Abscesses in the Periodontium

David Herrera,[1] Arie J. van Winkelhoff,[2] and Mariano Sanz[1]

[1]ETEP (Etiology and Therapy of Periodontal Diseases) Research Group, Faculty of Odontology, University Complutense, Madrid, Spain
[2]Faculty of Medical Sciences, Center for Dentistry and Oral Hygiene, University of Groningen, Groningen, The Netherlands

Introduction

Abscesses in the periodontium are one of the main reasons patients seek emergency care in the dental clinic. They are characterized as a localized purulent inflammation present in the periodontal tissues that causes pain and swelling, and, depending on the origin of the infection, they can be associated with different symptoms. These abscesses are caused by a broad group of acute infections that may originate from the tooth and/or the periodontium.

Classification and etiology

Although defined by the general term periodontal abscesses, this group of acute periodontal conditions has been classified depending on the evolution as chronic or acute, and depending on the location as single or multiple, gingival or periodontal if occurring in the supporting periodontal tissues. A classification was proposed by Meng (1999) that included: *gingival abscesses* (in previously healthy sites, caused by impaction of foreign bodies), *periodontal abscesses* (either acute or chronic, in relation to a periodontal pocket), and *pericoronal abscesses* (in relation to a partially erupted tooth). This classification was included in the revised classification system for periodontal diseases developed by the American Academy of Periodontology International Workshop for a Classification of Periodontal Diseases in 1999, which for the first time included periodontal abscesses as an independent entity.

The most appropriate classification of periodontal abscesses, however, is the one based on etiology. Depending on the origin of the acute infectious process, two types of abscesses may occur:

1. *Periodontitis-related abscess*: the acute infection originates from bacteria present at the subgingival biofilm in a deepened periodontal pocket
2. *Non-periodontitis-related abscess*: the acute infection originates from bacteria coming from another local source, such as a foreign body impaction, or from alterations of the integrity of the root leading to bacterial colonization.

In a periodontitis patient, a periodontal abscess represents a period of active tissue breakdown and is the result of an acute exacerbation of a chronic infection residing in the periodontal tissues. The abscess formation is usually due to the marginal closure of a deep periodontal pocket that prevents proper drainage. The existence of deep, tortuous pockets and deep concavities associated with furcation lesions, therefore, favors the development of these acute conditions. This acute inflammatory process is characterized by the local accumulation of neutrophils, remnants of tissue breakdown, and pus formation. If this pus retention is not drained from the pocket, the destructive process may progress rapidly.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Different pathogenic mechanisms can lead to abscess formation in the *periodontium*:

- *Exacerbation of a chronic lesion*. Such abscesses may develop in a deepened periodontal pocket without any obvious external influence, and may occur in (1) an untreated periodontitis patient or (2) as a recurrent infection during supportive periodontal therapy (Silva *et al.* 2008).
- *Post-therapy periodontal abscesses*. There are various causes of abscess formation during the course of active therapy:
  - *Post-scaling periodontal abscess* (Dello Russo 1985). When these lesions occur immediately after scaling or after routine professional prophylaxis, they are usually related to the presence of small fragments of remaining calculus that obstruct the pocket entrance once the edema in the gingival tissues has receded (Dello Russo 1985; Carranza 1990). This type of abscess formation can also occur when small fragments of calculus have been forced into the deep, previously non-inflamed periodontal tissues (Dello Russo 1985).
  - *Post-surgery periodontal abscess*. When an abscess occurs immediately following periodontal surgery, it is often the result of incomplete removal of subgingival calculus or the presence of foreign bodies in the periodontal tissues, such as sutures, regenerative devices, or pieces of periodontal pack (Garrett *et al.* 1997).
  - *Post-antibiotic periodontal abscess*. Treatment with systemic antibiotics without appropriate subgingival debridement in patients with advanced periodontitis may also cause abscess formation (Helovuo & Paunio 1989; Topoll *et al.* 1990; Helovuo *et al.* 1993). In these situations, the subgingival biofilm may be partially protected from the action of the antibiotic, resulting in an acute infection that leads to inflammation and tissue destruction. Helovuo *et al.* (1993) followed up patients with untreated periodontitis who were given broad-spectrum antibiotics (penicillin, erythromycin) for non-oral reasons and reported that 42% of them developed marginal abscesses within 4 weeks of the antibiotic therapy.

Non–periodontitis-related abscess formation may also occur in relation to a periodontal pocket, but in such cases, there is always an external local factor that explains the acute inflammatory process. These include:

- A foreign body impacted in the gingival sulcus or periodontal pocket (Gillette & Van House 1980; Abrams & Kopczyk 1983), such as oral hygiene devices (toothbrush, tooth picks, etc.) (Gillette & Van House, 1980; Abrams & Kopczyk 1983), orthodontic appliances, food particles, or even pieces of nail in subjects with nail-biting habits (Sousa *et al.* 2010).
- Anatomic factors affecting the root morphology, such as invaginated roots (Chen *et al.* 1990), presence of fissures (Goose 1981), external root resorption, root tears (Haney *et al.* 1992; Ishikawa *et al.* 1996;) or iatrogenic endodontic perforations (Abrams *et al.* 1992).

Prevalence

The prevalence of periodontal abscesses was studied in emergency dental clinics (Ahl *et al.* 1986; Galego-Feal *et al.* 1996), in general dental clinics (Lewis *et al.* 1990), in periodontitis patients before treatment (Gray *et al.* 1994), and in periodontitis patients during supportive periodontal therapy (SPT) (Kaldahl *et al.* 1996; McLeod *et al.* 1997).

Among all dental conditions in need of emergency treatment, periodontal abscesses represent between 8% and 14% (Ahl *et al.* 1986; Galego-Feal *et al.* 1996). Gray *et al.* (1994) monitored periodontal patients in a military clinic and found that periodontal abscesses had a prevalence of 27.5%. In this population, 13.5% of the patients undergoing active periodontal treatment had experienced abscess formation, while untreated patients showed a higher percentage of 59.7%. McLeod *et al.* (1997) followed 114 patients in SPT and identified 42 patients (27.5%) who had suffered from acute periodontal abscesses.

Kaldahl *et al.* (1996) studied the occurrence of periodontal abscesses in a prospective longitudinal treatment study over 7 years of periodontal maintenance. In the 51 patients included, 27 abscesses were detected and of these, 23 occurred in teeth treated only by coronal scaling, while only three occurred in teeth treated by root planing and one in teeth treated with surgical therapy. Of the 27 abscesses, 16 had an initial probing pocket depth of >6 mm, while at eight sites the probing depth was 5–6 mm.

Abscesses occur more often in molar sites, which represent >50% of all sites affected by abscess formation (Smith & Davies 1986; McLeod *et al.* 1997; Herrera *et al.* 2000a). This may be due to the presence of pockets involving the furcation and the complex anatomy and root morphology of multirooted teeth. In a clinical report in Colombian patients, however, the lower anterior incisors were the most frequently affected teeth (Jaramillo *et al.* 2005).

The occurrence of a periodontal abscess is important not only because it causes acute symptoms in the patient, but also because these acute infections may influence the prognosis of the affected teeth. When abscesses develop during SPT in teeth with residual deep periodontal pockets and reduced periodontal support, this additional periodontal destruction is frequently the main indication for tooth extraction (Chace & Low 1993; McLeod *et al.* 1997).

Pathogenesis and histopathology

The periodontal abscess lesion contains bacteria, bacterial products, inflammatory cells, tissue breakdown products, and serum. The precise pathogenesis of this

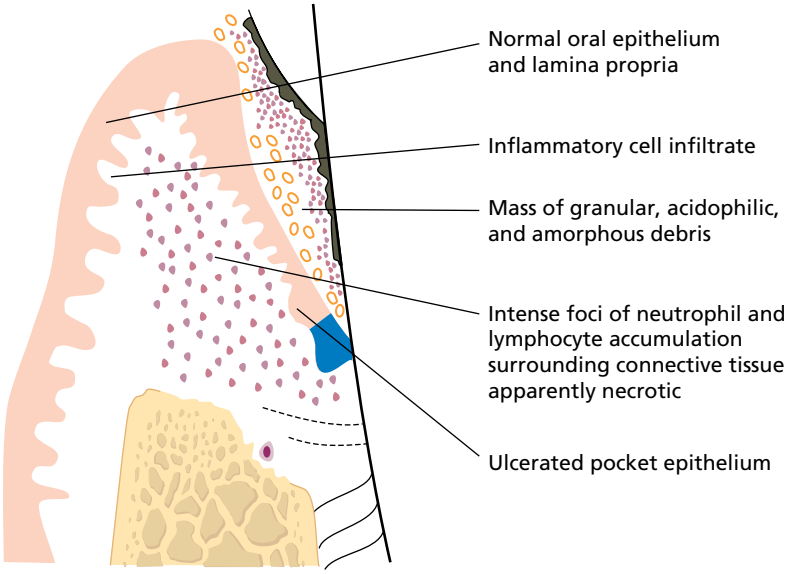

Fig. 24-1 Schematic diagram showing the pathology of a periodontal abscess.

lesion is still obscure. It is hypothesized that the occlusion of the periodontal pocket lumen, due to trauma or tissue tightening, will prevent proper drainage, resulting in the extension of the infection from the pocket into the soft tissues of the pocket wall, and the formation of the abscess. Although the invasion of bacteria into the soft tissue pocket wall could be the initiating event, it is the accumulation of leukocytes and the formation of an acute inflammatory infiltrate that causes the connective tissue destruction, encapsulation of the bacterial mass, and formation of pus. The accumulation of inflammatory cells and the resulting secretion of extracellular enzymes and inflammatory mediators, such as catabolic cytokines, is the main cause of connective tissue destruction. The bacterial load and virulence, together with the tissue resistance, will determine the course of this acute inflammatory process.

The histopathology of the abscess shows a central area filled with neutrophils, bacteria, and debris of soft tissue destruction. At a later stage, a pyogenic membrane, composed of macrophages and neutrophils, is organized to enucleate this central core. The rate of tissue destruction within the lesion will depend on the growth of bacteria inside the foci and their virulence, as well as on the local pH. An acidic environment will favor the release of lysosomal enzymes from the granulocytes and promote tissue destruction (DeWitt *et al.* 1985).

De Witt *et al.* (1985) studied biopsies sampled from 12 abscesses. These biopsies extended apically to the center of the abscess and were processed histologically. This revealed a normal oral epithelium and lamina propria, but the presence of an inflammatory cell infiltrate located laterally to the pocket epithelium. Within this infiltrate, there were accumulations of neutrophils and lymphocytes, together with tissue destruction and a mass of granular, acidophilic, debris (Fig. 24-1). Some of these biopsies were evaluated by electron microscopy, which demonstrated the presence of Gram-negative bacteria invading the pocket epithelium and the infiltrated connective tissue.

Microbiology

In review articles and textbooks it is usually cited that that purulent oral infections are polymicrobial and mainly caused by endogenous bacteria (Tabaqhali 1988). There are very few studies, however, that have investigated the specific microbiota of periodontal abscesses. Newman and Sims (1979) studied nine abscesses and found that 63.1% of the microbiota was comprised of strict anaerobes. Topoll *et al.* (1990) analyzed 20 abscesses in ten patients who had taken antibiotics prior to the study. They reported that 59.5% of the microbiota was made up of strict anaerobes. Herrera *et al.* (2000a) reported that 45.1% of the bacteria in the abscess material were anaerobes.

These studies have shown that the microbiota of periodontal abscesses does not differ from the microbiota of chronic periodontitis lesions. This microflora is polymicrobial and dominated by non-motile, Gram-negative, strict anaerobic, rod-shaped species. Among these bacteria, *Porphyromonas gingivalis* is probably the most virulent and relevant microorganism. The reported occurrence of *P. gingivalis* in periodontal abscesses ranged from 50% to 100% in bacterial culture studies (Newman & Sims 1979; van Winkelhoff *et al.* 1985; Topoll *et al.* 1990; Hafström *et al.* 1994; Herrera *et al.* 2000a; Jaramillo *et al.* 2005). Using molecular techniques, such as the polymerase chain reaction (PCR), Ashimoto *et al.* (1998) found *P. gingivalis* in all of the seven abscesses they studied. Eguchi *et al.* (2008), using a commercial molecular test (IAI-PadoTest 4.5; IAI Inc., IAI Institute, Zuchwil, Switzerland), also reported high prevalences of *P. gingivalis, Tannerella forsythia*, and *Treponema denticola*, and low prevalences of *Aggregatibacter actinomycetemcomitans*. Other anaerobic species that are usually found

include *Prevotella intermedia*, *Prevotella melaninogenica*, and *Fusobacterium nucleatum*. Spirochetes (*Treponema* spp.) are found in most cases (Ashimoto *et al.* 1998). The majority of the Gram-negative anaerobic species are non-fermentative and display moderate-to-strong proteolytic activity. Strict anaerobic, Gram-positive species frequently present in periodontal abscesses include *Parvimonas micra*, *Actinomyces* spp., and *Bifidobacterium* spp. Facultative anaerobic Gram-negative bacteria that can be isolated from periodontal abscesses include *Campylobacter* spp., *Capnocytophaga* spp., and *A. actinomycetemcomitans* (Hafström *et al.* 1994). The presence of Gram-negative enteric rods has also been reported (Jaramillo *et al.* 2005).

Diagnosis

The diagnosis of a periodontal abscess should be based on the overall evaluation and interpretation of the patient's symptomatology, together with the clinical and radiologic signs found during the oral examination (Corbet 2004).

The most frequent sign of a periodontal abscess is the presence of an ovoid elevation in the periodontal tissues along the lateral side of the root (Fig. 24-2). Abscesses located deep in the periodontium may be more difficult to identify as they may manifest as a diffuse swelling or simply a red area (Fig. 24-3), rather than a prominent swelling of the soft tissues. Another common finding is suppuration either through a fistula or, most commonly, through the pocket opening (Fig. 24-4). This suppuration may be spontaneous or occur when pressure is applied to the outer surface of the lesion.

The clinical symptomatology usually includes pain (from light discomfort to severe pain), tenderness of the gingiva, swelling, and sensitivity to percussion of the affected tooth. Other related symptoms are tooth elevation and increased tooth mobility (Fig. 24-5).

During the periodontal examination, the abscess is usually found at a site with a deep periodontal pocket. Signs associated with periodontitis such as bleeding on probing, suppuration, and sometimes increased tooth mobility are also frequently present (Smith & Davies 1986; Hafström *et al.* 1994; Herrera *et al.* 2000a). The radiographic examination may either reveal a normal appearance of the interdental bone or evident bone loss, ranging from just a widening of the periodontal ligament space to pronounced bone loss involving most of the affected root (Fig. 24-6).

Fig. 24-2 Periodontal abscess associated with a lower right first molar. Note the association between the abscess formation and the furcation lesion in this molar. The arrows indicate the apical limits of the abscess.

Fig. 24-3 Periodontal abscess associated with a mandibular second molar. Note the diffuse swelling affecting the entire buccal surface of the molar.

Fig. 24-4 Periodontal abscess associated with a lower right first molar. Note the spontaneous suppuration expressed through the gingival margin.

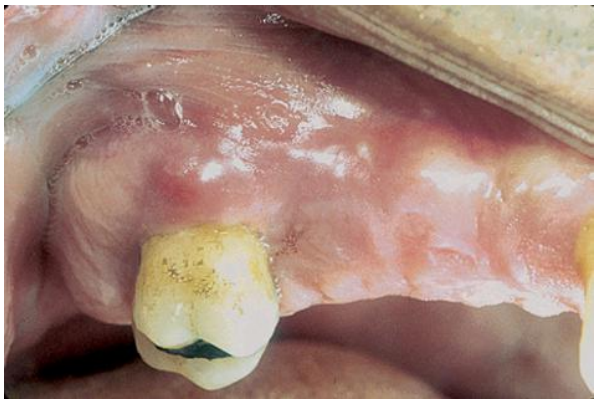

Fig. 24-5 Periodontal abscess associated with an upper right third molar. Note how this lesion is associated with tooth extrusion and mobility.

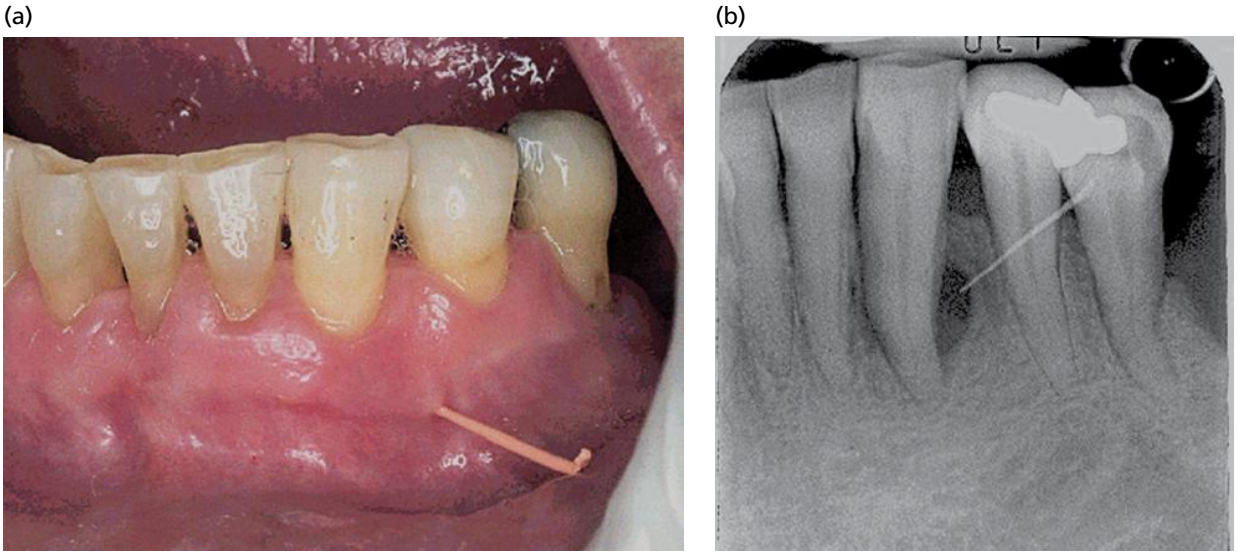

Fig. 24-6 (a) Periodontal abscess associated with a lower left canine. Note the fistulous tract opening demonstrated with a gutta-percha point. (b) Radiographic image of the lower canine shown in (a). Diagnosis of a periodontal abscess was made from the positive tooth vitality and absence of caries or restoration in the canine, and the presence of a deep periodontal pocket in the lingual aspect of this tooth.

In some patients, the occurrence of a periodontal abscess may be associated with elevated body temperature, malaise, and regional lymphadenopathy (Smith & Davies 1986; Carranza 1990; Ibbott *et al.* 1993; Herrera *et al.* 2000a). Herrera *et al.* (2000a) studied the laboratory data from patient's blood and urine taken immediately after the diagnosis of a periodontal abscess and reported that in 30% of the patients the number of blood leukocytes was elevated. The absolute number of blood neutrophils and monocytes was also elevated in 20–40% of the patients.

Differential diagnosis

The differential diagnosis of periodontal abscesses should always consider other abscesses that may occur in the oral cavity. Acute infections, such as periapical abscesses, lateral periapical cysts, vertical root fractures, and endoperiodontal lesions may have a similar appearance and symptomatology, although their etiology is different and therefore, their appropriate therapy will depend on an accurate differential diagnosis. Signs and symptoms indicating a periodontal origin include: a history of periodontal disease or previous periodontal therapy, presence of deep periodontal pockets with suppuration when probed, and, usually, tooth vitality. Radiographically, these affected teeth show crestal bone loss and frequently angular bony defects and furcation lesions. A likely periapical (endodontal) origin will include the following signs and symptoms: a history of caries or presence of advanced caries lesions, presence of restorations or root canal therapy, questionable or non-responsive to pulpal vitality tests, and presence of a sinus fistulous tract. Radiologically, there is usually evidence of a periapical radiolucency associated with a carious, restored or endodontically treated tooth. From the radiograph, the quality of the root canal therapy and the existence of endodontic files or perforations can be appreciated.

Although rare, other lesions in the oral cavity that have a similar appearance to a periodontal abscess must be considered. Parrish *et al.* (1989) described three cases of osteomyelitis in periodontitis patients, initially diagnosed as periodontal abscesses. The first sign of a tumor may be a periodontal abscess in the gingiva, such as squamous cell carcinomas (Torabinejad & Rick 1980; Kirkham *et al.* 1985; Kim *et al.* 2012), metastatic carcinomas from pancreatic origin (Selden *et al.* 1998), metastatic head and neck cancers (Elkhoury *et al.* 2004), eosinophilic granulomas diagnosed from rapid bone destruction after periodontal therapy (Girdler 1991), or a pyogenic granuloma (Panseriya & Hungund 2011). In cases where the abscess does not respond to conventional therapy, a biopsy and histopathologic diagnosis is always recommended (see also Chapter 18).

Treatment

The treatment of the periodontal abscess usually includes two stages: (1) the management of the acute lesion and (2) the appropriate treatment of the original and/or residual lesion, once the emergency situation has been controlled.

For the treatment of the acute lesion, different alternatives have been proposed: incision and drainage, scaling and root planing, periodontal surgery, and the use of different locally or systemically administered antibiotics.

Some authors have recommended a purely mechanical treatment with either surgical drainage through the pocket, or scaling and planing of the root

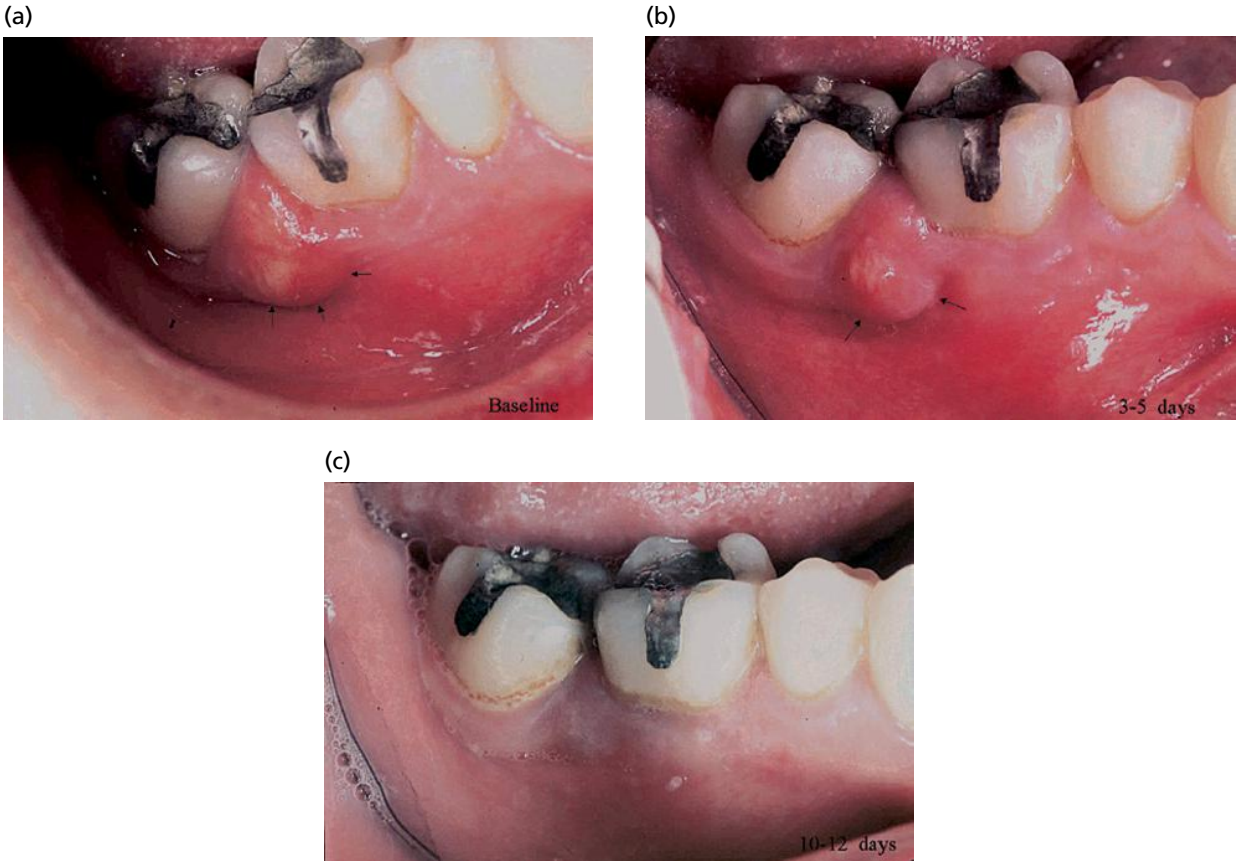

Fig. 24-7 Treatment of a periodontal abscess with systemic antibiotics (azithromycin, 500 mg for 3 days), without any mechanical therapy. (a) Baseline situation (arrows indicate apical limits of the abscess); (b) 5 days after antibiotic therapy (arrows indicate apical limits of the abscess); (c) 12 days after antibiotic therapy, just before the final periodontal instrumentation.

surface, together with compression and debridement of the soft tissue wall (Ahl *et al.* 1986; Ammons 1996). However, this mechanical therapy may cause irreversible damage to healthy periodontal tissues adjacent to the lesion, particularly when the swelling is diffuse or is associated with marked tissue tension. In order to avoid this damage to healthy periodontal tissues, other authors have recommended systemically administered antibiotics alone as the initial treatment for abscesses with marked swelling, tension, and pain. In such instances, once the acute condition has receded, mechanical debridement, including root planing, should be performed.

The clinical evidence on the efficacy of these different therapeutic approaches in the treatment of periodontal abscesses is scarce, since only a few prospective clinical studies are available. Smith and Davies (1986) studied 62 abscesses in 55 patients. Their proposed treatment included incision, drainage, and systemic metronidazole (200 mg t.i.d. for 5 days), and after the acute phase, regular periodontal treatment. Hafström *et al.* (1994) recommended supragingival debridement, together with systemic tetracycline therapy for 2 weeks, and reported good clinical outcomes when drainage and irrigation were added to the protocol. Similar good results were obtained in a controlled parallel study in which two systemic antibiotic regimens (amoxicillin/clavulanate, 500 + 125 mg t.i.d. for 8 days, and azithromycin, 500 mg once per day for 3 days) were used as the only treatment during the initial phase of therapy. This was followed by regular periodontal treatment once the acute phase had resolved (Herrera *et al.* 2000b). The study showed that the short-term clinical outcome with the use of both antibiotic regimens was successful, and the infectious process and abscess symptomatology were controlled without the use of concomitant or prior mechanical debridement (Fig. 24-7). There was a rapid reduction of pain, significant resolution of edema, redness and swelling, and the suppuration almost entirely disappeared. Periodontal outcome measurements, such as bleeding and periodontal probing depth, were also significantly reduced. Short-term microbiologic results demonstrated a reduction of the microbiota in the abscess, as well as the number of selected periodontal pathogens (Herrera *et al.* 2000b). None of these antibiotic therapies was able, however, to entirely resolve the infection, which implies that mechanical debridement, sometimes including the elevation of a surgical flap, is essential for the definitive treatment of this condition. Moreover, two different studies have provided information on the antibiotic susceptibility profiles of periodontal pathogens isolated from periodontal

Table 24-1 Antimicrobial agents that may be used in the treatment of periodontal abscesses.

Antimicrobial agent	Effective against	Properties
Penicillin V	Streptococci, some strict anaerobes	Poorly absorbed, affected by beta-lactamases, bactericidal
Amoxicillin	Most Gram-positive oral species, many Gram-negative species	Well absorbed, affected by beta-lactamases, but can be protected by clavulanic acid, bactericidal
Cephalexin	Anaerobes, streptococci, strict anaerobes, facultative	Well absorbed, affected by beta-lactamases, not effective against methicillin-resistant staphylococci, bactericidal
Ceftibuten	Gram-negative rods, broad-spectrum against Gram-negative and positive bacteria	Resistant to most β-lactamases, bactericidal, not effective against staphylococci, pseudomonads
Clindamycin	Gram-positive cocci including staphylococci	Bacteriostatic or bactericidal depending on local concentration and susceptibility of the pathogen, drug of choice in case of rapid local spread
Metronidazole	Gram-positive and Gram-negative anaerobes	Well absorbed, not effective against facultative bacteria, bactericidal
Azithromycin	Most anaerobes, Gram-positive and negative bacteria, many strict anaerobes	Good tissue concentration, bacteriostatic for most pathogens

abscesses and have reported the presence of resistant strains (Herrera *et al.* 2000b; Jaramillo *et al.* 2005). Antibiotics were locally administered in a study of 91 patients (Eguchi *et al.* 2008). These authors reported the use of irrigation with sterilized physiologic saline and 2% minocycline hydrochloride ointment (Periocline; Sunstar Inc., Osaka, Japan), compared with irrigation with sterilized physiologic saline without the local antibiotic. At 7 days, the microbiologic outcomes (frequency of detection) in the test group were better, as well as the periodontal pocket depth reduction (0.56 mm versus 0.18 mm).

Table 24-1 shows a number of different antibiotics that may be used in the treatment of a periodontal abscess. Recommended doses and regimens may differ between different countries. In principle, a high dose of the antibiotic delivered over a short period of time is recommended. If the patient is recovering appropriately, the antibiotic regimen should not be extended beyond 5 days. However, incision, drainage and debridement should always be considered as the first treatment option.

Complications

Tooth loss

Periodontal abscesses have been suggested as the main cause for tooth extraction during the phase of SPT (Chace & Low 1993). A tooth with a history of repeated abscess formation is considered to be a tooth with a questionable prognosis (Becker *et al.* 1984). In a retrospective study, 45% of teeth with periodontal abscesses during SPT were extracted (McLeod *et al.* 1997). Another retrospective study including 455 teeth with a questionable prognosis showed that 55 teeth (12%) were lost after a mean of 8.8 years, and that the main reason for tooth extraction was periodontal abscess formation (Chace & Low 1993). Smith and Davies (1986) evaluated 62 teeth with abscesses; 14 (22.6%) teeth were extracted as initial therapy, and nine (14.5%) after the acute phase. Of the 22 teeth treated and subsequently monitored, 14 had to be extracted over the following 3 years. A recent literature review suggested that an early diagnosis and an adequate therapy might be important in the management of a periodontal abscess in patients SPT, since under these conditions the prognosis of the affected tooth may not be affected (Silva *et al.* 2008).

Dissemination of the infection

A number of publications, mainly case reports, have described the spread of infection from a periodontal abscess to the systemic circulation and to different parts of the body. Two possible sources of dissemination of bacteria have been described:

- *Inside the tissues during therapy.* A case of pulmonary actinomycosis was related to the treatment of a periodontal abscess affecting a tooth that had been ultrasonically scaled 1 month earlier (Suzuki & Delisle 1984). A case of brain abscess was reported in a healthy patient with a periodontal abscess who had been treated 2 weeks earlier with drainage and curettage without systemic antibiotics. The microbiologic study of the brain lesions demonstrated, among other bacteria, *P. melaninogenica* and *Bacteroides* spp. (Gallaguer *et al.* 1981). A retrospective study on total knee arthroplasty infections (Waldman *et al.* 1997) discovered that nine of 74 infections had been previously treated for an oral infection, including the drainage of a periodontal abscess.

- *Due to bacteremia from an untreated abscess*. Cellulitis in breast cancer patients has been reported following gingivitis or the formation of a periodontal abscess (Manian 1997), due to transient bacteremia and reduced host defenses (radiation therapy and axillary dissection). A periodontal abscess was associated with the development of a cervical necrotizing fasciitis (Chan & McGurk 1997). A necrotizing cavernositis was also related to a severe periodontal infection, including three periodontal abscesses (Pearle & Wendel 1993).

Introduction

In the study of the pathogenesis and causality of periodontal disease processes, lesions of endodontic origin are significant as they frequently extend to and manifest themselves in the attachment apparatus. Not only do these lesions produce signs and symptoms of inflammation in apical areas of teeth, they may also induce tissue destruction along the lateral aspects of roots and in furcations of two- and multi-rooted teeth. In either instance, the lesions are maintained by noxious elements that derive from the pulpal space along openings to the periodontal tissues. Pathways connecting the two tissue compartments include foramina at the apex and lateral ramifications termed accessory canals.

Microorganisms residing in necrotic areas of a more or less broken down pulp usually maintain these lesions. Lesions of endodontic origin may also appear or persist following endodontic treatment (hereafter referred to as post-treatment endodontic lesions). In these cases, treatment measures aimed at either preventing the establishment of a root canal infection or resolving an already manifest infection have been unsuccessful. As root canal infections have been assumed to impact both the progression of periodontitis and the potential to achieve optimal results from periodontal therapy, the first part of this chapter describes the specific features and dynamic events that are associated with lesions of the pulp and the manner by which they may interfere with the periodontium.

The fact that the periodontium and the dental pulp are anatomically interconnected implies that exchange of noxious agents also may occur in the opposite direction, that is from the external environment to the pulp. A prerequisite for this is that those communication pathways that are normally secured by healthy periodontal tissue have been uncovered. This will occur as periodontal disease advances. The lesion of the pulp that may follow may cause both pain and tissue destruction. Resorptive processes and treatment measures aimed at managing periodontal disease enhance this potential as the accompanying exposure of dentinal tubules, by loss of cementum, establishes yet another passage across the body of the tooth structure. In fact, a common complication of periodontitis and periodontal therapy is commonly termed root dentin hypersensitivity, a condition associated with the direct exposure of dentin to the oral environment (Holland *et al*. 1997; for review see Gillam & Orchardson 2006).

The second part of this chapter is concerned with the consequences for the vital pulp of root surface exposure by periodontal disease and periodontal therapy. It also covers aspects of the mechanisms and clinical management of root dentin hypersensitivity.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Disease processes of the dental pulp

Causes

The dental pulp is normally well protected from injurious influences by an intact hard tissue encasement and by a healthy periodontium. The healthy condition of the pulp, however, is regularly challenged under clinical conditions. While some adverse influences are of minor significance and cause only negligible tissue injury and minimal discomfort to the patient, others threaten the pulp's vital functions and can result in infectious complications, with effects both locally and systemically. Lesions of the pulp may have either a direct infectious background or may be induced by non-infectious injury. Both causes will be covered here in some detail.

Of the non-infectious impairments, accidental trauma causing rupture of the neurovascular supply at the apex and major internal bleeding represents a distinct threat to the vitality of the pulp. Hence, concussions, subluxations, and various forms of tooth displacements may result in widespread ischemia leading to complete necrosis of the tissue. As the potential for tissue regeneration is slim in the fully developed tooth (Kristerson & Andreasen 1984), such pulp tissue necrosis, although not primarily infected, acts as a target for microbial invasion. The infecting microorganisms usually originate from the oral cavity. Following their penetration of cracks in the enamel and the dentinal tubules (Love 1996), multiplication in the necrotic pulp results in the development of inflammatory lesions of the periodontal tissues (Bergenholtz 1974; Sundqvist 1976).

Most pulpal conditions are initiated and maintained by infectious elements that access the pulp following loss of hard tissue integrity. Tooth destruction by caries is by far the most common source of bacterial exposure and is especially threatening when the lesion has reached the vicinity of the pulp tissue proper (see later). Also, fractures of teeth and dental restorative work bring an inherent risk for detrimental bacterial effects, should a restoration fail to seal completely the defect in the tooth substance (Bergenholtz 2000). Most risky are extensive restorations like full coverage crowns, which often require substantial sacrifice of healthy tooth tissue. Clearly in the short term, before the permanent restoration is cemented, the exposed tissue is subject to leakage of bacterial elements along the margins of the temporary restoration, especially if it adapts poorly to the remaining tooth substance. Yet, even though the pulp may have survived the initial stress of the cutting trauma and bacterial leakage, the injury induced usually results in considerable repair phenomena (scars). Such tissue changes involve hard tissue depositions and soft tissue fibrosis, which occur at the expense of vascularity and nerve tissue support (Bender & Seltzer 1972). Tissue alterations of this nature logically result in impaired immune defense function and, thus, reduce the potential for the pulp to resist future bacterial challenges.

Clinical follow-ups of teeth supplied with single crowns or included as abutments in bridge works have indeed demonstrated that pulp tissue necrosis is not a rare complication and may affect 10–20% of the treated teeth over a 10–15-year period (Bergenholtz & Nyman 1984; Karlsson 1986; Saunders & Saunders 1998; Cheung *et al*. 2005). In fact, the incidence of infected pulp necrosis has been reported to increase over the course of time (Bergenholtz & Nyman 1984; Cheung *et al*. 2005). A similar increased rate of pulpal infections has also been reported for young permanent teeth suffering traumatic ischemic injuries where pulps have been partly or completely replaced by hard tissue repair (Jacobsen & Kerekes 1977; Robertson *et al*. 1998).

Conclusion: Injurious elements that may put the vital functions of the pulp at risk include deep caries, accidental trauma, and dental restorative procedures. A single insult, such as a traumatic injury, may cause an immediate breakdown of the tissue by severing the neurovascular supply. In other instances, tissue breakdown is preceded by a direct bacterial exposure or follows tissue repair to non-infectious and infectious insults.

Progression and dynamic events

Although any injury may have serious implications for the vitality of the pulp, its ability to withstand insults, especially of a microbial nature, is far better if an intervening layer of dentin remains than if the tissue is directly exposed through the hard tissue barrier. In the former case, even a thin dentin wall, although permeable, usually allows the pulp to mount an appropriate inflammatory response to offset bacterial threats. The common observation that the pulp rarely suffers breakdown beneath a caries lesion confined to dentin is strong evidence of the pulp's defense potential (Reeves & Stanley 1966; Massler 1967; Kamal *et al*. 1997; see also review by Björndal & Mjör 2001). The mechanisms involved relate both to innate and adaptive immune responses (for reviews see Jontell *et al*. 1997; Hahn & Liewehr 2007; Farges *et al*. 2009), as well as to changes in dentin that constrict its permeability (for reviews see Pashley 1996; Bergenholtz 2000).

Experimental evidence to this effect derives from observations in both humans (Lundy & Stanley 1969; Warfvinge & Bergenholtz 1986) and experimental animals (Lervik & Mjör 1977; Warfvinge & Bergenholtz 1986; Taylor *et al*. 1988). In some of these studies, test cavities were prepared deep into dentin and were left unrestored and open to the oral environment (Lundy & Stanley 1969; Taylor *et al*. 1988). In other experimental series, similar cavities were challenged with soft carious dentin (Mjör & Tronstad 1972; Lervik & Mjör 1977) or components of dental plaque bacteria (Bergenholtz & Lindhe 1975; Warfvinge & Bergenholtz 1986). Reflecting the permeability of dentin to microbial elements, inflammatory sequelae consisting of

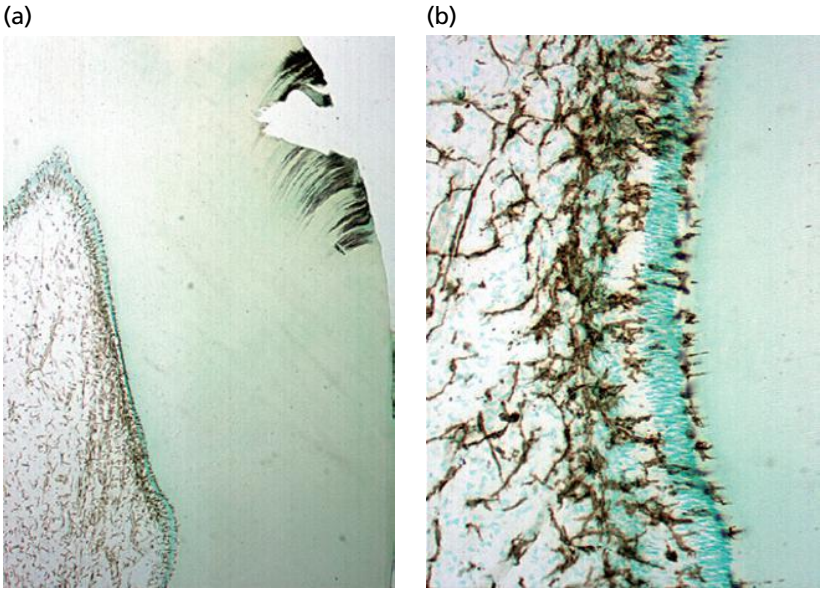

Fig. 25-1 (a) Defense response of a human dental pulp to superficial caries in dentin (defect and dark stain at upper right-hand corner) as represented by increased accumulation of Class II molecule-expressing dendritic cells. (b) Extensions of cytoplasmatic processes into the dentinal tubules are numerous. (Courtesy of T. Okiji.)

increased vascular permeability, migration of polymorphonuclear leukocytes (PMNs) (Bergenholtz & Lindhe 1975; Warfvinge & Bergenholtz 1986), and nerve fiber sproutings (Taylor *et al*. 1988) rapidly emerged in the pulp adjacent to the exposed dentinal tubules. The adaptive immune defense is also activated at very early stages as indicated by an increased presence of antigen-presenting cells, including dendritic cells, which soon appear in areas of the pulp next to both cavity preparations (Ohshima *et al*. 1995) and superficial caries (Kamal *et al*. 1997; Yoshiba *et al*. 1996) (Fig. 25-1). Yet, over the course of time, these responses subside and reparative dentin and soft tissue repair emerge, along with a reduction of immunocompetent cells and neural elements, at the site of the previous inflammatory event (Lundy & Stanley 1969; Lervik & Mjör 1977; Warfvinge & Bergenholtz 1986; Taylor *et al*. 1988; Kamal *et al*. 1997; Yoshiba *et al*. 2003). In the experiments involving unrestored human teeth (Lundy & Stanley 1969), patients experienced pain and increased sensitivity of the exposed dentin along with the initial inflammatory episode. As repair and healing progressed, the pain symptoms disappeared.

An important point is that although inflammatory responses develop rapidly and early to bacterial challenges, microorganisms *per se* are rarely able to penetrate the dentinal barrier and enter the pulp tissue, so long as it retains vital functions. Staining for bacteria in the histologic analysis of Lundy and Stanley (1969), for example, revealed that in no case, observed after 2–240 days, were organisms identified in the pulp tissue proper, while the exposed dentinal tubules were invaded to a varying extent. This finding once again demonstrates that dentin and pulp in concert are able to oppose bacterial threats.

By contrast, direct exposure of the pulp to the oral environment puts its vital functions at a clear risk as bacteria in the oral cavity now may gain direct access to the tissue. Even a minuscule exposure is critical, unless properly treated. There is little self-healing capacity that can bridge the defect as the pulp lacks epithelium and defense mechanisms may only prevent bacterial invasion of the pulpal space for a limited period of time.

Three clinical cases, displayed in Figs. 25-2, 25-3, and 25-4, demonstrate how pulpal inflammatory processes may typically develop and eventually progress to the adjoining periodontal tissues. In these cases, caries had advanced to expose the tissue at an earlier point in time.

In the first example (Fig. 25-2), an inflammatory lesion is present at the site where caries has exposed the pulpal tissue. A rather thick layer of reparative dentin has formed at the roof of the pulp chamber next to the exposure, indicating a repair response to previous irritation (Fig. 25-2a). Note that, except for the lesion area, the pulp displays normal tissue morphology with intact odontoblast layers lining the periphery of the tissue. Bacteria have accumulated (shown by blue stain in dentin) near the exposure site (Fig. 25-2c). The high magnification in Fig. 23-2d reveals numerous bacterial profiles in the pulp tissue proper as well, where they are opposed by infiltrating PMNs in the lesion area. In this particular case, the inflammatory process was clearly localized and both radiographic (Fig. 25-2a) and histologic examination gave no indication of interference with the periodontium.

A more advanced pulpal lesion is demonstrated in Fig. 25-3, where the inflammatory response to the distally located caries process in the lower molar has extended to the furcation area along a wide accessory canal (Fig. 25-3b). The alveolar bone in the furcation is resorbed and has been replaced by inflammatory tissue displaying proliferating epithelium (Fig. 25-3c). There is also an apical radiolucency at the distal root, while the apical region of the mesial root seems to be unaffected (Fig. 25-3a).

The third case (Fig. 25-4) shows necrosis of the coronal pulp following what has obviously been a

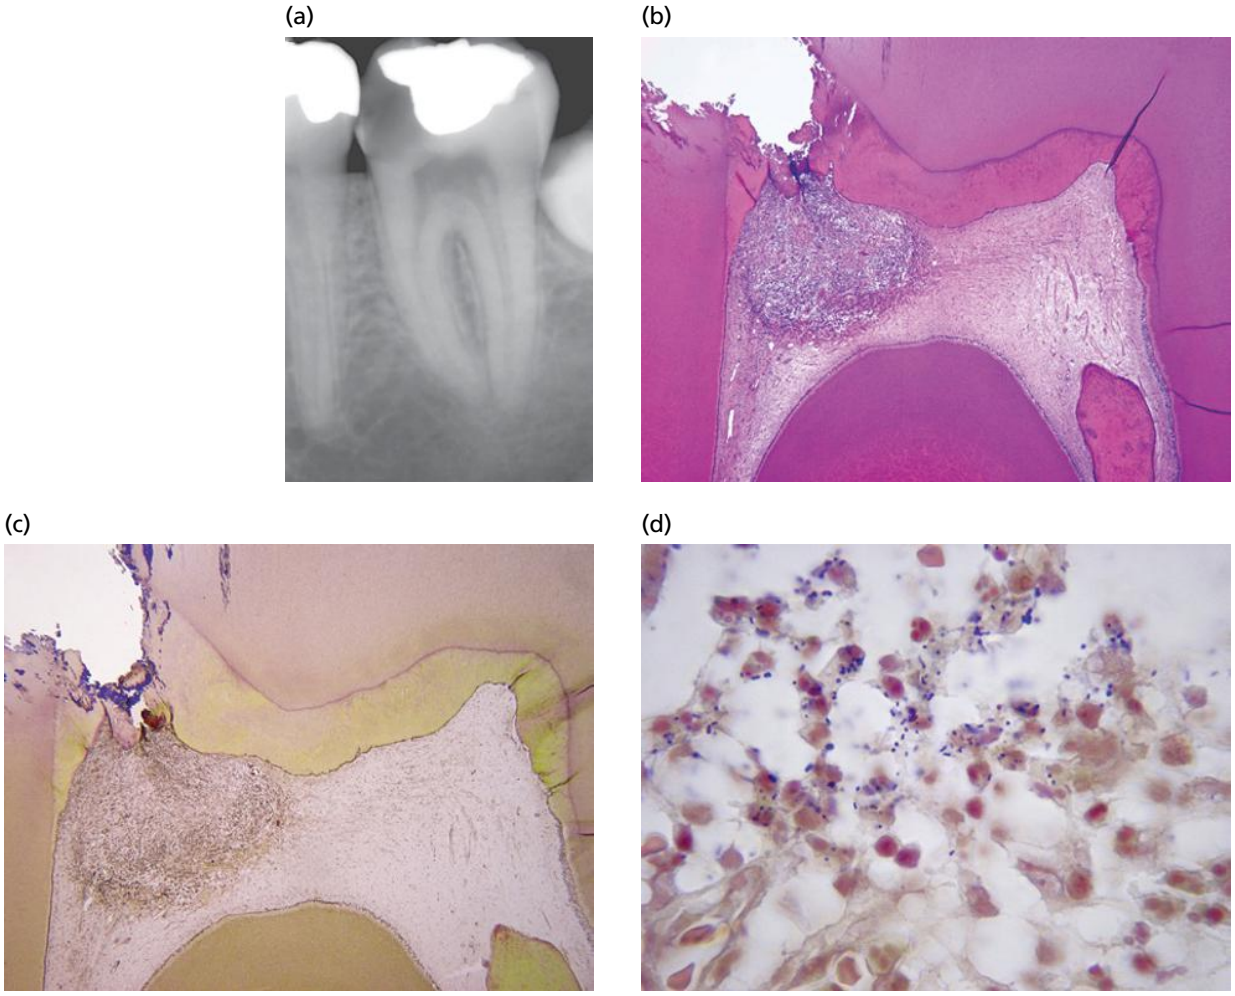

Fig. 25-2 (a) Radiograph of a second lower molar in a 30-year-old man with deep caries at the mesial aspect of the tooth. Patient suffered from typical signs of pulpitis including radiating pain and percussion sensitivity. (b) Localized inflammatory response in the pulp adjacent to the site of caries exposure. Except for hard tissue repair at the roof of the pulp chamber, the remainder of the pulp shows normal tissue structures. (c) Bacterial elements stained blue are prevalent at the exposure site as well as in the tissue lesion *per se* (d) (see also text).

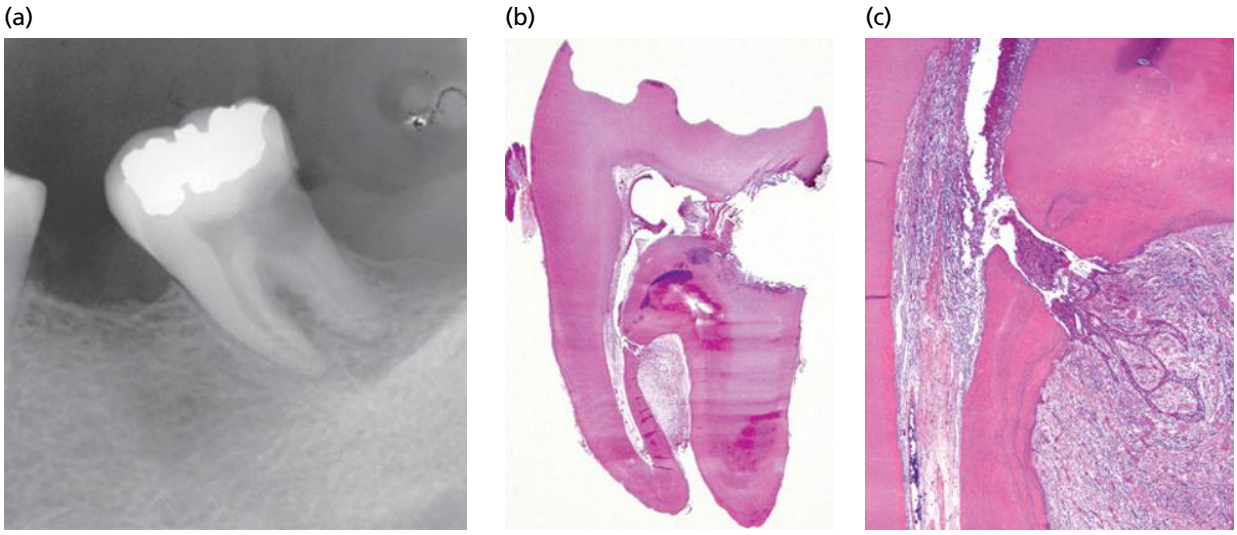

Fig. 25-3 (a) Tooth specimen of a 48-year-old man who presented with spontaneous pain, pain on mastication, percussion, and tooth mobility. (a) Deep caries lesion at the distal aspect. (b) Extensive inflammatory tissue destruction of the coronal pulp extends into the furcation along an accessory canal. (c) Higher magnification of the pulp–accessory canal–furcal area shows the expansion of the inflammatory process. Some epithelial proliferation can be seen at the exit of the accessory canal. More apically, the pulp has retained normal tissue structures. There was no clinical swelling or remarkable pocket probing depth in this case, indicating periodontal involvement (see also text).

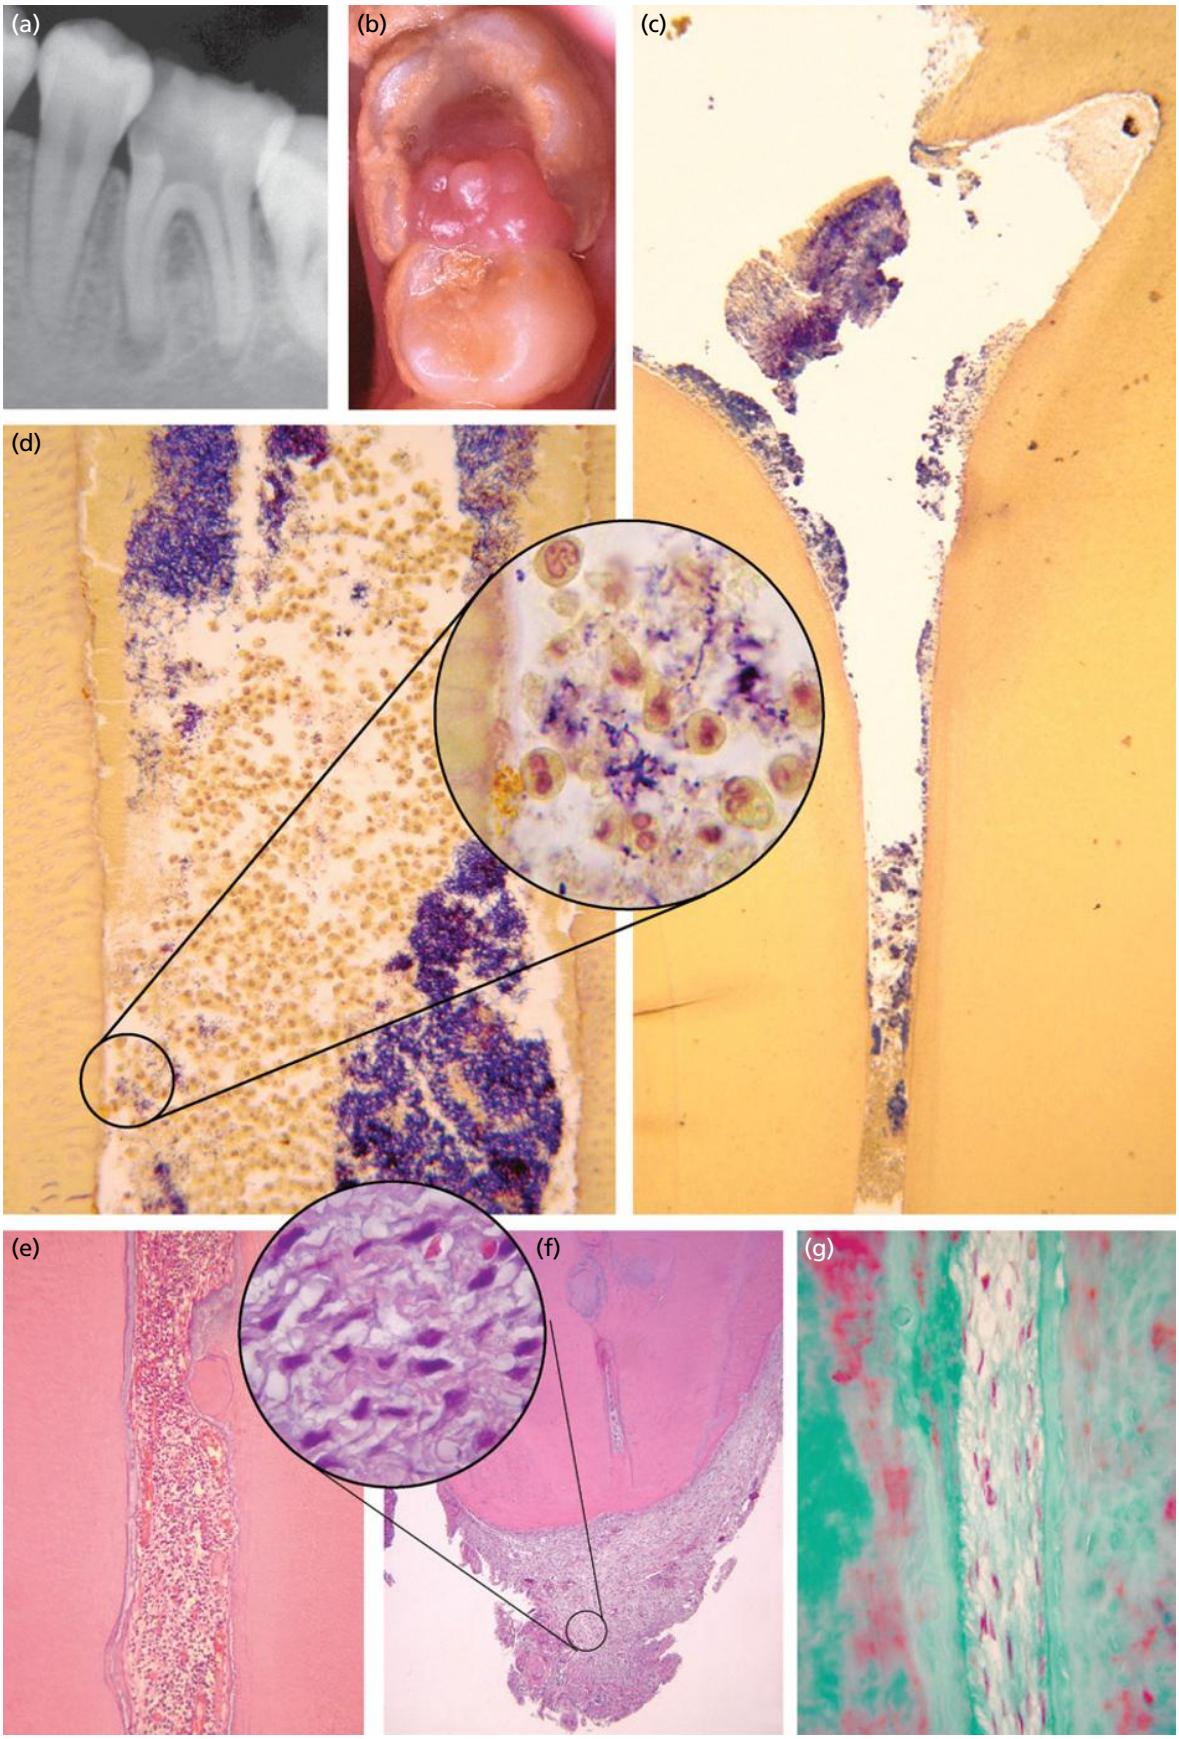

Fig. 25-4 (a–g) Tooth specimen of a 19-year-old female with extensive caries in a first lower molar that has led to partial pulp tissue breakdown, bacterial invasion, and establishment of an inflammatory defense line inside the pulpal space (see also text). (Source: Ricucci & Bergenholtz 2004. Reproduced with permission from John Wiley & Sons.)

rather long-standing caries process in a lower first molar. There are radiographic signs of apical periodontitis on both the distal and the mesial roots, and a widened periodontal ligament space in the furcation (Fig. 25-4a). At the mesial aspect of the tooth, gingival tissue has proliferated into the pulp chamber (Fig. 25-4b). Figure 25-4c displays an area of the pulpal space at the entrance to the distal root canal, where the pulp is necrotic and where bacterial cells have aggregated on the canal walls in a biofilm structure. Further down in the middle portion of the root, numerous PMNs meet the bacterial front and are engaged in phagocytosis (Fig. 25-4d and inset). In more apical portions of the canal, numerous widened blood vessels are seen along with an infiltrated pulp connective tissue (Fig. 25-4e). The most apical portion of the pulp shows normal tissue structure (Fig. 25-4g). The soft tissue attached to the root tip (Fig. 25-4f and inset), representing the apical radiolucency at the distal root in Fig. 25-4a, shows no inflammatory infiltrates.

Conclusion: The cases selected demonstrate an important function of the inflammatory defense in general that also applies to the dental pulp, which is to confine infectious elements and limit spread to other body compartments. The cases also demonstrate that a pulpal lesion has its prime focus directed at the source of the bacterial exposure. Hence, it is only following extension due to breakdown of the pulp and advancement of the bacterial front that periodontal tissue involvement is imminent. In some cases, this may occur at a rather early stage of the pulp tissue lesion, if an accessory canal becomes involved and connects with the marginal periodontium, such as in the case displayed in Fig. 25-3. In the absence of patent accessory canals, extensive breakdown of the pulp is first required before periodontal tissue lesions may become evident.

Accessory canals

Accessory canals are lateral ramifications off the root canal system that connect the neurovascular system of the pulp with that of the periodontal ligament. Such anastomoses are formed during the early phases of tooth development, but may become blocked or reduced in width during the completion of root formation. Patent communications of varying sizes, numbers, and locations, however, may remain in the fully developed tooth and serve as additional pathways for the neurovascular supply of the pulp beyond that of the main apical foramen.

Accessory canals can be observed in all groups of teeth. In fact, careful examinations of large numbers of extracted teeth, rendered transparent and injected with contrasting medium in the pulp chamber to allow three-dimensional visualization, have revealed accessory canals in cervical and middle root areas as well as in the apical root portions (de Deus 1975; Vertucci 1984). Clearly, the majority is found apically, whereas the prevalence tapers off in the middle and cervical root segments (de Deus 1975; Vertucci 1984). In a study of 1140 extracted human teeth from adult subjects, de Deus (1975) reported accessory canals in 27% of the examined teeth. These canals were distributed at various levels of the root (Fig. 25-5). Yet, in a study where teeth were examined in serial sections by histology, the frequency of accessory canals was found to be considerably higher. Investigating a sample of 493 teeth, Ricucci & Siqueira (2010b) observed accessory canals and/or apical ramifications at a rate of 75%. The high prevalence in this study can be explained by the ability of histology to detect even the finest ramifications, which may escape detection in teeth cleared and injected with disclosing solutions.

Molars harbor accessory canals more frequently than premolars and anterior teeth (Ricucci & Siqueira 2010b). Patent canals are especially common in the furcation areas, where they have been found in between 20% and 80% of examined teeth (Lowman *et al*. 1973; Vertucci & Williams 1974; Gutmann 1978; Vertucci 1984; Ricucci & Siqueira 2010b). Vertucci (2005) has distinguished different directions of entry by which accessory canals enter the furcation of mandibular molars. In some cases they run more or less vertically from the pulpal chamber. They may also extend off either root canal in a horizontal direction; 80% derive from the distal root canal (Vertucci 2005) (Fig. 25-6).

When accessory canals do occur, the potential for dissemination of inflammatogenic elements from a diseased pulp to the periodontium is obvious. There is no documentation yet available to indicate how often such lesions develop. Although clinical observations demonstrate occurrence (Figs. 25-3, 25-7, 25-8, 25-9), the rate at which endodontic lesions appear in the marginal periodontium from accessory and furcation canals seems to be low, as indicated by the lack of reports of this being a significant clinical problem. It is to be expected that the wider the accessory canals, the greater is the likelihood for overt lesions to develop. Diameters of furcation canals in mandibular molars, for example, have been reported to vary from just a few micrometers to 720 μm (Vertucci 2005). Consequently, thin accessory canals, with the potential to mediate only release of some infectious elements, may cause no more than a minor periodontal reaction that goes clinically undetected.

In the discussion of the extent to which accessory canals contribute to endodontic lesions in the periodontium, it is important to recognize the events that may occur in these spaces. Histologic observations of teeth with diseased pulps have demonstrated that the tissue therein will reflect the condition of the pulp in the main canal (Langeland 1987; Ricucci & Siqueira 2010b). Thus, it will remain

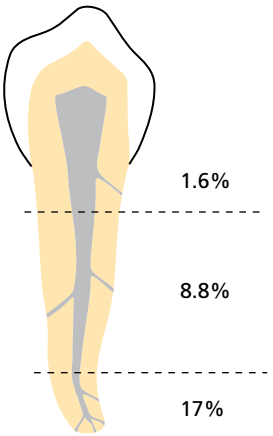

Fig. 25-5 Frequency of accessory canals at different levels of the root. Observations were made after teeth had been rendered transparent and the root canal system revealed with India ink. The percentages given for the coronal portion include those of bi- and tri-furcations of two- and multi-rooted teeth. (Data are average values from de Deus 1975.)

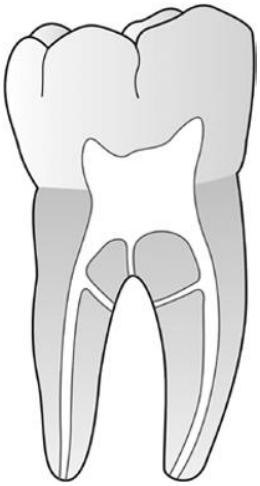

Fig. 25-6 Furcal canals of two- and multi-rooted teeth, when present, may extend into the periodontium from the pulpal space either in a horizontal or vertical direction or both. (Adapted from Vertucci 2005, with permission from John Wiley & Sons.)

vital and functional if this is also the case for the pulp in the main canal. Similarly, it may be inflamed if the adjacent area of the pulp is inflamed, and partially or totally necrotic if the pulp in the main canal is necrotic. In the latter case, inflammatory tissue may partly fill the ramification with bacterial organisms colonizing the pulpal portion of it (Fig. 25-9). Also, the entire ramification lumen may be clogged with bacteria

Subsequent to breakdown of the attachment apparatus in periodontitis, the neurovascular supply of the pulp along the accessory canals will certainly be severed as well. The extent to which the pulp will become critically inflamed concomitantly has been the subject of some controversy. While pulpal lesions of limited extension have been observed in teeth with periodontitis (Rubach & Mitchell 1965), possibly accompanied by symptoms of pulpitis, the pulp appears unlikely to succumb unless the subgingival biofilm has reached the vicinity of the main apical foramen (see later).

Conclusion: Although accessory canals do occur, most teeth seem to lack wide enough accessory canals to sustain periodontal tissue lesions in the cervical and middle root regions. This fact may explain why pulpal inflammatory lesions extending to the marginal periodontium are rarely seen. Most often they become centered on the root apices only. When present with a diameter similar to that of the apical foramen, accessory canals can certainly mediate lesions of endodontic origin in the marginal periodontium. In endodontically treated teeth, iatrogenic root perforations, carried out in conjunction with root canal instrumentation or post preparations, may serve as yet another pathway for dissemination of noxious elements to the periodontium (see Chapter 41).

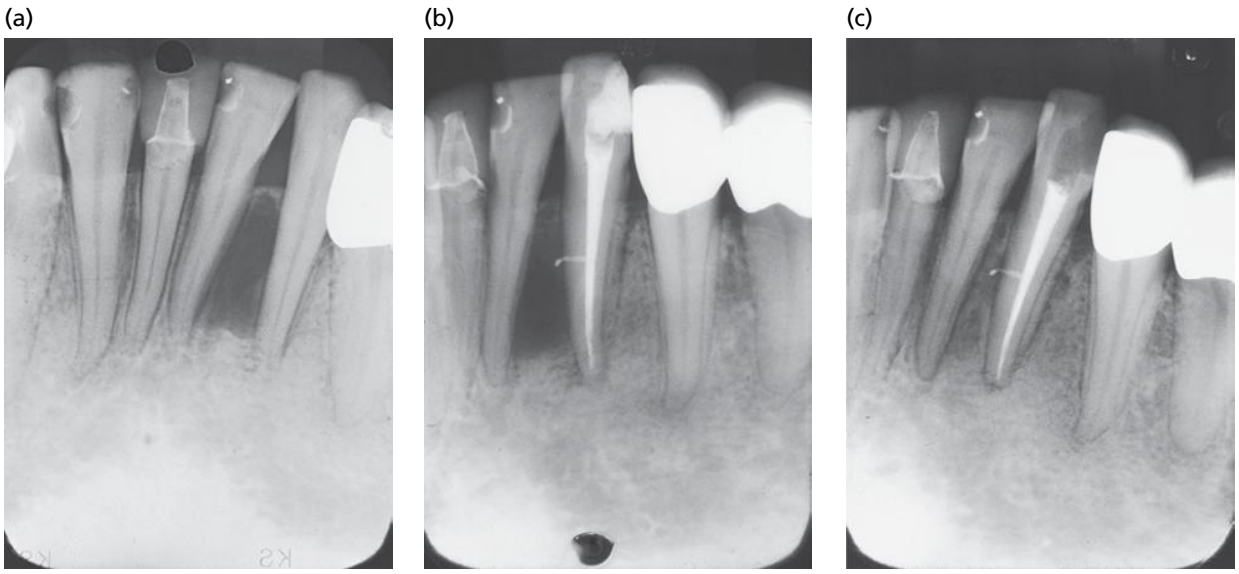

Fig. 25-7 (a) Lateral, alveolar bone destruction is observed between the roots of teeth 31 and 32. (b) Lesion in this case turned out to be associated with an accessory canal (filled in conjunction with the root filling procedure) emanating from an infected necrotic pulp in tooth 32. Periodontal tissue lesions to primary root canal infection

The ultimate outcome of an inflammatory breakdown of the pulp is microbial takeover of the pulpal space (primary root canal infection) (Fig. 25-10). As host defense mechanisms are unable to reach far into root canals of necrotic pulps in order to combat the infection and pave the way for regeneration of pulpal tissue, an inflammatory defense zone is established in the periodontal tissues at the exits of accessory canals and apical foramina. Hence, lesions of this nature remain as chronic processes unless treated. Because the inflammatory process most frequently becomes positioned near root apices, the term apical periodontitis is commonly employed. As lesions may also develop along the lateral aspects of roots, the expression endodontic lesion will be used throughout this chapter to denote a periodontal lesion in any position that is sustained by noxious elements of endodontic origin.

Features of the microbiota

The bacterial species that are able to initiate and maintain primary endodontic lesions have been studied in great detail over the years, primarily by sampling infected root canals followed by laboratory processing and phenotypic identification. The

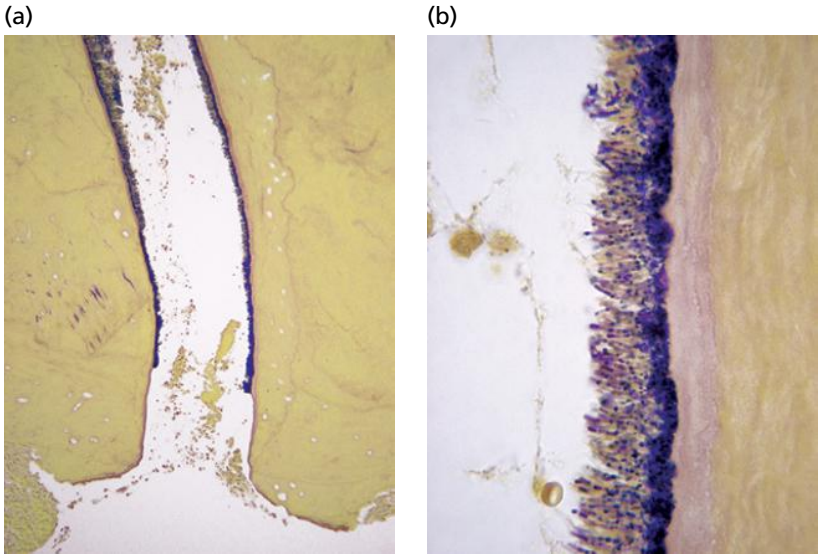

Fig. 25-10 (a) Tooth specimen with complete absence of pulp tissue. (b) Filaments and coccoid organisms are attached in a biofilm to the root canal walls. (Source: D. Ricucci, published in Svensäter & Bergenholtz 2004, reproduced with permission from John Wiley & Sons.)

purpose of such studies has been to identify organisms that are prevalent and which can be linked to more or less aggressive forms of apical periodontitis. Culture studies, especially those using techniques for isolation, cultivation, and identification of anaerobic bacteria, were of paramount importance to establish the infectious etiology of endodontic lesions. They revealed anaerobic oral bacteria as the main candidate pathogens associated with these lesions (Möller 1966; Bergenholtz 1974; Sundqvist 1976). In recent years, molecular identification methods, including polymerase chain reaction (PCR)-based and DNA hybridization methods, have greatly impacted the knowledge of the bacterial diversity in primary endodontic infections (Siqueira & Rôças 2014). In fact, the microbiota shows features similar to those of deep periodontal pockets as disclosed by culture and molecular studies (Kerekes & Olsen 1990; Siqueira & Rôças 2009b). The primary endodontic infections are characterized by a mixed community dominated by anaerobic bacteria, with a mean of 10–20 species/phylotypes per individual canal (Munson *et al.* 2002; Siqueira *et al.* 2004; Siqueira & Rôças 2005; Rôças & Siqueira 2008). A single infected canal may be colonized by 10^3–10^8 bacterial cells (Sundqvist 1976; Vianna *et al.* 2006b; Siqueira *et al.* 2007; Blome *et al.* 2008). The radiographic size of the endodontic lesion is directly proportional to the bacterial density and diversity in the root canal, that is the larger the lesion the more complex the microbiota (Sundqvist 1976; Rôças & Siqueira 2008).

Bacterial species/phylotypes frequently detected in primary infections by culture or molecular methods or both belong to diverse genera of Gram-negative (*Fusobacterium*, *Dialister*, *Porphyromonas*, *Prevotella*, *Tannerella*, and *Treponema*) and Gram-positive (*Parvimonas*, *Filifactor*, *Pseudoramibacter*, *Olsenella, Actinomyces*, *Peptostreptococcus, Streptococcus*, *Propionibacterium*, and *Eubacterium*) bacteria (Sundqvist 1976, 1992; Gomes *et al.* 1996; Siqueira *et al.* 2000; Fouad *et al.* 2002; Khemaleelakul *et al.* 2002; Munson *et al.* 2002; Foschi *et al.* 2005; Saito *et al.* 2006; Sakamoto *et al.* 2006; Rôças & Siqueira 2008; Siqueira & Rôças 2009a; Ribeiro *et al.* 2011). The pathogens implicated in periodontitis, such as *Tannerella forsythia, Porphyromonas gingivalis*, and *Treponema denticola,* have also been proposed as candidate pathogens in primary root canal infections (Gomes *et al.* 2007; Rôças *et al.* 2001). However, their association in trio, forming the so-called red complex, does not seem to be as important as it is in the pathogenesis of periodontitis (Fig. 25-11). *Aggregatibacter actinomycetemcomitans*, another important periodontal pathogen, has not been consistently detected in endodontic infections (Siqueira & Rôças 2009b), which suggests that the milieu of the necrotic root canal is not conducive to the establishment of this species.

Molecular studies have shown that about one-half of the bacterial species represent as yet uncultivated and uncharacterized bacteria (Ribeiro *et al.* 2011; Sakamoto *et al.* 2006). It is therefore reasonable to assume that several of these unrecognized bacteria participate in the pathogenesis of different forms of endodontic lesions. Yet, bacterial community profiling analyses have demonstrated a great interindividual variability in terms of species composition regardless of clinical disease condition (Siqueira *et al.* 2004; Machado de Oliveira *et al.* 2007; Li *et al.* 2010; Santos *et al.* 2011; Hong *et al.* 2013), indicating a heterogeneous etiology for endodontic lesions. A geography-related pattern in community profiles also seems to exist (Machado de Oliveira *et al.* 2007; Siqueira *et al.* 2008).

Endodontic lesions may present as symptomatic infections. One example is the acute apical abscess, which typically is characterized by intense pain and intraoral as well as facial swellings (see Chapter 41). While the infection often is confined to the root canal space, it may also reach the periapical tissues and, in abscessed cases, even spread to anatomical compartments of the head, neck, and throat. The microbiota involved with these abscesses is mixed

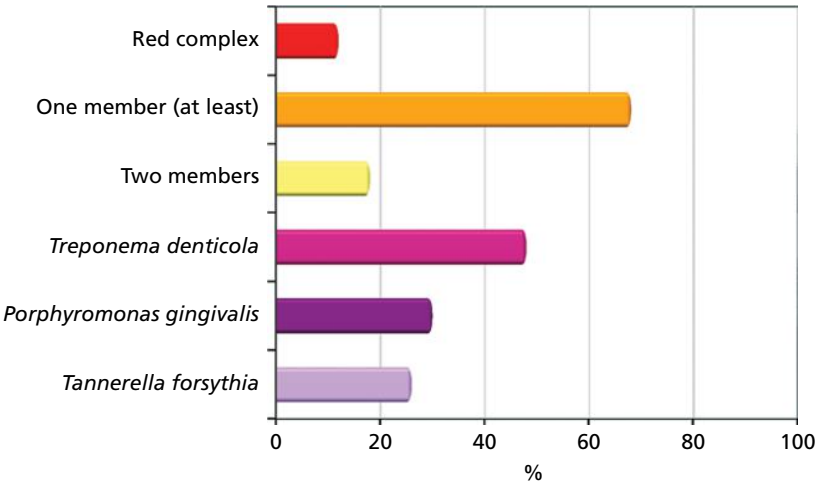

Fig. 25-11 Distribution of red complex bacteria in 50 cases of necrotic pulps with periradicular pathosis. (Data from Rôças *et al*. 2001.)

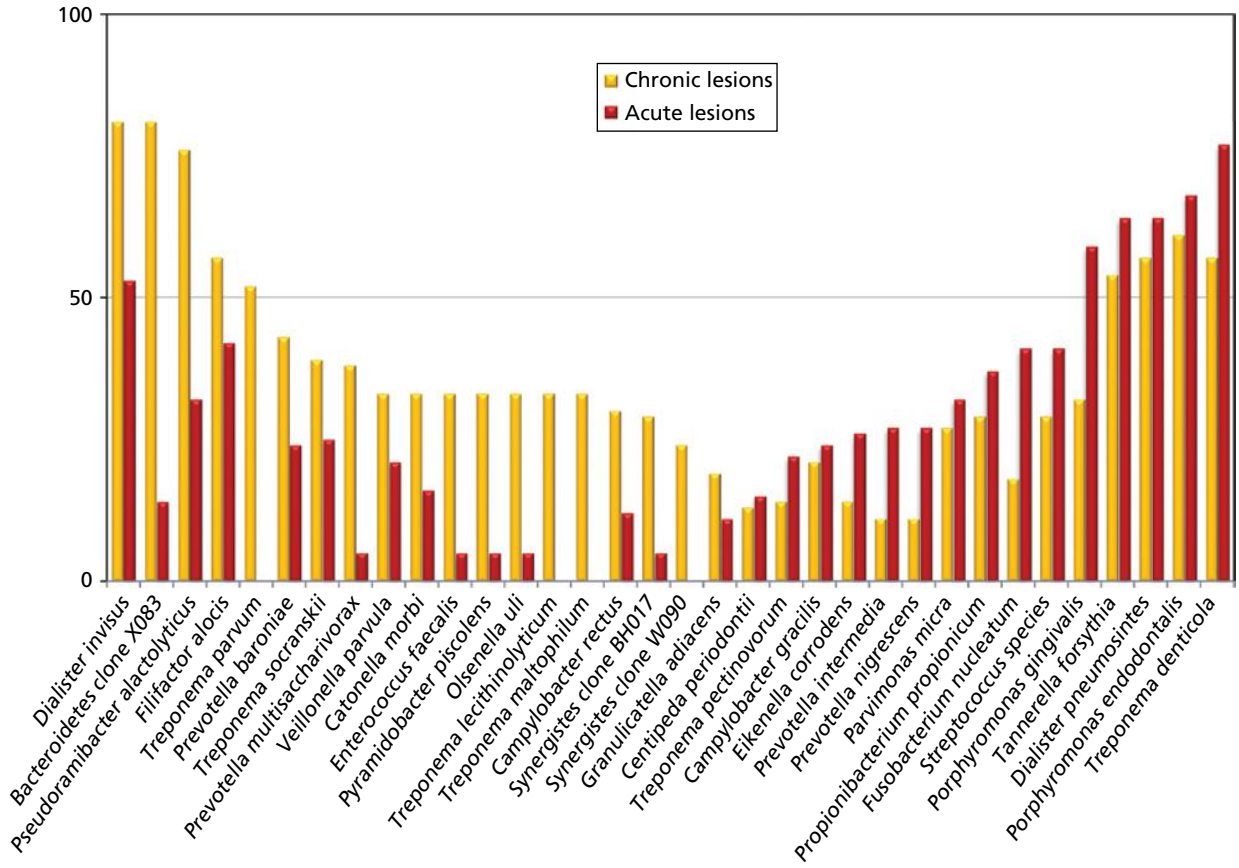

Fig. 25-12 Bacterial species/phylotypes detected in endodontic infections associated with chronic and acute endodontic lesions by species-specific nested polymerase chain reaction. (Data from Siqueira & Rôças 2005.)

but dominated by anaerobic bacteria (Williams *et al.* 1983; Kuriyama *et al.* 2000; Khemaleelakul *et al.* 2002; de Sousa *et al.* 2003; Siqueira *et al.* 2004; Sakamoto *et al.* 2006; Flynn *et al*. 2012). The bacterial load may range from 10^4 to 10^9 colony forming units (Williams *et al.* 1983; Lewis *et al.* 1986; Khemaleelakul *et al.* 2002), which means that the number of species is comparatively higher in canals of abscessed teeth than in canals of teeth with non-symptomatic and established lesions of apical periodontitis (Siqueira *et al*. 2004; Sakamoto *et al*. 2006).

There is no firm evidence in support of a single species being specifically involved with any particular sign or symptom of endodontic lesions. While some Gram-negative anaerobic bacteria have been found in association with symptomatic lesions (Sundqvist 1976; Griffee *et al.* 1980; van Winkelhoff *et al.* 1985; Yoshida *et al.* 1987; Gomes *et al.* 1996; Sakamoto *et al.* 2006), similar or even higher frequencies of the same organisms have been observed in asymptomatic teeth (Haapasalo *et al.* 1986; Baumgartner *et al*. 1999; Jung *et al.* 2000; Fouad *et al.* 2002; Siqueira *et al.* 2000; Rôças & Siqueira 2008) (Fig. 25-12). Hence, mechanisms other than the presence of a single pathogen seem to be the cause of symptomatic endodontic infections (Siqueira & Rôças 2013). These may include differences in virulence

among clonal types of the same species; bacterial interactions in multispecies communities resulting in additive or synergistic effects; bacterial population density; environment-regulated expression of virulence factors; and host resistance, which in turn may be modulated by systemic diseases, concomitant virus infection, environmental factors (stress, smoking), and genetic patterns (Siqueira & Barnett 2004).

