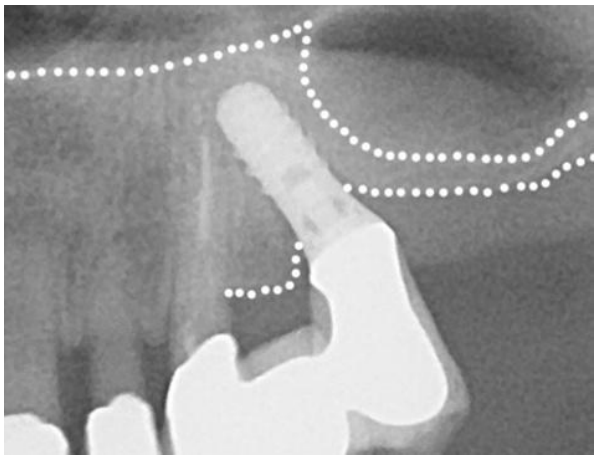

Fig. 51-3 Radiograph showing a tilted implant placed in the position of tooth 25 to avoid entering the sinus cavity. After remodeling, the bone level on the distal aspect of the implant is more apical than at the time of implant placement. This may lead to increased probing pocket depths around tilted implants. The dotted lines represent the outlines of the residual bone.

Fig. 51-4 Patient with a shortened dental arch. Three implants were placed in the positions of teeth 15, 14, and 25 without elevating the maxillary sinus floor and, subsequently, the patient's second premolar was restored.

avoiding grafting the maxillary sinus is to place tilted implants in a position mesial or distal to the sinus cavity if these areas have adequate bone (Fig. 51-3). Furthermore, extra-long zygomatic implants can be placed in the lateral part of the zygomatic bone.

However, in patients with appropriate residual bone height, minor augmentation of the sinus floor can be accomplished via the transalveolar approach using the osteotome technique (Summers 1994; Rosen *et al*. 1999; Ferrigno *et al*. 2006; Pjetursson *et al*. 2009a). The problem of inadequate bone height may be overcome by elevating the maxillary sinus floor via the closed technique to provide sufficient quantity of bone to support dental implants.

A more invasive treatment option in the posterior maxilla is the one- or two-stage sinus floor elevation with a lateral approach.

By mastering these different methods, most edentulous areas in the maxilla can by restored with implant-supported reconstructions. The concept of

a shortened dental arch must also be kept in mind. The work of Käyser (1981) has shown that patients maintained adequate (51–80%) chewing capacity with a premolar occlusion (Fig. 51-4).

Sinus floor elevation with a lateral approach

Anatomy of the maxillary sinus

The maxilla consists of a variety of anatomic structures, including the maxillary sinus, lateral nasal walls, pterygoid plates, associated vasculature structures, and teeth.

The maxillary sinus is pyramidal in shape. The base of the pyramid is the medial wall of the sinus and also the lateral wall of the nasal cavity, and its apex points towards the zygomatic bone. The roof of the sinus is also the floor of the orbit. The sinus has a non-physiologic drainage port high on the medial wall (maxillary ostium) that opens into the nasal cavity between the middle and lower nasal conchae.

The maxillary sinus maintains its overall size while the posterior teeth remain in function. It is, however, well known, that the sinus expands with age, and especially when posterior teeth are lost. The average volume of a fully developed sinus is about 15 mL but may range between 4.5 and 35.2 mL. The sinus cavity expands both inferiorly and laterally, potentially invading the canine region. This phenomenon is possibly the result of atrophy caused by reduced strain from occlusal function. One or more septa, termed "Underwood's septa", may divide the maxillary sinus into several recesses.

The overall prevalence of one or more sinus septa is between 26.5% and 31% (Ulm *et al*. 1995; Kim *et al*. 2006) and is most common in the area between the second premolar and the first molar. Edentulous segments have a higher prevalence of sinus septa than dentate maxillary segments.

The sinus is lined with respiratory epithelium (pseudo-stratified ciliated columnar epithelium) that covers a loose, highly vascular connective tissue (Fig. 51-5). Underneath the connective tissue, immediately next to the bony walls of the sinus, is the periosteum. These structures (epithelium, connective tissue, and periosteum) are collectively referred to as the Schneiderian membrane.

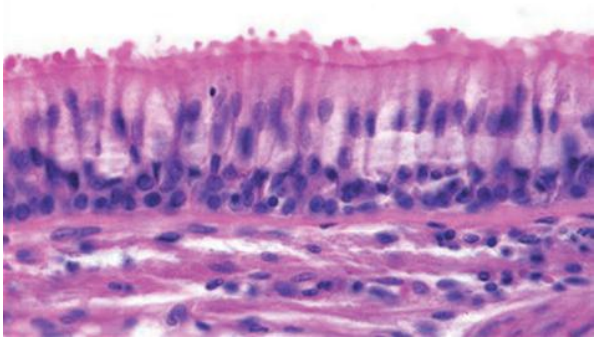

Fig. 51-5 Pseudostratified, ciliated columnar epithelium.

The blood supply to the maxillary sinus is derived primarily from the maxillary artery and, to a lesser degree, from the anterior ethmoidal and superior labial arteries. The sinus floor receives blood supply from the greater/lesser palatine and sphenopalatine arteries. These vessels penetrate the bony palate and ramify within the medial, lateral, and inferior walls of the sinus (Fig. 51-6). The posterior superior alveolar artery has tributaries that perfuse the posterior and lateral walls. The posterior superior alveolar and infraorbital arteries anastomose in the bony lateral wall, on average 19 mm from the alveolar bone crest (Solar *et al*. 1999). The dense vascular network of the maxilla reduces after tooth loss and with increased age. The vast majority of the blood vessels in the maxilla (70–100%) come from the periosteum (Chanavaz 1990, 1995). Venous drainage is into the sphenopalatine vein and pterygomaxillary plexus. Neural supply comes from branches of the maxillary nerve.

Non-hemolytic and alpha-hemolytic streptococci and *Neisseria* spp. are the normal commensal microbiota of the maxillary sinus. Staphylococci, diphtheroids, *Hemophilus* spp., pneumococci, *Mycoplasma* spp., and *Bacteroides* spp. are also found in varying amounts (Timmenga *et al*. 2003).

The healthy maxillary sinus is self-maintaining by postural drainage and actions of the ciliated epithelial lining, which propel bacteria toward the ostium. The maxillary sinus also produces mucus containing lysozymes and immunoglobulins. The significant vascularity of the Schneiderian membrane helps maintain its healthy state by allowing lymphocyte and immunoglobulin access to both the membrane and the sinus cavity.

The fact that the maxillary sinus opening to the nasal cavity is not in the lower part of the sinus (where a graft may be placed) is important and provides an anatomic rationale for sinus floor elevation, as the grafting procedure does not interfere with

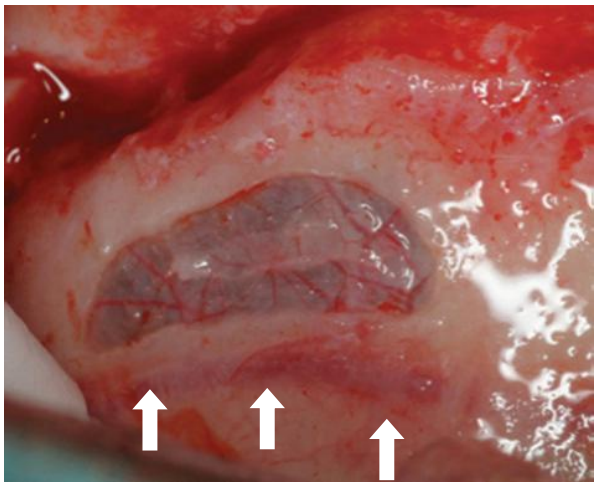

Fig. 51-6 Relatively large vessel integrated into the lateral wall of the sinus (arrows). Perforation of this vessel during preparation of the lateral window would cause excessive bleeding.

normal sinus function. In fact, a maxillary sinus floor elevation may improve symptoms of sinusitis/congestion by bringing the floor of the sinus closer to the drainage port.

Presurgical examination

Prior to planning complicated surgical procedures like elevation of the maxillary sinus floor, a thorough examination, including medical and dental history, should be obtained (see Chapters 28–30).

The dental and periodontal status is evaluated using clinical and radiologic examination methods. The vitality of the neighboring teeth has to be tested. The infraorbital, lateral nasal, and superior labial areas of the face must be examined regarding tenderness to palpation, swelling or asymmetry. The patient's history along with findings made during the clinical examination should provide sufficient information for diagnosing acute, allergic, and chronic sinusitis.

Preoperative screening to assess a potential pathologic condition in the maxillary sinus should include radiographic examination, such as orthopantomography (OPT), tomography, computed tomography (CT), cone-beam computed tomography (CBCT) or aquitomo-scans (see Chapter 30).

Before performing the sinus floor elevation surgery, all dentate patients should receive cause-related therapy (see Chapters 35–38).

Medical or surgical therapy of sinusitis, and removal of polyps and tumors must be completed prior to sinus floor elevation.

Indications and contraindications

The main indication for maxillary sinus floor elevation utilizing a lateral approach is reduced residual bone height, which does not allow standard implant placement or placement of implants in combination with minor sinus floor elevation using the osteotome technique. In cases of reduced bone height due to alveolar bone resorption and pneumatization of the sinus cavity, the so-called lateral approach, with or without horizontal bone augmentation, is indicated.

Contraindications for sinus floor elevation can by divided into three groups: intraoral contraindications, medical conditions, and local contraindications.

The *medical* contraindications include: chemotherapy or radiotherapy of the head and neck area at the time of sinus floor elevation or in the preceding 6 months, depending on the field of radiation; immunocompromised patients; medical conditions affecting bone metabolism; uncontrolled diabetes; drug or alcohol abuse; patient non-compliance; and psychiatric conditions.

Whether or not smoking is an absolute contraindication for maxillary sinus floor elevation remains controversial. In a case series, Mayfield *et al.* (2001) evaluated survival of implants placed in combination with bone augmentations (horizontal, vertical, and sinus elevations). The survival rate of these implants was 100% for non-smokers compared to only 43% for smokers after 4–6.5 years of functional loading. This reduced survival rate has been corroborated by several other authors (Bain & Moy 1993; Jensen *et al*. 1996; Gruica *et al*. 2004). However, a large study evaluating 2132 implants after sinus floor elevation with simultaneous implant placement found conflicting results (Peleg *et al*. 2006). Two hundred and twenty-six sinus floor elevations (627 implants) were performed on smokers, and 515 sinus floor elevations (1515 implants) on non-smokers. After a follow-up time of up to 9 years, the survival rate of the implants was 97.9%, and there were no statistically significant differences between survival rates in smokers and in non-smokers. A recent systematic review (Pjetursson *et al.* 2008) investigated the survival rate of implants inserted in combination with sinus floor elevation utilizing the lateral approach. Five of the included studies reported on the influence of smoking status of the patients, although not clearly defined, on implant survival after sinus floor elevation. A group of non-smokers who received 2159 implants and a group of smokers who received 863 implants were analyzed. The smokers had a higher annual failure rate (3.54%) compared with non-smokers (1.86%).

Alteration of the nasal–maxillary complex such that it interferes with normal ventilation as well as mucociliary clearance of the maxillary sinus, may be a contraindication for sinus floor elevation. However, such abnormal conditions may be clinically asymptomatic or only present with mild clinical symptoms. These conditions include viral, bacterial, and mycotic rhinosinusitis, allergic sinusitis, sinusitis caused by intrasinus foreign bodies, and odontogenic sinusitis resulting from necrotic pulp tissue. All odontogenic, periapical, and radicular cysts of the maxillary sinus should be treated prior to sinus floor elevation.

A sinus floor elevation under any of the above conditions may disturb the fine mucociliary balance, resulting in mucus stasis, suprainfection or a subacute sinusitis.

Absolute local contraindications for sinus floor elevation are: acute sinusitis; allergic rhinitis and chronic recurrent sinusitis; scarred and hypofunctional mucosae; local aggressive benign tumors; and malignant tumors.

Surgical techniques

The original Caldwell–Luc technique, commonly referred to as the lateral window or lateral approach, describes an osteotomy prepared in a superior position just anterior to the zygomatic buttress. Two other positions have also been described: a mid-maxillary position between the alveolar crest and zygomatic buttress area, and a low anterior position near the level of the existing alveolar ridge (Lazzara 1996;

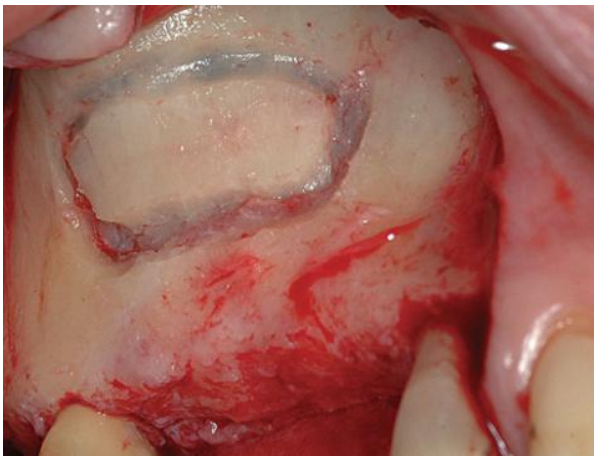

Fig. 51-7 Outline of the lateral window has been marked with a round bur.

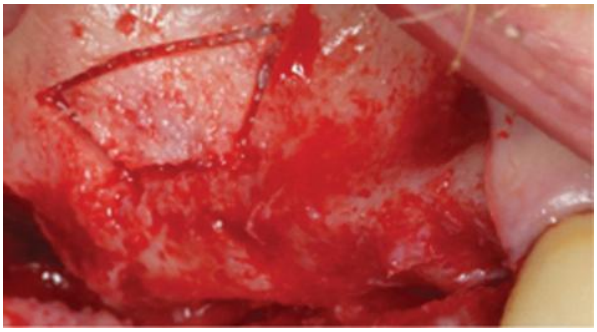

Fig. 51-8 Outline of the lateral window is made with a piezoelectric surgical tip, taking care not to perforate the membrane.

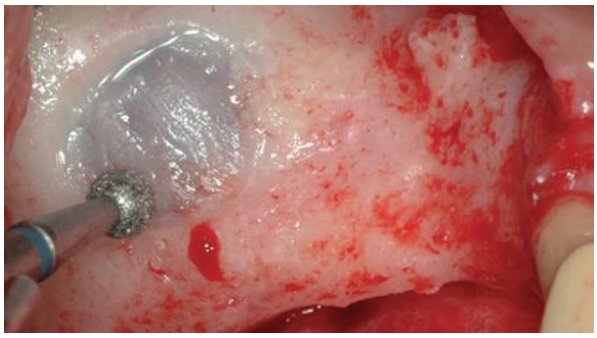

Fig. 51-9 Buccal bony plate is trimmed to a paper-thin lamella with a fine grit round diamond bur, avoiding perforation of the sinus membrane.

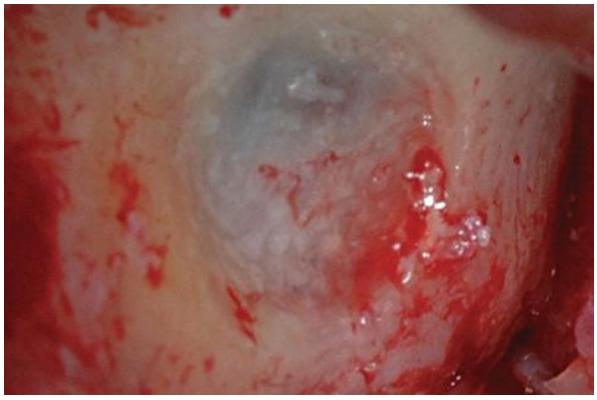

Fig. 51-10 After removing the buccal bony plate, the bluish hue of the sinus membrane becomes clearly visible.

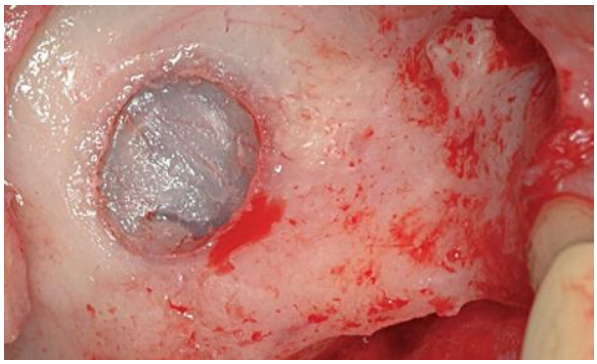

Fig. 51-11 Before elevating the sinus membrane, the entire buccal bone is removed to gain access to the membrane.

Zitzmann & Schärer 1998). The technique described below is a modification of these techniques:

1. A presurgical rinse with chlorhexidine 0.1% is performed for a period of 1 minute.
2. Local anesthesia is delivered buccal and palatal to the surgical area and tuberosity block anesthesia is performed.
3. The initial incision is mid-crestal, extending well beyond the planned extension of the osteotomy. The incision is carried on forward beyond the anterior border of the maxillary sinus. Releasing incisions are made anteriorly, extending into the buccal vestibulum to facilitate reflection of a full-thickness mucoperiosteal flap.
4. A mucoperiosteal flap is raised slightly superior to the anticipated height of the lateral window.
5. After the lateral sinus wall has been exposed, a round carbide bur (Fig. 51-7) in a straight hand piece or a piezoelectric surgical tip (Fig. 51-8 are used to mark the outline of the osteotomy. When the bone has been trimmed down to a thin bony plate, the preparation is continued with a round diamond bur (Fig. 51-9) in a straight hand piece or a diamond-coated piezoelectric surgical tip until the bluish hue of the sinus membrane is observed (Fig. 51-10). Three methods for handling the buccal cortical bone plate have been proposed. The most common one is thinning of the buccal bone to a paper-thin bone lamella using a round bur, and removing it prior to the elevation of the sinus membrane (Fig. 51-11). The second method is to fracture the cortical bony plate like a trap-door and use it as the superior border to the sinus compartment, leaving it attached to the underlying mucosa. Since the cortical bony plate is resistant to bone resorption, this may protect the graft. The third method is to remove the cortical bony plate during sinus floor elevation and replace it on the lateral aspect of the graft at the end of the grafting procedure. The rationale for this method was the notion that the lateral window would not completely heal without

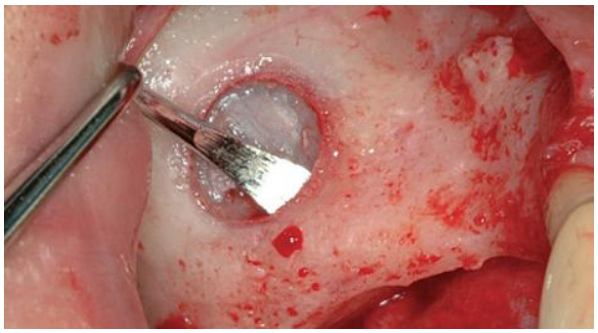

Fig. 51-12 Sinus membrane is carefully elevated using a blunt instrument. To avoid penetration, it is essential to keep contact with the underlying bone at all times during this procedure.

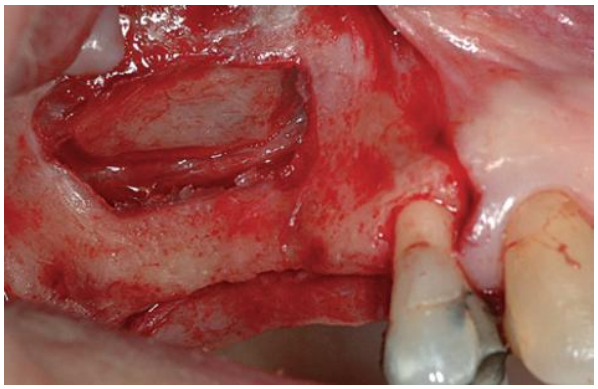

Fig. 51-13 Buccal cortical bony plate was fractured and moved upwards and inwards like a "trap-door". The cortical bony plate delineates the superior border of the maxillary sinus compartment.

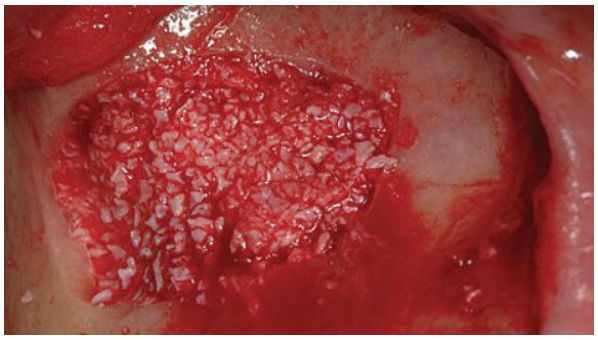

Fig. 51-14 Sinus compartment has been filled with a loosely packed 1 : 1 mixture of particulate autogenous bone and a xenograft.

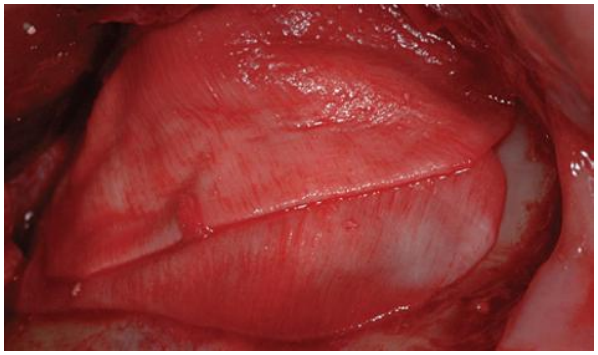

Fig. 51-15 Lateral window has been covered with single or double layer of resorbable barrier membrane.

replacement of its cortical plate. However, healing of the lateral window by bone apposition has been demonstrated to occur without replacing the cortical bony plate (Boyne 1993).

6. The next step is chosen according to the technique used. If the buccal wall is eliminated, the sinus membrane is elevated directly with blunt instruments (Fig. 51-12). On the other hand, gentle tapping is continued until movement of the bony plate is observed if the "trap-door" technique is used. Then, in combination with the elevation of the sinus membrane in the inferior part of the sinus, the bony plate is rotated inwards and upwards to provide adequate space for the grafting material (Fig. 51-13). Care should be taken not to perforate the sinus membrane.

Depending on the clinical condition and the surgeon's preference, a delayed (two-stage) or a one-stage sinus floor elevation simultaneously with the implant installation is chosen.

Two-stage sinus elevation (delayed installation of the implant)

1. Grafting material is placed in the compartment made by the elevation of the sinus membrane. The grafting material should not be densely packed, because this reduces the space needed for in-growth of newly forming bone. In addition, pressurizing the thin sinus membrane may result in a late perforation.
2. After the compartment has been filled with grafting material (Fig. 51-14), the lateral window is closed by covering it with a resorbable or a non-resorbable barrier membrane (Fig. 51-15). Subsequently, the flap is closed free of tension. In most conditions, there is a need for deep periosteal incisions to achieve tension-free closure.

One-stage sinus floor elevation with simultaneous implant placement

1. After the sinus membrane has been elevated, the implant sites are prepared. If rotary instruments are used, the sinus membrane has to be protected using a periosteal elevator (Fig. 51-16). Osteotomes of different diameters may be used to prepare the implant site, and then the membrane can be protected by inserting sterile gauze into the sinus compartment (Fig. 51-17).
2. The appropriate implant length is measured with a blunt depth gauge (Fig. 51-18). Before placing the implant, the grafting material is inserted into the medial part of the sinus compartment (Fig. 51-19). After implant placement (Fig. 51-20), the lateral part of the compartment is filled with grafting material (Fig. 51-21).
3. The subsequent steps coincide with those described for the two-stage procedure.

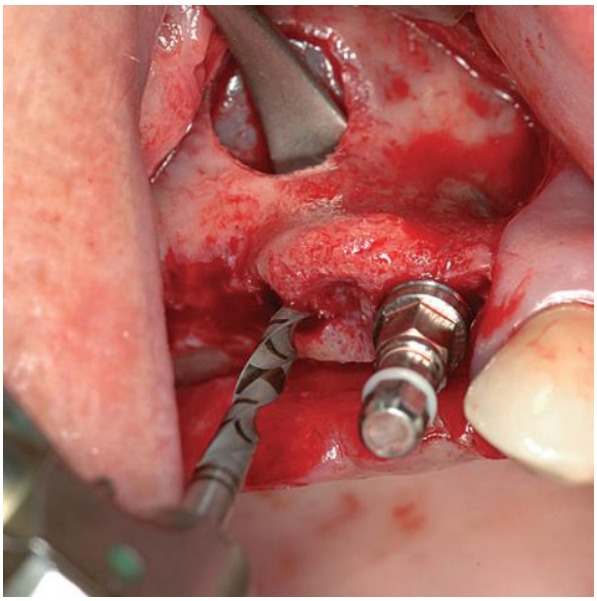

Fig. 51-16 Protection of the sinus membrane with a periosteal elevator in the sinus compartment when using rotary instruments to prepare the implant site.

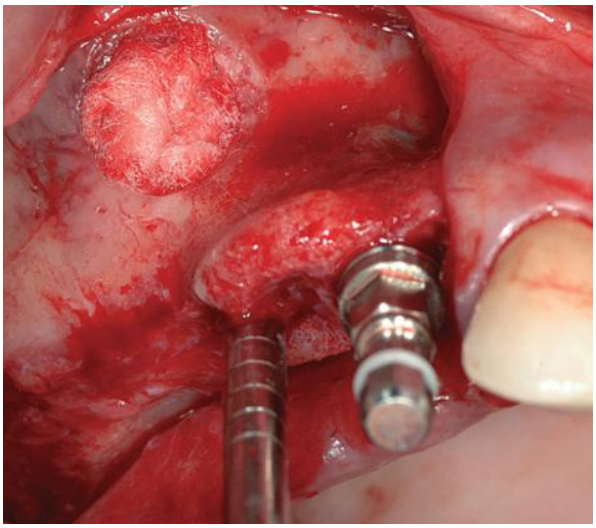

Fig. 51-17 Protection of the sinus membrane with sterile gauze inserted into the sinus compartment when using osteotomes to prepare the implant site.

The main differences between the methods used currently are the position and technique used to prepare the lateral window, the amount of sinus membrane elevation, the type of graft utilized, and the choice of one-stage or two-stage approaches.

Histomorphometric evidence of enhanced bone formation following membrane placement over the lateral window is available. In a randomized controlled clinical trial (Tarnow *et al*. 2000), a split-mouth design with bilateral sinus grafts was performed for 12 patients with or without covering the lateral window using a membrane. After 12 months, histologic samples were taken through the lateral window. The mean percentage of vital bone formation was 25.5% with and 11.9% without a covering barrier. Similar results were obtained in a controlled clinical trial (Froum *et al*. 1998) measuring bone formation in 113 sinuses grafted either with xenograft alone or a

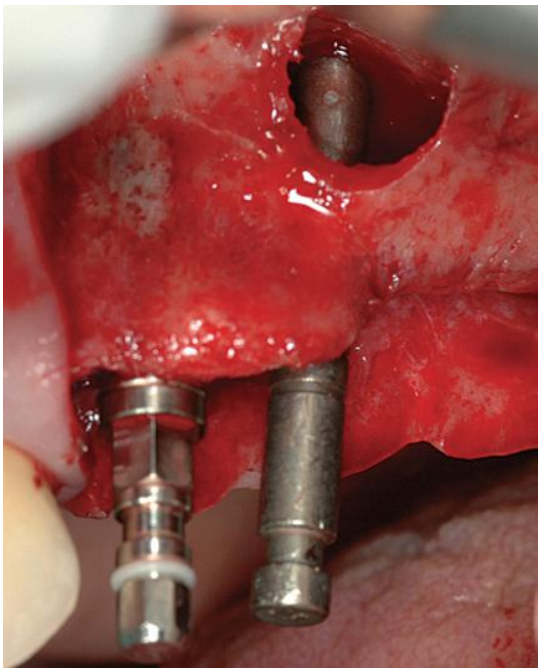

Fig. 51-18 Simultaneous sinus floor elevation and implant placement: height of the sinus compartment and implant length can be determined by inserting a blunt depth gauge into the implant site. Care must be taken not to apply too much pressure on the sinus membrane.

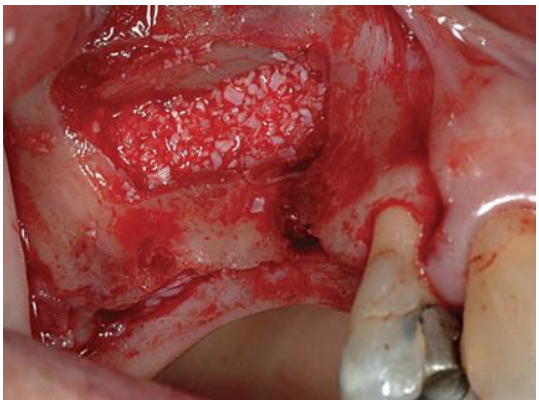

Fig. 51-19 Before placing the implants, grafting material has to be inserted into the medial part of the sinus compartment, because access to the medial part of the sinus compartment is restricted after implant installation.

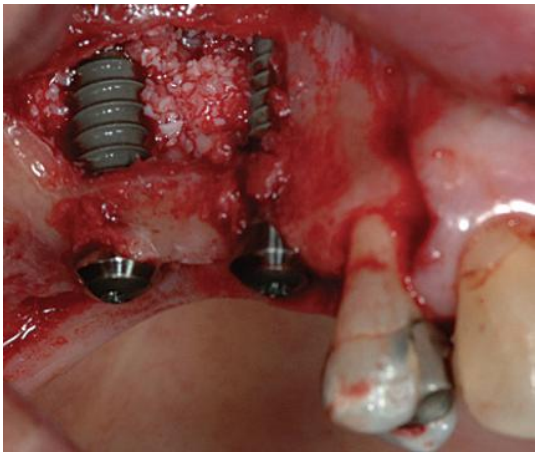

Fig. 51-20 Two implants have been installed after filling the medial part of the sinus compartment.

Fig. 51-21 After implant installation, the lateral part of the sinus compartment is filled with loosely packed grafting material.

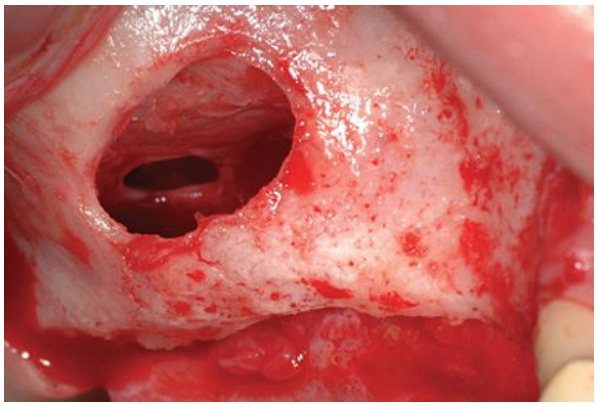

Fig. 51-22 Perforation of the sinus membrane. A medium-sized perforation can be detected after elevation of the membrane.

composite of xenograft and autograft. The mean vital bone formation was 27.6% when a membrane was used compared to 16% without. In a recent systematic review (Pjetursson *et al.* 2008), comparison of the failure rates of dental implants inserted in sinuses where the lateral access window was covered with a membrane with the survival rates of dental implants where the access window was not covered revealed annual failure rates of 0.79% and 4.04%, respectively.

Post-surgical care

In order to minimize postoperative pain and discomfort for the patient, surgical handling should be as atraumatic as possible. Precautions must be taken to avoid perforation of the flap and the sinus membrane. The bone should be kept moist during the surgery, and a tension-free primary flap closure is essential. The pain experienced by patients is mostly limited to the first days after surgery. Swelling and bruising of the area are usually the chief postoperative sequelae. Often, swelling and bruising extend from the inferior border of the orbit to the lower border of the mandible or even to the neck. In order to reduce swelling, it is important to cool the area with cooling pads, at least over the first postoperative hours. Occasionally, minor bleeding may arise from the nose. It is important to inform patients that some irritation in the nasal area may be expected. If the patient needs to sneeze, the nose should not be covered so that air pressure is allowed to escape. After the surgery, patients are placed on antibiotic prophylaxis and prescribed pain killers and non-steroidal anti-inflammatory drugs (NSAIDs). It remains controversial whether or not patients need steroidal anti-inflammatory administration after such a procedure. Furthermore, antiseptic rinses with 0.1–0.2% chlorhexidine twice daily are indicated for the first 3 weeks after surgery.

Complications

When performing sinus floor elevation, the risk of complications must be considered and their appropriate treatment foreseen.

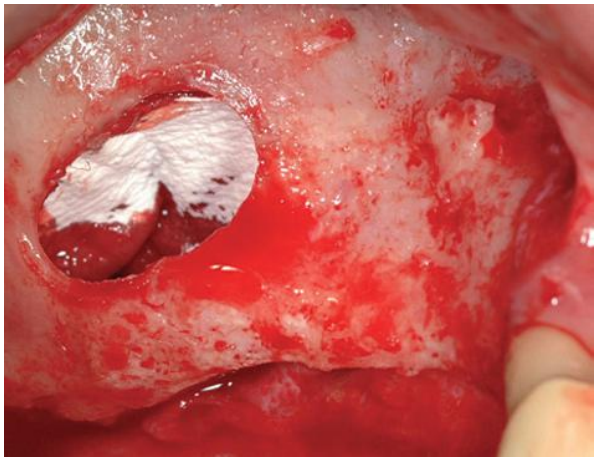

Fig. 51-23 Closure of small-to-medium-sized sinus membrane perforations by applying a resorbable barrier membrane.

The most common intraoperative complication is perforation of the sinus membrane (Fig. 51-22). The presence of maxillary sinus septa and root apices penetrating into the sinus may increase the risk of membrane perforation. The risk of perforation has been reported to be between 10% and 40% during surgery (Block & Kent 1997; Timmenga *et al.* 1997; Pikos 1999). In a recent systematic review (Pjetursson *et al.* 2008), the mean prevalence of membrane perforation, based on 20 of the included studies, was 19.5% and ranged from 0% to 58.3%. Whether or not this complication influences the survival rate of the implants is still controversial. Some authors (Khoury 1999) have reported a correlation between membrane perforation and implant failure, while other studies reported no correlation.

In the event of membrane perforation, it is recommended to elevate the membrane in the opposite direction to prevent further enlargement of the perforation. Smaller perforations (<5 mm) may be closed by using tissue fibrin glue, suturing or by covering them with a soft resorbable barrier membrane (Fig. 51-23). In cases of larger perforations, larger barrier membranes, lamellar bone plates or suturing may be used either alone or in combination with tissue fibrin glue to provide a superior border for the

grafting material. In instances of larger perforations, where a stable superior border cannot be achieved, the grafting of the maxillary sinus must by aborted and a second attempt at sinus floor elevation may be performed 6–9 months later (Tatum *et al*. 1993; van den Bergh *et al*. 2000).

Other complications that have been reported during surgery include excessive bleeding from the bony window or the sinus membrane, and wound dehiscences. Iatrogenic complications include injury to the infraorbital neurovascular bundle from deep dissection to free the flap from tension or blunt trauma due to the compression of the neurovascular bundle during retraction. Implant migration, hematoma, and adjacent tooth sensitivity have also been reported.

Infection of the grafted sinuses is a rare complication. In a meta-analysis based on 24 studies, the prevalence of infection was 2.9%, ranging from 0% to 7.4% (Pjetursson *et al.* 2008). The risk for infection increases with a membrane perforation. Hence, it is recommended to avoid sinus grafting and simultaneous implant placement in situations of large membrane perforations (Jensen *et al*. 1996). Infection of the grafted sinuses is usually seen 3–7 days post surgically and may lead to failure of the graft. A possible complication secondary to infection is parasinusitis with the spread of the infection to the orbita or even to the brain. For these reasons, infected sinus grafts must be treated immediately and aggressively. Surgical removal of the entire graft from the sinus cavity and administration of high doses of antibiotics are essential.

Sinusitis is another complication that may occur after sinus grafting. In a study evaluating the function of the maxillary sinus after sinus floor elevation (Timmenga *et al*. 1997), 45 patients who had received 85 sinus grafts underwent endoscopic examination. Of these, five were diagnosed with sinusitis. In these five patients, the endoscopic examination revealed oversized turbinates and septal deviation. Hence, the result of this study showed that the incidence of sinusitis was low and mainly found in patients with an anatomic or functional disorder prior to the sinus grafting.

Reported causes of late failure include chronic infection, graft exposure, loss of the entire bone graft, oroantral fistula, in-growth of soft tissue through the lateral window, granulation tissue replacing the graft, and sinus cysts.

Grafting materials

There are differences in opinion on the need to graft material when elevating the maxillary sinus floor.

Sinus floor elevation without grafting material

Studies in monkeys (Boyne 1993) showed that implants protruding into the maxillary sinus following elevation of the sinus membrane without grafting material, exhibited spontaneous bone formation over more than half of the implant's height. Hence, protrusion of an implant into the maxillary sinus does not appear to be an indication for bone grafting. In the same study, it was also seen that the design of the implant influenced the amount of spontaneous bone formation. Implants with open apices or deep-threaded configurations did not reveal substantial amounts of new bone formation. On the other hand, implants with rounded apices that penetrated 2–3 mm into the maxillary sinus tended to show spontaneous bone formation around their entire circumference. However, when the same implants penetrated 5 mm into the maxillary sinus, only a partial (51%) growth of new bone was seen towards the apex of the implant. This has also been demonstrated in clinical studies in humans.

Lundgren and co-workers (Lundgren *et al*. 2004; Hatano *et al*. 2007; Cricchio *et al.* 2011) have performed studies in which the lateral bone window was removed during the procedure and the sinus membrane was elevated and sutured against the lateral wall in an elevated position to create and maintain a compartment for blood clot formation. Finally, the bony lid was moved into its former position and secured with the overlying mucosa. Comparisons of pre- and post-operative CT radiography 6 months after the procedure clearly demonstrated new bone formation within the compartment created by the sinus membrane elevation procedure.

In a clinical study, 131 implants were placed using the lateral approach (Ellegaard *et al*. 2006). The sinus membrane was elevated and implants were inserted and left to protrude into the sinus cavity. The sinus membrane was allowed to settle onto the apex of the implants, thus creating a space to be filled with a blood coagulum. After a mean follow-up of 5 years, the survival rate of these implants was 90%. It must be kept in mind, however, that the residual bone height in this study was at least 3 mm to allow for a primary stability of the implants.

A recent longitudinal study following 84 patients who underwent 96 sinus floor elevations procedures with simultaneous placement of 239 implants without using grafting materials, demonstrated on intraoral radiographs an average intrasinus bone gain of 5.3 mm after 6 months of healing (Cricchio *et al.* 2011). After a mean follow-up of 3 years, the implant survival was 98.7%.

Autogenous bone

Autogenous bone grafts are considered the gold standard for grafting due to their maintenance of cellular viability and presumptive osteogenic capacity. The use of autogenous grafts in sinus floor elevation was first reported by Boyne and James (1980) and Tatum (1986).

Grafts may be harvested intraorally or extraorally. Common intraoral donor sites are the maxillary

tuberosity, the zygomatico-maxillary buttress, the zygoma, the mandibular symphysis, and the mandibular body and ramus (Fig. 51-24). Bone may be harvested in block section or in particulate form. The extraoral donor sites that have been utilized are the anterior and posterior iliac crest, tibial plateau, rib, and calvaria.

Autologous bone grafts contain bone morphogenic proteins (BMPs) that are capable of inducing osteogenic cells in the surrounding tissues. They also contain other growth factors essential for the process of graft incorporation. Processing of autograft, with grinding or morselizing, does not seem to disturb the viability of the osteogenic cells (Springer *et al*. 2004). The main source of osteogenic cells during graft consolidation is the periosteum which includes mesenchymal progenitor cells and provides a rich source of blood vessels. Osteoclasts are then required for remodeling of the graft–woven bone complex. The consolidation of the graft depends on the properties of the graft material and the osteogenic potential of the recipient bed. Initially, cortical bone grafts act as weight-bearing space fillers and remain a mixture of necrotic and viable bone for a prolonged period of time. The ideal graft material has to allow in-growth of blood vessels and formation of bone on its surfaces for integration into the recipient bed (osteoconductivity).

Where sinus floor elevations do not eventually receive dental implants, the bone grafts may resorb due to the lack of functional load and strain.

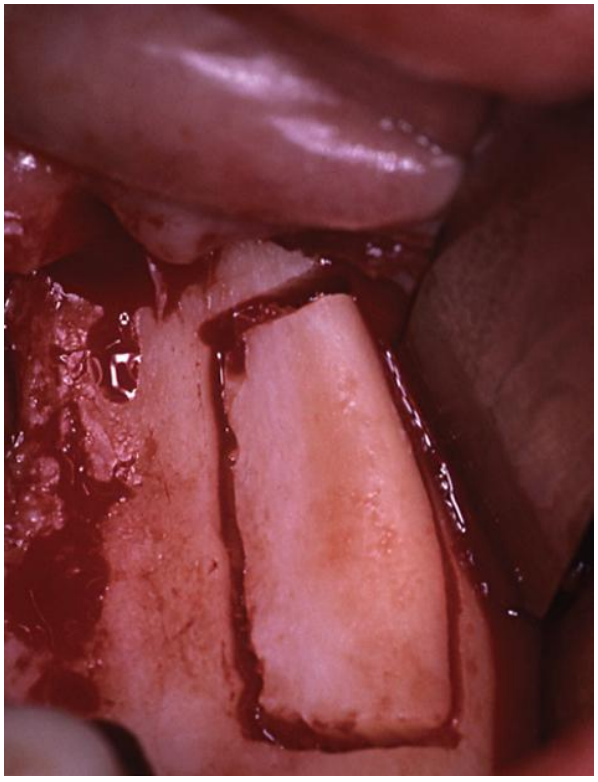

Fig. 51-24 Most suitable sites used to harvest block or particulate bone grafts intraorally are the mandibular body and the mandibular ramus.

Bone substitutes

Loss of autografts during healing occurs when resorption of the autograft exceeds new bone formation during the consolidation phase. Thus, to overcome excessive resorption of autografts, bone substitutes that are known for their slow resorption process are added to autografts to increase the stability of grafts during the consolidation phase.

Tricalcium phosphate was the first bone substitute to be applied successfully for sinus floor elevation (Tatum 1986). Over the years, allografts, alloplasts, and xenografts of various types have been used alone or in combination with autografts. Studies in animal models showed that the use of bone substitutes, such as bovine bone mineral, either alone or in combination with autografts, preserved the vertical height of the graft over time (Fig. 51-25). In a human study, sinus grafts consisting of autografts and demineralized allografts were observed over a period of time. A graft resorption of up to 25% was seen. Furthermore, a human study also showed significant reduction in graft volume when either autogenous bone alone or a mixture of autogenous bone and xenografts were used (Hatano *et al*. 2004). A recent study comparing the use of bone-added osteotome sinus floor elevation (BAOSFE) with sinus floor elevation utilizing the lateral approach, concluded minimal bone resorption was seen for both methods: 1.35 mm and 1.36 mm, respectively, over a period of 2 years after the procedure was performed (Kim *et al.* 2011). There is a definitive need for good long-term studies that address the stability of the different types of grafting materials in the maxillary sinuses over time.

Histologic analysis of human biopsy specimens from sinuses augmented with xenografts revealed that xenograft particles were mostly surrounded by mature compact bone (Fig. 51-26). In some Haversian canals, it was possible to observe small capillaries, mesenchymal cells, and osteoblasts in conjunction with new bone. No gaps were noted at the interface between the xenograft particles and the newly formed bone (Piattelli *et al*. 1999).

Fig. 51-25 1 : 1 mixture of particulate autologous bone and bone substitute. The autologous bone particles include viable osteogenic cells, bone morphogenic proteins, and other growth factors. The bone substitute is supposed to decrease the resorption of the grafting material.

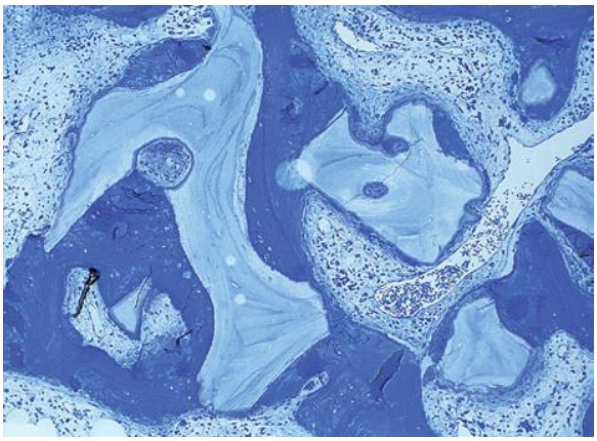

Fig. 51-26 Bovine bone mineral particles (xenograft) are mostly surrounded by new mature compact bone. No gaps can be seen at the interface between the xenograft particles and the newly formed bone. (Courtesy of D. D. Bosshardt.)

A human study evaluating bone formation after sinus floor elevation using xenografts alone or in combination with autogenous bone and/or demineralized freeze-dried bone allografts (DFDBAs) reported a statistically significant increase in vital bone formation when as little as 20% of autologous bone was added to the bone substitutes (Froum *et al*. 1998). The mean vital bone formation was 27.1% after a healing period of 6–9 months. However, comparative studies (Hising *et al*. 2001; Hallman *et al*. 2002a, b; Valentini & Abensur 2003) reported higher survival rates for implants placed into sinuses grafted with 100% xenograft as compared to those placed in sinuses grafted with 100% autogenous bone or composite graft of xenograft and autogenous bone.

In a recent systematic review (Pjetursson *et al*. 2008), an attempt was made to compare the survival rates of implants inserted into maxillary sinuses that had been grafted utilizing different grafting materials. The relative failure rates of the different types of grafting materials were analyzed with multivariable random-effect Poisson regression. In order to avoid the confounding factor of implant surfaces, only studies reporting on rough textured implants were included and machined-surface implants were excluded. Bone substitutes, a combination of autogenous bone and bone substitutes, and autogenous bone blocks all showed similar low annual failure rates of 1.13%, 1.10%, and 1.27%, respectively. The particulated autogenous bone graft, based on two studies, showed significantly lower annual failure rates of 0.06%. It must, however, be kept in mind that all types of grafting materials had high implant survival rates ranging between 96.3% and 99.8% after 3 years.

Another indication for using bone substitutes is to reduce the volume of bone that must be harvested. When a large sinus cavity is grafted with autologous bone alone, 5–6 mL of bone may be necessary. By using bone substitutes alone or in combination with autografts, the amount of autogenous bone to be harvested is greatly reduced.

Success and implant survival

Jensen *et al*. (1996) published the findings from the Consensus Conference of the Academy of Osseointegration. Retrospective data were collected from 38 clinicians who collectively performed 1007 sinus floor elevations and placed 2997 implants over a 10-year period. The majority of the implants had been followed for 3 years or more. Two hundred and twenty-nine implants were lost, resulting in an overall survival rate of 90.0%. However, the data were so variable that no definitive conclusions regarding the grafting material, type of implants, and timing of implant placement could be drawn.

Survival of implants cannot be the sole criterion for success of maxillary sinus floor elevation. Factors such as the preoperative residual bone height, long-term stability of the bone graft, and incidence of failing two-stage sinus grafting due to graft resorption must also be considered.

Of the 900 patient records that were screened for the Consensus Conference in 1996, only 100 had radiographs of adequate quality for analysis of the residual bone height. In total, only 145 sinus grafts in 100 patients with 349 implants were analyzed. After a mean follow-up period of 3.2 years, 20 implants were lost. Of the implants lost, 13 had been placed in residual bone with a height of 4 mm and seven in residual bone with a height of 5–8 mm. None of the implants placed in residual bone height of >8 mm were lost. There was a statistically significant difference in implant loss when residual bone height was ≤4 mm as compared to ≥5 mm (Jensen *et al*. 1996).

A critical appraisal of the dental literature on maxillary sinus floor elevation shows that the two-stage approach (delayed implant installation) is more likely to be used in situations with less residual bone height compared to the one-stage approach (simultaneous implant placement).

The efficacy of performing a one-stage sinus floor elevation in patients whose residual alveolar bone height in the posterior maxilla was between 3 and 5 mm was assessed (Peleg *et al*. 1999). Using the modified Caldwell–Luc technique, the maxillary sinus was elevated with composite grafts of symphysal autograft and DFDBA in a 1 : 1 ratio. One hundred and sixty implants were placed in 63 elevated sinuses. A 100% survival rate of the implants was reported after 4 years. In a second study using a similar protocol for 55 implants placed into 20 elevated sinuses, the residual alveolar bone height was only 1–2 mm (Peleg *et al*. 1998). All implants osseointegrated successfully, and no implants were lost after 2 years of functional loading.

One randomized controlled clinical trial has compared one- and two-stage sinus floor elevation, in 40 patients divided into groups (Wannfors *et al*. 2000). The residual bone height ranged from 2 to 7 mm. The reported survival rate for the one-stage protocol (Fig. 51-27) in 75 implants was 85.5%, as compared to

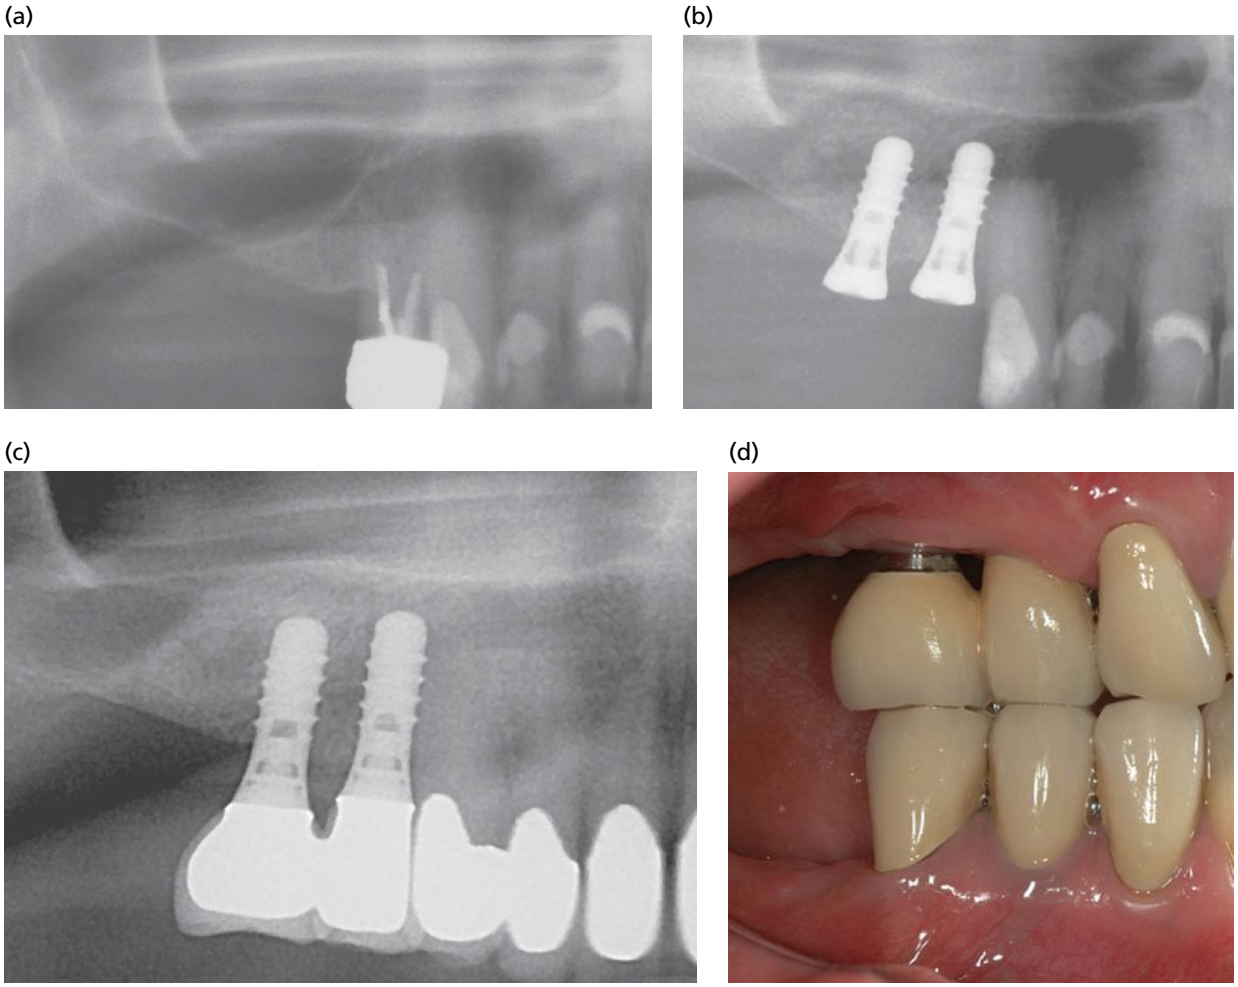

Fig. 51-27 One-stage sinus floor elevation. (a) Panoramic radiograph showing oblique inferior sinus borders and a residual bone height between 2 and 6 mm in the position of tooth 25. (b) Two implants were placed: a standard implant placement in the position of tooth 24 and an implant installed in combination with sinus floor elevation in the position of tooth 25. A 1 : 1 mixture of particulate autologous bone harvested from the maxillary tuberosities and the zygomatic bone combined with bovine bone mineral was used as the grafting material. (c) Panoramic radiograph taken 1 year after functional loading. A new inferior border of the maxillary sinus and a stable graft volume were evident. (d) Clinical picture at the 1-year follow-up visit.

90.5% for the two-stage protocol (Fig. 51-28) in 74 implants after 1 year in function. Apparently, the risk of implant failure in grafted areas was greater for the one-stage procedure than for the two-stage procedure, although the results did not reach statistical significance. In the systematic review previously mentioned (Pjetursson *et al.* 2008), one- and two-stage sinus floor elevations were compared (24 studies with 5672 implants using the one-stage approach and 24 studies with 3560 implants using the two-stage approach). The annual failure rates for the two methods were similar: 4.07% versus 3.19%, respectively. It must, however, be kept in mind that the one-stage approach is usually only applied when the residual bone height gives enough primary implant stability. Hence, the two-stage approach is usually used in more challenging situations with limited residual bone.

The stability of the sinus graft height was evaluated on panoramic radiographs for 349 implants. After a mean follow-up period of 3.2 years, the reduction of the graft height varied between 0.8 mm (autograft and alloplast) and 2.1 mm (autograft). This indicated that all of the graft materials appeared to be stable, with only 1–2 mm of the graft height being lost over the 3-year period (Jensen *et al*. 1996). Further studies evaluating the long-term stability of sinus grafts (Block *et al*. 1998; Hatano *et al*. 2004) yielded similar results.

Wallace and Froum (2003) published a systematic review of the effect of maxillary sinus floor elevation on the survival of dental implants. The inclusion criteria were human studies with a minimum of 20 interventions, a follow-up time of 1 year of functional loading, and implant survival as an outcome measure. The main results indicated:

- Survival rate of implants placed in conjunction with sinus floor elevation with the lateral approach varied between 61.7 and 100%, with an average of 91.8%.
- Implant survival rates compared favorably to reported survival rates for implants placed in the non-grafted maxilla.

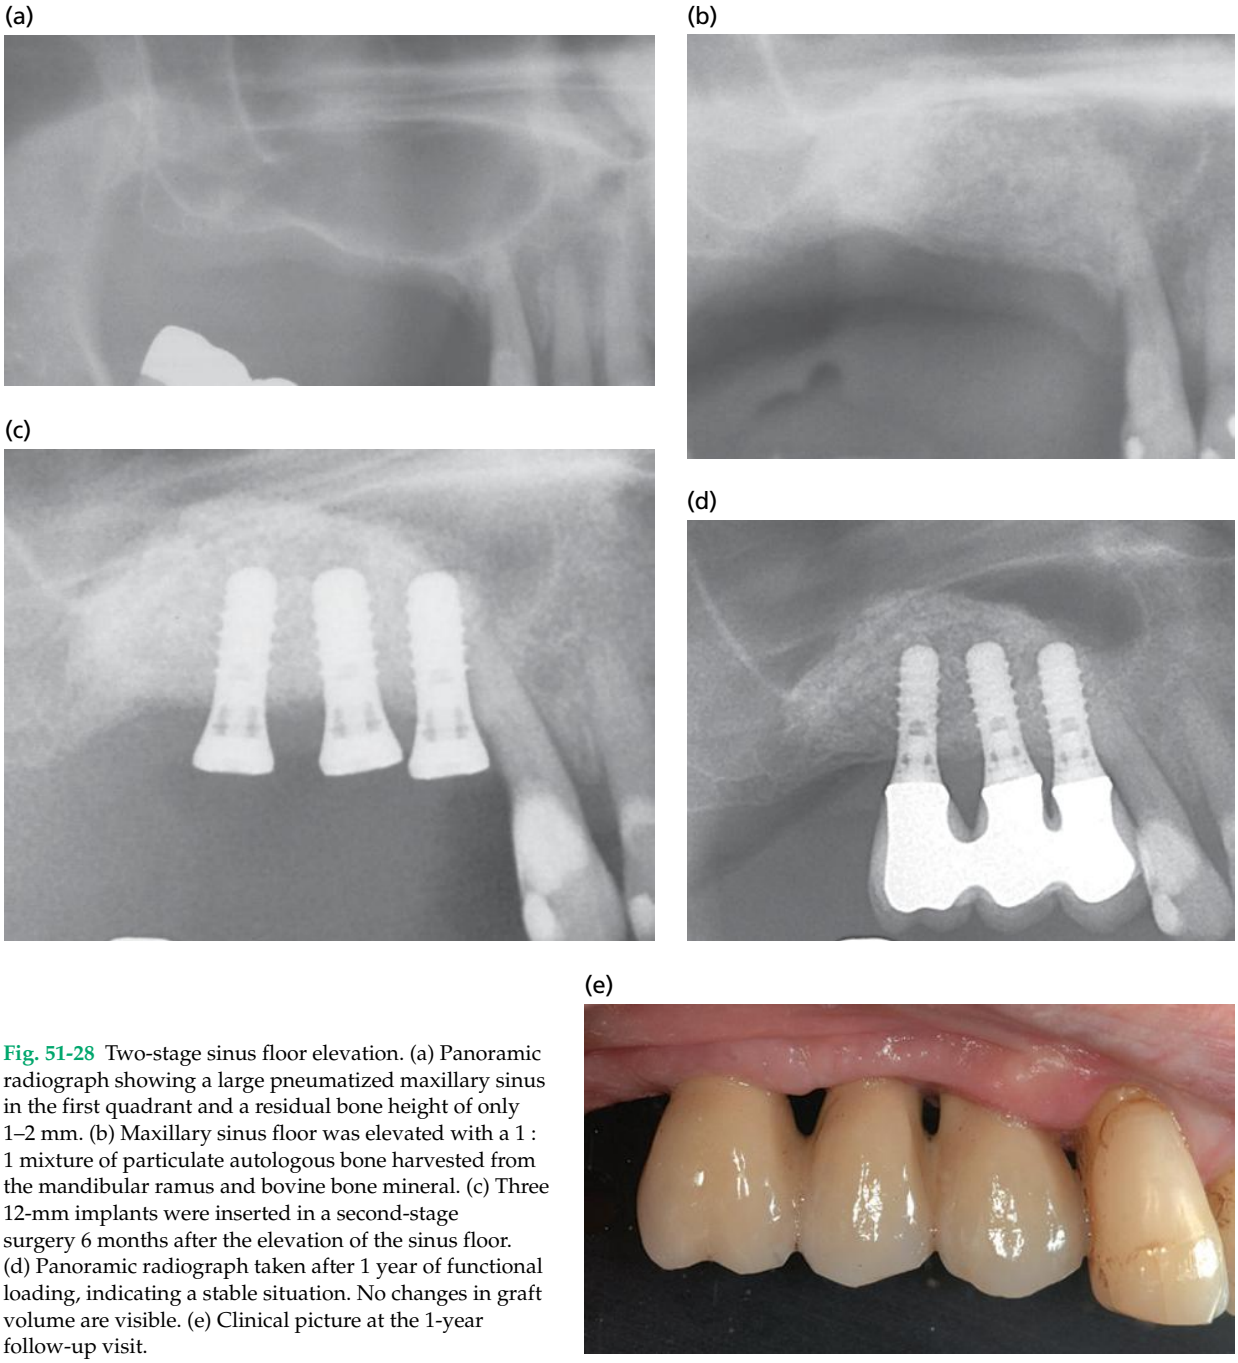

Fig. 51-28 Two-stage sinus floor elevation. (a) Panoramic radiograph showing a large pneumatized maxillary sinus in the first quadrant and a residual bone height of only 1–2 mm. (b) Maxillary sinus floor was elevated with a 1 : 1 mixture of particulate autologous bone harvested from the mandibular ramus and bovine bone mineral. (c) Three 12-mm implants were inserted in a second-stage surgery 6 months after the elevation of the sinus floor. (d) Panoramic radiograph taken after 1 year of functional loading, indicating a stable situation. No changes in graft volume are visible. (e) Clinical picture at the 1-year follow-up visit.

- Rough-surface implants yielded higher survival rates than machined-surface implants when placed in grafted sinuses.
- Implants placed into sinuses augmented with particulate autografts showed higher survival rates than those placed in sinuses that had been augmented with block grafts.
- Implant survival rates were higher when barrier membranes were placed over the lateral window.
- The utilization of grafts consisting of 100% autogenous bone or the inclusion of autogenous bone as a component of composite grafts did not affect implant survival.

A systematic review (Pjetursson *et al*. 2008) included 48 prospective and retrospective studies reporting on 12 020 implants inserted in combination with sinus floor elevation using the lateral approach. Meta-analysis of the included studies indicated an estimated annual failure rate of 3.48%, translating into a 3-year implant survival rate of 90.1% (95% CI 86.4–92.8%). However, when failure rates were analyzed at the subject level, the estimated annual failure rate was 6.04%, which translates to 16.6% of the subjects experiencing implant loss over a period of 3 years. One of the main conclusions of the meta-analysis was that the implant surface significantly affected the outcome of the treatment. The annual failure rate of machined-surface implants was 6.86% compared with an annual failure rate of 1.20% for rough-surface implants, which was a highly significant difference. The 3-year survival rate for rough-surface implants was 96.4% (95% CI 94.6–97.7%).

Sinus floor elevation with the transalveolar approach (osteotome technique)

The osteotome technique was first developed to compress soft, type III and IV maxillary bone. The concept is intended to increase the density of bone in the maxilla, leading to better primary stability of inserted dental implants.

In the maxilla, the bone crest in edentulous ridges is often narrow in the buccopalatal dimension. This limits the possibility of standard drilling when preparing an implant site. Thus, to address this difficult situation, tapered round osteotomes of increasing diameters have been used to expand the compactible cancellous maxillary bone and gently move it in a lateral direction to increase crestal width. This procedure is known as the "ridge expansion osteotome technique" and will not be addressed further in this chapter.

Tatum (1986) described the transalveolar approach to elevate the sinus floor. The osteotome technique for sinus floor elevation, using a set of osteotomes of varying diameters (Fig. 51-29) to prepare the implant site, was first presented by Summers (1994). The bone-added osteotome sinus floor elevation (BAOSFE), today referred to as the *Summers technique*, may be considered to be a more conservative and less invasive approach than the conventional lateral approach of sinus floor elevation. A small osteotomy is made through the crest of the edentulous ridge, at the inferior region of the maxillary sinus. This intrusion osteotomy procedure elevates the sinus membrane, thus creating a "tent" and space for bone graft placement and/or blood clot formation. It should be noted that the bone grafts are placed blindly into the space below the sinus membrane. Hence, the main disadvantage of this technique is the possibility of perforation of the sinus membrane. However, an endoscopic study has shown that the sinus floor can be elevated by up to 5 mm without perforating the membrane (Engelke & Deckwer 1997).

Fig. 51-29 Set of straight and tapered osteotomes used to prepare the implant site and to elevate the maxillary sinus floor.

Indications and contraindications

Indications for the transalveolar osteotome technique include a flat sinus floor with a residual bone height of at least 5 mm and adequate crestal bone width for implant installation.

Contraindications for the graft placement and/or blood clot formation technique are similar to those previously described for the lateral approach. In addition, however, patients with a history of inner ear complications and positional vertigo are not suitable for the osteotome technique. Regarding local contraindications, an oblique sinus floor (>45° inclination) is not suitable for the osteotome technique (Fig. 51-30), because osteotomes first enter the sinus cavity at the lower level of an oblique sinus floor, while still having bone resistance at the cranial level of the sinus floor. In this situation, there is a high risk of perforating the sinus membrane with the sharp margin of the osteotomes (Fig. 51-31).

Surgical technique

Only minor modifications (Rosen *et al*. 1999; Fugazzotto 2001; Chen & Cha 2005; Pjetursson *et al.* 2009a) to the original technique (Summers 1994) have been presented. The following describes a modification of the original technique:

1. Presurgical patient preparation includes oral rinsing with 0.1% chlorhexidine for a period of 1 minute.
2. Local anesthesia is administered into the buccal and palatal regions of the surgical area.
3. A mid-crestal incision with or without releasing incision is made and a full-thickness mucoperiosteal flap is raised.
4. With a surgical stent or a distance indicator, the implant positions are marked on the alveolar crest

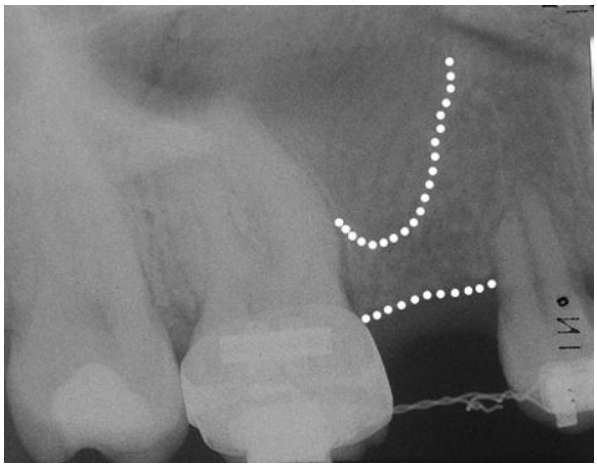

Fig. 51-30 Edentulous space in the position of tooth 15. The oblique inferior border of the maxillary sinus lies at approximately 60° to the inferior border of the alveolar crest (dotted lines represent the outlines of the residual bone). In a clinical situation like this, it is difficult to elevate the maxillary sinus floor with osteotomes and carries a high risk for perforating the sinus membrane.

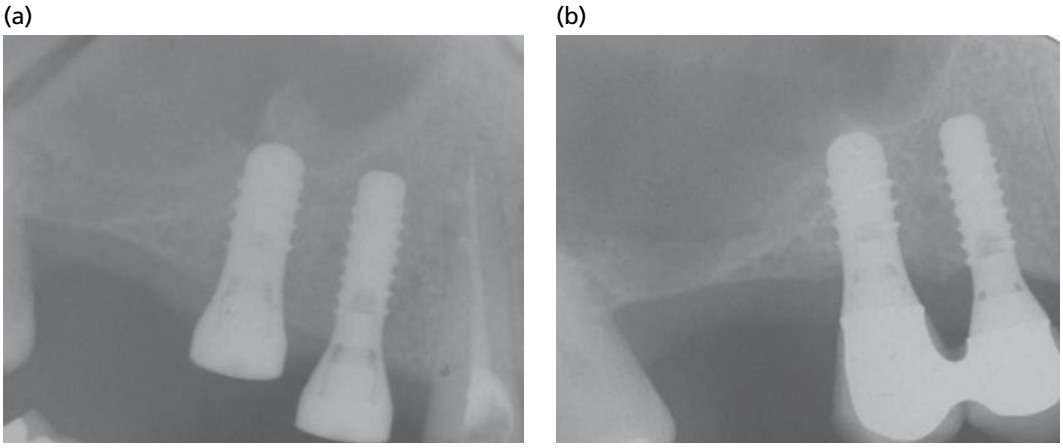

Fig. 51-31 (a) Sinus floor elevation was performed with the osteotome technique in a case with an oblique sinus floor. The cortical bone of the sinus floor was in-fractured and rolled-up, causing perforation of the sinus membrane. Due to the membrane perforation, no grafting material was utilized. (b) Same patient at the 5-year follow-up visit. The implant was stable, but only minor new bone formation is visible at the distal aspect of the implant.

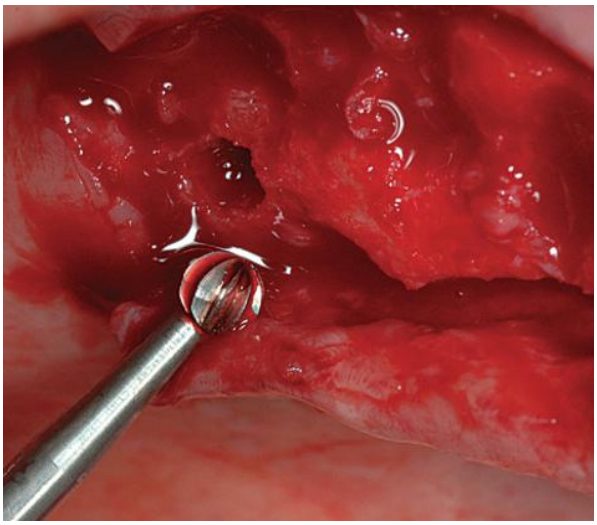

Fig. 51-32 Exact position of the implant site is first marked with a small round bur (#1) and then extended with two sizes of round burs (#2 and #3) to a diameter about 0.5–1 mm smaller than that of the implant to be installed.

with a small round bur (#1). After precisely locating the implant positions, the openings of the preparations are widened with two sizes of round burs (#2 and #3) to a diameter about 0.5–1 mm smaller than the implant diameter to be placed (Fig. 51-32).

5. The distance from the crestal floor of the ridge to the floor of the maxillary sinus, measured on the preoperative radiograph prior to implant site preparation, can, in most cases, be confirmed at surgery by penetrating the opening of the preparation with a blunt periodontal probe through the soft trabecular bone (type III or IV bone) to the floor of the maxillary sinus.
6. After confirming the distance to the sinus floor, pilot drills with small diameters (1–1.5 mm smaller than the implant diameter) are used to prepare the implant site to a distance approximately 2 mm below the sinus floor (Fig. 51-33a). In cases of soft type IV bone and a residual bone height of 5–6 mm, there is usually no need to use the pilot drills. It is sufficient to perforate the cortical bone at the alveolar crest with the round burs.
7. The first osteotome used in the implant site is tapered and has a small diameter (Fig. 51-34). With light malleting, the osteotome is pushed towards the compact bone of the sinus floor (Fig. 51-33b). After reaching the sinus floor, the osteotome is pushed about 1 mm further with light malleting in order to create a "greenstick" fracture on the compact bone of the sinus floor. A tapered osteotome of small diameter is chosen to minimize the force needed to fracture the compact bone.
8. The second tapered osteotome, with a diameter slightly larger then the first one, is used to increase the fracture area of the sinus floor (Fig. 51-35). It is applied to the same distance as the first one.
9. The third osteotome used is straight and has a diameter about 1–1.5 mm smaller than the implant to be placed (Fig. 51-36). Instead of using the osteotomes to fracture the sinus floor, piezoelectric surgery can be used. The advantage of the latter technique is that the perforation of the sinus floor may be achieved in a more controlled way than with osteotomes, and the risk of membrane perforation is thus reduced (Sohn *et al.* 2009). Moreover, this technique could reduce the risk of benign paroxysmal positional vertigo. The main disadvantage of this technique is that it is more time consuming than malleting, especially when the cortical bone at the sinus floor is relatively thick.

From this point onwards, the technique utilized in the surgical procedure depends on whether or not bone grafts or bone substitutes are to be placed.

Implant placement without grafting material

1. Without applying grafting material, the straight osteotome with a diameter about 1–1.5 mm smaller than that of the implant is pushed further into the sinus cavity until it penetrates the sinus floor.

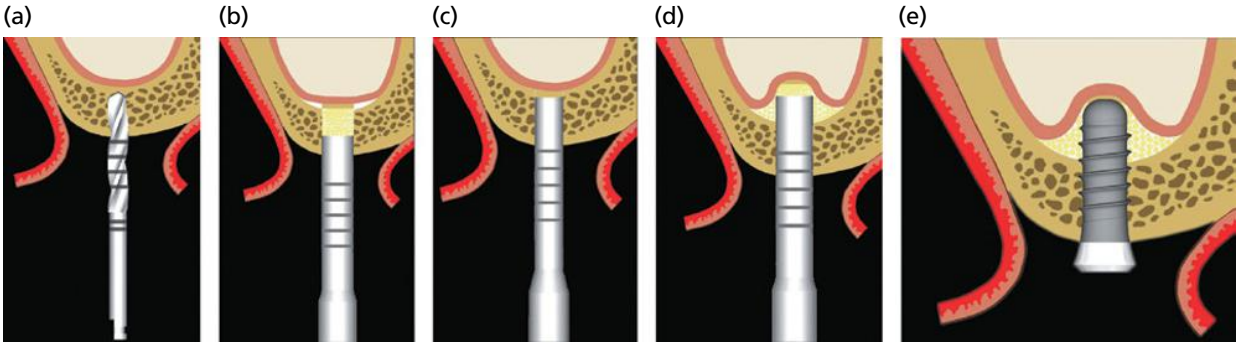

Fig. 51-33 (a) Implant site is prepared to a distance of approximately 2 mm below the sinus floor with a small diameter pilot drill. (b) After reaching the sinus floor, the osteotome is pushed approximately 1 mm further with light malleting in order to create a "greenstick" fracture on the compact bone of the sinus floor. (c) Grafting material is slowly pushed into the sinus cavity with a straight osteotome. This procedure is repeated several times. (d) Tip of the osteotome is only supposed to enter the sinus cavity after some grafting material has been pushed through the preparation site to elevate the sinus membrane. (e) Inserted implant and the grafting material maintain space below the sinus membrane.

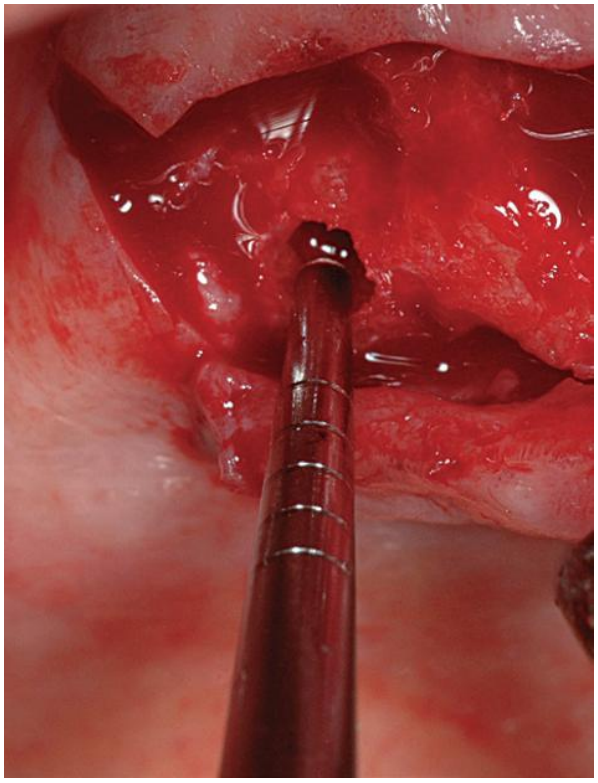

Fig. 51-34 First osteotome used in the implant site is a small-diameter tapered osteotome. Such an osteotome is chosen to minimize the force needed to fracture the compact bone.

2. The last osteotome to be used must have a form and diameter that are suitable for the implant to be placed. For example, for a cylindrical implant with a diameter of 4.1 mm, the last osteotome should be a straight osteotome with a diameter about 0.5 mm smaller than the implant diameter (3.5 mm). It is important that the last osteotome only enters the preparation site once (Fig. 51-37). If several attempts have to be made in sites with soft bone (type III or IV), there is a risk of increasing the diameter of the preparation and this may jeopardize achieving good primary stability. On the other hand, if the last osteotome diameter is too small compared to the implant diameter, too much force

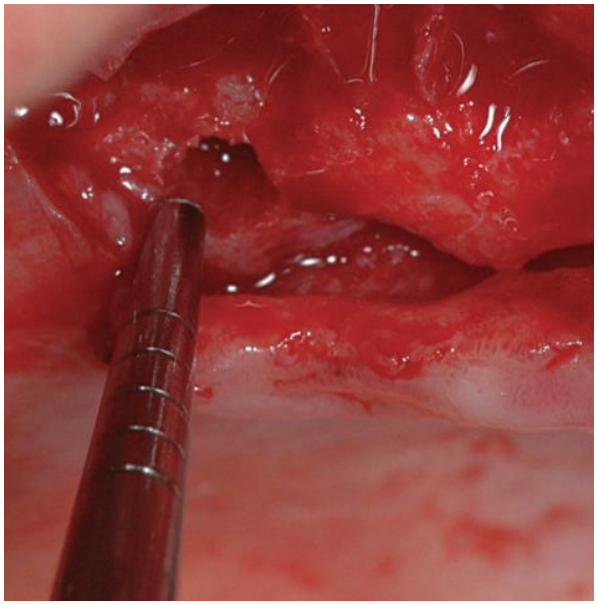

Fig. 51-35 Second osteotome, which is also tapered, but with a diameter slightly larger then the first one, is used to increase the fractured area of the sinus floor.

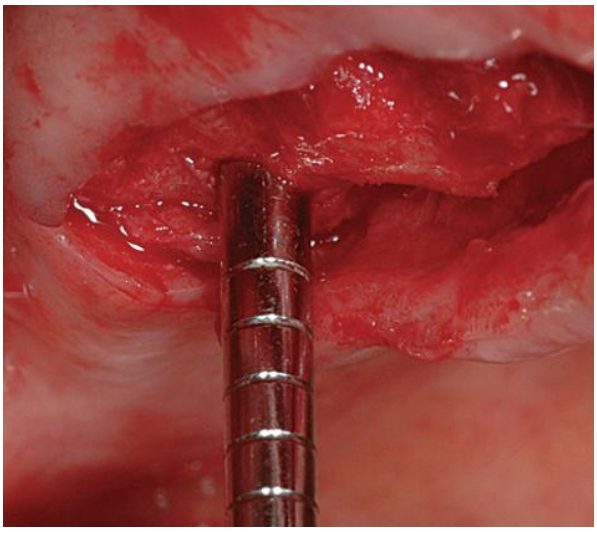

Fig. 51-36 Third osteotome used is a straight osteotome with a diameter about 1–1.5 mm smaller than that of the implant to be placed.

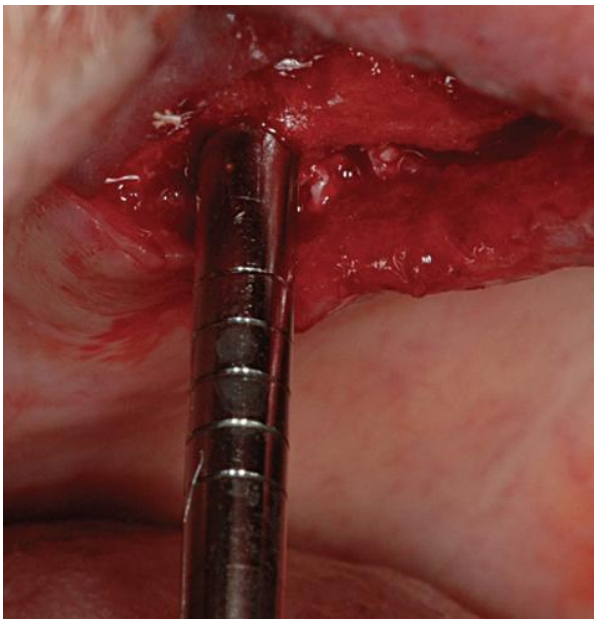

Fig. 51-37 Last osteotome used must have a form and diameter that are suitable for the implant to be placed. It is important that the last osteotome is allowed to enter the preparation site only once.

must be used to insert the implant. By squeezing the bone, more bone trauma and, hence, greater bone resorption will occur, delaying the osseointegration process (Abrahamsson *et al*. 2004). It is thus important, especially when placing implants in sites with reduced bone volume, that the fine balance between good primary stability and traumatizing the bone is respected.

3. During the entire preparation, it is crucial to maintain precise control over the penetration length. Regular osteotomes have sharp cutting edges; thus, their entry into the sinus cavity increases the risk of membrane perforation. The final step before placing the implant is to check that the preparation is patent to the planned insertion depth. An osteotome with a rounded tip or a depth gauge is pushed to a depth that is relevant for the implant diameter (Fig. 51-38).

Implant placement with grafting materials

1. When performing the osteotome technique with grafting materials, the osteotomes are not supposed to enter the sinus cavity *per se*. Repositioned bone particles, grafting materials, and the trapped fluid will create a hydraulic effect that moves the fractured sinus floor and sinus membrane upwards. The sinus membrane is less likely to tear under this kind of pressure.
2. After pushing the third osteotome up to the sinus floor and before placement of any grafting material, the sinus membrane must by tested for any perforations. This is done with the Valsalva maneuver (nose blowing). The patient compresses his/her nostrils (Fig. 51-39), and then blows his/her nose. If air leaks out of the implant site, the sinus membrane is perforated, and no grafting material should be placed into the sinus cavity.
3. If the sinus membrane is judged to be intact, the preparation is filled with grafting material (Fig. 51-40). The grafting material is then slowly pushed into the sinus cavity with the same straight third osteotome (Fig. 51-41). This procedure is repeated

Fig. 51-38 Final step before placing the implant is to check that the preparation is patent to the planned insertion depth. An osteotome with a rounded tip or a depth gauge is pushed to a depth that is relevant for the diameter of the implant.

Fig. 51-39 Testing the sinus membrane for perforation.

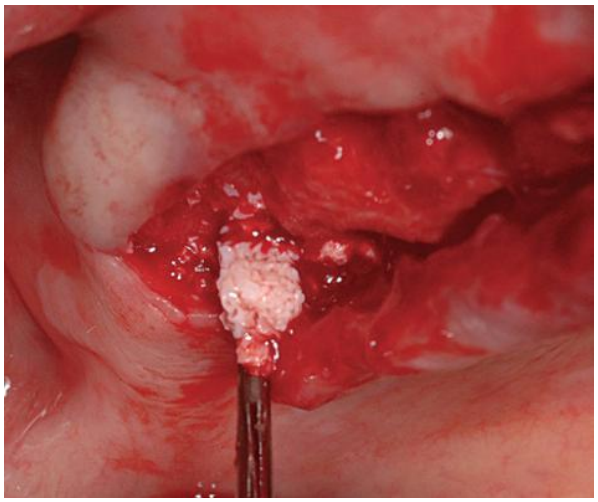

Fig. 51-40 Preparation site is filled four to five times with grafting material.

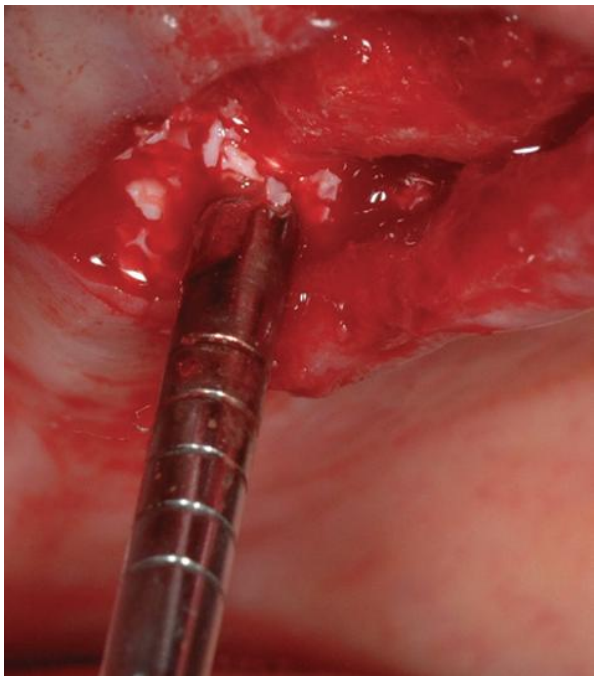

Fig. 51-41 Grafting material is then slowly pushed into the sinus cavity with a straight osteotome with a diameter about 1–1.5 mm smaller than that of the intended implant.

four to five times (see Fig. 51-33c) until about 0.2–0.3 g of grafting material has been pushed into the sinus cavity below the sinus membrane (Fig. 51-42). On the fourth and fifth time of applying grafting material, the tip of the osteotome may enter the maxillary sinus cavity by about 1 mm to test if there is resistance in the preparation site (see Fig. 51-31d).

4. Finally, before implant placement (Fig. 51-43), the preparation is checked for patency by repeating the Valsalva maneuver.

To achieve good primary stability in the soft trabecular bone on the posterior maxilla, implants with a slightly tapered configuration or implants with a

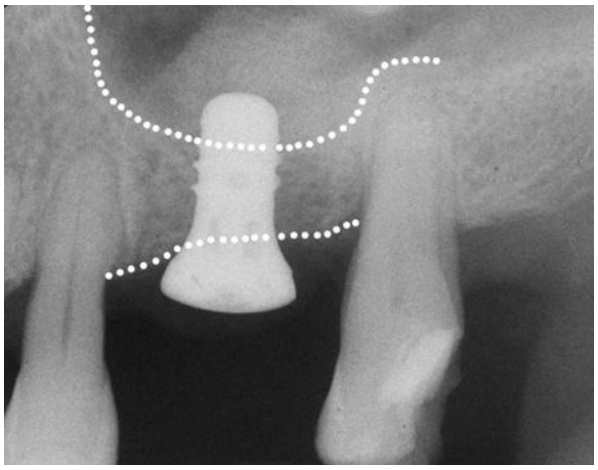

Fig. 51-42 Radiograph, taken after implant placement, showing a dome-shaped configuration of the graft. 0.25 g of grafting material (xenograft) was used to elevate the sinus membrane (dotted lines represent the outlines of the residual bone).

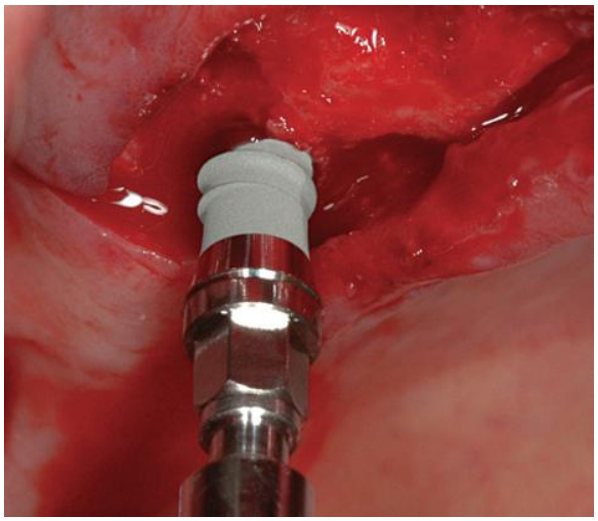

Fig. 51-43 Rough-textured implant was installed after preparing the implant site with the osteotome technique. Good primary stability was achieved.

tulip-shaped neck are recommended. However, it must always be kept in mind that applying too much force on the bone will result in greater bone resorption, delaying the osseointegration process (Abrahamsson *et al*. 2004).

Post-surgical care

The post-surgical care after placing implants with the osteotome technique is similar to that after standard implant placement. In addition to the standard oral home care, antiseptic rinsing with 0.1–0.2% chlorhexidine twice daily for the first 3 weeks after surgery is highly recommended. Although there have been no studies comparing post-surgical care with and without the use of prophylactic antibiotics, antibiotic prophylaxis for 1 week has been recommended in cases where bone substitutes are used.

Complications

Just as with the lateral approach, when performing transalveolar sinus floor elevation, the risk of complications must be considered and their appropriate treatment foreseen.

Again, the most common intraoperative complication is perforation of the sinus membrane. The bone grafts are placed blindly into the space below the sinus membrane and as a result there is the possibility of perforation of the sinus membrane. The presence of maxillary sinus septa and root apices penetrating into the sinus may increase the risk of membrane perforation. In a recent systematic review addressing the transalveolar sinus floor elevation in eight studies with 1621 implants, the incidence of perforation of the Schneiderian membrane varied between 0% and 21.4%, with a mean of 3.8% (Tan *et al.* 2008). Smaller perforations may be closed through the transalveolar preparation using tissue fibrin glue. In cases of larger perforations, access to close the window must be achieved through a lateral window. If the perforation occurs before any grafting material is inserted, the procedure should be aborted or shorter implants used.

Postoperative infections after transalveolar sinus floor elevation are rare complications (0–2.5%, mean 0.8%) (Tan *et al.* 2008). Other reported complications include postoperative hemorrhage, nasal bleeding, blocked nose, hematomas, and loosening of cover screws resulting in suppuration and benign paroxysmal positional vertigo (BPPV). BPPV may cause the patient substantial stress if not correctly identified and properly managed (Vernamonte *et al.* 2011). No air embolism was reported in the study using hydraulic sinus condensation (Chen & Cha 2005).

Pjetursson *et al.* (2009a) evaluated patient-centered outcomes after implant placement using the transalveolar approach. Of the 163 patients included in this study, 23% found the surgical experience unpleasant. When asked about other post-surgical complications, 5% of the patients felt their head was tilted too far back during the surgery, and 5% experienced vertigo, nausea and felt disoriented after the surgical procedure. Never the less, 90% of the patients would be willing to undergo implant therapy again if necessary and dentally indicated.

Grafting material

As discussed above for the lateral approach, there is still controversy with regards to the necessity of using grafting material to maintain the space for new bone formation after elevating the sinus membrane utilizing the osteotome technique.

In the original publication describing the transalveolar approach, Tatum (1986) did not use any grafting material to increase and maintain the volume of the elevated area. Later, Summers (1994) introduced the BAOSFE and a multicenter retrospective study of eight centers was initiated. Evaluation was carried out for 174 implants placed in 101 patients, with the type of grafting material used decided by the individual clinician. Autografts, allografts, and xenografts were used, alone or in combinations. The authors concluded that the type of grafting material did not influence implant survival (Rosen *et al*. 1999).

Of 19 studies included in a recent systematic review (Tan *et al*. 2008), 15 used grafting material, in three the procedure was performed without graft placement, and one did not report whether or not grafting material was used.

A recent clinical study (Nedir *et al.* 2010) reported on 25 10-mm dental implants inserted using the transalveolar approach without grafting material. The implants protruded on average 4.9 mm into the sinus cavity after surgery. After a follow-up of 5 years, the implant protrusion was reduced to 1.5 mm. Hence, 3.4 mm (70%) of the penetrating part of the implants showed spontaneous bone formation. In another clinical study, sinus floor remodeling after implant insertion using a modified transalveolar technique without grafting material was assessed radiographically (Schmidlin *et al.* 2008). The implant survival rate in the 24 patients available for follow-up was 100%. Bone filling around the implants was measured and compared with baseline digital radiographs. The mean height of the newly formed bone was 2.2 mm mesially and 2.5 mm distally, or 86.3% and 89.7% of new bone formation, respectively.

In a prospective study, 252 implants were inserted using the transalveolar sinus floor elevation technique with or without grafting material (Pjetursson *et al*. 2009b). For 35% of these implants, deproteinized bovine bone mineral with a particle size of 0.25–1 mm was used as grafting material, but for the remaining 164 implants, no grafting material was utilized. The mean radiographic bone gain using the transalveolar technique with grafting material was significantly more (4.1 mm, SD 2.4 mm) than that when no grafting material was used (1.7 mm, SD 2.0 mm). When grafting material is used, a cloudy dome-shaped structure with a hazy demarcation may be visible after implant placement. The size of this dome is usually reduced after remodeling but still increases the bone volume compared to the preoperative situation (Pjetursson *et al*. 2009b) (Fig. 51-44).

Brägger *et al.* (2004) investigated the patterns of tissue remodeling after placement of 25 implants in 19 patients using the osteotome technique with composite xenografts and autografts. Intraoral radiographs were obtained presurgically and post-surgically at 3 and 12 months. The mean height of the new bone apical and mesial to the implants was 1.52 mm at surgery, but this was reduced significantly to 1.24 mm at 3 months and 0.29 mm after 12 months (Fig. 51-45). It was concluded that the grafted area apical to the implants underwent shrinkage and remodeling (Fig. 51-46), and the original outline of the sinus was eventually consolidated and replaced by a new cortical plate.

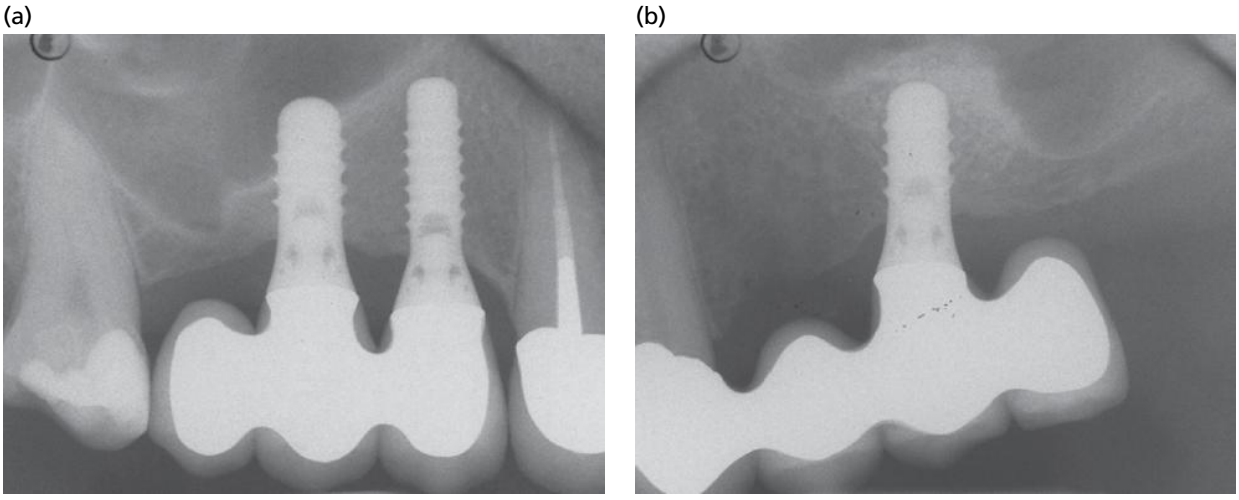

Fig. 51-44 (a) Radiograph taken at the 5-year follow-up visit of an implant placed in the first quadrant utilizing the osteotome technique without grafting material. A new cortical bony plate at the inferior border of the maxillary sinus is clearly visible, but no bony structure can be detected apical to the implant. (b) Radiograph (same patient) taken after 5 years in function of an implant placed in the second quadrant utilizing the osteotome technique with xenograft grafting material. A dome-shaped structure is clearly visible, documenting a definite increase in bone volume compared to the initial situation. The "dome" is surrounded by a new cortical bony plate.

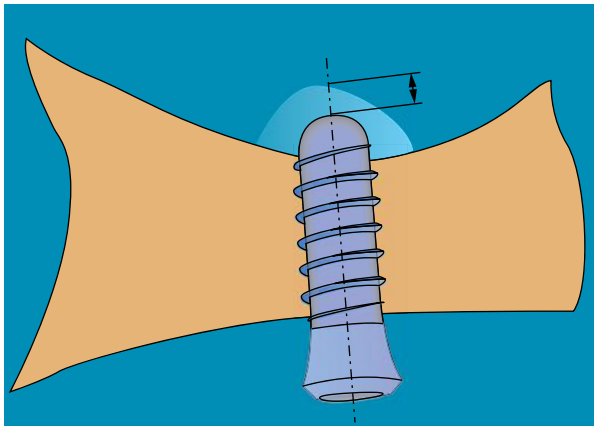

Fig. 51-45 Grafted area apical to the implants undergoes shrinkage and remodeling and the original border of the sinus is eventually consolidated and replaced by a new cortical plate. (Source: Brägger *et al*. 2004. Reproduced with permission from John Wiley & Sons.)

Success and implant survival

In a multicenter retrospective study evaluating the Summers technique applied to the placement of 174 implants in 101 patients, the implant survival rate was 96% when residual bone height was 5 mm or more, but dropped to 85.7% when residual bone height was 4 mm or less (Fig. 51-47) (Rosen *et al*. 1999). Similar results were reported in a recent prospective study in which 20% of the implants were placed in sites with residual bone height of <5 mm (Pjetursson *et al*. 2009a), which tested the limits of the osteotome technique. The survival rates were 91.3% for implant sites with ≤4 mm of residual bone height and 90% for sites with a residual bone height between 4 and 5 mm, compared with 100% for sites with a residual bone height of >5 mm. Moreover, for short 6-mm implants, the survival rate was only 48%. This clearly demonstrated that the transalveolar sinus floor elevation technique was most predictable when the residual alveolar bone height was ≥5 mm and with implants of ≥8 mm. This in turn indicates that the limit of the osteotome technique has been tested.

A recent systematic review (Tan *et al*. 2008) analyzed the survival and complication rates of implants inserted in combination with transalveolar sinus floor elevation. Meta-analysis of the 19 included studies indicated an estimated annual failure rate of 2.48%, which translates to an estimated survival rate of 92.8% (95% CI 87.4–96.0%) for implants placed in transalveolarly augmented sinuses after 3 years in function. Furthermore, subject-based analysis revealed an annual failure of 3.71%, which translates to implant loss in 10.5% of the subjects over 3 years.

Short implants

In the light of sinus floor elevation techniques being indicated to facilitate the installation of dental implants in the maxillary posterior region without adequate bone volume, these treatment alternatives have to be discussed with the patient (see Chapter 32). However, since patient-centered outcomes and morbidity associated with these procedures have not been addressed so far, it has to be anticipated that a great number of patients may not choose sinus floor elevation for their treatment. Hence, shortened dental arches (Käyser 1981) may have to be considered in treatment planning.

A variation to conventional implant installation in the posterior maxilla is the choice of short implants to avoid penetration into the sinus cavity. Jemt and Lekholm (1995) reported that implant failure in edentulous maxilla correlated significantly with bone quality, especially for short (7 mm) implants. Other

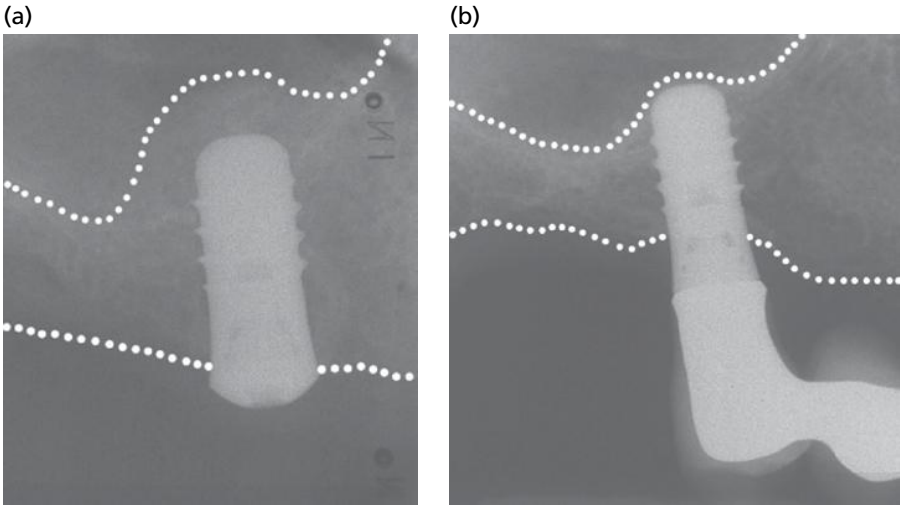

Fig. 51-46 (a) Radiograph taken immediately after implant insertion with the osteotome technique and grafting material, showing a cloudy dome-shaped structure extending 2–3 mm apical to the implant. (b) Radiograph of the same implant taken 1 year later showing significant reduction of the size of the "dome", but the new bony structure is clearly visible apical to the implant (dotted lines represent the outlines of the grafting material and the residual bone).

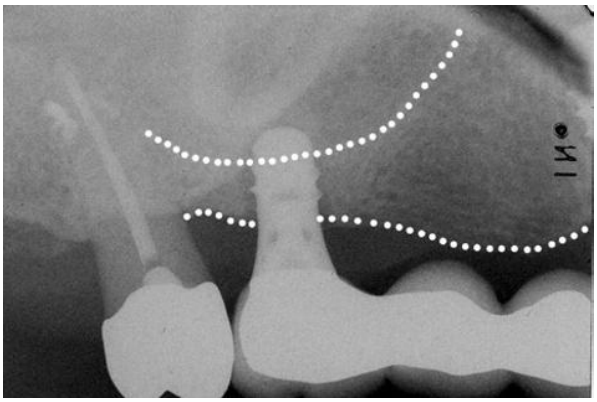

Fig. 51-47 Radiograph of a 6-mm implant that was inserted utilizing the osteotome technique without grafting material. The residual bone height was only 3 mm. After 6 months of functional loading, the implant became loose and had to be removed. After a healing time of 2 months, the maxillary sinus floor was elevated with the lateral approach and two new implants were placed simultaneously (dotted lines represent the outlines of the residual bone).

studies (Friberg *et al*. 1991; Jaffin & Berman 1991) have also reported low survival rates of short implants. However, it must be kept in mind that all these studies reported on implants with machined-surface geometries. Based on these studies and others, the clinical "dogma" has been followed that, generally, only long implants should be inserted in type IV "poor-quality" bone in the posterior maxilla.

A targeted review of study outcomes with short (7 mm) implants placed in partially edentulous patients concluded that machined-surface implants experienced greater failure rates than rough-surface implants (Hagi *et al*. 2004). The implant surface geometry appeared to be a major determinant of the performance of these short implants.

In a multicenter study evaluating 6-mm non-submerged rough-surface dental implants, only one of 208 short implants placed in the mandible was lost compared to six of 45 short implants placed in the maxilla (ten Bruggenkate *et al*. 1998). Four of the implants were lost during the healing phase, with three remaining in function. The survival rates were 99.5% and 86.7%, respectively, after a follow-up of up to 7 years.

In contrast, clinical studies on short implants with rough surfaces, designed for high initial stability, reported survival rates of about 95% (Fugazzotto *et al*. 2004; Renouard & Nisand 2005), which correlates with the survival rate reported for implants after 5 years in a systematic review (Berglundh *et al*. 2002). Two multicenter studies on rough-surface implants (Buser *et al*. 1997; Brocard *et al*. 2000) analyzed the survival and success rates of implants of different lengths. No significant differences were found between 8-, 10-, and 12-mm implants with rough-surface geometry after up to 8 years of follow-up.

The most recent review prepared for the Consensus Meeting of the European Association of Osseointegration (EAO) (Renouard & Nisand 2006) concluded on the basis of 12 studies on machined-surface implants and 22 studies on rough-textured implants meeting the inclusion criteria, that the survival and success rates of short (<10 mm) implants were comparable to those obtained with longer implants, provided that surgical preparation was related to bone density, rough-textured implants were employed, and operators' surgical skills were developed.

The use of short implants may be considered in sites thought unfavorable for implant placement, such as those associated with bone resorption or previous injury and trauma. While in these situations implant failure rates may be increased, outcomes should be compared with those associated with advanced surgical procedures such as bone grafting and sinus floor elevation.

Conclusion and clinical suggestions

In the posterior maxilla, implants with a morphometry designed to achieve high initial stability and a rough surface geometry giving high bone-to-implant contact during the initial healing phase (Abrahamsson *et al*. 2004) are preferred. Implants with slightly conical morphometry or implants with a wider implant neck tend to give better primary stability in cases of reduced residual bone height and soft bone geometry.

The clinical decision on which method (short implants, transalveolar approach or lateral approach) should be chosen, depends on the residual bone height of the alveolar crest and the surgeon's' preference. The following are suggested recommendations:

- Residual bone height of ≥8 mm and a flat sinus floor: standard implant placement (Fig. 51-48).
- Residual bone height of ≥8 mm and an oblique sinus floor: standard implant placement using a short implant or elevation of the maxillary sinus floor using the osteotome technique without grafting material (Fig. 51-49).
- Residual bone height of 5–7 mm and a relatively flat sinus floor: elevation of the maxillary sinus floor using the osteotome technique with grafting material that is resistant to resorption (Fig. 51-50).
- Residual bone height of 5–7 mm and an oblique sinus floor: elevation of the maxillary sinus floor using the lateral approach with grafting material, and simultaneous implant placement (one-stage) (Fig. 51-51).
- Residual bone height of 3–4 mm and a flat or oblique sinus floor: elevation of the maxillary sinus floor using the lateral approach with grafting

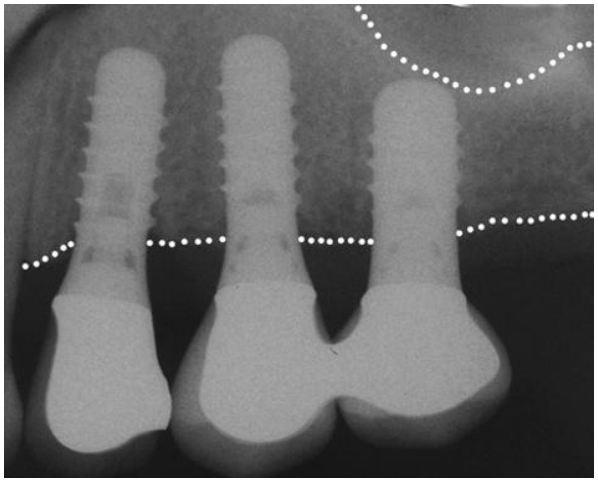

Fig. 51-48 Radiograph of a short (8 mm) implant in the posterior maxilla (dotted lines represent the outlines of the residual bone).

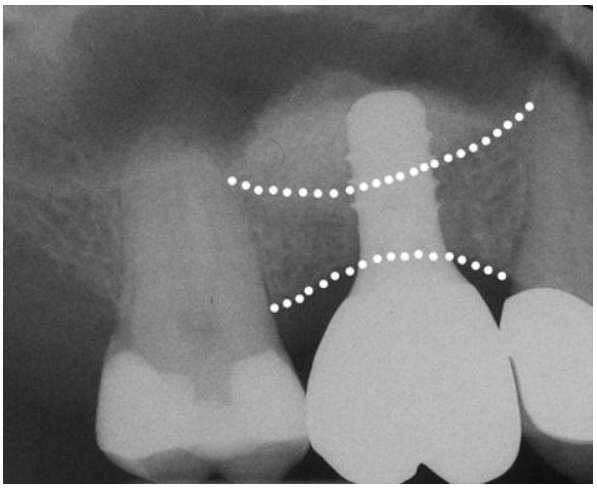

Fig. 51-50 Radiograph of an implant inserted in the posterior maxilla with a flat sinus floor and a residual bone height of 5–6 mm. The osteotome technique with grafting material was used. The radiograph shows a dome-shaped formation covering the entire apex of the implant (dotted lines represent the outlines of the residual bone).

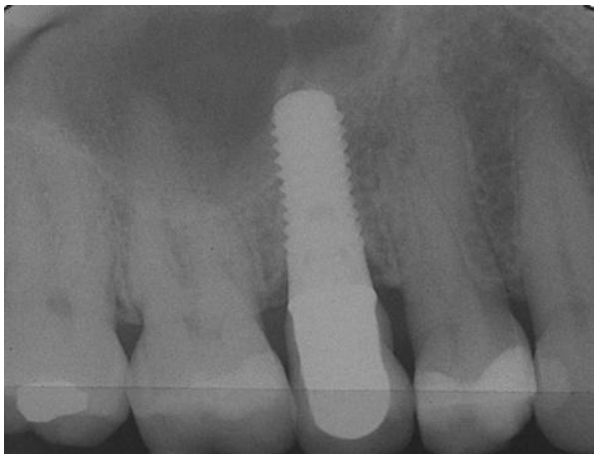

Fig. 51-49 Radiograph of an implant inserted in the posterior maxilla with an oblique sinus floor and a residual bone height of 8–10 mm. The osteotome technique without grafting material was used. The distal aspect of the apex of the implant extends into the sinus cavity, but the mesial aspect is covered with residual bone.

Part 16: Occlusal and Prosthetic Therapy

Chapter 52

Tooth-Supported Fixed Dental Prostheses

Jan Lindhe and Sture Nyman

Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Clinical symptoms of trauma from occlusion

Angular bony defects

It has been claimed that *angular bony defects* and *increased tooth mobility* are important symptoms of trauma from occlusion (Glickman 1965, 1967). The validity of this suggestion has, however, been questioned (see Chapter 14). Thus, angular bony defects have been found at teeth affected by *trauma from occlusion* as well as at teeth with normal occlusal function (Waerhaug 1979). This means that the presence of angular bony defects *cannot per se* be regarded as an exclusive symptom of trauma from occlusion.

Increased tooth mobility

Increased tooth mobility, determined clinically, is expressed in terms of amplitude of displacement of the crown of the tooth. Increased tooth mobility can, indeed, be observed in conjunction with *trauma from occlusion*. It may, however, also be the result of a reduction of the height of the alveolar bone with or without an accompanying angular bony defect caused by plaque-associated periodontal disease (see Chapter 16). Increased tooth mobility resulting from occlusal interferences may further indicate that the periodontal structures have adapted to an altered functional demand, that is a widened periodontal ligament with a normal tissue composition has become the end result of a previous phase of progressive tooth mobility (see Chapter 16) associated with trauma from occlusion.

Progressive (increasing) tooth mobility

In Chapter 16, it was concluded that the diagnosis of trauma from occlusion should be used solely in situations where a progressive mobility could be observed. Progressive tooth mobility can be identified only through a series of repeated tooth mobility measurements carried out over a period of several days or weeks.

Tooth mobility crown excursion/root displacement

Initial and secondary tooth mobility

A tooth which is surrounded by a normal periodontium may be moved (displaced) in horizontal and vertical directions, and may also be forced to perform limited rotational movements. Clinically, tooth

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

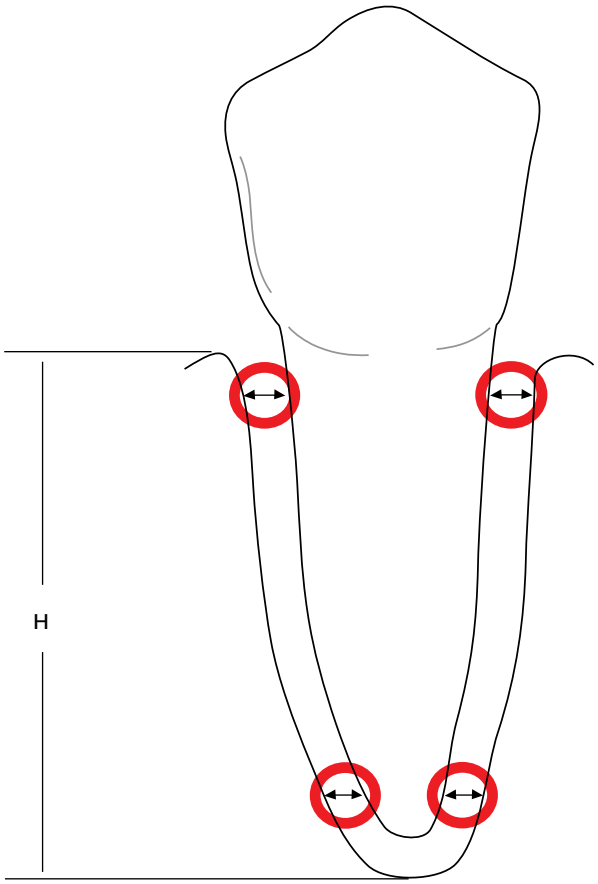

Fig. 52-1 Mobility of a tooth in a horizontal direction is dependent on the height of the alveolar bone (H), width of the periodontal ligament (encircled arrows), and shape and number of roots.

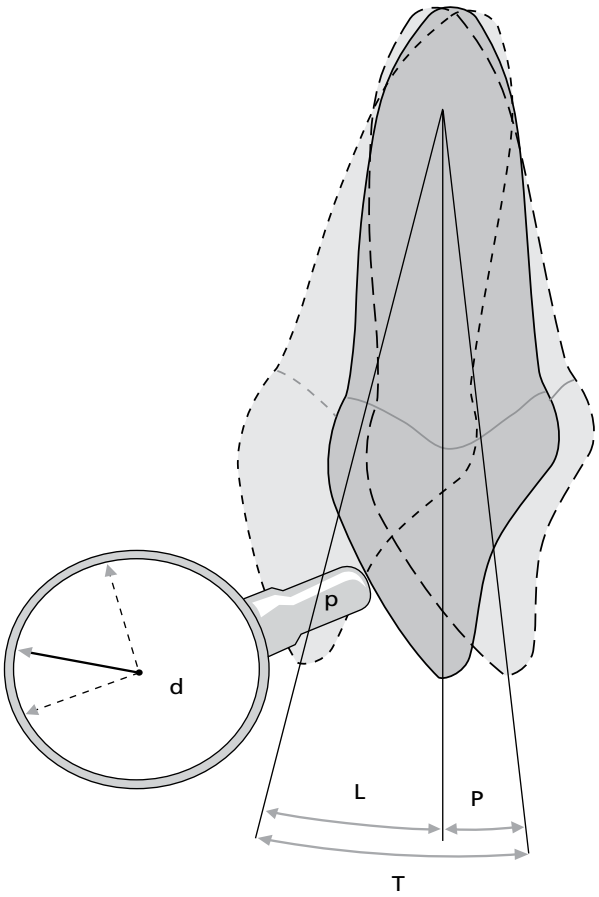

Fig. 52-2 Tooth mobility measurements by means of the Periodontometer. T = L + P = total excursion of the crown. (d, dial indicator; p, pointer; L, labial excursion of the crown; P, palatal excursion of the crown.)

mobility is usually assessed by exposing the crown of the tooth to a certain force and determining the distance the crown can be displaced in the buccal and/or lingual direction. The mobility (= movability) of a tooth in a horizontal direction is highly dependent on the height of the surrounding supporting bone, the width of the periodontal ligament, and the shape and number of roots present (Fig. 52-1).