In addition to bacteria, other microorganisms have been found in endodontic infections. Fungi, especially *Candida* species, although rarely recovered in primary infections, are more commonly detected in teeth with post-treatment disease (Waltimo *et al.* 1997; Cheung & Ho 2001; Peciuliene *et al.* 2001; Siqueira & Rôças 2004). Archaea and viruses may also be found, although their role in endodontic lesions has yet to be clarified. Archaea are prokaryotes distinct from bacteria that have been traditionally recognized as extremophiles, but recently detected in the human microbiota; in a few primary infected root canals, *Methanobrevibacter* spp. were recovered (Vianna *et al.* 2006a; Vickerman *et al.* 2007).

Although viruses cannot thrive in the necrotic root canal, there is a report of the presence of human immunodeficiency virus (HIV) in non-inflamed vital pulps of patients infected with this virus (Glick *et al.* 1991). Also, different herpesviruses have been detected in samples from periapical inflammatory lesions (Sabeti *et al.* 2003; Sabeti & Slots 2004; Chen *et al.* 2009; Saboia-Dantas *et al.* 2007; Ferreira *et al.* 2011). Their role in the disease process remains to be elucidated.

Evidence is mounting that endodontic lesions are biofilm-induced disease processes (Svensäter & Bergenholtz 2004). Morphologic studies demonstrate bacteria colonizing the root canal system in primary or persistent/secondary infections as sessile biofilm-like structures, usually covering the dentinal root canal walls (Nair 1987; Molven *et al.* 1991; Siqueira *et al.* 2002; Carr *et al.* 2009; Ricucci *et al.* 2009; Schaudinn *et al.* 2009) (see Fig. 25-10). Apical ramifications, lateral canals, and isthmuses connecting main root canals have all been shown to harbor bacterial cells frequently organized into biofilms (Nair *et al.* 2005; Ricucci & Siqueira 2010b) (Figs. 25-13, 25-14). Moreover, biofilms adhered to the apical root surface (extraradicular biofilms) have been reported in some

cases and regarded as a possible cause of post-treatment endodontic lesions (Fig. 25-15) (Tronstad *et al.* 1990; Ricucci *et al.* 2005).

Evaluating the prevalence of biofilms in 106 roots of untreated (primary root canal infections) and treated (persistent/secondary infections) teeth with endodontic lesions, Ricucci & Siqueira (2010a) reported the following main findings: (1) intraradicular biofilms were observed in the apical segment of 77% of the root canals of teeth with endodontic lesions (80% in untreated canals and 74% in treated canals); (2) intraradicular biofilms were usually thick and multilayered (composed of several layers of bacterial cells); (3) dentinal tubules underneath biofilms were often invaded by bacteria from the bottom of the biofilm structure; (4) biofilms were also seen covering the walls of apical ramifications, lateral canals, and isthmuses; (5) biofilm structures were much more common in root canals of teeth with large lesions; (6) extraradicular biofilms were infrequent, and when present were associated with intraradicular biofilms and clinical symptoms.

Periodontal tissue responses

The shape and character of the periodontal tissue response to a root canal infection may vary. Often lesions assume a limited and stable extension around the root apices and at orifices of accessory canals. The inflammatory process may then remain unchanged in size for years, although cyst transformation can result in substantial destruction of alveolar bone (Fig. 25-16). The initial expansion of an emerging lesion or exacerbation of an asymptomatic lesion can result in rapid and extensive destruction of the attachment apparatus. In certain cases, the periodontal tissue support can be lost to an extent that the gingival sulcus is involved, from where drainage of pus occurs to the oral environment (Fig. 25-17). Such an apical marginal communication along the root surface may later become a permanent pathway for pus that will be released periodically along what is simply a fistulous tract.

The character of the infecting microbiota, its overall metabolic activity, the infectious load, interactions among the community members, and the virulence factors they produce, together with the capacity of the host defense to confine and neutralize the bacterial elements, are important parameters that determine the course of the inflammatory process. Hence, growing and multiplying bacteria with capacities to invade the periodontal tissues and evade host defense mechanisms can induce acute manifestations of endodontic lesions. Monoinfections (caused by a single species) are normally unable to cause these lesions, which rather are maintained by groups of different species forming virulent partnerships, as inferred by culture studies (Dahlén 2002) and studies utilizing molecular methodology (Sakamoto *et al.* 2006; Siqueira *et al.* 2004). Hence, the disease outcome is dependent upon the varied bacterial interactions that occur among the members of the multispecies community in root canals and the pathogenicity that these interactions collectively result in (Siqueira & Rôças 2009a).

The endodontic microbiota associated with asymptomatic lesions is apparently less aggressive. This is likely to be linked to the poor nutritional supply that usually prevails in root canals and which puts the bacteria in a low state of metabolic activity. Nutrients are available primarily from tissue components of the necrotic pulp. In the absence of inflammatory exudate entering the root canal along apical foramina and accessory canals, bacteria will consequently have little drive to grow, multiply, and invade the periodontal tissue compartment. When this condition of relative starvation is broken by an increase of the nutritional supply, suppressed virulent strains can be revived and become the dominant organisms at the expense of the less virulent members of the microbial community. Consequently, acute exacerbations of asymptomatic endodontic lesions may occur, for example, when saliva and gingival exudates gain access to the root canal space following its direct exposure to the oral environment. Similarly, during endodontic treatment, inadvertent enlargement of the apical foramen increases the passageway for protein-rich inflammatory exudate into the root canal space.

While expanding bone resorption, exudation and influx of phagocytic cells characterize the acute manifestations of endodontic lesions, a balanced host–parasite relationship will be established sooner or later (Stashenko 1990; Nair 1997; Stashenko *et al.* 1998). Microscopically, the established lesion is characterized by a richly vascularized granulation tissue, which is infiltrated, to a varying degree, by inflammatory cells (Fig. 25-18). PMNs play a most important role in confining the infection to the pulpal space (Stashenko *et al.* 1995) and constitute an important cellular front line of host defense (see Fig. 25-14). The remainder

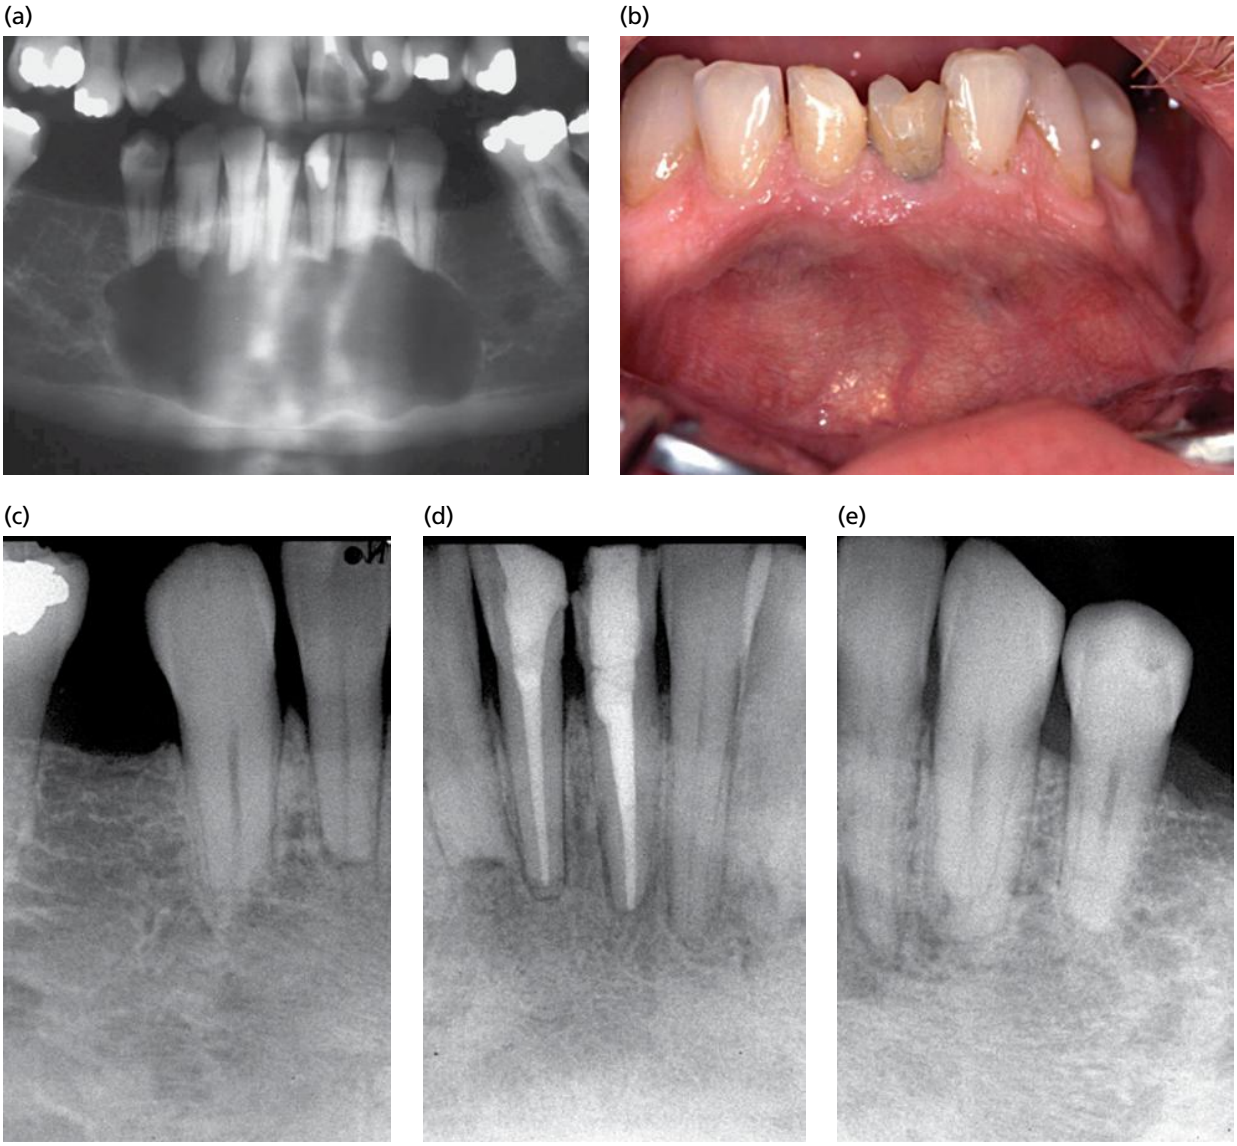

Fig. 25-16 (a) Extensive destruction of alveolar bone as a result of cyst transformation of a periapical lesion emanating from tooth 31. Note the root resorption of neighboring teeth. (b) Buccal protrusion of the process was non-painful to palpation. All teeth responded vital to pulp testing except for the root-filled tooth 31 and tooth 41. The latter tooth, however, had a vital pulp as revealed on entering the root canal. Treatment, carried out in collaboration with Dr Ulf Lekholm, included placement of an obturator for drainage, decompression, and saline irrigation of the cyst cavity over 6 months. Following its reduction, teeth 31 and 41 received completion of endodontic treatment and a residue of the process was excised surgically. (c–e) Complete resolution of the process 10 months post surgery.

of the lesion will be composed of a mixed cellular response (Fig. 23-18c) typical of a longstanding infectious process where various immunocompetent cells (*viz.* dendritic cells, macrophages, plasma cells, T and B cells) are prevalent (Torabinejad & Kettering 1985; Babal *et al*. 1987; Okiji *et al*. 1994; for reviews see Stashenko *et al*. 1998; Marton & Kiss 2000; Nair 2004; Marton & Kiss 2014). PMNs may nevertheless be dominant in areas of the main lesion and even form abscess cavities. With increasing distances from the root canal apertures, the established lesion harbors a decreasing number of inflammatory cells and an increasing amount of fibrovascular elements representing attempts at repair. More peripherally, there is a much stronger expression of fibroblastic activity and formation of new vessels. In the most peripheral portions of the lesion, a collagen-rich connective tissue normally separates it from the surrounding bone tissue (Bergenholtz *et al*. 1983) (Fig. 25-18a, d).

In the established lesion, the relative distribution of cellular and tissue elements may show great variation and some, but far from every lesion, may also contain proliferating epithelial cells (Nair 1997). The origin of epithelial strands is thought to be the epithelial rests of Malassez (Ten Cate 1972) that are stimulated to divide and proliferate by the release of pro-inflammatory cytokines and growth factors during the process of inflammation (Thesleff 1987; Lin *et al*. 1996; Suzuki *et al*. 2002). In the lesion, they appear to take a random course, but sometimes they may also attach to the root surface (Fig. 25-19) and eventually block the root canal exit

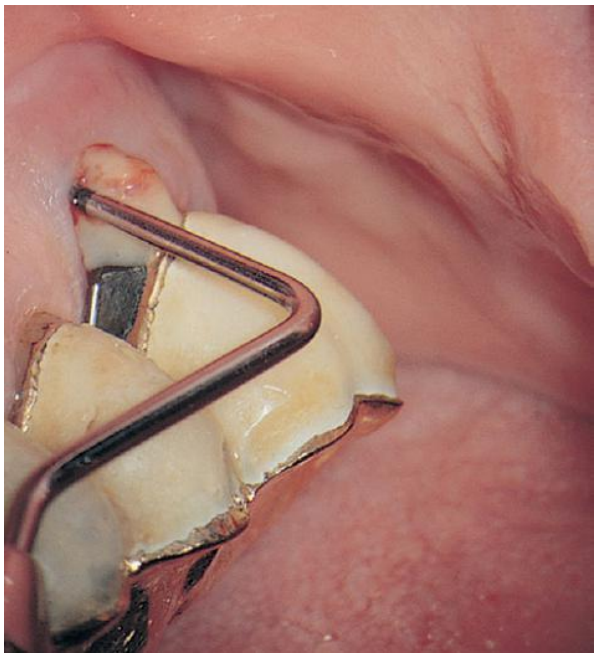

Fig. 25-17 Drainage of pus upon periodontal probing from a lesion of endodontic origin associated with an upper molar.

for bacterial advancement into the periapical tissue compartment (Nair & Schroeder 1985). Their contribution to periodontal pocket formation upon an endodontic lesion, developing in close proximity to the epithelial sulcus of the marginal periodontium, remains obscure.

Conclusion: Inflammatory processes of the periodontium associated with necrotic dental pulps have an infectious etiology similar to periodontal disease. An essential difference between the two disease entities is their different source of infection. While periodontal disease is maintained by bacterial biofilms in the dentogingival region, endodontic lesions are directed towards infectious elements released from the pulpal space. Bacteria involved in endodontic infections are predominantly anaerobic species usually organized in biofilms adhering to the inner walls of the root canal. Thus, the infection is commonly confined to the root canal space. Bacteria may be occasionally found in the periapical soft tissue lesion *per se* either in clusters or as bacterial biofilms on the external root surface.

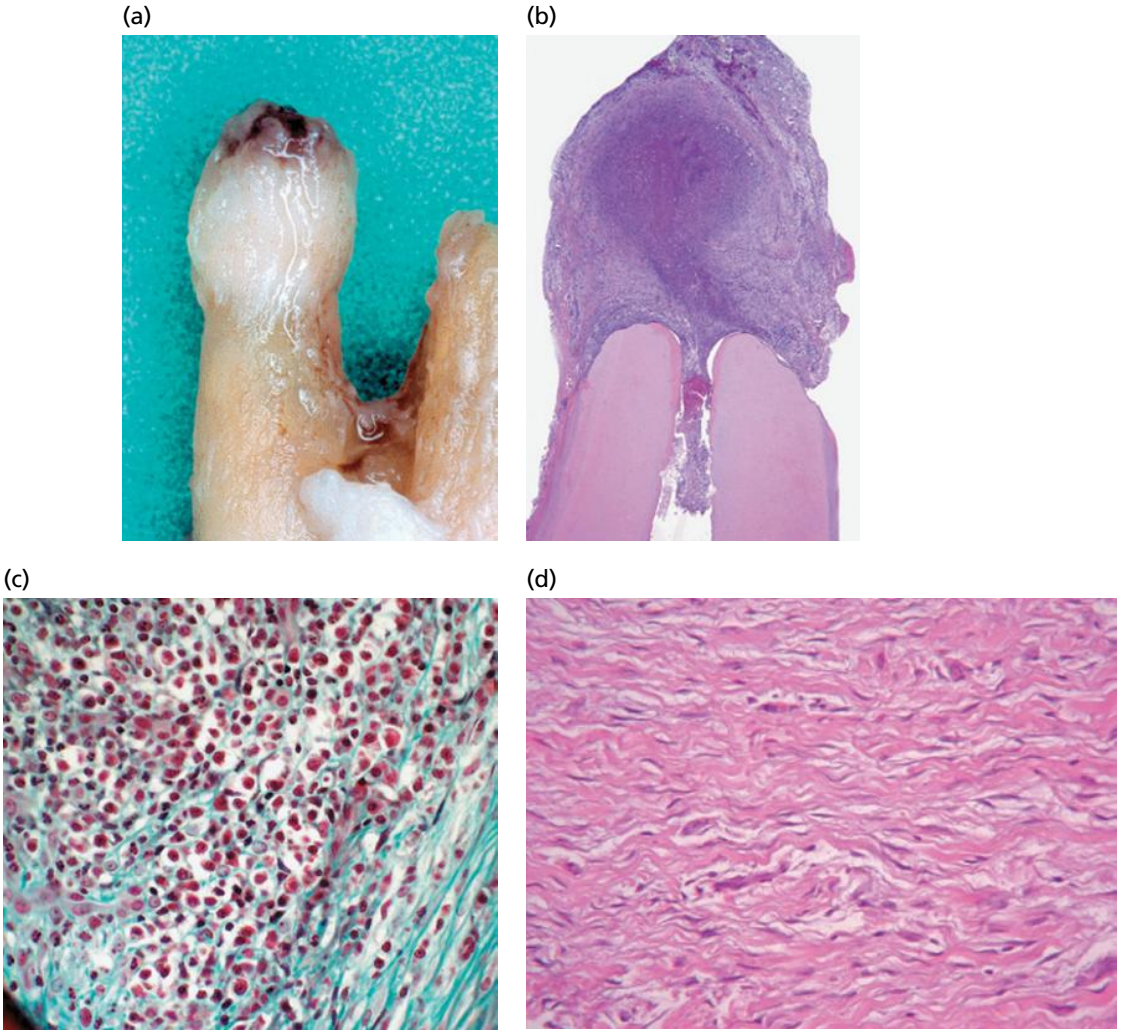

Fig. 25-18 Series of images demonstrating features of apical inflammatory lesions caused by root canal infection. (a) Soft lesion attached to the tip of the palatal root of an extracted upper molar. (b) Longitudinally cut tissue section through the root tip shows an overview of the lesion. The outer collagen-rich connective tissue confines the soft tissue lesion and attaches it to the root surface. (c) Typical mixed inflammatory cell infiltrate at the center of a lesion (from an apical lesion in a monkey). (d) In the most peripheral portion the connective of an established lesion is rich in collagen and devoid of inflammatory cells.

Endodontic lesions rarely involve the marginal periodontium, unless abscessed. Cyst transformation may occur but even then marginal involvement is not common. In its balanced form, the endodontic lesion is clearly localized and constitutes an immunologically active protection zone, which serves to prevent the dissemination of endodontic pathogens to surrounding tissues and distant body compartments.

Post-treatment endodontic lesions

Endodontic treatment seeks to curb symptomatic and non-symptomatic presentations of endodontic infections with the ultimate goal of maintaining or restoring the health of the periodontal tissues apically and laterally to the roots of teeth. Similar to the treatment of marginal periodontitis, the success of endodontic treatment depends largely on how effectively the cleaning procedure can be carried out. The complicated nature of the root canal system of many teeth, however, may limit the potential to completely get rid of diseased or infected and dead pulp tissue. The use of chemicals for disinfection purposes is therefore important in endodontics, especially in cases of infected pulp necrosis. Filling the instrumented root canal properly by leaving no unfilled spaces then determines the long-term outcome. Fluids and exudate from either the oral environment or the periapical tissue lesion may otherwise seep into the root canal and nourish residual bacteria that may have survived the treatment procedure, thus causing an emergent (developed after treatment), persistent (persisted despite treatment), or recurrent (redeveloped after having healed) post-treatment endodontic lesion. A root canal filling that occupies the entire instrumented canal space from its coronal entrance to its apical terminus is therefore a key goal of a well-executed endodontic treatment (for an overview of endodontic treatment principles, see appropriate texts).

As indicated by numerous cross-sectional population studies, post-treatment lesions are commonly observed in teeth in which the endodontic treatment has not met key standards for prevention and control of endodontic infection (for review see Eriksen *et al.* 2002). Post-treatment disease may nevertheless occur in 10–15% of treated teeth, even if state-of-the art treatment procedures are applied (Kerekes & Tronstad 1979; Sjögren *et al.* 1990; Ricucci *et al*. 2011). Hence, regardless of the technical quality of the root canal treatment, the causes of failure are to be found in either a persistent/secondary intraradicular infection, or sometimes in an associated extraradicular infection (see below).

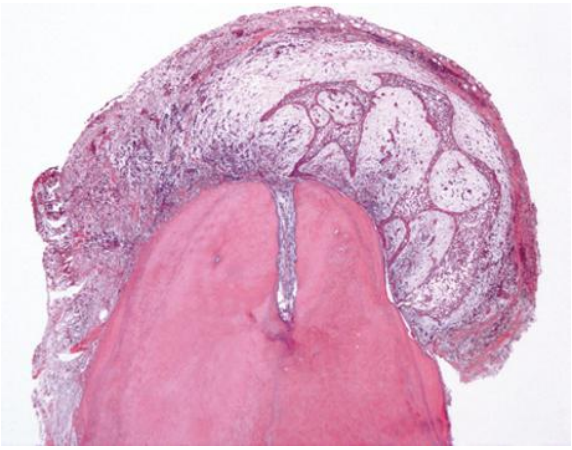

Fig. 25-19 Periapical inflammatory process with proliferating epithelium partially attached to the root surface.

(a)

(b)

Fig. 25-20 (a) Root tip of an extracted tooth with attached periapical inflammatory lesion. (b) High magnification of insert in (a) shows the bacterial front line well inside the apical foramen, where it is opposed by polymorphonuclear leukocytes.

The microbiota in root canal-treated teeth with a post-treatment endodontic lesion exhibits a decreased diversity and density in comparison with primary root canal infections. Well-treated canals may harbor one to five species, while the number of species in canals with inadequate endodontic treatment, similar to untreated canals, can reach up to 10–30 (Pinheiro *et al.* 2003; Siqueira & Rôças 2004; Sakamoto *et al.* 2008). A single treated canal with post-treatment disease can harbor from 10^3 to 10^7 bacterial cells (Peciuliene *et al.* 2001; Sedgley *et al.* 2006; Blome *et al.* 2008).

Culture and molecular studies have revealed that *Enterococcus faecalis* is the most frequently detected species in association with post-treatment disease (Engström 1964; Molander *et al.* 1998; Sundqvist *et al.* 1998; Pinheiro *et al.* 2003; Siqueira & Rôças 2004; Sedgley *et al.* 2006; Gomes *et al.* 2008; Schirrmeister *et al.* 2009), although its pathogenetic potential is not well confirmed (Chávez de Paz 2007). While the Gram-negative anaerobic segment is less frequently represented, other Gram-positive bacterial species, especially streptococci, may also be prevalent (Molander *et al.* 1998; Sundqvist *et al.* 1998; Pinheiro *et al.* 2003; Siqueira & Rôças 2004; Gomes *et al.* 2008; Sakamoto *et al.* 2008). Like primary endodontic infections, about one-half of the

Table 25-1 Characteristics of the root canal infection in primary and post-treatment endodontic lesions.

	Primary lesions	**Post-treatment lesion**
	Untreated teeth	Root canal-treated teeth
		
Type of infection	Primary intraradicular Extraradicular (abscess)	Persistent secondary intraradicular Extraradicular
Community	Multispecies	Multispecies, sometimes single
No. of species/canal	10–20	• Adequate treatment: 1–5 • Inadequate treatment: 10–30
No. of cells/canal	10^3–10^8	10^3–10^7
Most prevalent bacterial groups	Gram-negative/Gram-positive anaerobes	Gram-positive facultatives
Most prevalent species/genera	*Fusobacterium nucleatum* *Dialister* spp. *Porphyromonas* spp. *Prevotella* spp. *Treponema* spp. *Tannerella forsythia* *Filifactor alocis* *Pseudoramibacter alactolyticus* *Pyramidobacter piscolens* *Synergistes* spp. *Eikenella corrodens* *Olsenella* spp. *Parvimonas micra* *Campylobacter* spp.	*Enterococcus faecalis* *Candida albicans* (fungus) *Streptococcus* spp. *Pseudoramibacter alactolyticus* *Propionibacterium propionicum* *Filifactor alocis* *Dialister* spp. *Actinomyces* spp. *Pseudomonas aeruginosa* Enteric rods
Treatment	Root canal treatment Extraction	Root canal retreatment Apical surgery Extraction

species detected in persistent/secondary infections still remain to be cultivated and phenotypically characterized (Sakamoto *et al.* 2008).

Even though in most cases of post-treatment disease, bacteria are likely to be confined to the root canal space (Siqueira & Lopes 2001; Ricucci *et al.* 2009), case reports have indicated that post-treatment disease may also be related to extraradicular infection with *Actinomyces* spp. or *Propionibacterium propionicum*, a condition referred to as periapical actinomycosis (Sundqvist & Reuterving 1980; Happonen *et al.* 1986; Sjögren *et al.* 1988; Siqueira 2001; for review Haapasalo *et al.* 2008). Even though the front line of the infection in some cases may be established at the apical foramen or even beyond it, the host tissue–bacterial interface zone usually localizes somewhat short of the apical foramen (Fig. 25-20). In what may be a rare condition (Siqueira & Lopes 2001), bacteria in primary endodontic infections may overcome the host defenses and aggregate as a biofilm on the outer root surface (Lomçali *et al.* 1996) (see Fig. 23-15). Such structures have also been observed on root ends of teeth, which have not responded favorably to endodontic treatment (Tronstad *et al.* 1990; Ricucci *et al.* 2005).

Conclusion: Post-treatment endodontic lesions are usually caused by a persistent or secondary infection of the root canal space. The microbiota differs from the primary infection in terms of diversity and types of species involved (Table 25-1). While in some cases the cause of a persistent endodontic lesion may be an extraradicular bacterial infection, failure to attain the treatment objectives of endodontics often relates to inadequate infection control caused by insufficiently cleaned, shaped, disinfected as well as filled root canals.

Effects of periodontal disease and periodontal therapy on the condition of the pulp

Influences of periodontal disease

The formation of bacterial plaque on detached root surfaces following periodontal disease has the potential to induce inflammation in the pulp along the very same pathways as an endodontic infection can affect the periodontium in the opposite direction. Thus, bacterial products and substances released by the inflammatory process in the periodontium may gain access to the pulp via exposed accessory canals and apical foramina, as well as dentinal tubules.

A clear association between progressive periodontal disease and pulpal involvement, however, does not exist. While inflammatory alterations as well as localized inflammatory cell infiltrates and necrosis of pulp tissue have been observed adjacent to accessory canals in teeth exposed by periodontal disease (Seltzer *et al.* 1963; Rubach & Mitchell 1965), a number of clinical studies has failed to confirm a direct relationship between progression of periodontitis and pulp tissue changes (Mazur & Massler 1964; Czarnecki & Schilder 1979; Torabinejad & Kiger 1985). In the cases observed in these studies, the pulp remained fully functional without overt inflammatory changes even though the periodontal tissue breakdown was severe. As already pointed out, an important reason for the lack of pulp tissue involvement is that patent accessory canals are not invariably present and especially not in the cervical root portions. Another reason is that cementum obviously gives protection. It is only when the cementum layer has been damaged by, for example, instrumentation in periodontal therapy, wear from tooth cleaning, external root resorption, and root surface caries, that dentinal tubules can serve as pathways for microbial elements to the pulp (Figs. 25-21, 25-22, 25-23, 25-24).

The fact that tissue changes develop infrequently and even then only locally in the pulp of teeth subjected to periodontitis was underscored by an experimental study in monkeys (Bergenholtz & Lindhe 1978). Following a ligature-induced breakdown of the attachment apparatus, it was found that the majority of the root specimens examined (70%) exhibited no inflammatory changes, despite the fact that approximately 30–40% of the periodontal attachment was lost. The remaining roots (30%) displayed only small inflammatory cell infiltrates and/or formations of reparative dentin in the pulp subjacent to root areas exposed by the periodontal tissue destruction. These tissue changes were associated with root surface resorption (Fig. 25-21), supporting the view that dentinal tubules have to be uncovered before external irritants can be transmitted to the pulp. Consequently, the lack of correlation found in clinical observations between periodontal disease and pulp tissue alterations, may simply depend on the fact that few open pathways exist to the pulp in many periodontally involved teeth. Furthermore, as described

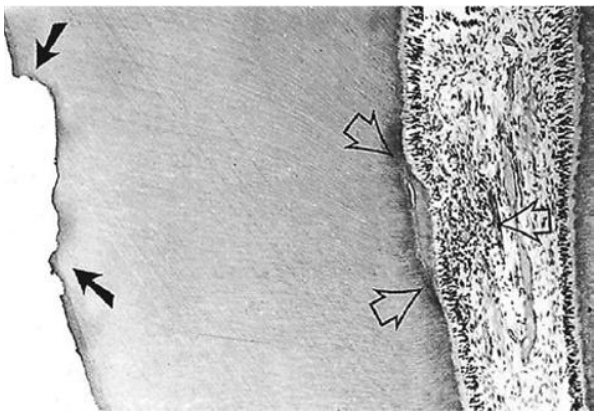

Fig. 25-21 Histologic section of a monkey tooth exposed to experimental periodontal tissue breakdown. Beneath the resorptive defects in the external root surface (black arrows), a minor inflammatory cell infiltrate and a small rim of reparative dentin have formed in the pulp (open arrows). (Source: Bergenholtz & Lindhe, 1978. Reproduced with permission from John Wiley & Sons.)

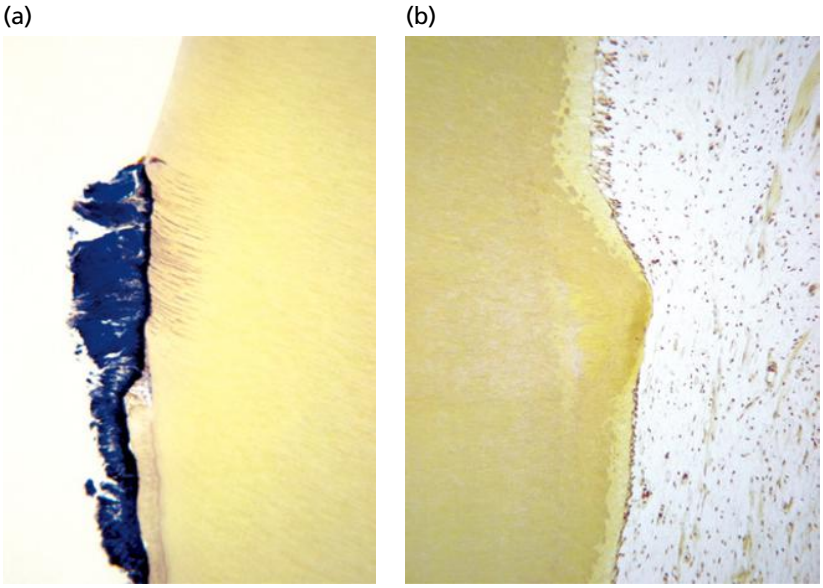

Fig. 25-22 (a) Histologic section of a human tooth specimen with bacterial accumulations on the external root surface. Where the cementum layer is missing bacterial organisms have entered the dentinal tubules. (b) Adjacent pulp tissue is minimally affected with slight disruption of the predentin zone and the odontoblast layer.

above, once the dentin–pulp complex has been exposed to bacterial elements, repair and healing will often be instituted soon after the initial inflammatory events, leaving the remaining tissue unaffected as a result of an effective host defense

In the study by Bergenholtz and Lindhe (1978), destructive periodontal disease was produced experimentally over a comparatively short period (5–7 months), while in humans a similar degree of destruction of periodontal tissue normally requires several years. It has been reported that the pulp of teeth with longstanding periodontal disease develops fibrosis and various forms of intrapulpal mineralizations (Bender & Seltzer 1972; Lantelme *et al*. 1976) (Fig. 25-23). If there is an association, it seems reasonable to assume that tissue changes of this nature represent the accumulated response of the pulp to the relatively weak, but repeatedly occurring, insults to the tissue over time, for example by microbial elements reaching the pulp over root surface exposures. Nonetheless the pulp can obviously remain healthy for as long as periodontal disease has not arrived at a terminal stage, when plaque accumulation and associated inflammatory lesions interfere with the neurovascular supply of the tissue through the main apical foramen (Langeland *et al*. 1974; Ricucci & Siqueira 2013) (Fig. 25-25).

Conclusion: Available documentation suggests that the vital functions of the pulp are rarely threatened by periodontal disease influences. In teeth with moderate breakdown of the attachment apparatus, the pulp usually remains functional and healthy. Breakdown of the pulp presumably does not occur until the periodontal disease process has reached a terminal stage, that is when plaque and the periodontal inflammatory process have progressed to the main apical foramina, whereby a retrograde destructive inflammatory pulpal lesion is initiated (see Fig. 25-25). Consequently, as long as the neurovascular supply through the main apical foramina remains intact, the pulp is usually capable of withstanding injurious elements released by the lesion in the periodontium.

Influence of periodontal treatment measures

Pocket/root debridement in periodontal therapy by hand instrumentation [scaling and root planing (SRP)] or ultrasonics is indispensable in the treatment of periodontal disease. However, this treatment is associated with a number of undesired side effects. Except for recession of gingival tissues resulting in exposure of root surfaces, the instrumentation *per se* may also inadvertently remove root cementum and the superficial parts of dentin. Thereby a large number of dentinal tubules will become exposed to the oral environment as treated root surfaces are normally left unprotected. Subsequent contact with microbial elements in the oral cavity is potentially harmful to the pulp and bacterial invasion of the exposed dentinal tubules may occur (Adriaens *et al*. 1988; Love 1996) (see Fig. 25-22). While localized inflammatory lesions may be initiated in the pulp, the experimental study by Bergenholtz and Lindhe (1978) did not record an increased incidence of pulpal lesions in teeth subjected to SRP in comparison to non-treated teeth subjected to periodontal tissue breakdown alone. In this study, root surfaces denuded of root cementum were exposed to the oral environment for up to 30 days. The finding that plaque accumulation on root dentin exposed by one session of SRP does not seriously threaten the vitality of the pulp has been confirmed in similarly designed experimental studies (Nilvéus & Selvig 1983; Hattler & Listgarten 1984). Yet, root dentin hypersensitivity may follow such treatment measures, causing an uncomfortable problem that is difficult to manage (see later).

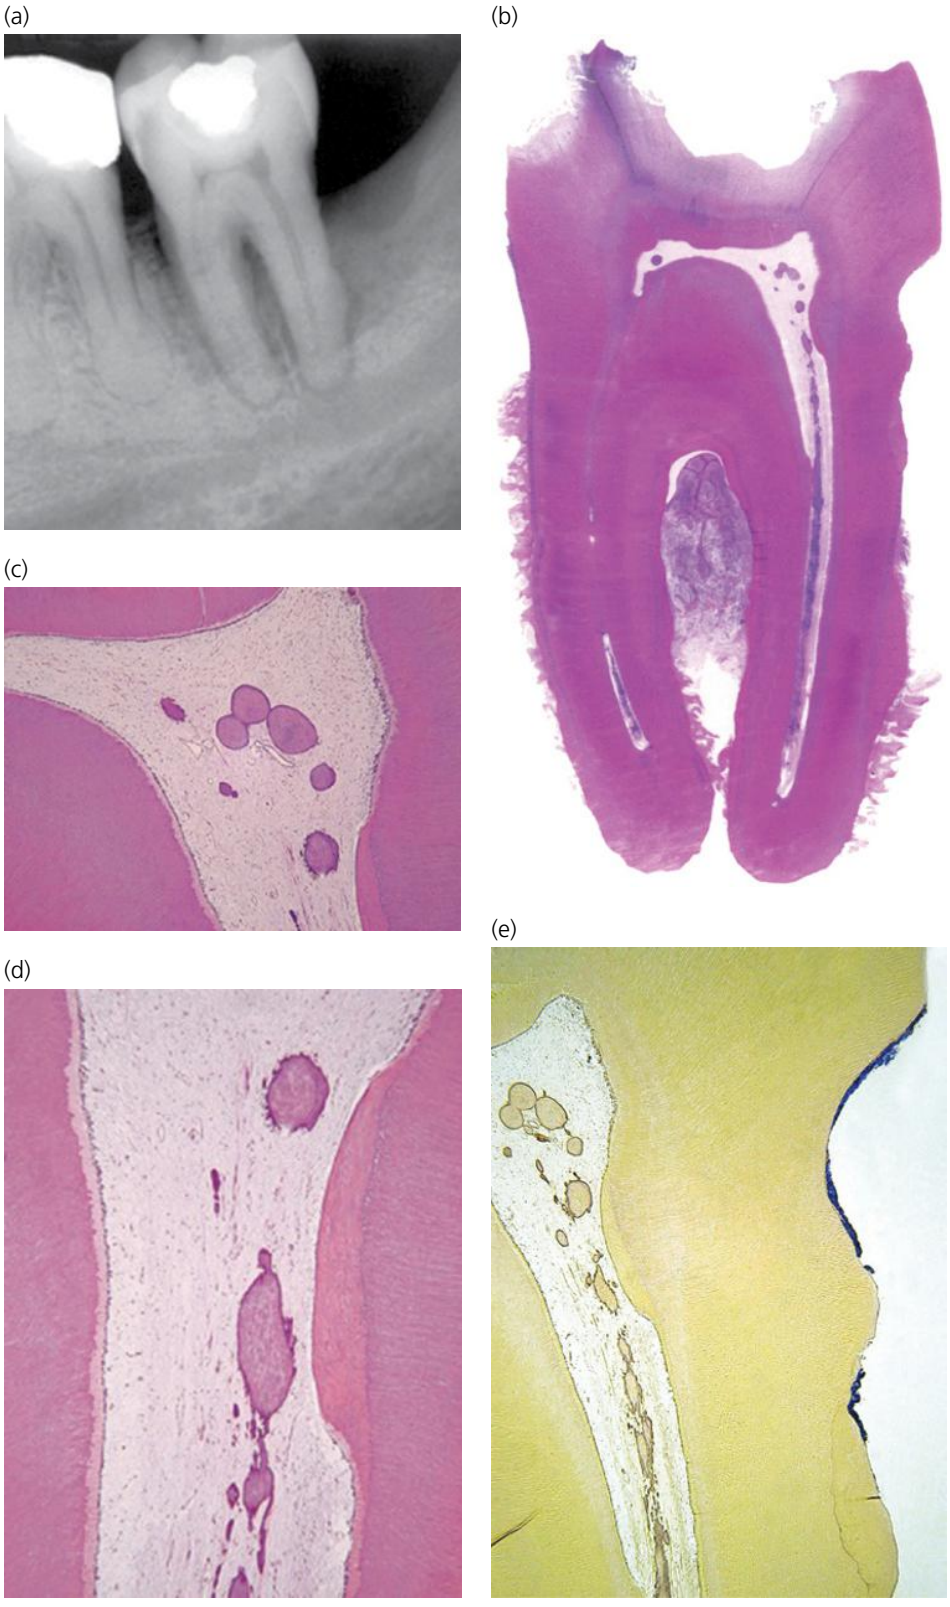

Fig. 25-23 (a) Lower molar with advanced periodontal tissue destruction. (b) Low power microphotograph demonstrates numerous mineralizations in the pulp tissue, which otherwise is in a healthy condition as demonstrated in (c) and (d). (e) Bacterial plaque accumulations on the external surface of the distal root.

During the maintenance phase of periodontal therapy, there are reasons to restrict repeated instrumentations, as instrumentation always removes some dentin. Such therapy can result in weakening of the tooth structure and also in extensive reparative dentin formation in the pulp (Fig. 25-26).

Conclusion: Results of clinical observations and animal experiments support the view that pocket/root debridement procedures normally do not threaten the vitality of the pulp. Localized inflammatory alterations may occur adjacent to instrumented root surfaces, followed by tissue repair in the form of hard tissue depositions on the root canal walls.

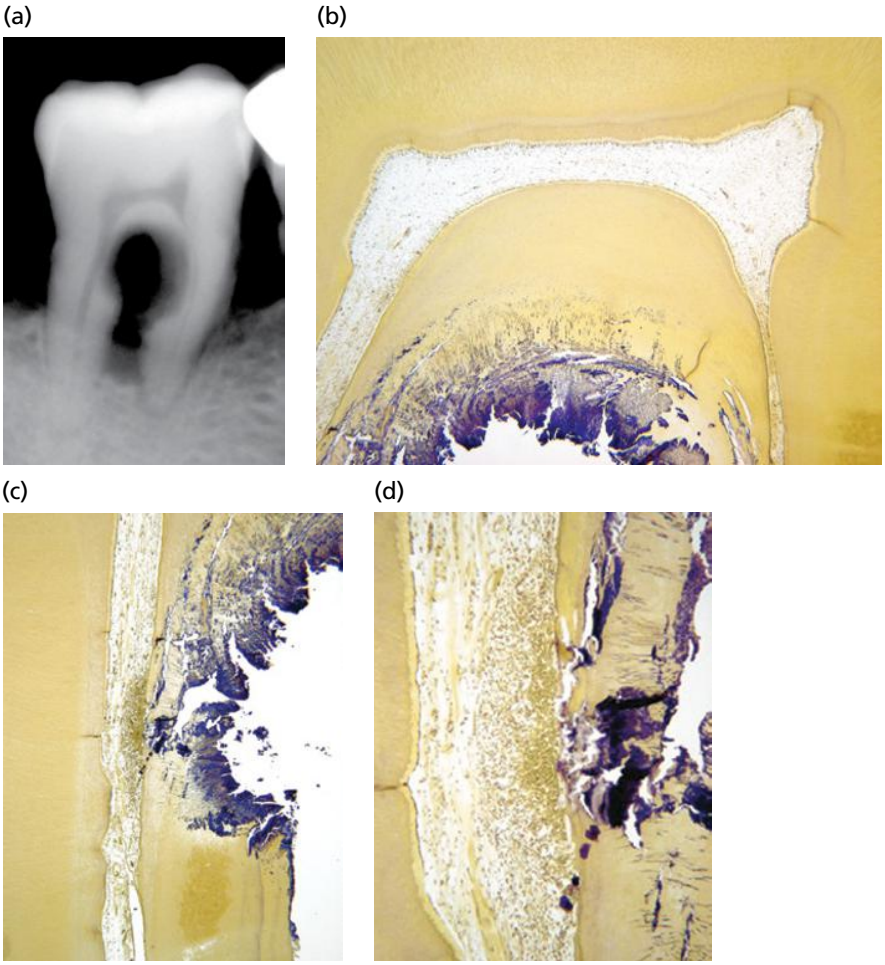

Fig. 25-24 (a) Tooth with extensive caries in the furcation region of a lower molar. (b) Note the overall normal tissue morphology of the pulp except for an area at the mid-root portion of the distal root, where the caries process has reached the pulp (c, d).

Root dentin hypersensitivity

Symptoms

Patients who have received pocket/root debridement in periodontal therapy may frequently experience sensitivity of the treated teeth to evaporative, tactile, thermal, and osmotic stimuli (Fischer *et al*. 1991; Kontturi-Närhi 1993; Chabanski *et al*. 1996; Tammaro *et al*. 2000; for review see Gillam & Orchardson 2006). Usually, the symptoms, when they occur, develop and peak during the first week, and then subside or disappear within the subsequent weeks; they are, although uncomfortable, most often a temporary and sustainable problem (Schuurs *et al*. 1995; Chabanski *et al* 1996; Gillam *et al*. 1999; Fardal *et al*. 2002). Occasionally, the condition may become a chronic pain problem and may persist for months or years. Although the number of well-controlled studies on the incidence after periodontal therapy is few (von Troll *et al*. 2002), patients appear to be especially at risk after periodontal surgery. In a comprehensive questionnaire survey, severe painful symptoms were reported to prevail in 26% of the subjects 6 months to 5 years after the completion of treatment, while 16%, treated non-surgically, reported pain symptoms (Kontturi-Närhi 1993). In a prospective, clinical trial comprising 35 patients in need of periodontal therapy for moderate-to-advanced periodontitis, the number of sensitive teeth increased following non-surgical periodontal instrumentation in comparison to non-instrumented teeth after initiating a self-performed oral hygiene program (Tammaro *et al*. 2000). While affecting a majority of the patients, pain was generally reported to be minor. Only a few teeth in a small number of the patients developed highly sensitive root surfaces.

The main initial symptom is sharp pain of rapid onset that disappears once the stimulus is removed. In more severe, long-standing cases, shorter or longer periods of lingering, dull or aching pain may be provoked, especially by cold drinks but also by hot and sweet food items. These symptoms of a pulpitis character may not only be localized to the tooth (teeth) in question, but also to both quadrants of the jaw. Even minimal contact with a toothbrush may elicit intense pain – a condition which is not only uncomfortable but also one that is likely to hinder proper oral hygiene measures.

Mechanisms

The painful condition has been given many names, including dentin sensitivity, cervical dentin hypersensitivity, root dentin sensitivity, and root dentin

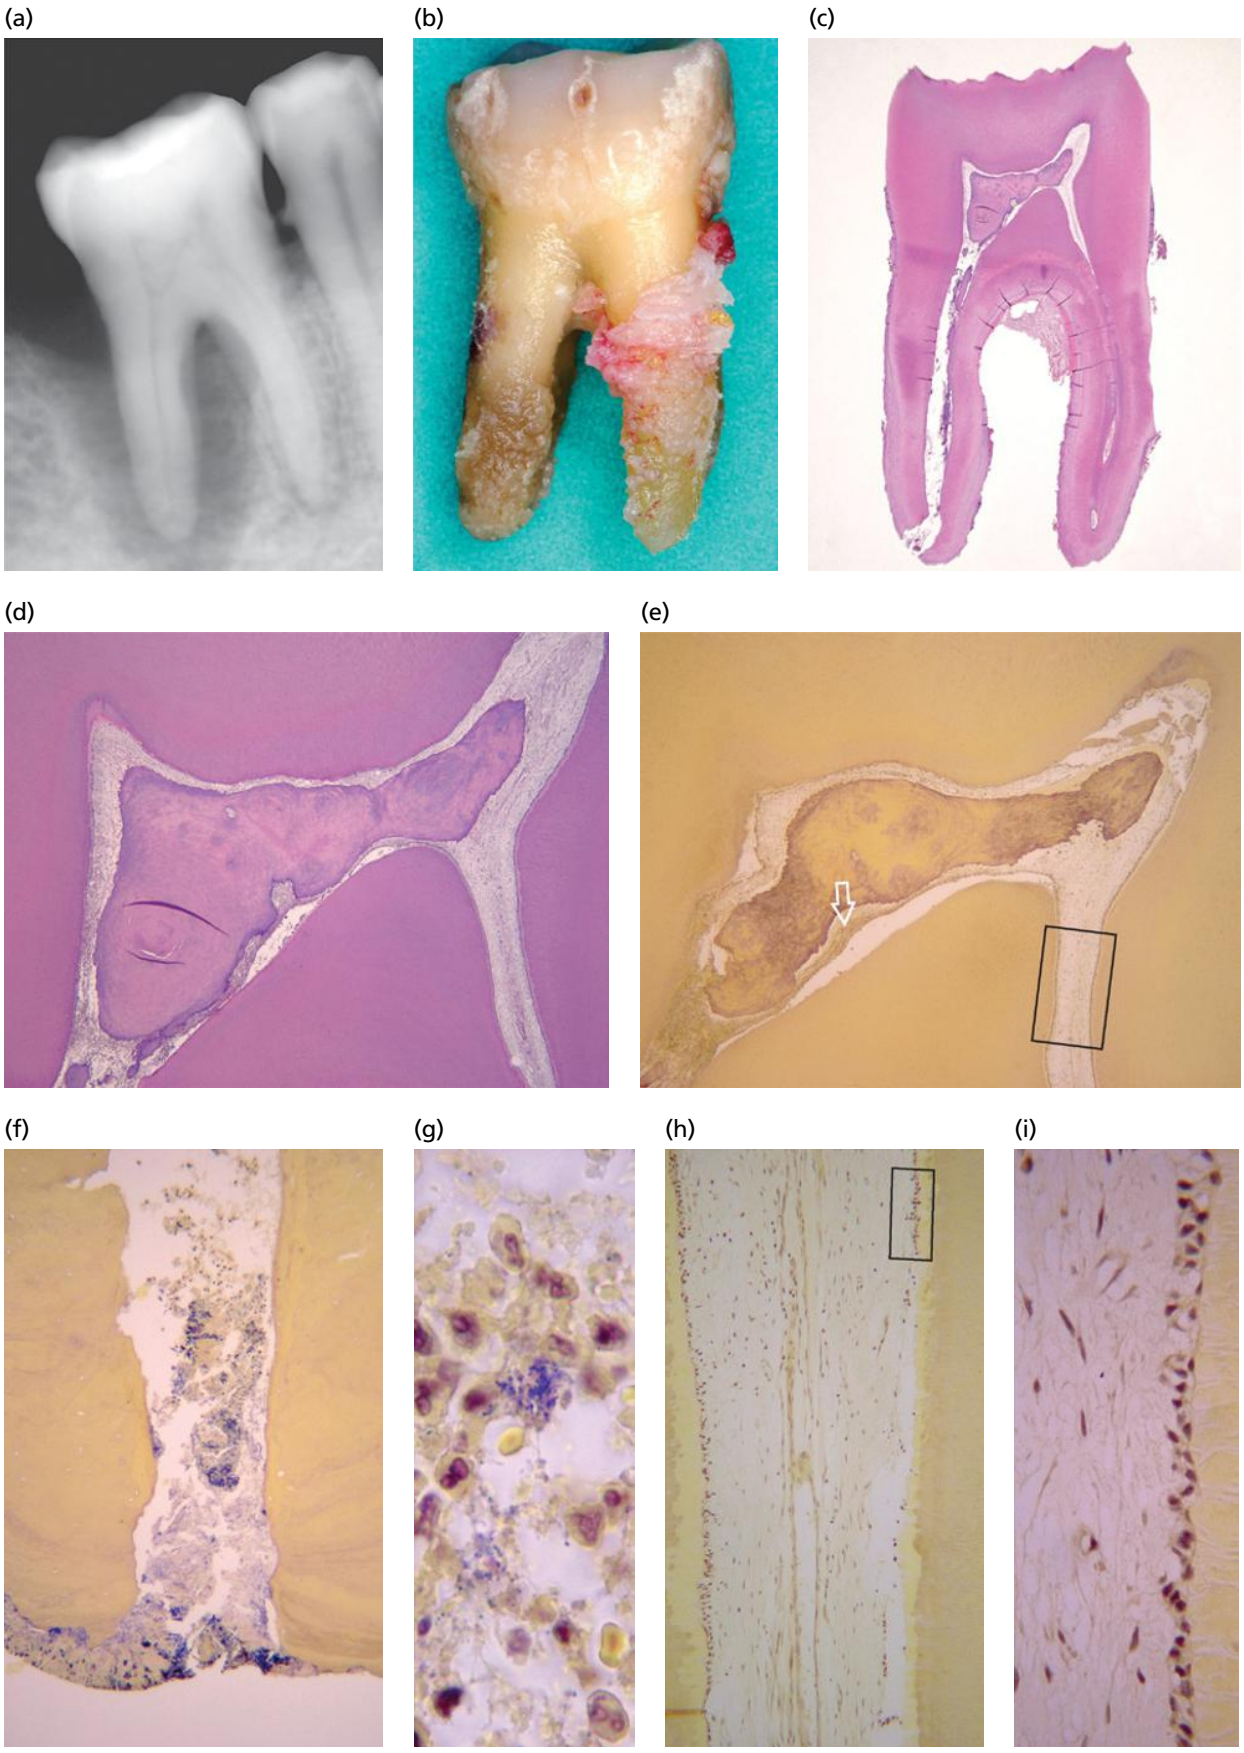

Fig. 25-25 (a) Extensive periodontal tissue breakdown circumscribing the distal root of a lower molar. (b, f) Plaque and calculus cover the root surface to the apical foramen. (c–g) Pulp is necrotic and infected all the way to the extensive hard tissue deposition in the coronal pulp (arrow in e). (f, g, i) Microphotographs enlarging marked area in (e) and (h) indicate that the pulp tissue of the mesial root is completely unaffected and displays normal tissue morphology. Tooth was sensitive in pulp vitality testing.

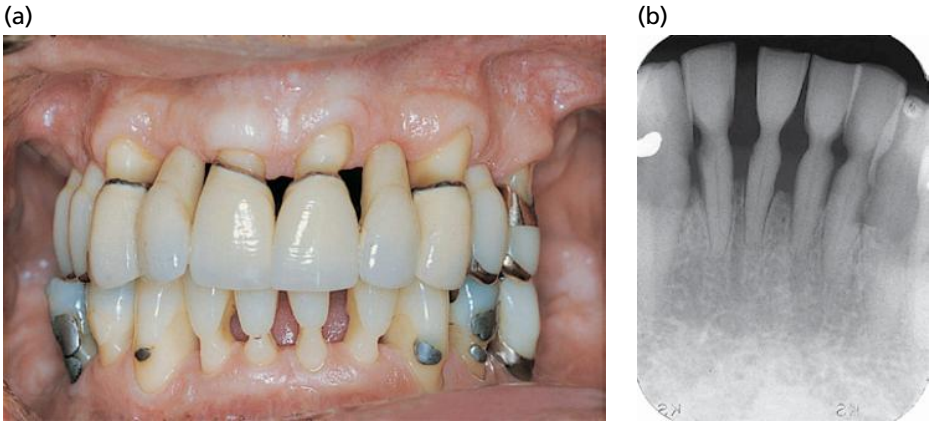

Fig. 25-26 (a) Clinical photograph of a patient in the maintenance phase for periodontal disease. While the gingival condition is excellent and there are no pocket probing depths, there is substantial loss of cervical root dentin. (b) Coronal portions of the pulp are obliterated by reparative dentin. One of the lower incisors later had a horizontal fracture, but without exposure of the pulp. (Courtesy of S. Nyman.)

hypersensitivity, reflecting some of the confusion that exists regarding its etiology (Gillam & Orchardson 2006). The fact that root surfaces become sensitive to a variety of externally derived stimuli after periodontal instrumentation is not surprising as dentinal tubules become exposed to the oral environment and subject to hydrodynamic forces. Hence, a variety of pain-evoking stimuli, including evaporative, tactile, thermal, and osmotic stimuli, may elicit sudden fluid shifts in the exposed tubules, thereby inducing a painful sensation according to the hydrodynamic theory of dentin sensitivity (Brännström 1966; Pashley 1996). This mechanism alone can certainly explain the sensitivity patients experience immediately after the instrumentation procedure and during a short period afterwards, but it does not explain why the symptoms affect only certain teeth and increase over the course of time, as well as prevail as a serious pain condition in certain patients.

The increase in pain intensity may have several explanations. To begin with, the smear layer formed on the root surface by the SRP procedure will be dissolved within a few days (Kerns *et al*. 1991). This in turn will increase the hydraulic conductance of the involved dentinal tubules (Pashley 1996) and thus decrease the peripheral resistance to fluid flow across dentin. Thereby, pain sensations will be more readily evoked. Open dentinal tubules will furthermore serve as pathways for diffusive transport of bacterial elements in the oral cavity to the pulp, which may initiate a localized inflammatory pulpal lesion (Bergenholtz & Lindhe 1975, 1978). Indeed, experiments in dogs have shown that dentin exposures left unprotected greatly enhance the sensitivity of the responding nerve fibers (Närhi *et al*. 1994). A large number of intradental A-delta fibers, normally inactive, then are able to respond (Närhi *et al*. 1996). Their receptive field will also widen (Närhi *et al*. 1996). In addition, sprouting of new terminal branches from pulpal axons may occur in the area subjacent to the root surface defect (Taylor *et al*. 1988). As already stated, sprouting of nerves is a temporary event and will subside if inflammation disappears; a feature which is consistent with their involvement in root dentin hypersensitivity (Byers & Närhi 1999). The increased sensitivity to cold that patients frequently experience has in recent years been linked to specific cold receptors existing in the pulp (Chidchuangchai *et al.* 2007; Ajcharanukul *et al.* 2011). In other words, an essential component of the increasing root sensitivity patients experience after an instrumentation procedure is likely to be related to a peripheral sensitization of pulpal nociceptors leading to what is termed primary hyperalgesia.

The fact that root dentin hypersensitivity often disappears a few weeks after the instrumentation procedure is best explained by the development of a natural occlusion of the exposed dentinal tubules. The deposition of mineral crystals in the tubular lumen may play an important role (Yoshiyama *et al*. 1989, 1990) (Fig. 25-27), first by inactivating the hydrodynamic mechanism for dentinal pain and second, by restricting the potential for an inward diffusion of bacterial elements to the pulp. The observation of few open tubules in non-sensitive root dentin (Hiatt & Johansen 1972; Absi *et al*. 1987; Yoshiyama *et al*. 1989; Cuenin *et al*. 1991; Oyama & Matsumoto 1991; Kontturi-Närhi 1993), while hypersensitive root areas show large numbers of wide, tubular apertures on their surfaces (Absi *et al*. 1987; Yoshiyama *et al*. 1989; Cuenin *et al*. 1991; Oyama & Matsumoto 1991; Kontturi-Närhi 1993), supports this view.

The fact that only certain individuals become seriously affected may be related to local factors in the oral cavity, as well as to the level of the subjects' pain perception. Certain dietary factors, in particular fruit juices, yoghurt, and wines, have been implicated in the causation of root dentin hypersensitivity (Addy *et al*. 1987). By their acidity and ability to etch dentin, these substances may dissolve occlusions of the dentinal tubules or prevent them from forming.

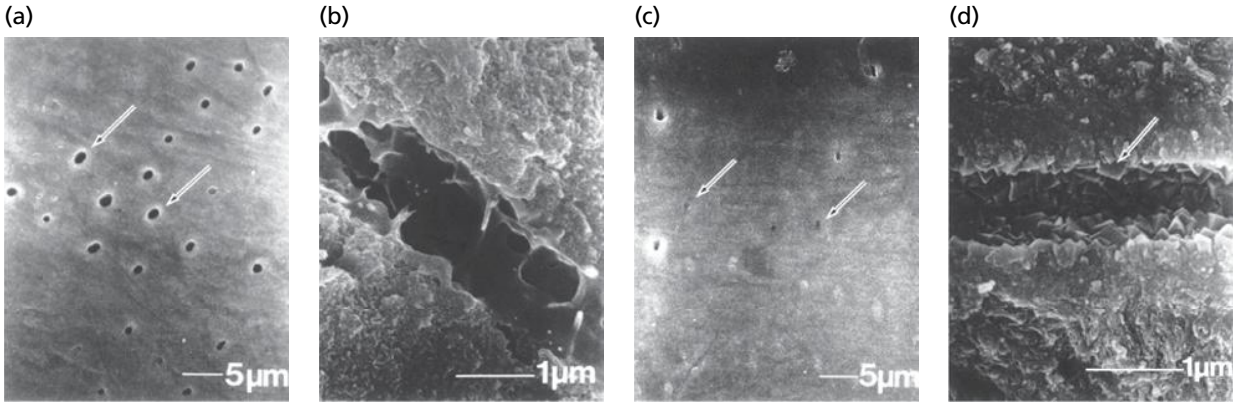

Fig. 25-27 Scanning electron microscopic images of root surface biopsies of hypersensitive (a, b) and of non-sensitive root dentin areas of human teeth (c, d). Numerous wide tubular apertures are seen in (a) (arrows). These tubules show no evidence of hard tissue deposition after being opened longitudinally (b). By contrast, most tubules are occluded in (c) (arrows) and below the surface rhombohedral crystals of 0.1–0.3 µm are present (d) (arrow). (Courtesy of M. Yoshiyama.)

It needs be recognized that pain is not only an expression of injury and noxious stimuli, but also a psychobiologic phenomenon with both a physiologic and psychological basis for its perception and reaction to it. Indeed, a variety of emotional elements may influence the subjective interpretation of pain. Anxiety, fear, and depression are factors that are known to affect pain perception, as well as the subject's ability to identify coping methods (Eli & Svensson 2010).

An important consideration in the deliberation of the mechanisms behind enhanced and lingering pain symptoms of root dentin hypersensitivity is the potential for central nervous system sensitization (Sessle 2011). It is now well documented that frequent and repeated pain stimulations result in structural and functional changes that allow the brain to respond more rapidly and more effectively to the same stimuli. Such an increase of the excitability of central neurons has a downside in that pain may continue as a memory function even if the peripheral cause has been eliminated. Thus, it is possible that central sensitization phenomena explain failure of treatment attempts in some patients.

Aspects of clinical management

Any treatment approach to root dentin hypersensitivity should be preceded by a careful consideration of conditions that may be the cause of, or contributory to, the symptoms. Cracked teeth including cusp fractures, fractured or leaky restorations, caries, erosions by acidic foods and regurgitations, as well as a variety of other exposures of dentin to the oral environment may cause pulpal pain sensations to the very same stimuli that elicit root dentin hypersensitivity. An area of exposed dentin may furthermore be more sensitive if there is irritation of the pulp from other areas of the tooth, for example from the margin of a restoration that is not well sealed from the oral environment (Närhi *et al*. 1994). Particular care should be taken to check and alleviate traumatic occlusion to reduce the excitability of pulpal nociceptors. Furthermore, dietary counseling should be given to patients who admit excessive consumption of citrus fruits, apples, or any other food or beverages that are acidic in nature, and caution given to avoid toothbrushing immediately afterwards.

Self-performed plaque control is important for the prevention and treatment of root dentin hypersensitivity. It has been observed clinically that, with time, teeth in patients with excellent oral hygiene habits develop hard, smooth, and insensitive root surfaces. Electron microscopic examination of dentin of such root surfaces has revealed that mineral deposits obliterate the tubular openings (Hiatt & Johansen 1972). However, when severe symptoms of root dentin hypersensitivity have emerged, it is often not possible to motivate the patient to maintain the degree of plaque control that is necessary to allow for a natural occlusion of the dentinal tubules. In such situations, an agent with the capacity to block the tubular openings may be beneficial, at least temporarily, so that proper oral hygiene measures can be reinforced.

In-office treatment or recommendation to use sensitivity-relieving toothpastes or both may then be attempted. However, the products and compounds presently available provide unpredictable remedy and at best only temporary relief (Gillam & Orchardson 2006; Cunha-Cruz *et al*. 2011). Since tubular patency of the exposed dentin seems to play a crucial role in the pathogenesis of hypersensitivity, most procedures are logically aimed at inducing occlusion of the peripheral openings. Some agents commonly employed, primarily for dentist-applied treatment, act by causing an astringent or coagulating effect on the tubular content. Over the years a variety of compounds have been used, including strontium chloride, sodium monofluorophosphate, sodium fluoride, calcium hypophosphate, calcium hydroxide, mineral trioxide aggregate (MTA), potassium nitrate, potassium oxalates, glutaraldehyde, ferric oxalate, stannous fluoride, bioactive glasses, and lasers (reviewed by Miglani *et al*. 2010) Among these, fluorides, glutaraldehyde/2-hydroxyethylmethacrylate (HEMA), potassium nitrates, and bonding

agents currently seem to be popular agents among practitioners (Cunha-Cruz *et al.* 2010). Recently, a desensitizing paste containing 8% arginine and calcium carbonate was developed for in-office use and in toothpastes (Cummins 2009). Also, a milk protein based on casein phosphopeptide and amorphous calcium phosphate, so-called Tooth Mousse, has, by virtue of its capacity to remineralize white spot caries lesions (Reynolds 2009), received interest as a means to prevent and treat root dentin hypersensitivity.

There may be several explanations why in-office treatments sometimes fail to remedy the problem. One is likely to be technical in nature in that it is often difficult to attain a completely dry dentin surface during the application of, for example, an astringent solution. Hence, the release of gingival fluid from the sulcus is not easily restrained by compressed air or other methods. Consequently, upon application of the agent, protein from the gingival exudate might primarily be coagulated rather than the tubular content. The precipitate is then easily removed upon subsequent tooth cleaning measures, leaving the tubules non-occluded. Furthermore, most agents may only cause a superficial block that will be dissolved over the course of time. Also, topical applications do not address the pain mechanisms associated with either peripheral or central sensitization of nociceptors. Agents able to decrease the excitability of intradental nerves have, therefore, been proposed based on the assumption that potassium ions released from formulations containing potassium salts (e.g. chlorides, nitrates, citrate, and oxalates) penetrate dentinal tubules and temper intradental nerve activity (Markowitz & Kim 1992; Orchardson & Peacock 1994). However, toothpastes with potassium-containing preparations as active ingredients showed promise in some clinical trials, but their ability to provide lasting effects was not confirmed in a meta-analysis comprising six studies (Poulsen *et al.* 2006). Similarly, a systematic review of clinical trials on potassium oxalates did not find evidence of clinical efficacy beyond the placebo effect, with the possible exception of 3% monohydrogen–monopotassium oxalate (Cunha-Cruz *et al.* 2011).

It needs be recognized that demonstrating a significant treatment effect of a given compound in clinical trials is fraught with several difficulties. One is to assemble a sample of patients of sufficient number that is well defined in terms of duration and level of the pain condition. Another is that dentin hypersensitivity may go into natural remission at any time. A large placebo effect operates in controlled trials of this nature and will narrow the gap within which treatment differences between test and control substances can be revealed (Yates *et al*. 1998, 2004). Furthermore, studies in this field have shown great heterogeneity in terms of study protocol regarding pain stimuli and scales, randomization, and allocation concealment, making comparisons of data between studies precarious (Cunha-Cruz *et al.* 2011). As of yet, there does not seem to be a universally accepted protocol to guide clinical studies evaluating desensitizing agents.

Any pain treatment should take into consideration the potential to prevent the condition from emerging in the first place. However, no well-proven protocol has yet been confirmed to effectively prevent root dentin hypersensitivity. Attempts to block the exposed dentinal tubules immediately following SRP should be an obvious approach and a couple of placebo-controlled studies have shown promise in that significantly fewer sensitive teeth were attained subsequent to instrumentation when 6% ferric oxalate (Wang *et al*. 1993), 3% potassium oxalate (Pillon *et al*. 2004) or 8% arginine and calcium carbonate (Hamlin *et al.* 2009) were applied topically. The long-term outcome of such procedures awaits confirmation.

Conclusion: Root dentin hypersensitivity frequently develops as an uncomfortable and sometimes difficult to treat ailment subsequent to SRP procedures in periodontal therapy. Although the exact mechanism for this condition is not well established, it is clearly related to open dentinal tubules that allow hydrodynamic mechanisms to elicit painful sensations upon external stimulation. Both peripheral and central sensitizations are likely to contribute to the more intense and lingering pain symptoms some patients develop after root dentin exposure.

Diagnosis and treatment planning should consider contributory etiologic factors, including overconsumption of acidic food items. Root dentin hypersensitivity should also be checked against other conditions causing similar pain symptoms and rule out cracked teeth, leaky restoration margins, caries in the tooth or in neighboring teeth, as well as trauma from occlusion. A large number of treatment methods are available for both in-office and over-the-counter applications. Some aim to block tubular patency of the exposed root dentin and others to decrease excitability of intradental nerves for reduced pain transmission. Unpredictable treatment results are to be expected and only temporary relief may be attained. In severe cases of root dentin hypersensitivity, where no remedy is achieved with any advice or treatment approach, pulpectomy and subsequent root filling are a last resort.

Part 7: Peri-implant Pathology

Chapter 26

Peri-implant Mucositis and Peri-implantitis

Tord Berglundh,[1] Jan Lindhe,[1] and Niklaus P. Lang[2,3]

Definitions

Peri-implant disease is a collective term used to describe inflammatory processes in tissues that surround implant(s), that is peri-implant mucositis and peri-implantitis (Albrektsson & Isidor 1994). Peri-implant mucositis is defined as an inflammatory lesion that resides in the mucosa, while peri-implantitis also affects the supporting bone (Lindhe & Meyle 2008) (Fig. 26-1).

Peri-implant mucosa

Following implant installation, a transmucosal passage is formed around the abutment portion of the device. The ridge mucosa at such sites adapts to the new functional demands and a peri-implant mucosa becomes established. The mucosa surrounding implants and the gingiva surrounding teeth have many features in common (Berglundh *et al*. 1991). Both types of tissues are lined with a keratinized oral epithelium; at clinically healthy sites, this is continuous with a thin non-keratinized barrier or junctional epithelium that faces the implant or the tooth surface. In the connective tissue immediately lateral to these thin epithelial linings, small infiltrates of inflammatory cells (neutrophils, macrophages, T cells, B cells) are frequently seen (Liljenberg *et al*. 1997). The inflammatory cells represent the host's defense against bacterial products and hence they may be considered as an important component of the biologic seal that separates the peri-implant and periodontal attachment tissues from the oral cavity (see also Chapters 3 and 13).

Peri-implant mucositis

Clinical features and diagnosis

The clinical features of peri-implant mucositis are in many respects similar to those of gingivitis at teeth and include classical symptoms of inflammation, such as swelling and redness (see Chapter 19). Differences in the morphology of the peri-implant mucosa and the lack of light transmission through the metal of the device or the crown restoration, however, may mask visible signs of inflammation. Assessment of peri-implant mucositis must therefore always include assessment of bleeding following probing (Fig. 26-2).

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

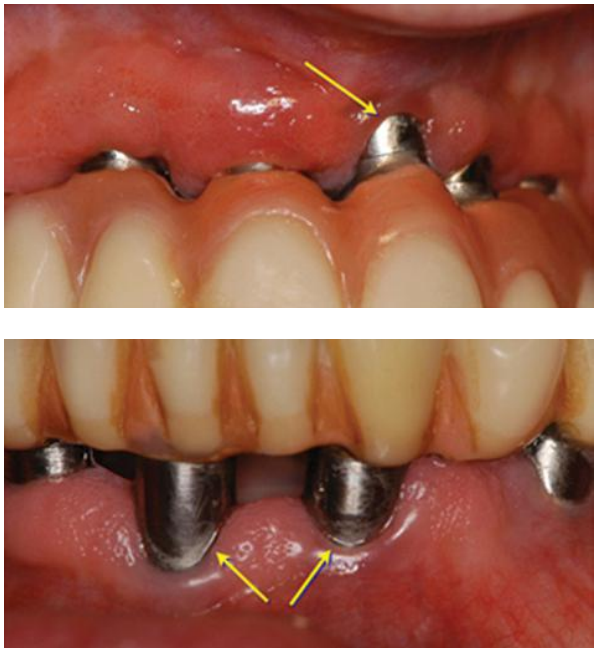

Fig. 26-2 Clinical symptoms of peri-implant mucositis, including varying signs of redness and swelling. Probing resulted in bleeding from the margin of the mucosa (arrows).

Clinical models

The response of the gingiva and the peri-implant mucosa to early and more longstanding periods of plaque formation was analyzed both in studies in humans and in experiments in animals. Pontoriero *et al*. (1994) engaged 20 partially edentulous human subjects in a clinical "Experimental gingivitis in man" (Löe *et al*. 1965) study. All subjects had been treated for advanced periodontal disease and thereafter had been restored with implants in one or several segments of the dentition. During a 6-month period following the prosthetic rehabilitation, the subjects were enrolled in a meticulous maintenance program that included regularly repeated supportive measures. A baseline examination was subsequently performed including assessment of plaque, soft tissue inflammation, probing pocket depth (PPD), soft tissue recession, and composition of oral biofilms. The participants refrained from all oral hygiene measures for 3 weeks. It was observed that during this interval, plaque build-up (amount and composition) and the soft tissue response to the microbial challenge, for example inflammation and PPD change, developed in a similar manner in the tooth and implant segments of the dentition.

Zitzmann *et al*. (2001) studied the response to plaque formation in the soft tissues at implant and tooth sites in humans. Twelve subjects with healthy periodontal and peri-implant conditions were asked to refrain from tooth/implant cleaning for a period of 3 weeks (Fig. 26-3). Clinical examinations were performed and soft tissue biopsies were harvested prior to and at the end of the plaque accumulation period. It was demonstrated that plaque build-up was associated with clinical signs of soft tissue inflammation and also an increase in the scale of soft tissue infiltrate by inflammatory cells.

Salvi *et al*. (2012) reported on the reversibility of experimentally-induced gingivitis/peri-implant mucositis in a study including 15 partially dentate subjects. Following an initial period of plaque formation to induce mucosal inflammation, oral hygiene procedures were re-instituted. The inflammation gradually resolved in the gingiva as well as in the peri-implant mucosa.

Preclinical models

In a carefully supervised experiment in the dog, Berglundh *et al*. (1992) compared the reaction of the gingiva and the peri-implant mucosa to 3 weeks of *de novo* plaque formation. The mandibular premolars in one side of the mandible were extracted, leaving the premolars on the contralateral side as controls. After 3 months of socket healing, implants were inserted in the edentulous ridge. The animals were placed in a plaque-control program to allow for ideal healing of the mucosa at the implants and to prevent gingivitis from occurring in the tooth segments of the dentition. After this healing period, the dogs were examined and samples from the minute biofilms that

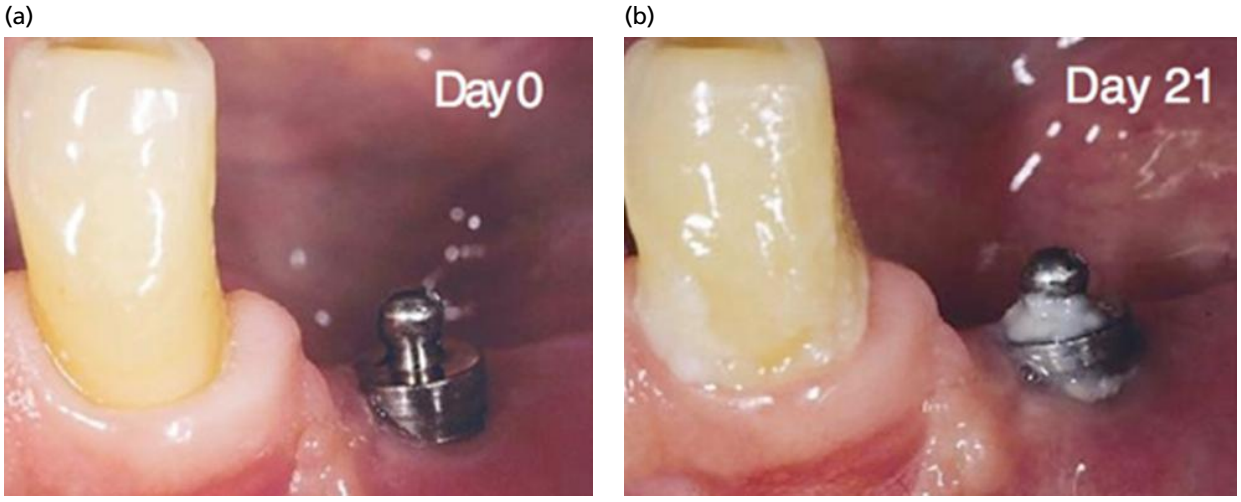

Fig. 26-3 (a) Clinical photograph of a site with healthy gingiva and peri-implant mucosa. (b) Same site following 3 weeks of plaque formation.

were present on the implant and the tooth surfaces were harvested. The plaque-control program was terminated and the animals given a soft diet that allowed gross plaque formation. Re-examinations, including clinical assessment, sampling of plaque from teeth and implants, as well as biopsy, were performed after 3 weeks. During the course of the study, it was observed that similar amounts of plaque formed on the teeth and implant segments of the dentition. The compositions of the developing plaques on the teeth and implants were also similar. It was therefore concluded that early microbial colonization on titanium implants followed the same pattern as that on teeth (Leonhardt *et al*. 1992). Both the gingiva and the peri-implant mucosa responded to this microbial colonization with the establishment of overt inflammatory lesions, that is infiltrates of leukocytes in the connective tissue. The lesions in the gingiva and in the peri-implant mucosa were similar both with respect to size and location. Hence, both lesions were consistently found in the marginal portion of the soft tissues and between the keratinized oral epithelium and the junctional or barrier epithelium.

With increasing duration of plaque build-up (3 months) in the dog model described above, the lesions in the peri-implant mucosa seemed to expand and progress further "apically", while the gingival lesions remained unchanged (Ericsson *et al*. 1992). Furthermore, the lesions in the peri-implant mucosa contained a much smaller number of fibroblasts than the corresponding infiltrates in the gingiva. In any inflammatory lesion of longstanding, periods of breakdown and periods of repair interchange. It was suggested, therefore, that in the gingival lesion, the amount of tissue breakdown that occurred during the 3-month interval was more or less fully compensated for by tissue build-up during a subsequent phase of repair. In the lesions in the peri-implant mucosa, the tissue breakdown was not fully recovered by reparative events. This reduced build-up may have been the reason for the resulting additional propagation and spread of the lesion in the peri-implant mucosa.

Fig. 26-4 Clinical photograph showing 5 months of undisturbed plaque formation on three different types of implants in a Beagle dog.

In a similar dog experiment, Abrahamsson *et al.* (1998) studied soft tissue lesions after 5 months of plaque formation at three different implant systems (Fig. 26-4). They observed that the response of the peri-implant mucosa to longstanding plaque formation appeared to be independent of the implant system that harbored the biofilm and that the apical extension of the inflammatory lesion was consistently within the dimensions of the barrier epithelium for all three implant systems (Fig. 26-5).

Conclusion: Peri-implant mucositis and gingivitis have many features in common. The host response to bacterial challenge at teeth and implants includes the development of clinical signs of inflammation and the establishment of inflammatory lesions in the mucosal/gingival connective tissues. Since peri-implant mucositis represents the obvious precursor of peri-implantitis, as does gingivitis for periodontitis, treatment of mucositis appears to be an important prerequisite for the prevention of peri-implantitis (Lang *et al*. 2011).

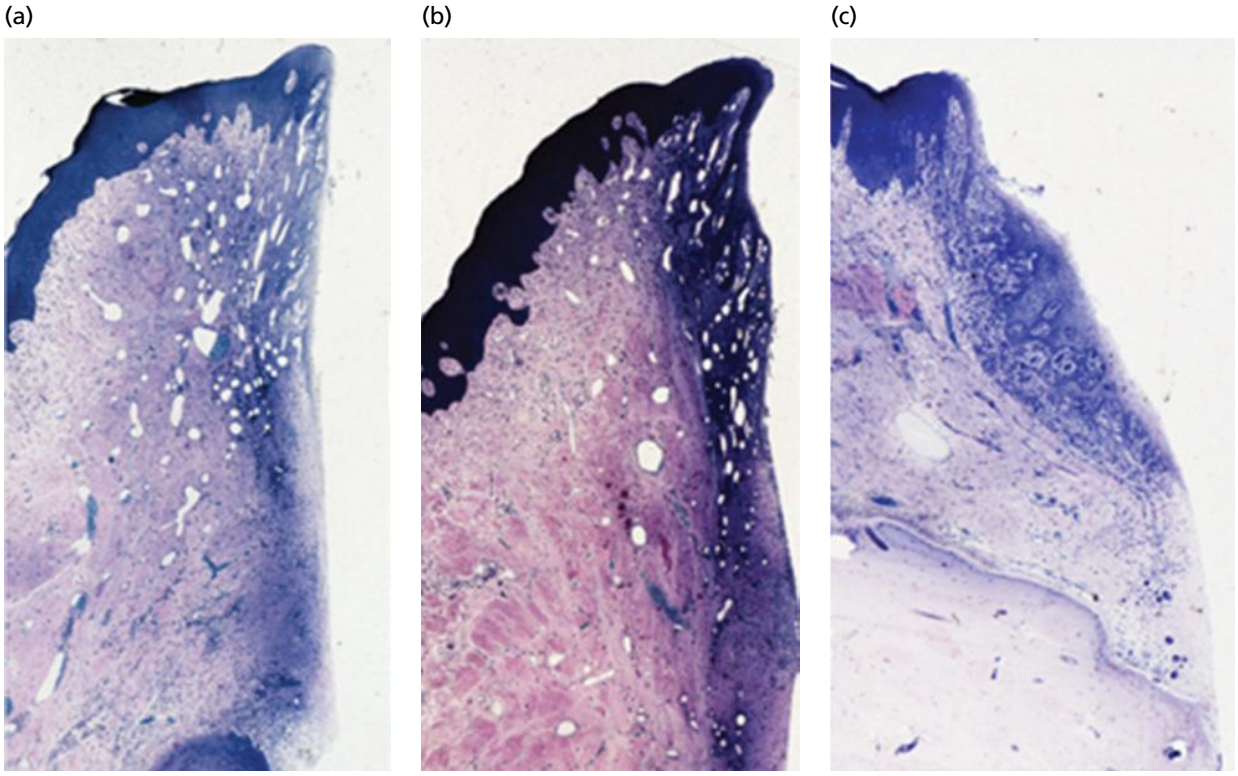

Fig. 26-5 (a–c) Microphotographs illustrating inflammatory cell infiltrates (ICT) established in the peri-implant mucosa around the three implant types shown in Fig. 26-4. The apical extension of the ICT is consistently within the dimension of the barrier epithelium for all three implant types.