The mechanism of tooth mobility was studied in detail by Mühlemann (1954, 1960) who described a standardized method for measuring even minor tooth displacements. Using the "Periodontometer", a small force [~45 kg (100 lb)] is applied to the crown of a tooth (Fig. 52-2). The crown starts to tip in the direction of the force. The resistance of the tooth-supporting structures against displacement of the root is low in the initial phase of force application and the crown is moved only 5/100–10/100 mm. This movement of the tooth was called "*initial tooth mobility*" (ITM) by Mühlemann (1954) and is the result of an *intra-alveolar* displacement of the root (Fig. 52-3). In the pressure zone (see Chapter 16), there is a 10% reduction in the width of the periodontal ligament and in the tension zone there is a corresponding increase. Mühlemann and Zander (1954) stated that "there are good reasons to assume that the initial displacement of the root (ITM)

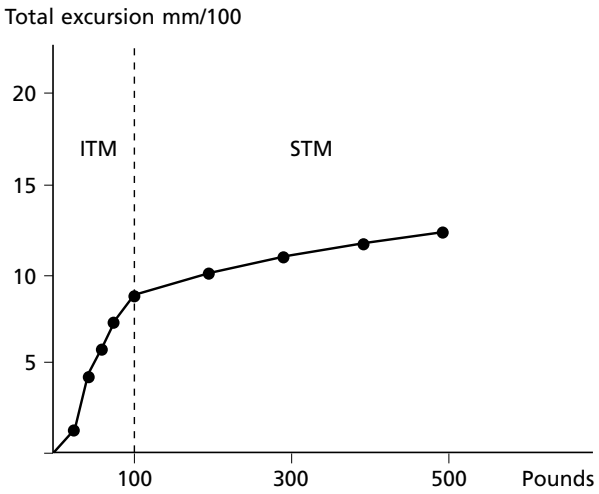

Fig. 52-3 Initial tooth mobility (ITM) is the excursion of the crown of a tooth when a force of 100 lb is applied to the crown. Secondary tooth mobility (STM) is the excursion of the crown of the tooth when a force of 500 lb is applied.

corresponds to a reorientation of the periodontal membrane fibers into a position of functional readiness towards tensile strength". The magnitude of the ITM varies from individual to individual, and from tooth to tooth, and is mainly dependent on the structure and organization of the periodontal

ligament. The ITM value of ankylosed teeth is therefore zero.

When a larger force [~225 kg (500 lb)] is applied to the crown, the fiber bundles on the tension side cannot offer sufficient resistance to further root displacement. The additional displacement of the crown that is observed in "*secondary tooth mobility*" (STM) (Fig. 52-3) occurs as a result of distortion and compression of the periodontium on the pressure side. According to Mühlemann (1960), the magnitude of STM, that is the excursion of the crown of the tooth when a force of 500 lb is applied, (1) varies between different types of teeth (e.g. incisors 10–12/100 mm, canines 5–9/100 mm, premolars 8–10/100 mm, and molars 4–8/100 mm); (2) is larger in children than in adults; and (3) is larger in females than males and increases during, for example, pregnancy. Furthermore, tooth mobility seems to vary during the course of the day; the lowest value is found in the evening and the largest in the morning.

A new method for determining tooth mobility was presented by Schulte and co-workers (Schulte 1987; Schulte *et al*. 1992) when the Periotest® (SiemensAG, Bensheim, Germany) system was introduced. This system measures the reaction of the periodontium to a defined percussion force which is applied to the tooth and delivered by a tapping instrument. A metal rod is accelerated to a speed of 0.2 m/s by the device and maintained at a constant velocity. Upon impact, the tooth is deflected and the rod decelerated. The contact time between the tapping head and the tooth varies between 0.3 and 2 ms and is shorter for stable than mobile teeth. The Periotest® scale (the Periotest values) ranges from −8 to +50 and the following ranges should be considered:

- −8 to +9: clinically firm teeth
- 10–19: first distinguishable sign of movement
- 20–29: crown deviates within 1 mm of its normal position
- 30–50: mobility is readily observed.

The Periotest® values correlate well with (1) tooth mobility assessed with a metric system, and (2) degree of periodontal disease and alveolar bone loss. Hence, this device is commonly used in the "every day" clinic and in various research settings

Clinical assessment of tooth mobility (physiologic and pathologic tooth mobility)

If, in the traditional clinical measurement of tooth mobility, a comparatively large force is exerted on the crown of a tooth which is surrounded by a normal periodontium, the tooth will tip within its alveolus until a closer contact has been established between the root and the marginal (or apical) bone tissue. The magnitude of this tipping movement, which is normally assessed using the tip of the crown as a reference point, is referred to as the "*physiologic*" tooth mobility. The term "*physiologic*" implies that "*pathologic*" tooth mobility may also occur. What, then, is "pathologic" tooth mobility?

1. If a similar force is applied to a tooth which is surrounded by a periodontal ligament with an increased width, the excursion of the crown in the horizontal direction will increase; the clinical measurement consequently demonstrates that the tooth has an increased mobility. Should this increased mobility be regarded as "pathologic"?
2. An increased tooth mobility, that is an increased displacement of the crown of the tooth after force application, can also be found in situations where the height of the alveolar bone has been reduced, but the remaining periodontal ligament has a normal width. At sites where this type of bone loss is extensive, the degree of tooth mobility (i.e. excursion of the crown) may be pronounced. Should this increased tooth mobility be regarded as "pathologic"?

   Figure 52-4b shows a tooth which is surrounded by alveolar bone of reduced height. The width of the remaining periodontal ligament, however, is within normal limits. A horizontally directed force applied to the crown of the tooth in this case will result in a larger excursion of the crown than if a similar force is applied to a tooth with normal

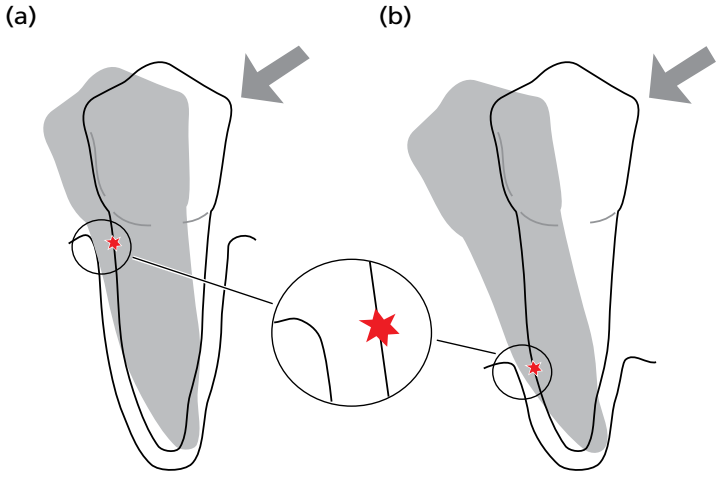

Fig. 52-4 (a) Normal "physiologic" mobility of a tooth with normal height of the alveolar bone and normal width of the periodontal ligament. (b) Mobility of a tooth with reduced height of the alveolar bone. The distance of the horizontal displacement of the reference point (*) on the roots is the same in the two situations (a, b).

height of the alveolar bone and normal width of the periodontal ligament (Fig. 52-4a). There are reasons to suggest that the so-called *increased mobility* measured in the case shown in Fig. 52-4b is, indeed, *physiologic*. The validity of this statement can easily be demonstrated if the displacement of the two teeth is assessed not from the crown, but from a point on the root at the level of the bone crest. If a horizontal force is directed to the teeth in Fig. 52-4, the reference points (*) on the root surfaces will be displaced a similar distance in both instances. Obviously, it is not the length of the excursive movement of the crown that is important from a biologic point of view, but the *displacement of the root* within its remaining periodontal ligament.

In plaque-associated periodontal disease, bone loss is a prominent feature. Another so-called classical symptom of periodontitis is "increased tooth mobility". It is important to realize, however, that in many situations with even or "horizontal" bone loss patterns, the increased crown displacement (tooth mobility) assessed by clinical measurements should, according to the above discussion, also be regarded as physiologic; the movement of the root within the space of its remaining "normal" periodontal ligament is normal.

3. Increased crown displacement (tooth mobility) may also be detected by clinical measurement where a "horizontal" force is applied to teeth with angular bony defects and/or increased width of the periodontal ligament. If this mobility does not increase gradually – from one observation interval to the next – the root is surrounded by a periodontal ligament of increased width but normal composition. This mobility should also be considered *physiologic* since the movement is a function of the height of the alveolar bone and the width of the periodontal ligament.
4. Only *progressively increasing tooth mobility*, which may occur in conjunction with trauma from occlusion, is characterized by active bone resorption (see Chapter 16) and which indicates the presence of inflammatory alterations within the periodontal ligament tissue, may be considered *pathologic*.

Treatment of increased tooth mobility

A number of situations will be described which may call for treatment aimed at reducing an increased tooth mobility.

Situation 1

Increased mobility of a tooth with increased width of the periodontal ligament but normal height of the alveolar bone

If a tooth (e.g. a maxillary premolar) is fitted with an improper filling or crown restoration, occlusal interferences develop and the surrounding periodontal tissues become the seat of inflammatory reactions, that is trauma from occlusion (Fig. 52-5). If the restoration is designed such that the crown of the tooth in occlusion is subjected to undue forces directed in a buccal direction, bone resorption phenomena develop in the buccomarginal and linguoapical pressure zones with a resulting increase of the width of the periodontal ligament in these zones. The tooth becomes hypermobile or moves away from the "traumatizing" position. Since such traumatizing forces in teeth with normal periodontium or overt gingivitis cannot result in pocket formation or loss of connective tissue attachment, the resulting increased mobility of the tooth should be regarded as a physiologic adaptation of the periodontal tissues to the altered functional demands. A proper correction of the anatomy of the occlusal surface of such a tooth, that is occlusal adjustment, will normalize the relationship between the antagonizing teeth in occlusion, thereby

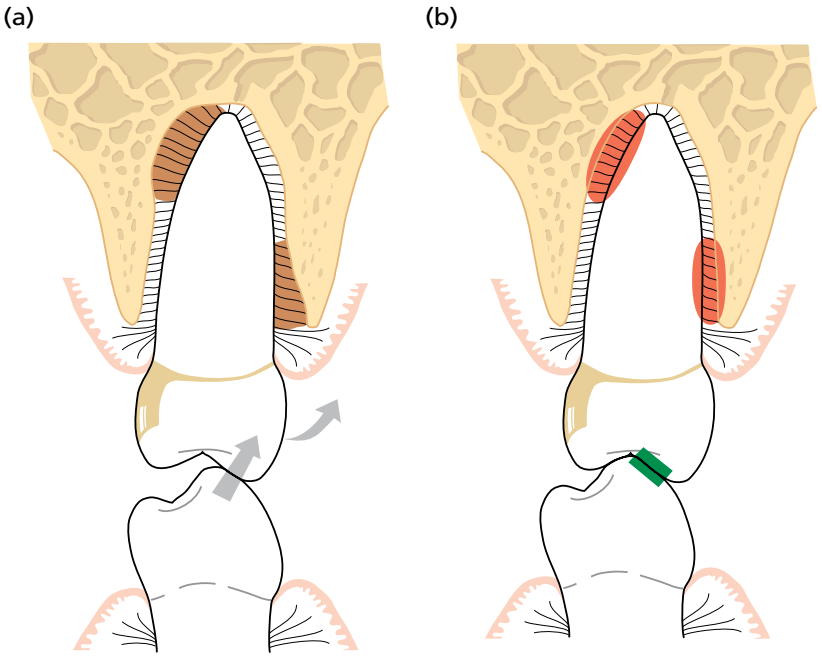

Fig. 52-5 (a) Contact relationship between a mandibular and a maxillary premolar in occlusion. The maxillary premolar is fitted with an artificial restoration with an improperly designed occlusal surface. Occlusion results in horizontally directed forces (arrows) which may produce an undue stress concentration within the "brown" areas of the periodontium of the maxillary tooth. Resorption of the alveolar bone occurs in these areas. A widening of the periodontal ligament can be detected as well as increased mobility of the tooth. (b) Following adjustment of the occlusion, the horizontal forces are reduced. This results in bone apposition ("red areas") and a normalization of the tooth mobility.

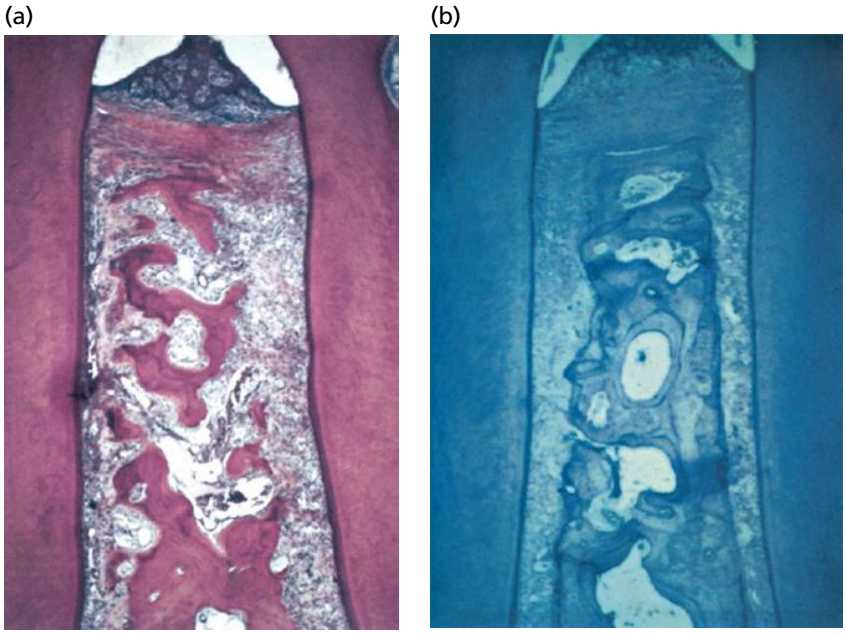

Fig. 52-6 Photomicrographs illustrating the interdental area between two mandibular premolars in the monkey. (a) Two premolars are exposed to jiggling forces. Note the reduction of alveolar bone in the area and the location of the bone crest. Ten weeks after the elimination of the jiggling forces, (b) a considerable regeneration of bone has occurred. Note the increase of the height of the interdental bone and the normalization of the width of the periodontal ligaments. The apical end of the junctional epithelium is located at the cemento-enamel junction. (Source: Polson *et al*. 1976a. Reproduced with permission from John Wiley & Sons.)

eliminating the excessive forces. As a result, apposition of bone will occur in the zones previously exposed to resorption, the width of the periodontal ligament will become normalized and the tooth stabilized, that is it reassumes its normal mobility (Fig. 52-5). In other words, resorption of alveolar bone which is caused by trauma from occlusion is a reversible process which can be treated by the elimination of occlusal interferences.

The capacity for bone regeneration after resorption following trauma from occlusion has been documented in a number of animal experiments (Waerhaug & Randers-Hansen 1966; Polson *et al*. 1976a; Karring *et al*. 1982; Nyman *et al*. 1982). In such experiments, the induced bone resorption not only involved the bone within the alveolus but also the alveolar bone crest. When the traumatizing forces were removed, bone tissue was deposited not only on the walls of the alveolus, thereby normalizing the width of the periodontal ligament, but also on the bone crest area, whereby the height of the alveolar bone was normalized (Fig. 52-6) (Polson *et al*. 1976a). In the presence of an untreated, plaque-associated lesion in the soft tissue, however, substantial bone regrowth did not always occur (Fig. 52-7) (Polson *et al*. 1976b).

Situation 2

Increased mobility of a tooth with increased width of the periodontal ligament and reduced height of the alveolar bone

When a dentition has been properly treated for moderate-to-advanced periodontal disease, gingival health is established in areas of the dentition where teeth are surrounded by periodontal structures of reduced height. If a tooth with a reduced periodontal tissue support is exposed to excessive horizontal forces (trauma from occlusion), inflammatory reactions develop in the pressure zones of the periodontal ligament with accompanying bone resorption. These alterations are similar to those which occur around a tooth with supporting structures of a normal height; the alveolar bone is resorbed, the width of the periodontal ligament is increased in the pressure/tension zones, and the tooth becomes hypermobile (Fig. 52-8a). If the excessive forces are reduced or eliminated by occlusal adjustment, bone apposition to the "pre-trauma" level will occur, the periodontal ligament will regain its normal width and the tooth will become stabilized (Fig. 52-8b).

Conclusion (situations 1 and 2): Occlusal adjustment is an effective therapy against increased tooth mobility when such mobility is caused by an *increased width* of the periodontal ligament.

Situation 3

Increased mobility of a tooth with reduced height of the alveolar bone and normal width of the periodontal ligament

The increased tooth mobility which is the result of a reduction in height of the alveolar bone without a concomitant increase in width of the periodontal membrane cannot be reduced or eliminated by occlusal adjustment. In teeth with normal width of the periodontal ligament, no further bone apposition

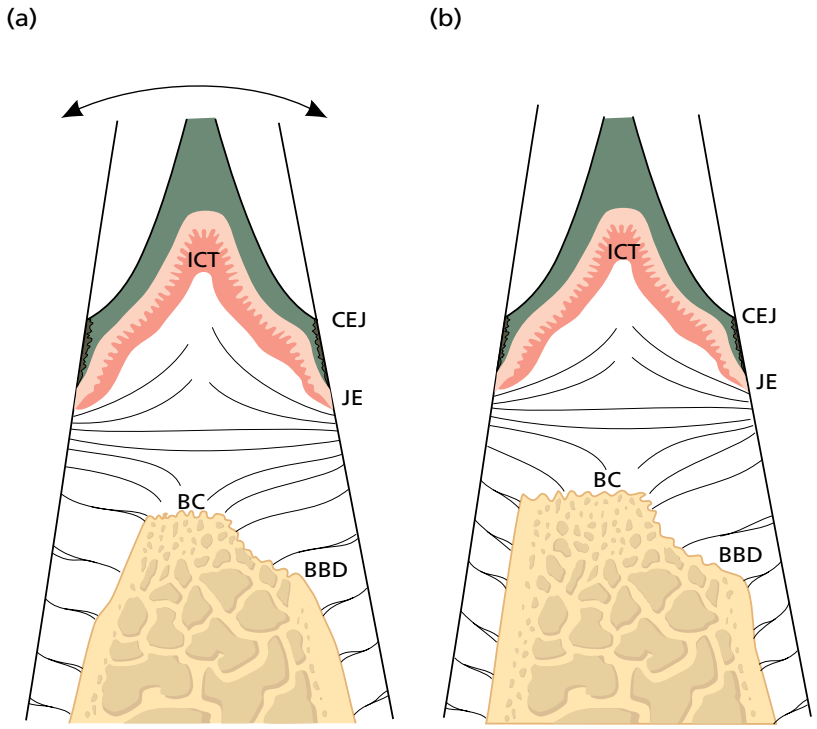

Fig. 52-7 In the presence of an existing marginal inflammation, alveolar bone lost by jiggling trauma (a), will not always regenerate following elimination of the traumatic forces (b). (ICT, infiltrated connective tissue; CEJ, cementoenamel junction; JE, apical end of junctional epithelium; BC, alveolar bone crest; BBD, bottom of angular bony defect.) (Source: Polson *et al*. 1976b. Reproduced with permission from John Wiley & Sons.)

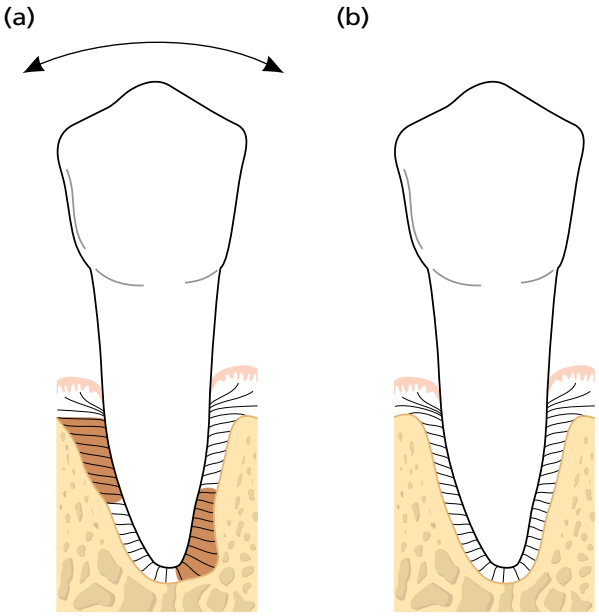

Fig. 52-8 If a tooth with reduced periodontal tissue support (a) has been exposed to excessive horizontal forces, a widened periodontal ligament space ("brown" areas) and increased mobility (arrow) result. (b) Following reduction or elimination of such forces, bone apposition will occur and the tooth will become stabilized.

on the walls of the alveoli can occur. If such an increased tooth mobility does not interfere with the patient's chewing function or comfort, no treatment is required. If the patient experiences the tooth mobility as disturbing, however, the mobility can only be reduced in this situation by splinting, that is by joining the mobile tooth/teeth together with other teeth in the jaw into a fixed unit – a splint.

A splint is "an appliance designed to stabilize mobile teeth" and may be fabricated in the form of joined composite fillings, fixed bridges, removable partial prostheses, etc.

Example: Case A, 64-year-old male

The periodontal condition of this patient is illustrated by the radiographs from the initial examination (Fig. 52-9). Periodontal disease has progressed to a level where, around the maxillary teeth, only the apical third or less of the roots is invested in supporting alveolar bone. The following discussion relates to the treatment of the maxillary dentition.

In the treatment planning of this case, it was decided that the first premolars (teeth 14 and 24) had to be extracted due to advanced periodontal disease and furcation involvement of degree III. For the same reasons, teeth 17 and 27 were scheduled for extraction. Teeth 16 and 26 were also found to have advanced loss of periodontal tissue support in combination with deep furcation involvements. The most likely *definitive* treatment should include periodontal and adjunctive therapy in the following parts of the dentition: 15 and 25, and 13, 12, 11, 21, 22, 23. For functional and esthetic reasons, teeth 14 and 24 obviously had to be replaced. The question now arose as to whether these two premolars should be replaced by two separate unilateral bridges, using 13, 15 and 23, 25 as abutment teeth, or if the increased mobility of these teeth and also of the anterior teeth (12, 11, 21, 22) (Fig. 52-9) called for a bridge of cross-arch design, with the extension 15–25, to obtain a splinting effect. If teeth 14 and 24 were replaced by two unilateral bridges, each one of these three-unit bridges would

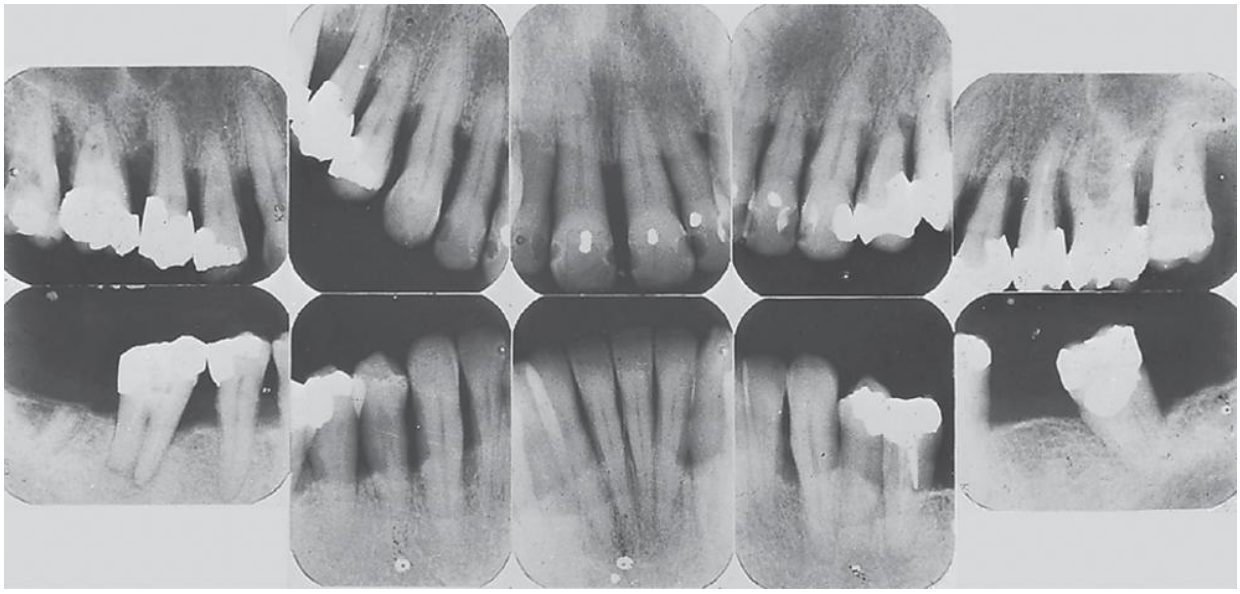

Fig. 52-9 Case A, 64-year-old male. Radiographs prior to therapy.

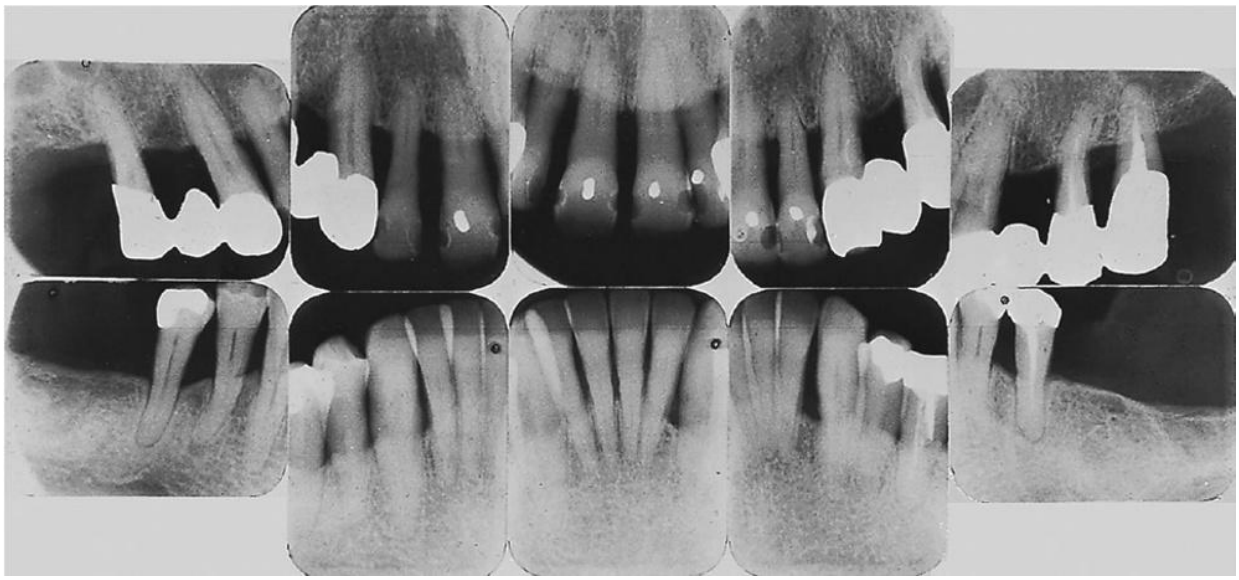

Fig. 52-10 Case A. Radiographs obtained 10 years after periodontal therapy and installation of two unilateral bridges in the maxilla.

exhibit the same degree of mobility in a buccolingual direction as the individual abutment teeth (degree 2) (Fig. 52-9), since a unilateral straight bridge would not have a stabilizing effect on the abutment teeth in this force direction.

From the radiographs it can be seen that the increased mobility observed in the maxillary teeth of this patient is associated mainly with reduced height of the alveolar bone and not with increased width of the periodontal ligaments. This means that the mobility of the individual teeth should be regarded as normal or "physiologic" for teeth with such a reduced height of the supporting tissues. This in turn implies that the increased tooth mobility in the present case does not call for treatment unless it interferes with the chewing comfort or jeopardizes the position of the front teeth. This particular patient had not recognized any functional problems related to the increased mobility of his maxillary teeth. Consequently, there was no reason to install a cross-arch bridge in order to splint the teeth, that is to reduce tooth mobility.

Following proper treatment of the plaque-associated periodontal lesions, two separate provisional bridges of unilateral design were produced (15, 14, 13; 23, 24, 25, 26 palatal root). The provisional acrylic bridges were used for 6 months during which time the occlusion, the mobility of the two bridges, and the position of the front teeth were all carefully monitored. After 6 months, no change of position of the lateral and central incisors and no increase of the mobility of the two provisional bridges had occurred, and the definitive restorative therapy was performed.

Figure 52-10 shows the radiographs obtained 10 years after initial therapy. The position of the front teeth and the mobility of the incisors and the two bridges had not changed during the course of the maintenance period. There had been no further loss of periodontal tissue support during the 10 years of observation, no further spread of the front teeth, and no widening of the periodontal ligaments around the individual teeth, including the abutment teeth for the bridgework.

Conclusion: Increased tooth mobility (or bridge mobility) as a result of reduced height of the alveolar bone can be accepted and splinting avoided, provided the occlusion is stable (no further migration or increasing mobility of individual teeth) and the degree of existing mobility does not disturb the patient's chewing ability or comfort. Consequently, splinting is indicated when the mobility of a tooth or a group of teeth is so increased that chewing ability and/or comfort are disturbed.

Situation 4

Progressive (increasing) mobility of a tooth (teeth) as a result of gradually increasing width of the reduced periodontal ligament

Often in cases of advanced periodontal disease the tissue destruction may have reached a level where extraction of one or several teeth cannot be avoided. In such a dentition, teeth which are still available for periodontal treatment may, after therapy, exhibit such a high degree of mobility, or even signs of progressively increasing mobility, that there is an obvious risk that the forces elicited during function may mechanically disrupt the remaining periodontal ligament components and result in the loss of the teeth.

It will only be possible to maintain such teeth by means of a splint. In such cases, a fixed splint has two objectives: (1) to stabilize hypermobile teeth and (2) to replace missing teeth.

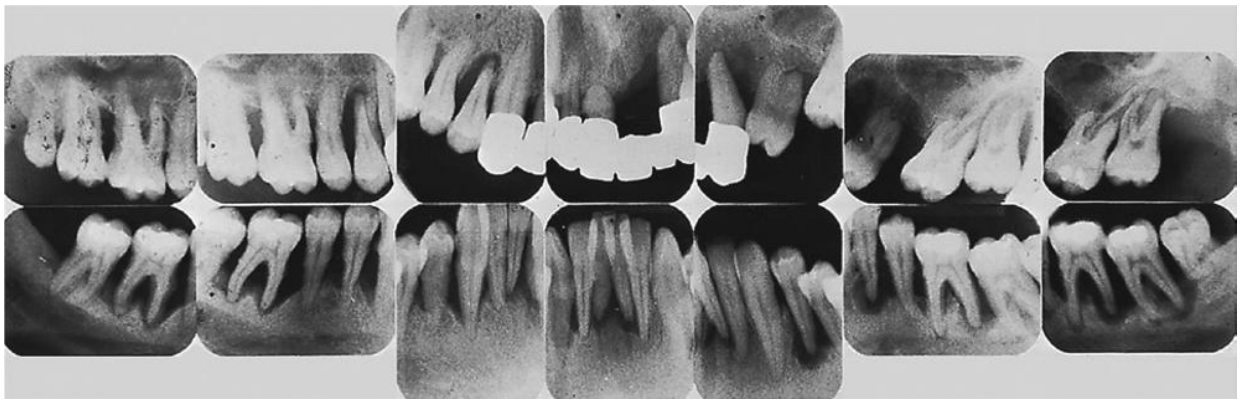

Fig. 52-11 Case B, 26-year-old male. Radiographs showing the periodontal conditions prior to therapy.

Fig. 52-12 Case B. Radiographs obtained after periodontal treatment and preparation of the abutment teeth for two fixed splints.

Example: Case B, 26-year-old male

Figure 52-11 shows the radiographs taken prior to therapy and Fig. 52-12 those obtained after periodontal treatment and preparation of the remaining teeth as abutments for two fixed splints. All teeth except 13, 12, and 33 have lost around 75% or more of the alveolar bone and widened periodontal ligaments are a frequent finding. The four distal abutments for the two splints are root-separated molars, the maintained roots being the following: the palatal root of tooth 17, the mesiobuccal root of tooth 26, and the mesial roots of teeth 36 and 47. It should be observed that tooth 24 is root-separated and the palatal root maintained with only minute amounts of periodontium left.

Immediately prior to insertion of the two splints, all teeth except 13, 12, and 33 displayed a mobility varying between degrees 1 and 3. From the radiographs in Fig. 52-12 it can be noted that there is an obvious risk of loss of a number of teeth such as 24, 26, 47, 45, 44, 43, and 36 if the patient is allowed to bite with a normal chewing force without the splints in position.

Despite the high degree of mobility of the individual teeth, the splints were entirely stable after insertion, and maintained their stability during a maintenance period of >12 years. Figure 52-13 shows the clinical status and Fig. 52-14 the radiographs obtained 10 years after therapy. From these radiographs it can be observed (compare with Fig. 52-12) that during the maintenance period there had been no further loss of alveolar bone or widening of the various periodontal ligament spaces.

Conclusion: Splinting is indicated when the periodontal support is so reduced that the mobility of the teeth is progressively increasing, that is when a tooth or a group of teeth are exposed to extraction forces during function.

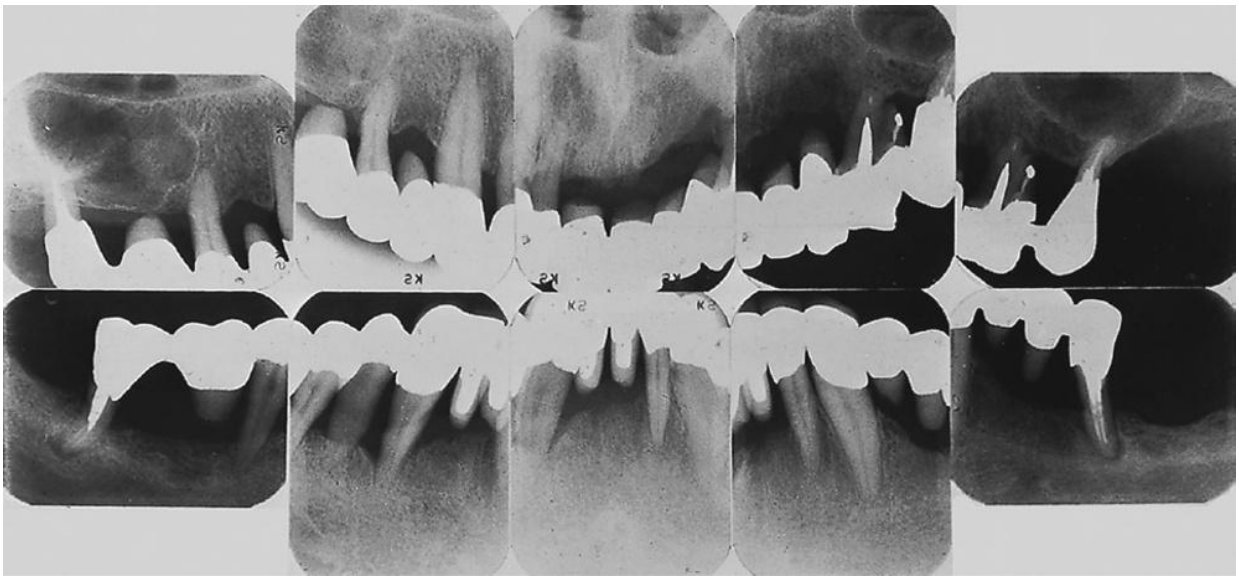

Fig. 52-14 Case B. Radiographs obtained 10 years after therapy.

Situation 5

Increased bridge mobility despite splinting

In patients with advanced periodontal disease, it can often be observed that the destruction of the periodontium has progressed to varying levels around different teeth and tooth surfaces in the dentition. Proper treatment of the plaque-associated lesions often includes multiple extractions. The remaining teeth may display an extreme reduction of the supporting tissues concomitant with increased or progressive tooth mobility. They may also be distributed in the jaw in such a way as to make it difficult, or impossible, to obtain a proper splinting effect even by means of a cross-arch bridge. The entire bridge/splint may exhibit mobility in frontal and/or lateral directions.

It was stated above (situation 3) that a certain mobility of a tooth or a bridge of unilateral design can be accepted provided this mobility does not interfere with the patient's chewing ability or comfort. This is also valid for a cross-arch bridge/splint. From a biologic point of view, there is no difference between increased tooth mobility on the one hand and increased bridge mobility on the other. However, neither progressive tooth mobility nor progressive bridge mobility are acceptable. In cases of extremely advanced periodontal disease, a cross-arch splint with an increased mobility may be regarded as an acceptable

result of rehabilitation. The maintenance of the status quo of the bridge/splint mobility and the prevention of tipping or orthodontic displacement of the total splint, however, requires particular attention regarding the design of the occlusion. Case C is an interesting illustration of this particular clinical problem.

Example: Case C, 52-year-old female

Figure 52-15 shows radiographs obtained at the initial examination. A 12-unit maxillary bridge was installed 10–15 years prior to the present examination using teeth 18, 15, 14, 13, 12, 11, 21, 22, 23, and 24 as abutments. After a detailed clinical examination it was obvious that teeth 15, 14, 22, and 24 could not be maintained because of severe symptoms of caries and periodontal disease. The remaining teeth were subjected to periodontal therapy and maintained as abutments for a new bridge/splint in the maxilla, extending from tooth 18 to the region of tooth 26, that is a cross-arch splint was installed which carried three cantilever units, namely 24, 25, and 26. The mobility of the individual abutment teeth immediately prior to insertion of the splint was the following: degree 1 (tooth 18), degree 0 (tooth 13), degree 2 (teeth 12 and 11), degree 3 (tooth 21), and degree 2 (tooth 23).

Radiographs obtained 5 years after therapy are shown in Fig. 52-16. The bridge/splint had a mobility of degree 1 immediately after its insertion and this mobility was unchanged 5 years later. The radiographs demonstrate that no further widening of the periodontal ligament had occurred around the individual teeth during the maintenance period.

When a cross-arch bridge/splint exhibits increased mobility, the center (fulcrum) of the movement must be identified. In order to prevent further increase in the mobility and/or to prevent displacement of the

Fig. 52-15 Case C, 52-year-old female. Radiographs obtained at the initial examination.

Fig. 52-16 Case C. Radiographs obtained 5 years after therapy.

bridge, it is essential to design the occlusion in such a way that when the bridge/splint is in contact with the teeth of the opposing jaw, it is subjected to a balanced load, that is equal force on each side of the fulcrum. If this can be achieved, the force to which the bridge is exposed in occlusion can be used to retain the fixed prosthesis in proper balance (thereby preventing a further increase of mobility).

Balanced loading of a mobile bridge/splint has to be established not only in the intercuspal position (IP) and centric occlusion (CP), but also in frontal and lateral excursive movements of the mandible if the bridge shows mobility or a tendency for tipping in the direction of such movements. In other words, a force which tends to displace the bridge in a certain direction has to be counteracted by the introduction of a balancing force on the opposite side of the fulcrum of the movement. If, for instance, a cross-arch splint in the maxilla exhibits mobility in the frontal direction in conjunction with protrusive movements of the mandible, the load applied to the bridge in the frontal region has to be counterbalanced by a load in the distal portions of the splint; this means that there must be a simultaneous and equal contact relationship between the occluding teeth in both the frontal and the posterior regions of the splint. If the splint is mobile in a lateral direction, the force acting on the working side of the jaw must be counteracted by a force established by the introduction of balancing contacts in the non-working side of the jaw. The principle for establishing stability of a *mobile* cross-arch splint is consequently the same as that used to obtain stability in a complete denture. In situations where distal abutment teeth are missing in a cross-arch bridge/splint with increased mobility, balance and functional stability may be obtained by means of cantilever units. It is important in this context to point out that balancing contacts on the non-working side should not be introduced in a bridge/splint in which no increased mobility can be observed.

The maxillary splint in Case C exhibited increased mobility in a frontal direction. Considering the small amount of periodontal support left around the anterior teeth, it is obvious that there would have been a risk of frontal displacement of the total bridge had the bridge terminated at the last abutment tooth (23) on the left side of the jaw. The installation of cantilever units in the 24 and 25 region prevented such a displacement of the bridge/splint by the introduction of a force counteracting the frontally directed forces during protrusive movements of the mandible (Fig. 52-17). In addition, the cantilever units provided bilateral contact relationship towards the mandibular teeth in the intercuspal position, that is bilateral stability of the bridge.

Fig. 52-17 Case C. Cantilever section including teeth 24, 25, and 26.

In cases similar to Case C, cantilever units can thus be used to prevent increasing mobility or displacement of a bridge/splint. It should, however, be pointed out that the insertion of cantilever units increases the risk of failures of a technical and biophysical character (fracture of the metal frame, fracture of abutment teeth, loss of retention, etc.).

In cases of severely advanced periodontal disease, it is often impossible to anticipate in the planning phase whether a bridge/splint will show signs of instability and increasing (progressive) mobility after insertion. In such cases, a provisional splint should always be inserted. Any alterations of the mobility of the bridge/splint can be observed over a prolonged period of time and the occlusion continuously adjusted until, after 4–6 months, it is known whether stability (i.e. no further increase of the mobility) can be achieved. The design of the occlusion of the provisional acrylic bridge is then reproduced in the permanent bridge construction. If, on the other hand, stability cannot be obtained, the rehabilitation of the case cannot be achieved with a fixed splint. The alternative treatment then is a complete denture or an implant-supported restoration.

Conclusion: An increased mobility of a cross-arch bridge/splint can be accepted provided the mobility does not disturb chewing ability or comfort and the mobility of the splint is not progressively increasing.

Implants in Restorative Dentistry

Niklaus P. Lang[1,2] and Giovanni E. Salvi[1]

[1] Department of Periodontology, School of Dental Medicine, University of Berne, Berne, Switzerland
[2] Center of Dental Medicine, University of Zurich, Zurich, Switzerland

Introduction

Ever since oral titanium implants were shown to yield high predictability (97–98%) for incorporation (Berglundh *et al*. 2002; Pjetursson *et al*. 2007, 2012) and satisfactory longevity [survival rates of 95.6% (95% CI 94.4–96.6%) after 5 years and approximately 93.1% (95% CI 90.5–95.0%) after 10 years of service] (Pjetursson *et al*. 2012), the choice of oral implants as abutments for reconstructing the dentition has revolutionized restorative dentistry. Without adequate evidence, some clinicians trust an implant abutment even more than a natural tooth (Lang-Hua *et al*. 2013), and there is an erroneous belief that oral implants now solve most prosthetic problems with a lot more ease and less risks than traditional reconstructive dentistry (Esfandiari *et al*. 2011).

Even though there is an increasing body of evidence documenting that implant-supported reconstructions have a three times higher incidence of technical complications compared to tooth-supported reconstructions (Lang *et al*. 2004; Pjetursson *et al*. 2004a, b; Tan *et al*. 2004; Pjetursson *et al*. 2012) and that the incidence of biologic complications remains approximately the same for the two alternatives, the trend in dentistry – unfortunately – is to prefer the implant over the tooth abutment (Esfandiari *et al*. 2011; Lang-Hua *et al*. 2013).

In this context, it has to be clearly stated that the decision to maintain and treat or to extract a compromised tooth has to precede the decision regarding the need for and the modalities of tooth replacement. In this sense, "*implants are here to replace missing teeth, they are not supposed to replace teeth.*"

If properly evaluated, the indication for oral implants as abutments in restorative dentistry is complementary to traditional approaches and in many instances, facilitates treatment planning.

Treatment concepts

When reconstructing a mutilated dentition, it has to be realized the two most common causes of tooth loss are caries and periodontitis. Only a small proportion of teeth are lost due to trauma or are not present due to agenesis. Hence, the vast majority of patients in need of reconstructions present with an oral biofilm infection of various severity and extent. It is evident that such patients need to be treated with a cause-related approach, that is systematic periodontal therapy has to precede any type of reconstructive therapy. It is of utmost importance that oral biofilm infections are controlled prior to the placement of oral implants, since residual periodontal pockets or untreated ecologic niches within the oral cavity may serve as a

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

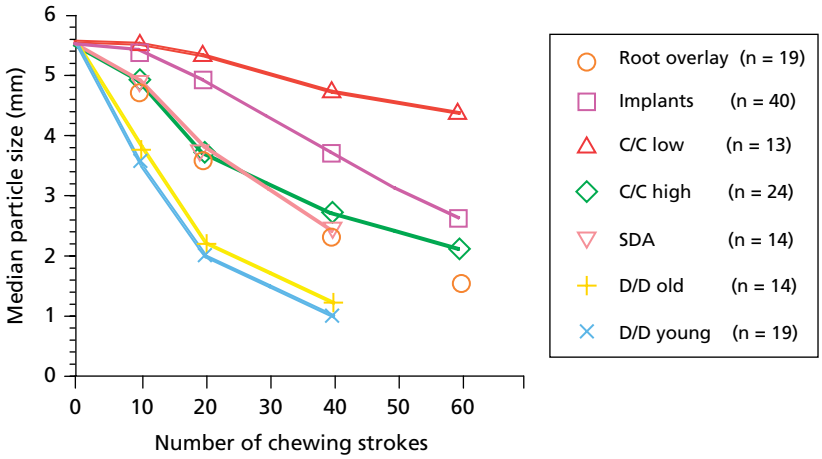

Fig. 53-1 Masticatory chewing efficiency. Number of chewing strokes needed to reach respective particle sizes of the same test food. (Source: Fontijn-Tekamp *et al*. 2000. Reproduced with permission from SAGE Publications.)

source of infection and jeopardize the health of the peri-implant region (Mombelli *et al*. 1995). Hence, implant installation and prosthetic reconstruction is generally not a treatment in itself, but belongs to a systematic approach of comprehensively establishing esthetic and functional demands under healthy conditions (see Chapter 34).

It is obvious that chewing function is affected both by tooth loss and the type of prosthetic reconstruction chosen to replace missing teeth. A quantitative comparison of chewing function by measuring bite force and chewing efficiency with identical methods in subjects with overdentures, complete full dentures, and natural dentitions was performed (Fontijn-Tekamp *et al*. 2000). In the latter group, chewing efficiency was significantly greater than that of patients with full dentures, irrespective of the nature of their mandibular ridge. By installing implants, bite force and chewing efficiency could be significantly improved, although the levels in dentate patients were not reached. Shortened dental arch patients exerted bite forces similar to those of patients with a complete natural dentition, but their chewing efficiency was slightly limited due to the reduced occlusal area. This, in turn, meant that patients with a shortened dental arch will have to perform approximately twice as many chewing strokes to reach the same efficiency as the fully dentate patient (Fig. 53-1.)

Limited treatment goals

Generally, efforts are made to completely reconstruct a partially edentulous dentition. The question arises whether or not missing teeth have to be replaced at all and to the full extent. Usually, single teeth are replaced because of predominantly esthetic demands, while multiple missing teeth may also affect functionality and chewing capacity and hence, are replaced to improve these aspects. However, it is evident from a number of cross-sectional and longitudinal studies (Käyser 1981; Battistuzzi *et al*. 1987; Witter *et al*. 1988, 1990a, b, 1991, 1994) that not all lost teeth are replaced. The loss of one or more molars especially has been thoroughly studied by the Nijmegen group of clinical researchers. No clinically significant differences were found in these studies between subjects with a complete dentition and those with reduced dental arches regarding masticatory capacity, signs and symptoms of temporomandibular disorders, migration of remaining teeth, periodontal support, and oral comfort.

Shortened dental arch concept

Studies on shortened dental arches (SDAs) have shown that dentitions comprising anterior and premolar teeth in general fulfil the requirements of a functional dentition, including patient-assessed oral comfort and chewing ability. A review of the literature on SDAs concluded that the concept deserves serious consideration in treatment planning for partially edentulous patients. However, with ongoing changes, for example in dental health and economy, the concept requires continuing research, evaluation, and discussion (Kanno & Carlsson 2006; Scheuber *et al*. 2012).

Special attention has to be given to the patient's own needs and desires for increased chewing capacity when considering the SDA as a limited treatment goal. Clinical observations as well as research findings indicate that elderly patients can function at an acceptable level with a reduced dentition consisting of 10 or even fewer occluding pairs of teeth (Käyser 1990). The World Health Organization (WHO) goal for the year 2020, namely to maintain a natural dentition of no less than 20 teeth throughout life, is also substantiated by a literature review that proposed dentition will assure oral function (Gotfredsen & Walls 2007).

The choice of implants as abutments to fulfil individual needs may, therefore, become a welcome treatment option within the concept of a shortened dental arch.

Indications for implants

Three major indications can be defined for the use of oral implants:

- To increase subjective chewing comfort
- To preserve natural tooth substance and adequate, existing reconstructions
- To replace strategically important missing teeth.

Increase of subjective chewing comfort

Studies have demonstrated that the installation of a small number of mandibular implants (two to four) may dramatically improve chewing function, especially if the edentulous mandibular ridge shows severe resorption (Fontijn-Tekamp *et al*. 2000, 2004a, b). Hence, it is evident that the completely edentulous patient will benefit from as few as two oral implants installed in the mandibular canine region (Fig. 53-2).

Likewise, subjective chewing comfort may be improved by supplementing single premolar chewing units in the posterior region in order to fulfil individual demands for more chewing capacity under a shortened dental arch concept (Fig. 53-3). It is imperative that the implants be placed in the prosthetically correct location, leaving enough space for an interdental (interimplant) space and observing the dimensions of a premolar width (7 mm).

Instead of adding chewing comfort in premolar units, implant systems with wider necks or platforms may be installed in order to truly mimic the replacement of the missing molars. In these instances, an interimplant distance of 8 mm has to be observed in order to create enough space for the molars and the interimplant space (Fig. 53-4).

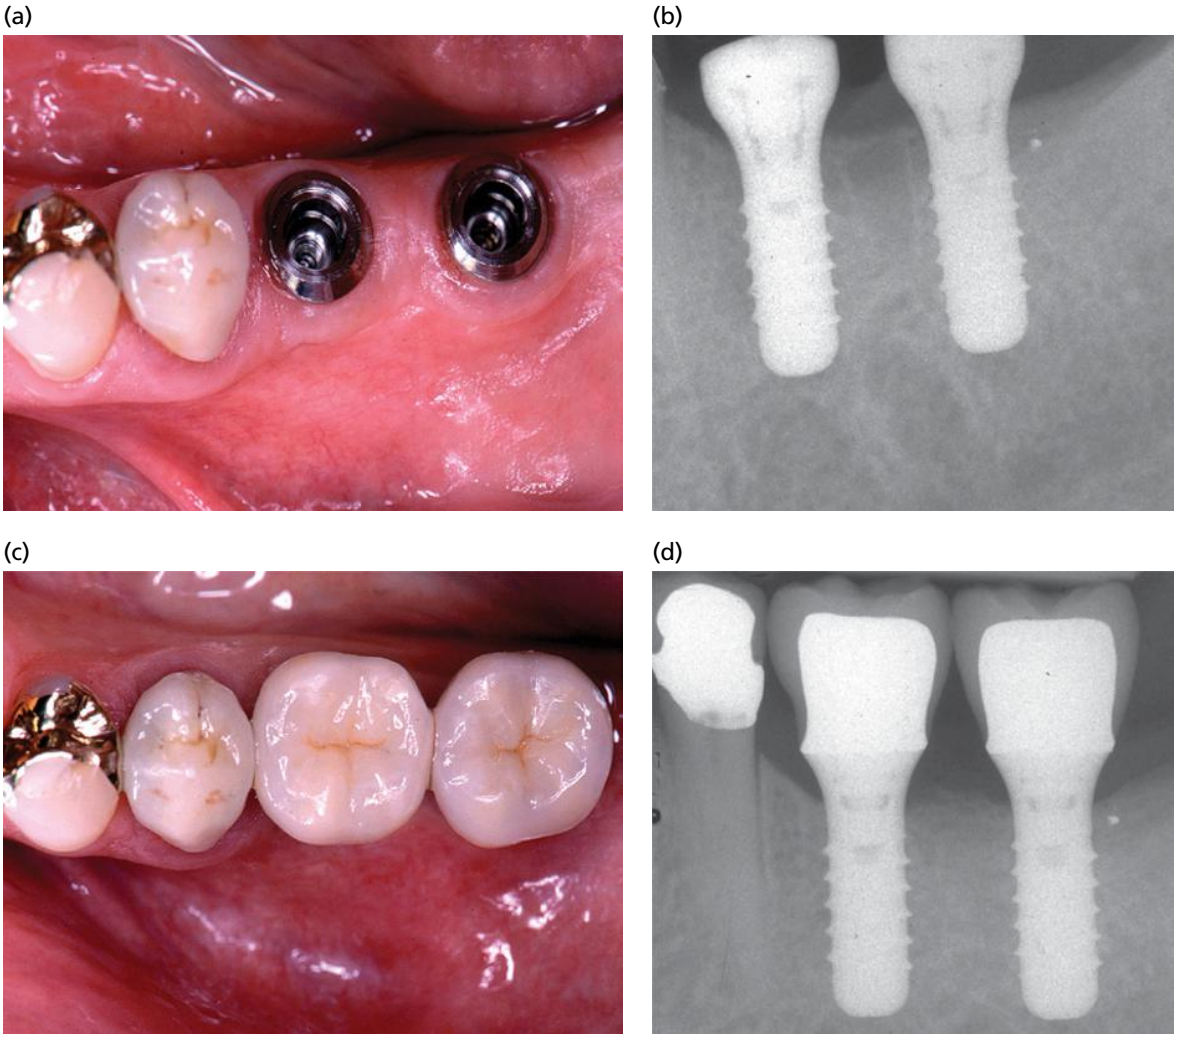

Fig. 53-4 Increasing subjective chewing comfort by replacing missing molars in a mandibular free-end situation. (a) Installation of two standard (4.1 mm diameter) Straumann® implants (8 mm) 6 and 14 mm distal of the distal aspect of tooth 35. (b) Radiographic control at the time of implant installation. (c) Two molar crowns on implants in positions 36 and 37, 8 years after installation. (d) Radiographic documentation, 8 years after loading of the implants.

Preservation of intact teeth or reconstructions

Considering the dimensions of premolars (7 mm) and molars (8 mm) and adequate space for the interdental/interimplant space (4–5 mm), edentulous ridges between existing teeth may be reconstructed and chewing comfort increased without involving adjacent teeth (Fig. 53-5). Obviously, risks can be minimized by reducing the length of bridge spans.

In combined molar and premolar reconstructions (Fig. 53-6), the surgical positioning of the implants has to be calculated in detail and restoration-driven stents may have to be used in order to create adequate conditions for prosthetic reconstruction.

Preservation of natural tooth substance and existing functional and satisfactory reconstructions

Oral implants are ideal abutments if natural tooth substance can be preserved. The preparation of a tooth to serve as an abutment for a crown or a bridge anchor opens about 40 000–70 000 dentinal tubules/mm^2. This, in turn, means that the integrity of a vital tooth is severely compromised. Even though a small proportion of abutment teeth will lose their vitality immediately as a sequela of the preparation procedure, it has been documented that approximately 10% of all vital abutments will have lost vitality after 10 years (Bergenholtz & Nyman 1984; Pjetursson *et al*. 2004a; Tan *et al*. 2004). Hence, it is obvious that an implant installation avoiding tooth preparation represents the most biologic way of replacing a missing tooth (Fig. 53-7).

In areas of esthetic priority, the replacement of a missing tooth with a single implant may – beyond doubt – provide the best and most esthetic treatment option (Fig. 53-8). This is especially true in a periodontally healthy dentition and in situations where the papillae towards the adjacent teeth are still present. By placing the implant in a slightly (1–2 mm) submucosal location, an optimal emergence profile can be achieved.

Instead of preserving natural tooth substance, the clinician may choose to save existing, still satisfactory

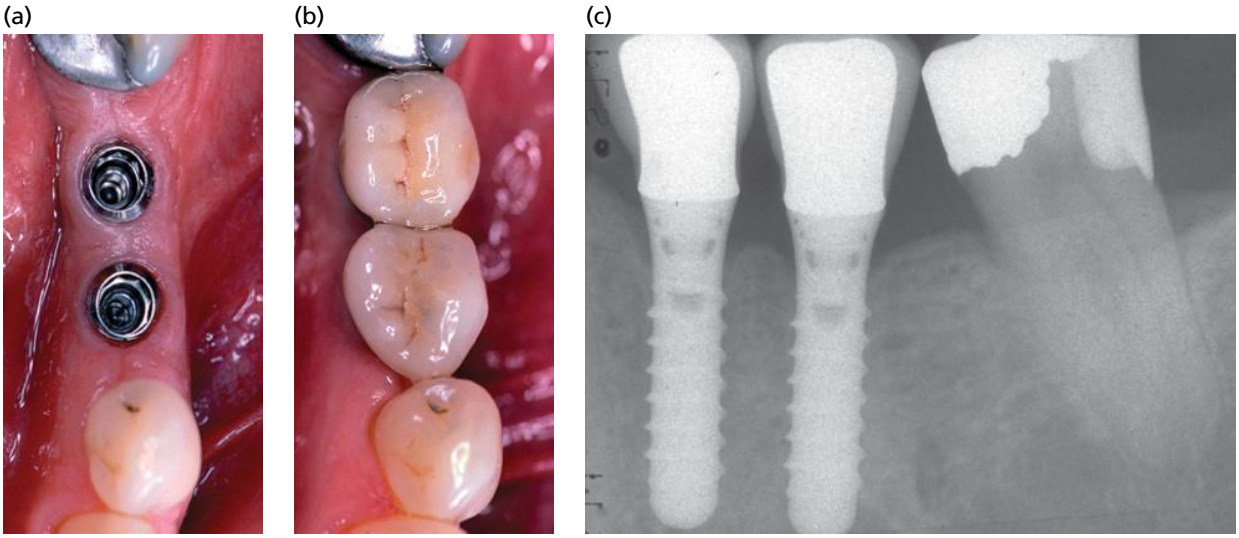

Fig. 53-5 Increasing subjective chewing comfort by closing a mandibular gap. (b) Installation of a standard (4.1 mm diameter) Straumann® implant 5 mm distal of the distal aspect of tooth 34 and a wide body (4.8 mm diameter), wide neck Straumann® implant 20 mm distal of the distal aspect of tooth 34 and 8 mm mesial of the mesial aspect of tooth 38. (c) Three-unit implant-supported fixed prosthesis filling the gap.

reconstructions, thereby simplifying the restoration of a mutilated dentition (Fig. 53-9). Occasionally, the reconstruction may have a smaller extent and hence, there is a reduced chance of encountering technical complications during the years of service.

Replacement of strategically important missing teeth

The loss of a strategically important tooth often creates a chain reaction of therapeutic measures that need to be taken. Treatment planning may become highly involved and extensive reconstructions may result from the loss of such a tooth. Especially in dentitions that have received multiple reconstructions, the loss of one strategic abutment may lead to a time-consuming and costly therapy (Fig. 53-10). Oral implants provide valuable and today indispensable treatment alternatives to the need to redo existing reconstructions. By installing oral implants in the strategically correct locations, partial reconstruction of a dentition may become possible. Obviously, installation of such implants has to be restoration driven. In cases with bone dehiscences or lack of

(a) Orthopantomogram revealing the neighboring anatomic structures (inferior mandibular nerve) and intact reconstructions on the teeth adjacent to the edentulous ridge. (b) Installation of two standard (4.1 mm diameter) and one wide body (4.8 mm diameter) Straumann® implants at a distance of 5 mm, 11 mm, and 20 mm, respectively, distal to the distal aspect of tooth 34. (c) Transmucosal implant installation for two premolar and one molar unit. Implants covered with healing caps. The intact crown on tooth 38 is visible. (d) Radiographic documentation after 5 years. Implant crowns are splinted because of the short (6 mm) implants (near the inferior mandibular nerve).

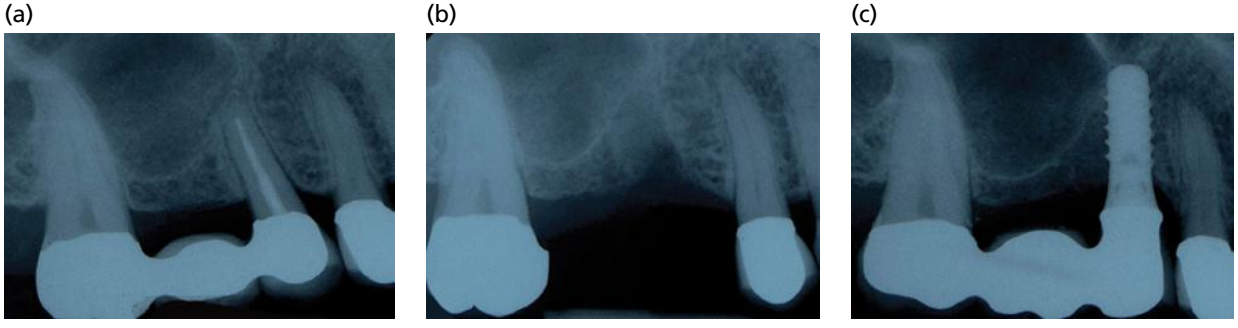

Fig. 53-10 Replacing strategically important teeth. (a) Fixed dental prosthesis is seated on abutment teeth 17 and 15. Tooth 15 was root canal treated and suffered from a root fracture which jeopardized the integrity of the entire reconstruction. (b) Bridge is separated between tooth 17 and pontic 16. (c) New fixed dental prosthesis was seated on the implant 15 and soldered to the existing, still satisfactory, crown 17. In this manner, the implant helped to avoid a costly and extensive reconstruction.

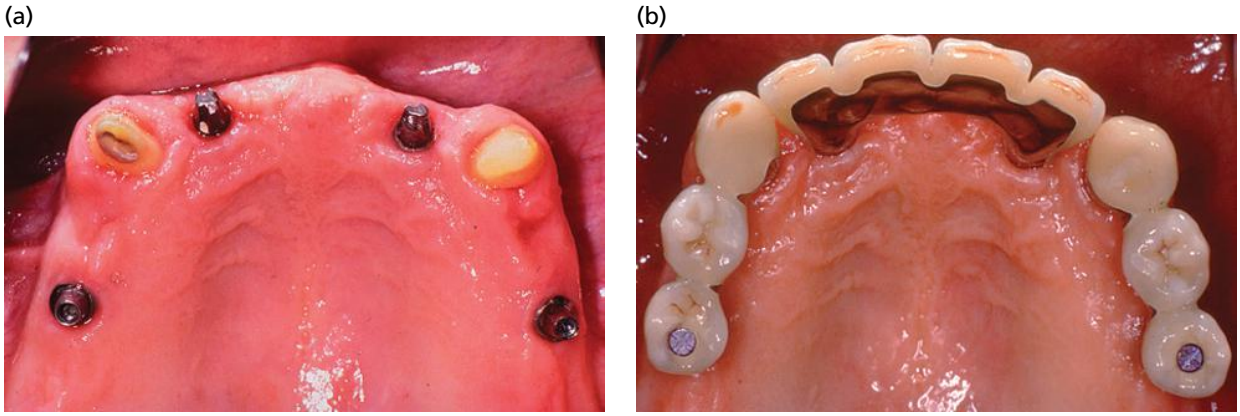

Fig. 53-11 Replacing strategically important abutments. (a) Only the two periodontally healthy maxillary canines 13 and 23 remain. To reconstruct this maxilla with a fixed dental prosthesis requires the installation of oral implants in strategically correct locations. An implant-supported maxillary front reconstruction and two mixed tooth–implant-supported reconstructions in the posterior segments were planned. (b) Eight years following implant installation. The maxillary front reconstruction is cemented on solid abutments that have been installed in the positions of teeth 12 and 22, that is 5 mm mesial of the mesial aspects of the canines. The posterior segment reconstructions are cemented on the canines and screw retained on two implants in the positions of teeth 15 and 25, that is the implants are placed 11 mm distal of the distal aspects of the canines, which allows the placement of three-unit reconstructions with minimal risks. A shortened dental arch as a limited treatment goal provides satisfactory chewing function.

adequate bone volumes, bone augmentation procedures may have to be performed (Fig. 53-11).

Conclusion

Oral implants are best used as abutments in restorative dentistry if the subjective chewing comfort has to be increased, natural tooth substance or existing satisfactory reconstructions have to be preserved, or strategically important missing teeth have to be replaced.

Hence, oral implants have become valuable, indispensable, and welcome treatment alternatives to traditional dental reconstructions. Obviously, oral implants should only be incorporated in oral cavities with healthy conditions, that is a thorough periodontal treatment has to precede restorative therapy.

Introduction

Importance of esthetics in implantology and its impact on patient quality of life

Esthetics has become an increasingly important topic in modern society. It is not only important in itself, but also relates to other more general concepts of well-being (Samorodnitzky-Naveh *et al.* 2007). The loss of one or more teeth in the zone of esthetic priority may impair the esthetic appearance of the patient and therefore, any treatment modality for reconstruction of the lost tissues must address both functional *and* esthetic outcomes.

The structural components of an implant anchored in the bone and covered by soft tissues differ in several aspects from those of a tooth with its periodontium (Berglundh *et al.* 1991; Abrahamsson *et al.* 1996; Lindhe & Berglundh 1998; Welander *et al.* 2008). The lack of root cementum on the implant surface influences the fiber orientation and attachment (Traini *et al.* 2005a, b; Tetè *et al.* 2009), which, in turn, may impair the natural morphology and surface characteristics of the soft tissues. An irregular mucosal arrangement and/or missing papillae, despite being healthy, may strike a discordant note, and be the main reason for an esthetically displeasing result (Garber & Salama 1996).

Several studies have confirmed an altered esthetic outcome after placement of implant-supported reconstructions in the upper anterior area (Chang *et al.* 1999a; Evans & Chen 2008; Schropp & Isidor 2008). In general, implant-supported clinical crowns have been evaluated to be longer than the non-restored contralateral teeth, and factors such as "topography

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

of the surrounding soft tissues", "form of the crown", and "contact point position" were found to have a statistically significant influence on the clinicians' determination of the overall satisfaction with appearance (Chang *et al*. 1999b).

The commonly used methodology to investigate patients' esthetic perception is ranking of clinical photographs according to esthetic discrepancies (Dong *et al*. 1999; Kokich *et al*. 1999; Van der Geld *et al*. 2007). However, the expert evaluation of patients' esthetic appearance is often biased and as a consequence, patient self-assessment of dentofacial esthetics through use of questionnaires has become a widely used approach. Surprisingly, patients' judgment of the esthetic result often revealed a higher degree of satisfaction than that judged by professionals (Kokich *et al*.1999; Flores-Mir et al. 2004), and the factors most strongly influencing satisfaction with appearance were age, gender, and tooth shade (Neumann *et al*. 1989; Dunn *et al*. 1996). A recent study by Mehl *et al*. (2009) evaluating the Oral Health Impact Profile (OHIP) (Slade & Spencer 1994), a scale assessing satisfaction with one's own dental appearance and commonly used for capturing dental esthetics, found that this did not evaluate patients' appearance adequately. One of the common problems is that the discriminatory power of most measures is low (Meijering *et al*. 1997) and often minimizes the assessment of specific esthetic concerns as compared with their psychosocial consequences (Larsson *et al*. 2010a). The Orofacial Esthetic Scale (OES) (Larsson *et al*. 2010b), developed especially for prosthodontic patients, is a brief questionnaire based on eight representative items that assess orofacial esthetic impacts and exhibit a good score reliability and validity.

A study by Wolfart *et al*. (2006) on prosthodontic patients evaluated general well-being with self-assessment of their dental appearance, and measured distinct esthetic concerns and psychosocial consequences of esthetic impairment. The orofacial appearance is a conceptual component which has a psychosocial impact on a patient's well-being and influences oral health-related quality of life (John *et al*. 2004). It is therefore important not only to evaluate the esthetic outcome with expert-based assessments, but also to include patient-based approaches (Ekfeldt *et al*. 1994; Avivi-Arber & Zarb 1996; Lamb & Ellis 1996). For profound evaluation, the patient's own assessment of his/her dentofacial esthetics should be captured by appropriate instruments and be included as a component when evaluating future implant success rates.

Decision-making process and informed consent

The long-term success and survival rates of implants inserted to replace missing teeth have been documented in several prospective studies and systematic reviews (Jung *et al*. 2012; Lang & Zitzmann 2012; Pjetursson *et al*. 2012). Although favorable long-term results of implant therapy have been reported, infections and esthetic adverse outcomes do occur. It is possible that some infections around implants, accompanied by esthetic problems, develop slowly. The results of a long-term follow-up study concluded that 9–12 years after implant installation, implant survival rates are high and implant loss seems to cluster within patients. In contrast, after the same period of observation, peri-implant lesions seem to be a common clinical entity (Roos-Jansåker 2007). These results necessitate critical patient evaluation before recommending implant-supported reconstruction, especially in young adult patients and those with a history of periodontal disease. In addition, patients need to understand their options and the likely benefits and potential side effects of each option. Unfortunately, when coming to a decision on treatment, clinicians often unwittingly invest too much confidence in their diagnostic accuracy (Berner & Graber 2008). This finding is not only valid for experts, but also for laypeople. The psychological literature has documented that people are not good at assessing what they know and generally tend to be overconfident in their judgments (Griffin & Tversky 1992; Kruger & Dunning 1999). This, in turn, means that patients have considerable knowledge gaps about treatment and outcomes even if they feel well informed. A recent cross-sectional survey concluded that there is a need to improve assessments of how informed patients are. More decision-specific items have to be created for each situation as they provide more details about what patients know and what potential information gaps they have (Sepucha *et al*. 2010). Using generic items such as patients' perceptions to assess the extent to which participants are informed is problematic. Interestingly, there was a positive relationship ($P = 0.07$) between knowledge scores and a patient's perception of being extremely well informed regarding surgical decisions, but not for medication and screening. A possible explanation for this finding is that surgery is a more significant decision that receives increased attention and involvement, which in turn raises a patient's awareness of his/her knowledge. In the multivariate regression analysis, only trust in the provider was significantly associated with perceptions of feeling extremely well informed.

Basically, trust in one's own surgeon is a fundamental requirement for accepting a treatment plan based on implant placement in the zone of esthetic importance. On the other hand, such trust may not actually correlate with whether or not the clinician has actually provided adequate information to allow the patient to make an informed decision. However, if a patient trusts his/her surgeon, he/she may be less likely to seek other sources of information or to be critical of what he/she is told.

In order to promote quality of care in implantology, informed patient choice has to be emphasized. It

is a key responsibility of clinicians to determine the extent to which patients are actually informed and whether or not they understand the planned treatment solution, the options, and the outcomes, including risks, for any major medical decision they face.

Preoperative diagnostics and risk analysis

Clinical measurements

An implant reconstruction in the area of esthetic importance should resemble a healthy, unrestored tooth in all aspects. For this, an initial, precise evaluation of the edentulous area and the periodontal condition of the neighboring teeth is of utmost importance. As the periodontal status of the residual dentition may influence the survival and success rates of the prospective implants (Mombelli *et al*. 1987; Pontoriero *et al.* 1994; Zitzmann *et al.* 2002), independently of the implant position in the dental arch, some parameters have to be evaluated routinely before starting treatment and while monitoring implant reconstructions over a lifetime, including assessment of oral hygiene habits by quantifying plaque accumulation using the original Plaque Index introduced by Silness and Löe (1964). A modified version of this index has been published to assess biofilm formation in the marginal area of implants (Mombelli *et al*. 1987). The presence of bleeding on probing (notated in records as BoP^+) has been shown to detect an inflammatory lesion in the gingiva around teeth. On the other hand, absence of BoP has been reported to represent periodontal health with a high negative predictive value (Lang *et al*. 1986, 1990). To be confident of acceptable presurgical hygiene conditions, it is recommended that the full-mouth bleeding scores are <20% (Lang *et al*. 1996; Tonetti *et al*. 1998). It has been shown that lipopolysaccharides from a variety of Gram-negative bacteria can inhibit gingival fibroblast proliferation, which, in turn, is responsible for the delayed healing of inflamed sites (Bartold *et al*. 1992). Additionally, an inflamed mucosa cannot be manipulated with the same precision as a healthy one, and primary wound closures are more difficult to achieve as inflamed soft tissues are ambiguous and at higher risk for soft tissue dehiscences during the early healing phases.

The periodontal probing depth today is still one of the most reliable and sensitive diagnostic investigations for the evaluation of the periodontal condition, even if some shortcomings have to be considered (Lang *et al*. 1994). The probing depth around teeth adjacent to an edentulous area is not only an indicator for periodontal treatment needs, but also an important prognostic value for the esthetic result. The presence of an interproximal papilla with a natural appearance between a tooth and an implant mainly depends on the level of the attachment at the neighboring tooth surfaces. For this reason, a preoperative precise recording of the probing pocket depth and the soft tissue level adjacent to an edentulous area, measured from the cementoenamel junction (CEJ) to the gingival margin (mucosal recession), is of utmost importance for the prediction of the post-surgical papillary morphology (Kan *et al*. 2003).

Another factor that influences the esthetic success of an implant reconstruction in the anterior area is the soft tissue biotype (Lee *et al*. 2011). Two periodontal biotypes have been described around teeth (Seibert & Lindhe 1989): (1) a thick flat one associated with quadratic teeth and a wide zone of keratinized mucosa, and (2) a thin, highly scalloped one with slender teeth. Numerous studies on humans show that the first of these is the preferred biotype for optimal surgical and prosthetic outcomes (Henriksson & Jemt 2004; Linkevicius *et al*. 2009; Bressan *et al.* 2010; Linkevicius *et al*. 2010). A thin tissue biotype is more friable, less vascularized, and accompanied by thinner underlying bone (Kois 2001), and seems to be more susceptible to mucosal dehiscences. Extrapolating from the observations of the soft tissue behavior around teeth, the peri-implant soft tissue can also be classified into thin and thick biotypes, with a range of transitional categories in between.

There is a lack of consensus concerning the methods used to measure the mucosal biotype. Some authors consider the soft tissues thin when the transparency of a periodontal probe in the sulcular area can be seen shining through the tissue (Kan *et al.* 2003; Evans & Chen 2008). Others have measured the tissue thickness with a periodontal probe or an endodontic file (Linkevicius *et al*. 2009), or an ultrasonic device (Müller *et al*. 2000), or have just recorded the width of the masticatory mucosa (Chen *et al.* 2009). In a recent study of 100 patients, experienced clinicians were able to visually recognize the thick flat biotype in >70% of the cases, but were unable to identify almost 50% of the thin scalloped biotypes (Linkevicius *et al*. 2009). These cases that were overlooked are precisely those that are susceptible to increased esthetic compromise, which clearly emphasizes the limitations of visual inspection alone and calls for the assessment of mucosal thickness.

Besides the clinical records of the residual dentition, especially around the teeth adjacent to the prospective implant sites, including their restorative condition (e.g. overhangs of fillings, precision and vertical location of crown margins), the inspection of the edentulous area is also important as it strongly influences the prognosis of the esthetic outcome and the additional therapies that are required. The extent of an edentulous space in the arch can be described based on the number of missing teeth. Several authors have tried to classify these areas regarding their morphologic characteristics (Allen *et al*. 1985; Seibert 1983; Wang & Al-Shammari 2002), dividing them into a horizontal and a vertical defect component. Depending on their extent, vertical hard and soft tissue defects show a much better prognosis for

augmentation than horizontal ones. In the latter, the attachment level at the teeth neighboring the defect limits the prognosis and therefore the prospective esthetic result.

Image-guided diagnostics

To ensure a proper planning of the implant position, which is a fundamental requirement in the zone of esthetic priority, the required information can be obtained from the aforementioned clinical examinations and additional appropriate image-guided diagnostics. In investigating an implant site in the anterior upper jaw, a clinician requires information on bone volume and quality, topography, and the relationship to important anatomic structures, such as the roots of neighboring teeth, nasal floor, vessels, and nerves (Harris *et al.* 2002). In the last decade, a rapid adoption of conventional computed tomography (CT) and more recently of cone-beam computed tomography (CBCT) can be observed in implant planning. There is legitimate concern from experts in the clinical and radiology fields that these technical developments will lead to a significant increase in the radiation exposure of patients without a proper risk–benefit analysis. For this reason, guidelines for the use of diagnostic imaging in implant dentistry have been published, based on a consensus workshop of the European Association for Osseointegration (EAO) (Harris *et al*. 2012).

In the upper anterior maxilla, the recommended standard radiographic technique consists of an intraoral radiograph before replacing a missing single tooth, and an additional panoramic image in partially dentate and edentulous patients. The need for cross-sectional imaging has to be carefully evaluated for a sufficient net benefit, weighing the total potential diagnostic or therapeutic benefit against the detrimental effects the exposure might have for the individual. The latter effects can be divided in two categories: (1) tissue reactions which are proportional to the dose and occur in all individuals when the dose is large enough, and (2) stochastic effects which are believed to have no threshold and can be considered as "chance" reactions. The ranges of effective dose for conventional radiography are small and <0.002 mSv for an intraoral single radiograph. The corresponding values for a panoramic image are 0.003–0.024 mSv and 0.019–0.674 mSv for a CBCT. In contrast, the dose of a conventional CT ranges from 0.280 to 1.410 mSv, which makes its value questionable in the therapeutic planning of an implant reconstruction in the upper anterior segment (Harris *et al*. 2012).

A cross-sectional image (CBCT) can be indicated in clinical situations where (1) clinical examinations or conventional radiography have failed to adequately identify the relevant anatomic boundaries or the absence of pathology; (2) such an image can provide additional information and help to minimize the risk of damage to important anatomic structures; (3) these are judged to be clinically borderline, with limited bone, and the surgeon considers that the morphology of the defect requires a more extensive augmentation procedure; and (4) implant positioning can be improved so that esthetic results are optimized. This information can be enhanced by using radiographic templates and surgical guides which help to translate the information from the radiographic evaluation into the clinical procedure. These surgical guides may be a prerequisite when multiple teeth are missing and a fixed reconstruction with implant-supported crowns and bridges is planned.

Visualization of prospective results for diagnostics and to inform patients

When treating the anterior zone of a patient's upper jaw, the wishes and expectations of each individual patient concerning the esthetic result have to be respected. Very often the patient's and the clinician's views of what constitutes an ideal esthetic outcome differ widely (Eagly *et al*. 1991; Langlois *et al*. 2000). While the patient is influenced by his/her self-perception, the social environment, the media, his/her own dental history, and many other factors, the clinician bases his/his choice of a certain clinical strategy on the current dental knowledge, the empirical experience, and, possibly, on available medical checklists. The latter especially carry a risk of standardizing the prospective results and disregarding the individuality and personality of each patient. To address this, the contact and communication with the patient in the diagnostic phase, but also during the following treatment stages, requires special attention as patients are often unable to articulate their wishes and concerns. This personal relationship cannot be replaced with scoring answers to a digital checklist of questions. Additionally, the translation of a digital analysis with the help of computer imaging software idealizes the prospective results, which may not reflect the actual situation. Especially in edentulous areas where a considerable amount of vertical tissue volume is missing, it can be difficult to reconstruct the tissue loss with surgical interventions alone, and clinicians must take care with what they promise patients regarding outcomes. Against this background, each treatment plan for a reconstruction in the zone of esthetic importance should be based on the interaction between all participating persons and must include the patient's opinions and desires.

All the rules that have been learned about tooth form, geometry, and harmony to recreate an esthetically pleasing smile can only be viewed as a general guide. Otherwise, all treatment goals would be the same for all patients and the facial physiognomy and uniqueness of each individual would be neglected.

To facilitate the communication within the treatment team (dentists, other physicians, and dental

technicians) and to include the patient in the decision-making process, the so-called Patient-supported Esthetic Protocol (PEP) (Gebhard 2013) has been developed. It is based on an iPad application (Apple Inc., Cupertino, CA, USA) which can record the patient's wishes and desired changes concerning his/her orofacial appearance, as well as all the diagnostic steps. It is not a checklist or an analysis of existing esthetic shortcomings. Checklists can be helpful to clinicians in identifying problems, but they have a tendency to overlook patient individuality and usually follow a set pattern that ends with a standardization of the procedure. The patient-supported esthetic protocol helps to visualize and develop the treatment goals over the course of the diagnostic steps: a diagnostic wax-up, its transformation into a mock-up for try-in, the provisionals, a full wax-up, the try-in of the first bake, and the final reconstruction (Fig. 54-1).

All the patient's wishes are noted, even those that appear unimportant (e.g. important treatment steps only when there is a full moon), before the clinician or technician starts to describe the individual physiognomy of the face and to define a certain position and form of the teeth. This becomes more crucial when several anterior teeth have to be replaced or restored (Fig. 54-2a). The position of the incisal edges are given by the lower lips. In an ideal set-up, the incisal edges should be slightly depressed at the junction between the lip vermillion and the oral mucosa when vocalizing the F sound (i.e. saying something like "frog" or "fifty five"). Based on this landmark, the form of the teeth and their tooth-to-tooth position can now be built up and transferred to a diagnostic wax-up and mock-up. The visualization of the prospective result is the decisive tool in the diagnostic phase and pictures are taken from the inserted mock-up to document the development of the treatment goals and to use in discussion of further adjustments with the patient. Proposals for changes are marked in red while the comments of the patient are noted in another color (in this case blue) (Fig. 54-2b, c). Once the shape and the arrangement of the teeth are ideal, the new findings are transferred to a provisional, which also serves as a diagnostic aid for the patient. Further adjustment and detail can be incorporated in the final ceramic reconstruction (Fig. 54-2d).

PEP forces clinicians and dental technicians to take the time necessary to deal with the patient's esthetic expectations, to communicate these to the treatment team, and to make notes on each individual step in the development of the prospective esthetic outcome. Additionally, it can be archived in the clinical records and be used for quality assurance.

Checklists and risk assessment (indications and contraindications)

Prior to selecting an implant-based solution, one should carefully review all possible treatment alternatives that have the potential to solve a given problem. Additionally, the advantages and disadvantages of the solutions should be comprehensively pondered, not only in light of long-term survival but also with respect to the esthetic outcome and its stability over time. The therapeutic modalities that can be used to replace a tooth in the zone of esthetic priority, without placing implants, are listed in Table 54-1. In cases with unrestored neighboring teeth, adhesive restorations have been shown to reliably replace single missing teeth in the anterior upper jaw with almost no preparations needed at the anchor teeth (Rosentritt *et al*. 2009).

In young adults especially, a prosthetic solution can be chosen that is documented to have an inferior survival rate in the literature but shows a better clinical predictability regarding the esthetic appearance. This solution gives time for new achievements and technologies in implantology to emerge that may facilitate the reconstruction at a later date (Fig. 54-3).

In comprehensive esthetic treatment planning, attention should be directed not only to implant alternatives but also to strategies aimed at improving the implant sites prior to placing the implant or even at improving a tooth's prognosis such that implant reconstruction can be postponed or even avoided. Based on our personal experience, orthodontic pretreatments especially can improve the clinical situation in many cases and provide a better esthetic prognosis for therapy. These pretreatments include forced eruptions (Giachetti *et al*. 2010) to increase the retention for placement of a conventional crown (Juloski *et al*. 2012) or to condition the site for later implant placement (Amato *et al*. 2012). Another orthodontic treatment option consists of changing the distribution pattern of the edentulous spaces by turning a neighboring two-unit space into two one-unit spaces (Fig. 54-4a). As previously mentioned, the latter situation has a much better predictability regarding the development of papillary-like structures, an important issue for a natural appearance. As shown in Fig. 54-4b, a palatally placed implant offers an absolute anchorage for orthodontic tooth movements without risk of negatively influencing the present occlusion. Additionally, the temporary implant may serve as an ideal anchor in many situations to firmly fix a provisional without any visible attachments on the anterior incisors and canines (Fig. 54-4c) until the implants can be loaded with provisional crowns (Fig. 54-4d).

In patients with open interdental spaces and one or more missing teeth to be replaced, a conventional fixed approach will be critical as a single diastema cannot be closed for symmetry reasons and thus, an implant-supported reconstruction becomes the treatment of choice. Besides diastemata, other situations which favor the inclusion of implants in the treatment plan are: (1) unrestored, healthy neighboring teeth; (2) compromised, risky abutments; (3) extended

• Orthodontic therapy (closure of edentulous spaces)
• Implant-supported prostheses (fixed, retrievable or removable suprastructures)
• Combinations of the above

edentulous areas; and (4) missing strategically important abutment teeth. The fulfillment of one or more of these criteria does not necessarily mean that the inclusion of implants in the treatment strategy is a given. Other risk factors related to the bone, soft tissue, and tooth (clinical crown) level have to be carefully evaluated and considered in the decision-making process (Table 54-2).

Provisional restorations and timing of the treatment sequences

In the anterior zone, provisional restorations have a variety of important functions. Provisional restorations should be used to evaluate esthetic, phonetic, and occlusal function prior to delivery of the final implant restorations, while preserving and/or enhancing the condition of the peri-implant mucosal tissues (Santosa 2007). An implant treatment approach in the edentulous anterior zone has three provisional phases:

Phase 1: from provisionalization immediately after tooth extraction to implant placement
Phase 2: from implant placement to abutment connection, prior to loading
Phase 3: from abutment connection to final crown/bridge placement, with loading of the implant and the development of the emergence and mucosa profile.

Phase 1: From tooth extraction to implant placement

After tooth extraction in the zone of esthetic priority, several options are available today to immediately replace the missing tooth/teeth with provisional restorations. These provisional restorations can be in the form of removable or fixed prostheses. It is of great importance for the patient to discuss the options as well as their advantages and disadvantages prior to the therapy. When a patient is going to lose one or more teeth in the anterior area of the upper jaw, an adequate provisional restoration will help give him/her back confidence.

Removable partial acrylic dentures have commonly been used after tooth extraction and possibly also throughout the entire implant therapy (Fig. 54-5). They are simple to construct, relatively inexpensive, and easy to adjust and fit. They can be easily modified in cases undergoing additional extractions by adding provisional teeth to their existing removable dentures at minimal cost. Care must be taken with the gingival portion of the provisional partial denture in order not to apply too much pressure to the healing site. Immediately after tooth extraction, the provisional restoration can be placed with ovate pontics

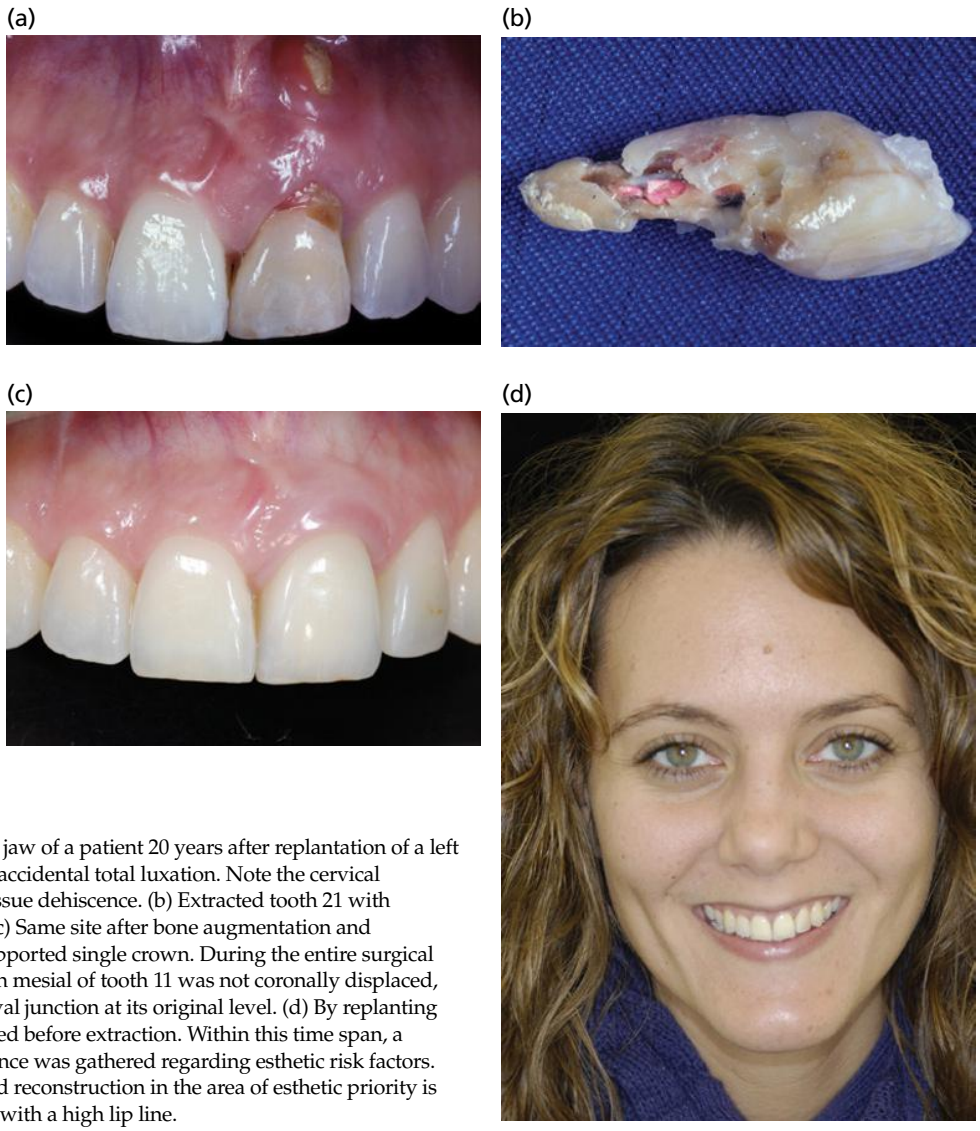

Fig. 54-3 (a) Anterior upper jaw of a patient 20 years after replantation of a left central incisor following an accidental total luxation. Note the cervical resorption and apical soft tissue dehiscence. (b) Extracted tooth 21 with extended root resorptions. (c) Same site after bone augmentation and placement of an implant-supported single crown. During the entire surgical treatment, the scar formation mesial of tooth 11 was not coronally displaced, maintaining the mucogingival junction at its original level. (d) By replanting tooth 21, 20 years were gained before extraction. Within this time span, a substantial amount of evidence was gathered regarding esthetic risk factors. Today, an implant-supported reconstruction in the area of esthetic priority is predictable even in patients with a high lip line.

Table 54-2 Risk factors for implant placement in the zone of esthetic importance.

	Low risk	Medium risk	High risk
Patient factors			
General health	Systemically healthy		Reduced defense
Smoking status	Non smoker	Occasional smoker	Smoker, heavy smoker
Compliance	Good		Poor
Esthetic expectations	Within normal limits		Very high
Lip line	Low	Medium	High
Dental/facial symmetries	Symmetric		Visible asymmetries
Interarch relationship	Normal situation		Deep bite situation
Hard and soft tissue factors			
Attachment level of neighboring teeth	Intact		Reduced
Periodontal and endodontic health	Healthy		Compromised
Distance contact area to bone level at neighboring teeth	<5 mm	5 mm	>5 mm
Ridge deficiencies	Intact alveolus	Lateral defect	Vertical or combined defect
Mesiodistal gap distance	One tooth (>7 mm)	One tooth (<7 mm)	Two neighboring units
Mucosal biotype	Low scalloped, thick	Medium	High scalloped, thin
Soft tissue surfaces	Intact		Texture irregularities, scar formations
Mucosal scalloping	Regular		Irregular
Tooth factors			
Crown forms	Squared shape		Triangular shape
Structural integrity	Intact, healthy	Sufficiently restored	Decayed, insufficiently restored
Line of incisal edges	Following lower lip		Irregular

extending into the extraction sockets to partially preserve the pre-extraction soft tissue morphology (Fig. 54-6). These removable partial acrylic dentures are not particularly comfortable because they have a certain resilience and cover part of the palate. There are alternatives to these tissue-borne provisional restorations. An Essix provisional (Fig. 54-7) may be used as a removable prosthesis in these cases, as well as in cases of limited interocclusal space or deep anterior overbite (Moskowitz *et al*. 1997; Santosa 2007). This prosthesis is made from acrylic teeth bonded to a clear vacuform material on a cast of the diagnostic wax up. The prosthesis provides protection to the underlying soft tissue and implant during the healing phase. Limitations of this provisional restoration include its inability to mold the surrounding soft tissue, and lack of patient compliance can cause rapid occlusal wear

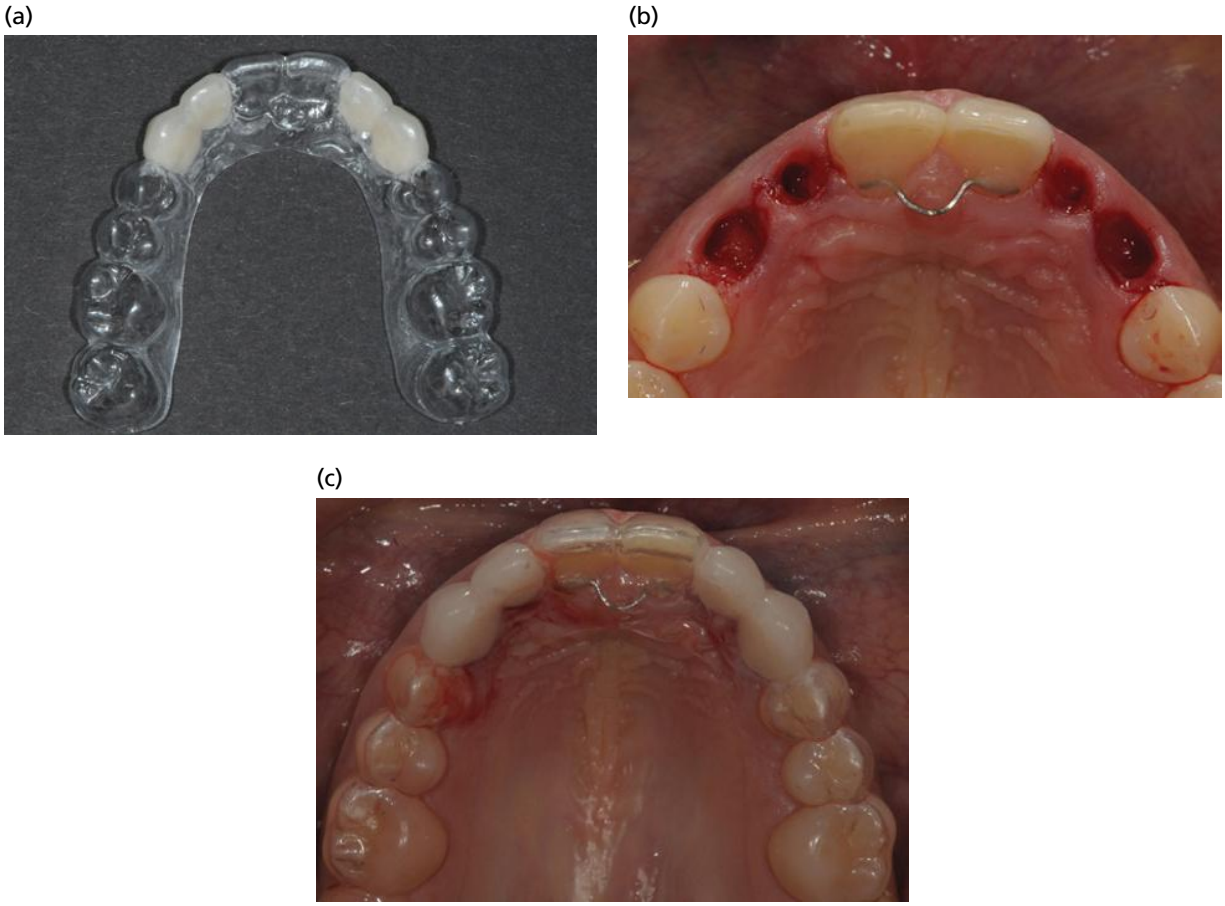

Fig. 54-7 (a) Occlusal view of an Essix provisional made from acrylic teeth bonded to a clear vacuform material. (b) Clinical occlusal view immediately after tooth extraction of the remaining deciduous teeth and before inserting the provisional restoration. (c) Clinical occlusal view of an Essix provisional after teeth extractions in the upper jaw.

from the vacuform material (Santosa 2007). However, some patients may not like wearing, or are unable to tolerate, a removable provisional prosthesis; thus, fixed provisional prosthesis are sometimes necessary.

Fixed tooth-supported provisional restorations in the anterior region are mainly resin-bonded pontics or bridges. The pontic can be an acrylic or porcelain tooth, or a decoronated extracted tooth. The resin-bonded acrylic tooth may be reinforced with composite resin and/or fiberglass. These types of provisional restorations are much more comfortable from a functional and phonetic view, and are more esthetic. However, their removal and rebonding after the surgical intervention requires more time and work from the dentist.

If a provisional restoration is needed for a longer time and more stability is required, a resin-bonded, cast metal framework prosthesis such as a Maryland Bridge is indicated (Fig. 54-8a, b). These are cemented to the neighboring teeth by means of acid etching (Fig. 54-8c) and the use of composites (Fig. 54-8d, e). They can be detached by removing the composite within the palatal perforations and using forceps interdentally and a hammer (Fig. 54-8f). This type of fixed provisional restorations also allows more than one missing tooth to be replaced (Fig. 54-8g). However, the relatively high laboratory costs of these resin-bonded, cast metal framework prostheses have to be taken into consideration.

Phase 2: From implant placement to abutment connection

During the period from implant placement to abutment connection, the same provisional restoration options are available as after tooth extraction. However, after implant placement, especially with the use of guided bone replacement (GBR) techniques, a significant swelling of the tissues must be anticipated. Soft tissue-borne prostheses used during this healing period may cause uncontrolled soft tissue pressure, defined as "transmucosal loading", leading to implant exposure, marginal bone loss, and/or failed integration (Cho *et al*. 2007; Santosa 2007). In order to avoid too much contact with the healing soft tissue, the provisional dentures need to be adjusted to give a distance of approximately 2–3 mm to the tissue after surgical interventions. In this context, Essix provisionals have advantages because they are vertically stabilized through the neighboring teeth and, therefore, cause less pressure on the tissue in cases of swelling.

Phase 3: From abutment connection to final crown/bridge placement

According to the preoperative risk assessment, it has to be decided whether an implant will heal best with a submucosal or transmucosal approach. In highly demanding cases with a high lip line, thin biotype and tissue deficiency, a submucosal approach is generally chosen in order to create soft tissue extra volume. In less demanding cases with thick biotypes, sufficient tissue, and possible soft tissue excess, a transmucosal approach with healing abutments or provisional reconstructions can be selected. Hence, the preoperative risk assessment and the intraoperative information (i.e. primary implant stability, bone defects, soft tissue quantity and quality) will determine the timing of the treatment sequences. In cases with lower risks and sufficient tissue, a more straightforward approach without abutment connection can be chosen (Fig. 54-9a). In contrast, higher risk cases demand another treatment sequence with a more complex approach, including abutment connections with or without soft tissue management (Fig. 54-9b). In both situations, a healing abutment is in place at this stage of the treatment and the clinician has to decide whether or not to use an implant-retained provisional reconstruction. In a clinical comparative study of 63 single-tooth implants in the anterior region in 55 patients, the test group received a provisional implant crown and the control group received a healing abutment (Jemt 1999). The results after 2 years revealed that the papilla volume and the marginal bone loss were not significantly different between the treatment groups. However, the results indicated that the use of provisional crowns restored soft tissue contour faster than healing abutments alone (Jemt 1999). Hence, implant-retained provisional reconstructions are mainly beneficial during the diagnostic phase and can be used to evaluate esthetics, phonetics, and function. Furthermore, they can serve as a communication tool between clinicians, laboratory technicians, and patients.

One of the most important functions of an implant-retained provisional restoration is to develop the desired soft tissue emergence profile. Dental implants differ from teeth in size and shape at the crestal bone and mucosa levels. After removal of healing caps, the geometry of the tissue profile is circular and does not match the corresponding one around teeth (Fig. 54-10). The tissue profile created by the emergence profile and form of the teeth has a more triangular shape, especially for incisors. Therefore, the peri-implant soft tissue profile has to be converted into a tissue profile that is in harmony with the neighboring dentition (Wittneben *et al*. 2013). This transition can either be performed through individualized healing abutments or implant-retained provisional restorations. These implant-retained provisional restorations can either be fabricated in an ideal contour (Fig. 54-11a) or with a reduced emergence profile (Fig. 54-11b). For the provisional with an ideal profile, the clinician works in a subtractive way by selectively reducing the diameter before inserting the provisional restoration. In contrast, for the provisional with a reduced

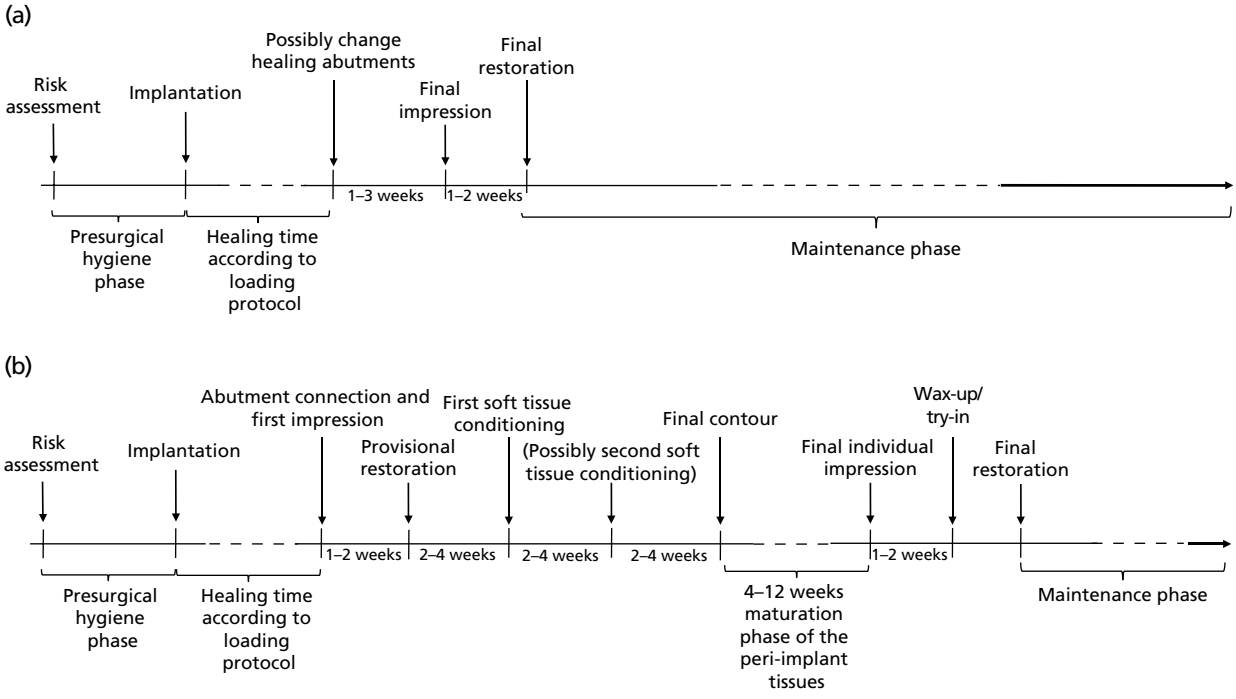

Fig. 54-9 (a) Timeline for a straightforward case without abutment connection and provisional implant-retained restorations. (b) Timeline for an advanced/complex case with abutment connection and provisional implant-retained restorations in order to condition the soft tissues.

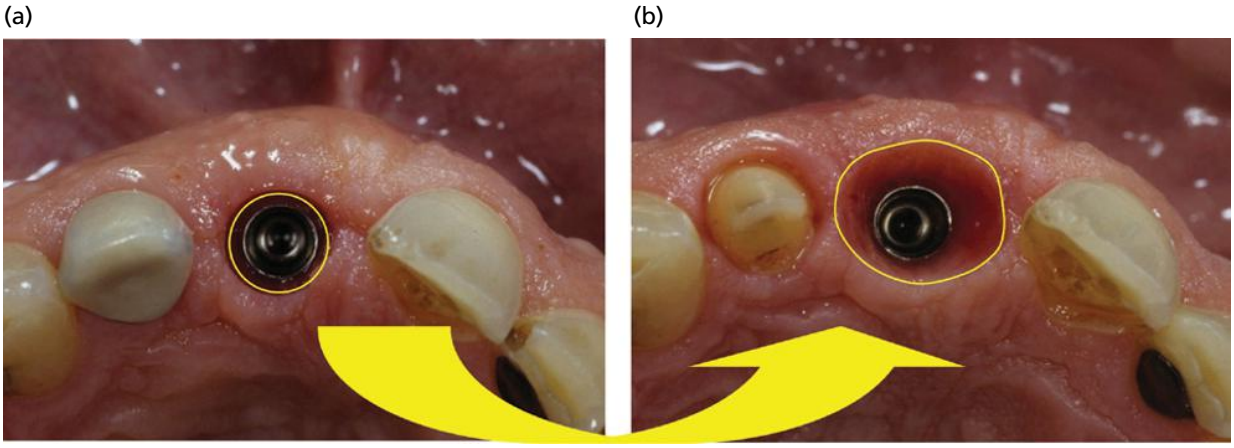

Fig. 54-10 (a) Transition of a circular soft tissue profile immediately after removing the healing abutment and (b) 8 weeks later after soft tissue conditioning with a screw-retained provisional implant restoration.

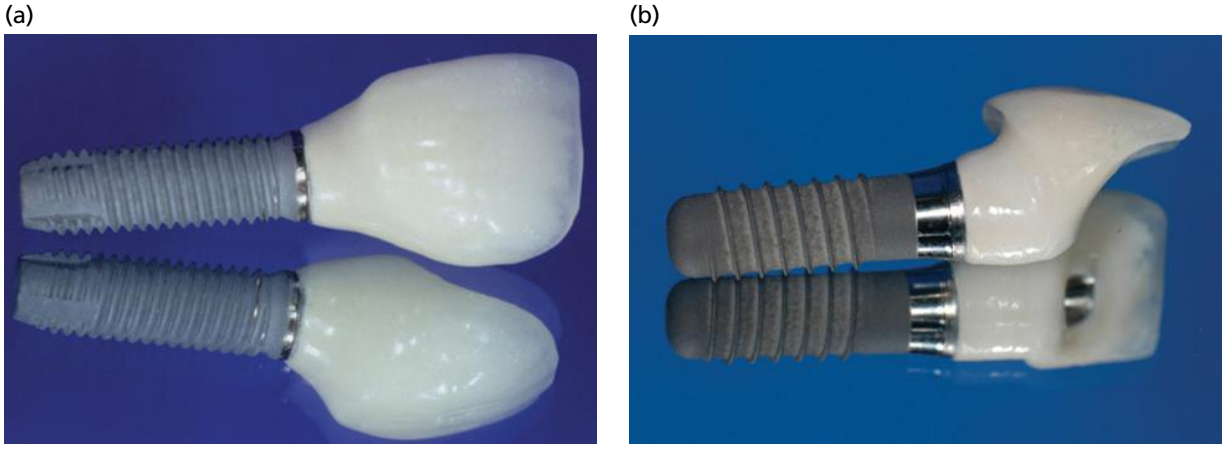

Fig. 54-11 (a) Provisional screw-retained reconstruction with an ideal emergence profile which needs to be individually reduced before insertion. (b) Provisional screw-retained reconstruction with a reduced emergence profile which needs to be individually adjusted by adding resin material before insertion.

emergence profile, the clinician works in an additive way by selectively adding resin material before inserting the provisional.

Provisional restorations can either be cemented or screw-retained. The decision to cement or screw-retain a provisional or final implant restoration depends on the clinical situations (i.e. angulations of the implant and implant position) and the clinician's preference regarding method of fixation. For proper soft tissue conditioning, a screw-retained provisional is preferred as it can be easily removed to allow volume to be added or removed for guiding the soft tissue in the desired direction.

Fixed implant-supported provisionals can be fabricated either in the laboratory or chair-side. In order to improve the soft tissue contour, the provisional reconstruction is inserted in order to apply slight pressure to form the mucosa. The pressure applied to the mucosa at insertion causes an ischemic reaction, a so-called "blanching" of the peri-implant soft tissue (Fig. 54-12), which should only be moderate and disappear within

Fig. 54-12 Screw-retained provisional reconstruction immediately after adjusting the emergence profile which causes an ischemic reaction in the surrounding tissue.

15 minutes (Cooper 2008). By customizing the shape and the contour of the provisional restoration, the peri-implant contour is improved and the emergence profile formed. This soft tissue conditioning process is performed over a period of 8–12 weeks by selectively adding flowable composite material or light-cured acrylic resin to the provisional reconstruction

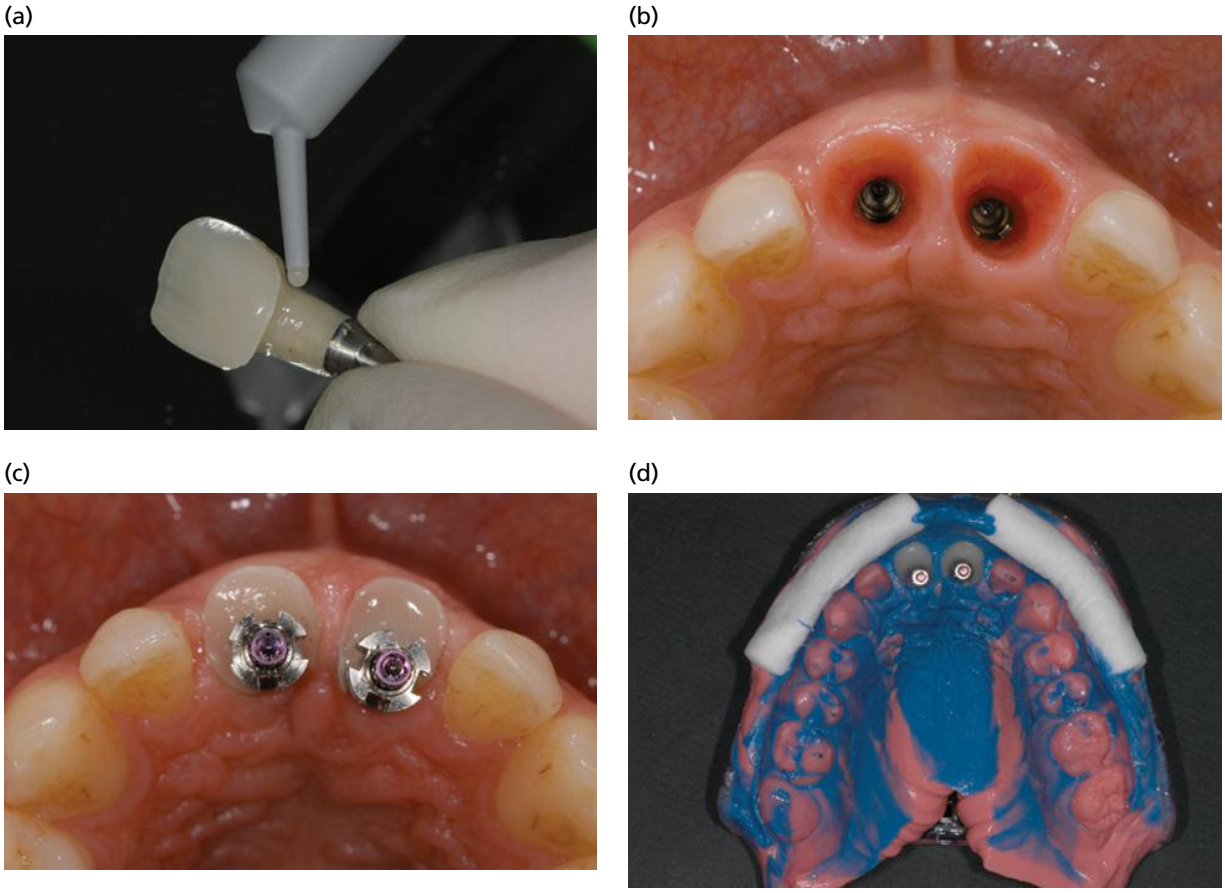

Fig. 54-13 (a) Applying flowable light-curing composite material to the provisional reconstruction after activating the surface. (b) Occlusal view after reaching the final emergence profile of the missing central incisors 11 and 2. (c) Individualized impression copings in place before impression taking. (d) Final impression capturing the information of the emergence profile created by the provisional restorations.

(Fig. 54-13a). After achieving the final emergence profile, it is important to transfer the created soft tissue profile to the final master cast (Fig. 54-13b). This can be achieved with an individualized impression coping that has the same tissue profile as the clinically approved provisional restoration (Fig. 54-13c, d). As the majority of soft tissue recession takes place within the first 3–6 months (Grunder 2000; Oates *et al*. 2002), it can be assumed that the soft tissue margin after the conditioning process will be stable and the final reconstruction can be fabricated.

Surgical considerations when dealing with implants in the zone of esthetic priority

Surgical aspects for an undisturbed wound healing

In general, denuded bone and exposed root surfaces as a result of the surgical intervention must be covered by the soft tissue flap if optimal outcomes are to be achieved. However, in implant surgery, inherent challenges may complicate the procedures. When dealing with implants in the zone of esthetic priority, clinicians are confronted with a variety of anatomic structures, such as hard and soft tissues adjacent to each other, resulting in wounds which are constituted of several interfaces of tissues that fundamentally differ in composition. Furthermore, flap stability and healing outcomes may be hampered during the postoperative phase as the oral cavity is an aqueous environment in which biofilm forms on non-shedding surfaces like teeth and implants and their prosthetic components. Consequently, bacterial colonization may jeopardize uneventful healing (Bartold *et al.* 1992). Also, the negative effect on wound stability and healing outcomes of the mechanical influences of continuous masticatory and other functions of the dentition should not be underestimated (Moore & Hill 1996).

Wound healing primarily depends on early formation and organization of the blood clot and the establishment of an attachment of the clot that is resistant to mechanical forces acting on the flap and opposing surfaces participating in the wound closure (Wikesjö *et al.* 1991b). Impaired clot adhesion may weaken the tensile strength of the wound during early healing events and leave the implant–mucosal flap interface susceptible to tearing, compared to physiologic tensile forces on wound margins (Wikesjö & Nilvéus 1990). Tensile forces vary depending on the stability of the blood clot and subsequently on the biochemical and mechanical properties of the wound bed

(Werfully *et al.* 2002). Hence, healing of peri-implant defects following flap surgery involves conceptually more complex processes than wound healing in most other sites of the body.

Most models investigating the tensile forces on wound margins have considered the interfaces in recession coverings (Wikesjö *et al.* 1991a; Pini-Prato *et al.* 2000). In only one study has the role of flap tension in primary wound closure been investigated in humans (Burkhardt & Lang 2010). In that study, 60 patients scheduled for single implant installation were recruited. Before suturing, the tensile forces on the flaps were recorded with an electronic device. After 1 week the wounds were inspected with regards to complete closure. While flaps under minimal tension of 0.01–0.1 N resulted in only a few (10%) wound dehiscences, flaps with higher closing forces (>0.1 N) yielded significantly increased percentages of wound dehiscences (>40%). This study also revealed that flaps with a thickness of >1 mm demonstrated significantly lower proportions of flap dehiscences at higher closing forces (>15 g) than thinner flaps (≤1 mm). The results of this study indicated a need to control the closing forces at the wound margins. In order to minimize tissue trauma, finer suture diameters may be helpful owing to the fact that thinner sutures (6-0, 7-0) lead to thread breakage rather than tissue tear and breakage (Burkhardt *et al.* 2008b).

It is evident that flap design, flap advancement, and suturing should receive greater attention in situations where mucoperiosteal and/or mucosal flaps are positioned to cover large peri-implant defects. Owing to the fact that the peri-implant wound is constituted of the connective tissue surface of the flap and an avascular surface such as titanium, ceramic or another alloplastic material, peri-implant defects require careful tissue management and stable flap adaptation, especially in the anterior zone of the upper jaw where the mucosal morphology and topography play an important role for the esthetic result.

Incisions and flap designs

Flaps can be classified according to their form (e.g. semilunar, triangular), the direction of the intraoperative advancement (e.g. rotating, apically or coronally advanced) or the composition of the contributing tissues (e.g. full thickness, split thickness). In contrast to connective tissue grafts, which receive their early nutrition by plasmatic diffusion, flaps are characterized by a still functioning network of vessels which provide the injured tissues with blood. Thus, it is evident that when planning the flap outline, attention should focus on the importance of maintaining a good blood supply from vessels entering at the base of a pedicle. To assure a good blood supply, it was recommended that two aspects are noted before starting with the first incision: (1) a broad flap base which allows many nutrient vessels to enter the flap and (2) a flap length-to-width ratio that should not exceed 2:1. These principles seemed to make sense because increasing the flap's width at its base increases the blood supply and supports a greater flap length. However, with a deeper insight into the biologic contexts and processes (Kleinheinz *et al.* 2005), these recommendations now appear rather too simplistic and have been proven to be a fallacy (Milton 1970). It cannot be assumed that major vessels enter the base of mucosal flaps at regular intervals. Additionally, Jeffcoat *et al.* (1982) showed in an animal experiment that the mandibular vasculature is also characterized by arterial vessels traversing somewhat obliquely in a general posterior to anterior direction. Most conclusions from studies focusing on vascular impairment are based on histologic examination of specimens after vascular perfusion and suggest that blood vessels remain intact and patent following surgery. Alternative techniques like fluorescein angiography (Mörmann *et al.* 1975; Mörmann & Ciancio 1977) and laser-Doppler flowmetry (Patiño-Marín *et al.* 2005; Retzepi *et al.* 2007a, b) are more reliable in qualitatively and quantitatively evaluating the vascularity and blood supply of an injured mucosal area.

Following horizontal incisions along the mucogingival junction, the blood supply of the gingiva was displayed with a fluorescent dye (Mörmann & Ciancio 1977). One day after the injury, the gingiva coronal to the incision line showed a severe anemia, which was more pronounced in the interdental and papillary area than in the tooth prominences. The authors explained the differences as the result of the influence of the collateral vessels coming from the ligament and contributing to the marginal vascularity.

These results have been confirmed in another angiographic dog study (McLean *et al.* 1995) comparing two different suture techniques for closing a mucoperiosteal flap. After flap adaptation, primary wound closure was achieved by either horizontal mattress suturing or interrupted single suturing. The flaps reached from $_2P_2$ to $_1M_1$ and were divided into three interproximal and two mid-buccal sites for analysis of intercapillary and vascular diffusion extent. It was realized that the sole act of flap elevation initiated substantial and significant vascular trauma. Significant reduction in flap circulation in relation to the presurgical baseline lasted for at least 3 days in the mid-buccal sites, but persisted for 7 days at the interproximal sites, independent of the applied suture techniques. This is an important finding and might have an impact on the decision regarding the ideal flap outline when dealing with implant placements or retreatments in the upper anterior zone where there is no collateral vascularity from the periodontal ligament.

Another factor influencing the vascularity of a flap is its length, especially when the flap is replaced on an avascular surface like a root or the alloplastic material of an implant or its components. Several studies confirm a decrease of the flap vascularity with increasing flap length (Mörmann & Ciancio

1977; McLean *et al*. 1995). Interestingly, in studies of the early healing stages, significantly greater portions of the flaps took up fluorescence from extravascular diffusion compared to from intracapillary circulation. While it is certainly prudent to avoid long pedicle flaps in implant surgery, other flap properties like thickness and alternate vascular sources deserve recognition.

Based on reliable knowledge of the distribution pattern and architecture of the arterial vascular system of the human oral mucosa, recommendations for ideal flap preparation and releasing incisions can be given (Kleinheinz *et al*. 2005): (1) avoid releasing incisions in the zone of esthetic priority; (2) place mid-crestal incisions in edentulous areas; (3) incise in the sulcular area around teeth and avoid marginal and paramarginal incisions; (4) if a releasing incision is required, cut the flap as short as possible and carry it out at the anterior border of the incision line (Fig. 54-14). The releasing incisions should not be placed on the buccal root prominences as there the mucosa is thicker between two teeth (Müller *et al*. 2000). Incision lines in the concavity between two teeth facilitate a firm flap adaptation and provide a better vascular network within the pedicle flap.

Implant placement in the zone of esthetic priority is often combined with GBR procedures and soft tissue augmentations to compensate for the lost tissue volumes and to restore the morphology of the implant housing in all three dimensions. To achieve a healing on primary intention, the soft tissue flaps must be mobilized to completely cover the augmented sites. Such flap advancement is limited and also has some adverse effects. The common method of flap lengthening consists of a periosteal incision at the base of the buccal flap. This technique releases the flap tension as the connective tissues of the lining mucosa contain elastic fibers. After cutting the dense collagen fibers of the periosteum, lining mucosa can be stretched, whereas the masticatory mucosa is almost inelastic. The extent of flap lengthening depends on the outline of the flap and has been evaluated in a recent cohort study (Park *et al*. 2012). Simply by placing one vertical releasing incision and pulling with a tension of 5 g, the flap could be mobilized by 1.1 ± 0.6 mm, which corresponds to 113.4% of its original length. These values increased to 1.9 ± 1.0 mm (124.2%) when a second vertical incision was made at the opposite end of the horizontal incision and became statistically highly significant after combining the two vertical releasing incisions with a periosteal releasing incision, yielding a flap advancement of 5.5 ± 1.5 mm (171.3%).

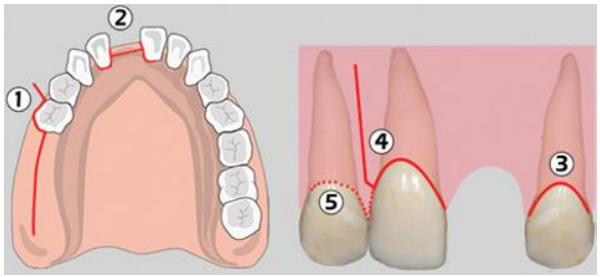

Fig. 54-14 Incision designs: 1, buccal releasing incisions just when needed, as long as necessary and as short as possible; 2, avoid releasing incisions in the zone of esthetic importance, open flap by crestal incisions; 3, incise sulcularly and precisely follow the soft tissue contour; 4, when using releasing incisions, place them besides the root prominences and start right-angled to the soft tissue margins (without coronal displacement); 5, for coronal advancements (dotted line), prepare a full papilla flap and not a papilla preservation flap.

The above-mentioned surgical technique facilitates primary wound closure but also has disadvantages. The masticatory mucosa will be coronally displaced to the crest and leave the buccal area of the implant covered by a zone of mobile, much thinner lining mucosa, which is more prone to soft tissue dehiscence formation (Bengazi *et al.* 1996). Additionally, the irregularity of the mucogingival junction can cause an esthetic problem in high lip line cases when a broad zone of soft tissues is displayed apical of the mucosal margin. In these cases, alternative surgical modalities have to be considered when flap advancement is required for primary wound closure.

As an optional surgical procedure, a free connective tissue graft may be placed on the crest at the reunion of the flap margins. If primary wound closure cannot be achieved, the graft will heal at secondary intention and protect the underlying bone or augmented area (Kan *et al.* 2009; Stimmelmayr *et al*. 2010), although there is only limited weak evidence in the literature that soft tissue grafts are effective in increasing mucosal thickness and improving the esthetic outcome (Esposito *et al*. 2012).

The soft tissue covering of the hard palate consists of masticatory mucosa which is rich in collagen fibers and, therefore, cannot be mobilized with just a U-shaped flap. More sophisticated flap designs are required, such as laterally positioned flaps (Nemcovsky *et al*. 1999; Peñarrocha *et al*. 2005) that are prepared in vertical layers such that the deeper portion, pedicled at the base, can be rotated to cover the denuded area. Similar plastic surgical procedures, based on horizontal flap advancement, are likewise appropriate for primary soft tissue closure in the esthetic zone without displacement of the mucogingival junction (Tinti & Parma-Benfenati 1995; Triaca *et al*. 2001).

Dealing with implants in the esthetic zone is considered to be an advanced or even complex procedure in dentistry and there are many different aspects to the pretreatment planning phase as well as the surgical and prosthetic execution (Devigus 2006). One often neglected aspect is scar formation. Compared to the healing of skin wounds, the oral mucosa is less prone to scar formation due to its different inflammatory cell infiltrate with lower levels of macrophages, neutrophils, T-cell infiltration, and the profibrotic cytokine transforming growth factor-beta 1 (TGF-β1) (Coleman *et al*. 1998; Szpaderska *et al*.

2003). Nevertheless, other factors such as flap tension and the precision of flap margin adaptation influence the extent of scar formation (Burgess *et al*. 1990; Nedelec *et al*. 2000) and each incision in the buccal mucosa of the anterior area of the upper jaw will increase the risk for an adverse esthetic outcome. The importance of masticatory mucosa around implants has raised controversy in the literature and there is only a low level of evidence that a lack of masticatory mucosa has a negative effect on the success rates and esthetic results of implant restorations (Cairo *et al*. 2008; Wennström & Derks 2012). Subjective observations by the authors and feedback from treated patients have suggested that it is beneficial to have a sufficient zone of masticatory mucosa around the implants to sculpt and form a scalloped marginal contour of the soft tissues, with a natural appearing surface texture and morphology, which also influence patient perception (Chang *et al.* 1999b). In a recent systematic review searching for evidence for the best surgical techniques to augment the masticatory mucosa around implants, the vestibuloplasty and apically repositioned flap ranked highest (Thoma *et al*. 2009). However, caution needs to be exercised in adopting this approach because an increase of the width of the masticatory mucosa does not guarantee an improvement of the esthetic result, and as an apically positioned flap always requires releasing incisions, scar formation and unfavorable mucosal textures may hamper the esthetic appearance. Therefore, from the start of implant treatment, the aim should be preservation of the masticatory mucosa and careful evaluation of all the surgical options based on the relevant factors which influence the biologic, functional, and esthetic outcome.

Clinical concepts for a single missing tooth

Before each implant placement in the anterior area of the upper jaw, a comprehensive presurgical risk analysis of a given maxillary anterior single-tooth gap has to be carried out. An increasing body of evidence indicates that the best parameter for achieving an esthetic single-tooth restoration is the interproximal bone height at the level of the teeth confining the edentulous gap (Tarnow *et al*. 1992; Choquet *et al*. 2001). The related bone should be within a physiologic distance (i.e. approximately 2 mm) of the CEJ and thus provide the essential support for the overlying soft tissue compartments. Consequently, preoperative diagnosis will include interproximal radiographic bone height assessment and periodontal probing of the soft tissue attachment level. If a case presents missing interproximal bone (Fig. 54-15a, b), alternative conventional prosthetic solutions need to be taken into consideration. In this particular case of a 38-year-old woman, a zirconia adhesive bridge was inserted after alveolar ridge augmentation procedures (Fig. 54-15c, d).

Sites with no or minor tissue deficiencies

If the risk analysis confirms a favorable vertical level of both soft tissue and underlying alveolar bone at the interproximal aspect of the two adjacent teeth on the one hand, and no major vestibular bone deficiencies on the other hand, the site can be considered appropriate for a straightforward implant surgical protocol. In order to ensure the best chance of a successful and long-lasting esthetic treatment outcome, the implant placement has to be carried out meticulously with attention to the key parameters such as low-trauma surgical principles in general and precise three-dimensional ("restoration-driven") implant positioning in particular (Fig. 54-16).

Sites with extended or severe tissue deficiencies

The risk analysis of a 23-year-old woman revealed a demanding clinical situation with missing buccal bone and a buccal probing pocket depth of 11 mm at the left central incisor (Fig. 54-17a, b). The radiographic analysis demonstrated intact mesial and distal crestal bone levels (Fig. 54-17c). This is an important prerequisite to maintaining the interdental soft tissue level. Based on the clinical and radiographic findings, the diagnosis was a vertical root fracture of tooth 21. After the patient had been informed of the diagnosis and the therapeutic options discussed, it was decided to extract the tooth and to replace it with an implant-supported single crown.

Due to the extended buccal bone defect, it was decided to perform a socket preservation technique to improve the soft tissue quality and quantity before implant placement and bone augmentation procedure (Fig. 54-18).

In this case of extended horizontal alveolar bone crest deficiencies, a simultaneous implant placement and lateral bone augmentation procedure is technically more difficult and less predictable, as the ultimate goal remains optimal "restoration-driven" implant positioning. Therefore, the feasibility of combining implant placement with a simultaneous bone regeneration procedure was evaluated by performing preoperative diagnostics and a CBCT scan. The CBCT revealed an extended buccal bone defect with a minimal amount of apical bone to stabilize the implant (Fig. 54-19).

After three-dimensional computer-assisted implant planning, a computer-guided template was fabricated within the dental laboratory. After a healing period of 6 weeks following tooth extraction, a mucoperiostal flap was elevated. This was achieved with a palatal crestal incision followed by sulcular incisions and a vertical releasing incision distal 22 (Fig. 54-20a). With the help of the computer-guided stent, it was possible to place the implant in the proper prosthetic position (Fig. 54-20b–f). Due to the complete loss of the buccal bone, a volume of stable

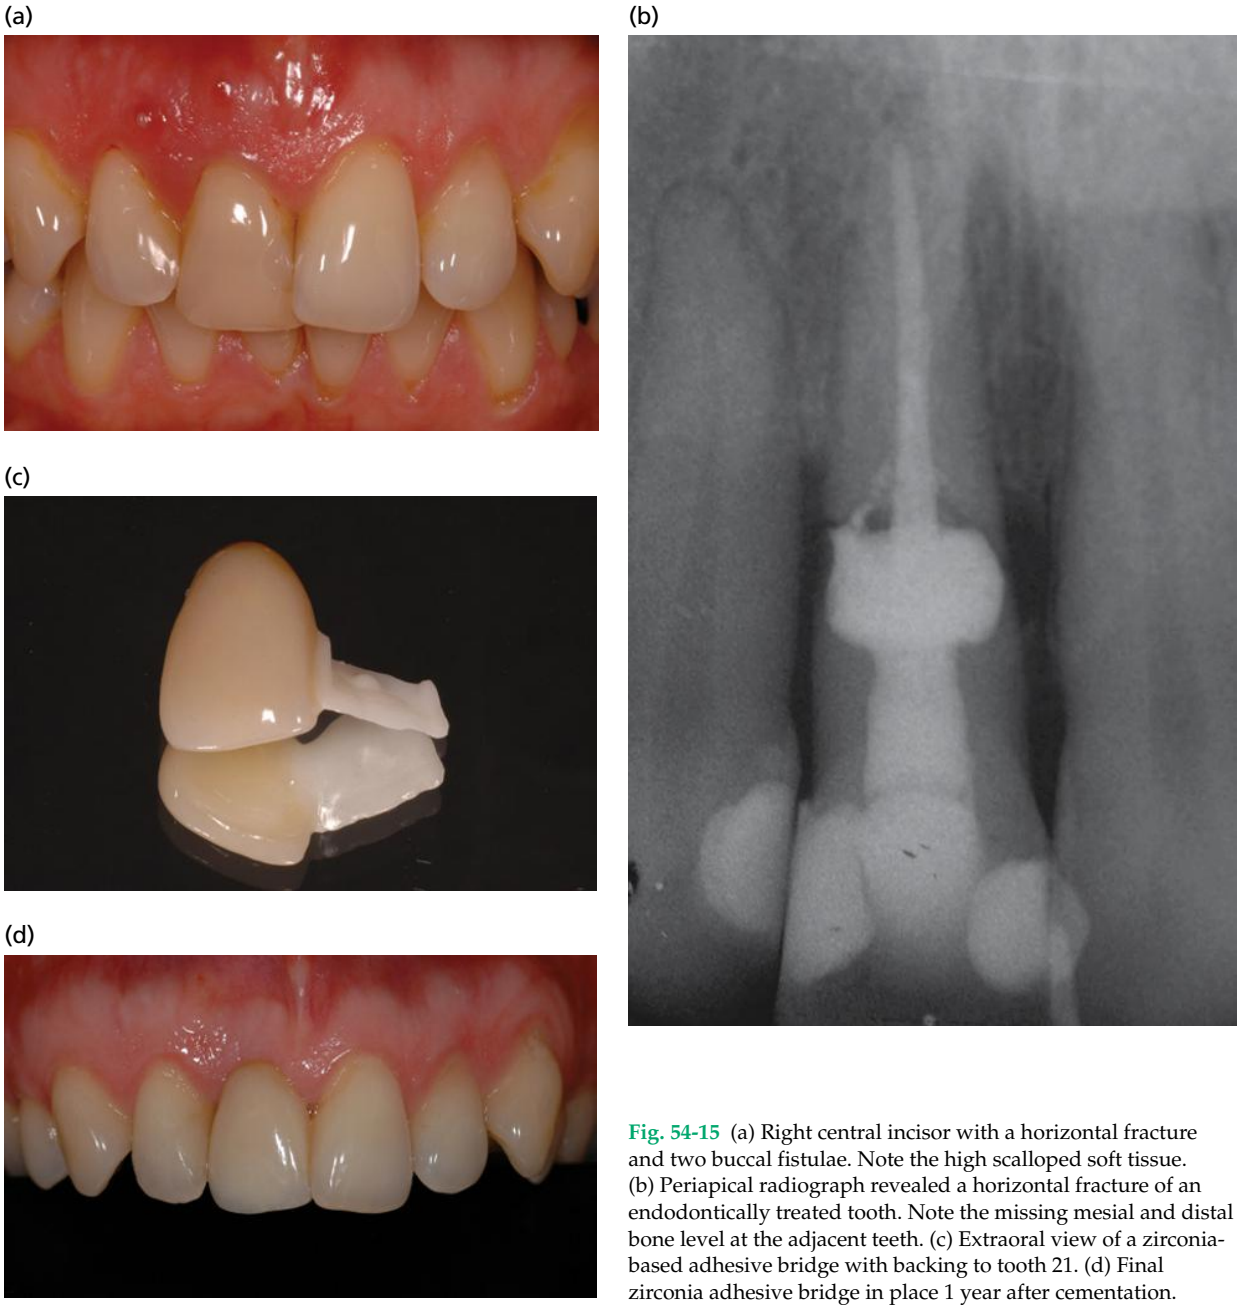

Fig. 54-15 (a) Right central incisor with a horizontal fracture and two buccal fistulae. Note the high scalloped soft tissue. (b) Periapical radiograph revealed a horizontal fracture of an endodontically treated tooth. Note the missing mesial and distal bone level at the adjacent teeth. (c) Extraoral view of a zirconia-based adhesive bridge with backing to tooth 21. (d) Final zirconia adhesive bridge in place 1 year after cementation.

non-bioresorbable membrane was chosen. After grafting the site with autogenous bone particles and demineralized bovine bone mineral (DBBM), a titanium-reinforced expanded polytetrafluoroethylene (ePTFE) membrane was applied to the defect morphology and adapted with titanium pins (Fig. 54-20g–i). Subsequently, the periosteum was released to achieve a completely passive soft tissue closure (Fig. 54-20j). After a healing period of 6 months, a full-thickness flap was elevated again in order to remove the non-bioresorbable membrane and the titanium pins (Fig. 54-20k–m). In addition, a connective tissue graft harvested from the palate was placed underneath the flap in order to increase the soft tissue volume (Fig. 54-20n). Six weeks later, a minimally invasive abutment connection was performed using a U-form incision and rotation of this flap to the buccal site (Fig. 54-20o–r). At the same time as the abutment connection, an impression was taken on the level of the implant shoulder (Fig. 54-20s). The screw-retained implant-borne provisional crown was used for diagnostic purposes and to form the emergence profile. After reaching the final soft tissue contour, a definitive individual impression was taken in order to capture the information from the temporary restoration (Fig. 54-21t, u). In this way, the clinical situation was transferred to the master cast, which contains a replica (analog) of the implant. This master cast was subsequently scanned in order to produce an individual zirconia abutment by means of a CAD/CAM procedure (Fig. 54-20v). By directly veneering this zirconia abutment, it was possible to provide the patient with a natural looking screw-retained all-ceramic crown (Fig. 54-20w, x).

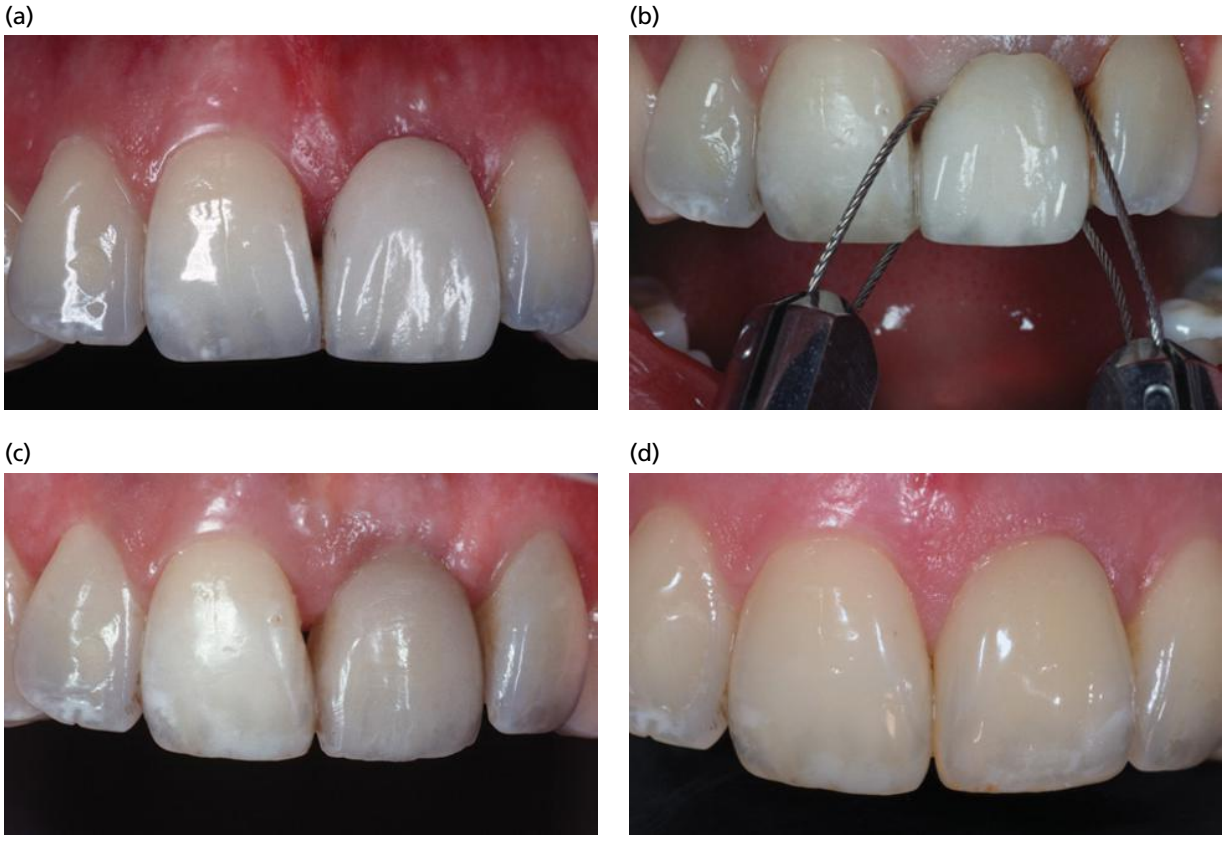

Fig. 54-16 (a) Adhesive bridge, fixed on both neighboring teeth, repeatedly lost its retention on tooth 22 after 7 years of loading. (b) Removal of the bridge after grinding the palatal attachment on tooth 11. (c) Intact, healed ridge without volume deficiencies allowed implant placement in a prosthetically correct position. Situation after provisionalization. (d) Final full-ceramic crown on a zirconia abutment and composite adjustments on a contralateral central incisor.

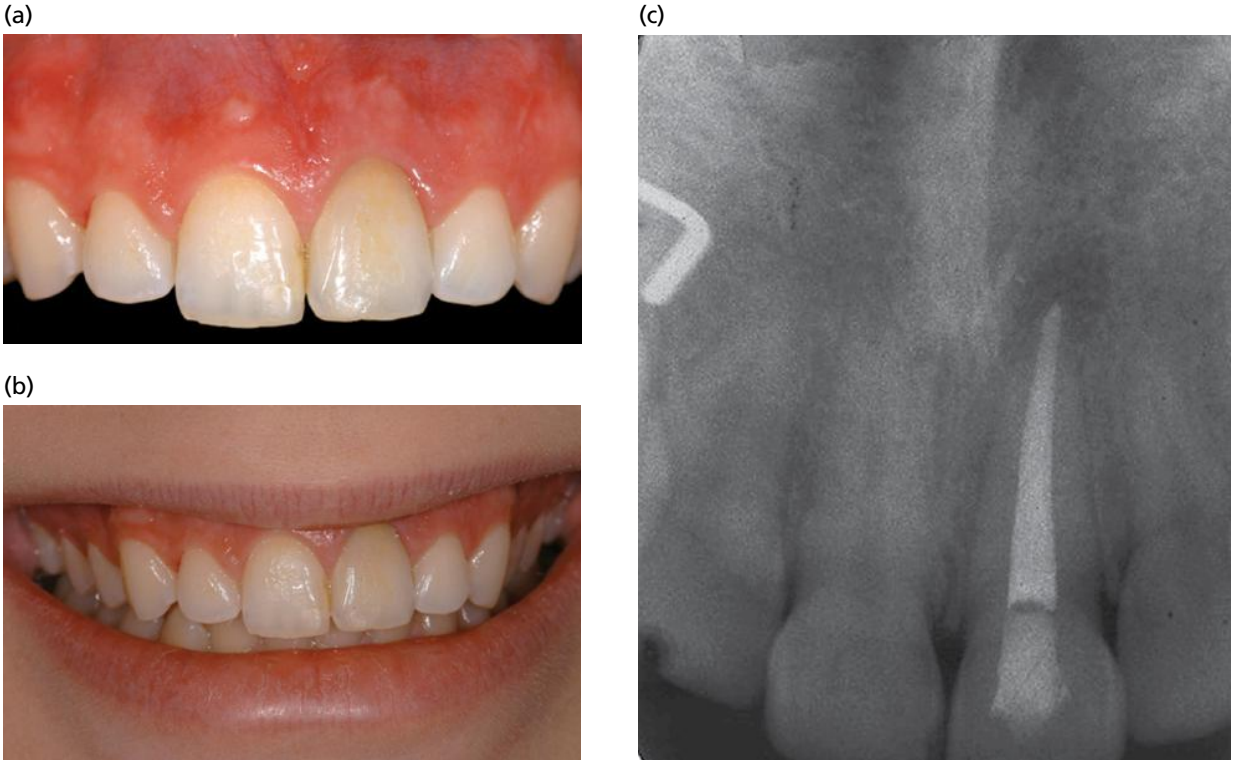

Fig. 54-17 (a) Preoperative view of a 23-year-old woman. Left central incisor shows slight discoloration and apical migration of the gingival margin. (b) Smile line was considered to be high and also the patient had high esthetic expectations. (c) Radiographic analysis revealed an endodontically treated incisor and an apical radiolucency. Mesial and distal bone levels were intact.

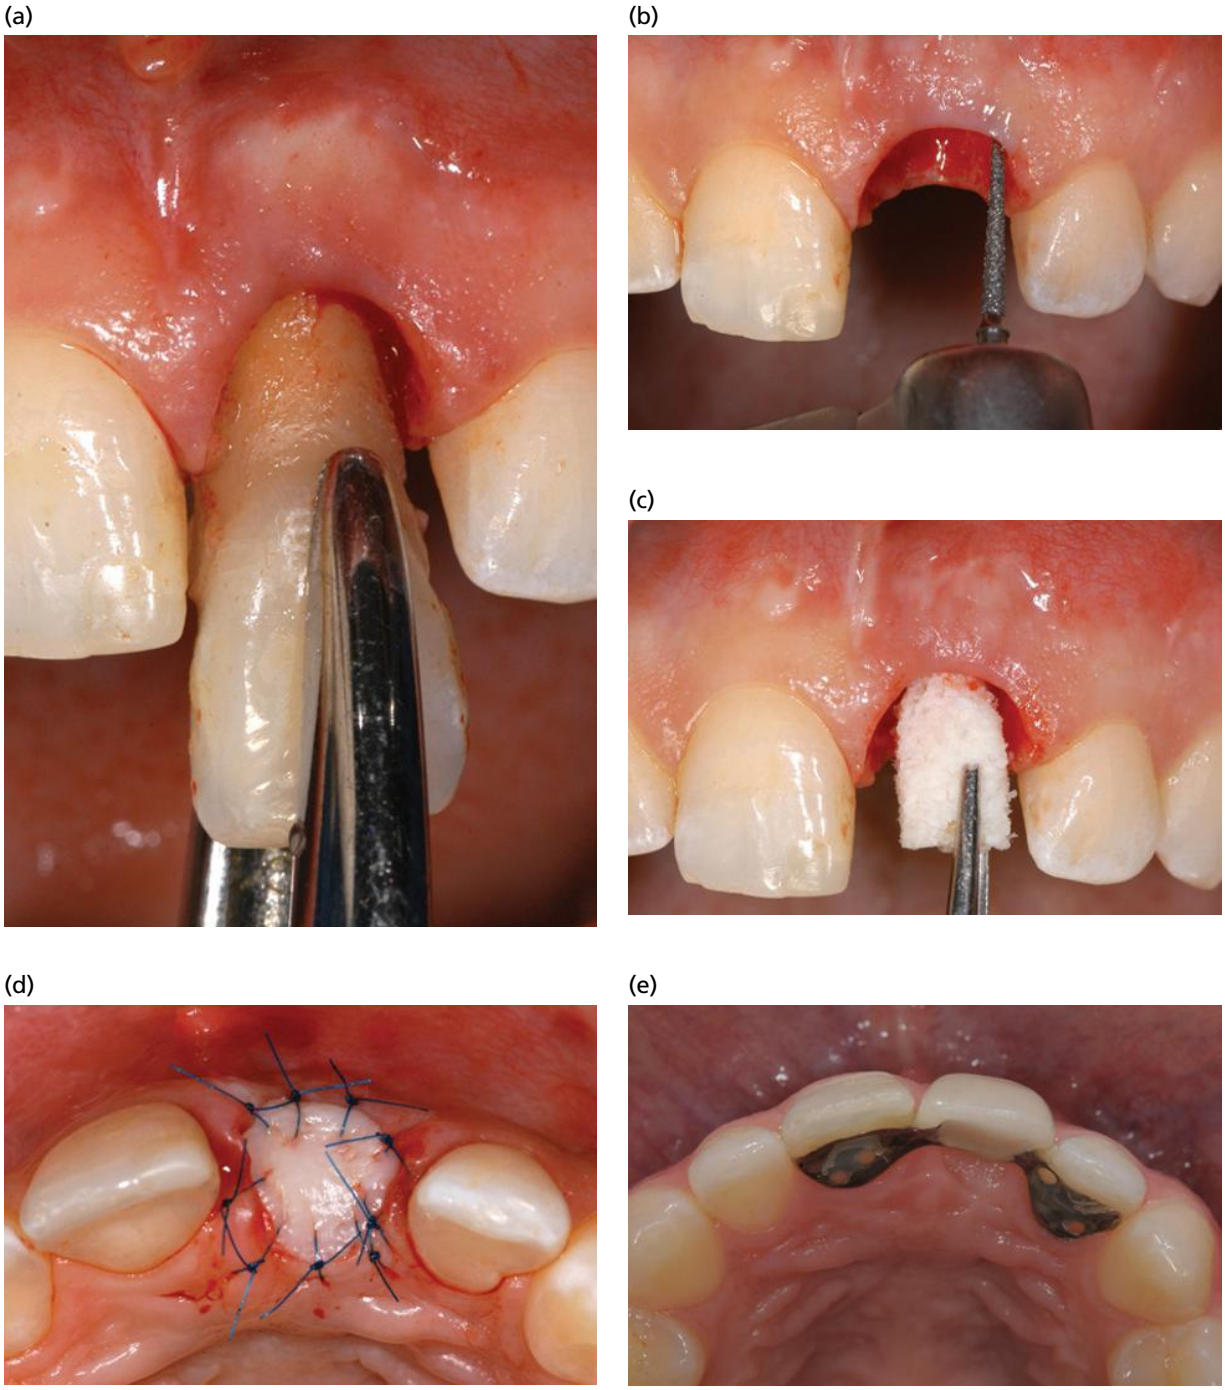

Fig. 54-18 Same patient as in Fig. 54-17. (a) Flapless and minimally-traumatic extraction was performed and followed by a socket preservation technique using deproteinized bovine bone mineral with 10% of collagen (DBBM-Coll) and a free mucosal graft. The main objective of this technique was to maintain soft tissue contour. (b) Internal epithelium of the socket was carefully removed using a diamond bur to promote bleeding and improve graft healing. (c) DBBM-Coll was shaped according to the root anatomy and placed into the socket. (d) After harvesting a free mucosal graft from the palate using a biopsy punch, the graft was carefully sutured and stabilized with 7/0 monofilament sutures. (e) Provisionalization with a temporary adhesive bridge (Maryland type).

Clinical concepts for multiple missing teeth

The normal consequence following the loss of two or more adjacent upper anterior teeth is a flattening of the edentulous segment. In particular, the disappearance, in an apical direction, of the crestal bone originally located between the incisor teeth can be observed. This phenomenon is not, or only minimally, present at the interproximal aspect of the remaining anterior teeth and thus explains the fundamental difference between a maxillary anterior single-tooth gap and a multiunit edentulous segment.

If two standard screw-type titanium implants are inserted to replace two missing maxillary central incisors (Fig. 54-21), an additional peri-implant bone remodeling process will take place. In the frontal plane, two different characteristic processes, one between the tooth and implant and the other between the two implants, can be distinguished. At the site

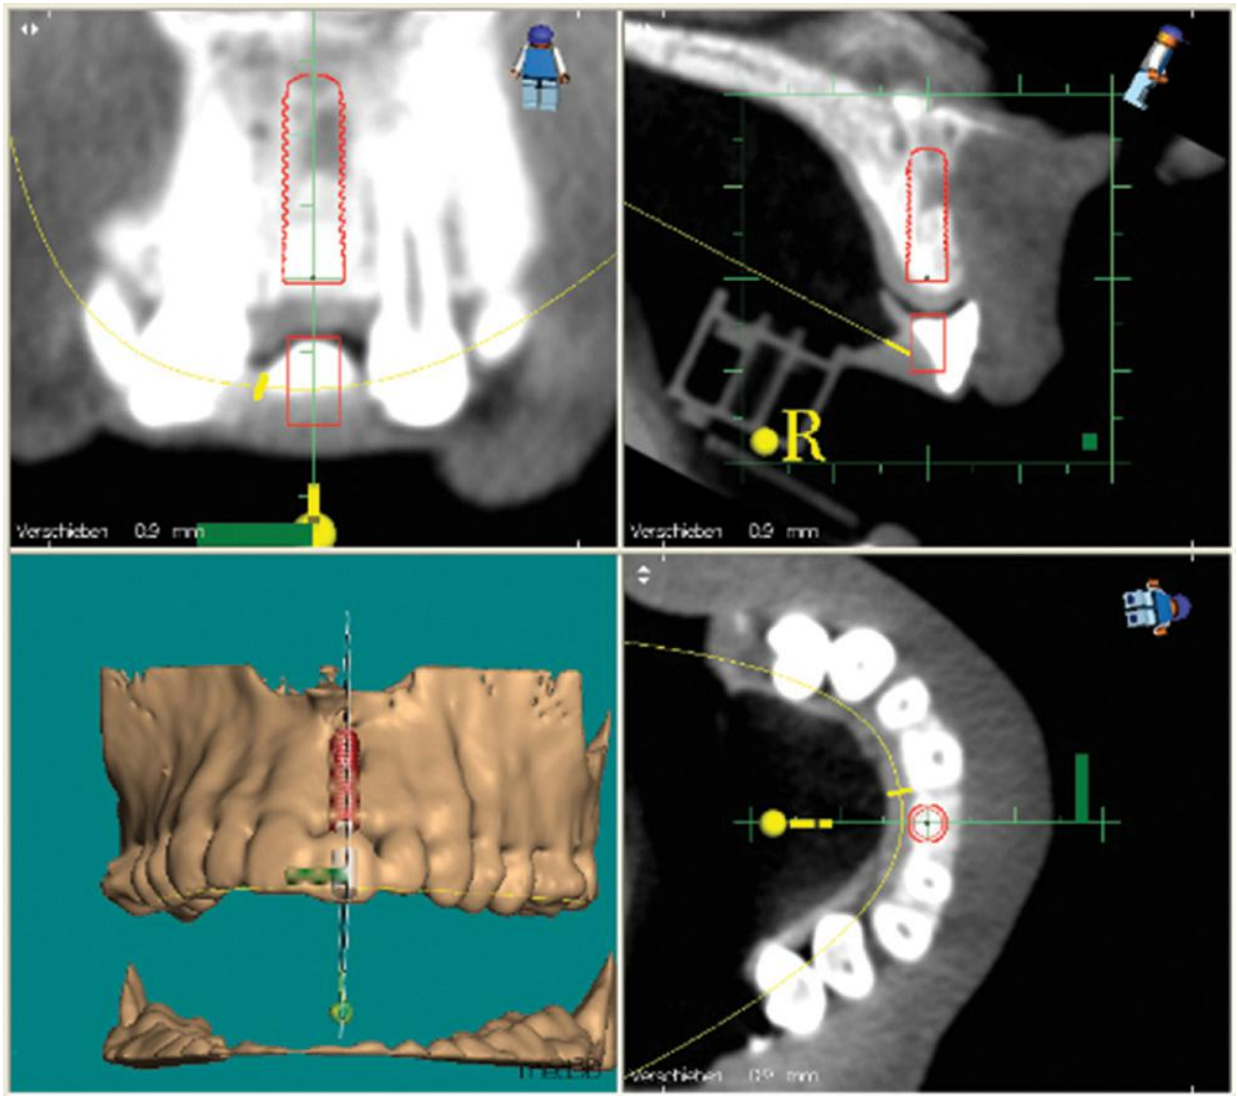

Fig. 54-19 Same patient as in Figs. 54-17 and 54-18. CBCT was obtained using a scanning template with barium sulfate ($BaSO_4$) teeth according to the previously performed wax-up. The ideal implant position was established using a 3D planning software and a surgical guide was fabricated.

between the tooth and implant, the tooth-sided interproximal bone height should theoretically remain at its original location, that is within 2 mm of the CEJ, from where the implant-sided interproximal bone height drops in an oblique manner towards the first implant-to-bone contact, normally located approximately 2 mm apical of the junction ("microgap") between the implant shoulder and the abutment or suprastructure. This phenomenon has been referred to in the literature as the establishment of a "biologic width" (Hermann *et al*. 1997, 2000, 2001a, 2001b). In contrast, the interimplant bone height normally decreases further in an apical direction, once the respective abutments or suprastructures are connected to the implant shoulder. This process is mostly accompanied by a loss of interimplant soft tissue height and hence may lead to unsightly, so-called "black interdental triangles". The schematic close-up views comparing the original dentate situation with the status after integration of two adjacent implant restorations, clearly demonstrate the negative consequences on the course of the marginal soft tissue line in a case of multiple adjacent maxillary anterior implants (Fig. 54-22).

For all of the above-mentioned reasons, the implant position and distribution in cases with multiple missing teeth in the area of esthetic priority are of great importance. With two missing central incisors, two implants will need to be placed with sufficient space between them. In cases of a missing central and a missing lateral incisor, it is preferable that only one implant at the position of the central incisor is placed, with a cantilever replacing the lateral incisor. Due to the small diameter of a lateral incisor, the mesiodistal dimension often does not allow two implants to be placed with sufficient interimplant distances. In the clinical situation of three missing incisors, including teeth 11, 21, and 22, it is recommended to place two implants. One option is to place two implants at positions 11 and 22 in order to have sufficient space

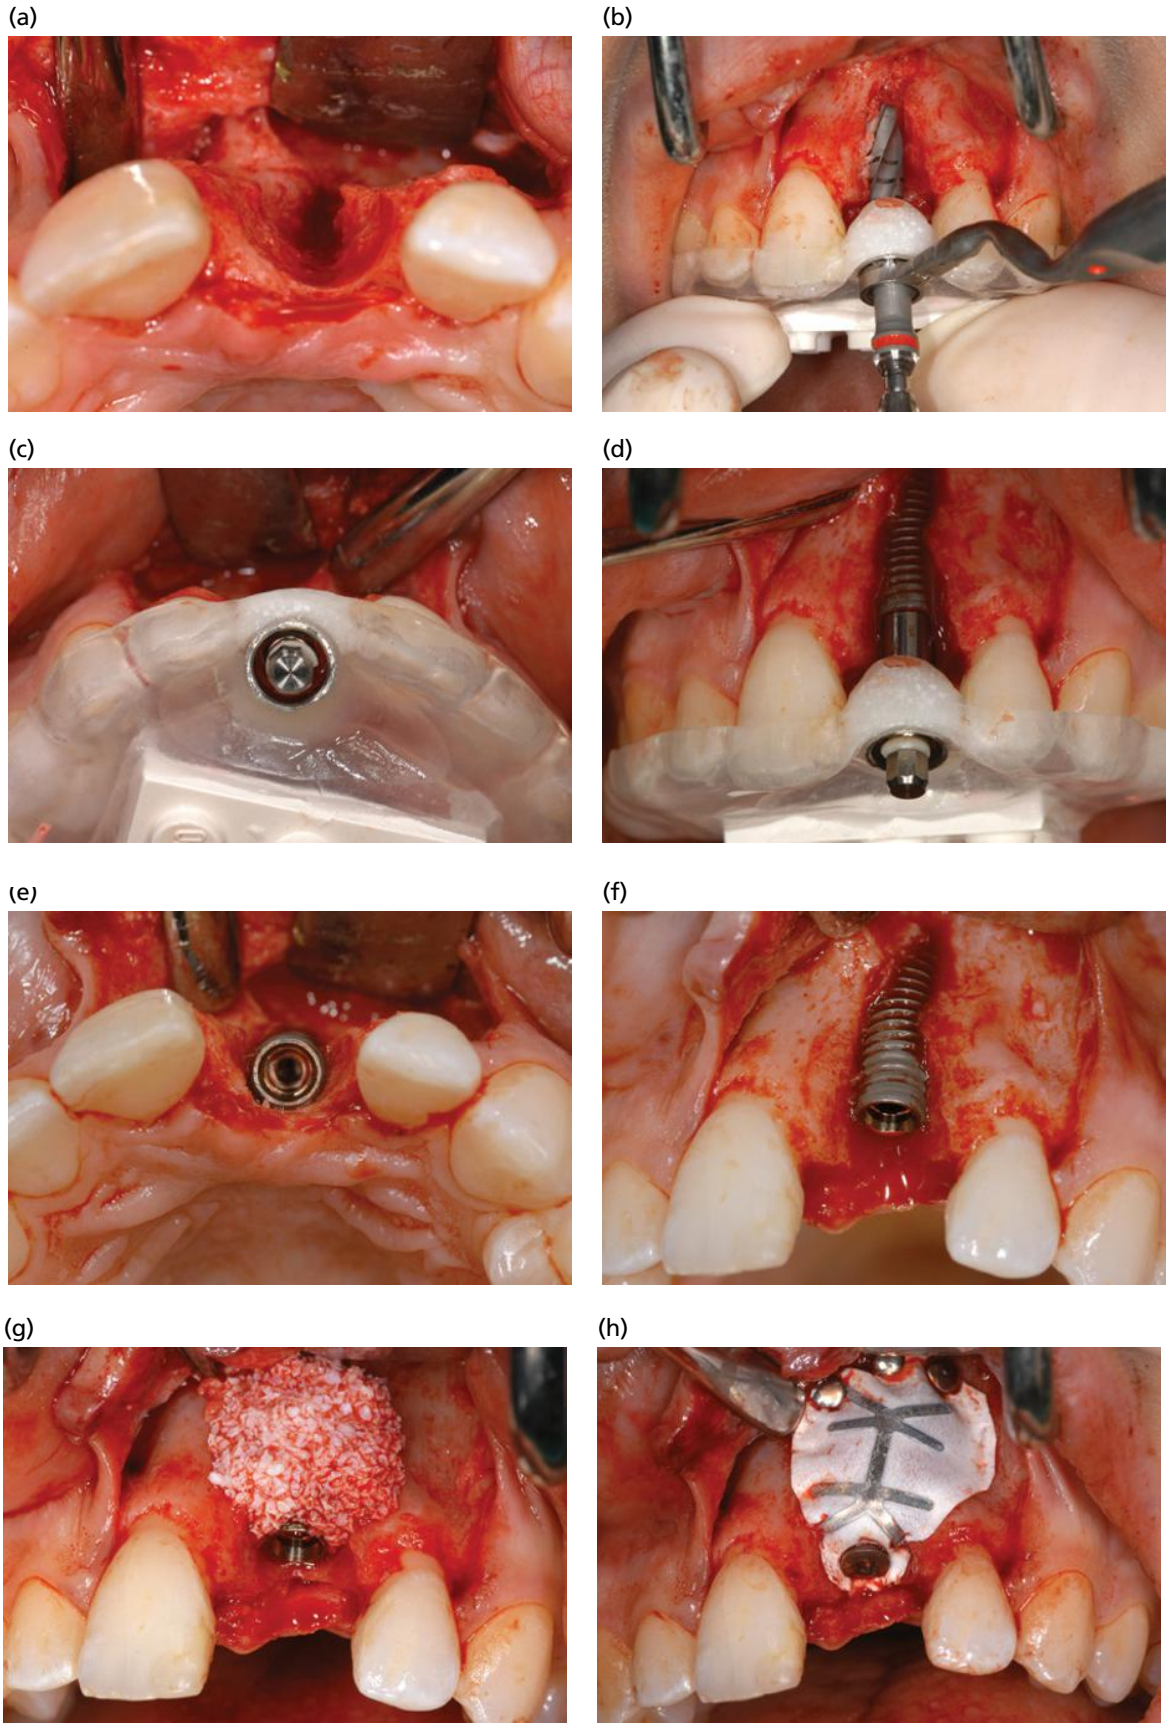

Fig. 54-20 Same patient as in Figs. 54-17, 54-18, and 54-19. (a) Six weeks after tooth extraction, a mucoperiosteal flap was elevated with distal vertical releasing incisions. The graft material that had been used to stabilize the soft tissue contour was removed before implant placement and further guided bone regeneration (GBR) procedures. Note the horizontal defect with a complete loss of the buccal wall. (b) Guided implant drilling was performed based on the CBCT and implant planning software helped to stabilize the drills during the preparation process. (c) Guided implant placement led to an ideal prosthetic implant position. (d) Ideal vertical position was achieved by placing the implant shoulder of a bone level type of implant approximately 3 mm below the mucosal margin of the prospective restoration. Note the expected dehiscence defect along the buccal wall. (e) Occlusal view of the implant in place. Note the non–self-containing buccal osseous defect, which limits the GBR options. (f) Buccal view of the bone level implant in place. Note the expected buccal dehiscence affecting almost the entire length of the implant. Primary stability was achieved thanks to the apical and palatal anchorage. (g) After placement of autogenous bone particles, harvested from the neighboring area, an additional layer of deproteinized bovine bone mineral (DBBM) was added on top of the implant in order to recreate the missing contour. (h) Due to the non–self-containing osseous defect, a volume of stable non-bioresorbable titanium-reinforced e-PTFE membrane was used in combination with titanium fixation pins. Additionally, the implant cover screw was used to stabilize the membrane.

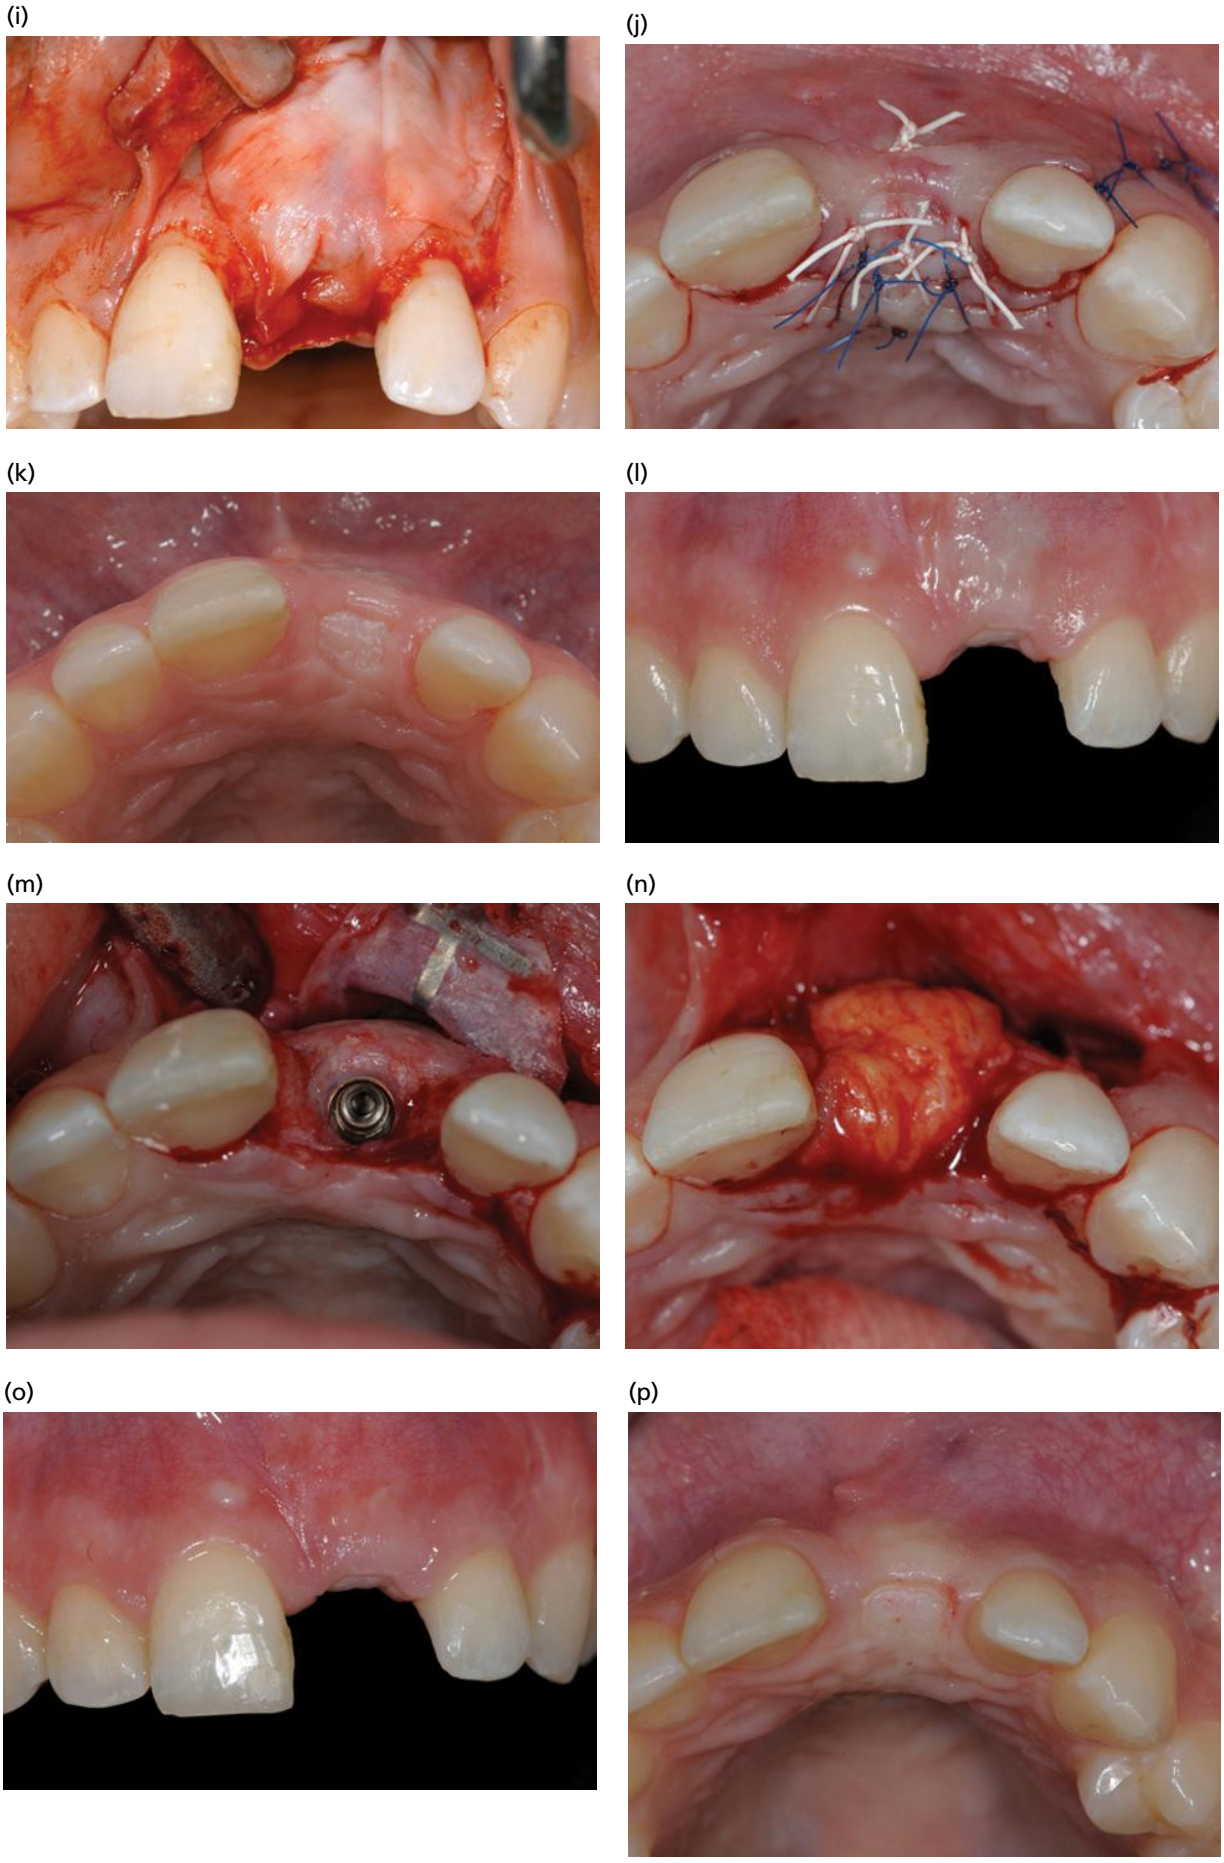

Fig. 54-20 (*Continued*) (i) Primary healing is crucial for GBR success. Accordingly, a collagen bioresorbable membrane was used to cover the e-PTFE non-bioresorbable membrane and decrease the risk of membrane exposure. (j) After a periosteal releasing incision, horizontal mattress sutures (5/0 e-PTFE) were used to approximate the wound borders and decrease flap tension. Further single interrupted sutures were used to close the wound. (k, l) Occlusal and buccal views after a healing period of 6 months. Note the maintained buccal ridge contour. (m) Full thickness flap was raised in order to remove the volume of stable e-PTFE non-bioresorbable membrane. The implant was completely covered by bone and the buccal contour was recreated. (n) Additionally, a connective tissue graft, harvested from the palate, was placed to augment both the occlusal and buccal aspects of the ridge. It was first sutured to the palate and then mobilized to the buccal site. (o, p) Occlusal and buccal views 6 weeks after completion of healing.

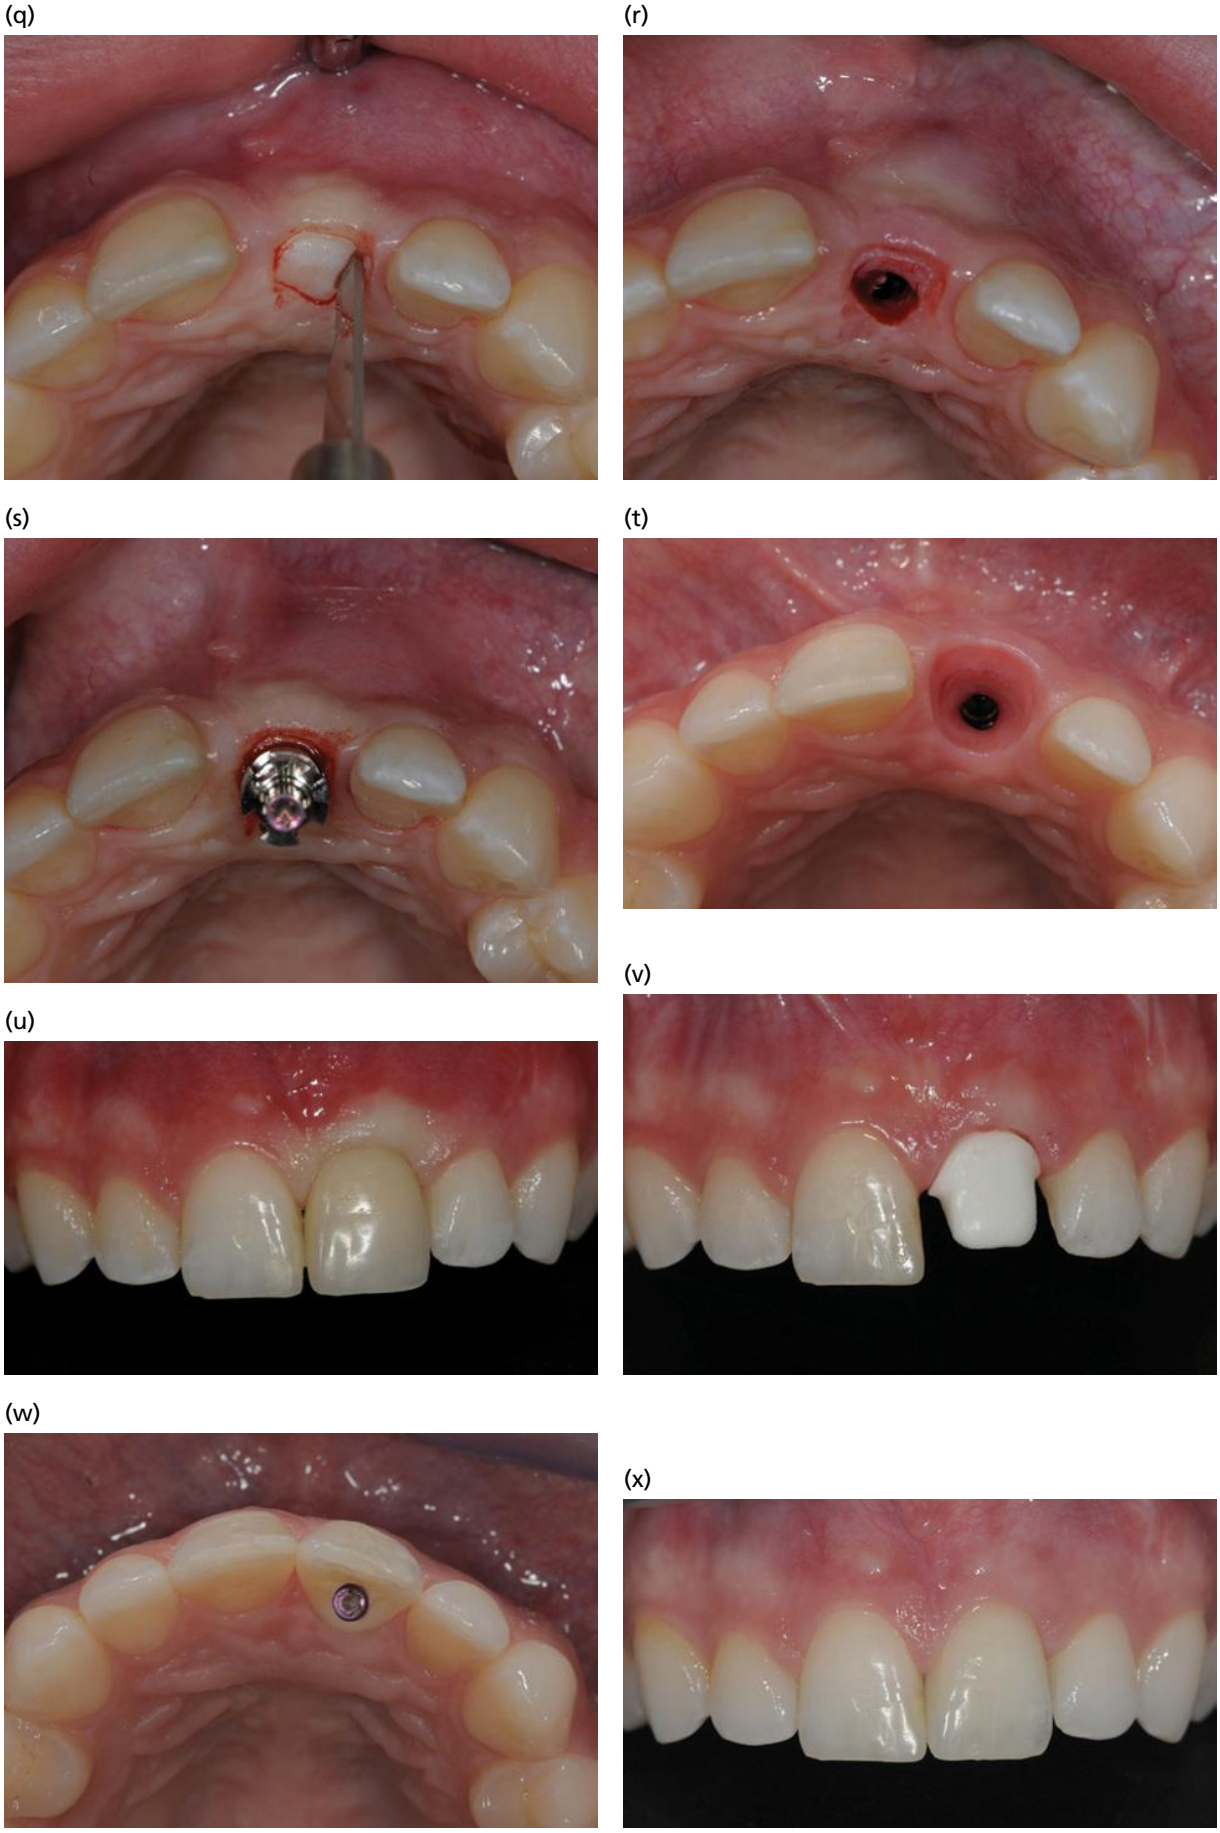

Fig. 54-20 (*Continued*) (q) Minimally invasive abutment connection was performed using a U-form incision technique. (r) Flap was then rotated to the buccal site. (s) Simultaneously, an impression was taken at the level of the implant shoulder and sent to the laboratory to fabricate a screw-retained acrylic provisional. (t) Progressive modifications of the provisional led to a buccal displacement of the soft tissues, and adequate emergence profile and gingival margins. (u) Wax-up try-in. (v) An individualized CAD/CAM zirconia abutment was designed. (w) Occlusal view of the final screw-retained restoration. Note the ideal position of the access hole for the prosthetic screw. (x) Final restoration was fabricated by direct ceramic veneering of the zirconia abutment. Note the symmetry between the soft tissue margin and contour, compared to the right central incisor.

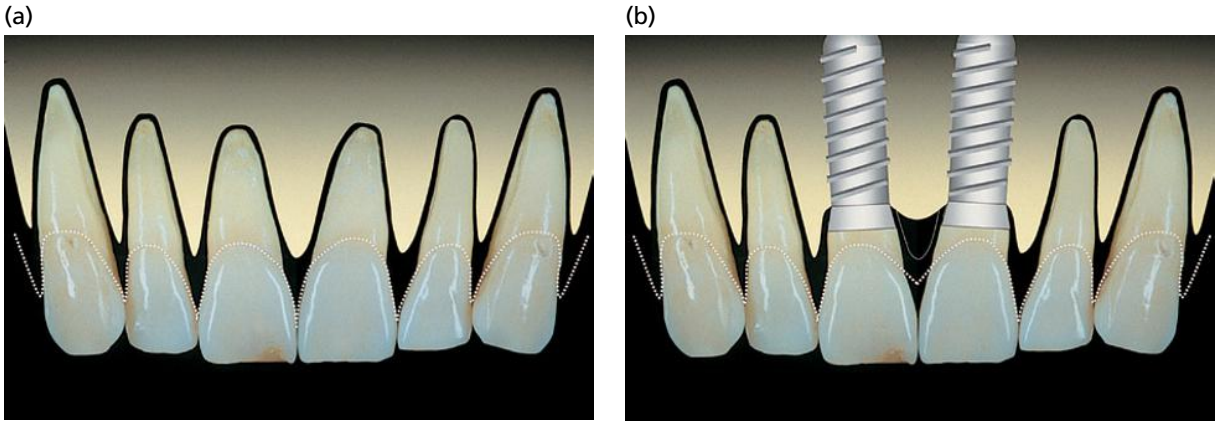

Fig. 54-21 (a) Schematic representation of the six maxillary anterior teeth, including their bony support and the course of the marginal soft tissue, corresponding ideally approximately to the cementoenamel junction (dotted line). (b) Loss of the two central incisors and their subsequent replacement by implant restorations normally leads to well-defined bone loss ("micro-gap", establishment of a "biologic width") around the implant sites. The main consequence from an esthetic point of view is vertical soft tissue deficiencies, namely between the adjacent implants (dotted lines).

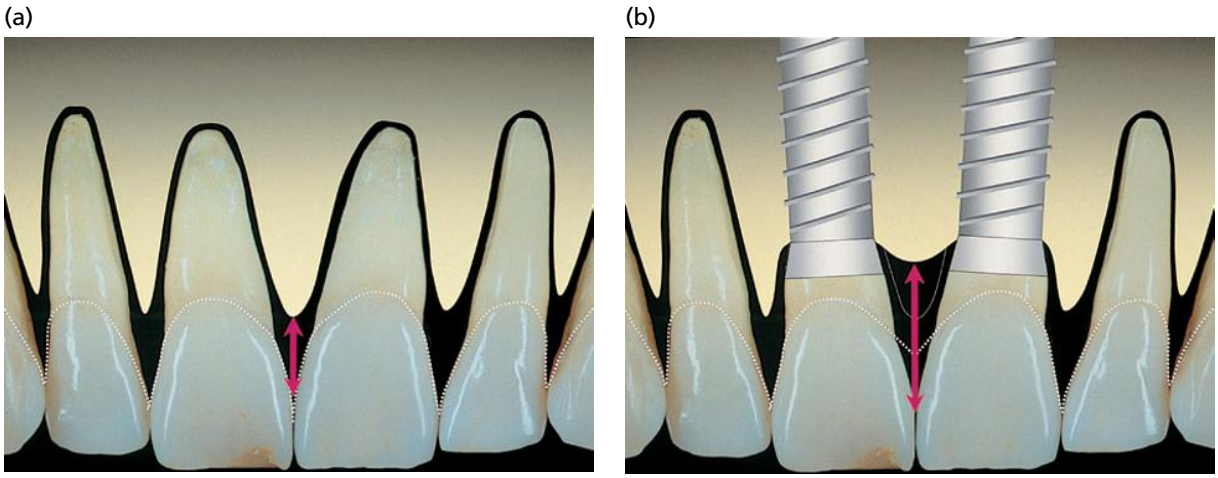

Fig. 54-22 (a) Schematic close-up view of the relationship between the cementoenamel junction, alveolar bone, and gingiva in the maxillary incisor area. (b) Same area after implant therapy. The arrow represents the distance between the interimplant bone crest and the interdental contact point. The lack of bony support for the interdental soft tissue often causes the appearance of black triangles, compromising the esthetic treatment outcome.

between the implants. The drawback of this option is the difficulty with creating a similar appearance of the emergence profile of an implant restoration (implant 11) and a pontic at position 21 with a prosthesis. Alternatively, if there is a sufficient mesiodistal dimension in the area of the two missing central incisors, one implant can be placed at position 11 and the other at position 21 with a cantilever to replace tooth 22. With this second option, two identical emergence profiles can be created, but has the drawback of having two implants next to each other. When all four incisors are lost, generally two implants are placed at the position of the two lateral incisors. This concept might also apply to the use of reduced diameter implants at positions 12 and 22.

Sites with minor tissue deficiencies

In cases with minor tissue deficiencies, the previously described shortcomings are also inherent in multiple adjacent implant restorations. Therefore, some restorative "tricks", including peri-implant soft tissue conditioning and a particular interproximal crown design, need to be implemented to predictably achieve an acceptable esthetic compromise.

The initial prosthetic planning, the implant surgery, and the prosthetic reconstruction for a 54-year-old man who in an accident had lost three incisors and one pontic at the position of tooth 21 are shown in Figs. 54-23, 54-24, and 54-25, respectively.

Sites with extended tissue deficiencies

A 55-year-old female patient presented a left central and a lateral incisor with periapical pathologies and insufficient tooth substance to maintain these teeth as abutments for conventional crowns. After careful evaluation from an endodontic and a prosthetic point of view, both teeth were judged to be hopeless and were scheduled for extraction. A missing central and

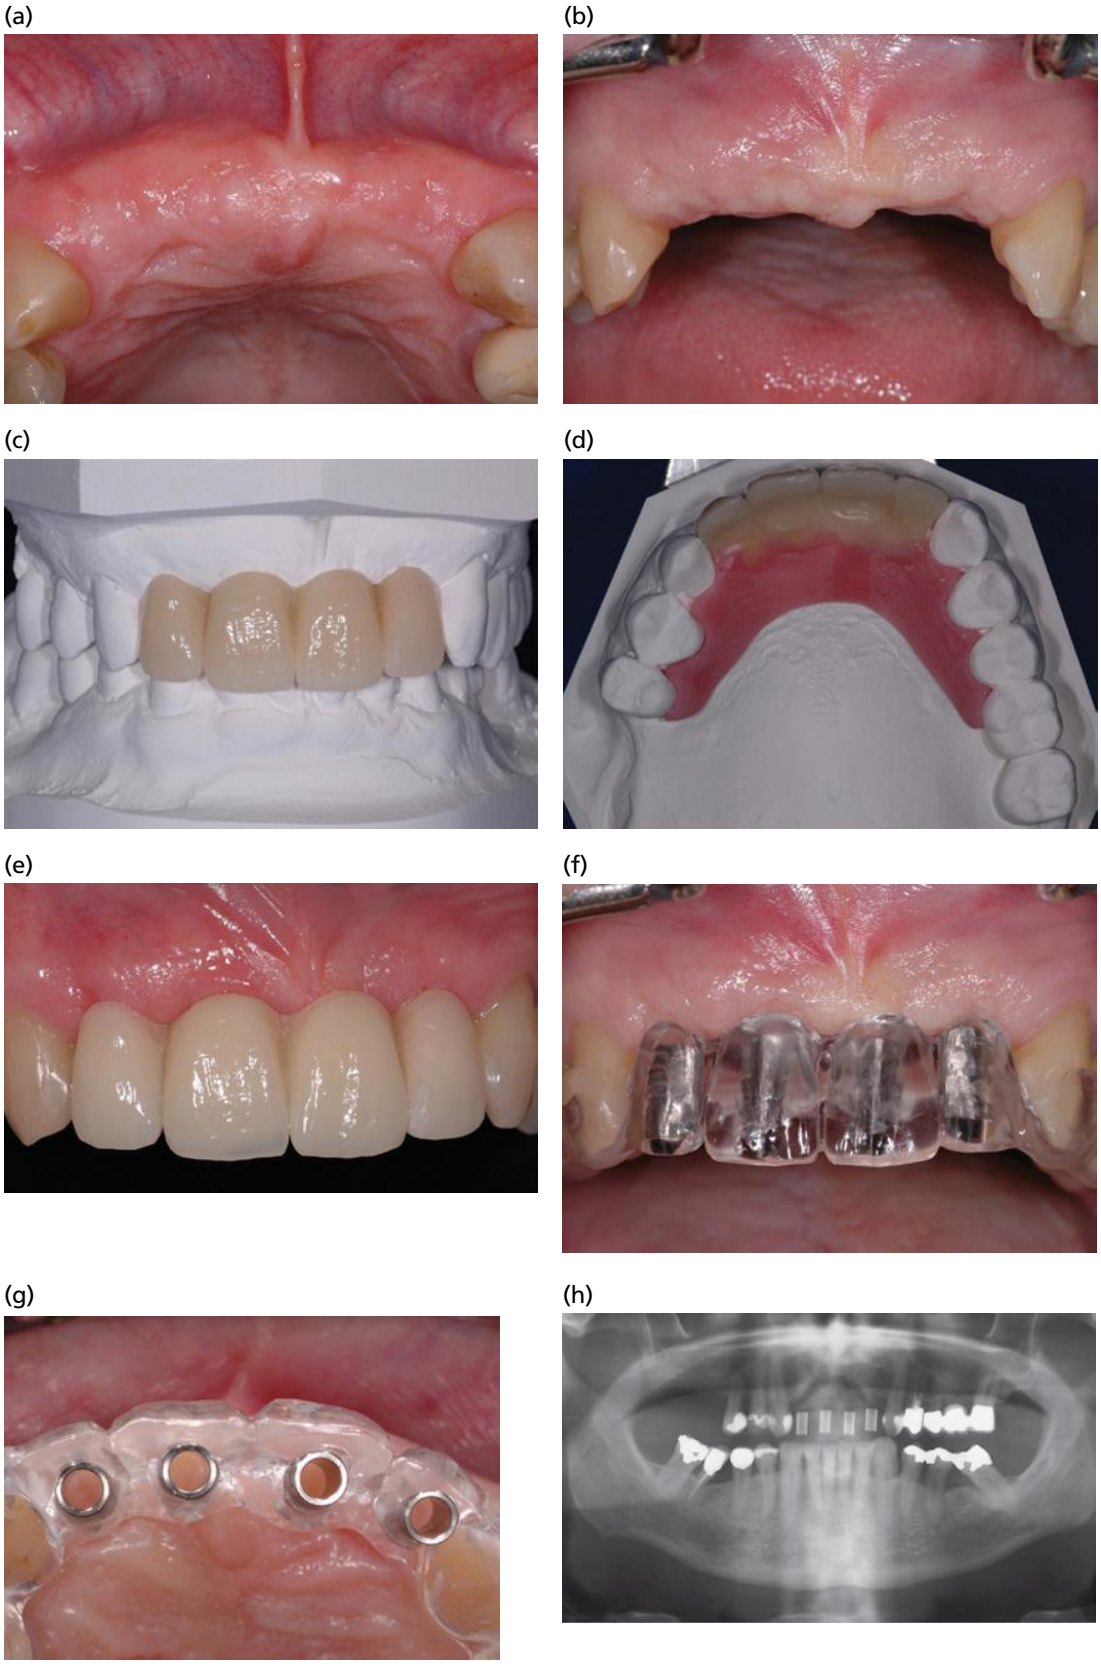

Fig. 54-23 (a) Initial occlusal view of four missing incisors revealing minor contour deficiencies. The 54-year-old male patient was referred after an accident, to restore these four missing teeth with a fixed dental prostheses. (b) Buccal view of the initial clinical presentation demonstrated a flat alveolar ridge with sufficient keratinized mucosa. A risk analysis was performed and the patient was informed about the treatment with implants. (c) Before starting implant therapy, the prosthesis was planned with the four missing teeth set up on a master cast. (d) Set-up was fabricated in a way that it could be used as a try-in within the oral cavity. (e) After placing the set-up within the patient's mouth, the functional, phonetic, and esthetic outcomes were assessed. Note the long contact areas in between the teeth that compensate for the lack of scalloping. (f) Based on the set-up, a radiographic and surgical template was fabricated with transparent PMMA material. (g) Occlusal view of the radiographic and surgical template with four titanium cylinders indicating the four possible implant positions. (h) Initial panoramic X-ray with the radiographic template in place. According to the available bone and the ideal implant distribution, two implants at positions 12 and 22 were planned.

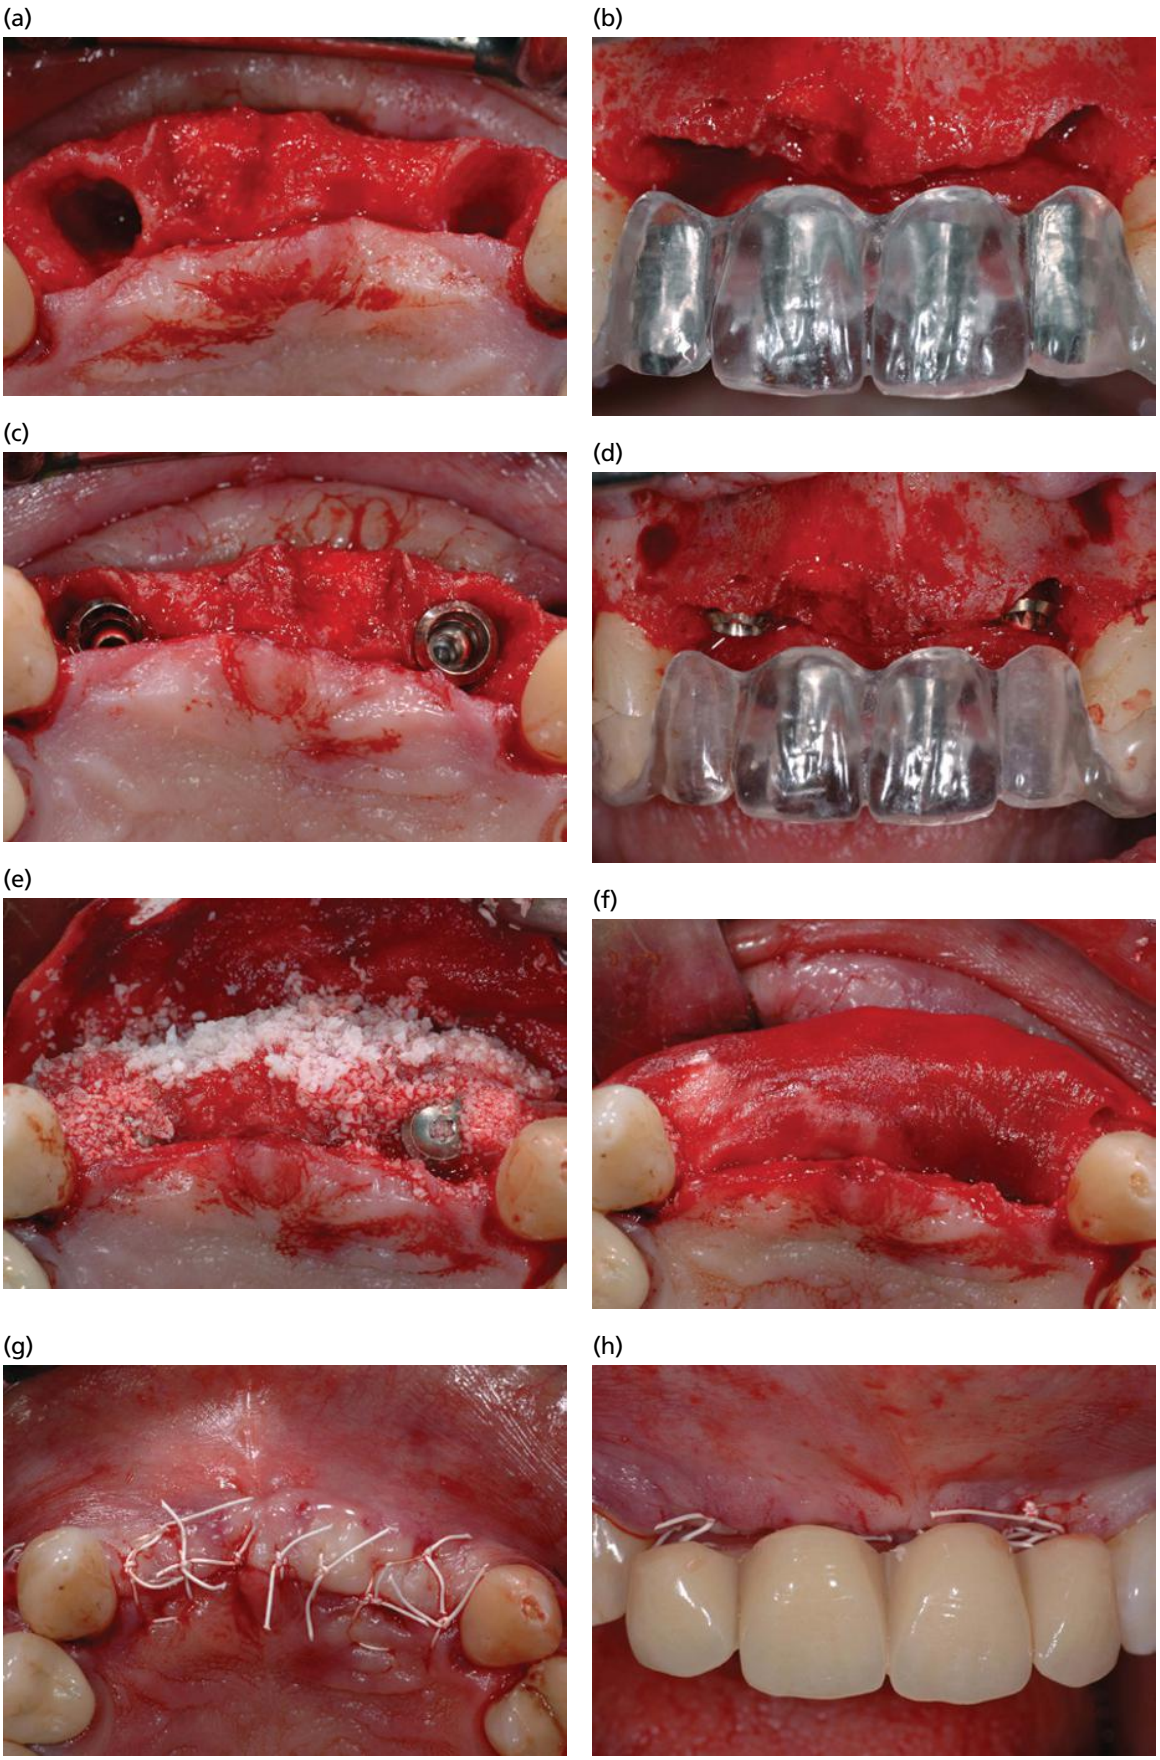

Fig. 54-24 Same patient as in Fig. 54-23. (a) Occlusal view of the edentulous alveolar ridge 8 weeks after extraction of the fractured anterior teeth. The former sockets were still visible. (b) Buccal view of the edentulous alveolar ridge with the surgical template in place indicating the ideal implant positions in relation to the horizontal and vertical dimensions. Note that the former radiographic template has been adapted to serve as a surgical template. (c) Two implants were placed at positions 12 and 22 according to the prosthetic plan. (d) The surgical template indicated the proper vertical implant position to be approximately 2 mm apical to the future implant crown margin with this type of soft tissue level implant. (e) A slowly resorbing bovine graft material was chosen to fill the gap between the implant and the buccal bone plate and to further augment the buccal bone contour. (f) Collagen membrane was used to cover the grafted area before soft tissue closure. (g) After periosteal releasing incisions were made, the mucoperiosteal flap was closed without tension using horizontal mattress and single interrupted sutures. (h) The removable temporary reconstruction was released to give a distance of 2–3 mm to the mucosa in order to compensate for the post-surgical swelling.

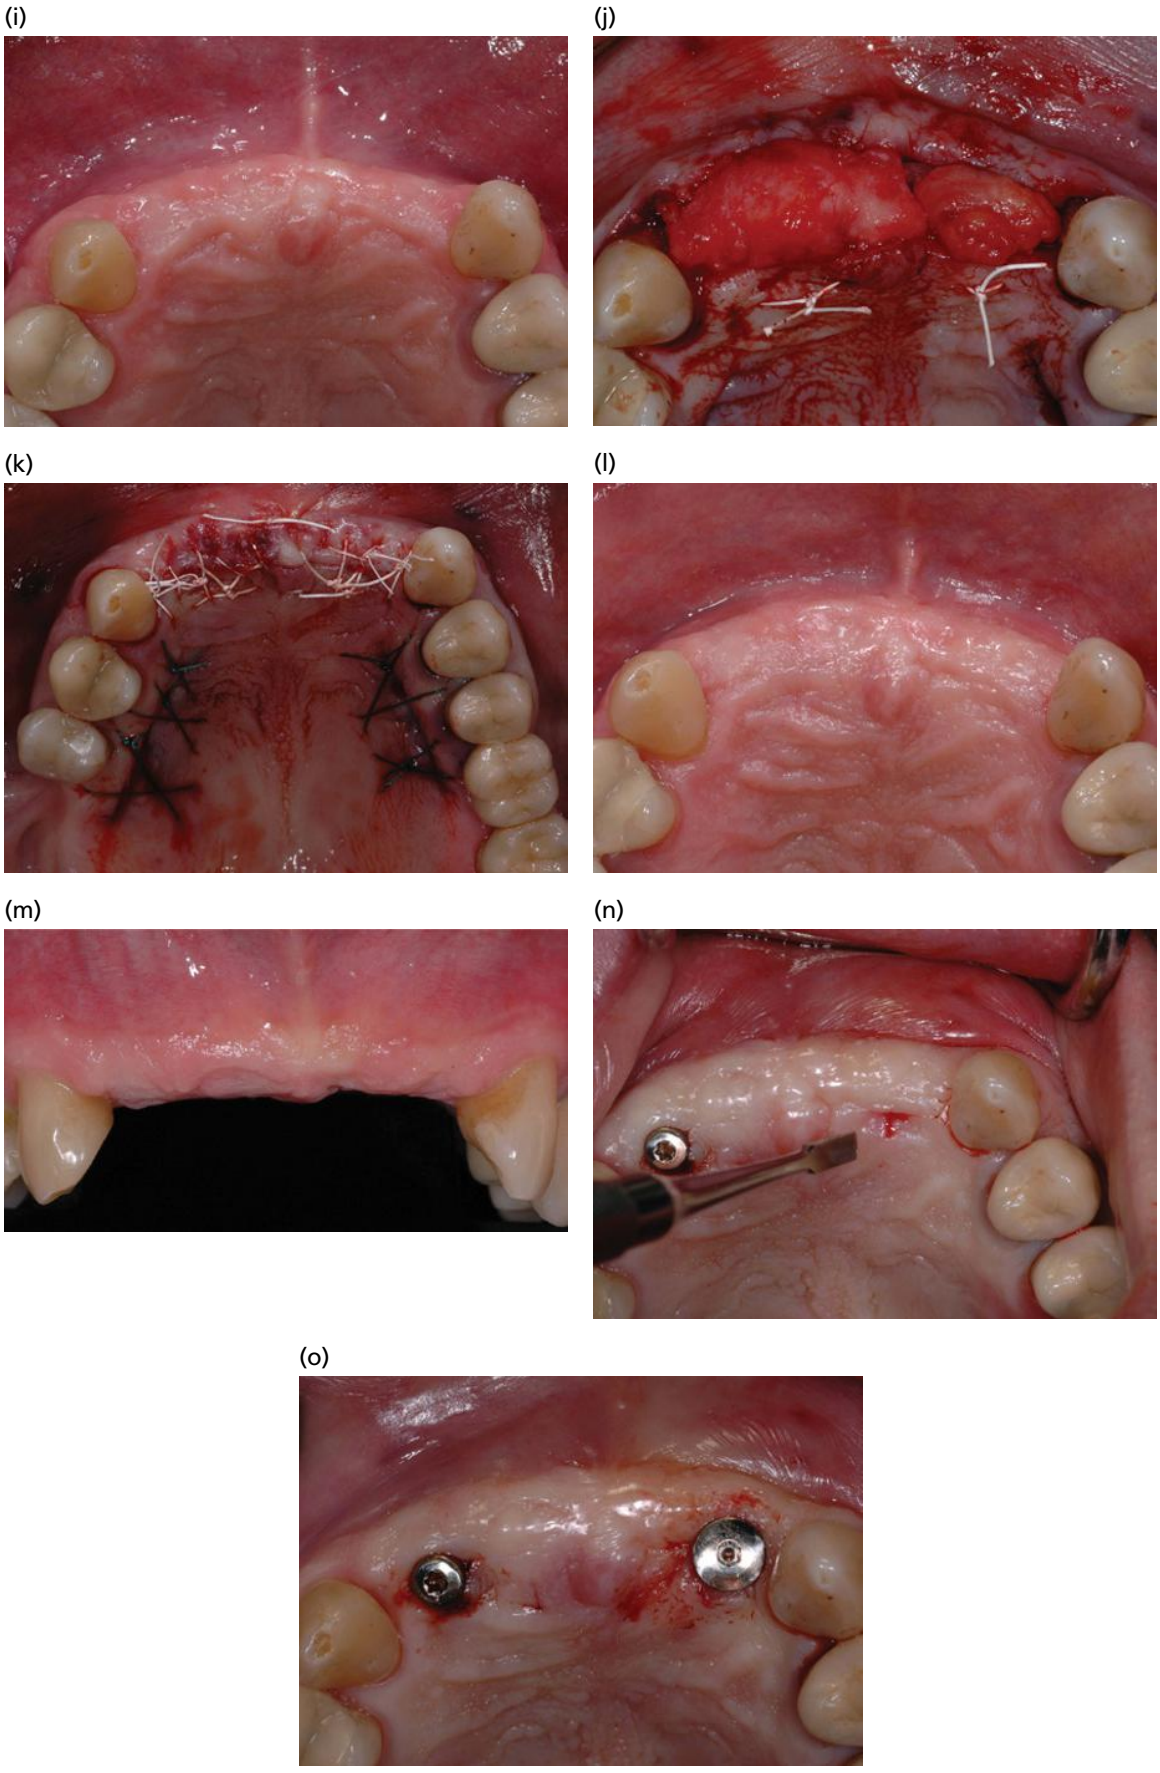

Fig. 54-24 (*continued*). (i) Three months after implant placement, re-evaluation of the alveolar contour revealed a slight horizontal discrepancy at the level of the soft tissues. In consultation with the patient, it was decided to perform an additional soft tissue grafting procedure in order to increase the buccal contour. (j) Two connective tissue grafts were harvested from both sites of the palate and placed in the area of the missing incisors. (k) Occlusal view after suturing of the recipient and the harvesting sites. (l) After soft tissue grafting, an ideal bucco-oral contour was achieved. (m) Buccal view revealed healthy soft tissues with sufficient keratinized width. (n) A minimally-invasive abutment connection with a "T-shape" incision was performed for both implant sites. (o) Titanium healing abutments were chosen and placed in such a way as to avoid overlap with the level of the neighboring soft tissue.

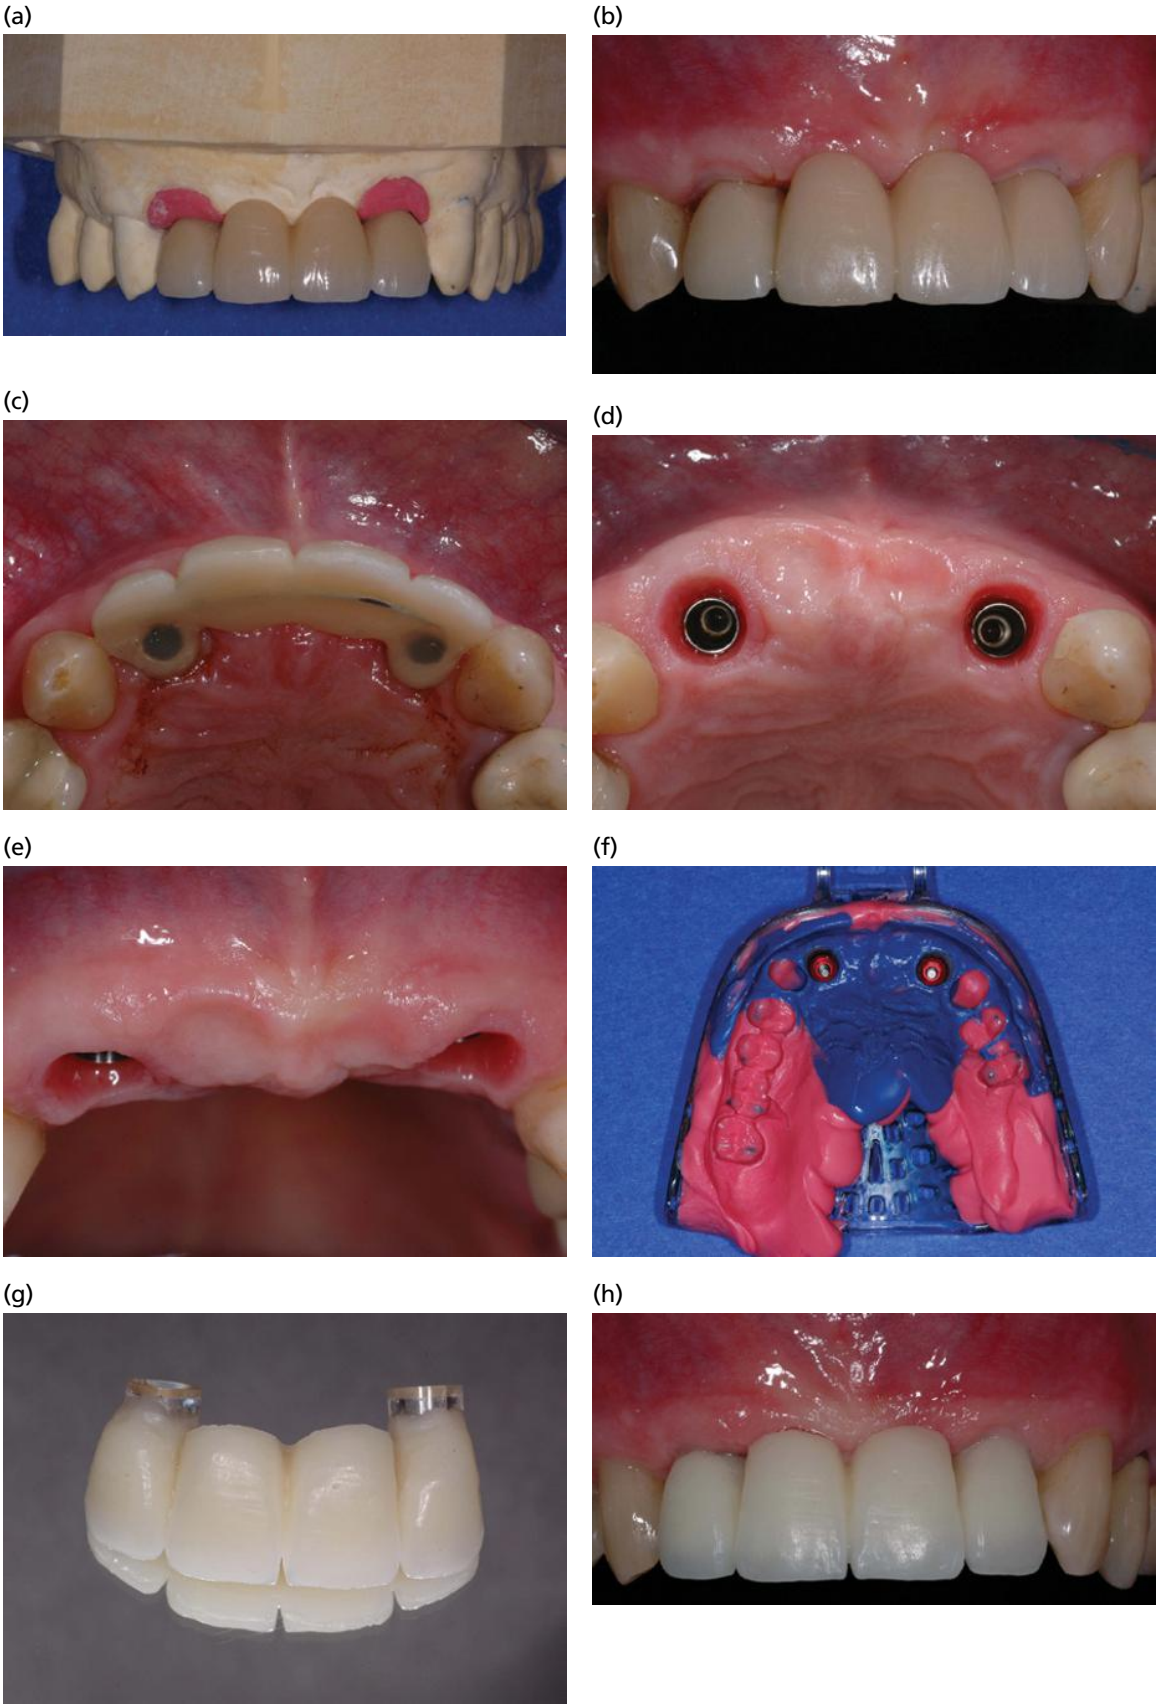

Fig. 54-25 Same patient as in Figs. 54-23 and 54-24. (a) After an impression was taken at the level of the implants, a temporary reconstruction made of resin was fabricated. (b) Screw-retained temporary resin reconstruction was inserted within the patient's mouths in order to start the soft tissue conditioning process, with flowable composite material subsequently added to the submucosal part of the temporary reconstruction. (c) Occlusal view of the screw-retained temporary reconstruction. (d) Occlusal view after completing the soft tissue conditioning process. Note the shape of the pontics for the two missing central incisors. (e) Buccal view of the soft tissue contour with a slight scalloping of the mucosa in between the pontics. (f) With the help of two individualized impression copings, a final impression was made using a polyether impression material. (g) A wax-up for try-in was fabricated on the master cast. (h) Wax-up within the patient's mouth, checking again for function, phonetics, and esthetics.

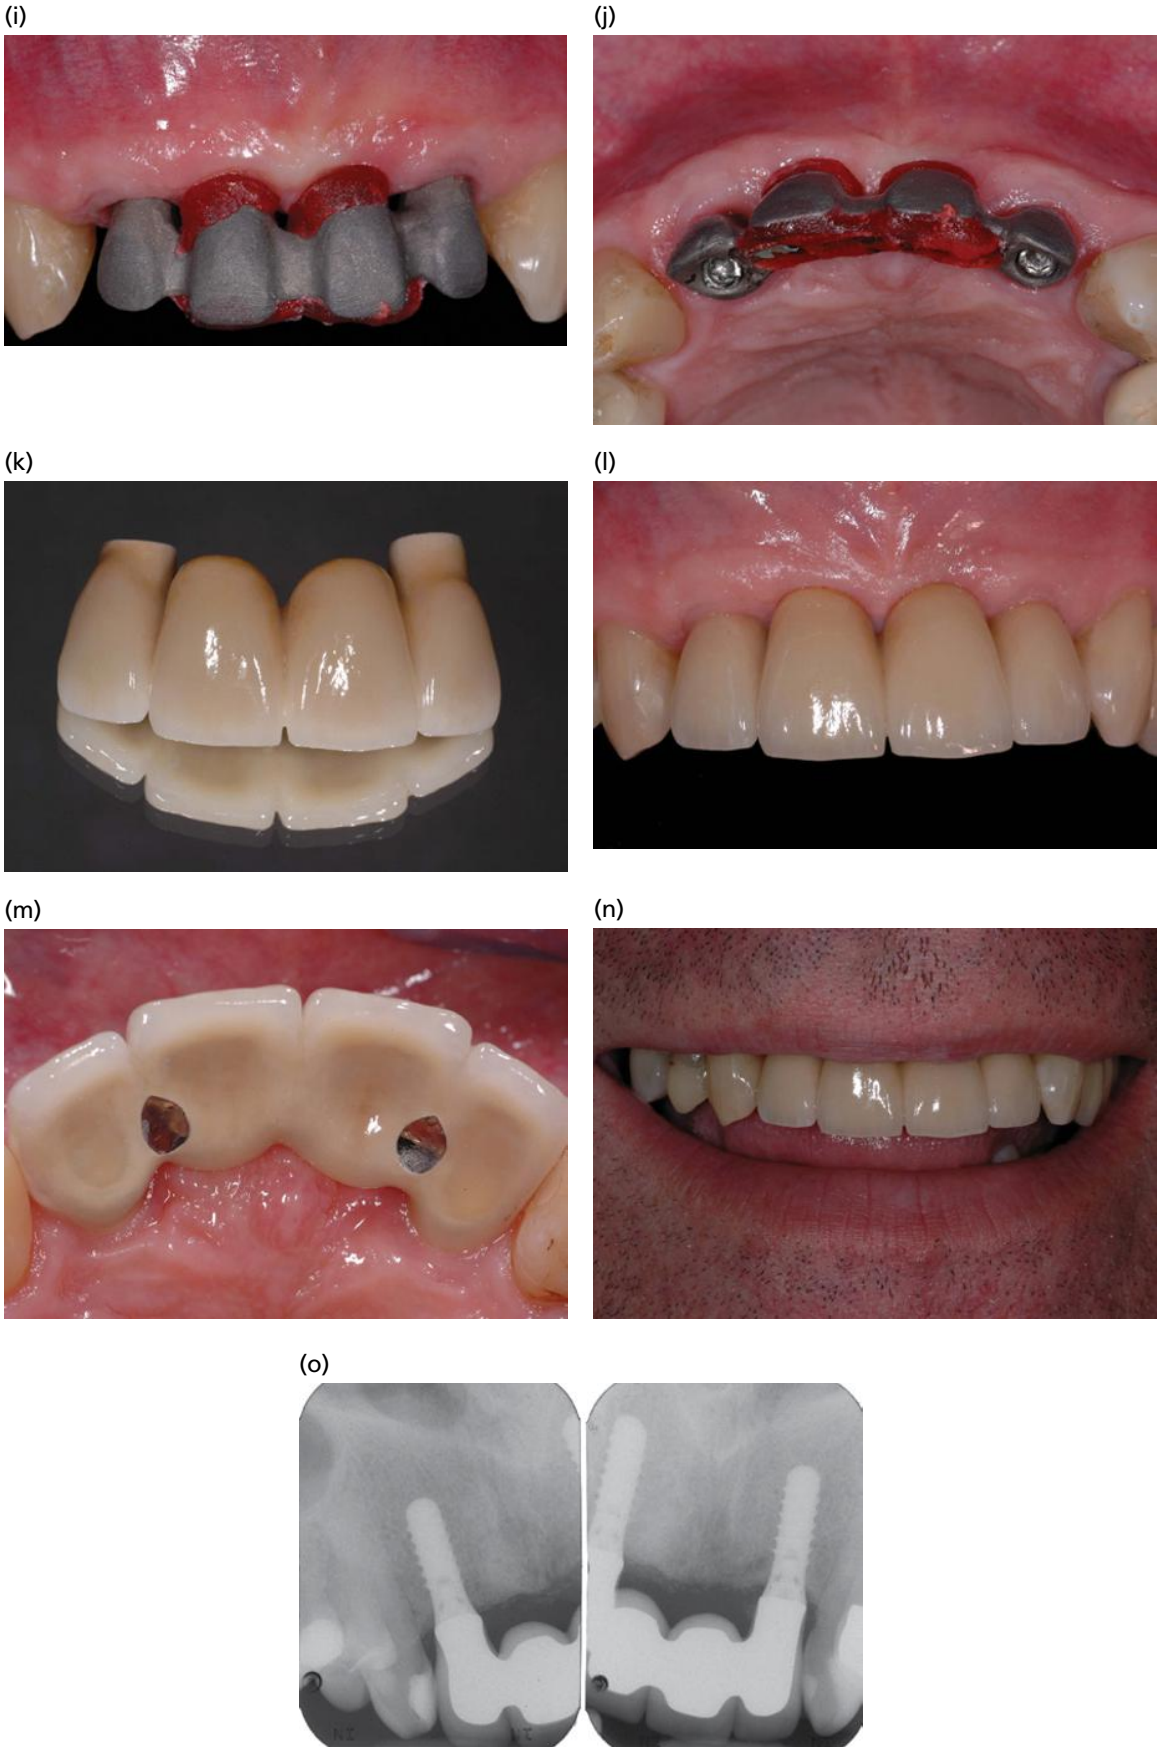

Fig 54-25 (*Continued*). (i) Buccal view of the metal framework. A PMMA material was used to capture the pontic areas. (j) Occlusal view of the metal framework demonstrating the ideal implant positions for a screw-retained reconstruction. (k) Extraoral view of the final screw-retained porcelain-to-metal reconstruction. (l) Buccal view of the final reconstruction in place. Note the slight papilla in between the two central incisors, but almost no papilla between the implant sites and the central incisors. (m) Occlusal view of the porcelain-fused-to-metal (PFM) reconstruction after covering the screw-access hole with composite material. (n) Final lip line of the patient without visible mucosal aspects apical to the implant-supported crowns and pontics. (o) Periapical X-rays 2 years after insertion of the final reconstruction, showing stable bone levels.

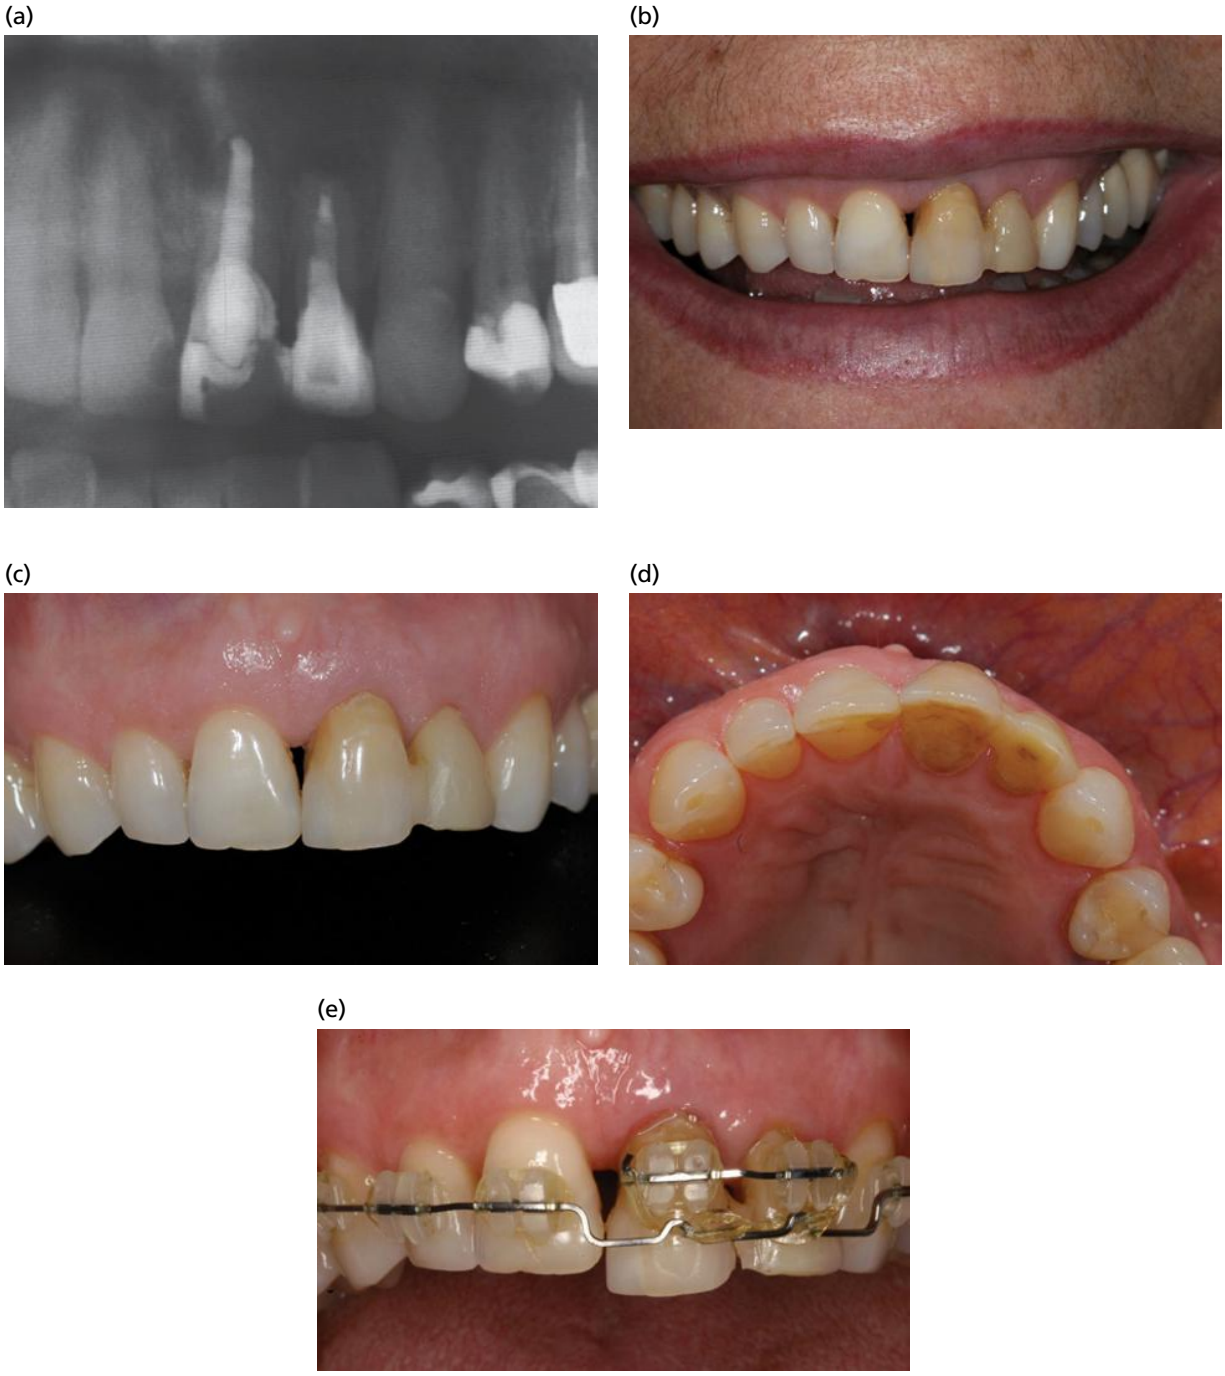

Fig. 54-26 (a) Initial radiograph of a 55-year-old female patient with a left central and a lateral incisor with periapical pathologies and insufficient tooth substance to maintain these teeth as abutments for conventional crowns. In addition, tooth 21 had a buccal fracture of the root. From an endodontic and a prosthetic point of view, both teeth are considered to be hopeless and were scheduled for extraction. (b, c) Esthetic analysis revealed a high lip line, a black triangle between the central incisors, and irregular gingival margins for the left central and lateral incisors compared to the contralateral tooth. Left central and lateral incisors were yellowish in color due to loss of tooth vitality. (d) Occlusal view of the initial clinical situation. Left central and lateral incisors were splinted due to their increased mobility. (e) After an extensive esthetic and functional analysis and diagnosis phase, the planned treatment was presented to and was discussed with the patient. Due to the irregular gingival margins, orthodontic tooth extrusion before extraction was preferred in order to coronally displace soft tissues. Only one implant in position 21 with an extension for position 22 planned. In order to correct the black triangle, a ceramic veneer for position 11 was planned.

lateral incisor is considered a very challenging situation because implants have to symmetrically match the contralateral incisors. This clinical case is shown in Figs. 54-26, 54-27, 54-28, 54-29, and 54-30 and represents a situation with more extended soft and hard tissue deficiencies.

Sites with severe tissue deficiencies

In a 25-year-old patient with severe soft and hard tissue deficiencies, due to an accident at the age of 12 years, the left central incisor had ankylosed very early with the result that there was a large soft tissue

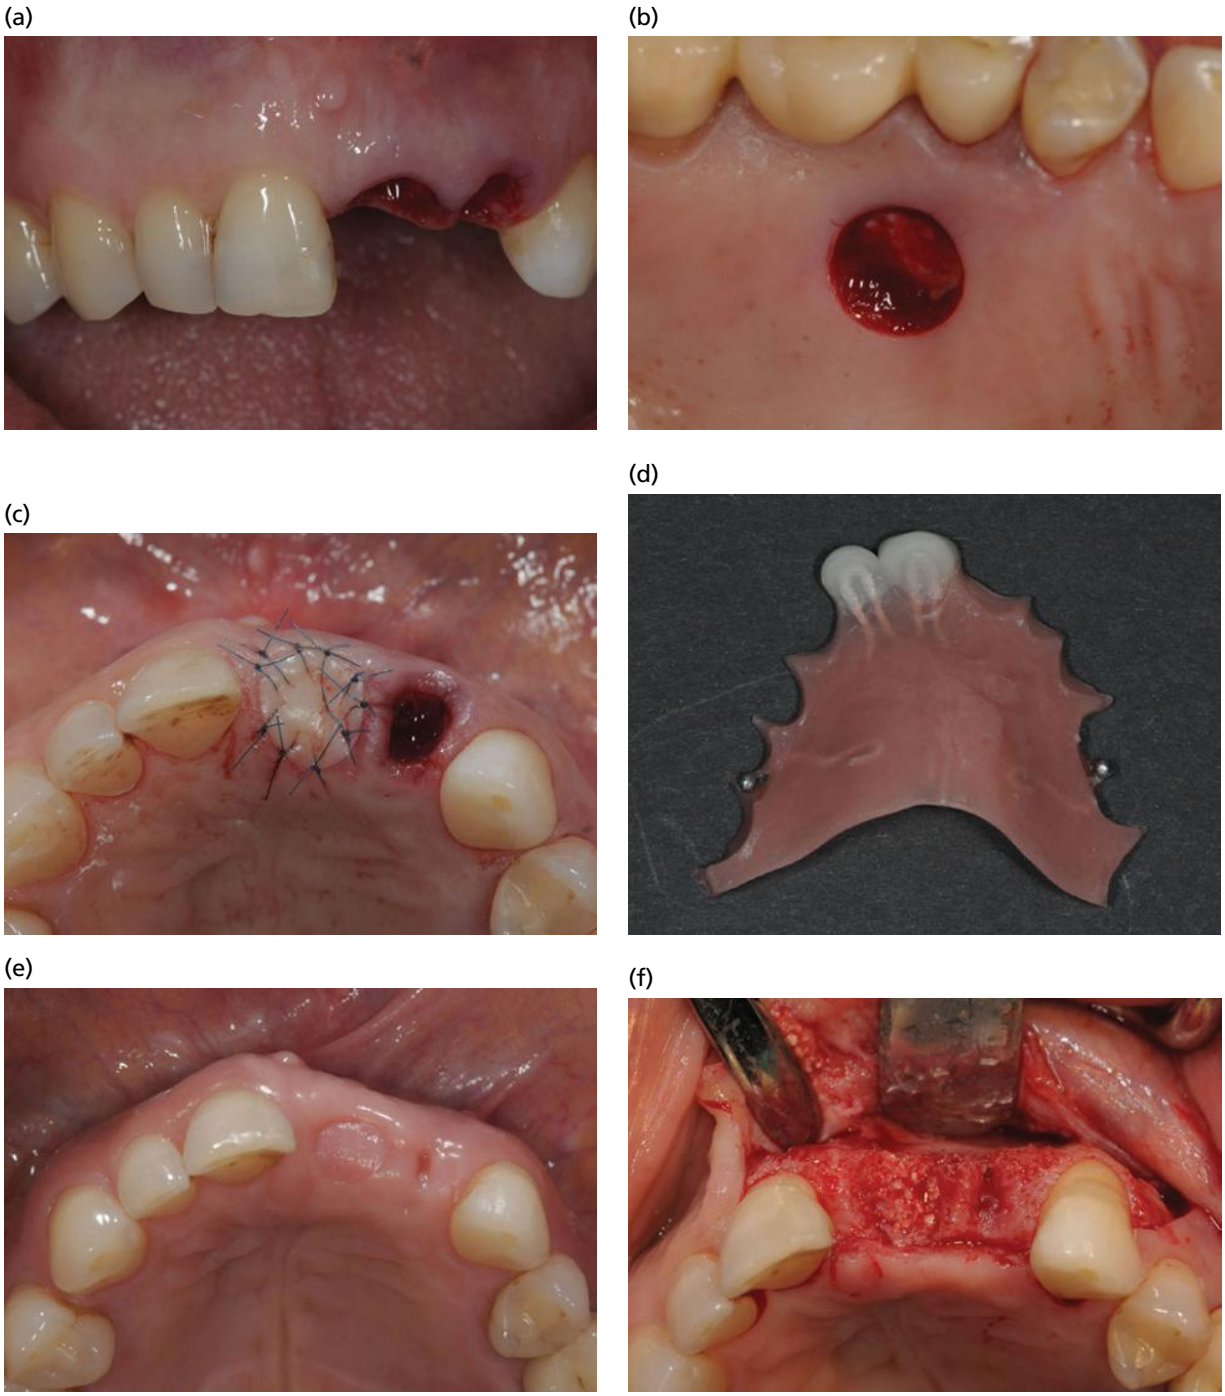

Fig. 54-27 Same patient as in Fig. 54-26. (a) After 2 months of active orthodontic movement and 4 months of retention, teeth 21 and 22 were extracted with minimum trauma. In order to maintain the alveolar ridge dimensions after tooth extraction, the socket of the central incisor was then filled with demineralized bovine bone mineral (DBBM) with 10% collagen. (b) Subsequently, a biopsy punch was used to obtain a free mucosal graft from the palate. The area between the first molar and second premolar is generally preferred for this. (c) Free mucosal graft was placed on top of the DBBM-Collagen and sutured with 6/0 monofilament. Careful adaption is crucial for survival and success. Special attention should be paid to the adaptation of the interproximal areas. (d) A removable provisional acrylic restoration was prepared and placed after the extractions. (e) Eight weeks after extraction, the soft tissues had completely healed and ridge volume was maintained. (f) A mucoperiosteal flap with a vertical releasing incision distal to the canine was elevated. Note the presence of the DBBM particles in the extraction socket.