Peri-implantitis

Clinical features and diagnosis

Peri-implantitis represents a clinical condition that includes the presence of an inflammatory lesion in the peri-implant mucosa and loss of peri-implant bone. Therefore, diagnosis of peri-implantitis requires detection of both bleeding on probing (BoP) and bone loss on radiographs. Peri-implantitis initially affects the marginal part of the peri-implant tissues and the implant may remain stable and in function for varying periods of time. Implant mobility is therefore not an essential symptom for peri-implantitis, but may occur in the final stage of disease progression and indicates complete loss of integration.

As pointed out for the clinical characteristics of peri-implant mucositis, various factors such as the morphology of the peri-implant mucosa and position of the implant may also influence the clinical appearance of inflammation in peri-implantitis. Probing is therefore a prerequisite in the examination of peri-implant tissues and should include assessment of both BoP and PPD. Pus is a common finding in peri-implantitis sites (Fransson *et al*. 2008).

Hence, the clinical appearance of peri-implantitis may vary and may not always be associated with overt signs of pathology. Two different cases are shown in Figs. 26-6 and 26-7. While plaque and calculus together with clinical signs of inflammation are present in the case shown in Fig. 26-6, the case shown in Fig. 26-7 does not reveal such symptoms. Probing the site shown in Fig. 26-7, however, revealed a PPD of about 10 mm, BoP, and suppuration.

Fig. 26-6 Clinical symptoms of peri-implantitis. Note the large amounts of plaque and calculus and visible signs of inflammation in the peri-implant mucosa.

Bone loss around implants observed in radiographs obtained from sites with peri-implantitis (Fig. 26-8) appears also to be symmetric, that is there is a similar amount of bone loss at mesial, distal, buccal, and lingual aspects of the implants. The morphology of the osseous defect, however, may vary depending on the buccal–lingual (palatal) dimension of the alveolar ridge. Thus, in sites where the width of the ridge exceeds that of the peri-implantitis lesion, a buccal and lingual bone wall may remain and a crater form. Conversely, in sites with a narrow ridge, the buccal and lingual bone will be resorbed and lost during progression of peri-implantitis.

Conclusion: Symptoms of peri-implantitis relate to the infectious/inflammatory nature of the lesion.

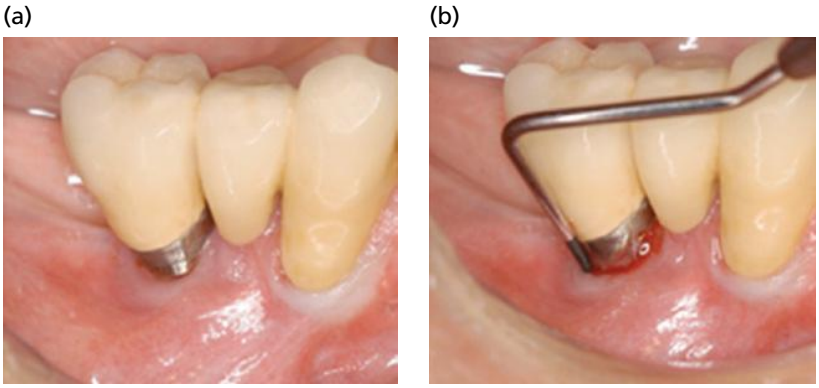

Fig. 26-7 Clinical photographs from an implant-supported crown in the premolar position in the left side of the mandible. (a) No or minor signs of inflammation in the surrounding mucosa. (b) Probing resulted in bleeding and suppuration from the implant site in the lateral incisor position.

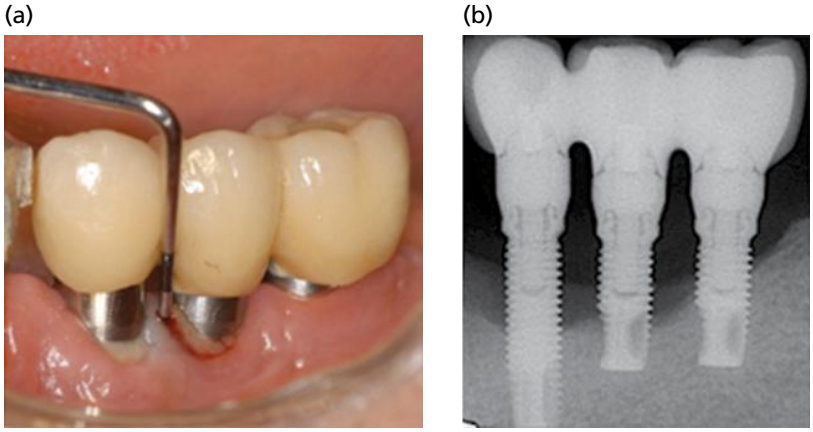

Fig. 26-8 Clinical (a) and radiographic (b) characteristics of three implant sites with peri-implantitis in the left side of the mandible. Note the presence of swelling and suppuration in the peri-implant mucosa (a) and the pronounced bone loss around the implants in the radiograph (b).

Thus, in addition to radiographic evidence of bone loss, consistently there are clinical signs of mucosal inflammation, including swelling and redness of the mucosa as well as bleeding on gentle probing. Suppuration from the "pocket" is also a frequent finding. The implant may remain stable until only minute amounts of "osseointegration" remain.

Human biopsy material

While precise information exists on the histopathology of human periodontitis, so far only few studies have evaluated peri-implantitis lesions in humans (Berglundh *et al*. 2011). Studies providing information on tissues harvested from peri-implantitis sites disclosed that the mucosa contained large inflammatory cell infiltrates. Sanz *et al*. (1991) analyzed soft tissue biopsies from six patients with peri-implantitis and reported that 65% of the connective tissue portion was occupied by inflammatory cells. Piattelli *et al*. (1998) described some pathologic features of tissues harvested from 230 retrieved implants: at sites where the implants had been removed due to peri-implantitis, "an inflammatory infiltrate, composed of macrophages, lymphocytes and plasma cells, was found in the connective tissue around the implants". In a study including 12 human peri-implantitis lesions, Berglundh *et al*. (2004) found that the mucosa contained very large lesions in which numerous plasma cells, lymphocytes, and macrophages were present (Fig. 26-9). It was furthermore observed that the inflammatory cell infiltrate consistently extended to an area apical to the pocket epithelium and that the apical part of the soft tissue lesion frequently reached the bone tissue. Berglundh *et al*. (2004) also reported that numerous neutrophil granulocytes (polymorphonuclear leukocytes) were present in the lesions. Such cells occurred not only in the pocket epithelium and associated areas of the lesions, but also in perivascular compartments in the center of the infiltrate, that is distant from the implant surface. In the apical part of the lesion, the inflamed connective tissue appeared to be in direct contact with the biofilm on the implant surface. Gualini and Berglundh (2003) used immunohistochemical techniques to analyze the composition of peri-implantitis in a study of six subjects. Neutrophils were found in large numbers in the central portions of the infiltrate. This finding was in agreement with that made by Hultin *et al*. (2002) who analyzed the exudate that could be harvested from implant sites in 17 patients with peri-implantitis and reported the presence of large numbers of neutrophils. Immunohistochemical techniques have also been used to evaluate differences between peri-implantitis and periodontitis lesions. Bullon *et al*. (2004) observed that both types of lesions contained T and B lymphocytes, plasma cells, and macrophages, while

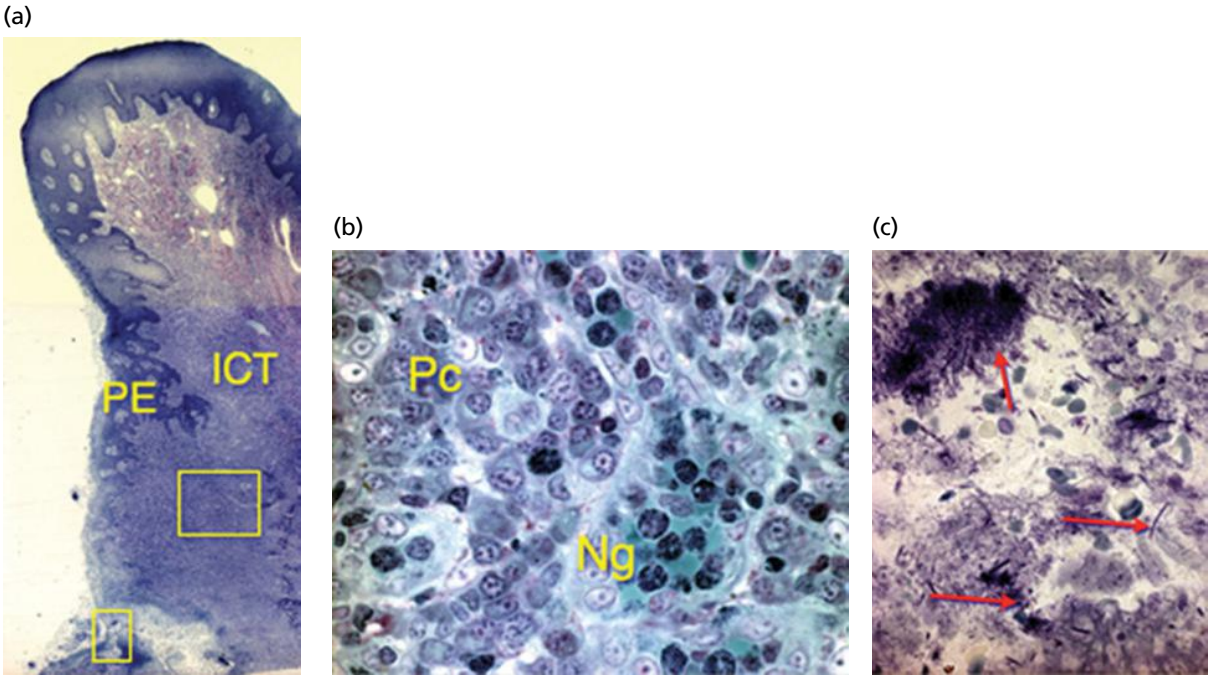

Fig. 26-9 (a) Microphotograph showing a human peri-implantitis lesion. Note the large inflammatory cell infiltrate (ICT) lateral to the pocket epithelium (PE). The implant was positioned to the left. (b) Outlined area in (a) in the profound portion of the ICT including large numbers of plasma cells (Pc) and neutrophil granulocytes (Ng). (c) Outlined area in (a) in the apical part of the ICT facing the pocket. Arrows indicate clusters of microorganisms.

Konttinen *et al*. (2006) reported that the number of cells positive for interleukin-1 alpha (IL-1α) and IL-6 was larger and the number of tumor necrosis factor-alpha (TNF-α)–positive cells smaller in peri-implantitis than in periodontitis lesions.

Preclinical models

In order to study the ability of the peri-implant mucosa to respond to long-standing plaque exposure and to manage the associated inflammatory lesions, an experimental periodontitis/peri-implantitis model was developed in the dog (Lindhe *et al*. 1992) and in the monkey (Lang *et al*. 1993; Schou *et al*. 1993). Although the experiments had somewhat varying design, their outcomes were almost identical and, hence, only the result from the dog model will be reported.

In the dog model (Lindhe *et al*. 1992), the premolars were extracted on one side of the mandible, implants were inserted, and abutment connection performed 3 months later. During the healing phase, a strict plaque control regimen was maintained and healthy tissue conditions were thereby established in all tooth and implant sites to be monitored. On a given day, the periodontitis and peri-implantitis lesions were induced. This was accomplished by terminating the plaque control regimen and placing cotton ligatures around the neck of both the premolar teeth and the implants. The ligatures were forced into a position apical to the soft tissue margins. A "pocket" between the tooth/gingiva and implant/mucosa was thereby created, a submarginal biofilm rapidly formed, and inflammatory lesions developed in the neighboring tissues. Radiographs obtained after 6 weeks of the experiment revealed that a substantial amount of bone tissue had been lost at both teeth and implant sites. The ligatures were removed. After a further 4 weeks, the animals were re-examined, radiographs obtained, bacteria sampled, and biopsies of tooth and implant sites harvested. It was observed that the plaque that had formed in the deep "pockets" was similar at tooth and implant sites, and was dominated by Gram-negative and anaerobic species (Leonhardt *et al*. 1992). This observation is consistent with findings in humans indicating that the microbiota at teeth and implants shares many features, but also that the microbiota at healthy and diseased sites – tooth sites as well as implant sites – is very different. Thus, implants and teeth that are surrounded by healthy soft tissues are associated with biofilms with small numbers of Gram-positive coccoid cells and rods. Sites with extensive periodontal and peri-implant inflammation harbor biofilms with large numbers of Gram-negative anaerobic bacteria (see Chapters 10 and 11).

Histopathologic examination of the biopsy samples from the dog study (Lindhe *et al*. 1992) revealed that there were marked differences in the size and location of the inflammatory lesions at periodontal and peri-implant sites. Thus, while the lesions in the plaque-associated periodontal sites were consistently separated from the alveolar bone by a 1-mm wide zone of non-inflamed connective tissue, the lesion in the peri-implant tissue in most situations extended to

the alveolar bone. It was concluded that the pattern of spread of inflammation was different in periodontal and peri-implant tissues. It was suggested that the peri-implant tissues, in variance with the periodontal tissues, are poorly organized to resolve progressive, plaque-associated lesions. The validity of this conclusion was substantiated in subsequent studies (Marinello *et al*. 1995; Ericsson *et al*. 1996; Persson *et al*. 1996; Gotfredsen *et al*. 2002), using similar models but allowing for different periods of tissue breakdown.

In the preclinical studies reported above, the experimental models used ligatures to induce peri-implantitis by disrupting the soft tissue seal around the implant and thereby allowing a biofilm to form in a submarginal location. The ensuing host response included an inflammatory lesion in the mucosa that over time became progressively larger. Cells in the lesion activated systems of reactions that promoted degradation of connective tissue and bone. The placement of a new ligature in a more "apical" position allowed the destructive process to continue. The size and type of ligature (e.g. cotton, silk), their corono apical position in the pocket, as well as the number of replacements determined the rate and magnitude of tissue breakdown in this so-called experimental peri-implantitis model (Berglundh *et al*. 2011).

Zitzmann *et al.* (2004) used 21 sites in dogs to study experimental peri-implantitis. After the lesions had become established, the ligatures were removed and the sites were monitored for an additional 12-months. It was observed that in 16 sites the destructive conditions persisted and caused progressive bone loss. In the remaining five sites, however, the lesions became encapsulated and no further breakdown of peri-implant bone took place.

This so-called "spontaneous progression model" (Zitzmann *et al*. 2004) was subsequently used by Berglundh *et al*. (2007). They examined the tissue reaction around custom-made implants with either a smooth, polished surface or a roughened SLA (sandblasted, large grit, acid etched) surface. During the pre-experimental period of ligature-induced breakdown, similar amounts of bone loss occurred around the two types of implants. Evaluation 5 months after the removal of ligatures, however, revealed that bone loss had progressed and that the size of the inflammatory lesion in the connective tissue was larger at the implants with the rough than with the smooth surface. The area of plaque was also larger at implants with the rough surface. It was concluded that the progression of peri-implantitis, if left untreated, is more pronounced at implants with a moderately rough surface than at implants with a polished surface.

While the study by Berglundh *et al*. (2007) used implants with custom-made surfaces, Albouy *et al*. (2008, 2009) analyzed differences in spontaneous progression of experimental peri-implantitis between commercially available implants with SLA, TiOblast, TiUnite, and turned surfaces. Spontaneous progression occurred with all implant types during the 6-month period after ligature removal. The histologic examination revealed that all specimens presented with large inflammatory lesions that extended apical of the pocket epithelium. The pocket compartment was occupied by pus, biofilm, and calculus, and the uncovered apical part of the inflammatory cell infiltrate faced the biofilm. Osteoclasts in large numbers were detected on the surface of the crestal bone and other giant-like cells occurred in the soft tissue lesion, distant from the crestal bone.

Albouy *et al*. (2012) in a subsequent experiment in dogs repeated the spontaneous progression model using implants with a similar geometry and with two different surfaces (turned and TiUnite). During the 6 months after ligature removal, a significantly larger amount of bone loss occurred around the implants with the modified surface than around the implants with the turned surface. In addition, the dimensions of inflammatory lesions, pocket epithelium, and biofilm were larger at the implants with a modified surface.

The spontaneous progression model was also used in an experiment aimed at evaluating differences between peri-implantitis and periodontitis. Thus, Carcuac *et al*. (2013) used the dog model and two kinds of implants. Experimental peri-implantitis and periodontitis were induced by ligature placement plaque formation. The ligatures were removed after 10 weeks and bone level changes were evaluated in radiographs during the following 6 months. It was reported that the amount of bone loss that occurred following ligature removal was significantly larger at implants with a modified surface than at implants with a turned surface and at teeth (Fig. 26-10). The results from the histologic examination confirmed previous findings (Lindhe *et al*. 1992) and revealed that peri-implantitis sites exhibited inflammatory lesions that were larger and extended closer to the bone crest than those in periodontitis (Figs. 26-11 and 26-12). Carcuac *et al.* (2013) also reported that the lesions in peri-implantitis contained larger proportions of neutrophil granulocytes and osteoclasts than lesions in periodontitis.

Conclusion: Peri-implantitis lesions are poorly encapsulated, extend to the marginal bone tissue, and may, if allowed to progress, lead to the loss of the implant. The large numbers of neutrophils in the peri-implantitis lesion and the absence of an epithelial lining between the lesion and the biofilm, indicate that the peri-implantitis lesions have features that are different from those of periodontitis lesions. Progression of peri-implantitis is more pronounced at implants with rough than at those with smooth surfaces.

(b) Close-up of outlined area in (a) showing the large infiltrate (ICT) apical of the pocket epithelium and in direct contact with the biofilm on the implant surface. Osteoclasts (arrows) are present on the bone surface. (PE, pocket epithelium.)

Prevalence of peri-implant diseases

Peri-implant mucositis

It is well known that assessments of the prevalence of periodontal diseases are influenced by the selection of case definitions. A higher threshold for disease criteria results in a lower prevalence. Similarly, case definitions also influence the assessment of prevalence of peri-implant diseases. Tomasi and Derks (2012) in a review identified seven different case definitions for peri-implant mucositis and another seven case definitions for peri-implantitis. BoP is a critical marker for the detection of inflammation in the peri-implant mucosa and, hence, is useful in the assessment of peri-implant mucositis. Thus, implant sites that are BoP positive but exhibit no bone loss should be diagnosed as peri-implant mucositis.

Reports on the prevalence of mucositis have, in addition to BoP, included varying levels of PPD for the diagnosis of peri-implant mucositis. Thus, Roos-Jansåker *et al*. (2006a) in a cross-sectional study on 206 patients with 987 implants applied a case definition that combined BoP and PPD of ≥4 mm, and reported that 48% of the patients and 16% of the implants had mucositis. Roos-Jansåker *et al*. (2006a) also reported that BoP at implant sites occurred in about 50% of the implants with no history of bone loss. Koldsland *et al*. (2010) in a cross-sectional study on 109 implant patients reported that about 40% of the patients and 27% of the implant sites presented with BoP and no detectable bone loss. Based on the above findings, it is reasonable to conclude that peri-implant mucositis is common in patients with dental implants.

Peri-implantitis

BoP is a marker also for peri-implantitis, that is implant sites that exhibit peri-implant mucositis together with *detectable bone loss* (in radiographs). In a consensus report from the VIII European Workshop on Periodontology (Sanz & Chapple 2012) it was recommended that a threshold of detectable bone loss around implants should be two to three times the measurement error, that is inter- and intra-examiner variability (about 0.4 mm). As for most diseases, data on the prevalence of peri-implantitis should be presented on a subject basis, whereas information regarding the number or proportion of affected implants may serve as a description of the extent of the disease.

While the finding of BoP and/or pus is an accepted clinical parameter, the amount of bone loss (assessed in radiographs) that will allow the diagnosis peri-implantitis is controversial. Table 26-1 describes studies on the prevalence of peri-implantits using different

Table 26-1 Studies on the prevalence of peri-implantitis that included >100 patients with a mean follow-up of >5 years. Different case definitions with regards to threshold levels on bone loss were used.

Study	Number of patients/implants	Function time range (years) (mean)	Case definitions Thresholds of bone loss	Prevalence (%) in patients/implants
Fransson *et al*. (2005)	662/3413	5–20 (9.1)	Bone level ≥3 threads (1.8 mm apical of reference point) and detectable bone loss (0.6 mm) from year 1	27.8/12.4

NR, not reported.

case definitions regarding threshold levels of bone loss. Fransson *et al*. (2005) evaluated the prevalence of progressive bone loss at implants (Brånemark System) with a function time of 5–20 years in 662 subjects. Implants that presented with bone levels at three or more threads of an implant (i.e. 1.8 mm apical to the implant neck) were identified. In addition, progressive bone loss at such implants was defined as bone loss (one thread; 0.6 mm) occurring between the 1-year examination and the 5–20 years of follow-up examination. It was reported that 27.8% (184) of the 662 included subjects had one or more implants with "progressive" bone loss. In a subsequent clinical study, Fransson *et al*. (2008) reported that about 94% of the implant sites with "progressive" bone loss exhibited BoP. The extent of peri-implantitis and the pattern of bone loss were also analyzed. About 40% of the implant sites in the peri-implantitis–affected subjects exhibited progressive bone loss. Peri-implantitis occurred in all jaw locations but was most frequent in the mandibular front region (Fransson *et al*. 2009). Further analysis using multilevel modeling revealed that bone loss in peri-implantitis had a non-linear pattern and increased over time (Fransson *et al*. 2010).

Roos-Jansåker *et al*. (2006a) examined 216 implant-treated patients after 9–14 years of function and reported that 16% of the subjects and 6.6% of the implants had peri-implantitis. However, they used a different definition of peri-implantitis from that used by Fransson *et al*. (2005) and suggested that a certain amount of bone loss (1.8 mm compared with the 1-year data) together with BoP should be required for the diagnosis of peri-implantitis. Data presented in the study by Roos-Jansåker *et al*. (2006a) indicated that different thresholds of bone loss influenced the reported prevalence of peri-implantitis. Thus, bone loss of 0.6–1.2 mm from year 1 was detected in 56.6% of the patients (see Table 26-1). Similar findings were reported by Koldsland *et al*. (2010) from a study of the prevalence of peri-implantitis in a group of 109 patients: using threshold bone losses of 0.4 mm, 2 mm, and 3 mm, 47.1%, 20.7%, and 11.7% of the patients displayed peri-implantitis, respectively. High thresholds for bone loss were also applied by Roccuzzo *et al*. (2010) and Zetterqvist *et al*. (2010). In the 10-year prospective study on 101 implant patients by Roccuzzo *et al*. (2010), 22.8% of the patients presented with bone loss of ≥3 mm, while in the 5-year study by Zetterqvist *et al*. (2010), only one of 112 patients exhibited bone loss of >5 mm. Cecchinato *et al*. (2013) presented data on peri-implantitis using four different thresholds of bone

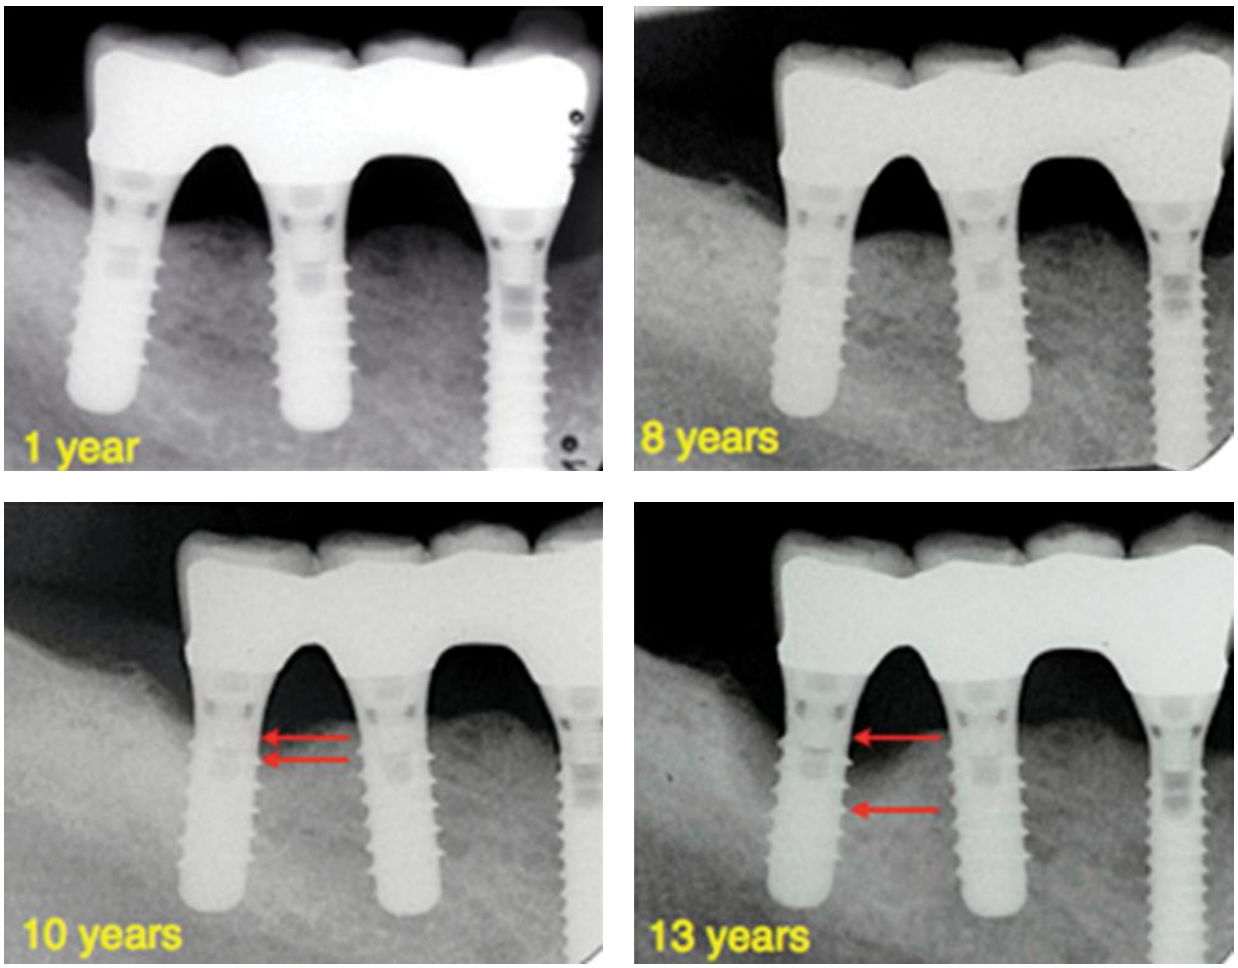

Fig. 26-13 Radiographic characteristics of three implant sites in the right side of the mandible at 1, 8, 10, and 13 years of follow-up. While no bone loss occurred between the 1-year and the 8-year examinations, the 10-year and 13-year examinations revealed that about 1 mm and 4 mm, respectively, of bone loss occurred around the posterior implant.

loss ranging from 0.5 to 2 mm. Over this range, the prevalence of the condition declined from 30% to 8% of the examined patients.

Taken together, the threshold level of bone loss used in a case definition strongly influences the results from the assessment of prevalence of peri-implantitis. This problem is illustrated in Fig. 26-13. The radiographic bone loss that occurred around the posterior implant between the 8-year and the 10-year examination was about 1 mm, while the bone loss that was assessed at 13 years of follow-up amounted to 4 mm. Thus, the use of a threshold level of bone loss of ≥1 mm would not account for the bone level change that occurred between 8 and 10 years.

Consensus statements from the 8th EFP Workshop identified shortcomings in assessments of the prevalence of peri-implantitis (Tomasi & Derks 2012; Sanz & Chapple 2012). The cross-sectional studies referred to in the reviews mainly used convenience samples of limited size. Such samples may not represent the target population (i.e. the true prevalence). Current data, however, indicate that both peri-implant mucositis and peri-implantitis are common in patients with dental implants. The proportion of patients exhibiting one or more implants with peri-implantitis, identified with case definitions that included bone loss of >0.5 mm after year 1, varies between 30% and 55%.

Risk factors for peri-implantitis

Risk factors for peri-implantitis can be categorized according to the patient, clinician/treatment procedures, and implant characteristics.

Patients at risk

There is evidence that patients with a high susceptibility to periodontitis exhibit a higher risk for peri-implantitis. A number of systematic reviews have been published in this field and outcomes of implant therapy in periodontally compromised patients are discussed in detail in Chapter 33. Although few clinical studies were included in the systematic reviews, they consistently showed higher frequencies of implant loss, marginal bone loss, and clinical signs of inflammation in peri-implant soft tissues in patients with a history of periodontitis (Hardt *et al*. 2002; Karoussis *et al*. 2003; Roos-Jansåker *et al*. 2006b). In line with the association between history of periodontitis and peri-implantitis, it is logical to assume that known modifying factors for periodontitis, such as smoking and diabetes, may also be valid for peri-implantitis. Heitz-Mayfield (2008) in a review concluded that poor oral hygiene, history of periodontitis, and cigarette smoking are risk indicators for peri-implant diseases. Roccuzzo *et al*. (2010) in a 10-year prospective study reported that patients with a history of severe periodontitis and, in particular, a subgroup of these patients who did not attain a supportive periodontal therapy program, presented with a larger number of lost implants and a higher number of sites with marginal bone loss than periodontally healthy patients. This underlines the importance of supportive therapy in general, but in particular in patients with a history of severe periodontitis.

Design of suprastructure

Treatment procedures and the design of prosthesis may also be regarded as a potential risk for peri-implantitis. The neglect of access for self-performed and professional infection control procedures when designing the supraconstruction to be connected to implants entails an increased risk for peri-implant disease. In the attempt to accomplish appropriate prosthetic rehabilitation in terms of function, as well as to address phonetic and esthetic demands, clinicians may overlook the need for self-performed oral hygiene (Fig. 26-12). It is imperative that the implant-supported prosthesis allows appropriate access for infection control.

Implant surface characteristics

Risk factors for peri-implant disease also relate to specific features of the implants, such as design and surface characteristics. While clinical evidence in this field is weak, data from preclinical studies indicate that implant surface characteristics influence progression of peri-implantitis. Baelum and Ellegaard (2004) presented data on 128 patients whose dentition was restored with implant-supported prosthesis using either implants with a rough surface [titanium plasma sprayed (TPS)] or implants with a moderately rough surface (TiOblast). Patients with the rough surface implants presented with higher frequencies of implant loss after 5 (5.7% versus 2.6%) and 10 years (22.3% versus 2.6%) of follow-up. While the proportions of implants demonstrating pronounced bone loss (≥3.5 mm) after 5 years were 5.6% and 5.0% for the two types of implants, the data obtained from the 10-year examination indicated a higher frequency of such sites for the rough surface implants than the moderately rough surface implants (13.6% versus 5.0%). It should be realized, however, that the patients examined at the 5-year and 10-year follow-up in this study represented only about 30–50% of the total sample. Åstrand *et al*. (2004) in a 3-year study on 28 patients with implants with a turned or rough (TPS) surface reported that peri-implantitis was found in seven of the rough surface implants but in none of the turned surface implants. Mir-Mari *et al*. (2012) presented data from a cross-sectional study on the frequency of peri-implantitis in a group of 245 patients who had received implants with a turned surface, TiUnite surface, and Osseotite surface. While the overall proportion of implants exhibiting peri-implantitis was 9.1%, the frequencies for the different surface categories were 9.3% (turned), 10.1% (TiUnite), and 6.0% (Osseotite). The authors also presented the results on frequencies on peri-implantitis

with regards to the function time of the different types of implants and concluded that turned implants had the longest mean follow-up (11.3 years), while TiUnite and Osseotite surface implants were followed up for 3.5 and 5.9 years, respectively. The results thus indicate that implant surface characteristics may influence the onset of peri-implantitis.

In the series of preclinical studies described above (Berglundh *et al*. 2007; Albouy *et al*. 2008, 2009, 2012) it was demonstrated that the implant surface characteristics influenced the degree of spontaneous progression of experimentally induced peri-implantitis. It should be kept in mind, however, that in these studies, a limited number of implant types were evaluated. It is thus not possible to determine if any particular type of implant system or implant surface is associated with a greater risk for peri-implantitis. On the other hand, the experimental studies do demonstrate that continuous plaque formation at sites where a peri-implantitis lesion has become established and ligatures removed, may result in additional destruction of soft and hard tissue components of peri-implant tissues and that this progression of disease is influenced by implant surface characteristics.

Conclusion

Studies in man and experiments in animals have documented that *de novo* formation of a biofilm on the implant surface initiates a host response that involves the establishment of an inflammatory lesion in the peri-implant mucosa (peri-implant mucositis). This lesion is initially located in the connective tissue immediately lateral to the barrier epithelium and is, in many respects, similar to that which develops in the gingiva when plaque forms on adjacent tooth surfaces. In the continued presence of a submarginal biofilm, the lesion in the marginal mucosa around implants may occasionally spread in an "apical" direction to involve the hard tissue, compromise osseointegration, cause varying degrees of marginal bone loss (peri-implantitis), and eventually cause the loss of the implant.

Introduction

The structure and function of the periodontium is determined by the integration of four main tissues: periodontal ligament (PDL), tooth root cementum, alveolar bone, and gingiva. Collectively, they provide a biologic and physical barrier to multiple challenges that the teeth sustain as a result of the occlusal function and the challenging microbial environment of the oral cavity. This integrity is most commonly compromised due to chronic inflammation triggered by complex bacterial communities. Nonetheless, the periodontium represents a resilient organ that could be described as a dynamic structure that is sensitive to a variety of factors and with an inherent capacity to translate mechanical stimuli into biochemical signals that govern its homeostasis (Burger *et al*. 1995; Duncan & Turner 1995; Marotti 2000; Marotti & Palumbo 2007; Bonewald & Johnson 2008). Its structure and function during remodeling and healing is determined by the orchestration of important bioactive proteins [platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), fibroblast growth factor (FGF), bone morphogenetic proteins (BMPs), insulin-like growth factor-1 (IGF-1), transforming growth factor beta 1 (TGF-β1), etc.] (Long *et al*. 2002; Sato *et al*. 2002; Tsuji *et al*. 2004; Yang *et al*. 2006), resulting in an increased adaptive potential that protects and maintains the integrity of its four fundamental components (Fig. 27-1).

In humans, the detrimental changes that the tooth-supporting tissues undergo are primarily the result of inflammatory periodontal diseases that undermine and disrupt the functional and structural integrity of the alveolar bone, the PDL, and the cementum. The restoration of the original structure, properties, and function of these tissues is the ideal and desired outcome of periodontal therapy. Unfortunately, altered healing often disrupts the normal restoration of the periodontium and as a result different clinically compromised outcomes can be identified.

Wound healing: Outcomes and definitions

Before exploring the cascade of cellular and molecular events of wound healing, it is essential that the particular healing patterns that have been recognized in the periodontal complex are appreciated (Table 27-1). From a basic histologic point of view, the types of healing outcomes that can be met in the periodontium are described in Table 27-2.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

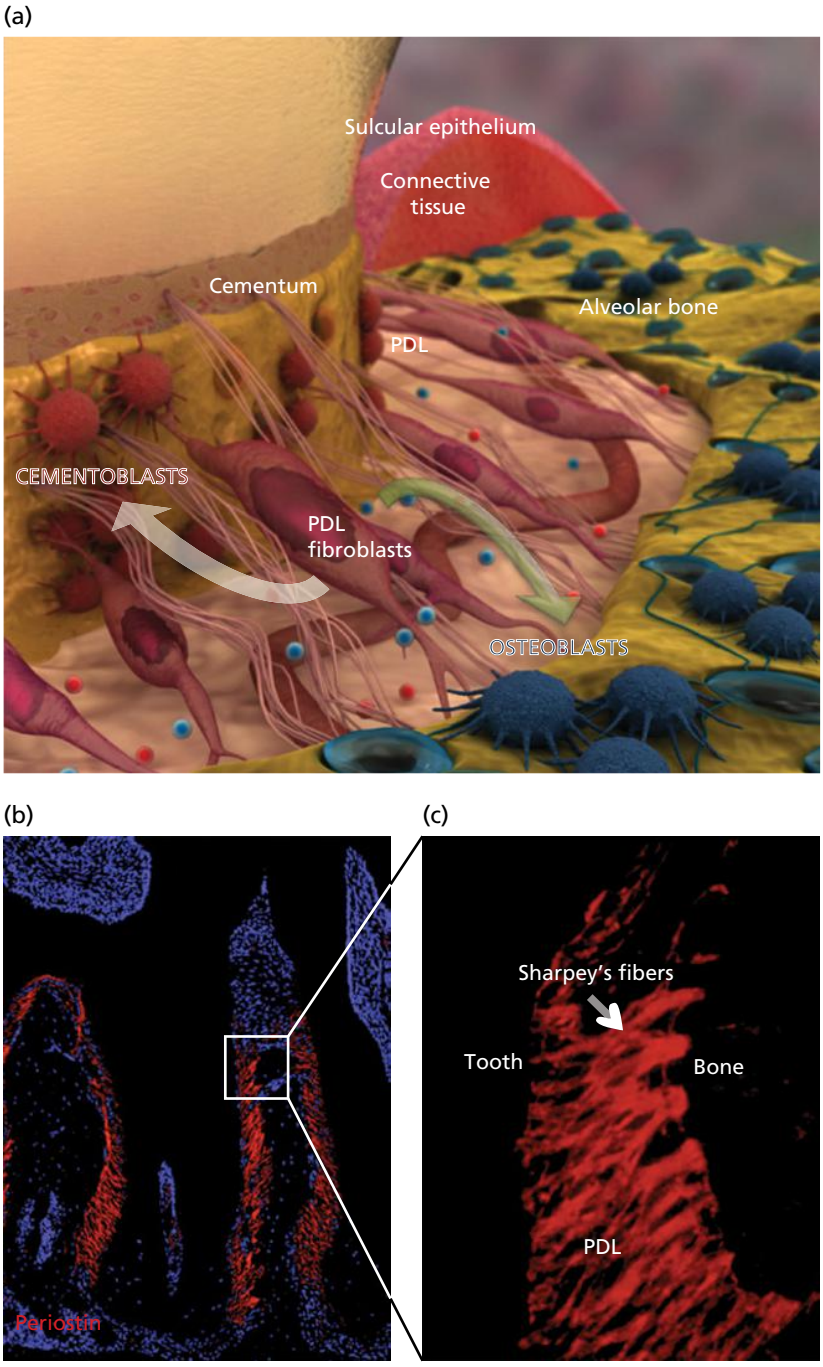

Fig. 27-1 (a) The tooth-supporting apparatus (i.e. periodontium) includes the alveolar bone, the periodontal ligament (PDL), the cementum, and the gingiva. Collectively, they represent a dynamic tissue complex with mechanical and biologic functions that synergistically determine the tissue adaptive potential and its ability to sustain microbiologic and mechanical challenges. (b) The functional periodontal system is characterized by distinct fibrilar structures known as Sharpey's fibers that connect the alveolar bone to the tooth surface cementum (red fluorescent immunostaining for periostin).

Table 27-1 Healing patterns in the periodontal tissues.

Healing by first intention	Involves the wound edges being brought together using sutures. Primary intention wounds are associated with minimal tissue loss and regeneration predominates over fibrosis
Healing by second intention	Occurs in surgical wounds that are left to heal without approximating the edges. The wound then fills with granulation tissue from the bottom up. The epithelium then fills in over the top of the granulation tissue. Scarring is evident as there is significant fibrosis
Healing by third intention	Where there is great loss of tissue, the wound must heal by contraction of the wound edges and the formation of granulation tissue. In some cases, the presence of a foreign body or infection may be suspected, and these wounds are left open deliberately for several days until the potential complication has resolved. When resolution has occurred, the wound edges can be brought together (approximated) and the wound proceeds to heal
Partial-thickness healing	Occurs when a partial-thickness wound is closed primarily by epithelialization. This wound healing involves the superficial portion of the dermis (lamina propria). There is minimal collagen deposition and an absence of wound contraction

Table 27-2 Outcomes of periodontal wound healing.

Repair	Healing of a wound by tissue that does not fully restore the architecture or the function of the part. Within the periodontal wound, it refers to restoration of a normal gingival sulcus at the same level as the base of the previous pathologic periodontal pocket. Often repair is typified by the presence of a long junctional epithelium
Reattachment	Refers to the reattachment of the gingiva to areas from which it was mechanically removed
New attachment	Occurs when newly generated fibers are embedded in new cementum on a portion of the root that was uncovered by disease
Regeneration	Reproduction or reconstruction of a lost or injured part in such a way that the architecture and function of the lost or injured tissues are completely restored. This takes place by growing precursor cells replacing lost tissue
Resorption	Loss or blunting of some portion of a root, sometimes idiopathic, but also associated with orthodontic tooth movement, inflammation, trauma, endocrine disorders, and neoplasia
Ankylosis	Fusion of the tooth and the alveolar bone

Table 27-3 Applications of cell therapies for periodontal tissue engineering.

Wound healing biology

The process of wound healing is the body's primary mechanism to restore tissue integrity upon injury. If wound healing does not occur properly, chronic disruption of the protective barrier may lead to severe physiologic, immunologic, and metabolic abnormalities. Wound healing basically represents a dynamic process that involves several cell types and biologic mediators. Within the active system of the periodontal wound, cell populations migrate, differentiate, and proliferate; epithelial and connective tissues interact; and a vast array of cytokines and extracellular matrix (ECM) molecules orchestrates the whole process that takes place in overlapping phases.

Phases of wound healing

The general principles of healing, and the cellular and molecular events observed in extraoral sites, also apply to the healing processes that take place following periodontal surgery. Traumatic injury causes capillary damage and hemorrhage, and, as a result, a blood clot is formed. The formation of a clot is the immediate response to any trauma. The clot has two functions: it temporarily protects the denuded tissues and it serves as a provisional matrix for cell migration. The blood clot consists of all cellular components of blood (including red and white blood cells and platelets) in a matrix of fibrin, plasma fibronectin, vitronectin, and thrombosporin. Beyond this, the process has been divided into three stages:

1. Inflammation phase
2. Granulation phase
3. Matrix formation and remodeling (maturation) phase (Wikesjo *et al*. 1992).

Each of the steps of wound healing is essential to success, but the initial healing process often determines the outcome.

Inflammatory phase

The growth factors present in the clot recruit inflammatory cells, and then serve to regulate the granulation process. Within hours of injury, inflammatory cells (predominantly neutrophils and monocytes) populate the clot. These cells cleanse the wound of bacteria and necrotic tissue through phagocytosis and release of enzymes and toxic oxygen products. Within 3 days, the inflammatory reaction moves into its late phase. Macrophages migrate into the wound area and these macrophages contribute to the cleansing process by phagocytosis of used polymorphonuclear leukocytes and erythrocytes. Additionally, macrophages release a number of biologically active molecules such as inflammatory cytokines and tissue growth factors, which recruit further inflammatory cells as well as fibroblastic and endothelial cells, thus playing an essential role in the transition of the wound from the inflammatory into the granulation tissue formation phase.

Granulation phase

The neutrophil population is overtaken by macrophages within a few days. Macrophages also serve the purpose of wound decontamination. They play an important role in the formation of granulation tissue. Granulation tissue formation begins on approximately day 4. Macrophages constitutively release growth factors that promote the healing process. Growth factors and cytokines secreted by macrophages are involved in the proliferation and migration of fibroblasts, endothelial cells, and smooth muscle cells into the wound area. The cells in the wound proliferate around the radius of the wound site developing cell-to-cell and cell-to-matrix connections. Macrophages and fibroblasts continue to express growth factors that regulate the healing process, both in an exocrine and autocrine manner. Studies have shown that wound sites supplemented with growth factors have an accelerated rate of granulation tissue formation (Sporn *et al*. 1983). At 7 days after initiation of wound healing, granulation dominates the wound site and the initial collagen fibers are being formed. Eventually, cells and matrix form cell-to-cell and cell-to-matrix links that generate a concerted tension resulting in tissue contraction. The phase of granulation tissue formation gradually develops into the final phase of healing in which the reformed, more cell-rich tissue undergoes maturation and sequenced remodeling to meet functional needs

Maturation phase

Fibroblasts responsible for the replacement of the provisional ECM produce a new collagen-rich matrix. Approximately 1 week following wounding, and once the collagen matrix has been synthesized, some fibroblasts undergo transformation into myofibroblasts and express α-smooth muscle actin. This transformation and synthesis is responsible for wound contraction. Endothelial cells, responsible for angiogenesis, migrate into the provisional wound matrix to form vascular tubes and loops, and as the provisional matrix matures, the endothelial cells undergo programmed cell death (apoptosis) and the number of vascular units is reduced. Maturation of the granulation tissue will lead to the regeneration or repair (scar formation) of the injured tissues. Whether the damaged tissues heal by regeneration or repair depends upon two crucial factors: the availability of the necessary cell type(s) and the presence or absence of cues and signals necessary to recruit and stimulate these cells.

Factors that affect healing

It is important to remember that in the periodontium as well as in other areas of the body the healing potential is affected by local and systemic factors.

Local factors

Healing after gingival and periodontal surgery can be delayed and altered by numerous local factors. Some of these factors include:

- Plaque microorganisms
- Excessive tissue manipulation during treatment
- Trauma to the tissues
- Presence of foreign bodies
- Repetitive treatment procedures that disrupt the orderly cellular activity during the healing process
- Inappropriate vascular perfusion to the surrounding area.

Healing is therefore improved by debridement (removal of degenerated and necrotic tissue), immobilization of the healing area, and pressure on the wound. The cellular activity in healing entails an increase in oxygen consumption. However, healing of the gingival tissue is not accelerated by artificially increasing the oxygen supply beyond the normal requirements (Glickman *et al*. 1950).

Systemic factors

It is clearly reported that healing capacity diminishes with age (Holm-Pedersen & Löe 1971). Healing is also impaired by insufficient food intake; systemic disorders that interfere with the use of nutrients; and deficiencies in vitamin C (Barr 1965), proteins (Stahl 1962), and other nutrients.

Hormones also have an impact on healing. Systemically administered glucocorticoids such as cortisone hinder repair by depressing the inflammatory reaction or by inhibiting the growth of fibroblasts, the production of collagen, and the formation of endothelial cells. Systemic stress, thyroidectomy, testosterone, adrenocorticotropic hormone, and large doses of estrogen suppress the formation of granulation tissue and impair healing (Butcher & Klingsberg 1963).

Progesterone increases and accelerates the vascularization of immature granulation tissue (Lindhe & Brånemark 1968) and appears to increase the susceptibility of the gingival tissue to mechanical injury by causing dilation of the marginal vessels (Hugoson 1970).

Periodontal wound healing

For functional periodontal regeneration to occur, temporal and spatial progress in a similar sequence to that involved in the natural formation and development of the periodontium is needed (Chen *et al*. 2011). Although the exact cellular and molecular events are still not clear, cells must first migrate and attach to the denuded root surface. By using the rat fenestration defect model, a microenvironment that favors the proliferation, migration, and maturation of mesenchymal progenitors to the defective area of the PDL or the host bone has been observed (Lekic *et al*. 1996a, b). This process is mediated and coordinated by soluble factors, other cells, and ECM. The early healing process follows the conserved sequence of wound healing that is initiated by blood coagulation and migration of neutrophils and monocytes for wound debridement and bone resorption. Bone formation typically initiates from the bony margins of the lesions (Rajshankar *et al*. 1998). Within days after surgery, a thin cementum layer with a connective tissue attachment can be observed, particularly on the apical side of the teeth where the cementum is thicker compared with the narrow coronal region (King *et al*. 1997). Once mineralized tissues are established, PDL fiber orientation, directionality, and integration into both cementum and alveolar bone are mediated by appropriate mechanical loading (Mine *et al*. 2005; Rios *et al*. 2011). It is therefore crucial that investigators, according to the timeline these processes follow, select the appropriate time point(s) to determine the therapeutic efficacy "window" of a candidate periodontal-engineered device or bioactive molecule (Fig. 27-2).

Periodontal wound healing certainly is considered a more complex process compared to epidermal wound healing. The native periodontium includes cementum, a functionally oriented PDL, alveolar bone, and gingiva. The interfaces between these tissues as well as the transgingival position of the tooth represent a constant challenge during the restoration of the integrity of the native structures as they seek to create a new connection to the non-vascular and non-vital hard tissue of the root surface within the context of an open system that is permanently contaminated and under a significant "bacterial load". It is therefore not surprising that the healing that results following all types of gingival and periodontal therapy can be quite variable.

The most basic requirement for successful periodontal treatment is a clean, biofilm-free, decontaminated root surface. Therapy includes both surgical and non-surgical modalities, which result in instrumentation of the affected tissue. This creates a wound in

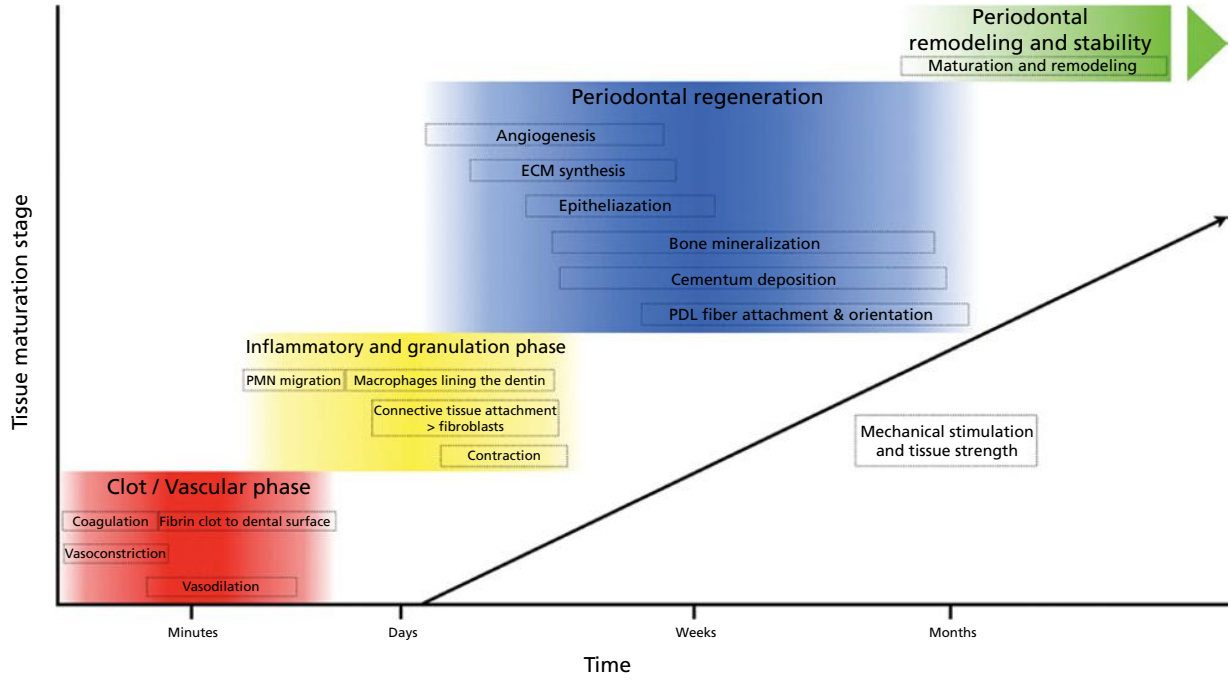

Fig. 27-2 Stages of periodontal wound healing. Optimal periodontal healing requires different processes in a sequential manner. After the initial coagulation phase, inflammatory reaction, and granulation tissue formation events, progenitor cells involved in multitissue regeneration are locally recruited and mediate the bioavailability of important growth factors. As the healing progresses, mechanical stimuli increase and promote an organized extracellular matrix (ECM) synthesis as well as cementum and bone formation and maturation. Once those structures are established, periodontal ligament (PDL) fibers are organized and oriented. Progressively, the tissues mature and ultimately increase in mechanical strength. Remodeling processes continue in the regenerated periodontium as an essential mechanism that monitors the adaptation potential to the challenging local and systemic environment.

periodontal tissues that are stressed by inflammation. The results of therapy are dependent on the ability of the body to heal afterwards and the mechanisms that dictate these processes. It is important to understand that the order of events during wound healing after therapy depend on a complex set of biologic communications in the area of interest.

Research on periodontal wound healing in the past provided the basic understanding of the mechanisms favoring periodontal tissue regeneration. A number of valuable findings at both the cellular and molecular levels was revealed and subsequently used in the engineering of the regenerative biomaterials that are available in periodontal medicine today.

The morphology of a periodontal wound comprises the gingival epithelium, gingival connective tissue, PDL, and hard tissue components such as alveolar bone and cementum or dentin on the dental root surface. This particular composition affects both the healing events in each tissue component as well as in the entire periodontal site. While the healing of gingival epithelia and their underlying connective tissues concludes in a number of weeks, the regeneration of PDL, root cementum, and alveolar bone generally occurs over a number of weeks or months. With the aim of wound closure, the final outcome of wound healing in the epithelium is the formation of the junctional epithelium surrounding the dentition (Caton *et al*. 1980). The healing of gingival connective tissue, on the other hand, results in a significant reduction of its volume, thus clinically causing both gingival recession and reduction of the periodontal pocket depth. PDL is shown to regenerate on newly formed cementum created by cementoblasts originating from the PDL granulation tissue (Karring *et al*. 1985). Furthermore, alveolar bone modeling occurs following the stimulation of mesenchymal cells from the gingival connective tissue, which are transformed into osteoprogenitor cells by locally expressed BMPs (Krebsbach *et al*. 2000; Sykaras & Opperman 2003).

A series of classical animal studies demonstrated that the tissue derived from alveolar bone or gingival connective tissue lacks cells with the potential to produce a new attachment between the PDL and newly formed cementum (Karring *et al*. 1980; Nyman *et al*. 1980). Moreover, granulation tissue derived from the gingival connective tissue or alveolar bone results in root resorption or ankylosis when placed in contact with the dental root surface. It should be expected, therefore, that these complications would occur more frequently following regenerative periodontal surgery, particularly following those procedures which include the placement of grafting materials to stimulate bone formation. The reason for root resorption is rarely identified; however, it may be that following the surgical intervention, the dentogingival epithelium migrates apically along the root surface, forming a protective barrier against the root surface (Bjorn *et al*. 1965; Karring *et al*. 1984). The findings from these animal experiments revealed that ultimately the PDL tissue contains cells with the potential to form a new connective tissue attachment (Karring *et al*. 1985).

Typically, the down-growth of the epithelium along the tooth root surface reaches the level of the PDL before the latter has regenerated with new layers of cementum and newly inserted connective tissue fibers. Therefore, in order to enable and promote the healing towards the rebuilding of cementum and PDL, the gingival epithelium must be hindered in its creation of a long junctional epithelium along the root surface down to the former level of the PDL.

These principles of periodontal wound healing provide the basic understanding of the events that follow wounding in surgical interventions. In order to achieve new connective tissue attachment, the granulation tissue derived from PDL cells has to be given both space and time to format and mature to new cementum and PDL.

Healing after periodontal surgery

Healing after gingival and periodontal surgery represents a more complex situation, particularly in cases where the periodontal tissue is apposed to an instrumented root surface deprived of its periodontal attachment. In this case, the wound margins are not two opposing vascular gingival margins but comprise the rigid non-vascular mineralized tooth surface on one side, and the connective tissue and epithelium of the gingival flap on the other (Fig. 27-3). Early healing events at the dentogingival interface have been examined using dentin blocks implanted in edentulous alveolar ridges, submerged under gingival flaps, in dogs (Wikesjo *et al*. 1991).

Clot formation at the interface between the tooth and a gingival flap is initiated as blood elements are imposed onto the root surface during surgery and at wound closure in a seemingly random manner.

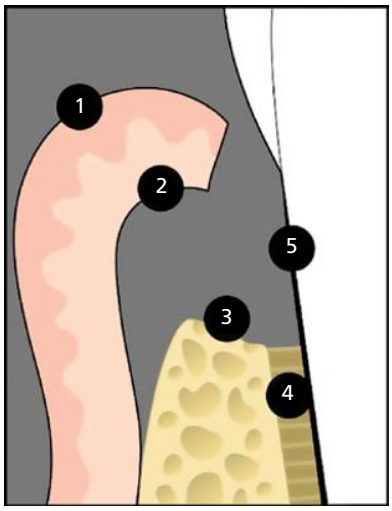

Fig. 27-3 Periodontal wound following flap surgery: (1) gingival epithelium; (2) gingival connective tissue; (3) alveolar bone; (4) periodontal ligament; and (5) cementum or dentin on the dental root surface.

This represents the very first healing event at the tooth–gingival flap interface (i.e. the absorption and adhesion of plasma proteins onto the root surface) (Wikesjo *et al*. 1991). Within minutes, a fibrin clot attached to the root surface is developed. Within hours, the early phase of inflammation may be observed as inflammatory cells, predominantly neutrophils and monocytes, accumulate on the root surface, and within 3 days the late phase of inflammation dominates the healing picture as macrophages migrate into the wound followed by the formation of granulation tissue. At 7 days, a connective tissue attachment may be forming at the root surface as collagenous elements appear to be orientated in close proximity to the dentin surface. Resorptive remodeling of the dentin surface may be evident at this observation interval.

Within 14 days, the newly formed collagen fibers may show an arrangement indicative of physical attachment to the dentin (Selvig *et al*. 1988). Ramfjord *et al.* (1966) reported that collagen maturation of collagenous tissues and functional orientation of the connective tissue takes 3–5 weeks. In addition, new bone deposition starts to occur from days 10–21 (Wilderman 1964). Eventually, cementum formation may be initiated, but not until at least 3 weeks after wound closure (Hiatt *et al*. 1968).

Only a few experimental studies have evaluated the functional integrity of a maturing periodontal wound. Hiatt *et al.* (1968) examined the tensile strength of the tooth–gingival flap interface following reconstructive surgery of relatively small surgical dehiscence defects over the maxillary canine teeth in the dog. They found that the tensile strength increased from approximately 200 g at 3 days post surgery to 340 g at 5–7 days post surgery, and to >1700 g at 2 weeks post surgery. In other words, they found that a relatively limited periodontal wound might not reach functional integrity until 2 weeks post surgery. These data suggest that wound integrity during the early healing phase depends primarily on the stabilization of the gingival flaps offered by suturing.

Histologic studies have shown that various surgical periodontal procedures can lead to different patterns of healing. Empirically, periodontal healing has generally been characterized by maturation of the gingival connective tissue, some regeneration of alveolar bone and cementum, and, most importantly, epithelialization of the root surface (Listgarten & Rosenberg 1979). Long junctional epithelium is commonly found on the root surface after traditional periodontal surgery and provides protection against bacterial invasion and ankylosis. However, downgrowth of epithelium from the gingival margin prevents the coronal migration of PDL cells, which are responsible for the formation of connective tissue attachment (Fig. 27-4).

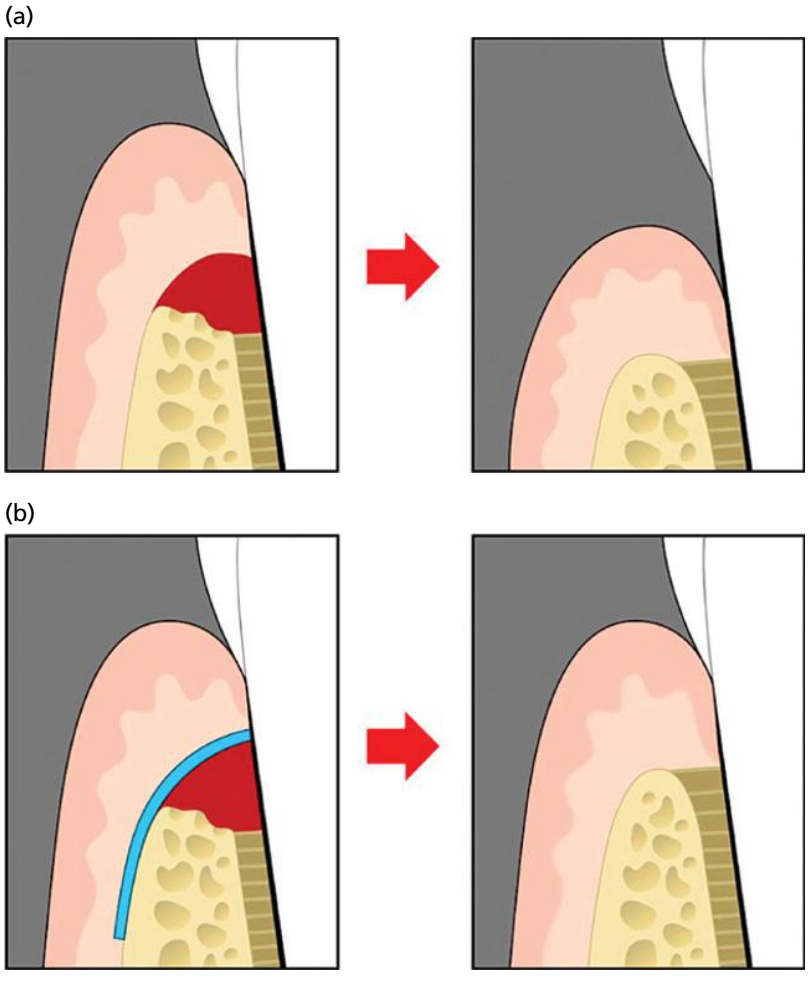

Fig. 27-4 (a) Regular healing process following the periodontal flap adaptation with significant reduction of the attachment apparatus. (b) In order to enable and promote the healing towards the rebuilding of the cementum and periodontal ligament, the gingival epithelium must be hindered from creating a long junctional epithelium along the root surface down to the former level of the periodontal ligament (e.g. by placement of a bioresorbable membrane).

Soft tissue management in early regenerative attempts adhering to the principle of epithelial exclusion has included repeated subgingival curettage during healing to control epithelialization of the root surface. More recent approaches have included the prevention of the gingival epithelium from contacting the root surface during the early healing phase by utilization of a cell-occluding membrane. Human as well as animal studies have reported the success with a membrane in facilitating the migration and proliferation of cells from the PDL and alveolar bone in the wound space (Nyman *et al*. 1982; Gottlow *et al*. 1984).

The general concepts of healing have been applied in the environment of periodontal tissues. Several investigations have been conducted in attempts to elucidate the exact mechanisms that guide the process and determine the final healing pattern.

Advanced regenerative approaches to periodontal tissue reconstruction

Periodontal regeneration is assessed by probing measures, radiographic analysis, direct measurements of new bone, and histology (Reddy & Jeffcoat 1999). Many cases that are considered clinically successful, including cases with significant regrowth of alveolar bone, may histologically still show an epithelial lining along the treated root surface instead of newly formed PDL and cementum (Listgarten & Rosenberg 1979). In general, however, the clinical outcome of periodontal regenerative techniques has been shown to depend on (1) patient-associated factors such as plaque control, smoking habits, residual periodontal infection, or membrane exposure in guided tissue regeneration (GTR) procedures; (2) effects of occlusal forces that deliver intermittent loads in axial and transverse dimensions; as well as (3) factors associated with the clinical skills of the operator, such as the failure of primary closure of the surgical wound (McCulloch 1993). Even though modified flap designs and microsurgical approaches have been shown to positively affect the outcome of both soft and hard tissue regeneration, the clinical success for periodontal regeneration remains limited in many cases. Moreover, the surgical protocols for regenerative procedures are skill demanding and may therefore may not be achievable for a number of clinicians. Consequently, both clinical and preclinical research continues to evaluate advanced regenerative approaches (Ramseier *et al*. 2012) using new barrier

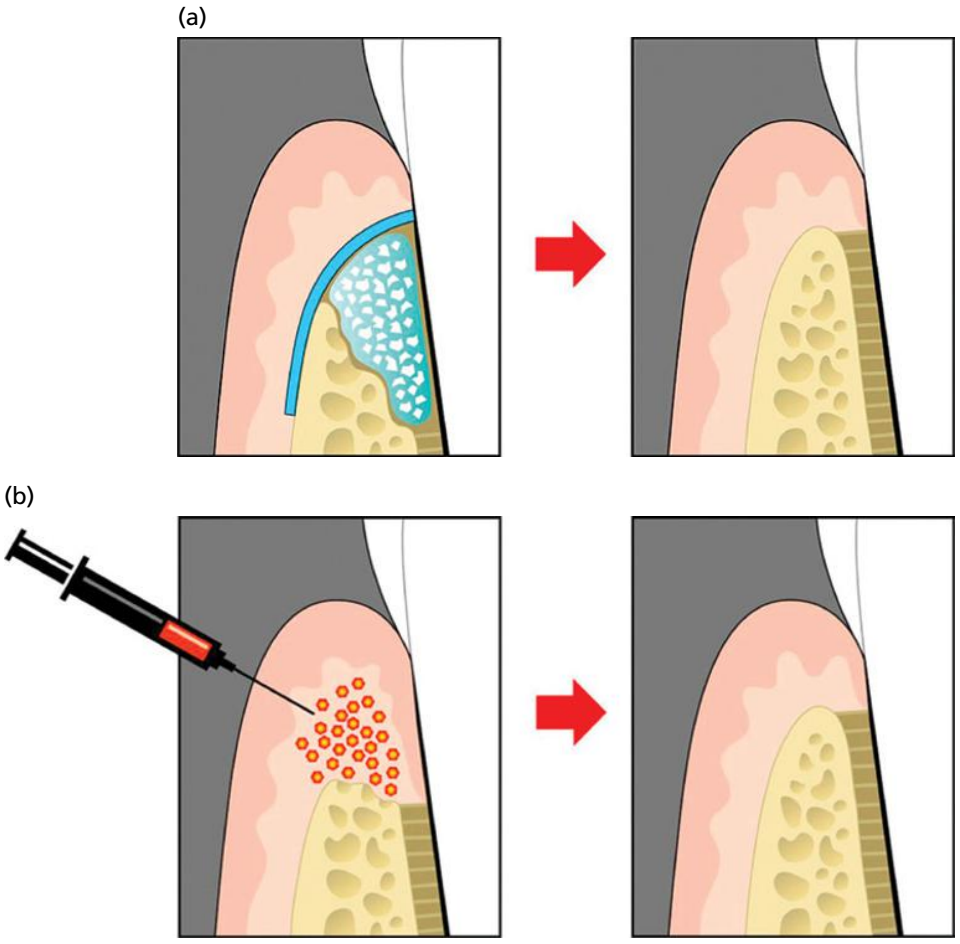

Fig. 27-5 Advanced approaches for regenerating tooth-supporting structures. (a) Application of a graft material (e.g. bone ceramic) and growth factor into an infrabony defect covered by a bioresorbable membrane. (b) Application of gene vectors for the transduction of growth factors producing target cells.

membrane techniques (Jung *et al*. 2006), cell-growth stimulating proteins (Giannobile 1996; Dereka *et al*. 2006; Kaigler *et al*. 2006) or gene delivery applications (Ramseier *et al*. 2006), respectively, in order to simplify and enhance the rebuilding of missing periodontal support (Fig. 27-5).

Regenerative surgery

Regenerative periodontal therapy comprises techniques that are particularly designed to restore lost parts of the tooth-supporting structures, including cementum, PDL, and bone. The most common periodontal indications for these procedures include deep infrabony defects, furcation defects of upper premolar and molar teeth, and localized gingival recession defects. The clinical success for periodontal regeneration still remains limited in many cases. Consequently, both clinical and preclinical research continues to advance the field of periodontal regenerative therapy by evaluating innovative tissue engineering approaches that include optimized scaffold fabrication technology, new barrier membrane techniques (Jung *et al*. 2006), cell-growth stimulating proteins (Giannobile 1996; Dereka *et al*. 2006; Kaigler *et al*. 2006) as well as cell and gene delivery applications (Ramseier *et al*. 2006) (Fig. 27-6).

Guided tissue regeneration

Histologic findings from periodontal regeneration studies and Melcher's concepts of "compartmentalization" revealed that a new connective tissue attachment could be predicted if the cells from the PDL settle on the root surface during healing (Melcher 1976). Hence, the clinical applications of GTR in periodontics involve the placement of a physical barrier membrane to enable the previously periodontitis-affected tooth root surface to be repopulated with cells from the PDL, cells from the lamina propria of the gingival corium, cementum cells, and alveolar bone. GTR techniques utilize barrier membranes to facilitate the migration of bone cells and PDL cells to the defects by refraining soft tissue cells from penetrating it. This knowledge has been the key to developing standard clinical procedures for the placement of a fabricated membrane in GTR. GTR has recently been combined with the delivery of different factors that are incorporated to augment the regenerative response.

Clinical applications of growth factors for use in periodontal regeneration

A number of studies have focused on the modification of the periodontitis-involved root surface in order to advance the formation of a new connective tissue attachment. However, despite histologic evidence of regeneration following root surface biomodification with citric acid, the outcomes of controlled clinical trials have failed to show any improvements in clinical conditions compared to non–acid-treated controls (Fuentes *et al*. 1993; Mariotti 2003). In recent years, biomodification of the root surface with enamel matrix proteins during periodontal surgery and following demineralization with ethylenediaminetetra-acetic acid (EDTA) has been introduced to promote periodontal regeneration. The application of enamel matrix proteins (amelogenins) has also been evaluated as a promoter of periodontal regeneration since it initiates events that occur during the growth of periodontal tissues (Gestrelius *et al*. 2000). The commercially available product, Emdogain®, a purified acid extract of porcine origin contains *enamel matrix derivate* (EMD), which has demonstrated the ability to advance periodontal regeneration (Sculean *et al*. 2007). Thus far, EMD alone or in combination with grafts has demonstrated its potential to effectively treat intraosseous defects and the clinical results appear to be stable long term (Trombelli & Farina 2008).

Platelet-derived growth factor (PDGF) is a member of a multifunctional polypeptide family and exerts its biologic effects on cell proliferation, migration, ECM synthesis, and antiapoptosis (Heldin *et al*. 1989; Rosenkranz & Kazlauskas 1999). The clinical application of PDGF has been shown to successfully advance alveolar bone repair and clinical attachment level gain. Initial clinical trials reported the successful repair of class II furcations using demineralized freeze-dried bone allograft (DFDBA) saturated with rhPDGF-BB (Nevins *et al*. 2003). Subsequently, rhPDGF-BB mixed with a synthetic beta-tricalcium phosphate (β-TCP) matrix was shown to advance the repair of deep infrabony pockets as measured by radiographic bone fill in a large multicenter randomized controlled trial (Nevins *et al*. 2005, 2013). Both studies also demonstrated that the use of rhPDGF-BB was safe and effective in the treatment of periodontal osseous defects.

Bone morphogenetic proteins (BMPs) are multifunctional polypeptides which have potent bone regenerative capacity. Fiorellini *et al*. (2005) reported that in a human buccal wall defect model, bone formation following tooth extraction was significant when the defect was treated with recombinant human BMP-2 (rhBMP-2) delivered by a bioabsorbable collagen sponge, compared to treatment with the collagen sponge alone. Furthermore, BMP-7, also known as osteogenic protein 1 (OP-1), stimulates bone regeneration around teeth, endosseous dental implants, and in maxillary sinus floor augmentation procedures (Giannobile *et al*. 1998; van den Bergh *et al*. 2000).

In general, topical delivery of growth factors to periodontal wounds has shown promise, but as yet the impact is insufficient for the promotion of predictable periodontal tissue engineering (Kaigler *et al*. 2006). Growth factor proteins, once delivered to the target site, tend to suffer from instability and quick dilution, presumably due to proteolytic breakdown, receptor-mediated endocytosis, and solubility of the

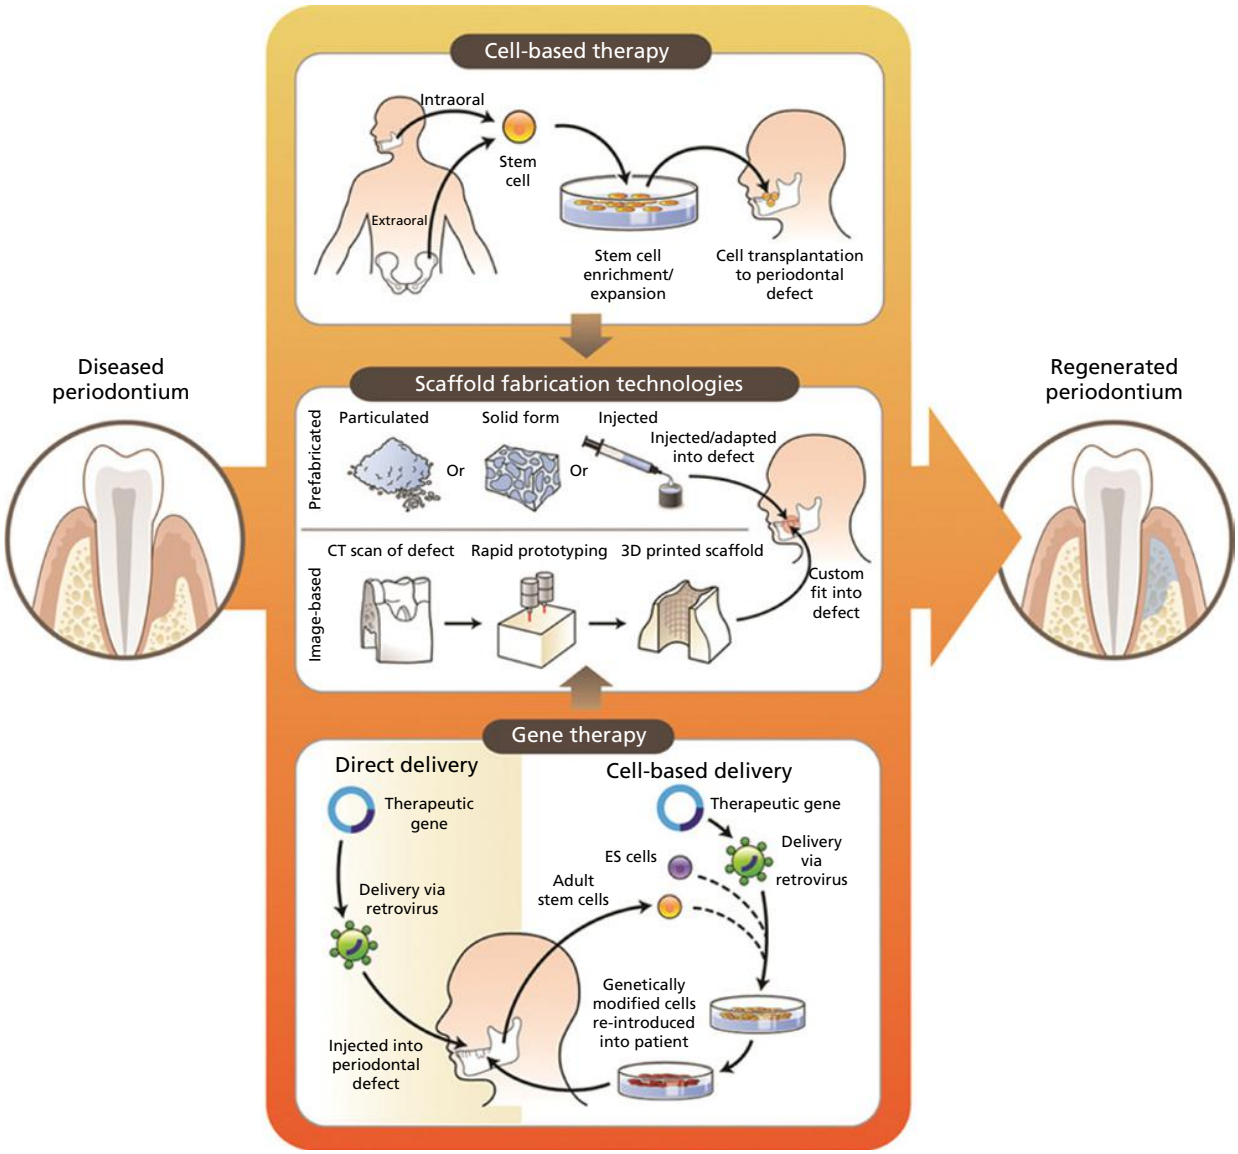

Fig. 27-6 Cell- and gene-based technologies using scaffolding matrices for periodontal tissue engineering. Extraoral and intraoral stem cells represent a viable and accessible alternative source to harvest and expand multipotent colonies. Adequate cell density could be reached *in vitro* in a controlled environment and made readily available for reimplantation into a periodontal defect site. The available direct and cell-based delivery of a therapeutic gene has being shown to increase the regenerative potential and enhance the availability of important factors. The gene of interest is either injected directly into the periodontal defect via a retrovirus or alternatively is incorporated into a stem cell that is subsequently expanded and delivered to the area of interest. Prefabricated and image-based scaffolds are becoming an essential component of regenerative medicine. A defined supporting structure allows the localization and guidance of the appropriate cells and proteins, and the establishment of a mechanically competent environment. Currently, scaffolds for periodontal regeneration are available in particulated, solid, and injectable forms. New developing technology has allowed the customization of scaffolds that would fit into the periodontal defect and include an external and an internal architecture that enhances tissue orientation and regeneration. This schematic diagram highlights the potential of integrating the available tissue engineering strategies to enhance the outcome of periodontal regenerative therapy. (ES cells, embryonic stem cells.)

delivery vehicle. Because their half-lives are significantly reduced, the period of exposure may not be sufficient to act on osteoblasts, cementoblasts or PDL cells. A recent clinical trial evaluated the regenerative effects of systemic delivery of teriparatide, a recombinant form of parathyroid hormone (PTH). The study demonstrated a periodontal anabolic effect favoring a regenerative outcome. Following periodontal surgery, teriparatide was systemically delivered for 6 weeks and results compared with a placebo control. Delivery of this recombinant molecule in this fashion was associated with improved clinical outcomes, including greater resolution of alveolar bone defects and accelerated osseous wound healing (Bashutski *et al*. 2010).

Cell therapy for periodontal regeneration

Another emerging regenerative approach in the management of soft and hard tissue defects involves cell therapy (Table 27-1). For regeneration of interdental papillae, early investigations of cell therapy

using cultivated fibroblasts have shown success in the treatment of interdental papillary insufficiency (McGuire & Scheyer 2007). For larger soft tissue defects, a human oral mucosa equivalent, made of autogenous keratinocytes (EVPOME) placed on a cadaveric dermal carrier (Alloderm®), has shown efficacy in wound healing when compared to the dermal carrier alone (Izumi *et al.* 2003). EVPOME has also been successfully used to treat patients affected by squamous cell carcinoma of the tongue, leukoplakia of the tongue, gingiva, and buccal mucosa, or hypoplasia of the alveolar ridge (Hotta *et al*. 2007). In other soft tissue applications, allogenic foreskin fibroblasts have been utilized to promote keratinized tissue formation at mucogingival defects (McGuire & Nunn 2005). A tissue-engineered living cellular construct comprised of viable neonatal keratinocytes and fibroblasts has been evaluated for its ability to increase keratinized gingiva around teeth, and rendered similar clinical outcomes to conventional gingival autografts (McGuire *et al.* 2011). This cell construct also has a strong potential to stimulate the expression of angiogenic factors as compared with autogenous free gingival grafts

Fig. 27-7 (a) A 32-year-old male patient with severe periodontitis. Tooth 13 shows a probing pocket depth (PPD) of 10 mm distobuccal and a clinical attachment level (CAL) of 14 mm. (b) Periapical radiograph shows the infrabony defect distal to tooth 13. (c) After the buccal incision of the papilla, the interdental tissue is preserved attached to the palatal flap. After debridement of the granulation tissue and root planing, the infrabony defect is classified and measured: the predominant component is a 7-mm deep three-wall defect. One year after surgical intervention, the distal site of tooth 13 shows a PPD of 2 mm (gain of 8 mm from initial measurement) and a CAL of 7 mm (gain of 7 mm) (d) and the radiograph shows defect filling (e).

during early wound-healing stages and, therefore, constitutes a promising material for gingival grafting (Morelli *et al.* 2011).