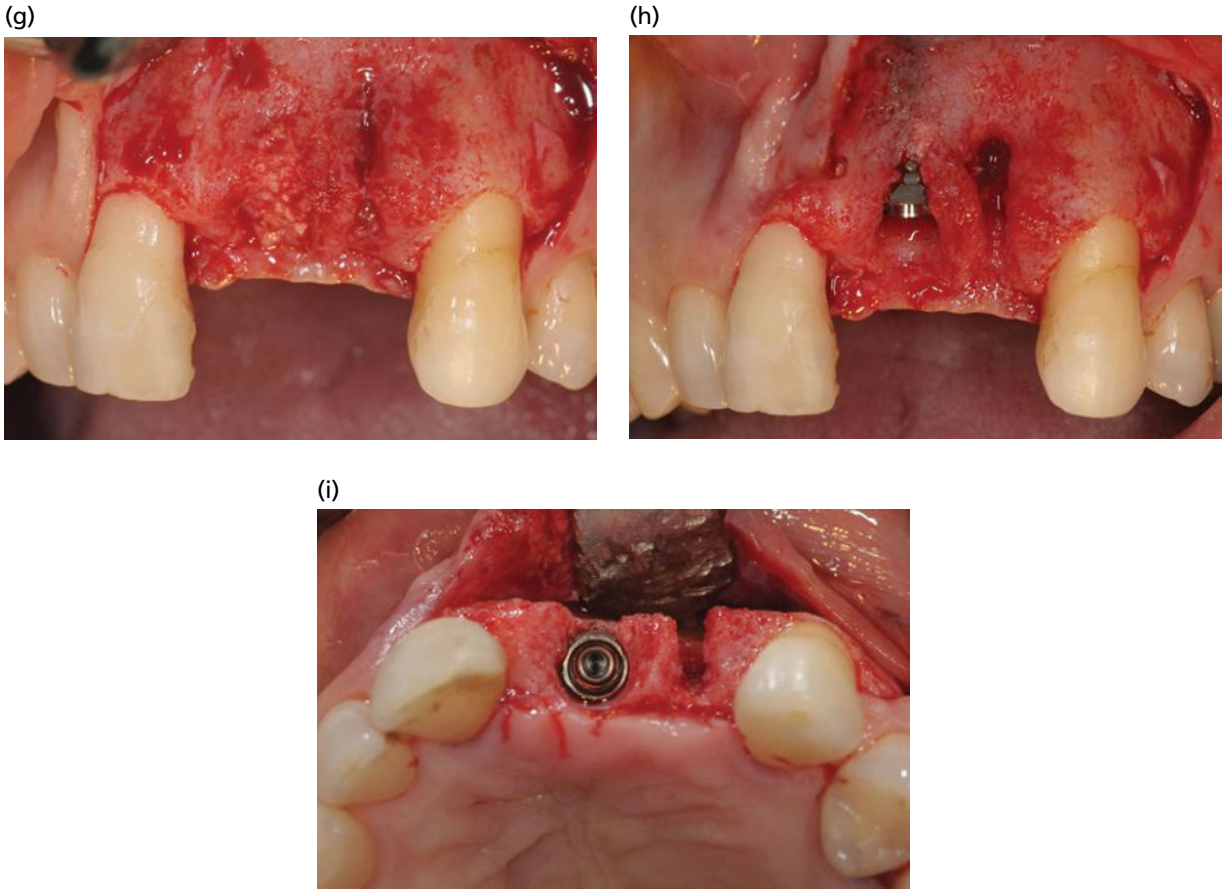

Fig. 54-27 (*Continued*) (g) Buccal view after flap elevation. Note the difference between the central incisor socket and lateral incisor socket, which was left empty. (h) A bone level implant was placed according to the prospective restoration and gingival margins. Vertical position was 3–4 mm apical of the prospective gingival margin. Note the buccal dehiscence of 3 mm. (i) Occlusal view revealed an ideal implant position and a self-containing defect affecting the buccal aspect of the implant. Guided bone regeneration with DBBM and bioresorbable collagen membrane was indicated.

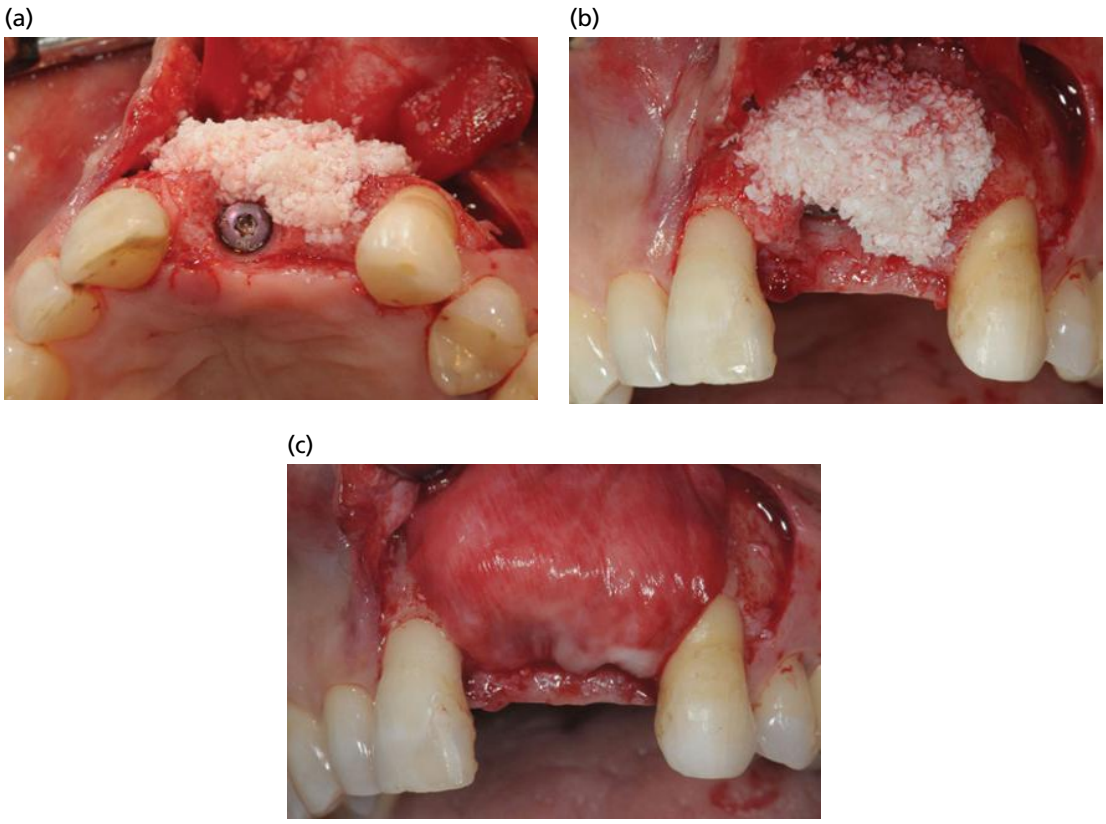

Fig. 54-28 Same patient as in Figs. 54-26 and 54-27. (a, b) For the guided bone regeneration (GBR) procedure, autogenous bone particles from the surrounding area were placed on top of the implant surface and then covered by a deproteinized bovine bone substitute. Overcorrection of the defect was performed to compensate for further material displacement during membrane placement and suturing. (c) A bioresorbable collagen membrane was shaped in order to adapt it to the defect, and it was fixed apically with two bioresorbable pins.

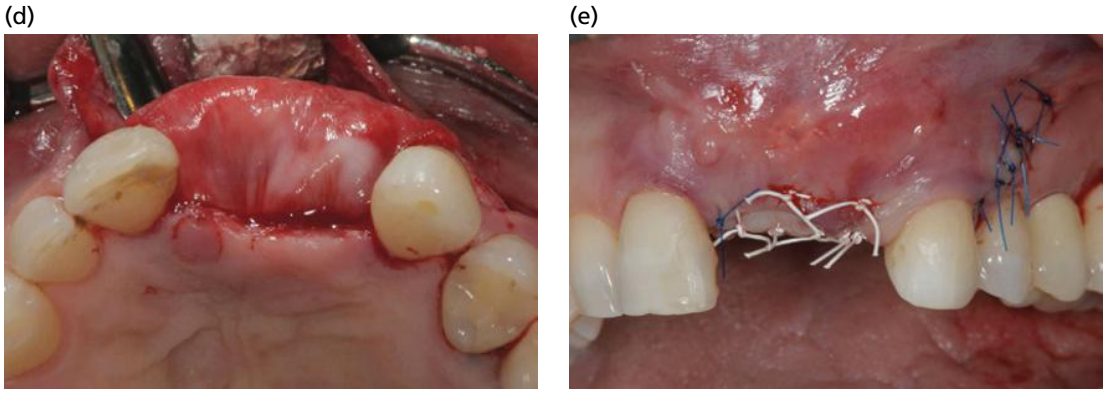

Fig. 54-28 (*Continued*) (d) Occlusal view shows the overcorrection of the defect in order to compensate for further material displacement and resorption. (e) Tension-free soft tissue closure is a critical issue when GBR is performed. Horizontal releasing incisions in the periosteum were executed prior to suturing to ensure relaxation of the flap. Then, horizontal mattress sutures were placed to approximate wound margins and reduce flap tension. Finally, an e-PTFE membrane and monofilament 5/0 sutures were placed in the crestal and vertical incisions without tension to ensure flap adaptation.

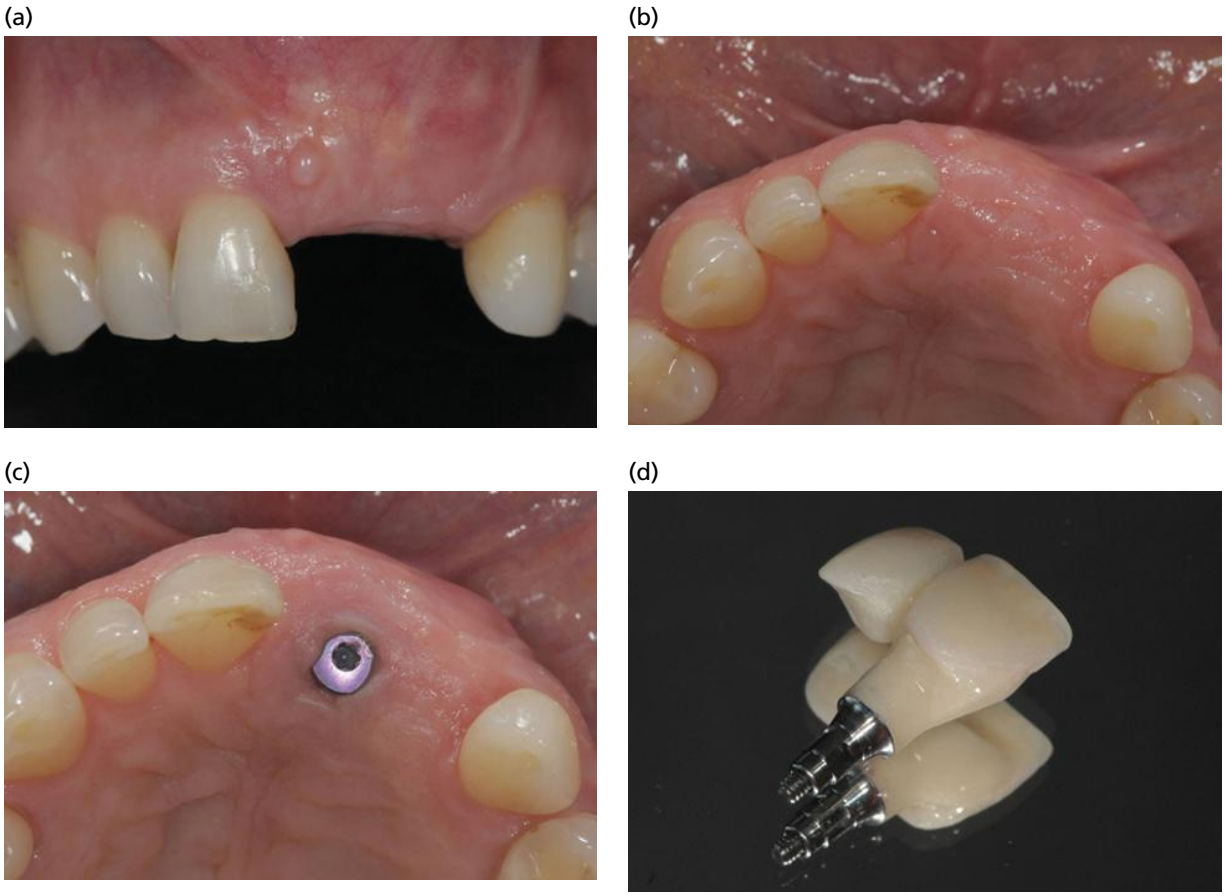

Fig. 54-29 Same patient as in Figs. 54-26, 54-27, and 54-28. (a) Three months after implant placement, soft tissues were completely healed and healthy. (b) At that time, a connective tissue graft was performed 4 weeks prior to second-stage surgery. The aim of the connective tissue graft was to increase the soft tissue thickness at the occlusobuccal aspect of the ridge. (c) Minimally-invasive second-stage surgery was performed with just a small palatal incision and displacement of soft tissues slightly buccally. Direct impression technique with an open tray was used and a healing abutment was placed. (d) Two weeks later, a provisional screw-retained restoration was placed. The provisional restoration was designed to give the ideal buccal size and shape, but the technician left the inner part empty. This empty space was then progressively filled in the clinic by the dentist in order to compress and displace the soft tissues in the desired direction.

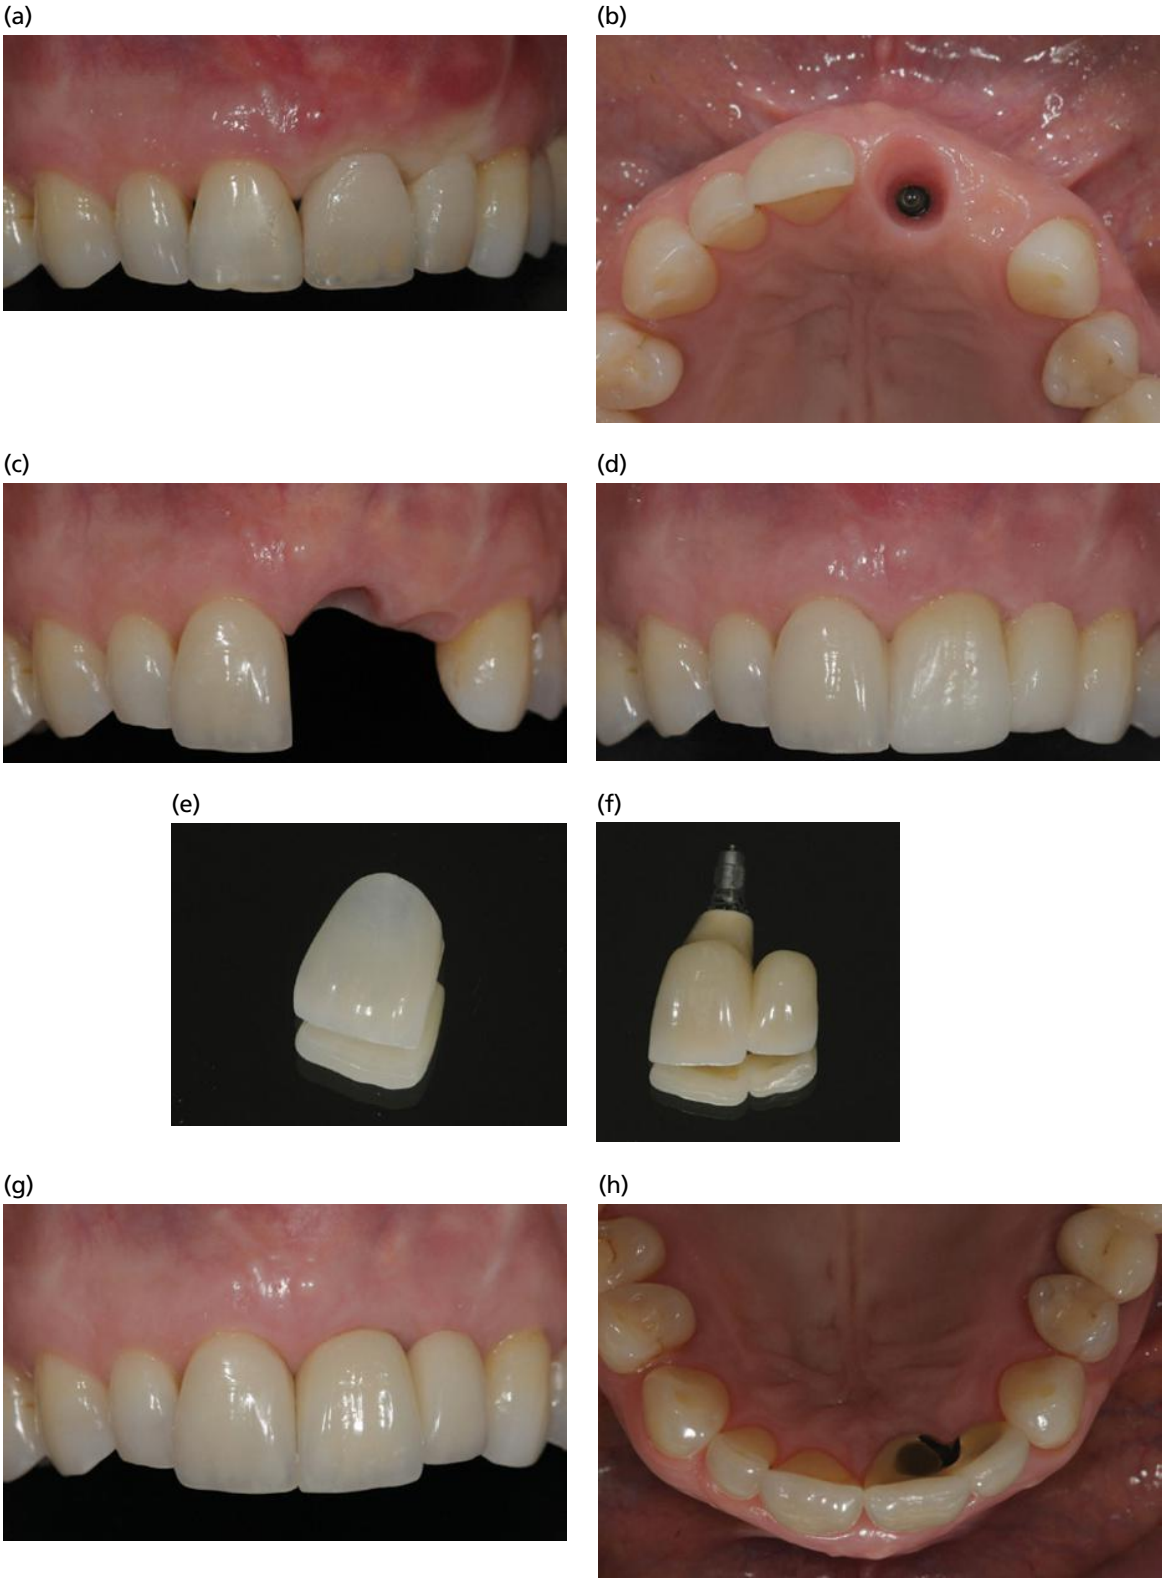

Fig. 54-30 Same patient as in Fig. 54-26, 54-27, 54-28 and 54-29. (a) Provisional restoration in place. Note the pressure on the soft tissues. Ideally, whitish mucosa should recover a normal pink color after some minutes. (b) Occlusal view after the soft tissue conditioning process with the temporary reconstruction. (c) Buccal view of the finally shaped soft tissue margins before crown placement. (d) Wax-up and veneer try-in revealed that the progressive modifications of the provisional had led to a buccal displacement of the soft tissues and adequate mucosal margins. (e) To improve the final esthetic result and achieve symmetry, a facial veneer was prepared for the right central incisor. A slight change in the original shape of the central incisors and an apical contact point lead to closure of the black triangle. (f) Final screw-retained porcelain-fused-to-metal (PFM) restoration with a distal cantilever replacing 22. (g) Final screw-retained restoration (21 with extension 22) and all-ceramic veneer (11) in place. Note the perfect integration with the soft tissues and the aligned gingival margins. (h) Occlusal view of the final reconstruction. Due to the limited interocclusal distance, the connector to the extension was left in metal. The screw access hole was still covered with a provisional resin material which was to be replaced with a permanent composite material.

(i)

(j)

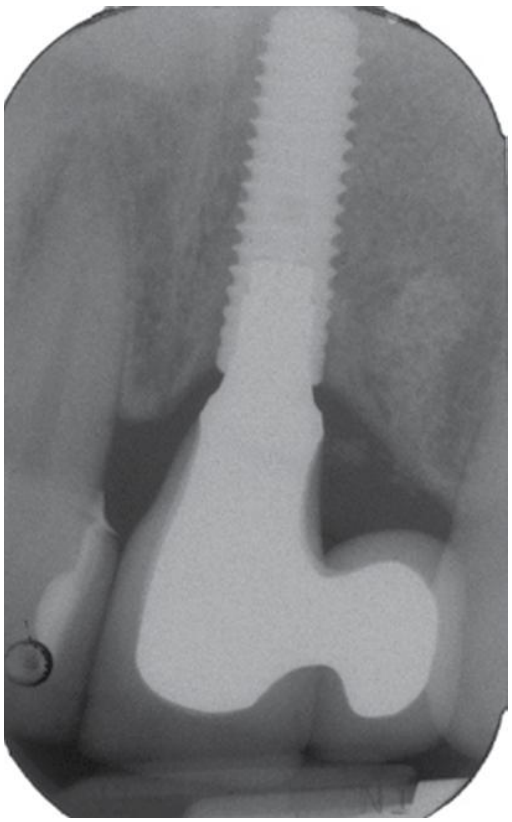

Fig 54-30 (*Continued*). (i) Smile line revealed an esthetically pleasing result with the reconstruction perfectly integrated within the rest of the dentition and the soft tissues. (j) Final result 1 year after insertion of the screw-retained PFM reconstruction on position 21 with a cantilever to position 22.

Fig. 54-31 A 25-year-old male patient presented with a missing right central and lateral incisor and a very early ankylosed left central incisor due to a ski accident at the age of 12 years.

dehiscence on the buccal aspect of tooth 21. The risk analysis and treatment plan were presented to and discussed with the patient. The treatment plan included the extraction of ankylosed tooth 21 with a soft tissue graft in order to restore the soft tissues before further surgical interventions. The further treatment plan comprised a primary bone augmentation procedure with an autogenous bone block, two implants with two implant-supported crowns, and prosthetic modifications of 13 into 12 and 14 into 13 using either composite or veneers. The clinical steps are shown in Figs. 54-31, 54-32, 54-33, 54-34, and 54-35.

Prosthetic reconstruction in the zone of esthetic priority

Prosthetic reconstruction in the anterior area of the upper jaw is of upmost importance. As high implant survival and success rates have been reported, the esthetic outcome of the reconstruction has become the main focus of interest in these sensitive areas. The prosthetic reconstruction should imitate the appearance of the healthy teeth as closely as possible. When deciding the final prosthetic reconstruction, three major questions need to be addressed: (1) screw-retained reconstruction or cemented reconstruction?; (2) standardized prefabricated or customized abutments?; (3) porcelain-fused-to-metal (PFM) or all-ceramic reconstructions?

Screw-retained versus cemented reconstructions

Before an abutment can be selected, the first decision that needs to be made is whether a screw-retained or a cemented reconstruction is to be used. This important decision process is discussed in detail in Chapter 55. In brief, screw-retained reconstructions allow a better retrievability and facilitate the replacement and the maintenance of a reconstruction. In addition, it is easier to shape the emergence profile with screw-retained implant provisionals and to transfer the contour to the master cast. However, screw-retained restorations usually involve more

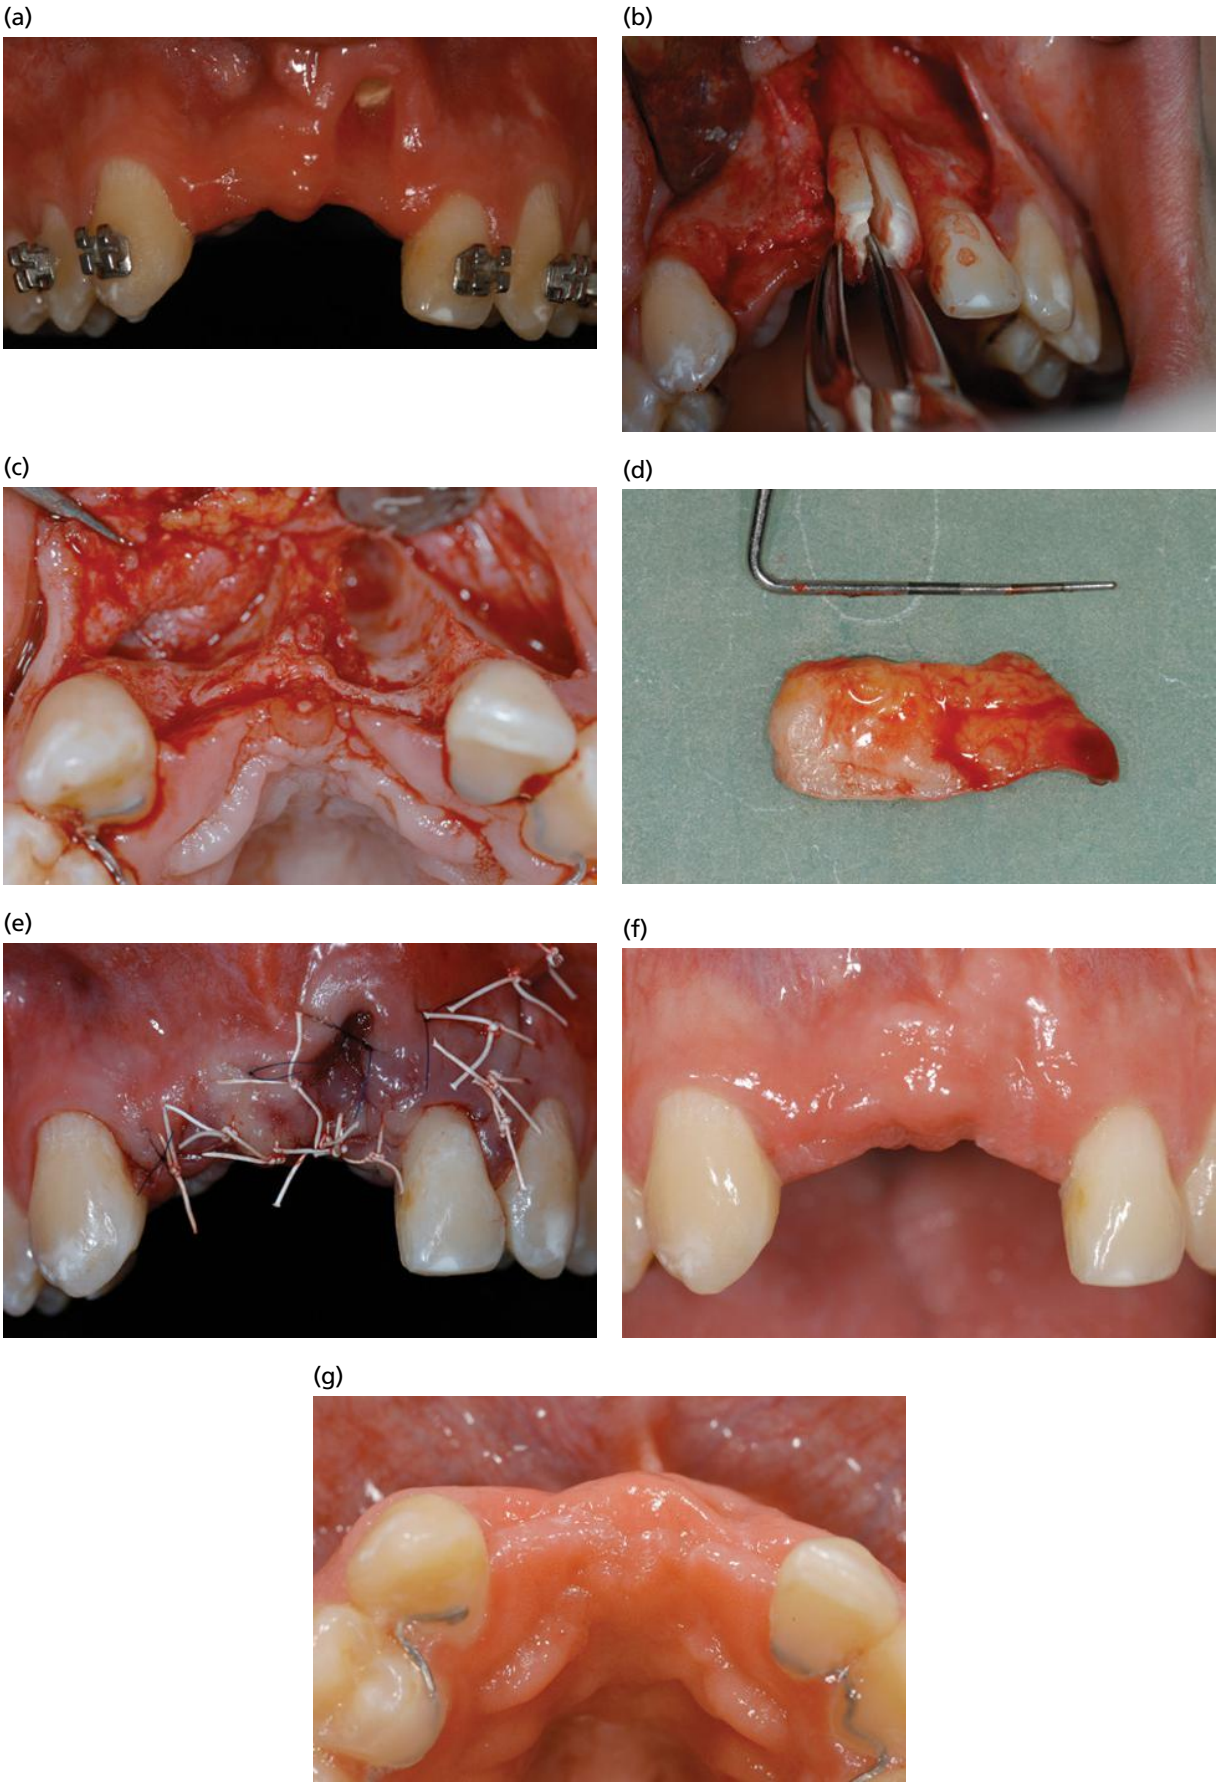

Fig. 54-32 Same patient as in Fig. 54-31. (a) Four weeks after cutting tooth 21 at the bone level in order to allow the soft tissue to partially regenerate the large soft tissue deficiency. (b) Mucoperiosteal flap was elevated to expose the root for extraction after dissecting the remaining root. (c) Occlusal view of the defect after the extraction. Bone level was maintained at the right canine but there was a horizontal defect all around the edentulous area and a vertical defect affecting the mesial aspect of tooth 22. (d) Connective tissue graft was harvested from the palate to cover the soft tissue defect. (e) Connective tissue graft was sutured in the area of the extraction socket in order to improve quantity and quality of the soft tissues for further procedures. (f) Three months after extraction, the buccal view revealed that the healing of the soft tissues was complete and the mucosal architecture restored. (g) Occlusal view 3 months after tooth extraction showed sufficient keratinized tissue for bone augmentation.

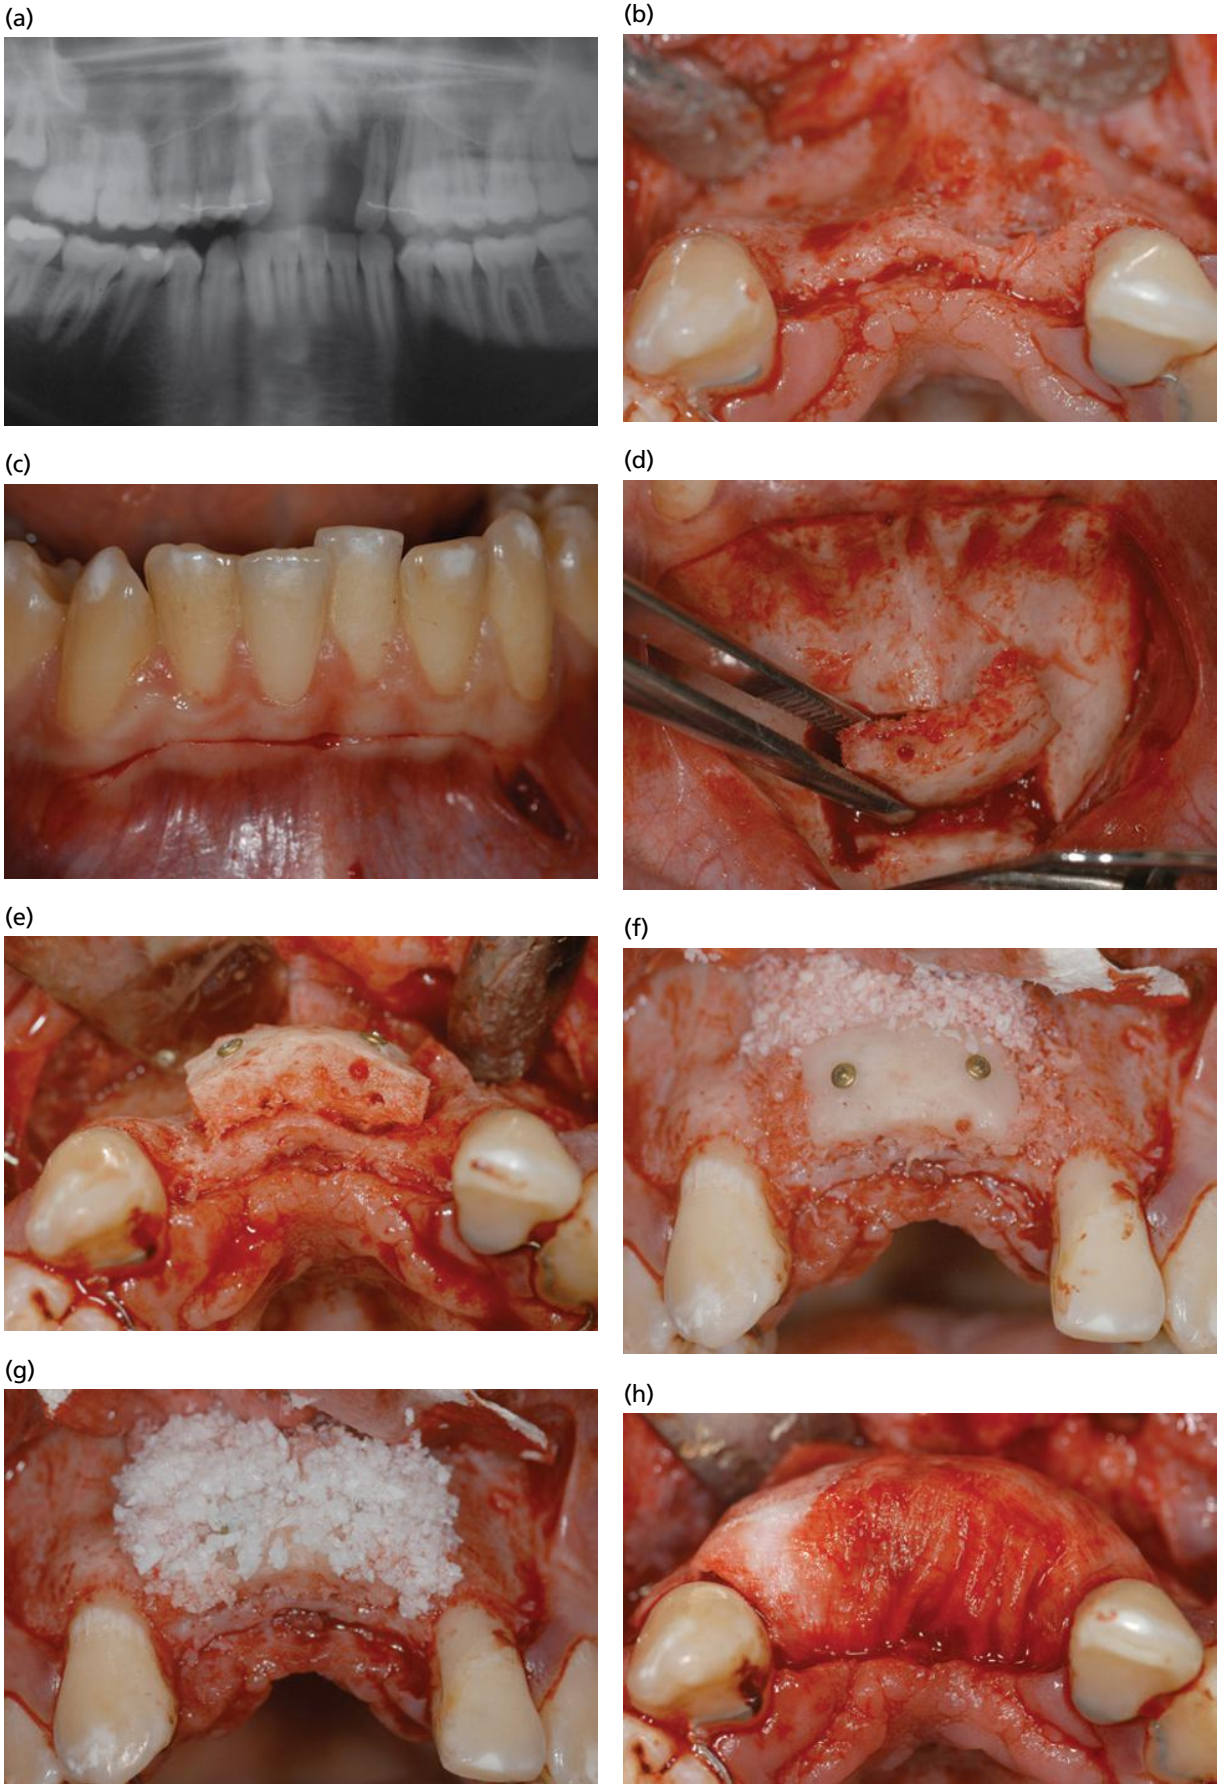

Fig. 54-33 Same patient as in Figs. 54-31 and 54-32. (a) Panoramic X-ray before bone augmentation procedures. (b) A mucoperiosteal flap was elevated with a slightly palatal crestal incision and two releasing incisions distal to tooth 13 and distal to tooth 22. Due to the horizontal defect, the implant could not be placed and a previous autogenous bone block was indicated. (c) In the chin area, a horizontal incision 1 mm above the mucogingival margin was performed from canine to canine with small distal apical releasing incisions. (d) Precise graft harvesting was done with an ultrasonic device, for which a minimum distance of 5 mm from the tooth apex, mental foramina, and chin base had to be respected. Finally, bone chips were obtained with a bone scraper. (e) Bone block was fixed in the desired position with two screws. (f) Empty spaces were filled with bone chips and deproteinized bovine bone mineral (DBBM). (g) A layer of DBBM was placed on top of the bone block to compensate for bone resorption during healing. (h) Finally, the augmented area was covered by a bioresorbable collagen membrane, which was stabilized apically with two bioresorbable pins. Subsequently, after making proper periosteal releasing incisions, the mucoperiosteal flap was closed.

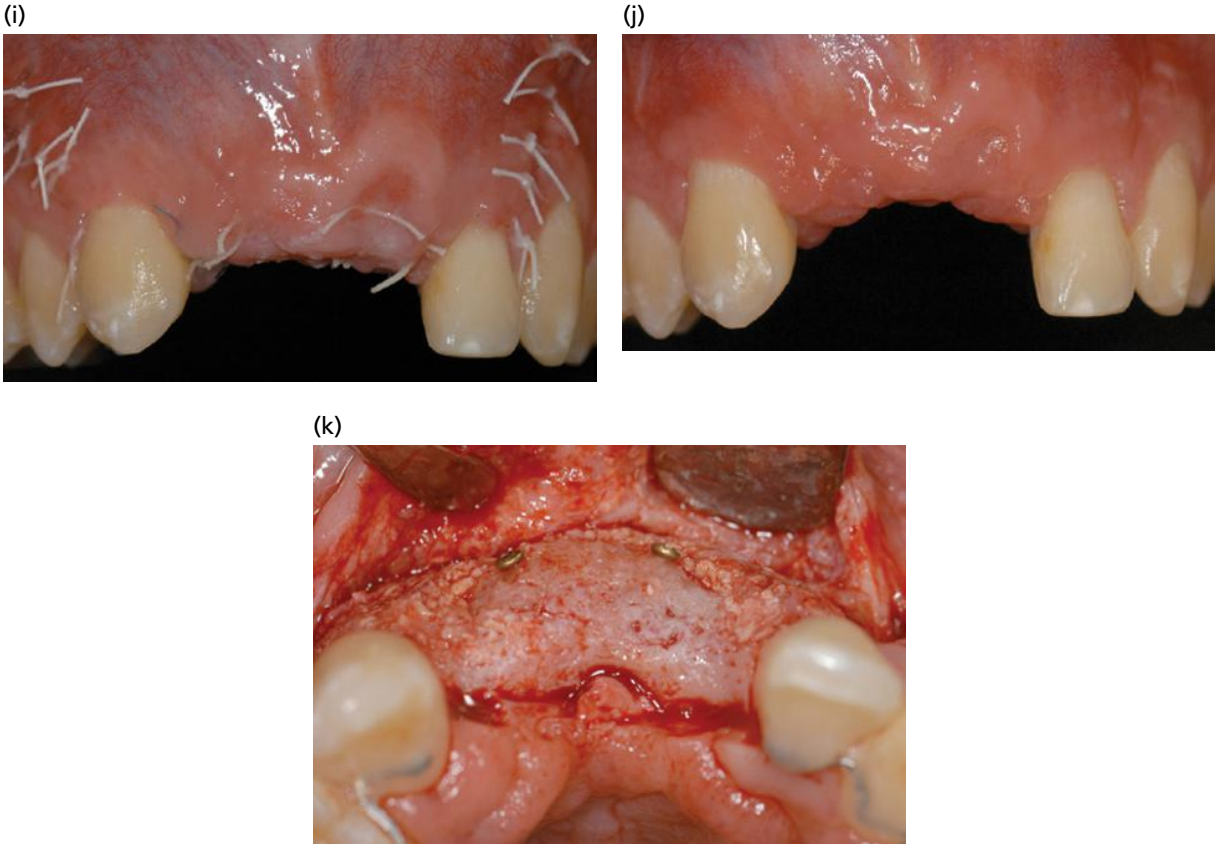

Fig. 54-33 (*Continued*). (i) Ten days after bone augmentation the healing process was uneventful and sutures could removed. (j) Buccal view of the soft tissue after 5 months of healing before implant surgery was performed. Ideally, implant placement should be performed between 4 and 6 months after a bone block graft in order to ensure integration and stability, but also to avoid too much bone resorption. (k) After elevation of a mucoperiostal flap, the occlusal view demonstrated a well-integrated autogenous bone block with minimal resorption.

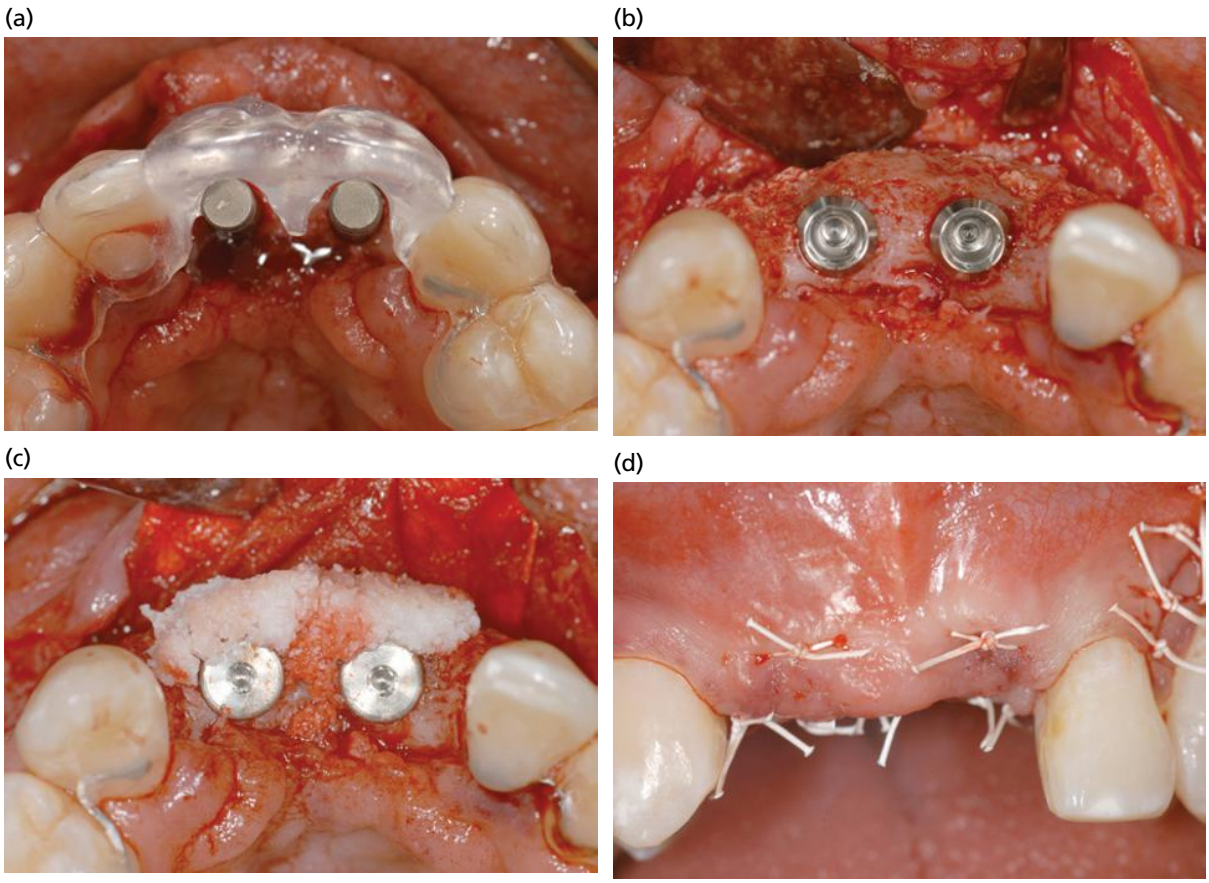

Fig. 54-34 (a) Same patient as in Figs. 54-30, 54-31, 54-32, and 54-3. (a) Conventional surgical splint based on previous wax-up facilitated the ideal prosthetic position for the implants. (b) Two soft tissue-level implants were placed at the ideal prosthetic position without any bone defects. (c) To prevent future bone resorption and to maintain buccal bone volume, additional guided bone regeneration (GBR) was performed with DBBM and a bioresorbable collagen membrane. (d) Flap closure was accomplished with two horizontal mattress sutures and single interrupted sutures.

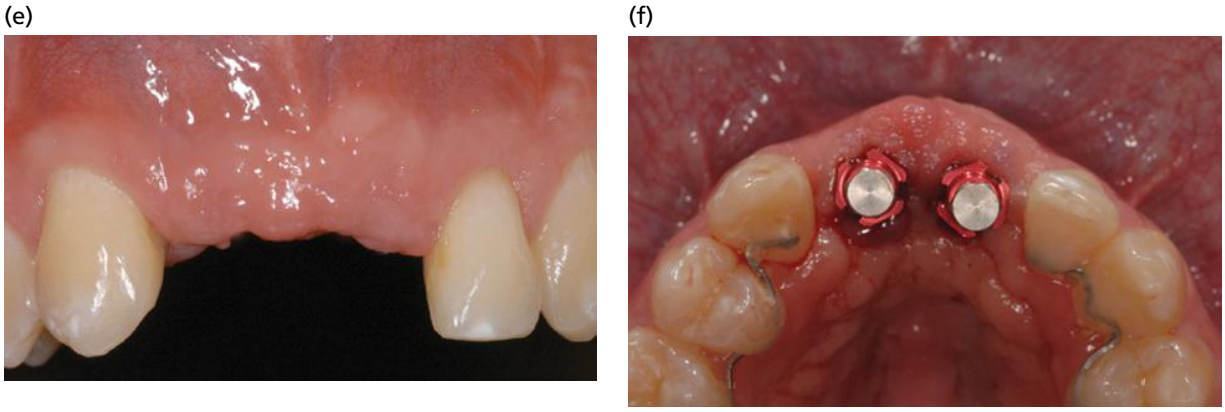

Fig. 54-34 (*Continued*). (e) Buccal view after 3 months of implant healing right before abutment connection. (f) Occlusal view with impression copings in place after second-stage surgery.

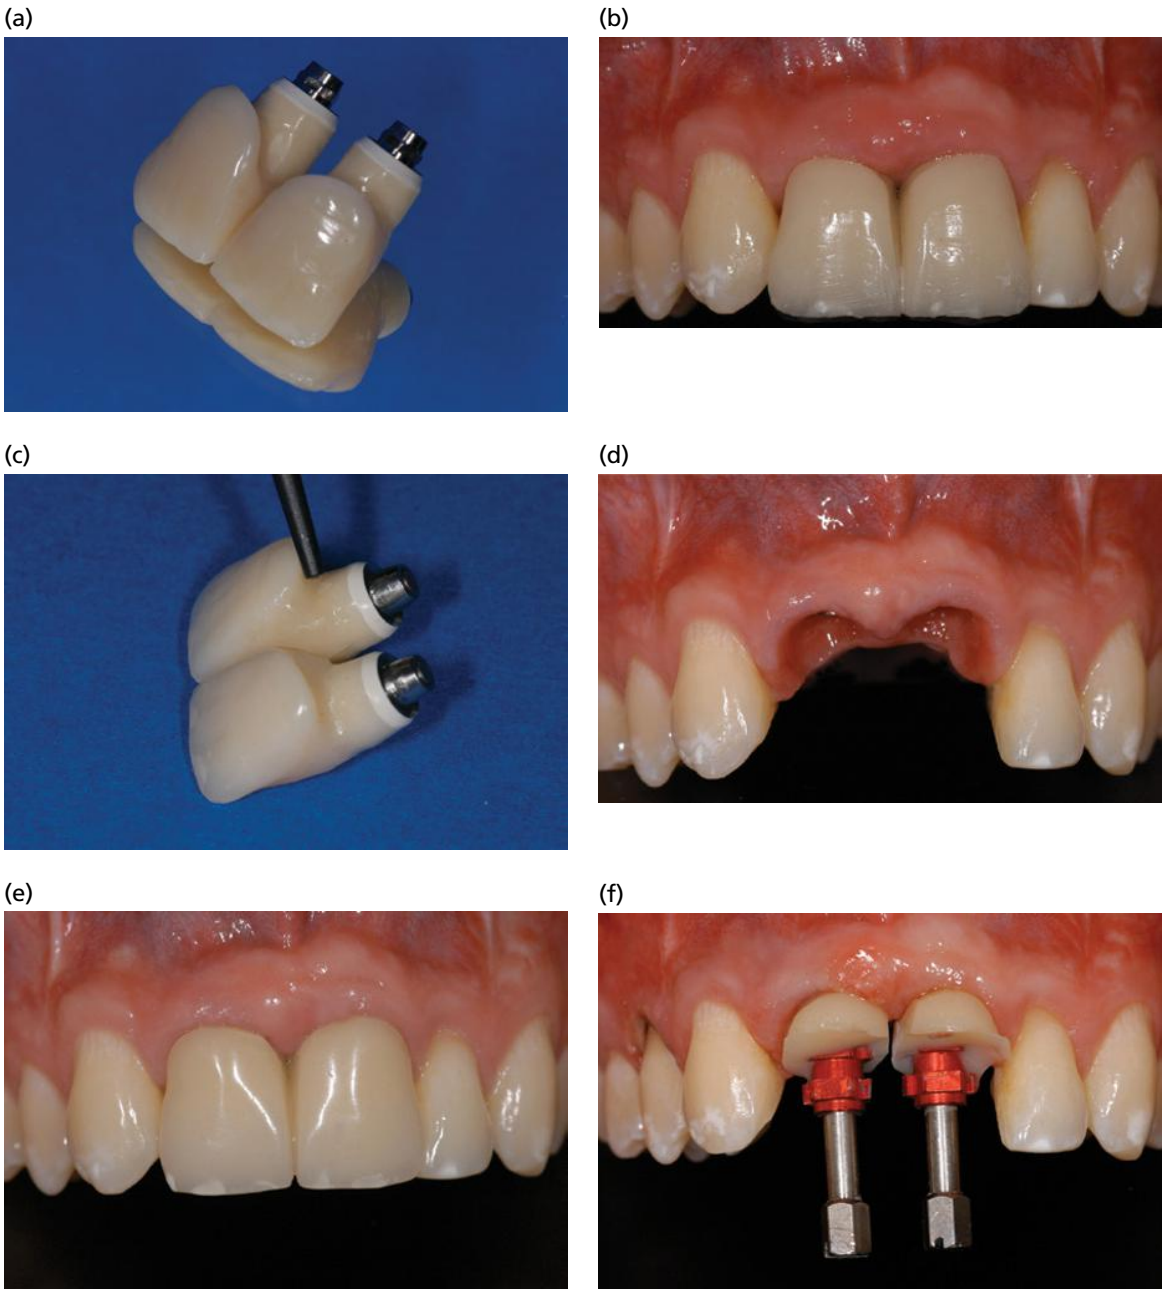

Fig. 54-35 Same patient as in Figs. 54-31, 54-32, 54-33, and 54-34. (a) The dental technician fabricated provisional acrylic restorations on top of a plastic abutment. The buccal aspect of the crown was designed according to the ideal shape based on the wax-up. The apical part of the provisional was removed to leave enough space for the soft tissues. (b) Buccal view of the screw-retained provisional restoration. The acrylic provisional restoration was used to improve the emergence profile of the two implants. (c) Flowable composite was used to progressively fill the concavity in order to push the soft tissues buccally and create an adequate emergence profile. (d) Progressive light and controlled pressure applied to the buccal soft tissues created the adequate emergence profile. (e) Provisional restoration after 6 months. Adequate emergence profile and soft tissue contour were achieved. (f) Buccal view of two individualized impression copings to capture the emergence profile for a precise transfer to the cast. Note the correction of scar tissue buccomesial of tooth 11 with a diamond bur and the crown lengthening of tooth 14 in order to better mimic a canine.

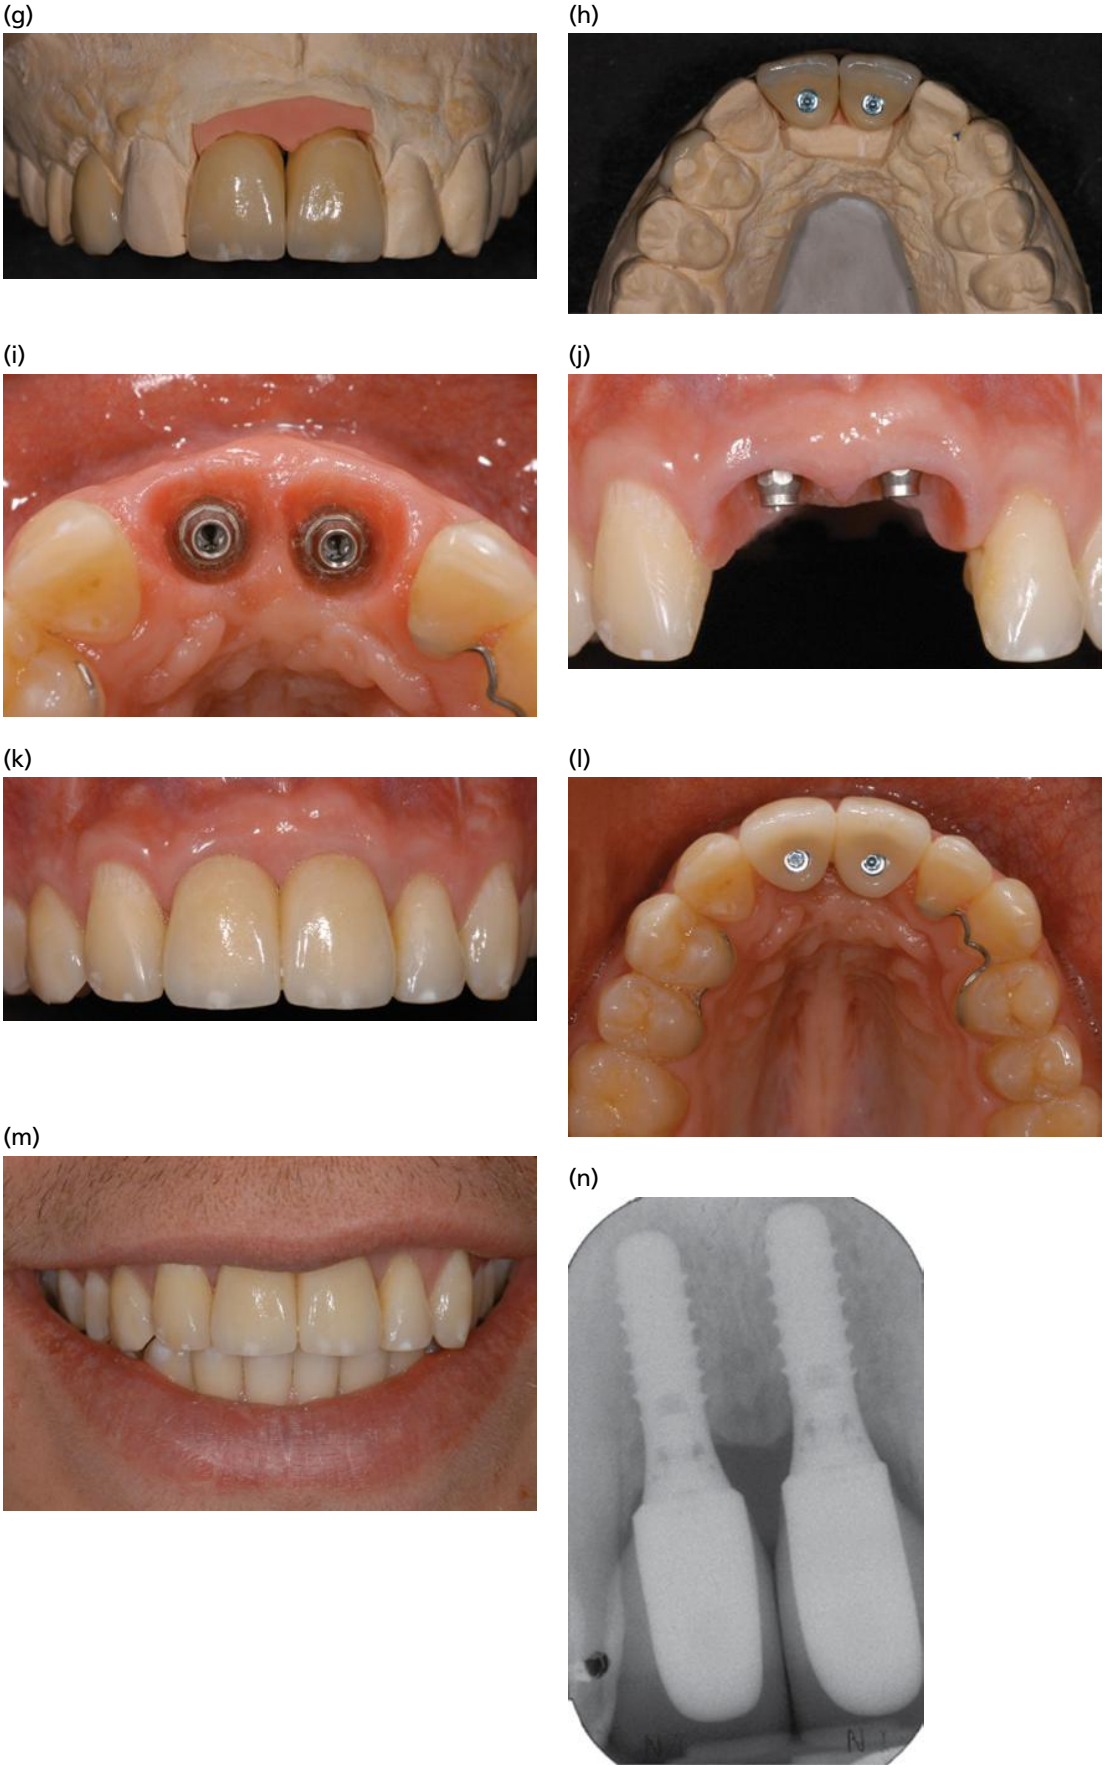

Fig. 54-35 (*Continued*). (g) Buccal view of two all-ceramic restorations and a veneer on tooth 14. A single tooth implant-supported solution was chosen. In order to compensate for the missing interimplant tissue, a long contact area was created. (h) Occlusal view of the screw-retained single-unit restorations and the veneer on tooth 14 on the master cast. (i) Occlusal view of the implants before final insertion of the two crowns. Note the thickness of the buccal soft tissue and the customized emergence profile that has been created during the provisional phase. (j) Buccal view of the soft tissue situation immediately before crown placement. Long-term provisional restoration and successive modifications led to pleasing mucosal margins and the creation of a minimal papilla. Tooth 13 had been shaped and adapted with composite to mimic a lateral incisor. (k) Final restoration in place. The right first premolar was modified with slight preparation and a ceramic veneer to look like a canine. Characterization with some white spots in the incisal edge and lines in the area of the neck created the look of a natural dentition. (l) Occlusal view of the final reconstruction in place. The ideal implant position allowed the screw access hole to be in the right place. (m) After a long treatment of close to 2 years, an esthetically pleasing result was achieved based on the integration of the restoration within the rest of the structures of the mouth and the face. (n) Final periapical X-ray demonstrating two bone level implants 3 years after loading.

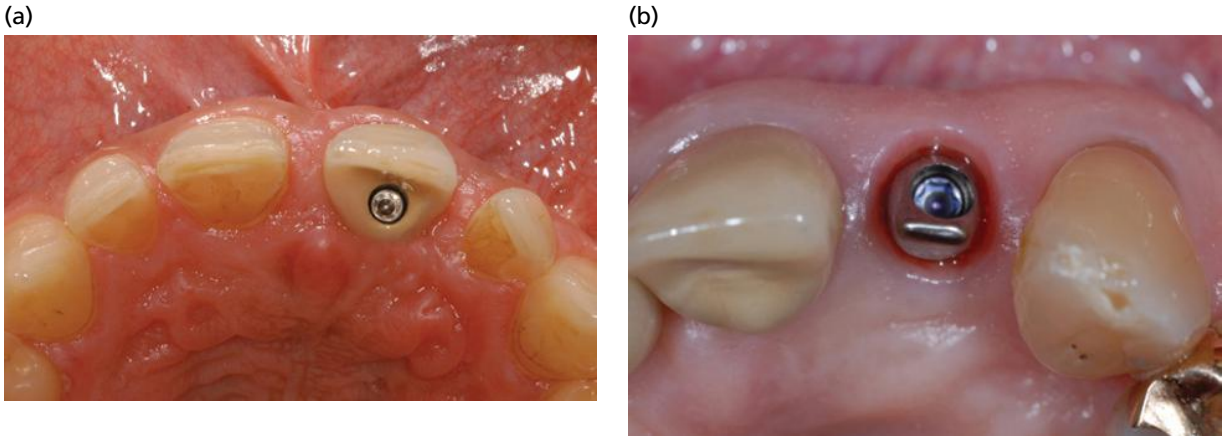

Fig. 54-36 (a) For a screw-retained restoration, an ideal implant position and axis is of great importance for a proper position of the screw-access hole. (b) A cemented restoration with an individualized abutment can compensate for a too buccally tilted implant position.

complex and more expensive laboratory procedures and can suffer from inherent mechanical complications such as screw loosening and fractures (McGlumphy *et al*. 1998; Pietrabissa *et al*. 2000). In contrast to the screw-retained restorations (Fig. 54-36a, where the ideal implant axis is a prerequisite, the cemented restoration offers the option to better compensate for a suboptimal implant position (Fig. 54-36b). Cement-retained implant reconstructions offer excellent esthetics due to the absence of the screw access hole, and incur lower technical costs than screw-retained restorations due to the reduced number of implant components and fewer technical steps that are needed (Taylor & Agar 2002). A variety of disadvantages of cemented reconstructions have been reported: difficulty of cement removal, more complex retrievability, and the possibility of crown loosening due to loss of retention (Breeding *et al*. 1992; Agar *et al*. 1997; Kent *et al*. 1997; Chee *et al*. 1999; Michalakis *et al*. 2003). These disadvantages can be minimized by choosing the correct abutment design and type.

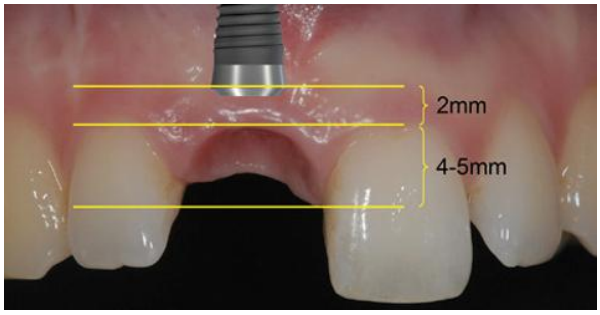

Fig. 54-37 Depth of an implant shoulder in a normally scalloped anterior site.

Fig. 54-38 CAD/CAM fabricated zirconia abutment.

Standardized prefabricated versus customized abutments

Each patient should be individually analyzed in order to decide whether to use a standardized prefabricated abutment or a customized abutment when esthetics play an important role. A thorough assessment includes the following factors: (1) soft tissue morphology, including soft tissue scalloping and vertical implant position; (2) discrepancy between the cross-sections of implant and tooth; (3) clinical and dental technical handling; (4) costs.

Anterior implant sites are often characterized by a high scalloped mucosal margin (Fig. 54-37). Implant shoulders, which are positioned 2–3 mm apical to the buccal mucosal margin have a proximal depths of up to 7–8 mm depending on the individual scalloping of the soft tissue (Fig. 54-38). If a standardized abutment that does not follow the soft tissue margin is used, removal of the excess cement is difficult, especially in the mesial and distal areas. The influence of the remaining cement on the health of the peri-implant

tissue has been recently investigated (Wilson 2009). It was demonstrated that excess dental cement was associated with signs of peri-implant disease in the majority (81%) of cemented single-unit fixed dental prostheses with mainly standardized abutments. Clinical and endoscopic signs of peri-implant disease were absent in 74% of the implants after removal of the excess cement. Hence, it seems that meticulous removal of cement is an important prerequisite for peri-implant health. An *in vitro* study evaluated the efficiency of cement removal from restorations luted to titanium abutments with simulated subgingival margins (Agar *et al.* 1997). It was concluded, that in each case there was remaining cement. It seems that, even under standardized conditions, it was not possible to completely remove composite, glass–ionomer or zinc–phosphate cement from a clinical analog model with crown margins located 1.5–3 mm submucosally. Therefore, in clinical situations with high scalloped soft tissue morphologies and deep vertical implant positions, customized abutments are recommended. These abutments allow an individual emergence profile of the reconstruction to be obtained directly by the abutment (Figs. 54-39, 54.40a). Hence, the crown margin can be located no >1.5 mm below the soft tissue margin and following the scalloping of the mucosa (Figs. 54-40b).

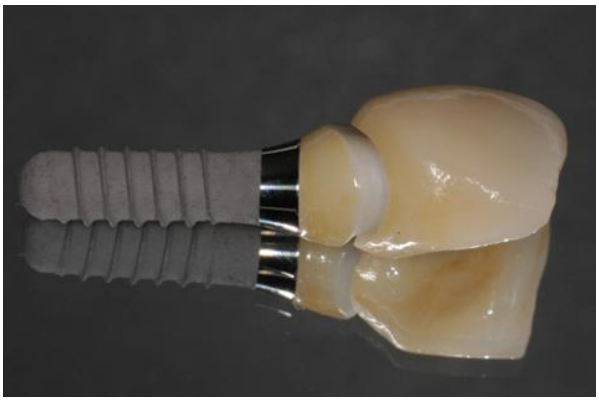

Fig. 54-39 Individualizing the CAD/CAM abutment in order to better match the color of the all-ceramic crown.

Customized abutments can be fabricated either by copy-milling techniques or by means of computer-guided (CAD/CAM) systems. For both manufacturing procedures, a resin or wax model of the desired abutment is designed on a master cast by the dental technician. This prospective abutment can be used as a guide to individually shape an ingot with a copy-milling machine (Glauser *et al.* 2004). In computer-aided manufacturing, these abutments can be scanned, digitized, and the data sent to a central production facility via the internet (Kucey & Fraser 2000). Today more and more customized CAD/CAM abutments are being virtually designed without previous fabrication of a pro-abutment.

This procedure allows many options for individualizing the abutment to the clinical situation. However, from a clinical and technical handling perspective, it is more time consuming and slightly more expensive compared to the manufacture of standardized prefabricated abutments. Therefore, in clinical situations with flat gingival morphologies, shallowly placed implants, and minor discrepancy between the cross-sections of the implant and tooth, standardized prefabricated abutments are the therapy of choice (Fig. 54-41). After the decision about a standardized prefabricated and customized abutment, it is important to choose the material of the abutment and the reconstruction.

Porcelain-fused-to-metal versus all-ceramic abutments

In the anterior zone of the upper jaw, the choice of abutment material is mainly influenced by the soft tissue architecture, the esthetic expectations of the patient, and the esthetic goal to be achieved with the reconstruction, that is the value and color of the neighboring teeth. The gray color of titanium abutments needs to be masked with metal–ceramic reconstructions. Due to refinements of the veneering ceramics for metallic frameworks, excellent esthetic results can be achieved with this kind of reconstructions. However, many authors have reported that the grayish color of

Fig. 54-40 (a) Customized zirconia abutment following the gingival morphology before cementing the all-ceramic crown. (b) Final clinical result after cementing the all-ceramic crown 21.

Fig. 54-41 Flat gingival morphology in an elderly patient where a standard abutment is indicated.

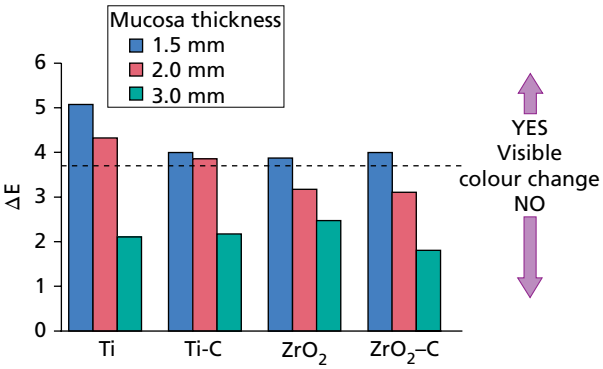

Fig. 54-42 Bar chart illustrating the ΔE values for the different materials evaluated under different mucosal thicknesses. The line at ΔE = 3.7 represents the critical ΔE threshold for intraoral color distinction as perceived by the naked eye. (Ti, titanium; Ti-C, veneered titanium; ZrO_2, zirconia; ZrO_2-C, veneered zirconia.)

the abutments impairs the esthetic result due to a discoloration of the peri-implant soft tissues (McCartney *et al.* 1993; Sadoun & Perelmuter 1997; Yildirim *et al.* 2000; Henriksson & Jemt 2003). It is often reported that ceramic abutments are esthetically advantageous as their color is similar to that of natural teeth. Different clinical and preclinical studies have been performed to evaluate the color change effect of all-ceramic restorations compared to PFM restorations on the marginal peri-implant soft tissue (Jung *et al.* 2008). In a randomized controlled clinical trial, 30 patients were divided into two groups of 15 subjects each. The all-ceramic group received all-ceramic crowns on Al_2O_3-based abutments, while the PFM group received PFM crowns on titanium or gold abutments (Jung *et al.* 2008). A reflectance spectrophotometer was used to measure the color difference between the mid-facial peri-implant mucosa after insertion of the restoration and that of the gingival margin of the corresponding neighboring tooth. It was demonstrated that all-ceramic restorations revealed a significantly better color match compared to the unrestored teeth than PFM restorations. It was also shown that increasing the thickness of the soft tissue by using connective tissue grafts reduced the risk for soft tissue discoloration independent of the reconstruction material. This is important clinical information; however, it would be of great interest to know the critical thickness of the mucosa that is needed to mask the grayish color of titanium abutments.

In order to evaluate this critical thickness, an *in vitro* study analyzed the influence of mucosal thickness on color changes caused by different abutment materials: titanium, veneered titanium, zirconia, and veneered zirconia (Jung *et al.* 2007). It was demonstrated that all restorative materials induced an overall color change, which decreased with increase in soft-tissue thickness. Titanium induced the most pronounced color change of all materials tested. Zirconia, however, did not induce a visible color change at mucosal thicknesses of 2 and 3 mm, irrespective of whether or not it had been veneered. The human eye could not distinguish a color change for any test specimen at a mucosal thickness of 3 mm. It can, therefore, be concluded that 2 mm is the critical mucosal thickness and the following clinical recommendations might be given: (1) with a mucosal thickness of >2–3 mm, PFM or all-ceramic reconstructions can be recommended, and (2) with a thin gingiva of ≤2 mm, either a soft tissue graft or an all-ceramic reconstruction is indicated (Jung *et al.* 2007; Fig 54-42).

In addition to the esthetic evaluation, the decision whether or not to use an all-ceramic or a metal abutment should also be based on the clinical performance and the mechanical properties. A recent systematic review of the performance of ceramic and metal implant abutments supporting fixed implant reconstructions included a total of 29 clinical studies (Sailer *et al.* 2009). The estimated 5-year failure rates for ceramic and metal abutments appeared to be similar, with no evidence for differences in the technical and biologic outcomes of ceramic and metal abutments. However, for ceramic abutments, only a limited number of studies and abutments were analyzed, and the follow-up time was also limited.

Esthetic failures

All treatment modalities in any dentoalveolar segment that are visible upon full smile and which include the placement of one or more implants, must be classified as an advanced or even complex procedure. For that reason, esthetic failures do occur, most often due to the lack of proper preoperative planning. Compared to conventional approaches with crowns on teeth, the risk for buccal soft tissue dehiscences is more pronounced around implant-supported reconstructions (Bengazi *et al.* 1996; Oates *et al.* 2002; Zigdon & Machtei 2008) and these are the major cause of adverse esthetic effects at implant sites. Follow-up studies document that most of the soft tissue changes happen within the first 6 months after prosthetic loading (Bengazi *et al.* 1996; Schropp *et al.* 2003; Cosyn *et al.* 2012; Pieri *et al.* 2013). Another frequently observed esthetic impairment is the lack of papillary-like structures between tooth and implant or between two implants (Schropp *et al.* 2005; Chow & Wang 2010;

Chang *et al*. 2012; Perez *et al*. 2012). Regarding this aspect, the esthetic appearance seems to improve over time, mainly dependent on the attachment level of the adjacent teeth (Finne *et al.* 2012). The lack of papillae not only influences the patient's satisfaction with the esthetic appearance, but also his/her phonetic speech (Suphanantachat *et al*. 2012).

Only one case report (Hidaka & Ueno 2012) and two prospective studies have been published regarding the treatment of such complications (Burkhardt *et al*. 2008a; Zucchelli *et al*. 2012). The results clearly indicate the difficulty in classifying soft tissue defects around implants in order to give a reliable prognosis for the treatment outcome.

Classification of esthetic failures

A classification of soft tissue inadequacies around implants should allow the severity of the lesion to be diagnosed and the prognosis of the treatment evaluated. Murphy (1997) has described the desirable characteristics of such a classification of defects. It should be (1) useful, (2) exhaustive, (3) disjointed (no particular case should fall into more than one class), and (4) simple. It is obvious that many local factors influence the therapeutic outcome of surgical retreatments: hard and soft tissue characteristics (e.g. volume, thickness, surface textures, scar formations), vertical and horizontal position of the implant, neighboring structures (tooth/implant), and presence or absence of inflammation. As a consequence, the prediction of a certain result is a complex process that should consider data from reliable studies and cannot be drawn from theoretical considerations. Additionally, other recognized patient- and technique-related prognostic factors and the operator's skill can decisively influence the outcome and make a relevant classification system almost impossible.

Nevertheless, based on our personal experience, some guidelines can be given. Before planning to surgically rebuild the architecture of the soft tissues in the anterior upper jaw for esthetic reasons, the tissues should be free from mucositis and/or peri-implantitis and the patient must be compliant. Thus, first interventions might aim to eliminate inflammatory reactions and improve the soft tissue conditions. Once the conditions are favorable for a further intervention, the surgical limits should be well balanced with the patient's wishes and expectations. Depending on the above-mentioned variables, good results can be achieved concerning the coverage of buccal mucosal dehiscences, while the anatomic prerequisites of the approximal soft tissues do not allow a prognosis which justifies a surgical intervention to augment the volume of these structures. In a prospective cohort study (Burkhardt *et al*. 2008a), ten consecutively treated patients each with one buccal soft tissue dehiscence at an implant site were evaluated postoperatively concerning the amount of coverage up to 6 months. A substantial amount of soft tissue coverage was achieved immediately following the intervention (coronally advanced flap combined with a connective tissue graft), with a mean percentage coverage of 99.3%. After 3 months of healing, however, a clinically and statistically significant soft tissue shrinkage was noted at each treated site, which continued for up to 6 months, at which time the mean coverage was 66%.

In another study, 20 patients each with a single soft tissue dehiscence in the zone of esthetic importance were enrolled (Zucchelli *et al.* 2012). The treatment consisted of crown removal, preparation of the underlying abutment, a coronally advanced flap combined with a connective tissue graft, and placement of a new reconstruction. One year after treatment, the mean coverage of the previously denuded implant areas was still 96.3%, and 75% of the treated cases showed complete coverage of the defects. These results are promising, but we must not ignore the fact that the preoperative defect characteristics in this patient cohort were not ideal for coverage. Additionally, the prosthetic crowns had been rebuilt, which further increased the treatment effort and costs.

The CEJ to height of the interdental papillae dimension has been demonstrated to influence the outcome of recession coverage around teeth (Zucchelli *et al*. 2006). It is obvious that this dimension cannot directly be extrapolated to the implant site as the level of the CEJ can only be approximated from the contralateral teeth if these are present and have not undergone any restoration at all. In order to estimate the result of mucosal defect coverage at implant sites, the prospective level of the CEJ has to be related to the height of the papillary structure and bony support mesial and distal of the dehiscence defect.

Recommendations for retreatment of esthetic failures

Based on the above-mentioned criteria, it can be concluded that in cases with a flattened or even no papillary morphology, the prognosis for a surgical treatment to improve the soft tissue appearance is poor, and the treatment modalities must focus on prosthetic adjustments only or placement of an epithesis to mask the defect (Fig. 54-43).

In situations with favorable conditions regarding coverage of the dehiscence defect, a surgical approach can be considered (Fig. 54-44). Basically, the combined approach of a coronally advanced flap with an underlying connective tissue graft seems to stabilize the wound and provides a better prognosis.

A bucco-oral position of implants has been shown to be one of the main reasons for post-prosthetic soft tissue shrinkage at implant sites (Evans & Chen 2008). If the implant has been placed in a too labial position, beyond an imaginary tangent drawn between the buccal CEJ of the adjacent teeth, a dehiscence coverage alone would not change the causative factors and the result later on would be a similar

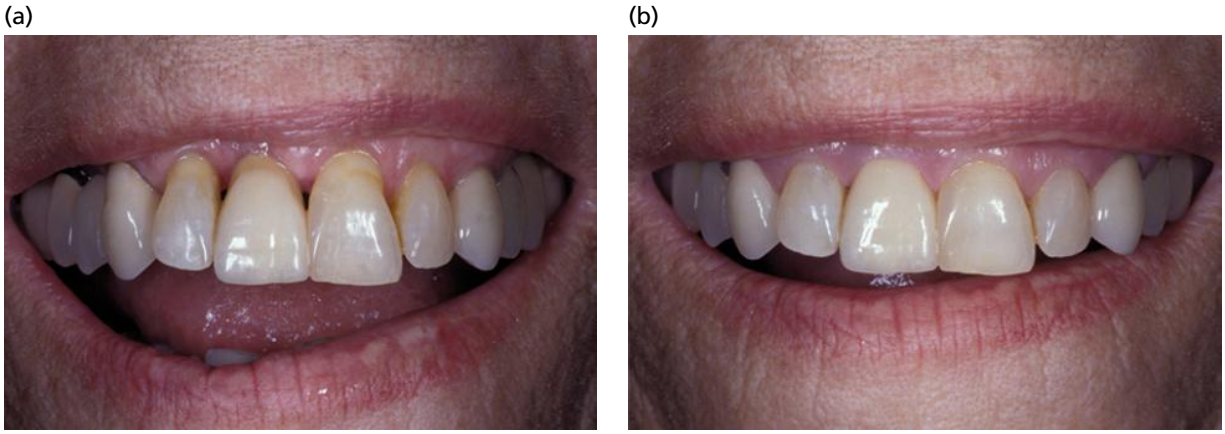

Fig. 54-43 (a) Implant-supported crown with open triangles between the crowns. (b) Correction of such an impairment cannot be achieved with a surgical intervention. An epithesis made of silicon improved the esthetic appearance.

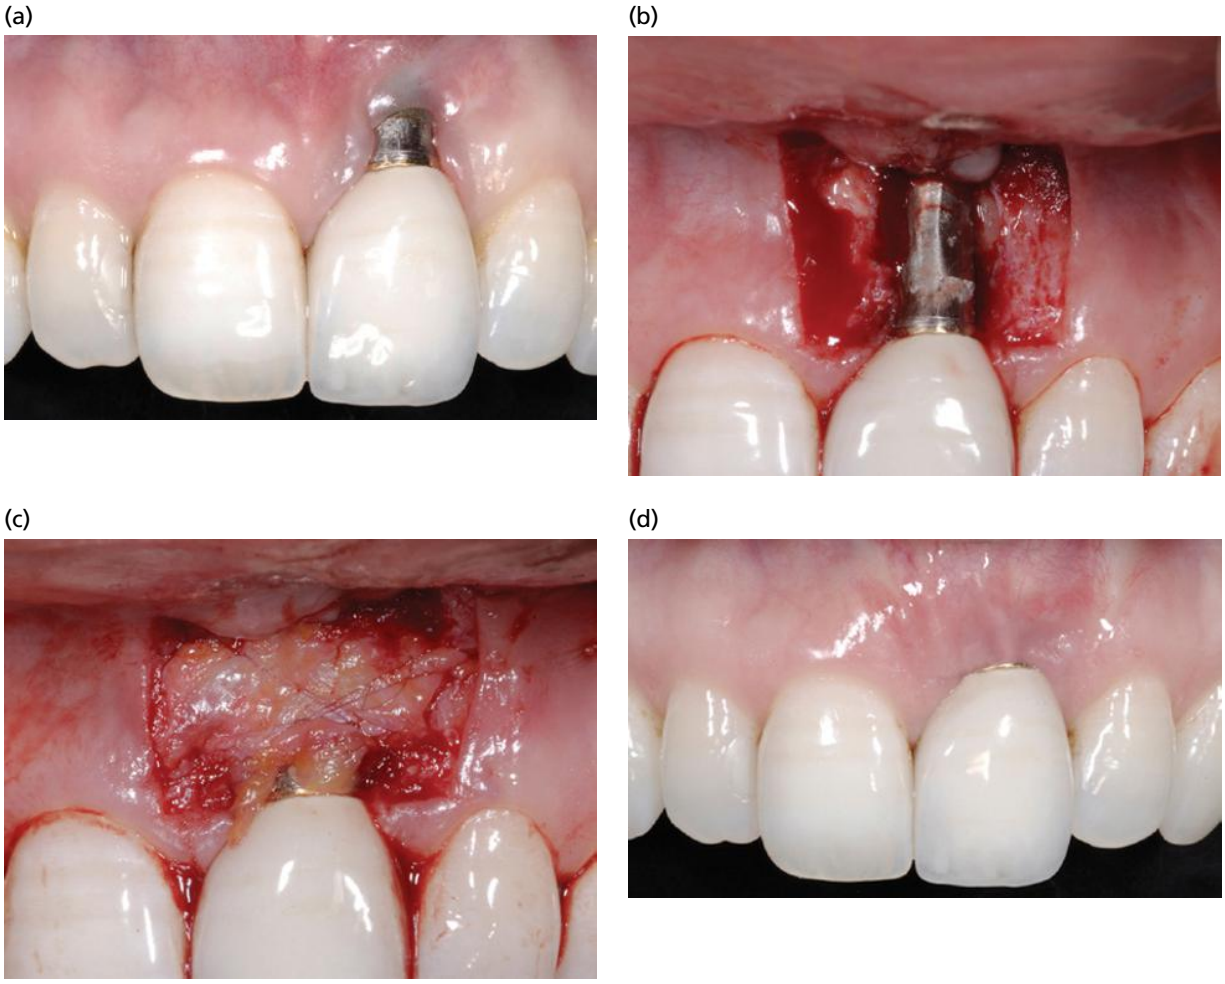

Fig. 54-44 (a) Buccally placed implant covered by a thin mucosa, resulting in a soft tissue dehiscence. (b) To augment the keratinized mucosa, a double pedicle papilla flap was prepared after smoothing out the implant surface. (c) For thickening the marginal mucosa, a connective tissue graft was placed underneath the flap. (d) Almost complete coverage of the mucosal dehiscence could be achieved combined with a functional improvement (mucosal thickening).

situation. In such circumstances, the soft tissues have to be augmented and in most cases a new reconstruction is indicated. To facilitate the surgical procedure and improve the prognosis, the implant has to be resubmerged (Fig. 54-45).

In cases with a completely malpositioned implant, the only promising solution is removal of the implant. However, this treatment option has to be carefully evaluated as the removal of a fully osseointegrated implant is a demanding surgical procedure that carries the potential risk of further impairment of the esthetic result. Furthermore, the reconstruction in such a situation is often time consuming as it requires several treatment steps

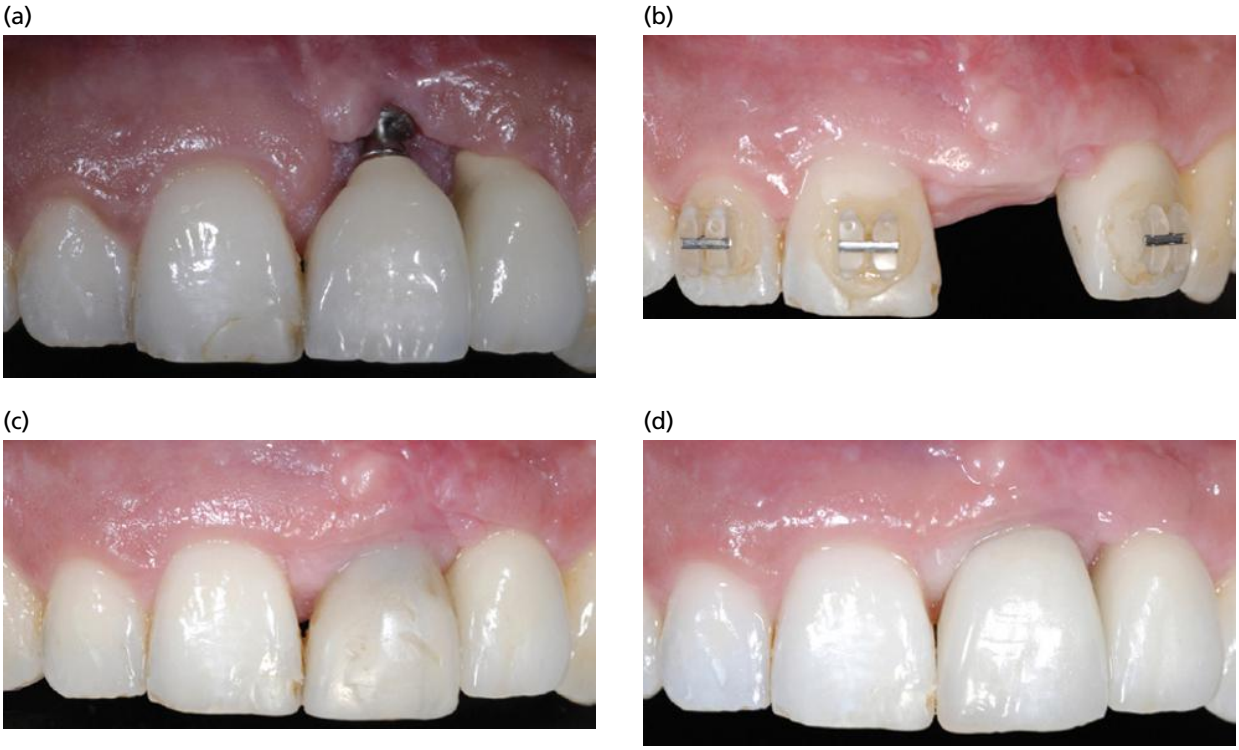

Fig. 54-45 (a) Status a few years after the accident with loss of central and lateral incisors and subsequent implant reconstruction of the missing teeth. Note the scar formation and mucosal dehiscence around the implant-supported crown 21. (b) Implant has been resubmerged and primarily covered by a palatally-pedicled flap and two connective tissue grafts underneath. (c) Three months after healing, the abutment connection was performed and a provisional crown was placed. This crown was left *in situ* for >1 year. (d) Final crown was completely custom-made and fabricated to compensate for the buccal implant position. The soft tissue margin remained stable over the following years.

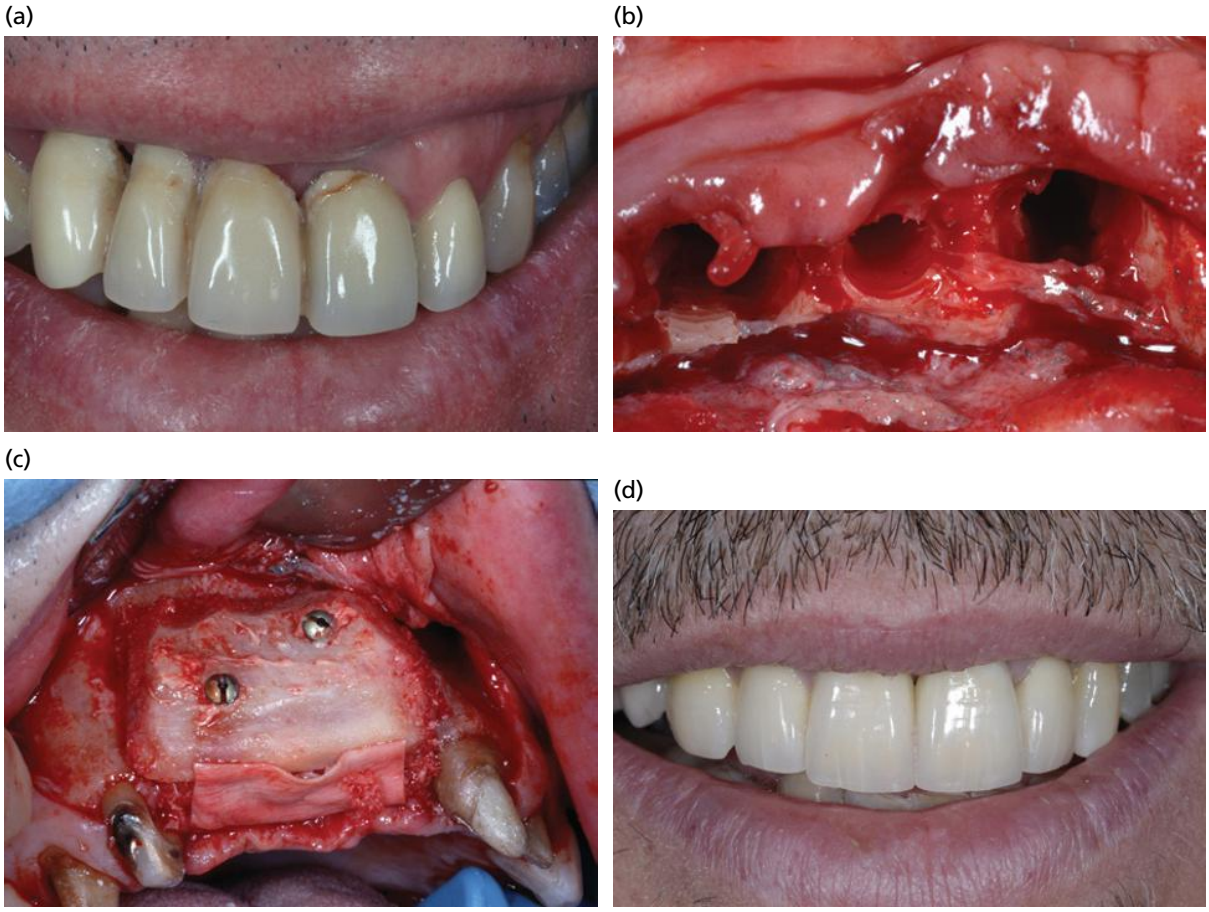

Fig. 54-46 (a) Case of malpositioned implants in the areas 13, 12 and 11, placed far too apically. (b) Fully osseointegrated implants (machined surfaces) could be unscrewed. (c) Extended bone augmentation compensated for the vertical and horizontal volume deficiency. (d) Several additional soft tissue augmentations were indicated to increase the tissue volume of the papilla-like structures with a natural appearance.

(Fig. 54-46) and is costly for the patient. To date, there are no reliable recommendations in the literature for how to remove an implant without causing a substantial amount of bone loss. It can be speculated that an implant with a modern rough surface cannot just be unscrewed by applying a reverse torque. The force required to remove a short implant with a rough surface is >100 Ncm and increases with increasing implant length. In contrast, the required reverse torque to unscrew a fully osseointegrated implant with a machined surface has been measured to be in the range of 35 Ncm and it is not proportional to the implant length (Bernard *et al*. 2003). Applying torque forces >100 Ncm on an implant risks breaking the alveolar structure.

Based on the proverb "a stitch in the time saves nine", it must be emphasized that the surgical correction of esthetic complications is a demanding intervention in most respects and to date, there are no generally recommended treatment options in the literature offering a good prognosis based on literature data. Thus, the clinician's attention should be directed to the alternative treatment modalities before choosing an implant-supported reconstruction. This would help to prevent severe esthetic failures.

Concluding remarks and perspectives

Within the last two decades the concepts and therapeutic modalities have been developed to solve most of the problems of partial edentulism in the zone of esthetic priority. Additionally, the majority of these concepts have been proven in the published literature data and the decisive risk factors are well known.

Nevertheless, each implant-based restoration in a zone which is visible upon full smile, requires special attention and represents a demanding procedure even if the prerequisites for a good outcome appear to be fulfilled at first glance. As implant placement is a non-reversible act, careful presurgical planning is mandatory and special attention must be paid to the alternative options with all their benefits and side effects. It is a duty of clinicians to make sure that patients have understood the planned treatment solution, including the risks this carries for a possible adverse esthetic outcome.

Chapter 55

Implants in the Posterior Dentition

Ronald E. Jung,[1] Daniel S. Thoma,[1] and Urs C. Belser[2]

[1] Clinic of Fixed and Removable Prosthodontics, Center of Dental and Oral Medicine and Cranio-Maxillofacial Surgery, University of Zurich, Zurich, Switzerland
[2] Department of Prosthetic Dentistry, School of Dental Medicine, University of Geneva, Geneva, Switzerland

Introduction

The overall favorable long-term survival and success rates reported in the literature for osseointegrated implants in the treatment of various types of edentulism (Brånemark *et al.* 1995; Jemt *et al.* 1996; Lindquist *et al.* 1996; Buser *et al.* 1997; Andersson *et al.* 1998a; Buser *et al.* 1998a; Eckert & Wollan 1998; Lindh *et al.* 1998; Mericske-Stern 1998; ten Bruggenkate *et al.* 1998; Wyatt & Zarb 1998; Gunne *et al.* 1999; Lekholm *et al.* 1999; Van Steenberghe *et al.* 1999; Wismeijer *et al.* 1999; Behneke *et al.* 2000; Hosny *et al.* 2000; Hultin *et al.* 2000; Weber *et al.* 2000; Boioli *et al.* 2001; Gomez-Roman *et al.* 2001; Kiener *et al.* 2001; Mengel *et al.* 2001; Oetterli *et al.* 2001; Zitzmann *et al.* 2001; Bernard & Belser 2002; Buser *et al.* 2002; Haas *et al.* 2002; Leonhardt *et al.* 2002; Romeo *et al.* 2002; Esposito *et al.* 2009; Bragger *et al.* 2011) permit consideration of dental implants as one of the reliable therapeutic modalities during the establishment of any prosthetic treatment plan. In numerous clinical situations, implants can clearly contribute to a notable simplification of therapy, frequently enabling removable prostheses to be avoided, keeping it less invasive with respect to remaining tooth structure, or rendering the treatment both more elegant and versatile as well as more predictable (Belser *et al.* 2000).

Beyond any doubt, the advent of osseointegration has had a fundamental impact on the therapeutic approach and strategies implemented today in the field of prosthetic rehabilitation of the compromised posterior dentition. The implant statistics of the University of Geneva School of Dental Medicine, for example, reveal that from April 1989 until December 2011 > 8700 implants of 6–12 mm in length were

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

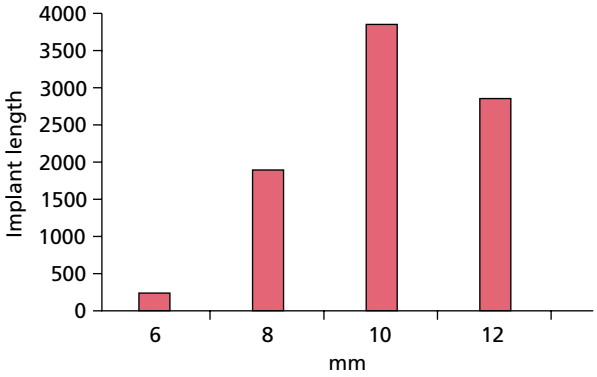

Fig. 55-2 Implant statistics from the University of Geneva, 1989–2011: Implant length distribution.

inserted in about 3250 patients presenting with different types of edentulism (Figs. 55-1, 55-2). This treatment modality is increasingly applied worldwide and has had a tremendous influence on traditional prosthodontic attitudes (Beumer *et al.* 1993; Zarb & Schmitt 1995; Tarnow *et al.* 1997; Zitzmann & Marinello 1999; Belser *et al.* 2000; Schwartz-Arad & Dolev 2000; Bragger *et al.* 2001; Deporter *et al.* 2001; Zitzmann & Marinello 2002). Since most of the established dental implant systems today comprise a wide range of mostly screw-type implants with different diameters and dimensions to replace missing premolars and molars (Fig. 55-3), the versatility of implant therapy in the load-carrying part of the dentition of partially edentulous patients has been significantly enhanced. As part of a textbook focusing essentially on clinical periodontology, this chapter addresses implant therapy performed in the posterior segments of partially dentate patients. In this context, the use of implants may often significantly reduce the inherent risk of "borderline" conventional tooth-borne fixed dental prostheses (FDPs) (e.g. prostheses based on compromised abutment teeth, long-span FDPs, cantilevers) by implementing the principle of segmentation. It is currently widely accepted that – in comparison with extended splinted prosthetic segments – small ones are preferable as they are easier to fabricate, generally provide improved "passive fit" and marginal fidelity, offer better access for the patient's oral hygiene, and

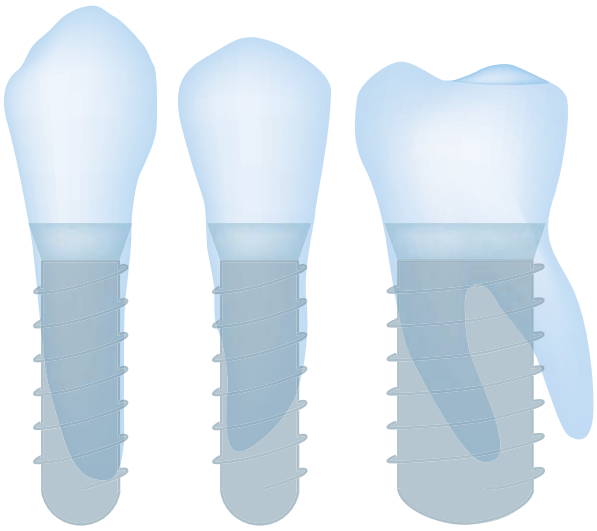

Fig. 55-3 Different implant diameters are available for the replacement of posterior teeth.

ultimately are less complicated to handle where there is need for re-intervention.

It is the aim of this chapter to present clinically-oriented guidelines and procedures for implant therapy of various types of edentulism located in the load-carrying part of the dentition, addressing the partially dentate patient and focusing on implant-supported FDPs.

Indications for implants in the posterior dentition

When it comes to partial edentulism in the posterior segments of the jaws, implants are increasingly used either to preserve sound mineralized tooth structure or to avoid partial removable dental prostheses (RDPs) and high-risk conventional FDPs. This includes situations with missing teeth in otherwise intact dentitions (Fig. 55-4), the distally shortened dental arch (Fig. 55-5), extended edentulous segments, missing "strategic" tooth abutments, and structurally, endodontically or periodontally compromised potential abutment teeth (Table 55-1).

Numerous other indications have been added to the so-called classical indications for the use of implants – severely atrophied edentulous jaws, missing teeth in otherwise intact dentitions (congenitally missing tooth/teeth loss due to trauma or to a localized endodontic/restorative/periodontal complication or failure), and the distally shortened dental arch (particularly when premolars are missing). Among these other indications, one should also mention all the strategies aimed at either reducing the prosthodontic risk in general or rendering the treatment simpler and more cost-effective. Virtually no limits on the placement of implants seem to exist any more owing, for example, to advanced bone augmentation techniques, comprising anterior sinus floor elevation and distraction osteogenesis (Buser *et al.* 1993, 1995, 1996, 1998b; Chiapasco *et al.* 1999; Buser & von Arx

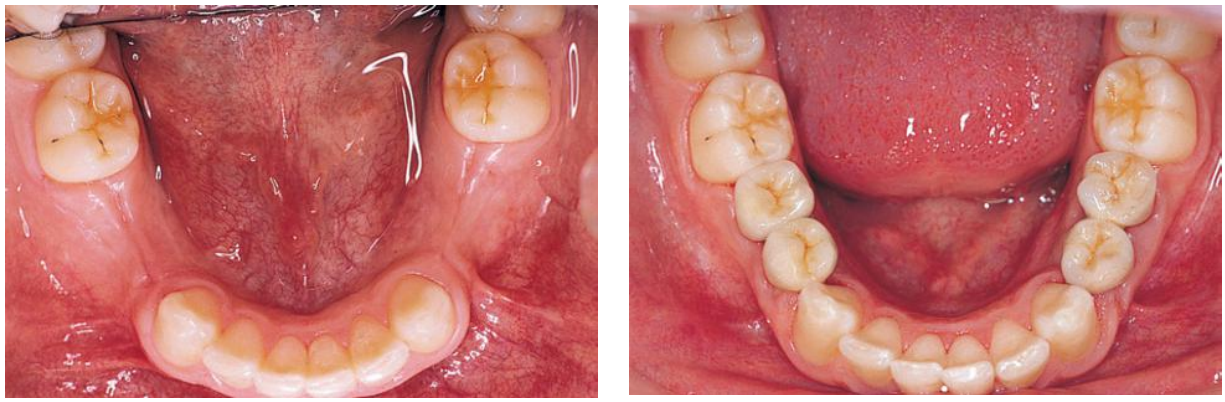

Fig. 55-4 (a) Occlusal view of the mandible of a 22-year-old male patient. All premolars are congenitally missing; the remainder of the dentition is intact. (b) Final view after insertion of four implants, restored with cemented metal–ceramic suprastructures.

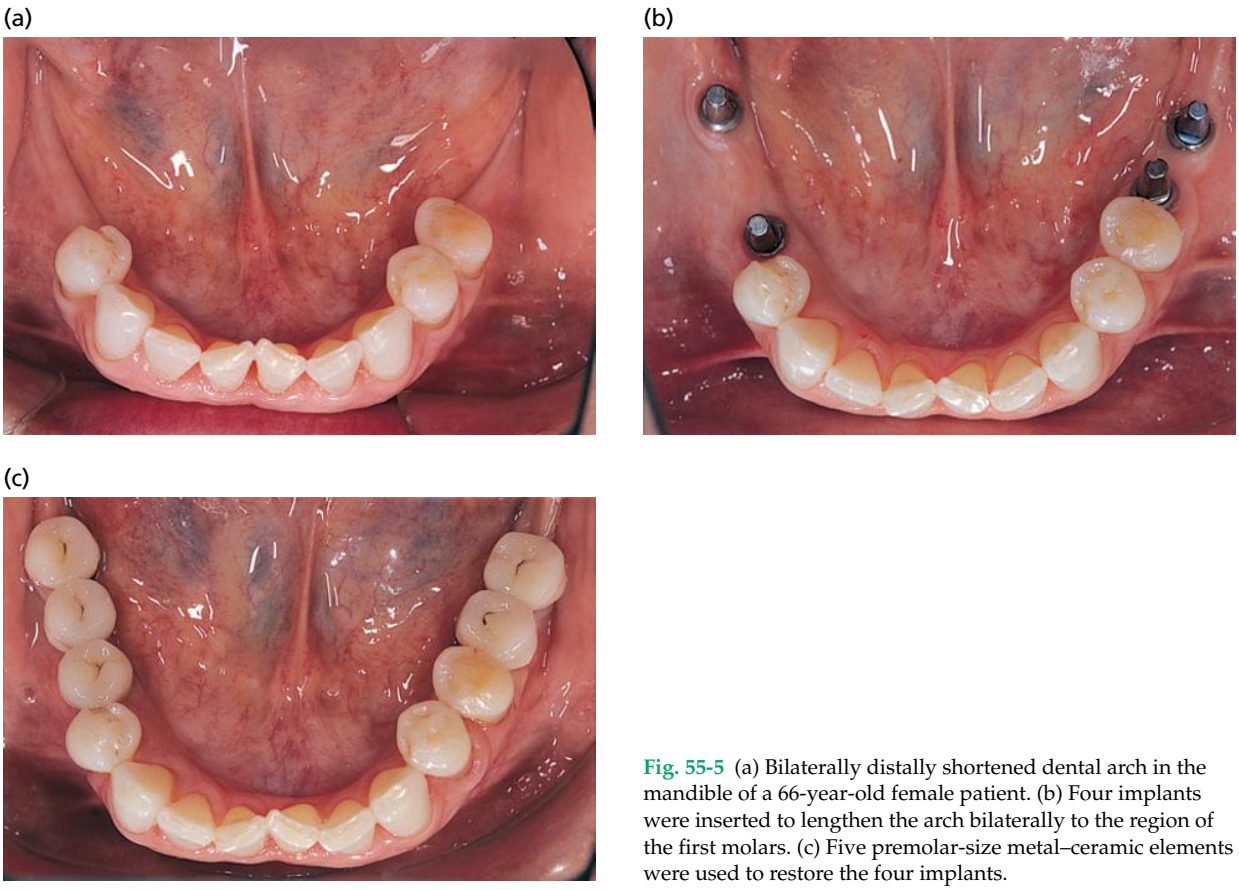

Fig. 55-5 (a) Bilaterally distally shortened dental arch in the mandible of a 66-year-old female patient. (b) Four implants were inserted to lengthen the arch bilaterally to the region of the first molars. (c) Five premolar-size metal–ceramic elements were used to restore the four implants.

Table 55-1 Indications for posterior implants.

- Replacement of missing teeth in intact dentitions (e.g. congenitally missing premolars), that is preservation of tooth structure
- Avoidance of removable partial dentures (RDPs)
- Increase of the number of abutments:
  - Reduction of the prosthetic risk
  - Application of the principle of segmenting
  - Ease of eventual re-interventions
- Maintenance of pre-existing crowns and fixed dental prostheses (FDPs)
- Following prosthetic complications and failures

2000; Chiapasco *et al.* 2001; Simion *et al.* 2001; von Arx *et al.* 2001a, b; Buser *et al.* 2002).

The rapid advance in terms of the broad utilization of dental implants is not exclusively based on the associated favorable long-term reports for this treatment modality. Other parameters such as purely "mechanical" advantages and the availability of prefabricated components and auxiliary parts, which in turn contribute notably to the simplification of the treatment, also have had a significant impact on current concepts and strategies (Table 55-2). Furthermore, clinical decision-making based on

Table 55-2 Impact of dental implants related to the treatment of posterior partial edentulism.

- Favorable overall long-term results
- Preservation of mineralized tooth structure
- "Mechanical" advantages:
  - Commercially pure (c.p.) titanium (biocompatibility, mechanical properties, no risk for caries)
  - Reproducible, prefabricated ("machined") primary, secondary, and tertiary components and auxiliary parts
- Simplified clinical and laboratory protocols

Table 55-3 "High-risk" conventional fixed partial dentures.

- Long-span fixed partial bridges
- Cantilever units (mainly distal extensions)
- Missing "strategic" tooth abutments
- Structurally-/periodontally-/endodontically-compromised tooth abutments
- Reduced interarch distance
- Presence of occlusal parafunctions/bruxism

Table 55-4 Controversial issues related to posterior implant restorations.

- Adequate number, size (length/diameter), design, and distribution of implants
- Cemented versus screw-retained (transocclusal/transverse screw retention)
- Single units versus splinted adjacent implant restorations
- Longest possible versus shorter implants
- Impact of implant axis
- Optimal implant shoulder sink depth
- Minimum ratio between implant length and suprastructure height
- Combination of natural teeth and implants in the same restoration
- Design of the optimal abutment-to-implant connection
- Implant-specific occlusal concepts, including occluding restorative materials, non-axial loading, type of guidance during mandibular excursions
- Healing times prior to functional loading (immediate/early/delayed)
- Significance of offset/staggered implant positioning

prosthetically-oriented risk assessment (Table 55-3) frequently leads to the need for an increased number of abutments. The objective is to reduce the overall risk associated with a given prosthetic solution on the one hand, and to implement the principle of segmenting on the other.

Controversial issues

Despite the ever-growing body of scientific evidence indicating that implant therapy in the partially edentulous patient is an overall highly predictable treatment modality, several conceptual issues remain controversial (Table 55-4). These controversial issues include open questions addressing adequate number, size, and distribution of implants for optimal therapy of a given type and configuration of partial edentulism, as well as parameters related to occlusion and occlusal materials, to implant axis, to the minimal acceptable ratio between suprastructure height and implant length, and – last but not least – to questions focusing more specifically on the mechanical aspects and requirements of posterior implant prosthodontics. Among these, the kinds of connection between implant and abutment in particular have to be mentioned. Most of these questions will be discussed in the remainder of this chapter, at length where possible and appropriate, or more superficially where solid information is missing or where the topic is more adequately covered by other authors of this textbook.

General considerations and decision-making for implants in the posterior dentition

Decision-making between implant-supported reconstruction and tooth-supported fixed dental prostheses

When it comes to the decision-making process between implant-supported reconstruction and tooth-supported FDPs, the related decision criteria should be derived essentially from scientific evidence and objective prosthetically-oriented risk assessments, as well as patient-related factors, including cost effectiveness and quality of life.

In the clinical situation of a hopeless tooth in the posterior dentition, the therapeutic options are a conventional bridge or an implant-supported single crown (Fig. 55-6). In terms of a hierarchy of decisions, the most important question is whether or not the prognosis of an implant-supported reconstruction is similar to that of a tooth-supported FDP. A systematic review of implant-supported single crowns reported an estimated survival rate of 96.8% after 5 years and 89.8% after 10 years (Jung *et al.* 2008). These results were similar to the data reported for tooth-supported FDPs, revealing a survival rate of 93.8% after 5 years and of 89.1% after 10 years (Pjetursson *et al.* 2004). From a prognosis point of view, neither of the two treatment modalities appears to be superior to the other. However, it has to be considered that the type of complications seems to be different with each modality. Conventional tooth-supported bridges reveal more biologic complications like caries and loss of abutment vitality, whereas implant-supported single crowns show more technical complications like abutment or occlusal screw loosening. This has an impact on the severity and the invasiveness of the therapeutic intervention during the maintenance phase.