The benefits of using somatic cells for the regeneration of soft and hard tissues in the craniofacial area have been illustrated in several preclinical and clinical studies. However, their lack of self-renewal capability and their commitment toward a single cellular phenotype limit their use in the treatment of more challenging craniofacial defects. Stem cells might have a greater potential in this arena as they can reproduce themselves (*self-renewal*) and differentiate into a variety of specialized cell types (*potency*). *Bone marrow stromal cells* (BMSCs) are characterized by elevated renewal potency and by the ability to differentiate into osteoblasts, chondroblasts, adipocytes, myocytes, and fibroblasts when transplanted *in vivo* (Prockop 1997). MSCs can be obtained from a variety of sources, but autologous MSCs isolated from bone marrow of the iliac crest offer a predictable and a cost-effective therapy for the treatment of severely atrophic maxillary and mandibular ridges when compared to harvested autogenous bone (Soltan *et al*. 2007). Bone repair cells (ixmyelocel-T®; Aastrom Biosciences) consisting of autologous bone marrow-derived cells expanded in an *ex vivo*, closed, and automated single-pass perfusion (SPP) have recently demonstrated the ability to accelerate bone regeneration in localized alveolar defects (Kaigler *et al* 2013). Because these cells include MSCs, they may not only serve to provide a source of stem and progenitor cells to a wound healing site, but may also be actively involved in the establishment of a vasculature which can support and sustain tissue regeneration.

Gene therapeutics for periodontal tissue repair

Although encouraging results for periodontal regeneration have been reported from various clinical investigations using recombinant tissue growth factors, topical protein delivery from existing vehicles

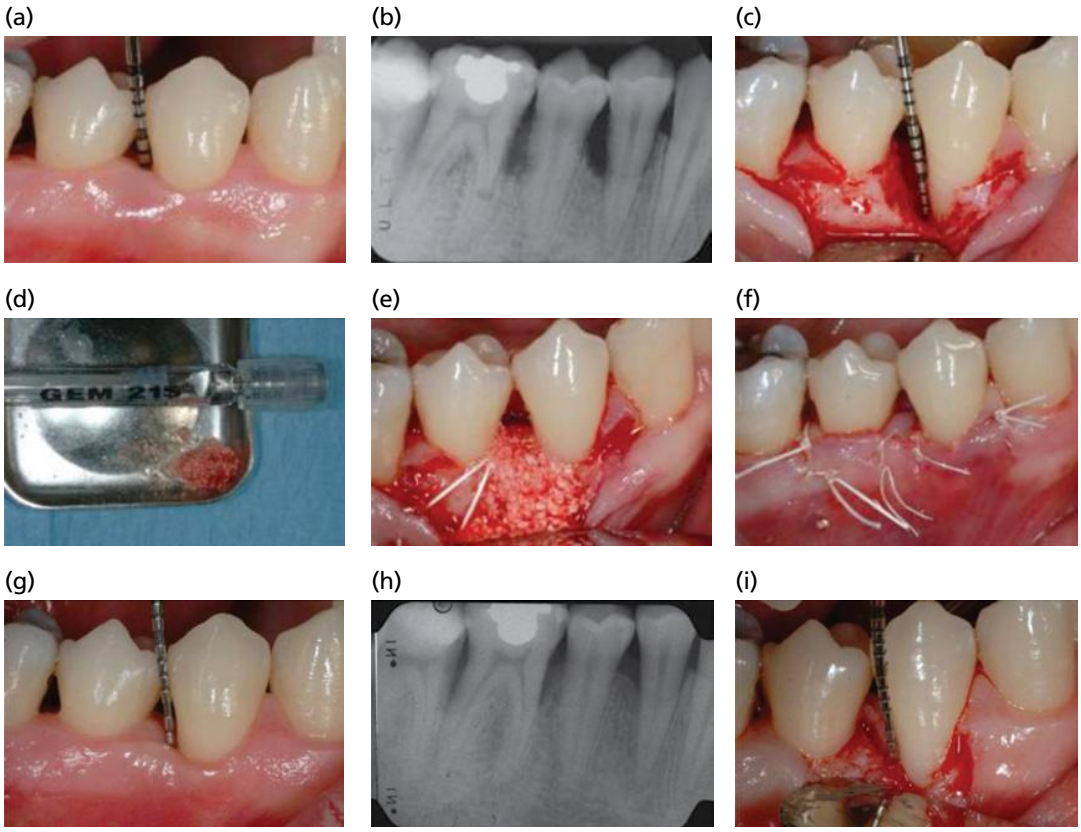

Fig. 27-8 (a) A 27-year-old patient at the re-evaluation visit after the initial phase showed three sites with a pocket probing depth (PPD) of <6 mm; the one distal to tooth 44 had a PPD of 7 mm and no gingival recession. (b) Periapical radiograph shows a one-wall defect distal to tooth 44 and a lesion between teeth 45 and 46. (c) Measurement of the pure one-wall defect shows an infrabony component of 6 mm. (d) Grafting material of the GEM 21S® is mixed with a few particles of autogenous bone chips, collected from the surgical area with a Rhodes instrument, and with the liquid component of the GEM 21S® [platelet-derived growth factor (PDGF)]. (e) Liquid PDGF is placed in the defect together with the graft to rebuild the lost bone. (f) An off-set internal mattress suture is performed to keep and stabilize the flap coronal. A second internal mattress suture is performed with 7-0 Gor Tex® to allow optimal adaptation of the flap margins without interference from the epithelium. The two internal mattress sutures are tied but not knotted until there is a perfect tension-free closure of the wound. Two additional interrupted 7-0 sutures are placed to assure stable contact between the connective tissues of the edges of the flaps. The mesial and distal papilla are stabilized with additional interrupted sutures. Nine months after surgery the PPD is 2 mm (g), the periapical radiograph shows a good bone fill of the one-wall bony defect (h), and surgical re-entry shows formation of new bone (i).

has limitations such as transient biologic activity, protease inactivation, and poor bioavailability. Therefore, newer approaches seek to develop methodologies that optimize growth factor targeting to maximize the therapeutic outcome of periodontal regenerative procedures. Genetic approaches in periodontal tissue engineering show early progress in achieving delivery of growth factor genes such as *PDGF* or *BMP* to periodontal lesions (Kaigler *et al*. 2006). Gene transfer methods may circumvent many of the limitations with protein delivery to soft tissue wounds (Giannobile 2002; Baum *et al*. 2003). It has been shown that growth factors (Franceschi *et al*. 2000; Krebsbach *et al*. 2000; Jin *et al*. 2004) or soluble forms of cytokine receptors (Taba *et al*. 2005) applied by gene transfer are more sustainable than proteins applied in a single application. Thus, gene therapy may achieve greater bioavailability of growth factors within periodontal wounds and thus provide greater regenerative potential.

Conclusion

The periodontal healing process is governed by a complex multifactorial mechanism in which a number of local and systemic, micro- and macro-environmental variables interplay to define the final result. Only a profound understanding of biologic and clinical variables affecting the outcome of gingival and periodontal surgical procedures will allow clinicians to manipulate critical factors effectively in order to optimize the outcome and increase the predictability of periodontal regenerative (Figs. 27-7, 27-8). This chapter has given a brief presentation of the healing mechanisms which are initiated in periodontal tissues following basic periodontal surgical procedures. The complexity of the cellular and molecular events that are activated during and after a periodontal intervention lead to some important conclusions:

- As clinicians, we must minimize any deviations from the strict surgical protocols in order to ensure the risk of any unfavorable healing events is minimized.
- As scientists, we should be able to translate the clinical signs and symptoms into the language of physiology and histology, and understand their nature so that interventions can be modified accordingly.

Chapter 28

Concepts in Periodontal Tissue Regeneration

Thorkild Karring[1] and Jan Lindhe[2]

[1]Department of Periodontology and Oral Gerontology, Royal Dental College, University of Aarhus, Aarhus, Denmark
[2]Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Introduction

In risk assessment in periodontal patients, the presence of sites with a residual pocket depth of ≥6 mm after active treatment plays a significant role in predicting future periodontal destruction (Haffajee *et al*. 1991; Grbic & Lamster 1992; Claffey & Egelberg 1995). Thus, an important goal of periodontal therapy is to reduce pocket depth in order to prevent further disease progression. Usually, this goal can be accomplished by non-surgical therapy in patients with moderate periodontitis, whereas in severe cases, particularly in the presence of intrabony defects and furcations, the treatment must be supplemented with periodontal surgery. A fundamental objective of periodontal surgery is to provide access for proper instrumentation and cleaning of the root surface; in addition, most surgical procedures result in the elimination or the reduction of the soft tissue component of the periodontal pocket. Generally, the elimination of deep pockets is achieved by gingivectomy or apical displacement of raised tissue flaps, sometimes associated with bone contouring. In recent years, however, the use of regenerative procedures aimed at restoring the lost periodontal support has become more common.

Periodontal treatment, both surgical and non-surgical, results in recession of the gingival margin after healing (Isidor *et al*. 1984). In severe cases of periodontitis, this recession may lead to poor esthetic outcomes, especially visible in the front tooth region of the maxilla and at sites at which bone contouring procedures have been used. Treatment of such cases without bone contouring, on the other hand, may make residual pockets inaccessible to proper self-performed tooth cleaning during post-treatment maintenance. These problems can be avoided or reduced by applying regenerative procedures to restore the lost periodontal attachment in the bone defects. Thus, the indication for regenerative periodontal therapy is often based on esthetic considerations, as well as the fact that this treatment may improve the function or long-term prognosis of the treated teeth.

Gingival recession and root exposure may represent an esthetic problem to the patient, and are often associated with root sensitivity. In such situations

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

there is an obvious indication to apply regenerative periodontal therapy to obtain root coverage that may not only improve esthetics but also reduce root sensitivity. Successful root coverage implies regeneration of the attachment apparatus, including cementum with inserting collagen fibers, on the exposed root surface, as well as restoration of the anatomy of the mucogingival complex.

Another indication for regenerative periodontal therapy is an open furcation in multirooted teeth. The furcation area is often inaccessible to adequate instrumentation and frequently the roots show concavities and furrows which make proper cleaning of the area difficult/impossible after resective surgery. Considering the long-term results and complications reported following treatment of furcations by traditional resective therapy (Hamp *et al*. 1975; Bühler 1988), it is reasonable to anticipate that the long-term prognosis of furcation-involved teeth can be improved considerably by successful regenerative periodontal therapy.

Case reports also exist demonstrating that "hopeless" teeth with deep vertical defects, increased tooth mobility or through-and-through furcations can be successfully treated with regenerative periodontal therapy (Gottlow *et al*. 1986). However, controlled clinical trials or serial case reports presenting a reasonable predictability of treating such advanced cases are not available.

Regenerative periodontal surgery

Regenerative periodontal therapy comprises procedures which are specially designed to restore those parts of the tooth-supporting apparatus which have been lost due to periodontitis. Regeneration is defined as a reproduction or reconstruction of a lost or injured part in such a way that the architecture and function of the lost or injured tissues are completely restored (American Academy of Periodontology 1992). This means that the attachment of the tooth has been regenerated when new cementum with inserting collagen fibers has formed on the detached root surface, while regeneration of the periodontal supporting apparatus (periodontium) also includes regrowth of the alveolar bone.

Procedures aimed at restoring lost periodontal support have also been described as "reattachment" or "new attachment" procedures. The term "reattachment" was used to describe the regeneration of a fibrous attachment to a root surface surgically or mechanically deprived of its periodontal ligament tissue, whereas the term "new attachment" was preferred in the situation where the fibrous attachment was restored on a root surface deprived of its connective tissue attachment due to the progression of periodontitis. Research findings, however, indicate that there is no difference regarding the possibility of restoring a connective tissue attachment, whether this has been lost because of periodontal disease or mechanically removed (Nyman *et al*. 1982; Isidor *et al*. 1985). Therefore, it was suggested that the term "new attachment" should be used to describe the formation of new cementum with inserting collagen fibers on a root surface deprived of its periodontal ligament tissue, whether or not this has occurred because of periodontal disease or by mechanical means, and that the term "reattachment" should be confined to describing the reunion of surrounding soft tissue and a root surface with preserved periodontal ligament tissue (Isidor *et al*. 1985).

Periodontal regeneration has been reported to occur following a variety of surgical approaches involving root surface biomodification, often combined with coronally advanced flap procedures, the placement of bone grafts or bone substitutes in periodontal defects, or the use of organic or synthetic barrier membranes [guided tissue regeneration (GTR)]. However, many cases that clinically are considered successful, including cases with significant regrowth of alveolar bone, may histologically show an epithelial lining along the treated root surface instead of deposition of new cementum (Caton & Zander 1976; Listgarten & Rosenberg 1979).

Successful regeneration is assessed by periodontal probing, radiographic analysis, bone sounding, and histologic examination of biopsy specimens. Although histology remains the gold standard in assessing true periodontal regeneration, periodontal probing, direct bone measurements, and radiographic measurements of osseous changes are used in the majority of studies of regenerative therapy (Reddy & Jeffcoat 1999).

At the American Academy of Periodontology World Workshop in Periodontics in 1996, the fulfillment of the following criteria was required in order for a periodontal regenerative procedure to be considered as a therapy which can encourage regeneration:

1. Human histologic specimens demonstrating formation of new cementum, periodontal ligament, and bone coronal to a notch indicating the apical extension of the periodontitis-affected root surface
2. Controlled human clinical trials demonstrating improved clinical probing attachment and bone
3. Controlled animal histologic studies demonstrating formation of new cementum, periodontal ligament, and bone.

In addition, however, it seems reasonable to require that a regenerative procedure is based on a biologic concept which, based on current knowledge about periodontal wound healing, can explain why the treatment results in periodontal regeneration.

Periodontal wound healing

Regeneration of the periodontium must include the formation of new cementum with inserting collagen fibers on the previously periodontitis-involved root surfaces and the regrowth of the alveolar bone. However, whether regrowth of alveolar bone should always be considered a requirement for success

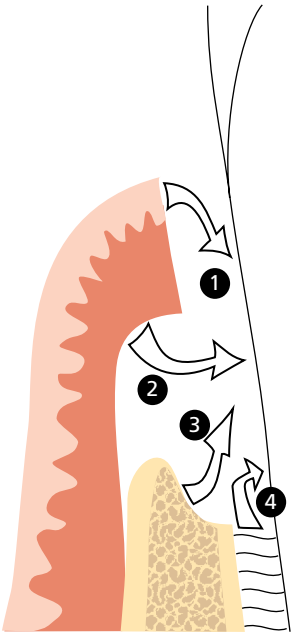

Fig. 28-1 Following flap surgery, the curetted root surface may be repopulated by (1) epithelial cells, (2) gingival connective tissue cells, (3) bone cells, or (4) periodontal ligament cells.

following regenerative periodontal surgery is a matter of discussion. The basis for this discussion is that a fibrous attachment may exist without opposing bone in a normal dentition, not affected by periodontitis, in the presence of bone dehiscenses and fenestrations (see Fig. 1-74).

In 1976, Melcher suggested in a review paper that the type of cell which repopulates the root surface after periodontal surgery determines the nature of the attachment that will form. After flap surgery, the curetted root surface may be repopulated by four different types of cell (Fig. 28-1):

1. Epithelial cells
2. Cells derived from the gingival connective tissue
3. Cells derived from the bone
4. Cells derived from the periodontal ligament.

Previously, in most attempts to restore lost tooth support, particular attention was directed towards the regeneration of the alveolar bone. An investigation was carried out in dogs in order to examine the relationship between the re-establishment of a connective tissue attachment to the root surface and the regrowth of alveolar bone (Nyman & Karring 1979). After elevation of mucoperiostal flaps, the marginal 5–7 mm of the buccal alveolar bone of each experimental tooth was removed (Fig. 28-2). During this procedure, care was taken to minimize mechanical injury to the connective tissue attachment on the root surface. Prior to flap closure, a notch, serving as a landmark for the histologic measurements, was prepared in the root surface at the level of the surgically reduced bone crest. After 8 months of healing, the animals were sacrificed. Histologic analysis demonstrated that although a connective tissue attachment

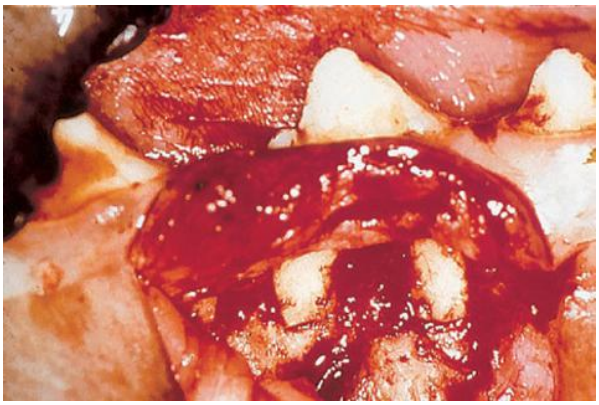

Fig. 28-2 Following flap elevation, the buccal bone, including a part of the inter-radicular and interproximal alveolar bone, is removed without injuring the connective tissue attachment on the root surface.

was consistently re-established on the roots, the amount of bone regeneration varied widely. In some roots, bone regrowth was negligible (Fig. 28-3), whereas in others the bone had regenerated to its normal level. These results demonstrated that the amount of bone regrowth is unrelated to the re-establishment of a connective tissue attachment.

Another experiment in monkeys (Lindhe *et al*. 1984) examined whether the presence of bone may stimulate the formation of a new connective tissue attachment. Mandibular and maxillary incisors were extracted and re-implanted in their own sockets under the following four experimental conditions (Fig. 28-4):

1. Non–root-planed teeth were re-implanted into sockets with normal bone height
2. Teeth, root planed in their coronal portion, were re-implanted into sockets with normal bone height
3. Non–root-planed teeth were re-implanted into sockets with a reduced bone height
4. Teeth, root planed in their coronal portion, were re-implanted into sockets with reduced bone height.

Histologic examination after 6 months of healing revealed that a fibrous reunion was established in areas where the periodontal connective tissue attachment was retained at the time of re-implantation. However, in areas where the periodontal ligament tissue had been removed, the epithelium had consistently migrated to the apical extension of root instrumentation (Fig. 28-5). This healing occurred irrespective of the presence or absence of bone, indicating that the establishment of a connective tissue attachment is unrelated to the presence of alveolar bone.

Using orthodontic appliances, Karring *et al*. (1982) tilted maxillary second and third incisors in the labial direction in dogs. Subsequently, these teeth were moved back to their original position. During the same period the contralateral incisors were moved to a labially deviated position. The orthodontic appliances were then used to retain the teeth in these positions for a period of 5 months before sacrifice of the

animals. Histologic analysis demonstrated that in all experimental teeth, the apical termination of the junctional epithelium was at the cementoenamel junction. In the teeth which were retained in their labially displaced position, the level of the alveolar bone was reduced to a position about 4.5 mm apical of the cementoenamel junction (Fig. 28-6a), while in the teeth which were moved back to their original position, the alveolar bone crest was located at a normal level relative to the cementoenamel junction (Fig. 28-6b). This experiment demonstrated that bone resorption or bone regeneration may be induced by orthodontic forces on teeth with a pristine connective tissue attachment. The experiments described above indicate that the re-establishment of a connective tissue attachment to the root surface and the regeneration of the alveolar bone are not related to each other.

The use of bone grafts in regenerative periodontal therapy is based on the assumption that the promotion of bone regrowth may also induce cells in the bone to produce a new cementum layer with inserting collagen fibers on previously periodontitis-involved root surfaces. However, histologic studies in both humans and animals have demonstrated that grafting procedures often result in healing with a long junctional epithelium rather than a new connective tissue attachment (Caton & Zander 1976; Listgarten & Rosenberg 1979; Moscow *et al*. 1979).

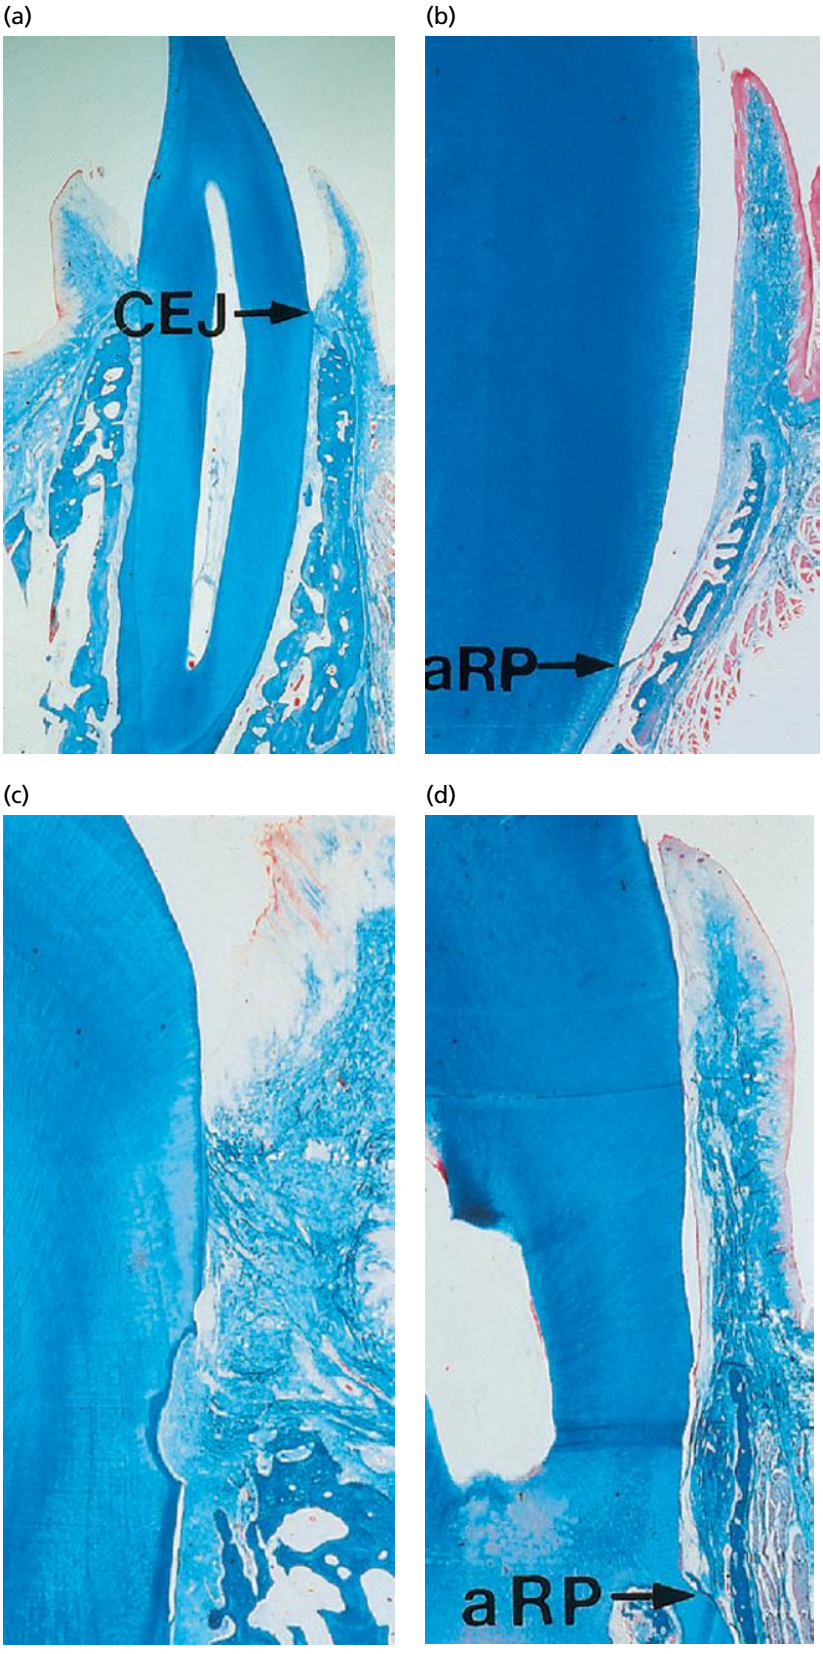

Fig. 28-5 Microphotographs showing the histologic features after 6 months of healing, under the four experimental conditions illustrated in Fig. 25-4a–d. The teeth in (b) and (d) are those that are root planed in their coronal portion, and the teeth in (a) and (b) are those re-implanted in sockets with normal bone height. A fibrous reunion was established in areas where the connective tissue attachment was retained (a and c), while the epithelium has migrated to the apical extension of root instrumentation (aRP) where the attachment was removed (b and d). (CEJ, cementoenamel junction.)

Ellegaard *et al*. (1973, 1974, 1975, 1976) and Nielsen *et al*. (1980, 1981) reported that grafting materials in periodontal bony defects may be:

1. *Osteoproliferative (osteogenetic)*: new bone is formed by bone-forming cells contained in the grafted material
2. *Osteoconductive*: the grafted material does not contribute to new bone formation *per se* but serves as a scaffold for bone formation originating from adjacent host bone
3. *Osteoinductive*: bone formation is induced in the surrounding soft tissue immediately adjacent to the grafted material.

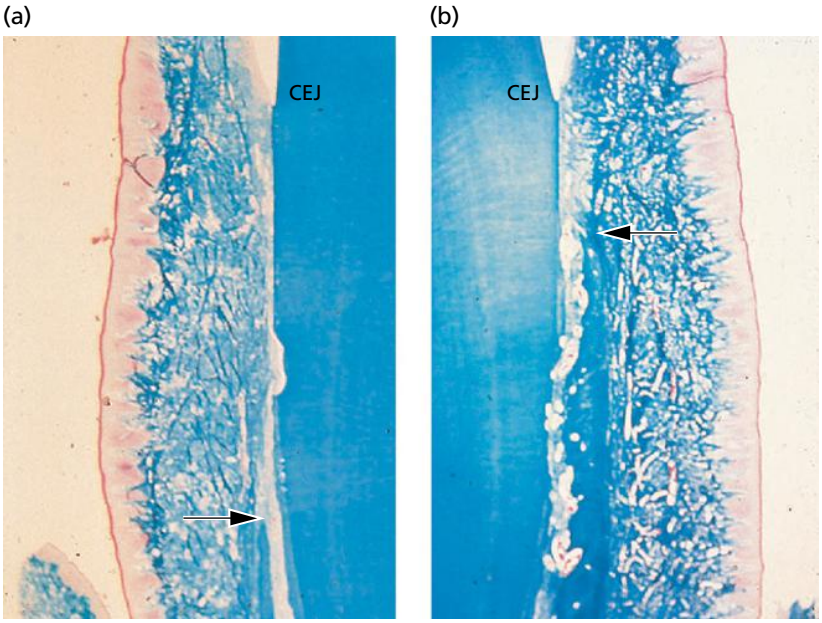

Fig. 28-6 Microphotographs of (a) a tooth retained in its labially displaced position and (b) a tooth moved back to its original position. The level of alveolar bone (arrow) is reduced in (a), while it has regenerated to its normal level (arrow) in (b). The apical termination of the junctional epithelium is at the cementoenamel junction (CEJ) in both situations.

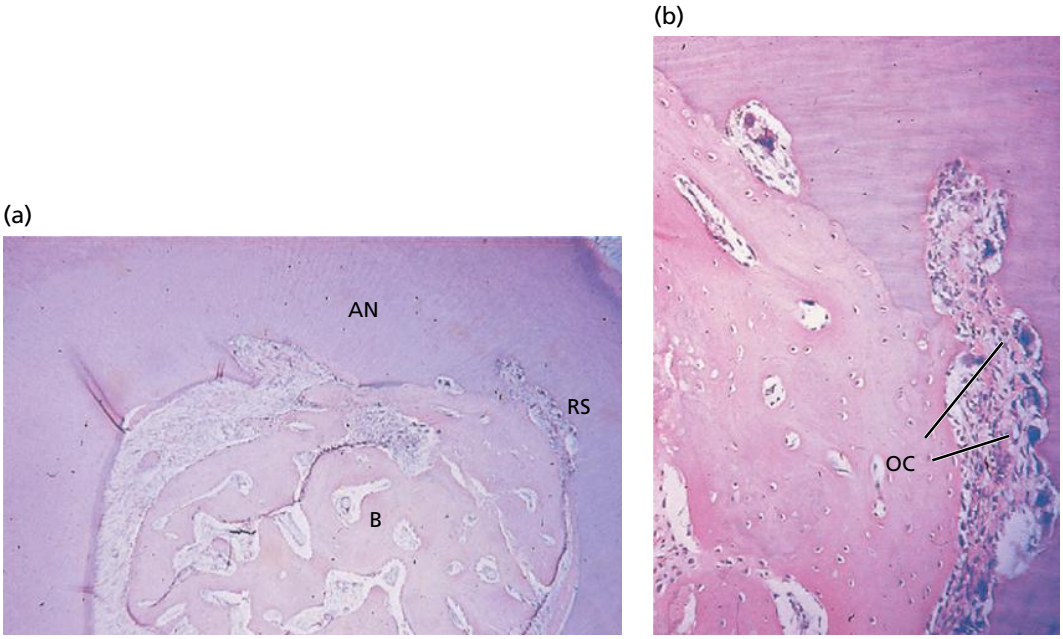

Fig. 28-7 (a) Microphotograph of furcation 6 weeks after grafting with iliac crest marrow. The furcation is completely filled with bone (B), but ankylosis (AN) and root resorption (RS) can be seen. (b) Higher magnification of the area in (a) showing ankylosis and resorption. (OC, osteoclasts.)

These studies, where various types of bone graft were placed in intrabony defects or inter-radicular lesions, revealed that cells survived transplantation only in iliac bone marrow grafts. Transplantation of iliac bone marrow grafts almost consistently resulted in bone fill in the experimental defects, but healing was frequently accompanied by ankylosis and root resorption (Fig. 28-7). The iliac bone marrow grafts exerted an osteogeneic effect, and it was suggested that this was responsible for the induction of root resorption (Ellegaard *et al*. 1973, 1974). Bone grafts harvested from jaw bone and xenografts did not actively contribute to bone formation, but served as a scaffold for new bone formation (i.e. an osteoconductive effect). Often, however, these bone grafts were not reached by the new bone growing out from the host bone, but existed as isolated particles surrounded by a bone-like or cementum-like substance (Fig. 28-8). It was found that the treated bifurcation defects became filled mainly with granulation tissue derived from the periodontal ligament (Fig. 28-9). Nielsen *et al*. (1980) suggested that this invasion of ligament tissue inhibited bone formation and that the new cementum on the root surface in the bifurcation defects, including the cementum-like substance observed around the implanted bone particles, was formed by periodontal ligament cells (Fig. 28-8). Thus, it appeared from these studies that the key cells in periodontal regeneration are periodontal ligament cells rather than bone cells.

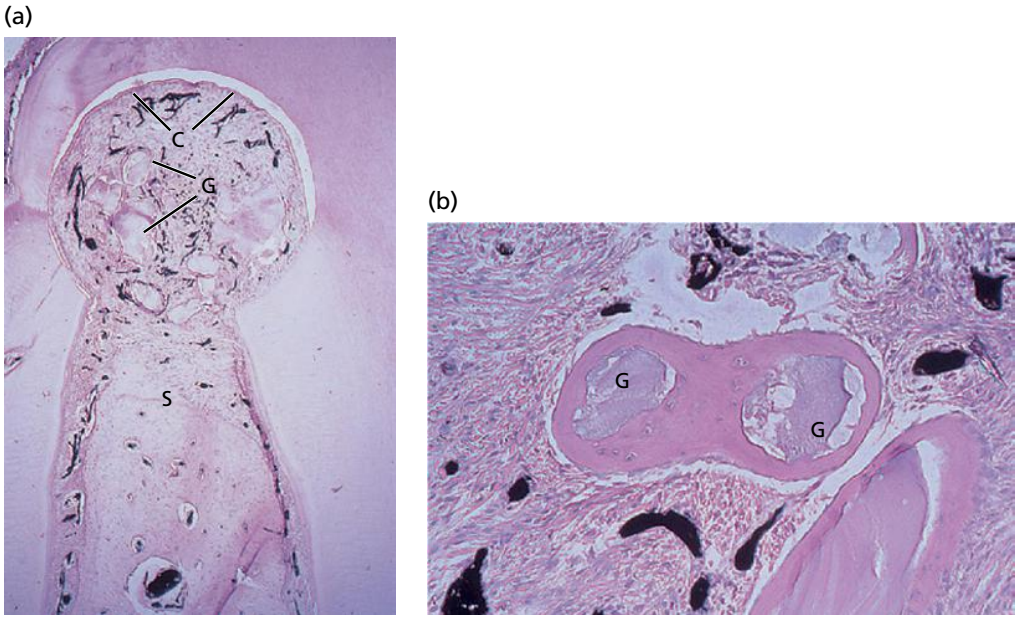

Fig. 28-8 (a) Microphotograph of a healed bifurcation defect following transplantation of non-vital bone grafts. The grafts (G) have not been reached by bone formation from the inter-radicular septum (S), but occur as isolated particles surrounded by "cementum". Cementum (C) and new connective tissue attachment formation have taken place along the entire circumference of the bifurcation. (b) High magnification of isolated bone grafts (G) with newly-formed "cementum" on the surface.

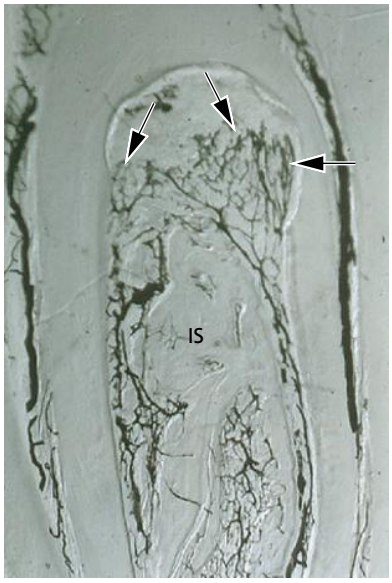

Fig. 28-9 Cleared specimen from a 1-week-old bifurcation defect treated with bone grafts. Judging from the course of the blood vessels, the granulation tissue in the defect has developed mainly from the periodontal ligament (arrows) and only to a minor extent from the inter-radicular septum (IS).

Regenerative capacity of bone cells

The ability of newly formed tissue originating from bone to produce a new connective tissue attachment was examined in a study by Karring *et al*. (1980). Roots of periodontitis-affected teeth were extracted and placed in surgically created sockets in edentulous areas of dogs. The implanted roots were covered with tissue flaps (submerged) and the results of healing were examined histologically after 3 months. A periodontal ligament was re-established in the apical portion of the re-implanted roots where, at the time of implantation, remnants of periodontal ligament tissue were preserved. In the coronal portion of the roots which were previously exposed to periodontitis and then scaled and planed, healing had consistently resulted in ankylosis and root resorption (Fig. 28-10). On the basis of this finding, it was concluded that tissue derived from bone lacks cells with the potential to produce a new connective tissue attachment.

Regenerative capacity of gingival connective tissue cells

Another experiment (Nyman *et al*. 1980) examined the potential of gingival connective tissue to produce a new connective tissue attachment. Teeth were treated as described in the experiment above but were not transplanted into sockets. Instead they were placed in bone concavities prepared on the buccal aspect of the jaw and subsequently covered by tissue flaps. Thus, half the circumference of the roots was in contact with bone while the remaining half faced the gingival connective tissue at the subsurface of the flaps. Histologic examination after 3 months of healing showed areas with periodontal ligament in the apical portion of the roots where, at the time of implantation, periodontal ligament tissue was preserved. In the coronal, previously exposed part of the roots, no signs of new connective tissue attachment were present. The root portion located in contact with gingival connective tissue demonstrated connective tissue with fibers oriented parallel to the root surface and without attachment to the root. However, root resorption occurred at the majority of the surfaces (Fig. 28-11). On the basis of this result it was concluded that gingival connective tissue also lacks

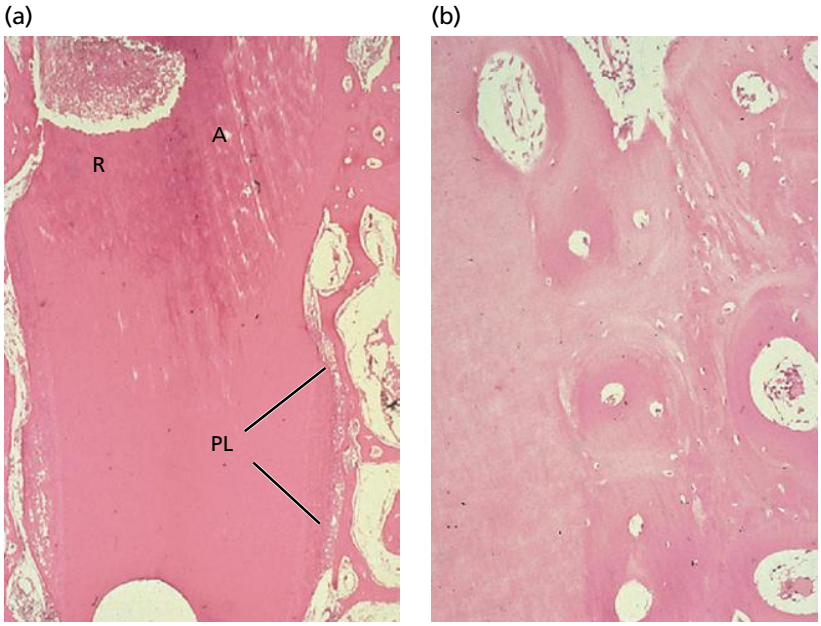

Fig. 28-10 (a) Microphotograph of a re-implanted root after 3 months of healing. A periodontal ligament (PL) has become re-established in the apical portion of the root, whereas ankylosis (A) and root resorption (R) are the predominant features in the coronal portion. (b) High magnification of the ankylosis seen in (a).

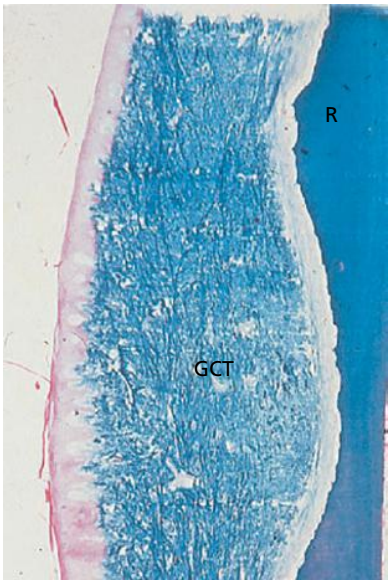

Fig. 28-11 Microphotograph of root (R) which has been re-implanted with its surface facing the gingival connective tissue (GCT). The surface exhibits extensive resorption.

cells with the potential to produce a new connective tissue attachment.

Regenerative capacity of periodontal ligament cells

In the experiments described above, root resorption was also observed occasionally in the apical portion of the extracted and re-implanted roots (Karring *et al*. 1980; Nyman *et al*. 1980). It was suggested that this occurred because the periodontal ligament tissue retained on this part of the root had been injured during extraction, thereby allowing bone or gingival connective tissue to contact the root surface during healing and induce resorption. It was assumed that this damage to the retained periodontal ligament tissue had also restricted its potential to proliferate in the coronal direction along the root surface. Indeed, in a later study (Karring *et al*. 1985), where periodontitis-involved roots were retained in their sockets and subsequently submerged, significant amounts of new connective tissue attachment formed on the coronal portion of the roots (Fig. 28-12). The finding of new attachment only on the roots with a non-impaired periodontal ligament, and never on the extracted and re-implanted roots with an impaired ligament, indicates that periodontal ligament tissue contains cells with the potential to form a new connective tissue attachment on a detached root surface.

Active root resorption occurred consistently at the root surfaces above the coronal extension of the new

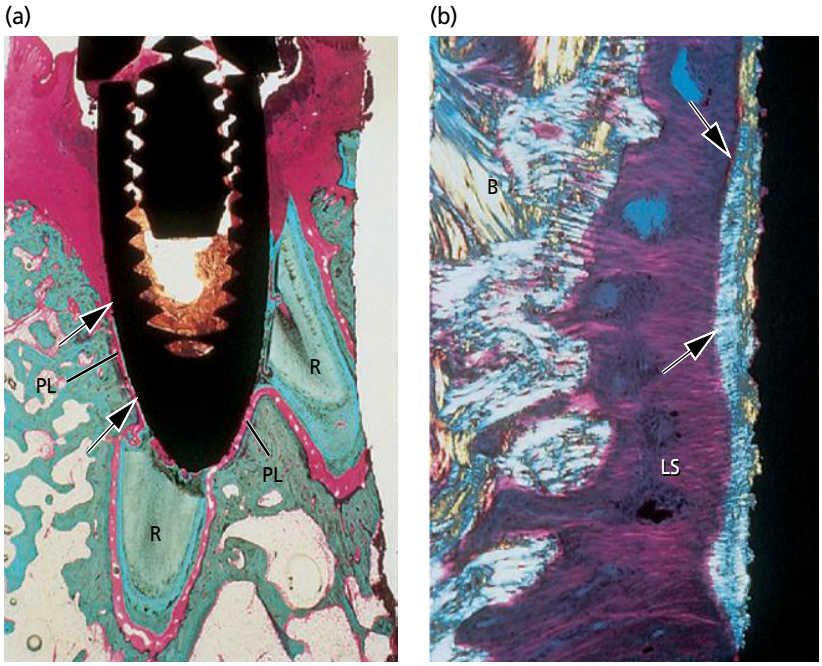

Fig. 28-13 (a) Microphotograph of a titanium implant placed in contact with retained root tips. A distinct cementum layer (arrows) and periodontal ligament (PL) in continuity with that on the roots (R) is visible on the implant surface. (b) High magnification in polarized light of the periodontal ligament formed around the implant seen in (a). A cementum layer (arrows) with Sharpey's fibers is present at the implant surface. Principal fibers, oriented perpendicular to the surface, are running across the ligament space (LS) and are inserting in the opposing bone (B) as in natural teeth (see Fig. 1-71).

attachment (Fig. 28-12). It was suggested that this resorption was induced by gingival connective tissue which had proliferated apically from the covering tissue flap. Thus, only cells in the periodontal ligament seem capable of regenerating lost periodontal attachment.

The final evidence that the progenitor cells for new attachment formation reside in the periodontal ligament was provided by studies in which titanium dental implants were placed in contact with retained root tips whose periodontal ligament served as a source of cells which could populate the implant surface during healing (Buser *et al*. 1990a, b; Warrer *et al*. 1993). Microscopic analysis revealed that a distinct layer of cementum with inserting collagen fibers had formed on the surfaces of the implants (Fig. 28-13a), and that these fibers, often oriented perpendicular to the surface, were embedded in the opposite bone (Fig. 28-13b). Control implants (Fig. 28-14) placed without contact with retained roots healed with the characteristic features of osseointegration (i.e. direct contact between bone and implant surface).

Further proof of the ability of periodontal ligament cells to produce a new connective tissue attachment was provided by Parlar *et al*. (2005) using a novel and unique experimental model in dogs. After resection of the crowns of the canine teeth in the dogs, the roots were hollowed to a depth of 5 mm, leaving a thin dentinal wall. Slits were then prepared in the cavity wall to create passages from this chamber to the surrounding periodontal ligament. A titanium implant was placed into the center of each

Fig. 28-14 Microphotograph of a titanium implant placed without contact with retained roots (control). This implant has healed with a direct contact between the bone and the implant surface (osseointegration).

chamber, and finally a collagen barrier was placed over the chamber before the roots were submerged. Histologic analysis after 4 months of healing revealed that a periodontal ligament, bone, and root cementum had formed between the implant and the dentinal wall of the chamber. Due to the invasion of

periodontal ligament tissue through the slits into the chamber, cementum had formed on the implant as well as on the dentinal wall, and a periodontal ligament was consistently interposed between the implant and the bone and between the bone and the dentinal wall.

Thus, there is strong evidence that the progenitor cells for periodontal attachment formation reside in the periodontal ligament and not in the alveolar bone as previously assumed (Melcher *et al*. 1987).

Role of epithelium in periodontal wound healing

Some of the roots in the experiment described above (Karring *et al*. 1985) penetrated the covering mucosa at early stages of healing, thereby allowing the epithelium to grow apically along the root surface. The amount of new connective tissue attachment on these roots was considerably smaller than that formed on the roots which remained submerged throughout the study. This finding and those of other investigators (Moscow 1964; Kon *et al*. 1969; Proye & Polson 1982) indicate that the apical migration of epithelium reduces the coronal gain of attachment, evidently by preventing periodontal ligament cells from repopulating the root surface (Fig. 28-15).

Down-growth of epithelium into the periodontal lesion most likely occurs to a varying extent during healing following most flap and grafting procedures applied in regenerative periodontal therapy, which may explain the varying results reported. This view is supported by the results of the monkey study by Caton *et al*. (1980). These investigators examined healing in ligature-induced periodontal lesions following treatment with four different regenerative surgical procedures:

1. Root planing and soft tissue curettage
2. Widman flap surgery without bone grafting
3. Widman flap surgery with the placement of frozen autogeneous red bone marrow and cancellous bone
4. Beta-tricalcium phosphate in intrabony defects.

Healing following all of these treatment modalities resulted in the formation of a long junctional epithelium extending to, or close to, the same level as before treatment.

Fig. 28-15 Microphotograph illustrating an intrabony defect after regenerative treatment. New bone (NB) has formed in the defect, but epithelium has migrated apically along the root surface to the notch (arrow) in the root surface indicating the bottom of the defect before treatment.

Root resorption

In the experimental studies described previously, granulation tissue, derived from gingival connective tissue or bone, caused root resorption when contacting the curetted root surface during healing following surgery (Karring *et al*. 1980, 1985; Nyman *et al*. 1980). It should be expected, therefore, that this phenomenon would occur as a frequent complication of periodontal surgery, particularly following those procedures which include the placement of grafting materials to stimulate bone formation. The reason why root resorption is rarely seen is most likely that, postoperatively, the dentogingival epithelium migrates apically to form a protective barrier against the root surface (Fig. 28-15). This view is supported by the results of an experimental study in monkeys (Karring *et al*. 1984) in which roots, which previously had been subjected to ligature-induced periodontitis, were extracted and re-implanted in contact with bone and connective tissue, and covered with a tissue flap (submerged). After varying time intervals, the submerged roots were exposed to the oral cavity by a second incision (wounding) through the covering mucosa, thereby permitting the epithelium to migrate into the wound. In specimens where the wounding occurred within 2 weeks (Fig. 28-16), the previously diseased part of the roots was covered by epithelium and showed no signs of resorption. With increasing intervals between implantation of the roots and the wounding, a steadily diminishing part of the diseased root surface was covered by epithelium, and root resorption and ankylosis became progressively more pronounced (Fig. 28-17). This observation concurs with results presented by Björn *et al*. (1965) who treated 11 periodontally diseased teeth in seven human volunteers, using the submerging technique which prevented apical migration of the dentogingival epithelium. The authors reported that root resorption was indeed a common complication following this kind of therapy.

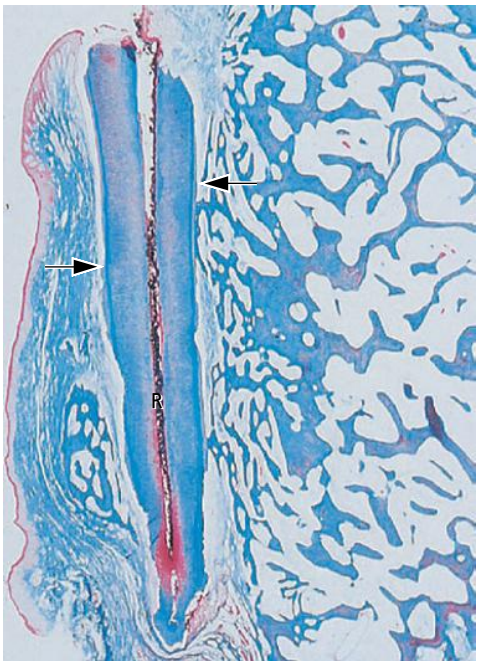

Fig. 28-16 Microphotograph of an implanted root (R) where epithelium was allowed to migrate into the wound after 2 weeks. The epithelium has migrated along the coronal, previously periodontitis-involved, root surfaces down to the level indicated by the arrows. In the areas covered by epithelium, there are no signs of resorption. Apical to this level, the root surfaces demonstrate root resorption.

Fig. 28-17 Microphotograph of an implanted root (R) where epithelium was allowed to migrate into the wound after 4 weeks. The epithelium (arrows) covers only the coronal cut root surface. Extensive resorption is seen on the surface facing the gingival connective tissue (GCT) and resorption and ankylosis are seen on the surface facing the bone tissue (B).

Regenerative concepts

One of the first methods used in attempts to obtain new attachment was scaling and root planing combined with soft tissue curettage (i.e. mechanical removal of the diseased root cementum and the pocket epithelium). Studies in humans (e.g. McCall 1926; Orban 1948; Beube 1952; Waerhaug 1952; Schaffer & Zander 1953; Carranza 1954, 1960) and in animals (e.g. Beube 1947; Ramfjord 1951; Kon *et al.* 1969) showed that this type of periodontal therapy resulted not only in the establishment of gingival health, but also in a reduction of the initially recorded pocket depth. This decrease in the depth of the periodontal pocket was assumed to be partly the result of shrinkage of the initially inflamed gingiva, but partly also the effect of the formation of a new connective tissue attachment in the apical part of the pocket.

The possibility of obtaining new attachment became widely accepted with the work of Prichard (1957a, b), in which new attachment formation in intrabony periodontal lesions was reported as a predictable outcome of treatment. Seventeen cases were presented of whom four were subjected to a re-entry surgical procedure, revealing that these defects were filled with bone. The technique of Prichard (1957b, 1960) was only used for the treatment of three-wall intrabony defects, and the results obtained suggested that the morphology of the periodontal bony defect was essential for the establishment of a predictable prognosis. Goldman and Cohen (1958) introduced a classification of periodontal intrabony defects which was based on the number of osseous walls surrounding the defect, being either three-wall, two-wall or one-wall defects or a combination of such situations (Fig. 28-18).

The technique of Prichard (1957a, b, 1960) included the elevation of tissue flaps in order to get access to the defect. All granulation tissue in the defect was removed and the root surface was scaled and planed. In order to enhance regeneration of bone, small perforations were made with a bur at several sites on the bone walls. The flaps were sutured to accomplish complete coverage of the defect. Many clinical investigators have claimed that new attachment resulted following this type of treatment, but there is little quantitative or qualitative documentation (Patur & Glickmann 1962; Wade 1962, 1966; Ellegaard & Löe 1971). Patur and Glickmann (1962) reported a clinical study including 24 intrabony defects treated according to the Prichard technique (Prichard, 1957a, b). The outcome was evaluated by comparing preoperative and postoperative radiographs, measurements of the alveolar bone level adjacent to the root, and study casts taken during operation and postoperatively after reflecting buccal and lingual flaps. The authors reported that new attachment had occurred in two-wall and three-wall intrabony defects but not in one-wall defects. Results from a study by Ellegaard

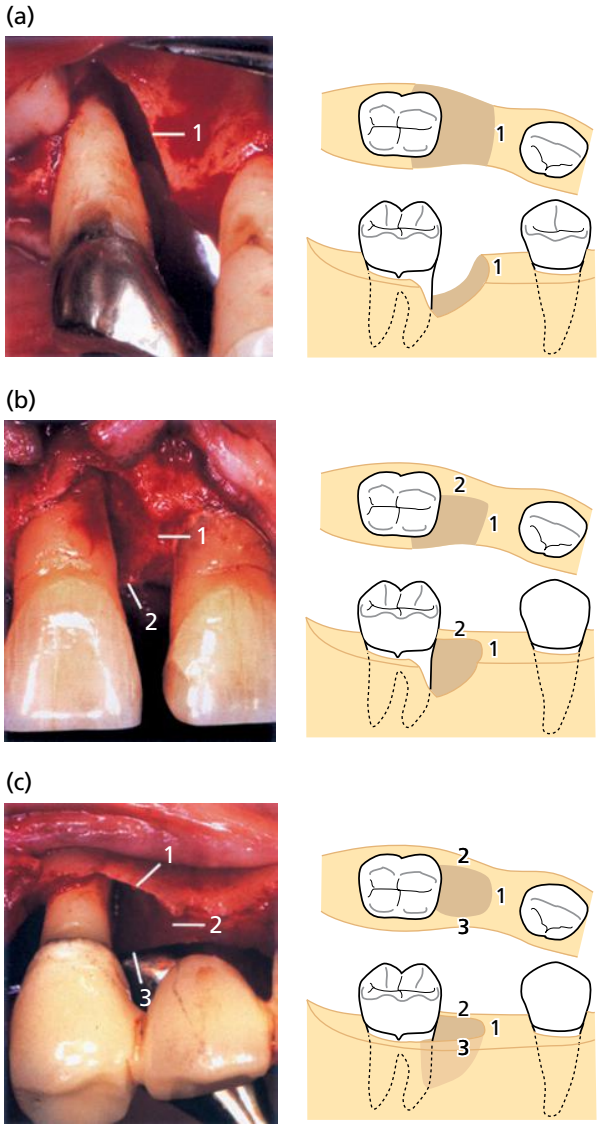

Fig. 28-18 Progression of periodontitis at a different rate on neighboring tooth surfaces results in the development of intrabony defects. Based on the number of surrounding bone walls, such defects are classified as one-wall (a), two-wall (b) or three-wall (c) defects.

and Löe (1971) comprising 191 defects in 24 patients with periodontal disease indicated that complete regeneration, determined radiographically and by periodontal probing, had occurred in around 70% of the three-wall defects, in 40% of the combined two-wall and three-wall defects, and in 45% of the two-wall defects.

In a later study by Rosling *et al*. (1976), 124 intrabony defects in 12 patients were treated by means of the modified Widman flap procedure (Ramfjord & Nissle 1974). Following treatment the patients were recalled twice per month for professional tooth cleaning. Re-examination performed clinically and on radiographs 2 years after therapy demonstrated bone fill-in of two-wall as well as three-wall defects. The authors suggested that this regrowth of bone was also associated with the formation of new connective tissue attachment and ascribed the successful healing mainly to the optimal standard of oral hygiene which was maintained in all patients during healing. A clinical study with almost identical results was presented by Polson and Heijl (1978). The results of several histologic studies in animals and humans, on the other hand, indicate that formation of new periodontal attachment is by no means predictable following subgingival curettage or flap surgery (Listgarten & Rosenberg 1979; Caton & Nyman 1980; Caton *et al*. 1980; Steiner *et al*. 1981; Stahl *et al*. 1983; Bowers *et al*. 1989a).

Grafting procedures

In a number of clinical trials and animal experiments, the flap approach was combined with the placement of bone grafts or implant materials into the curetted bony defects with the aim of stimulating periodontal regeneration. The various graft and implant materials used so far can be placed into four categories:

1. *Autogenous grafts*: grafts transferred from one position to another within the same individual. This type of graft comprises cortical bone or cancellous bone and marrow, and is harvested either from intraoral or extraoral donor sites.
2. *Allogeneic grafts*: grafts transferred between genetically dissimilar members of the same species. Frozen cancellous bone and marrow and freeze-dried bone have been used.
3. *Xenogeneic grafts*: grafts taken from a donor of another species.
4. *Alloplastic materials*: synthetic or inorganic implant materials which are used as substitutes for bone grafts.

The rationale behind the use of bone grafts or alloplastic materials is the assumption that both the regrowth of alveolar bone and the formation of new attachment would be stimulated because these materials may either (1) contain bone-forming cells (osteogenesis) or (2) serve as a scaffold for bone formation (osteoconduction), or because (3) the matrix of the bone grafts contains bone-inducing substances (osteoinduction) (Urist 1980; Brunsvold & Mellonig 1993). Such complete regeneration of the periodontal attachment apparatus following grafting procedures would imply, however, that cells derived from bone possess the ability to form new cementum with inserting collagen fibers on a previously periodontitis-involved root surface (Melcher *et al*. 1987). This assumption is in conflict with current knowledge about the biology of periodontal wound healing, that repopulation of the detached root surface with cells from the periodontal ligament is the prerequisite for new attachment formation. This means that all therapeutic procedures involving the placement of bone grafts or bone substitute implants are based on a biologic concept which cannot explain how such treatment results in regeneration of the periodontium.

The effect of using bone grafts or alloplastic materials for periodontal regeneration has mainly

been examined in case reports, while histologic evidence of new attachment and controlled clinical studies is limited. The results from such reports vary and the documentation presented usually consists of preoperative and postoperative probing attachment levels (PALs), radiographic interpretations or re-entry procedures.

Root surface biomodification

Much research has been directed to altering the periodontitis-involved root surface in a manner that will promote the formation of a new connective tissue attachment. Removal of bacterial deposits, calculus, and endotoxins from the cementum is generally considered essential for the formation of a new connective attachment (Garrett 1977). However, it was suggested by Stahl *et al*. (1972) that demineralization of the root surface, exposing the collagen of the dentin, would facilitate the deposition of cementum by inducing mesenchymal cells in the adjacent tissue to differentiate into cementoblasts. The biologic concept is that exposure of collagen fibers of the dentin matrix may facilitate adhesion of the blood clot to the root surface and thereby favor migration of the fibroblasts. However, it is doubtful whether this concept is in accordance with current knowledge about periodontal wound healing since there is no evidence that the exposure of collagen fibers of the dentin matrix facilitates repopulation of the root surface with cells derived from the periodontal ligament. As mentioned previously, periodontal ligament cells are required for the accomplishment of a new connective tissue attachment.

Several studies using various animal models have demonstrated an improved healing response histologically following citric acid and tetracycline root surface demineralization (Register & Burdick 1976; Crigger *et al*. 1978; Polson & Proye 1982; Claffey *et al*. 1987). However, in a study in dogs where naturally occurring furcations were treated with citric acid, several specimens demonstrated ankylosis and root resorption (Bogle *et al*. 1981). This finding corroborates that of Magnusson *et al*. (1985) in monkeys, where citric acid conditioning in combination with coronally displaced tissue flaps was evaluated after 6 months. These investigators found root resorption on 28 of 40 surfaces examined and 21 of these also showed ankylosis.

New connective tissue attachment following citric acid demineralization of root surfaces has been demonstrated histologically in humans (Cole *et al*. 1980; Frank *et al*. 1983; Stahl *et al*. 1983; Stahl & Froum 1991). Cole *et al*. (1980) showed histologic evidence of a new connective tissue attachment and bone formation coronal to reference notches placed in the apical extent of calculus identified on the root surface at the time of surgery. However, despite histologic evidence of regeneration following root surface biomodification with citric acid, results of controlled clinical trials failed to show any improvements in clinical conditions compared to controls not treated with acid (Moore *et al*. 1987; Fuentes *et al*. 1993).

Modification of the root surface with the use of topically applied enamel matrix proteins (Emdogain®) during surgery and following demineralization with ethylenediaminetetra-acetic acid (EDTA) has been introduced to enhance periodontal regeneration. The biologic concept is that the application of enamel matrix proteins (including amelogenins) may promote periodontal regeneration because it mimics events that take place during the development of the periodontal tissues (Hammarström 1997; Gestrelius *et al*. 2000). This view is based on the finding that the cells of Hertwig's epithelial root sheath deposit enamel matrix proteins on the root surface prior to cementum formation and that these proteins are the initiating factor for the formation of cementum. The commercially available product Emdogain®, a purified acid extract of porcine origin, contains enamel matrix derivatives (EMDs), which are supposed to be able to promote periodontal regeneration. However, it is not completely clear how this concept is in accordance with current knowledge about periodontal wound healing, since no evidence has been provided that it is cells derived from the periodontal ligament that are encouraged to repopulate the root surface after treatment. In fact, a study in dogs (Araùjo *et al*. 2003) where re-implanted roots that had been extracted and deprived of vital cementoblasts and subsequently treated with EMD failed to prevent ankylosis and root resorption, indicating that the root surfaces did not become repopulated with cells with the capacity to form cementum. A subsequent study *in vitro* also failed to confirm that EMDs have any significant effect on periodontal ligament cell proliferation (Chong *et al*. 2006).

In case series reports, a 4–4.5 mm gain of clinical attachment and about a 70% bone fill in intrabony defects were reported following treatment with EMD (Heden *et al*. 1999; Heden 2000). In a multicenter clinical study involving 33 subjects with 34 paired intrabony defects, application of EMD resulted in larger amounts of PAL gain (2.2 mm) and statistically significantly more bone gain (2.6 mm) than open-flap debridement after 36 months, evaluated clinically and radiographically (Heijl *et al*. 1997). Similar results were reported in another split-mouth clinical trial (23 patients) (Froum *et al*. 2001). In that study a probing pocket depth (PPD) reduction of 4.9 mm, a PAL gain of 4.3 mm, and a bone gain of 3.8 mm (evaluated by re-entry surgery) were observed after EMD application in 53 intrabony defects. These values were statistically significantly larger than those obtained by flap surgery (2.2 mm, 2.7 mm, and 1.5 mm, respectively, in 31 defects).

In a prospective multicenter randomized controlled clinical trial, the clinical outcomes of papilla preservation flap surgery [simplified papilla preservation flap (SPPF)] with or without the application of

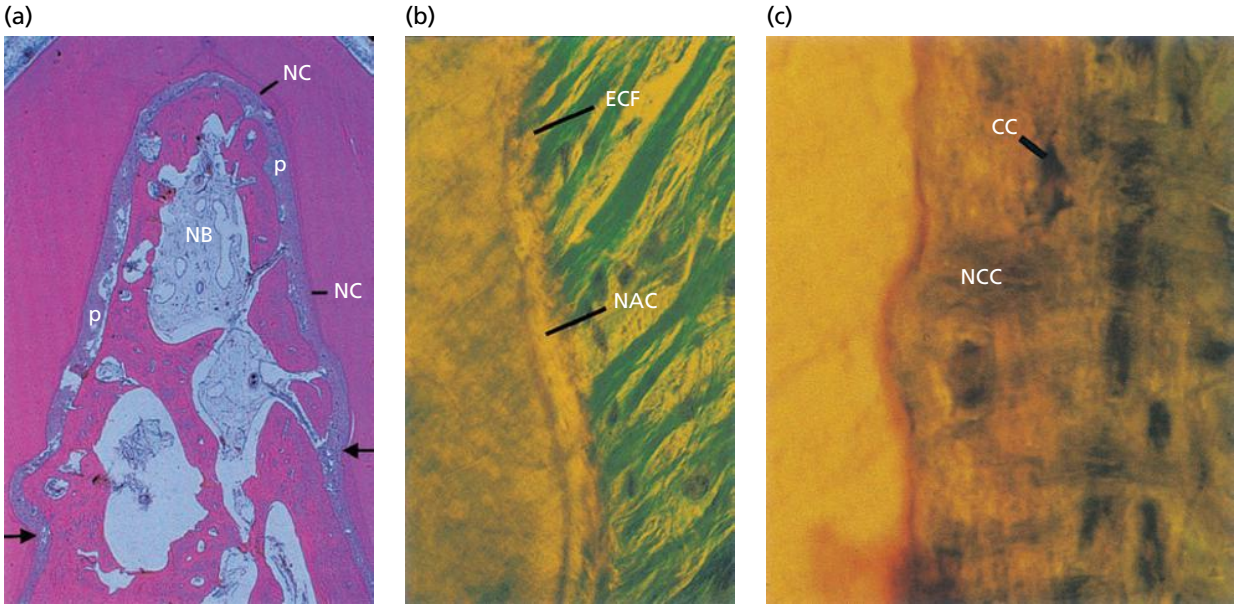

Fig. 28-19 (a) Photomicrograph of a grade III furcation defect in a dog following root surface biomodification with enamel matrix proteins and subsequently covered with a resorbable membrane. The defect has healed completely with bone (NB), a periodontal ligament (p), and new cementum (NC). The arrows indicate the apical extension of the lesion. (b) Cementum (NAC) formed on the root surface in the apical portion of the defect was acellular with inserting extrinsic collagen fibers (ECF), while (c) new cellular cementum (NCC) had formed in the coronal portion. (cc, cells.)

enamel matrix proteins were compared (Tonetti *et al*. 2002). A total of 83 test and 83 control patients with similar baseline periodontal conditions and defect characteristics were treated with either SPPF and Emdogain® or with SPPF alone. The test defects exhibited significantly more clinical attachment level (CAL) gain than the controls (3.1 ± 1.5 mm and 2.5 ± 1.5 mm, respectively).

When application of EMD was compared with GTR treatment, similar clinical improvements were obtained. In a randomized controlled clinical study, Pontoriero *et al*. (1999) compared EMD application with GTR with resorbable (two kinds: Guidor and Resolut) and non-resorbable (e-PTFE) membranes in intrabony defects. After 12 months, there were no significant differences among the groups, and EMD application resulted in a PPD reduction of 4.4 mm and a PAL gain of 2.9 mm, while the corresponding values from the membrane-treated sites (both GTR groups combined) were 4.5 mm and 3.1 mm, respectively. Silvestri *et al*. (2000) reported a PPD reduction of 4.8 mm and a PAL gain of 4.5 mm after EMD application in intrabony defects versus 5.9 mm and 4.8 mm, respectively, after GTR with non-resorbable membranes. Similar results were reported by other investigators (Sculean *et al*. 1999a, b; Silvestri *et al*. 2000, 2003; Sanz *et al*. 2004). There are studies indicating that following the application EMD in intrabony defects, clinical improvements can be achieved by the additional use of some bone graft materials (Zucchelli *et al*. 2003; Gurinsky *et al*. 2004; Trombelli *et al*. 2006), although others have failed to demonstrate a beneficial effect of this combined treatment (Sculean *et al*. 2005).

Histologic evidence of new cementum formation with inserting collagen fibers on a previously periodontitis-affected root surface and the formation of new alveolar bone in human specimens have been demonstrated following EMD treatment (Mellonig 1999; Sculean *et al*. 1999b). However, while in the study of Mellonig (1999) healing had occurred with acellular cementum on the root surface, the newly formed cementum in the study of Sculean *et al*. (1999b) displayed a predominantly cellular character. The ability of EMD to produce regeneration has been confirmed in controlled animal experiments (Fig. 28-19), following the treatment of intrabony, furcation, and dehiscence defects (Hammarström *et al*. 1997; Araùjo & Lindhe 1998; Sculean *et al*. 2000). In a later study, it was shown in monkeys that the combined application of EMD and autogenous bone grafts may improve periodontal regeneration in periodontal defects, compared to flap surgery alone (Cochran *et al*. 2003).

Guided tissue regeneration

The experimental studies (Karring *et al*. 1980; Nyman *et al*. 1980; Buser *et al*. 1990a, b; Warrer *et al*. 1993) described previously have documented that the progenitor cells for the formation of a new connective tissue attachment reside in the periodontal ligament. Consequently, it should be expected that a new connective tissue attachment would be predictably achieved if such cells populate the root surface during healing. This view was confirmed in a study in monkeys in which both gingival connective tissue and gingival epithelium were prevented from contacting the root surface during healing by the use of

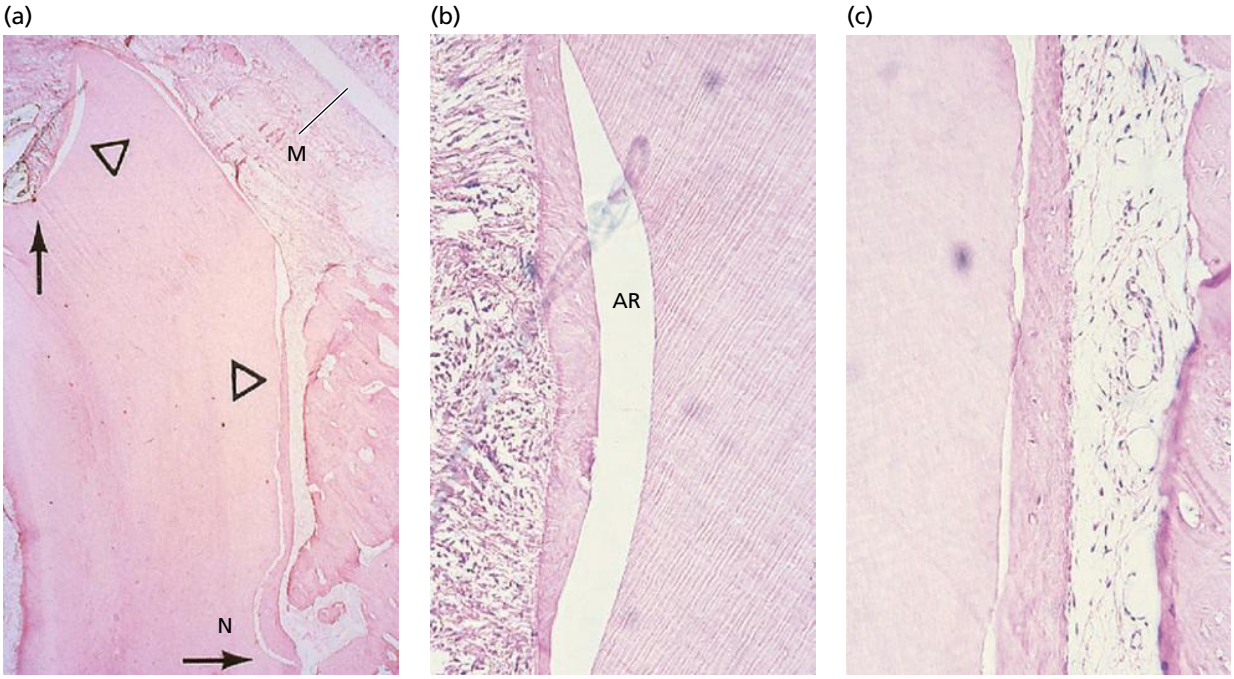

Fig. 28-20 (a) Microphotograph of membrane (M)-covered root. Newly formed cementum is visible along the entire length of the buccal root surface coronal to the notch (N) and also on part of the coronal cut surface (arrow). (b, c) Higher magnifications of the areas at the upper and lower triangles in (a), showing that collagen fibers are inserted into the newly formed cementum. (AR, artifact.)

a barrier membrane (Gottlow *et al*. 1984). After reduction of the supporting tissues around selected experimental teeth, the root surfaces were exposed to plaque accumulation for 6 months. Soft tissue flaps were then raised and the exposed root surfaces were curetted. The crowns of the teeth were resected and the roots were submerged. However, prior to complete closure of the wound, a membrane was placed over the curetted root surfaces on one side of the jaws in order (1) to prevent gingival connective tissue from contacting the root surface during healing, and (2) to provide a space for in-growth of periodontal ligament tissue. No membranes were placed over the contralateral roots. The histologic analysis after 3 months of healing demonstrated that the roots covered with membranes exhibited considerably more new attachment than the non-covered roots (Fig. 28-20). In four of the nine test roots, new cementum covered the entire length of the root. In all control specimens, the surface coronal to the newly formed cementum presented multinucleated cells and resorption cavities. In one control specimen, virtually half the root was resorbed. Coronal regrowth of alveolar bone had occurred to a varying extent in test and control roots, and no relationship was found between the amount of new cementum formation and the degree of bone regrowth. The results of this study strongly suggested that the exclusion of epithelial and gingival connective tissue cells from the healing area by the use of a physical barrier may allow (guide) periodontal ligament cells to repopulate the detached root surface. This observation provided the basis for the clinical application of the treatment principle termed "guided tissue regeneration" (GTR).

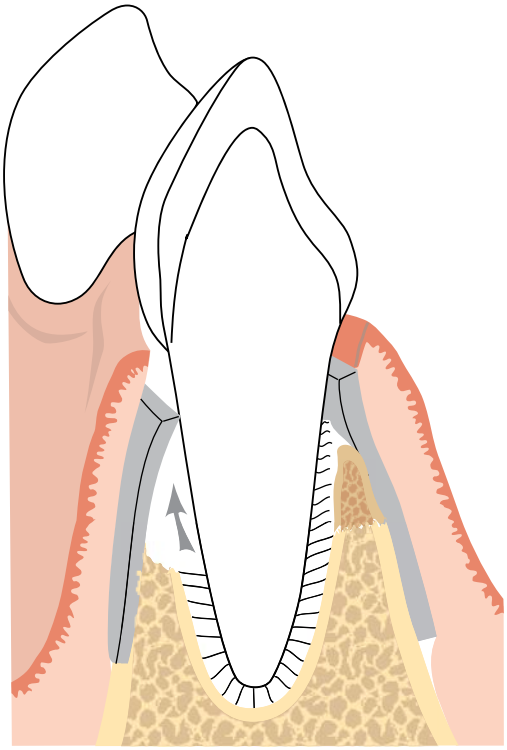

Fig. 28-21 Schematic diagram showing the placement of the physical barrier which prevents the epithelium and gingival connective tissue from contacting the root surface during healing. At the same time, the membrane allows cells from the periodontal ligament (arrow) to repopulate the previously periodontitis-involved root surface.

Thus, GTR treatment involves the placement of a physical barrier to ensure that the previous periodontitis-affected root surface becomes repopulated with cells from the periodontal ligament (Fig. 28-21).

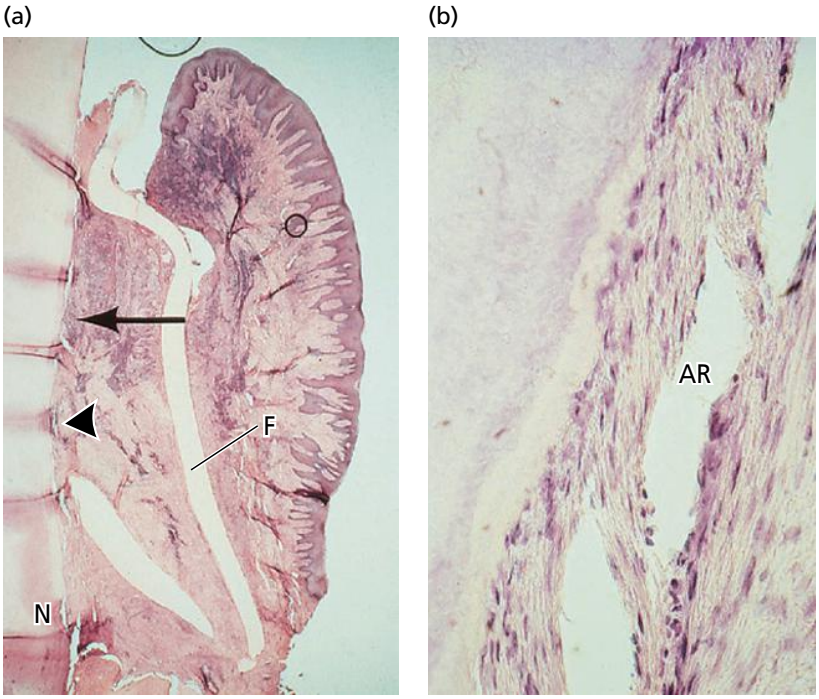

Fig. 28-22 (a) Microphotograph of a human tooth 3 months following guided tissue regeneration treatment using a Millipore filter (F). New cementum with inserting collagen fibers (about 5 mm) has formed from the notch (N) to the level of the arrow. Bone formation beneath the filter is lacking, probably due to the inflammatory infiltrate seen in the tissues adjacent to the filter. (b) Higher magnification of the area indicated by the arrowhead in (a) showing newly formed cementum with inserting collagen fibers. (AR, artifact.)

Treatment of the first human tooth with GTR was reported by Nyman *et al*. (1982). Due to extensive periodontal destruction, the tooth was scheduled for extraction. This offered the possibility of obtaining histologic documentation of the result of the treatment. Following elevation of full thickness flaps, scaling of the root surface, and removal of all granulation tissue, an 11-mm deep periodontal lesion was ascertained. Prior to flap closure, a membrane was adjusted to cover parts of the detached root surfaces, the osseous defect, and parts of the surrounding bone. Histologic analysis after 3 months of healing revealed that new cementum with inserting collagen fibers had formed on the previously exposed root surface (Fig. 28-22). In a later study (Gottlow *et al*. 1986), 12 cases treated with GTR were evaluated clinically, and for five of these cases histologic documentation was also presented. The results showed that considerable, but varying, amounts of new connective tissue attachment had formed on the treated teeth. Frequently, however, bone formation was incomplete. The varying results were ascribed to factors such as the amount of remaining periodontal ligament, the morphology of the treated defect, technical difficulties regarding membrane placement, gingival recession, and bacterial contamination of the membrane and the wound during healing.

GTR has been studied in a number of clinical trials (e.g. Tonetti *et al*. 2004) for the treatment of various periodontal defects such as intrabony defects (for review see Cortellini & Bowers 1995), furcation involvements (for review see Machtei & Schallhorn 1995; Karring & Cortellini 1999), and localized gingival recession defects (Pini-Prato *et al*. 1996). The efficiency of GTR in producing periodontal regeneration in these defects has been documented in animal studies (Gottlow *et al*. 1990; Araùjo *et al*. 1998; Laurell *et al*. 2006) and in several controlled clinical trials.

The clinical outcomes of GTR are most frequently evaluated by changes in CAL, bone levels, PPD, and the position of the gingival margin. In some of the studies on grade II and III furcations, horizontal changes in clinical attachment, bone level, and pocket depth were also measured. However, evidence of true regeneration of periodontal attachment can only be provided by histologic means.

Assessment of periodontal regeneration

In most studies on the effect of regenerative periodontal surgery, the outcomes are evaluated by probing attachment level measurements, radiographic analysis or re-entry operations. However, such methods do not provide proof of a true gain of attachment (i.e. formation of cementum with inserting collagen fibers coronal to the attachment level before treatment).

Periodontal probing

The inability of periodontal probing to determine accurately the coronal level of the connective tissue attachment has been demonstrated by several investigators (Listgarten *et al*. 1976; Armitage *et al*. 1977; Van der Velden & de Vries 1978). It is known from these studies that, in the inflamed periodontium, the probe does not stop precisely at the coronal level of the connective tissue attachment. Usually, it penetrates 0.5 mm or more into the connective tissue, surpassing the transition between the apical extension of the dentogingival epithelium and the coronal level of

connective tissue attachment. After therapy, when the inflammatory lesion is resolved, the probe tip tends to stop coronal to the apical termination of the epithelium. Following treatment of intrabony defects, new bone may form so close to the tooth surface that the probe cannot penetrate (Caton & Zander 1976). Thus, a gain of PAL following therapy does not necessarily mean that a true gain of connective tissue attachment has been accomplished. More likely, it is a reflection of improved health of the surrounding soft tissues which offer increased resistance to probe penetration.

Radiographic analysis and re-entry operations

Healing of intrabony defects following regenerative surgery is often documented by measurements made on radiographs obtained in a standardized and reproducible manner and/or assessed in conjunction with a re-entry operation. Analysis of radiographs before and after therapy, and inspection of the treated area during a re-entry operation, can certainly provide evidence of new bone formation. However, such "bone fill" does not prove formation of new root cementum with inserting collagen fibers (i.e. a new periodontal ligament). In fact, it was demonstrated by Caton and Zander (1976) and Moscow *et al*. (1979) that despite the fact that bone regeneration has occurred adjacent to the root in intrabony defects, a junctional epithelium is interposed between the newly formed bone and the curetted root surface. This means that radiographic analysis and assessments of bone formation by re-entry operations are unreliable methods for the documentation of new attachment formation.

Histologic methods

In several studies healing has been analyzed in histologic sections of block biopsies obtained after various forms of regenerative periodontal therapy. Histologic analysis is the only valid method to assess the formation of a true new attachment, but it requires that the location of the attachment level prior to therapy can be assessed with reasonable accuracy. In a few studies, histologic reference notches were placed in the apical extent of calculus deposits, identified on the root surface at the time of surgery (Cole *et al*. 1980; Bowers *et al*. 1989b, c). Usually, however, a reference is obtained by producing a notch in the root surface at the level of the reduced bone height. Although such a notch may not reflect the exact extent of the periodontitis-involved root surface prior to treatment, it is considered an adequate landmark for the assessment of new attachment (Isidor *et al*. 1985). It was also suggested that clinical signs of probing attachment gain and bone fill can be accepted as evidence of periodontal regeneration in the evaluation of GTR procedures (Lindhe & Echeverria 1994). This suggestion was based on evidence of a new attachment apparatus in histologic specimens from human biopsies harvested following GTR treatment (Nyman *et al*. 1982; Gottlow *et al*. 1986; Becker *et al*. 1987; Stahl *et al*. 1990; Cortellini *et al*. 1993) and on the biologic concept of GTR (Karring *et al*. 1980, 1985, 1993; Nyman *et al*. 1980; Gottlow *et al*. 1984).

Conclusion

There is evidence that the progenitor cells for regeneration of a lost periodontal attachment are present in the periodontal ligament. Consequently, a periodontal regenerative procedure needs to encourage repopulation of the previous periodontitis-affected root surface with cells from the periodontal ligament.

GTR and conditioning of the root surface with enamel matrix proteins represent the best documented regenerative procedures for obtaining periodontal regeneration in periodontal lesions, although there is some uncertainty whether enamel matrix proteins in fact stimulate the proliferation of periodontal ligament cells.

Placement of bone grafts or bone substitute implants is based on a biologic concept which cannot explain how such treatment results in regeneration of the periodontium.

Part 9: Examination Protocols

Chapter 29

Examination of Patients

Giovanni E. Salvi,[1] Tord Berglundh,[2] and Niklaus P. Lang[1,3]

Patient's history

As a basis for comprehensive treatment planning and understanding of the patient's needs, social and economic situations, as well as general medical conditions, the history of the patient is a revealing documentation. In order to expedite history taking, a health questionnaire may be filled out by the patient prior to the initial examination. This questionnaire should be constructed in such a way that the professional can immediately identify compromising or risk factors that may modify the treatment plan and hence, may have to be discussed in detail with the patient during the initial visit. The assessment of the patient's history requires an evaluation of the following six aspects: (1) chief complaint, (2) social and family history, (3) dental history, (4) oral hygiene habits, (5) smoking history, and (6) medical history and medications.

Chief complaint and expectations

It is essential to realize the patient's needs and desires for treatment. If a patient has been referred for specific treatment, the extent of the desired treatment has to be defined and the referring dentist should be informed of the intentions for treatment. Self-referring patients usually have specific desires and expectations regarding treatment outcomes. These may not be congruent with the true assessment of a professional with respect to the clinical situation. Optimal treatment results for an individual patient may only be achieved if the patient's demands can be balanced with the objective evaluation of the disease and the projected treatment outcomes. Therefore, the patient's expectations have to be taken seriously and must be considered in the evaluation to achieve harmony with the clinical situation.

Social and family history

Before assessing the clinical condition in detail, it is advantageous to elucidate the patient's social environment and to get a feel for his/her priorities in life, including attitude towards periodontal therapy and rehabilitation with dental implants. Likewise, a family history may be important, especially with respect to aggressive forms of periodontitis.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Dental history

These aspects include an assessment of previous dental care and maintenance visits, if not documented by a referring dentist. In this context, information regarding signs and symptoms of periodontitis noted by the patient, such as migration and increasing mobility of teeth, bleeding gums, food impaction, and difficulties in chewing, have to be explored. Chewing comfort and the possible need for tooth replacement with dental implants is determined.

Oral hygiene habits

In addition to the exploration of the patient's routine dental care, including frequency and duration of daily toothbrushing, his/her knowledge about interdental cleansing devices and additional chemical supportive agents and regular use of fluorides should be assessed.

Smoking history

Since cigarette smoking has been documented to be the second most important risk factor after inadequate plaque control (Kinane *et al*. 2006) in the etiology and pathogenesis of periodontal diseases, the importance of smoking counseling cannot be overestimated. Moreover, based on the fact that cigarette smokers display an increased risk for biologic implant complications and implant loss compared with nonsmokers (Strietzel *et al*. 2007; Heitz-Mayfield & Huynh-Ba 2009), the assessment of the smoking history represents an important step in the consideration of candidates for implant therapy. Determination of the smoking status should include detailed information about exposure time and quantity. Further aspects of smoking cessation programs are presented in Chapter 35.

Medical history and medications

General medical aspects may be extracted from the health questionnaire constructed to highlight any medical risk factors for routine periodontal and/or implant therapy. The four major complexes of complications encountered in patients may be prevented by checking the medical history with respect to: (1) cardiovascular and circulatory risks, (2) bleeding disorders, (3) infective risks, and (4) allergic reactions. Further aspects are presented in Chapter 31.

In light of the increasing consumption of medications in the aging population, an accurate assessment of the patient's prescribed medications and their potential interactions and effects on therapeutic procedures has to be made. With respect to treatment planning with dental implants, it may be appropriate to contact the patient's physician for detailed information relevant to systemic risks (Bornstein *et al*. 2009).

Genetic testing before periodontal and implant therapy

Cytokine gene polymorphisms may modulate the host response to bacterial challenge and influence susceptibility to periodontitis and peri-implantitis. Based on current evidence, however, it may be considered premature to recommend systematic genetic screening of patients with periodontal diseases and candidates for implant therapy (Huynh-Ba *et al*. 2007, 2008).

Signs and symptoms of periodontal diseases and their assessment

Periodontal diseases are characterized by gingival color and texture alterations, for example redness and swelling, as well as an increased tendency to bleeding on probing (BoP) the gingival sulcus/pocket area (Fig. 29-1). In addition, the periodontal tissues may exhibit a reduced resistance to probing that is perceived as increased probing depth and/or tissue recession. Advanced stages of periodontitis may also be associated with increased tooth mobility as well as drifting or flaring of teeth (Fig. 29-2).

On radiographs, periodontitis may be recognized by moderate-to-advanced loss of alveolar bone (Fig. 29-3). Bone loss is defined either as "horizontal" or "angular". If bone loss has progressed at similar rates in the dentition, the crestal contour of the remaining bone will be even and bone loss is defined as "horizontal". In contrast, angular bony defects are the result of bone loss that has occurred at different rates around teeth/tooth surfaces and, hence, is defined as "vertical" or "angular" bone loss.

In a histologic section, periodontitisis is characterized by the presence of an inflammatory cell infiltrate within a 1–2-mm wide zone of gingival connective tissue adjacent to the subgingival biofilm on the tooth (Fig. 29-4). Within the infiltrated area there is a pronounced loss of collagen. In more advanced forms of periodontitis, marked loss of connective tissue attachment to the root and apical down-growth of the dentogingival epithelium along the root are important characteristics.

Outcomes from experimental and clinical research have demonstrated that chronic and aggressive forms of periodontal disease:

- Affect individuals with various susceptibility at different rates (Löe *et al*. 1986)
- Affect different parts of the dentition to a varying degree (Papapanou *et al*. 1988)
- Are site specific in nature for a given area (Socransky *et al*. 1984)
- Are sometimes progressive in character and, if left untreated, may result in tooth loss (Löe *et al*. 1986)
- Can be successfully treated and maintained long term (Hirschfeld & Wasserman 1978; Rosling *et al*. 2001; Axelsson *et al*. 2004).

Fig. 29-1 (a–g) Buccal/labial and palatal/lingual views of a 59-year-old male patient diagnosed with advanced generalized chronic periodontitis with furcation involvement.

For effective treatment planning, the location, topography, and extent of periodontal lesions must be recognized in all parts of the dentition. It is, therefore, mandatory to examine all sites of all teeth for the presence or absence of periodontal lesions. This in turn means that single-rooted teeth have to be examined at four sites at least (e.g. mesial, buccal, distal, and oral) and multirooted teeth at six sites at least (e.g. mesiobuccal, buccal, distobuccal, disto-oral, oral, and mesio-oral) with special attention to the furcation areas.

Since periodontitis includes inflammatory alterations to the gingiva and a progressive loss of periodontal attachment and alveolar bone, comprehensive examination must include assessments of such pathologic alterations.

Fig. 29-2 Buccal migration of tooth 13 as a sign of advanced periodontitis.

Figure 29-1 shows the clinical status of a 59-year-old patient diagnosed with advanced generalized chronic periodontitis. The examination procedures used to assess the location and extent of periodontal disease will be demonstrated by using this case as an example.

Gingiva

Clinical signs of gingivitis include changes in color and texture of the soft marginal gingival tissue and BoP.

Various index systems have been developed to describe gingivitis in epidemiologic and clinical research (see Chapter 7). Even though the composition of the inflammatory infiltrate can only be identified on histologic sections, inflamed gingival tissue can be correctly diagnosed on the basis of the tendency to BoP. The symptom "bleeding on probing" to the bottom of the gingival sulcus/pocket is associated with the presence of an inflammatory cell infiltrate.

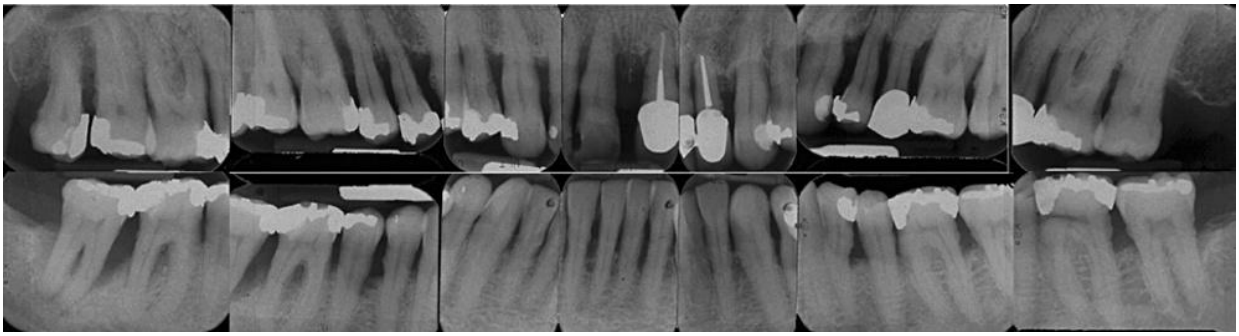

Fig. 29-3 Periapical radiographs of the patient presented in Fig. 29-1.

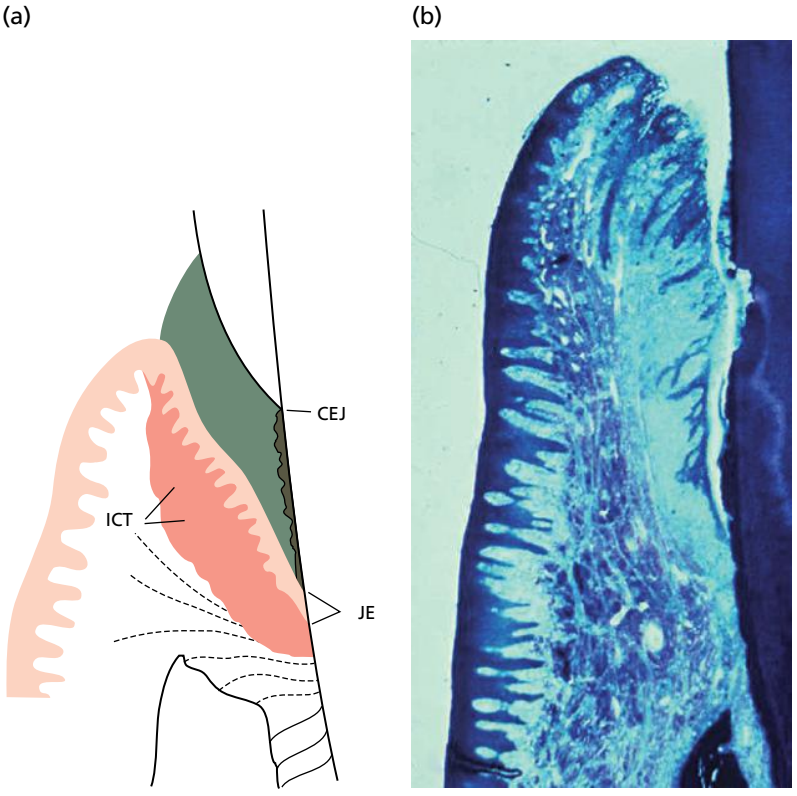

Fig. 29-4 (a) Schematic diagram and (b) histologic section showing the characteristics of periodontal disease. Note the zone of infiltrated connective tissue (ICT) lateral to the junctional epithelium (JE). (CEJ, cementoenamel junction.)

The occurrence of such bleeding, especially in repeated examinations, is indicative of disease progression (Lang *et al*. 1986), although the predictive value of this single parameter remains rather low (i.e. 30%). On the other hand, the absence of BoP yields a high negative predictive value (i.e. 98.5%) and, hence, is an important indicator of periodontal stability (Lang *et al*. 1990; Joss *et al*. 1994). Since trauma to the tissues provoked by probing should be avoided if the true vascular permeability changes associated with inflammation are to be assessed, a probing pressure of 0.25 N should be applied when assessing "bleeding on probing" (Lang *et al*. 1991; Karayiannis *et al*. 1992). The identification of the apical extent of the gingival lesion is made in conjunction with *pocket probing depth* (PPD) measurements. In sites where "shallow" pockets are present, inflammatory lesions residing in the overt portion of the gingiva are distinguished by probing in the superficial marginal tissue. When the infiltrate resides in sites with attachment loss, the inflammatory lesion in the apical part of the pocket must be identified by probing to the bottom of the deepened pocket.

Bleeding on probing

A periodontal probe is inserted to the "bottom" of the gingival/periodontal pocket by applying light force and is moved gently along the tooth (root) surface (Fig. 29-5). If bleeding is provoked upon retrieval of the probe, the site examined is considered "BoP"-positive and, hence, is inflamed.

Fig. 29-5 Pocket probing depth in conjunction with bleeding on probing.

Figure 29-6 shows the chart used to identify BoP-positive sites in a dichotomous way at the initial examination. Each tooth in the chart is represented and each tooth surface is indicated by a triangle. The inner segments represent the palatal/lingual gingival units, the outer segments the buccal/labial units, and the remaining fields the two approximal gingival units. The fields of the chart corresponding to the inflamed gingival units are marked in red. The mean BoP score (i.e. gingivitis) is given as a percentage. In the example shown in Fig. 29-1, 104 of a total of 116 gingival units bled on probing, amounting to a BoP percentage of 89%. This method of charting not only serves as a means of documenting areas of health and disease in the dentition, but charting during the course of therapy or maintenance will disclose sites which become healthy or remain inflamed. The topographical pattern will also identify sites with consistent or repeated BoP at various observation periods.

Keratinized mucosa at implant recipient sites

In order to maintain health and tissue stability around dental implants, the presence of a minimum width of keratinized mucosa has been postulated. A width of keratinized mucosa of <2 mm has been debated in the literature as a contributing factor for impaired plaque control with consequent increase in inflammation around dental implants (Bouri *et al*. 2008; Schrott *et al*. 2009; Crespi *et al*. 2010). The findings of a systematic review, however, showed that the evidence in support of the need for keratinized mucosa around dental implants in order to maintain health and stability is limited (Wennström & Derks 2012). Nevertheless, the dimensions of the keratinized mucosa in edentulous areas should be evaluated in candidates for implant therapy.

Periodontal ligament and root cementum

In order to evaluate the amount of tissue lost in periodontitis and also to identify the apical extension of the inflammatory lesion, the following parameters should be recorded:

- Pocket probing depth (PPD)
- Probing attachment level (PAL)
- Furcation involvement (FI).
- Tooth mobility (TM).

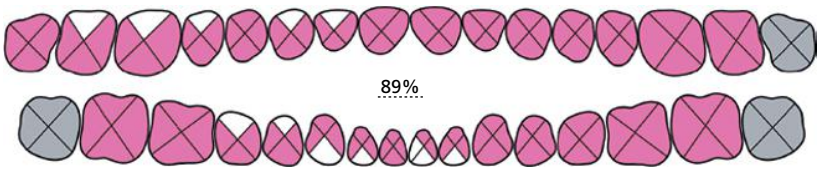

Fig. 29-6 Chart used to identify bleeding on probing-positive sites in a dichotomous way at the initial examination and during maintenance care.

Assessment of probing pocket depth

The probing depth, that is the distance from the gingival margin to the bottom of the gingival sulcus/pocket, is measured to the nearest millimeter by means of a graduated periodontal probe with a standardized tip diameter of approximately 0.4–0.5 mm (Fig. 29-7).

Fig. 29-7 Examples of graduated periodontal probes with a standardized tip diameter of approximately 0.4–0.5 mm.

The pocket depth should be assessed at each surface of all teeth in the dentition. In the periodontal chart (Fig. 29-8), PPDs of <4 mm are indicated in black numbers, while deeper PPDs (i.e. ≥4 mm) are marked in red. This allows an immediate evaluation of diseased sites (i.e. red numbers) both from an extent and a severity point of view. The chart may be used for case presentation and discussion with the patient.

Results from PPD measurements will only in rare situations [when the gingival margin co-incides with the cementoenamel junction (CEJ)] give proper information regarding the extent of loss of probing attachment. For example, an inflammatory edema may cause swelling of the free gingiva resulting in coronal displacement of the gingival margin without a concomitant migration of the dentogingival epithelium to a level apical to the CEJ. In such a situation,

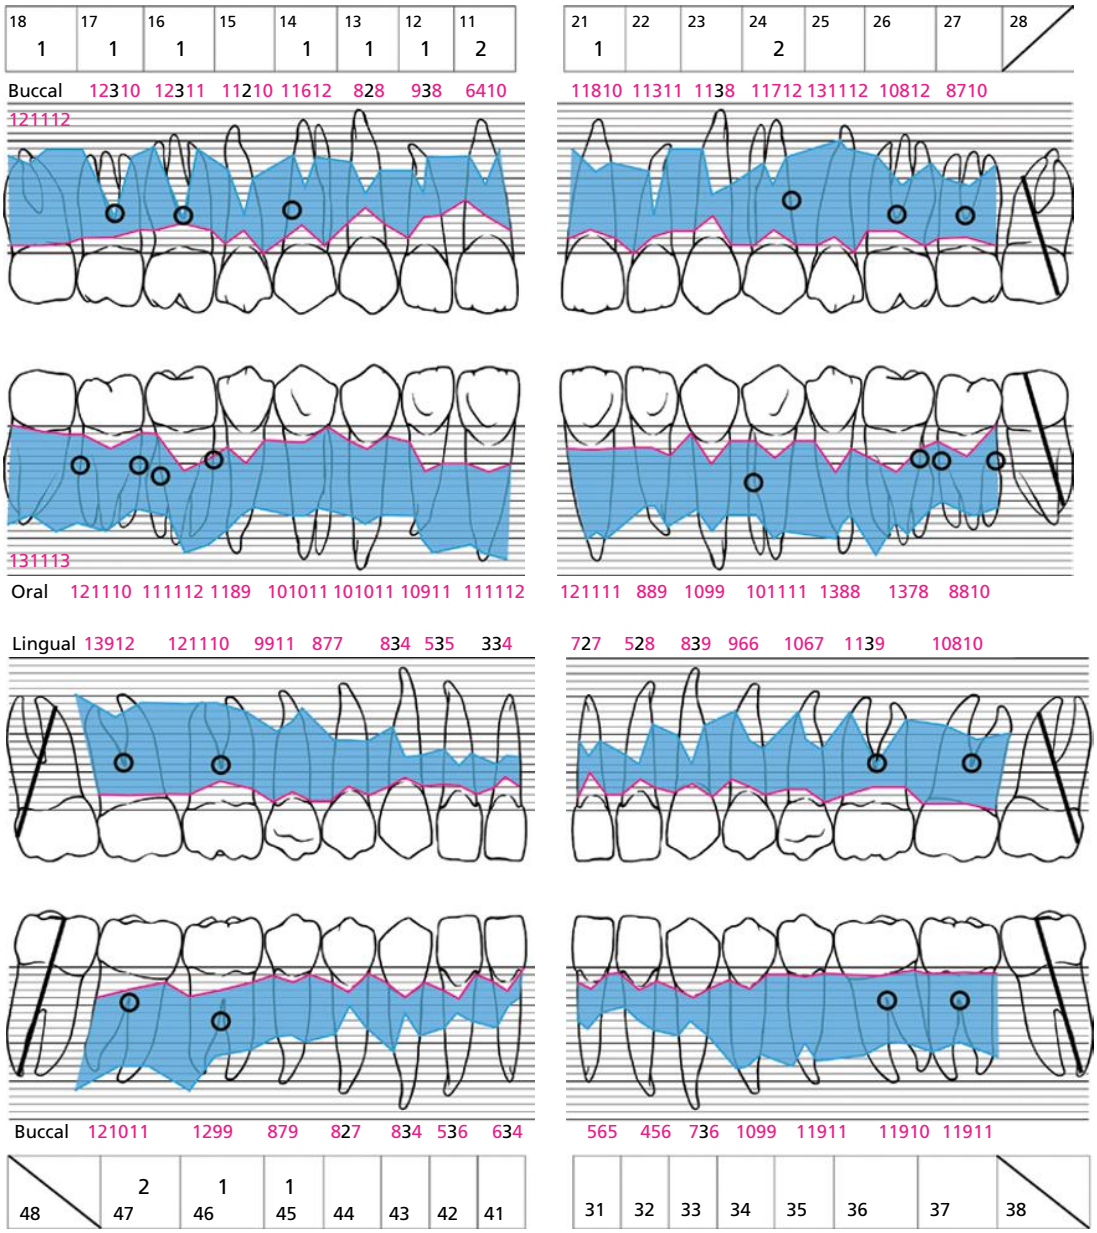

Fig. 29-8 Periodontal chart indicating probing pocket depth (PPD) of <4 mm in black numbers and PPD of ≥4 mm in red numbers.

a pocket depth exceeding 3–4 mm represents a "pseudo-pocket". In other situations, an obvious loss of periodontal attachment may have occurred without a concomitant increase of PPD. A situation of this kind is shown in Fig. 29-9, where multiple recessions of the gingiva can be seen. Hence, the assessment of the PPD in relation to the CEJ is an indispensable parameter for the evaluation of the periodontal condition (i.e. PAL).

Assessment of probing attachment level

PAL may be assessed to the nearest millimeter by means of a graduated probe and expressed as the distance in millimeters from the CEJ to the bottom of the probeable gingival/periodontal pocket. The clinical assessment requires the measurement of the distance from the free gingival margin (FGM) to the CEJ for each tooth surface. After recording this, PAL may be calculated from the periodontal chart (i.e. PPD – distance CEJ–FGM). In cases with gingival recessions, the distance CEJ–FGM turns negative and, hence, will be added to the PPD to determine PAL.

Errors inherent in periodontal probing

The distances recorded in a periodontal examination using a periodontal probe have generally been assumed to represent a fairly accurate estimate of the PPD or PAL at a given site. In other words, the tip of the periodontal probe has been assumed to identify the

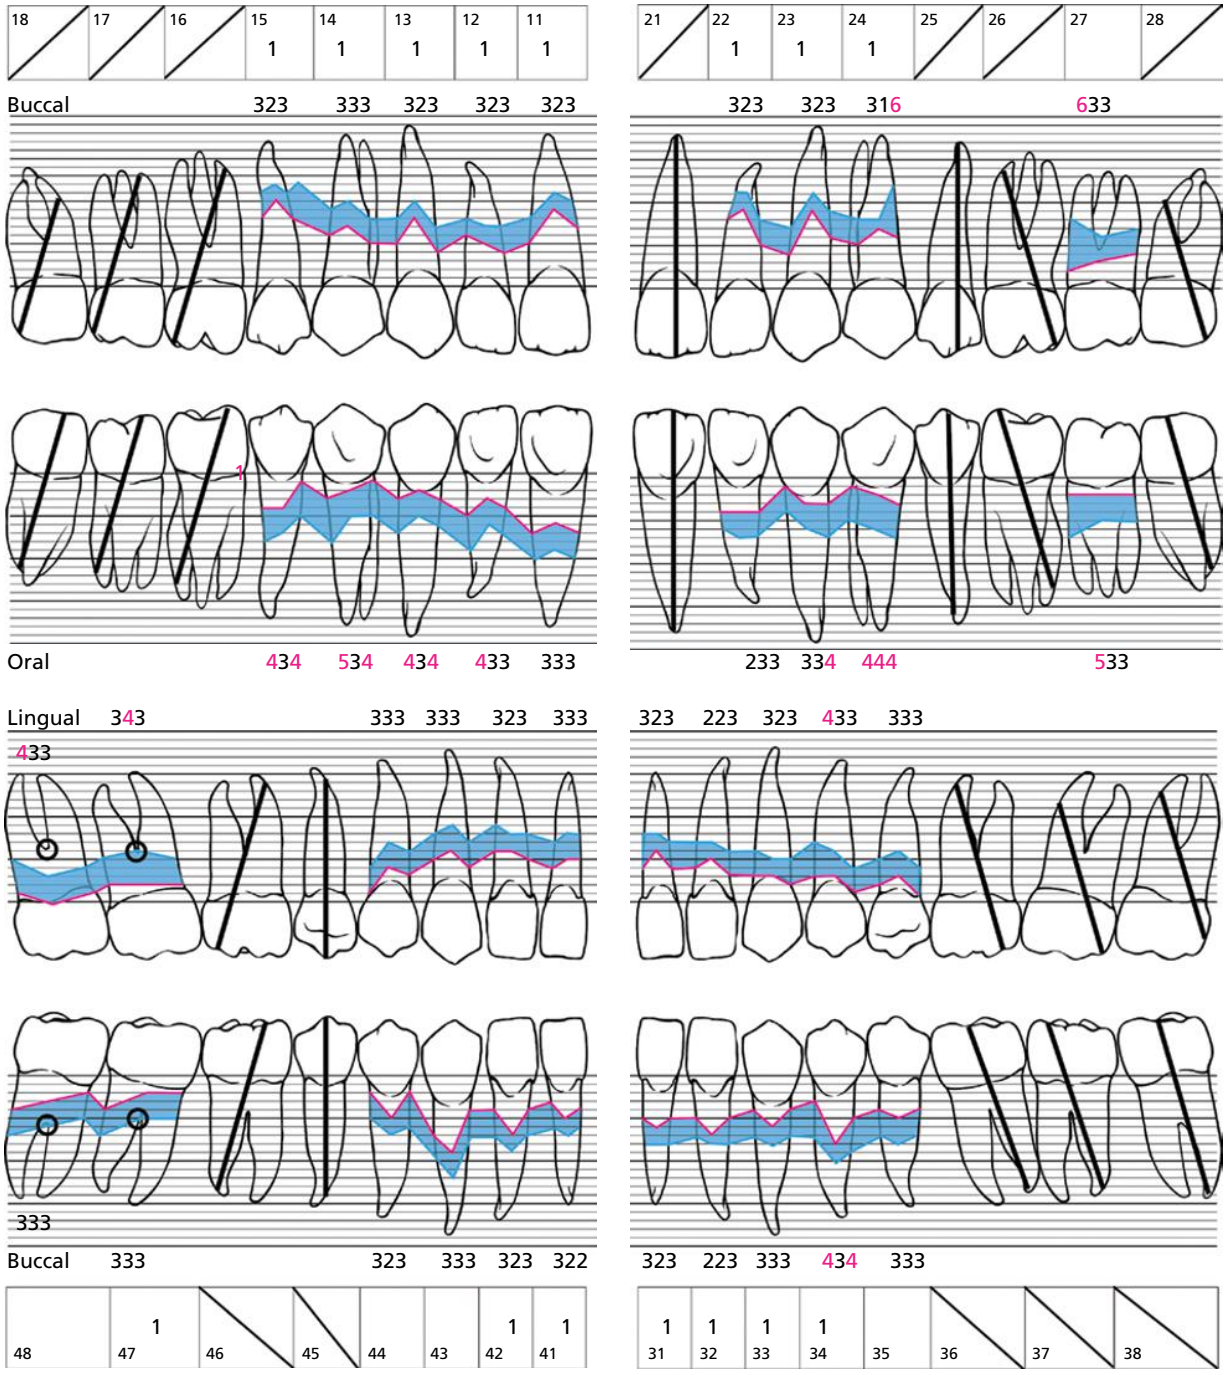

Fig. 29-9 Periodontal chart indicating that attachment loss has occurred without a concomitant increase of probing pocket depth. Multiple buccal/labial as well as palatal/lingual gingival recessions can be seen.

level of the most apical cells of the dentogingival (junctional) epithelium. Results from research, however, have indicated that this is seldom the case (Saglie *et al*. 1975; Listgarten *et al*. 1976; Armitage *et al*. 1977; Spray *et al*. 1978; Robinson & Vitek 1979; van der Velden 1979; Magnusson & Listgarten 1980; Polson *et al*. 1980). A variety of factors influence measurements made with periodontal probes, including the (1) thickness of the probe used; (2) angulation and positioning of the probe due to anatomic features such as the contour of the tooth surface; (3) graduation scale of the periodontal probe; (4) pressure applied on the instrument during probing; and (5) degree of inflammatory cell infiltration in the soft tissue and accompanying loss of collagen. Therefore, a distinction should be made between the histologic and the clinical PPD to differentiate between the depth of the actual anatomic defect and the measurement recorded by the probe (Listgarten 1980).

Measurement errors as a result of factors such as the thickness of the probe, contour of the tooth surface, and incorrect angulation and graduation scale of the probe can be reduced or avoided by the selection of a standardized instrument and careful management of the examination procedure. More difficult to avoid, however, are errors resulting from variations in probing force and the extent of inflammatory alterations of the periodontal tissues. As a rule, the greater the probing pressure applied, the deeper the penetration of the probe into the tissue. In this context, it should be realized that in investigations designed to disclose the probing pressure (force) used by different clinicians, this was found to range from 0.03 to 1.3 N (Gabathuler & Hassell 1971; Hassell *et al*. 1973), and also to differ by as much as two-fold for the same dentist from one examination to another. In order to exclude measurement errors related to the effect of variations in probing pressure, so-called pressure-sensitive probes have been developed. Such probes enable the examiner to probe with a predetermined pressure (van der Velden & de Vries 1978; Vitek *et al*. 1979; Polson *et al*. 1980). However, over- and under-estimation of the "true" PPD or PAL may also occur when this type of probing device is employed (Armitage *et al*. 1977; Robinson & Vitek 1979; Polson *et al*. 1980). When the connective tissue subjacent to the pocket epithelium is infiltrated by inflammatory cells (Fig. 29-10), the periodontal probe will penetrate beyond the apical termination of the dentogingival epithelium, resulting in an overestimation of the "true" depth of the pocket. Conversely, when the inflammatory infiltrate decreases in size following successful periodontal treatment and a concomitant deposition of new collagen occurs within the previously inflamed tissue area, the dentogingival tissue will become more resistant to penetration by the probe. The probe may then fail to reach the apical termination of the epithelium using the same probing pressure and the "true" PPD or PAL is underestimated. The magnitude of the difference between the probing measurement and the histologic "true" pocket depth (Fig. 29-10) may range from fractions of a millimeter to a couple of millimeters (Listgarten 1980).

From this discussion it should be understood that reductions in PPD and/or gain of PAL, assessed by periodontal probing, following periodontal treatment, do not necessarily indicate the formation of a new connective tissue attachment at the bottom of the treated lesion. Rather, such a change may merely represent a resolution of the inflammatory process and may thus occur without an accompanying histologic gain of attachment (Fig. 29-10). In this context it should be realized that the terms "probing pocket depth" (PPD) and "probing attachment level" (PAL) have replaced the previously used terms "pocket depth" and "gain and loss of attachment". Likewise, the term PAL is used in conjunction with "gain" and/or "loss" to indicate that changes in PAL have been assessed by clinical probing.

Current knowledge of the histopathology of periodontal lesions and healing thereof has thus altered

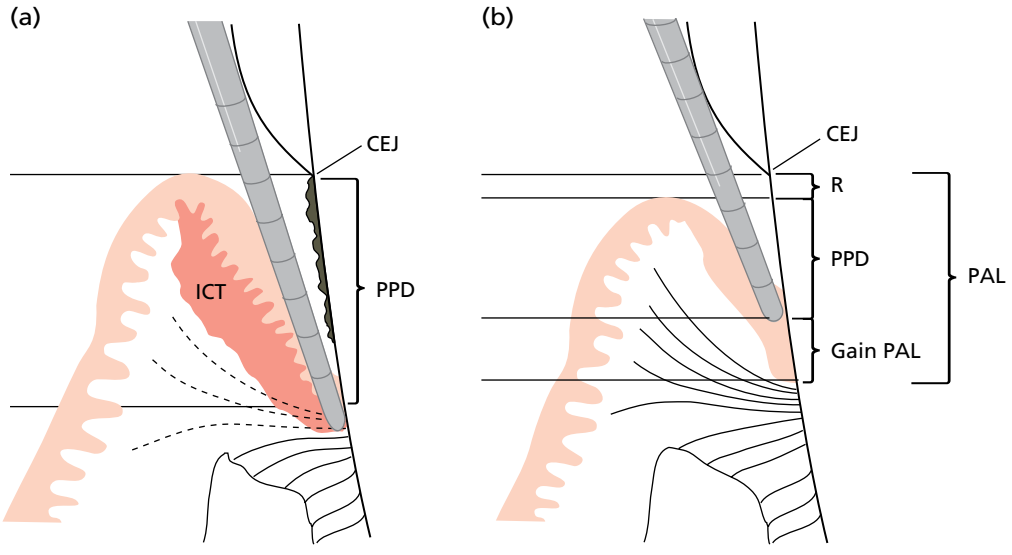

Fig. 29-10 (a) In the presence of an inflammatory cell infiltrate (ICT) in the connective tissue of the gingiva, the periodontal probe penetrates apically to the bottom of the histologic pocket. (b) Following successful periodontal therapy, the swelling is reduced and the connective tissue cell infiltrate is replaced by collagen. The periodontal probe fails to reach the apical part of the dentogingival epithelium. (CEJ, cementoenamel junction; PPD, probing pocket depth; PAL, probing attachment level; R, recession; Gain PAL, recorded false gain of attachment ("clinical attachment").)

confidence in the validity of periodontal probing. However, despite difficulties in interpreting the significance of PPD and PAL measurements, such determinations still give the clinician a useful estimate of the degree of disease involvement, particularly when the information obtained is related to other findings of the examination procedure, such as BoP and changes in alveolar bone height.

In recent years, periodontal probing procedures have been standardized to the extent that automated probing systems, for example the Florida Probe™, provides periodontal charts which document PPD, PAL, BoP, FI, and TM (Gibbs *et al*. 1988). Also, repeated examinations allow the comparison of parameters and, hence, an assessment of the healing process (Fig. 29-11).

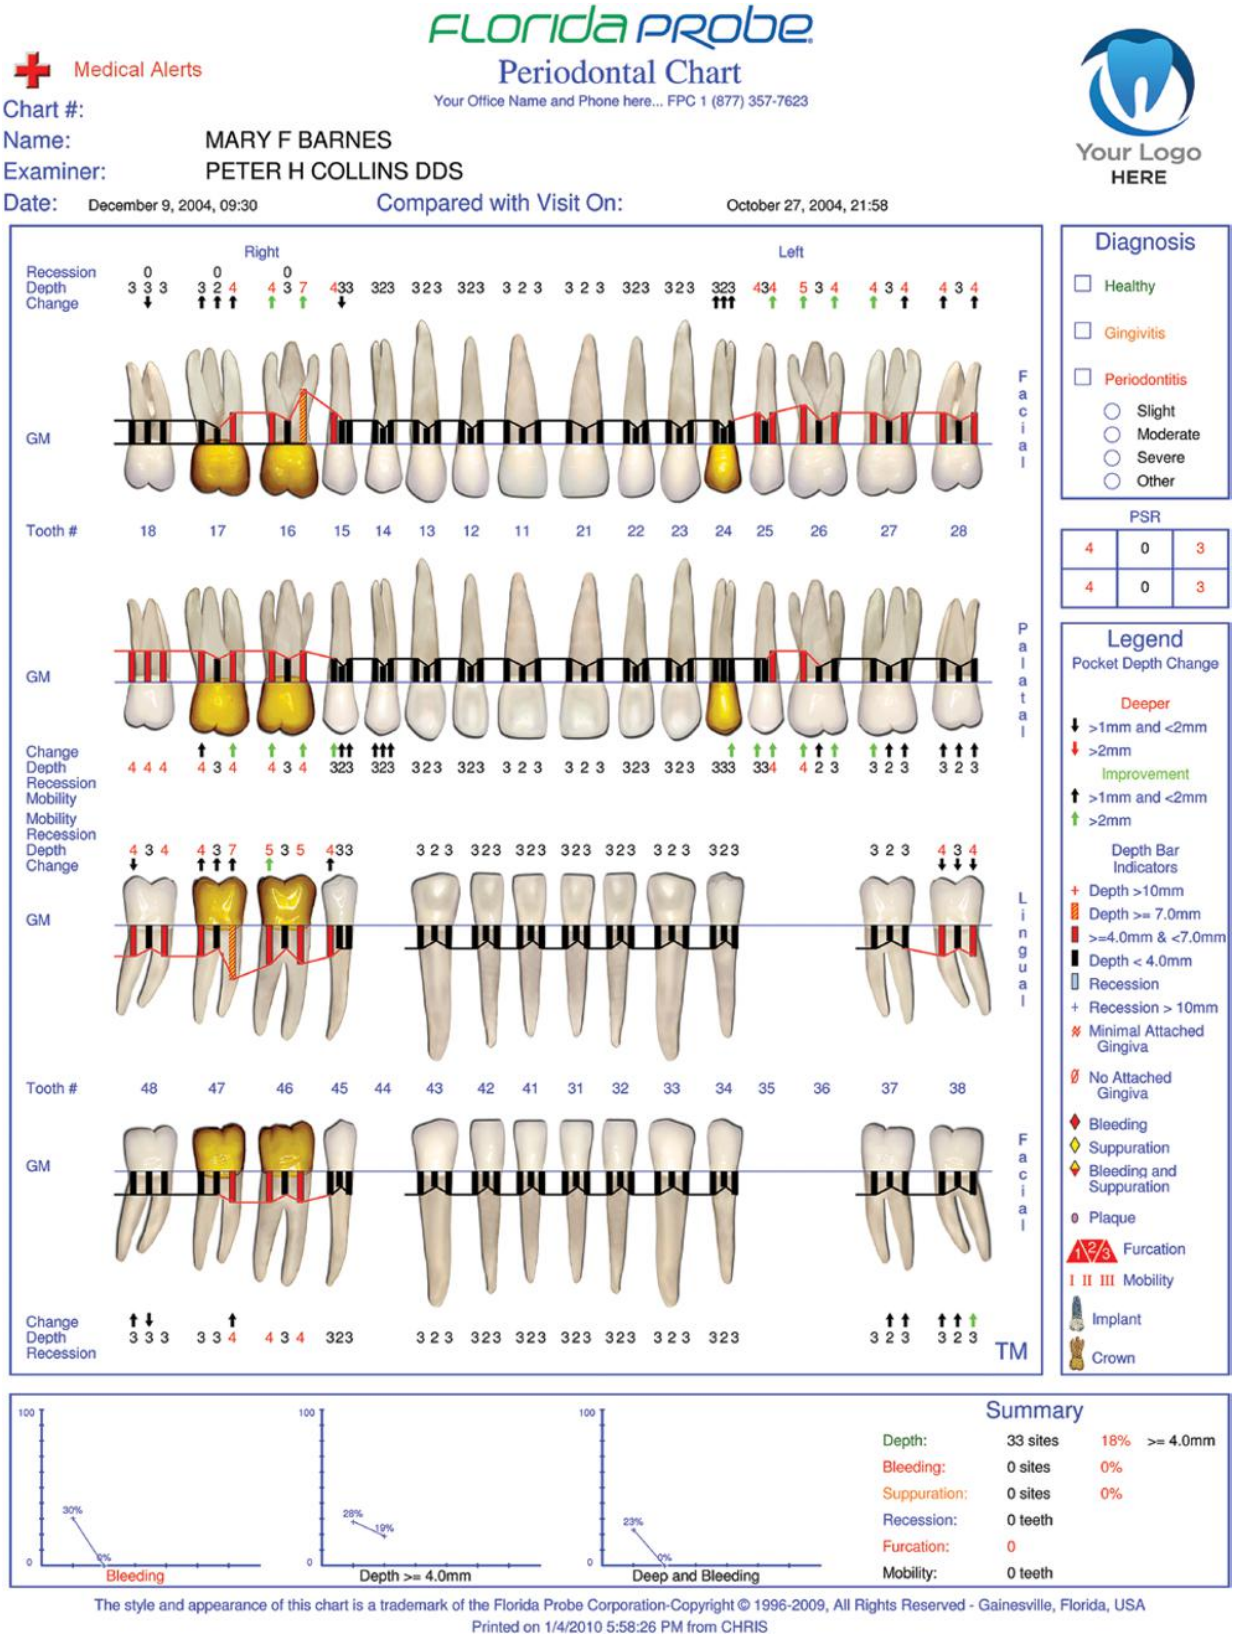

Fig. 29-11 Periodontal chart using an automated probing system (Florida Probe™). Source: Florida Probe Corporation. (c) Copyright 1996 to 2009.

Assessment of furcation involvement

The progression of periodontitis around multirooted teeth may involve the destruction of the supporting structures of the furcation area (Fig. 29-12). In order to plan the treatment of such involvement, a detailed and precise identification of the presence and extent of periodontal tissue breakdown within the furcation area is of importance for proper diagnosis.

Fig. 29-12 Superficial (tooth 46) and deep (tooth 16) periodontal tissue destruction in the buccal furcation areas.

FI is assessed from all the entrances of possible periodontal lesions of multirooted teeth, that is buccal and/or lingual entrances of the mandibular molars. Maxillary molars and premolars are examined from the buccal, distopalatal, and mesiopalatal entrances. Owing to the position of the first maxillary molars within the alveolar process, the furcation between the mesiobuccal and the palatal roots is best explored from the palatal aspect (Fig. 29-13).

FI is explored using a curved periodontal probe with 3-mm graduations (Nabers furcation probe; Fig. 29-14). Depending on the penetration depth, the FI is classified as "superficial" or "deep":

- *Class I*: horizontal probing depth of ≤3 mm from one or two entrances
- *Class II*: horizontal probing depth of >3 mm from at most one entrance and/or in combination with a FI class I

(a) (b)

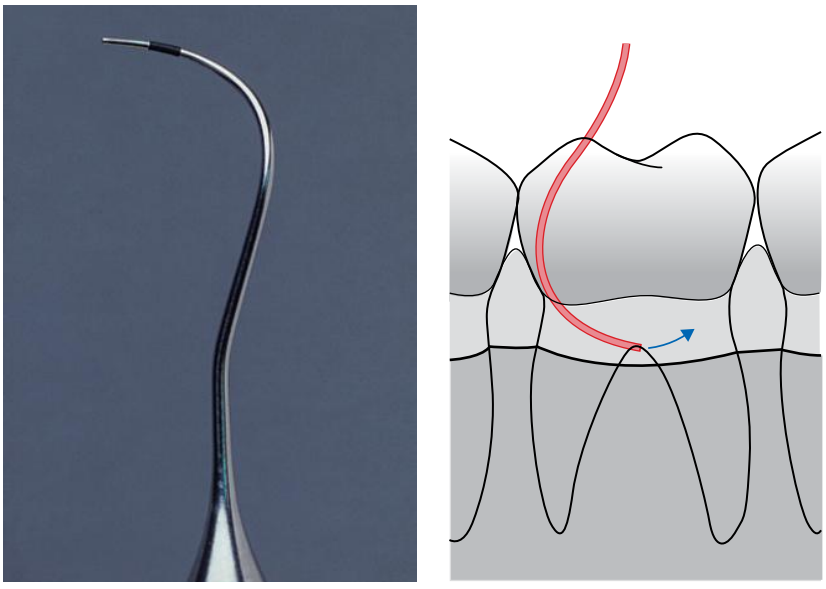

Fig. 29-14 (a, b) Furcation involvement is explored using a curved periodontal probe with 3-mm graduations (Nabers furcation probe).

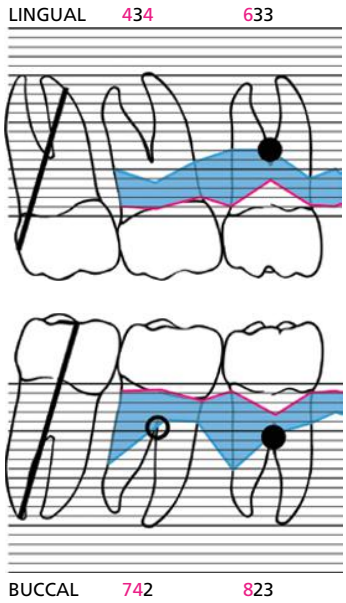

Fig. 29-15 Furcation involvement (FI) shown in the periodontal chart. Open circles represent a superficial FI (i.e horizontal probe penetration of < 3 mm), whereas filled black circles represent a deep FI (i.e. horizontal probe penetration of ≥ 3 mm).

- *Class III*: horizontal probing depth of >3 mm from two or more entrances usually represents a "through-and-through" destruction of the supporting tissues in the furcation.

The FI class is presented on the periodontal chart (Fig. 29-15) together with a description of which tooth surface the involvement has been identified on. The effects of various therapeutic approaches to the management of multirooted teeth with FI has been systematically appraised (Huynh-Ba *et al*. 2009). A detailed description of the management of furcation-involved teeth is presented in Chapter 40.

Assessment of tooth mobility

Increased TM may be classified according to Miller (1950):

- *Degree 0*: "physiologic" mobility measured at the crown level. The tooth shows mobility of 0.1–0.2 mm in the horizontal direction within the alveolus
- *Degree 1*: increased mobility of the crown of the tooth of at the most 1 mm in the the horizontal direction
- *Degree 2*: visually increased mobility of the crown of the tooth exceeding 1 mm in the horizontal direction
- *Degree 3*: severe mobility of the crown of the tooth in both horizontal and vertical directions, and impinging on the function of the tooth.

The continuous loss of the supporting tissues during progressionn of plaque-associated periodontal disease progression may result in increased TM. However, it must be understood that plaque-associated periodontal disease is not the only cause of increased tooth mobility. For instance, overloading of teeth and trauma from occlusion may result in tooth hypermobility. Increased TM can frequently also be observed in conjunction with periapical lesions or immediately following periodontal surgery. From a therapeutic point of view it is important, therefore, to assess not only the degree of increased TM, but also the cause of the observed hypermobility (see Chapters 16 and 58).

All data collected from measurements of PPD and PAL, as well as assessments of FI and TM, are included in the periodontal chart (see Fig. 29-8). The various teeth in this chart are denoted according to the two-digit system adopted by the World Dental Federation (FDI) in 1970.

Alveolar bone

Radiographic analysis

Radiographs provide information on the height and configuration of the interproximal alveolar bone (see Fig. 29-3). Obscuring structures such as tooth roots often make it difficult to identify the outline of the buccal and lingual alveolar bony crest. The analysis of the radiographs must, therefore, be combined with a detailed evaluation of the periodontal chart in order to correctly estimate the "horizontal" and " angular" bony defects.

Unlike the periodontal chart, which represents a sensitive diagnostic estimate of the lesions, the radiographic analysis is a specific diagnostic test yielding few false-negative results and, hence, confirms the periodontal chart (Lang & Hill 1977).

To enable meaningful comparative analysis, a reproducible radiographic technique should be used: a long-cone paralleling technique (Updegrave 1951) is recommended (Fig. 29-16).

Radiographic evaluation of implant recipient sites

In order to evaluate vertical bone height at potential implant recipient sites, panoramic radiography is a reliable diagnostic tool to determine the preoperative implant length in premolar and molar mandibular areas (Vazquez *et al*. 2013). Furthermore, to accurately determine the bone volume and morphology at future implant recipient sites, cone-beam computed tomography (CBCT) may offer valuable information in select indications such as implant placement in conjunction with sinus floor elevation (Harris *et al*. 2012).

Diagnosis of periodontal lesions

Based on the information regarding the condition of the various periodontal structures (i.e. the gingiva, periodontal ligament, and alveolar bone) obtained

through the comprehensive examination presented above, the periodontal condition of the patient as well as each tooth may be classified according to four different tooth-based diagnoses (Fig. 29-17, Table 29-1).

Gingivitis

This diagnosis is applied to teeth displaying BoP. The sulcus depth usually remains at 1–3 mm irrespective of the level of clinical attachment. "Pseudopockets" may be present in cases of slightly increased probing depth without concomitant attachment and alveolar bone loss and presence/absence of BoP. The diagnosis of gingivitis usually characterizes lesions confined to the gingival margin.

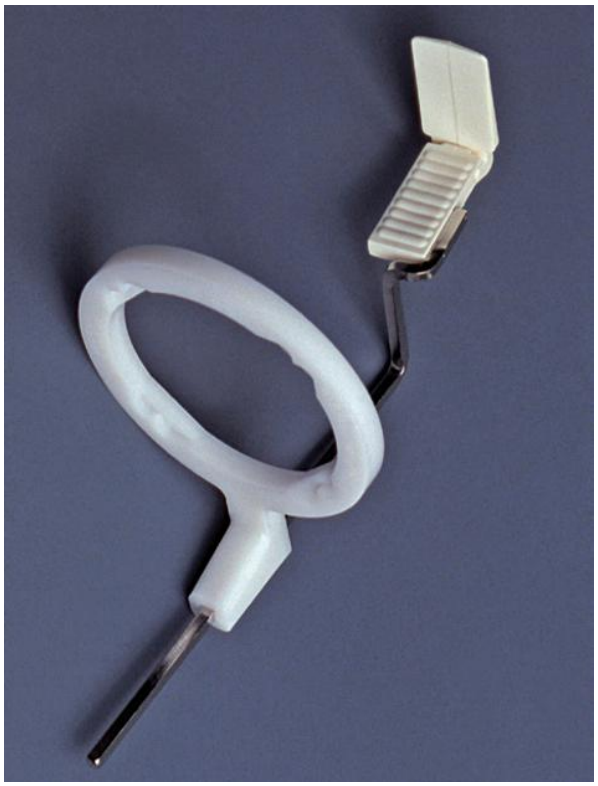

Fig. 29-16 Use of a Rinn film holder and a long-cone paralleling technique yields reproducible radiographs.

Parodontitis

Paradontitis superficialis (mild-to-moderate periodontitis)

Gingivitis in combination with attachment loss is termed "periodontitis". If the PPD does not exceed 6 mm, a diagnosis of mild-to-moderate periodontitis is given irrespective of the morphology of the periodontal lesions. This diagnosis may, therefore, be applied to teeth with "horizontal" loss of supporting tissues, thus representing suprabony lesions, and/or to teeth with "angular" or "vertical" loss of supporting tissues, thus representing infrabony lesions. "Infrabony" lesions include "intrabony one-, two- and three-wall defects", as well as "craters" between two adjacent teeth.

Parodontitis profunda (advanced periodontitis)

If the PPD exceeds 6 mm, a diagnosis of advanced periodontitis is given irrespective of the morphology of the periodontal lesions. As for mild-to-moderate periodontitis, angular as well as horizontal alveolar bone loss are included in this diagnosis. The distinction between mild-to-moderate and advanced periodontitis is based on increased PPD alone.

Parodontitis inter-radicularis (periodontitis in the furcation area)

Adjunctive diagnoses may be attributed to multirooted teeth with FI (see earlier): superficial FI if the horizontal PPD is ≤3 mm (parodontitis inter-radicularis superficialis) and deep FI for horizontal PPD of >3 mm (parodontitis inter-radicularis profunda).

Fig. 29-17 Chart of the individual tooth diagnoses of the patient presented in Fig. 29-1.

In the presence of necrotizing and/or ulcerative lesions, these terms may be added to tooth-related diagnoses of both gingivitis and periodontitis (Chapter 22). Acute lesions, including gingival and periodontal abscesses, are diagnosed as indicated in Chapter 24.

The various teeth of the patient whose clinical status is shown in Fig. 29-1, radiographs in Fig. 29-3, and periodontal chart in Fig. 29-8 received the diagnoses described in Fig. 29-17.

Oral hygiene status

In conjunction with examination of the periodontal tissues, the patient's oral hygiene practices must also be evaluated. Absence or presence of plaque on each tooth surface in the dentition is recorded in a dichotomous manner (O'Leary *et al*. 1972). The bacterial deposits may be stained with a disclosing solution to facilitate their detection. The presence of plaque is marked in appropriate fields in the plaque chart (Fig. 29-18). The mean plaque score for the dentition is given as a percentage in correspondence with the system used for BoP (see Fig. 29-6).

Alterations with respect to the presence of plaque and gingival inflammation are monitored in a simple way by the repeated use of the combined BoP (see Fig. 29-6) and plaque (Fig. 29-18) charts during the course of treatment. Repeated plaque recordings alone (Fig. 29-18) are predominantly indicated during the initial phase of periodontal therapy (i.e. infection control) and are used for improving self-performed plaque control. Repeated BoP charts alone (Fig. 29-6), on the other hand, are predominantly recommended during supportive periodontal therapy (SPT).

Table 29-1 Diagnoses of periodontal tissue conditions around each tooth in the dentition according to main criteria (i.e. the periodontal chart and radiographic analysis) and additional criteria (i.e. bleeding on probing).

Diagnosis	Main criteria	Additional criteria
Gingivitis	BoP No loss of PAL and alveolar bone PPD ≤3 mm Pseudo-pockets	
Parodontitis superficialis (mild-to-moderate periodontitis)	PPD ≤5 mm irrespective of the morphology of the periodontal lesion Angular and/or horizontal alveolar bone loss	BoP
Parodontitis profunda (advanced periodontitis)	PPD ≥6 mm irrespective of the morphology of the periodontal lesion Angular and/or horizontal alveolar bone loss	BoP
Parodontitis inter-radicularis (periodontitis in the furcation area)	Horizontal PPD ≤3 mm: superficial FI Horizontal PPD >3 mm: deep FI	BoP

PAL, probing attachment level; PPD, probing pocket depth; BoP, bleeding on probing; FI, furcation involvement.

Additional dental examinations

In addition to the assessment of plaque, retentive factors for plaque, such as supra- and sub-gingival calculus and defective margins of dental restorations, should be identified. Furthermore, the assessment of tooth sensitivity is essential for comprehensive treatment planning. Sensitivity to percussion may indicate acute changes in pulp vitality and lead to emergency treatment prior to systematic periodontal therapy. It is obvious that a complete examination and assessment of the patient will need to include a search for carious lesions, both clinically and radiographically.

A screening for functional disturbances may be performed using a short (i.e. 1/2 minute) test (Shore 1963). In this test, harmonious function of the jaws with simultaneous palpation of the temporomandibular joints during opening, closing, and excursive movements is verified. Maximal mouth opening is assessed and finally, the lodge of the lateral pterygoid muscles is palpated for muscle tenderness. Further morphologic characteristics of the dentition as well as occlusal and articulating contacts may be identified.

Conclusion

The methods described in this chapter for the examination of patients with periodontal diseases and candidates for implant therapy provide a thorough analysis of the presence, extent, and severity of disease in the dentition. The periodontal classification of the patient and the correct diagnosis for each individual tooth should form the basis for a pretherapeutic prognosis and treatment planning for the individual patient.

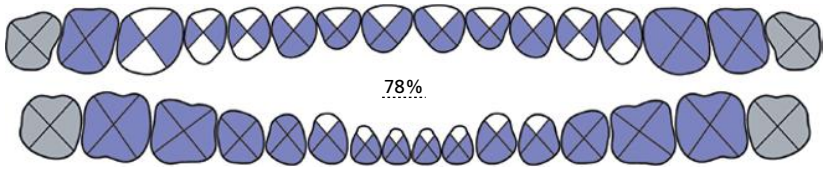

Fig. 29-18 Presence of bacterial deposits is marked in the appropriate fields in the plaque chart.

Chapter 30

Diagnostic Imaging of the Periodontal and Implant Patient

Bernard Koong

School of Dentistry, Faculty of Medicine, Dentistry and Health Sciences,
University of Western Australia, Perth, Australia

Introduction

Our understanding of periodontal diseases and implant dentistry continues to grow exponentially. Similarly, the options and techniques available for their radiologic examination continue to evolve rapidly. The modern-day clinician must be suitably equipped with sufficient and accurate information to be able to prescribe the appropriate radiologic test. The practice of dentistry, especially orofacial implantology, based solely on traditional intraoral and panoramic radiography is no longer considered an acceptable standard of care in many parts of this world. The clinician of today must consider all available modalities and carefully weigh the diagnostic benefit against the potential biologic cost of diagnostic imaging; the ALARA (as low as reasonably achievable) principle should be considered in making these decisions. It is recognized that certain imaging modalities may not be readily available in some parts of the world. The monetary cost of some imaging techniques may also be relatively high and potentially prohibitive, although this must be weighed against the financial cost of the potential treatment. Typically, the financial cost of diagnostic imaging, including advanced modalities, is a fraction of the cost of the implant prosthesis or periodontal therapy and maintenance over time. Ultimately, it is the clinician who makes the decision as to which modality is best employed, based on the clinical findings. It is also the clinician's responsibility to ensure that the imaging is performed optimally or referred to radiologists who are appropriately skilled in orofacial imaging. Most importantly, the clinician must ensure that the imaging dataset is evaluated in entirety and interpreted by appropriately skilled persons.

It is of paramount importance that clinicians remain up to date and it is recognized that technological

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

advances typically outstrip the publication of studies related to the technology.

Interpretation of the radiologic examination

Prescribing the appropriate imaging modality and ensuring optimal imaging protocols and techniques are used will produce optimal images to aid in diagnosis. In many ways, the interpretation of the images created is the most important aspect of diagnostic imaging. This applies to the practice of radiology generally and certainly includes diagnostic imaging in relation to the periodontal and implant patient. Failure to ensure thorough and accurate interpretation denies the diagnostic benefit to the patient who has received ionizing radiation associated with the radiologic study. Therefore, this chapter dedicates a section to the key aspects of radiologic interpretation, with particular reference to periodontology and implant dentistry.

For periodontal bone loss, appropriate interpretation is required to confirm that the bone loss is inflammatory in nature and not related to another disease process. The morphology and severity of the periodontal defects as well as the associated contributing factors are also important. In addition, other dentoalveolar findings including caries, periapical disease, and the state of the existing restorative therapy, must be evaluated so that an overall diagnosis, prognosis, and treatment plan can be made.

In implant dentistry, diagnostic imaging firstly provides an opportunity to evaluate the site(s) of an intended implant and the adjacent bony and soft tissues for the presence and nature of pathology (Figs. 30-1, 30-2). The relevant findings with regards to the suitability and planning for implants are obviously crucial. It is also important that the remaining dentoalveolar structures are thoroughly evaluated so that the planning of the implant is not performed in isolation; in other words, implant therapy must be planned as part of the overall orofacial treatment plan.

The ability to perform morphologic analyses (e.g. the shape and extent of a periodontal defect) and plan surgical procedures (e.g. implant planning) with a specific imaging modality is not the same as the skill set required to evaluate radiologic images for the presence of disease and interpret the radiologic features of a lesion. Radiologic interpretation is based upon the knowledge of disease processes and the behavior of diseases within a specific anatomic region. It involves the application of an algorithm which requires a specific knowledge base and skill set. These allow the identification of normal structures and presence of abnormalities. Combined with an understanding of the specific radiologic characteristics of various pathologies, this contributes substantially to diagnosis.

In dentistry, the observer may also be the examining clinician and often has a preconception as to the likely diagnosis. In these scenarios, there is potential for a quick perusal of the radiologic study to confirm clinical suspicions rather than a thorough evaluation of the radiologic study. An example is where preliminary clinical findings suggest the presence of an inflammatory periodontal defect and radiologic interpretation effectively ends as soon as a lucent appearance is noted in association with the roots. A thorough radiologic evaluation to identify the features of an inflammatory lesion is not carried out, potentially leading to misdiagnosis. Clinicians are encouraged to avoid this inappropriate application of diagnostic imaging.

It is important that the diagnostic imaging and interpretation is completed prior to biopsy or other surgical intervention. Appropriate radiologic interpretation can assist in identifying the optimal and/or safe site(s) for biopsy. Also, some lesions should be excluded prior to biopsy or surgical intervention. Of note are the vascular malformations. In addition, surgical procedures and biopsies often significantly

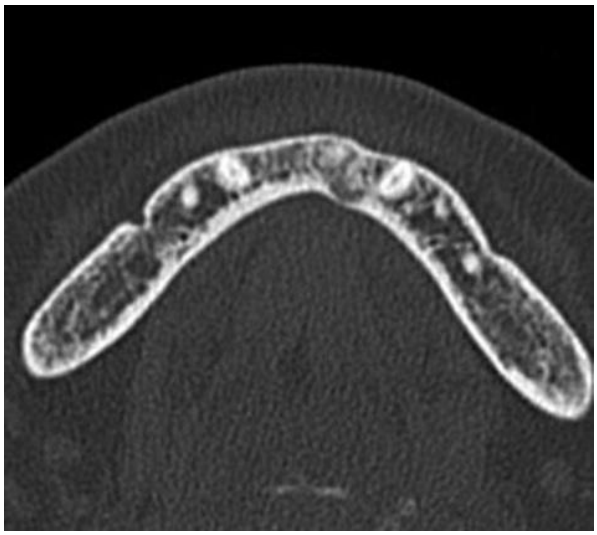

Fig. 30-1 Axial low-dose MCT image demonstrates the presence of cementosseous dysplasia at the 32 region where an implant was planned. Note the sclerotic borders.

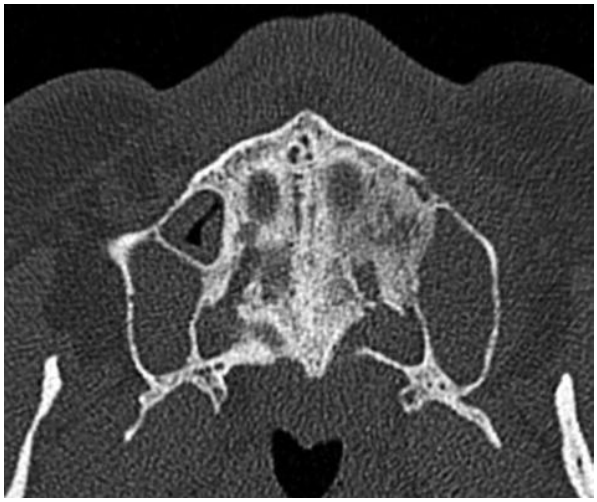

Fig. 30-2 Axial low-dose CBCT axial image demonstrates a left maxillary fibrous dysplasia in an area intended for implant placement. Note the internal ground-glass appearances.

alter the radiologic appearances of a lesion by introducing inflammatory changes, potentially compromising diagnosis.

The clinician responsible for the radiologic examination must ensure that all the information obtained in the radiologic study is thoroughly evaluated, not just the region of interest, for example the dentoalveolar structures only. If the clinician responsible for the study does not have appropriate and recognized training in the interpretation of a particular study, the clinician must then ensure that the radiologic study is interpreted by radiologists who have the appropriate training and skill set. It must be recognized that the knowledge and skill involved in the interpretation of intraoral and panoramic radiographic images is not the same as that for the interpretation of volumetric data, including multislice/multidetector computed tomography (MCT) and cone-beam computed tomography (CBCT).The medicolegal right that general and specialist dentists have to perform complex surgery does not imply that they have had appropriate training nor the skill set to carry out the procedure competently. Similarly, it must be remembered that the legal right to operate a particular radiologic machine does not imply sufficient knowledge to interpret the information captured. The associated ethical and medicolegal implications require consideration.

A thorough discussion of radiologic interpretation is not within the scope of this chapter and, while there are useful publications on this topic (White & Pharoah 2009; Koong 2012), clinically-based guided training is required to develop a competent level of interpretive skill. However, the generic key requirements and steps will be briefly discussed, followed by a section which will apply these principles to periodontology and implantology.

Basic prerequisites

Radiologic anatomy

A detailed understanding of three-dimensional anatomy and how structures appear radiologically, depending on the imaging modality employed, is essential. Knowledge of normal variants and their radiologic appearances in the various modalities is also a requirement. Obviously, larger field of view (FOV) two-dimensional (2D) images will include more structures, requiring a broader knowledge base. The radiologic anatomy as depicted on plain 2D images differs from that seen in volumetric datasets from modalities such as MCT and CBCT. The ability to identify the presence of disease is extremely limited if the clinician is not thoroughly familiar with radiologic appearances of all anatomic structures and normal morphologic variants. It must be emphasized that not all abnormalities present as overt opacities or lucencies (Fig. 30-3).

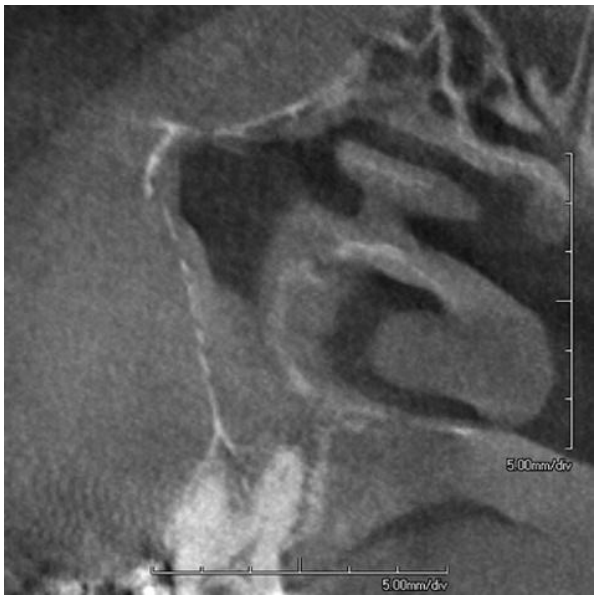

Fig. 30-3 Low-dose CBCT corrected sagittal image demonstrates small cortical erosions related to an infiltrative lesion such as a lymphoma. The patient had presented with facial swelling and discomfort, originally thought to be of dentoalveolar origin.

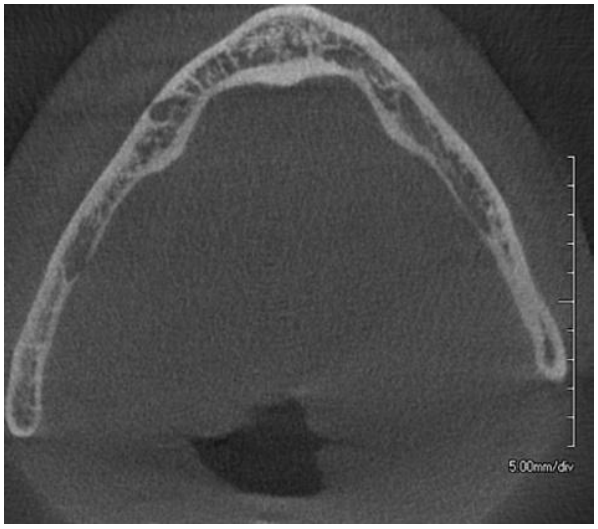

Fig. 30-4 Low-dose CBCT axial image of a left-sided pharyngeal mass, proven to be a squamous cell carcinoma.

Pathology

The person carrying out the interpretation must possess knowledge of diseases which are potentially associated with all structures included in the radiologic study. Appreciation of the clinical significance of these various diseases is also crucial. Many imaging techniques capture a significant proportion of the orofacial structures. Panoramic and cephalometric projections obviously include many other facial structures, apart from the dentoalveolar structures. To varying degrees, MCT and CBCT scans include the paranasal sinuses, pharyngeal air spaces, skull base, cervical spine, and upper neck (Fig. 30-4). All structures included in a radiologic examination must

be evaluated for the presence of pathology, by persons with appropriate and recognized training.

Imaging modality

There are numerous imaging techniques which can be applied in the radiologic examination of the orofacial structures, including intraoral radiographs, other plain 2D views, the panoramic tomograph, MCT, CBCT, MRI, ultrasound, and nuclear medicine. The clinician of today must be familiar with all available modalities, including their various strengths and limitations. This will allow the selection of the optimal modality, while minimizing the radiation dose delivered to the patient. Recognition of the limitations of a particular technique is essential when interpreting a radiologic study. The effects of the various protocols employed on image quality must also be understood. Importantly, just because a specific structure can be seen in a radiologic examination does not mean that it is sufficiently well demonstrated for accurate interpretation. A different modality may be required. A description and comparison of the key features of the various radiologic modalities commonly applied in dentistry is provided in a later a section.

Viewing conditions

Optimal viewing conditions are essential for the identification of all relevant features within the radiologic images. A subtle change in the radiologic appearance of an anatomic structure can be related to a significant abnormality. Ambient light must be kept to a minimum and extraneous light from a viewing box should be obscured. Digital images viewed on a computer monitor can be manipulated. The quality of the computer monitor must be of sufficient standard. For analog images, optical magnification and use of a brighter light source can be critical. The interpretation of plain 2D radiographic digital images printed on paper can be problematic. Even an image printed onto high quality paper from a high quality printer does not demonstrate the same optical range as film or good quality monitors. Optimal imaging is assumed and the technical aspects are well described in many texts.

Key steps in interpretation

Recognizing the presence of an abnormality

The practitioner/radiologist is responsible for interrogating all structures within a FOV/entire volume of a radiologic examination, not just for the primary focus of the study, such as implant planning (Carter *et al*. 2008). The process of interrogating radiologic images for abnormalities varies, depending on the modality (Koong 2010). For example, the algorithm and skill set required to accurately and thoroughly analyze MCT and CBCT data (using multiplanar reformatted images) differ from those employed for intraoral and panoramic images. Every normal anatomic structure captured in the study must be specifically identified and evaluated. This is essential since not all lesions are always obvious. For example, the absence of a cortical boundary of a structure can reflect the presence of significant disease (Fig. 30-3). The appearance of a wide stylomandibular notch (seen on CBCT or MCT examination of a maxilla or mandible) is a radiologic feature of a mass associated with the deep lobe of the parotid gland. This is important since deep lobe parotid masses are often not clinically symptomatic until they are relatively large. This feature is of particular relevance in CBCT as the soft tissue mass itself is not evident or poorly demonstrated.

Radiologic evaluation of a lesion

The following describes a series of steps which assists in the identification of the important radiologic characteristics of a lesion. This provides information on the behavior and nature of the lesion. These features are also important from a surgical viewpoint.

Location

First, prior to focusing on a known or obvious lesion, the entire FOV or scan must be analyzed for the presence of related lesions. It is important to identify if the disease is multifocal or generalized, rather than solitary. Another key point in this step is to attempt to identify the point at which the lesion originated. The location and extent of the lesion can provide useful information about the likely tissues involved. For example, a lesion centered below the mandibular canal is unlikely to be odontogenic in nature.

Shape and contour

The shape of the lesion can provide useful information regarding its nature. True cysts such as the dentigerous cyst are generally spherical or ovoid and expansile (Fig. 30-5). In contrast, a keratocystic odontogenic tumour often demonstrates a scalloped peripheral morphology and is non-expansile within the body of the mandible. An osteoma typically presents as an expansile, homogenous, well-defined bony prominence with a smooth convex periosteal surface, while an osteochondroma tends to demonstrate a more irregular surface with more heterogenous internal appearances. A bone island typically demonstrates a well-defined homogenous non-expansile opaque appearance, isodense with cortical bone (Fig. 30-6).

Border

The first part of this step is to identify if the border of a lesion is well defined or poorly defined. If a lesion is well defined, this border has to be further examined

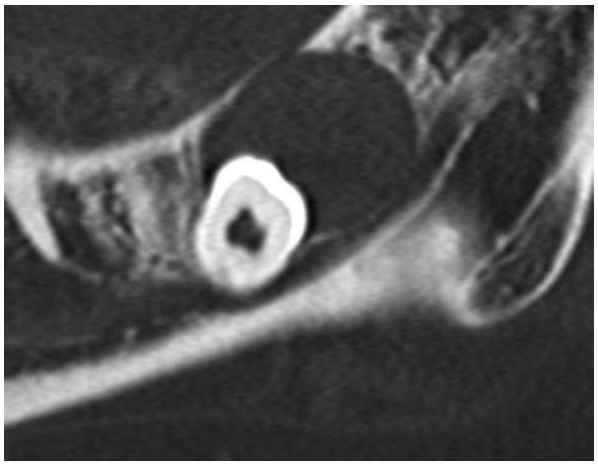

Fig. 30-5 Low-dose MCT corrected sagittal image demonstrates a dentigerous cyst related to an impacted third molar. Note the corticated margin and compression of the superior aspect of the mandibular canal.

Fig. 30-6 Low-dose MCT corrected sagittal image demonstrates a bone island with well-defined margins.

and subcategorized. Most well-defined borders fall into one of the following descriptions:

- *Sharp delineation* between normal and abnormal, with no other appreciable features. These lesions are commonly referred to as "punched out". Multiple myeloma is a classic example.
- *Corticated border*. This describes a sharp, opaque, usually curved line (Fig. 30-5).
- *Sclerotic border*. This refers to an opaque border which is thicker (to varying extents) and much less uniform than a corticated border. Most chronic inflammatory bony lesions, including plaque-related inflammatory periodontal diseases, demonstrate sclerotic margins, which reflect the reaction of the surrounding trabecular bone to the inflammatory lesion (Fig. 30-7). However, other lesions, such as cemento-osseous dysplasia (Fig. 30-1) and some malignant lesions (Fig. 30-8), can also demonstrate sclerotic margins.
- *Surrounding lucent margin*. This is typically only seen in association with opaque and mixed-density lesions. In most cases, this lucent margin reflects the presence of layer of soft tissue surrounding the lesion.

Fig. 30-7 Periapical radiograph demonstrates a periapical hypodense inflammatory lesion associated with tooth 34. There are focal regions where the margins appear better defined, related to chronicity. The sclerotic margins are evident, also related to the chronic nature of this lesion. Note the sclerotic appearance at the apical aspect of tooth 35, which likely reflects reactive sclerosis related to an inflammatory lesion, although the apical periodontal ligament is not obviously widened (likely obscured by the sclerosis on this 2D view).

An ill-defined border should be further analyzed and categorized into one of the following:

- *Gradual change from abnormal to normal*. Acute inflammatory lesions, including plaque-related inflammatory periodontal bone loss, are good examples. However, it should be noted that the borders of more chronic inflammatory lesions tend to appear better defined, especially on plain 2D imaging (Fig. 30-7).
- *Aggressive margin*. Malignant lesions display these borders. Aggressive and infiltrative margins include the appearance of lytic extensions into the adjacent bone. Unusual enlargement of adjacent marrow spaces is another feature. Irregular widening of the periodontal ligament spaces with focal multiple regions of destruction of the lamina dura is an example of the leading edge of an infiltrative lesion spreading around tooth roots. These dentoalveolar malignant lesions are easily misinterpreted for inflammatory diseases if appropriate analysis is not performed. (Fig. 30-8).

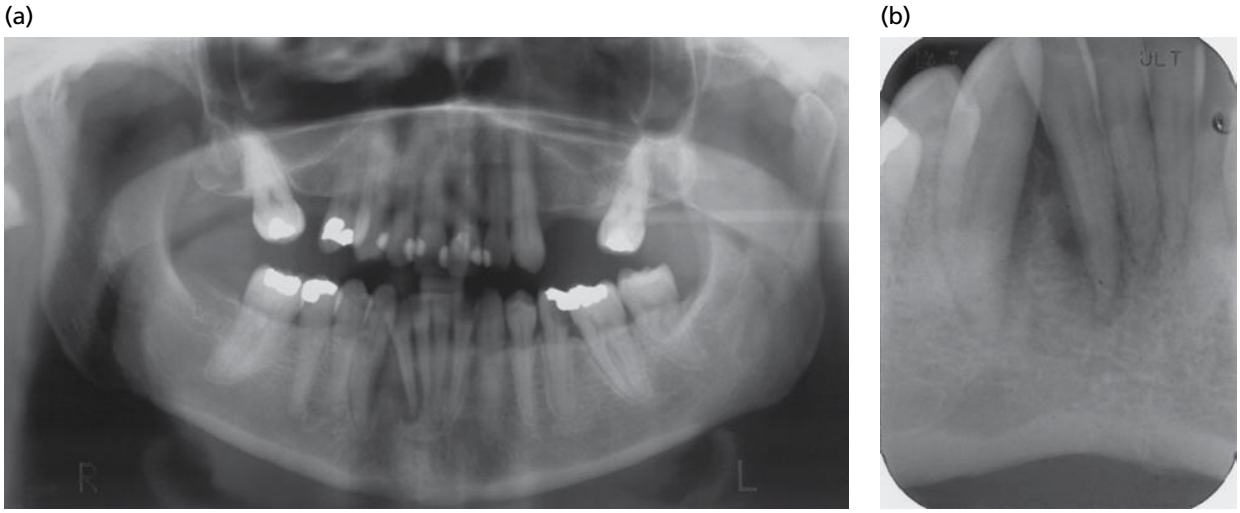

Fig. 30-8 (a) Panoramic and (b) periapical radiographs demonstrate a malignant breast metastatic lesion at the 43–41 region. Note the irregular widening of the perioidontal ligament spaces with focal lucencies extending further in the periapical view. These features are not well demonstrated on the panoramic radiograph, related to the typical limitations of this view. The adjacent sclerosis is also evident, which is typical of these lesions.

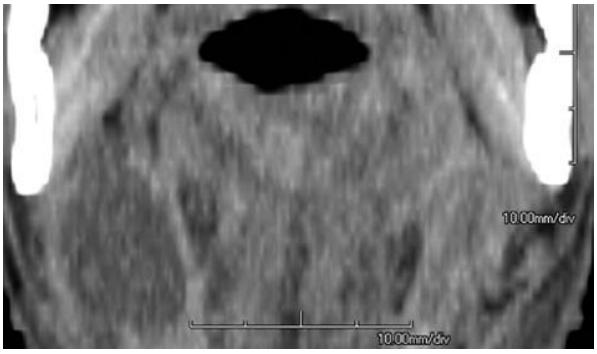

Fig. 30-9 Low-dose MCT coronal image demonstrates fluid collection within the right submandibular space, related to abscess collection from a dentoalveolar infection. This is of urgent surgical relevance and cannot be identified with present day CBCT.

Fig. 30-10 Reduced dose axial MCT image demonstrates left-sided fluid density collection related to a ranula. This would not be appreciated with present day CBCT.

Internal appearances

A complete lucent lesion seen on plain 2D views usually reflects the presence of air/gas, fluid or soft tissue. Inflammatory periodontal lesions are classically lucent internally. Typically, air/gas appears more lucent than fluid and soft tissue on plain 2D imaging. MCT has far superior soft tissue contrast resolution and can demonstrate density differences between different types of soft tissues (Figs. 30-9, 30-10). Currently, CBCT is unable to demonstrate these differences sufficiently well. It is important to note that soft tissues lesions are often best evaluated with MRI.

The density of completely opaque lesions should first be identified, for example, isodense with cortical bone. The degree of homogeneity or heterogeneity should then be identified and any consistent pattern recognized. Fibrous dysplasia classically demonstrates a ground-glass appearance internally (Fig. 30-1). Bone islands are usually homogenous internally and isodense with cortical bone (Fig. 30-6).

There are also lesions which appear both lucent and opaque internally. In these cases, it is necessary to identify the nature of the opacities, for example bony, odontoid or dystrophic calcification. The pattern and distribution of these internal opacities are also important, since many lesions often demonstrate particular patterns. For example, a multilocular ameloblastoma classically demonstrates coarse curvilinear septae, while central giant cell granulomas often reveal much finer septae. Osteomyelitis can demonstrate heterogenous internal appearances, with focal irregular lucent and sclerotic foci.

Adjacent anatomic structures

The way in which normal anatomic structures influence the growth, expansion, and spread of a lesion, and the effects of a lesion on these anatomic structures are important. These features provide clues to the behavior of the lesion. For example, all true cysts (including radicular cysts) displace the mandibular canal (Fig. 30-5), while periodontal inflammatory lesions do not. Displacement of teeth is a characteristic of a lesion with mass effect that is usually benign in nature, although it must be recognized that there are other causes of tooth movement, for example occlusal forces on teeth with reduced alveolar bone support.

Effacement of cortical boundaries can occur with a variety of lesions, including inflammatory lesions. This requires special attention as malignant lesions often demonstrate this feature (Fig. 30-3).

Interpretation of the findings

Many lesions demonstrate similar features. Also, specific lesions do not always present classically and often only demonstrate a few or even just one classical characteristic. Therefore, in addition to identifying the key radiologic features of a lesion, the observer has to weigh the various features which have been identified. This requires knowledge of the classical radiologic features of the possible pathologies as well as training and experience in the interpretation of this information. For example, periodontal and periapical lucent lesions are often inflammatory in nature. However, malignant lesions can be associated with teeth and are also lucent. Furthermore, some malignancies demonstrate adjacent sclerosis which can appear similar to the reactive sclerosis typically seen in chronic inflammatory lesions. In these cases, the invasive features of margins become critical for appropriate diagnosis (Fig. 30-8).

As mentioned earlier, fibrous dysplasia classically presents with ground-glass appearances internally (Fig. 30-1). However, it is not uncommon that it demonstrates a more heterogenous internal appearance (Fig. 30-11). In these cases, other features, such as the particular nature of the expansion, must be recognized for appropriate interpretation and diagnosis.

Radiologic interpretation in relation to inflammatory periodontal disease

The radiologic examination of the patient with periodontal disease is primarily employed to provide information on the supporting bony structures of teeth.

Key radiologic features

Applying the principles described above, the key radiologic characteristics of inflammatory periodontal disease are discussed.

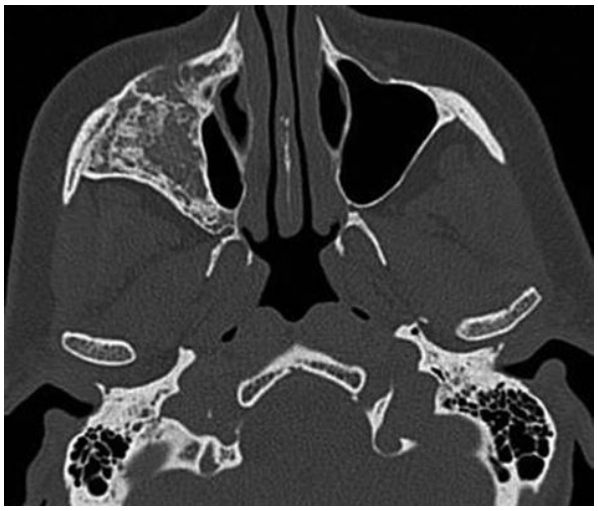

Fig. 30-11 Reduced dose axial MCT image demonstrates a right maxillary fibrous dysplasia. Note the less typical heterogenous internal appearance of this expansile lesion.