At the next level in the hierarchy for the decision-making process is the clinical assessment and the patient's expectations. The clinical analysis comprises the comprehensive evaluation of the

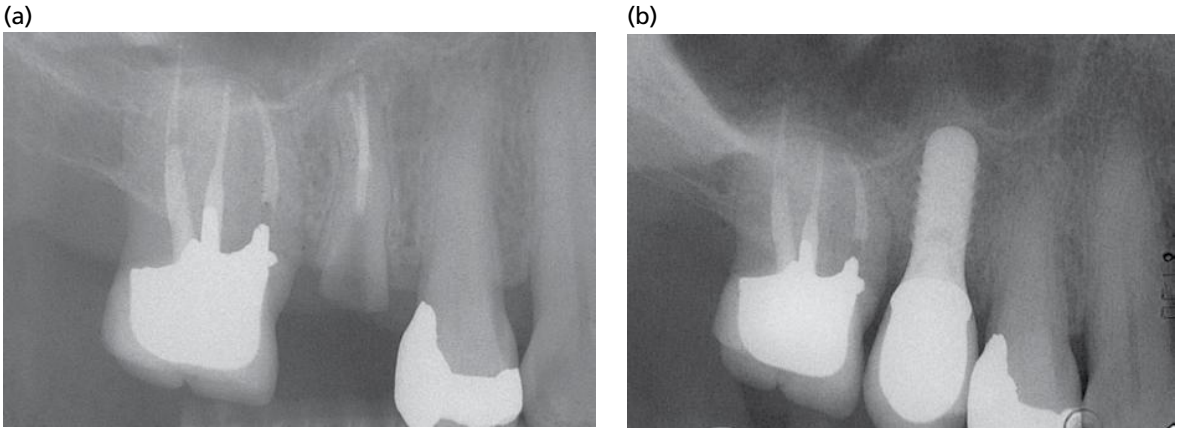

Fig. 55-6 (a) *Ad hoc* radiograph of the upper right posterior sextant. Note the presence of a structurally greatly compromised second premolar with a periapical pathology. Based on the clinical and radiographic assessment, tooth 15 was considered hopeless. (b) Postoperative radiograph shows that the root of the second premolar was replaced by a single-tooth implant restoration. In particular, the pre-existing metal–ceramic crown on the first molar could be maintained with this approach.

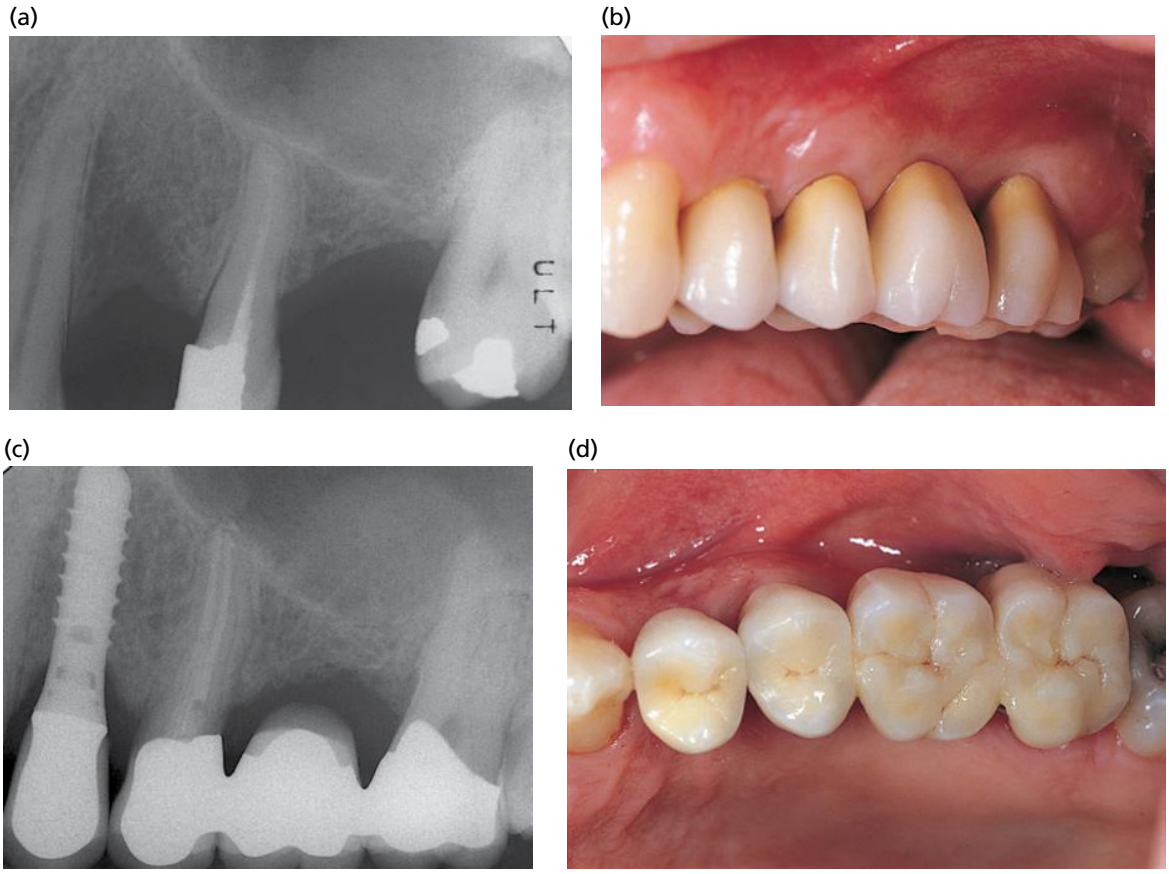

Fig. 55-7 (a) Preoperative radiograph of the left maxilla, revealing two missing dental elements. Note in particular an intact canine, a structurally reduced second premolar, and an extended recessus of the sinus in the area of the missing first molar. (b) Vestibular view of the prosthetic rehabilitation of the maxillary left quadrant: an implant-supported single-tooth restoration on the site of the first premolar, and a three-unit tooth-borne FDP to replace the missing first molar. (c) Postoperative radiograph documents that an endodontic revision has been performed on the second premolar prior to its restoration with an adhesive carbon-fiber, post-based build-up and a metal–ceramic crown. (d) An identical prosthetic design has been applied for both the implant-supported and the tooth-supported restoration.

neighboring natural abutment teeth, including their structural, restorative, periodontal, and endodontic status. This objective evaluation is of primary importance and represents an ever increasing challenge to the clinician. This is illustrated by a maxillary posterior segment where both the first premolar and the first molar were missing (Fig. 55-7). The insertion of a five-unit tooth-borne FDP was considered too invasive given the intact canine, and also not suitable because of a slightly questionable status of

the endodontically-treated second premolar in view of its eventual use as a so-called "peer-abutment". Finally, an implant had been placed at the site of the missing first premolar and subsequently restored with a single-unit restoration. As the proximity of the maxillary sinus at the location of the missing first molar would have required a grafting procedure to make an implant installation possible, a three-unit tooth-supported FPD was ultimately chosen, after having duly discussed the relevant advantages and shortcomings with the patient. Having attributed a "strategic value" to the moderately compromised second premolar by using it as an abutment for a short-span bridge, there was still a difficulty in consistently establishing clinical treatment plans that were fully based on scientific evidence.

Finally, the patient's expectations and requests are very important in the decision-making process. Besides the prognosis and the invasiveness of the reconstruction, the patient will want to know the cost difference and the treatment time difference between implant-supported reconstructions and tooth-supported FDPs. In a retrospective clinical study performed in private practice, 37 patients received 41 conventional FDPs and 52 patients received 59 implant-supported single crowns (Bragger *et al.* 2005b). The aim was to assess and compare the economic aspects by recording the number of visits, chair-side time, treatment costs, and costs for implant components and laboratory work. It was reported that the implant treatment required more visits than FDP treatment; however, the total treatment time was similar. Regarding the costs, the laboratory costs and the total treatment costs were higher for FDPs than for implant-supported single crowns. Even when considering opportunity costs for each visit, the implant solution was less expensive. It was stated that over a short observation period of 1–4 years, the implant reconstruction demonstrated a more favorable cost-to-effectiveness ratio. Especially in clinical situations with either non- or minimally restored teeth and sufficient bone, the implant reconstruction is to be recommended from an economic point of view (Bragger *et al.* 2005a).

Conclusion: The decision-making process between implant-supported reconstruction and tooth-supported FDPs should be based on the prognosis and the complication rate, the clinical assessment of the neighboring teeth and the anatomic condition of the edentulous area, and the patient's expectations.

Implant restorations with cantilever units

There is strong evidence in the dental literature that cantilever units – in particular distal extensions – of conventional tooth-borne FDPs are associated with a significantly higher 10-year complication/failure rate when compared to FDPs featuring a mesial and a distal abutment and a central pontic (Pjetursson *et al.* 2004, 2007). Failures could be attributed to decisive factors such as non-vital abutment teeth as well as specific occlusal conditions such as a reduced interarch distance and/or occlusal parafunctions (Glantz & Nilner 1998). In a more recent prospective cohort study on partially dentate patients treated with implant-supported cantilever FDPs (Romeo *et al.* 2009), the authors reported highly favorable long-term success rates and concluded that the risk of mechanical failures was lower with cantilevered implant-borne reconstructions than with comparable conventional fixed situations. Risks, however, do exist. As loss of retention, one of the frequent complications encountered with conventional cantilevered prostheses, can easily be prevented with implant-supported restorations of this type, the latter seem to be a viable alternative in cases where the local alveolar bone crest conditions do not allow the insertion of an implant at the most favorable location (Wennström *et al.* 2004; Bragger *et al.* 2005a; Halg *et al.* 2008; Zurdo *et al.* 2009; Aglietta *et al.* 2012). In such situations, the clinician has to ponder whether a bone augmentation procedure (simultaneous or staged) can be objectively justified in order to allow the insertion of an implant at the optimal position, or if the risk for complications of a more simple, straightforward approach, that is implant insertion requiring a cantilever restoration, can be considered low. In this context, a recent study retrospectively compared posterior maxillary and mandibular implant-supported single crowns comprising a cantilever extension with posterior FDPs supported by two implants and similarly featuring a cantilever extension (Aglietta *et al.* 2012). No implant loss was registered in either group, yielding a 100% survival rate. Mean marginal bone levels and probing pocket depths were not statistically different between the groups at baseline and at the follow-up examination. The authors concluded that the presence of one mesial or distal cantilever extension in the posterior part of the jaws does not jeopardize either the survival or marginal bone levels of implants supporting single crowns or short-span FDP after an observation period of at least 5 years. From a treatment planning point of view, these data may permit consideration of short-span implant-supported FDPs as a valid treatment option for the replacement of missing posterior teeth that avoids the more complex surgical bone augmentation procedures that are necessary for placement of an implant in a traditionally optimal position from a prosthodontic point of view. Hence, one may speak of a minor change of paradigms. It has to be underlined in this context, however, that basic prosthodontic design principles, such as increased dimensions of the connectors, have to be respected to avoid mechanical complications.

The 16-year clinical and radiographic follow-up of a posterior mandibular three-unit FDP featuring a premolar-size mesial cantilever extension is shown in Fig. 55-8.

Combination of implant and natural tooth support

Combined tooth- and implant-supported FDPs are a treatment option in clinical situations where bone deficiencies only allow the placement of one implant

(a)

(b)

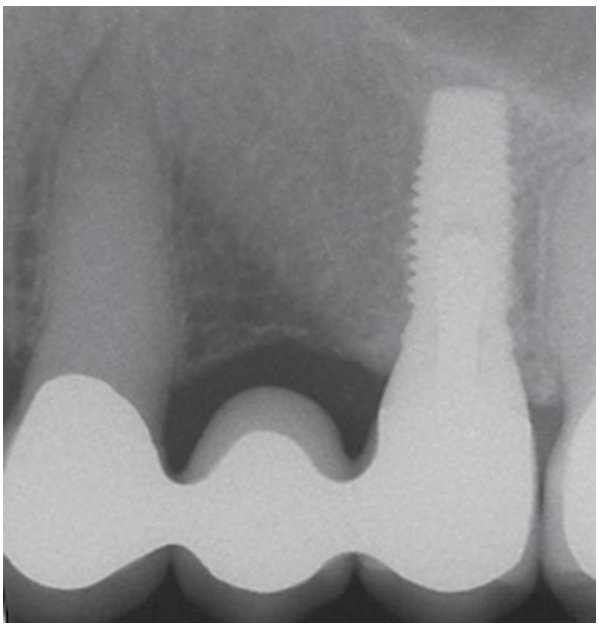

Fig. 55-9 (a) Clinical view and (b) radiograph of a combined tooth- and implant-supported FDP after 5 years of function. This therapy was chosen due to limited bone volume in the area of 24 in order to avoid horizontal bone augmentation procedure.

(e.g. posterior sites) or for patients with limited finances. The potential advantages of combined FDPs are lower patient morbidity and lower treatment cost (Fig. 55-9). From a biomechanical point of view, the splinting of teeth and implants is a challenge due to the different mobility of a tooth in comparison to an osseointegrated implant (Weinberg 1993). In order to overcome this problem, rigid and non-rigid connectors have been proposed. The effects of the two connection types have been analyzed with finite element analysis or other simulation models (Nishimura *et al.* 1999; Menicucci *et al.* 2002; Lin *et al.* 2008; Srinivasan & Padmanabhan 2008; Burak Ozcelik *et al.* 2011), and by means of *in vitro* (Rangert *et al.* 1991; Breeding *et al.* 1995) and *in vivo* (Naert *et al.* 2001a, b; Block *et al.* 2002; Nickenig *et al.* 2006, 2008) studies. The issue remains controversial, but overall it seems that the use of a rigid

connector results in a better clinical outcome (Chee & Mordohai 2010).

From a clinical perspective, the most important issue is the survival and complication rates of combined FDPs in comparison with FDPs supported by implants only. The survival rates of combined FDPs have been analyzed in a number of clinical studies (Gunne *et al.* 1999; Hosny *et al.* 2000; Kindberg *et al.* 2001; Lindh *et al.* 2001; Naert *et al.* 2001a; Block *et al.* 2002; Mau *et al.* 2002; Tangerud *et al.* 2002; Nickenig *et al.* 2006; Akca & Cehreli 2008; Nickenig *et al.* 2008; Bragger *et al.* 2011). Systematic reviews on combined FDPs reported a 5-year FDP survival rate of 90.1% (Lang *et al.* 2004) to 94.7% (Mamalis *et al.* 2012). At 10 years, the survival rates ranged from 77.8% (Mamalis *et al.* 2012) to 82.1% (Lang *et al.* 2004), which are significantly lower than the 10-year survival rates of FDPs supported by implants only (Pjetursson *et al.* 2004). An important factor leading to the loss of the combined FDPs was a relatively high rate of abutment tooth loss (10.6%) and implant loss (15.6%) (Lang *et al.* 2004). A particular biologic complication for combined FDPs is the intrusion of the abutment teeth, which was reported to occur in 5.2% of all teeth. Intrusion appears to be more frequent with the use of a non-rigid connection between teeth and implants (Block *et al.* 2002).

Conclusion: The indications for combined tooth- and implant-supported FDPs are limited due to their relatively low survival rates. If a combined FDP is to be inserted, a rigid connector should be chosen.

Splinted versus single-unit restorations of multiple adjacent posterior implants

In situations with multiple adjacent implants, the dentist faces the decision between fabricating either splinted or unsplinted implant crowns. The rationale for splinting implants is to evenly distribute loading forces on all the implants in order to minimize the stress on the marginal bone, implants, and prosthetic components. Dentists usually give the following reasons for splinting adjacent implants:

- Poor bone quality or major bone augmentation procedures (e.g. sinus floor elevation (Figs. 55-10, 55-11)
- Short implants or reduced diameter implants
- Anticipation of high occlusal forces (e.g. bruxism)
- Easier handling for the dentist (no adjustment of interproximal contacts is necessary).

The main arguments against splinting are:

- Perfect framework fit is more difficult to achieve with a multiunit FDP
- Interproximal hygiene is more demanding (if the use of interdental brushes or floss is hampered by the connector)

Fig. 55-10 Clinical image of a posterior reconstruction with splinted implants.

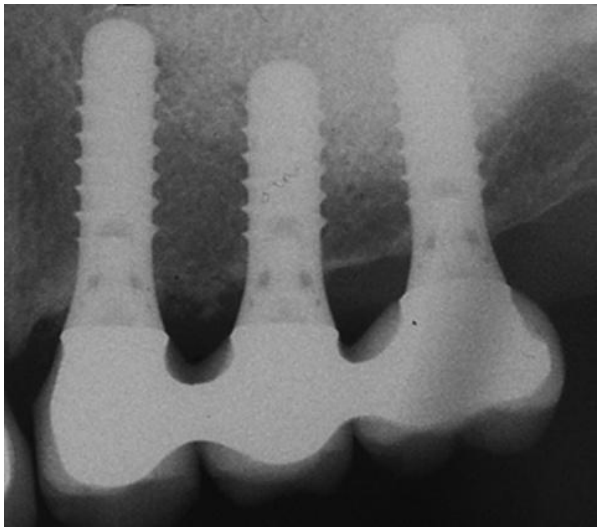

Fig. 55-11 Radiograph of three splinted implants placed after sinus floor elevation.

- Re-intervention is more complicated for multi- than single-unit FDPs (especially for cemented FDPs).

In the literature, the issue of splinting adjacent implants is controversial (Grossmann *et al.* 2005). *In vitro* studies measured the stress resulting from non-axial forces in splinted and unsplinted restorations at two different points: at the implants and in the marginal bone. Splinting did not reduce the stress in the cervical region of the implants in an *in vitro* study (Guichet *et al.* 2002; Wang *et al.* 2002; Nissan *et al.* 2010), but it reduced the stress on the peri-implant bone in a finite element analysis (Wang *et al.* 2002). A photoelastic study showed that splinted restorations distributed the stresses more evenly between the implants (Guichet *et al.* 2002). It remains unclear which one of these findings is clinically relevant. The few clinical studies directly addressing the issue reported no difference in survival rate or marginal bone loss between splinted and unsplinted implants (Naert *et al.* 2002; Vigolo & Zaccaria 2010). The concept of splinting adjacent implants is also challenged

Fig. 55-12 Clinical image of unsplinted implants in bone of good quality.

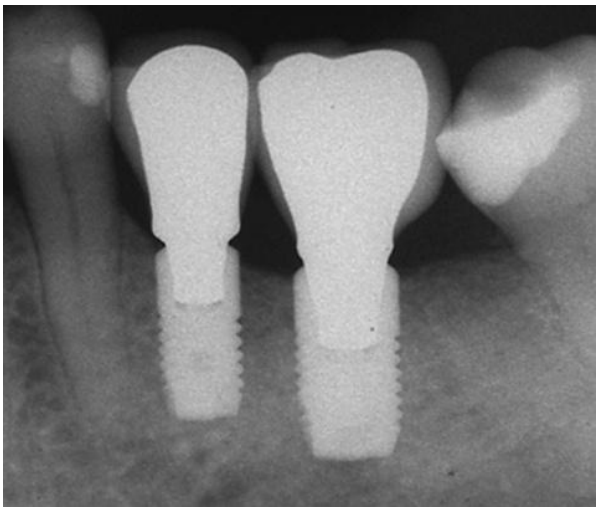

Fig. 55-13 Radiograph of two unsplinted single-tooth implants.

by the evidence for high survival and success rates of unsplinted short implants (Fugazzotto 2008). In general, there is no evidence that overloading of osseointegrated implants is a phenomenon that occurs under standard clinical conditions. Thus, there is probably no need to distribute loading forces over several implants and no need to splint implants of standard diameter and length in sufficient bone quality and in patients without parafunctional habits (Figs. 55-12, 55-13).

Longest possible versus shorter implants, including impact of crown-to-implant ratio

Clinicians are quite frequently confronted with posterior edentulous jaw segments that present all of the major prerequisites for successful implant therapy listed earlier in this chapter, with the exception of sufficient vertical bone height for the insertion of one or several implants featuring what is broadly accepted as an adequate length of the implants *per se* and also in relation to the prospective height of the suprastructures. The question that arises is whether there is a minimal implant length required in the context of posterior single-unit restorations and whether the ratio between implant length and suprastructure height has an influence on crestal bone resorption and ultimately on the longevity of the entire implant–suprastructure complex.

Standard-length implants (≥10 mm) have been universally recommended for many years, as it was widely accepted that this length was reasonable for a predictable success; the functional forces exerted on the implant were assumed to be distributed over a large surface area throughout the entire length of the implant. Another factor, which may have undermined the use of shorter implants, was the hypothesized elastic deformation of such implants under load. This intrabony deformation occurring under short-duration loading (e.g. chewing cycles) was reported to be considerably superior to that of standard-length implants, especially when subjected to lateral force vectors resulting in greater bending moments and thus inducing an increased stress on the crestal bone. However, later experimental studies concluded that this stress might not be minimized if the length of the implant is increased. Hence, it has been claimed that the generated interface stresses are, in fact, concentrated on the crestal bone and not redistributed over the entire length of the implant, and that shorter implants may even be more favorable in terms of peri-implant bone stimulation and resulting bone density (Renouard & Nisand 2006).

Currently, implants that are <8 mm long are broadly considered as "short implants", whereas early descriptions of "standard-length implants" refer to implants with intrabony lengths of ≥10 mm. Short dental implants were engineered to avoid interferences with vital anatomic structures (e.g. mandibular nerve canal, maxillary sinus), to reduce surgical trauma and associated risks, to decrease the morbidity involved with advanced grafting/bone augmentation procedures, and to foster "prosthetically-driven" implant positioning. As a result, these short dental implants may directly increase patient comfort and compliance, as well as minimize the amount of radiologic investigation and the number of visits, chairside time, and costs involved.

The analysis of the implant data collected at the University of Geneva School of Dental Medicine in the frame of a prospective multicenter study from 1989 to 2011, permitted the conclusion that shorter implants (6–8 mm) did not show higher average crestal bone resorption than longer implants (10–12 mm), and that a so-called unfavorable ratio between implant length and suprastructure height did not lead to more pronounced crestal bone resorption (Bernard *et al.* 1995; Bernard & Belser 2002; Blanes *et al.* 2007a, b). These data are corroborated by other reports (ten Bruggenkate *et al.* 1998; Bischof *et al.* 2001; Deporter *et al.* 2001; Heitz-Mayfield *et al.* 2004; Nedir *et al.* 2004; Bischof *et al.* 2006; Fugazzotto 2008; Birdi *et al.* 2010; Rossi *et al.* 2010; Esposito *et al.* 2011).

(a)

(b)

Fig. 55-14 (a) Occlusal view of a single tooth implant crown on a short 6-mm implant in the area of 36. (b) Radiograph of this single tooth crown after 2 years of function.

A representative clinical example of a posterior single-tooth FDPs, featuring so-called unfavorable implant length-to-suprastructure height ratios, is shown in Fig. 55-14.

A recent literature review based on 53 clinical studies involving a total of 4778 short implants (<8 mm, observation time up to 14 years), reported a cumulative survival rate of 90.4% (Srinivasan *et al.* 2012). Of the 4778 implants, the 1608 with a micro-rough surface revealed a cumulative survival rate of 97.2% (observation time up to 9 years), whereas an overall survival rate of 88.6% (observation time up to 14 years) was calculated for the 7-mm short implants with machined surfaces. The overall cumulative survival rates, that is regardless of the surface type, reported for either the maxilla or mandible were 83.3% and 92.6%, respectively, based on a total of 2709 implants placed in an identified location. Hence, it was concluded that short implants with micro-rough surfaces have similar survival and success rates to those reported for standard-length implants (10–12 mm). Based on a shorter observation time and involving a limited number of implants and studies, it would appear that even 4-mm implants may lead to similarly favorable survival rates. However, clinical common sense and manufacturing limitations on the one hand, and concerns relative to peri-implantitis (Quirynen *et al.* 2002) and technical complications (fatigue) related to implant components (screws, abutments) on the other hand, may lead to the conclusion that the use of such "ultra-short" implants should be limited to particular clinical situations. Clearly, prospective clinical trials with standardized protocols and well-defined study parameters are still needed to further assess treatment outcomes and predictability relative to short implants.

Implants in sites with extended vertical bone volume deficiencies

It is quite common that distally shortened dental arches do not feature an adequate local bone volume at the prospective implant sites. This may refer to bone height, bone width, alveolar bone crest axis or to the vicinity of noble structures such as the mandibular alveolar nerve canal or the anterior part of the maxillary sinus. Often, a combination of several of the mentioned limitations is encountered. Implant insertion is clearly a three-dimensional surgical and restorative procedure and a "restoration-driven" rather than "bone-driven" implant placement is widely recommended. Therefore, a meticulous presurgical site analysis – based on the envisioned treatment objective – is of primary importance. In order to keep the treatment as easy and cost-effective as possible, one should evaluate comprehensively all available treatment options. Among the options to be considered are: (1) primary or simultaneous bone augmentation procedures in combination with standard-length implants; (2) use of shorter implants and therefore avoiding extensive bone regenerative procedures; and (3) even a minor deviation from the ideal implant position without accepting the risk that this treatment adversely affects predictability, longevity, and/or subjective comfort (Ilizarov 1989a, b; Raghoebar *et al.* 1996; Howell *et al.* 1997; Simion *et al.* 2006; Pjetursson *et al.* 2008, 2009b; Esposito *et al.* 2011).

Maxilla: sinus floor elevation versus short implants

In the posterior regions of the maxilla, the clinician is often confronted with a reduced bone height due to a close relationship to the maxillary sinus. In these cases, different options exist: (1) primary sinus elevation and subsequent implant placement; (2) implant placement with simultaneous sinus elevation (transalveolar approach or lateral window technique); (3) use of shorter implants to avoid extensive bone augmentation procedures; and (4) installation of angulated zygoma implants (Chen *et al.* 2007; Davo *et al.* 2007; Pjetursson *et al.* 2009b; Esposito *et al.* 2011). The last of these options is mostly performed in edentulous cases by experienced maxillofacial surgeons, and has only been documented in a few case reports (Davo 2009; Bedrossian 2010).

Primary sinus augmentation procedures are indicated in cases with insufficient implant stability, which are often encountered when the vertical ridge height is <4 mm (Pjetursson *et al.* 2008). This procedure is well documented, predictable, and can lead to high implant survival rates, provided that rough surface implants are used (Wallace & Froum 2003; Pjetursson *et al.* 2008). (Fig. 55-15). However, the overall treatment time is maximized since a healing time of several months (3–12 months depending on the graft material used) is required before implant placement can be performed. In some cases, primary implant stability can be achieved (ridge height 3–6 mm) (Fig. 55-16) when standard-length implants are placed simultaneously with either one of the two sinus elevation procedures (transalveolar or lateral window approach) (Summers 1994; Rosen *et al.* 1999; Pjetursson *et al.* 2009a, b). Simultaneous bone augmentation and implant placement can reduce the overall treatment time and costs, and limit the number of surgical interventions. Implant survival rates are reported to be similar for all three sinus elevation procedures (transalveolar approach, lateral window one-stage or two-stage approach) with estimated implant survival rates over 3 years ranging between 88.5% and 98.3% (Pjetursson *et al.* 2008; Tan *et al.* 2008). However, the transalveolar procedure offers benefits in being less invasive and less time-consuming (Fontana *et al.* 2008).

Over the years, implant designs, surfaces, lengths, and diameters have changed significantly. Previously, implants were bicortically anchored in the jaw to assure stability. Thus, the longest possible implant length was used depending on the existing jaw height. This concept was overruled when it was demonstrated that bicortical implant anchorage may not be advantageous over monocortical anchorage (Ivanoff *et al.* 2000; Attard & Zarb 2004). Nowadays, available implant lengths have decreased continuously due to advances in implant surfaces and design. Currently, implants with an infrabony part >8 mm are considered to be standard-length implants with clinically reported high success and survival rates (Hobkirk & Wiskott 2006). Nevertheless, the existing ridge height is often below 8 mm in posterior segments of the jaw and therefore does not allow placement of a standard-length implant. In order to overcome limitations associated with extensive bone augmentation procedures and to simplify the clinical procedures, shorter implants were developed, but rarely used in clinical studies. This was mainly due to speculations of a mechanical nature. The use of shorter implants potentially implies drawbacks such as an unfavorable crown-to-implant ratio and risk of loss of osseointegration due to mechanical overload. However, neither loss of osseointegration due to mechanical overload nor high crown-to-implant ratios have proven to be of clinical relevance based on preclinical and clinical data (Gotfredsen *et al.* 2001a, b, c; Blanes *et al.* 2007a, b; Schneider *et al.* 2012). In addition, more recent systematic reviews failed to demonstrate statistically significant differences with respect to the survival rates of short rough surface implants versus longer implants, or to find a relationship between implant length and failure rate (Kotsovilis *et al.* 2009; Telleman *et al.* 2011; Neldam & Pinholt 2012;). Compared to standard-length implants in combination with extensive bone grafting procedures, the use of shorter implants potentially provides a variety of benefits: lower risk of damage to adjacent structures (roots, nerves, vessels, sinus), fewer complications, less invasiveness, fewer diagnostic procedures necessary, less diagnostic and surgical skill necessary, shorter treatment time, easier removal in case of failure, and less patient morbidity (Renouard & Nisand 2005). In order to demonstrate that the use of short implants may result in similar survival rates to those for longer implants with sinus elevation procedures, various studies have been conducted and others are ongoing. In a recent randomized controlled clinical trial, short implants (5 mm) were compared to long implants (10 mm) placed in augmented sinuses (Esposito *et al.* 2011). At 1-year post loading, the results demonstrated similar survival rates for both implant lengths and treatments. However, the use of short implants was associated with a faster and cheaper treatment and less patient morbidity (Esposito *et al.* 2011). Even though only short-term results are available, these indicate that the use of short implants in the posterior maxilla may be considered a valuable treatment option (Felice *et al.* 2009a) (Fig. 55-17).

Mandible: vertical ridge augmentation versus short implants

In cases with a reduced ridge height in the mandible, three options exist: primary vertical ridge augmentation and subsequent implant installation; simultaneous implant placement with vertical ridge augmentation; and the use of short implants (Simion *et al.* 2001, 2007; Rocchietta *et al.* 2008; Felice *et al.*

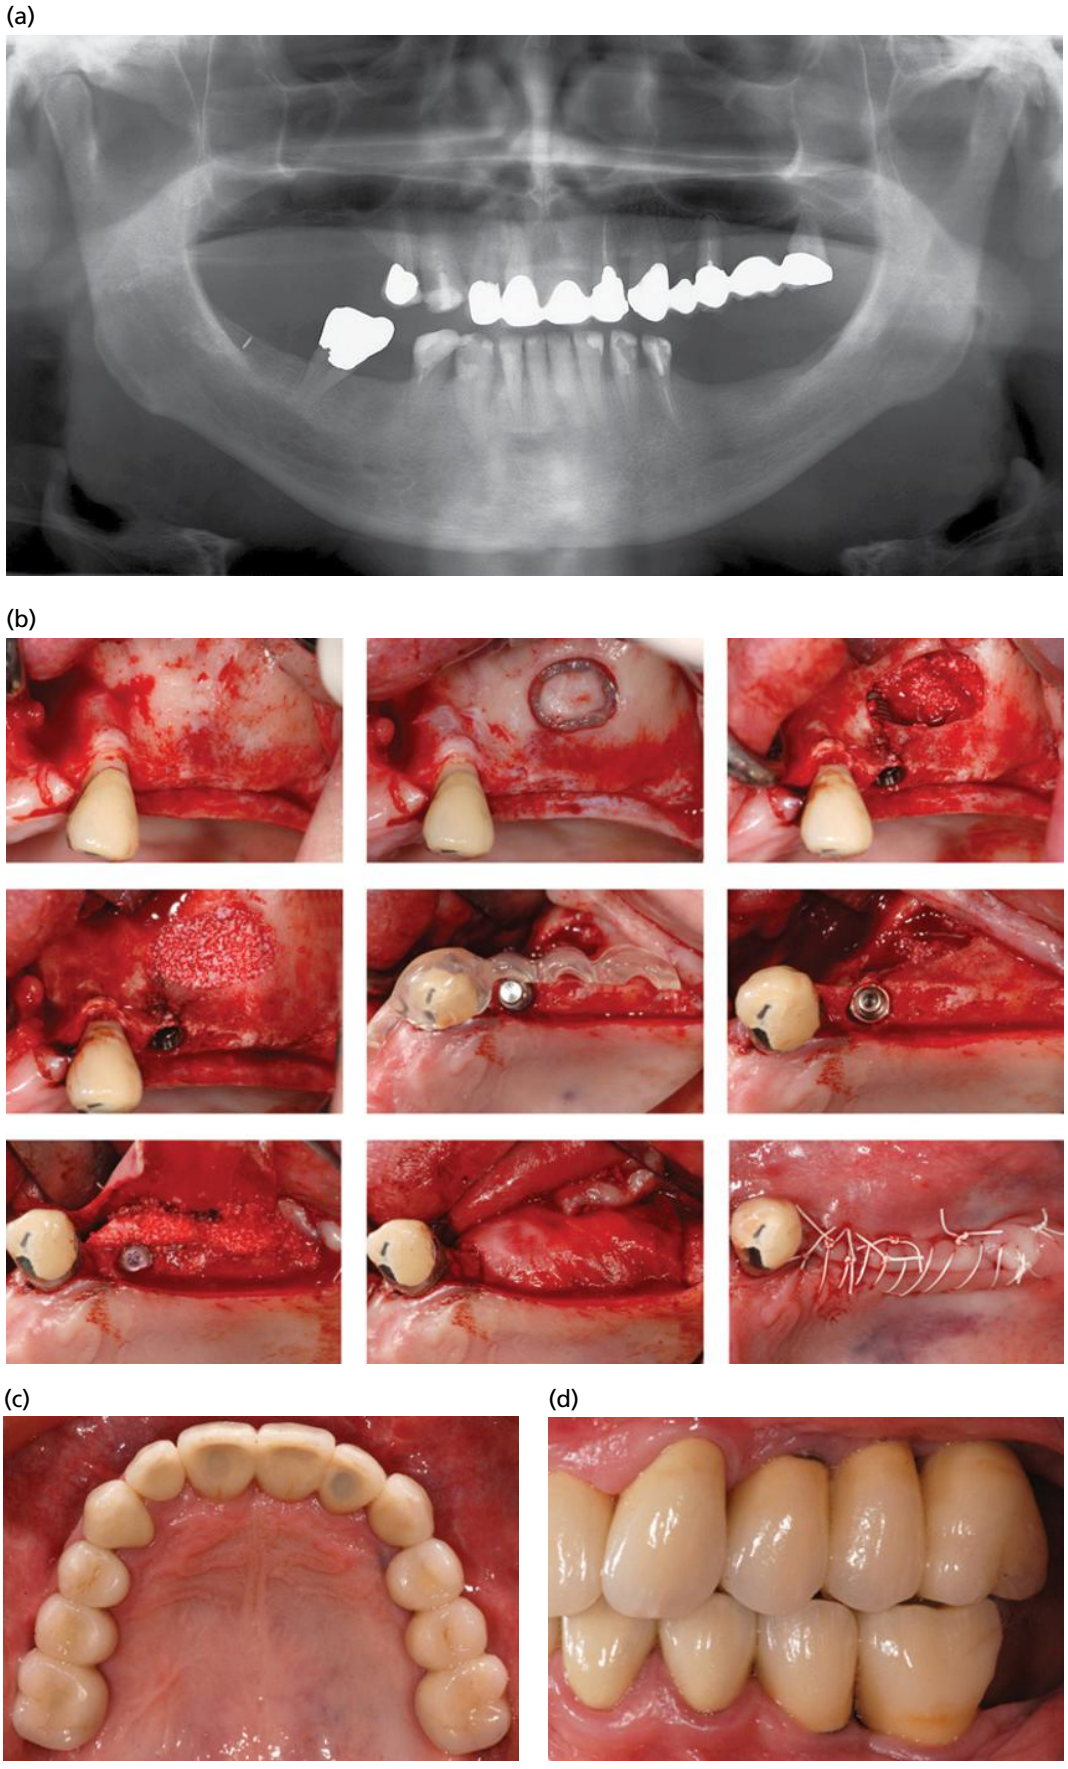

Fig. 55-15 (a) Panoramic radiograph revealed an extended vertical ridge deficiency in the upper left and right jaw. Teeth 25 and 27 are hopeless. A two-stage sinus elevation procedure was performed in region 16 and 26. One-stage sinus elevation was performed in region 24. (b) Sinus elevation procedure performed with the lateral window approach. Two-stage sinus elevation procedure was performed in region 26. 2009a). Primary ridge augmentation procedures that allow the placement of standard-length implants have been proposed to result in smaller crown-to-implant ratios, better esthetics, and better cleanability of the prosthetic reconstruction (Mecall & Rosenfeld 1991). An array of different techniques (Ilizarov 1989a, b; Chiapasco *et al.* 2007; Merli *et al.* 2007, 2010) have been described for primary bone augmentation, including guided bone regeneration (GBR), distraction osteogenesis (DO), and onlay bone grafting (OB). The success rates of these techniques vary quite extensively. In addition, only a limited number of publications are available and these are from a confined number of surgeons who are able to perform these treatments successfully. Their general use has therefore not been recommended based on the outcomes of a systematic review (Rocchietta *et al.* 2008). The main reasons

for this lack of recommendation included great variability in outcomes, a high rate of complications (extending up to 75%), and operator sensitivity (Rocchietta *et al.* 2008). In contrast, the use of shorter implants may avoid extensive bone regenerative procedures in cases with a ridge height exceeding 6 mm. Comparative clinical studies demonstrated fewer implant failures and fewer wound dehiscences associated with short implants compared to primary ridge augmentation and longer implants (Felice *et al.* 2009a, b; Esposito *et al.* 2011). Similarly to in the maxilla, both patients and clinicians may benefit from the use of short implants. However, more comparative clinical studies with documented long-term data need to be provided.

Preoperative diagnostics and provisional reconstructions in the posterior dentition

Preoperative prosthetic diagnostics

Dental implants are placed to support reconstructions (Esposito *et al.* 1998), and therefore, prosthetically-driven implant placement is a prerequisite for the achievement of an ideal biomechanical, functional, and esthetic treatment result. Together with site evaluation and risk assessment, the preoperative prosthetic diagnostics are essential for correct treatment planning in implant dentistry. The larger the span and higher the complexity of the planned reconstruction, the more important are the preoperative diagnostics.

Prosthetic diagnostics are conventionally performed by means of a diagnostic set-up manufactured on plaster models (Fig. 55-18). Over the past years, several systems for computer-assisted design of reconstructions based on the data obtained from optical scans have been developed (Mormann *et al.* 1987; Syrek *et al.* 2010) (Fig. 55-19).

The three-dimensional space available for the reconstruction will have a significant impact on the prosthetic planning. In cases with reduced or excessive mesiodistal or vertical (distance from the prospective restorative margin to the opposing occlusion) space, adjunctive therapy may be necessary to adjust the space to that needed for the planned reconstruction (Fig. 55-20). This may involve orthodontic, surgical, reconstructive or endodontic treatment procedures. Therefore, such clinical situations will result in an increased complexity of the treatment with dental implants.

Prior to the selection of implant type and three-dimensional (3D) planning, the following prosthetic elements have to be defined:

- Reconstruction design
- Prospective mucosal margin
- Retention type
- Occlusal schema.

Fig. 55-18 Conventional wax-up on a cast.

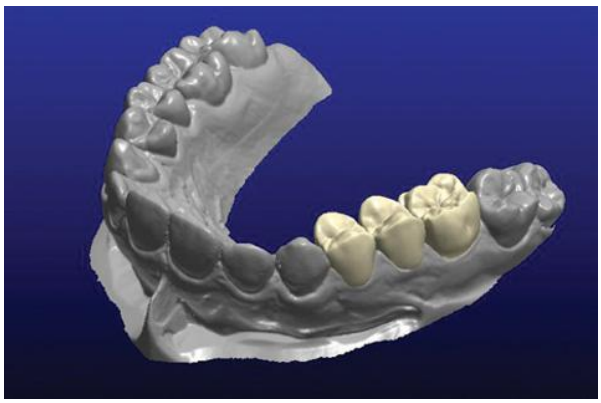

Fig. 55-19 Digital set-up as a screen view.

Fig. 55-20 Reduced vertical amount of space in the area of missing teeth 24, 25, and 26 due to elongation of antagonist teeth.

Three-dimensional radiographic diagnostics and planning

The introduction of cone-beam computed tomography (CBCT) has allowed the acquisition of 3D images with an adequate quality for dentomaxillofacial examinations (Suomalainen *et al.* 2009; Fatemitabar & Nikgoo 2010) at reduced radiation doses compared to conventional multislice computed tomography (CT) (Rustemeyer *et al.* 2004; Ludlow *et al.* 2006; Ludlow & Ivanovic 2008). The radiation burden of CBCT is, however, considerably higher in comparison

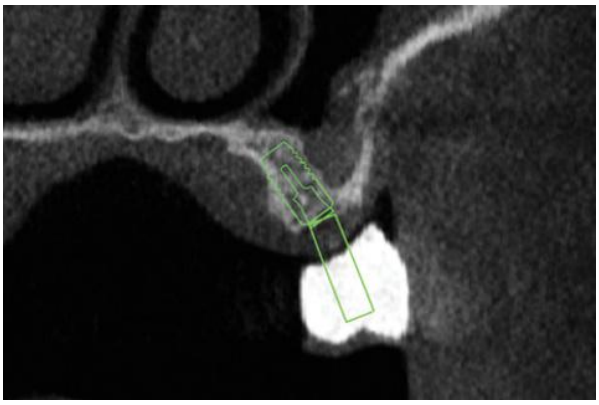

Fig. 55-21 Implant planning aimed at avoiding sinus floor elevation.

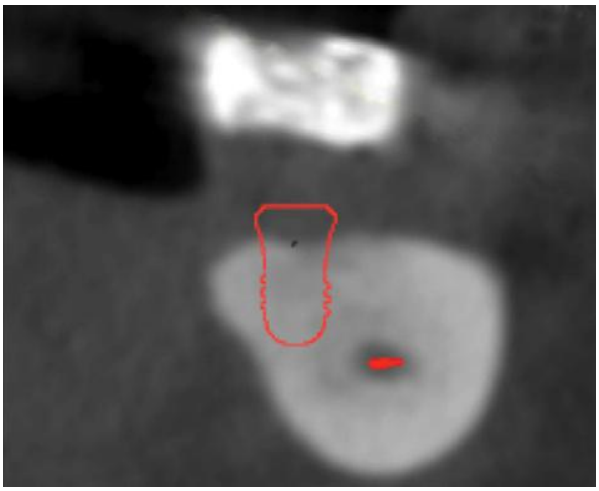

Fig. 55-22 Implant position planning lingual to the inferior alveolar nerve canal.

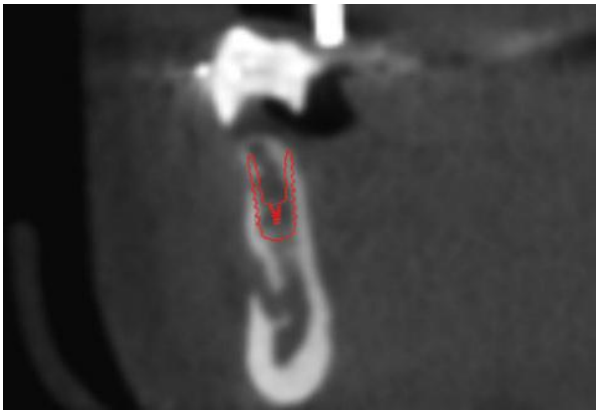

Fig. 55-23 Three-dimensional implant planning in a site with limited bone width.

to conventional two-dimensional (2D) radiography. Therefore, cross-sectional imaging should only be undertaken when it gives a justifiable benefit to the patient (Harris *et al.* 2002).

Several software programs for computer-assisted implant planning based on the data from CT scans have been recently developed (Jung *et al.* 2009a; Schneider *et al.* 2009). A prerequisite for optimal implant planning when using such systems is the combination of the information on bone anatomy with the 3D image of the previously planned prosthetic reconstruction. This can be achieved by means of radio-opaque prosthetic templates or by superimposing a digital set-up on the CT image. To transfer the preoperatively planned implant position to the surgical site, intraoperative (static) guidance or (dynamic) navigation is required (Hämmerle *et al.* 2009). Due to the limitation of computer-assisted implant planning and placement regarding accuracy (Jung *et al.* 2009a; Schneider *et al.* 2009), the clinician should always allow an adequate safety margin for the relevant anatomic structures (Harris *et al.* 2002).

The following clinical situations may benefit from 3D radiographic diagnostics and planning:

- 2D radiographs have failed to identify relevant anatomic structures
- Due to the proximity of the maxillary sinus or inferior alveolar nerve canal, there appears to be a need for sinus floor elevation or vertical bone augmentation (Figs. 55-21, 55-22)
- In sites with limited bone width where there appears to be a need for lateral bone augmentation (Fig. 55-23).

Provisional reconstructions

The period of time between the beginning of therapy and implant loading in implant dentistry may amount to several months. Due to the functional and esthetic impairments during this period, it might be necessary to intermediately restore the edentulous region by means of a provisional reconstruction. Additionally, the provisional reconstruction may be indicated in order to test the ideal design of the final reconstruction and patient's adaptation to the planned reconstruction.

The selection of provisional type has to be based on the patient's requirements, conditions of the edentulous site, prosthetic requirements of the adjacent teeth, duration of the provisional phase, and financial considerations. The following types of temporary reconstruction are available:

- Removable partial denture (Fig. 55-24)
- Removable thermoplastic sheet containing pontics of missing teeth (Essix provisional) (Fig. 55-25)
- Fixed partial denture (if full coverage of the adjacent teeth is required).

Resin-bonded partial dentures are generally unfavorable for the provisionalization of posterior dentition due to the risk of debonding and fractures.

A correctly designed provisional should include the ability to accommodate changes of the underlying soft tissue and avoid uncontrolled pressure on healing implants and augmented regions.

Fig. 55-24 Provisional removable partial denture.

Fig. 55-25 Clear thermoplastic sheet containing pontics of the missing teeth.

Clinical concepts for the restoration of free-end situations with fixed implant-supported prostheses

Free-end situations in the posterior dentition represent a frequent indication for the use of dental implants. Whenever possible, the adopted treatment strategy consists of restoring the shortened dental arch to the region of the first molars. Occasionally, implant therapy is restricted to the premolar area, according to the principles of the well-established premolar occlusion concept, or extended to the second molar area if an antagonistic contact has to be established for an opposing natural second molar.

Number, size, and distribution of implants

It is still unclear to date how many implants of which dimension and at which location are required to optimally rehabilitate a given edentulous segment in the load-carrying part of the dentition. Several different recommendations and related strategies are currently in use, mostly derived from traditional prosthodontic experience and attitudes, and based on so-called clinical experience and common sense rather than on solid scientific evidence. In defense of this situation, one should be aware, however, that it is often difficult to design and carry out randomized clinical trials evaluating exclusively and without interference one specific parameter of conceptual relevance.

In a situation where the canine is the most distal remaining tooth of a dental arch, at least five different options can be considered if it is planned that the missing teeth up to the first molar area are to be replaced): (1) replacement of each missing occlusal unit by one implant (Fig. 55-26a); (2) a mesial and a distal implant to support a three-unit FDP with a central pontic (Fig. 55-26b); (3) two distal implants to permit the insertion of a three-unit FDP with a mesial cantilever (Fig. 55-26c); (4) two mesial implants to sustain a three-unit FDP with a distal cantilever (55-26d); and (5) only one distally inserted implant in view of a four-unit FDP combining implant and natural tooth support (Fig. 55-26c).

As far as the recommendation to use premolar-size units for implant-borne posterior FDPs is concerned, it has proven its practical validity in >10 years of clinical experience (Buser *et al.* 1997; Bernard & Belser 2002). In fact, a crown featuring a mesiodistal diameter of 7–8 mm at its occlusal surface allows the optimal generation of a harmonious axial profile, gradually emerging from the standard-implant shoulder (diameter 4–5 mm on average) to the maximum circumference. In addition, the width of the occlusal table is confined, thereby limiting the risk for unfavorable bending moments to the implant–abutment–suprastructure complex (Belser *et al.* 2000).

Based on an increasing body of scientific evidence, most clinicians' first choice is the mesial and distal implant and the FDP with the central pontic (Fig. 55-27). Prospective long-term data (Buser *et al.* 1997; Bernard & Belser 2002) have confirmed the efficacy and predictability of this specific modality. In fact, it permits the defined treatment objective to be reached with a minimum number of implants and associated costs. Although formal evidence at the level of prospectively documented, randomized clinical trials is still lacking, it appears from clinical experience that the use of two implants to support a four-unit FPD with two central pontics (Fig. 55-28) may be adequate in certain clinical situations. Clinicians tend to use this approach in the presence of favorable bone conditions, permitting standard-size or wide diameter implants of appropriate length (i.e. ≥8 mm).

If the alveolar bone crest dimension is also sufficient in an orofacial direction, the utilization of wide diameter/wide platform implants is preferred (Bischof *et al.* 2006). Due to their increased dimensions, a better adapted suprastructure volume and improved axial emergence profile of the implant restoration – when compared to a so-called premolar unit – can be achieved in the molar area (Fig. 55-29). In this way, the intercuspation with an opposing natural molar is also facilitated.

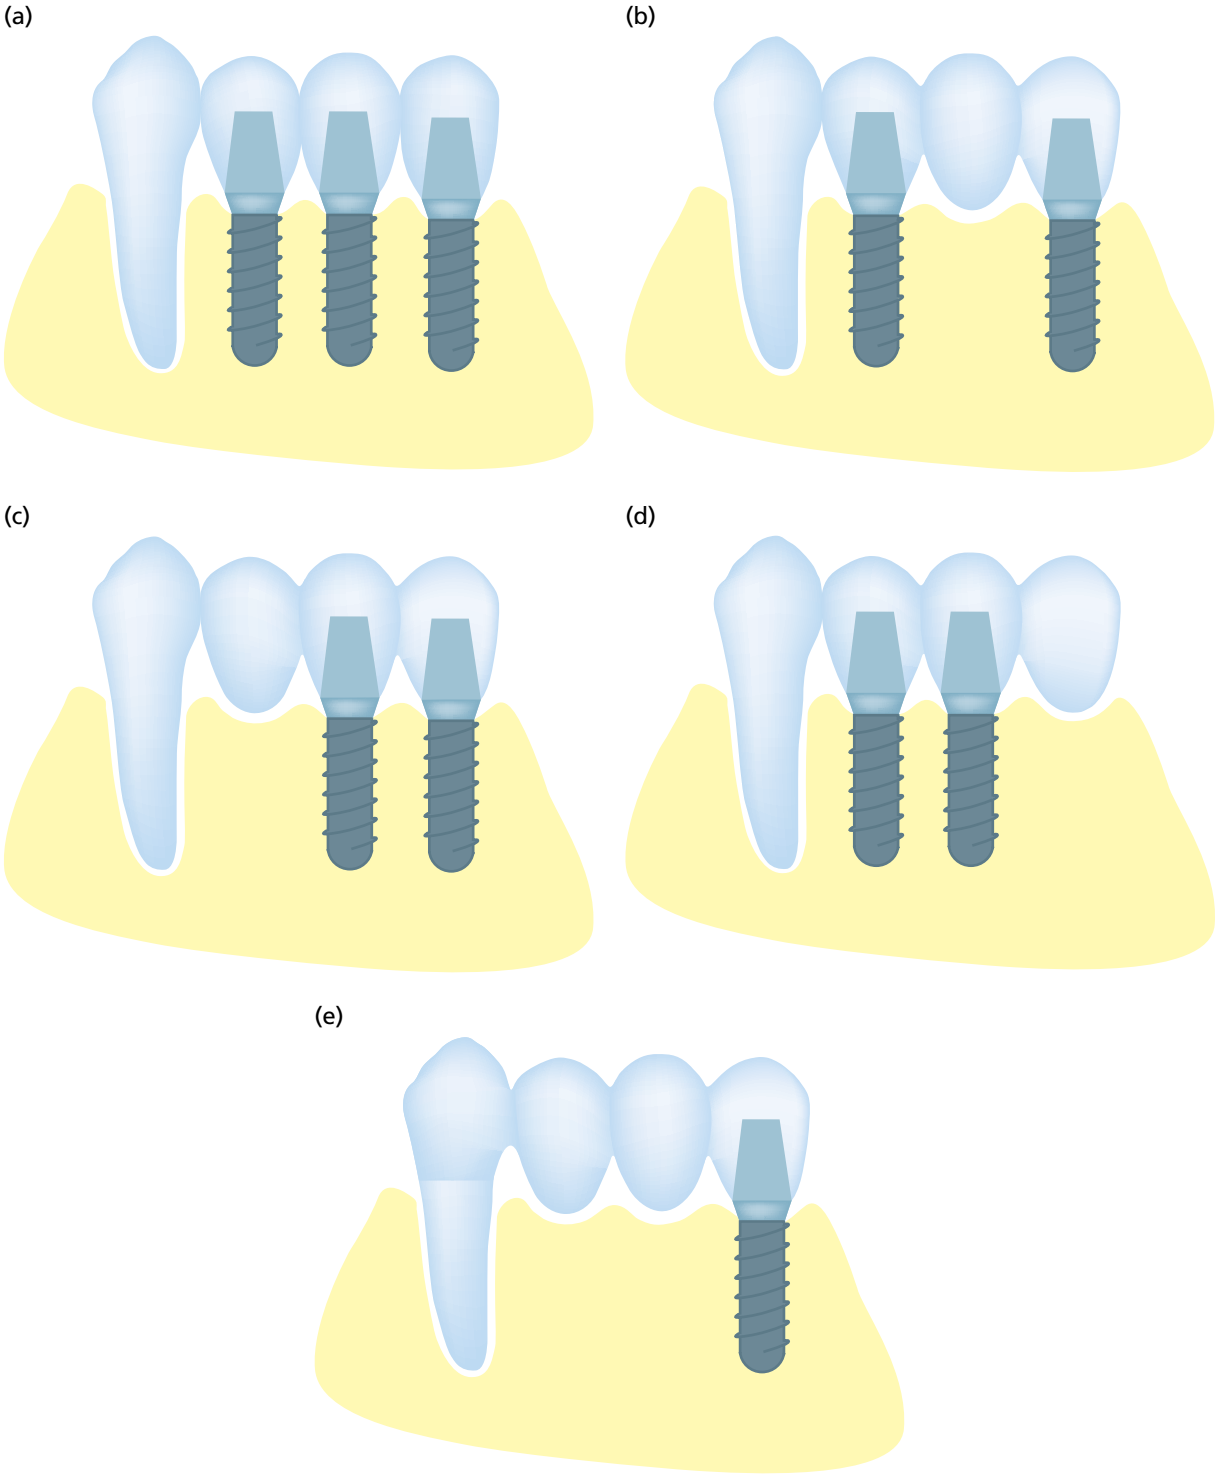

Fig. 55-26 Schematic representation of the distally shortened dental arch. (a) One therapeutic option consists of replacing each missing occlusal unit up to the first molar area with an implant. (b) An alternative option would be the replacement of the three missing occlusal units with two implants to support a three-unit suprastructure with a central pontic. (c) In a case of an inadequate bone volume in the area of the missing first premolar, the placement of two distal implants may be considered, leading to a three-unit suprastructure with a mesial cantilever. (d) In a case of an inadequate bone volume in the area of the missing first molar, the placement of two mesial implants may be considered, leading to a three-unit suprastructure with a distal cantilever. (e) In a case of inadequate bone volume in the area of the two missing premolars, the placement of a distal implant may be considered, leading to a four-unit suprastructure with a mixed (tooth and implant) support.

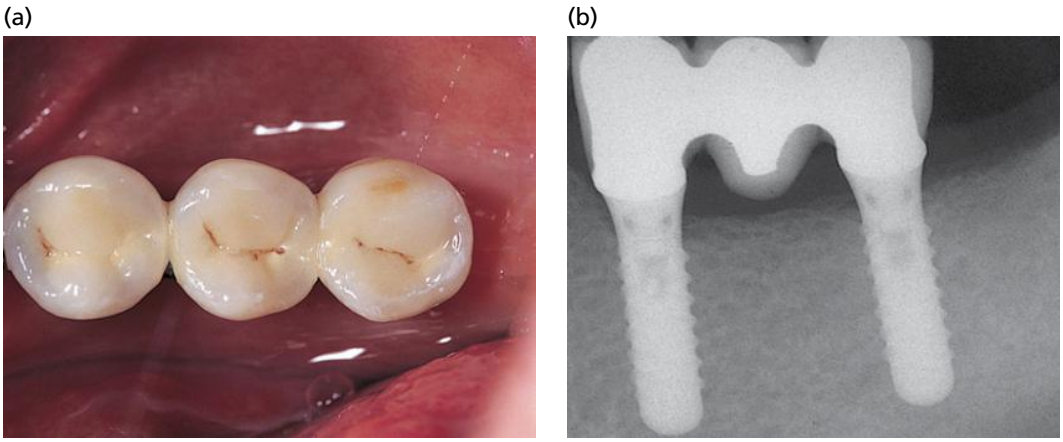

Fig. 55-27 (a) Occlusal view of a cemented three-unit metal–ceramic FPD, supported by a mesial and a distal implant. (b) Corresponding 3-year follow-up radiograph confirms stable conditions at the implant–bone interface of the two 12-mm solid screw implants.

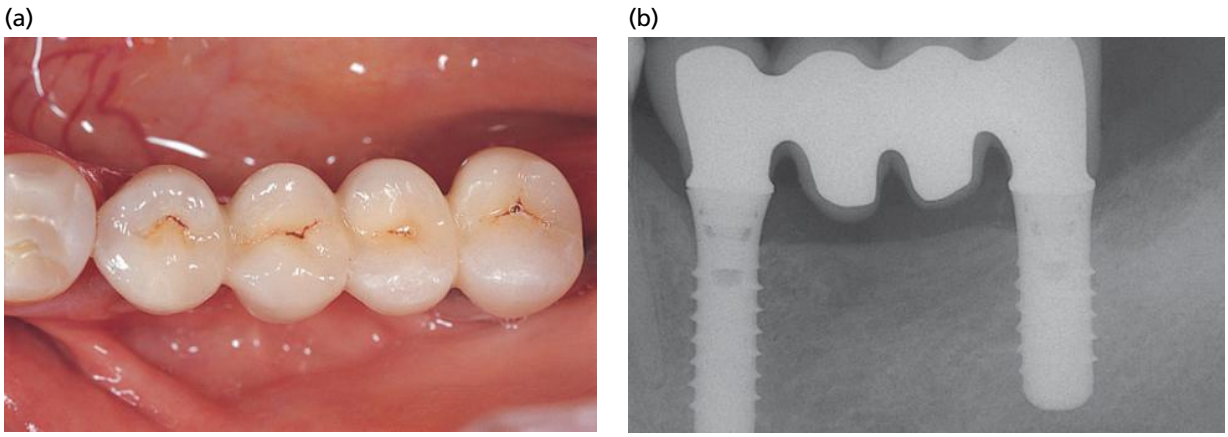

Fig. 55-28 (a) Occlusal view of a cemented four-unit metal–ceramic FPD supported by a mesial and a distal implant. (b) Corresponding 2-year follow-up radiograph documents that at the distal site a 10-mm solid screw implant with an increased diameter ("wide-body implant") has been used.

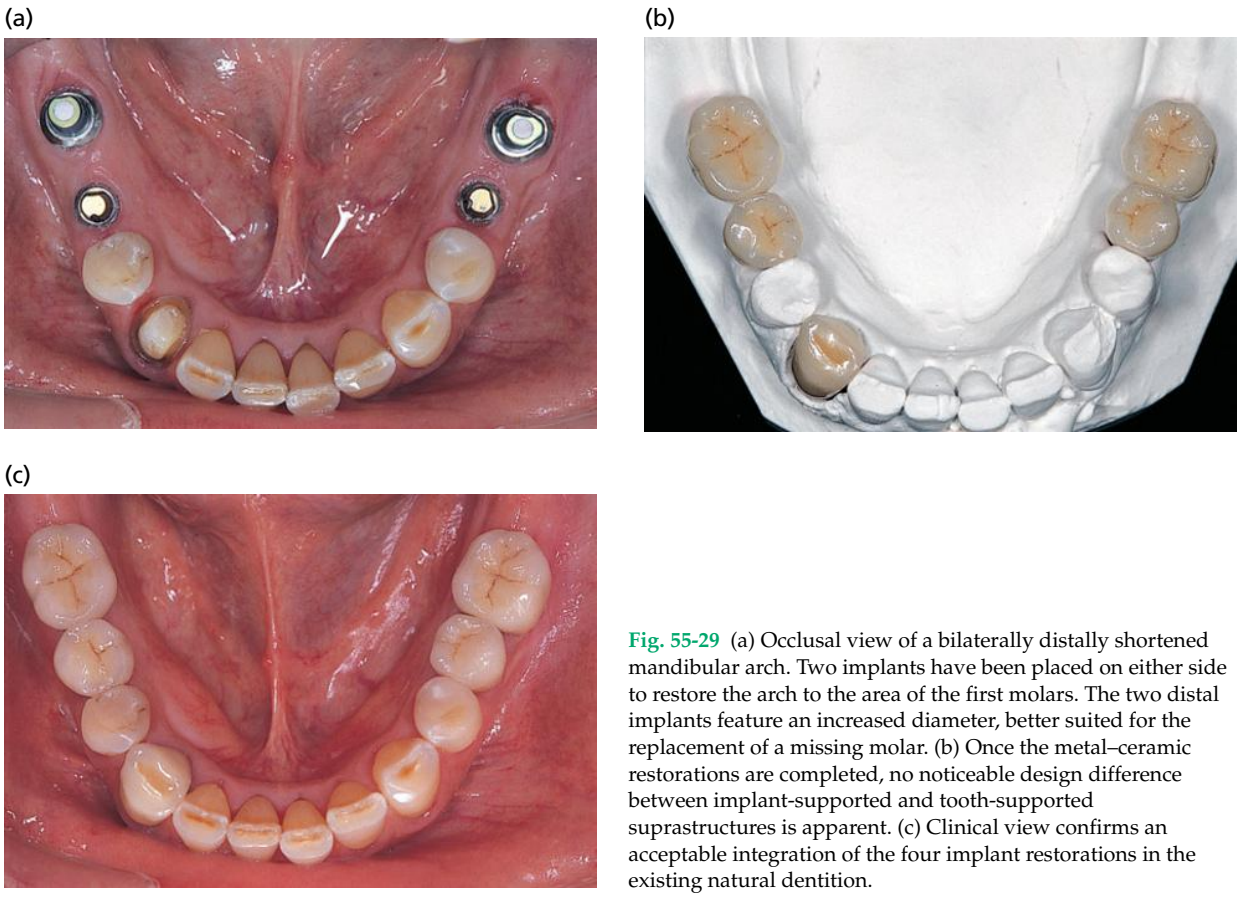

Fig. 55-29 (a) Occlusal view of a bilaterally distally shortened mandibular arch. Two implants have been placed on either side to restore the arch to the area of the first molars. The two distal implants feature an increased diameter, better suited for the replacement of a missing molar. (b) Once the metal–ceramic restorations are completed, no noticeable design difference between implant-supported and tooth-supported suprastructures is apparent. (c) Clinical view confirms an acceptable integration of the four implant restorations in the existing natural dentition.

Clinical concepts for multiunit tooth-bound posterior implant restorations

Number, size, and distribution of implants

When it comes to implant therapy in extended posterior edentulous segments confined mesially and distally by the remaining teeth, the question about optimal number, size, and distribution of implants has to be raised again. Among the key parameters to be addressed during the decision-making process are the mesiodistal dimension of the edentulous segment, the precise alveolar bone crest volume (including bone height and crest width in an orofacial direction), the opposing dentition (premolars or molars), interarch distance, and specific occlusal parameters, as well as the periodontal, endodontic, and structural conditions of the neighboring teeth.

One feasible approach consists of segmenting the edentulous space in premolar-size units of approximately 7 mm in mesiodistal diameter at the level of the occlusal plane, and of approximately 5 mm at the prospective implant shoulder. At posterior locations, clinicians increasingly prefer a rather superficial implant shoulder location or in many instances even a supramucosal one, so measurements can be carried out at the crest level of study casts. It is important during this process to anticipate a minimal distance between implant shoulders of approximately 2 mm, and between a natural tooth and an implant of about 1.5 mm (to be measured at the interproximal soft tissue level). Again, the treatment objective – a long-lasting implant-supported FDP – should be predictably reached (1) with optimal efficacy and (2) with minimum invasiveness and cost. The remaining controversy of whether each missing occlusal unit should be replaced by one implant or whether a minimal number of implants should be used, has already been addressed earlier in this chapter.

In the case of three missing occlusal units and no other particular restrictive conditions such as limited local bone volume, the authors recommend the insertion of a mesial and a distal implant to support a three-unit FDP with a central pontic (Fig. 55-30). This approach permits the fabrication of three metal–ceramic elements with a mesiodistal diameter of about 7 mm each. Based on an average implant shoulder dimension of approximately 5 mm, one can anticipate a gradually increasing, harmonious emergence profile from the implant shoulder to the occlusal surface. In order to satisfy the remaining important dimensional conditions, that is respecting the minimal distance between adjacent implants and in between teeth and implants, one needs to dispose of a minimal total mesiodistal gap of 21–22 mm.

In the case of two missing occlusal units, one should try as a general rule to select the largest possible implant diameters with respect to the total mesiodistal distance of the given tooth-bound edentulous segment. Decisive parameters are again interimplant distance and space between implants and adjacent teeth, as well as the orofacial crest width at the two prospective implant sites. For a total gap diameter of about 14–15 mm, two standard-size implants are most suitable (Fig. 55-31), while for one of 17–18 mm the combination of one standard and one wide diameter/wide platform implant is considered adequate (Fig. 55-32). It goes without saying that the latter choice also requires the appropriate orofacial bone volume.

These are just the frequently encountered clinical examples, and for the function of other morphology and dimensions of edentulous tooth-bound segments, additional approaches and implant combinations may be envisioned (Fig. 55-33). Such a

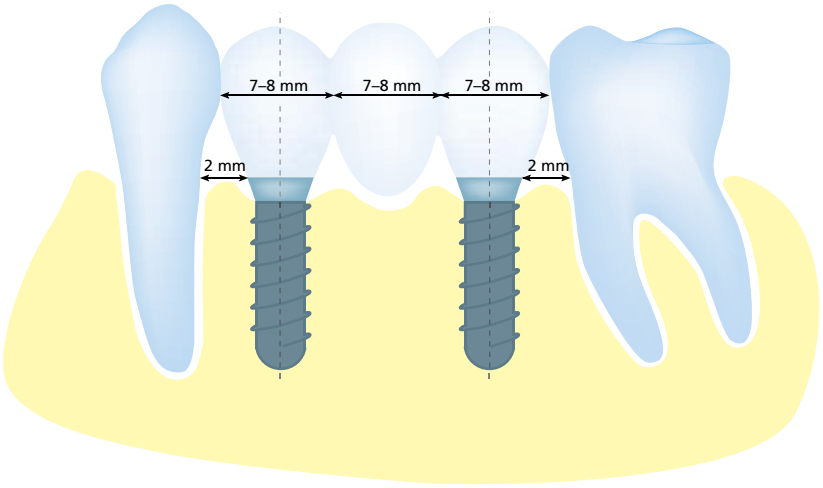

Fig. 55-30 In a case of three missing occlusal units, an implant-supported FDP with a centric pontic (approximately 7 mm in width) might be the therapy of choice.

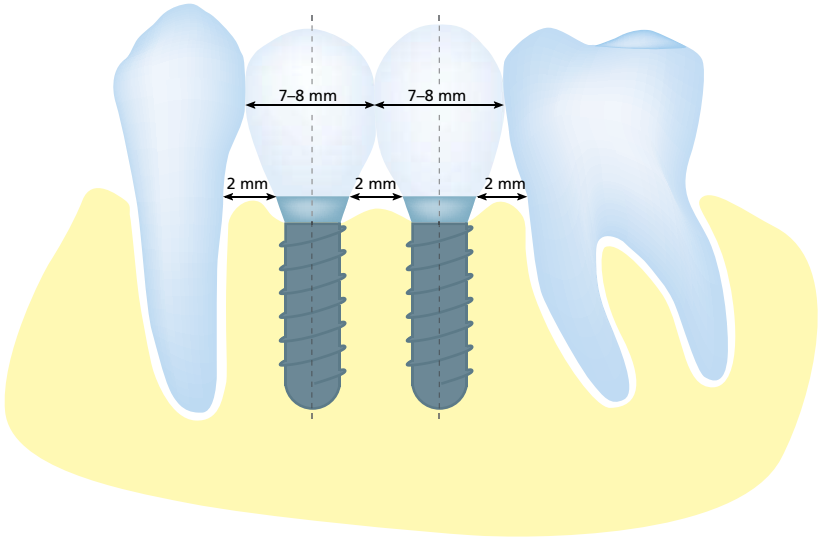

Fig. 55-31 If a given tooth-bound edentulous space only permits the insertion of two adjacent implants, a minimal interimplant distance of 2 mm and a minimal implant-to-tooth distance of 2 mm should be respected.

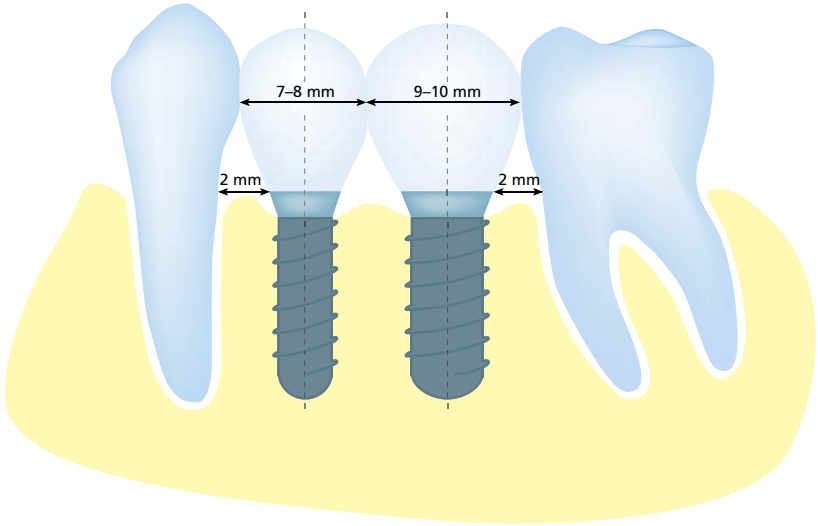

Fig. 55-32 In the presence of a mesiodistal gap width of approximately 17 mm, the combination of a standard and an increased-diameter implant may be considered. The same minimal interimplant and implant-to-tooth distances have to be respected.

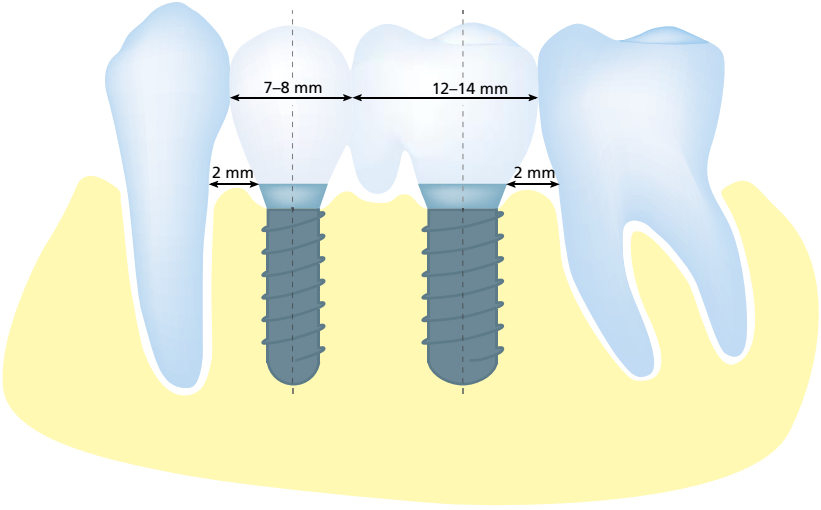

Fig. 55-33 If a posterior mesiodistal gap has a width of approximately 20 mm, a small central pontic should be considered to simplify the cleaning process.

clinical situation is shown in Fig. 55-34. The gap diameter required the two adjacent implants to be spaced wider than the normally advocated interproximal 2 mm. The laboratory technician compensated for this excess of space with a root-imitation pontic, which in turn provided an excellent guide facilitating the use of an interdental brush (Fig. 55-34a).

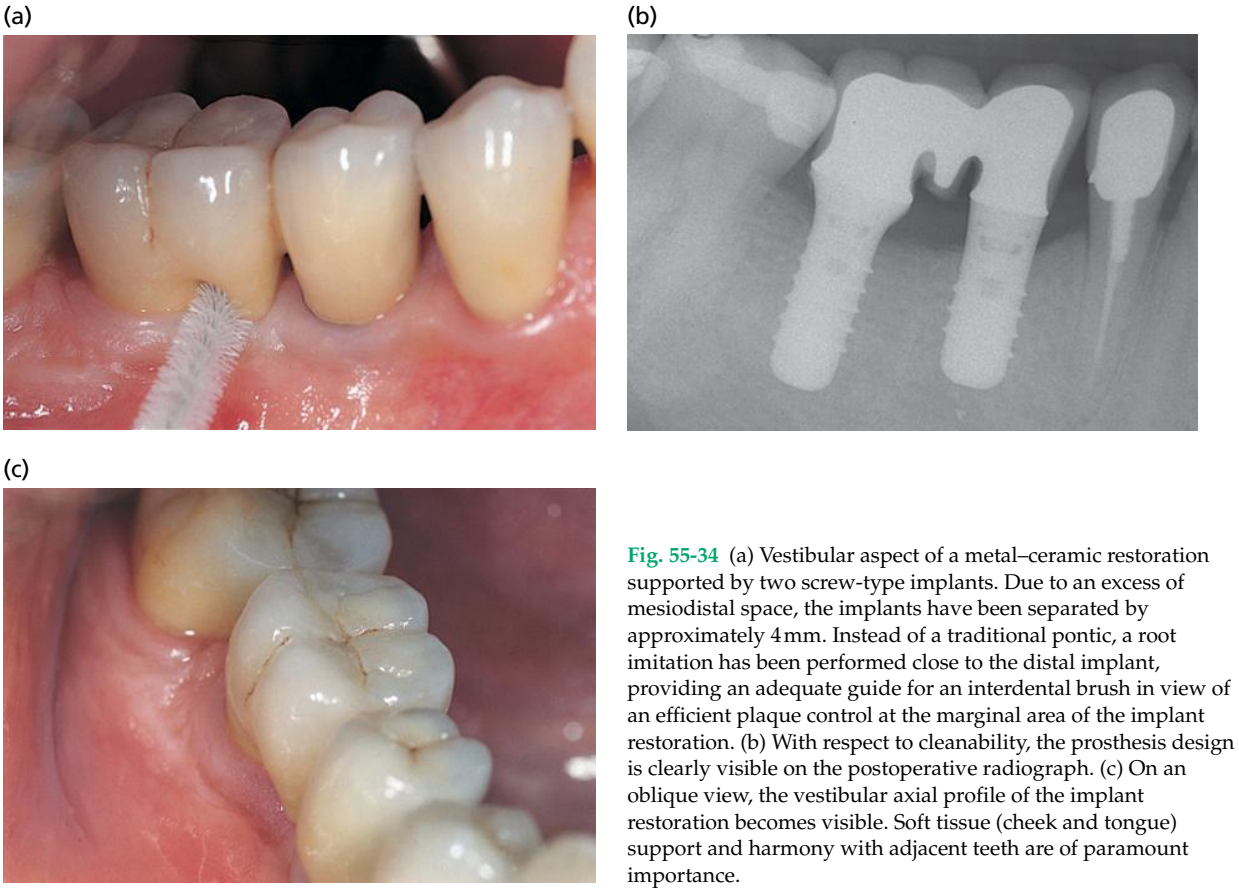

Fig. 55-34 (a) Vestibular aspect of a metal–ceramic restoration supported by two screw-type implants. Due to an excess of mesiodistal space, the implants have been separated by approximately 4 mm. Instead of a traditional pontic, a root imitation has been performed close to the distal implant, providing an adequate guide for an interdental brush in view of an efficient plaque control at the marginal area of the implant restoration. (b) With respect to cleanability, the prosthesis design is clearly visible on the postoperative radiograph. (c) On an oblique view, the vestibular axial profile of the implant restoration becomes visible. Soft tissue (cheek and tongue) support and harmony with adjacent teeth are of paramount importance.

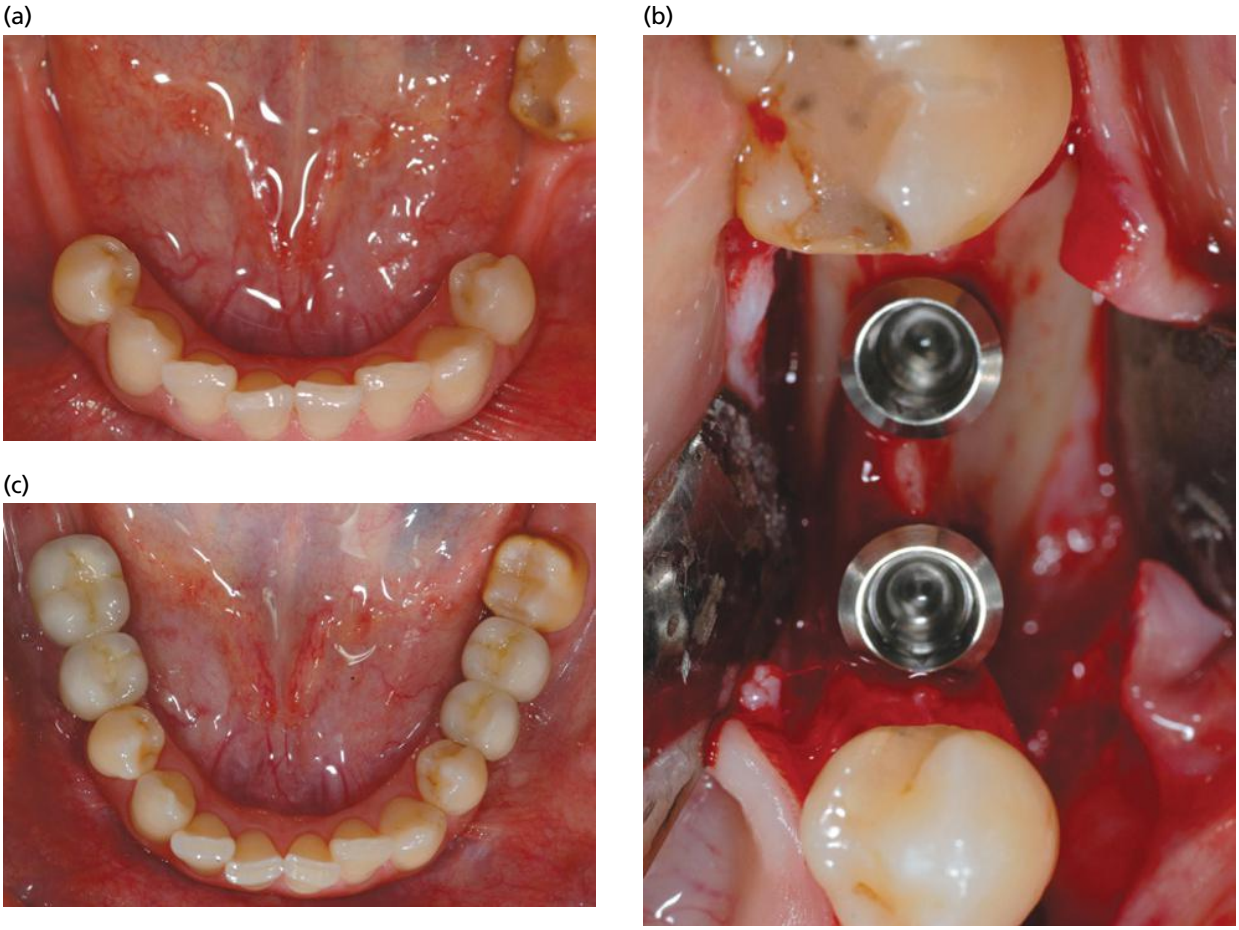

Fig. 55-35 (a) Occlusal view of a tooth-bound edentulous gap with missing teeth 35 and 36. (b) Mesiodistal gap dimensions allowed to two standard-diameter implants to be placed a the required distances in between the implants and next to the neighboring teeth. (c) Occlusal view of the final reconstructions after 1 year in function.

(d)

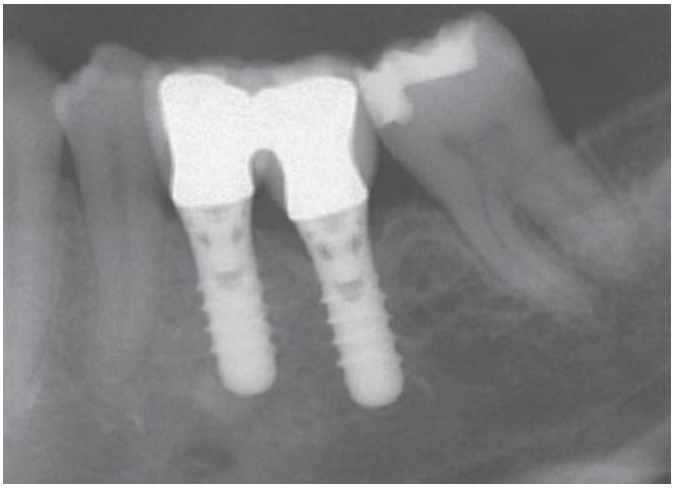

Fig. 55-35 (*Continued*) (d) Radiograph of the two splinted implants after 1 year in function.

(a)

(b)

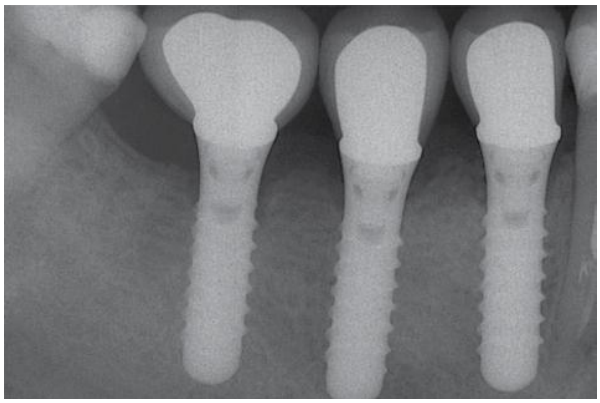

Fig. 55-36 (a) Occlusal view of three independent, implant-supported fixed metal–ceramic restorations in the right posterior mandible. (b) As confirmed by the follow-up radiograph, an increased (more molar-like) dimension was given to the most distal restoration, despite the fact that a standard-size implant had to be used for restricted bone volume reasons.

Further clinical examples with different mesiodistal gap widths are shown in Figs. 55-35 and 55-36.

Clinical concepts for posterior single-tooth replacement

At the time when most implant systems had basically only one "standard" dimension at disposition, this corresponded to approximately 4–5 mm at the implant shoulder and thus was optimally suited for premolar-size restorations, with a continuously increasing (in the coronal direction) flat axial emergence profile and a mesiodistal diameter of about 7–8 mm at the occlusal surface. However, clinicians were not infrequently faced with posterior single-tooth sites that did not comply with these dimensions, for example in cases of missing first molars or after the loss of persisting deciduous (primary) second molars. As a consequence, the resulting implant restorations featured either unfavorable excessive interproximal overcontour or wide open embrasures. The first situation was difficult to clean, while the second led to undesired food retention (impaction). Nowadays, most of the leading implant manufacturers offer wide body/wide platform implants designed for the replacement of multirooted teeth.

Premolar-size single-tooth restorations

When it comes to posterior single-tooth gaps that correspond dimensionally to an average premolar, standard-size screw-form implants are well suited. The implant dimensions, which include both the intrabony part and the implant shoulder, offer the additional advantage of being mostly compatible with a limited bone volume in an orofacial direction. Whenever feasible, a straightforward low-maintenance restorative design is advocated, which normally consists of a cementable porcelain-fused-to-metal (PFM) crown with vestibular and oral axial contours that are in harmony with the adjacent teeth and thus provide adequate guidance for the cheek and tongue (Fig. 55-37).

As one increasingly strives for the best possible biologic, functional, and esthetic integration of a given implant restoration in the pre-existing dentition, 3D preoperative site analysis is of paramount importance. It is not infrequent that this subsequently calls for a multidisciplinary approach, which may

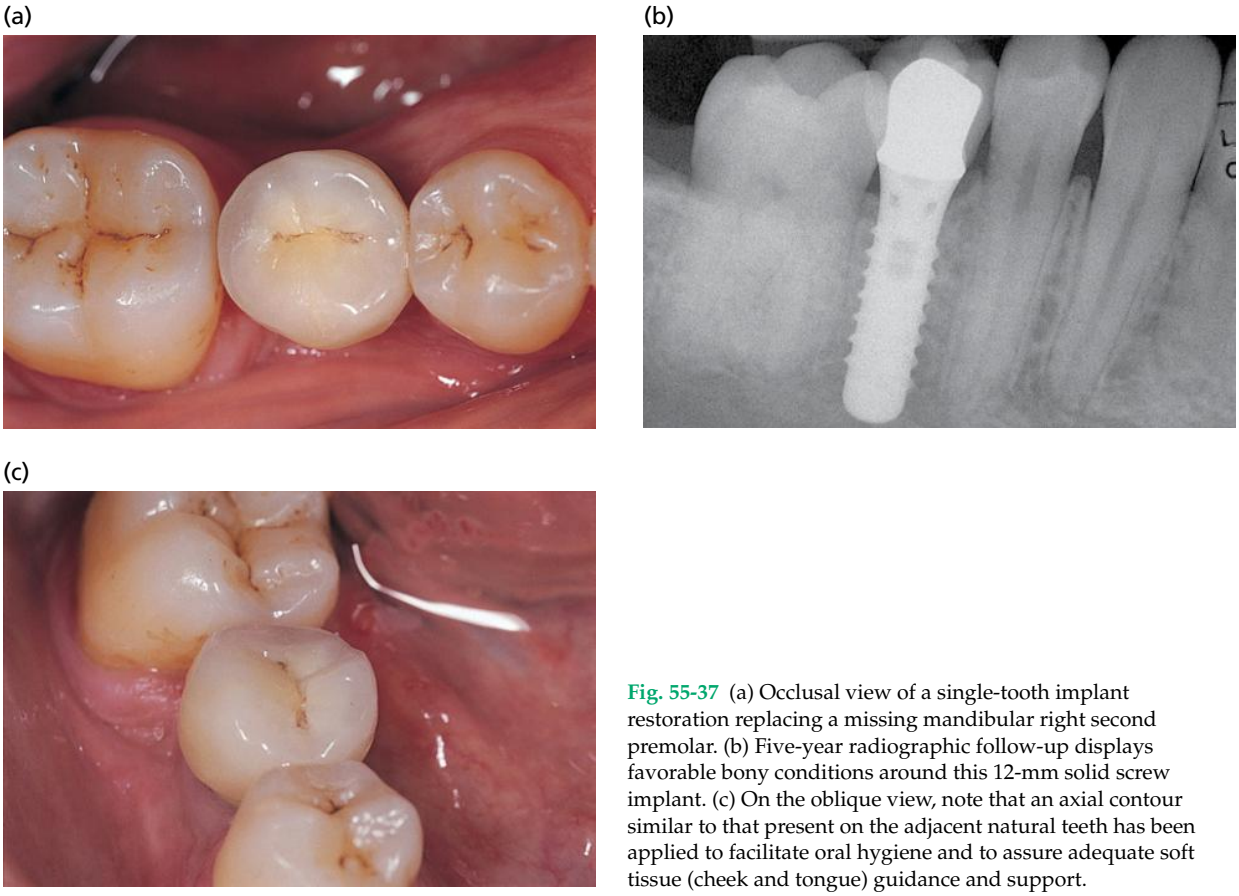

Fig. 55-37 (a) Occlusal view of a single-tooth implant restoration replacing a missing mandibular right second premolar. (b) Five-year radiographic follow-up displays favorable bony conditions around this 12-mm solid screw implant. (c) On the oblique view, note that an axial contour similar to that present on the adjacent natural teeth has been applied to facilitate oral hygiene and to assure adequate soft tissue (cheek and tongue) guidance and support.

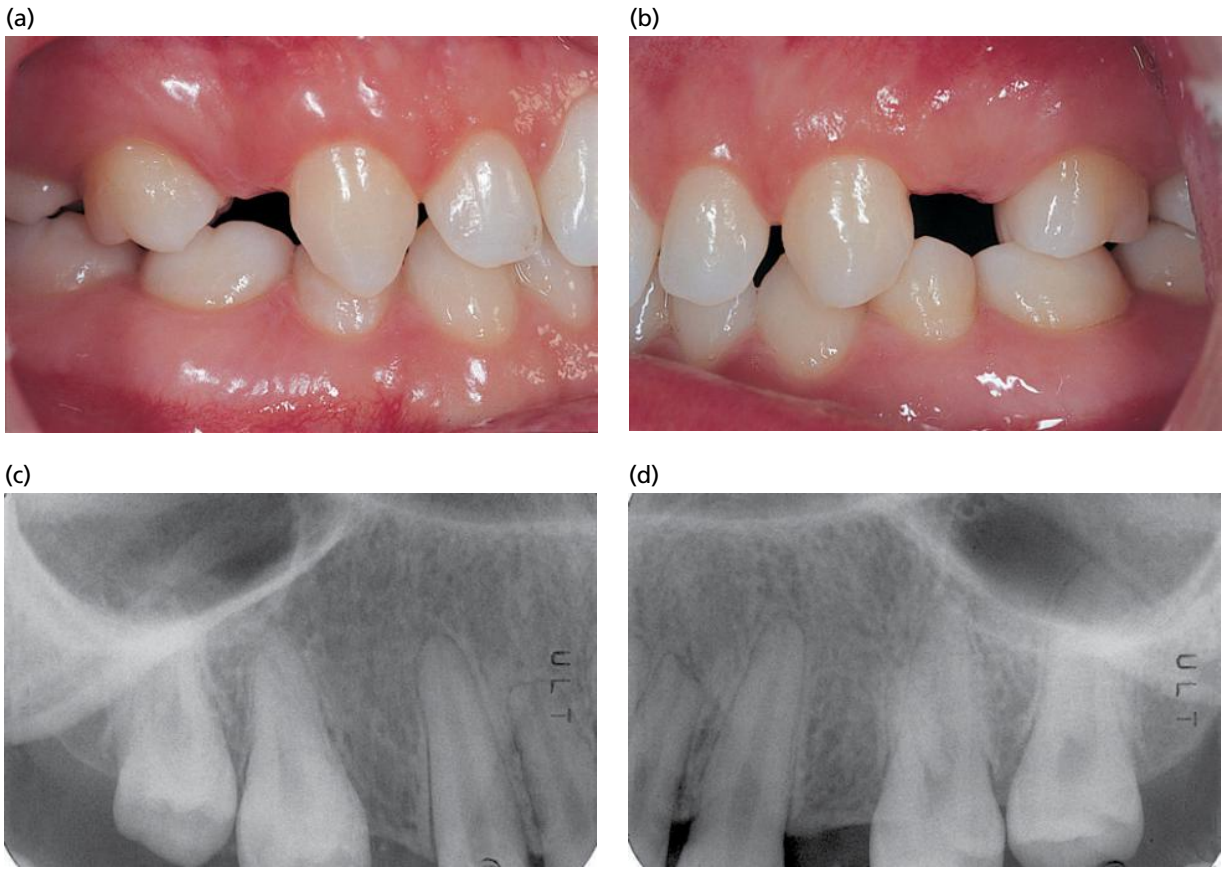

Fig. 55-38 (a) Right lateral view of a 19-year-old female patient, congenitally missing all four permanent maxillary premolars. Note both an inadequate mesiodistal gap width and a reduced interarch distance. (b) Similar situation regarding the interarch distance is present on the patient's left side. (c) Corresponding radiograph underlines the need for additional orthodontic therapy prior to the insertion of an implant in order to optimize the gap width and the inter-radicular distance. (d) Although to a lesser degree, presurgical orthodontic therapy is also indicated for the maxillary left posterior segment.

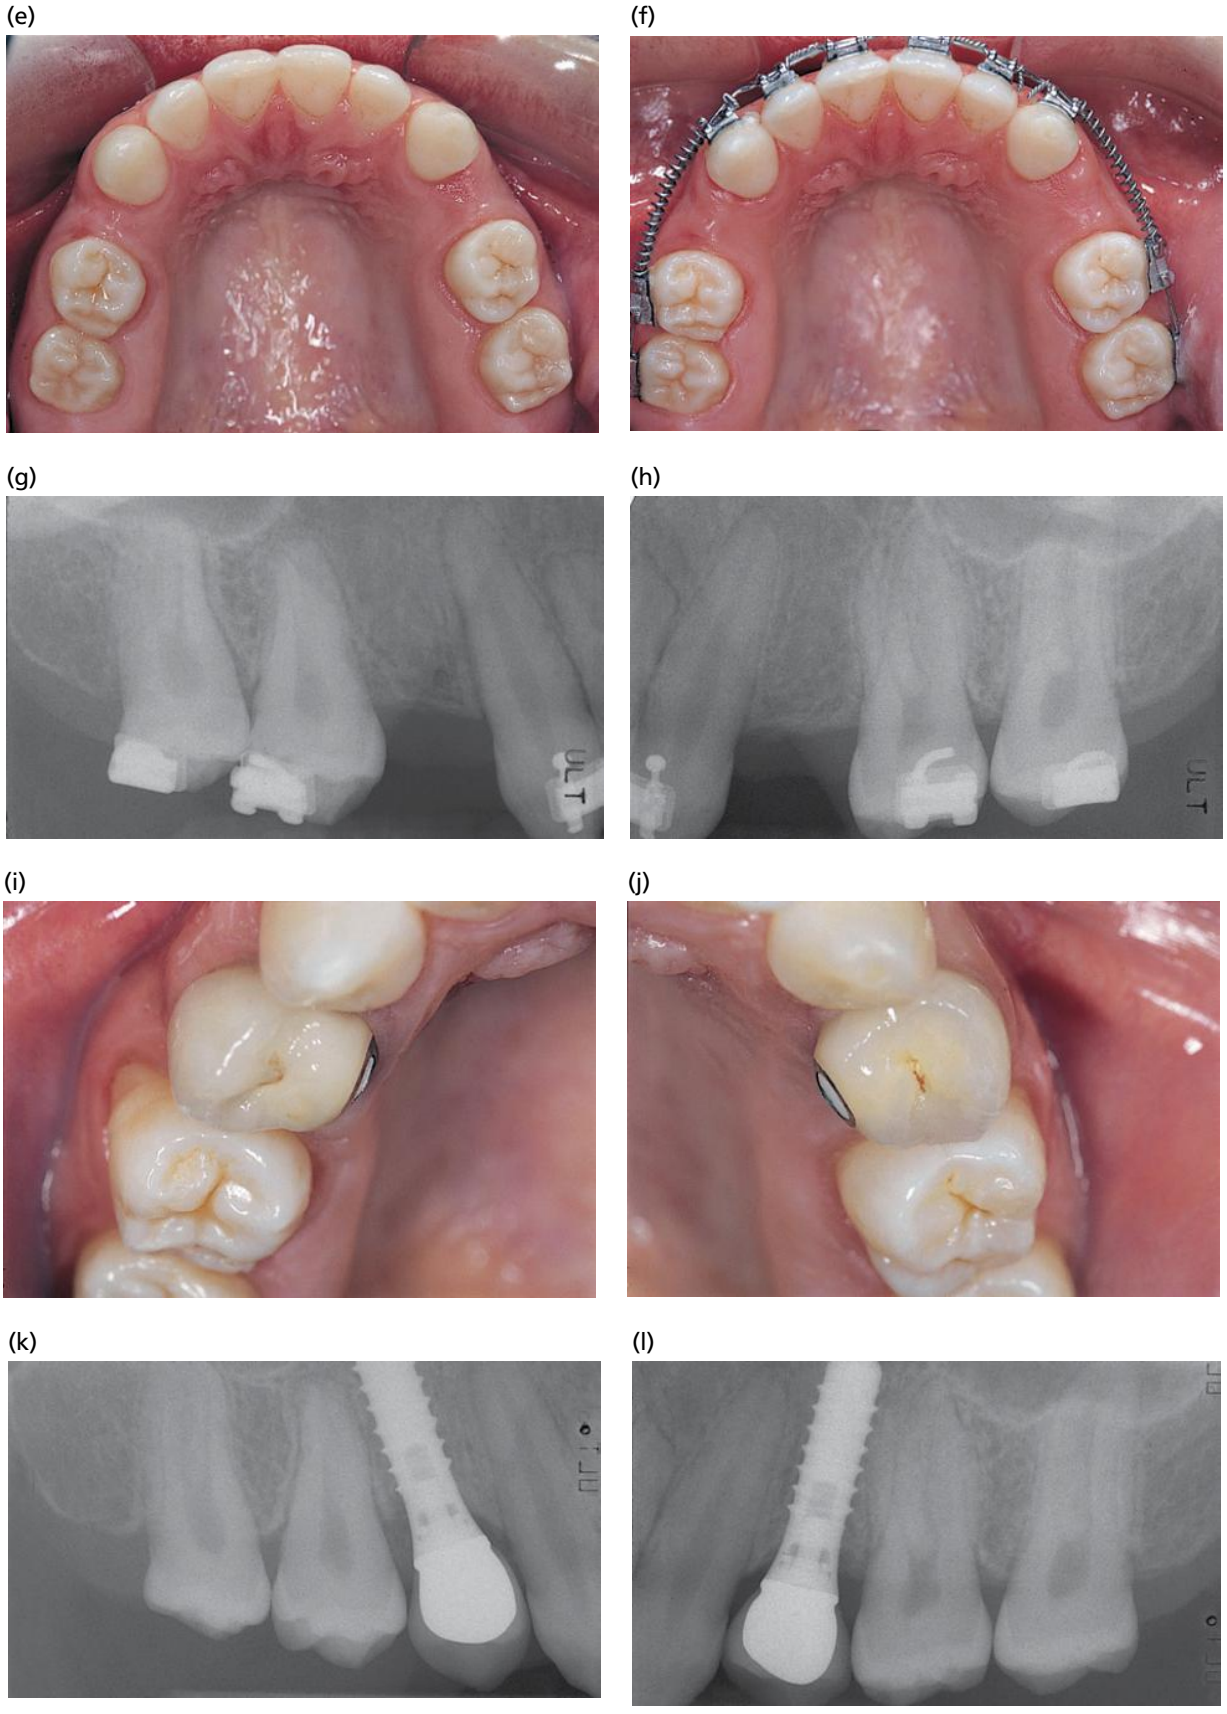

Fig. 55-38 (*Continued*) (e) Clinical occlusal view displays the bilateral edentulous spaces in the premolar area. Despite previously performed orthodontic therapy, aimed at reducing the edentulous spaces to the size of one premolar, the mesiodistal gap width on the right side is insufficient for the insertion of an implant. (f) After 6 months of additional orthodontic treatment using an upper fixed full-arch appliance, the dimensions of the two prospective implant sites appear compatible with this kind of therapy. (g) Corresponding radiograph confirms adequate space in the upper right premolar region for the placement of a standard single-tooth implant. (h) Similar presurgical situation is radiographically confirmed for the upper left premolar site. (i) Right oblique occlusal view of the implant restoration clearly demonstrates the advantage of the transverse screw-retention design: no occlusal screw access channel interfering with the functional occlusal morphology and esthetics or with structural requirements inherent to the metal–ceramic technology. (j) As described for the patient's right side, the left maxillary fixed single-tooth implant restoration integrates appropriately with the existing natural dentition. (k) Follow-up radiograph taken 1 year after the insertion of the 12-mm solid screw implant shows adequate marginal fidelity and stable conditions at the bone–implant interface. (l) Similar findings are present in the corresponding left-sided follow-up radiograph.

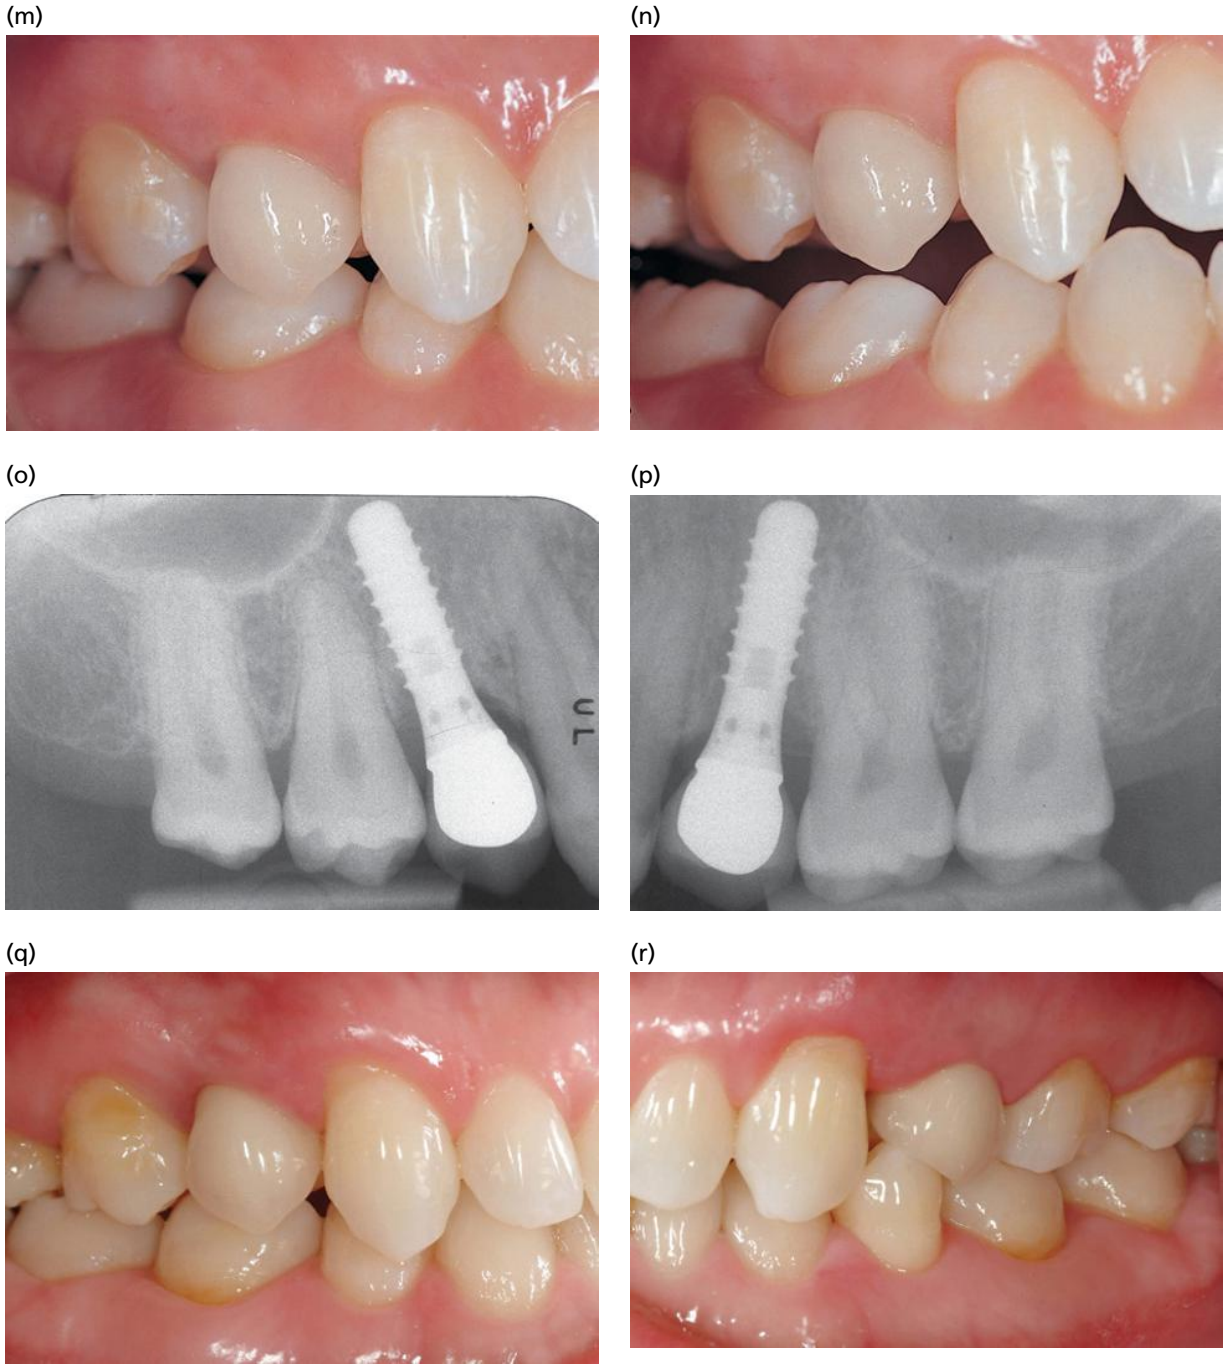

Fig. 55-38 (*Continued*) (m) Final right lateral view in centric occlusion shows acceptable general interarch conditions and related intercuspation. (n) During the right lateral excursion of the mandible (working-side movement), a canine guidance could be established. (o) Periapical X-ray after 13 years of loading shows stable crestal bone levels at the upper right premolar. (p) At the upper left side, the periapical radiograph shows very stable bone-to-implant conditions 13 years after crown insertion. (q) Buccal clinical view at the right side shows the implant crown after 13 years of loading. The soft tissue around the implant remained very stable. However, a recession was detected at the neighboring tooth 13. (r) Clinical view of the left side also reveals very stable soft tissue conditions 13 years after implant crown insertion. The soft tissue is slightly inflamed.

also include presurgical orthodontic therapy (Fig. 55-38). The objective is clearly to create local conditions that are best suited for the type of therapy chosen. If implants are to be involved, the local bone and soft tissue anatomy, as well as the mesiodistal and orofacial distances of a given edentulous segment, have to comply optimally with the most appropriate implant dimensions. Quite often, the mesiodistal gap dimensions have to be optimized orthodontically and neighboring roots aligned, so that they will not interfere with "restoration-driven" implant positioning. The case shown in Fig. 55-38 demonstrates a preoperative situation which does not allow posterior implants to be placed without a preoperative orthodontic therapy.

Molar-size single-tooth restorations

If a given posterior single-tooth gap instead corresponds to the mesiodistal dimension of a molar, it is recommended, for the reasons given in the previous

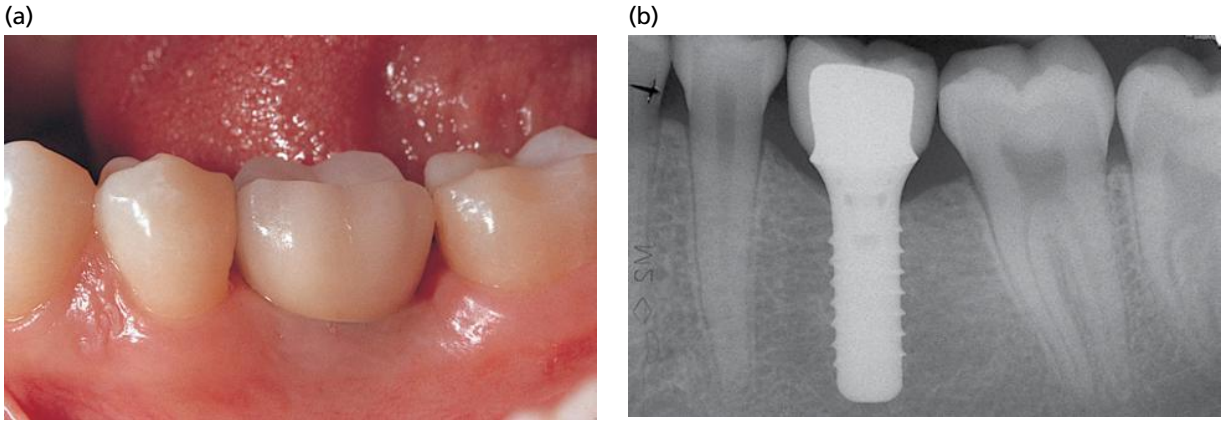

Fig. 55-39 (a) In a case of the replacement of a single missing molar, the use of an implant with corresponding dimensions is recommended to permit a restoration featuring optimal subjective comfort and cleanability. (b) On the 1-year radiographic follow-up, a diameter- increased implant can be noted, which is essential for a suprastructure design without extremely open interdental embrasures, which would be prone to food retention and oral parafunctions.

paragraph, that the insertion of a wide-neck implant is planned (Bahat & Handelsman 1996). This approach, however, also requires the appropriate bone volume in an orofacial direction. If this is not the case, presurgical site analysis, eventually in the form of a bone mapping, should identify whether it is possible to combine an implant placement with a lateral bone augmentation procedure using a simultaneous approach. If the local bone anatomy requires bone augmentation according to a staged protocol, one has to carefully ponder and discuss with the patient if this additional effort, risk, and ultimately also cost can be justified by an anticipated implant restoration featuring close-to-ideal axial contours and embrasures.

A clinical example demonstrating the potential of increased diameter implants for the optimal replacement of a single missing mandibular molar is given in Fig. 55-39.

Prosthetic reconstructions in the posterior dentition

Loading concepts for the posterior dentition

Loading concepts in implant dentistry have been widely discussed in the literature. Initially, healing phases of 3 months in the mandible and 6 months in the maxilla were recommended (Brånemark *et al.* 1977). To meet the patient's expectations for earlier prosthetic rehabilitation, shortened healing periods between implant installation and loading have been introduced. A variety of influencing factors, like initial implant stability, implant surface characteristics, bone quantity, bone healing, interim prosthesis design, and occlusal pattern during the healing phase, have been identified for successful osseointegration with modified loading protocols (Chiapasco 2004). Developments of the implant design especially, including structured and chemically modified surfaces, have led to the accelerated osseointegration of implants (Abrahamsson *et al.* 2004; Buser *et al.* 2004; Bornstein *et al.* 2008). With these improvements and increased knowledge of patient- and site-related risk factors allowing more comprehensive patient selection, earlier loading of implants has become possible.

So far no consensus has been found in the terminology for timing of loading. Depending on the reference, "immediate" loading is defined as a restoration within 48 hours (Weber *et al.* 2009) or within 7 days (Esposito *et al.* 2007) after implant placement; "early" loading between 48 hours and 3 months (Weber *et al.* 2009) or 7 days to 2 months (Esposito *et al.* 2007); "conventional" loading between 3 and 6 months (Weber *et al.* 2009) or later than 2 months (Esposito *et al.* 2007); and "delayed" loading as later than this (Weber *et al.* 2009) (Table 55-5).

Loading concepts for fully edentulous patients

In fully edentulous patients, immediate or early loading in the maxilla using removable prostheses is scarcely documented. Survival rates of 87–96% after only 2 years have been reported (Gallucci *et al.* 2009). Immediately or early loaded implants supporting fixed reconstructions show superior survival rates in the maxilla and mandible over removable prostheses. The degree of scientific documentation and the implant survival rate after immediate or early loading are generally higher in the mandible than in the maxilla (Table 55-6).

Loading concepts for partially edentulous patients

In patients with partially edentulous posterior segments, various studies have confirmed high implant survival of immediately or early loaded implants, ranging from 93% to 100% after 1–7 years (Cordaro *et al.* 2009; Roccuzzo *et al.* 2009). Overall, immediate loading seems to be inferior in terms of implant survival compared to early loading. Implants placed in the mandible perform better than in the maxilla, which is attributed to differences in bone quality. Conventional loading should be the procedure of choice for partially edentulous posterior sites (maxilla and

Table 55-5 Terminology of loading times.

mandible) in cases of low implant stability, extensive bone augmentation or patient-related risk factors (e.g. parafunction) (Weber *et al.* 2009) (Table 55-7).

Loading concepts for single-tooth replacements

Based on a systematic review including seven clinical studies with a total of 188 implants, mainly placed in the mandible, it was documented that implants restored with single crowns in the molar region showed survival rates of 91–100% after 6 months to 3 years if loaded immediately (Atieh *et al.* 2010) (Table 55-8).

It is important to point out that the scientific documentation is almost exclusively based on studies with implants placed in sites with sufficient bone and without concomitant bone augmentation techniques. Therefore, little scientific documentation exists on outcomes of implants placed with simultaneous GBR procedures. Depending on the size of the bone defect, it might be advisable to allow for longer healing periods after implant placement in conjunction with GBR procedures (Zembic *et al.* 2010). Human histologic data show a marked increase of bone in grafted sites between 6 and 8 months after augmentation (Fugazzotto 2003). In clinical practice, loading of implants 3–6 months after placement together with GBR procedures has been documented to be a successful concept after 3–5 years of observation (Jung *et al.* 2009b; Truninger *et al.* 2011).

In general, immediate or early loading can be considered in patients with a high primary implant stability and without systemic risk factors or

significant peri-implant bone defects. Splinted fixed reconstructions are favored over removable or single crown reconstructions in the posterior segments. If possible, immediate or early reconstructions should be free from occlusal load (Cordaro *et al.* 2009; Gallucci *et al.* 2009; Roccuzzo *et al.* 2009; Weber *et al.* 2009).

Screw-retained versus cemented reconstructions

When it comes to the prosthetic reconstruction of implants in the posterior region, the clinician has to decide whether to attach the suprastructure by means of screw-retention or cementation to the abutment or the implant. The decision is based on both general and clinical considerations.

General considerations

The major advantages of screw-retained prostheses include retrievability and accessibility, facilitating replacement and maintenance of the reconstruction (Chee *et al.* 1999; Michalakis *et al.* 2003). In addition, it is easier to shape the emergence profile with screw-retained implant provisionals and to transfer the contour to the master cast. Screw-retained restorations usually involve more complex and more expensive laboratory procedures and can suffer from inherent mechanical complications such as screw loosening and fractures (McGlumphy *et al.* 1998; Pietrabissa *et al.* 2000). Furthermore, the presence of a screw access hole may impede the occlusal morphology and thus, interfere with the occlusion (Hebel & Gajjar 1997). The ceramic layer is thereby discontinued, which could have an impact on the stability of the ceramics in the long-term. This assumption is supported by several *in vitro* studies, which found a higher fracture resistance and fewer chip on the veneered ceramics of cemented metal–ceramic crowns than of screw-retained implant crowns (Torrado *et al.* 2004; Karl *et al.* 2007; Zarone *et al.* 2007; Al-Omari *et al.* 2010; Shadid *et al.* 2011). These findings should be interpreted with caution however, since any clinical relevance supported by long-term clinical studies is lacking. Further clinical complications include the loss of the screw access hole restoration. This is reported to be the second most common technical complication based on a systematic review focusing on implant-supported FDPs (Lang *et al.* 2004) and occurred at a rate of 8.2% in a clinical study (Ortorp & Jemt 1999; Ortorp *et al.* 1999).