Location, origin, and distribution

Plaque-related inflammatory periodontal bone loss originates at the alveolar crest. A lesion that does not demonstrate morphology compatible with this requires further careful analysis and potentially additional tests. Malignant lesions of the alveolar process can resemble inflammatory periodontal defects, although careful analysis will usually reveal that the appearances are not typical of a lesion that originated at the alveolar crest (Fig. 30-8). Langerhans cell histiocytosis is another example of a lesion involving the alveolar process that can appear similar to periodontitis, except that it often appears to be centered at the mid-root region rather than the alveolar crest. Periodontitis can be limited to focal region(s) (involving one or a few teeth) or widely distributed (involving most or all teeth).

More aggressive forms of periodontal disease tend to be seen in younger patients (usually under 30 years of age), often beginning in puberty. The periodontal bone loss is usually rapid and may roughly correlate with tooth eruption, favoring the incisors and first molars. These aggressive forms may also present with more generalized periodontal bone loss, not limited to the incisors and molars (Brown *et al*. 1996).

Severity of periodontal bone loss

Severity of bone loss can be classified as follows:

- *Early bone loss* ranges from slight blunting, loss of cortex, decreased density or a less defined or irregular appearance of the alveolar crests, to bone loss of up to 1 mm (Fig. 30-12)
- *Moderate bone loss* ranges between 1 mm of periodontal bone loss up to the mid-root point (Fig. 30-13)
- *Severe bone loss* extends beyond the mid-root or the bony defect involves a furcation (Figs. 30-14, 30-15, 30-16, 30-17, 30-18).

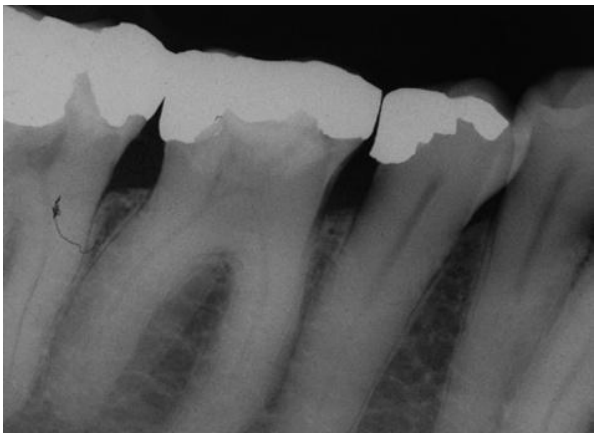

Fig. 30-12 Cropped periapical radiograph demonstrates early moderate periodontal bone loss. Note the overhang at the distal aspect of tooth 45.

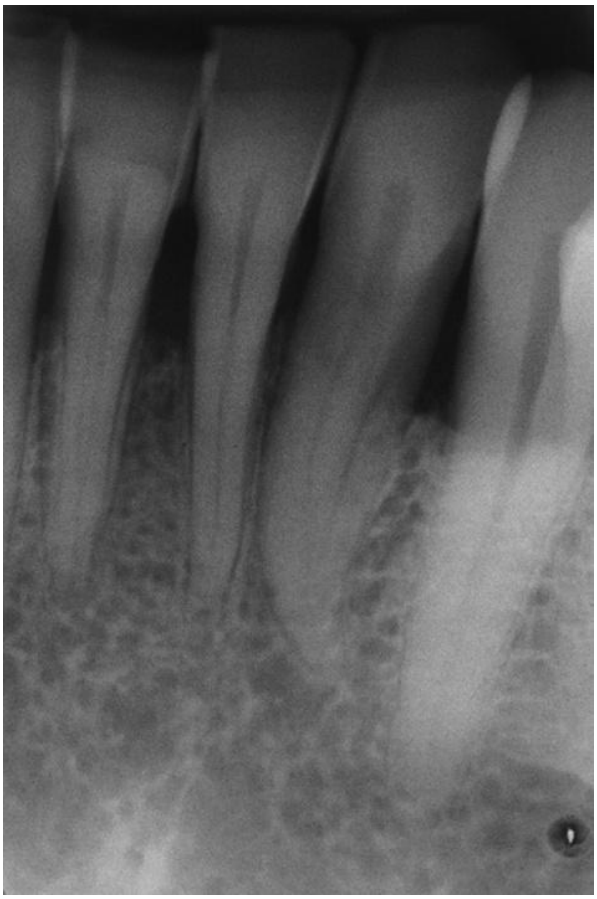

Fig. 30-13 Periapical radiograph demonstrates moderate horizontal periodontal bone loss. Note the absence of the interdental alveolar crest.

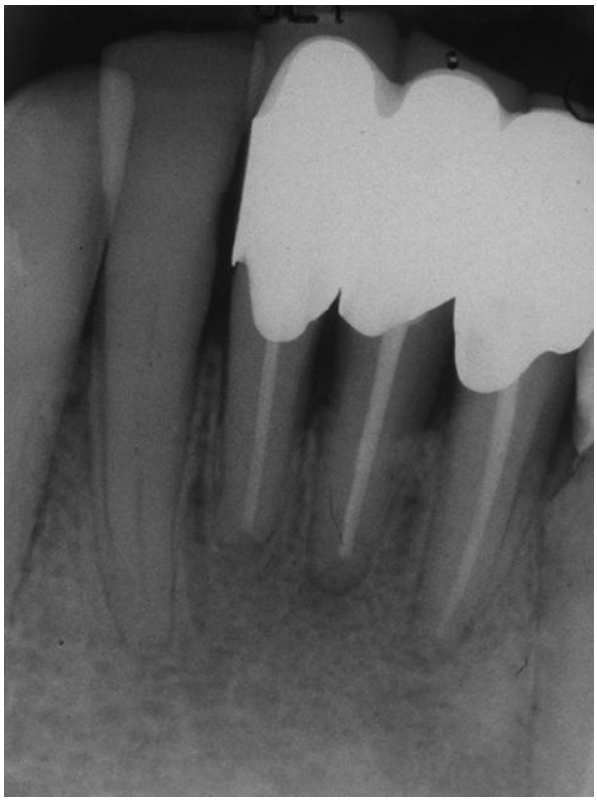

Fig. 30-14 Periapical radiograph demonstrates moderate-to-severe periodontal bone loss. Note the slight overhang at the distal aspect of tooth 41.

Fig. 30-15 Periapical radiograph demonstrates moderate-to-severe periodontal bone loss with widened periodontal ligament spaces, especially at tooth 31, related to increased mobility.

It should be recognized that radiologically detectable periodontal bone loss is preceded by clinically detectable inflammatory periodontal disease (Goodson *et al*. 1984). It must also be noted that the presence of periodontal bone loss, or indeed the severity in itself, does not indicate the presence of disease activity; in other words, the bone loss may be related to previous disease activity that has been controlled by appropriate therapy. The limitations of the radiographic examination of periodontal bone loss, especially intraoral and panoramic radiography, must be recognized and correlation with clinical findings is important (Mann *et al*. 1985; Khocht *et al*. 1996).

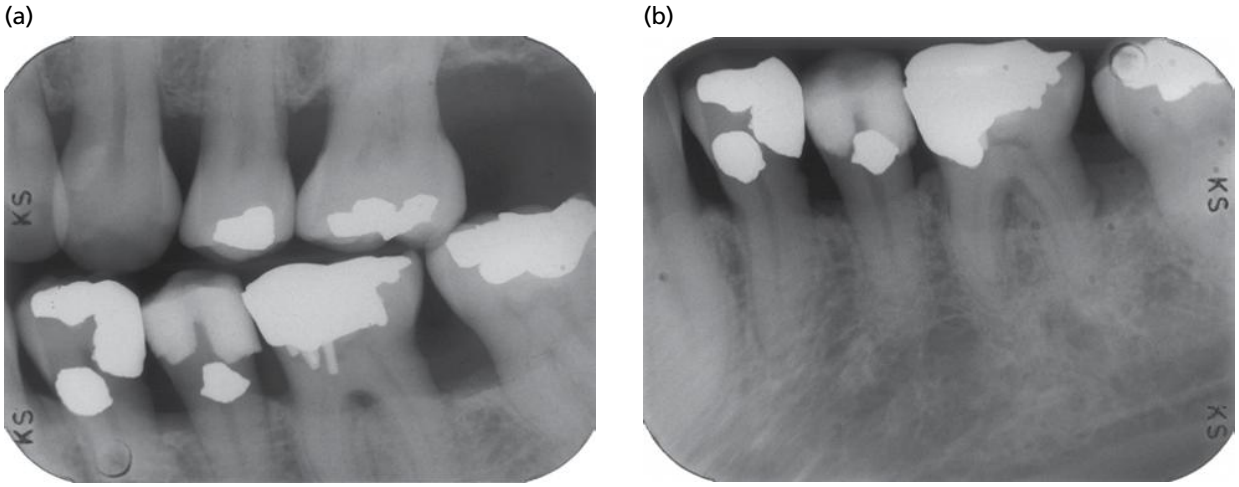

Fig. 30-16 (a) Bitewing radiograph demonstrates primarily horizontal bone loss. The furcation lucency of tooth 36 likely reflects severe periodontal bone loss at tooth 36. Note that this tooth 36 furcation lucency is not well appreciated on the periapical radiograph (b) with appearance of widened periodontal ligament space, suggesting minimal furcation involvement, related to a slightly different vertical projection angle. Also related to variation in projection angle, the horizontal bone loss between teeth 36 and 37 demonstrated on the bitewing appears as a hypodense focus in the periapical radiograph, raising the possibility of a crater defect, or that the bone loss is more severe buccally or lingually, with absence of either cortex. There is a distal overhang associated with tooth 35; this is seen on the bitewing radiograph but is not as obvious on the periapical view. Note the mesial angular defect of tooth 26, likely largely a two-walled defect.

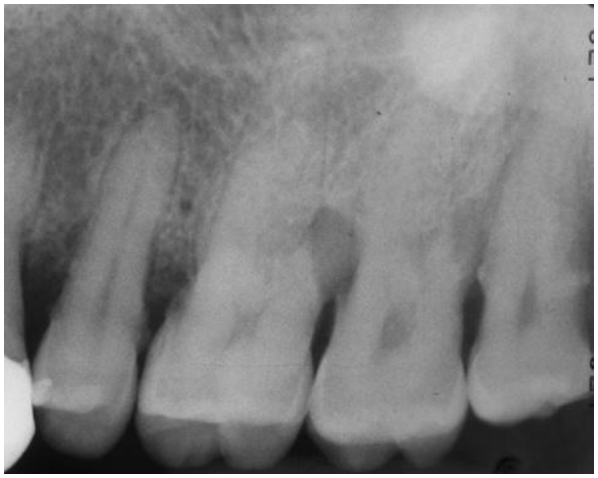

Fig. 30-17 Periapical radiograph demonstrates the "J-shaped" lucent appearance associated with tooth 26, suggesting a furcation defect. A similar appearance, but more subtle, is associated with tooth 27. When clinically indicated, these defects are best identified and the morphology better appreciated with MCT and CBCT.

Morphology of periodontal bone loss

Horizontal bone loss

The bone loss is parallel with the cementoenamel junction (CEJ), usually involving multiple teeth (Figs. 30-12, 30-16).

Angular/vertical defects

The bone loss is uneven and oblique, centered upon one tooth more than the adjacent tooth (Figs. 30-16, 30-18, 30-19).

Fig. 30-18 Periapical radiograph demonstrates severe angular periodontal bone loss. The appearance of the distal angular defect suggests a largely two-walled defect; there may be a focal region superiorly where it is single-walled and likely a three-walled defect at the apical third of this root. The appearance of the mesial angular defect suggests a three-walled defect. A perio-endo defect is also suspected. The absence of periapical bone apically may be obscured by residual buccal and lingual bone. Note the adjacent substantial reactive sclerosis, related to chronicity. Where clinically indicated, these defects are best evaluated with MCT and CBCT.

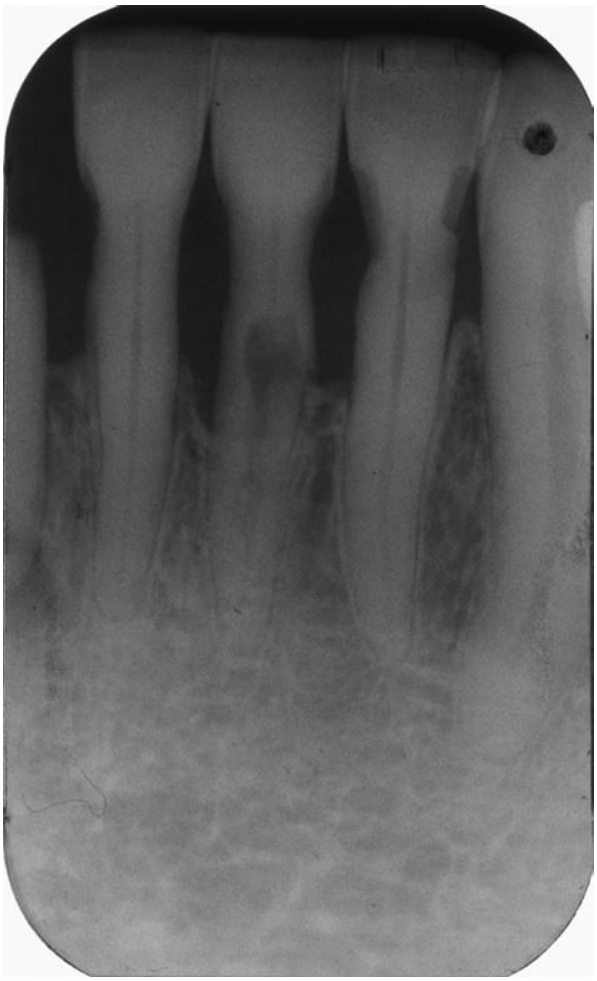

Fig. 30-19 Periapical radiograph demonstrates minor-to-moderate largely horizontal periodontal bone loss with an angular defect at the mesial aspect of tooth 31, likely a single-walled defect. This angular defect likely extends lingually or labially. Note the lucent radicular appearance of tooth 31, related to internal resorption.

Interdental crater defect

These occur at the crest where it is usually a two-walled defect, with relative preservation of the buccal and lingual cortex. It is often not appreciated on plain 2D imaging, but may appear as a focal hypodense region at the superior aspect of the interdental bone. Figures 30-16 and 30-20 demonstrate the difficulty in identifying these defects with intraoral radiography.

Infrabony defects

These refer to focal bone loss which extends along a root surface apically. This defect can be:

- *Three-walled*, where both buccal and lingual cortices are preserved (Fig. 30-18)
- *Two-walled*, where a buccal or lingual cortex is effaced (Figs. 30-16, 30-18)
- *Single-walled*, where both buccal and lingual cortices are effaced (Figs. 30-18, 30-19).

In the intraoral 2D projection, the single-walled defect appears lucent and well defined, and the three-walled defect appears hypodense rather than completely lucent with borders that can appear less well defined.

The identification of the presence of periodontal defects and appreciation of the defect morphology, including vertical defects, is best appreciated with volumetric imaging techniques, including MCT and CBCT (Figs. 30-21, 30-22, 30-23, 30-24, 30-25, 30-26) (Langen *et al*. 1995; Fuhrmann *et al*. 1995, 1997; Mengel *et al*. 2005; Misch *et al*. 2006; Mol & Balasundaram 2008; Vandenberghe *et al*. 2008) It should be noted that vertical defects can be associated with a specific local cause or contributing factor, for example a vertical root fracture (Figs. 30-23, 30-24, 30-26) and overhang.

(a) (b)

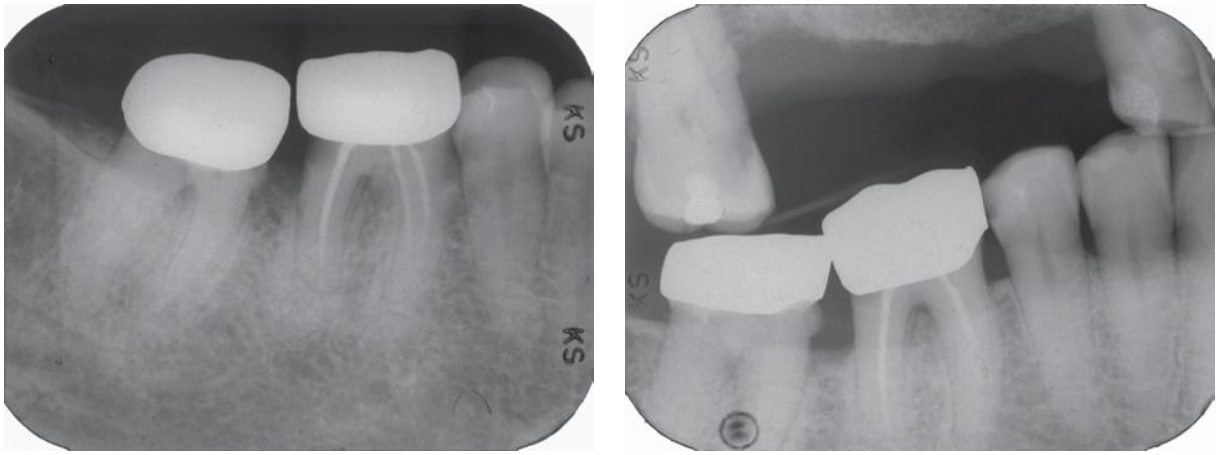

Fig. 30-20 (a) Periapical and (b) bitewing radiographs demonstrate the difference in appearance of the periodontal defects, especially between teeth 46 and 47. The horizontal defect between both these molars is well demonstrated on the bitewing view, but the periapical view only demonstrates a hypodense appearance, which could be misinterpreted as a slight decrease in density or a crater defect. This is related to the difference in vertical projection angle. Interestingly, the mesial calculus deposit of tooth 47 is not as well demonstrated on the periapical view, while the distal cervical caries of tooth 46 is not well demonstrated on the bitewing view. The distal deficiency associated with the tooth 45 restoration is not as well appreciated on the periapical view, related to a difference in the horizontal projection angle. Note the appearance of a slightly widened periodontal ligament space at the tooth 46 furcation, raising the possibility of an early furcation defect.

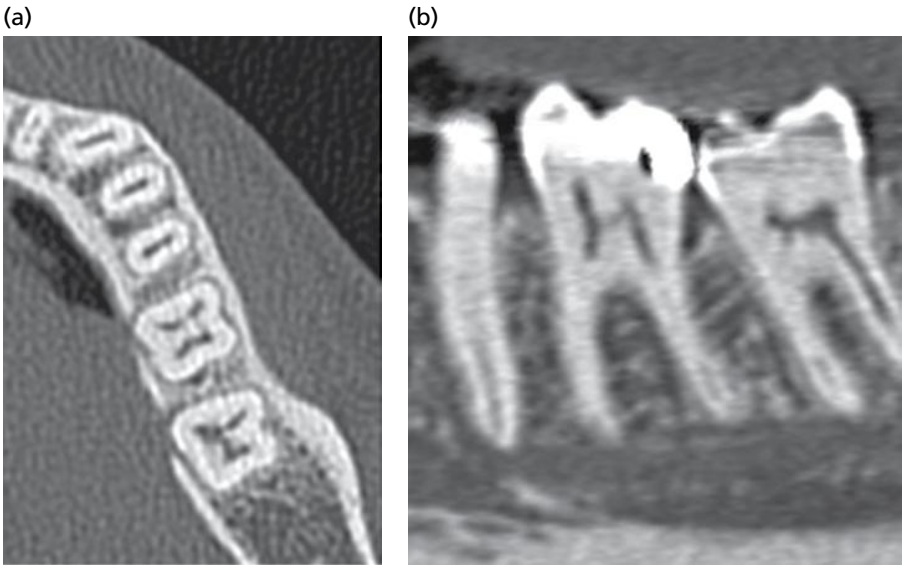

Fig. 30-21 (a) Axial and (b) corrected sagittal low-dose MCT images demonstrate a focal distal angular defect of tooth 36, which is narrow buccolingually. This would not be appreciated on an intraoral radiograph, as this narrow defect would be obscured by projection of the buccal and lingual bone.

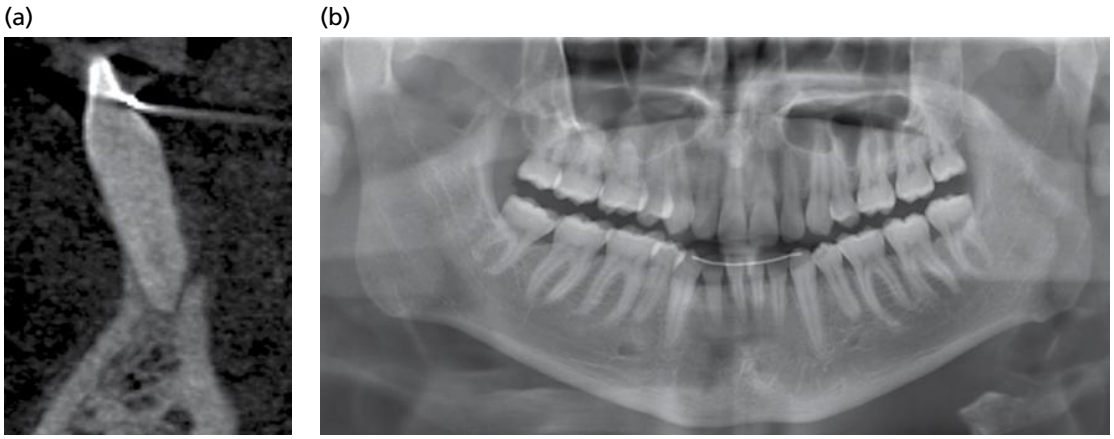

Fig. 30-22 (a) Sagittal low-dose CBCT image demonstrates focal severe lingual periodontal defect of tooth 41 with lingual cortical dehiscence approaching the apex. Note also the widened apical periodontal ligament space which is likely related to increased mobility, although it is difficult to completely exclude early pulpal involvement. (b) This tooth 31 periodontal defect is not well demonstrated on the panoramic radiograph.

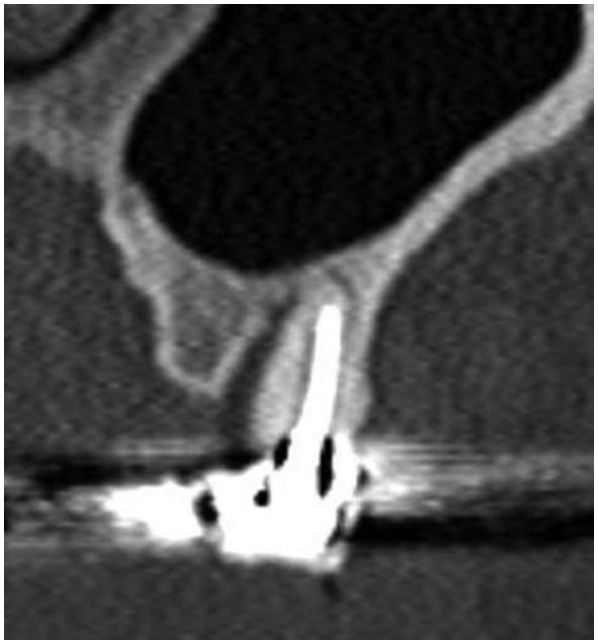

Fig. 30-23 Low-dose coronal MCT image demonstrates a severe narrow palatal vertical periodontal defect associated with this root of tooth 16. This is likely related to a vertical root fracture. Undisplaced root fractures can be subresolution and not detected with MCT or CBCT. This palatal periodontal defect would not be detected on an intraoral radiograph. Note the adjacent reactive sclerosis, likely related to the chronic nature of the lesion.

Fig. 30-24 Low-dose coronal MCT image demonstrates a vertical palatal periodontal defect of the endodontically treated tooth 25, with some residual palatal cortex. This would not be appreciated on intraoral or panoramic radiography. This appearance raises the possibility of a vertical root fracture. Undisplaced root fractures can be subresolution and not identified with MCT or CBCT.

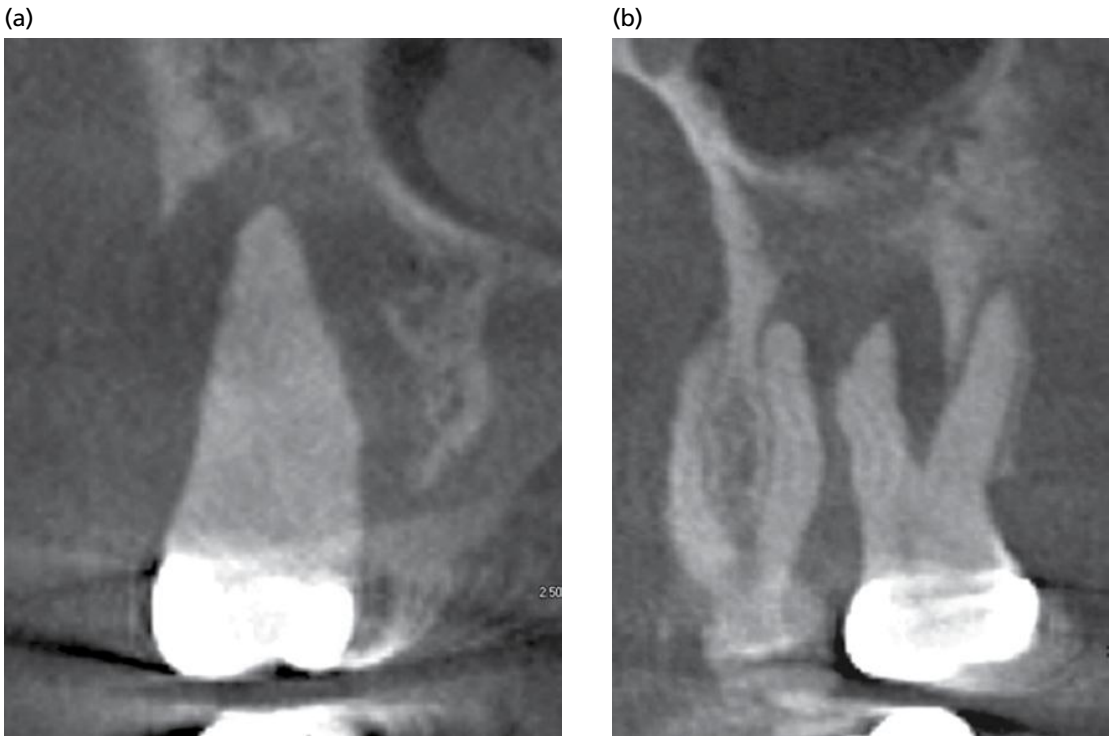

Fig. 30-25 (a) Low-dose coronal and (b) sagittal CBCT images demonstrate severe angular and perio-endo defects involving both tooth 26 distobuccal and tooth 27 mesiobuccal roots. The coronal image of the tooth 16 mesiobuccal root shows the associated buccal cortical dehiscence while also demonstrating preservation of the residual palatal bone of the alveolar process adjacent to the perio-endo defect. The morphology of these defects is best appreciated with multiplanar reformatted (MPR) images on a computer.

Fig. 30-26 Axial low-dose CBCT image demonstrates narrow buccal and distopalatal periodontal defects, likely associated with vertical root fracture of this endodontically treated tooth 35. Undisplaced root fractures can be subresolution, not identified with CBCT or MCT. Note the substantial beam hardening associated with the non-metallic obturation of this premolar.

Fig. 30-27 Periapical radiograph demonstrating lucent lesions at the furcation and root apices, likely inflammatory. The adjacent substantial sclerosis is likely reactive, related to chronicity. It is suspected that the furcation lesion is of pulpal origin, rather than periodontal. There is likely ongoing endodontic management of this molar.

Furcation defects

On intraoral 2D views, early inflammatory disease involvement of a furcation usually presents radiologically as a widened periodontal ligament space at the furcation (Figs. 30-16, 30-20). As the disease progresses, a lucent bony defect is visualized at the furcation (Fig. 30-16). It should also be noted that an inflammatory furcation lesion may also be of pulpal origin, related to accessory pulpal canals, root resorption or iatrogenic perforation (Figs. 30-27, 30-28).

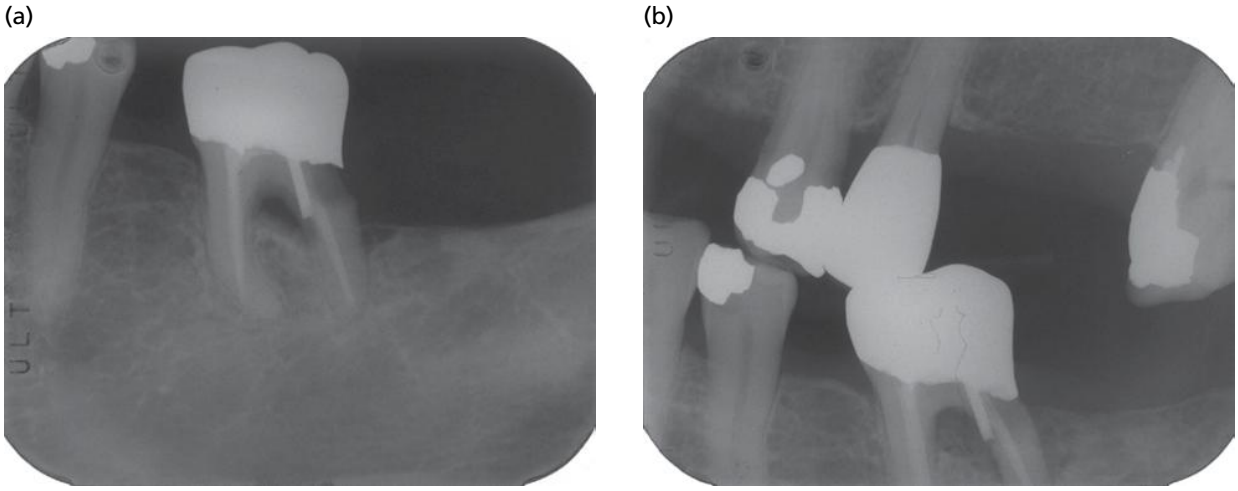

Fig. 30-28 (a) Periapical and (b) bitewing radiographs demonstrate a lucent furcation inflammatory lesion, more obvious on the periapical view. This is likely related to perforation associated with the post of the distal root, more definitively demonstrated on the bitewing view. Interestingly, the distal cervical caries is also better demonstrated on the periapical view.

Fig. 30-29 (a) Low-dose axial MCT image demonstrates the precise morphology of the severe periodontal bone loss of tooth 16 with bony furcation involvement. (b) Panoramic radiograph does not demonstrate this defect, although the degree of periodontal bone loss would raise the possibility of a furcation defect. Note that this defect morphology is best appreciated by interrogating the MCT dataset with multiplanar reformatted (MPR) images on a computer.

On plain 2D imaging, lucent and relatively well-defined mandibular molar furcations are usually only seen when there is destruction of either the buccal or lingual cortical plates, or both. If both or one of cortices are preserved, the mandibular molar furcation defect appears as a focal region of varying hypodensity and definition. With limitations, multiple projections with application of parallax principles can be helpful in identifying if the furcation defect is centered buccally or lingually. In some cases, the buccal or lingual cortical loss extends further than at the furcation, resulting in a hypodense appearance at the furcation region where the periodontal ligament space can appear slightly widened. This appearance of a widened furcation periodontal ligament space may be related to less attenuation of the X-ray photons from the normally present buccal and/or lingual cortices, rather than to true furcation disease.

Precise plain 2D radiographic examination for furcation defects is limited, especially of the maxillary molars, largely because of the presence of the palatal root. The classically described "J-shaped" lucent appearance is sometimes seen (Fig. 30-17). The precise location, extent, and morphology of periodontal defects, including furcation defects, is better appreciated with MCT and CBCT (Figs. 30-29, 30-30, 30-31, 30-32, 30-33) (Langen *et al*. 1995; Fuhrmann *et al*. 1995, 1997; Mengel *et al*. 2005; Misch *et al*. 2006; Mol & Balasundaram 2008; Vandenberghe *et al*. 2008).

Perio-endo defects

These are lucent lesions extending from the crestal bone to the apex of a tooth root, but are not always clearly apparent on plain 2D imaging, often because of the projection of the adjacent tooth and bony structures. MCT or CBCT better demonstrate these defects (Figs. 30-18, 30-25, 30-32, 30-33, 30-34).

Fig. 30-30 Low-dose MCT axial image demonstrates a furcation defect of tooth 16, where the buccal roots are in close proximity. Access and debridement of this trifurcation defect would be very difficult, if not impossible, without root surgery. Note the extension of the distal periodontal bone loss of tooth 17 to the distal concavity. The morphology of these defects is more precisely evaluated with multiplanar reformatted (MPR) images on a computer.

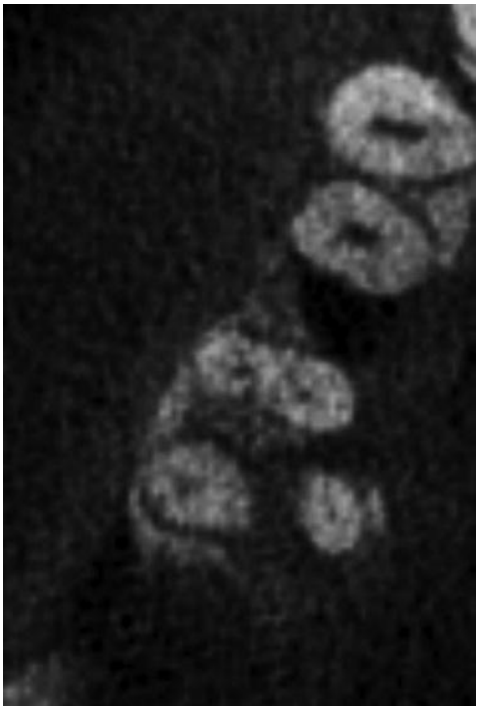

Fig. 30-31 Low-dose CBCT axial image demonstrating a class III bony furcation defect of the tri-rooted tooth 46, extending from the distal to the lingual aspect. The reduced image quality is related to the patient's head size and the low-dose protocol and unit employed. The morphology of this defect is best appreciated with multiplanar reformatted (MPR) images on a computer.

These defects may reflect contiguity of periodontal and periapical inflammatory lesions, where both lesions are sufficiently large that they essentially merge to form one larger lesion. These perio-endo defects could also be primarily or solely of periodontic or endodontic origin. Radiologically, it can be difficult to distinguish between the various causes, although the morphology of the lesion may provide useful clues which can be correlated with the clinical findings. For example, an inflammatory perio-endo defect involving a root, where the apical aspect of the defect is much larger and the periodontal bone loss elsewhere is more limited, may raise the suspicion that this lesion is at least primarily of pulpal origin.

Similar to vertical defects, perio-endo defects can also be associated with a specific local cause or contributing factor, such as a vertical root fracture.

Acute periodontal abscess

This acute inflammatory lesion is usually not seen on plain 2D radiography and CBCT. The lesion identified on these views often largely reflects the chronic bony destruction, which has taken some time to occur. An abscess and/or inflammatory infiltrate can extend into the adjacent soft tissues (see later).

Border

While inflammatory lesions are classically relatively ill defined, inflammatory periodontal bone loss is usually chronic in nature. Therefore, the margins often appear relatively well defined.

Internal appearances of periodontal defects

Inflammatory periodontal bony lesions are lucent internally. Occasionally, oral debris is seen.

Adjacent structures

Hypodense or lucent appearances adjacent to an inflammatory lesion often reflect a loss of trabecular bone related to progression of the disease. This less dense appearance is related to a decrease in the density as well as the number of trabeculae.

Sclerosis of the adjacent bone (increased density) is quite commonly seen. This is a reaction of the adjacent trabecular bone to the inflammatory lesion, with deposition of bone on the trabeculae resulting in thicker trabeculae and smaller marrow spaces. This takes time and reactive sclerosis therefore reflects the chronic nature of the dentoalveolar inflammatory lesion (Figs. 30-7, 30-18, 30-23, 30-27, 30-34). Substantially sclerotic mandibular appearances are not infrequently seen. It is also important to recognize that this sclerosis may persist following successful therapy, usually for extended periods; that is, this sclerosis is residual and does not indicate ongoing active disease.

Fig. 30-32 (a) Low-dose axial and (b) coronal MCT images demonstrating a class III bony furcation defect of tooth 16, with perio-endo defect of the palatal root (coronal image). Note the extension of the periodontal bone loss of tooth 17 to the inter-radicular grooves. The morphology of these defects is best evaluated on computer, with multiplanar reformatted (MPR) images. (c) Axial MRI STIR sequence demonstrates the edema between teeth 16 and 17, and also associated with the furcation defect of tooth 16. (d) Axial MRI T1 sequence demonstrates normal fatty marrow interdentally between the premolars and also anteriorly. These features are not demonstrated with MCT or CBCT.

Periapical and severe periodontal inflammatory lesions affecting the maxillary posterior teeth often induce a reactive change at the maxillary sinus bases. Apical inflammatory lesions and periodontal inflammatory lesions which approximate the root often result in a focal reaction of the periosteum, a focal periostitis. Radiologically, this appears as a focal dome-shaped, curvilamina opacity over the inflammatory lesion at the sinus base (Fig. 30-34). These inflammatory lesions may thin, elevate or even focally efface the cortical floor of the maxillary sinus. In addition, periapical and periodontal inflammatory lesions which closely approximate the maxillary antral bases almost always induce a reactive mucosal thickening at the maxillary sinus floor (Fig. 30-34).

Fig. 30-33 Sagittal low-dose CBCT image demonstrates furcation and perio-endo defects of tooth 36.

When inflammatory lesions extend to cortical boundaries, the inflammatory products can extend through the cortex (which clinically and radiologically appear preserved) to elevate the periosteum. This elevated periosteum lays down a lamina of bone, often referred to as periosteal response or periosteal new bone formation. Radiologically, a bony curvilamina opacity adjacent and largely parallel to the cortex is seen. In cases where there are multiple chronic and acute phases, multiple opaque lamina are seen. Periosteal response is often seen in osteomyelitis, but is rarely seen with periodontal disease, except where this is severe and aggressive.

When there is frank extension of periodontal and periapical inflammatory lesions into the adjacent soft tissues, there is usually radiologically evident effacement of the bony cortex, however small. These

(a)

(b)

Fig. 30-34 (a) Axial and (b) sagittal low-dose MCT image: There is a class III bony furcation defect of tooth 27 extending from the distal to the buccal aspects (axial image). There is also a perio-endo defect of tooth 28 with associated focal periostitis and reactive mucosal thickening at the left maxillary antral base. The adjacent sclerosis is likely also reactive. Note also the early distal bony furcation involvement of tooth 26 and mesial caries of tooth 28.

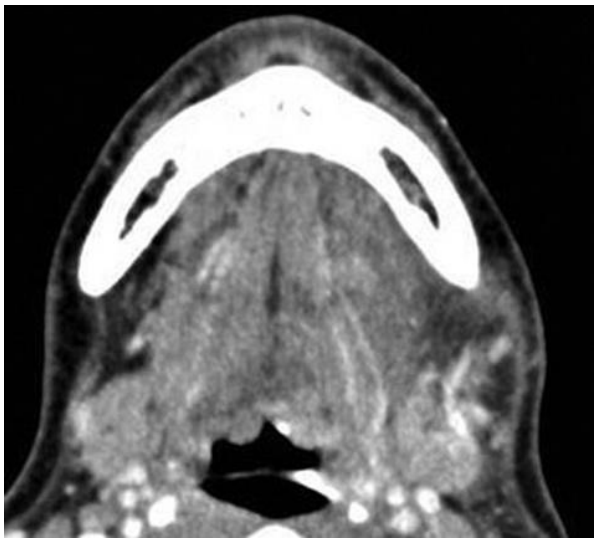

Fig. 30-35 MCT axial soft tissue window image (with intravenous contrast) demonstrates inflammatory infiltrate within the left submandibular space from a left mandibular periapical lesion. Note the minimal prominence of the left lateral pharyngeal wall. When severe, compromise of the airway can be life threatening.

cortical defects often appear as lucencies on 2D views, more lucent if both cortices are involved. However, these lucencies may not be appreciated on 2D imaging when projected over more opaque structures, such as the tooth root itself. These cortical defects are best visualized with MCT or CBCT. However, infection within the soft tissues cannot be examined with plain 2D radiography or CBCT, and MCT, often with intravenous contrast, is then the modality of choice. The details of these examinations are beyond the scope of this text. MCT features, including the presence of inflammatory infiltrate, fat streaking, contrast enhancement, abscess collection, and periosteal new bone formation, can be useful in the evaluation of an acute periodontal inflammatory lesion. The location and extent of cellulitis and extent of abscess collection as well as airway patency are findings with potentially urgent clinical and surgical relevance (Figs. 30-9, 30-35).

Related factors

There are many factors which influence inflammatory periodontal disease. Many of the locally related factors are sometimes identified radiologically. However, it must be recognized that these factors may not be identified radiologically, particularly when subtle and especially with 2D radiography. Local factors include:

- Calculus deposits (Figs. 30-20, 30-36)
- Restorative therapy-related factors, including overhangs, deficiencies, open margins, incorrect contours, and open contacts (Figs. 30-12, 30-14, 30-16)
- Caries occurring or extending cervically (Figs. 31-20, 31-28, 30-34)

Fig. 30-36 Periapical radiograph demonstrates horizontal bone loss and calculus deposits.

- Root fractures (Figs. 30-23, 30-26)
- Perforations related to endodontic therapy and post preparations (Fig. 30-28)
- Increased mobility and/or increased occlusal loading, usually presenting with widened periodontal ligament spaces (Fig. 30-15). This widening can involve the entire root or be seen only apically and cervically. A thickened lamina dura is sometimes evident
- Hypercementosis is often idiopathic but can also be related to increased loading
- Crown-to-root ratio of a tooth may be relevant to the prognosis
- Presence of apical inflammatory lesions (Figs. 30-7, 30-27) may affect the prognosis and treatment planning.

Differential diagnosis

Essentially, any lesion which results in the loss of periodontal bone can resemble plaque-related inflammatory bone loss.

A malignant lesion, for example squamous cell carcinoma or adenoid cystic carcinoma, can resemble periodontitis. Malignant metastatic lesions such as adenocarcinoma from the breast can also resemble

periodontitis. However, there are almost always differences in the radiologic appearances. Most importantly, the appearance of infiltrative and invasive margins and of the leading edge are key radiologic features (Fig. 30-8). When occurring within the alveolar process, Langerhans cell histiocystosis can also resemble periodontitis-related bone loss. However, these lesions tend to be centered at the mid-root, in contrast to inflammatory periodontal bone loss which begins at the alveolar crest. Benign tumors can also occasionally resemble periodontal bone loss, although mass effect is often seen with these and may result in unusual tooth displacement.

If suspicious appearances are noted on a 2D radiographic image, further evaluation with MCT must be considered. Malignant lesions are not optimally evaluated with CBCT, because of the limitations of this technique, including poor visualization of the soft tissues. Intravenous contrast is usually required for these examinations. Sometimes, the malignant features are not obvious, especially on 2D radiography, requiring a high level of interpretive skill to identify them. Specialist radiologic opinion should be considered.

As a general rule, focal moderate-to-severe periodontal defects, where the periodontium elsewhere is essentially within normal limits, should be evaluated carefully. Biopsy should be considered if there is clinical suspicion that the lesion is not inflammatory. If the clinical and radiologic findings support the presence of inflammatory bone loss and there is no pretreatment indication for biopsy or other tests, post-management clinical and radiologic review should be considered.

Pathology involving other regions of the jaws and adjacent structures

Appropriate radiologic examination also provides an opportunity to identify other pathology within the jaws or affecting the adjacent structures. These findings, even if not directly related to the inflammatory periodontal disease, may affect the overall diagnosis and treatment planning.

Frequency of periodontal radiologic examinations

The frequency of radiologic examination for the patient with periodontal disease is dependent on the clinical findings and treatment response. Radiologic documentation of the disease sites prior to periodontal treatment is important, both for diagnosis and also as a baseline in the evaluation of interval change. It is important to emphasize that the presence and severity of periodontal bone loss does not indicate the presence of active disease. Clinical evaluation and radiologic evidence of interval change are important in this regards.

Implant imaging

The importance of and the key steps involved in evaluating the region intended for implant placement for presence of pathology have been discussed earlier. The importance of evaluating other dentoalveolar and oral structures in relation to an overall treatment plan was also recognized.

An appropriate radiologic study also obviously provides an opportunity to evaluate the site(s) in relation to the implant placement itself. Preliminary radiologic studies often contribute to the initial diagnosis and clinical decision as to whether implant therapy is the optimal choice in the overall management. To varying extents and to varying levels of accuracy, the various imaging techniques aid in the selection of the optimal implant and planning of the most favorable location and orientation, and also facilitate surgical planning. It is critical that radiologic diagnostic information is maximized and appropriately applied to achieve the best possible outcome, and minimize complications and failures. It must be emphasized that the radiologic findings must be combined with the clinical information in the planning of the implant. For example, while there may appear to be sufficient bone volume at a particular site, the angulation of the implant required for a satisfactory result may still require bone augmentation. Some of the key parameters in implant planning where appropriate imaging (Figs. 30-37, 30-38, 30-39, 30-40, 30-41 30-42, 30-43, 30-44, 30-45) can contribute are:

- Bone height (craniocaudal dimension)
- Faciolingual/faciopalatal width
- Mesiodistal dimension
- Bone morphology
- Presence and prominence of anatomic features:
  - Sublingual and submandibular fossae
  - Incisive and canine fossae
- Neurovascular canals and foramina, including:
  - Mandibular canal and the mental foramen
  - Incisive canal and foramen
  - Mandibular lingual canals and foramina (Laboda 1990; Mason *et al*. 1990; Katakami *et al*. 2009; Tagaya *et al*. 2009; Givol *et al*. 2000)
  - Greater palatine canal and foramen
- Cortical thickness and density
- Extent and morphology of the alveolar recesses of the maxillary sinus bases.

Normal variants of anatomy must be kept in mind and appropriate imaging applied so that these are identified. Substantial variations in many anatomic structures are well known, such as the degree of extension of the alveolar recesses of the maxillary sinuses into the maxillary alveolar process. Large variations in the location of the mandibular canal and mental foramina, the location and size of the maxillary incisive canals, as well as prominences of the

Fig. 30-37 Low-dose cross-sectional MCT image of the tooth 43 site demonstrates new bone formation, with some remodeling, within the tooth socket.

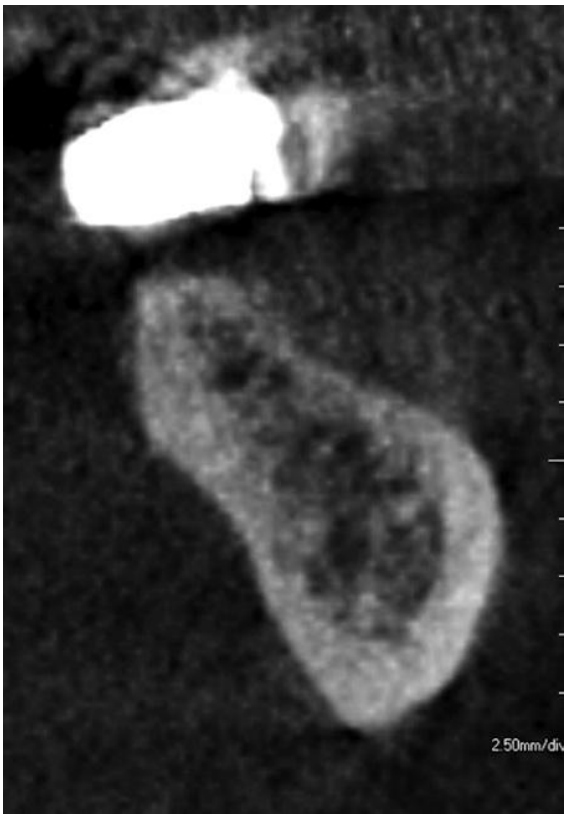

Fig. 30-39 Low-dose reformatted cross-sectional image of a tooth 36 site. There has been postextraction bony remodeling. Note the slight-to-moderate submandibular concavity. The mandibular canal is visualized.

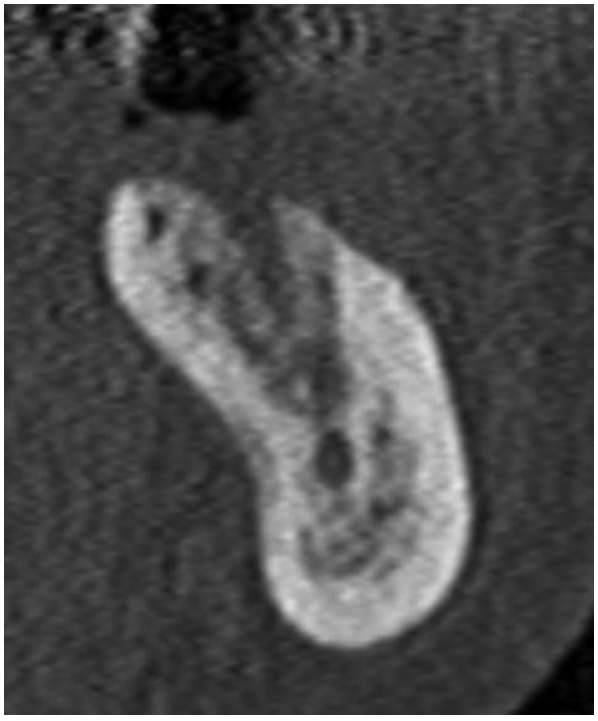

Fig. 30-38 Low-dose cross-sectional MCT image of a tooth 36 site demonstrates substantial peripheral new bone formation. The mandibular canal is visualized at the apical aspect of the healing socket. Note the slight-to-moderate submandibular concavity.

Fig. 30-40 Low-dose cross-sectional MCT image of a premolar site demonstrates the mental foramen and adjacent mandibular canal. Note the relatively narrow residual ridge and the moderately prominent sublingual concavity.

Fig. 30-41 Low-dose cross-sectional CBCT image of a mandibular molar site demonstrates a moderate submandibular concavity. The mandibular canal is visualized.

Fig. 30-42 Low-dose cross-sectional MCT image of site 15. Note the proximity of the maxillary antral base at the buccal aspect.

(a) (b)

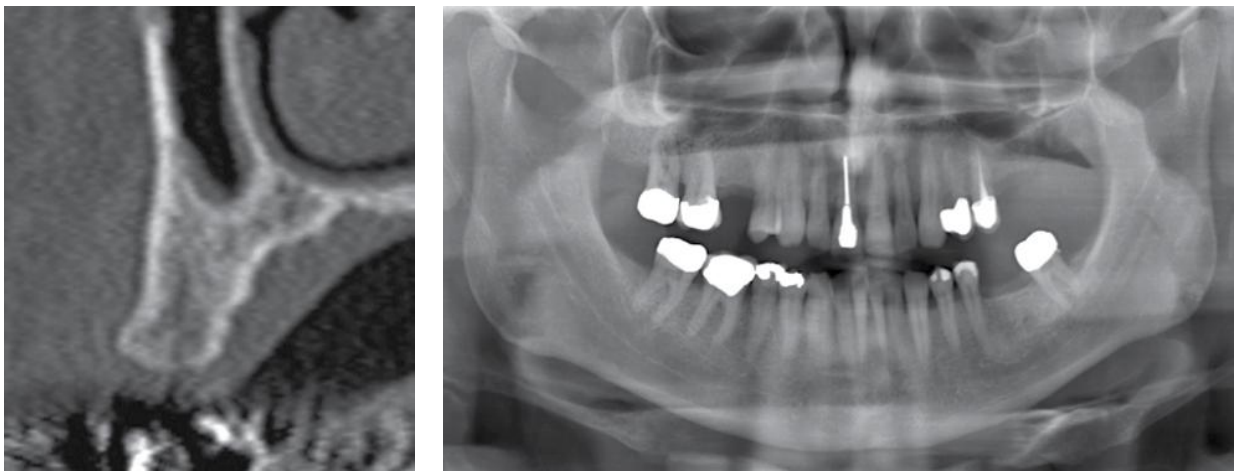

Fig. 30-43 (a) Low-dose cross-sectional MCT image demonstrating the buccolingual concaved morphology of the maxillary antral base at site 15. (b) This is not appreciated on the panoramic view, giving the false impression of a larger bone height.

sublingual and submandibular fossae are also well known. Multiple mental foramina and mandibular canals as well as variation in the length and extent of the anterior loop of the canal leading to the mental foramen have also been described (Arzouman *et al*. 1993; Naitoh *et al*. 2009a; Uchida *et al*. 2009; Kuribayashi *et al*. 2010; Apostolakis & Brown 2012; de Oliveira-Santos *et al*. 2012). The presence of lingual canals and foramina of the mandible have also been commonly reported and considered potentially life threatening in relation to the surgical placement of implants (Laboda 1990; Mason *et al*. 1990; Givol *et al*. 2000; Katakami *et al*. 2009; Tagaya *et al*. 2009). It is essential that the imaging modality selected is capable of accurately demonstrating these critical structures. These normal variants are discussed in further detail in the section on MCT and CBCT below.

Imaging modalities

Intraoral radiographs

Intraoral radiographs represent a series of small FOV 2D images. Essentially, 3D structures are projected over each other onto a flat detector. This is a high-resolution modality, available in almost all dental

Fig. 30-44 Axial low-dose MCT image demonstrates the tooth site 13. The mesiodistal dimension at this site is smaller palatally, which would not be appreciated on 2D radiography. Note that these interdental dimensions are best evaluated on axial images, rather than cross-sectional and panoramic slices.

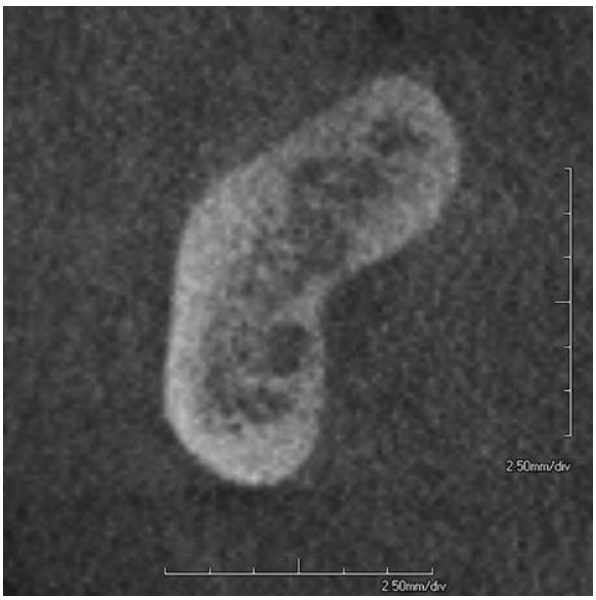

Fig. 30-45 Cross-sectional low-dose CBCT image of a mandibular molar site demonstrates a prominent submandibular concavity. The mandibular canal is visualized.

settings, and can be relatively inexpensive. However, the limitations must be recognized.

In relation to the periodontal patient, only the proximal structures are sufficiently well visualized. Alterations in density may provide only limited information regarding the status of buccal/labial and lingual/palatal periodontal bone (Fig. 30-23). Multiple projections employing parallax principles can be useful, although the true 3D morphology of a periodontal bony defect is not demonstrated on intraoral radiography. Obviously, a certain level of bone demineralization or loss must occur before bony change is detected radiologically. This is particularly true with plain 2D imaging, including intraoral radiography, where a lesion must cause sufficient loss of osseous structure to be visualized. In other words, the lesion must cause sufficient decrease in bone density and/or bony destruction, especially in the faciolingual dimension, to be identified on 2D imaging. For example, narrow vertical periodontal defects are often not detected on intraoral views (Figs. 30-21, 30-26). Many lesions are not identified on 2D radiography until buccal or lingual cortices are effaced. Soft tissues are not examined with this technique, although the profile of the overlying soft tissue, for example the operculum over an impacted third molar, is occasionally seen. Projection of dense or thick bony structures over the area of interest on intraoral radiography may obscure a periodontal defect, for example an external oblique ridge and the inferior cortex of the zygomatic process of the maxilla.

Whenever possible, the paralleling technique must be employed for periapical radiography. Interestingly, the bitewing projection is usually more accurate in the evaluation of periodontal bone loss, as the primary beam is more perpendicular to the long axis of the teeth. This may be the projection of choice where the periodontal bone loss is not expected to be severe. There is often compromise in the projection angles in periapical imaging, which can result in the inaccurate reflection of the true periodontal bone levels (Figs. 30-16, 30-20). However, the opposite can sometimes be true (Fig. 30-28). Therefore, it is crucial that the observer is aware of the precise angle of projection. Detailed examination of the other anatomic structures in the FOV can be helpful in identifying the projection. One method is to evaluate the coronal morphology, where the degree of superimposition of cusps of posterior teeth upon each other provides clues to the vertical angle of projection. Obviously, the degree of overlap of proximal crown surfaces may provide clues to the horizontal projection angle.

Several associated techniques have been explored to assist in the comparison of images to evaluate for bony changes. Grids and subtraction radiography both rely on exact detector placement and projection angle, which is not easily achieved and rather impractical in the clinical setting.

In the evaluation of periodontal bone loss, periapical radiography is not as accurate as CBCT and MCT (Furhmann *et al*. 1995; Langen *et al*. 1995; Mol & Balasundaram. 2008; Vandenberghe *et al*., 2008). It has also been shown that the presence and the morphology of periodontal defects is more accurately identified by CBCT and MCT (Fuhrmann *et al*. 1995;

Langen *et al*. 1995; Fuhrmann *et al*. 1997; Misch *et al*. 2006), as discussed in the relevant section below. The need to employ CBCT or MCT in the evaluation of periodontal defects remains dependent on the clinical findings of each individual case. For example, CBCT may be indicated in a case with moderate periodontal disease where there is suspicion of narrow vertical or furcation defects which are not obvious clinically. CBCT may also be preferable to a full-mouth intraoral series or multiple periapical radiographs. To arrive at the optimal decision, the clinician must be thoroughly acquainted with the capabilities of MCT and CBCT, as well as the associated radiation doses (see relevant section below).

The presence and extent of periapical disease is also obviously of importance to the overall diagnosis of the periodontal patient. Volumetric imaging modalities like MCT and CBCT have been shown to be significantly superior in identifying the presence of periapical lesions than periapical radiographs (Velvart *et al*. 2001; Huumonen *et al*. 2006; Lofthag-Hansen et al. 2007; Stavropoulos & Wenzel 2007; Low *et al*. 2008; Estrela *et al*. 2008). Volumetric imaging provides more information with regards to the radiologic features of a periapical lesion and has been shown to be more accurate with regards to the diagnosis of the periapical lesion (Simon *et al*. 2006).

In dental implantology, periapical radiography can provide a useful initial view. However, the limitations of this application must be well understood. These 2D views obviously provide no cross-sectional information. For example, submandibular and sublingual fossae and the morphology of the alveolar recess of a maxillary sinus base are not accurately appreciated, but are well demonstrated with MCT and CBCT (Figs. 30-38, 30-39, 30-40, 30-41, 30-42, 30-43). Assuming a paralleling technique, the residual ridge and implant orientation may not be at the same "angle" as the intended implant. Only a small area of jaw is imaged unless multiple views are obtained. The relative inaccuracy of periapical radiography generally, compared to MCT and CBCT, must be recognized (Furhmann *et al*. 1995; Langen *et al*. 1995; Williams *et al*. 2006; Mol & Balasundaram 2008; Vandenberghe *et al*. 2008). CBCT and MCT have also been shown to more accurately identify the mandibular canal than the periapical radiograph (Klinge *et al*. 1989; Lindh *et al*. 1992). While appreciating the availability of radiologic equipment, it should be noted that the planning of an implant solely based upon a periapical radiograph is no longer considered an appropriate standard of care in several parts of the world.

The periapical radiograph remains an important technique in post-implant imaging, although the difficulties in obtaining these views are recognized. While it has been shown to accurately demonstrate peri-implant defects (De Smet *et al*. 2002; Corpas Ldos *et al*. 2011), only the proximal bone is demonstrated, unlike with volumetric techniques (Figs. 30-46, 30-47). However, it has the advantage of absence of image artifacts associated with implants, unlike as often seen on CBCT (Pauwels *et al*. 2013) and also MCT studies (Figs. 30-48, 30-49). If clinically indicated, the periapical radiograph can still be useful even if the entire implant cannot be included in the

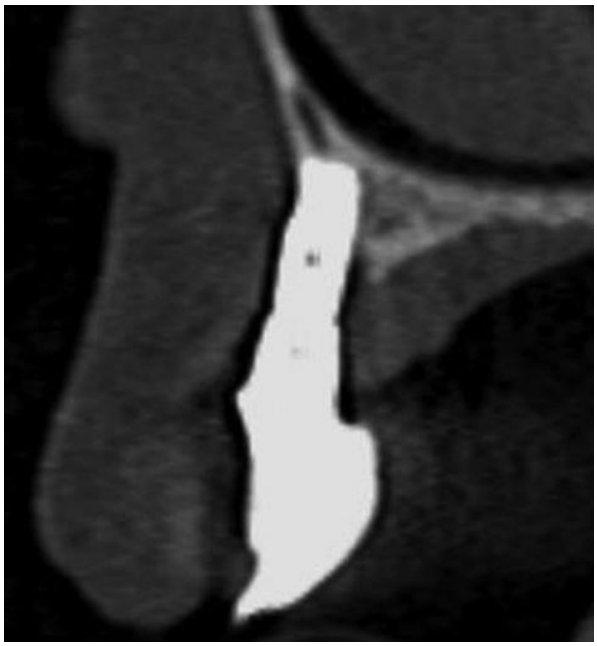

Fig. 30-46 Cross-sectional low-dose MCT image demonstrates moderate-to-severe peri-implant bone loss associated with the tooth site 13 implant.

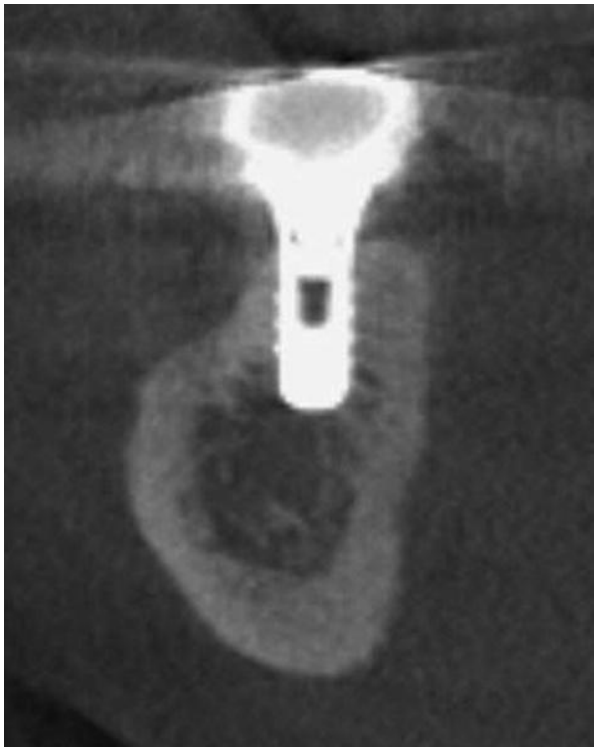

Fig. 30-47 Cross-sectional low-dose CBCT image of a mandibular posterior implant, demonstrating no associated focal osseous abnormality buccally and lingually. The separation of the implant apex and the mandibular canal is accurately appreciated.

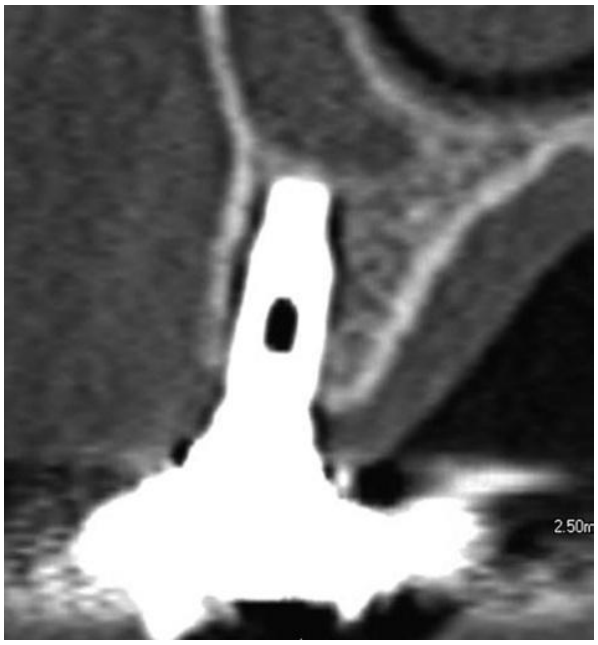

Fig. 30-48 Cross-sectional low-dose MCT image of a tooth site 15 implant demonstrates the lucent artifact immediately adjacent to the implant.

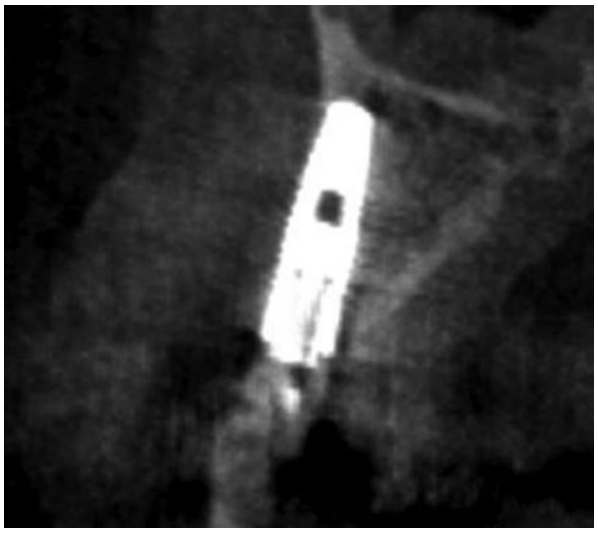

Fig. 30-49 Cross-sectional low-dose CBCT image of a tooth site 12 implant demonstrates largely absent labial bone over this implant. Note the beam hardening artifact typical of CBCT.

FOV, as long as the detector is parallel to the implant and the central X-ray beam is perpendicular to both. MCT and CBCT should be considered if the intraoral radiograph does not provide the information required for diagnosis, as discussed in the relevant section below.

With some implant systems, intraoral radiographs can be useful in confirming the optimal position of the abutments. An optimal paralleling technique is required.

Panoramic radiographs

The panoramic radiograph is a unique form of conventional tomography. Like conventional tomography, this technique relies on motion of the detector and the X-ray tube during image capture. Motion unsharpness results in more blurring of the structures that are not in the plane of interest. The panoramic radiograph is essentially a thick curvilinear tomogram where the plane of interest is curved along the line of the alveolar arches. Therefore, it only provides 2D information, with no cross-sectional information for the arches.

In addition to the limitations of 2D views already discussed in relation to intraoral radiography, there are further well-known and substantial limitations of panoramic radiography, including:

- Lower resolution
- Overlapping structures, for example C-spine, soft tissues, air spaces
- Objects outside the focal trough are not imaged
- Ghost images
- Double images
- Magnification:
  - Machine dependent
  - Unpredicatable, even with the same patient in the same machine
  - Uneven magnification within one single image
- Image distortion
- Objects nearer the film/detector (buccal) are narrowed
- Lingual objects appear more superior
- Varying foreshortening and elongation
- No 3D information on:
  - Ridge width and orientation
  - Submandibular fossa
  - Incisive fossa
  - Mandibular canal location
  - Mental foramen
  - Incisive canal and foramen
  - Maxillary sinus
  - Floor of nasal cavity.

The challenges associated with the accurate interpretation of a panoramic radiograph are often underestimated, and incorrect interpretation is often related to a lack of understanding of the many limitations. For example, many structures depicted on a panoramic radiograph are not sufficiently well demonstrated to rule out the presence of pathology nor evaluate the nature of the disease (Figs. 30-8, 30-50). Another common error arises from lack of understanding of the specific projection angle at one specific point of the image, which changes throughout and is usually horizontally and vertically oblique. For example, the orientation of an impacted tooth seen on a panoramic radiograph is often not a true reflection (Fig. 30-51). Limited knowledge of the radiologic anatomy and insufficient knowledge of all pathologies (including the radiologic features) which could arise or manifest within the orofacial structures included in these views, also contribute to potentially erroneous interpretation.

In addition to the limitations associated with intraoral radiography, the substantial limitations of

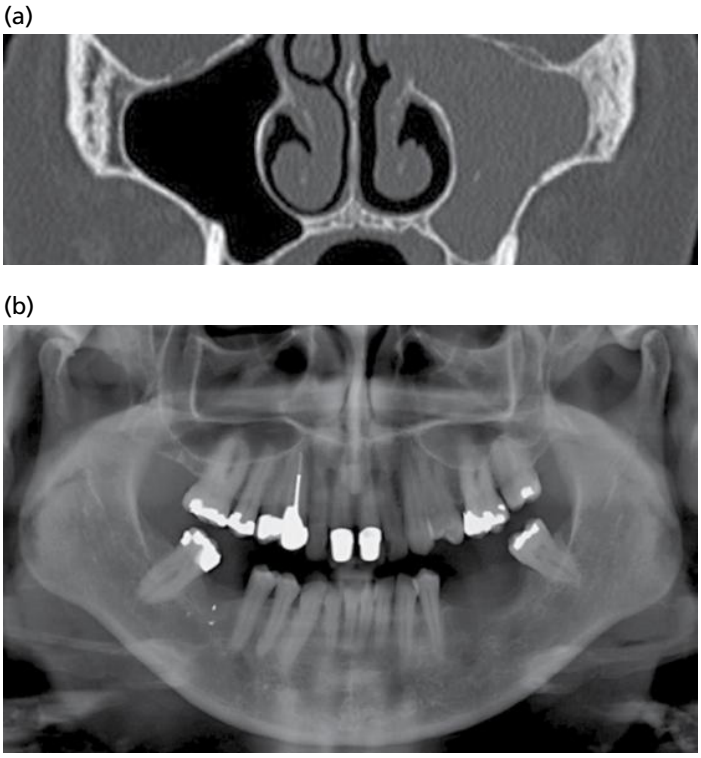

Fig. 30-50 (a) Opacified left maxillary sinus extending into the left ostiomeatal unit with sclerotic sinus walls and internal opacities is demonstrated on the coronal MCT image. This appearance is compatible with chronic inflammatory disease where there may be fungal superinfection. (b) This left maxillary sinus disease is not appreciated on the panoramic radiograph, highlighting the many and substantial limitations of panoramic radiographs, including for evaluation of the maxillary sinuses.

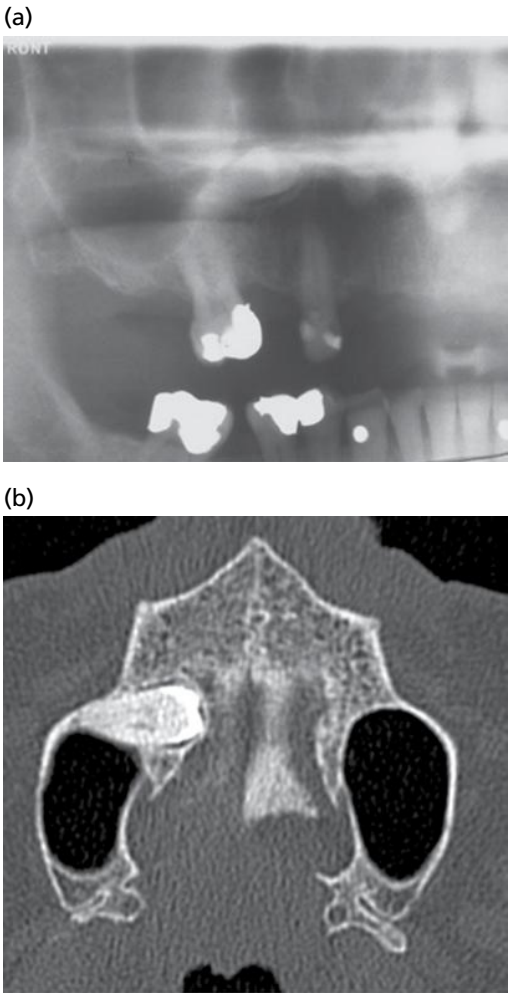

Fig. 30-51 (a) Cropped panoramic radiograph demonstrates an impacted right maxillary premolar with the crown directed mesially, which does not reflect the true orientation, related to the obliquity of the projection typical of these views. (b) True orientation of this premolar, with crown directed medially, is demonstrated on the axial low-dose MCT image.

the panoramic radiograph described also apply in the evaluation of periodontal bone (Fig. 30-29). Also of note, the vertical magnification of teeth varies within the single panoramic image (Thanyakarn *et al*. 1992), which can result in incorrect estimates of periodontal bone loss.

While the panoramic radiograph is useful in providing a rough estimate of the size of a lesion within a jaw, it has substantial limitations when a more accurate evaluation of the 3D relationship of structures and dimensional accuracy is required (Thanyakarn *et al.* 1992; Bou Serhal *et al*. 2002; Sharan & Madjar 2006). Its application in final implant planning is therefore limited. It had been suggested that, if a larger error is allowed for measurements, panoramic views remain useful for final implant planning (Vazquez *et al*. 2008). However, not being able to appreciate structures in the third dimension remains a significant issue. Examples include the inability to accurately appreciate important morphologic variations such as the submandibular, sublingual, and other fossae (Figs. 30-40, 30-41, 30-45), and variations in the extent and morphology of the alveolar recesses of the maxillary sinuses (Fig. 30-43).

It is also well known that the mandibular canal is not infrequently difficult to identify on a panoramic view. In addition, on the panoramic view, a mandibular canal which is located towards the buccal aspect of the body of the mandible will give the impression of a larger available vertical distance from the ridge crest. This is related to the typically negative vertical angle of the X-ray tube. It has been shown that MCT is superior in accurately identifying the precise location of the mandibular canal (Klinge *et al*. 1989; Lindh *et al*. 1992) and the normal variants of these canals (Naitoh *et al* 2007). The superiority of MCT and CBCT over the panoramic radiograph in implant planning is more thoroughly discussed in the section on MCT and CBCT below.

While recognizing that access to imaging equipment and appropriate radiologic support can be the limiting factor, it should be noted that the planning of implants from just panoramic and intraoral radiograph is no longer considered the appropriate standard of care in many parts of the world. The possibility of complications, including inferior alveolar nerve injury and life-threatening hemorrhage, should be considered given the relatively elective nature of implant placement, in contrast to, for example, the surgical excision of a tumor or enucleation of a cyst.

With regards to post-implant imaging, the discussed limitations of the panoramic radiograph also apply, in addition to those associated with intraoral radiography. The panoramic radiograph may provide a useful initial evaluation of peri-implant bone, with the view to further periapical radiographic, CBCT or MCT examinations, as indicated.

The importance of identifying the presence of other dentoalveolar diseases in the radiologic examination of the periodontal and implant patient has already been discussed. It is accepted that periapical lesions are not as well identified on panoramic radiographs as on periapical radiographs (Rohlin *et al*. 1989). Indeed, MCT and CBCT are superior to periapical and panoramic radiographs in identifying these lesions (Velvart *et al*. 2001; Huumonen *et al*. 2006; Lofthag-Hansen *et al*. 2007; Stavropoulos & Wenzel 2007; Estrela *et al*. 2008; Low *et al*. 2008). It should also be recognized that the intraoral radiographs are superior to panoramic radiographs in the identification of caries, the bitewing being superior to the periapical radiograph (Akarslan *et al*. 2008).

In summary, the panoramic radiograph remains a useful modality, especially for initial overall evaluation. However, its substantial limitations must be well understood. Incorrect interpretation and inappropriate application of this view, without due regard to the significant inaccuracies, can lead to erroneous diagnosis with disastrous consequences.

Conventional tomography

As described earlier, conventional tomography relies on the motion of both the detector and the X-ray tube during image capture. The motion unsharpness results in most blurring of the structures furthest from the plane of interest and least blurring for those within the plane in interest. It has traditionally been applied to the study of high-contrast structures, for example the temporomandibular joint, and in implant planning.

While providing information in the cross-sectional plane, conventional tomography has now been largely superseded by MCT and CBCT. The limitations of conventional tomography include:

- Low resolution
- Parasite lines in linear tomography
- Objects close to the plane of interest are less blurred and may still be seen, for example an adjacent mandibular torus
- Thin slices (e.g. 1 mm) are not practical and resultant images are usually not diagnostic
- Thick slices (e.g. 3 mm or thicker) can result in:
  - Increased superimposition of adjacent structures
  - Phantom images: apparent structures that do not exist, related to superimposition of repetitive structures outside the of plane of interest, for example trabeculae and teeth
- Time consuming and patient discomfort.

The angle of the tomographic section at the site of interest is decided by the radiographer. There is no reliable way in which the clinician can verify this angle, which may not be the same as the angle intended for implant placement. Errors and need for repeats with this technique are not uncommon, related to the precision required for implant planning. Compared to modern-day low-dose CBCT and MCT (with appropriate protocols), the potential benefit of the lower radiation dose levels associated with conventional tomography is questionable. Conventional tomograms for implant planning require careful interpretation as the anatomic structures are not always easily identified. The position of the mandibular canal is more accurately identified on MCT (Klinge *et al*. 1989; Ylikontiola *et al*. 2002).

Multislice/multidetector computed tomography and cone-beam computed tomography

In any discussion regarding radiographic equipment, the pace of evolution of this technology and the relative lag in peer-reviewed published studies must be recognized. While this applies to most technologies, it is particularly true of MCT and CBCT.

In simple terms, MCT uses finely collimated, flat, fan-shaped beams which rotate around the patient in a helical progression to acquire slices of image data. In contrast, CBCT machines employ a divergent cone/pyramidal-shaped beam, obtaining multiple planar projections (similar to traditional 2D radiographic images) in a single rotation. These cone-shaped beams are similar to those of X-ray units for 2D radiography. With both MCT and CBCT, computers are used to reconstruct 3D information from the acquired raw data, typically employing a back-projection algorithm. Many modern MCT machines are able to employ iterative reconstruction, which may allow for even lower dose imaging.

Review papers comparing CBCT and MCT technology (Koong 2010) provide more detail; the essential considerations are discussed below.

Presently, CBCT machines have been reported to produce images with a voxel resolution range of 0.076–0.4 mm (Scarfe *et al*. 2008; White 2008). However, this higher resolution of CBCT compared to MCT can be significantly reduced by other factors (Draenert *et al*. 2007; Sanders *et al*. 2007; Watanabe *et al*. 2011).

MCT scans are performed with patients in a supine position, while most of the presently used orofacial

CBCT units acquire image data with patients standing or sitting. In addition, for a similar volume, MCT scans acquire data faster than CBCT. Therefore, the potential motion-related image degradation is higher with CBCT.

With CBCT, a substantially larger volume of orofacial structures is irradiated during each planar basis projection and large area detectors are used. These result in a much larger amount of Compton scatter, significantly increasing image noise compared to MCT. This noise, combined with the typically lower energy photons of CBCT, result in a significantly lower signal-to-noise ratio compared to MCT. Therefore, CBCT images can be more difficult to evaluate, since the structures of interest do not "stand out" as much from the increased "background noise", compared to MCT. This smaller variation between usually more radiodense and less radiodense structures is typical of CBCT images; in other words the image is "flatter". This must be considered when interpreting CBCT studies. For example, sclerosis may not be as easily appreciated on CBCT compared to MCT.

Beam hardening is usually a significant disadvantage of CBCT compared to MCT (Draenert *et al*. 2007; Sanders *et al*. 2007), again related to the typically low signal nature of CBCT. X-ray beams are typically polychromatic, with a range of photon energies. As the beam traverses the human body, low energy photons are absorbed first, altering the quality of the beam This contributes to the appearance of shadows and bands associated with dense structures. In contrast, beam hardening associated with dense nonmetallic objects is usually not significant on MCT scans of the orofacial structures. For example, these beam hardening artifacts related to gutta percha associated with endodontic therapy are often seen on CBCT (Fig. 30-26) but not on MCT (Fig. 30-24). Beam hardening increases with patient head size and denser structures, especially where these structures are in close proximity (see Fig. 30-60).

Metal artifact (extreme attenuation) from metallic restorations is more significant with MCT than CBCT. However, considering the described limitations of CBCT, including beam hardening (Draenert *et al*. 2007; Sanders *et al*. 2007), the overall weakness in relation to metallic restorations is similar for both techniques (Figs. 30-23, 30-47)

It must be noted that CBCT and MCT image quality varies between different makes and models. However, it is generally accepted that this variation in image quality from different MCT makes and models is smaller. Importantly, it must be recognized that MCT machines offer a far larger range of protocols. Therefore, a substantially larger range in image quality can be delivered by the same MCT unit. CBCT machines typically offer a significantly smaller range of imaging protocol options.