In contrast to the screw-retained restorations, where the ideal implant axis is a prerequisite, the cemented restoration offers the option to better compensate for a suboptimal implant position. The restoration of inadequately positioned implants is facilitated through cementation and the esthetics of the restoration can be enhanced since the screw access hole is not visible (Chee *et al.* 1999; Taylor & Agar 2002). One of the major advantages of cement-retained restorations therefore is the absence of a screw opening. As well as the above-mentioned advantageous esthetics, an optimal occlusal morphology and a sound ceramic layer are enabled (Hebel & Gajjar 1997). Cemented restorations incur lower technical costs than screw-retained restorations due to a reduced number of implant components and the fewer technical steps needed (Taylor & Agar 2002). A variety of disadvantages for cemented reconstructions have been reported, including the difficulty of removing cement without increasing the risk of peri-implant disease, a more complex retrievability of the reconstruction, and the possibility of crown loosening due to loss of retention (Breeding *et al.* 1992; Agar *et al.* 1997; Kent *et al.* 1997; Chee *et al.* 1999; Michalakis *et al.* 2003). Loss of retention can amount to 5.5% at 5 years and 16% at 10 years at implant-supported fixed partial dentures and single crowns (Bragger *et al.* 2001; Jung *et al.* 2008).

To assure long-term success of a cemented crown, an adequate retention and resistance form as well as sufficient restorative space is required. In situations with only 4 mm of interocclusal space (distance from the implant surface to the opposing teeth), adequate retention of cemented restorations is unrealistic (Chee & Jivraj 2006). In those cases, screw-retained restorations are the only predictable solution.

Clinical considerations

Clinically, the choice between using screw-retained or cemented reconstructions is controversial and mostly depends on the preference of the clinician (Misch 1995; Hebel & Gajjar 1997; Chee *et al.* 1999; Michalakis *et al.* 2003). Numerous clinical and *in vitro* studies evaluated the outcomes of screw-retained compared to cement-retained restorations: (1) the survival rates of implants and reconstructions, (2) technical parameters, (3) biologic outcomes, (4) esthetics, and (5) economic aspects were considered.

Implant/prosthodontic survival rates

With regard to the survival of implants and restorations, no differences were reported in either a 3-year prospective clinical study or a randomized controlled study with a 4-year follow-up on cemented and screw-retained implant reconstructions (Vigolo *et al.* 2004; Weber *et al.* 2006). These results were confirmed in a systematic review focusing on the comparison of the two treatment modalities (Weber & Sukotjo 2007). Based on the meta-analysis, no statistically significant differences with respect to the survival of implants (98.1% for cemented and 97.7% for screw-retained restorations at 6 years) and reconstructions (93.2% and 83.4%, respectively, at 6 years) were found (Weber & Sukotjo 2007). According to these results, it is not evident that one method of retention is superior to the other for both implants and reconstructions.

Technical considerations

The literature reports conflicting data on the incidence of technical complications at screw-retained and

cemented reconstructions. Additionally, the reported studies have included different numbers of these two fixation types, and only a few are randomized and controlled. Thus, it remains difficult to draw any conclusions relevant to the clinic. Some studies support a higher number of complications for screw-retained restorations (Levine *et al.* 2002; Duncan *et al.* 2003), whereas a more recent study found that cemented FPDs are associated with more complications than screw-retained FPDs (10.4% versus 5.9%) (Nedir *et al.* 2006). In that study, porcelain fractures occurred in 16 cemented reconstructions and two screw-retained ones (Nedir *et al.* 2006). Another study reported no significant differences in technical complications (not considering screw loosening) at screw-retained FPDs compared to cemented FPDs on implants (Bragger *et al.* 2001). Tightening of the screw was necessary in 21 of 45 screw-retained reconstructions, whereas recementation was necessary in 20 of 127 cases (De Boever *et al.* 2006). The higher number of cemented restorations might explain the significantly higher percentage of complications at screw-retained reconstructions compared to cemented reconstructions.

Biologic considerations

From a biologic point of view, no significant differences in probing depth, bleeding on probing, amount of keratinized mucosa, mucosal inflammation, and plaque were observed at 4 years in a randomized prospective study comparing cemented and screw-retained single implant crowns (Vigolo *et al.* 2004). These data are supported by a more recent study, which also found no differences for bleeding on probing between cemented and screw-retained anterior implant crowns (Cutrim *et al.* 2012), while contrary results with a more favorable peri-implant tissue response were reported earlier for screw-retained restorations (Weber *et al.* 2006). Still, it has been stated that the design of the implant–abutment junction may have an impact on the amount of bacterial penetration into the internal part of dental implants and may influence the peri-implant soft and hard tissues (Hermann *et al.* 2001; Piattelli *et al.* 2001). However, there is limited information available with respect to differences in the microbial penetration of the microgap of implants with different connection designs. Furthermore, the clinical relevance of this is questionable.

Esthetic considerations

Deviations from the optimal implant position and angulation can lead to an unesthetic restoration in case of screw-retained implant reconstructions, due to the visible screw access hole which is difficult to cover with composite (Walton & MacEntee 1994). Thus, in these cases, cement-retained restorations are indicated in order to achieve an acceptable esthetic outcome. When comparing the pink esthetic scores of screw-retained and cemented anterior crowns, no significant differences were found in a recent study (Cutrim *et al.* 2012).

Economic considerations

In posterior regions, the clinician has the option to keep the margin of the restoration more superficial than is possible in the anterior regions due to a minor esthetic priority. Thus, the more affordable standardized cemented restorations represent a viable treatment option for the posterior area. In contrast, in the anterior region, esthetics play a major role. In these cases, either screw-retained restorations or cemented individualized abutments and crowns might be the first choice and help to avoid problems associated with removal of cement or remnants, as well as visible crown margins in case of recessions.

Conclusion: On the basis of the existing scientific evidence, the decision to cement or screw-retain an implant restoration can rest on a clinician's personal preference, provided that the implants are placed in a manner that allows both options (implant placement enabling optimal location of the screw access hole at screw-retained restorations). Ideally, the choice should depend on each particular patient situation, including anatomic, economic, and esthetic factors. Figures 55-40, 55-41, and 55-42 show three clinical cases. Proposed indications for the two retention systems are listed in Table 55-9.

Selection criteria for choice of restorative materials (abutments/crowns)

The posterior region of the jaw bears the most load and as such must be mechanically stable. Biocompatible materials are needed for restorations. Today, a large variety of biocompatible materials is available due to the widespread use of CAD/CAM technology. Different factors are crucial to making the right decision between the optimal material and the reconstruction type for the posterior region.

In general, a choice can be made between two kinds of abutments: prefabricated and customized. The decision-making process should be based on a variety of clinical, technical, and biologic factors: For implant reconstructions (irrespective of their location), an adequate emergence profile is a prerequisite for healthy soft and hard tissue integration (biologic width), as well as ease of cleaning for the patient and a natural appearance. In case of low scalloped soft tissues and an appropriate distance between the implant shoulder and the crown margin (i.e. 3 mm), a biologic width can be established and the use of prefabricated abutments is indicated. The formation of a biologic width is reported to occur also in a horizontal direction (approximately 1.5 mm) (Tarnow *et al.* 2000).

In molar areas, a large deviation between implant and crown diameters can be found. In these situations, customized abutments together with the ideal emergence profile allow the crown margin to follow the present mucosal outline (Marchack 1996). Further conditions, like a limited vertical distance between

Divergent or unfavorable implant position		x
Costs		x

the crown and the surrounding bone, a prosthetically inadequate implant position, and a thin highly scalloped mucosa, require customization of abutments even in posterior regions (Fig. 55-42f).

A large variety of materials is available both for prefabricated and customized abutments (gold, titanium, alumina, and zirconia). Metal abutments offer excellent material stability and exhibit very good clinical outcomes (Sailer *et al.* 2009a). For a long time, they were considered to be the "gold standard" in posterior regions of the jaws (Henry *et al.* 1996; Andersson *et al.* 1998b; Scheller *et al.* 1998). Today, high strength ceramics are competing with the well-documented metal materials. However, it remains controversial whether or not use of the former in posterior regions is acceptable.

Alumina abutments, the first generation of high-strength ceramic abutments, showed fracture rates ranging from 1.9% to 7% (Andersson *et al.* 2001, 2003). Zirconia, the subsequently developed high-strength ceramic, exhibits twice the bending strength and fracture toughness of alumina (Rieger 1989; Tinschert *et al.* 2001) and was, therefore, considered an alternative material for posterior sites.

Satisfactory clinical outcomes and survival rates were reported for zirconia abutments at premolar and molar sites (Canullo 2007; Zembic *et al.* 2009; Nakamura *et al.* 2010; Nothdurft & Pospiech 2010). Although these results are promising, zirconia abutment fractures have been described (Villa *et al.* 2010; Ekfeldt *et al.* 2011; Roe *et al.* 2011). It is thus still necessary to prove that zirconia abutments represent a safe treatment option for posterior implant restorations (Nakamura *et al.* 2010). Hence, for now metal abutments remain the "gold standard" for molar regions.

Besides mechanical stability, the biocompatibility of the implant abutment is decisive. Titanium abutments led to the development of stable peri-implant soft tissues, consisting of a junctional epithelium and underlying connective tissue firmly adhering to the abutment surface (Abrahamsson *et al.* 1998). Alumina and zirconia both exhibited equal or even better

biologic outcomes compared to titanium (Abrahamsson *et al.* 1998; Nakamura *et al.* 2010). Furthermore, less plaque accumulation was found at zirconia as compared to titanium (Rimondini *et al.* 2002; Scarano *et al.* 2004; Degidi *et al.* 2006). Thus, from a biologic point of view, alumina, zirconia, and titanium are equivalent. In contrast, gold abutments led to peri-implant soft tissue inflammation and bone resorption in animal experiments (Abrahamsson *et al.* 1998; Welander *et al.* 2008).

Fig. 55-43 Similar esthetic appearance of implant crowns 35 and 36 restored with different materials (35: metal–ceramic crown cemented on an individualized titanium abutment; 36: all-ceramic crown cemented on an individualized zirconia abutment). The choice of the abutment and crown material was based on a randomization protocol of a randomized controlled clinical trial. (Source: Sailer *et al.* 2009b. Reproduced with permission from John Wiley & Sons.)

Even though esthetics is of minimal importance in the posterior region of the jaw, it still has a certain influence on the decision-making process. The dark color of metals was reported to cause esthetic problems, raising the need for more esthetic solutions also in posterior regions (Sailer *et al.* 2009b). Both titanium and zirconia abutments induced a similar amount of mucosal discoloration compared to natural teeth (Sailer *et al.* 2009b; Zembic *et al.* 2009) (Fig. 55-43). The mucosal thickness was around 2 mm for both abutment materials (Sailer *et al.* 2009b; Zembic *et al.* 2009). With an increased soft tissue thickness (>2 mm), it can be expected that the abutment material will have less influence on the soft tissue color (Jung *et al.* 2007, 2008). Thus, in these cases, both titanium and zirconia abutments are suitable. In cases with a mucosal thickness of <2 mm, zirconia abutments might be preferable also in posterior sites from an esthetic point of view.

All-ceramic (Fig. 55-44) and metal–ceramic (Fig. 55-45) single-implant crowns exhibited excellent survival rates in recent systematic reviews, ranging from 99.8% to

Fig. 55-44 (a) Example of a complete rehabilitation of the maxilla with zirconia-based reconstructions including posterior implant-supported screw-retained zirconia crowns. 100% at 5 years (Jung *et al.* 2008; Sailer *et al.* 2009a). Hence, both types of reconstructions may be considered as treatment options. It should be considered that the abutment material may have an influence on the stability of all-ceramic crowns. It was recommended that all-ceramic crowns should be used in combination with ceramic abutments in order to reduce the risk for fracture and esthetic failure (Sailer *et al.* 2009a). In a randomized controlled trial of all-ceramic and metal–ceramic single-implant crowns in posterior regions, no differences in the survival rates were found at 3 years of function (Zembic *et al.* 2009). Minor chipping of the veneering ceramic was the only technical complication (Zembic *et al.* 2009).

Interestingly, all-ceramic implant FDPs with zirconia frameworks also showed good clinical survival rates (Larsson *et al.* 2006; Larsson & Vult von Steyern 2010). No fractures occurred in the zirconia frameworks. In contrast, high rates of veneering ceramic fractures (Figs. 55-46, 55-47) of up to 70% raised major concern with this type of implant reconstruction (Larsson & Vult von Steyern 2010). Other studies have confirmed the high incidence of chipping at zirconia-based implant-supported reconstructions (Glauser *et al.* 2004; Larsson *et al.* 2006; Canullo 2007; Nothdurft & Pospiech 2010). Numerous factors

Fig. 55-46 Fractures of the cervical portion of the veneering ceramic (chips) at a posterior single-tooth zirconia-based crown.

Fig. 55-47 Chipping of the buccal veneering ceramic of an implant-borne zirconia-based cemented FDP 4 years after insertion.

might contribute to this problem and are being analyzed at present; however, the major cause and solution have not been found yet (Al-Dohan *et al.* 2004; Ashkanani *et al.* 2008; Tsalouchou *et al.* 2008; Fischer *et al.* 2009). As a consequence, currently metal–ceramics should be preferred for posterior multiunit FDPs.

Concluding remarks and perspectives

The possibility of performing highly predictable treatments by using dental implants in the load-carrying part of the dentition offers the clinicians a broad range of therapeutic options for any kind of edentulism. In this context, the use of implants may often significantly reduce the inherent risk of "borderline" conventional tooth-borne FDPs (e.g. prostheses based on compromised abutment teeth, long-span FDPs, cantilevers) by implementing the principle of segmentation. This evolution is dynamic and holds promise for further significant developments.

Acknowledgments

The authors wish to acknowledge and thank Drs Goran Benic, Irena Sailer, David Schneider, Karin Wolleb, Anja Zembic (School of Dental Medicine, University of Zurich), Jean-Pierre Bernard, Stephan Dieth, Thierry Doumas, German Gallucci, Robin Jaquet (School of Dental Medicine, University of Geneva) and Daniel Buser (School of Dental Medicine, University of Berne) for their clinical contributions and their help in preparing the different chapters in the different editions. Furthermore, our gratitude is extended to Gisela Müller (MSc) for competent assistance in development the present chapter.

Chapter 56

Role of Implant–Implant- and Tooth–Implant-Supported Fixed Partial Dentures

Clark M. Stanford[1] and Lyndon F. Cooper[2]

[1]Dental Administration, University of Illinois at Chicago, College of Dentistry, Chicago, IL, USA
[2]Department of Prosthodontics, University of North Carolina, Chapel Hill, NC, USA

Introduction

The restoration of a partially edentulous situation involves a combination of systematic diagnosis, treatment planning, and careful assessment of the therapy choices and the outcomes. The replacement of a continuous span of teeth creates challenges that involve assessment of anatomy, physiology, cost, time, impact on oral health quality of life, and patient desires. A critical part of modern care is to assure tooth replacement therapy is provided in an economic and expedient manner. Dental implants offer advantages for many clinical situations. In certain situations, the restoration of missing teeth using individual free-standing implant-supported crowns is a logical and satisfactory treatment option. At other times, use of an implant-supported fixed partial denture (FPD) is the most satisfactory approach (Fig. 56-1). Because of functional and esthetic priorities, anterior and posterior multi-tooth implant restorations can present different clinical challenges. This chapter considers implant–implant supported FPDs (bridges) separately from tooth–implant-supported prosthesis since each type of prosthesis is unique and creates its own novel issues. The use of a fixed complete denture (FCD) to replace all of the teeth in an arch can be considered a form of FPD.

Patient assessment

For predictable esthetic and functional outcomes of implant treatment, comprehensive diagnostic and treatment planning is required (Stanford 2005a; Bidra 2011; Drago & Carpentieri 2011). As a member of the implant team, the prosthodontist collaborates with the surgical specialist, laboratory technician, and allied team members such as radiologists, and dental and surgical assistants. The initial assessment of the patient's medical and dental history assists in the determination of the implant system and devices that will meet the patient's therapeutic needs. The patient interview should establish the patient's individual esthetic requirements. The assessment should determine a patient's history of bruxism, periodontal disease (and type of disease), tobacco use, uncontrolled diabetes mellitus, and metabolic diseases of bone (Moy *et al.* 2005; Ahmed *et al.* 2012; Cochran & Nevins 2012; Froum & Rosen 2012; Wadsworth 2013). Implant therapy may have a variable prognosis in patients with advanced chronic periodontitis,

although with maintenance therapy a more predictable outcome can be achieved (Nevins & Langer 1995; Ellegaard *et al*. 1997; Brocard *et al*. 2000; Pjetursson *et al*. 2004; Wennström *et al*. 2004a). Maintenance therapy is vital since longitudinal bone loss around implants may occur and can be observed after many years of asymptomatic clinical service (Hardt *et al*. 2002). In addition, the assessment should educate patients about the etiology of tooth loss, reveal their attitudes towards treatment as well as their ability to tolerate it, and inform them of the estimated therapy costs (Pjetursson *et al*. 2005; Stanford 2005a). Throughout the surgical and prosthetic phases of the implant reconstruction, the dental practitioner should obtain comprehensive written and verbal informed consent to treatment from the patient. The consent form should document the risks and benefits of the proposed treatment plan, as well as the alternative treatments that have been discussed with the patient, including the option of no treatment and its consequences. This initial assessment phase should provide the clinical team with sufficient information

Fig. 56-2 Diagnostic wax-up for implant therapy demonstrating desired contours for the planned definitive restorations.

to characterize the patient-related risk factors influencing the care plan.

To assure that implant location and the number and dimension of implants are congruent with the anticipated prosthesis, it is essential that the dentist designs and composes the proposed prosthesis during the diagnostic phase. Planning will dictate the number and dimension of implants, their position and angulation. The plan will assimilate all clinical, radiographic, and psychological information gathered from the patient interview, clinical examination, and radiographic survey. During the clinical exam, the dentist should carefully evaluate the shape and contour of the residual ridge, and evaluate other sites in the mouth for the potential risk of recession. A careful evaluation of the patient's risk factors for soft and hard tissue changes, whatever final restoration is planned, should be made not only to comply with the informed consent process, but also to encourage realistic patient expectations. However, to move beyond assessing the feasibility of implant treatment, it is essential to utilize articulated diagnostic study casts to fully assess the tissue architecture and relationship of teeth and mucosa with the existing edentulous areas. Thus, the initial clinical examination should conclude only when sufficient materials are available to accurately mount diagnostic casts and interpret the study casts and screening radiographs using recorded clinical information. Based on this diagnostic information, a surgical guide or denture can be fabricated through the process of developing a diagnostic waxing of the planned prostheses and this can direct or indicate the desired implant position and angulation, the probable abutment dimension and angulation, and the possible need for hard/soft tissue augmentation before or during implant placement (Fig. 56-2). The diagnostic wax-up is a key step in the assessment of local risk factors affecting FPD supported by dental implants and is critical to the process of strategically planning implant placement to limit these risks.

Implant treatment planning for the edentulous arch

The mandibular arch can be restored using a FCD, FPD or overdenture. The FCD has either a gold casting or CAD/CAM-milled titanium or chromium cobalt framework, full milled monolithic zirconia or conventional acrylic resin teeth, or teeth veneered with porcelain (Adell *et al*. 1990; Ozkurt & Kazazoglu 2010). An overdenture with an attachment to the implant can be fully supported and retained by the implant(s), or a combination mucosa/implant-borne prosthesis can be used. Clinical studies indicate high patient acceptance of this form of therapy (Feine *et al*. 1994, 2002; Duyck *et al*. 2004; Naert *et al*. 2004a, b; Zitzmann *et al*. 2005)

Prosthesis design and full-arch tooth replacement therapy

If minimal bone resorption exists, restoring the edentulous maxillae with a porcelain-fused-to-metal (PFM) restoration will have a reasonable outcome (Stanford 2005a). The restorative dentist must perform a diagnostic work-up including impressions, jaw relationship records, and an esthetic try-in using prosthetic denture teeth on a trial denture base, a diagnostic wax-up template, or a CAD-milled composite template of a computer-aided esthetic set-up. Lip support and smile line (i.e. anterior and posterior occlusal planes) of the diagnostic denture set-up or "mock-up" should be evaluated intraorally. It is useful to evaluate the patient's lip support with and without the anterior facial denture flange (Lewis *et al*. 1992; Stanford 2002). The amount of tooth exposure at the anterior smile line (relaxed and exaggerated), provides clues about the expected crown length, gingival display, and potential need to use gingival-tone porcelain for appropriate tooth length and esthetics in a full-arch reconstruction. Communication and discussion with the dental laboratory technician is very helpful at this point, prior to finalizing the treatment plan. A fixed maxillary prosthesis has greater incidences of esthetic, phonetic, and oral hygiene problems compared with an overdenture prosthesis, in part associated with excessively long anterior teeth, excessive facial cantilever pontics, and mesiodistal complications with embrasures. Given the clinical and laboratory complexity of these prostheses, a maxillary overdenture on four to six implants may be an alternative (Phillips & Wong 2001; Anon 2003; Naert *et al*. 2004b).

Complete-arch fixed complete dentures

A complete-arch FCD provides excellent function and patient acceptance (Lewis *et al*. 1992; Feine *et al*. 1994). During the diagnostic phases, the advantages and disadvantages of the FCD compared with those of an overdenture should be discussed with the patient. If using a metal–ceramic full-arch fixed reconstruction, consideration should be given to replacing every three teeth with a three-unit FPD on two implants (e.g. 13–11) using the pontic contours to adjust for implant alignment and esthetic demands (Stanford 2002). A fixed maxillary reconstruction entails four, six or eight implants (first molar, first premolar, canine. and central incisor) with four independent FPDs (molar to premolar, canine to central incisor, bilaterally). With care taken to limit loading, up to six implants may be used with distal cantilevers on two FPDs (cantilever pontics limited to one premolar-size tooth). An overdenture should use a sufficient number of implants for long-term stability, typically four in the maxilla (canine and second premolar region) and two in the lower canine or first premolar region (Mericske-Stern *et al*. 2000).

Using the denture set-up, a radiographic guide is fabricated with radio-opaque markers (e.g. gutta percha or bur shanks) within the denture at the sites of interest. An alternative approach involves duplicating the denture set-up with teeth made from 5% medical-grade barium sulfate mixed with clear autopolymerizing resin or the use of temporary cement painted on the outside of the teeth on an all-acrylic resin partial or complete denture (and on the intaglio side) as a reference marker for contours to be identified on a cone-beam computed tomography (CBCT) scan. This approach allows easy visualization of tooth size, angle, and position in the CT-aided treatment planning. In the mandible, the trial set-up evaluates the height and position of the prosthetic teeth relative to the symphyseal cross-sectional anatomy. A conventional FCD with acrylic teeth bonded to a titanium alloy framework requires a minimum of 15 mm between the alveolar bony crest to the planned incisal edge (Stanford 2005a). If the vertical dimension of occlusion and jaw anatomy is insufficient, one alternative is to perform an aggressive alveoectomy or to rehabilitate with metal–ceramic restorations (along with treatment planning for the additional cost).

Radiographic information and diagnostic set-up will help determine the type of definitive prosthesis design. Skeletal class I and II relationships with minimal resorption may allow normal contours and lip support with an FCD. A prognathic class III relationship can increase prosthetic problems, especially if implants cannot be placed distal to the mental foramens, limiting the anteroposterior spread of the implants and consequent biomechanical challenges. In such cases, an overdenture approach yields a more predictable result (Naert *et al*. 1997) or a tilted implant approach can be used in which the distal implants are placed at 30° toward the back of the mouth and angled abutments upright the implant relationship to the occlusal plane (Cavalli *et al*. 2012; Grandi *et al*. 2012; Patzelt *et al*. 2013).

Prosthesis design and partially edentulous tooth replacement therapy

Clinician or patient preferences for the use of implants for restoration of partial edentulism using FPDs must be carefully weighed against the potential limitations associated with this therapy. Technical complications related to implant components and suprastructures are more frequently reported than complications related to peri-implant tissues (Berglundh *et al.* 2002). Also, complications with implant-supported FPDs are together more frequent than implant loss or implant fracture. For example, Bragger *et al.* (2001) reported that over a 10-year follow-up period the percentage of reconstructions without any biologic or technical failures/complications was 66.5% for single crown-implant restorations, 54.4% for implant-supported FPDs, and 50% for tooth–implant-supported FPDs. Importantly, the authors concluded that prostheses with a history of complications were at greater risk of implant failure. It may be possible to infer that complications reflect the functional features of the prosthesis or the patient and, furthermore, that some of these complications are due to limitations in implant and prosthesis planning, placement, or

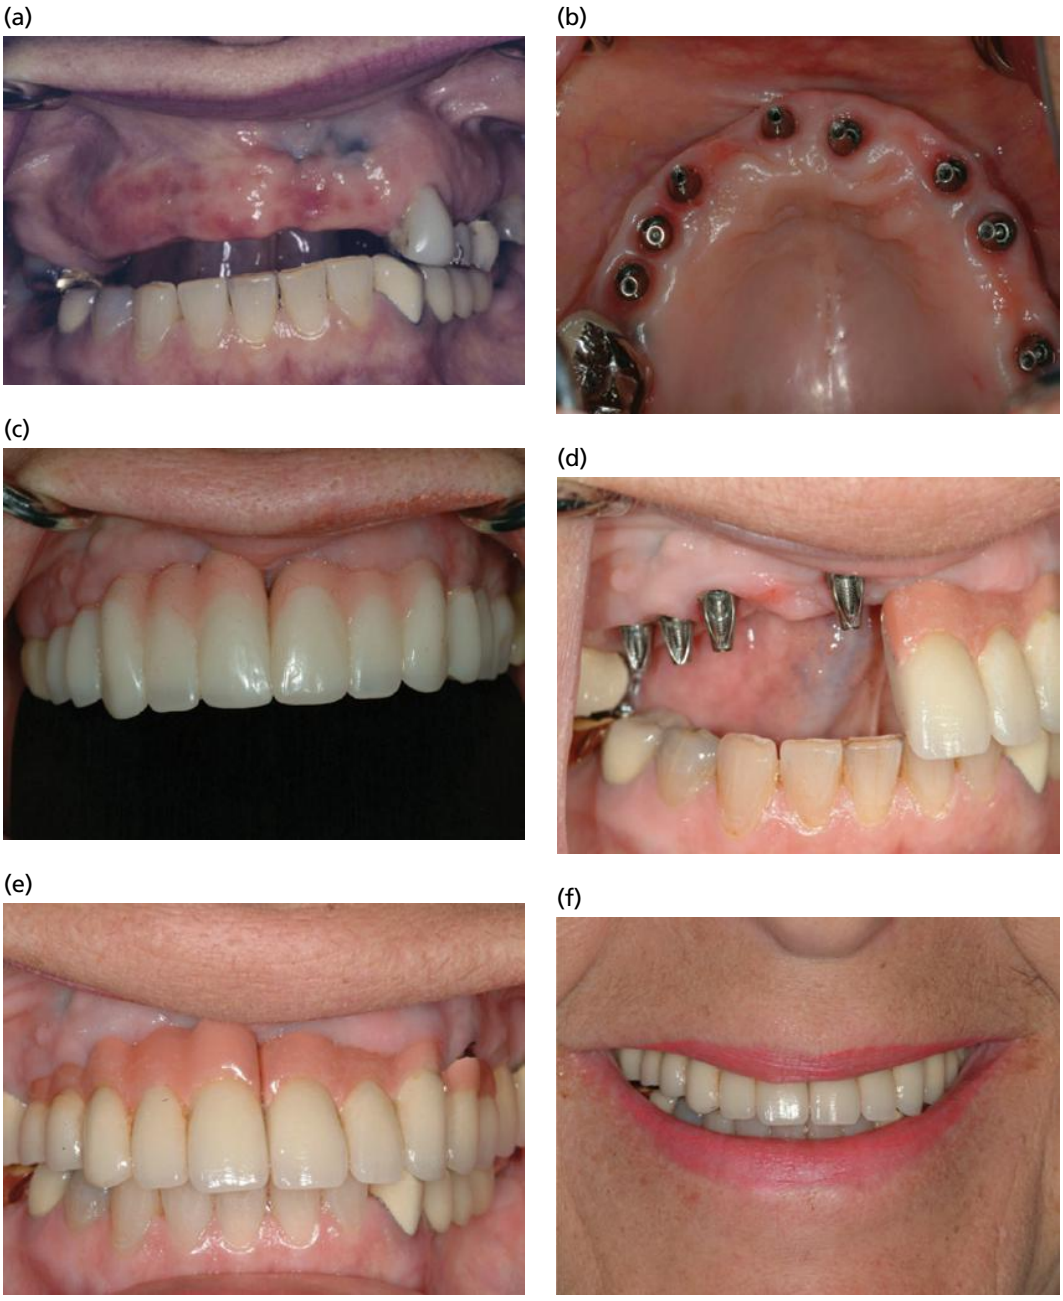

Fig. 56-3 Use of fixed partial dentures to restore missing hard and soft tissue. (a) Patient presented with a 40-year history of an edentulous space in the maxilla. Following placement of eight implants (b), a long-term acrylic resin provisional was fabricated simulating the desired tooth and soft tissue dimensions (c). (d) Based on the long-term provisional, metal–ceramic fixed prostheses were fabricated using mucosa-colored ceramic materials on a metal framework. (e, f) Five-year recall demonstrating fixed prosthetic outcomes and anterior esthetics.

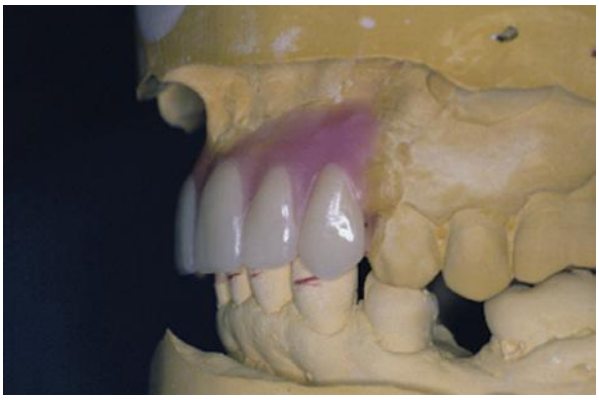
construction, or the innate limitations of implant components. Complications most frequently observed for FPDs include veneer fracture, opposing restoration fracture, bridge screw loosening or fracture, abutment screw loosening or fracture, and metal framework fracture (Goodacre *et al.* 2003a). The considerations for treatment planning of implant-supported FPDs must include features that affect not only implant success, but also abutment and bridge screw performance, prosthesis esthetics, and longevity (Fig. 56-3).

Primary among clinical considerations for any implant prostheses is some estimation of the potential forces that will be exerted during function. It is well recognized that masticatory forces increase as the point of interaction moves posterior in the arch. Additionally, damaging bending moments are increased with the acting lever arm length. Greater concern is warranted when implants are planned to support prostheses with large occlusogingival dimension (extensive resorption) or for prostheses with extensive mesial, buccal or lingual cantilevers or any substantial distal cantilever (discussed below). Additional immediate considerations typically address the esthetic potential of the prosthesis. These are clearly most relevant for anterior FPDs. Tooth-like restorations are dependent on proper dimensions and, again, greater concern is raised with increasing residual ridge resorption. However, basic features of implant placement such as avoiding encroachment of embrasures are critically important for anterior FPDs. These features are revealed by evaluating the diagnostic wax-up and conveying this information to the surgical guide (Fig. 56-4).

The current absence of discrete rules that govern the precise number and dimension of implants (or a particular implant) needed to support any given masticatory function is acknowledged. Renouard and Rangert (2008) proposed that support factors can be attributed to implants and that relative risk can be assigned to various clinical scenarios. This approach of recognizing relative risk factors and modifying the clinical approach to therapy – even in a subjective way—merits consideration. At the very least, each clinical scenario should be considered in terms of prosthetic and implant risk both biologically and biomechanically, and treatment should be adapted to recognize these risks if possible. Obvious examples include the use of additional or larger implants to support molar function as opposed to premolar function, and the avoidance of distal cantilevers in patients with bruxism.

A simple strategy for reducing the biomechanical risks to implants and prostheses of implant-supported FPDs is to use treatment planning procedures to assure that the abutment–crown interfaces are located beneath the cervical aspect of the terminal mesial and distal crowns of all prostheses whenever possible. This approach reduces the length of bending moments, irrespective of the imposed load, and assures that the implant and abutment do not encroach on the embrasures to limit oral hygiene or esthetic potential of the restoration (see Fig. 56-1).

(a)



(b)

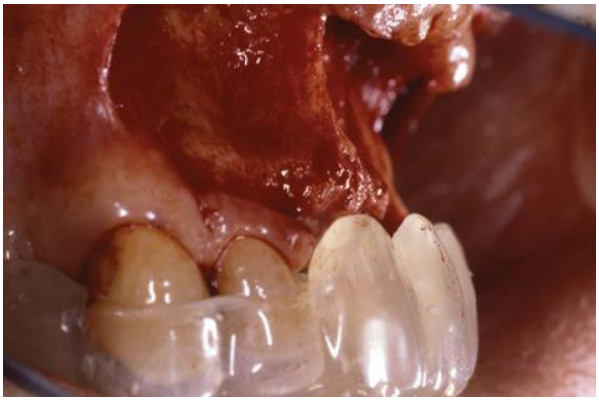


Fig. 56-4 (a) Diagnostic wax-up demonstrating desired tooth position and wax used to demonstrate the amount of planned augmentation needed. (b) At the time of site development, the surgical guide demonstrates the difference between the desired tooth position and the residual ridge.

When multiple implants are placed in an edentulous span, careful treatment planning will indicate the mesial and distal widths of the desired restorative teeth. This plan will in turn indicate proposed sites where implants (e.g. every other tooth) may be placed for stability of the prosthesis. Choice of implant location (and angle of placement) depends on available osseous tissues, soft tissue thickness, esthetics, phonetics, and need for ridge development.

When having a dialog with patients about the desired tooth replacement therapy, clinicians often recommend an implant-per-tooth approach. When this approach is done with individual free-standing crowns, it provides the potential for a natural tooth-by-tooth replacement. However, a significant issue for the prosthetic restoration can be created if the implants are not placed in exactly the desired location. Therefore, the use of short-span FPDs has certain general advantages. First, the use of two implants to replace three teeth enables the technician to judiciously use the pontic contours to alter the shape and contour of the prosthesis to compensate for implants that are not optimally positioned. For instance,

implants that emerge at the desired interproximal area can be compensated for with the use of angled abutments or customized CAD/CAM abutments that facilitate use of connector dimensions that give an illusion of natural teeth. Another advantage cited by some is the establishment of interproximal contacts between the prosthesis and adjacent teeth.

In order to assess the predictability of these types of restorations, clinical research studies need to be assessed. Randomized controlled clinical trials of partially edentulous patients with a history of periodontal bone loss were evaluated in a 5-year trial by Wennström *et al.* (2004a). This study reported on 149 self-tapping implants (AstraTech AB, Mölndal, Sweden) placed in maxillae (n = 83) and mandibles (n = 66) in the premolar and molar area. Each patient received two implants (machined surface versus grit blasted with TiO_2) that were allowed to heal for 6 months prior to loading. Screw-retained FPDs were completed and maintenance therapy provided following the CIST program (Lang *et al*. 2004a). Implant loss was 5.9% at the subject level. FPDs demonstrated a total 5-year bone loss from implant placement of 0.41 ± 0.78 mm (subject level) (Wennström *et al*. 2004a). There was a statistical difference in the frequency of bone loss between implants placed in the upper versus those placed in the lower jaw: 38% of the maxillary implants demonstrated >1-mm bone loss, while 9% of the FPDs in the lower arch had >1 mm bone loss at 5 years. Previous studies evaluating bone loss with the implant system used in this study in a variety of research protocols have reported mean marginal bone loss from implant placement to be an average of −0.46 ± 0.38 mm (Olsson *et al*. 1995; Yusuf & Ratra 1996; Karlsson *et al*. 1997; Makkonen *et al*. 1997; Norton 1997; Arvidson *et al*. 1998; Karlsson *et al*. 1998; Astrand *et al*. 1999; Cooper *et al*. 1999; Palmer *et al*. 2000; Puchades-Roman *et al*. 2000; van Steenberghe *et al*. 2000; Cooper *et al*. 2001; Gotfredsen & Karlsson 2001; Norton 2001; Steveling *et al*. 2001; Weibrich *et al*. 2001; Engquist *et al*. 2002; Wennström *et al*. 2004a, b; Palmer *et al*. 2005; Rasmusson *et al*. 2005; Wennström *et al*. 2005). When implants were placed in the posterior maxilla with the indirect sinus lift technique and restored with FPDs at 6 weeks using a fluoride-modified implant, outcomes demonstrated bone loss of −0.19 to −0.4 mm (SD = 0.73) from implant placement, with a 98.3% cumulative implant survival rate (CISR) (Stanford 2006). These data support the concept that partially edentulous patients can be restored with FPDs (Gotfredsen & Karlsson 2001). However, post-insertion maintenance is critical. Hardt *et al.* (2002) observed in a population with a history of bone loss associated with periodontitis, that poor oral hygiene and compliance with maintenance therapy resulted in an elevated failure rate of 8% at 5 years, and 62% of the implants in patients susceptible to periodontitis versus 44% in the non-perio groups demonstrated >2 mm of bone loss (Hardt *et al*. 2002). This emphasizes the need for ongoing supportive care for patients undergoing tooth replacement therapy (Lang *et al*. 2004a; Schou *et al*. 2004).

Cantilever pontics

In managing tooth replacement therapy, often a mesial or distal extension is needed off the retainer. The use of cantilever extensions increases the mechanical angular moment on the prosthesis and the potential for early fatigue and prosthetic complications (Brunski 2003). The use of cantilever extensions was first advocated as a routine prosthetic approach in the Toronto mandibular FCD for the edentulous arch (Zarb 1988; Zarb & Schmitt 1990a, b, 1991). Clinical studies on the use of cantilever extensions suggest greater complications with extensions longer than 15 mm, although there are many opinion-based recommendations that range from 10 to 20 mm (Shackleton *et al*. 1994) Cantilever extensions do increase the angular moment on the most distal implant and abutment connection, and complications such as loosening screws, fractured components, etc. are related to a combination of factors including cantilever design, composition, occlusion, jaw relationships, and implant/abutment design (Brunski *et al*. 1986). In an analysis of survival over 80 months of FCDs with an acrylic resin tooth replacement and of the external hex Brånemark system, Shackleton *et al.* (1994) observed a 100% survival rate for cantilever extensions of <15 mm but of <30% for extensions of >15 mm.

In the anterior quadrant where esthetics are desired, there are often missing lateral incisors that leave only minimal mesiodistal space for implant placement. One option may be to use narrow diameter implants in such sites, but control of occlusion is important (Stanford 2005b). An alternative, especially when there are missing adjacent teeth, is to use cantilever pontics of minimal dimension to replace the missing teeth (Fig. 56-5). This has the potential for more predictable esthetics without requiring excessive site development, expense, and time. The use of cantilever pontics in the posterior quadrants is more controversial. Cantilever pontics in metal–ceramic FPDs create larger moment arms on the prosthesis and have the potential to increase mechanical complications with the implant–abutment stack (Stanford 1999; Brunski 2000; Brunski *et al*. 2000; Gratton *et al*. 2001; Brunski 2003). There are times when posterior cantilever pontics are useful, but the clinician should primarily consider them for esthetics and also for areas of controlled occlusal forces. Further, their use with metal–ceramic FPDs should be limited, with no more than a premolar-sized pontic (~7 mm mesiodistal dimension) and only light centric occlusal contacts on the pontic (Stanford 2005b)

There are ongoing issues regarding cemented relative to screw-retained FPDs. While the choice of prosthesis is dependent on multiple factors (clinician

Fig. 56-5 Use of cantilever pontics to replace missing lateral incisors as a part of fixed partial denture (FPD) therapy. (a) Four implants were placed in the maxilla in the second premolar and canine region. (b) A four-unit FPD with cantilever pontics (12 and 22) was fabricated, allowing restoration of eight missing teeth with four implants (c) and establishment of an acceptable esthetic result (d).

preference, flexibility, passivity of fit, cost, etc.), there are times when one or the other approach is preferable. For instance, in situations where the patient has multiple clinical signs of recession (thin tissue biotype, recession, lack of keratinized mucosa, etc.), a screw-retained fixed prosthesis may be preferable (Stanford 2005a), as this approach will allow the clinician to remove the prosthesis at a later point in time and make repairs which may salvage the prosthesis. Patients with a history of implant loss in the area, difficult implant placement or elevated medical risk are other indications to consider a screw-retained fixed prosthesis. Further, if the prosthesis needs to be routinely removed (e.g. in a research protocol) for accurate measurement of pocket probing depths (PPDs) and bleeding on probing (BoP), the clinician may want to choose a screw-retained prosthesis.

There are also indications for fabricating a fixed prosthesis that replaces both hard and soft tissues (Garcia & Verrett 2004). In sites where there has been considerable loss of supporting structures, as is common following trauma or long-term chronic bone loss such as with periodontal disease, it may be necessary to replace both dental and osseous supporting structures (see Fig. 56-3). If this cannot be accomplished with biologic site development, the clinician may need to reconstruct this area with a combination of porcelain teeth developed with the appropriate mesiodistal and incisogingival dimensions to match the adjacent teeth and blend into the esthetic contours of the dentition and face. In doing so, it may become obvious that the gingival tissues need to be replicated in "mucosa"-colored porcelain or acrylic (Fig. 56-6). The development of tissue-matched mucosal shades takes significant laboratory skill and dexterity, and often means the patient needs to be seen directly by both the technician and the restorative dentist (Malament 2000; Malament & Neeser 2004) Customized mucosal shades often need to be developed and matched chair side. While these approaches can be quite time consuming, the end results can be quite satisfactory and surpass what can be accomplished with repeated soft tissue procedures (Fig. 56-6). The restorative dentist needs to carefully assess the patient early in the diagnostic process for implant therapy and determine if he/she is at elevated risk for unpredictable loss of soft tissue. Key factors to assess are thin tissue biotype, previous history of recession, mucosal inflammation, and tooth loss due to trauma or chronic progressive osseous disease (e.g. periodontitis). All of these conditions influence the stability and position of the mucosal tissues following implant tooth replacement therapy.

Fig. 56-6 Soft and hard tissue prosthetic replacement. (a) Patient presented with soft tissue loss in the area of 21 and 22. (b) Missing mucosal and hard tissue contours were replaced with a combination of gingival and tooth-colored ceramic materials, achieving a prosthetic solution to a difficult esthetic situation (c).

Immediate provisionalization

The application of implant FPDs has a unique role, especially in early and immediate loading procedures. While the splinting of implants for long-term osseointegration is not considered routinely necessary, the early splinting of multiple implants during the osseous healing process is considered important (Cooper *et al*. 2002, 2005; Slaets *et al*. 2005; Cooper *et al*. 2006; De Kok *et al*. 2006; Duyck Vandamme *et al*. 2006). Immediate provisionalization procedures have the potential to provide rapid function, esthetics, and patient satisfaction, and the use of implant-supported FPD prosthetic designs plays an intimate role in controlling micromotion and allowing successful outcomes similar to those with conventional loading procedures (De Kok *et al*. 2006; Duyck *et al*. 2006; Hall *et al*. 2006; Peleg *et al*. 2006) .

The immediate provisionalization of implant-supported FPDs has a unique role in the retreatment of failing fixed prostheses. When large fixed prostheses are present with only one or two failing abutments, further tooth-supported restoration often requires extensive restoration. This is particularly true if strategic abutments, such as a canine or terminal abutment tooth, are not salvageable due to caries, fracture or localized periodontitis. In such cases, segmental resection of the failed tooth and supported pontic teeth can be replaced by dental implants. The advantages are obvious in terms of preventing retreatment with a much larger FPD and providing an esthetic and functional treatment option for an anterior restoration.

Disadvantages of implant–implant fixed partial dentures

The disadvantages of FPDs on implants are associated with increased difficulty with cleaning and maintaining the prosthesis, along with the prosthesis complications associated with a conventional tooth-supported FPD. There is the potential that the patient will not be satisfied with the inability to clean between the retainers and pontic contours. FPDs on implants can also be more difficult to fabricate in the laboratory: there may be issues with the path of insertion on the abutments (necessitating customized abutment) or difficulties in obtaining draw and passive fit between multiple abutments. There is also the danger of mechanical wear and material failure with the completed prosthesis, such as abutment loosening, prosthesis fracture or veneer material failure. The use of screw-retained prostheses may be helpful if retrievability is critical, but the screw access hole appears to weaken the strength of the veneering material. Lastly, there is also the danger that if one of the supporting implants is lost or the abutment demonstrates recession, exposing the transmucosal titanium surface, the entire prosthesis may have to be replaced, which increases both the treatment time and expense to the patient.

In assessing the clinical success of implant-supported FPDs, it is often difficult to determine outcomes due to incomplete reporting, yet the primary measure of evidence-based care is the systematic assessment of the clinical question of interest. The literature supporting the use of this type of prosthesis is often retrospective in nature, with different outcome measures, end points, duration of recall, etc. This makes comparisons between studies difficult and limited. In the assessment of prosthodontic mechanical complications, the pattern of defects often will vary in a time-dependent pattern. In implant-supported FPDs, early failures (before loading) are often associated with implant loss (Goodacre *et al.* 2003b). As discussed by Pjetursson *et al.* (2004), implant loss prior to restoration can be expected on average to occur in 2.5% of all placed implants, with an additional 2–3% lost over the first 5 years of function. In this systematic assessment, 21 of the 176 reviewed studies were considered reliable based on inclusion and exclusion criteria. The authors summarized the current literature for five implant systems in 1123 patients (total of 1336 FPDs on 3578 implants) followed for at least 5 years. Implant survival, FPD survival, success, and complications were reported (Table 56-1). While the authors outlined that this type of assessment is limited by the quality of the studies, their duration, number of drop-outs, and reliability, but in this instance, with the limited dataset, they

reported the most common complication to be loss of veneering material (often acrylic facings), followed by other mechanical complications inherent in screw-retained style prosthesis. Biologic complications, such as peri-implantitis (PPD >5 mm) with BoP, were reported in one study to occur in an average 10% of patients (Pjetursson *et al.* 2004). Pjetursson *et al.* (2004) used a random-effects Poisson modeling approach to determine a pooled cumulative rate of 8.6% for biologic complications (95% CI 5.1–14.1%) based on an assessment of nine studies providing sufficient information for analysis.

FPDs supported by two or more implants provide a valuable treatment option. It has a role in providing rehabilitation for patients with challenging implant positions and angulation, lost hard and soft tissues, at reduced cost and may allow avoidance of some grafting procedures (e.g. sinus grafting). The selection of an FPD supported by implants often represents the alternative to selecting a much larger FPD supported by many teeth (Table 56-2). While reviews suggest that there may be little difference in the long-term complication rates for FPDs supported by teeth and implants, it is of practical importance that implant-supported FPDs often are smaller prostheses that are economically efficient over the long term. FPDs also serve a vital role in immediate loading procedures by controlling loading during the healing phase. FPDs do present prosthetic challenges and the final result may not be acceptable to all patients. On balance, however, the use of FPDs plays a valuable role in providing multiple tooth replacement therapy.

Table 56-1 Implant-supported fixed partial dentures (FPDs) after an average of 5 years of follow-up.[a]

	Average	95% Confidence interval
Implant survival (%)	95.6	93.3–97.2
FPD prosthesis survival (%)[b]	95	92.2–96.8
FPD success (%)[c]	61.3	55.3–66.8
Complications (%)	38.7	
Veneer fracture	13.2	8.3–20.6
Lost occlusal restorations	8.2	
Loose screws	5.8	3.8–8.7
Fractured abutments/ occlusal screws	1.5	0.8–2.8
Fractured implants	0.4	0.1–1.2

[a] 90% of the FPDs were screw-retained.
[b] Survival defined as retained in function within the mouth. Prostheses may have had multiple repairs.
[c] Success defined as in function with no clinical complications.
Data from Pjetursson *et al.* (2004).

Tooth–implant fixed partial dentures

The use of dental implants combined with teeth as retainers for FPDs has been advocated by a number of clinicians to restore multiple missing teeth. There are multiple case reports in the literature of prosthesis designs that have either a rigid connection between the natural tooth and implant retainers or a non-rigid connection to ostensibly allow individual movement of the implant(s) relative to the greater mobility of the natural teeth (Stanford & Brand 1999). The difference in mobility can be greater than an order magnitude, with mobility of 50–200 μm for teeth with a healthy periodontal ligament, while an integrated implant will have a mobility of <10 μm (Brunski & Hipp 1984; Brunski 1988a, b; Rangert *et al.* 1997; Brunski 1999, 2003). The use of implant–tooth FPDs has the potential to reduce cost, time, and morbidity, especially if the outcomes provide a service to the patient that is equivalent to those for

Table 56-2 Local features to be considered in risk assessment for implant-supported fixed partial dentures (FPDs).

FPD location	Anterior location has higher esthetic risk Posterior location may have higher functional risk
Length of span	Long span increases complexity of prosthesis Short span may result in abutment crowding and restricts hygiene
Occlusogingival dimension	Increased occlusogingival dimension results in longer bending moments at abutment and bridge screws Reduced occlusogingival dimension (<6 mm) may limit prosthesis construction and integrity
Excessive vertical residual ridge resorption	Excessive vertical residual ridge resorption results in excessive occlusogingival dimension of the restoration
Implant malpositioning	Buccal or lingual malpositioning creates unintended buccal or lingual cantilever of prosthesis Mesial or distal malpositioning encroaches on embrasure and hygiene access; both reduce esthetic potential Excessive deep placement increases bending moment at abutment screws, may create an anaerobic environment, can lead to bone resorption and esthetic complications
Thin mucosal biotype	Risk of mucosal resorption and unesthetic display of abutment material
History of periodontitis	Risk of peri-implantitis if control is absent May need multiple staged procedures for hard and soft tissue augmentation

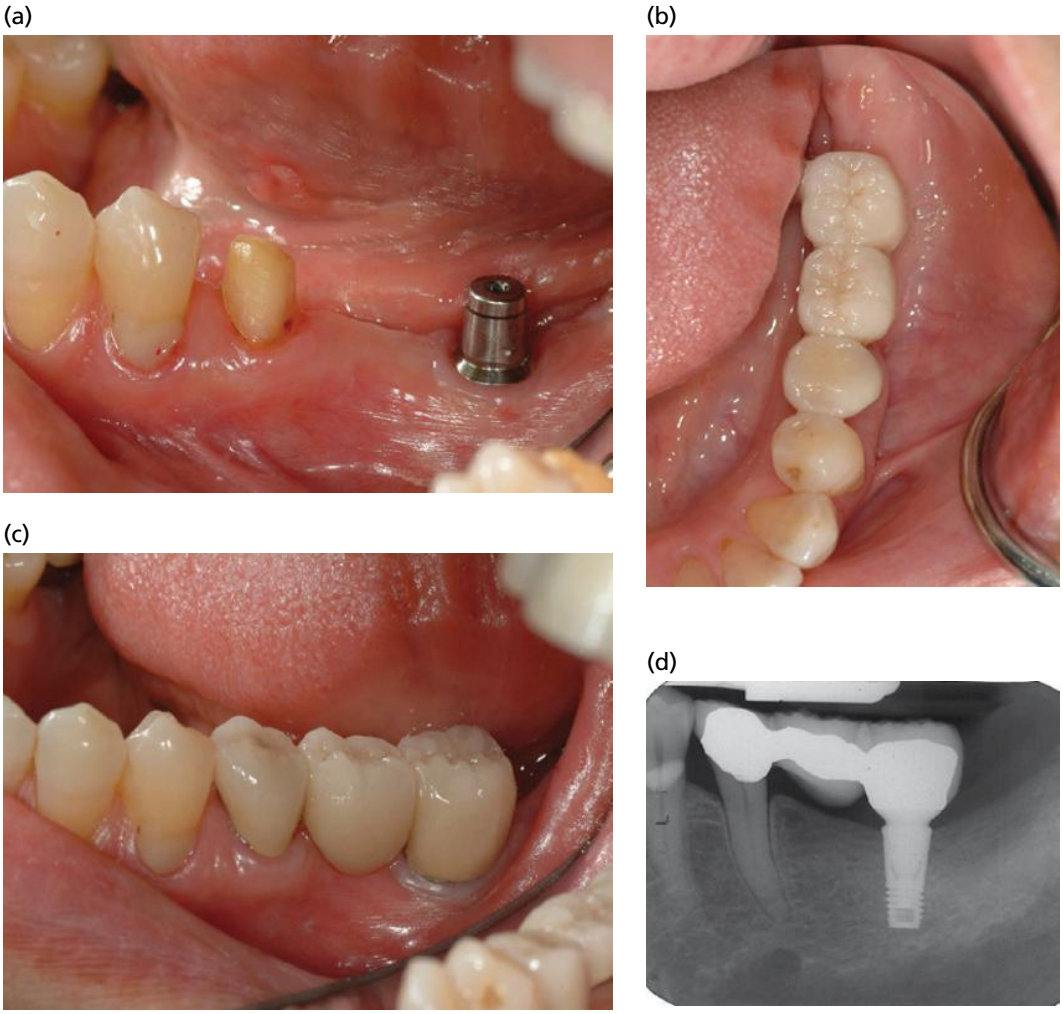

Fig. 56-7 Implant–tooth fixed partial denture (FPD). (a) Use of a rigid FPD framework on a three-unit FPD (35–37). (b) Metal–ceramic prosthesis was cemented and monitored with frequent recall over 5 years (c). (d) Five-year recall radiograph indicates healthy periapical and peri-implant osseous tissues.

implant–implant FPDs or single-tooth implant restorations (Fig. 56-7). The advantages though must be balanced against the potential complication of pathology associated with the dental retainers or the implant(s). The fate of both is tied together. Lang *et al.* (2004b) performed a systematic review of clinical studies evaluating tooth–implant FPDs over at least 5 years and identified 13 studies using the inclusion/exclusion criteria. Of these, nine were prospective and four retrospective, addressing outcomes with five different implant systems in 555 patients (538 FPDs on 1002 implants), the majority (91%) of which were reported to be screw-retained. Of those studies with follow-up of 5–6.5 years, 25 of the 932 implants installed were lost prior to restoration and 65 during the recall period, giving a 5-year implant survival rate of 90.1% (CI 82.4–94.5%) (Lang *et al*. 2004b). In a second group of studies where patients were followed for10 years post implant, implant survival was estimated at 82.1% (CI 55.8–93.6%). Following the same theme, a systematic review of biologic and technical complications (Berglundh *et al*. 2002) indicated that tooth–implant-borne FPDs were at greater risk for implant loss (irrespective of complications leading to abutment tooth loss) than implant–implant FPDs. Prosthesis survival at 5 years was estimated to be 94.1% (CI 90.2–96.5%), and 77.8% (CI 66.4–85.7%) at 10 years. By 5 years, 3.2% of dental abutments had been lost due to fracture, caries, endodontic or periodontal complications (Lang *et al*. 2004b). If the patient has the option to restore the missing teeth with conventional removable partial denture therapy combined with implant-fixed prosthodontics, it is interesting to assess the long-term outcomes. Aquilino *et al*. (2001) evaluated a large insurance dataset to assess outcomes of dental abutments in bounded edentulous spaces. In this study, 10-year Kaplan–Meier estimates indicated dental abutments restored with FPDs had a 97% 5-year and a 92% 10-year survival rate, compared to only 77% at 5 years and 56% at 10 years for removable partial denture abutments.

A number of concerns have been raised concerning connecting teeth to implants with FPDs. Some of these complications are associated with technical complications of the prosthesis. For instance, the prognosis of the FPD can be shortened by veneer fractures and other esthetic issues (Kindberg *et al*.

2001). Loss of retention through fracture of the abutment/prosthetic screws or loss of cement retention is possible. In a systematic review of two studies that assessed lost retention (Hosny *et al*. 2000; Naert *et al*. 2001), Lang *et al.* (2004b) reported an average loss of 6.2% (CI 3.7–10.4%) at 5 years. Endodontic complications on the abutment teeth can also be a significant concern, with 3–28% of teeth needing post-insertion root canal therapy (average of 11%) (Goodacre *et al*. 2003b). Naert *et al*. (2001) reported on complications after a mean period of 6.5 (1.5–15) years in a retrospective comparison study of implant–implant FPDs to tooth–implant FPDs with 123 patients in each group. Complications included a history of chronic apical periodontitis (3.5%), tooth fracture (0.6%) along with a tooth intrusion (3.4%), and cement failure (8%) (Naert *et al*. 2001). An interesting and unusual observation was natural tooth intrusion (Pesun 1997). Earlier use of implants combined with teeth advocated the use of non-rigid attachments within the prosthetic design to allow differential movement between the implant and tooth. In some cases, the natural tooth appears to retract away from the prosthesis. This phenomenon has been suggested to be due to the interplay of disuse atrophy, food impaction, rebound memory of the periodontal ligament, and/or mechanical binding (Rieder & Parel 1993; Schlumberger *et al*. 1998; Cordaro *et al*. 2005; Palmer *et al*. 2005). In a multicenter study, Block *et al*. (2002) assessed posterior FPDs either rigidly connected or non-rigidly connected with one type of attachment. Of the 30 subjects followed over 5 years, there was no difference in bone loss between the two types of connections, but there was a 66% incidence of measurable intrusion in the non-rigid group versus 44% in the rigid group. The authors concluded that tooth–implant FPDs had a higher level of maintenance and postoperative complications. Fugazzotto *et al*. (1999) retrospectively assessed a multigroup practice outcome for 843 patients (1206 implants, 3096 attachments) over a period of 3–14 years, and observed nine instances of intrusion (0.3%) associated with fractured or lost lateral set screws (rigid retention). In a prospective 3-year study, Palmer *et al*. (2005) evaluated 19 subjects with rigid cemented prosthesis between natural teeth and implants. The short-term outcomes at 3 years showed implant bone loss no greater than expected (0.78 ± 0.64 mm), with no signs of intrusion with the rigid tooth–implant FPD designs. These results have led to the clinical recommendation that if the clinician needs to join natural teeth with implants, a rigid connection is used with close monitoring for clinical signs of complications (Naert *et al*. 2001; Palmer *et al*. 2005; Stanford 2005a).

FPDs used to join teeth to implants is a controversial issue. There are times when an assessment of clinical needs, patient desires, costs, time, and risk support the consideration of this treatment option. It is critical that the patient is informed of the relative risks associated with this type of prosthesis, implant, and abutment tooth in the process of informed consent.

Conclusion

FPD therapy for the restoration of multiple missing teeth has a long track record in dental implant care. Connecting two or more implants, or in selective cases teeth with implants, can provide a stable, esthetic, and predictable outcome. All treatment options need to start with a careful assessment of anatomy, clinical parameters, and patient needs and desires. The patient needs to be informed of the assumptions made in treatment planning and the relative costs and benefits that this treatment approach can provide.

Introduction

The quality of dental implants has significantly improved since their introduction and this has been coupled with a steady increase in clinical success and/or survival rate (Cochran 1996; Esposito *et al.* 1998; Lindh *et al.* 1998; Jokstad *et al.* 2003). The biologic aspect particularly, namely osseointegration, has been the target of intensive investigation and there have been conspicuous advances. As a part of these developments, there have been continuous efforts to improve the characteristics, micro/nano topographies, and chemistries of the implant surface. A major change in surface topography can be summarized by the evolution from a machined surface to a production-based moderately roughened surface. Superior biologic response, or osseointegration, to roughened implant surfaces has been widely documented in the literature (Astrand *et al*. 1999; Rocci *et al*. 2003; Schneider *et al*. 2003). The cumulative effect of all this effort is reflected in the extremely high biologic success rate of dental implants. However, complications do occur and can be related to both biologic and prosthetic issues. This chapter discusses potential complications of dental implant-supported restorations, focusing particularly on complications related to the prosthetic aspects of therapy.

Clinical complications in conventional fixed restorations

Implant dentistry shares many of the long-term mechanical complications of conventional dental restorative therapy. Goodacre *et al.* (2003a, b) presented data regarding the incidence of clinical complications associated with conventional fixed dental restorations/prostheses, including single crowns (all-metal, metal–ceramic, resin-veneered metal) and fixed partial dentures (FPDs) (all-metal, metal–ceramic, resin-veneered metal); all-ceramic crowns; resin-bonded prostheses; and posts and cores. This study still holds significant relevance. Regarding single crowns, the most common complication was post-cementation endodontic therapy (3%), followed by porcelain fracture (3%), loss of retention (2%), periodontal disease (0.6%), and caries (0.4%). Regarding FPDs though, the most common complications were caries (18% abutments; 8% prostheses), need for endodontic treatment (11% abutments; 7% prostheses), loss of retention (7%),

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

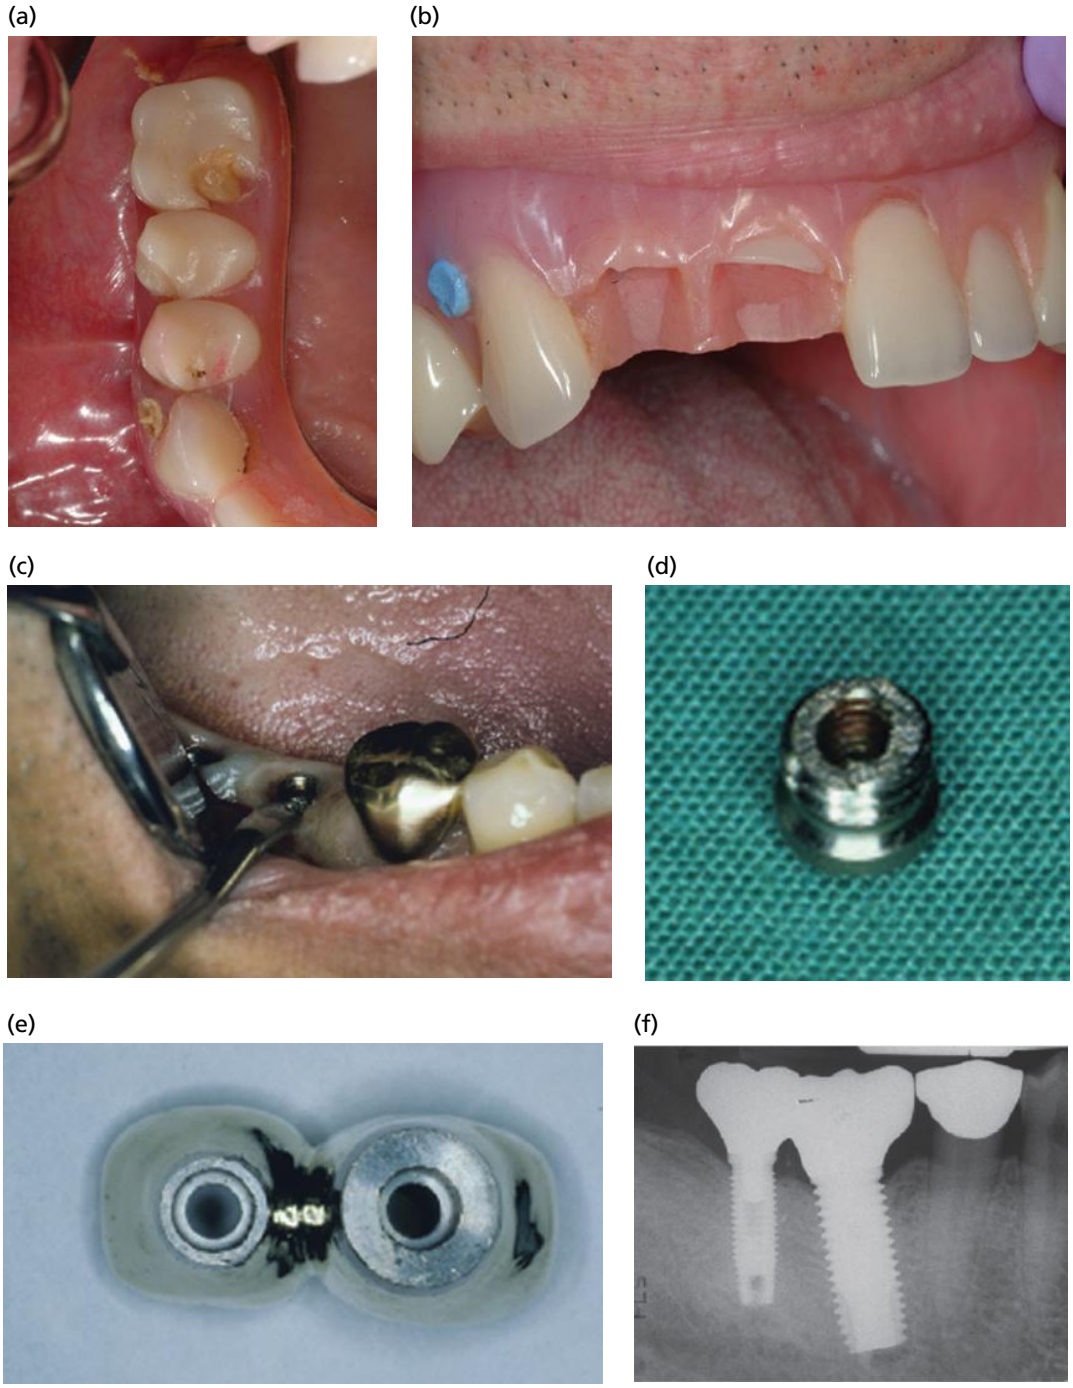

Fig. 57-1 Prosthetic challenges related to wear and component fracture. Wear, fracture, and change in esthetics are common with acrylic resin teeth (a), as are fractures of acrylic resin prosthetic teeth on fixed complete dentures (b). While implant fractures are rare, the consequences are challenging. (c) Case example of implant that was mobile 2 years after delivery; the prosthesis was removed and the head of the implant was found to be fractured (d). (e) Implant was replaced with a wide diameter implant in order to increase the wall thickness and provide a greater abutment–implant interface. (f) Recall at 10 years.

esthetics (6%), periodontal disease (4%), tooth fracture (3%), prosthesis fracture (2%), and porcelain veneer fracture (2%). In this narrative review, the authors concluded that complication incidence with conventional FPDs was significantly higher than that for single crowns. In addressing issues related to implant restorations, material failure and wear is a common occurrence with both dental and implant-supported restorations (Fig. 57-1). It is likely that the higher biomechanical complexity of the design of the prosthesis contributes to higher complication incidence. Among the complications, pulpal complications, periodontal disease, and caries will apply to only tooth-supported restorations (Goodacre *et al.* 2003a, b).

Tan *et al.* (2004) assessed the long-term success/survival rate of conventional FPDs in a systematic review and evaluated the failure rates of FPDs due to specific biologic and technical complications. The meta-analysis indicated a 10-year survival rate (retention with or without intervention during the recall period) for FPDs of 89.1%, but a 10-year success rate

(no intervention needed over the recall period) of 71.1%. In general, the mean 10-year survival rate of conventional FPDs was 90% and mean success rate was 80% in the literature. In this study, the most common reasons for dental FPD failure included periodontal disease and secondary caries. Regarding the complications related to caries, the 10-year risk for decay on abutments was 9.5%, but only 2.6% of FPDs were lost as a result of this disease process. In this study, it was clear that loss of vitality of abutment teeth occurred at a date that was later than could be attributed to the trauma from the preparation of the teeth. This may either indicate a slow progressive tissue degeneration induced by the procedure or reflect the increased susceptibility of pulpal infection by dentinal tubules in advanced periodontitis (Bergenholtz & Nyman 1984). The presence of cast post and dowels and non-vital abutments, especially distal abutments, has been shown to be associated with increased loss of retention and fracture of teeth and cores. This cautions against over dependence on non-vital teeth as strategic abutments. The 10-year risk of loss of FPDs due to recurrent periodontitis was only 0.5%. Overall, there seemed to be no adverse changes in FPDs incorporated into periodontally well-maintained teeth/patients, even in those patients who presented with a history of advanced periodontal disease. Where the recall or maintenance is less stringent, periodontal breakdown may occur, and may be more pronounced when margins are subgingivally located (Valderhaug & Karlsen 1976). Secondary use of the bridge for removable prosthesis has a detrimental effect on the gingival tissue (Libby *et al.* 1997). The 10-year risk for technical complications such as loss of retention, loss due to abutment fracture, and material complications were also calculated in this study. An issue in any of these studies is the multifactorial nature of the causes of failure. The highest 10-year risk was for loss of retention (6.4%). Far lower was the 10-year risk for the loss of FPDs due to abutment tooth fracture (3.2% for fractures of the framework, veneers, and/or cores) and relatively low 10-year risks were obtained for material complications. A comparison of the difference in survival between FPDs with acrylic facings and metal–ceramic FPDs showed that over an 18-year period, 38% of FPDs with acrylic facings and 4% of metal–ceramic FPDs were replaced (Sundh & Odman 1997). Reasons cited for the higher failures in the former were the greater incidence of discoloration and fracture after extensive wear of the older acrylic resin material.

Clinical complications in implant-supported restorations

Biologic complications

Surgical complications

Surgical complications directly related to implant placement are generally rare. However, due to the surgical nature of implant therapy, it is impossible to avoid surgical sequelae. Surgical methods excluding tissue flap openings (so-called "flapless approaches") seek to minimize surgical trauma but carry their own risks. Goodacre *et al.* (2003b) provided data regarding the types of complications that have been reported in conjunction with endosseous root-form implants. The most common surgical complications associated with implant surgery were hemorrhage-related complications (24%), neurosensory disturbance (7%), and mandibular fracture (0.3%).

Implant loss

There is no known single factor that can cause implant loss. Some of the factors generally accepted to be involved in the etiology include infection and/or contamination, patients' physical status, trauma from surgical procedures, excessive and/or premature occlusal loading, cement retention, etc. Most surgery-related implant losses can be managed by maintaining a strict infection control protocol, meticulous patient screening prior to the surgery, and reducing the surgical time/trauma. Occlusal loading is a more challenging factor since the operator has more limited control over it. Premature occlusal loading can be detrimental to osseointegration when it is combined with excessive load and/or off-axis force. This can happen during the stage of early or immediate provisionalization and indicates that the patient should be closely monitored during this initial healing period. In the literature, it has been stated that overloading at any stage of osseointegration can lead to bone loss or even complete disintegration of the implant (Isidor 1996, 1997; Brunski *et al*. 2000; Steigenga *et al*. 2003). However, the concept of implant "overload" has been questioned as a series of studies indicated bone is highly responsive to dynamic loads and is resistant to bone loss even at high levels of occlusal function (Stanford & Brand 1999; Duyck *et al.* 2000, 2001; Stanford 2005b). The primary concern regarding mechanical forces (occlusion) and implant outcomes should focus more on mechanical breakdown of materials rather than a loss of the biologic interface.

According to the literature, implant loss ranges from a high of 19% with maxillary overdentures to a low of 3% with both mandibular fixed complete dentures (FCDs) and single crowns (Goodacre *et al*. 2003a). Implant loss has conventionally been greater with implants of 10 mm or less in length compared with implants of >10 mm long (ten Bruggenkate *et al*. 1998; Lekholm *et al*. 1999; Friberg *et al*. 2000; Palmer *et al*. 2000), but with the improved implant systems now available, this may longer be true (Atieh *et al*. 2012). Implant loss is more likely to occur in the presence of type IV bone compared with more favorably typed bones (Stanford 1999; Stanford & Brand 1999; Stanford 2005b). Other risk factors that have been suggested include smoking, and prior history of

periodontal disease or radiation therapy (Moy *et al.* 2005; Ahmed *et al*. 2012; Cochran & Nevins 2012; Esposito *et al*. 2012; Pjetursson *et al*. 2012; Wadsworth 2013). If loss of implant occurred, approximately half or more of the lost implants were lost prior to functional loading. This result is in agreement with the result from an earlier systematic review (Berglundh *et al*. 2002).

Peri-implant complications

Possible peri-implant complications include marginal bone loss, peri-implant mucosal inflammation/proliferation, soft/hard tissue fenestration/dehiscence, fistula, etc. It is widely accepted that continuous marginal bone loss around established implants over time jeopardizes the potential success and/or survival of the implant therapy. Factors that potentially induce marginal bone loss include surgical trauma during implant placement, trauma during repeated abutment insertions and removal, functional load transfer and concentration, micro-motion at the implant–abutment junction, and peri-implant gingival inflammation, potentially induced by a range of prosthodontic factors. According to the literature, the mean bone loss over the first year post implant is 0.9–1.5 mm, and the subsequent loss per year is around 0.1 mm (Albrektsson *et al*. 1986). More recently, bone loss of <0.5 mm has been proposed as a common standard (Albrektsson *et al*. 2013).

Peri-implant inflammation and its role in bone loss have recently gained significant attention. In part, this inflammation can be represented by conventional measures such as bleeding on probing (BoP), purulence, and local hyperemia (Fig. 57-2). The presence of such a mucositis in the absence of bone loss is referred to as "peri-mucositis", in contrast to the same set of presenting signs and symptoms but with the addition of progressive mesial and distal bone loss, referred to as "peri-implantitis" (Mombelli & Decaillet 2011). Peri-implantitis is defined as an inflammatory reaction associated with the vertical loss of supporting bone in the tissues around a functioning implant (Albrektsson *et al*. 1994) (Fig. 57-3). Note that this diagnosis does not denote any causative reason for the inflammatory etiology and in fact, a combination of host factors (genetic and epigenetic, such as the risk factors associated with aggressive periodontitis), environmental factors (e.g. smoking), microbial biofilm (flora, virulence, microbial genetic/epigenetic, and environmental responses), in addition to prosthodontic etiologic factors (e.g. crown/FPD contours, loose retainers, retained cement, etc.) are probably involved (Stanford 2010). Clinically, peri-implantitis can be detected with the formation of vertical bony defects and increasing probing depth. Radiographically, a saucer-shaped vertical radiolucent lesion may be observed to form around the implant over a period of time (typically years in service) (Fig. 57-3). This should be differentiated from short-term formation of the same radiographic appearance, which often represents fracture of an oral implant.

From a prosthetic perspective, the onset of peri-mucositis or peri-implantitis (associated with bone loss) can lead to soft tissue recession and unesthetic show of abutment or prosthetic components. Recent epidemiologic cross-sectional data suggest this occurs in 10% of implants or 20% of patients after about 10 years of service (Mombelli & Decaillet 2011). There has been considerable discussion about the significant number of cases of peri-implantitis that are related to retained dental cement (especially resin-based cement) on the transmucosal portion of the implant abutment. The retained cement allows elevated retention of a biofilm and this acts as an idiopathic cause for early implant loss (Wadhwani *et al.* 2012).

Marginal defects on the facial aspect of the implant complex are not only esthetically compromising, but can jeopardize the stability and long-term success of the implant. These defects, dehiscence or fenestration, are typically caused by the resorption of the buccal/labial plate of the alveolar bone. This is especially a concern when immediately placing implants upon

Fig. 57-2 Peri-implant disease can be assessed by presence of bleeding on probing, purulence, and increasing probing depths over time.

Fig. 57-3 Peri-implantitis is observed radiographically as vertical crater-like defects around the implants.

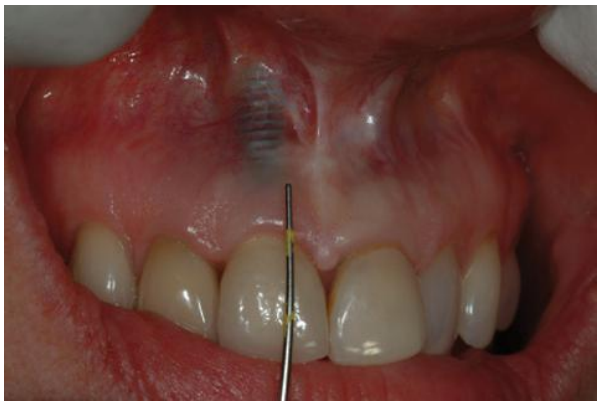

Fig. 57-4 Immediate implant placement into extraction sockets can lead to facial wall dehiscence and bone loss since the implant body will not prevent loss of the bundle bone on the socket wall.

extraction of a tooth (Fig. 57-4) (Araújo & Lindhe 2011; Januario *et al.* 2011; Sanz *et al*. 2014). In order to prevent this type of defect, it is important to maintain a minimum of 1-mm thickness of buccal/labial plate (Stanford 2005a). However, in certain areas, this may be difficult to achieve. To reduce the risks of facial marginal defects, one can utilize bone augmentation procedures, mainly autogenous, around the marginal alveolar bone in order to maintain the thickness around the implants. Autogenous bone particles derived from the drilling of the osteotomy may be enough for the purpose. In terms of the timing of implant placement after tooth extraction, it is generally accepted that immediate placement has a greater risk of facial marginal defects compared to delayed placement (Nemcovsky *et al*. 2002).

Malpositioned implants

A "malpositioned implant" is defined as an implant placed in a position that creates restorative and biomechanical challenges. A malpositioned implant can be caused by numerous factors. The most common is the deficiency of the osseous housing around the proposed implant site. Bone resorption is observed in osseous remodeling following tooth loss, osteoporosis, orthopedic revisions, craniofacial defects, or post oral cancer ablation associated with surgery/radiation. For the best biologic, biomechanical, and esthetic result of implant rehabilitations, proper implant placement is essential. The placement of an implant into a defective osseous site not only prevents adequate positioning of the final prosthetic restoration, but also results in compromised integration and subsequently a poor prognosis for the therapeutic outcome. In order to place an implant in the optimal prosthetic position for a restoration, augmentation procedures are often necessary. Current approaches in bone reconstruction use biomaterials, autografts or allografts, although restrictions on all these techniques exist. Restrictions include donor site morbidity and donor shortage for autografts (Damien & Parson 1991), as well as immunologic barriers for allografts and the risk, albeit low, of transmitting infectious diseases (Meyer *et al.* 2004). Numerous artificial bone substitutes containing metals, ceramics, and polymers have been introduced to maintain bone function.

If the status of the existing, deficient bone is addressed prior to the surgery and the restorative dentist/prosthodontist confirms it will be possible to fabricate the final prosthesis with the implant(s) in the proposed location, generally implant placement can be a straight forward procedure. The implant team and the patient are faced with a significant complication when the implants are placed only in the available bone, ignoring the optimal desired prosthetic position (Fig. 57-5). Communication between the surgical and restorative teams is vital. The best way of communicating between the two parties is through the use of comprehensive treatment planning, diagnostic wax-up on mounted casts, and fabrication of a surgical guide. The standard protocol for placing implants will start with a treatment plan developed by the restorative dentist. The surgical guide represents the ideal position and angle of the implant determined by a series of diagnostic procedures. It should ideally indicate the three dimensions of the proposed implant position – horizontal position, vertical position, and angle (Fig. 57-6). Horizontally, the surgical guide should clearly indicate the buccolingual and mesiodistal location of the proposed site. In most cases, this is determined from the morphology and location of the diagnostic wax-up of the missing tooth. Vertically, the surgical guide should indicate how deep the surgeon should place the implant relative to the planned cementoenamel junction (CEJ). This is particularly important for implants placed in the esthetic zone. As a general rule, the restorative margin for an implant-supported restoration should be located at the vertical height, slightly deeper than that of the CEJ of the adjacent teeth. Thus, with an implant system in which the head of the implant represents the restorative margin, the implant should be placed 3 mm below the planned CEJ or occasionally on a line connecting the CEJ of adjacent teeth and the facial aspect of the implant body placed 2 mm to the palatal aspect of the same CEJ reference point (the "3 × 2 rule") (Cooper & Pin-Harry 2013) When an implant system is capable of adjusting the height of the restorative margin through a separate abutment(s), the placement depth of the implant may be more flexible (Fig. 57-7). Whichever system is used, the surgical guide should include a component that notifies the surgeon of the proposed depth of the implant. The angle of the implant should also be correct to prevent facial or lingual fenestration of the implant, as well as implant penetration into the radicular portions of adjacent teeth or other structures. The angle should be correct for the prosthesis as well. Should the angle of the implant be too facial, the restorative dentist could face significant esthetic challenges, for example screw

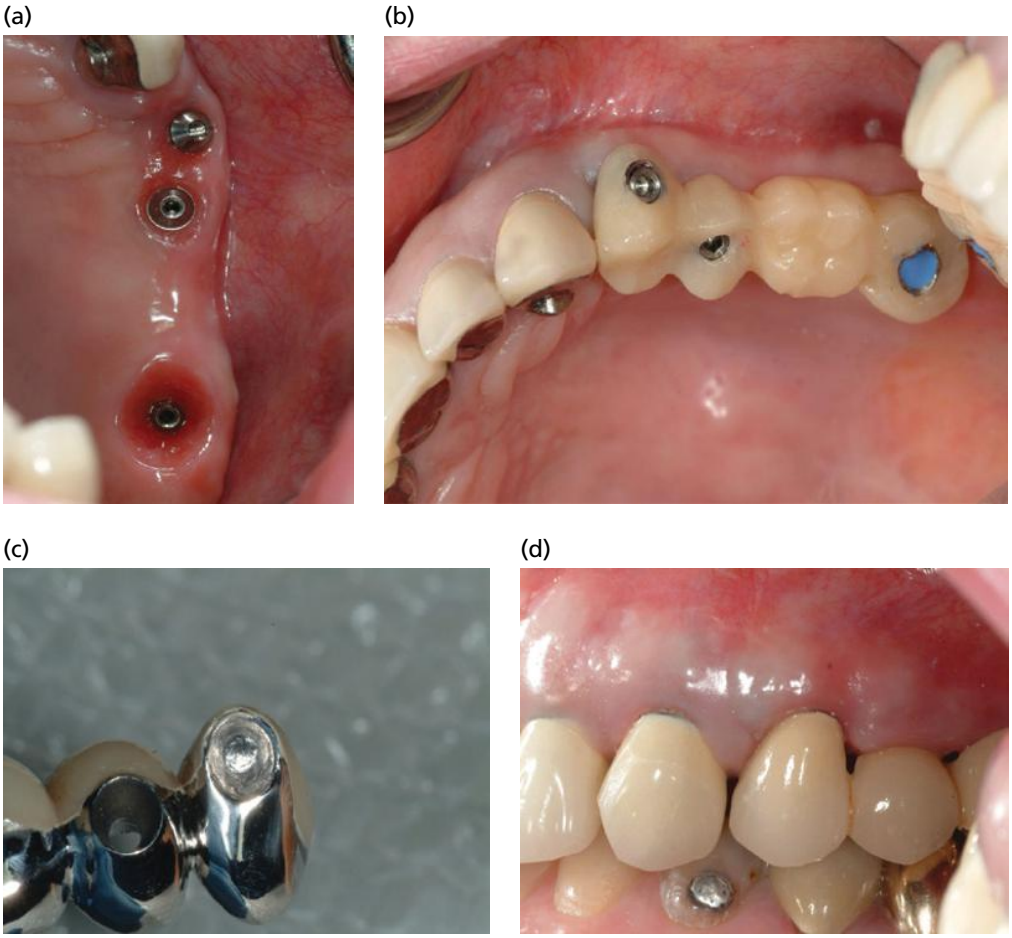

Fig. 57-5 Prosthetic complications with malpositioned implants. (a) Patient had an implant placed in the area of 24 with facial angulation. (b) Provisional fixed bridge demonstrated the facial position. Due to the depth and position of the implant, a fixed prosthesis was made that rested on the implant abutment (c), allowing a satisfactory esthetic and functional restoration (d).

Fig. 57-6 Surgical guides for implant placement. Using a guide with a restrictive channel allows for evaluation in diagnostic imaging studies and during the surgical placement phase.

Fig. 57-7 Restorative margin may be the head of the implant with certain implant designs, necessitating the surgeon having a clear idea of where the final margin will be when placing the implant. Other systems use an abutment for cemented restorations that allows variation in the vertical position of the restorative margin.

access hole position, necessity of using angled abutments, CAD/CAM customized abutments, etc. (Fig. 57-8).

Mechanical complications

Overdenture complications

Numerous studies indicate that the use of an acrylic-based implant overdenture has the highest number of postoperative complications, where complication is defined as a need for some form of intervention, the degree of which is not necessarily defined. Complications include loss of overdenture attachment retention or fracture of the attachment system, fracture of components of the denture, prosthesis-related adjustments, etc.

Goodacre *et al.* (2003a) suggested the most common complication in this category was the need for adjustments due to loss of retention and/or attachment system fracture. O-ring systems, Hader-bar and clip-, IMZ-, Ceka-, ERA-, ZAAG, and, more recently, Locator-attachments, all use various forms of plastic components within the anchorage system. Over time, the plastic component tends to wear and distort, which is actually a good thing, since this motivates

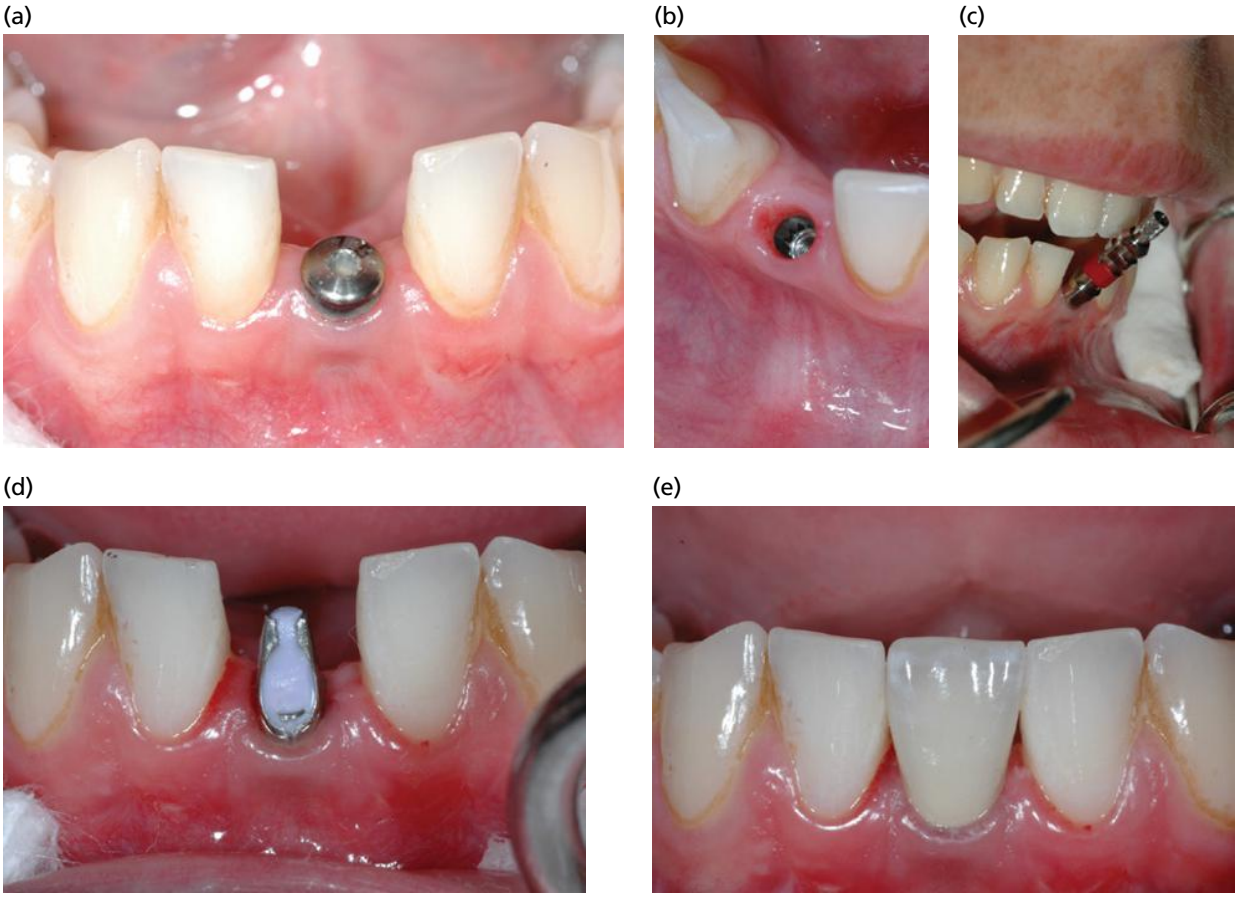

Fig. 57-8 Innovative use of abutments. (a) Patient presented with a healing abutment indicating placement within the residual ridge. Soft tissue health (b) was adequate, though the final impression coping (c) indicates an angled position relative to the remaining teeth. (d, e) Patient was restored with a cement-retained restoration, but using a low profile abutment.

patients to return for recall appointments. Traditional ball attachment systems utilize metal spring matrices and these tend to deform and lose retention with time. Studies that have assessed the difference in frequency of maintenance requirement between bar/clip systems and individual attachment systems indicate that individual attachment systems require more frequent adjustments due to loss of retention of the matrix or patrix (van Kampen *et al*. 2003; Walton 2003; MacEntee *et al*. 2005). However, the simplicity and ease of the repair procedure in some individual attachment systems may reduce frequent complications and have led to the increasing popularity of these abutment designs (e.g. the Locator System in North America). Systems with exchangeable plastic components especially have become popular due to easy maintenance procedures. Further, the conversion of a complete denture patient who rarely returns for maintenance therapy into a routine recall patient (valuable for early caries detection, oral cancer exams, etc.) who is motivated to have his/her attachment system serviced provides a valuable ethical service for the patient.

Because of the housing and attachment components, overdentures typically have a reduced thickness of acrylic resin base in certain areas compared to conventional dentures. It is these thin areas that have a higher risk of fracture. In addition, patients with implant-supported overdentures have a tendency to generate higher masticatory force compared to patients with conventional dentures. The incidence of acrylic base fracture may increase depending on the opposing occlusion. For example, an overdenture opposing an implant-supported FCD will be at a greater risk of fracture, accelerated wear or prosthetic tooth fracture than one opposing a conventional denture. Overdenture fracture is a relatively common problem according to some studies, and could be as high as 7% of all the mechanical complications related to implant-supported restorations (Carlson & Carlsson 1994; Goodacre *et al*. 2003a).

Prosthesis-related adjustments include reline/rebase of the overdenture, occlusal adjustments, and with denture adjustment due to soft tissue complications. Normally, the hard and soft tissue under the overdenture will remodel with time. Additionally, overdentures, based on their design, allow limited rotational movements between the abutment and the anchorage system. This means there will be positive vertical and horizontal load on the edentulous ridge, in the area away from the anchorage system. Changes in mucosal adaptation of the prostheses will induce subsequent problems like occlusion changes and soft tissue trauma.

Fracture of fixed restoration veneers/fixed restorations

Without the periodontal ligament to provide shock absorption and proprioceptive reflex, dental implants are essentially ankylosed to the surrounding bone. Further, patients tend to generate higher masticatory forces on implant-supported restorations relative to the natural dentition. It has been reported that the maximum bite force generated with conventional dentures is around 50–60 N, whereas a full-arch implant-supported restoration can generate a bite force above 200 N (Carr & Laney 1987; Mericske-Stern *et al*. 1996; Fontijn-Tekamp *et al*. 1998; Morneburg & Proschel 2002; Steigenga *et al*. 2003). As a result, an implant-supported prosthesis is exposed to a risk of higher restorative material failure. Among prosthetic failures, studies suggest fracture of the restorative veneer material is the most common type of mechanical complication (Fig. 57.9). Fracture can occur both of the veneering porcelain and of resin-based prosthetic teeth. Veneer fracture can happen anywhere in the mouth: restorations in areas of heavy functional forces and higher non-axial forces such as the occlusal surfaces of mandibular posterior restorations, facial cusps of maxillary posterior restorations, and maxillary anterior restorations. To reduce or avoid material failure, especially veneer material fracture, the restoration should have sound supporting structures. The framework that supports the restorative veneer should have sufficient strength and stability to safely support the overlying veneer material. It should have minimal flexure even under functional loading – veneer materials usually lack tensile strength and as a result are weak under flexural stress. The framework should be carefully designed so that it will provide maximum support with no areas of the veneer material unsupported (Fig. 57-10), which today often means use of a milled high strength alloy such as zirconia, chromium cobalt, or titanium alloy. Another important approach to reducing complications with veneering materials is control of the occlusion. To reduce or eliminate excessive stress on one particular tooth or restoration, wide distribution of the occlusal force will be better than loads concentrated on a localized area. Also, limiting the main occlusal force on the restoration directly supported by implants may be beneficial; cantilevered restorations may be at higher risk of fracture than those supported by the implant/abutment under identical occlusal loads (Becker 2004; Pjetursson *et al*. 2004).

Implant-borne restorations with occlusal wear are more evident in implant- versus dental-supported restorations. Especially when there is a mismatch of opposing restorative materials, wear can be dramatic. Thus, one must be prudent in not only selecting the material for the occlusal surface of the restoration, but also the status of polishing to avoid serious maintenance issues. It is known that porcelain can be abrasive when opposed with enamel, metal, resin, or even porcelain, especially when this does not have a highly polished surface (Monasky & Taylor 1971). An exposed opaque layer and use of external characterizations with metal oxides all add to the abrasiveness of porcelain and should be used with care.

A rare but possible complication is the fracture of mandibular implant-supported FCDs at the midline (Fig. 57-11). It is speculated that flexure of the edentulous mandible during function can cause this type of complication. With repeated extreme mouth opening, fatigue can accumulate in the metal framework, and once this accumulated fatigue exceeds the fatigue strength of the material, the prosthesis may facture or veneering material delaminate from the framework. Clinically, patients with this type of restoration may feel tightness of the mandible, especially during function, and once the restoration fails, they express "relief" from the tightness. To avoid this problem, fabricating a two-piece fixed restoration has been advocated, although it can generate its own problem: because of the lack of the bracing effect and rigidity of the framework, these restorations may tend to have a higher incidence of retention screw-related problems.

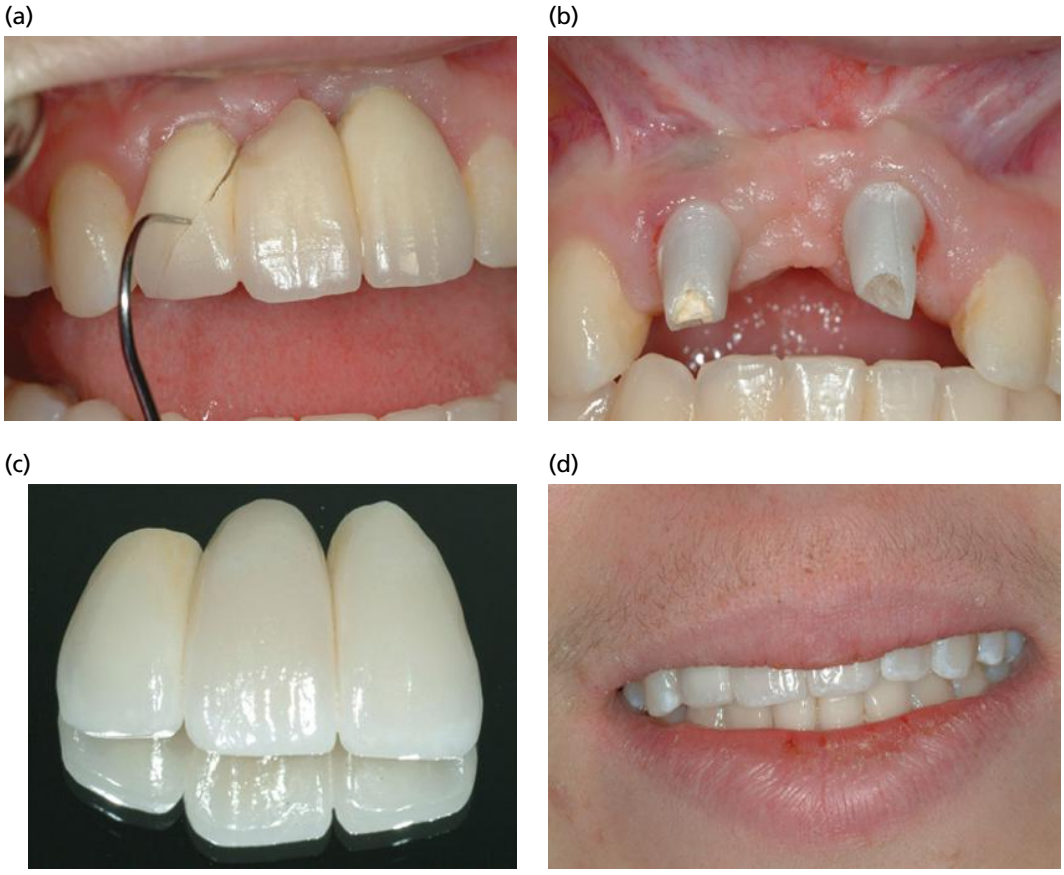

Fig. 57-10 Fractured all-ceramic implant restoration. Patient had a three-unit fixed partial denture with glass-infused ceramic structure. (a) Restoration demonstrated catastrophic rupture 2 years after delivery. Restoration was removed (b), zirconia abutments cleaned and a new zirconia reinforced FPD fabricated for enhanced strength (c). (d) Final esthetic appearance of the FPD.

Fig. 57-11 Splitting full-arch metal–ceramic restoration at the midline to reduce impact of mandibular flexure.

Implant screw-related complications

Numerous studies indicate that complications related to the screw components of the implant system are common and require clinical intervention, which could range from simple retightening of the screw(s) to total replacement of the abutment and screw(s). This requires additional time from both dentists and patients and incurs additional cost. Jemt and Linden (1992) observed, with earlier screw abutment designs, screw loosening in 49% of maxillary implant-supported restorations and 21% of prostheses in the mandible. They also observed that 57% of the abutment screw loosening occurred within the first year of service and only 37% remained stable over a 3-year period. Goodacre *et al.* (2003a) observed that the frequency of complications related to implant screws, like screw loosening or fracture, for abutment or prosthetic screws could account for as much as 19% of all the potential mechanical complications in implant restorations. Ding *et al.* (2003) reported that the incidence of screw loosening for an external hex system could be as high as 38%, which suggests one reason for the reduced popularity of this abutment–implant connection. In their systematic review, Pjetursson *et al.* (2004) observed that abutment or occlusal screw loosening/fracture was the third most common technical complication, behind only veneer fracture after restoration and loss of occlusal screw access restoration. Its cumulative incidence after 5 years of follow-up was 7.3% (Pjetursson *et al*. 2004).

Theoretically, the lifespan of an abutment or prosthetic screw in an implant restoration needs to be $>10^8$ cycles of loading or approximately 20 years, assuming the system is accurately constructed and the loading conditions simulate the natural oral environment (Patterson & Johns 1992). However, there are several factors that, if not designed or functioning properly, could drastically reduce the predicted service life, resulting in screw loosening and/or fracture. For example, the abutment–implant

interface geometry, precision of fit and/or passivity of components, and the amount of preload may reduce service life. For the older external hexagonal implant system studies, it was shown that larger implant–abutment contact area provided superior stability of the system and resistance to screw complications, and this was a driving force for the use of wider diameter implant devices (Binon 2000). Additionally, precise antirotational features should be present for the joint components to withstand rotational movements that could potentially cause screw loosening in butt-joint configurations (Khraisat 2005). Precise fit of the abutment to the implant interface is highly important. In a study on machining accuracy of several different external hex implant systems, all systems demonstrated rotational movement in excess of 4° (Binon 1995). The "slip-joint" figures, such as in external hex implant systems, are naturally vulnerable to vibration and micro-motion during functional loading (Schwarz 2000; Hoyer *et al.* 2001). This has led to the popularity of conus or internal abutment to implant systems in the last 10 years. In the absence of passivity between the implant components, it has been shown that screws accumulate internal stress, which eventually results in metal fatigue failure and screw loosening/fracture (Kano *et al.* 2006). The resulting clamping force between the abutment and implant generated by the screw is called *preload*. In an external hex system, the preload, along with the frictional force of the abutment–implant joint wall, is the major force resisting functional loads. In most implant systems, a tightening torque is applied and the preload stress at the interface is increased to what it should be within the elastic range of the screw material. The screw tightening should result in an optimum preload level for the maximum outcome of the implant complex after dynamic loading. The literature indicates that as long as the external loading stress does not exceed the preload stress, the abutment–implant connection can be regarded as safe (Patterson & Johns 1992; Lang *et al.* 2003). Insufficient or excessive preload stress could compromise the lifespan of the abutment–implant connection.

Chronic problems associated with the external hex– or butt–joint interface implant systems have been documented. Because of these inherent problems with the external hex design, investigators have presented new concepts in implant design, which aim to improve support and reduce the complications associated with the external hex design, by means of additional frictional force between the internal wall of the implant and the external wall of a one-piece abutment/abutment screw. ten Bruggenkate *et al.* (1998) proposed an 8° internal-taper connection between the implant and abutment. The original concept of Morse taper comes from engineering, particularly from the area of machine taper. When connecting exchangeable working bits into the work piece, a popular and very effective method is to use frictional forces between the two components, where the pressure of the spindle against the work piece drives the tapered shank tightly into the tapered hole. The friction across the entire interface surface area provides a surprisingly large amount of torque transmission. The abutment–implant junction can be designed such that an internal connection is utilized with minimal taper (2–15°), while the screw base portion of the abutment will be connected into the receiving portion of the implant. There are numerous studies reporting on the higher mechanical and enhanced clinical behavior of these internal connection implants (Binon 2000). Norton (1997, 1999) verified that the internal conical designed systems significantly enhanced the resistance of the connection system against external bending forces. Levine *et al.* (1999) found that the internal connection showed a significantly lower incidence (3.6% to 5.3%) of screw-related complications compared to external hex designed systems. The use of the internal interference fit abutment designs has simplified the prosthetic phase of therapy and increased the long-term stability of the screw–joint connections (Stanford & Brand 1999; Brunski 2000, 2003; Jokstad *et al*. 2003).

Abutment-related complications

In positioning an abutment into the implant, there are potential mechanical complications that can arise. One common issue is incomplete seating of the abutment in the implant body (Fig. 57-12). Depending

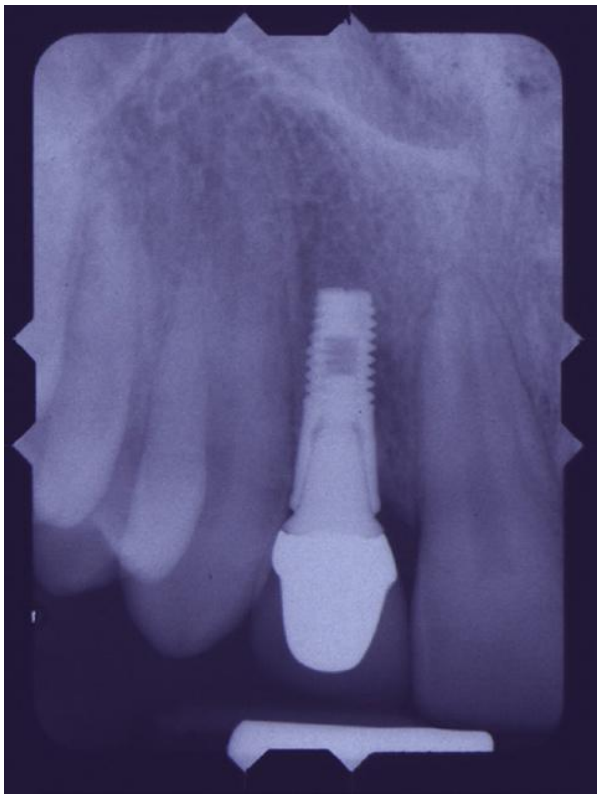

Fig. 57-12 Incomplete seating of abutment in a two-piece implant system. Implant abutment was incompletely seated in the implant due to contact on the adjacent osseous contours.

on the implant position and depth, it is also possible that the peri-implant bone may inhibit complete seating of the abutment (giving the dentist the impression that the abutment is fully seated when in fact it is resting on adjacent bone). This may or may not be evident on a radiograph, depending on the implant–abutment angulation relative to the central beam of the radiographic unit.

Since most prefabricated abutments are produced in standard size and shape, it can be challenging to customize these to individual patients. Modification of a prefabricated abutment may in turn compromise the biomechanical properties of the abutment to achieve an esthetic result. More recently, systems have shifted form a modified "stock" or "prefabricated" titanium abutment to the use of CAD/CAM milling approaches. The latter approach provides industrial tolerance and manufacturing control, and a more predictable long-term abutment–implant solution.

When the head of the implant is placed below the adjacent bone, the bone can develop a sloped architecture, extending from the periodontal ligament support of the adjacent teeth down and across to the implant. This often happens in the maxilla area where implants are generally placed deeper to avoid esthetic issues. Periodically this scalloped osseous architecture necessitates the prosthodontist to assess and then modify the abutment, and occasionally the implant body in this area (Fig. 57-13). In this case, the mucosal transition zone of the abutment is modified to avoid placing pressure on the bone and soft tissues. It is also helpful to develop a flat or even concave emergence profile of the final restoration to maintain soft tissue dimensions around the restoration (Stanford 2005a).

Other issues related to prosthetic complications

Implant angulation and prosthetic complications

The impact of angled implants on clinical outcomes is often of significant concern. As far back as 1995, Clelland *et al.* evaluated the stresses and strains generated by an abutment system capable of three angulations (0°, 15°, and 20°). They observed that peak stresses were located in the cortical bone, and the magnitude of these stresses increased with an increase in the abutment angulation. The maximum stress values were generally within the physiologic parameters described for animals, but in one case, the peak compressive stress for the 20° abutment was slightly above this physiologic zone. Peak tensile strains also increased with abutment angulation, but maximum compressive strain values were the same for all three angles. This study suggested that angled abutments were safely used relative to the bone stability around the implant body (Clelland *et al*. 1995).

One advocated approach has been to use multiple implants and to place a faciolingual offset between

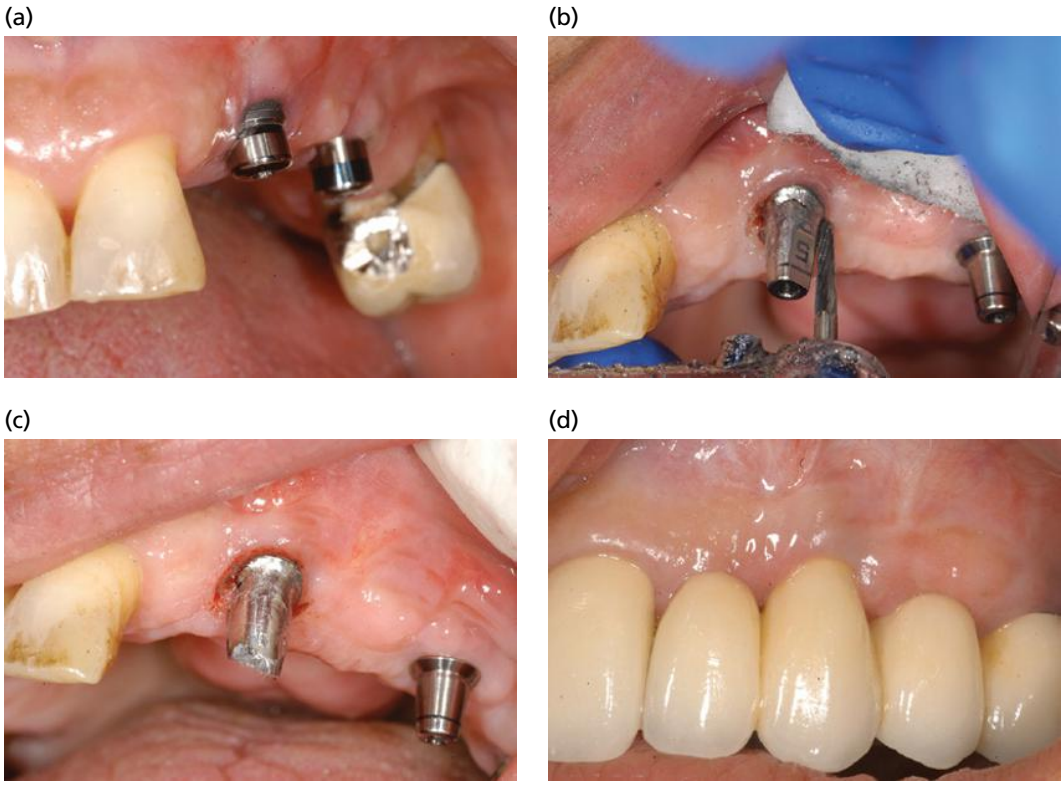

Fig. 57-13 Implant and abutment modification. Patient presented with soft tissue dehiscence in an integrated implant (a), necessitating placement of an abutment and preparation of the abutment and implant body (b). A fixed partial denture was fabricated using the modified abutment (c) that achieved a reasonable esthetic and functional outcome for this compromised situation (d).

them to enhance the mechanical stability of a connected FPD. Sutpideler *et al.* (2004) evaluated the effect of an offset on the transmission of force to bone-supporting implants aligned in either a straight-line configuration or an offset configuration. They also addressed the effect of different prosthesis heights and different directions of force application. They observed that vertical loading of an implant-supported prosthesis produced the lowest stress on the supporting bone, and increasing the angle resulted in greater stress that theoretically simulated surrounding bone. They also observed that reducing the height of the prosthesis from 12 mm to 6 mm (crown-to-implant ratio) or establishing an offset implant location for the middle of three implants may reduce stress, but this reduction did not compensate for the increase in stress found with non-axial loading (Sutpideler *et al*. 2004). This concept has been extended with the recent advocacy for the intentional placement of implants at significant angulation relative to each other (tilted implant position) to avoid vital structures and sinus cavities, and to improve the putative biomechanical position of the implants (Krennmair *et al.* 2005; Esposito *et al.* 2012; Truninger *et al*. 2012).

Chun *et al.* (2006) investigated the effect of three different abutment types (one-piece, internal hex, and external hex) on the stress distribution in bone under vertical and inclined loads by finite element analysis. For one-piece implant designs, they observed the load was transferred evenly into bone as well as within the implant system. However, the maximum stress generated in bone with the one-piece system was always higher than that generated with the internal hex implant, regardless of load angle inclination. In the case of the internal hex implant, the contact condition with friction between abutment and implant in the tapered joints and at the abutment neck reduced the effect of bending caused by the horizontal component of inclined load. The maximum stress in bone was highest for the external hex implants (Chun *et al*. 2006).

Erneklint *et al.* (2006) evaluated the load resistance in a conical implant system with two different screw-retained abutment angled designs (20° and 45°) and three different retaining-screw materials. They observed that the 20° abutment withstood non-axial forces to a greater extent than the 45° abutment, regardless of the retaining-screw material. The 45° abutment failed under oblique loads between 450 and 530 N, while the 20° abutment failed at 1280–1570 N. Differences between the retaining-screw materials were more obvious in the 20° abutment, but also were not insignificant in the 45° abutment. In general, it was concluded that abutment taper angles were more important than retaining-screw material in determining the assembly strength (Erneklint *et al*. 2006).

The angulation of the implants can also influence the outcomes of implant overdenture therapy. Gulizio *et al.* (2005) evaluated the retentive capacity of gold and titanium overdenture attachments placed on implants positioned at 0°, 10°, 20°, and 30° from a vertical reference axis. They observed significant differences in retention of gold matrices when ball abutments were positioned at 20° and 30°, but not at 0° and 10°. Also, they noted significantly higher variance in retention among the titanium matrices, despite the finding that angle was not a factor affecting retention for titanium matrices. In other words, the angle of the implants had an effect on the retention of gold matrices, but not on titanium matrices. This study supports the clinical observation that implant-supported overdentures have higher maintenance needs and may have higher long-term ongoing costs relative to conventional tooth replacement therapies (Naert *et al*. 2004a, b; Krennmair *et al*. 2005; Zitzmann *et al*. 2005; Trakas *et al*. 2006; Visser *et al*. 2006).

Screw-retained versus cement-retained restorations

The method of attachment of the prosthesis to the implant/abutment can cause prosthetic complications. The major advantages of screw-retained implant-supported restorations include their retrievability and freedom from residual cement problems (Wadhwani *et al*. 2012). Thus this type of restoration scheme can be applied when there is a need for future removal, for example for hygiene maintenance or when the prognosis of the restoration is questionable. It could also be applied when the restorative margin is located too deep for removal of excess cement. The same advantage applies to the provisional restorations as well. However, this type of restoration has inherent disadvantages. The required screw access hole may compromise the esthetics and occlusion, and potentially the strength of the restoration due to the lack of material around the screw access shaft through the prosthesis. The presence of the prosthetic screw itself may bring screw complications. Additionally, this type of restoration is more sensitive to the passive fit of the restoration to the supporting implants.

Regarding the clinical performance of each type of restoration, the literature indicates that screw-retained restorations may present more postoperative complications compared to cement-retained restorations (although much of this literature is based on older abutment to implant designs). Duncan *et al.* (2003) reported that patients restored with screw-retained restorations had problems with prosthetic screws and screw access hole filling material, while after 3 years no complications had been encountered by patients restored with cement-retained restorations. Karl *et al.* (2006) found that cement-retained FPDs may result in lower strain levels compared to conventional screw-retained FPDs at the time of either the cementation or screw-tightening procedure. Higher strain level at the time of load delivery may reduce the passivity of the fit of the restoration and

increase potential future complications. This result is in accordance with other *in vitro* studies (Guichet *et al*. 2000; Taylor *et al*. 2000). However, this study tentatively suggests that regardless of the type of restoration, no true passive fit can be achieved. Skalak (1983) theorized that a non-passive fit of the restoration could induce biologic and prosthetic complications. However, Jemt and Book (1996) reported that they could find no direct association between implant prosthesis misfits and marginal bone loss over 5 years. Vigolo *et al.* (2004) found no evidence of difference in the behavior of the peri-implant marginal bone and soft tissue response around screw-retained and cement-retained single-tooth implant restorations.

Overall, there is no consensus on the superiority of one type over the other, and the choice depends on the clinical situation and operator's preference.

Ceramic abutments

Ceramic implant abutments have recently gained in popularity due to their superior esthetic results compared to conventional titanium abutments, especially in thin tissue biotypes (Stanford 2005a; Leutert *et al*. 2012). Because of the strength concerns, reinforced ceramic abutment are currently the first choice, for example alumina (Al_2O_3) or yettria-stabilized zirconia (ZrO_2) (Fig. 57-10). These abutments were introduced during the 1990s and the first consisted of densely sintered aluminum oxide (alumina). Andersson *et al.* (2003) conducted a 5-year multicenter prospective study evaluating the clinical outcome of alumina ceramic abutments. According to this study, the cumulative success rate for alumina ceramic abutments was 98.1% at 5 years compared to 100% for conventional titanium abutments. More recently, zirconia has become popular for ceramic implant abutments. Because ceramic materials are vulnerable to tensile stress, especially around defects or cracks, a ceramic material with higher fracture toughness will be a good material for ceramic abutments. Zirconia is generally known to have a higher range of fracture toughness (K_{IC} ~7–15 $MPam^{-1}$) than alumina (K_{IC} ~4–4.5 $MPam^{-1}$). Its fracture toughness is comparable to that of metal alloys (K_{IC} ≥20 $MPam^{-1}$) (Piconi & Maccauro 1999; Kelly 2004; Marinis *et al*. 2013). Zirconia is known to have the relatively unique property of transformation toughening, where the metastable tetragonal phase can be converted into the monoclinic phase with associated volume expansion (Chevalier 2006). This phenomenon is induced by stress concentration at defective or crack tips: the crack is compressed and its growth retarded. This is the main mechanism for the higher fracture toughness of zirconia, and it could significantly extend the reliability and lifetime of the restoration. However, there is little evidence that the abutment retains this property after being reduced to <1 mm during clinical usage. Further, the hydrolytic properties of water interacting with the material during aging (hydrolytic aging or "low temperature degradation") is still an active area of laboratory investigation (Rekow & Thompson 2005; Denry & Kelly 2008). Depending on the design, an all-ceramic abutment can fail either due to misindexing within the implant (since the abutment is harder than the titanium body) or body fracture, often due to laboratory adjustments to the CAD/CAM abutment (Fig. 57-14). There are outstanding questions relative to the use of this material, including long-term fatigue strength, degree of preparation/wall thickness needed, intraoral sites, clinical long-term prognosis, etc. Due to its relatively recent introduction, few studies have assessed the clinical performance of these abutments (Att *et al*. 2006; Denry & Holloway 2006; Deville *et al*. 2006; Itinoche *et al*. 2006; Studart *et al*. 2006).