With regard to diagnostic imaging for the planning of implants, both MCT and CBCT allow superior 3D appreciation of the morphology and relevant structures, as well as more accurate measurements of the various relevant dimensions for implant placement, compared to common dental views, including panoramic and intraoral radiography (Klinge *et al*. 1989; Lindh *et al*. 1992, 1997; Ylikontiola *et al*. 2002; Hanazawa *et al*. 2004; Kobayashi *et al*. 2004; Marmulla *et al*. 2005; de Morais *et al*. 2007; Nickenig *et al*. 2007; Naitoh *et al*. 2007; Loubele *et al*. 2008; Suomalainen *et al*. 2008; Kamburoglu *et al*. 2009).

The differences between CBCT and MCT discussed earlier should be considered. With particular relevance to implant planning, measurements for common dental procedures performed on images from MCT and CBCT scans have been shown to be similar and sufficiently accurate (Klinge *et al*. 1989; Hanazawa *et al*. 2004; Kobayashi *et al*. 2004; Loubele *et al*. 2005; Marmulla *et al*. 2005; Suomalainen *et al*. 2008; Kamburoglu *et al*. 2009; Nickenig *et al*. 2010). It is generally accepted that the error is ± 1 mm. However, it should be recognized that studies also demonstrate that, for a small percentage of scans, the error is larger than ± 1 mm. It is suspected that many factors, including observer variations, viewing methods, and the window levels and widths selected, can contribute to these errors. Extreme care to ensure correct imaging and reformatting of MCT and CBCT studies, as well as precise and careful measurements made on the appropriate multiplanar images, are recommended. MCT and CBCT have been shown to be more accurate in identifying important structures (e.g. mandibular canal) and allow for more accurate measurement compared to panoramic and intraoral 2D radiography (Klinge *et al*. 1989; Lindh *et al*. 1992; Ylikontiola *et al*. 2002; Howe 2009; Kamburoglu *et al*. 2009).

Variations in normal anatomy, some of which are well known, have been mentioned previously. The large variation in the morphology of the base of the maxillary sinuses and various extensions of the alveolar recesses are examples. It is well accepted that this variation is much more accurately demonstrated with MCT and CBCT (Fig. 30-43), compared to common dental views, including panoramic and intraoral radiography. Similarly, large variations in the prominences of the submandibular and sublingual fossae are not appreciated on 2D radiography (Figs. 30-38, 30-40, 30-41, 30-45). Life-threatening hemorrhage related to vascular damage at implant surgery following perforation of the mandibular cortex has been reported, emphasizing the importance of precise preimplant knowledge of the mandibular lingual morphology of each specific case (Laboda 1990; Mason *et al*. 1990; Givol 2000).

The considerable variation in the 3D location of the mandibular canal is well known. This canal is more accurately examined with volumetric imaging (Klinge *et al*. 1989; Lindh *et al*. 1992). Other normal variations of neurovascular bundles and the unpredictability of these variants have also been reported, including bifid mandibular canals (Naitoh *et al*. 2009a; Kuribayashi *et al*. 2010; de Oliveira-Santos *et al*. 2011) (Figs. 30-52). The panoramic radiograph does not reliably identify the presence of bifid mandibular

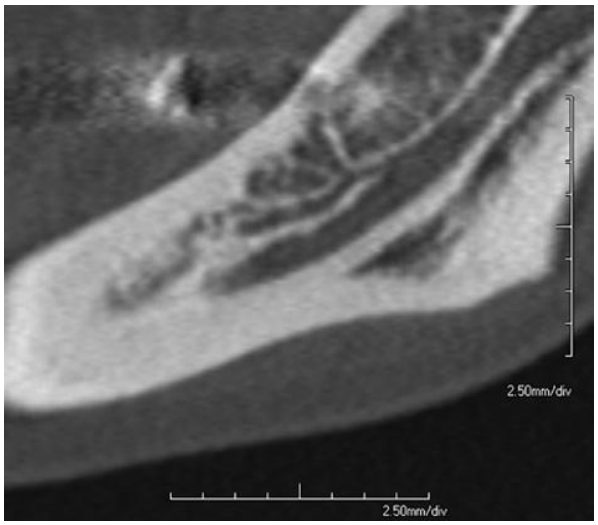

Fig. 30-52 Corrected sagittal low-dose MCT image partially demonstrates a bifid mandibular canal. Multiplanar images are required to fully appreciate this, best performed on a computer.

Fig. 30-53 Surface rendered low-dose MCT image demonstrates two right mental foramina.

Fig. 30-54 Surface rendered low-dose MCT image demonstrates two left mental foramina.

Fig. 30-55 Corrected axial low-dose MCT image demonstrates the anterior loop of the left mandibular canal as it leads to the mental foramen.

canals and volumetric imaging is superior in this respect (Naitoh *et al*. 2007; Kuribayashi *et al*. 2010; Fukami *et al*. 2011; Kim *et al*. 2011). The presence of bifid mandibular canals is more prevalent than generally realized, potentially occurring in between 10% and 20% of the population (Kuribayashi *et al*. 2010; de Oliveira-Santos et al. 2011). This author's experience suggests that the presence of multiple mental foramina is also more common than is generally expected and not appreciated in the panoramic radiograph (Figs. 30-53, 30-54). The anterior aspect of the mandibular canal often traverses anteriorly prior to curving posterobucally and often superiorly to the mental foramen. There is large and unpredictable variation in the extent of this anterior loop of the mandibular canal, and it has been shown that this is not reliably evaluated with the panoramic radiograph (Arzouman *et al*. 1993; Uchida *et al*. 2009; Apostolakis & Brown 2011). This author's experience supports these findings, which can only be accurately evaluated with volumetric techniques (Fig. 30-55).

Lingual neurovascular canals and foramina of the body of the mandible are present in most people (Figs. 30-56, 30-57), with substantial variation in their

Fig. 30-56 Sagittal low-dose MCT image demonstrates two lingual canals and foramina at the mandibular symphyseal region.

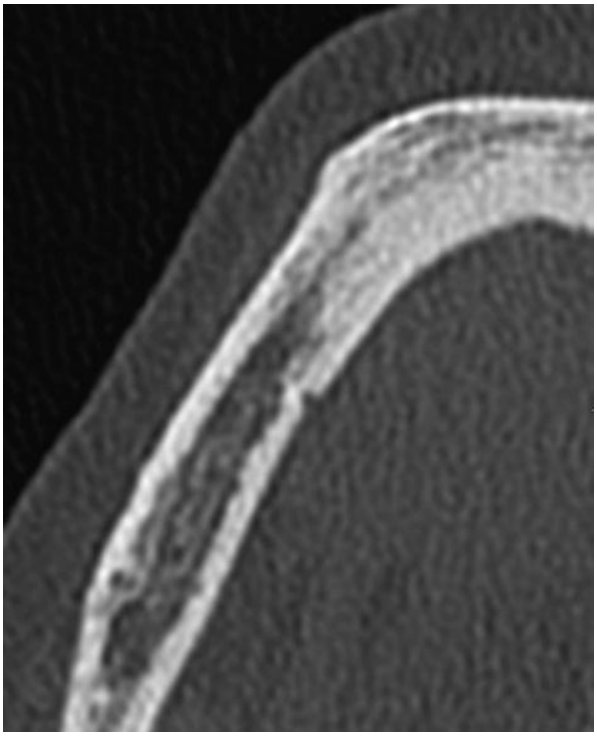

Fig. 30-57 Axial low-dose MCT image demonstrates a lingual canal and foramen of the right body of the mandible. This accessory canal and foramen is best fully appreciated with multiplanar reformatted (MPR) images using a computer.

locations, which is considered to be of surgical relevance because of the possibility of vascular trauma (Liang *et al*. 2006; Vandewalle *et al*. 2006; Liang *et al*. 2007; Katakami *et al*. 2009; Tagaya *et al.* 2009). It is therefore considered important that these lingual canals are identified, and it has been demonstrated that these canals and foramina can only be visualized with MCT and CBCT (Katakami *et al*. 2009; Tagaya *et al.* 2009).

The location of the mandibular incisive canal has been considered to be potentially relevant to implant placement (Jacobs *et al*. 2007); complication from implant placement involving this canal has been reported (Kohavi & Bar-Ziv 1996). Variations in the morphology and width of the maxillary incisive canal are well known (Jacobs *et al*. 2007).

The MCT pixel/voxel value (Hounsfield/CT number) has an almost linear correlation with density (Araki & Okano 2011), and is therefore a useful tool in evaluating bone density in relation to implant placement. In contrast, CBCT voxel values are not absolute and do not have a linear correlation with density (Araki & Okano 2013). This is probably related to the various limitations of CBCT described earlier, including beam hardening and adjacent structures. While some authors suggest that the evaluation of CBCT pixel/voxel density values may still be of some use (Naitoh *et al*. 2009b, 2010a, b; Isoda *et al*. 2012), caution is recommended. CBCT pixel density values perhaps have some application as an extremely rough estimate of bone density.

In post-implant imaging, the limitations of CBCT (Pauwels *et al*. 2013) in relation to adjacent artifacts is recognized. Implant-related artifacts associated with MCT also exist. However, both MCT and CBCT have been shown to accurately evaluate peri-implant defects (Mengel *et al*. 2006). The peri-implant bone density is not well examined with CBCT (Corpas Ldos *et al*. 2011). This author's experience, to date, is that varying degrees of artifact associated with implants are usually seen on MCT and CBCT scans (with machine- and protocol-dependent differences) (Figs. 30-48, 30-49, 30-58, 30-59) Therefore, it is likely that, to varying extents, narrow and subtle peri-implant defects may not be detected and it is often difficult to evaluate peri-implant bone levels. With CBCT, the beam hardening artifact is substantial between two or more implants in close proximity (Fig. 30-60). In this respect, intraoral radiography is superior. The panoramic radiograph may be a useful initial view although, in relation to intraoral radiography, the typical additional limitations apply. While only proximal bone is demonstrated and the entire implant length may not be included in the periapical FOV, it still remains useful, assuming paralleling technique. If imaging is clinically indicated, especially if there is suspicion for the presence of buccal or lingual defects, a need to evaluate the implant position in the buccolingual dimension, unexplained complications or concern for the presence of associated undiagnosed adjacent pathology, MCT or CBCT should be considered (Fig. 30-61).

Periodontal bone loss is more accurately identified and the morphology of the defects is better examined

Fig. 30-58 Coronal low-dose MCT image demonstrates the lucent artifact adjacent to the left mandibular implant.

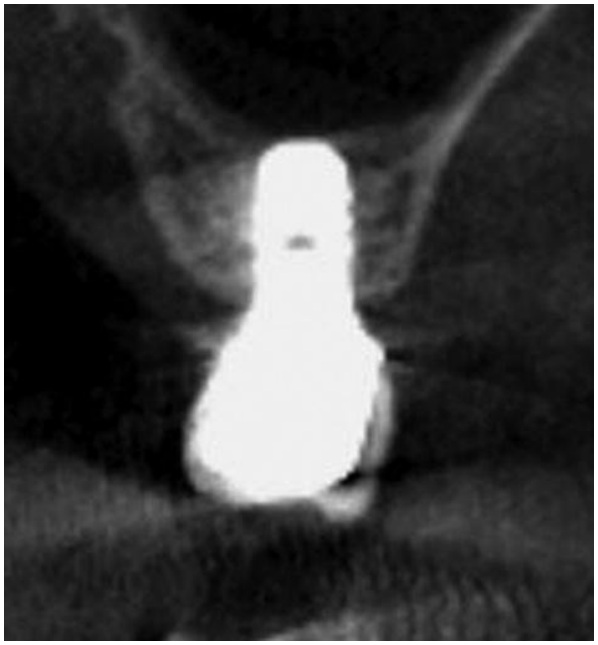

Fig. 30-59 Coronal low-dose CBCT image demonstrates the beam hardening artifact associated with the implant and restoration.

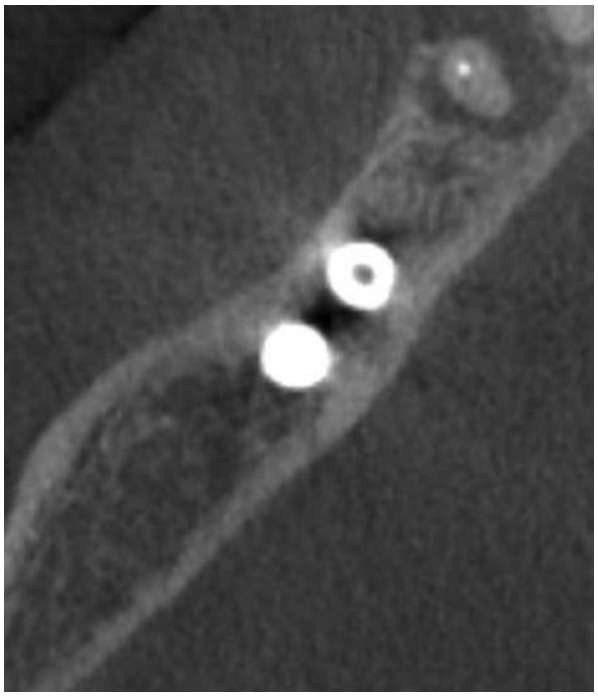

Fig. 30-60 Axial low-dose CBCT image demonstrates the substantial beam hardening artifact between two dense structures; in this case, the two right mandibular implants.

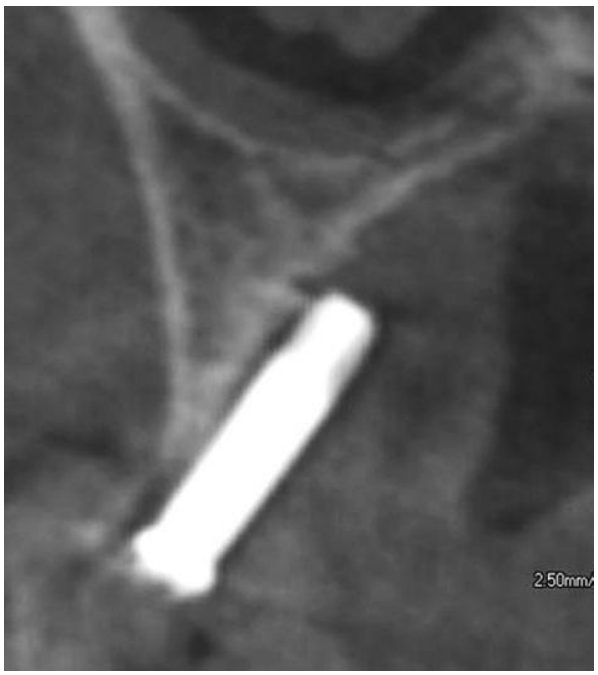

Fig. 30-61 Corrected low-dose CBCT image demonstrates a palatally placed implant which would not be appreciated on 2D radiography. It would be clinically difficult to palpate this implant in view of the thick overlying palatal soft tissue (note the visualized palatal soft tissue profile).

by MCT and CBCT than periapical radiography (Fuhrmann *et al*. 1995; Langen *et al*. 1995; Fuhrmann *et al*. 1997; Mengel *et al*. 2005, Misch *et al*. 2006; Mol *et al*. 2008; Vandenberghe *et al*. 2008). This significant advantage of volumetric imaging over plain 2D radiography and the limitations of the latter have been discussed in earlier sections. The prescription of the optimal modality is based upon the clinical findings and diagnostic needs of a specific case. The importance of thorough knowledge of the various modalities has also been mentioned earlier (refer to the sections on Intraoral radiography and Panoramic radiography).

It is beyond the scope of this chapter to discuss all the potential specific applications of MCT and CBCT. However, the importance of identification of other

dentoalveolar diseases in the radiologic evaluation of the periodontal and implant patient has been discussed. Both MCT and CBCT are superior to periapical radiography in the diagnosis of periapical disease and endodontics (Velvart *et al*. 2001; Huumonen *et al*. 2006; Simon *et al*. 2006; Lofthag-Hansen *et al*. 2007; Mora *et al*. 2007; Nair & Nair 2007; Patel *et al*. 2007; Stavropoulos *et al*. 2007; Low *et al*. 2008).

The inability of CBCT to evaluate caries in the presence of metallic or even radiodense restorations is obvious. In the absence of restorations, studies evaluating the role of CBCT in caries diagnosis seem promising (van Daatselaar *et al*. 2004; Akdeniz *et al*. 2006; Kalathingal *et al*. 2006; Tsuchida *et al*. 2007; Haiter-Neto *et al*. 2008). However, further research studies, especially *in vivo* studies, are required. At present, it remains prudent to employ bitewing radiography when there is an indication for radiologic evaluation for caries.

The soft tissue contrast resolution of current CBCT is poor and is much better with MCT (Watanabe *et al*. 2011). MCT allows evaluation of various soft tissue structures, soft tissue lesions, and also soft tissue changes related to bony lesions. This important diagnostic advantage can be further enhanced with the use of intravenous contrast. This visualization of the soft tissues with MCT can be of significant diagnostic value. For example, orofacial soft tissue lesions (including infections) can present clinically similar to dental infections, which can be demonstrated on an MCT scan but not a CBCT scan. Indeed, MCT can occasionally assist in the identification of the infected tooth, where CBCT and 2D radiography cannot, by demonstrating the location of a soft tissue centred periapical infection, where there are focal cortical fenestrations over a few root apices with no evidence of intrabony periapical lesion. MCT imaging for implant planning can demonstrate adjacent soft tissue lesions with direct surgical relevance to implant planning (e.g. an adjacent arteriovenous malformation with no cutaneous manifestations) and also identify the presence of adjacent serious disease. It should be noted that many soft tissue lesions may be best examined with MRI.

MCT currently remains a more powerful and flexible imaging modality than CBCT in orofacial diagnosis. The advantages of MCT can be critical in the diagnosis of orofacial disease, including dentoalveolar inflammatory disease. It seems prudent to continue evaluating more complex and diagnostically challenging dentoalveolar cases and more serious/significant pathologies with MCT rather than with CBCT. CBCT should be considered in the daily practice of modern clinical dentistry, although there is varying clinical scientific evidence supporting the overall benefits of using CBCT. While the advantages seem obvious, further clinically-based studies are required to confirm these benefits of CBCT, especially in relation to intraoral 2D radiography, panoramic radiography, and MCT. The use of optimal CBCT protocols to produce diagnostic images remains critical. Associated costs, accessibility, and other related factors also require consideration. Rather than replacing other modalities, CBCT complements intraoral 2D radiography, panoramic radiography, MCT, and other techniques, including MRI, ultrasound, and nuclear medicine (Koong 2010). CBCT is not the modality of choice in many clinical scenarios. Indeed, for all cases where CBCT is considered, all other modalities, especially MCT, must also be considered.

Both CBCT and MCT units can export data in DICOM file format standard. This allows both MCT and CBCT data to be viewed with a range of third-party software used for diagnostic and treatment planning purposes, including the creation of 3D models and various applications related to image-guided surgery.

A variety of computer-assisted implant surgery systems based on MCT and CBCT data are available. There is some variation in the application and accuracy of the various computer-guided systems, which are largely favorable, although the final implant position usually does not perfectly correlate with the virtually planned implant position (Eggers *et al*. 2009; Jung *et al*. 2009; Valente *et al*. 2009; Barnea *et a*l. 2010; Pettersson *et al*. 2010; Widmann *et al*. 2010). It is prudent that the clinician is familiar with the accuracy and limitations of any particular system employed. Appropriate training is crucial and the application of this technology does not negate the practice of the usual surgical principles and precautions.

Magnetic resonance imaging

Unlike the other modalities discussed in this chapter, MRI does not employ ionizing radiation. It involves the alignment of the nuclei of many atoms in a strong magnetic field. Radiofrequency pulses are applied, rotating the protons away from the direction induced by the magnet. At the end of the pulse sequence, relaxation occurs and the energy released, in the form of radiofrequency signals, is detected by a receiver coil. The image is then reconstructed (Fourier transform) by a computer.

There are no known biologic side effects associated with MRI. It is particularly useful in the evaluation of soft tissue, generally superior to MCT. Note that soft tissue lesions cannot be evaluated with CBCT. Various MRI sequences can be employed to visualize and highlight different types of tissues and also changes within tissue. For example, it can demonstrate edema within bone marrow, which cannot be identified with MCT or CBCT. The use of intravenous gadolinium allows for further radiologic characterization of lesions.

MRI generally has a lower spatial resolution compared to modern-day MCT and CBCT. More subtle bony changes may be subresolution and not detected. MCT remains the imaging modality of choice for osseous lesions, especially subtle changes. Small

calcific deposits may be undetected on MRI. It can overestimate the extent of tumors, due to the response of adjacent tissues.

Compared to MCT and CBCT, MRI generally involves longer imaging times. Claustrophobia can be an issue for some patients, although modern wider and shorter bore machines have significantly reduced this problem. The presence of ferromagnetic metals usually contraindicates an MRI scan, for example cardiac pacemakers, cerebral aneurysmal clips, and a foreign body within the orbit.

The periodontal bone loss demonstrated on MCT and CBCT studies does not, in itself, mean that the disease is active. MRI can demonstrate the edema associated with current inflammation (Fig. 30-32). On implant imaging, the mandibular canal borders are sometimes not visualized with MCT or CBCT. In these cases, MRI can be useful in identifying the precise location of the inferior alveolar neurovascular bundle.

Comparison of radiation dose levels

The International Commission on Radiological Protection (ICRP) released new tissue weight recommendations for calculating effective doses in 2007 (ICRP 2007). The key change from the previous 1990 recommendations in relation to oral and maxillofacial imaging is the inclusion of the salivary glands (0.01). Therefore, calculated effective doses for orofacial imaging using the 2007 tissue weights are higher than if the 1990 tissue weighting factors are used. Interestingly, this increase is particularly dramatic for the panoramic radiograph, related to the focus of the rotational centers during imaging (Gijbels *et al*. 2001; Ludlow & Ivanovic 2008) Care must be taken when evaluating the literature. For ease of comparison with previous investigations, it may remain necessary to refer to dose calculations based on the 1990 ICRP recommendations, although it must be recognized that these are now not considered to be as accurate as calculations based on the 2007 recommendations.

The range of reported effective doses delivered by orofacial CBCT units is extremely wide; from 6 to 806 μSv (1990 tissue weights) and 27–1073 μSv (2007 tissue weights) (Ludlow *et al*. 2003; Schulze *et al*. 2004; Ludlow *et al*. 2006; Kumar *et al*. 2007; Ludlow *et al*. 2008; Scarfe *et al*. 2008; White 2008; Okano *et al*. 2009; Roberts *et al*. 2009; Suomalainen *et al*. 2009; Davies *et al*. 2012). Compared to MCT, there is substantially less control over CBCT protocols and the wide range of CBCT doses delivered is largely unit specific. Also of importance, some small FOV units deliver larger doses than some larger FOV units. The difficulties associated with making a detailed comparison of the radiation dose levels from various units in published studies is recognized (De Vos *et al*. 2009). This is due to a variety of factors, including variation in device properties, FOV, quality of detectors, frame rates, and image quality. Some of these factors are not easily quantified and it can be overly complex to study and report a comparison of every possible combination of factors associated with various units. Attempts to report these findings in simple tables can be misleading. For example, a study may report that two CBCT units deliver similar doses for approximately the same FOV (i.e. similar volume). However, there may be differences in image quality. The "standard" dose reported for one machine may not produce the optimal image quality for practical clinical application and most operators may routinely employ a different protocol which delivers a much higher dose level than the one reported. Also, one machine may be able to substantially decrease the dose delivered while maintaining diagnostic image quality, while the other is not able to achieve this.

MCT studies of the jaws have been reported to deliver effective doses between 180 and 2100 μSv (1990 tissue weights) and 474–1410 μSv (2007 tissue weights), with substantial variation in scanning protocols (Ngan *et al*. 2003; Loubele *et al*. 2005; Ludlow *et al*. 2008; Loubele *et al*. 2009; Suomalainen *et al*. 2009). While there are differences between various MCT units, the doses delivered for jaw examinations are very much dependent on the imaging protocols.

In comparing MCT and CBCT, it should be noted (from the information provided above) that, where appropriate MCT low-dose protocols are employed, the doses delivered can be lower than those from several CBCT units. It has been demonstrated that appropriate MCT protocols can be employed which substantially reduce radiation dose levels without significantly compromising image quality (Loubele *et al*. 2005). It has also been demonstrated that low MCT doses can indeed be comparable to those delivered by some CBCT units and that MCT may be the imaging modality of choice, given its advantages (Rustemeyer *et al*. 2004). This author's experience supports these findings and indicates that a variety of low-dose MCT protocols can produce diagnostic images for many purposes in dentistry. However, there are currently a few CBCT units which are able to deliver doses that are lower than those achievable with modern-day MCT machines, for the same volume, while maintaining diagnostic image quality. This will, no doubt, change as both CBCT and MCT technology continues to evolve.

The reported effective dose levels delivered by panoramic radiographic machines also vary significantly, with a range of 4.7–54 μSv (ICRP 1990) (Ludlow *et al*. 2003; Ngan *et al*. 2003; Kobayashi *et al*. 2004; Gijbels *et al*. 2005; Gavala *et al*. 2009). Note is made of the dose calculations based on the 1990 ICRP tissue weight recommendations in this instance, to facilitate comparison with older studies. Variation in the curve of the rotational centers likely contributes to the substantial variation between machines (Kaeppler 2008). It should be noted that some recent CBCT units can deliver doses that are lower than those delivered by some panoramic machines, generally the older analog models.

A full-mouth 2D intraoral radiographic series with round collimation has been reported to deliver effective radiation dose levels between 170.7 and 388 μSv (ICRP 2007; Ludlow *et al*. 2008-). It is noted that, based upon the available dose data discussed above, some ultra low-dose CBCT units are able to deliver lower doses than an intraoral 2D radiographic series, depending on the number of 2D projections, technique, and detector employed. Where CBCT is indicated, the employment of ultra low-dose CBCT units is crucial.

The constant and relatively rapid evolution of imaging technology is recognized. It is crucial to emphasize the importance of remaining up to date with these technological advances. Critical evaluation of peer-reviewed publications is necessary, although it has been noted that the comparison of different modalities, makes, and models is a complex task. Simplified summaries and tables usually do not truly reflect the intricacies, full capabilities, and weaknesses of particular makes and models. The lag between published literature and the availability of newly developed technology is also recognized. Therefore, an in-depth understanding of the technology, combined with a review of available valid studies, provides the best opportunity for a balanced evaluation of imaging technology.

Chapter 31

Patient-Specific Risk Assessment for Implant Therapy

Giovanni E. Salvi[1] and Niklaus P. Lang[1,2]

[1]Department of Periodontology, School of Dental Medicine, University of Berne, Berne, Switzerland
[2]Center of Dental Medicine, University of Zurich, Zurich, Switzerland

Introduction

From a patient's perspective, the successful implant is esthetically acceptable, comfortable, low cost, and functional. Practitioners usually discuss implant success in terms of level of marginal bone and absence of deep probing depths and mucosal inflammation. Although the two sets of criteria are not in conflict, they emphasize different points of view. During the consultation visit, before any care is delivered, the practitioner should discuss, based on patient-centered outcomes, what can be expected from the placement of the implant.

A final comprehensive treatment plan should be presented to the patient that includes all recommended dental therapy and alternative treatment options. The patient should also be informed about the sequence of the clinical procedures, risks and costs involved, and the anticipated total treatment time. This discussion between practitioner and patient is critically important in lowering the overall risk of treatment problems. Patients who understand what will be done, and why, are more likely to cooperate with the recommended treatment.

Systemic factors

Patient-based risk assessment begins with taking comprehensive medical and dental histories, as well as conducting a complete examination of the candidate for implant therapy.

A comprehensive medical history should include past and present medications and any substance use or abuse. A standard medical history form filled out and signed by the patient is an efficient way to collect basic information. This should always be followed by an interview to explore in more detail any potential medical risks of implant therapy. If any uncertainties remain regarding the patient's health after the interview, a written medical consultation should be obtained from the patient's physician.

Medical conditions

Osteoporosis

Osteoporosis is a complex group of systemic skeletal conditions characterized by low bone mass and microarchitectural deterioration of bone tissue. Osteoporotic

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

bone is fragile and has an increased susceptibility to fracture. Primary osteoporosis is a common condition and is diagnosed when other disorders known to cause osteoporosis are not present. Secondary osteoporosis is diagnosed when the condition is related to, or occurs as a consequence of, osteoporosis-inducing circumstances. These might include diet (e.g. starvation, calcium deficiency), congenital conditions (e.g. hypophosphatasia, osteogenesis imperfecta), drugs (e.g. alcohol abuse, glucocorticoids), endocrine disorders (e.g. Cushing's syndrome), and certain systemic diseases (e.g. diabetes mellitus, rheumatoid arthritis). Osteoporosis is assessed using bone densitometry in which a patient's bone mass or bone mineral density (BMD) is determined. BMD refers to grams of bone mineral per square centimeter (g/cm^2) of bone cross-section.

Scientific evidence indicates that there are no convincing findings that dental implant placement is contraindicated in the osteoporotic patient (Otomo-Corgel 2012). Implants placed in individuals with osteoporosis appear to successfully osseointegrate and can be retained for years (von Wowern & Gotfredsen 2001). However, in cases of secondary osteoporosis there are often accompanying illnesses or conditions that increase the risk of implant failure (e.g. poorly controlled diabetes mellitus, corticosteroid medications). Therefore, in the patient-specific risk assessment, the presence of osteoporosis should alert the clinician to the possible presence of osteoporosis-associated circumstances that are known to increase the risk of implant failure.

Diabetes mellitus

Although there is a slight tendency for more failures of implants in a population with diabetes compared to a non-diabetic population, the increased risk is not substantial in patients who are under good metabolic control (Shernoff *et al*. 1994; Kapur *et al*. 1998; Balshi & Wolfinger 1999; Fiorellini *et al*. 2000; Morris *et al*. 2000; Olson *et al*. 2000).

Patients with diabetes under suboptimal metabolic control often experience wound-healing difficulties and have an increased susceptibility to infections due to a variety of problems associated with immune dysfunctions. Solid clinical evidence, however, for the association of glycemic control with implant failure is lacking (Oates *et al*. 2013). In the risk evaluation of patients with diabetes, it is important to establish the level of metabolic control of the disease. A useful test to determine the level of control over the last 90 days is a blood test for glycosylated hemoglobin (HbA1c). This is a test for the percentage of hemoglobin to which glucose is bound. Normal values for a healthy individual or a patient with diabetes under good metabolic control are HbA1c of <6–6.5% and fasting blood glucose of <6.1 mmol/L (110 mg/dL). Paients with diabetes with HbA1c values of >8% are under poor control and have an elevated risk of encountering wound-healing problems and infection if dental implants are placed.

Immunosuppression

In the early years of the acquired immune deficiency syndrome (AIDS) epidemic, placement of dental implants was ill advised since affected patients developed major life-threatening oral infections. With the advent of effective HAART (i.e. highly active antiretroviral therapy) regimens, most human immunodeficiency virus (HIV)-positive patients who take their medications live for many years without developing severe opportunistic infections. There have been no controlled studies dealing with the risk of dental implant failures in HIV-positive individuals. However, several case reports suggest that placement of dental implants in HIV-positive patients is not associated with elevated failure rates (Rajnay & Hochstetter 1998; Baron *et al*. 2004; Shetty & Achong 2005; Achong *et al*. 2006). Low T-helper (CD4) cell counts (i.e. <200/μL) do not appear to predict increased susceptibility to intraoral wound infections or elevated failure rates of dental implants (Achong *et al*. 2006). Although more studies are needed, it appears that it is safe to place dental implants if the patient's HIV disease is under medical control.

History of radiation therapy to the jaws

Patients who have received radiation (i.e. absorbed dose of ≥60 Gy) to the head and neck as part of the treatment for malignancies are at an increased risk of developing osteoradionecrosis (ORN). Most cases of this complication of cancer treatment are triggered by the extraction of teeth or other oral surgery procedures such as insertion of implants. Implant failure rates of up to 40% have been reported in patients who have a history of radiation therapy (Granström *et al*. 1993; Beumer *et al*. 1995; Lindquist *et al*. 1988; Granström *et al*. 1999). At one time it was believed that ORN was due to vascular derangement and hypoxia of bone cells caused by the tissue-damaging effects of radiation (Teng & Futran 2005). Based on this hypothesis, it has been recommended that oral surgical procedures in patients at risk of ORN be performed in conjunction with hyperbaric oxygen (HBO) therapy. Indeed, Granström *et al*. (1999) reported that use of HBO therapy improved implant survival rates. However, the value of HBO therapy for the management of ORN has been called into question partly based on a placebo-controlled, randomized clinical trial (Annane *et al*. 2004) and other reports showing no advantage from HBO interventions (Maier *et al*. 2000; Gal *et al*. 2003). In addition, a systematic review by Coulthard *et al*. (2008) indicated that there is no high-quality evidence that HBO therapy improves implant survival in irradiated patients.

It is now believed that the pathogenesis of ONR is much more complex than a simple hypoxia-related

phenomenon related to poor vascularity of irradiated tissues. Current evidence supports the view that ONR is a fibroatrophic process (Teng & Futran 2005). From the perspective of risk-assessment procedures for implant placement, patients who have a history of irradiation to the jaws should be considered at high risk for implant failure and HBO interventions will probably not lower that risk.

Hematologic and lymphoreticular disorders

A number of hematologic and lymphoreticular disorders carry an increased susceptibility to periodontitis and other infections (Kinane 1999). Among these disorders are agranulocytosis, acquired neutropenias, cyclic neutropenias, leukocyte adherence deficiency, and aplastic anemia (e.g. Fanconi's syndrome). Since patients with these diseases frequently lose teeth early in life, they often have extensive prosthetic needs that can be met by the placement of dental implants. In the risk-assessment process prior to implant placement, the major concern to be considered is the increased susceptibility to infections that could occur around any implants that might be placed. There are no well-controlled studies of the success rates of implants placed in patients with these disorders. However, implants can be placed if the patient's disease is under control or in remission and a regular supportive therapy program must be an integral part of the overall treatment plan.

Medications

Bisphosphonates

Bisphosphonates are a widely prescribed class of drugs used for the treatment of osteoporosis and to reduce the bone-lytic effects of certain malignancies such as multiple myeloma and metastatic breast cancer (Woo *et al*. 2006). These pyrophosphate drugs are potent inhibitors of osteoclast activity that also have antiangiogenic effects by inhibiting the production of vascular endothelial growth factor (VEGF). The drugs have a high affinity for hydroxyapatite, are rapidly incorporated into all parts of the skeleton, and have a very long half-life (i.e. decades). Relative potencies of the agents depend on their formulation. A complication associated with the use of bisphosphonates is the increased risk of developing osteonecrosis of the jaws [i.e. bisphopsphonate-related osteonecrosis of the jaws (BRONJ)] (Ruggiero *et al*. 2004; Marx *et al*. 2005; Braun & Iacono 2006). The vast majority of cases of BRONJ occur in cancer patients who have received high-potency aminobisphosphonates (e.g. zoledronate, pamidronate) given intravenously to decrease the osteolytic effects of multiple myeloma or malignancies that have metastasized to bone (e.g. breast or prostate cancer).

Of major concern to the prospective implant patient who has been taking an oral bisphosphonate for osteoporosis is the possible risk of developing BRONJ after implant placement. Oral bisphosphonates have been reported to be associated with implant failure (Starck & Epker 1995) and BRONJ (Ruggiero *et al*. 2004; Marx *et al*. 2005; Kwon *et al*. 2014). Since bisphosphonates tightly bind to hydroxyapatite and have a very long half-life, it is likely that the length of time a patient has been taking oral bisphosphonates is important in determining the level of risk. Since oral bisphosphonates slowly accumulate in bone with time, an osteoporosis patient who has been taking the drug for 1 year is at a lower risk of developing BRONJ or implant failure than someone who has been on the drug for many years. It should be kept in mind that bone-remodeling processes are inhibited in patients who have been chronically taking oral bisphosphonates for osteoporosis. Collectively, the duration, route (i.e. oral or intravenous), type of bisphosphonate, and dosage of the medication play an important role in the development of BRONJ (Bornstein *et al*. 2009; Madrid & Sanz 2009a; Otomo-Corgel 2012).

Anticoagulants

Patients who have blood coagulation disorders or are taking high doses of anticoagulants are at an elevated risk of experiencing postoperative bleeding problems after implant surgery. Some patients with coagulation disorders may be at an elevated risk of implant failure (van Steenberghe *et al*. 2003), whereas other patients who chronically take oral anticoagulants can safely receive dental implants (Weischer *et al*. 2005). Patients who are on continuous oral anticoagulant therapy (e.g. coumarin derivatives) to reduce the risk of thromboembolic events and require dental implants for optimal restorative care should be evaluated on a case-by-case basis. Most of these patients can safely continue their warfarin or other anticoagulant therapy when they have standard dental implant surgery (Madrid & Sanz 2009b). In such patients, local bleeding after the placement of dental implants can usually be well controlled by conventional hemostatic methods. The risk of developing life-threatening bleeding or bleeding that cannot be controlled using local measures following placement of dental implants is so low that there is no need to stop oral anticoagulant therapy (Beirne 2005). In addition, the risk of discontinuing anticoagulant medication prior to implant surgery, thereby increasing the probability of thromboembolic events, must be accounted for (Madrid & Sanz 2009b).

Therapeutic levels of an anticoagulant drug such as warfarin are measured by the international normalized ratio (INR), which is the patient's prothrombin time (PT) divided by the mean normal PT for the laboratory (i.e. the PTR). The PTR is then adjusted for the reagents used to arrive at a standardized INR value that will be comparable anywhere in the world. A higher INR reflects a higher level of anticoagulation

with an attendant increased risk of hemorrhage (Herman *et al*. 1997). Although there are insufficient data to draw any evidence-based conclusions, placement of single implants is regarded as safe when the INR target values are 2.0–2.4 (Herman *et al*. 1997).

Cancer chemotherapy

Oral cancer patients are frequently candidates for the placement of dental implants since prostheses designed to replace missing portions of the jaws need to be anchored to implants. Since antimitotic drugs used as chemotherapy for cancer might affect wound healing and suppress certain components of the immune system, it is important to know if these drugs interfere with osseointegration and success of dental implants. In a retrospective study, implant success was compared in 16 oral cancer patients who had no chemotherapy with that in 20 patients who received postsurgical adjuvant chemotherapy with either cisplatin or carboplatin and 5-fluorouracil (Kovács 2001). It was found that these drugs did not have any detrimental effects on the survival and success of implants placed in the mandible. It has also been reported that some cancer patients who received cytotoxic antineoplastic drugs experienced infections around existing dental implants (Karr *et al*. 1992). Therefore, it is important to recognize that many anticancer drugs suppress or kill cells necessary for optimal innate and adaptive immunity. Patients who are receiving cancer chemotherapy should have thorough periodontal and supportive therapy in order to minimize the development of biologic complications.

Immunosuppressive agents

Any medication that interferes with wound healing or suppresses components of innate and adaptive immunity (e.g. corticosteroids) can theoretically increase the risk of implant failure. These drugs are potent anti-inflammatory agents that are widely used for the management of a wide variety of medical conditions, such as after liver transplants (Gu & Yu 2011). They can interfere with wound healing by blocking key inflammatory events needed for satisfactory repair. In addition, through their immunosuppressive effects on lymphocytes, they can increase the rate of postoperative infections. In general, these undesirable effects are greatest in patients who take high doses of the drugs for long periods of time.

Age

In adult patients, age is usually not considered an important risk factor for implant loss. Indeed, most longitudinal studies of survival rates of implants include some subjects who are well over 75 years of age (Dao *et al*. 1993; Hutton *et al*. 1995; Nevins & Langer 1995; Davarpanah *et al*. 2002; Becktor *et al*. 2004; Fugazzotto *et al*. 2004; Karoussis *et al*. 2004; Fransson *et al*. 2005; Herrmann *et al*. 2005; Quirynen *et al*. 2005; Mundt *et al*. 2006; Wagenberg & Froum 2006). An upper age limit is usually not listed as an exclusion criterion in such studies. Several reports indicate that there is no statistically significant relationship between the age of the patient and implant failure (Dao *et al*. 1993; Hutton *et al*. 1995; Bryant & Zarb 1998; Fransson *et al*. 2005; Herrmann *et al*. 2005; Mundt *et al*. 2006; Wagenberg & Froum 2006). It cannot be excluded that there may have been some selection bias in these studies since older patients might have been excluded for medical reasons. On the other hand, older individuals included in these studies may be atypical in that they were healthy enough to be good candidates for implant placement.

In one retrospective study of the success of 4680 dental implants placed by a single surgeon over a 21-year period in 1140 patients, it was reported that increasing age was strongly associated with implant failure (Moy *et al*. 2005). A univariate analysis of the data indicated that compared to patients younger than 40 years (n = 181), patients in the 60–79-year age group (n = 499) yielded a significantly higher risk of implant failure (relative risk 2.24; $P = 0.05$). However, in a multivariate analysis of the data from the entire study population, age was not a significant predictor of implant failure (Moy *et al*. 2005).

Growth considerations

At the other end of the spectrum, a potential problem associated with the placement of dental implants in still-growing children and adolescents is the possibility of interfering with growth patterns of the jaws (Op Heij *et al*. 2003). Osseointegrated implants in growing jaws behave like ankylosed teeth in that they do not erupt and the surrounding alveolar housing remains underdeveloped. Dental implants may be of great help to young people who have lost teeth due to trauma or have congenitally missing permanent teeth. However, because of the potential deleterious effects of implants on growing jaws, it is highly recommended that implants are not placed until craniofacial growth has ceased or is almost complete (Thilander *et al*. 2001).

Untreated periodontitis and oral hygiene habits

The association between self-performed oral hygiene levels and peri-implantitis has been shown to be dose-dependent (Ferreira *et al*. 2006). Partially edentulous patients with very poor and poor oral hygiene are at statistically significantly higher risks of developing peri-implant mucositis and peri-implantitis compared with patients with proper plaque control (Ferreira *et al*. 2006). A direct cause–effect relationship between a 3-week period of abolished oral hygiene practices with experimental plaque accumulation

and the development of peri-implant mucositis has been shown in humans (Pontoriero *et al*. 1994; Zitzmann *et al*. 2001; Salvi *et al*. 2012). A period of 3 weeks of resumed oral hygiene practices followed the experimental plaque accumulation period (Salvi *et al*. 2012). Despite resumed optimal plaque control, however, 3 weeks of wound healing were insufficient to re-establish pre-experimental levels of peri-implant mucosal health (Salvi *et al*. 2012). Furthermore, it has been shown that partially edentulous patients with high plaque scores before implant placement experience more implant losses than those with lower plaque levels (van Steenberghe *et al*. 1993).

Based on this evidence, it may be postulated that, if left untreated, peri-implant mucositis may lead to progressive destruction of peri-implant marginal bone (i.e. peri-implantitis) and, eventually, implant loss.

Moreover, high percentages of implants diagnosed with peri-implantitis are associated with the presence of iatrogenic factors such as cement remnants (Wilson 2009) and with an inadequate access for self-performed oral hygiene (Serino & Ström 2009). These findings indicate that, in addition to insufficient oral hygiene habits, plaque-retentive factors are related to the presence of peri-implantitis.

Based on this evidence any patient-specific risk assessment should include an evaluation of the patient's ability to maintain high levels of self-performed plaque control (Salvi & Lang 2004).

History of treated periodontitis

Periodontitis-susceptible patients treated for their periodontal conditions may experience more biologic complications and implant losses compared with non-periodontitis patients (Hardt *et al*. 2002; Karoussis *et al*. 2003; Ong *et al*. 2008; De Boever *et al*. 2009; Matarasso *et al*. 2010; Aglietta *et al*. 2011). This observation is of special interest in patients treated for aggressive periodontitis and rehabilitated with dental implants (De Boever *et al*. 2009; Swierkot *et al*. 2012). One implication of these findings is that patients who have lost their teeth because of periodontitis might also be more susceptible to peri-implant infections.

Outcomes from long-term clinical studies of patients with treated periodontal conditions indicated that residual pocket probing depths (PPD) of ≥6 mm, full-mouth bleeding on probing (BoP^+) ≥30%, and heavy smoking (i.e. ≥20 cigarettes/day) represented risk factors for periodontal disease progression and tooth loss over a mean period of 11 years of supportive periodontal therapy (SPT) (Matuliene *et al*. 2008). Moreover, findings from two clinical studies indicated that residual PPD of ≥5 mm and BoP^+ after completion of periodontal therapy represented risk factors for the survival and success rates of implants placed in periodontally compromised patients (Lee *et al*. 2012; Pjetursson *et al*. 2012). In a retrospective case–control study, the effects of periodontal conditions on the outcomes of implant therapy were evaluated in periodontally compromised patients stratified according to the presence of one or more residual PPD of ≥6 mm after a mean follow-up period of 8.2 years (Lee *et al*. 2012). Patients with one or more residual PPD of ≥6 mm displayed a significantly greater mean peri-implant PPD and radiographic bone loss compared with both periodontally healthy and periodontally compromised patients without residual PPD, respectively (Lee *et al*. 2012). Moreover, patients with one or more residual PPD of ≥6 mm had significantly more implants with a PPD of ≥5 mm, BoP^+, and radiographic bone loss compared with either of the other two groups of patients (Lee *et al*. 2012). Residual PPD of ≥5 mm at the end of active periodontal therapy represented a significant risk for the onset of peri-implantitis and implant loss over a mean follow-up period of 7.9 years (Pjetursson *et al*. 2012). In addition, patients enrolled in regular SPT and developing periodontal re-infections were at greater risk for peri-implantitis and implant loss compared with periodontally stable patients (Pjetursson *et al*. 2012).

From a microbiologic point of view, a similar composition of the subgingival microbiota was found in pockets around teeth and implants with similar probing depths (Papaioannou *et al*. 1996; Sbordone *et al*. 1999; Hultin *et al*. 2000; Agerbaek *et al*. 2006). Moreover, evidence exists that periodontal pockets might serve as reservoirs of bacterial pathogens (Apse *et al*. 1989; Quirynen & Listgarten 1990; Mombelli *et al*. 1995; Papaioannou *et al*. 1996; Fürst *et al*. 2007; Salvi *et al*. 2008) that may be transmitted from teeth to implants (Quirynen *et al*. 1996; Sumida *et al*. 2002). Therefore, the risk assessment of patients with a history of treated periodontitis should emphasize the increased risk of developing peri-implantitis and highlight the importance of successful periodontal therapy and regular SPT.

Compliance with supportive periodontal therapy

Based on the fact that biologic implant complications are characterized by etiologic factors similar to those involved in the development of periodontal diseases (Heitz-Mayfield & Lang 2010), it may be assumed that long-term survival and success rates of dental implants can be achieved by applying the same principles used during SPT of natural teeth. Findings from long-term clinical studies demonstrated that compliance with SPT is an essential component for the prevention of disease recurrence (e.g. caries and periodontitis) and tooth loss (Lindhe & Nyman 1984, Ramfjord 1987; Kaldahl *et al*. 1996; Rosling *et al*. 2001; Axelsson *et al*. 2004). Patients treated for advanced periodontitis and subsequently enrolled in a regular SPT program experienced a mean incidence of tooth loss ranging between 2% and 5% over an observation

period of 10 years (Lindhe & Nyman 1984; Yi *et al*. 1995; Rosling *et al*. 2001; König *et al*. 2002; Karoussis *et al*. 2004). On the other hand, lack of compliance with SPT was associated with disease progression and higher rates of tooth loss (Axelsson *et al*. 2004; Ng *et al*. 2011; Costa *et al*. 2012a). In the majority of patients complying with SPT, periodontal disease progression and tooth loss occurred rarely (Ng *et al*. 2011). In non-compliant patients, however, a seven-fold increase in tooth loss due to periodontitis was reported compared with compliant patients (Ng *et al*. 2011). Despite the evident benefits of SPT, however, only a minority of patients complied with the recommended recall intervals (Mendoza *et al*. 1991; Checchi *et al*. 1994; Demetriou *et al*. 1995).

Peri-implant mucositis represents a common finding among patients not enrolled in a regular SPT program including anti-infective preventive measures (Roos-Jansåker *et al*. 2006). Lack of adherence of partially edentulous patients with dental implants to a regular SPT program was associated with a higher incidences of peri-implantitis and implant loss compared with those of compliant patients (Roccuzzo *et al*. 2010; Costa *et al*. 2012b; Roccuzzo *et al*. 2012). In partially edentulous patients, pre-existing peri-implant mucositis in conjunction with lack of SPT was associated with a higher incidence of peri-implantitis over a 5-year follow-up period (Costa *et al*. 2012b). The outcomes of that study (Costa *et al*. 2012b) yielded a 5-year incidence of peri-implantitis of 18.0% in the group of patients with SPT and of 43.9% in the group without SPT. The logistic regression analysis revealed that lack of SPT within the overall patient sample was significantly associated with peri-implantitis with an odds ratio (OR) of 5.92. Moreover, a diagnosis of periodontitis was significantly associated with the occurrence of peri-implantitis in the overall patient sample (OR 9.20) and particularly in patients without SPT (OR 11.43) (Costa *et al*. 2012b). Patients with a history of moderate-to-severe periodontitis and erratic compliance with SPT yielded a significantly higher incidence of implant losses and peri-implant bone loss of ≥3 mm compared with compliant patients after a follow-up period of 10 years (Roccuzzo *et al*. 2010, 2012, 2014). On the other hand, low incidences of peri-implant bone loss and high implant survival rates were reported in patients treated for periodontal disease and enrolled in regular SPT (Wennström *et al*. 2004; Rodrigo *et al*. 2012). Patients attending a SPT program two to three times a year over the 5 years following implant placement experienced a high implant survival rate (i.e. 97.3%), a low amount of bone level changes during the final 4 years (0.02 mm/year), and a low percentage (11%) of implants with >2 mm of bone loss (Wennström *et al*. 2004).

Outcomes of a prospective cohort study with a 5-year follow-up indicated that implants placed in patients with treated periodontal conditions and enrolled in SPT yielded a 20% prevalence of mucositis (Rodrigo *et al*. 2012). In that study (Rodrigo *et al*. 2012), upon diagnosis of mucositis or peri-implantitis, all implants with the exception of one were successfully treated according to a cumulative interceptive anti-infective protocol (Lang *et al*. 1997). In addition, data indicated that patients susceptible to periodontitis who received dental implants as part of their oral rehabilitation displayed a higher rate of compliance with scheduled SPT appointments compared with patients who underwent periodontal surgery without receiving dental implants (Cardaropoli & Gaveglio 2012). Hence, in order to achieve high long-term survival and success rates of dental implants, enrolment in regular SPT including anti-infective preventive measures should be implemented (Salvi & Zitzmann 2014). Therapy of peri-implant mucositis should be considered as a preventive measure for the onset of peri-implantitis.

Smoking history

Smoking is now generally accepted as an important modifiable risk factor for the development and progression of periodontitis (Johnson & Hill 2004). The reasons that smokers are more susceptible to both periodontitis and peri-implantitis are complex, but usually involve impairment of innate and adaptive immune responses (Kinane & Chestnutt 2000; Johnson & Hill 2004) and interference with wound healing (Johnson & Hill 2004; Labriola *et al*. 2005). Based on data from several longitudinal studies on implant survival, cigarette smoking has been identified as a statistically significant risk factor for implant loss (Bain & Moy 1993; Strietzel *et al*. 2007). In addition, smoking has been associated with increased risk for peri-implant marginal bone loss (Lindquist *et al*. 1997; Galindo-Moreno *et al*. 2005; Nitzan *et al*. 2005, Aglietta *et al*. 2011) and postoperative complications after sinus floor elevation and placement of onlay bone grafts (Levin *et al*. 2004). Smoking is such a strong risk factor for implant failure that smoking-cessation protocols are implemented as part of the treatment plan for implant patients (Bain 1996; Johnson & Hill 2004).

Although smoking does not represent an absolute contraindication for implant placement, smokers should be informed that they are at increased risk of implant loss and development of peri-implantitis with OR ranging from 3.6 to 4.6 (Heitz-Mayfield & Huynh-Ba 2009).

Genetic susceptibility traits

Genetic polymorphisms are small variations in base-pair components of DNA that occur with a frequency of approximately 1–2% in the general population (Kornman & Newman 2000). These small variations in genes are biologically normal and do not cause disease. However, gene polymorphisms can affect in subtle ways how different people respond to

environmental challenges. Within the context of risk assessment for implant therapy, they affect how people respond to a microbial challenge and how efficiently their wounds heal.

Polymorphisms in the interleukin-1 (*IL-1*) gene cluster on chromosome 2q13 have been associated with a hyper-responsive inflammatory reaction to a microbial challenge. A specific composite genotype of *IL-1A* and *IL-1B* polymorphisms, consisting of allele 2 of both *IL-1A* −889 (or the concordant +4845) and *IL-1B* +3954 was associated with an increased risk of severe chronic periodontitis in non-smokers (Kornman *et al*. 1997). Several investigators have attempted to determine whether this composite *IL-1* genotype can serve as a risk marker for biologic complications such as marginal bone loss or even implant loss (Wilson & Nunn 1999; Rogers *et al*. 2002; Feloutzis *et al*. 2003; Gruica *et al*. 2004; Jansson *et al*. 2005). All of these reports found that being positive for the composite *IL-1* genotype was not associated with an increased risk of marginal bone loss or other implant-related problems. Hence, based on available evidence, it may be considered premature to recommend a systematic genetic screening of patients who are candidates for implant therapy (Huynh-Ba *et al*. 2008; Dereka *et al*. 2012).

Conclusion

Patient-based risk-assessment represents a process in which an attempt is made to identify factors or indicators increasing the risk of complications that eventually lead to implant loss. Risk assessment of the implant patient is a critically important preamble to treatment planning and if properly done, can minimize the complications associated with dental implants. In many cases, early identification of these factors or indicators makes it possible to avoid or eliminate them, thereby increasing the chances of long-term implant survival and success. Most of the systemic risk factors for implant complications are those that increase the patient's susceptibility to infections or those that interfere with wound healing. Important risk factors that can interfere with wound healing around dental implants are long-term use of bisphosphonates, history of radiation therapy of the jaws, and poor metabolic control of diabetes mellitus. Additional factors such as parafunctional habits (e.g. bruxism) and relationships of the jaws (e.g. vertical and sagittal dimensions) should be included in a comprehensive patient-based risk assessment.

Based on the fact that untreated oral infections can lead to implant complications, it is highly recommended that any endodontic, periodontal, and other oral infections be treated prior to implant placement.

Part 10: Treatment Planning Protocols

Chapter 32

Treatment Planning of Patients with Periodontal Diseases

Giovanni E. Salvi,[1] Jan Lindhe,[2] and Niklaus P. Lang[1,3]

Introduction

Caries and periodontal diseases represent opportunistic infections associated with biofilm formation on the surfaces of teeth. Factors such as bacterial specificity and pathogenicity as well as the disposition of the individual for disease, for example local and general resistance, may influence the onset, rate of progression, and clinical characteristics of the plaque-associated dental disorders. Findings from animal experiments and longitudinal studies in humans, however, have demonstrated that treatment, including the elimination or the control of the biofilm infection and the introduction of careful plaque control measures, in most, if not all, cases results in dental and periodontal health. Even if health cannot always be achieved and maintained, the arrest of disease progression following treatment must be the goal of modern dental care.

The treatment of patients affected by caries and periodontal disease, including symptoms of associated pathologic conditions such as pulpitis, periapical periodontitis, marginal abscesses, tooth migration, etc., may be divided into four different phases:

1. Systemic phase of therapy, including smoking counseling
2. Initial (or hygienic) phase of periodontal therapy, that is cause-related therapy
3. Corrective phase of therapy, that is additional measures such as periodontal surgery and/or endodontic therapy, implant surgery, restorative, orthodontic, and/or prosthetic treatment
4. Maintenance phase (care), that is supportive periodontal therapy (SPT).

Treatment goals

In every patient diagnosed with periodontitis, a treatment strategy including the elimination of the opportunistic infection must be defined and followed. This treatment strategy must also define the clinical outcome parameters to be reached through therapy. Such clinical parameters include:

- Reduction or resolution of gingivitis [bleeding on probing (BoP)]: a full-mouth mean BoP of ≤25% should be reached

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

- Reduction in probing pocket depth (PPD): no residual pockets with a PPD of >5 mm should be present.
- Elimination of open furcations in multirooted teeth: furcation involvement should not exceed 2–3 mm in the horizontal direction
- Absence of pain
- Individually satisfactory esthetics and function.

It must be emphasized that risk factors for periodontitis that can be controlled must be addressed as well. The three main risk factors for chronic periodontitis are improper plaque control, cigarette smoking, and uncontrolled diabetes mellitus (Kinane *et al*. 2006).

Systemic phase

The goal of this phase is to eliminate or decrease the influence of systemic conditions on the outcomes of therapy and to protect the patient and the dental care providers against infectious hazards. Consultation with the patient's physician or specialist should enable appropriate preventive measures to be taken, if necessary. Efforts must be made to stimulate a smoker to enroll in a smoking cessation program. Additional aspects are discussed in Chapters 35 and 36.

Initial (hygienic) phase

This phase represents the major cause-related therapy. Hence, the objective of this phase is the achievement of clean and infection-free conditions in the oral cavity through complete removal of all soft and hard deposits and their retentive factors. Furthermore, this phase should aim at motivating the patient to perform optimal plaque control. The initial phase of periodontal therapy is concluded by a re-evaluation and a planning of both additional and supportive therapies.

Corrective phase (additional therapeutic measures)

This phase addresses the sequelae of the opportunistic infections and includes therapeutic measures such as periodontal and implant surgery, endodontic therapy, restorative and/or prosthetic treatment. The volume of corrective therapy required and the selection of means for the restorative and prosthetic therapy can be determined only when the level of success of the cause-related therapy has been properly evaluated. The patient's willingness and ability to cooperate in the overall therapy must determine the content of the corrective treatment. If this cooperation is unsatisfactory, it may not be worth initiating treatment procedures and there will be no permanent improvement of oral health, function, and esthetics. The validity of this statement can be exemplified by the results of studies aimed at assessing the relative value of different types of surgical methods in the treatment of periodontal disease. Thus, a number of clinical trials (Lindhe & Nyman 1975; Nyman *et al*. 1975; Rosling *et al*. 1976a, b; Nyman *et al*. 1977; Nyman & Lindhe 1979) have demonstrated that gingivectomy and flap procedures performed in patients with proper plaque control levels often result in gain of alveolar bone and clinical attachment, while surgery in plaque-contaminated dentitions may cause additional destruction of the periodontium.

Maintenance phase (supportive periodontal therapy)

The aim of this treatment is the prevention of reinfection and disease recurrence. For each individual patient a recall system must be designed that includes (1) assessment of deepened sites with bleeding on probing, (2) instrumentation of such sites, and (3) fluoride application for the prevention of dental caries (see Chapter 60). In addition, this treatment involves the regular control of prosthetic restorations incorporated during the corrective phase of therapy. Tooth sensitivity testing is to be applied to abutment teeth owing to the fact that loss of vitality represents a frequently encountered complication (Bergenholtz & Nyman 1984; Lang *et al*. 2004; Lulic *et al*. 2007). Based upon the individual caries activity, bitewing radiographs should be incorporated in SPT at regular intervals.

Screening for periodontal disease

A patient seeking dental care is usually screened for the presence of carious lesions by means of clinical and radiographic tools. Likewise, it is imperative that such a patient is screened for the presence of periodontitis as well, using a procedure termed the basic periodontal examination (BPE) [or periodontal screening record (PSR)].

Basic periodontal examination

The goal of the BPE is to screen the periodontal conditions of a new patient and to facilitate treatment planning. BPE scoring will allow the therapist to identify a patient with:

- Reasonably healthy periodontal conditions, but in need of long-term preventive measures
- Periodontitis and in need of periodontal therapy.

In the BPE, the screening of each tooth or implant is evaluated. For this purpose, the use of a thin graduated periodontal probe is recommended. At least two sites per tooth/implant (i.e. mesiobuccal and distobuccal) should be probed using a light force (i.e. 0.2 N). Each dentate sextant within the dentition is given a BPE code or score, whereby the *highest* individual site score is used.

BPE system code

- *Code 0*: PPD ≤3 mm, BoP⁻, no calculus or overhanging fillings (Fig. 32-1a)
- *Code 1*: PPD ≤3 mm, BoP⁺, no calculus or overhanging fillings (Fig. 32-1b).
- *Code 2*: PPD ≤3 mm, BoP⁺, presence of supra- and/or sub-gingival calculus and/or overhanging fillings (Fig. 32-1c).
- *Code 3*: PPD >3 mm but ≤5 mm, BoP⁺ (Fig. 32-1d).
- *Code 4*: PPD >5 mm (Fig. 32-1e).

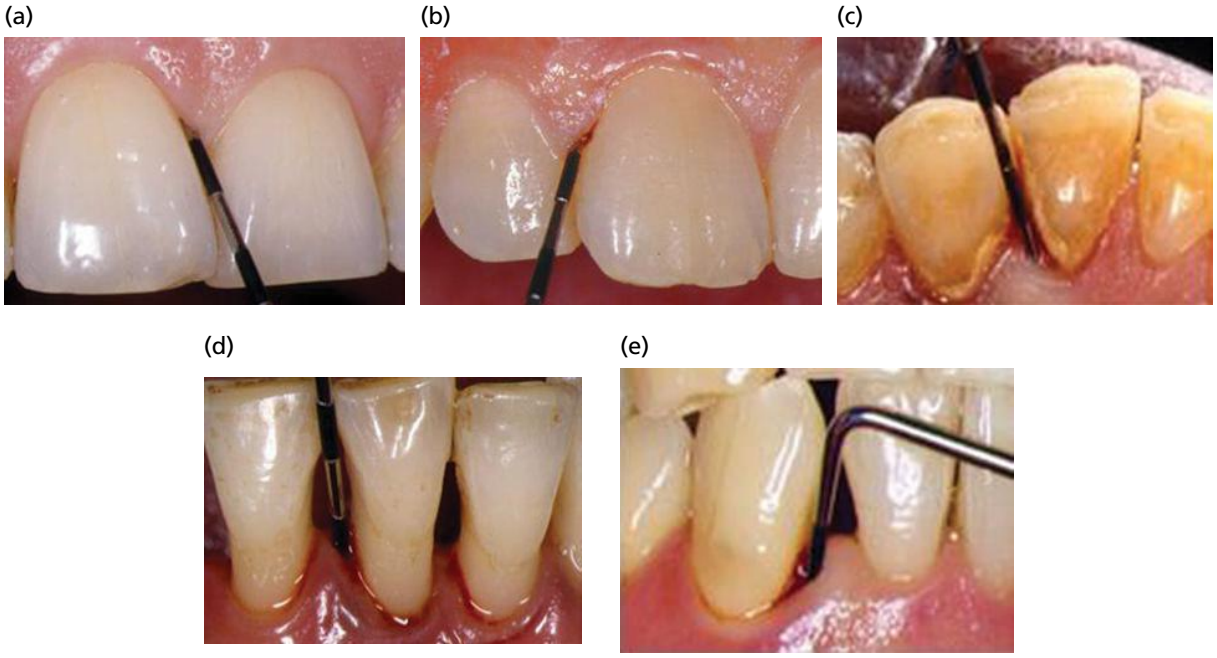

Fig. 32-1 Clinical illustration of the basic periodontal examination scores: (a) code 0, (b) code 1, (c) code 2, (d) code 3, (e) code 4.

Fig. 32-2 (a–d) Clinical status of a 27-year-old female patient (S.B.) diagnosed with generalized aggressive periodontitis with furcation involvement.

If an examiner identifies one single site with a PPD of >5 mm within a sextant, the sextant will receive a code of 4, and no further assessments are needed in that particular sextant. Patients with sextants given codes of 0, 1 or 2 belong to the relatively periodontally healthy category. A patient exhibiting a sextant with codes of 3 or 4 must undergo a more comprehensive periodontal examination (for details see Chapter 29).

The aim of the following text is to explain the overall objectives of the treatment planning of patients with BPE codes of 3 and 4 undergoing a comprehensive diagnostic process.

Diagnosis

The basis for the treatment planning described in this chapter is established from the clinical data collected from the patient's examination (see Chapter 29). As an example, a 27-year-old female patient (S.B.), who was systemically healthy and a non-smoker, was examined with respect to her periodontal condition: gingival sites displaying signs of *BoP* were identified, *PPD* were measured, the *periodontal attachment level* was calculated, *furcation involvements* were graded, *tooth mobility* was assessed, and the radiographs were analyzed to determine the *height* and *outline* of the *alveolar bone crest*.

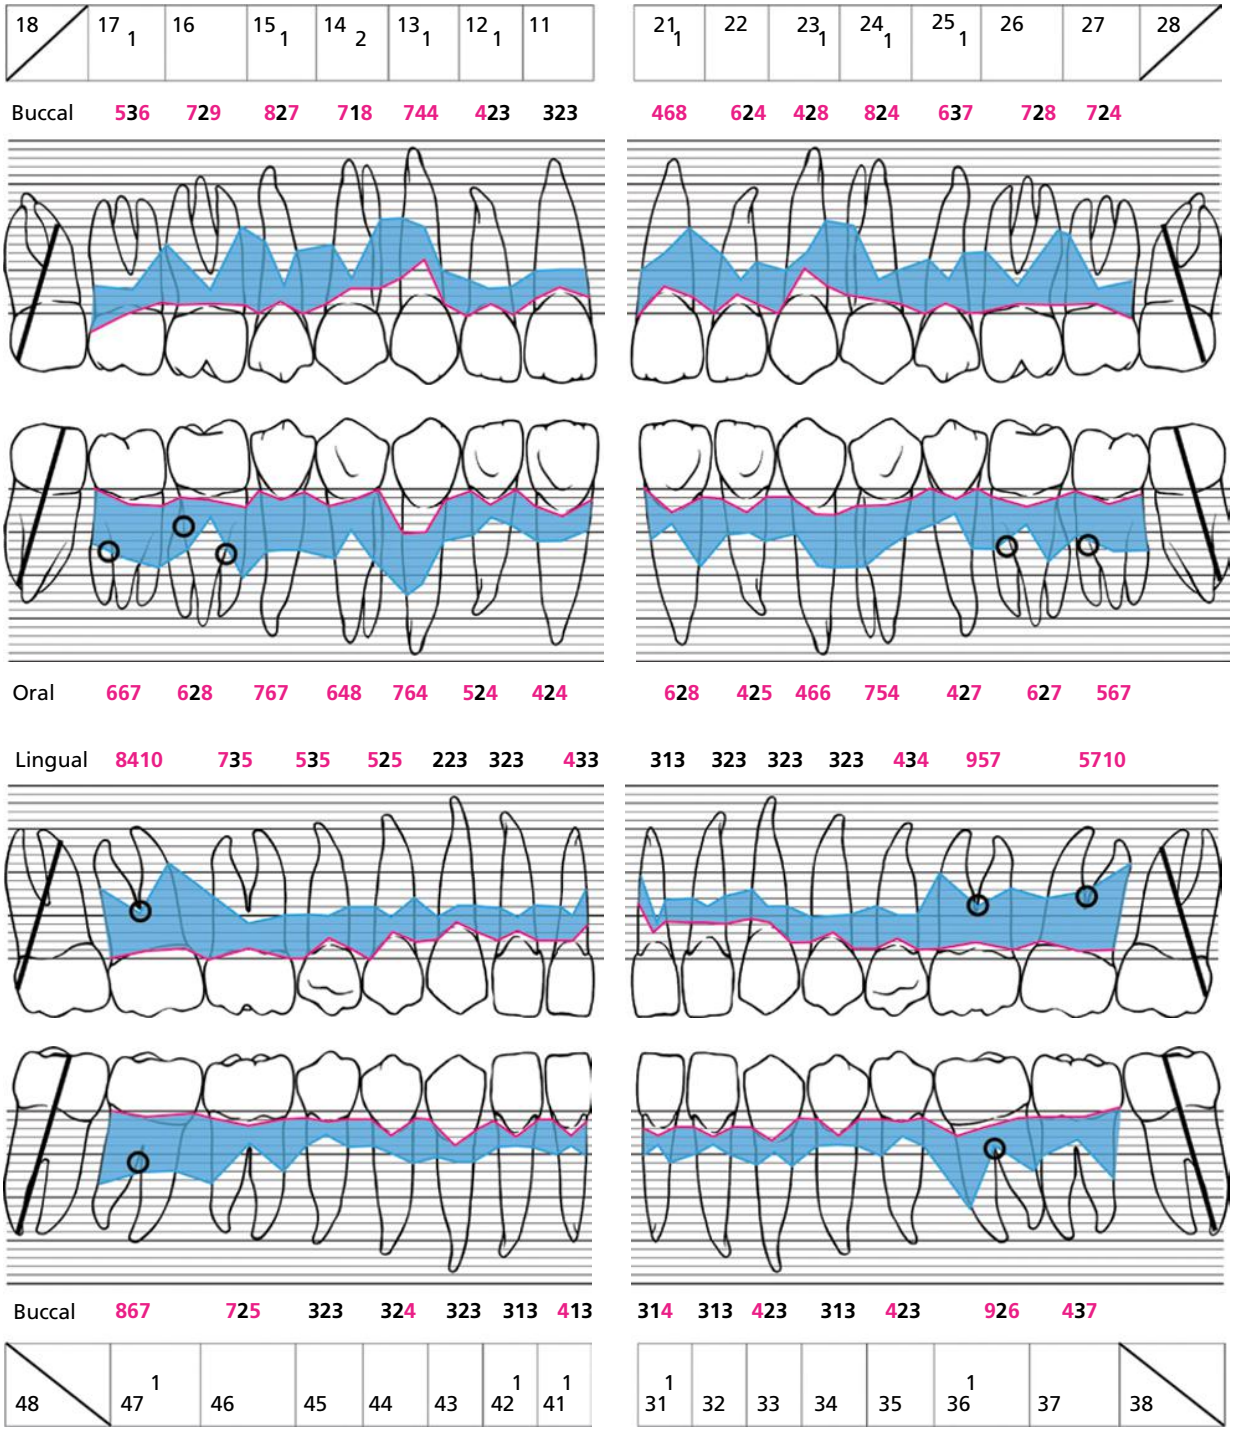

Fig. 32-3 Periodontal chart of the patient presented in Fig. 32-2.

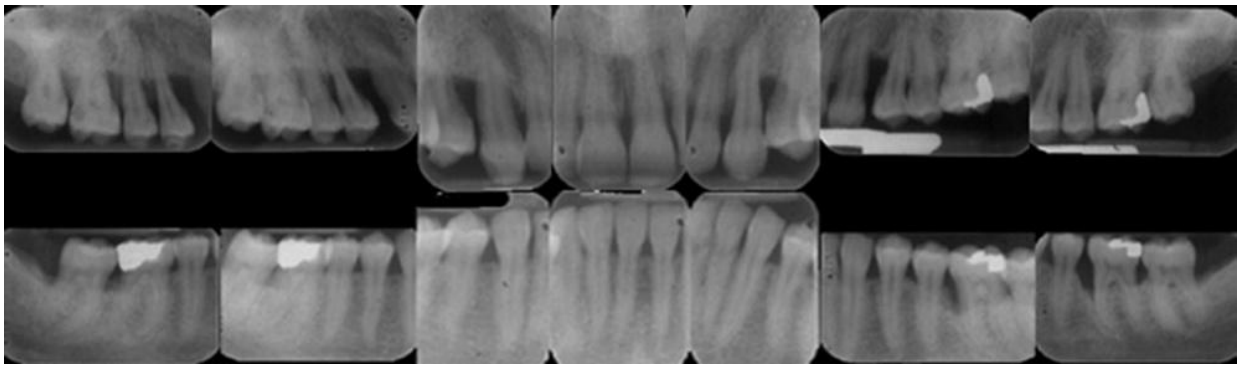

Fig. 32-4 Radiographs of the patient presented in Fig. 32-2.

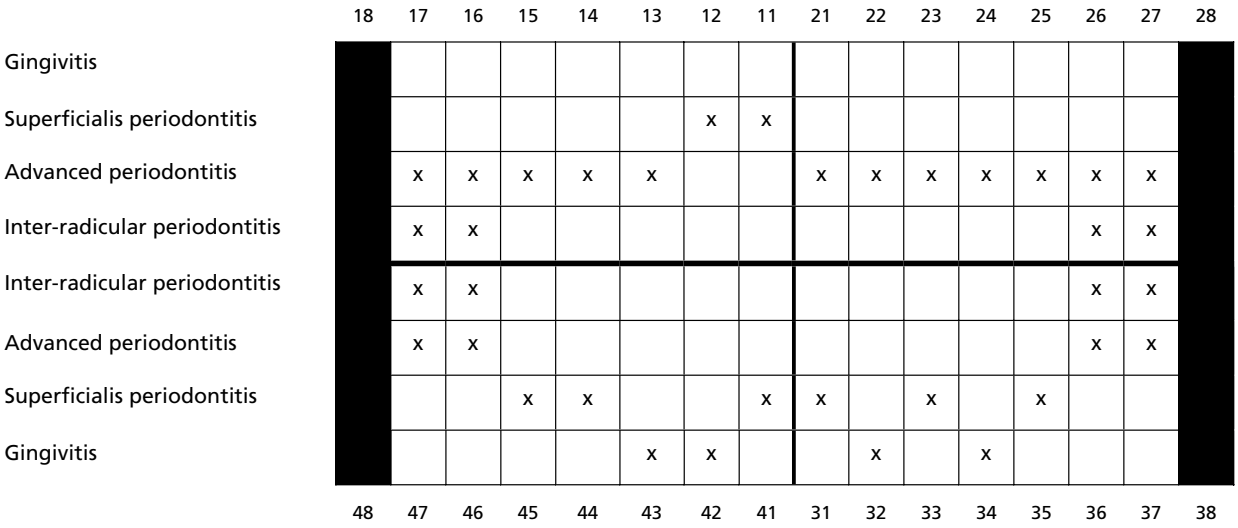

Fig. 32-5 Single tooth diagnosis of the patient presented in Fig. 32-2.

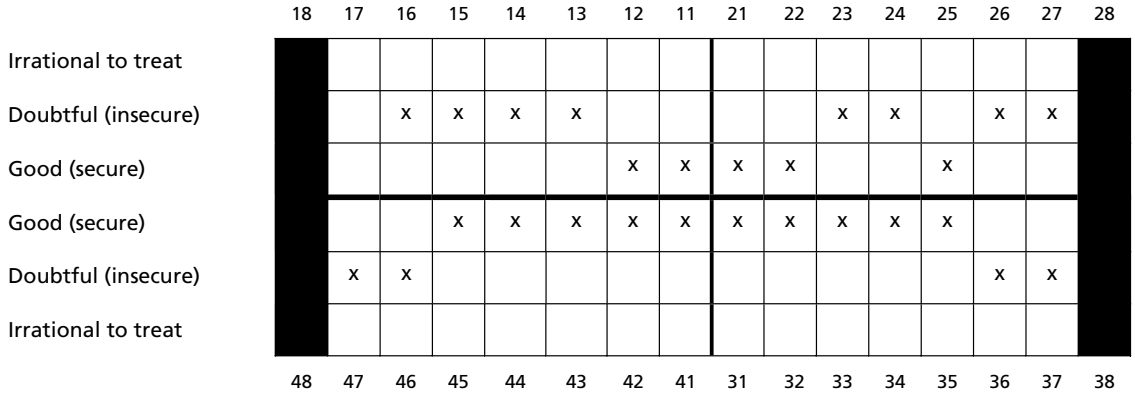

Fig. 32-6 Pretherapeutic single-tooth prognosis of the patient presented in Fig. 32-2.

The clinical characteristics of the dentition of this patient are shown in Fig. 32-2. The periodontal chart and the radiographs are presented in Fig. 32-3 and Fig. 32-4, respectively. Based on these findings, each tooth in the dentition was given a diagnosis (Fig. 32-5) and a pretherapeutic prognosis (Fig. 32-6). In addition to the examination of the periodontal condition, detailed assessments of primary and recurrent caries were made for all tooth surfaces in the dentition. Furthermore, the patient was examined with respect to endodontic and occlusal problems as well as temporomandibular joint dysfunctions.

Treatment planning

Initial treatment plan

Provided that the patient's examination has been completed (see Chapter 29) and a diagnosis of all pathologic conditions has been made, an initial treatment

plan can be established. At this early stage in the management of a patient, it is, in most instances, impossible to make definite decisions regarding all aspects of the treatment sequence, because:

1. *Degree of success of initial therapy is unknown*. The re-evaluation after initial, cause-related therapy forms the basis for the selection of the type of additional therapy. The degree of disease elimination that can be reached depends on the outcome of subgingival instrumentation, but also on the patient's ability and willingness to exercise proper plaque control and to adopt adequate dietary habits.
2. *Patient's "subjective" need for additional (periodontal and/or restorative) therapy is unknown*. When the dentist has completed the examination of the patient and an inventory has been made regarding periodontal disease, caries, pulpal disease, and temporomandibular joint disorders, the observations are presented to the patient (i.e. "the case presentation"). During the case presentation session it is important to find out if the patient's subjective need for dental therapy coincides with the dentist's professional appreciation of the kind and volume of therapy that is required. It is important that the dentist understands that the main objective of dental therapy, besides *elimination of pain, is to satisfy the patient's demands regarding chewing function (comfort) and esthetics*, demands that certainly vary considerably from one individual to another.
3. *Result of some treatment steps cannot be predicted.* In patients exhibiting advanced forms of caries and periodontal disease, it is often impossible to anticipate whether or not all teeth that are present at the initial examination can be successfully treated, or to predict the result of certain parts of the intended therapy. In other words, critical and difficult parts of the treatment must be performed first, and the outcome of this treatment must be evaluated before all aspects of the definitive corrective treatment can be properly anticipated and described.

Pretherapeutic single tooth prognosis

Based on the results of the comprehensive examination, including assessments of periodontitis, caries, tooth sensitivity, and the resulting diagnosis, as well as consideration of the patient's needs regarding esthetics and function, a pretherapeutic prognosis for each individual tooth (root) is made.

Three major questions are addressed:

1. Which tooth/root has a "*good" (safe)* prognosis?
2. Which tooth/root is "*irrational-to-treat*"?
3. Which tooth/root has a "*doubtful" (insecure)* prognosis?

Teeth with a *good* prognosis will require relatively simple therapy and may be regarded as secure abutments for function.

(a)

(b)

(c)

Fig. 32-7 (a–c) Clinical front and lateral views of the patient presented in Fig. 32-2 at re-evaluation after initial periodontal therapy.

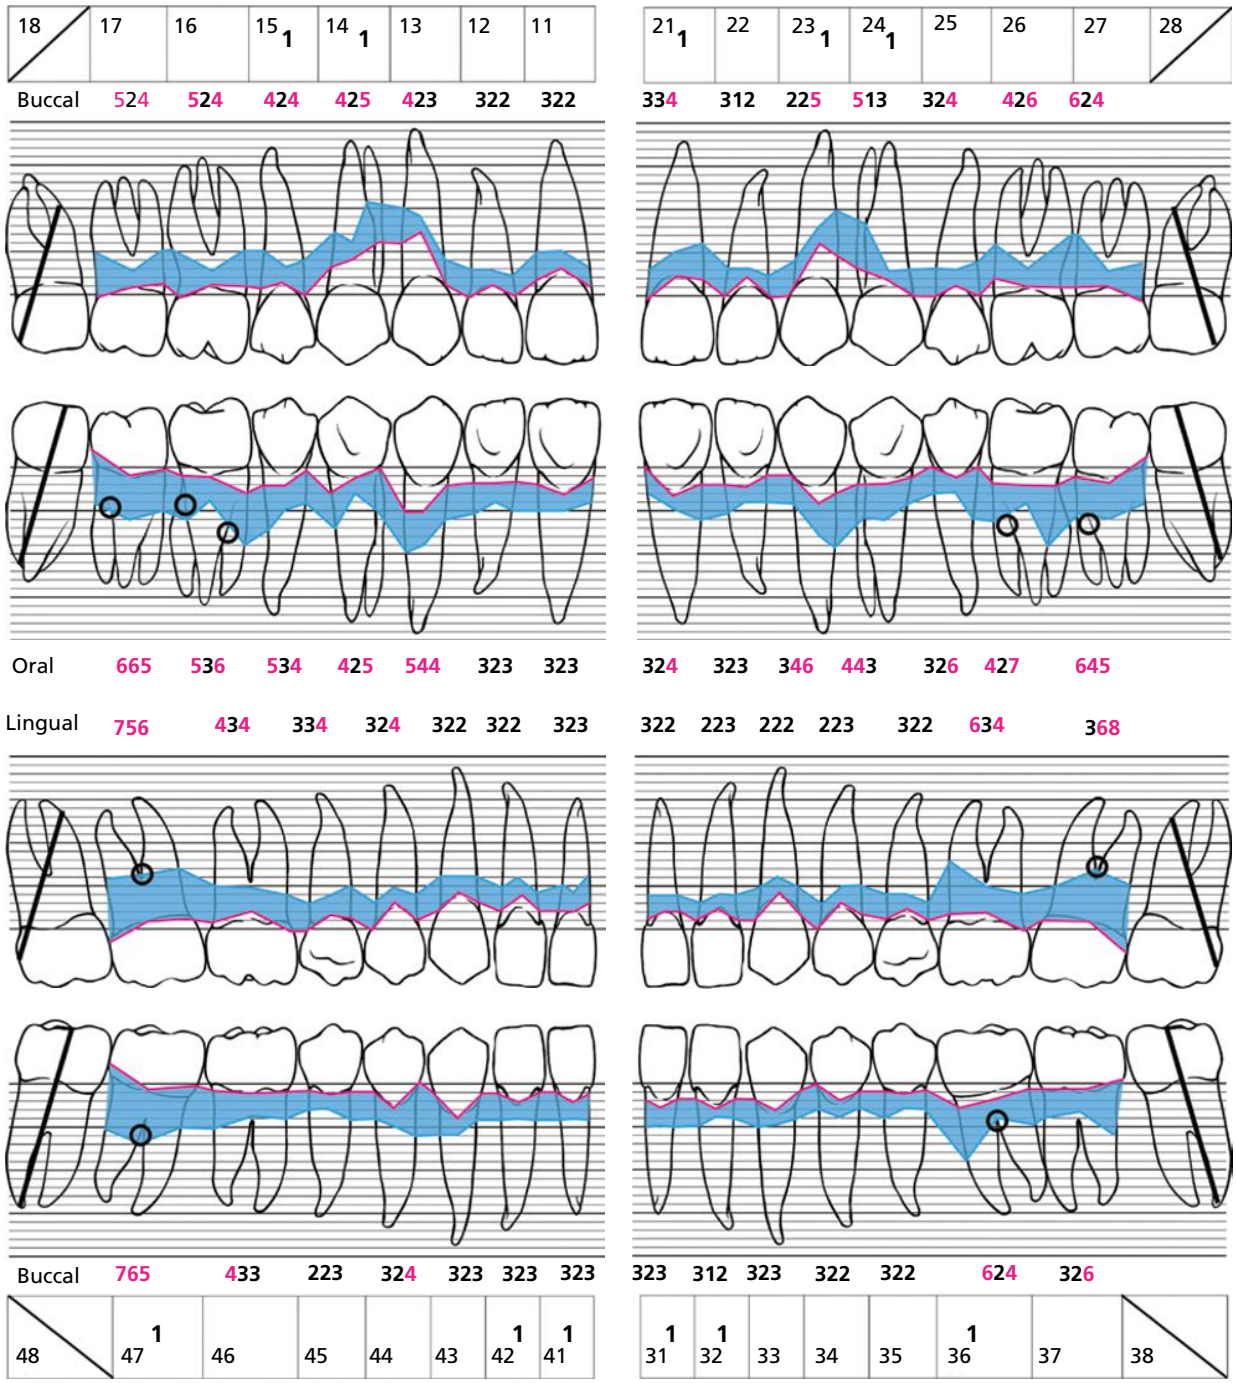

Fig. 32-8 Periodontal chart of the patient presented in Fig. 32-2 at re-evaluation after initial periodontal therapy.