Esthetic complications

The most frustrating and challenging complication is unacceptable esthetic outcomes. With a growing population of esthetically concerned patients, esthetic complications are a serious matter even if the implant team has done its best throughout the procedure. This is an important issue that the implant team and the patient need to be aware of and endeavor to find solutions to prevent or overcome. Common esthetic complications include complications due to malposition of oral implants, black interproximal spaces, thin tissue "biotypes", and unfavorable soft tissue responses.

The potential cause and impact of malpositioned implants was described earlier. A very difficult aspect of implant rehabilitation is that sometimes a slight malpositioning can induce dramatic esthetic compromises which only become evident when the technician is working with the case. A facially malpositioned implant can become a major challenge for the restorative team (see Figs 57-5, 57-8, 57-13). In this case, the restorative dentist may have to address a variety of potential problems, including excessive incisogingival dimensions of the crown, exposed head of the implant, unequal gingival margins, etc. Usually, the facially malpositioned implants create greater problems than other malpositioned implants. A position 1 mm lingual to the implant in the maxillary esthetic zone can create a prosthetic challenge in achieving a final restoration that appears even and uniform with the natural dentition. Mesially or distally malpositioned implants can induce improper anatomy of the restoration as the technician attempts to compensate for implant components in the interproximal space (Fig. 57-15).

Unfavorable soft tissue response can also make the treatment very difficult. It is generally accepted that individuals who have relatively thin attached gingiva, or thin tissue biotype, are more vulnerable to gingival/periodontal disease and subsequent

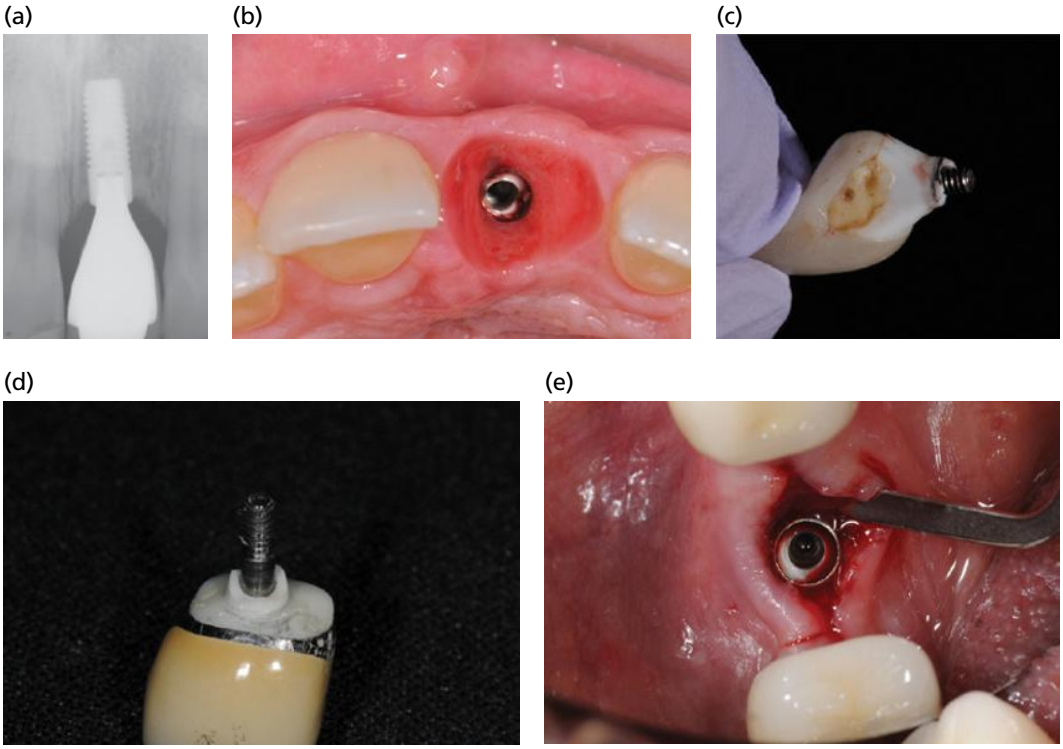

Fig. 57-14 Fracture of all-ceramic abutments. (a) Two years following delivery of the crown and zirconia abutment, the patient had a loose 21. (b) On removal of the crown/abutment, a fractured portion of the index of the abutment was observed within the implant. (c) This type of fracture may be due to misseating of the index within the implant. Note the residual resin cement on the transmucosal aspect of the abutment, yet the lack of this appearance on the radiograph (a). (d) Fractures can also occur with the body of the abutment (commonly due to laboratory adjustment to the ceramic), leading to the need to remove the fractured portion with a surgical microscope. (e) Note the position of the fracture within the body of the abutment.

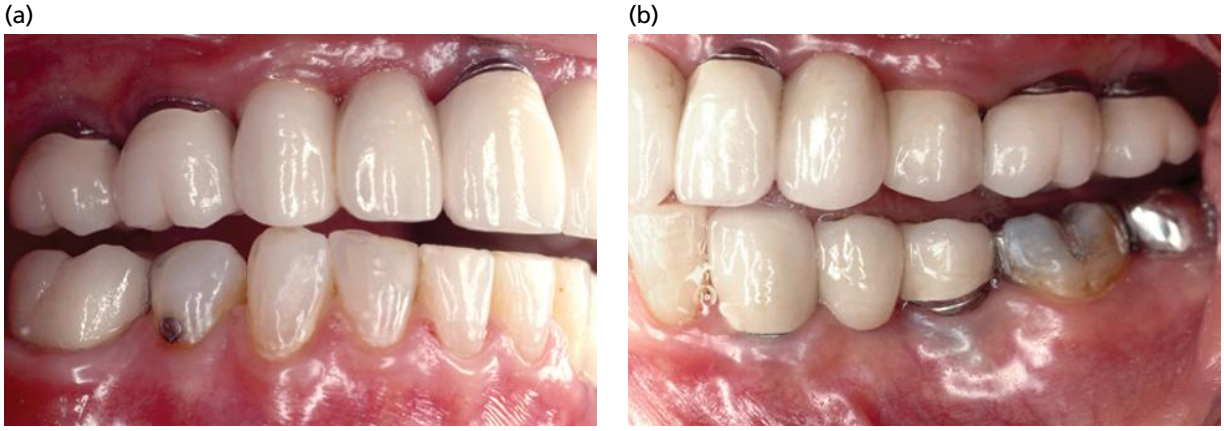

Fig. 57-15 Soft tissue recession on the facial aspect of an implant-supported restoration.

sequelae, including gingival recession (Sailer *et al.* 2007). Similar findings are reported for the tissue response around implant restorations (Kan *et al.* 2003). Thin biotype tissues tend to show a greater recessive response to trauma. Restorative procedures like preparation, impression, repeated abutment/provisional removal or even toothbrushing can sometimes cause enough trauma to these thin biotype tissues to result in significant recession that compromises the treatment outcome. It is very important to identify the tissue type early at the treatment planning stage to prevent unfavorable treatment outcome (Fig. 57-16).

Fig. 57-16 Challenges in creating esthetic outcomes when implants are insufficiently placed. Example demonstrates teeth 11 and 21 with compromised contours due to the close proximity of the implants.

Success/survival rate of implant-supported prostheses

As previously described, the biologic success/survival rate is extremely high and has become more predictable even in areas that were considered to be of high risk (e.g. the maxillary posterior region). It may be beneficial to know what the literature indicates regarding the success/survival rate of restorations fabricated on osseointegrated implants. Pjetursson *et al.* (2004) obtained estimates of the long-term survival/success rates of implant-supported FPDs and of the incidence of technical complications in partially edentulous patients over an observation period of >5 years. In this study, "FPD survival" was defined as "the FPD remaining *in situ* with or without modification for the observation period", as compared to the definition of "FPD success", which was "FPD being free of all complications over the entire observation period". The cumulative FPD survival rate was 95% after 5 years and 86.7% after 10 years. The authors noted the important fact that most of the prosthetic complications occurred after 5 years of clinical service. The underlying issue this illustrates is the problem associated with the rapid rate of manufacturing market changes in implant products and components. By the time the restoration needs repair or replacement, the required components may be difficult, if not impossible, to obtain. Regarding comparison of different implant systems, there is little evidence that any one system is superior to another in terms of mechanical failure. Implant–abutment joint geometry, design of the restoration, and patient factors like parafunctional habits or heavy occlusal forces tend to have more impact on the outcome of implant-supported restorations than implant surface material or topography (Rangert *et al*. 1995; Astrand *et al*. 1999; Naert *et al*. 2002a, b). Some studies indicate that the cumulative complication rate of prosthetic problems can be as high as 43.1% after 5 years (Jemt *et al*. 2003), compared to other studies finding it to be as low as 19.3% after 5 years (Bragger *et al.* 2001; Pjetursson *et al*. 2004). Together these studies indicate that after 5 years one may expect one in four implant-supported restorations to require some type of repair, whether minor, such as screw or abutment tightening, or major, such as entire restoration replacement. This implies that significant chair time may be necessary for the maintenance of these restorations (Pjetursson *et al*. 2004).

Berglundh *et al.* (2002) also noted the higher mechanical/technical complication rate compared to the biologic complication rate. This study observed several interesting aspects: the incidence of implant loss prior to functional loading was three-fold higher when multiple implants were placed for larger restorations like overdentures or fixed complete restorations, compared to single-tooth restorations. Implant loss during function occurred in 2–3% of implants supporting fixed reconstructions, while twice as many implants were lost in overdenture therapy over a 5-year period. In this case, the highest frequency of implant loss during function occurred in the maxilla.

Conclusion

Implant therapy as a form of tooth replacement therapy provides many benefits. As with any form of prosthetic rehabilitation, it has limitations, including wear, material fatigue and fracture, soft tissue recession and subsequent complications, and increased maintenance and costs. The benefits though can be enormous, including enhanced patient quality of life with a definitive replacement of teeth. Patients need to be aware during the treatment planning process that the treatment provided may need to be replaced periodically as normal aging and wear occurs. Specific patient-based risk factors such as parafunctional habits should be discussed and the patient made aware of the risks to the prosthetic reconstructions.

Part 17: Orthodontics and Periodontics

Chapter 58

Tooth Movement in the Periodontally Compromised Patient

Mariano Sanz and Conchita Martin

Faculty of Odontology, University of Complutense, Madrid, Spain

Introduction: Biologic principles of orthodontic tooth movement

Physiologic tooth movements are those that a tooth makes to attain, and then to maintain, its functional position. They are associated with the processes of tooth growth and eruption, and also occur when external forces are applied. *Orthodontic movements* are those generated by external forces applied in a controlled manner with the purpose of attaining a predetermined tooth movement. In both types of tooth movements, the transmission of mechanical forces from the root to the periodontal ligament (PDL) will elicit biologic reactions between the cells and the extracellular matrix, leading to modeling and remodeling processes in the neighboring alveolar bone housing and, as a result, change of the tooth spatial position.

The application of orthodontic forces causes a physical distortion within the PDL that evokes a series of cell–matrix interactions. These trigger a series of biochemical reaction cascades that change cell physiology through changes in extracellular, cell membrane, and nuclear transduction mechanisms (Masella & Meister 2006). These adaptive responses to applied orthodontic forces are highly sophisticated biologic processes, transforming mechanical forces into controlled cellular activities that are regulated by different neurotransmitters, growth factors, cytokines, and mediators, and hence eliciting a controlled inflammatory response in the absence of pathology (Meikle 2006).

Depending on the amount and direction of the mechanical force applied to a tooth, the resulting tooth movement will vary. A mechanical force perpendicular to the longitudinal axis of a tooth produces wide areas of pressure on one side of the root and corresponding areas of tension on the other. If the force could be placed near the center of resistance of the root, the resulting movement would be a horizontal translation of the tooth or a bodily movement. In this type of movement, there is an even distribution of pressure and tension areas on both sides of the root. This movement, however, is impossible in most clinical situations since the root is invested in bone and the only surface available to apply the orthodontic force is the crown. In orthodontic treatment, therefore, the forces need to be applied against the tooth crown via some kind of system or appliance that ensures a two-point contact to enable the necessary couple that transfers the applied force to the tooth center of rotation. The point of application of such movement will vary depending on the site of the force application, the shape of

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

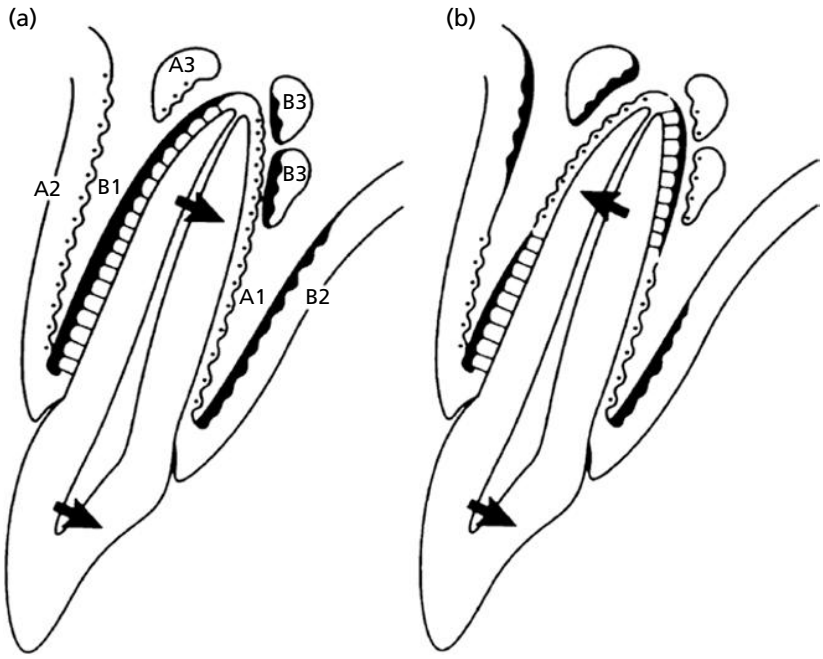

Fig. 58-1 (a) Mechanical force perpendicular to the longitudinal axis of a tooth produces wide areas of pressure on one side of the root and corresponding areas of tension on the other. (b) Point of application of the force varies depending on the site of the force application, shape of the tooth, and architecture of the tooth-supporting system. The resulting movement will be a combination of bodily and tilting movements, leading to pressure and tension forces on either side of the root and a varying distribution of the stress along the periodontal ligament.

the tooth, and the architecture of the tooth-supporting system. The resulting movement will be a combination of bodily and tilting movements leading to pressure and tension forces on either side of the root and a varying distribution of the stress along the PDL (Fig. 58-1). In general, the tension side will make the PDL space wider, hence stretching the fibers and evoking cellular processes leading to bone formation. In contrast, the periodontal space on the pressure side becomes narrower, thus evoking cellular processes leading to bone resorption.

Application of light mechanical forces (approximately 50–100 g/tooth) on the pressure side is associated with "direct bone resorption". In these situations the vessels are patent and the physiology of the cells and tissues is preserved. In contrast, stronger mechanical forces will cause a crushing injury to PDL tissues, with cell death, hyalinization, and the formation of cell-free areas between the PDL and the adjacent alveolar bone, which will interfere with the tooth movement and will slow the biologic processes. Patient variability in the response to similar mechanical forces is common in orthodontic practice and there are many possible reasons for this heterogeneity, such as differences in alveolar bone mineral density, in vascularity, in the number of available bone cells, and in the many inherent cellular and metabolic responses due to differences in the patient's genome that dictate differences in cell recruitment, differentiation, and function, as well as in the expression of the many proteins and regulatory molecules that intervene in bone metabolism.

The objective of orthodontic therapy is to correct malocclusions and altered tooth positions by utilizing orthodontic appliances and techniques that combine compression and tension forces applied on the appropriate tooth surfaces (Wise & King 2008; Meikle 2006; Dolce *et al*. 2002). This therapy has distinctive characteristics when applied to dentitions in growing bone (such as in children and adolescents) compared to dentitions where the bone has stopped growing (in adults). In the first case, the orthodontic therapy combines guidance of the jaw's growth to the adequate intermaxillary relationships with dentoalveolar tooth movements. In adults, orthodontic therapy is limited to dentoalveolar tooth movements and in many instances to teeth with a healthy but reduced PDL as a consequence of periodontal disease. With the increasing esthetic demands of modern society, an increasing number of adult patients are seeking orthodontic treatment to correct common conditions such as anterior tooth diastemata, crowding, uneven gingival margins, or loss of interdental papillae.

In patients suffering from moderate and severe chronic periodontitis, the combination of bone loss, early tooth loss, and primary or secondary tooth trauma causes pathologic tooth migration and frequently severe malocclusions and malpositions, which lead to further deterioration of the patient's dentition. In these situations, orthodontic therapy is a prerequisite to restore the patient's functional dentition. The treatment of these patients requires a close coordination and collaboration between the orthodontist, the periodontist, and the restorative dentist to optimize treatment outcomes. This chapter specifically reviews how orthodontic therapy can be implemented in adults with periodontally affected dentitions.

Periodontal and orthodontic diagnosis

It is a prerequisite in any adult patient seeking orthodontic therapy to achieve periodontal health and therefore, a periodontal diagnosis including oral examination, periodontal charting, and a complete

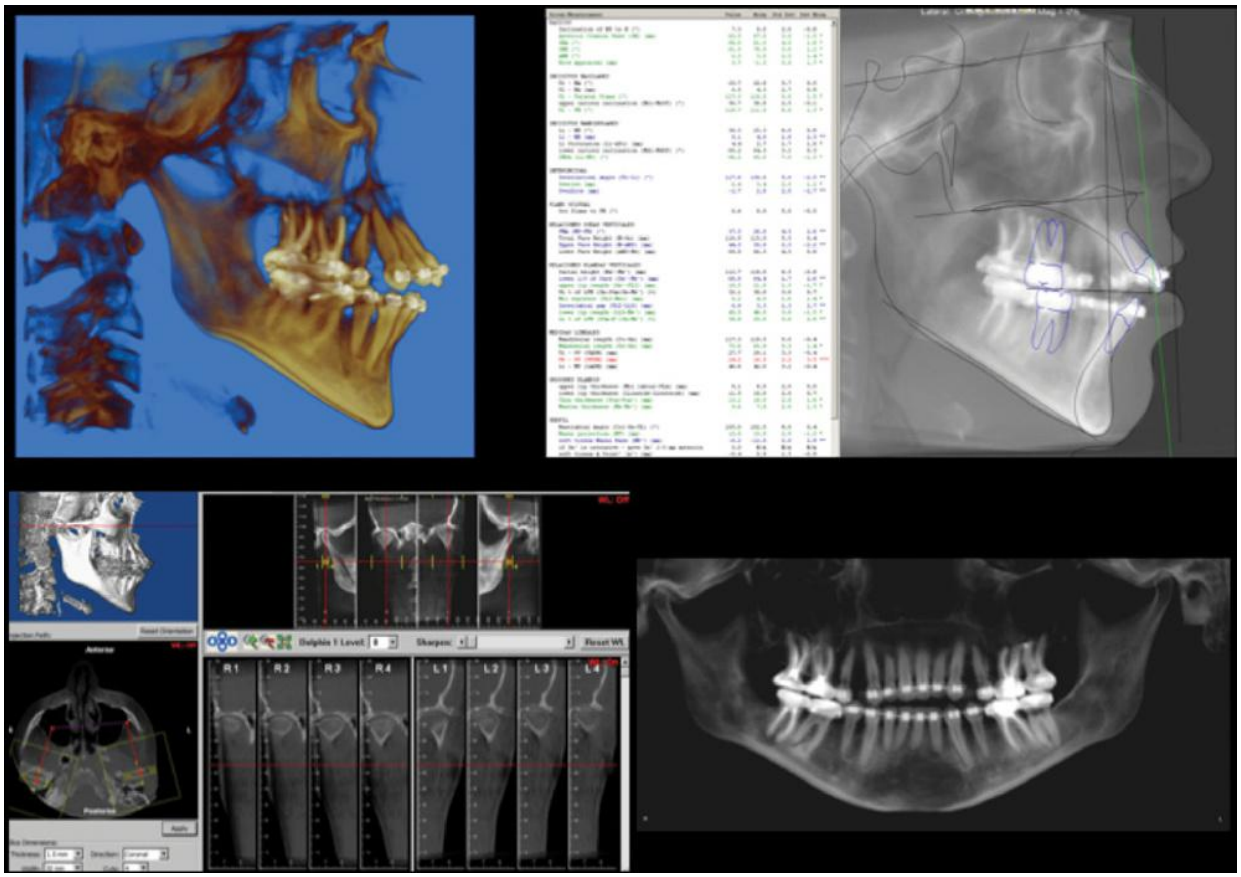

Fig. 58-2 Different diagnostic methods used in orthodontic treatment planning. The classical combination of orthopantomography (OPG) and cranium lateral radiography allows a cephalometric analysis, with cone-beam computed tomography (CBCT) providing further information on the morphologic aspects of the craniofacial complex.

periapical radiographic series should always be carried out before the start of the orthodontic therapy. Periodontal charting should include recording of full-mouth probing pocket depths, presence of gingival recessions, bleeding on probing, and plaque accumulation in four to six sites per tooth, as well as the evaluation of tooth mobility, presence of furcation involvements, and mucogingival defects.

In conjunction with the periodontal examination, it is important to evaluate carefully the status of the remaining dentition with close attention to the presence of undiagnosed caries or presence of periapical pathology which may interfere with the orthodontic therapy. If these pathologies are present, appropriate restorative and/or endodontic therapy should also be carried out before the start of the orthodontic therapy.

In the diagnosis of the patient's malocclusion, the appropriate intraoral and extraoral examination should be conducted with close collaboration between the orthodontist and the periodontist. In the extraoral examination, a full-smile analysis will assess the shape and form of the lips, the tooth, and the gingival exposure, as well as the exposure of the posterior corridors. In the intraoral examination, a static and dynamic occlusal examination should determine the presence of prematurities in maximum intercuspidation, as well as the presence of interferences in protrusive and lateral disclusive movements. The intermaxillar relationships should be studied on the appropriate intraoral and extraoral records. Appropriately mounted intraoral models should reveal the shape of both arches, presence of diastemata, tooth crowding, tooth rotations, anomalies in the size, shape and number of teeth, and their interocclusal relationships. Classically, the combination of orthopantomography (OPG) and cranium lateral radiography will allow a cephalometric analysis leading to the appropriate diagnosis of the patient's malocclusion. Cone-beam computed tomography (CBCT) has broadened the diagnostic opportunities for examining the morphologic aspects of the craniofacial complex, including evaluation of the buccal alveolar bone height and thickness, and assessment of the transverse dimension, presence of ectopic and supernumerary teeth, as well as the position of the soft tissues in relation to the bone envelope (Fig. 58-2).

In the treatment of adult patients it is also important to undertake a detailed medical and drug history. Adult patients often suffer from medical conditions or take several medications that might interfere with the periodontal and/or the orthodontic therapy. To assure the appropriate response to periodontal therapy, patients who smoke should be advised to cease

and patients who are diabetic or prediabetic should achieve appropriate glycemic control.

With regards to orthodontic therapy, it is important to obtain an accurate drug-consumption history, since adults frequently take different drugs, vitamins, and non-steroidal anti-inflammatory drugs (NSAIDs) that may influence the cells targeted by the orthodontic forces during tooth movement. It has been demonstrated that NSIADs not only effectively reduce inflammation and pain, but also affect the sequence of tooth movement by inhibiting, or at least reducing, the associated inflammatory and bone resorptive processes. New-generation anti-inflammatory drugs such as nabumetone have also been shown to reduce the amount of root resorption with intrusive orthodontic forces, without affecting the pace of tooth movement (Krishnan & Davidovitch 2006). Another group of drugs that may affect adult patients under orthodontic care are muscle relaxants, such as cyclobenzaprine, and tricyclic antidepressants, such as amitriptyline and benzodiazepines. The main side effect of the latter is xerostomia, which can negatively affect the proper maintenance of oral hygiene, and hence the proper periodontal health during the orthodontic therapy. Similarly, in patients requiring chronic use of inhalers with steroids, such as those suffering from asthma, oral candidiasis and xerostomia are common. Appropriate measures should be implemented in these patients, such as the use of topical antifungal agents and salivary substitutes before and during the orthodontic treatment.

A condition that frequently affects women in adult age is osteoporosis and most of the current therapies for this disease are antiresorptive (bisphosphonates, selective estrogen receptor modulators, and calcitonin), which may slow the remodeling phase (resorption) of bone turnover and potentially interfere with orthodontic therapies. Similarly, in patients suffering from rheumatoid arthritis or other chronic inflammatory conditions, therapy aims to block the catabolic cytokine production responsible for the damage to soft tissues and bones (TNF or interleukin antagonists). These immune-modulatory agents might also interfere with the orthodontic tooth movement.

Another group of drugs that need special consideration are those associated with gingival hyperplasia, such as phenytoin used for seizure disorders, calcium channel blockers used as antihypertensive drugs, or cyclosporin A used in organ transplant patients. These drugs induce gingival hyperplasia, which might prevent the application of certain orthodontic mechanics, as well as the maintenance of proper oral hygiene and periodontal health.

Tooth movement might also be affected in patients who have recently received chemotherapy with busulfan/cyclophosphamide (<2 years of disease-free life), since these drugs are known to damage the precursor cells involved in bone remodeling processes.

Treatment planning

Once the patient has undertaken the needed dental and periodontal treatment and achieved full oral and periodontal health, an orthodontic and multidisciplinary treatment plan should be designed, taking into account the patient's main concerns and expectations, as well as the functional and esthetic objectives that can realistically be accomplished with the orthodontic therapy.

Periodontal considerations

The effects of orthodontic treatment on the periodontium have been extensively studied. The primary etiologic factor in periodontal tissue inflammation and destruction is infection, and since orthodontic tooth movements must be carried out in the absence of inflammation, the accumulation of dental biofilm during orthodontic treatment must be prevented and closely monitored. This is particularly important since fixed orthodontic appliances facilitate plaque accumulation and hinder the patient's oral hygiene. Moreover, in some patients with poor oral hygiene, the fixed orthodontic appliances may promote gingival hyperplasia, especially in the lower incisor area. In these situations, continuation of the orthodontic therapy requires the resolution of the inflammation and the re-establishment of proper hygienic measures. This is usually accomplished by removal of the orthodontic appliance and the application of appropriate periodontal therapy. Sometimes the appropriate position of the tissues in relation to the clinical crown can only be reached by surgical removal of the excessive gingival tissue (Sanders 1999; Graber & Vanarsdall 1994).

There are contradictory findings in the scientific literature on the impact of malocclusion and orthodontic appliances on periodontal health. Some clinical studies have reported a mean increase in probing depth of about 0.5 mm during orthodontic treatment, which is usually a result of inflammatory changes rather than periodontal attachment loss (Ristic *et al*. 2007; van Gastel *et al*. 2008). A comparative clinical trial has shown that molars with bands exhibit greater gingival inflammation and loss of attachment than bonded molars (Boyd & Baumrind 1992). Other studies, however, have reported the presence of gingival inflammation as a result of the accumulation of subgingival plaque around the bands, but without loss of attachment (Diamanti-Kipioti *et al*. 1987; Huser *et al*. 1990) or without demonstrating significant differences in other clinical periodontal parameters when comparing banding and bonding procedures (van Gastel *et al*. 2008; Sinclair *et al*. 1987). In fact, many clinical studies have clearly shown that with adequate plaque control, the orthodontic treatment of patients with reduced but healthy periodontium achieves the orthodontic objectives without aggravating their periodontal conditions, and the risk of periodontal recurrence in these patients is not increased during orthodontic

Fig. 58-3 Patient with severe chronic periodontitis, together with pathologic tooth migration, secondary occlusal trauma, and severe esthetic and functional impairment. (a) Intraoral initial clinical pictures. (b) Initial orthopantomogram (OPG), lateral cephalogram, and periapical series.

therapy (Re *et al*. 2000). If the periodontal inflammation is not fully controlled during the orthodontic treatment, however, these inflammatory processes can accelerate the progression of periodontal destruction, leading to further loss of attachment (Fig. 58-3).

Before the start of the orthodontic therapy, the patient needs to demonstrate excellent oral hygiene and gingival and periodontal health. If the patient does not demonstrate acceptable levels of oral hygiene, he/she must be adequately motivated until these levels are achieved before the start of the orthodontic treatment, and he/she should be informed that the orthodontic treatment might be terminated if the lack of adequate infection control poses a significant risk of periodontal breakdown. The orthodontic therapy should not start before 6 months after the completion of periodontal therapy, in order to carry out the orthodontic tooth movements in fully healed periodontal tissues. The patient's compliance and the clinical periodontal parameters should be recorded just before starting orthodontic treatment, assuring the presence of only shallow probing pocket depths, minimal plaque accumulation, and no bleeding on probing.

Orthodontic considerations

Orthodontic tooth movement *per se* does not cause attachment loss and gingival recession (Wennström 1996). In areas of thin buccal gingival tissue or when

there is absence of a minimum width of keratinized gingival tissue, however, labial orthodontic tooth movement can result in bone dehiscences, thus creating an environment in which plaque and/or toothbrush trauma may result in attachment loss and localized gingival recessions (Wennström 1996; Artun & Krogstad 1987; Coatoam *et al*. 1981; Maynard 1987). In the presence of a thick gingival tissue, gingival recessions will not occur, even when labial or expansive tooth movements are carried out (Wennström 1996; Artun & Krogstad 1987; Coatoam *et al*. 1981; Maynard 1987). In situations of thin labial gingival tissue or when there is a lack of keratinized gingiva, if the orthodontist plans to move the affected tooth or root labially, the gingival tissue should be augmented with the appropriate mucogingival

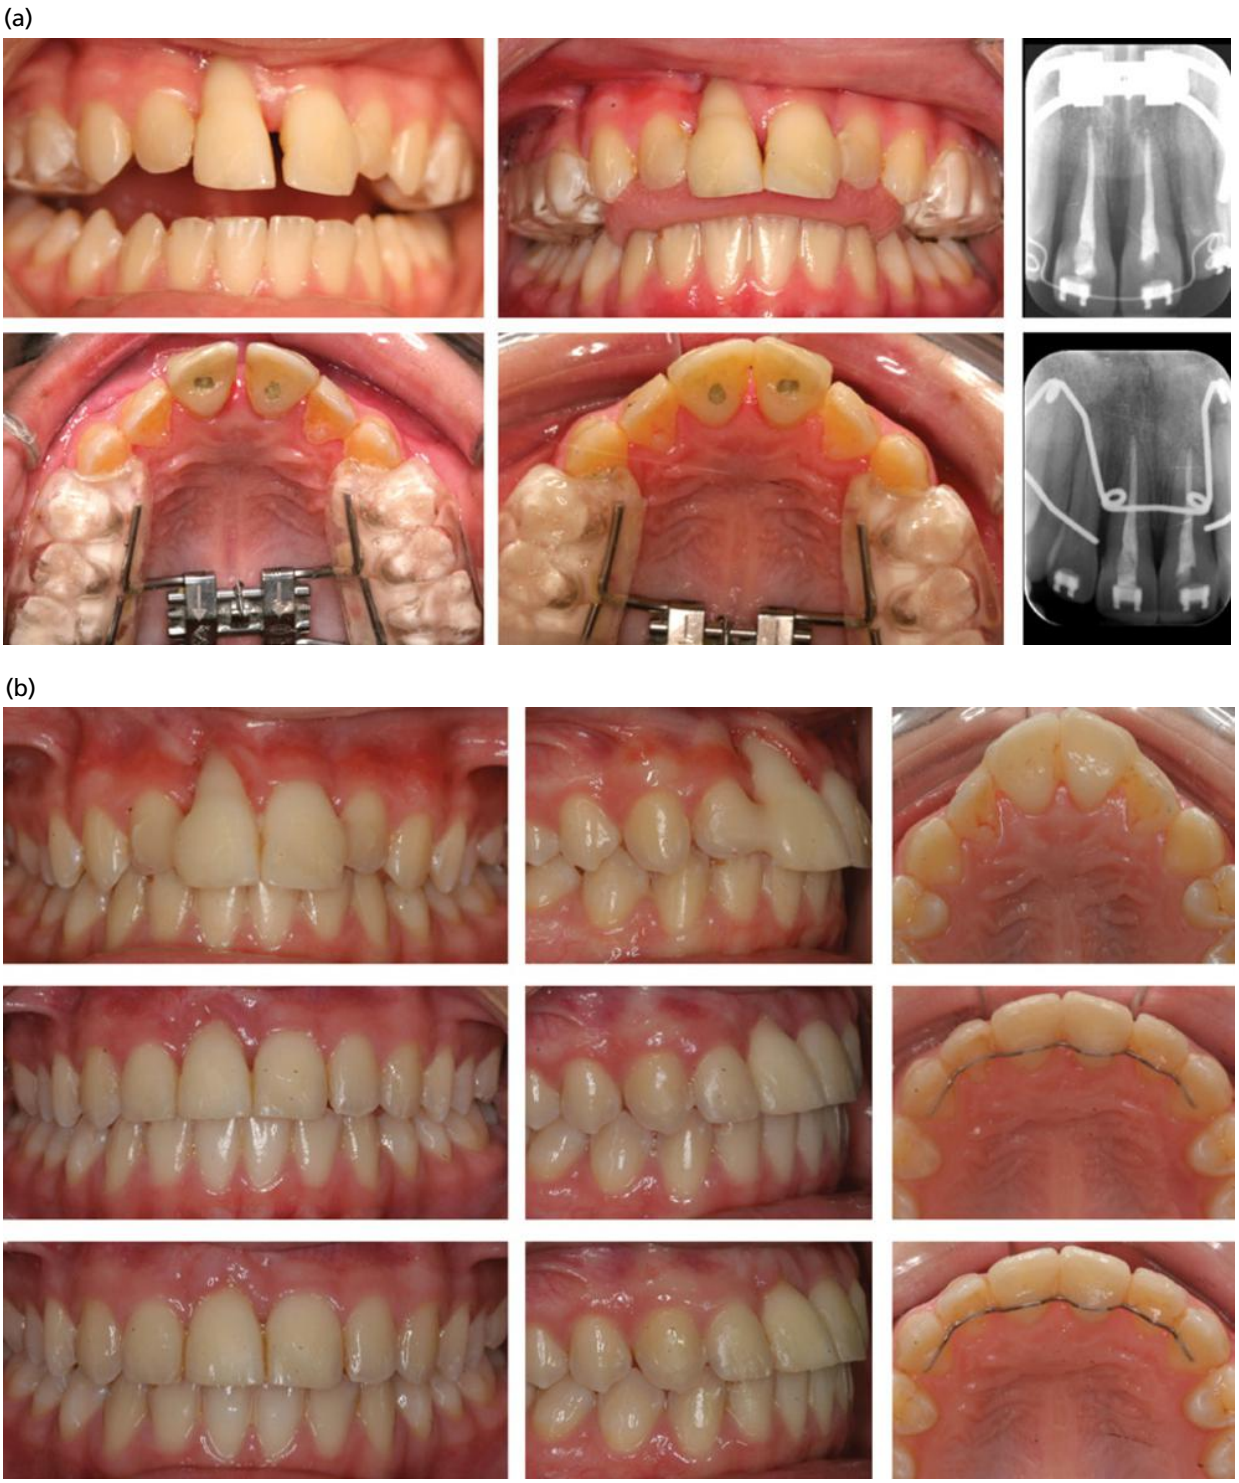

Fig. 58-4 Patient with localized gingival recession and absence of keratinized tissue in a central incisor prior to orthodontic therapy. (a) Orthodontic therapy was initiated by rapid palatal expansion. (b) Prior to expansion and retraction of upper central incisors, an autogenous gingival graft was placed. The final intraoral images demonstrate the root coverage of the recession by a combination of grafting and lingual tooth movements.

surgical techniques before the orthodontic tooth movement is started. In contrast, if a labially positioned tooth is orthodontically moved lingually, the bone dehiscence may disappear and the gingival thickness increase (Steiner *et al*. 1981; Karring *et al*. 1982; Wennström *et al*. 1987). In these situations, the mucogingival conditions should be closely monitored during the orthodontic therapy and the possible indication for a mucogingival surgical procedure should be evaluated during and after the orthodontic treatment (Fig. 58-4).

Some authors have reported the risk of gingival recessions in the area of maxillary premolars and molars when rapid maxillary expansion movements are carried out after mid-palatine suture fusion (after 20 years of age) (Graber & Vanarsdall 1994). Similarly, the movement of teeth into edentulous spaces (areas of reduced buccolingual bone dimension) is often possible with slow, light orthodontic forces, depending on the tooth-to-bone width ratio, although sometimes loss of alveolar bone and the presence of dehiscences have been reported, even under optimal conditions (Stepovich 1979; Hom & Turley 1984; Pontoriero *et al*. 1987; Goldberg & Turley 1989; Fuhrmann *et al*. 1995; Wehrbein *et al*. 1995).

Goldberg and Turley (1989) studied the periodontal changes associated with orthodontic space closure of edentulous maxillary first molar areas in adults. With a space closure averaging 5.3 mm, the resulting vertical bone loss averaged 1.2 mm in the second molar and 0.6 mm in the second premolar, with 60% of the teeth showing ≤1.5 mm of bone loss. Although space closure can be considered a potential solution in the absence of the first permanent molar, attachment loss and space reopening can be common complications.

Orthodontic treatment

Once orthodontic therapy starts, periodontal patients should be closely monitored for any signs of recurrence of periodontal pathology and they should be frequently recalled for professional infection control. These recall visits should be customized according to the severity of the reduced periodontium and the associated patient risk factors (smoking, diabetes, etc.). At each visit, the relapsing pockets and gingival bleeding should be monitored and if necessary, appropriate root instrumentation, together with other concomitant therapy (adjunctive antiseptics, such as chlorhexidine, cetyl pyridinium chloride or phenolic compounds) should be implemented.

In patients with a reduced periodontium, the total surface of the periodontal ligament that receives the orthodontic forces is significantly less and the tooth's center of resistance is displaced apically, which results in the expression of greater moments of force. In these situations the orthodontic treatment should be carefully planned and monitored in order to achieve bodily, instead of tipping, tooth movements (Melsen 1988). In terms of orthodontic appliances, it is always advisable to use the simplest orthodontic system for diminishing plaque accumulation and thus facilitating oral hygiene practices. It has been shown, although only short term, that the design of the bracket may significantly influence bacterial accumulation and gingival inflammation (van Gastel *et al*. 2007). In this context, self-ligating brackets or wire ligatures are considered better than elastomeric ligatures (Turkkahraman *et al*. 2005; Alves de Souza *et al*. 2008).

The presence of reduced periodontal support also implies different anchorage requirements and in many situations, the use of skeletal anchorage devices, such as orthodontic mini-screws, mini-plates or conventional dental implants, is recommended for a better control of three-dimensional tooth movements (Fig. 58-5).

After finishing orthodontic treatment and once the final tooth position has been achieved, a permanent retention is recommended in patients with a reduced periodontium. Retainers bonded to both canines and incisors are usually the chosen retention method, although in some studies these lingual fixed retainers have shown an adverse influence on the periodontal parameters (Pandis *et al*. 2007; Levin *et al*. 2008), while in others no significant long-term periodontal changes were shown (Reitan 1969). In some severe cases, a two-retainer approach is chosen, using a conventional lingual retainer and a segmented retainer in each interdental segment, inserted within the crowns of two adjacent teeth and covered with composite resin. Removable retainers should be avoided in order to prevent pathologic jiggling movements on the periodontally compromised teeth.

Specific orthodontic tooth movements

Extrusion movements

Tooth extrusion is a predictable tooth movement to level bone margins or to lengthen the clinical crown for restorative purposes or in the presence of tooth fractures at the level or below the bone crest. When extruding teeth with a healthy periodontium, a concomitant displacement of the gingival margin and the mucogingival junction occurs in 80% and 52.5% of cases, respectively (Pikdoken *et al*. 2009). Similar results have been reported in experimental studies: the free and attached gingiva followed the tooth movement in 90% and 80% of cases, respectively, while the mucogingival junction remained in the same position (Berglundh *et al*. 1991; Kajiyama *et al*. 1993).

In the presence of intrabony defects, orthodontic extrusive movements will predictably eliminate the angular bony defect, but the periodontal attachment levels will remain unaltered. This treatment option is particularly indicated in the presence of one-wall intrabony defects, since in these lesions periodontal

regenerative techniques do not have a favorable prognosis and the intact connective tissue attachment will be positioned in a more coronal position (Ingber 1974). Simon *et al*. (1980) evaluated histologically and radiographically orthondontic extrusion of endodontically-treated teeth in dogs. At 2 weeks, areas containing immature bone or osteoid were identified histologically in the periodontal ligament of normal width. Radiographically, these areas around the roots appeared radiolucent. By the seventh week, however, both the radiographic image and histologic characteristics were normal.

Orthodontic extrusion of "hopeless" teeth prior to implant placement has been proposed with the objective of displacing the bone coronally and thus improving the bone availability in the alveolar crest, which is an alternative to bone augmentation procedures in areas of deficient bone. Korayem *et al*. (2008) have recently reported a systematic review of this indication. Even though most of the selected

(e) Patient before treatment, after restorative therapy, and 3 years post retention.

studies were case reports or case series describing orthodontic extrusion of periodontally hopeless maxillary anterior teeth, all of the publications reported improvements in bone availability at the implant recipient site, with qualitative and quantitative gains in alveolar bone and soft tissues. In spite of the heterogeneity of the different orthodontic methods reported in the different studies, the authors developed treatment guidelines recommending: (1) the use of light, constant, extrusive forces of 15 g for the anterior teeth to 50 g for the posterior teeth; (2) the rate of extrusion should be maintained at a slow and steady rate of no >2.0 mm/month; (3) a buccal root torque component may be applied concomitantly to increase the buccolingual bulk of alveolar bone; (4) a retention and stabilization period of no <1 month for every month of active extrusion prior to extraction; and (5) overlay wires (anchorage wires) to reinforce anchorage and avoid tipping of adjacent teeth toward the tooth undergoing active extrusion (Fig. 58-6).

Molar uprighting

The orthodontic uprighting of mesially tilted molars achieves similar outcomes to the extrusive movements in angular bony lesions. In this case, the angular bony lesion only occurs in the mesial aspect of the inclined molar and this lesion will disappear and the bone crest will level, although without modifying the periodontal attachment levels. In these clinical situations, the recommended movement is to displace the tooth away from the defect in a disto-occlusal direction, thus causing tension in the periodontal ligament collagen fibers and making the contour of the alveolar crest shallower (Diedrich 1996). Even though the level of the connective tissue attachment remains unchanged, the new anatomic position of the molar usually translates into an improvement in probing depth levels and crown-to-root ratio (Brown 1973) (Fig. 58-7).

If the mesially tilted molar has a furcation involvement, the orthodontic tooth movement may exacerbate the periodontal lesion, unless strict infection control prevents the development of any periodontal inflammation (Burch *et al*. 1992). A valid alternative in these clinical situations is to treat the furcation lesion with appropriate therapy (hemisection or bysection) and then, before the final restorative therapy, carry out the orthodontic movement in one or both roots until the ideal tooth position is reached (Muller *et al*. 1995).

Orthodontic tooth movements through cortical bone

When the alveolar width between the buccal and lingual cortical plates is not appropriate, orthodontic tooth movement into these areas may cause complications. Tooth movement through cortical bone may retard the rate of the movement and buccal and/or lingual bone dehiscences may develop. To avoid these unwanted consequences, bone augmentation procedures to increase the alveolar bone width before the orthodontic movement have been suggested (Diedrich 1996).

Edentulous ridge contraction is the physiologic consequence of tooth extraction. Most of the buccolingual reduction in the edentulous ridge will occur within the first 3 months after tooth extraction (Schropp *et al.* 2003), although this resorptive process may continue, albeit at a slower rate (Carlsson *et al*. 1967). Several authors have recommended orthodontic tooth movement into recently extracted areas to counteract this resorptive process and thus develop a new edentulous ridge. Ostler and Kokich (1994) demonstrated in a sample of 20 patients that this orthodontic tooth movement developed a new edentulous ridge with <1% of bone contraction at 4 years. Similar results were reported in an experimental study in dogs where the pressure side (towards the socket) showed increased bone height, while on the tension side the bone level remained unaltered (Lindskog-Stokland *et al*. 1993).

In edentulous areas the orthodontic movement of teeth with a reduced but healthy periodontium is usually possible with minimal loss of bone, provided the movement is parallel to the ridge and light orthodontic forces are used (Hom & Turley 1984), although even under the most optimal conditions, loss of attachment and bone support may occur (Goldberg & Turley 1989).

Experimental studies have shown that when bodily movements are carried out through the cortical bone in a labial direction, there is no bone formation in the buccal aspect of the tooth and a dehiscence defect occurs (Steiner *et al.* 1981). The labial root movement *per se* does not cause attachment loss and gingival recession, but results in bone dehiscence and thin soft tissues, which develop a site of low resistance for attachment loss due to inflammation or trauma (Wennström 1996). In contrast, lingual movements of labially displaced teeth showing dehiscence defects will result in new bone formation in the buccal aspect of the root, as well as soft tissue augmentation (Karring *et al*. 1982; Wennström *et al*. 1987). Wennström (1996) recommended the treatment of localized gingival recessions with orthodontic movements whenever the affected tooth was labially displaced and lingual orthodontic movements were possible. Pini Prato *et al.* (2000), however, recommended the placement of a gingival autograft prior to the orthodontic therapy in these situations in order to prevent periodontal attachment loss and the occurrence of recession defects, since pure lingual root movements through cortical bone are difficult and in most cases crown tipping or rotation components will occur, hence moving the root buccally and causing further bone dehiscence and soft tissue loss. Djeu *et al.* (2002) did not find a correlation between orthodontic labial inclination of mandibular central

incisors and the development of gingival recessions in a retrospective clinical study. Similar results have been reported by Artun and Grobety (2001) and by Ruf *et al.* (1998) in children. In adults, however, a prospective study showed a significant correlation between the incidence and the severity of recession lesions with excessive proinclination (>10°) of the mandibular incisors (Artun & Krogstad 1987). The main risk factors for developing or aggravating recession lesions after adult orthodontic therapy are the presence of a thin gingival biotype, an insufficient width of keratinized gingiva, gingival inflammation, and the presence of recession lesions before the orthodontic treatment (Melsen & Allais 2005). The final tooth inclination (>95°) and the thickness of the marginal gingiva (<0.5 mm) have been associated with the occurrence of recessions in mandibular central incisors in adults after orthodontic treatment (Yared *et al*. 2006). However, a recent longitudinal study in adults with mandibular prognathism subjected to orthognathic surgery concluded that, in spite of extensive labial tipping, there was no negative outcome for periodontal tissues of the mandibular incisors (Ari-Demirkaya & Ilhan 2008) (Fig. 58-8).

Intrusive tooth movements

Intrusive tooth movements can be attempted even in the situation of reduced periodontal support provided the periodontal tissues do not have any inflammation and the plaque control is excellent. Melsen *et al.* (1989) recommended the use of light forces for these intrusive movements (5–15 g/tooth) in order to avoid root resorption, mainly in teeth with reduced periodontal support with an increased crown-to-root ratio. There is controversy whether this orthodontic tooth movement should be recommended in the presence of angular bony lesions and intrabony defects. Ericsson *et al*. (1977) demonstrated in dogs that intrusive movements in the presence of plaque transform the supragingival plaque into subgingival plaque and periodontal pockets and infrabony defects develop as a result. Polson *et al.* (1984), however, showed that intrabony defects were resolved when teeth are moved bodily into the bony defect, provided there is no inflammation. Healing occurred through the formation of a long junctional epithelium and the periodontal attachment levels did not change. These results were contradicted by Melsen (1988), who in monkeys also demonstrated the resolution of bone defects by intrusive movement whenever a healthy gingival environment was assured, but healing occurred through the formation of a new connective tissue attachment and periodontal regeneration. In humans, several clinical studies have also shown improvements in clinical attachment levels with intrusive tooth movements in the absence of periodontal inflammation (Melsen *et al*. 1989; Cardaropoli *et al.* 2001).

Corrente *et al*. (2003) recommended the treatment of infrabony defects in anterior teeth by combining surgical periodontal therapy with intrusive orthodontic movements, and reported significant attachment gains and radiographic bone fill. Similarly, Re *et al*. (2004) reported a 50% reduction in recession after intrusion of periodontally comprised teeth. These movements, however, are not always predictable and some authors have recommended that intrabony defects are first treated with surgical periodontal regenerative procedures, followed by the intrusive tooth movement (Diedrich 1996; Re *et al*. 2002a). In the presence of circumferential bony lesions, providing they are not deep, orthodontic intrusive movements can resolve the defect. If these defects, however, are deep and wide angular lesions not amenable to periodontal regenerative procedures, orthodontic intrusive movements might also be recommended to improve the defect anatomy before carrying out the regenerative procedure (Rabie *et al*. 2001; Passanezi *et al*. 2007) (Fig. 58-9).

(b)

(c)

Fig. 58-9 (*Continued*) (b) Initial panoramic and lateral cephalogram depicting the bone loss. The periodontal charting after therapy shows lack of periodontal pockets except in the lower anterior region, with tooth 41 having a hopeless prognosis. (c) Orthodontic therapy was aimed at aligning the teeth by intrusion of maxillary teeth. Note the slight root resorption of the upper laterals after the orthodontic tooth movement.

(d)

Fig. 58-9 (*Continued*) (d) End of orthodontic therapy with proper alignment of the upper incisors and re-establishment of an occlusal plane. Note the resolution of the deep overbite by orthodontic tooth intrusion.

Orthodontic intrusion movements have also been recommended for leveling gingival margins with the adjacent teeth when treating extruded and malaligned teeth, since the mucogingival junction and the gingival margin will move apically together with the tooth (Erkan *et al.* 2007).

Orthodontic tooth movements and periodontal regeneration

Periodontal regenerative procedures are frequent in the treatment of chronic periodontitis, particularly in the presence of angular bony defects. These surgical techniques aim to establish a new periodontal attachment apparatus to a root surface previously affected by the destructive process of periodontitis. Histologically, periodontal regeneration requires the formation of new cementum on the affected root and the establishment of a new connective tissue attachment between the new cementum and the alveolar bone. Several regenerative technologies have demonstrated these outcomes in experimental studies, such as guided tissue regeneration (GTR), bone graft materials, and enamel matrix derivatives (EMDs), and the evidence on their clinical efficacy has been reported in several recent systematic reviews (see Chapter 45).

When orthodontic tooth movements are indicated in patients for whom periodontal regenerative surgeries have formed part of their periodontal therapy, there has been a debate on whether the quality of tooth movements through the regenerated periodontium might be different or whether these movements might create unwanted effects (root resorption, bone loss, ankylosis, etc.). There has also been controversy on the optimum timing for starting the orthodontic therapy after the regenerative procedure, as well as the necessary stability after moving teeth into regenerated areas. Most of these questions have been answered by experimental studies and further corroborated with clinical human research.

Diedrich *et al.* (1996) conducted a series of experimental studies demonstrating that the use of both resorbable and non-resorbable barrier membranes achieved periodontal regeneration and the subsequent orthodontic treatment did not affect the newly gained periodontal structures. Subsequently, several case reports in humans have corroborated these experimental results, also demonstrating the long-term stability of these periodontal structures when subjected to orthodontic therapy (Stelzel & Flores-de-Jacoby 1995; Efeoglu *et al.* 1997; Stelzel & Flores-de-Jacoby 1998; Aguirre-Zorzano *et al.* 1999).

Barrier membranes has also been utilized on fresh extraction sockets with the aim of preserving the edentulous ridge by preventing the remodeling processes of the socket walls (Tiefengraber *et al.* 2002). When teeth subsequently moved into these regenerated areas, the orthodontic therapy was uneventful and there were no complications. One of the limitations on the use of barrier membranes is the collapse of the barrier into the defect when the anatomy of the defect does not allow for space maintenance. To overcome this limitation, different bone grafts have been used to fill the defect and to support the barrier membrane.

Orthodontic tooth movements through regenerated bone after using xenografts of bovine origin have also been investigated in animal studies (Araújo *et al.* 2001; Kawamoto *et al.* 2002, 2003; da Silva *et al.* 2006; Zhang *et al.* 2006). Araújo *et al.* (2001) showed that orthodontic tooth movement was possible without

Fig. 58-10 Patient with severe chronic periodontitis, presence of deep intrabony defects in maxillary teeth, and severe malocclusion. (a) Intraoral images before orthodontic therapy. Note the anterior diastema, severe extrusion of maxillary right posterior teeth, and presence of edentulous spaces. (b) Initial panoramic, lateral cephalogram and periapical radiographic series depicting the bone loss and presence of deep intrabony defects in the upper incisors and the upper and lower left premolars.

any complication. The graft material was partially resorbed on the pressure side, while there was no sign of resorption on the tension side. These findings are explained by the enhanced osteoclastic activity with the tooth movement. Similar observations were made by da Silva *et al*. (2006) who implanted xenogeneic grafts into furcation defects. After the healing process, each tooth either underwent orthodontic tooth movement or remained in its initial position. They found no differences in the amount of newly developed bone and no signs of root resorption. Similar results were reported with the use of synthetic biomaterials and bio-glasses in rats (Hossain *et al*. 1996; Kawamoto *et al*. 2002; Zhang *et al*. 2006).

The results from these experimental studies have been corroborated in several clinical case series in humans where orthodontic movements were carried out in teeth previously treated with allogeneic and xenogeneic grafts and collagen barrier membranes. These cases showed stable bone levels 12–18 months after the end of the orthodontic therapy, without any unwanted side effects (Yilmaz *et al.* 2000; Ogihara & Marks 2002; Re *et al.* 2002b; Naaman *et al*. 2004; Maeda *et al.* 2005; Cardaropoli *et al*. 2006; Ogihara & Marks 2006; Pinheiro *et al*. 2006). There are however, no clinical trials comparing the outcome of orthodontic therapy in teeth with and without previous regenerative therapy (Fig. 58-10).

Fig. 58-10 (*Continued*) (c) Regenerative surgical procedure using guided tissue regeneration with a xenogeneic bone graft and a collagen resorbable membrane to treat the deep one-two wall defect in tooth 21. Dental implants were placed in the posterior mandible for anchorage during orthodontic therapy. Similarly, micro-screws were placed in the maxillary right posterior tooth for anchorage for the intrusive movements. (d) Orthodontic therapy was aimed at intruding the upper posterior right segment, aligning the teeth, closing the diastema, and distributing the spaces prior to final implant therapy in the posterior maxilla. The orthodontic tooth movements in the maxilla were carried out 9 months after the periodontal regenerative procedure.

(f)

Fig. 58-10 (*Continued*) (e) Final radiographs depicting stable bone levels and resolution of the intrabony defects. (f) End of orthodontic therapy with proper alignment of the upper incisors and re-establishment of an occlusal plane. Final restorations were done using full ceramic crowns.

Uneventful results have also been demonstrated for orthodontic movements in teeth previously treated with EMDs in both experimental studies (Diedrich 1996) as well as in human clinical case reports (Juzanx & Giovannoli 2007).

Pathologic tooth migration

Pathologic tooth migration (PTM) is a common complication of moderate-to-severe periodontitis and is often the motivation for patients to seek orthodontic therapy. It is characterized by significant changes in tooth position as a consequence of the disruption of the forces that maintain teeth in a normal relationship and it usually presents clinically by extrusion and flaring out of the anterior maxillary teeth, resulting in diastemata and increased overbite. Prevalence of PTM among periodontal patients has been reported to range between 30% and 55%. The etiology of PTM appears to be multifactorial, although the destruction of periodontal supporting tissues seems to be a major factor. In these teeth with reduced periodontal support, non-axial occlusive forces might contribute to the abnormal migration of teeth. This is frequent when posterior teeth are lost and the subsequent lack of arch integrity with an anterior component of force leads to a posterior bite collapse with loss of the vertical dimension. The soft tissue forces of the tongue, cheeks, and lips can also play a role in these unwanted tooth migrations, mostly resulting in the extrusion and flaring of the anterior teeth.

Treatment of this complex anatomic and functional condition requires a multidisciplinary approach with complete periodontal therapy to eliminate the infection and the inflammation of the periodontal tissues, followed by orthodontic therapy and restoration of the lost dentition with dental implants and/or prosthetic restorations (Fig. 58-11).

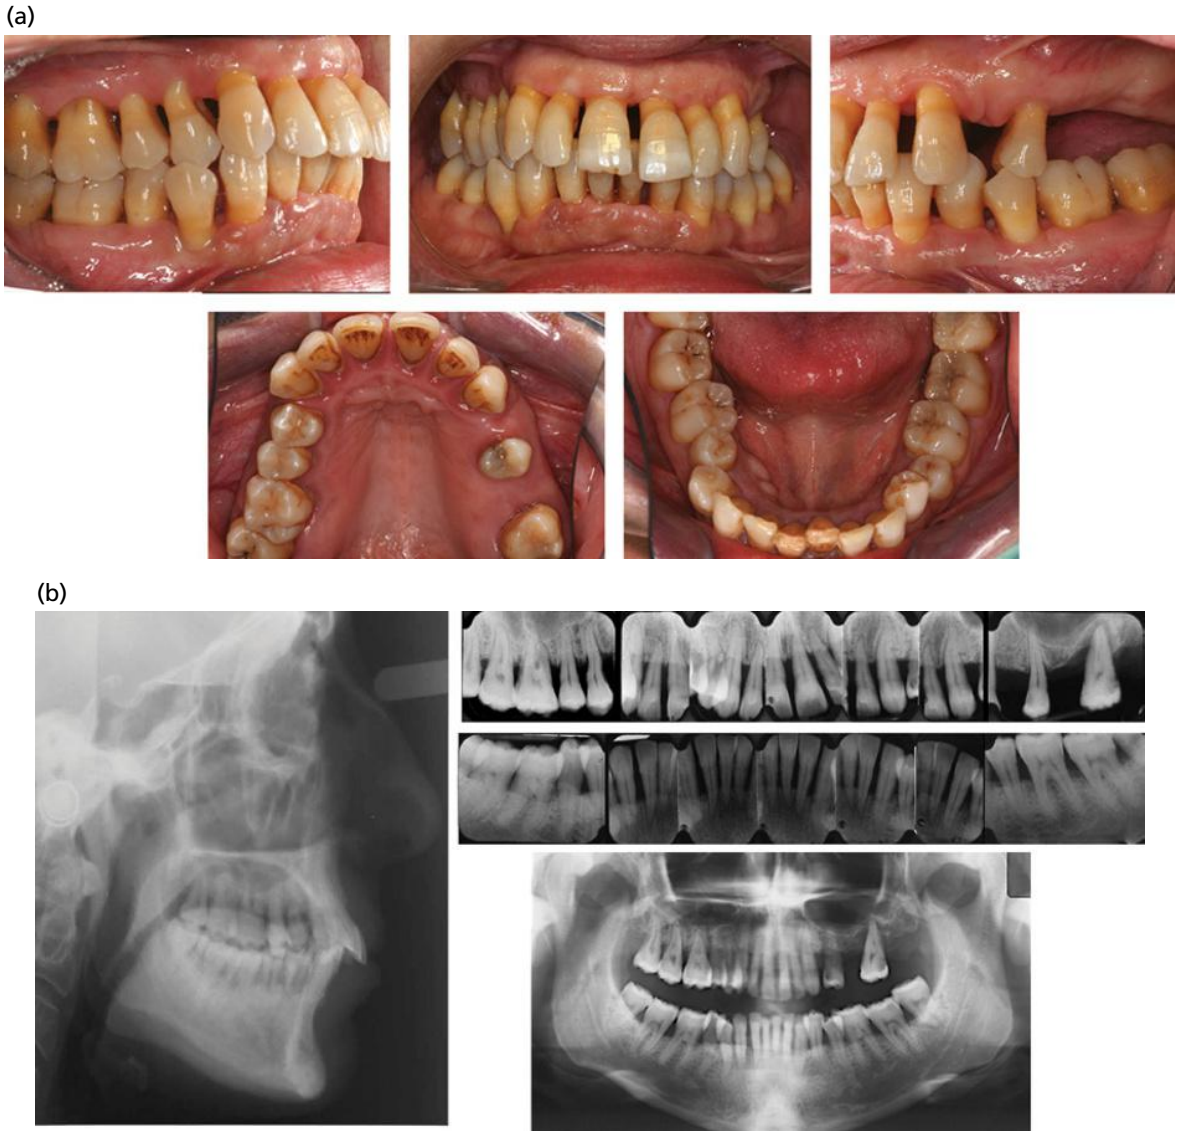

Fig. 58-11 Patient with severe chronic periodontitis, together with pathologic tooth migration, posterior right cross-bite, and posterior bite collapse. (a) Intraoral images after periodontal and before orthodontic therapy. (b) Radiographic images demonstrating the severe bone loss. Note the hopeless prognosis of tooth 26.

Fig. 58-11 (*Continued*) (c) Orthodontic therapy was aimed at intruding the upper anterior segment, aligning the teeth, and distributing the spaces prior to final implant therapy in the posterior left maxilla. (d) Final retention and esthetic treatment was accomplished with composite veneers. Note the improvement in the esthetic result and the lack of interdental papillae following the restorative work.

Multidisciplinary treatment of esthetic problems

During the course of orthodontic therapy in periodontally affected dentitions, the advent of unesthetic complications is relatively frequent, mainly related to loss of interdental papillae, gingival margin discrepancies or excessive gingival exposure (Kokich 1996; Gkantidis *et al*. 2010). Kurth and Kokich (2001) have reported a 38% prevalence of open gingival embrasures in the region of the maxillary incisors after adult orthodontic treatment. Improper root angulation, divergent or triangular-shaped crown forms, and periodontal bone loss are factors associated with this unwanted effect. Burke *et al*. (1994) correlated the incidence and size of pretreatment tooth overlap with the post-treatment gingival embrasure space between maxillary central incisors

in orthodontic patients. Another important factor in the loss of the interdental papilla is bone loss. Tarnow et al. (1992) correlated the distance from the contact point to the crest of bone with the presence or absence of the interproximal dental papilla. When this distance was ≤5 mm, the papilla was present in almost 100% of cases; when 6 mm, 56%; and when ≥7 mm, 27%. In the clinical situation where there is a combination of severe anterior crowding and periodontal bone loss, orthodontic therapy should be aimed not only at attaining the proper tooth alignment of the teeth, but also reducing the interdental space in order to compress the interdental soft tissues to force the formation of a new papilla. In these situations, the orthodontic tooth movement should be combined with restorative procedures aimed at raising the contact point, thus creating the illusion of a healthy interdental papilla.

The gingival marginal relationships of the upper anterior teeth play an important role in the esthetic appearance of the smile. These gingival marginal contours should mimic the natural anatomy of the tooth cementoenamel junction (CEJ), providing adequate scalloping with thin marginal tissues and papillae filling the interdental spaces. When orthodontic therapy is applied to periodontally affected dentitions, gingival marginal discrepancies are frequent and should be treated orthodontically with minor intrusive or extrusive tooth movements until the correct marginal alignment is reached. In situations with clear presence of localized marginal recessions, the appropriate mucogingival surgical techniques for root coverage should be implemented before the orthodontic tooth movement (see Figs 58-3, 58-5, 58-11).

It is very important to evaluate these gingival marginal discrepancies in relationship to the patient's gingival exposure during smiling and the length of the tooth clinical crowns (Kokich 1996). Depending on these factors, different combinations of periodontal plastic surgical techniques and orthodontic tooth movements will be indicated. In some situations, the indication will be the extrusion of the longer tooth and subsequent grinding of its incisal edge, while in others, it will be intrusion of the shorter tooth with subsequent reconstruction of its incisal edge.

The problem of excessive gingival exposure (a gummy smile) can also be found frequently in adults requiring adult orthodontic treatment. There can be several reasons for this: excessive maxillary growth, tooth extrusion in deep anterior overbites, and delayed apical migration of the gingival margin over the maxillary anterior teeth. Its esthetic correction largely depends on its etiology.

If the cause of the gummy smile is the extrusion of the upper anterior teeth, orthodontic intrusion will solve the problem, hence eliminating the excessive gingival display. In contrast, retardation of the physiologic apical migration of gingival margins will require a mucogingival excisional surgical correction. In situations with a clear skeletal cause, an orthognathic surgical approach is the only corrective solution.

Chapter 59

Implants Used for Orthodontic Anchorage

Marc A. Schätzle[1] and Niklaus P. Lang[1,2]

[1]Clinic of Orthodontics and Pediatric Dentistry, Center of Dental Medicine, University of Zurich, Zurich, Switzerland
[2]Department of Periodontology, School of Dental Medicine, University of Berne, Berne, Switzerland

Introduction

Anchorage is one of the limiting factors in orthodontics and its control is essential for successful orthodontic treatment. The term "orthodontic anchorage" was first introduced by Angle (1907) and later defined by Ottofy (1923). Orthodontic anchorage denotes the nature and degree of resistance to displacement of teeth offered by an anatomic unit when used for the purpose of tooth movement. The principle of orthodontic anchorage is implicitly explained in Newton's third law (1687), according to which an applied force can be divided into an *action* component and an equal and opposite *reaction* moment. However, even today, there is no evidence for the exact relation between an applied force and the velocity of the induced tooth movement (Ren *et al*. 2003). Nevertheless, reciprocal effects must be evaluated and controlled in orthodontic treatment.

Orthodontic anchorage is oriented to the quality of the biologic anchorage of the teeth. This is influenced by a number of factors such as the size of the root surfaces available for periodontal attachment, height of the periodontal attachment, density and structure of the alveolar bone, turnover rate of the periodontal tissues, muscular activity, occlusal forces, craniofacial morphology, and nature of the tooth movement planned for the intended correction (Diedrich 1993). Basically, each tooth has its own anchorage potential as well as a tendency to move when force is applied to it. When teeth are used as anchorage, the inappropriate movements of the anchoring units may result in a prolonged treatment time, and unpredictable or less-than-ideal outcomes.

To maximize tooth-related anchorage, techniques such as differential torque (Burstone 1982), moving the roots of the anchor teeth into the buccal cortical bone (Ricketts 1976), and distal inclination of the molars (Tweed 1941; Begg & Kesling 1977) may be used. If the periodontal anchorage is inadequate with respect to the intended treatment goal, additional intraoral and/or extraoral anchorage may be needed to avoid negative effects. Among these, extraoral (Kingsley 1880) and intermaxillary (Stewart *et al.* 1978) anchorage appliances are the most common. While the teeth are the most frequent anatomic units used for anchorage in orthodontic therapy, other structures, such as the gingiva or perioral soft tissues by means of plates or lip bumpers (Nevant *et al*. 1991;

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Osborn *et al.* 1991, Grossen & Ingervall 1995; Ferro *et al*. 2004), the lingual mandibular alveolar bone, the occipital bone, and the neck are also alternative support structures.

However, additional anchorage to provide extraoral and intraoral forces is visible and hence, compliance dependent (Nanda & Kierl 1992), as well as associated with the risk of undesirable effects such as tipping of the occlusal plane, protrusion, gingival recession of mandibular incisors, and extrusion of teeth.

Implants, mini-screws, and ankylosed teeth, do not possess a normal periodontal ligament as they are in direct contact with bone. As a consequence, they do not move when low-to-moderate orthodontic forces are applied (Melsen & Lang 2001; Hsieh *et al.* 2008; Wehrbein & Göllner 2009) and hence, may be used for "absolute anchorage" that is independent of patient compliance.

Evolution of implants for orthodontic anchorage

Skeletal anchorage was first attempted in 1945. Gainsforth and Higley (1945) placed vitallium screws and stainless steel wires into the ramus of dog mandibles and applied elastics that extended from the screw to the hook of a maxillary archwire to distally tip/retract the canine by immediate orthodontic loading (Fig. 59-1). Even though the authors did not describe the development of infection, the failures encountered may be attributed to infection and the lack of antibiotics at that time, as well as the early dynamic loading of the screws. Although minor tooth movement was accomplished using basal bone anchorage in two animals, an effective orthodontic force could not be maintained for >31 days.

Skeletal anchorage systems have since evolved from two directions. One such development originated from orthognatic fixation techniques used in maxillofacial surgery. The pioneers Creekmore and Eklund (1983) used a vitallium bone screw to treat a patient with a deep impinging overbite. The screw was inserted in the anterior nasal spine to intrude and correct the upper incisors using an elastic thread from the screw to the incisors 10 days after the screw had been placed. Subsequently, Kanomi (1997) described a mini-screw specially designed for orthodontic use.

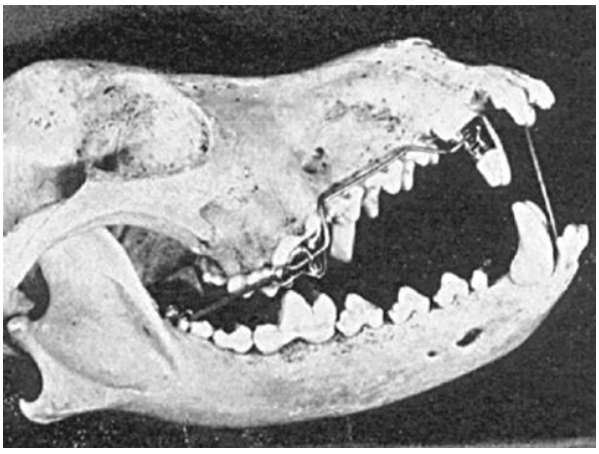

Fig. 59-1 Orthodontic appliance using vitallium screw anchorage. (Source: Gainsforth & Higley 1945. Reproduced with permission from Elsevier.)

The second development originated from applications in implant dentistry. Linkow (1969) used blade implants for rubber band anchorage to retract teeth, but never presented long-term outcomes. Later, endosseous implants for orthodontic anchorage were suggested (Ödman *et al.* 1988; Shapiro & Kokich 1988; Ödman *et al.* 1994). As indicated in various animal studies, osseointegrated titanium implants remained positionally stable under orthodontic loading and thus could be used for orthodontic anchorage (Turley *et al.* 1980; Roberts *et al*. 1984; Turley *et al.* 1988; Roberts *et al.* 1989; Wehrbein & Dietrich 1993; Wehrbein 1994; Wehrbein *et al.* 1998; De Pauw *et al.* 1999; Majzoub *et al.* 1999) (Fig. 59-2). This resulted in the development of specially designed implants in the retromolar area (Roberts *et al.* 1990) and the palatal site of the maxilla (Triaca *et al.* 1992; Wehrbein *et al.* 1996a). Both applications are used for direct or indirect anchorage, as described later.

From a clinical point of view, it is of relevance whether implants are to be used only as temporary anchorage devices (TADs) (Daskalogiannakis 2000) or are subsequently to be used as abutment for supporting prosthetic appliances. These aspects determine insertion sites, implant type and dimensions, as well as type of orthodontic anchorage. Moreover, the fact that these devices may need to be placed in growing patient is of particular importance. In these cases, only TADs are suitable.

Prosthetic implants for orthodontic anchorage

The insertion site of prosthetic implants for orthodontic anchorage is determined by the subsequent use of the implant as a prosthetic abutment. The length and diameter of implants depend on the later prosthetic use. Their positions within the alveolar process and number, however, have to be selected with reference to prospective final tooth position and space after orthodontic treatment.

It may be confusing to determine the location of the prosthetic implants before orthodontic therapy. This is especially true if the teeth are moving towards or away from the implant during orthodontic treatment. In these situations, the presumptive outcomes must be predetermined to achieve the proper implant location and the correct size of the crowns and pontics on the implant-supported prosthesis. In order to use oral implants for both orthodontic anchorage as well as the subsequent restorative therapy, protocols have been developed for determining the accurate placement of dental

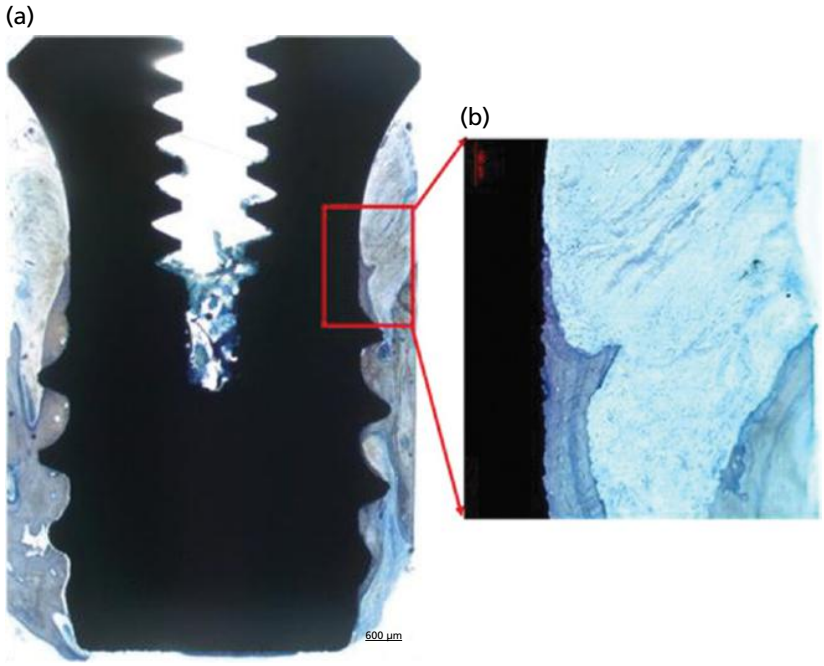

Fig. 59-2 (a) Histologic overview of a second-generation explanted palatal implant (4.1 mm × 4.2 mm; staining: toluidine blue, original magnification × 16). (b) Margin of bone coverage is at the junction (enlargement, staining: toluidine blue, original magnification × 100) between the microretentive SLA surface of the implant body and the smooth machined surface of the transmucosal neck. (Source: Jung *et al.* 2011a. Reproduced with permission from Springer Science and Business Media.)

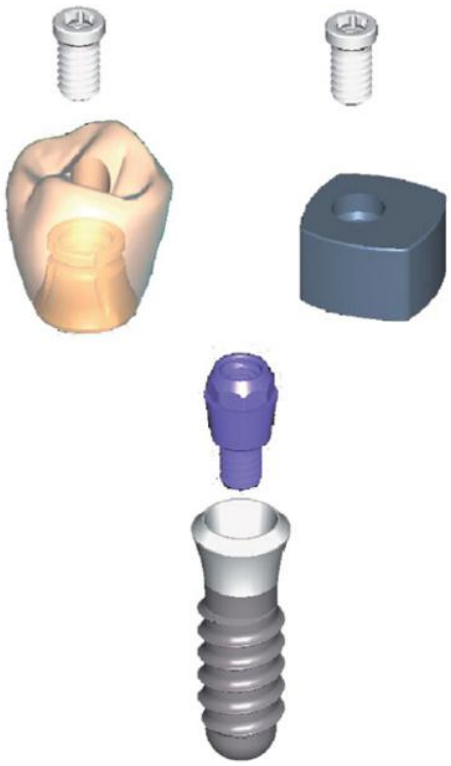

Fig. 59-3 Schematic illustration of the assembly of an orthodontic base on an oral implant intended for prosthetic use after the orthodontic treatment.

implants for prosthetic reconstruction before orthodontic therapy (Smalley 1995; Smalley & Blanco 1995). The clinician determines the proper implant location using a plastic placement guide that is constructed based on information derived from a diagnostic wax-up. Therefore, it is necessary to construct the set-up casts from an exact duplicate of the tooth and base portions of the original dental casts. The bases are used as a reference for the proposed position of the implant.

An orthodontic attachment is then either fixed to the provisional crown or to a prefabricated bonding base (Figs. 59-3, 59-4; see also Fig. 59-7). The orthodontic force acts at the implant suprastructure. The reactive moments and forces are then directly transmitted to the implant and its adjacent bone (direct implant anchorage).

Bone reaction to orthodontic implant loading

Dental implants should not only fulfil prosthetic stability, but also withstand the stress and strain applied during orthodontic treatment. The effect of orthodontic loading to the adjacent bone of the oral implant is of great interest, because the applied forces should not have a negative impact on the peri-implant bone and, therefore, should not impair the long-term prognosis as a prosthetic abutment. However, increased turnover of peri-implant bone is a commonly observed phenomenon with loading (Gotfredsen *et al.* 2001; Melsen 2001; Melsen & Lang 2001; Trisi & Rebaudi 2002). It has been demonstrated that the local strain distribution has a significant impact on the biologic activity of the peri-implant bone tissue. However, there are substantial differences between orthodontic forces and occlusal loading. Orthodontic forces are continuous and horizontal, while occlusal loads are discontinuous and mainly applied in a vertical direction on the implants/teeth.

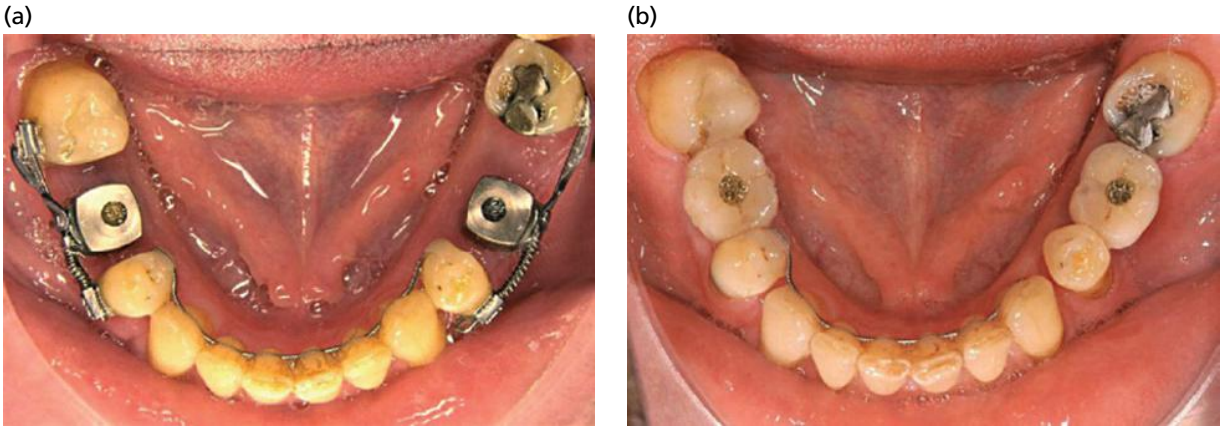

Fig. 59-4 Use of oral implants intended for prosthetic reconstruction as anchorage for orthodontic treatment. (a) Prefabricated orthodontic base as anchorage element. (b) Reconstruction of teeth 35 and 45 on oral implants following orthodontic treatment. (Courtesy P. Göllner and T. Liechti, Berne).

Table 59-1 Bone tissue turnover characteristics of alveolar bone in a relation to the magnitude of strain applied.

Strain values	Bone appositional surface in percentage	Resting bone (homeostatic surface in percentage	Bone resorptive surface in percentage
>6700 µstrain			
Mean	16.4	21.2	51.5
95% confidence interval	11–22	16–26	42–62
3400–6600 µstrain			
Mean	62.7	16.9	5.0
95% confidence interval	56–70	12–22	1–9
<3300 µstrain			
Mean	20.9	61.9	43.5
95% confidence interval	15–29	56–68	34–53

Source: Melsen & Lang (2001).

In monkeys, specially designed oral implants were inserted and subjected to well-defined continuous loading (Melsen & Lang 2001) (Table 59-1). None of the implants had lost osseointegration after 11 weeks of loading, but loading significantly influenced the turnover of the alveolar bone in the vicinity of the implants. Bone apposition was most frequently found when the calculated strain varied between 3400 and 6600 µstrain. Several other studies of applied orthodontic forces confirmed the apposition or increase in bone density rather than loss of bone surrounding an oral implant (Roberts *et al.* 1984; Wehrbein & Diedrich 1993; Asikainen *et al.* 1997; Akin-Nergiz *et al.* 1998).

Finite element analysis, however, indicated that not all force systems might be tolerated on a long-term basis. High strain values (>6700 µstrain) resulted in a negative balance between bone apposition and bone resorption (Melsen & Lang 2001). An study using a monkey model demonstrated that six of eight implants failed under excessive loading in the lateral direction during an 18-month period of observation (Isidor 1996). Similar findings were demonstrated in an experimental dog study (Hsieh *et al.* 2008). All implants loaded with a light continuous orthodontic force (100–200 g) remained stable during the whole study period and showed no displacement up to 6 months. However, tipping movement was observed 3 months after the implants were loaded with a force of >500 g. The extent of movement increased further after 6 months of force loading (Figs. 59-5, 59-6). The displacement occurred without loss of stability. Radiographic examination showed no apparent bone loss at the crestal area and around implant fixtures. The application of a well-controlled continuous force may be a critical factor leading to displacement with continuous bone formation in the surrounding peri-implant tissue.

Tipping of the implants might be a response to structural adaptation to strain (Frost 1987). The response to loading of intense strain may be the formation of woven bone, which possibly represents a physiologic process of microfracture repair (Burr *et al.* 1989; Jee & Li 1990; Melsen 1999). Displacement of implants under a high strain for a long period of time results from the accumulation of trabecular microfractures and adaptative remodeling during the orthodontic force application. Possible fatigue failure of cancellous bone around the loaded fixtures has also been postulated. If the damage exceeds repair on one side of an implant, then it is likely that implant migration will continue and the displacement will become obvious (Hsieh *et al.* 2008).

Even though osseointegrated implants might be considered to be "absolute" under low-to-moderate orthodontic loading over a long time (Turley *et al.* 1980; Roberts *et al.* 1984; Turley *et al.* 1988; Roberts *et al.* 1989; Wehrbein & Dietrich 1993; Wehrbein 1994; Wehrbein *et al.* 1998; De Pauw *et al.* 1999; Majzoub *et al.* 1999), but if the applied force exceeds a certain threshold of physiologic adaptation, the negative balance in the biologic

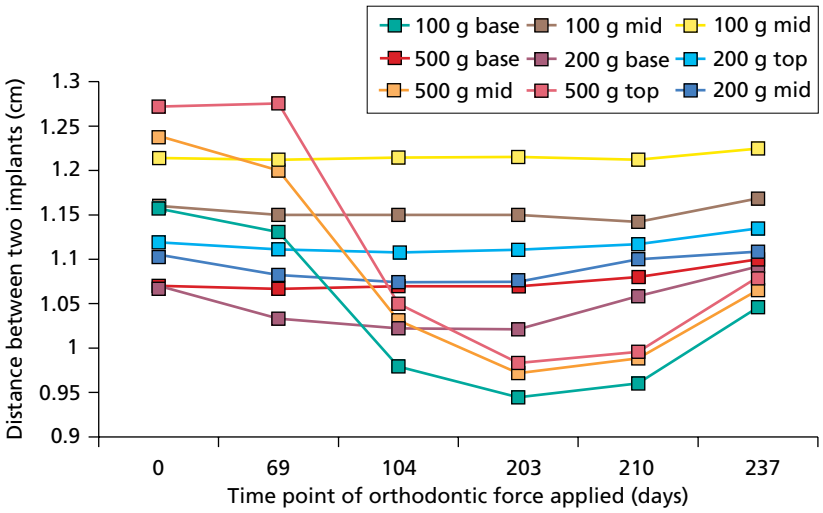

Fig. 59-5 Changes of distance between two implants measured at different levels after various durations of 100, 200, and 500 g force applications. (Source: Hsieh *et al*. 2008. Reproduced with permission from John Wiley & Sons.)

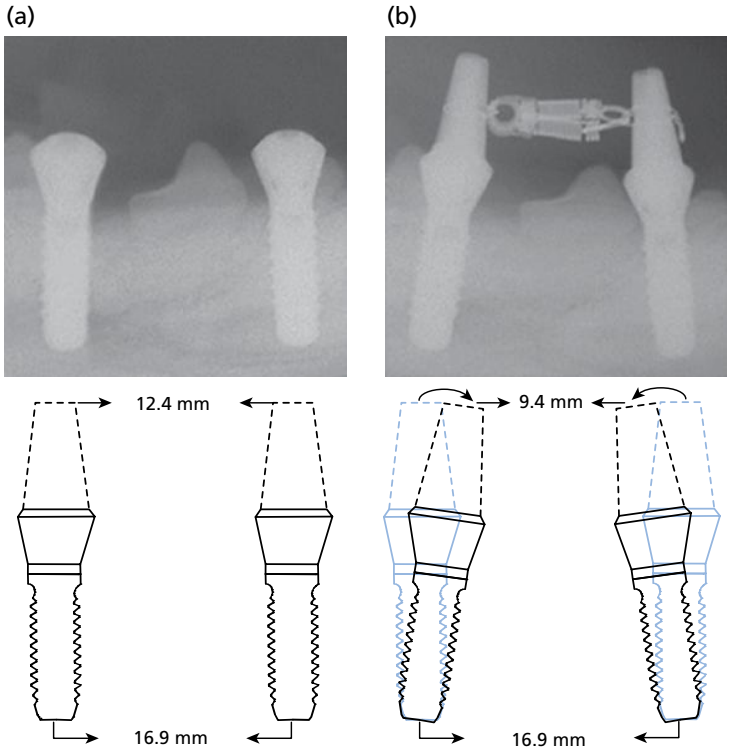

Fig. 59-6 Radiographs and the sketched illustrations showing the change of implant position after 6 months of a 500 g pulling force loading (Source: Hsieh *et al*. 2008. Reproduced with permission from John Wiley & Sons.)

response of peri-implant bone could possibly cause the displacement of the previously uneventful implant without marginal bone loss or complete disintegration. Therefore, endosseous implants may not be considered in all circumstances to be true "solid" or "ankylosed" anchorage, because of the dynamically biologic responses toward the stimuli from the surrounding environment under heavy loading (Isidor 1996; Melsen & Lang 2001; Hsieh *et al*. 2008).

Indications for prosthetic oral implants for orthodontic anchorage

Orthodontic anchorage provided by prosthetic oral implants may be indicated for partially edentulous adult patients with intra-arch malposition of teeth to correct over-eruption, infra-eruption or tipping of teeth; to retract anteriorly displaced frontal teeth and intra-arch protraction of teeth that are positioned distally to reduce a multi-tooth gap; or to improve tooth position in edentulous spaces (Fig. 59-7). Prosthetic oral implants might also be used for the correction of interarch malocclusion of single teeth or the entire dentition.

The most important factor in the entire process is interdisciplinary communication and planning. It is critically important for the orthodontist, periodontist, and restorative dentist to work closely as a team during the planning and treatment to achieve the best possible final result (Kokich 1996).

Prosthetic oral implant anchorage in growing orthodontic patients

The use of prosthetic oral implants in growing individuals has been studied in both clinical (Ödman *et al*. 1988; Thilander *et al*. 1994, 1999) and animal

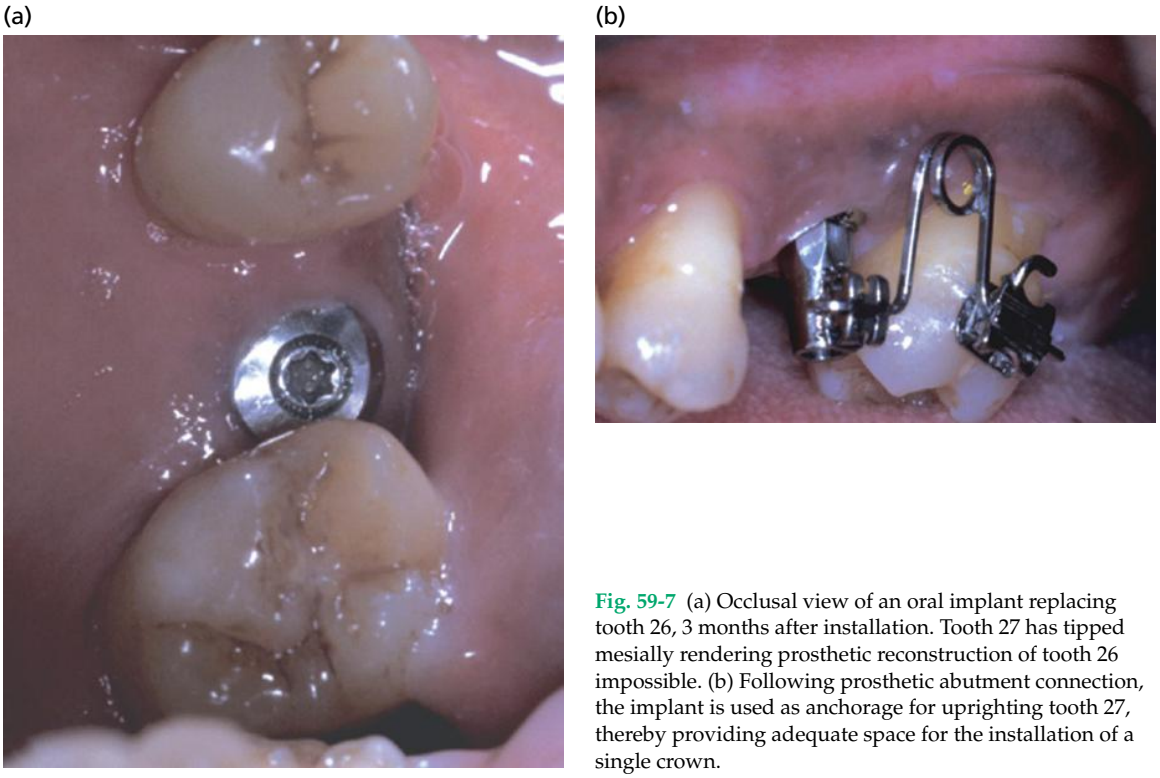

Fig. 59-7 (a) Occlusal view of an oral implant replacing tooth 26, 3 months after installation. Tooth 27 has tipped mesially rendering prosthetic reconstruction of tooth 26 impossible. (b) Following prosthetic abutment connection, the implant is used as anchorage for uprighting tooth 27, thereby providing adequate space for the installation of a single crown.

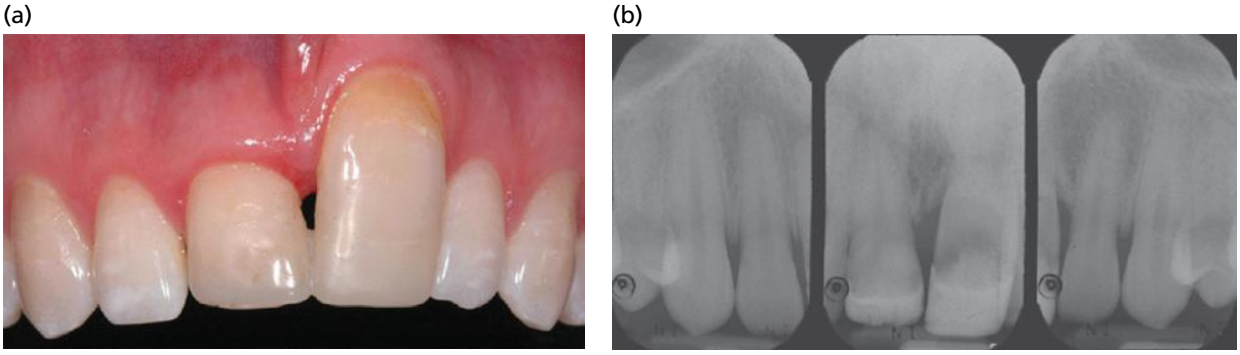

Fig.59-8 (a) Ankylosed tooth 21 after trauma and on-going composite adaptation throughout several years. Tooth 21 has not followed the changes associated with alveolar process growth. (b) Radiographic documentation 6 years following trauma of tooth 21, showing the development of the alveolar process with concomitant ankylosis of tooth 21.

studies (Ödman *et al.* 1991; Thilander *et al.* 1992; Sennerby *et al*. 1993). Like ankylosed teeth (Fig. 59-8), oral implants do not follow the developmental changes of the alveolar processes encountered in combination with continuous eruption of adjacent teeth (Fig. 59-9).

Moreover, the osseointegrated implants cannot be displaced in all dimensions during growth of the jaws (Thilander *et al.* 1994; Iseri & Solow 1996) and, hence, can impair the development of the surrounding bony structures and of adjacent teeth, leading to an infraocclusion of the single-tooth implant in the subsequent formative years (Bernard *et al.* 2004). Implant therapy in young individuals with residual growth potential has been addressed in several studies and identified major impairment in esthetic outcomes, especially in anterior implant-borne restorations.

However, treatment options for gaps between front teeth after dental trauma or agenesis in growing patients, based on skeletal anchorage, may serve as a useful adjunct (Figs. 59-10, 59-11) (Göllner *et al.* 2009a) to conventional options, such as space maintainers, adhesive bridges (Marinello *et al.* 1988), autotransplantation of teeth (Paulsen & Andreasen 1998; Czochrowska *et al.* 2000) or orthodontic space closure (Czochrowska *et al.* 2003; Kugel *et al*. 2006). Fixation of dentures to palatal implants ensures stability even in the presence of mixed dentition and may be fitted to the vertical growth of the alveolar process at any time by grinding the plastic base.

To assess the remaining facial growth potential, hand–wrist radiographs have been proposed, but do not appear to be specific enough. The best method of evaluating the completion of facial growth is based

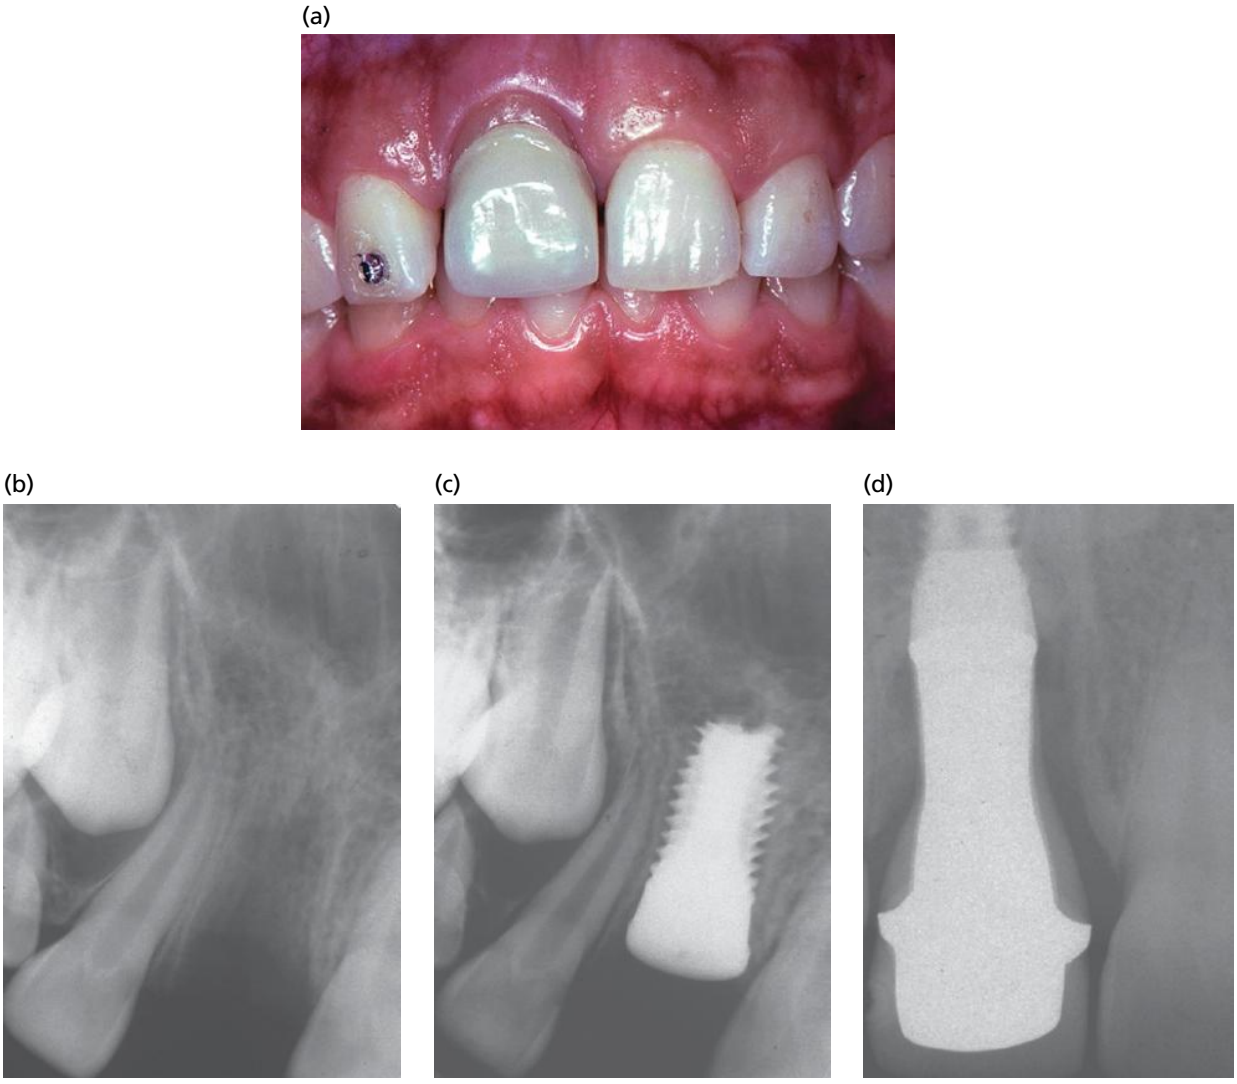

Fig.59-9 (a) Oral implant placed prematurely (at age 9 years) in a growing patient. The implant did not follow the growth development of the alveolar process, resulting in the need for multiple (3×) replacement of the prosthetic reconstruction until adolescence. Unsatisfactory esthetic outcomes persisted. on the superimposition of sequential cephalometric radiographs. It is, therefore, advisable to await the completion of adolescent growth in height. At that point, a cephalometric radiograph should be taken. Another radiograph should be taken at least 6 months to a year later. If, when these radiographs are superimposed, no change is seen in vertical facial height (nasion to menton), completion of facial growth may be assumed. The installation of an oral implant at that time may no longer be associated with significant eruption of adjacent teeth (Kokich 2004).

In most adult patients, however, completion of facial growth is assumed and yet, residual growth and aging changes affecting the alveolar process may be encountered. This was documented in a retrospective study (Bernard *et al*. 2004), supporting the assumption that mature adults also may exhibit major vertical steps in growth after anterior restorations were inserted on osseointegrated implants, due to continuing vertical eruption of the adjacent teeth.

Orthodontic implants as temporary anchorage devices

Fundamental differences with respect to implant dimensions, insertion sites, type of implant anchorage, and intended duration of implant use exist. The most important difference is whether or not a TAD is to be removed after completion of the intended orthodontic tooth movement (Daskalogiannakis 2000).

Implant designs and dimensions

As regular orthodontic patients do not display edentulous bony ridges for the insertion of an implant, implants for orthodontic anchorage must be placed in areas other than the usual topographic locations foreseen for the replacement of missing teeth. Besides the installation of orthodontic anchorage implants into the retromolar area of the mandible (Roberts *et al.* 1990; Higuchi & Slack 1991), the mid-sagittal palatal region (Triaca *et al.* 1992; Block & Hoffmann 1995; Wehrbein *et al*. 1996b) was also proposed.

The introduction of diameter-reduced TADs, such as mini-screws (<2 mm) of various lengths (Kanomi 1997; Costa *et al*. 1998) and titanium pins (Bousquet *et al*. 1996), as well as L-shaped miniplates with the long arm exposed to the oral cavity (Umemori *et al*. 1999) and zygomatic anchors (De Clerck *et al*. 2002) both fixed by bone screws, has offered new additional insertion sites: the interradicular septum (Bousquet *et al.* 1996; Kanomi 1997), the supra-apical and infra-zygomatical area (Kanomi 1997; Costa *et al*. 1998; Umemori *et al.* 1999;

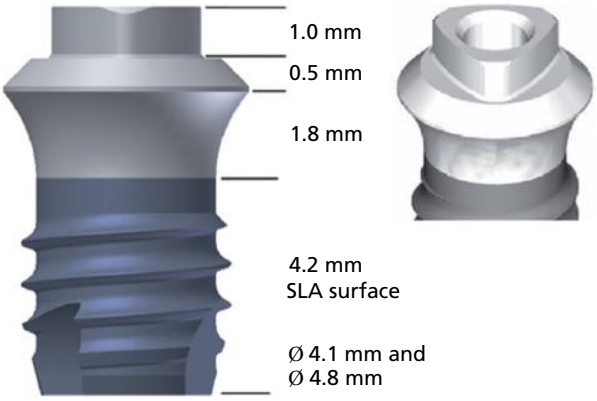

Fig. 59-12 Orthosystem® (Institut Straumann, Waldenburg, Switzerland) designed for orthodontic anchorage with an intraosseous SLA rough surface, a smooth transmucosal portion, and a trigonal orthodontic fixation base. (Courtesy of Institut Straumann AG.)

De Clerck *et al.* 2002), and the mandibular symphysis (Costa *et al.* 1998).

Length-reduced orthodontic anchorage devices such as titanium flat screws (Triaca *et al.* 1992), resorbable orthodontic implant anchors (Glatzmaier *et al.* 1995), T-shaped orthodontic implants (Wehrbein *et al.* 1996a) (Orthosystem®; Institut Straumann, Waldenburg, Switzerland), and the Graz implant-supported pendulum (Byloff *et al.* 2000) were subsequently introduced.

Another device, the Onplant® (Block & Hofmann 1995), placed subperiostally, is a smooth titanium disk with a hydroxyapatite-coated surface that is supposed to connect to the bone. Owing to the submerged installation, the monitoring of the healing process of the Onplant® may be troublesome, and its osseointegration may be questionable (Celenza & Hochman 2000). In a systematic review on the survival and failure rates of orthodontic TAD, the Onplant® showed the highest failure rate of 17.2% (95% CI 5.9–35.8%) and it may therefore be regarded as obsolete (Schätzle *et al.* 2009b).

The most widely used orthodontic anchorage system is the Orthosytem® (Institut Straumann). This titanium implant has three distinct features (Fig. 59-12): a self-tapping endosseous body, 4.2 mm long and either 4.1 mm or 4.8 mm in diameter, designed to be inserted into bone; a smooth neck portion (4.8 mm in diameter and 1.8 mm in length) serving as the transmucosal part; and a trigonal head for orthodontic appliance fixation.

Insertion sites for palatal implants

The incomplete closure of the median palatal suture during childhood and early adolescence might be a limiting factor for the installation of orthodontic implants in the mid-sagittal region for fully grown juveniles and adults. When analyzing the palatal suture status on occlusal films of young adults, a radiologically invisible mid-palatal suture is not a histologic equivalent of a fused or closed suture, respectively. Rather, it corresponds histologically to a relatively large area of interdigitation, an oblique running suture course in relation to the X-ray path or bone structures projecting above the suture course (Wehrbein & Yildizhan 2001). Therefore, the paramedian regions of the hard palate (Bernhart *et al.* 2000, 2001) may represent a feasible alternative implant site. With respect to anatomic limitations, sites chosen for palatal orthodontic anchorage device insertion should be carefully evaluated to avoid perforation of the inferior nasal turbinate (Wehrbein *et al.* 1996b). Pre-implantation examinations of the anterior palate have shown that the vertical bone volume decreases from the anterior to the posterior region.

The presence of the palatal suture and the limited bone thickness of the hard palate available may be causes of concern for the achievement of stability of palatal implants. However, a histologic evaluation of palatal anatomic sites for implant insertion showed that in most cases, a good primary stability of TADs might be achieved in the mid-palatal and paramedian areas of the anterior palate, as the bone conditions are favorable and available bone quantity is high (Wehrbein 2008). From this point of view, the mid-palatal bone area is a favorable region for short TAD placement, as most frequently relatively compact bone is present in this area. Thereby, from a morphologic standpoint, a good primary stability should be achieved and the success rate as well as the bone-to-implant contact should be high in the palatal bone. However, a small percentage of cases (9%) remains in whom critical bone conditions for implant placement may be present (loose spongious bone) (Wehrbein 2008).

Nevertheless, it may be useful to perform imaging diagnosis before palatal implant insertion. Dental computed tomography (CT) and/or lateral cephalograms have been recommended for evaluating the vertical bone volume of the hard palate presurgically. Dental CT of the alveolar process is well established for the evaluation of the alveolar bone volume before implant placement (Lindh *et al.* 1995). It may also be used to assess the vertical bone volume of the hard palate and is currently the most accurate method for this.

A number of authors recommend the routine application of these procedures for preoperative diagnosis and planning of skeletal TADs, especially for palatal implants (Bernhart *et al.* 2000; Bantleon *et al.* 2002; Gahleitner *et al.* 2004; Kang *et al.* 2007; King *et al.* 2007; Wexler *et al.* 2007). However, this recommendation is largely based on theoretical considerations of potential complications, such as perforation of the nasal floor or damage to the incisory nerve (Jung *et al.* 2011b).

The greatest mean thickness of the vertical bone volume was identified on low-dose dental CT to be about 6–9 mm posterior to the incisal foramen in the mid-sagittal plane (Bernhart *et al.* 2000). Avoiding the

mid-palatal suture, the area suitable for implant placement is, therefore, located 6–9 mm posterior to the incisal foramen and 3–6 mm lateral to the mid-sagittal plane. If the necessary bone volume for an orthodontic implant installation is defined as 4 mm or more, 95% of the patients investigated in the study by Bernhart *et al.* (2000) had adequate vertical bone volume for accommodating palatal implants with a length of 4 mm, and this agreed with other clinical reports (Schiel *et al.* 1996). Insisting on obtaining precise information for the intended implant sites before placing palatal implants using lateral cephalograms rather than CT examination was proposed (Wehrbein *et al.* 1999a). Since the former are used for orthodontic diagnosis and treatment planning, this would spare patients from additional radiation exposure. Furthermore, superimposition of structures in CT scans renders this methodology complicated, imprecise, and hazardous for the presurgical assessment of bone volumes for orthodontic anchorage implants.

On wire-marked skulls, the highest bony demarcation of the palatal complex seen radiographically largely coincided with the nasal floor, rather than with the mid-sagittal nasal septum, which offers additional vertical bone height (Wehrbein *et al.* 1999a). Hence, it was suggested that the vertical bone heights in the anterior and middle thirds of the hard palate were at least 2 mm greater than identified on lateral cephalograms. A safety level of at least 2 mm is, therefore, recommended when planning treatment on the basis of lateral cephalograms (Wehrbein *et al.* 1999a). The vertical dimension on lateral cephalometry reflects the minimum quantity of bone, which is usually seen in the parasagittal plane, and not the maximum quantity of vertical bone in the median plane. Therefore, preoperative CT or cone-beam computed tomography (CBCT) is only indicated when lateral cephalometry reveals a marginal quantity of bone (Jung *et al.* 2011b, 2012b).

It must be realized that even though some implants may project beyond the nasal floor in lateral cephalograms, they may represent false-positive results rather than actual penetrations into the nasal cavity (Crismani *et al.* 2005c). If the palatal complex is perforated, intraoperative probing with a periodontal probe or a sinus probe must be performed for verification.

In addition to the palatal bony morphology, the anteroposterior location and inclination of the implant when placed mid-sagitally must also take into account both the pretreatment and planned final position of the maxillary central incisor (Figs. 59-13, 59-14).

A distinction has to be made between the vertical bone volume in the mid-sagittal and the paramedian regions as the indication for implant treatment in the mid-sagittal plane should be limited to adults and fully grown juveniles due to possible developmental disturbances of the palatal suture (Glatzmaier *et al.* 1995; Wehrbein *et al.* 1996).

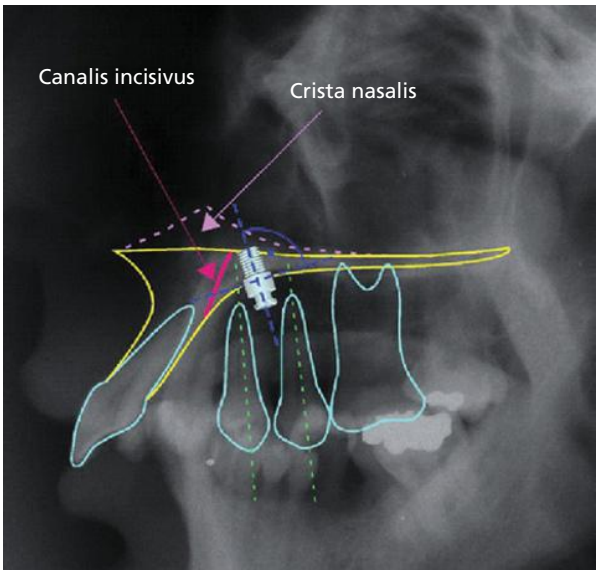

Fig. 59-13 Most palatal implants are installed satisfactorily when the location of entry into the cortical bone is at the anteroposterior level of the maxillary first and second premolars, perpendicular to the palatal surface (Source: Männchen & Schätzle 2008. Reproduced with permission from John Wiley & Sons.)

Palatal implants and their possible effects in growing patients

During growth, maxillary expansion in the transverse direction is the result of two processes: appositional remodeling of the alveolar process and growth of the palatal suture (Björk & Skieller 1974). While the remodeling process leads to the expansion of the dental arches, the growth in the median suture leads to the expansion of the palate and this is the most important factor in the development of the maxillary width. An average growth in maxillary width of 3 mm between the ages 10 and 18 years was demonstrated (Björk & Skieller 1977). Since the median or paramedian anterior palate may be chosen as the insertion site for palatal implants, the question arises whether or not the implantation of an orthodontic anchorage device may affect normal transversal palatal growth. Palatal implants affected normal transverse growth in an animal study (Asscherickx *et al.* 2005). It could be shown that implant placement resulted in less transversal sutural growth.

Deficient transverse maxillary width may also cause maxillary arch length discrepancies, as demonstrated for canine impaction (McConnell *et al.* 1996). Therefore, all interventions that might cause a restriction in normal transverse maxillary growth should be avoided. Because it has been shown that the insertion of implants in the median palatal suture in adolescent Beagle dogs could cause restriction in normal transverse development of the palate (McConnell *et al.* 1996), orthodontic palatal implants are better installed in paramedian areas in growing individuals. Moreover, studies have suggested that the installation of orthodontic implants in the mid-palatal suture of growing patients is contraindicated because of the

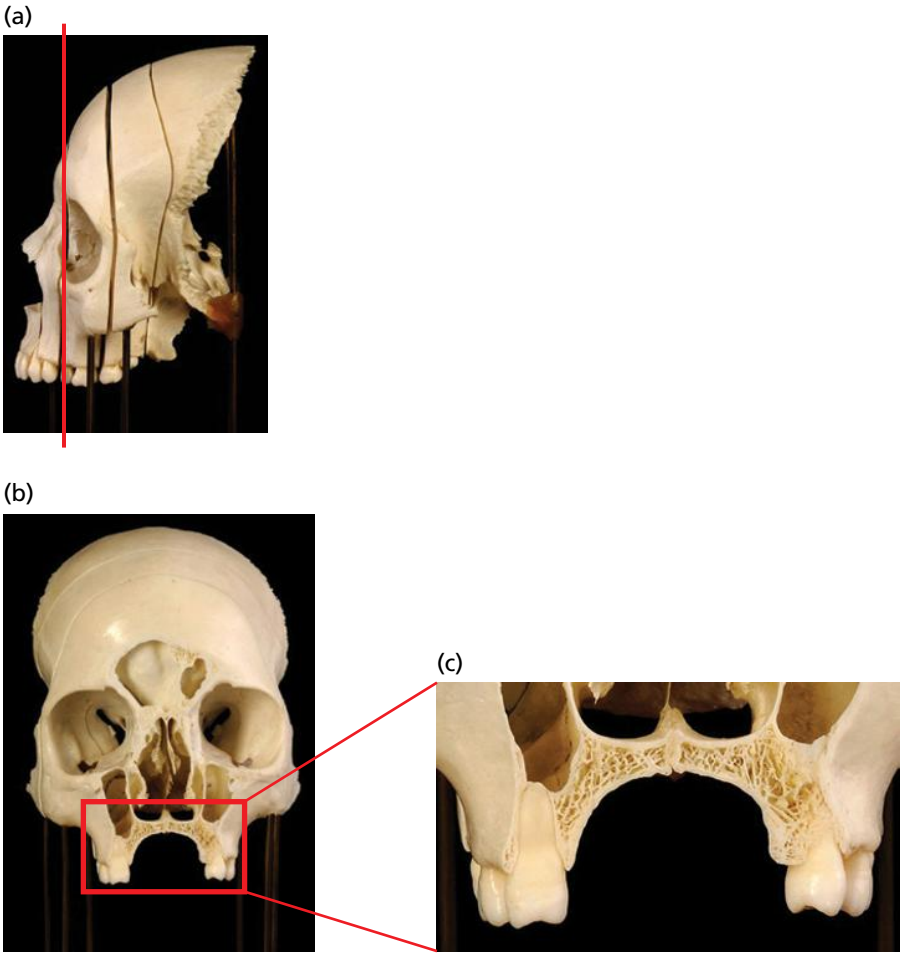

Fig. 59-14 (a–c) Macerated skull illustrating the location of the palatal implant insertion site at the anteroposterior level of the maxillary first and second premolars.

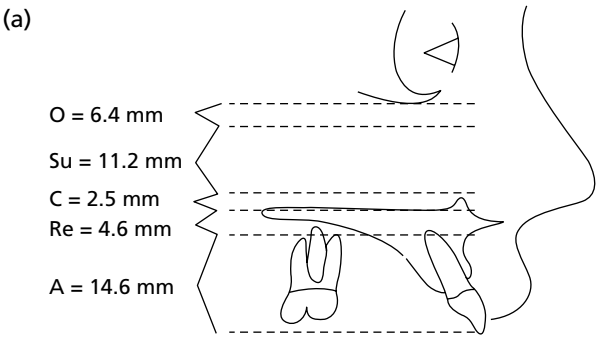
questionable quality of bone to provide adequate primary stability (Bernhart *et al.* 2001; Lioubavina-Hack *et al.* 2006). However, this could not be confirmed in a human histologic study (Wehrbein 2008). The paramedian region of the anterior palate, in contrast, is largely stable from a growth point of view (Thilander 1995).

The most important vertical growth changes are the result of the displacement of the maxillary complex and surface remodeling processes. The sutural lowering of the maxillary complex as well as the apposition at the orbital floor and at the infrazygomatic crest will not be affected by implant installation in the palate. The resorptive lowering of the nasal floor, however, and the increase of the maxillary alveolar bone height might be influenced. The mean degree of growth from the age of 4 years to adulthood has been identified (Björk & Skieller 1977). The nasal floor appears to drift 4.6 mm caudally, and the height of the maxillary alveolar bone appears to increase by 14.6 mm. Assuming that about one-third of these growth changes take place between the age of 12 years and adulthood implies a residual vertical growth of about 1.5 mm in the palate and of about 5 mm in the maxillary alveolar bone height (Fig. 59-15).



(b) Vertical growth 4 years – adult

Osseointegrated implants are in direct contact with bone, do not possess a periodontal ligament, and, hence, behave like anklyosed teeth. Therefore, an osseointegrated palatal implant will remain 1.5 mm behind its surrounding bone, whereas an implant placed in the alveolar bone will produce an infra-occlusion of 5 mm during the same period. Consequently, palatal implants directly or indirectly attached to teeth lead to an infra-eruption of a single tooth, several teeth or the whole upper dentition. By influencing the maxillary vertical growth dimension, the horizontal displacement of the mandible will also be affected and will, therefore, have a closing effect on the mandibular plane angle (anterior mandible rotation). It must be considered, however, that palatal implants as TAD usually remain *in situ* for 1–2 years. Thus, potential vertical and transversal growth impairments are likely to be limited to values of <1 mm.

Clinical procedures and loading time schedule for palatal implant installation

Patient stress during implantation and/or explantation and subsequent wound healing may be minimized by applying a minimally traumatic surgical

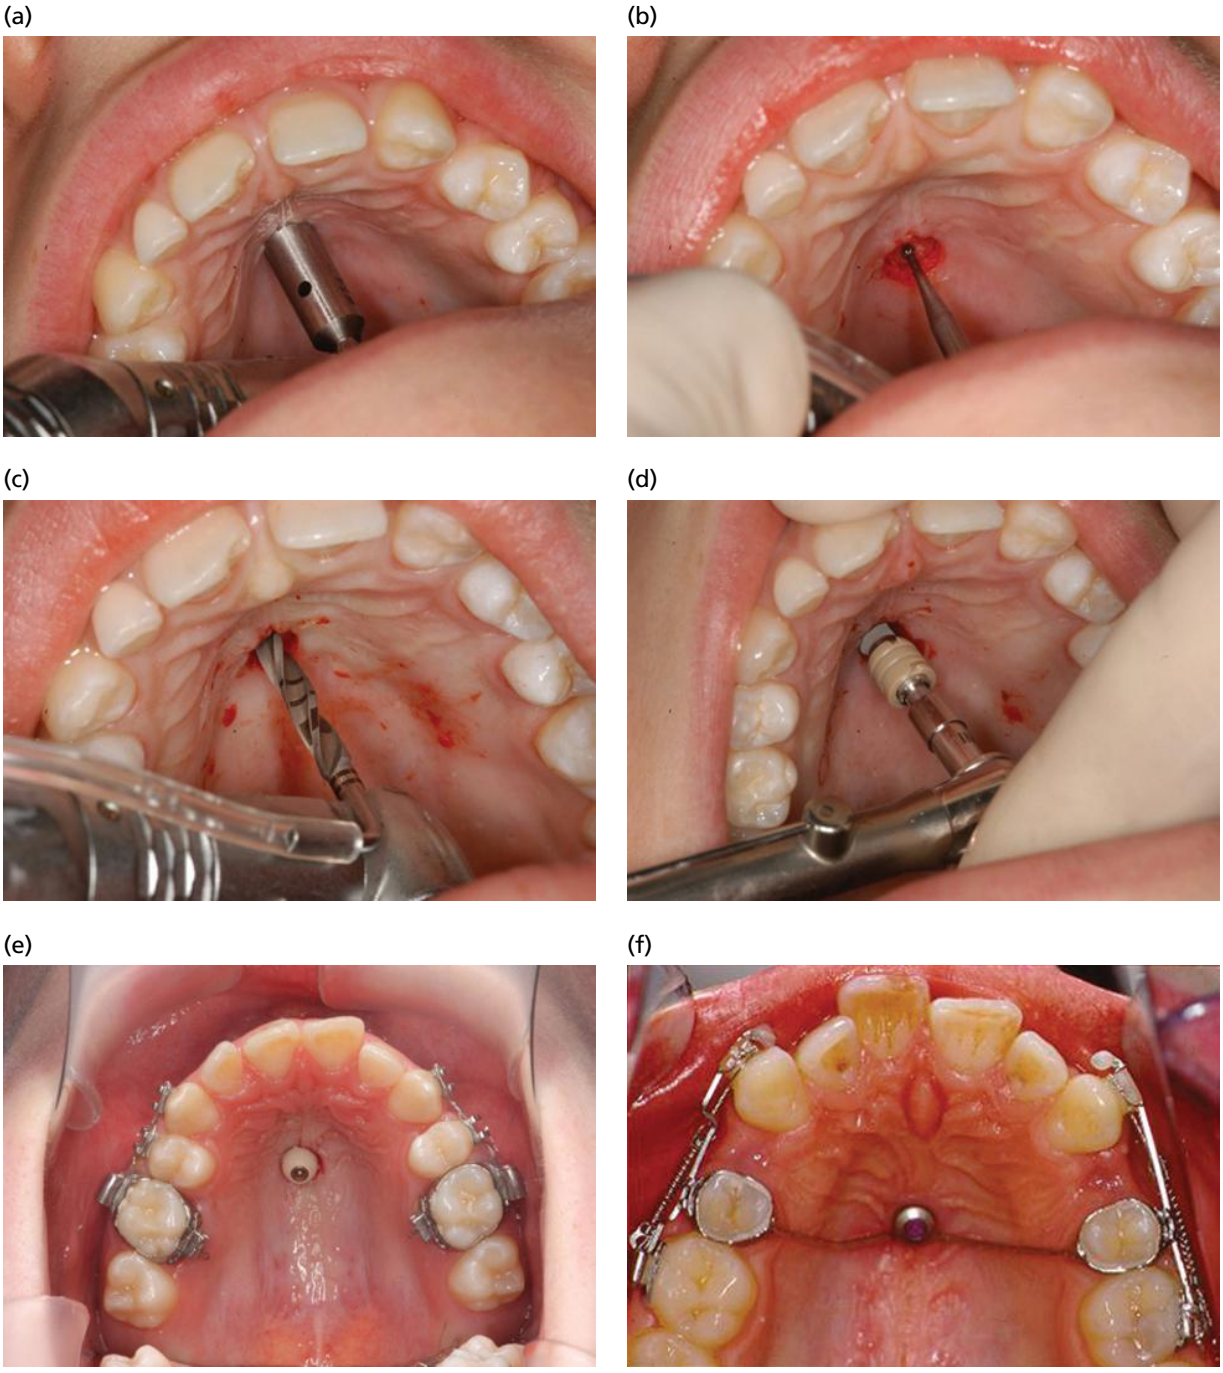

Fig. 59-16 Clinical procedures to install a palatal Orthosystem® (Institut Straumann, Waldenburg, Switzerland). (a) Perforation of the palatal mucosa using a system-compatible punch or trephine. technique. Under palatal local anesthesia, the palatal mucosa is perforated to the cortical bone using a mucosal punch or a system-compatible trephine during explantation, and removed with an elevator or a curette (Fig. 59-16a). After smoothing the exposed bone surface to prevent the profile drill from slipping, the center of the implant site is marked with a round bur (Fig. 59-16b). The implant bed is then prepared to the required depth using a series of pilot and twist drills (Fig. 59-16c). The drilling axis perpendicular to the bone surface is defined based on the presurgical cephalometric analysis. While preparing the insertion site, intermediate drilling and cooling of the drilling channel continuously with precooled physiologic saline or Ringer's solution should be performed. The implant is then hand-installed as far as possible, and a ratchet is used to tighten the implant to its final position (Fig. 59-16d). In a randomized clinical study of the pain intensity and discomfort in 120 patients following palatal implant placement and premolar extraction, it was shown that pain intensity after surgical installation of an Orthosystem® implant was significantly less than after installation of an Onplant® or premolar extraction (Feldmann *et al.* 2007). The implant is covered with the healing cap to prevent the inner screw well of the implant from clogging up and from being covered by hyperplastic mucosal tissue (Fig. 59-16e). After insertion, the palatal Orthosystem® implant is allowed to heal *in situ* for 12 weeks during which time it should not be loaded.

In some cases, there may be a premature loss of the implant prior to orthodontic load. This loss may be caused by the lack of adequate primary stability. Such insufficient primary stability causes an inappropriate healing and the possible premature loss of the implant (Friberg *et al.* 1991; Lioubavina-Hack *et al.* 2006). Therefore, it is generally recommended to use the 4.1-mm diameter palatal Orthosystem® implant. The 4.8-mm diameter device should only be used if the prerequisite of primary stability cannot be achieved with the smaller (regular 4.1 mm)-diameter implant.

Following the placement of an endosseous implant, primary mechanical stability is gradually replaced by biologic bonding. The transition from primary mechanical stability, provided by the implant design, to biologic stability provided by the osseointegration process occurs during the first month of wound healing (Berglundh *et al.* 2003; Schätzle *et al.* 2009a). In an experimental human study on the transition from primary to secondary stability by means of resonance frequency analysis, it could be shown that this transition from bone resorption to apposition corresponding to an increasing stability was evident 35 days (5 weeks) after implant installation and it took almost 84 days (12 weeks) to reach the initially measured values of the implant stability quotient (Crismani *et al.* 2006; Schätzle *et al.* 2009a). During this critical time, the orthodontic implant should not be used as anchorage.

The installation of implants as absolute anchorage devices facilitates and accelerates orthodontic

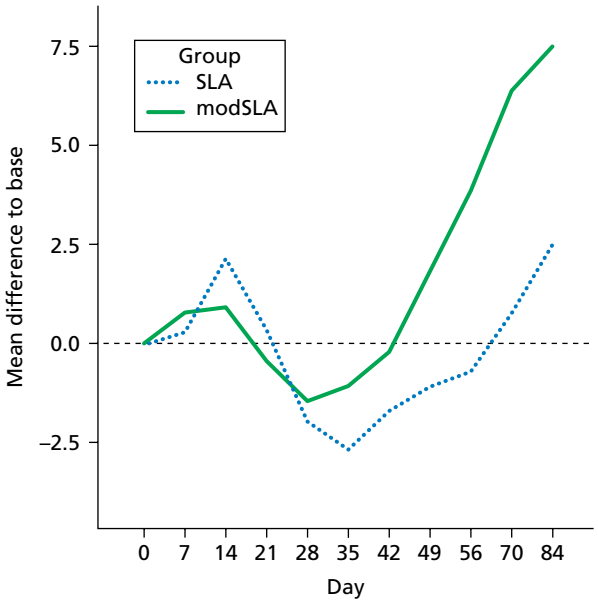

Fig. 59-17 Mean implant stability quotient (ISQ) changes in SLA and modSLA palatal implants from the baseline. (modSLA, modified sandblasted/acid-etched.) (Source: Schätzle *et al.* 2009a. Reproduced with permission from John Wiley & Sons.)

therapy (Trisi & Rebaudi 2002), even though there is still an inactive waiting time of at least 3 months after insertion (12 week healing time) (Wehrbein *et al.* 1996a, 1998; Keles *et al.* 2003; Crismani *et al.* 2005a, b). Especially in adult patients, there is a growing need to reduce this inactive waiting time and to reduce the risk for implant failure during early loading. There are several studies that have reported a successful outcome of early/immediate-loaded conventional dental implants placed in the edentulous ridge (Calandriello *et al.* 2003; Rocci *et al.* 2003; Bischof *et al.* 2004; Gallucci *et al.* 2004; Glauser *et al.* 2004; Jaffin *et al.* 2004). However, there are only two studies evaluating early loaded palatal orthodontic implants in humans by means of resonance frequency analysis (RFA). A retrospective clinical study of immediate versus conventional loading of palatal implants in humans reported a higher failure rate and a lower bone-to-implant contact rate for immediate indirect loading of palatal implants (Göllner *et al.* 2009b). On this basis, the possibility of loading palatal orthodontic implants earlier than recommended in the aforementioned literature was suggested with caution (Crismani *et al.* 2006; Schätzle *et al.* 2009a) (Fig. 59-17). A prospective multicenter study presented encouraging results: immediate indirect loading of palatal implants yielded success rates equivalent to those for conventional loading to 4 N after 6 months (Jung *et al.* 20011c). In a bicenter study, however, the vast majority of the implant failures occurred in the first and the second month post insertion (Jung *et al.* 2012a).

There is still a lack of histologic documentation about adequate healing periods before loading orthodontic implants in the palatal region. Further studies are needed to document the sequential histologic changes in the transition from primary stability to the process of osseointegration, and to define possible shorter appropriate healing periods.

After the recommended inactive healing period, an impression is taken for the construction of the transpalatal arch (TPA) connection (Fig. 59-16f, g). After integration of the TPA, the implant-related orthodontic treatment is begun. Depending on the treatment goal, schedule, and TPA design, different palatal arches may be necessary during the course of treatment in the same patient.

Direct or indirect orthodontic implant anchorage

Reliable three-dimensional attachment of orthodontic wires to the orthodontic implant is of crucial importance. There are two principles in using implants for orthodontic anchorage:

- Orthodontic forces are applied at anchorage teeth that are not to be moved and are to be kept in position through a rigid connection (e.g. TPA, lingual arch) with the implant (*indirect anchorage*) (Wehrbein *et al.* 1996). The element connected directly to teeth may limit the tooth movements and require adaptation or refabrication of the TPA by a dental technician (Fig. 59-16f).
- If force systems act directly between the teeth to be moved and the implant (*direct anchorage*), then the TPA may be adapted more easily by adjusting the active sectional wires (Männchen 1999). It must be considered, however, that the implant should be placed paramedian on the same side in order to keep the torque moments as low as possible, should a direct unilateral sagittal force is applied to the implant (Fig.59-16 g).

The three-dimensional attachment of the orthodontic wire to the implant may be guaranteed by using a clamping cap, a welding or soldering cap, or a post cap with a pre-lased wire.

Besides offering reliable fixation to the implant abutment, the connecting element must be sufficiently rigid to prevent deflection. A mean loss of anchorage of approximately 1 mm from retracting or torqueing of incisors to the buccal segment has been reported (Wehrbein *et al.* 1999). This was probably due to deformation of the TPA and/or a slight rotational play of the supraconstruction. Although this anchorage loss might be clinically irrelevant, the preactivation of the connecting element in the opposite direction may help to avoid this side effect.

It is clear that implant-supported teeth receive continuous loading stimulation. Unfavorable jiggling forces on anchor teeth, as found in compliance-dependent anchorage aids, might be reduced or

avoided. This may play a more decisive role in cases with reduced periodontal anchorage.

Stability and success rates

Despite the small dimensions, orthodontic implant anchoring devices must maintain positional stability under orthodontic loading in order to serve as absolute anchorage. As connective tissue encapsulation would initiate implant dislocation, osseointegration is a prerequisite. Histologic examination of explanted human orthodontic implant bone specimens inserted palatally revealed that osseointegration is maintained during long-term orthodontic loading under clinical conditions (see Figs. 59-2, 59-3). The percentage of implant-to-bone contact in patients varied between 34% and 93%, with an average of 75% (Wehrbein *et al.* 1998; Jung *et al.* 2011a), which is obviously an adequate anchorage to withstand orthodontic loading.

There are only two retrospective cohort studies reporting the success rate of 70 (Männchen & Schätzle 2008) and 239 (Jung *et al.* 2012a) palatal Orthosystem® implants. Of these, approximately 5% did not successfully osseointegrate and were lost during the healing phase, which might be attributed to either parafunctional activity of the tongue or artificial direct trauma due to a toothbrush (Asscherickx *et al.* 2010). The surgeon's experience also markedly influenced the success of palatal implants (Arcuri *et al.* 2007; Sandler *et al.* 2008; Jung et al. 2012a).

Due to the fact that only a very small percentage of loaded palatal implants were lost under orthodontic loading – 1.5% (Männchen & Schätzle) and 0.8% (Jung *et al.* 2012a) – no factors related to the design of the device, the concept of anchorage, loading forces or the direction of loading could be identified. In other words, palatal implants are largely robust against the variability in the type of appliance, the type of anchorage, and the dimension of loading forces or directions. This also holds true for demographic parameters as no association of implant survival with age or gender could be found (Jung *et al.* 2012a). The success rates for palatal implants after orthodontic loading are comparable to those reported for conventional oral implants (Berglundh *et al.* 2002; Pjetursson *et al.* 2007). On the basis of a systematic review, it was concluded that for the maxillary arch, palatal implants are a clearly superior treatment option compared with all other skeletal anchorage devices. Palatal implants offer safe and effective anchorage possibilities with a high survival rate (>90%) and few side effects or problems during treatment (Schätzle *et al.* 2009b).

Implant removal

No reports exist on "sleeping orthodontic palatal implants". As a consequence, they have to be removed after completion of the orthodontic

Fig. 59-18 Traditional removal set of a standard trephine of 5.5 mm in diameter and a mounted implant cylinder for guidance. (Source: Hänggi *et al.* 2014.)

Fig. 59-19 Customized implant key with an almost triangular-shaped internal notch (left) that precisely grasps the implant head as it is tightened with an occlusal screw (right). (Source: Hänggi *et al.* 2014.)

treatment. By means of a system-compatible trephine, the peri-implant bone is separated from the device. Then, the implant may be explanted together with the surrounding bone by slow rotations with an extraction forceps (Fig. 59-18). The implant is then retrieved (see Fig. 59-16 h, i). Full recovery at the original anchorage site may be observed 3–4 weeks after implant removal.

As a variation, the implant–bone contact may be broken by turning a customized implant key counterclockwise with an almost triangular-shaped internal notch securely grasping the implant head as it is tightened with an occlusal screw (Fig. 59-19) using the ratchet used for seating the implant. The explanted palatal implant may have no bone appending to it,

except in its apical antirotational grooves (Fig. 59-20) (Hänggi *et al*. 2014). Palatal implant removal without a drilling trephine might be beneficial. Furthermore, by reducing the amount of bone retrieved on implant removal, the range of surgical complications and adverse patient reactions might be reduced. Clinical studies, however, are necessary to document the superiority of this new non-invasive palatal implant removal procedure compared to removal with a trephine (Hänggi *et al*. 2014).

Fig. 59-20 Explanted palatal implant with no bone appending to it, except in its apical antirotational grooves. (Source: Hänggi *et al*. 2014.)

In a retrospective study (Fäh & Schätzle 2014), a wide spectrum of surgical complications and adverse patient reactions after palatal implant installation and removal was found. In all but one implantation, these were of a transitional nature and of minor severity. Prolonged hypoesthesia of the anterior palate occurred in one patient after implantation. Nasal floor perforation seems to be rather crucial during explantation and may need to be closed surgically to prevent a persistent oronasal fistula. Although the risk of permanent sensory impairment of the anterior palatal region or damage to the nerve–vessel thread is small, the patient must be well informed of this risk.

Advantages and disadvantages

Even though the orthodontic treatment may be completed faster and with more predictability with implants, patients have to undergo two minor surgical procedures. Additionally, an inactive waiting time after implant installation is still required. The extra cost for placing a palatal orthodontic implant must be balanced against other treatment options. Besides consideration of cooperation and esthetic aspects, the costs of orthognathic surgery and/or prosthetic reconstruction may be avoided or reduced by installation of an implant for orthodontic anchorage. In cases in which the palatal implant is directly loaded, bonding of the whole jaw or the entire dentition may not be necessary (Fig. 59-21). The main risks encountered with the use of orthodontic implant anchorage are the development of peri-implant infection, oroantral connection and/or implant loss prior to completion of orthodontic treatment.

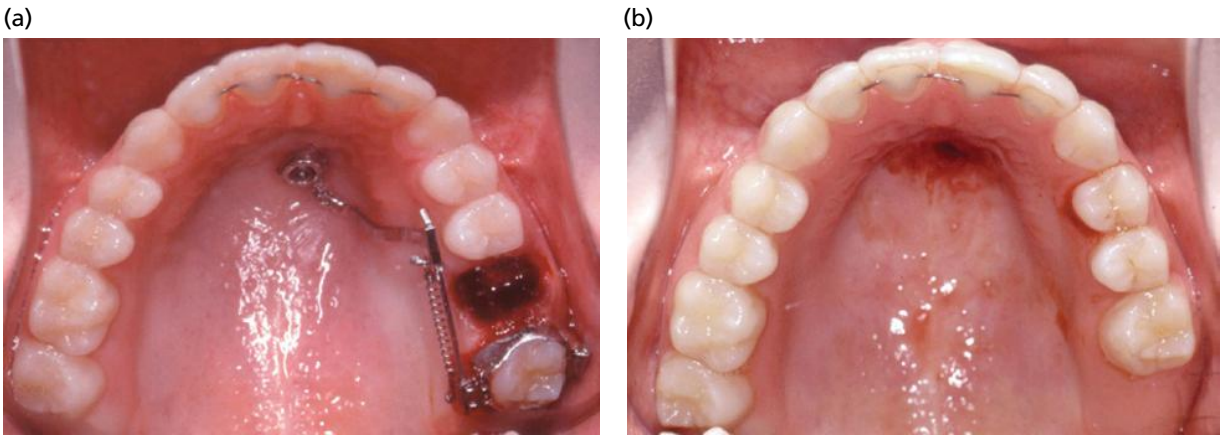

Fig. 59-21 Absolute anchorage by means of a palatal orthodontic implant avoiding the need for bonding the entire maxillary dentition with fixed orthodontic appliances. (a) After the extraction of tooth 26, protraction of tooth 27 was initiated by direct implant loading. (b) At implant and orthodontic appliance removal, the gap between teeth 25 and 27 has been completely closed, thereby avoiding the placement of a fixed partial denture. (Courtesy of R. Männchen, Winterthur.)

Conclusion

Osseointegrated implants provide absolute orthodontic anchorage under low-to-moderate orthodontic loading and, hence, are considered to be superior to any orthodontic tooth-borne anchorage device (Schätzle *et al*. 2009b). Indications for orthodontic implant anchorage include: inadequate periodontal anchorage, non-compliant patients for extra- and/or intra-oral anchorage aids, prevention of potential side effects of conventional anchorage devices, esthetic aspects or avoidance of orthognathic surgery after growth completion. Moreover, prosthetic reconstruction may be avoided. The simplicity of their use, minimal stress during surgical implant installation (Feldmann *et al*. 2007) and removal (Fäh & Schätzle 2014), as well as the reliable success rates are prerequisites for the high acceptance of this treatment by orthodontic patients. It must be kept in mind, however, that treatment objectives may be achieved with several treatment plans. Proper orthodontic anchorage should be chosen according to the preceding diagnosis and to fit the appropriate treatment plan.

Part 18: Supportive Care

Chapter 60

Supportive Periodontal Therapy

Niklaus P. Lang,[1,2] Giedrė Matulienė,[3] Giovanni E. Salvi,[1] and Maurizio S. Tonetti[4]

Clinical trials on the long-term effects of the treatment of periodontitis have clearly demonstrated that post-therapeutic professional maintenance care is an integral part of this treatment. This also constitutes the only means of assuring the maintenance of long-term beneficial therapeutic effects. Re-infection could be prevented or kept to a minimum in most patients, mainly through rigid surveillance involving visits to professionals at regular intervals. However, the maintenance systems presented in the various studies do not give a clear concept with general validity for the frequency of maintenance visits to professionals and the mode of maintenance therapy. In some patients there may be a danger that re-infection and recurrent disease are neglected, while in others there may be a tendency to over treat.

Objective criteria for assessing the patient's individual risk for recurrent disease have been the focus of attention in recent years. However, this evaluation still has to be based on a probability estimate derived from the assessment of the patient, tooth or tooth-site risk.

The purpose of this chapter is to discuss the basics of continuous patient monitoring following active periodontal therapy in order to prevent re-infection and progression of periodontal disease following therapy. The mode and extent of interceptive therapeutic measures needed to achieve this goal will also be evaluated.

Definition

Periodontal treatment includes:

1. Systemic evaluation of the patient's health
2. Cause-related therapeutic phase with, in some cases
3. Corrective phase involving periodontal surgical procedures
4. Maintenance phase.

The 3rd World Workshop of the American Academy of Periodontology (1989) renamed this treatment phase "supportive periodontal therapy" (SPT). This term expresses the essential need for therapeutic measures to support the patient's own efforts to control periodontal infections and to avoid re-infection. Regular visits to the therapist should serve as a positive

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

feedback mechanism between the patient and the therapist with the purpose of ensuring that patients can maintain their dentitions in a healthy status for the longest possible time. An integral part of SPT is the continuous diagnostic monitoring of the patient in order to intercept with adequate therapy and to optimize the therapeutic interventions tailored to the patient's needs.

Basic paradigms for the prevention of periodontal disease

Periodontal maintenance care, or SPT, follows the paradigms of the etiology and pathogenesis of periodontal disease and must consider the fact that these diseases represent opportunistic infections.

Almost 50 years ago, a cause–effect relationship between the accumulation of bacterial plaque on teeth and the development of gingivitis was proven (Löe *et al*. 1965). This relationship was also documented by the restoration of gingival health following plaque removal. Ten years later, this relationship was further characterized when loss of connective tissue attachment and resorption of alveolar bone with plaque accumulation and the development of periodontal disease was shown in laboratory animals (Lindhe *et al*. 1975). Since some of these animals did not develop periodontal disease despite a persistent plaque accumulation for 48 months, it must be considered that the composition of the microbiota or the host's defense mechanisms or susceptibility to disease may vary from individual to individual. Nevertheless, in the study mentioned, the initiation of periodontal disease was always preceded by obvious signs of gingivitis. Hence, it seems reasonable to predict that the elimination of gingival inflammation and the maintenance of healthy gingival tissues will prevent both the initiation and the recurrence of periodontal disease. In fact, as early as 1746, Fauchard stated that "little or no care as to the cleaning of teeth is ordinarily the cause of all diseases that destroy them".

From the clinical point of view, the above-mentioned results must be translated into the necessity for proper and regular personal plaque elimination, at least in patients treated for or susceptible to periodontal disease. This simple principle may be difficult to implement in all patients; however, interceptive professional supportive therapy at regular intervals may, to a certain extent, compensate for the lack of personal compliance with regard to oral hygiene standards.

These aspects have been imitated in a Beagle dog model with naturally occurring periodontal disease (Morrison *et al*. 1979). Two groups of animals were used. The test group was subjected to initial scaling and root planing and, subsequently, plaque was eliminated by daily toothbrushing and biweekly polishing with rubber cups for a period of 3 years. In the control group, no initial scaling and no oral hygiene practices were performed during the same period of time. Every 6 months, however, the teeth in two diagonally opposed jaw quadrants in both test and control animals were scaled and root planed. The results showed that the reduction of probing pocket depth (PPD) and the gain of probing attachment obtained after the initial scaling and root planing in the test animals, were maintained throughout the entire course of the study irrespective of whether or not repeated scaling and root planing had been performed. The control animals, on the other hand, continued to show increasing PPD and loss of attachment in all quadrants irrespective of whether or not repeated scaling and root planing had been performed. However, in the jaw quadrants where the teeth were repeatedly instrumented every 6 months, the progression of periodontal destruction was significantly less pronounced (Fig. 60-1). These results indicate that professional supportive therapy, performed at regular intervals, may, to a certain extent, compensate for a "suboptimal" personal oral hygiene standard. In this respect, it has been demonstrated that following root instrumentation, the subgingival microbiota is significantly altered in quantity and quality (Listgarten *et al*. 1978), and that the re-establishment of a disease-associated, subgingival microbiota may take several months (Listgarten *et al*. 1978; Slots *et al*. 1979; Mousquès *et al*. 1980; Caton *et al*. 1982; Magnusson *et al*. 1984).

In a number of longitudinal clinical studies on the outcome of periodontal therapy, the crucial role of SPT in maintaining successful results has been documented (Ramfjord *et al*. 1968; Lindhe & Nyman 1975; Ramfjord *et al*. 1975; Rosling *et al*. 1976; Nyman *et al*. 1977; Knowles *et al*. 1979, 1980; Badersten *et al*. 1981, Hill *et al*. 1981; Lindhe *et al*. 1982a, b; Pihlström *et al*. 1983; Westfelt *et al*. 1983a; Lindhe & Nyman 1984; Westfelt *et al*. 1985; Isidor & Karring 1986; Badersten *et al*. 1987; Kaldahl *et al*. 1988). In all these studies, PPD and clinical attachment level were maintained as a result of a well-organized professional maintenance care program (recall intervals varying between 3 and 6 months), irrespective of the initial treatment modality performed.

In one of the studies (Nyman *et al*. 1977), an alarming result was that patients treated for advanced periodontal disease involving surgical techniques, but not enrolled in a supervised maintenance care program, exhibited recurrent periodontitis, including loss of attachment, at a rate three to five times higher than documented for natural progression of periodontal disease in population groups with high disease susceptibility (Löe *et al*. 1978, 1986). Within this area, the effect of negligence in providing adequate supportive maintenance care following periodontal treatment was studied over a 6-year period by Axelsson and Lindhe (1981a). Following presurgical root instrumentation and instruction in oral hygiene practices, all study patients were subjected to modified Widman flap procedures. During a 2-month healing period, professional tooth cleaning was performed

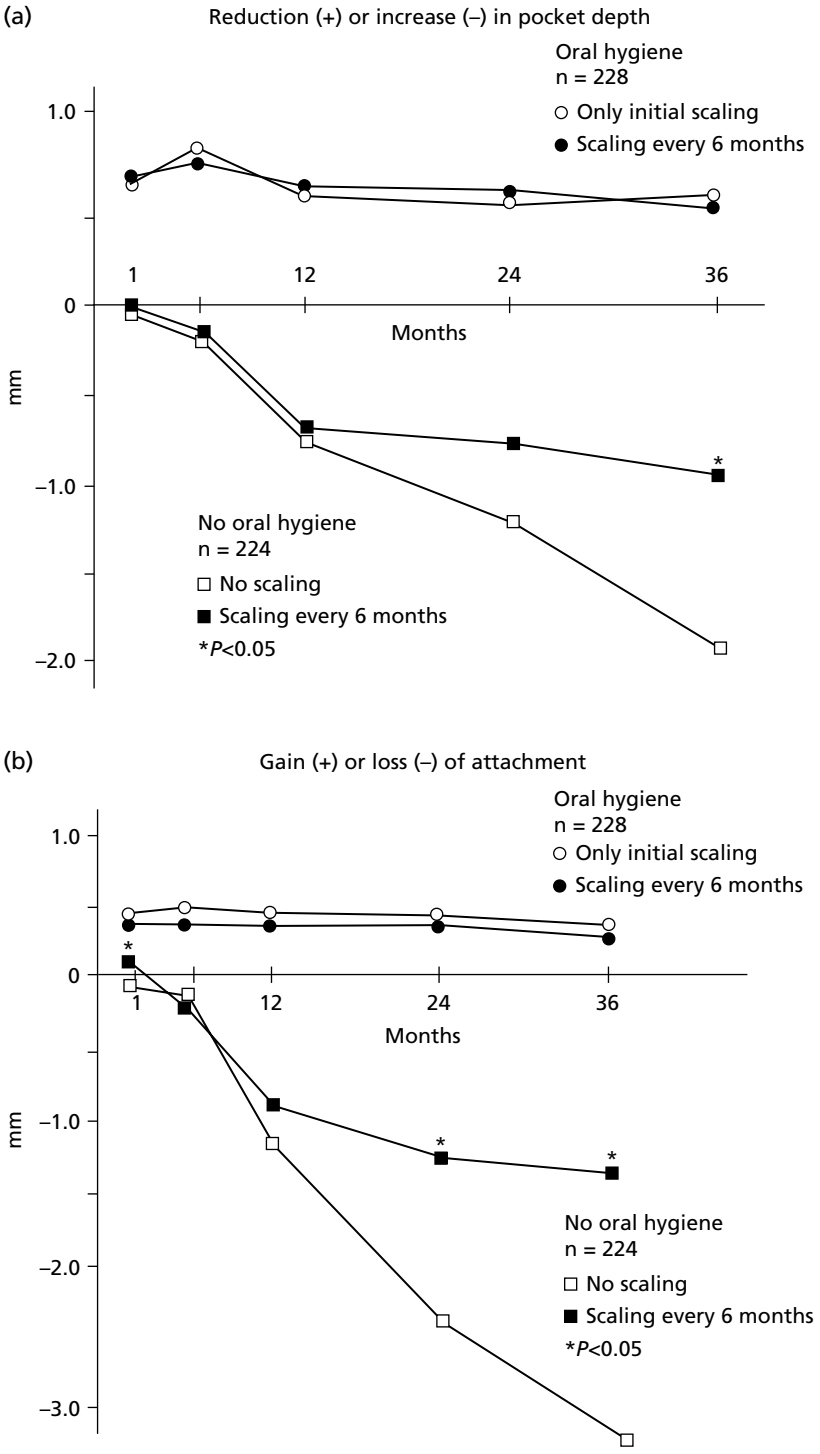

Fig. 60-1 (a) Mean probing depth reduction (+) or increase in probing depth (–) in millimeters with or without repeated scaling and root planing in experimental (oral hygiene) and control (no oral hygiene) animals relative to baseline means. (b) Mean gain (+) or loss (–) of probing attachment with or without repeated scaling and root planing in experimental (oral hygiene) and control (no oral hygiene) animals relative to baseline means. (Data from Morrison *et al*. 1979.)

every 2 weeks. Following this time period, baseline clinical data were obtained and one in every three patients was dismissed from the clinic, while the other two were enrolled in a professionally conducted maintenance program with a recall once every 3 months. These patients maintained excellent oral hygiene and consequently yielded a very low frequency of bleeding sites. In addition, PPD and probing attachment levels were maintained unchanged over the 6-year period. In contrast, the non-recalled patients demonstrated obvious signs of recurrent periodontitis at the 3-year and 6-year re-examinations. Further evidence for the likelihood of recurrent disease in patients not subjected to professional maintenance care was presented by Kerr (1981). Five years after successful treatment, 45% of the patients presented with periodontal conditions similar to their status before treatment. Supportive therapy had only been provided at intervals varying between 9 and 18 months.

Even though the number of well-controlled longitudinal clinical trials is rather limited for patients who, in addition to periodontal treatment, have undergone extensive reconstructive therapy, it should be realized that the concept of professional maintenance care has unrestricted validity. In a longitudinal study of

combined periodontal and prosthetic treatment of patients with advanced periodontal disease, periodontal health could be maintained over a study period of 5–8 years with regular recall appointments scheduled every 3–6 months (Nyman & Lindhe 1979). Similar results have been presented by Valderhaug and Birkeland (1976) and by Valderhaug (1980) for periods of up to 15 years. Another study of 36 patients who received extensive poly-unit cantilevered bridgework following periodontal therapy, confirmed the maintenance of periodontal health over 5–12 years (Laurell *et al*. 1991). More recent studies on the long-term maintenance of periodontal patients who, following successful treatment of chronic periodontitis, were reconstructed with extensive fixed reconstructions, revealed that regularly performed SPT resulted in periodontal stability. Only 1.3% (Hämmerle *et al*. 2000) and 2.0% (Moser *et al*. 2002) of the abutments showed some minor attachment loss during these long periods of observation (10 and 11 years, respectively). In contrast, a report of insurance cases who were not regularly maintained by SPT yielded a recurrence rate for periodontitis of almost 10% after an observation of 6.5 years (Randow *et al*. 1986).

Summary: The etiology of gingivitis and periodontitis is fairly well understood. However, the causative factors, that is the microbial challenge which induces and maintains the inflammatory response, may not be completely eliminated from the dentogingival environment for any length of time. This requires the professional removal of all microbial deposits in the supragingival and subgingival areas at regular intervals, since recolonization will occur following the debridement procedures, leading to a re-infection of the ecologic niche and, hence, further progression of the disease process. Numerous well-controlled clinical trials, however, have documented that such a development can be prevented over very long periods of time only by regular interference with the subgingival environment aimed at removal of the subgingival bacteria.

Patients at risk for periodontitis without supportive periodontal therapy

The effect of omission of SPT in patients with periodontitis may best be studied either in untreated populations or patient groups with poor compliance.

One of the few studies documenting untreated periodontitis-susceptible patients reported on the continuous loss of periodontal attachment as well as teeth in Sri Lankan tea plantation workers receiving no dental therapy (Löe *et al*. 1986). In this – for the Western world – rather unique model situation, an average loss of 0.3 mm per tooth surface and per year was encountered. Also, the laborers lost between 0.1 and 0.3 teeth per year as a result of periodontitis. In another untreated group in the US, 0.61 teeth were lost per year during an observation period of 4 years (Becker *et al*. 1979). This is in dramatic contrast to reports on tooth loss in well-maintained patients treated for periodontitis (e.g. Hirschfeld & Wasserman 1978; McFall 1982; Becker *et al*. 1984; Wilson *et al*. 1987). Such patients were either completely stable and lost no teeth during maintenance periods ranging up to 22 years, or lost only very little periodontal attachment and only 0.03 teeth (Hirschfeld & Wasserman 1978) or 0.06 teeth (Wilson *et al*. 1987).

Non-complying, but periodontitis-susceptible, patients receiving no SPT following periodontal surgical interventions continued to lose periodontal attachment at a rate of approximately 1 mm per year regardless of the type of surgery chosen (Nyman *et al*. 1977). This is almost three times greater than would be expected as a result of the "natural" course of periodontal disease progression (Löe *et al*. 1978, 1986).

In a British study of a private practice situation (Kerr 1981) where the patients were referred back to the general dentist after periodontal therapy, 45% of the patients showed complete re-infection after 5 years.

Similar results have been described for private practice patients who decided not to participate in an organized maintenance care program following active periodontal therapy (Becker *et al*. 1984). Subsequent examinations revealed clear signs of recurrent periodontal disease, including increased PPD and involvement of furcations of multirooted teeth concomitant with tooth loss. Also, loss of alveolar bone observed on radiographs and tooth loss have been reported for a group of patients in whom post-therapeutic supportive maintenance care was provided less frequently than once every 12 months (De Vore *et al*. 1986).

From all these studies, it is evident that periodontal treatment is ineffective in maintaining periodontal health if supportive maintenance care is neglected, denied or omitted.

The most impressive documentation of the lack of SPT in disease-susceptible individuals is probably that from a clinical trial in which one-third of the patients had been sent back to the referring general practitioner for maintenance, while two-thirds of the patients received SPT in a well-organized maintenance system (Axelsson & Lindhe 1981a). The 77 patients were examined before treatment, 2 months after the last surgical procedure, and 3 and 6 years later. The 52 patients on the carefully designed SPT system visited the program every 2 months for the first 2 years and every 3 months for the remaining 4 years of the observation period. The results obtained from the second examination (2 months after the last surgery) showed that the effect of the initial treatment was good in both groups. Subsequently, the recall patients were able to maintain proper oral hygiene and unaltered attachment levels. In the non-recall group, plaque scores increased markedly from the baseline values, as did the number of inflamed gingival units (Fig. 60-2a). Concomitantly, there were obvious signs of recurrent periodontitis. The mean

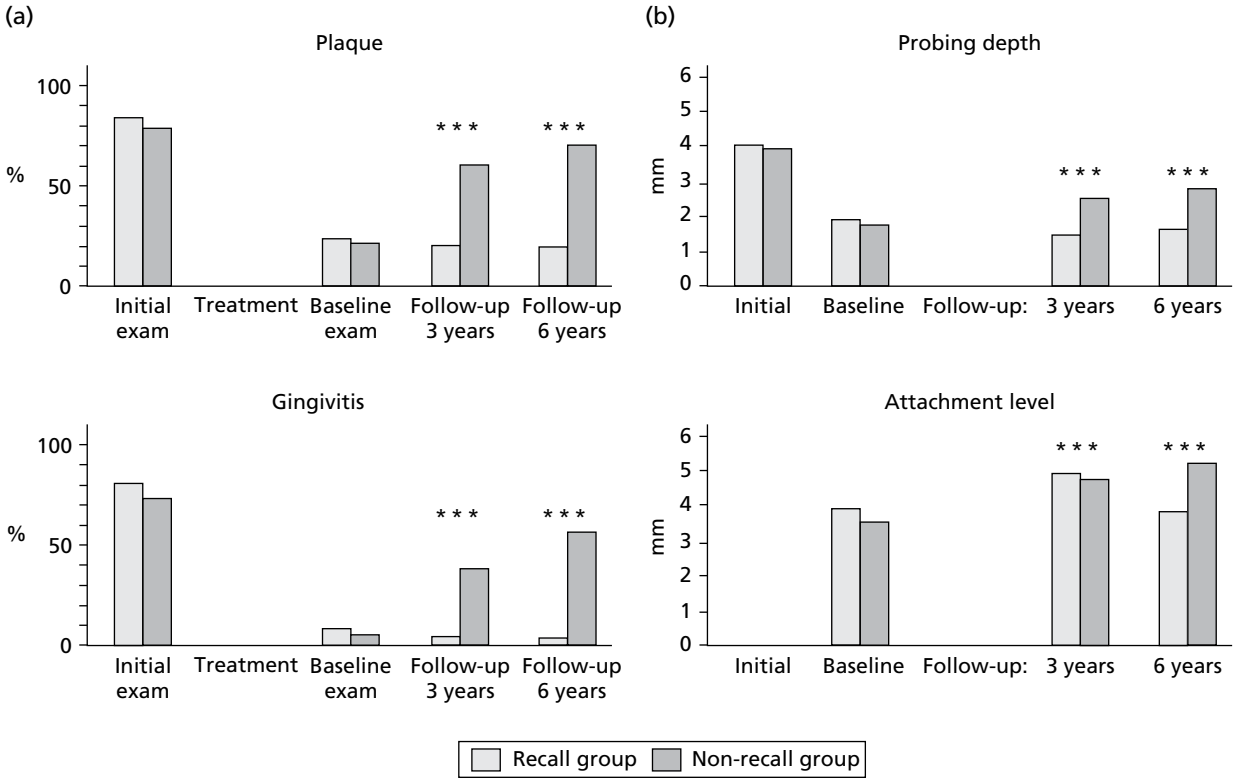

Fig. 60-2 Histograms showing (a) average percentages of tooth surfaces harboring visible plaque (above) and inflamed gingival units (bleeding on probing) (below), and (b) average probing depth (above) and probing attachment levels (below), at initial, baseline, and follow-up examinations. (Data from Axelsson & Lindhe 1981b.)

Table 60-1 Percentage of sites showing various changes in probing attachment level between baseline examination, 2 months after completion of active periodontal therapy, and at follow-up examination 6 years later.

Change in attachment level	Percentage of surfaces showing change	
	Recall	Non-recall
Attachment level improved	17	1
No change	72	10
Attachment level worse by:		
≥1 mm	10	34
2–5 mm	1	55

values for pocket depth and attachment levels at the 3-year and 6-year examinations were higher than at baseline (Fig. 60-2b). In the recall group, approximately 99% of the tooth surfaces showed either improvement, no change or <1 mm loss of attachment, compared to 45% in the non-recall group (Table 60-1). In the latter patients, 55% of the sites showed a further loss of attachment of 2–5 mm at the 6-year examination, and 20% of the pockets were 4 mm deep or more (Tables 60-1, 60-2).

Summary: Patients susceptible to periodontal disease are at high risk for re-infection and progression of periodontal lesions without meticulously organized and performed SPT. Since all patients who are treated for periodontal diseases belong to this risk category by virtue of their past history, an adequate maintenance care program is of utmost importance for a beneficial long-term treatment outcome. SPT has to be aimed at the regular removal of the subgingival microbiota and must be supplemented by the patient's efforts for optimal supragingival plaque control.

Supportive periodontal therapy for patients with gingivitis

Several studies, predominantly in children, have documented that periodic professional prophylactic visits in conjunction with reinforcement of personal oral hygiene are effective in controlling gingivitis (Badersten *et al*. 1975; Poulsen *et al*. 1976; Axelsson & Lindhe 1981a, b; Bellini *et al*. 1981). This, however, does not imply that maintenance visits in childhood preclude the development of more severe disease later in life. It is obvious, therefore, that SPT must be a lifelong commitment of both the patient and the profession.

Adults whose effective oral hygiene was combined with periodic professional prophylaxis were clearly healthier periodontally than patients who did not participate in such programs (Lövdal *et al*. 1961; Suomi *et al*. 1971). One particular study of historical significance was performed on 1428 adults from an industrial company in Oslo, Norway (Lövdal *et al*. 1961). Over a 5-year observation period, the subjects were recalled two to four times per year for

Table 60-2 Percentage of various probing depths in recall and non-recall patients at the initial examination, 2 months after active periodontal treatment, and at 3- and 6-year follow-up visits.

Examinations	Percentage of pockets of various depths					
	≤3 mm		4–6 mm		≥7 mm	
	Recall	Non-recall	Recall	Non-recall	Recall	Non-recall
Initial	35	50	58	38	8	12
Baseline	99	99	1	1	0	0
3 years	99	91	1	9	0	0
6 years	99	80	1	19	0	1

Adapted from Axelsson & Lindhe (1981b), with permission from John Wiley & Sons.

instruction in oral hygiene and supragingival and subgingival scaling. Gingival conditions improved by approximately 60% and tooth loss was reduced by about 50% of what would be expected without these efforts.

In another study (Suomi *et al*. 1971), loss of periodontal tissue support in young individuals with gingivitis or only loss of small amounts of attachment was followed over 3 years. An experimental group receiving scaling and instruction in oral hygiene every 3 months yielded significantly less plaque and gingival inflammation than the control group in which no special efforts had been made. The mean loss of probing attachment was only 0.08 mm per surface in the experimental as opposed to 0.3 mm in the control group.

When adult patients with gingivitis were treated with scaling and root planing, but did not improve their oral hygiene procedures, the gingival condition did not improve compared with individuals receiving prophylaxis at 6-month intervals (Listgarten & Schifter 1982).

Summary: The available information indicates that the prevention of gingival inflammation and early loss of attachment in patients with gingivitis depends primarily on the level of personal plaque control, but also on further measures to reduce the accumulation of supragingival and subgingival plaque.

Supportive periodontal therapy for patients with periodontitis

As mentioned previously, a series of longitudinal studies on periodontal therapeutic modalities have been performed, first at the University of Michigan, USA, later at the University of Gothenburg, Sweden, and also at the Universities of Minnesota, Nebraska, and Loma Linda, USA. These studies always enrolled patients into a well-organized maintenance care system with recall visits at regular intervals (generally 3–4 months). Although the patients performed plaque control with various degrees of efficacy, the SPT resulted in excellent maintenance of postoperative attachment levels in most patients (Knowles 1973; Ramfjord *et al*. 1982).

On average, excellent treatment results with maintained reduced PPD and maintained gains of probing attachment were documented for most of the patients in the longitudinal studies irrespective of the treatment modality chosen (Ramfjord *et al*. 1975; Lindhe & Nyman 1975; Rosling *et al*. 1976; Nyman *et al*. 1977; Knowles *et al*. 1979, 1980; Badersten *et al*. 1981; Hill *et al*. 1981; Hill *et al*. 1981; Lindhe *et al*. 1982a; Pihlström *et al*. 1983; Westfelt *et al*. 1983a, b, 1985; Isidor & Karring 1986; Badersten *et al*. 1987).

In a study on 75 patients with extremely advanced periodontitis, who had been successfully treated for the disease with cause-related therapy and modified Widman flap procedures (Lindhe & Nyman 1984), recurrent infection occurred in only very few sites during a 14-year period of effective SPT. However, it has to be realized that recurrent periodontitis was noted at completely unpredictable time intervals, but was concentrated in about 25% of the patient population (15 of 61). This suggests that, in a periodontitis-susceptible risk population, the majority of patients can be "cured" provided an optimally organized SPT is performed, while a relatively small proportion of patients (20–25%) will suffer from occasional episodes of recurrent periodontal re-infection. It is obviously a challenge for the therapist to identify such patients with very high disease susceptibility and to monitor the dentitions for recurrent periodontitis on a long-term basis.

In contrast to the study by Lindhe and Nyman (1984), which exclusively involved patients with advanced periodontitis, another study on 52 patients with generalized mild-to-moderate adult periodontitis addressed the efficacy of SPT 8 years following completion of cause-related periodontal therapy (Brägger *et al*. 1992). Full-mouth intraoral radiographs were used to assess changes in the radiographic alveolar bone height as a percentage of the total tooth length. As a result of cause-related therapy, a gain in probing attachment was followed by a loss of 0.5–0.8 mm over the following 8 years. The radiographic loss of alveolar bone height in the same time period was <2% and thus clinically insignificant. In this patient group initially presenting with mild-to-moderate periodontitis, the frequency of SPT rendered per year did not affect the rate of progression of periodontal disease. However, patients seeking SPT less frequently than once per year over 8 years lost further periodontal attachment during the period of

observation. From these studies it is evident that patients who have had periodontitis need some kind of SPT. Obviously, the frequency of SPT visits has to be adapted to the risk of susceptibility for the disease. Patients with advanced periodontitis may need SPT at a regular and rather short time interval (3–4 months), while for mild-to-moderate forms of periodontitis, one annual visit may be enough to prevent further loss of attachment.

More recently, the effect of a 30-year plaque-control–based maintenance program in a private dental office on tooth mortality, caries, and periodontal disease progression was presented (Axelsson *et al*. 2004). This prospective controlled cohort study initially included 375 test and 180 control patients who received traditional maintenance care (by the referring dentist once or twice a year). After 6 years, the control group was discontinued. The test group was subjected to prophylactic visits every second month for the first 2 years and every 3–12 months (according to their individual needs) over 3–30 years. The prophylactic visits to the dental hygienist included plaque disclosure and professional mechanical tooth cleaning, including the use of a fluoride-containing dentifrice. During the 30 years of maintenance, very few teeth were lost (0.4–1.8), and rare teeth loss was predominately the result of root fractures. Over the 30 years of maintenance, 1.2–2.1 new carious lesions (>80% secondary caries) were found. During this period, only 2–4% of all sites exhibited periodontal attachment loss of ≥2 mm. This unique study clearly demonstrated that SPT based on plaque control tailored to the individual needs of the patient will result in very low tooth mortality, minimal recurrent caries, and almost complete periodontal stability.

Summary: SPT is an absolute prerequisite to guarantee beneficial treatment outcomes with maintained levels of clinical attachment over long periods of time. For the majority of patients, the maintenance of treatment results has been documented for up to 14 years, and in a private practice situation even up to 30 years, but it has to be realized that a small proportion of patients will experience recurrent infections with progression of periodontal lesions in a few sites in a completely unpredictable mode. The continuous risk assessment at subject, tooth, and tooth-site levels, therefore, represents a challenge for the SPT concept.

Continuous multilevel risk assessment

As opposed to an initial periodontal diagnosis which considers the sequelae of the disease process, in other words documents the net loss of periodontal attachment, the concomitant formation of periodontal pockets, and the existence of inflammation, clinical diagnosis during SPT has to be based on the variations of the health status following successful active periodontal treatment. This, in turn, means that a new baseline has to be established once the treatment goals of active periodontal therapy (i.e. phases 1–3) are reached and periodontal health is restored (Claffey 1991). This baseline includes the level of clinical attachment achieved while the inflammatory parameters are supposed to be under control. Under optimal circumstances, supportive periodontal care would maintain the clinical attachment levels obtained after active therapy for many years. However, if re-infection occurs, the loss of clinical attachment will progress. The relevant question is, therefore, which clinical parameters serve as early indicators for a new onset or recurrence of the periodontal disease process, that is re-infection and progression of periodontal breakdown of a previously treated periodontal site? It is also very important to achieve consistency in the definition of a "progressive" case in order to be able to interpret the results of clinical studies evaluating risk factors/indicators for the disease progression. Such a definition was proposed during the 5th European Workshop in Periodontology (Tonetti & Claffey 2005): presence of two or more teeth with longitudinal loss of proximal attachment of ≥3 mm. Where serial proximal attachment level measurements are not available, longitudinal radiographic bone loss of ≥2 mm at two or more teeth may be used as a substitute.

From a clinical point of view, the stability of periodontal conditions reflects a dynamic equilibrium between bacterial aggression and effective host response. As such, this homeostasis is prone to sudden changes whenever one of the two factors prevails. Hence, it is evident that the diagnostic process must be based on continuous monitoring of the multilevel risk profile. The intervals between diagnostic assessments must also be chosen based on the overall risk profile and the expected benefit. To schedule patients for SPT on the basis of an individual risk evaluation for recurrence of disease has been demonstrated to be cost-effective (Axelsson & Lindhe 1981a, b; Axelsson *et al*. 1991).

By virtue of their previous disease predisposition, patients under a periodontal maintenance program represent a population with a moderate-to-high risk for recurrent periodontal infection. As opposed to the general population without such a history, periodontal patients need to participate in a well-organized recall system which should provide both continuous risk assessment and adequate supportive care. Without this, the patients are likely to experience progressive loss of periodontal attachment (Axelsson & Lindhe 1981a; Kerr 1981; Becker *et al*. 1984; Cortellini *et al*. 1994, 1996). On the other hand, it is important to determine the level of risk for progression in each individual patient in order to be able to determine the frequency and extent of professional support necessary to maintain the attachment levels obtained following active therapy. The determination of such risk level would thus prevent undertreatment and also excessive overtreatment during SPT (Brägger *et al*. 1992).

Subject periodontal risk assessment

The patient's risk for recurrence of periodontitis may be evaluated on the basis of a number of clinical conditions whereby no single parameter displays a paramount role. The entire spectrum of risk factors and risk indicators should be evaluated simultaneously. For this purpose, a functional diagram has been constructed (Fig. 60-3) (Lang & Tonetti 2003) including the following aspects:

- Percentage of bleeding on probing (BoP)
- Prevalence of residual pockets >4 mm
- Loss of teeth from a total of 28 teeth
- Loss of periodontal support in relation to the patient's age
- Systemic and genetic conditions
- Environmental factors such as cigarette smoking.

Each parameter has its own scale for minor, moderate, and high-risk profiles. A comprehensive evaluation of these factors after active periodontal therapy will provide an individualized total risk profile and determine the frequency and complexity of SPT visits. Modifications may be made to the functional diagram if additional factors become important in the future. The validity of the periodontal risk assessment (PRA) in identifying various patient-based risk levels for disease progression following active periodontal treatment has been tested in several cohort studies around the world (Lang *et al.* 2015).

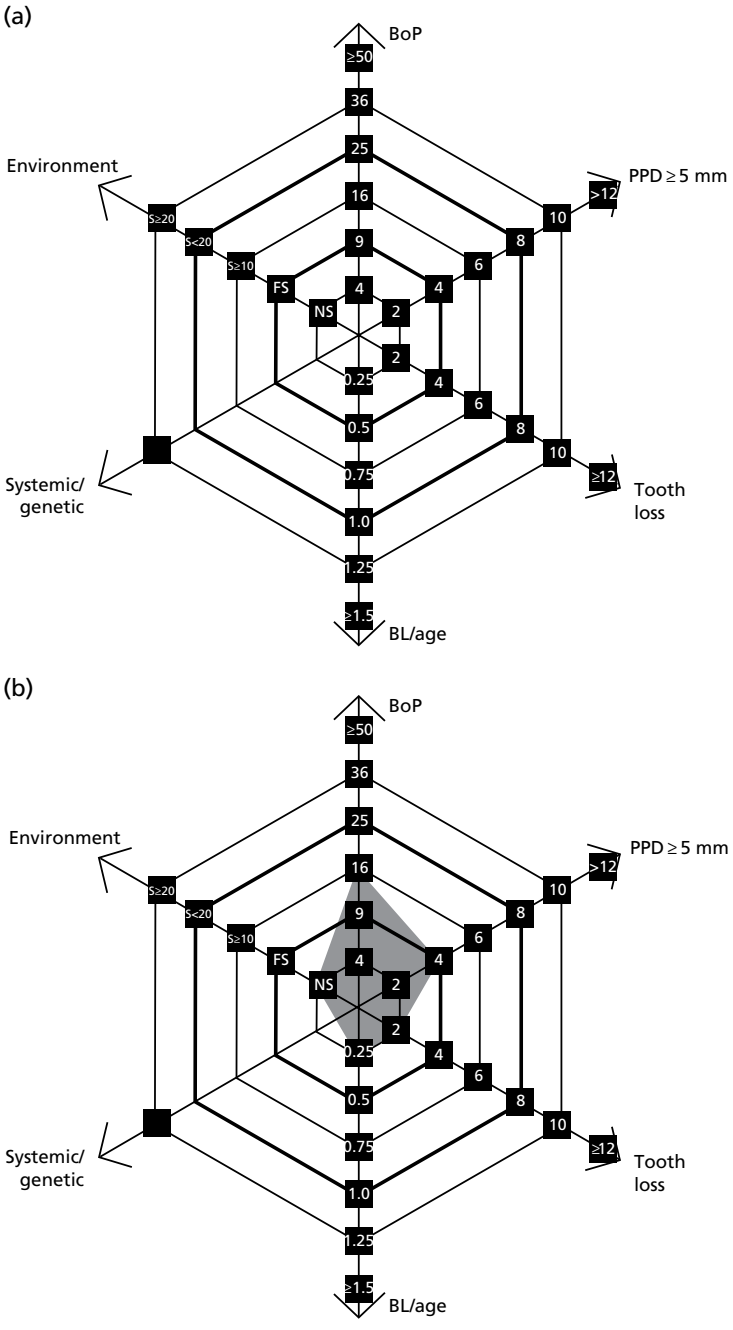

Fig. 60-3 (a) Functional diagram to evaluate the patient's risk for recurrence of periodontitis. Each vector represents one risk factor or indicator with an area of relatively low risk, an area of moderate risk, and an area of high risk for disease progression. All factors have to be evaluated together and hence the area of relatively low risk is found within the center circle of the polygon, while the area of high risk is found outside the periphery of the second polygon in bold. Between the two rings in bold, there is the area of moderate risk. (b) Functional diagram of a low-risk maintenance patient. Bleeding on probing (BoP) is 15%, four residual pockets of ≥5 mm are diagnosed, two teeth have been lost, the bone factor in relation to the patient's age is 0.25, no systemic factor is known, and the patient is a non-smoker.

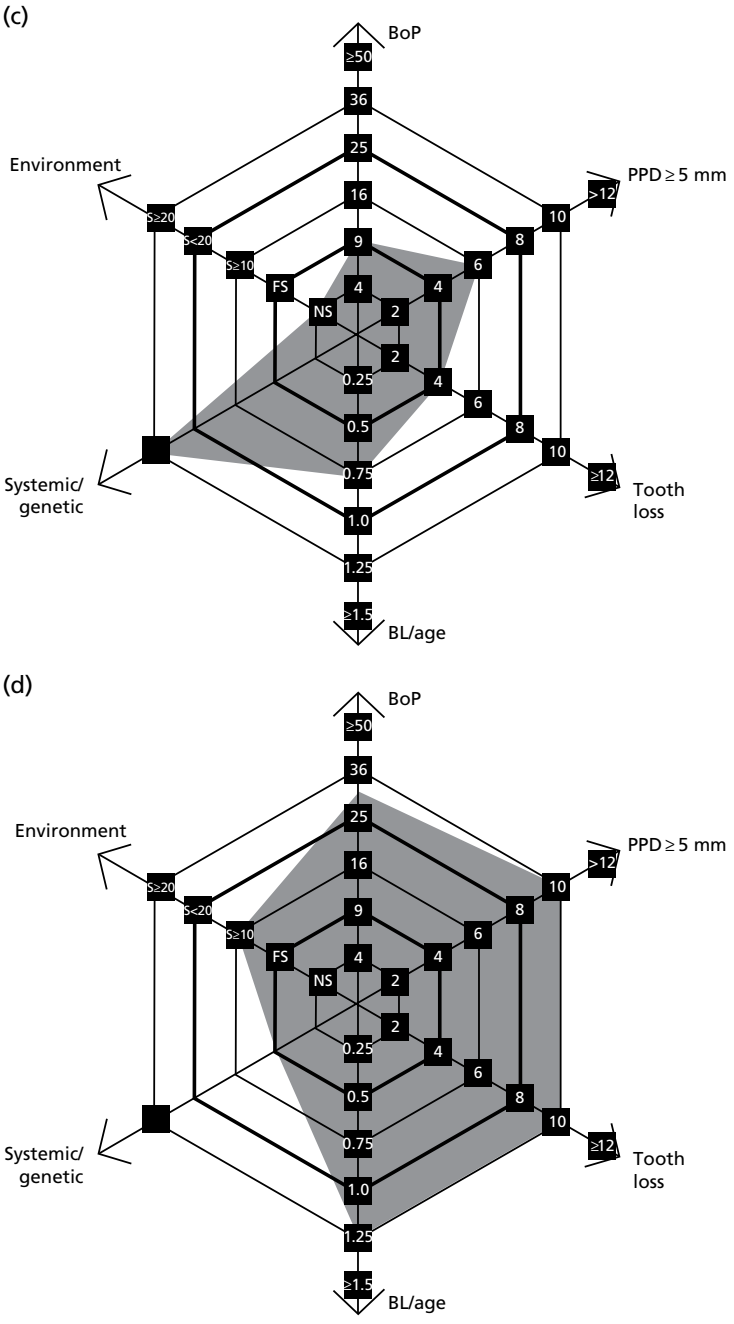

Fig. 60-3 (*continued*). (c) Functional diagram of a medium-risk maintenance patient. BoP is 9%, six residual pockets of ≥5 mm are diagnosed, four teeth have been lost, the bone factor in relation to the patient's age is 0.75, the patient has type I diabetes, but is a non-smoker. (d) Functional diagram of a high-risk maintenance patient. BoP is 32%, ten residual pockets of ≥5 mm are diagnosed, ten teeth have been lost, the bone factor in relation to the patient's age is 1.25, no systemic factors are known, and the patient is an occasional smoker. (BL, bone loss; PPD, probing pocket depth.)

Compliance with recall system

Several investigations have indicated that only a minority of periodontal patients comply with the prescribed supportive periodontal care (Wilson *et al*. 1984; Mendoza *et al*. 1991; Checchi *et al*. 1994; Demetriou *et al*. 1995). Since it has been clearly established that treated periodontal patients who comply with regular periodontal maintenance appointments have a better prognosis than patients who do not comply (Axelsson & Lindhe 1981a; Becker *et al*. 1984; Cortellini *et al*. 1994, 1996), non-compliant or poorly compliant patients should be considered at higher risk for periodontal disease progression. A report that investigated the personality differences of patients participating in a regular recall program following periodontal therapy as compared to patients who did not, revealed that the latter patients had higher incidences of stressful life events and less stable personal relationships (Becker *et al*. 1988).

Oral hygiene

Since bacterial plaque is by far the most important etiologic agent for the occurrence of periodontal diseases (for review see Kornman & Löe 1993), it is evident that the full-mouth assessment of the bacterial load must have a pivotal role in the determination of the risk for disease recurrence. It has to be realized, however, that regular interference with the microbial ecosystem during periodontal maintenance will eventually obscure such obvious associations. In patients treated with various surgical and non-surgical modalities, it has been clearly established that

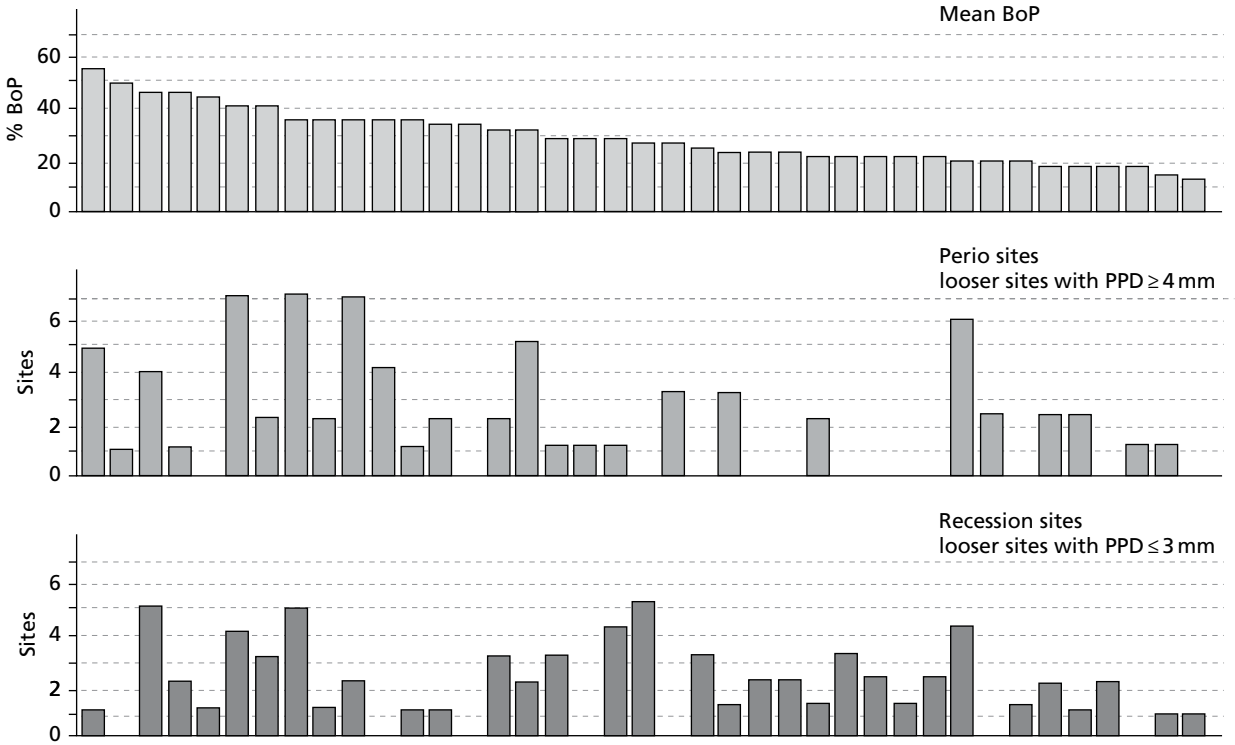

Fig. 60-4 Distribution of "looser" sites [probing pocket depth (PPD) of ≥4 mm) due to periodontal disease progression with or without concomitant recession, dependent on the mean bleeding on probing (BoP) percentage during an observation period of 4 years. Patients are sorted by decreasing mean BoP percentages. Patients with <20% BOP have a significantly lower risk for disease recurrence. (Data from Joss *et al*. 1994.)

plaque-infected dentitions will yield recurrence of periodontal disease in multiple locations, while dentitions under plaque control and regular supportive care maintain periodontal stability for many years (Rosling *et al*. 1976; Axelsson & Lindhe 1981a, b). Studies have thus far not identified a level of plaque infection compatible with maintenance of periodontal health. However, in a clinical set-up, a plaque control record of 20–40% might be tolerated by most patients. It is important to realize that the full-mouth plaque score has to be related to the host response of the patient, in other words compared to inflammatory parameters.

Percentage of sites with bleeding on probing

Bleeding on gentle probing represents an objective inflammatory parameter which has been incorporated into index systems for the evaluation of periodontal conditions (Löe & Silness 1963; Mühlemann & Son 1971) and is also used as a parameter on its own. In a patient's risk assessment for recurrence of periodontitis, BoP reflects, at least in part, the patient's compliance and standards of oral hygiene performance. No acceptable level of prevalence of BoP in the dentition above which there is a higher risk for disease recurrence has been established. However, a BoP prevalence of 25% was the cut-off point between patients with maintained periodontal stability for 4 years and patients with recurrent disease in the same timeframe in a prospective study in a private practice (Joss *et al*. 1994) (Fig. 60-4). Further evidence of BoP percentages between 20% and 30% determining a higher risk for disease progression originates from studies by Claffey *et al*. (1990) and Badersten *et al*. (1990).

In assessing the patient's risk for disease progression, BoP percentages reflect a summary of the patient's ability to perform proper plaque control, his/her host response to the bacterial challenge, and his/her compliance. The percentage of BoP, therefore, is used as the first risk factor in the functional diagram of risk assessment (see Fig. 60-3). The scale runs in a quadratic mode with 4, 9, 16, 25, 36, and >49% being the divisions on the vector.

Individuals with low mean BoP percentages (<10% of the surfaces) may be regarded as patients with a low risk for recurrent disease (Lang *et al*. 1990), while patients with mean BoP percentages of >25% should be considered to be at high risk for re-infection.

Prevalence of residual pockets of >4 mm

The enumeration of the residual pockets with a PPD of >4 mm represents, to a certain extent, the degree of success of the periodontal treatment rendered. Although this depth *per se* does not make much sense when considered as a sole parameter, the evaluation in conjunction with other parameters, such as BoP and/or suppuration, will reflect existing ecologic niches from and in which re-infection might occur. It is, therefore, conceivable that periodontal stability in a dentition is reflected by a minimal number of

residual pockets. At a site level, the presence of deep residual pockets after initial periodontal therapy and deepening of pockets during supportive periodontal care has been associated with high risk for disease progression (Badersten *et al*. 1990; Claffey *et al*. 1990). At the patient level, however, this evidence is scarce. In one study of 16 patients suffering from advanced periodontitis (Claffey & Egelberg 1995), the presence of high proportions of residual PPD of ≥6 mm after initial periodontal therapy indicated patient susceptibility for further attachment loss over a 42-month period. In a recent retrospective study of mean duration of 11.3 years, SPT was provided for 172 patients treated for periodontitis (Matuliene *et al*. 2008). Analysis of the data at the patient level demonstrated that, besides heavy smoking (≥20 cigarettes/day), SPT duration exceeding 10 years, initial diagnosis of advanced periodontitis (Tonetti and Claffey 2005), and the presence of at least one site with PPD of ≥6 mm or nine or more sites with PPD of ≥5 mm contribute significantly to the risk of periodontitis progression (Matuliene *et al*. 2008).

On the other hand, it has to be realized that an increased number of residual pockets does not necessarily imply an increased risk for re-infection or disease progression, since a number of longitudinal studies have established that, depending on the individual supportive therapy provided, even deeper pockets may be stable without further disease progression for years (e.g. Knowles *et al*. 1979; Lindhe & Nyman 1984).

Nevertheless, in assessing the patient's risk for disease progression, the number of residual pockets with a PPD of ≥5 mm is assessed as the second risk indicator for recurrent disease in the functional diagram of risk assessment (see Fig. 60-3). The scale runs in a linear mode with 2, 4, 6, 8, 10, and ≥12% being the divisions on the vector. Individuals with up to four residual pockets may be regarded as at a relatively low risk, while patients with more than eight residual pockets may be regarded as at high risk for recurrent disease.

Loss of teeth from a total of 28 teeth

Although the reason for tooth loss may not be known, the number of remaining teeth in a dentition reflects the functionality of the dentition. Mandibular stability and individual optimal function may be assured even with a shortened dental arch of premolar to premolar occlusion, that is 20 teeth. The shortened dental arch does not seem to predispose the individual to mandibular dysfunction (Witter *et al*. 1990, 1994). However, if more than eight teeth from a total of 28 teeth are lost, oral function is usually impaired (Käyser 1981, 1994, 1996). Since tooth loss also represents a true end-point outcome variable reflecting the patient's history of oral diseases and trauma, it is logical to incorporate this risk indicator as the third parameter in the functional diagram of risk assessment (see Fig. 60-3). The number of teeth lost from the dentition without the third molars (28 teeth) is counted, irrespective of their replacement. The scale runs also in a linear mode with 2, 4, 6, 8, 10, and ≥12% being the divisions on the vector.

Individuals with up to four teeth lost may be regarded as patients at low risk, while patients with more than eight teeth lost may be considered as being at high risk.

Loss of periodontal support in relation to the patient's age

The extent and prevalence of periodontal attachment loss (i.e. previous disease experience and susceptibility), as evaluated by the height of the alveolar bone on radiographs, may represent the most obvious indicator of subject risk when related to the patient's age. In light of the present understanding of periodontal disease progression, and the evidence that both onset and rate of progression of periodontitis might vary among individuals and over different timeframes (van der Velden 1991), it has to be realized that previous attachment loss in relation to the patient's age does not rule out the possibility of rapidly progressing lesions. Therefore, the actual risk for further disease progression in a given individual may occasionally be underestimated. Hopefully, the rate of progression of disease has been positively affected by the treatment rendered and, hence, previous attachment loss in relation to the patient's age may be a more accurate indicator during SPT than before active periodontal treatment. Given the hypothesis that a dentition may be functional for the most likely life expectancy of the subject in the presence of a reduced height of periodontal support (i.e. 25–50% of the root length), the risk assessment in treated periodontal patients may represent a reliable prognostic indicator for the stability of the overall treatment goal of keeping a functional dentition for a lifetime (Papapanou *et al*. 1988).

The estimation of the loss of alveolar bone is performed in the posterior region on either periapical radiographs, in which the worst site affected is estimated gross as a percentage of the root length, or on bitewing radiographs in which the worst site affected is estimated in millimeters. One millimeter equates to 10% bone loss. The percentage is then divided by the patient's age. This results in a factor. As an example, a 40-year-old patient with 20% bone loss (BL) at the worst posterior site affected would be scored BL/Age = 0.5. Another 40-year-old patient with 50% BL at the worst posterior site scores BL/Age = 1.25.

In assessing the patient's risk for disease progression, the extent of alveolar bone loss in relation to his/her age is estimated as the fourth risk indicator for recurrent disease in the functional diagram of risk assessment (see Fig. 60-3). The scale runs in increments of 0.25 of the factor BL/Age, with 0.5 being the division between low and moderate risk, and 1.0

being the division between moderate and high risk for disease progression. This, in turn, means that a patient who has lost a higher percentage of posterior alveolar bone than expected for his/her own age is at high risk regarding this vector in a multifactorial assessment of risk.

Systemic conditions

The most substantiated evidence for modification of disease susceptibility and/or progression of periodontal disease arises from studies on type I and type II (insulin-dependent and non–insulin-dependent) diabetes mellitus populations (Gusberti *et al*. 1983; Emrich *et al*. 1991; Genco & Löe 1993).

It has to be realized that the impact of diabetes on periodontal diseases has been documented in patients with untreated periodontal disease, while, as of today, no clear evidence is available for treated patients. It is reasonable, however, to assume that the influence of systemic conditions may also affect recurrence of disease.

In recent years, genetic markers have become available to determine various genotypes of patients regarding their susceptibility for periodontal diseases. Research on the interleukin-1 (IL-1) polymorphisms has indicated that *IL-1* genotype-positive patients show more advanced periodontitis lesions than *IL-1* genotype-negative patients of the same age group (Kornman *et al*. 1997). Also, there is a trend to higher tooth loss in the *IL-1* genotype-positive subjects (McGuire & Nunn 1999). In a retrospective analysis of over 300 well-maintained periodontal patients, the *IL-1* genotype-positive patients showed significantly higher BoP percentages, and a higher proportion of these patients yielded higher BoP percentages during a 1-year recall period than the *IL-1* genotype-negative control patients (Lang *et al*. 2000). Also, the latter group had twice as many patients with improved BoP percentages during the same maintenance period, indicating that *IL-1* genotype-positive subjects do indeed represent a group of hyperreactive subjects even if they are regularly maintained by effective SPT (Lang *et al*. 2000). In a prospective study over 5 years on Australian white and blue collar workers at a university campus, the *IL-1* genotype-positive group aged above 50 years showed significantly deeper PPD than their *IL-1* genotype-negative counterparts, especially when they were non-smokers.

In assessing the patient's risk for disease progression, systemic factors are only considered, if known, as the fifth risk indicator for recurrent disease in the functional diagram of risk assessment (see Fig. 60-3). In this case, the area of high risk is marked for this vector. If not known or absent, systemic factors are not taken into account in the overall evaluation of risk.

Research on the association and/or modifying influence on susceptibility and progression of periodontitis of physical or psychological stress is sparse (Cohen-Cole *et al*. 1981; Green *et al*. 1986; Freeman & Goss 1993). The hormonal changes associated with this condition, however, are well documented (Selye 1950).

Cigarette smoking

Consumption of tobacco, predominantly in the form of smoking or chewing, affects the susceptibility and the treatment outcome of patients with adult periodontitis. Classical explanations for these observations have included the association between smoking habits and poor oral hygiene, as well as lack of awareness of general health issues (Pindborg 1949; Rivera-Hidalgo 1986). More recent evidence, however, has established that smoking *per se* represents not only a risk marker, but probably also a true risk factor for periodontitis (Ismail *et al*. 1983; Bergström 1989; Bergström *et al*. 1991; Haber *et al*. 1993). In a young population (19–30 years of age), 51–56% of periodontitis was associated with cigarette smoking (Haber *et al*. 1993). The association of smoking and periodontitis has been shown to be dose-dependent (Haber *et al*. 1993). It has also been shown that smoking affects the treatment outcome after scaling and root planing (Preber & Bergström 1985), modified Widman flap surgery (Preber & Bergström 1990), and regenerative periodontal therapy (Tonetti *et al*. 1995). Furthermore, a high proportion of so-called refractory patients has been identified as smokers (Bergström & Blomlöf 1992). The impact of cigarette smoking on the long-term effects of periodontal therapy in a population undergoing supportive periodontal care has been reported. Smokers displayed less favorable healing responses both at re-evaluation and during a 6-year period of supportive periodontal care (Baumert-Ah *et al*. 1994). This was confirmed in another study in which higher percentages of heavy smokers experienced more multiple (≥9) residual pockets (≥5 mm) than non-smokers both after active periodontal therapy (31.2% versus 7.3%, respectively) and after 11 years of SPT (52.4% versus 14.8%, respectively) (Matuliene *et al*. 2008). In this study, heavy smoking was found to be a significant risk factor for periodontitis progression. Moreover, smoking was the main statistically significant risk factor for the recurrence of periodontitis after 10.5 years of SPT in the 84 patients with aggressive periodontitis. More than half of the current smokers in this study showed a recurrence of disease at re-examination and had a ten-fold increased risk for a relapse compared with non-smokers (Bäumer *et al*. 2011). In a systematic review of 13 observational studies of long-term periodontal maintenance, smoking was found to be associated with tooth loss, which could be interpreted as the end-point event of periodontitis progression (Chambrone *et al*. 2010).

In conclusion, today there is enough evidence relating cigarette smoking to impaired outcomes

during supportive periodontal care. Therefore, it seems reasonable to include heavy smokers (>20 cigarettes/day) in a higher risk group during maintenance.

In assessing the patient's risk for disease progression, environmental factors such as smoking must be considered as the sixth risk factor for recurrent disease in the functional diagram of risk assessment (see Fig. 60-3). While non-smokers (NS) and former smokers (FS) (>5 years since cessation) have a relatively low risk for recurrence of periodontitis, heavy smokers (HS), as defined by smoking more than one pack per day, are definitely at high risk. Occasional (OS; <10 cigarettes/day) and moderate smokers (MS; 11–19 cigarettes/day) may be considered at moderate risk for disease progression.

Calculating the patient's individual periodontal risk assessment

Based on the six parameters specified above, a multifunctional diagram is constructed for the PRA. In this diagram, the vectors have been constructed on the basis of the scientific evidence available. It is obvious that ongoing validation may result in slight modifications.

- *Low periodontal risk (PR) patient*: all parameters within the low-risk categories or at the most one parameter in the moderate-risk category (Fig. 60-3b)
- *Moderate PR patient*: at least two parameters in the moderate category, but at most only one parameter in the high-risk category (Fig. 60-3c)
- *High PR patient*: at least two parameters in the high-risk category (Fig. 60-3d).

The application of the multifunctional diagram for the subject-based PRA was validated in several studies. A 4-year prospective cohort study (Persson *et al*. 2003) yielded complete periodontal stability after individually tailored recall intervals for all patients with a negative *IL-1* gene polymorphism. For the *IL-1* genotype-positive patients, however, the PRA resulted only in periodontal stability for 90% of the patients. On the other hand, two recently published studies of 100 and 160 patients evaluating the results of SPT of mean duration of >10 years demonstrated that patients with a high-risk profile after active periodontal therapy were more prone to recurrence of periodontitis (Matuliene *et al.* 2010) and to tooth loss (Eickholz *et al*. 2008; Matuliene *et al*. 2010) than the patients with a moderate- or a low-risk profile.

Summary: The subject risk assessment may estimate the risk for susceptibility to progression of periodontal disease. It consists of an assessment of the level of infection (full-mouth BoP), the prevalence of residual periodontal pockets, tooth loss, an estimation of the loss of periodontal support in relation to the patient's age, an evaluation of the systemic conditions of the patient, and finally, an evaluation of environmental and behavioral factors such as smoking and stress. All these factors should be contemplated and evaluated together. A functional diagram (see Fig. 60-3) may help the clinician in determining the risk for disease progression at the subject level. This may be useful in customizing the frequency and content of SPT visits.

Tooth risk assessment

Tooth position within the dental arch

Early clinical surveys have associated the prevalence and severity of periodontal diseases with malocclusion and irregularities of tooth position (Ditto & Hall 1954; Bilimoria 1963). However, many subsequent studies using clinical evaluation methods could not confirm these conclusions (Beagrie & James 1962; Geiger 1962; Gould & Picton 1966). Although a relationship between crowding and increased plaque retention and gingival inflammation has been established (Ingervall *et al*. 1977; Buckley 1980; Griffith & Addy 1981; Hörup *et al*. 1987), no significant correlation between anterior overjet and overbite (Geiger *et al*. 1973), crowding and spacing (Geiger *et al*. 1974) or axial inclinations and tooth drifts (Geiger & Wasserman 1980) and periodontal destruction, that is attachment loss subsequent to gingival inflammation, could be established. It is evident from the literature mentioned that crowding of teeth might eventually affect the amount of plaque mass formed in dentitions with irregular oral hygiene practices, thus contributing to the development of chronic gingivitis. However, as of today, it remains to be demonstrated whether tooth malposition within the dental arch leads to an increased risk for periodontal attachment loss.

Furcation involvement

Multirooted teeth with periodontal lesions extending into the furcation area have been the subject of intensive therapeutic studies for many years (Kalkwarf & Reinhardt 1988). Retrospective analyses of large patient populations in the private periodontal practices of periodontal specialists (Hirschfeld & Wasserman 1978; McFall 1982) have clearly established that multirooted teeth appear to be at high risk for loss during the maintenance phase. The most impressive long-term documentation maintained 600 patients for an average duration of 22 years, and 10% of these patients were even maintained for >30 years (Hirschfeld & Wasserman 1978). While 83% of the patients could be considered "well maintained" and had lost only 0–3 teeth during the observation period, a patient group of 4% (25) was identified with an extreme risk for disease progression and had lost between 10 and 23 teeth during a regularly scheduled maintenance program. Irrespective of whether the patient group was of low, moderate, or high risk for

disease progression during maintenance, the majority of the teeth lost were furcation-involved molars (Hirschfeld & Wasserman 1978). Similar results were obtained in a study of 100 treated periodontal patients maintained for 15 years or longer (McFall 1982).

Prospective studies on periodontal therapy in multirooted teeth have also revealed significant differences between non-molar sites and molar flat surfaces on the one hand, and molar furcation sites on the other, when looking at treatment outcomes evaluated as BoP frequency, PPD reductions, and levels of attachment (Nordland *et al*. 1987). Again, teeth with furcation involvement and an original PPD of >6 mm had reduced treatment outcomes.

The assumption that the prognosis for single-rooted teeth and non–furcation-involved multirooted teeth is better than that for furcation-involved multirooted teeth was also confirmed by Ramfjord *et al*. (1987) in a prospective study over 5 years. It has to be realized, however, that these results are not intended to imply that furcation-involved teeth should be extracted, since all the prospective studies have documented a rather good overall prognosis for such teeth if regular supportive care is provided by a well-organized maintenance program.

Iatrogenic factors

Overhanging restorations and ill-fitting crown margins certainly represent areas for plaque retention, and there is an abundance of association studies documenting increased prevalence of periodontal lesions in the presence of iatrogenic factors (for review see Leon 1977). Depending on the supragingival or subgingival location of such factors, their influence on the risk for disease progression has to be considered. It has been established that slightly subgingivally located overhanging restorations will, indeed, change the ecologic niche, providing more favorable conditions for the establishment of a Gram-negative anaerobic microbiota (Lang *et al*. 1983). There is no doubt that shifts in the subgingival microflora towards a more periodontopathic microbiota, if unaffected by treatment, represent an increased risk for periodontal breakdown.

Residual periodontal support

Although many clinicians believe that teeth with reduced periodontal support are unable to function alone and should be extracted or splinted, there is clear evidence from longitudinal studies that teeth with severely reduced, but healthy, periodontal support can function either individually or as abutments for many years without any further loss of attachment (Nyman & Lindhe 1979; Nyman & Ericsson 1982; Brägger *et al*. 1990). Hence, teeth that have been successfully periodontally treated can be maintained over decades and function as abutments in fixed bridgework or as individual chewing units irrespective of the amount of residual periodontal support, provided that physiologic masticatory forces do not subject such teeth to a progressive trauma which may lead to spontaneous extraction. Obviously, by virtue of the already reduced support, should disease progression occur in severely compromised teeth, they may exfoliate spontaneously.

Mobility

In light of the discussion on abutment teeth with severely reduced but healthy periodontal support, tooth mobility may be an indicator for progressive traumatic lesions, provided that the mobility is increasing continuously (Nyman & Lang 1994). When assessing tooth mobility, it has to be realized that two factors may contribute to hypermobility: (1) a widening of the periodontal ligament as a result of unidirectional or multidirectional forces to the crown, high and frequent enough to induce resorption of the alveolar bone walls; and (2) the height of the periodontal supporting tissues. If this is reduced due to prior periodontal disease, but the width of the periodontal ligament is unchanged, the amplitude of root mobility within the remaining periodontium is the same as in a tooth with normal height, but the leverage on the tooth following application of forces to the crown is changed. Therefore, it has to be realized that all teeth that have lost periodontal support have increased tooth mobility as defined by crown displacement upon application of a given force. Nevertheless, this hypermobility should be regarded as physiologic (Nyman & Lindhe 1976).

Since tooth mobility is probably more frequently affected by reduced periodontal height rather than unidirectional or multidirectional application of forces on the tooth, its significance in the evaluation of periodontal conditions has to be questioned. Several studies have indicated that tooth mobility varies greatly before, during, and after periodontal therapy (Persson 1980, 1981a, b). From these studies it can be concluded that periodontally involved teeth show a decrease in mobility following non-surgical and/or surgical periodontal procedures. However, following surgical procedures, tooth mobility may temporarily increase during the healing phase and may resume decreased values later on. Provisional splinting as an adjunct to non-surgical or surgical therapy does not seem to affect the final tooth mobility.

Summary: The tooth risk assessment encompasses an estimation of the residual periodontal support, an evaluation of tooth positioning, furcation involvements, presence of iatrogenic factors, and a determination of tooth mobility to evaluate functional stability. A risk assessment at tooth level may be useful in evaluating the prognosis and function of an individual tooth and may indicate the need for specific therapeutic measures during SPT visits.

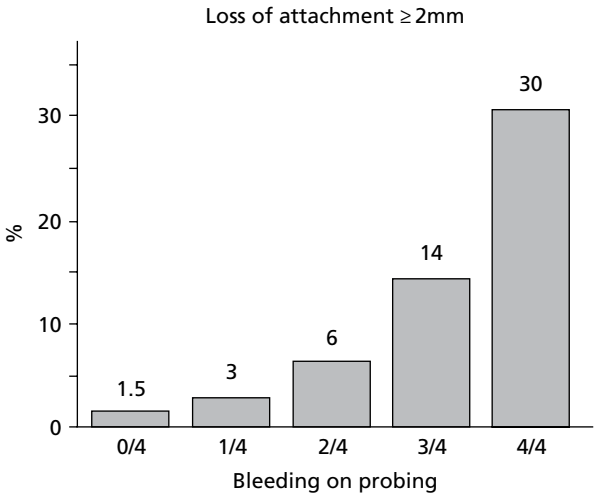

Fig. 60-5 Positive predictive values for loss of probing attachment of ≥2 mm in 2 years in sites which bled on probing 0, 1, 2, 3 or 4 times at four SPT visits in a total of 48 patients following active periodontal therapy. (Data from Lang *et al*. 1986.)

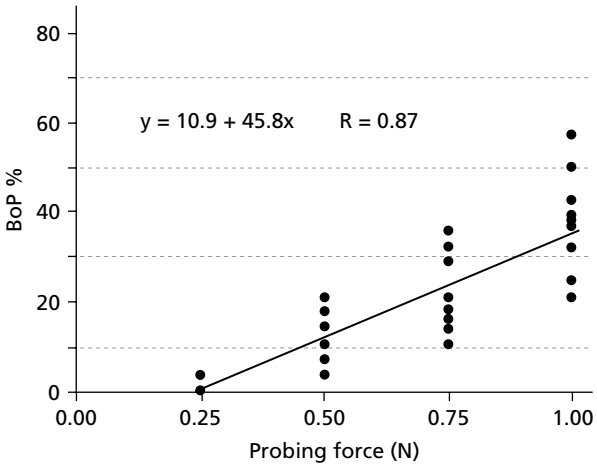

Fig. 60-6 Regression analysis between mean bleeding on probing (BoP) percentage and probing forces applied in young dental hygiene students with a healthy gingiva and normal anatomy. A very high correlation coefficient (R = 0.87) and an almost linear correlation between probing force and BoP percentage was found. (Data from Lang *et al*. 1991.)

Site risk assessment

Bleeding on probing

Absence of BoP is a reliable parameter to indicate periodontal stability if the test procedure for assessing BoP has been standardized (Lang *et al*. 1990). Presence of bleeding upon standardized probing will indicate the presence of gingival inflammation. Whether or not repeated BoP over time will predict the progression of a lesion is, however, questionable (Lang *et al*. 1986, 1990; Vanooteghem *et al*. 1987). Nevertheless, a 30% probability for attachment loss occurring in the future may be predicted for sites repeatedly positive for BoP (Fig. 60-5) (Badersten *et al*. 1985; Lang *et al*. 1986; Vanooteghem *et al*. 1987; Badersten *et al*. 1990; Claffey *et al*. 1990; Vanooteghem *et al*. 1990).

Obviously, BoP is rather sensitive to the different forces applied to the tissues. An almost linear relationship (R = 0.87) existed between the probing force applied and the percentage of bleeding sites in a study of healthy young adults (Fig. 60-6) (Lang *et al*. 1991). If the probing force exceeded 0.25 N (25 g), the tissues were traumatized and bleeding was provoked as a result of trauma, rather than as a result of tissue alterations due to inflammation. To assess the "true" percentage of bleeding sites due to inflammation, a probing force of 0.25 N or less should be applied, which clinically means a light probing force. This has also been confirmed for patients who have experienced loss of attachment, in other words with successfully treated advanced periodontitis (Fig. 60-7) (Karayiannis *et al*. 1991; Lang *et al*. 1991).

Since absence of BoP at 0.25 N indicated periodontal stability with a negative predictive value of 98–99% (Lang *et al*. 1990), this clinical parameter is the most reliable for monitoring patients over time in daily practice. Non-bleeding sites may be considered periodontally stable. On the other hand, bleeding

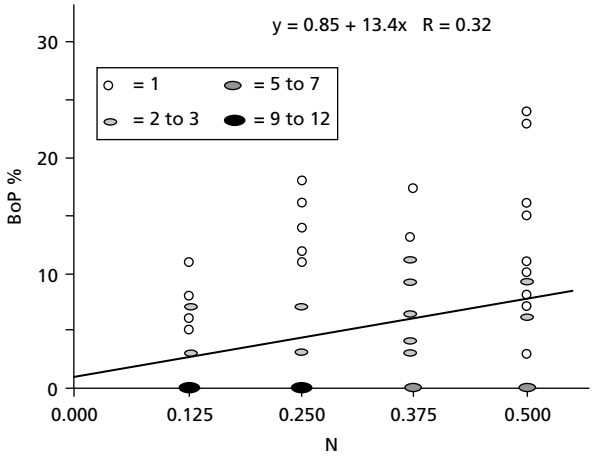

Fig. 60-7 Regression analysis between mean bleeding on probing (BoP) percentage and probing forces applied in subjects with successfully treated periodontitis: a reduced, but healthy, periodontium. (Data from Karayiannis *et al*. 1991.)

sites seem to have an increased risk for progression of periodontitis, especially when the same site bleeds at repeated evaluations over time (Lang *et al*. 1986; Claffey *et al*. 1990).

It is, therefore, advisable to register the sites with BoP in a dichotomous way using a constant force of 0.25 N. This allows the calculation of the mean BoP for the patient, and also yields the topographic location of the bleeding site. Repeated scores during maintenance will reveal the surfaces at higher risk for loss of attachment.

Probing depth and loss of attachment

Clinical probing is the most commonly used parameter both to document loss of attachment and to establish a diagnosis of periodontitis. There are, however, some sources of error inherent in this method which contribute to the variability in the

measurements. Among these are (1) the dimension of the periodontal probe; (2) the placement of the probe and obtaining a reference point; (3) the crudeness of the measurement scale; (4) the probing force; and (5) the gingival tissue conditions.

In spite of the recognized method errors inherent in clinical probing, this diagnostic procedure has not only been the most commonly used but is also the most reliable parameter for the evaluation of the periodontal tissues. It has to be realized that increased PPD and loss of probing attachment are parameters which reflect the history of periodontitis rather than its current state of activity. In order to obtain a more realistic assessment of the disease progression or, more commonly, the healing following therapy, multiple evaluations should be performed. Obviously, the first evaluation prior to therapy will yield results confounded by greater measurement error than evaluations following therapy. The reference point (cementoenamel junction) may be obstructed by calculus or by dental restorations, and the condition of the gingival tissues may allow an easy penetration of the periodontal probe into the tissues, even though the probe position and force applied are standardized. These biologic variables (tissue conditions and calculus) may be minimized following initial periodontal therapy, and hence, repeated periodontal evaluations using probing will improve the metric assessment. The first periodontal evaluation after healing following initial periodontal therapy should, therefore, be taken as the baseline for long-term clinical monitoring (Claffey 1994).

Suppuration

In a proportion of periodontal lesions, pus will develop and may drain through the orifice of a pocket. This criterion of suppuration may be recognized while clinically probing the lesion, or preferably, by using a ball burnisher (Singh *et al*. 1977). Several longitudinal studies on the results of periodontal therapy have evaluated clinical parameters, including suppuration, for the prediction of future loss of attachment (Badersten *et al*. 1985, 1990; Claffey *et al*. 1990). In all these studies, the presence of suppuration increased the positive predictive value for disease progression in combination with other clinical parameters, such as BoP and increased probing depth. Hence, following therapy, a suppurating lesion may provide evidence that the periodontitis site is undergoing a period of exacerbation (Kaldahl *et al*. 1990).

Summary: The tooth site risk assessment includes the registration of BoP, probing depth, loss of attachment, and suppuration. A risk assessment at the site level may be useful in evaluating periodontal disease activity and determining periodontal stability or ongoing inflammation. The site risk assessment is essential for the identification of the sites to be instrumented during SPT.

Radiographic evaluation of periodontal disease progression

As a consequence of the clinical risk assessments, the decision may be made to gather radiographic information on the periodontal conditions as well (Hirschmann *et al*. 1994). The task may be related to a generalized pattern of disease progression or a localized monitoring. Not only periodontal aspects, but also a comprehensive approach, should influence the choice of the radiographic technique (Rohlin & Akerblom 1992). Periodic radiographic surveys that are not based on clinical signs and symptoms should not be scheduled simply to confirm health.

Radiographic perception of periodontal changes is characterized by a high specificity, but a low sensitivity, with underestimation of the severity of a periodontal defect (Hämmerle *et al*. 1990; Åkesson *et al*. 1992). The undetectability of minute changes at the alveolar crest is related to overprojections and variations in projection geometry when taking repeated radiographs (Lang & Hill 1977; Goodson *et al*. 1984; Jenkins *et al*. 1992). This may result in mimicked variations in the alveolar bone height, obscured furcation status, etc. In addition, film processing variations may result in unreliable assessments of alveolar bone density changes (Rams *et al*. 1994).

The standard procedure for periodontal evaluations is based on a film-holder system with alignment for a long-cone paralleling technique (Rushton & Horner 1994). The addition of simple pins to the film-holder to provide a repositioning reference impressively reduced the methodologic error (Carpio *et al*. 1994).

In general, standards in oral radiology related to choice of a technique, quality of film processing, and diagnosis need to be improved (Brägger 1996).

Clinical implementation

The *three levels* of risk assessment presented represent a logical sequence for the clinical evaluation prior to rendering treatment during maintenance. The information gathered from a stepwise evaluation should not impinge on, but should rather improve, the efficacy of secondary prophylactic periodontal care and treatment. A logical sequence of checks and examinations may be easily obtained in a short period of time and at no extra cost in terms of laboratory tests. The information obtained from clinical monitoring and multilevel risk assessment facilitates an immediate appreciation of the periodontal health status of an individual and his/her possible risk for further infection and/or disease progression.

Most longitudinal studies published to date have been based on single-level, that is site or tooth, risk assessment, rather than accounting for the most evident factor in risk assessment: the patient. Ample evidence indicates that a minority of patients will continue to present problems and hence, the appropriate maintenance program for them will differ

completely from that visualized in the majority of the patients. Even in those studies where this fact has been explicitly addressed (Hirschfeld & Wasserman 1978), the factors determining whether a patient belongs to a well-maintained group or to a group with continuous loss of periodontal attachment have not been identified.

Summary: It is suggested that patients are evaluated at the *three different levels* mentioned. At the patient level, loss of support in relation to patient age, full-mouth plaque and/or BoP scores, and prevalence of residual pockets are evaluated, together with the presence of systemic conditions or environmental factors, such as smoking, which can influence the prognosis. The clinical utility of this first level of risk assessment influences primarily the determination of the recall frequency and time requirements of maintenance. It should also provide a perspective for the evaluation of the risk assessment conducted at the tooth and tooth-site levels.

At the tooth and tooth-site levels, residual periodontal support, inflammatory parameters and their persistence, presence of difficult to access ecologic niches, such as furcations, and presence of iatrogenic factors have to be put into perspective with the patient's overall risk profile (Fig. 60-8). The clinical utility of tooth and tooth-site risk assessment relates to the rational allocation of the recall time available for therapeutic intervention to the sites with higher risk, and possibly to the selection of different forms of therapeutic intervention.

Objectives for supportive periodontal therapy

The objective of maintenance care must be the continued preservation of gingival and periodontal health, obtained as a result of the active periodontal treatment. Irrespective of whether or not additional treatment such as prosthetic reconstructions or placement of implants has been rendered, the regular and adequate removal of supragingival plaque by the patient is, therefore, a prerequisite for a good long-term prognosis. In order to achieve these goals, regular clinical re-evaluations with appropriate interceptive treatment, continued psychological support and encouragement of the patient, and a lifelong commitment by the therapists are required.

General rules regarding frequency of maintenance care visits are difficult to define. However, there are a few aspects to consider in this respect: the patient's individual oral hygiene standard, the prevalence of sites exhibiting BoP, and the pretherapeutic attachment level and alveolar bone height. This in turn means that patients with suboptimal plaque control and/or concomitant high prevalence of bleeding sites should be recalled more frequently than patients exhibiting excellent plaque control and healthy gingival tissues. Nevertheless, patients with healthy gingival conditions, but with a severely reduced height of periodontal support, should also be recalled at short time intervals (not exceeding 3–4 months) in order to exclude or at least reduce the risk of additional tooth

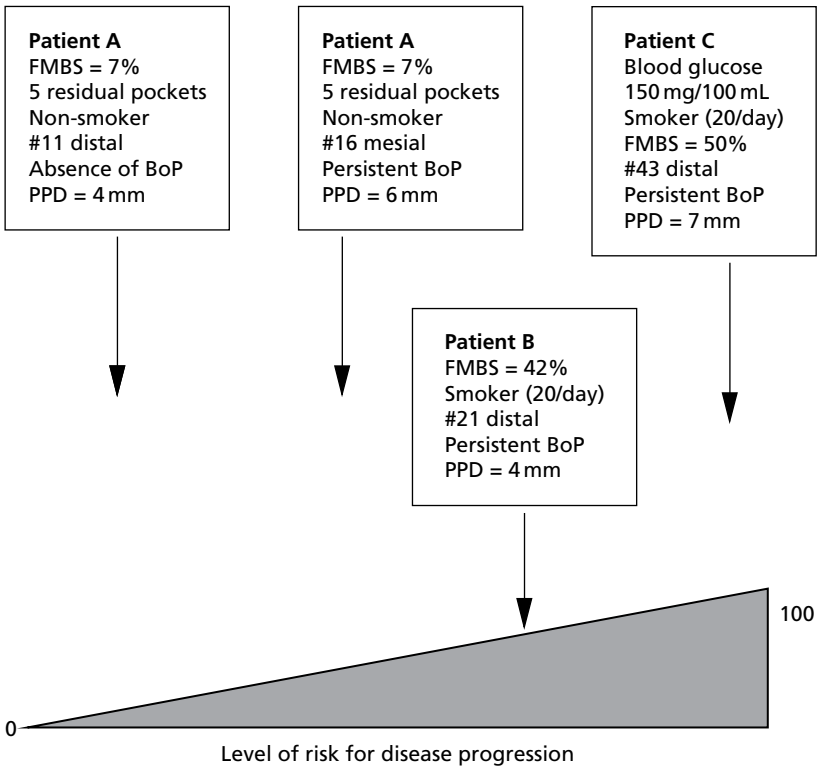

Fig. 60-8 Continuous multiple level risk assessment. Subject, tooth, and site parameters are combined to establish the clinical risk for disease progression. Note that different sites in the same patient may have a different level of risk. Subject-based risk factors are used to put the tooth and/or site risk assessment in perspective. (FMBS, full-mouth bleeding score; PPD, probing pocket depth.)

loss. In most of the longitudinal studies referred to above, positive treatment results were maintained with regular maintenance care provided at 3–6-month intervals. It seems reasonable to commence post-therapeutic maintenance with recall visits once every 3–4 months and then shorten or prolong these intervals in accordance with the aspects discussed above.

Since clinical attachment levels are usually stable 6 months following active periodontal therapy, it has been suggested that the first 6 months after completion of therapy be considered a healing phase (Westfelt *et al*. 1983b) during which frequent professional tooth cleaning has been recommended. Following this healing phase, it is generally agreed to recall patients treated for periodontal disease at intervals of 3–4 months in a well-organized system of SPT. It has to be realized that tissue contours may be subjected to remodeling processes despite stable clinical attachment levels and, hence, morphologic changes may still improve the accessibility of all tooth surfaces to oral hygiene practices for months and even years. Proper oral hygiene practices appear to be the most important patient factor that can guarantee long-term stability of treatment results (Knowles *et al*. 1979; Ramfjord *et al*. 1982; Lindhe & Nyman 1984; Ramfjord *et al*. 1987). This, in turn, necessitates optimization of the patient's skills and continuous motivation and reinforcement to perform adequate mechanical oral hygiene practices, although chemical agents, such as the potent antiseptic chlorhexidine, may substitute and later complement the patient's efforts during the healing phase, when mechanical practices are difficult (Westfelt *et al*. 1983a). It is obvious that regular recall visits for SPT should be scheduled soon after completion of cause-related therapy, even if periodontal surgical procedures are still to be performed following a careful re-evaluation of the tissue response. To postpone the organization of a maintenance care program until corrective procedures such as surgery, endodontic, implant, operative or reconstructive therapy have been performed may reinforce a possible misconception by the patient that the professional visits to a therapist or hygienist guarantee positive treatment outcomes and optimal long-term prognosis rather than the patient's own regular performance of individually optimal and adequate oral hygiene practices.

Supportive periodontal therapy in daily practice

The recall hour should be planned to meet the patient's individual needs. It basically consists of four different sections which may require various amounts of time during a regularly scheduled visit:

1. Examination, re-evaluation, and diagnosis (ERD)
2. Motivation, re-instruction, and instrumentation (MRI)
3. Treatment of re-infected sites (TRS)
4. Polishing of the entire dentition, application of fluorides, and determination of future SPT (PFD).

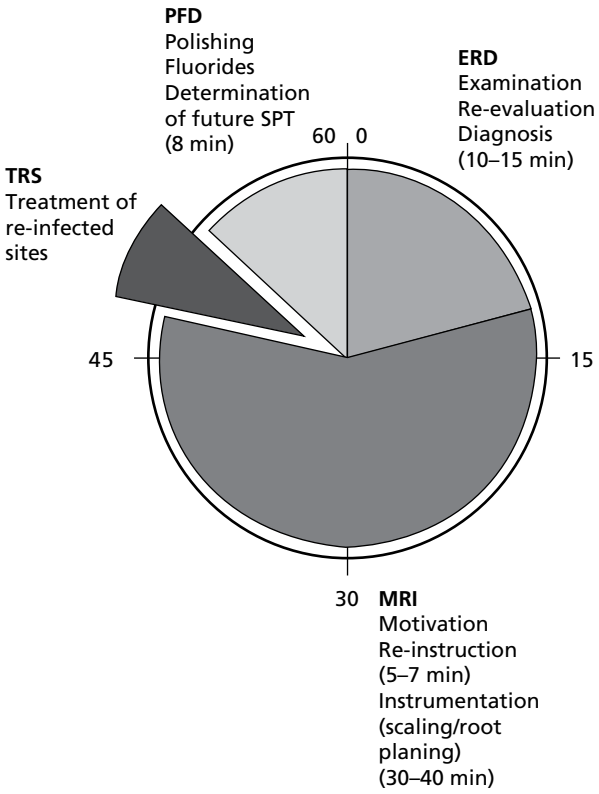

Fig. 60-9 SPT recall hour is divided into four sections. (1) Examination, re-evaluation, and diagnosis (ERD) providing information on stable and inflamed sites. This segment uses 10–15 minutes. (2) Motivation, re-instruction of oral hygiene where indicated, and instrumentation (MRI) use the bulk of the recall hour (30–40 minutes). Sites diagnosed as not stable are instrumented. (3) Treatment of re-infected sites (TRS) may require a second appointment. (4) Polishing all tooth surfaces, application of fluorides, and determination of the future recall interval (PFD) conclude the recall hour (5–10 minutes).

The SPT recall hour (Fig. 60-9) generally consists of 10–15 minutes of diagnostic procedures (ERD) followed by 30–40 minutes of motivation, re-instruction, and instrumentation (MRI), with the instrumentation concentrated on the sites diagnosed with persistent inflammation. Treatment of re-infected sites (TRS) may include small surgical corrections, applications of local drug delivery devices or just intensive instrumentation under local anesthesia. Such procedures, if judged necessary, may require an additional appointment. The recall hour is normally concluded with polishing of the entire dentition, application of fluorides, and another assessment of the situation, including the determination of future SPT visits (PFD). Approximately 5–10 minutes have to be reserved for this section.

Examination, re-evaluation, and diagnosis

Since patients on SPT may experience significant changes in their health status and the use of

medications, an update of the information on general health issues is appropriate. Changes in health status and medications should be noted. In middle-aged to elderly patients especially, these aspects might influence the future management of the patient. An extraoral and intraoral soft tissue examination should be performed at any SPT visit to detect any abnormalities and to act as a screening for oral cancer. The lateral borders of the tongue and the floor of the mouth should be inspected in particular. An evaluation of the patient's risk factors will also influence the choice of future SPT and the determination of the recall interval at the end of the maintenance visit. Following the assessment of the subject's risk factors, the tooth site-related risk factors are evaluated. As indicated above, the diagnostic procedure usually includes an assessment of the following:

- Oral hygiene and plaque situation
- Determination of sites with BoP, indicating persistent inflammation
- Scoring of clinical probing depths and clinical attachment levels. The latter is quite time-consuming and requires the assessment of the location of the cementoenamel junction as a reference mark on all (six) sites of each root. Therefore, an SPT evaluation usually only includes scoring of clinical probing depths
- Inspection of re-infected sites with pus formation
- Evaluation of existing reconstructions, including vitality checks for abutment teeth
- Exploration for carious lesions.

All these evaluations are performed for both teeth and oral implants. Occasionally, conventional dental radiographs should be obtained at SPT visits. Especially for devitalized teeth, abutment teeth and oral implants, single periapical films exposed with a parallel and preferably standardized technique are of great value. Bitewing radiographs are of special interest for caries diagnostic purposes. They also reveal plaque-retentive areas such as overhanging fillings and ill-fitting crown margins. Since only approximately 10–15 minutes are available for this section, these assessments have to be performed in a well-organized fashion. It is preferable to have a dental assistant available to note all the results of the diagnostic tests unless a voice-activated computer-assisted recording system is used.

Motivation, re-instruction, and instrumentation

This aspect uses most of the available time of the SPT visit. When informed about the results of the diagnostic procedures, for example the total percentage BoP score or the number of pockets exceeding 4 mm, the patient may be motivated either in a confirmatory way in the case of low scores or in a challenging fashion in the case of high scores. Since encouragement usually has a greater impact on future positive developments than negative criticism, every effort should be made to acknowledge the patient's performance.

Fig. 60-10 Wedge-shaped defects apical to the cementoenamel junction following recession of the gingival tissues resulting from overzealous or faulty toothbrushing.

Patients who have experienced a relapse in their adequate oral hygiene practices need to be further motivated. Positive encouragement is especially appropriate if a patient's personal life situation has influenced his/her performance. Standard "lecturing" should be replaced by an individual approach.

Occasionally, patients present with hard tissue lesions (wedge-shaped dental defects) which suggest overzealous and/or faulty mechanical tooth cleaning (Fig. 60-10). Such habits should be broken and the patient re-instructed in toothbrushing techniques which emphasize vibratory rather than scrubbing movements.

Since it appears impossible to instrument 168 tooth sites in a complete dentition in the time allocated, only those sites which exhibit signs of inflammation and/or active disease progression will be re-instrumented during SPT visits. Trauma from repeated instrumentation of healthy sites will inevitably result in continued loss of attachment (Lindhe *et al*. 1982a). In contrast, residual pockets of ≥6 mm may lead to periodontitis progression and tooth loss (Badersten *et al*. 1990; Claffey *et al*. 1990, Matuliene *et al*. 2008). Interestingly, the association of the residual PPD with tooth loss over a mean of 11.3 years of maintenance was calculated at the site and at the tooth level (Table 60-3). Starting from a residual PPD of 4 mm, the increase of the PPD by 1 mm was highly statistically significantly associated with tooth loss

Table 60-3 Results from multilevel logistic regression models for the association of site probing pocket depth (PPD) and deepest PPD of a tooth at the end of therapy with tooth loss during supportive periodontal therapy of mean duration of 11.3 years (not accounting for bleeding on probing).

PPD (mm)	Site level			Tooth level		
	OR	95% CI	*P* value	OR	95% CI	*P* value
≤3	1.0					
4	2.6	2.2–3.1	<0.0001	2.5	1.8–3.6	<0.0001
5	5.8	4.3–7.9	<0.0001	7.7	4.8–12.3	<0.0001
6	9.3	6.2–13.9	<0.0001	11.0	6.1–20.1	<0.0001
≥7	37.9	17.9–80.2	<0.0001	64.2	24.9–165.1	<0.0001

OR, odds ratio; CI, confidence interval.

(Matuliene *et al*. 2008). Hence, all the BoP-positive sites and all pockets with a PPD exceeding 4 mm are carefully rescaled and root planed as instrumenting healthy sites repeatedly will inevitably result in mechanically-induced loss of attachment (Lindhe *et al*. 1982a).

Similar observations were made in clinical studies by Claffey *et al*. (1988): loss of clinical attachment levels immediately following instrumentation was observed in 24% of the sites. It is also known from regression analyses of several longitudinal studies (e.g. Lindhe *et al*. 1982b) that probing attachment may be lost following instrumentation of pockets below a "critical probing depth" of approximately 2.9 mm. Instrumentation of shallow sulci is, therefore, not recommended. As it has been shown in several studies that sites that do not bleed on probing represent stable sites (Lang *et al*. 1986, 1990; Joss *et al*. 1994), it appears reasonable to leave non-bleeding sites for polishing only and to concentrate on periodontal sites with a positive BoP test or PPD of >5 mm. To protect the hard tissues, root planing should be performed with great caution. The deliberate removal of "contaminated" cementum during SPT is no longer justified (Nyman *et al*. 1986, 1988; Mombelli *et al*. 1995). During SPT visits, root surface instrumentation should be aimed especially at the removal of subgingival plaque rather than "diseased" cementum. This may require a more differentiated approach than hitherto recommended. In this respect, the use of ultrasonics may have to be re-evaluated.

Treatment of re-infected sites

Single sites, especially furcation sites or sites that are difficult to access, may occasionally be re-infected and demonstrate suppuration. Such sites require a thorough instrumentation under anesthesia, the local application of antibiotics in controlled-release devices or even open debridement with surgical access. It is evident that such therapeutic procedures may be too time-consuming to be performed during the routine recall hour, and hence, it may be necessary to reschedule the patient for another appointment. Omission of thorough retreatment of such sites or only performing incomplete root instrumentation during SPT may result in continued loss of probing attachment (Kaldahl *et al*. 1988; Kalkwarf *et al*. 1989).

Treatment choices for re-infected sites should be based on an analysis of the most likely causes for the re-infection. Generalized re-infections are usually the result of inadequate SPT. Although not all sites positive for BoP may further progress and lose attachment, high BoP percentages call for more intensive care and more frequent SPT visits. Sometimes, a second visit 2–3 weeks after the recall may be indicated to check the patient's performance in oral home care. It is particularly important to supervise patients closely for advanced periodontitis if they have a high subject risk assessment (Westfelt *et al*. 1983b; Ramfjord 1987). Local re-infections may either be the result of inadequate plaque control in a local area or the formation of ecologic niches conducive to periodontal pathogens. The risk assessment at the tooth level may identify such niches which are inaccessible for regular oral hygiene practices. Furcation involvements often represent special periodontal risk factors which may require additional therapy to be performed following diagnosis in the regular SPT visit.

Polishing, fluorides, and determination of recall interval

The recall hour is concluded with polishing the entire dentition to remove all remaining soft deposits and stains. This may give the patient a feeling of freshness and facilitates the diagnosis of early carious lesions. Following polishing, fluorides should be applied in high concentration in order to replace the fluorides which may have been removed by instrumentation from the superficial layers of the teeth. Fluoride or chlorhexidine varnishes may also be applied to prevent root surface caries, especially in areas with gingival recession. The determination of future SPT visits must be based on the patient's risk assessment.

Summary: Figure 60-11 provides a flowchart for SPT. The SPT recall hour is divided into four sections. While the first 10–15 minutes are reserved for examination, re-evaluation, and diagnosis, the second and most time-consuming section of 30–40 minutes is devoted to re-instruction and instrumentation of sites identified to be at risk in the diagnostic process. Some re-infected sites may require further treatment, and hence, the patient may have to be rescheduled for an additional appointment. The recall hour is concluded by polishing the dentition, applying fluorides, and determining the frequency of future SPT visits.