Teeth that are considered "*irrational-to-treat*" should be extracted during initial, cause-related therapy. Such teeth may be identified on the basis of the following criteria:

- *Periodontal*:
  - Recurrent periodontal abscesses
  - Combined periodontal–endodontic lesions
  - Attachment loss to the apical region
- *Endodontic:*
  - Root perforation in the apical half of the root
  - Extensive periapical lesions (diameter >6 mm)
- *Dental*:
  - Vertical fracture of the root (hairline fractures)
  - Oblique fracture in the middle third of the root
  - Caries lesions extending into the root canal
- *Functional*:
  - Third molars without antagonists and with periodontitis/caries.

Teeth with a *doubtful* prognosis are usually in need of comprehensive therapy and must be brought into the category of teeth with a *good* prognosis by means of additional therapy. Such teeth may be identified on the basis of the following criteria:

- *Periodontal*:
  - Furcation involvement (class II or III)
  - Angular (i.e. vertical) bony defects
  - "Horizontal" bone loss involving >⅔ of the root

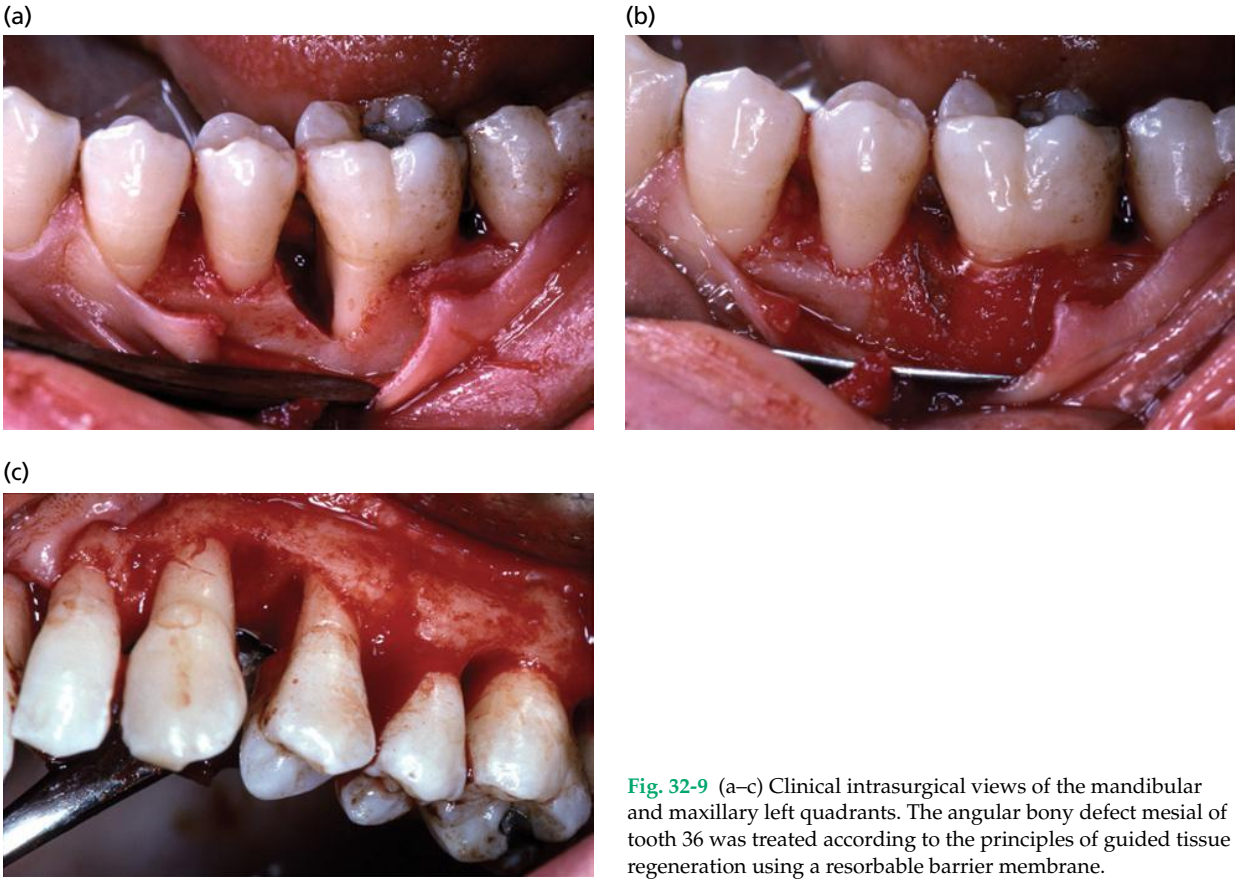

Fig. 32-9 (a–c) Clinical intrasurgical views of the mandibular and maxillary left quadrants. The angular bony defect mesial of tooth 36 was treated according to the principles of guided tissue regeneration using a resorbable barrier membrane.

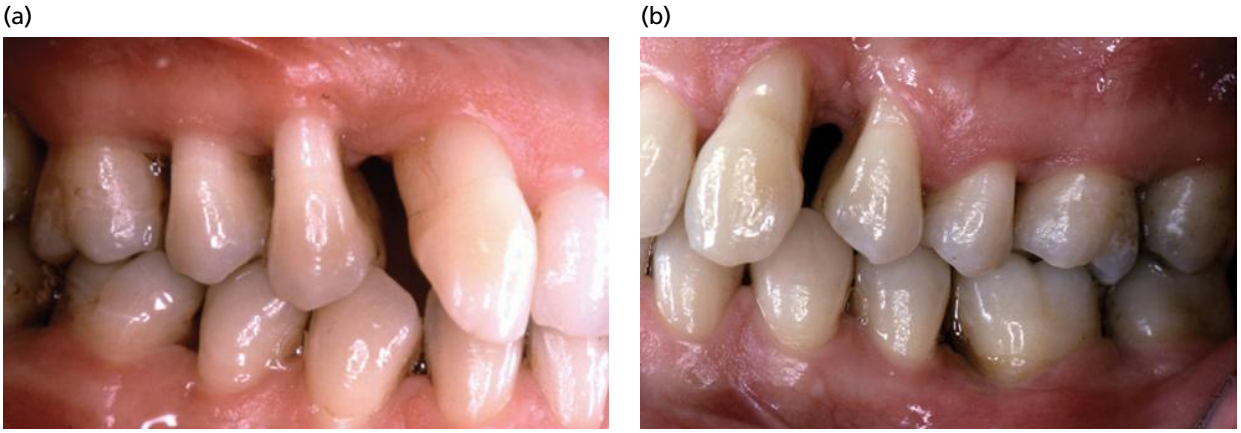

Fig. 32-10 (a, b) Clinical lateral views of the patient presented in Fig. 32-2 at re-evaluation after periodontal surgery.

- *Endodontic*:
  - Incomplete root canal therapy
  - Periapical pathology
  - Presence of voluminous posts/screws
- *Dental*:
  - Extensive root caries.

Case presentation

The "case presentation" is an essential component of the initial treatment plan and must include a description for the patient of different therapeutic goals and the modalities by which these may be reached. At the case presentation for patient S.B., the following treatment plan was described:

- Teeth 12–22 and 45–35 in the dentition will probably not confront the dentist with any major therapeutic challenges. For the remaining teeth in the dentition, however, the treatment plan may involve several additional measures.

Expected benefits inherent to a certain treatment plan versus obvious disadvantages should always be explained to and discussed with the patient. His/her attitude to the alternatives presented must guide the dentist in the design of the overall treatment plan.

Based on the pretherapeutic single-tooth prognosis (Fig. 32-6), following detailed treatment plan described below was presented to the patient.

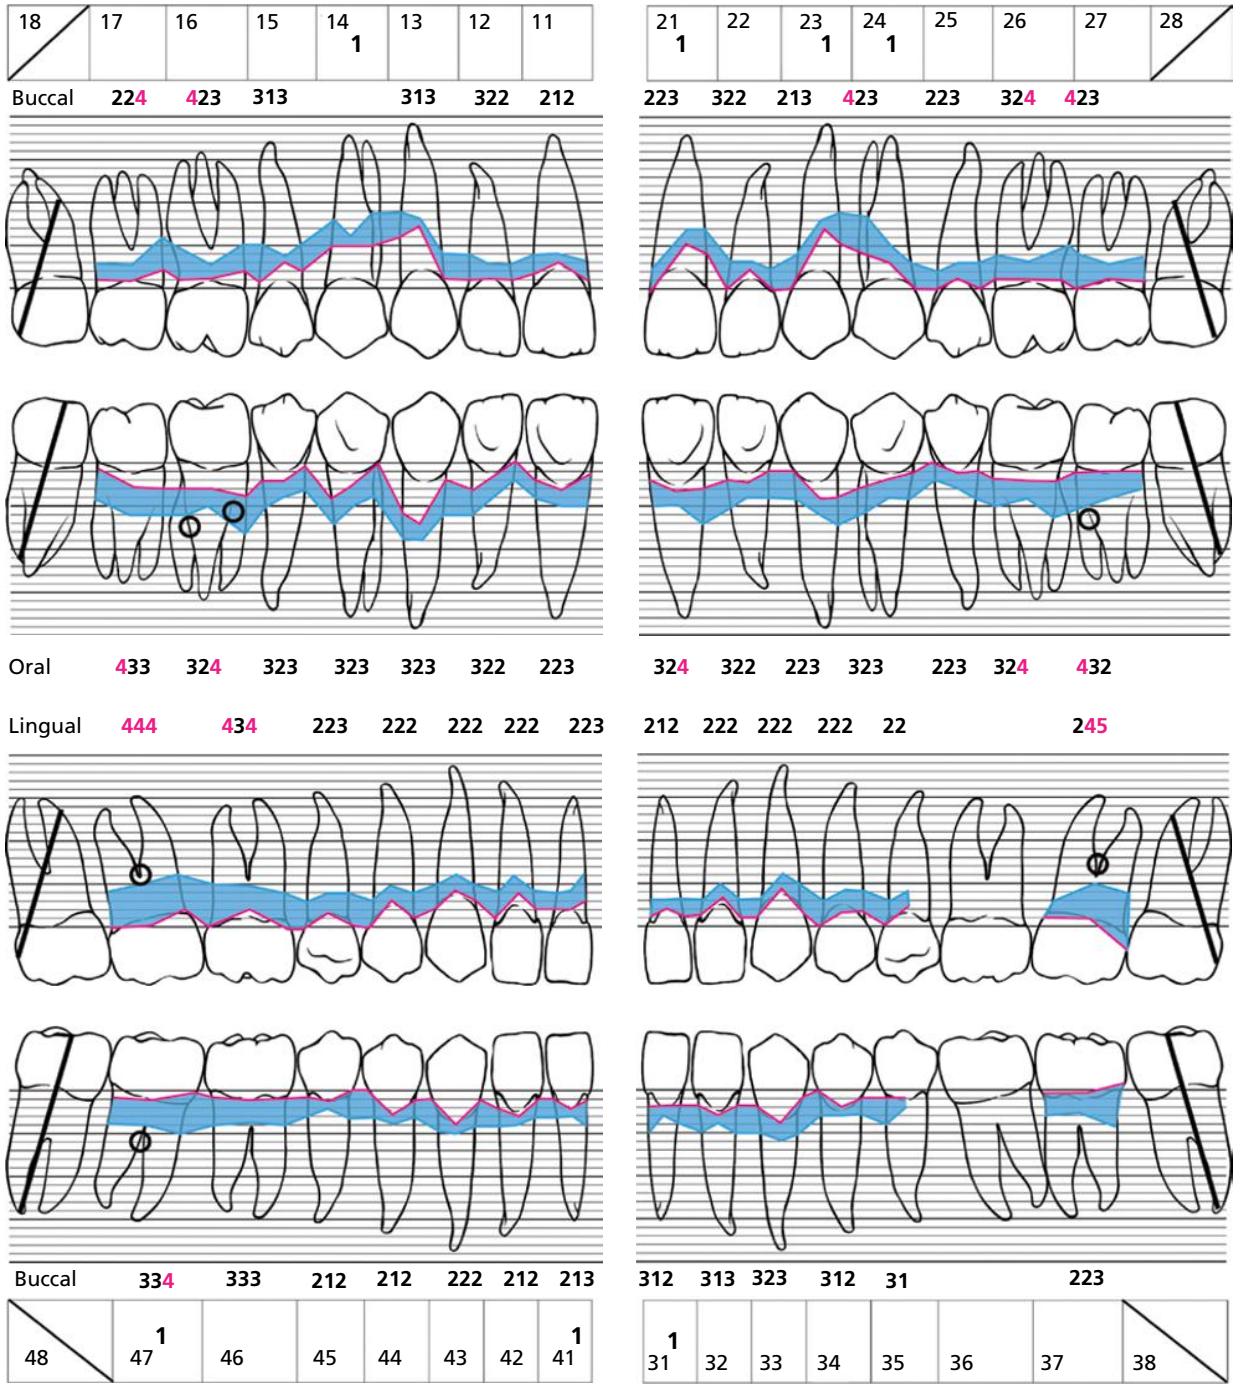

Fig. 32-11 Periodontal chart of the patient presented in Fig. 32-2 at re-evaluation after periodontal surgery.

Systemic phase

Owing to the fact that the patient was systemically healthy and a non-smoker, no medical examination or smoking cessation counseling was required.

Initial phase (cause-related therapy)

The treatment was initiated and included the following measures to eliminate or control the bacterial infection:

1. *Motivation* of the patient and *instruction* in oral hygiene practices with subsequent check-ups and re-instruction.
2. *Scaling and root planing* under local anesthesia in combination with removal of plaque retentive factors (and teeth irrational to treat, if any).
3. *Excavation and restoration* of carious lesions (teeth 16 and 26).
4. *Endodontic treatment* of tooth 46.

Re-evaluation of treatment

The initial phase of therapy is completed with a thorough analysis of the results obtained with respect to the elimination or degree of control of the dental infections. This implies that a re-evaluation of the patient's periodontal conditions and caries activity must be performed. The results of this re-evaluation

(Figs. 32-7, 32-8) form the basis for the selection, if necessary, of additional corrective measures to be performed in the phase of definitive treatment (i.e. corrective phase). In order to provide time for the tissues to heal, the re-evaluation should be performed not earlier than 6–8 weeks following the last session of instrumentation.

Planning of the corrective phase (i.e. additional periodontal therapy)

If the results from the re-evaluation, made 6–8 weeks after the termination of the initial treatment phase, show that periodontal disease and caries have been brought under control and the treatment goals (*see* above) have either been reached completely or have been approached substantially, the additional treatment may be carried out. The main goal of this phase is to correct the sequelae caused by oral infections (i.e. periodontal disease and caries). The following procedures may be performed:

- *Additional endodontic treatment with/without post-and-core build-ups.*
- *Periodontal surgery*: type (i.e. open flap debridement, regenerative or resective surgery) and extent of surgical treatment should be based on PPD measurements, degree of furcation involvement, and "BoP" scores assessed at re-evaluation. Periodontal surgery is often confined to those areas of the dentition where the inflammatory lesions were not resolved by root instrumentation alone, in areas with angular bony defects or in furcation-involved molars.
- *Installation of oral implants*: in regions of the dentition where tooth abutments are missing, implant therapy for esthetic and functional reasons may be considered. It is essential to realize that implant therapy must be initiated when all dental infections are under control, that is after successful periodontal therapy.
- *Definitive restorative and prosthetic treatment*, including fixed or removable dental prostheses.

Corrective phase (additional therapy)

Patient S.B. exhibited, after initial therapy, low plaque and gingivitis scores (i.e. 5–10%) and no active carious lesions. The corrective phase, therefore, included the following components:

1. *Periodontal surgery (i.e. open flap debridement)* in the maxillary left and right quadrants as well as in the mandibular molar regions (Fig. 32-9)
2. *Guided tissue regeneration (GTR)* for tooth 36
3. *Re-evaluation* after periodontal surgery (Figs. 32-10, 32-11)
4. *Orthodontic therapy* in the maxillary front area (Fig. 32-12)
5. *Restorative therapy* in the maxillary front area for esthetic reasons (Fig. 32-13).

Re-evaluation after corrective phase

The corrective phase of therapy is completed with a thorough analysis of the results obtained with respect to the elimination of the sequelae of periodontal tissue destruction (Figs. 32-14, 32-15, 32-16). This implies that a re-evaluation of the patient's periodontal and peri-implant conditions must be performed. The results of this re-evaluation form the basis for the assessment of the residual periodontal risk. The outcomes of the periodontal risk assessment (PRA), in turn, will determine the recall frequency of the patient during the maintenance phase.

Maintenance phase (supportive periodontal therapy)

Following completion of cause-related therapy, the patient must be enrolled in a recall system aimed at preventing the recurrence of oral infections (i.e. periodontitis, caries, and peri-implantitis). *Supportive periodontal therpay* (SPT) should be scheduled at the re-evaluation after initial therapy and independently of the need for additional therapy. The time interval between the recall appointments should be based on a PRA (see Chapter 60) established at the re-evaluation

after corrective phase. It has been well established that self-performed plaque control combined with regular attendance of maintenance care visits following active periodontal treatment represent effective means of controlling gingivitis and periodontitis and limiting tooth mortality over a 30-year period (Axelsson *et al*. 2004). It is important to emphasize, however, that the recall program must be designed to meet the individual needs of the patient. According to a PRA performed after completion of active therapy, some patients should be recalled every 3 months, while others may need to be checked only once a year (Lang & Tonetti 2003).

At the recall visits the following procedures should be carried out:

1. Update of the medical and smoking history
2. Soft tissue examination as a cancer screening
3. Recording of the full-mouth PPD of ≥5 mm with concomitant BoP
4. Re-instrumentation of bleeding sites with a PPD of ≥5 mm
5. Polishing and fluoridation for the prevention of dental caries.

Patient S.B., who is presented to describe the guiding principles of treatment planning, was, during the first 6 months after active treatment, recalled twice (i.e. every 3 months) and subsequently only once every 6 months based on the individual PRA.

Concluding remarks

The overall treatment plan and the sequence of the different treatment procedures used for patient S.B. were selected for presentation in order to illustrate the following principle: *in patients exhibiting a generalized advanced breakdown of the periodontal tissues, but with an intact number of teeth, considerable efforts should be made to maintain all teeth*. Extraction of a single tooth in such a dentition will frequently call for the extraction of several others for "prosthetic reasons". The end result of such an approach thus includes a prosthetic rehabilitation that, if the treatment planning had been properly done, could have been avoided.

The large variety of treatment problems that different patients present may obviously require deviations from the sequence of treatment phases (i.e. systemic phase, initial cause-related therapy, corrective therapy, and maintenance care) discussed above. Such deviations may be accepted as long as the fundamental principles characterizing the treatment phases are understood.

Case report

A patient is presented below together with a brief description of his specific dental problems and the treatment delivered in order to demonstrate the rationale behind such treatment phases.

Patient S.K. (male, 35 years old)

Initial examination

The chief complaint of the patient was the slightly increased mobility of tooth 21. The periodontal conditions (i.e. PPD, furcation involvements, tooth mobility, and periapical radiographs) from the initial examination are shown in Fig. 32-17.

The data obtained from the initial examination disclosed the presence of an advanced destruction of the supporting tissues in most parts of the dentition (Fig. 32-18) and the presence of several angular bony defects (Fig. 32-19). The full-mouth plaque score (FMPS) and full-mouth bleeding score (FMBS) were 32% and 86%, respectively. The patient was systemically healthy and a former smoker.

Diagnosis

The patient was diagnosed with a generalized chronic periodontitis with furcation involvement.

Etiology

The supra- and sub-gingival bacterial deposits were identified as the main etiologic factors. Past cigarette smoking was considered a modifying factor.

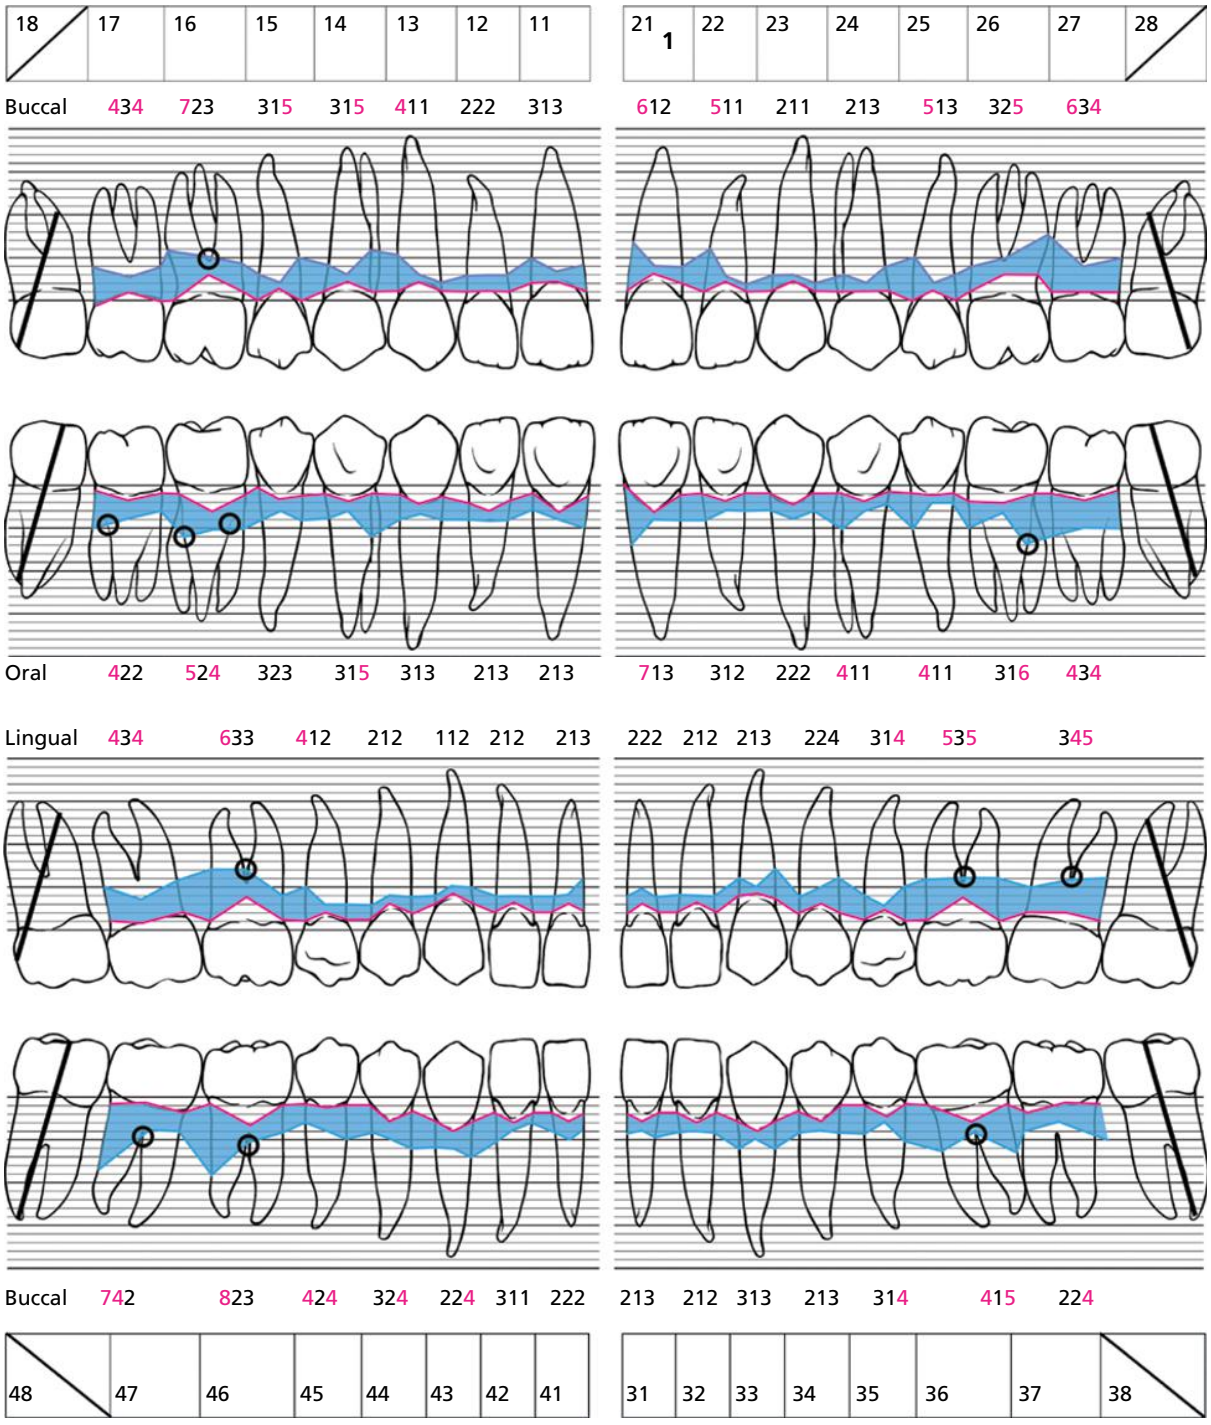

Fig. 32-22 Periodontal chart at re-evaluation after initial therapy of the patient presented in Fig. 32-17.

Pretherapeutic single-tooth prognosis

Teeth 28, 38, and 48 were missing. Tooth 18 was impacted and considered irrational to treat. Teeth 13, 12, 11, and 23 in the maxilla and 45–35 in the mandible were classified as secure. A doubtful prognosis was assigned to teeth 17, 16, 15, 14, 21, 22, 24, 25, 26, and 27 in the maxilla and to teeth 36, 37, 46, and 47 in the mandible (Fig. 32-20).

Treatment planning

In the treatment planning of this relatively young patient, it seemed reasonable to anticipate the retention of all teeth of his periodontally compromised dentition. The prerequisites for a good long-term prognosis after therapy included (1) optimal self-performed plaque control, (2) proper healing of the periodontal tissues following non-surgical and surgical therapy, and (3) a carefully monitored maintenance care program. As stated above, tooth 21 displayed increased mobility, but this did not disturb the chewing comfort of the patient.

In such a relatively young patient, extensive efforts were made to properly treat inflammatory periodontal disease in the entire dentition, in order to avoid tooth extraction and subsequent prosthetic rehabilitation.

Treatment

Subsequent to initial examination, the patient was given a detailed "case presentation" and information regarding the alternative goals of and prerequisites for the overall treatment. This information included a description of the role of dental biofilms in the etiology of periodontal disease and the significance of optimal plaque control for a successful outcome of therapy. A treatment program was subsequently planned which aimed at maintaining all teeth. The overall treatment was performed in the following sequence.

Initial cause-related therapy

The patient was counseled not to start smoking again. After thorough motivation, the patient was instructed in the toothbrushing technique according to Bass (1954) and in the use of interdental brushes. Scaling and root planing of all teeth was performed under local anesthesia. The front and lateral views as well as the periodontal chart at re-evaluation after initial therapy are shown in Figs. 32-21 and 32-22, respectively.

Additional therapy

The need for additional therapy was based on the re-evaluation after initial therapy (Fig. 32-22). Periodontal surgery in conjunction with regenerative procedures was deemed necessary in all quadrants. During access flap surgery in the first quadrant extending from tooth 13 to 17, tooth 18 was extracted. Between the upper front teeth 11 and 21, the modified papilla preservation technique (Cortellini *et al*. 1995) was chosen in the surgical procedure to gain access to the angular bony defect of tooth 21 (Fig. 32-23). In this area, the application of enamel matrix derivatives (i.e. Emdogain®) aimed at regenerating the lost periodontal tissues on the mesial aspect of tooth 21.

In the third quadrant, the surgical access flap extended from tooth 35 to 37. In the fourth quadrant, flap surgery in conjunction with the simplified papilla preservation technique (Cortellini *et al.* 1999) was applied to gain access to the angular bony defect on the distal aspect of tooth 46. In this area, the application of enamel matrix derivatives (i.e. Emdogain®) aimed at regenerating the lost periodontal tissues. Six months after completion of the corrective phase (Fig. 32-24), a re-evaluation of the periodontal conditions (Fig. 32-25), including on radiographs (Figs. 32-26, 32-27), followed by a PRA were performed.

Supportive periodontal therapy

After completion of initial and corrective therapy, the patient was recalled for maintenance care every 3 months. During recall appointments, sites bleeding on probing and with a PPD of ≥5 mm were re-instrumented. If necessary, the patient was re-motivated and re-instructed in oral hygiene procedures. Fluoride was regularly applied in order to prevent the onset of dental caries.

Chapter 33

Treatment Planning for Implant Therapy in the Periodontally Compromised Patient

Jan L. Wennström[1] and Niklaus P. Lang[2,3]

[1] Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden
[2] Department of Periodontology, School of Dental Medicine, University of Berne, Berne, Switzerland
[3] Center of Dental Medicine, University of Zurich, Zurich, Switzerland

The use of dental implants for replacement of missing teeth is a viable option in the rehabilitation of the periodontally compromised patient, and certainly the availability of this treatment option may also influence decisions regarding the preservation of teeth with varying degrees of periodontal tissue destruction.

Prognosis of implant therapy in the periodontally compromised patient

Global data on survival rates of dental implants indicate a rather low incidence of implant loss. The question is, however, whether the long-term prognosis for implants is better than that for teeth. In a systematic review by Berglundh *et al.* (2002), including 16 studies reporting data on implant-supporting fixed partial dentures (FPDs), the overall 5-year failure rate was about 5%. In the few studies that included a follow-up of 10 years, the overall rate of implant loss was about 10%. It should be noted, however, that these studies did not specifically address the prognosis of implant therapy in periodontally compromised patients. Hardt *et al.* (2002) reported from a 5-year retrospective study that 8% of the implants were lost in patients who at the time of implant placement presented advanced loss of periodontal support at their natural teeth. The corresponding figure in patients without periodontal tissue destruction was only 3% (Table 33-1). In the periodontally compromised patients, most of the implants that were lost were so-called late failures. Furthermore, after 5 years 64% of the periodontally compromised patients showed a mean bone loss at the implants of >2 mm compared to only 24% of the non-compromised patients. Karoussis

et al. (2003) found a failure rate of 10% after 10 years in patients who had been treated for periodontitis before implant placement, compared to 4% in patients who had received implant therapy because of tooth loss for reasons other than periodontal disease. Roccuzzo *et al.* (2010) reported from a 10-year prospective longitudinal study an implant loss of 10% among periodontally compromised patients, compared to 3% among periodontally healthy patients. Moreover, periodontally compromised patients who did not completely adhere to the regular supportive care program presented an even higher implant failure rate. Taken together the data reported above indicate that there is an increased risk for implant failure in individuals susceptible to periodontitis.

A question of concern in relation to treatment decisions in a periodontally compromised patient is whether or not the failure rate of implants is different from that of teeth. In order to answer this question the incidence of tooth loss in periodontally treated patients needs to be known. Based on data from studies involving patients who have been treated for advanced periodontal disease and thereafter been provided with regular supportive periodontal therapy (SPT), the average incidence of tooth loss during a 10-year period can be estimated to be between 2% and 5% (Table 33-2). These percentages, in comparison with the data for implant loss presented above, indicate that the prognosis for long-term survival of implants is not better than that for properly treated periodontitis-affected teeth. Furthermore, evidence is accumulating that suggests that longitudinal bone loss at implants is positively correlated with periodontal disease susceptibility (Hardt *et al.* 2001; Matarasso *et al.* 2010; Roccuzzo *et al.* 2010) and that implant therapy in the periodontally compromised patient may not be as successful as the global data for implant therapy in general has indicated.

Strategies in treatment planning

A comprehensive clinical and radiographic examination forms the basis for the treatment planning of the periodontally compromised patient. In relation to implant therapy, careful risk assessments should also be made (see Chapter 31) and additional radiographic examinations may be required (see Chapter 30). The goal of treatment is to satisfy the patient's demands regarding chewing comfort and esthetics, with a favorable long-term prognosis of the restoration. The use of implants as a means to restore chewing function and esthetics in the periodontitis-susceptible patient has to be carefully evaluated in relation to the patient's standard of infection control. In partially dentate patients with remaining periodontal lesions, implants are rapidly colonized by periodontal pathogens, which indicates that periodontal pockets may act as reservoirs for microbial colonization of implants (see Chapter 10). Since there is no evidence that the host response to the microbial challenge is altered when a tooth is substituted with an implant, it should be anticipated that a periodontitis-susceptible individual with improper infection control will face similar risk for disease-induced bone loss at implants and teeth.

Elimination of periodontitis lesions before implant placement and the establishment of a high standard of infection control are consequently decisive factors for the success of implant therapy. Regular recalls for supportive care and monitoring with regard to the occurrence of clinical signs of periodontal/peri-implant infections should be scheduled after the completion of the therapy (see Chapter 60). Provided such a treatment program is firmly adhered to, the long-term success of implant therapy in the periodontally compromised patient is enhanced (Wennström *et al.* 2004; Roccuzzo *et al.* 2010).

Treatment decisions: Case reports

Posterior segments

In the periodontally compromised patient, the posterior segments of the dentition are usually those that are most severely affected by the disease and tooth loss. Figure 33-1 shows the clinical and radiographic status of a 53-year-old male following the completion of basic periodontal therapy for the establishment of infection control. Following periodontal treatment, the patient, originally diagnosed with severe chronic periodontitis, demonstrated a high standard of self-performed infection control and all lesions in the periodontal tissues had been resolved. Because of the severity of the periodontal destruction, remaining teeth posterior to the canines in the maxilla as well as one remaining mandibular molar had to be removed. Hence, the dentition was markedly reduced, not only with regard to the number of teeth but also in terms of the amount of remaining periodontal support. From a chewing comfort point of view, the patient was in

need of prosthetic rehabilitation, particularly in the posterior segments of the maxilla. The treatment options available included (1) a removable prosthesis or (2) implant-supported FPDs. Considering that the remaining teeth showed slightly increased mobility, implant-supported FPD seemed the more appropriate. In addition, the patient, if possible, preferred to have fixed prosthetic reconstructions.

Clinical and radiographic evaluation of the posterior jaw segments of the maxilla revealed that two implants might be placed in quadrant 1 between the canine and the anterior border of the maxillary sinus, while the dimension of the bone inferior to the sinus was judged inadequate for placement of implants (Fig. 33-1b, c). If the implant in position 15 was placed along the anterior wall of the sinus cavity and angulated slightly distally, space might be available to insert a pontic between the two implants and to provide the patient with a three-unit FPD. In quadrant 2, the bone dimensions were more favorable and it was judged feasible to install three implants. Hence, by providing the patient with two three-unit implant-supported FPDs in the posterior segments of the maxilla, a premolar occlusion could be established. The patient considered this treatment solution to be satisfactory with regard to his demands for improved chewing function. He had no requests for improved esthetics in the anterior segments, most likely because

of a low lip line and because he only exposed the incisial half of the crown when smiling.

Figure 33-1d–f shows the outcome of the restorative treatment. In order to further improve the patient's chewing comfort, a single implant was inserted in the left side of the mandible, after the second premolar had been tilted mesially. After completion of the restorative treatment, the patient was enrolled in a maintenance care program, including recalls once every 6 months to secure a high standard of infection control and to provide preventive means to reduce the risk for development of root caries. The 10-year follow-up status (Fig. 33-1g, h) revealed healthy marginal tissues and no loss of supporting structures at both the implants and the teeth. The standard of self-performed infection control was excellent throughout the follow-up period.

Conclusion

The treatment outcome in this case clearly illustrates that the periodontitis-susceptible patient can be successfully treated with the use of implants and without signs of peri-implant bone loss over time, provided proper infection control is established and maintained. The recall visits for supportive therapy must include careful evaluation of both the periodontal and the peri-implant tissues for detection of signs of pathology, and proper decisions regarding indicated treatment (see Chapter 60).

Tooth versus implant

Treatment decisions regarding implant therapy or advanced periodontal therapy often relate to a single tooth. Figure 33-2 shows such a case. A 67-year-old woman presented with a localized advanced periodontal lesion at an abutment tooth in a three-unit FPD. The FPD was about 15 years old and the patient had no esthetic or functional complaints with regard to the FPD. Tooth 15 had a 10-mm deep pocket at the mesial aspect. The pocket was associated with a wide angular bone defect, and the tooth was positioned with its root in close proximity to the anterior wall of the maxillary sinus. If the tooth was extracted, a marked remodeling of the ridge in the area could be anticipated, and the amount of bone available in the region might become insufficient for implant placement to support a new FPD, unless sinus elevation and bone grafting procedures were performed.

The question in the treatment planning with regard to tooth 15 was whether there was a reasonable chance of saving tooth 15 and maintaining the FPD with periodontal therapy, or whether the tooth should be extracted and implants placed to support a new FPD? Considering the great functional value of the tooth, it was decided to perform flap elevation and to evaluate the potential for tissue regeneration. Following debridement (Fig. 33-2c), it was observed that the defect was wide and had the morphology of a combined one-/two-/three-wall defect. A regenerative approach (application of enamel matrix proteins; see Chapter 45) was selected. The healing resulted in a 6 mm gain in clinical attachment level and radiographic bone fill. The amount of soft tissue recession was minimal, as can be seen in the 6-year follow-up documentation (Fig. 33-2d, e).

Conclusion

Considering that implant therapy in this case most likely would have required sinus elevation and bone grafting to satisfy the patient's demands for esthetics and chewing function, the maintenance of tooth 15 through proper periodontal therapy was of great benefit to the patient.

Aggressive periodontitis

Figure 33-3 shows a 22-year-old female patient diagnosed with aggressive periodontitis. The first molar in the maxillary right quadrant and in the mandibular left quadrant had already been lost due to advanced periodontal destruction. The patient asked for prosthetic replacement of the missing teeth. The clinical examination also disclosed the presence of deep angular defects at the first molar in the mandibular right quadrant and at the second premolar in the maxillary right quadrant. It seemed reasonable to plan for implant-supported restorations to replace the missing teeth 16 and 36. The more difficult question, however, related to the treatment of the periodontally compromised teeth 15 and 46 (Fig. 33-3c, d): Was it possible to successfully eliminate the periodontal lesions at teeth 15 and 46 with a good long-term prognosis for the teeth? Or should the teeth be removed and replaced with implant-supported restorations? Extraction of tooth 15 may be seen as a rational decision since implant therapy was planned in the region of tooth 16. However, from an esthetic perspective, it was preferable to maintain tooth 15 because the crown was intact and there was no loss of attachment or soft tissue height at the mesial aspect of the tooth (Fig. 33-3b).

Patients with aggressive periodontitis can be successfully treated, as is well documented in the literature. Further, by applying a regenerative method in the surgical treatment of deep angular defects like those at teeth 15 and 46, the chance of attachment gain of a magnitude of >4 mm is markedly increased (Giannobile *et al.* 2003; Murphy & Gunsolley 2003). Hence, the treatment decisions made in this case were to first establish proper infection control and then to apply a regenerative surgical approach (guided tissue regeneration) in the periodontal treatment of the lesions at teeth 15 and 46.

Evaluation of the periodontal healing revealed closure of the pockets and *de novo* bone tissue formation. Single implant-supported restorations were subsequently performed to address the loss of teeth

16 and 36 (Fig. 33-3e). After completion of the active treatment, the patient was assigned to a supportive care program with recall appointments once every 6 months. Figure 33-3f–i shows the outcome at 12 years post treatment. The regained height of the periodontal tissue support at teeth 15 and 46 following the active treatment was maintained over the years, and optimal bone height is seen around the single implants. The good long-term prognosis in this case is attributed to a high quality of infection control and careful monitoring during the maintenance period.

Furcation problems

Even if the goal of the treatment of patients with periodontitis is preservation of teeth, there may be situations when this goal seems less meaningful

in relation to the patient's need for prosthetic rehabilitation. Such a situation is illustrated in Fig. 33-4. The patient was missing the two premolars in the first quadrant and the molars present had advanced periodontal destruction and through-and-through furcation involvement (class III). The patient requested a fixed restoration to substitute for the missing premolars. A possible treatment solution following periodontal therapy could involve root separation of the molars, after proper endodontic therapy, and the maintenance of, for example, the palatal roots of the molars to be used as posterior abutments in a fixed tooth-supported prosthesis 17 … 13. However, advanced inter-radicular periodontal destruction was identified by furcation probing, indicating that the palatal roots might not have enough remaining periodontal support in order to provide functional stability of a straight FPD (17 … 13). The clinical and radiographic examination revealed that the alveolar process in the premolar–molar region had proper dimensions for implant placement. An alternative treatment solution to

satisfy the patient's demands for improved function and esthetics could therefore include implant placement to support an FPD.

The decision in this case was to extract the two molars and, following proper periodontal treatment of the remaining dentition and establishment of adequate infection control, to provide the patient with a three-unit implant-supported FPD and a single-crown restoration on tooth 13 (Fig. 33-4e, f). After completion of active treatment, this patient was enrolled in a maintenance care program including recall appointments once every 4 months.

Single-tooth problem in the esthetic zone

Figure 33-5 shows the maxillary front tooth region of a 45-year-old female patient diagnosed with generalized chronic periodontitis. The right central incisor has severe periodontal destruction with probing pocket depths (PPDs) of 10–11 mm and obvious signs of inflammation at its distal and palatal surfaces. The tooth responded positively to sensibility testing. Interdental black triangles can be seen in the entire anterior tooth region because of approximal loss of periodontal attachment and soft tissue recession. Based on the results of the comprehensive examination, tooth 11 was judged to have a questionable prognosis, whereas it would be possible to resolve the periodontal lesions at the other anterior teeth by non-surgical means and improved self-performed infection control. Since the patient had a high lip line, potential recession of the soft tissue margins as a consequence of the treatment was a factor that had to be considered, particularly in relation to the treatment decision for the severely affected right central incisor. Regenerative therapy may have allowed the tooth to be maintained, but would the treatment result in acceptable esthetics? The facts that the defect had a wide extension (buccolingually) and that the adjacent teeth presented with approximal attachment loss indicated that there was an obvious risk for loss of tissue height during healing following a surgical intervention. An alternative treatment approach could include the extraction of tooth 11 and installation of a single implant. This alternative solution would also offer the possibility of correcting the position of the crown of tooth 11. In discussing the different treatment alternatives and their consequences with the patient, it was apparent that she preferred to have the position of the tooth corrected as part of the treatment. Hence, based on the careful analysis of the esthetic problems associated with the treatment of the tooth, it was decided to extract the tooth and make an implant-supported restoration. By using the crown together with a portion of the root as a pontic, support to the surrounding soft tissues during initial healing of the extraction socket was provided (Fig. 33-5f).

Evaluation of the outcome of the cause-related phase of therapy, which included oral hygiene instructions, plaque control evaluations, and full-mouth pocket/root debridement, disclosed no remaining pathologically deepened pockets in the front tooth region (Fig. 33-5g). The radiographic evaluation of the extraction site 2 months after the removal of tooth 11 (Fig. 33-5h) showed a preserved bone height at the neighboring approximal tooth sites and gain of bone in the extraction socket. Clinically, only minor changes had taken place in the position of the soft tissue margin at the extraction site. A single implant was installed and after 3 months the prosthetic therapy was completed.

Following the completion of the active treatment, the patient was scheduled for supportive care every 6 months. Figure 33-5i–k shows the clinical and radiographic status at the 1-year follow-up examination. The position of the soft tissue margin was at a similar level at the implant-supported crown and the contralateral incisor. Compared to the pretreatment conditions (Fig. 33-5a), only minimal changes in the position of the soft tissue margins at the implant-borne restoration were evident. Overall some recession of the soft tissue margin had occurred as a consequence of the establishment of healthy marginal tissues.

Conclusion: Although it may be possible to maintain a tooth with severe local periodontal destruction by regenerative periodontal surgery, soft tissue recession as a consequence of the treatment may render the treatment outcome unsatisfactory from an esthetic perspective. Selection of a treatment approach involving tooth extraction and implant therapy instead of periodontal therapy should be based on a careful evaluation of the potential of the various treatment approaches to satisfy the patient's demands for esthetics.

Conclusion

The prognosis for the properly treated periodontitis-affected tooth is at least as good as that for the implant. An increased risk of failure of implant therapy has been reported for periodontitis-susceptible patients. Proper infection control is a critical factor for the long-term success of implant therapy in the periodontally compromised patient. Regular recalls for monitoring with regard to clinical signs of pathology and supportive care should be an integral part of the implant treatment protocol for the periodontally compromised patient.

Chapter 34

Systemic Phase of Therapy

Niklaus P. Lang,[1,2] Christoph A. Ramseier,[1] and Hans-Rudolf Baur[3]

[1] Department of Periodontology, School of Dental Medicine, University of Berne, Berne, Switzerland

Introduction

The systemic phase of periodontal therapy should be concerned with general health implications of periodontal diseases and periodontal treatment. While the former aspects are described in Chapters 14, 15, 18, and 23, the latter aspects are presented in this chapter.

The systemic phase of periodontal therapy is designed to protect the patient against unforeseen systemic reactions, to prevent complications affecting the general health of the patient, and to protect the healthcare providers from (predominantly infectious) hazards in conjunction with the treatment of patients at risk.

In order to adequately plan the systemic phase, results from a health questionnaire (see Chapter 26) filled in by the patient in the waiting area, the family and social history, the general medical, and, in particular, the tobacco use history have to be evaluated. Also, any extra- and intra-oral findings pertinent to the patient's systemic health have to be considered.

The systemic phase of periodontal therapy encompasses:

- Precautions for protecting the general health of the dental team and other patients against infectious and contagious diseases
- Protection against potentially harmful systemic effects of routine therapy
- Making allowances for systemic diseases or disorders that may influence the etiology of the patient's periodontal conditions, the healing potential, and the systemic response to therapy
- Controlling anxiety and low pain threshold
- Risk assessment and considerations of systemic supportive therapy
- Smoking counseling and instituting tobacco use cessation programs.

Protection of the dental team and other patients against infectious diseases

As a general principle, routine periodontal therapy should be postponed in a patient with an active contagious state of a disease until he/she has received adequate medical treatment. Given the fact that patients may not always be aware of such a state or that all manifestations of disease may have abated, but the patient may still be a carrier of infectious agents, routine dental treatment should be carried out under special precautions against transmission of the most serious diseases that can be transmitted orally. These include infectious hepatitis (Levin *et al*. 1974), human immunodeficiency virus (HIV) infection, and venereal diseases (Chue 1975). Hygiene in the dental office, therefore, has to address the most contagious level of infective agents, the hepatitis viruses, and cope with the prevention of the transmission of these infections.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

As a minimal precaution, the wearing of rubber gloves and a mouth mask is highly recommended for all dental therapy in all patients. Also, protective glasses for both the therapist and the patient should be worn during procedures generating aerosols.

Herpes simplex virus (Nahmias & Roizman 1973) and tuberculosis are further infectious diseases with a high transmission potential. Special precautions should be observed in patients with a recent history (2–3 years) of infectious hepatitis, although the dental team may be vaccinated against hepatitis. If the medical history and the oral examination reveal that the patient may have overt or hidden systemic disease, he/she should be referred for medical examination prior to being enrolled into comprehensive periodontal care.

Protection of the patient's health

A number of systemic conditions may affect treatment planning, although they may have no direct relevance to the pathogenesis and healing potential of periodontal lesions. Since over 50% of all patients over 40 years of age may have systemic conditions or take medications affecting periodontal therapy, these aspects have to be carefully appraised prior to instituting further therapeutic measures.

For patients with life-threatening systemic conditions, such as coronary insufficiency or hypertensive heart disease, their physicians should be consulted about appropriate management and whether treatment should be performed in a hospital or clinic rather than a private practice setting. If the dental office is considered to be an adequate environment for treating these patients, shorter appointments should be scheduled. The treatment should be performed with complete pain control using local anesthesia without any or with minimal vasoconstrictive substitutes.

Prevention of complications

The complications most commonly encountered in the dental office are:

- Infection
- Bleeding
- Cardiovascular incidents
- Allergic reactions
- Specific medications: bisphosphonates.

These may be prevented if appropriate precautions are taken. Hence, gaining awareness of possible complications from a medical history is an important step in treatment planning and comprehensive patient care.

Infection, specifically bacterial endocarditis

Patients with cardiac disease or disorders involving the endocardium are susceptible to endocarditis as a result of blood-borne infection. Such conditions include rheumatic heart disease, congenital valvular heart defects, aortic valvular diseases, and collagen diseases involving the endocardium. Patients wearing prosthetic valves belong to a special high-risk group. In addition, patients wearing prosthetic heart appliances belong to this risk group.

The major procedures thought to be the cause of bacterial endocarditis are extractions and scaling and/or root planing, possibly leading to significant bleeding and bacteremia (Durack 1995). Hence, it is not surprising that national societies have issued guidelines for antibiotic prophylaxis against bacterial endocarditis: USA (Dajani *et al*. 1997) and UK (Gould *et al*. 2006; Federation Dentaire Internationale 1987). The common belief is that bacteremia occurs only when dental procedures cause bleeding and not when there is no bleeding. Hence, procedures such as extractions, root instrumentation, and periodontal and implant surgical procedures would require antibiotic prophylaxis, while, for example, the placement of fillings does not. This hypothesis was addressed in a study in children for whom 14 various dentogingival manipulative procedures were evaluated (Roberts *et al*. 1997). It was clearly demonstrated that there was no relationship between the existence of bleeding and bacteremia. However, the number of oral organisms isolated from the blood was statistically significantly higher when bleeding was present. It was concluded that the cumulative exposure to bacteremia is significantly greater from "everyday" procedures, compared to dental procedures, and hence, the cause of bacterial endocarditis may be attributable to such cumulative everyday exposures that are often thousands to millions of times greater than that occurring following surgical procedures, such as extractions of teeth (Roberts 1999).

Antibiotic prophylaxis to prevent bacterial endocarditis is predominantly based on anecdotal and circumstantial evidence, and hence, the cause of bacterial endocarditis is much more likely to be due to such cumulative everyday exposures which occur much more often than dental procedures (Baltch *et al*. 1982). A case study, however, did not identify a link between endocarditis and dental treatment (Guntheroth 1984; Strom *et al*. 1998). Moreover, accumulating evidence suggests that bacteremia may easily be produced, for example by toothbrushing or chewing gum, rather than by single procedures causing bleeding. Hence, understanding of endocarditis causation has shifted from procedure-related bacteremia to cumulative or "everyday" bacteremia (Gould *et al*. 2006).

Indeed, a systematic review by the Cochrane Collaboration (Oliver *et al*. 2004) concluded that there was no conclusive evidence to support the use of prophylactic penicillin to prevent bacterial endocarditis in invasive dental procedures. This review did not identify any randomized controlled clinical trials, any controlled clinical trials or any cohort studies. From a total of three case–control studies (Imperiale & Horowitz 1990; Van der Meer *et al*. 1992; Lacassin

Table 34-1 Recommendations of the British Society for Antimicrobial Chemotherapy (BSAC) for the prophylaxis of high-risk bacterial endocarditis.

Population	Age			Timing of dose before procedure
	>10 years	≥5 to <10 years	>5 years	
General	Amoxicillin 2 g *per os*	Amoxicillin 1.5 g *per os*	Amoxicillin 750 mg *per os*	1 hour
Allergic to penicillin	Clindamycin 600 mg *per os*	Clindamycin 300 mg *per os*	Clindamycin 150 mg *per os*	1 hour
Allergic to penicillin and unable to swallow capsules	Azithromycin 500 mg *per os*	Azithromycin 300 mg *per os*	Azithromycin 200 mg *per os*	1 hour

Where a course of treatment involves several visits, the antibiotic regimen should alternate between amoxicillin and clindamycin.
Preoperative mouth rinse with chlorhexidine gluconate 0.2% (10 mL for 1 minute).

et al. 1995), only one study (Van der Meer *et al*. 1992) complied with the inclusion criteria. Details of 349 individuals who developed definite native-valve endocarditis in the Netherlands within a 2-year period were collected. Controls had not been diagnosed with endocarditis, but had one of the cardiac conditions and were outpatients of one of five hospitals. Controls were matched for age and had undergone a dental procedure within 180 days of their interview. No significant protective effect of antibiotic prophylaxis was seen against endocarditis.

It has to be acknowledged, however, that clinicians feel bound by guidelines and medicolegal considerations to provide antibiotic prophylaxis rather than by the best available evidence. Ethically, practitioners need to discuss the potential benefits and harms of antibiotic prophylaxis with patients and their cardiologists before the decision is made to administer antibiotics (Oliver *et al*. 2004). Considering the change in paradigms regarding bacterial endocarditis, a task force of the British Society for Antimicrobial Chemotherapy published new guidelines (Gould *et al*. 2006) (Table 34-1). According to these, the practice of giving antibiotics is reserved for those patients with a history of healed bacterial endocarditis, prosthetic heart valves, and surgically constructed conduits, while patients with other cardiac abnormalities should no longer receive antibiotic prophylaxis before dental procedures. The American Heart Association has recently issued similar guidelines (Lockhart *et al.* 2013; Costantinides *et al.* 2014). An information summary for the patient has been published by the British Society for Antimicrobial Chemotherapy (Table 34-2).

Table 34-2 British Society for Antimicrobial Chemotherapy (BSAC) Prevention of Infective Endocarditis Guidelines. Information for Patients and Parents (February 2006).

A BSAC group of experts has spent a lot of time carefully looking at whether dental treatment procedures are a possible cause of infective endocarditis (IE) [sometimes called bacterial endocarditis (BE)], which is infection of the heart valve.

After a very detailed analysis of all the available evidence they have concluded that there is no evidence that dental treatment procedures increase the risk of these infections.

Therefore, it is recommended that the current practice of giving patients antibiotics before dental treatment be stopped for all patients with cardiac abnormalities, except for those who have a history of healed IE, prosthetic heart valves and surgically constructed conduits.

The main reasons for this are the lack of any supporting evidence that dental treatment leads to IE and the increasing worry that administration of antibiotics may lead to other serious complications such as anaphylaxis (severe allergy) or antibiotic resistance.

The advice from the BSAC is that patients should concentrate on achieving and keeping a high standard of oral and dental health, as this does reduce the risk of endocarditis. Help for this will be provided by your Dental Professional.

Bleeding

Due consideration must be given to patients on anticoagulant medication or on preventive anticoagulant drugs such as salicylates. For the first group of patients, a consultation with their physician is indispensable. Especially prior to periodontal or implant surgical procedures, intake of anticoagulant medication should be temporarily adjusted in cooperation with the physician. Careful planning and timing of these procedures are mandatory.

Salicylate therapy does not generally create issues for routine dental therapy, including surgical procedures, although consultation with the patient's physician is still advisable.

Individuals with known cirrhosis of the liver, or even patients with high alcohol consumption over many years without diagnosed cirrhosis, are at a potential risk for bleeding complications during periodontal and/or implant surgery, as their clotting mechanisms may be affected (Nichols *et al*. 1974). Again, medical consultation is recommended prior to periodontal treatment of such patients.

Extra precautions against bleeding should be taken when treating patients with any kind of blood dyscrasia or hemophilia. Following mandatory consultation with the patient's physician, it is

recommended to render treatment in small segments (only a few teeth being instrumented at each visit) and to apply periodontal dressings over the treated area, even if the treatment only consisted of root instrumentation. With systematic periodontal treatment and institution of efficacious oral hygiene measures, the annoying symptom of oral bleeding can often be controlled irrespective of the patient's bleeding disorder.

Cardiovascular incidents

Cardiac patients are often treated with anticoagulants and, hence, may develop bleeding problems (as indicated above), especially if the given drugs (e.g. aspirin, indomethacin, sulfonamide, tetracycline) interact with coagulation. Other cardiovascular drugs (antihypertensives, antiarrhythmics, diuretics) are often given to these patients and may increase the danger of hypotensive episodes during dental treatment.

Stress associated with dental procedures may precipitate anginal pain or congestive heart failure in patients with cardiovascular disease. Therefore, every effort should be made in this patient population to keep dental appointments brief and to control anxiety and pain.

Allergic reactions and drug interactions

Full awareness of the patient's known allergies and the medications he/she is taking is essential before any drug is prescribed or administered during treatment. The most common allergic reactions encountered in the dental office are those to some local anesthetics (Novocain®), penicillins, sulfa derivatives, and disinfectants, such as iodine. In case of known allergies, such drugs must be avoided. A consultation with the patient's physician is advisable to discuss the possible administration of replacement drugs.

Many patients – over 90% over the age of 60 years – regularly take medications for various systemic conditions. Special attention has to be devoted to possible drug interactions, especially in the elderly. Drugs prescribed as part of periodontal therapy or used during treatment may interfere with the effectiveness of drugs the patient is already taking, possibly creating a hazardous interaction. Hence, no new drugs should be prescribed without fully understanding their possible interaction with drugs already in use. Dentists should never change an existing drug therapy without prior discussion with and preferably written consent from the physician.

Many patients regularly take tranquilizers and antidepressant drugs that have the potential for summation and synergistic effects with drugs that may be used during periodontal therapy. Moreover, the interaction and potentiation of these drugs with alcohol should be discussed with the patient.

Systemic diseases, disorders or conditions influencing pathogenesis and healing potential

All possible attempts should be made to alleviate the effects of systemic diseases, such as blood disorders and diabetes mellitus, before any periodontal treatment is initiated. However, cause-related therapy may easily be carried out and generally results in remarkable success even during active stages of these systemic conditions. How far the treatment plan should progress with respect to pocket reduction and/or regenerative procedures depends on the seriousness of the patient's systemic involvement and likewise, to a great extent, on the potential threat to the patient's health from incomplete periodontal therapy.

Diabetes control, as an example, may be facilitated by successful control of the periodontal infection (Grossi *et al*. 1997; Genco *et al*. 2005). Thus, periodontal treatment may have a beneficial effect on the systemic health of the patient (see Chapter 23). Palliative treatment of advanced periodontitis with furcation involvement and residual deep pockets that cannot be reduced should not be undertaken for such patients. Rather, the involved teeth with repeated abscesses and pus formation should be extracted if necessary to accomplish infection control.

Clinical experience indicates that the healing response of the periodontal tissues is as good in patients with diabetes as in healthy individuals provided that the diabetes is fairly well controlled. However, juveniles with diabetes may have angiopathic changes associated with a lowered resistance to infection that may require the use of antibiotics following periodontal or implant surgery. With controlled diabetes, premedication with antibiotics is not indicated. Hypoglycemia may be aggravated by the stress of periodontal surgery and, hence, precautions have to be taken to avoid hypoglycemic reactions in such patients.

Therapeutic doses of cortisone over a long period of time may cause considerable metabolic effects with systemic manifestations of a reduced rate of fibroblastic activity and hence, a lowered resistance to infection during wound healing. Nevertheless, such patients can be treated successfully by regular cause-related therapy with no significant delay in healing. The use of antibiotics is not recommended for these patients, unless there is a serious infectious condition in the mouth associated with the development of fever.

Specific medications: Bisphosphonates as a threat to implant therapy

More than 10 years ago it was discovered that nitrogen-containing bisphosphonates inhibit an enzyme that controls osteoclastic function. The inhibition of this enzyme also inhibits the migration of the cells

responsible for osseous healing. Hence, it is most likely that osteonecrosis may result from the inhibition of cell migration in case of surgically exposed bone such as in implant installation. Bisphosphonate-related osteonecrosis of the jaws (BRONJ), therefore, represents a risk that should not be underestimated even in patients who are taking *oral* bisphosphonates. It should be a warning to all dentists that BRONJ has been observed as early as 1 year after the *oral* administration of biphosphonates (Sedghizadeh *et al*. 2009). Following the reporting of these results, a new pharmacokinetic model was developed to assess drug accumulation at 1 year. In this model, the accumulated concentration of bisphosphonates in bone appeared to predict toxic levels that lead to poor healing following exposure of jaw bone as a result of surgical therapy (Landesberg *et al.* 2008). In this model, the relevant toxicity level does not necessarily affect osteoclasts as hitherto believed, but it affects keratinocytes, endothelial cells, fibroblasts, macrophages, osteoblasts, osteoclast precursor bone marrow cells, and T cells. All these cells are heavily involved in the healing of surgically denuded bone. Hence, it is most likely that nitrogen-containing bisphosphonates impair osseous wound healing and this leads to BRONJ. Non-nitrogen bisphosphonates do not cause BRONJ.

The *in vitro* threshold for inhibition of keratinocyte migration (0.1 µM) was used as the toxic bisphosphonate level for wound healing inhibition in cases of surgically denuded bone. By administering an equivalent of 70 mg of Fosamax® weekly, the number of doses resulting in toxic threshold levels could be calculated for various bone masses. The size of an individual's skeleton may therefore be the determining factor for the risk of BRONJ. Since the total quantity of bone mineral in which nitrogen-containing bisphosphonates are stored affects the toxic threshold of a patient, it is obvious that the skeleton of smaller patients will reach toxic levels sooner than that of larger patients. Once the toxic threshold for nitrogen-containing bisphosphonates in bone is surpassed, osteoclastic resorption will release enough drug to inhibit the ingrowth of the cells indispensable for healing of denuded bone.

In patients on bisphosphonate medication, it is of utmost importance to carefully evaluate the history of the medication and relate it to the habitus of the patient before making decisions on possible implant or other surgical therapy. Consulting with the patient's physician is highly recommended.

Control of anxiety and pain

Many patients interested in maintaining a healthy dentition do not regularly seek dental care because of anxiety and apprehension related to such treatment. A recent study conducted in Australia revealed a prevalence of dental fear in adults ranging from 7.8% to 18.8% and of dental phobia ranging from 0.9% to 5.4% (Armfield 2010). Modern dentistry now offers a variety of effective means for controlling pain and apprehension. This, in turn, means that dental treatment should no longer be as feared by these patients. During the history taking and oral examination, the patient's profile regarding anxiety and pain thresholds should be considered.

Prior to therapy, it may be indicated to premedicate an apprehensive patient using diazepams (benzodiazepine, Valium®, 2–5 mg) taken the night before, in the morning, and half an hour before an extensive and/or surgical procedure. Painless dental care can be achieved by carefully applying local anesthetics.

Postoperative analgesic medication, such as nonsteroidal anti-inflammatory drugs (NSAIDs) with analgesic and antipyretic properties, are recommended. Diclofenac potassium, the active ingredient of Voltaren® Rapide, inhibits prostaglandin synthesis by interfering with the action of prostaglandin synthetase. Following any kind of periodontal and implant surgery, 50 mg twice daily of Voltaren® Rapide is administered for 3 days. In addition, further adjunctive pain killers (mefenaminic acid, e.g. Ponstan® or Mephadolor® 500 mg not more frequently than every 6–8 hours) may be prescribed depending on the individual patient's need and pain threshold.

Favorable interactions between the patient, the therapist, and the entire office staff may contribute to the control of anxiety, but may require more time and consideration than that allocated to the routine patient.

Tobacco cessation counseling

Second to poor oral hygiene habits, cigarette smoking constitutes the most important modifiable risk factor in the etiology and pathogenesis of periodontal diseases (Ramseier 2005). A careful assessment of the patient's smoking history has therefore become indispensable for comprehensive periodontal care.

In order to support periodontal patients to quit tobacco use, it is helpful for the clinician to have a proper understanding of the genesis of tobacco dependence. The term *tobacco dependence* refers to the condition of tobacco users suffering from both psychological tobacco use dependence and physical addiction to nicotine. Therefore, in order to predictably help smokers to quit, all approaches supporting tobacco use cessation should include both behavioral support to address the psychological component of the dependence and pharmacotherapy to treat the physical symptoms of withdrawal.

Today, professional evidence-based methods for tobacco use cessation predominantly consist of professional behavioral change counseling applying the so-called "5A method" (Ask, Advise, Assess, Assist and Arrange) in combination with pharmacotherapy. It has been shown that the success rates for smoking cessation counseling are generally dependent on (1) the amount of time spent counseling the individual and (2) the prescribed drug. The success rates achieved by counseling lasting for 1–3 minutes, 4–30 minutes,

31–90 minutes, and >90 minutes are 14.0%, 18.8%, 26.5%, and 28.4 %, respectively (Fiore *et al*. 2008).

For practical reasons, periodontal care of smokers includes brief tobacco use interventions lasting 3–5 minutes at each appointment, while focusing on the following strategy (Ramseier *et al*. 2010):

1. *Ask*: It is well recognized that the general medical history form plays a critical role in asking all patients about their tobacco use history. Asking all patients on a regular basis allows a non-threatening introduction to the ensuing conversation between the oral healthcare professional and the patient.
2. *Assess*: When further asked about their readiness to quit smoking, tobacco users often reply that they want to quit smoking "sometime" but that the time is not yet right. There are certain things they need to do first, which are seen as more important than giving up smoking. Even if the patient feels that he/she is ready to quit smoking, there still may be some uncertainty about the next steps. He/she may experience a lack confidence to achieve this goal and feel under prepared to make a quit attempt. Behind this attitude is often the fear of failure, potential change to social habits, or worry about unwanted weight gain.
3. *Assist and refer*: As mentioned above, providing assistance to the patient who wants to quit tobacco requires a combination of behavioral modification techniques and pharmacologic support. Making the arrangements for ongoing support either via the dental office or other healthcare agencies may provide the patients with valuable resources as they undertake a quit attempt. When available, referral to professional tobacco cessation counseling services, whether in-house (including suitably trained dental personnel) or external (i.e. www.quitline.com) should be pursued.

Conclusion

The goals of the systemic phase of periodontal therapy are to appraise aspects that both the dental team and the systemic health of the patient may need to be protected against. Infection control in the dental office plays a central role. Protecting the patient against presumptive complications, such as infection, especially bacterial endocarditis, bleeding, cardiovascular incidences, and allergies, requires in-depth knowledge of the patient's medical history and oral examination.

Bacterial endocarditis prophylaxis is nowadays reserved for those patients with a history of a healed bacterial endocarditis, prosthetic heart valves or surgically constructed conduits, while the use of antibiotics before dental treatment is unnecessary for patients with other cardiac abnormalities. Patients with systemic diseases such as diabetes mellitus or cardiovascular diseases usually are treated with a number of medications that may interact with drugs prescribed during periodontal therapy. Precautions should be taken, and consultation with the patient's physician prior to systematic periodontal therapy is recommended.

It has to be realized that periodontal treatment may have a beneficial effect on the systemic health of the patient as well. Glycemic control may be facilitated in patients with diabetes if proper periodontal therapy is rendered.

Finally, smoking counseling is part of modern periodontal treatment owing to the fact that, after inadequate oral hygiene standards, cigarette smoking constitutes the second most important risk factor for periodontitis.

Health behavior change counseling in periodontal care

Periodontal health is supported by appropriate behaviors such as regularly self-performed plaque control, avoidance of tobacco, and glycemic control with diabetes mellitus type 2. Inadequate oral hygiene, tobacco use, and uncontrolled glucose levels, on the other hand, have a destructive impact on periodontal tissues. The prevention and control of periodontal disease needs to be addressed at both the population and the individual level. The dental community involved with oral health care should gain an understanding of the health effects of inappropriate behaviors in order to successfully target prevention and disease control. As a consequence, services for primary and secondary prevention at an individual level oriented towards the change of inappropriate behavior become a professional responsibility for all oral healthcare providers.

Data from epidemiologic studies consistently reveal the prevalence of periodontal disease to be >50% in the adult population (Albandar *et al*. 1999; Albandar 2002). In addition to the causal relationship with dental biofilms, a positive association between periodontal disease and tobacco use has been documented (Bergstrom 1989; Haber *et al*. 1993; Tomar & Asma 2000). Tobacco use contributes to the global burden of public health with almost one-third of the adult population using various forms of tobacco and an increasing number of annual deaths from tobacco-related diseases. Moreover, dietary factors have been shown to significantly impact chronic diseases, including obesity, cardiovascular diseases, diabetes type 2, cancer, osteoporosis, and oral diseases (Petersen 2003).

There is growing evidence that the patient's individual behavior is influential or even critical for the success of periodontal therapy since its results appear to be limited in patients lacking appropriate behavior. In a literature review by Ramseier (2005), it was shown that second to plaque control, smoking cessation was the most important measure for the management of chronic periodontitis. Therefore, it appears to be reasonable in clinical concepts for periodontal care to (1) include assessments of patient behavior, and, if necessary, (2) apply effective behavior change counseling methods.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

The challenge

Traditional periodontal care includes instruction on proper oral hygiene methods. In practice, as an example, a demonstration of a suitable toothbrushing method is given to the patient, followed by recommendations for both the frequency and the time spent per brushing. Past and recent studies on the effectiveness of oral hygiene instructions have consistently revealed that patient adherence to a proper daily oral hygiene regimen generally remains poor (Johansson *et al*. 1984; Schuz *et al*. 2006). The reinforcement of oral hygiene habits through additional appointments can, to some degree compensate for the ineffectiveness of one-off or repeated oral hygiene instructions. However, due to weak patient adherence, visits for supportive periodontal care are often cancelled, resulting in a lack of professional maintenance care and the further potential for recurrence of periodontal disease (Wilson *et al*. 1984; Demetriou *et al*. 1995; Schuz *et al*. 2006).

Unfortunately, many health education approaches seem to be inefficient in accomplishing long-term change, potentially leading to frustration for both the patient and the clinician. The following hypothetical dialog between a clinician (Dr) and a patient (P) illustrates how using a directive advice-oriented method for behavior change counseling may lead to an unproductive conversation and little likelihood of change by the patient:

Dr "Are you flossing regularly?"
P "Yes, but not as often as I should."
Dr "I strongly recommend that you floss every day. As you probably know, there are serious consequences if you don't floss frequently enough."
P "I know I should do it more often, but…"
Dr "It's not something that is optional. It is very important!"
P "I know … … but I don't have the time!"

Since the clinician does not offer the patient a chance to discuss the reasons to floss, as well as the patient's perceived barriers to flossing, the conversation reaches an impasse and behavior change will be unlikely. In certain cases, the patient may even be blamed for poor compliance and further oral health education may be seen to be pointless.

In order to achieve reliable, effective outcomes in periodontal care, hypothetically, it may be necessary to apply different behavior change counseling methods for each individual and behavior. According to the standard of care for oral hygiene instructions, for example the correct use of a cleaning device, may be repeatedly demonstrated, while for tobacco use cessation, in addition to pharmacotherapy, the 5As method (Ask, Advise, Assess, Assist, Arrange) may be used (Fiore 2000). From a practical point of view, however, it may be complicated and even discouraging to approach the periodontal patient with a variety of different methods targeting the same purpose, that is establishing appropriate behavior to improve the outcomes of both periodontal therapy and long-term supportive periodontal care.

Hence, aiming for simplicity, it may be preferable to apply approaches based upon *one single method* for behavior change counseling in periodontal care that is shown to be effective in both primary and secondary prevention of oral diseases. This method should be:

- Based on the best available evidence
- Applicable to oral hygiene behavior, tobacco use prevention and cessation, and dietary counseling
- Suitable for implementation by the dental practice team in a cost-effective way.

Communication with the periodontal patient

Different styles of communication are used – even sometimes unconsciously – when interacting with other people in everyday life. For communication with the periodontal patient, however, it seems appropriate that the dental clinician from time to time specifically adapts his/her manner to the individual behavioral needs of the patient and to the patient's own way of communicating his/her chief complaints. Rollnick *et al.* (2007) presented a three-styles (directing, guiding or following) model for healthcare clinicians to use in communicating with their patients in daily practice:

- *Directing* style: includes the delivery of expert advice and support. This has traditionally been a standard approach within dental care settings. Directing is appropriately used where there is a good rapport between the clinician and the patient. The advice should be well timed, personally relevant, and delivered in such a way as to engage the patient. A directing style can be used after the patient has said something like: "What can I do to stop the need to descale every time I come back here?"
- *Following* style: needs listening skills and is appropriately used when situations require sensitivity (such as when a patient is sad or upset). The goal of a clinician using a following style is not to solve the patient's problem immediately, but to provide support and encouragement. As an example, the following style can be used after the patient has said something like: "There's so much going on in my life. I am discouraged to worry about my teeth too?"
- *Guiding* style: the clinician collaborates with the patient to help him/her identify his/her own goals, and how he/she might best achieve them. This style is most appropriate when talking to patients about making health behavior changes – especially to patients who may be ambivalent about changing. The guiding style can be used after the patient has said something like: "I know that smoking isn't good for me, but it's the only pleasure I have in life."

When it comes to health behavior change issues, some patients may require "direction" – particularly those who have stated that they want further advice or support. Others may have more pressing concerns and therefore need to be "followed". Those patients who appear to know what they need to do, but have not managed to do it yet, will be most receptive to a "guiding" style (Rollnick *et al*. 2007).

During patient communication, in general, it is important to be sensitive to the patient's reaction to a particular style of communication. If the clinician feels that his/her rapport with the patient seems to be wavering, this should be an alert that a particular style does not appear to be working and another style should be tried to maintain the rapport.

In all communication with the patient it should be remembered that the patient should only be asked questions when it is comfortable for him/her to respond (i.e. without interference from instruments and/or the clinician). Without this consideration, communication success will be challenged as the patient may feel a loss of control.

OARS

There are four primary activities to be considered when communicating with the periodontal patient. These can be summarized with the acronym OARS: Open-ended questions, Affirm the patient, Reflect, and Summarize.

- *Ask open-ended questions*. Approaching the patient with multiple closed-ended questions (those that will be answered with a "yes" or "no") gives the patient a rather passive role. In contrast, open-ended questions invite thought, collaboration, and effort on the part of the patient. Example: "How do you feel about your smoking?"
- *Affirm the patient*. It is human nature to presume a negative attitude when one's own behavior is scrutinized. Acknowledging the patient's strengths and appreciation of his/her honesty will decrease defensiveness, increase openness, and the likelihood of change. Example: "You have been clear about why you're not very concerned about your toothbrushing and I appreciate that honesty."
- *Reflect what the patient is communicating*. Reflection is the primary way to demonstrate empathy (ability to understand another person's perspective). Appropriate reflection includes the genuine effort to understand the patient's perspective. It (1) captures the underlying meaning of the patient's words, (2) is concise, (3) is spoken as an observation or a comment, and (4) conveys understanding rather than judgment. Example: "You really seem to have lost hope that you ever really can quit smoking."
- *Summarize*. Summarizing demonstrates interest, organizes the interview, and gets things back on track if necessary. It involves the compilation of the thoughts on change that the patient has expressed during the counseling. Example: "So there's a big part of you that doesn't feel ready to change right now. You really enjoy smoking, but you have been a little worried by the way some people react when they find out that you smoke. Is that about right?"

Understanding motivational interviewing

As discussed, health *education* efforts provided by practitioners are frequently ineffective in changing patient behavior. Considerable behavioral research suggests that the root of this common problem can be traced back to a false assumption inherent in the health education approach. Specifically, it is assumed that behavior change is simply a function of a patient having the requisite knowledge or understanding, and all that is required is for the practitioner to provide the relevant information. Motivational interviewing (MI), in contrast, is based on a different assumption of human behavior change. It assumes that knowledge is insufficient to bring about behavior change and that, instead, sustained behavior change is much more likely when change is connected to something the individual values. In other words, motivation is elicited "from within the patient" rather than externally imposed upon the patient by a practitioner. In MI it is assumed that individuals have "within them" their own reasons for changing and that the role of the practitioner is to elicit and reinforce these reasons.

MI originated in the field of alcohol addictive behavior, but has increasingly been applied to a wide variety of other behavior change problems, including tobacco use, diet, and exercise (Burke *et al*. 2004; Hettema *et al*. 2005). The method was developed by William Richard Miller in response to his observations of the confrontational approach that was standard treatment for patients with alcohol problems in the 1970s. In contrast, he observed that the research literature suggested that positive outcomes were related to a strong bond or "therapeutic alliance" between counselor and patient. Miller developed an empathy-centered treatment which used the *therapeutic alliance* and *empathy* to engender the client's inherent motivation to change (Miller 1983). Subsequently, Miller met Stephen Rollnick, the co-founder of the MI method, who had been concentrating on ambivalence, or the extent to which the client envisioned the pros and cons of changing. Miller and Rollnick began to explore the use of language during MI, concentrating on the elicitation of client "change talk" to promote behavior change. In 1991, Miller and Rollnick published the first edition of *Motivational Interviewing: Preparing People to Change Addictive Behaviors* in which they provided a detailed description of the approach. Since then, there has been an explosion in the research and application of MI, with many researchers addressing the applicability

of the method to addressing health behavior change (Resnicow *et al*. 2002). Recently, various approaches to the implementation of MI in the dental setting have been published (Ramseier & Suvan 2010).

MI has been defined as "a client-centered, directive method for enhancing intrinsic motivation to change by exploring and resolving ambivalence" (Miller & Rollnick 2002). The client-centered element refers to the emphasis that is placed on understanding and working from the perspective of the patient and his/her view of what it means to make a behavior change. For example, rather than a clinician simply telling a patient about the benefits of quitting smoking (from the practitioner perspective), the practitioner invites the patient to describe *his/her own view* of the advantages of quitting and disadvantages of continuing to smoke. Although the patient's perspective is central, because MI is also directive, the practitioner takes deliberate steps to facilitate a particular behavioral outcome. For example, without ignoring patient concerns about changing, the practitioner selectively reinforces and encourages elaboration of any patient statements that are oriented toward the possibility or benefits of making a change. By eliciting and elaborating upon the patient's own reasons for change, the motivation to change that is fostered is intrinsic or internal, rather than externally imposed. This approach rests on the assumption that individuals are almost always ambivalent about changing their behavior (i.e. it is almost always the case that individuals can identify both pros and cons of changing). MI practitioners therefore attempt to enhance intrinsic reasons for change by facilitating an exploration and resolution of the patient's underlying ambivalence.

General principles

Although MI methods and techniques provide a wealth of guidance on what to do and what not to do when counseling patients, Miller and Rollnick have emphasized that to be an effective MI practitioner it is more important to embody the underlying philosophy than to be able to apply the collection of techniques. They have identified four general principles that capture the underlying philosophy of the method:

1. A practitioner should *express empathy* for the patient's behavior change dilemma. In other words, the practitioner should communicate acceptance of the patient's perspective, providing and *expressing* full acknowledgement of the patient's feelings and concerns.
2. *Discrepancy* should be developed between the patient's current behavior and how he/she would ideally like to behave to be consistent with his/her broader goals and values. For example, the goal of being strong or responsible, or a good spouse or parent, can often be linked to being healthy and suggests the need for improved health behaviors.
3. *Roll with resistance*. When patients argue against change there is a strong tendency to fall into the trap of providing counter arguments. As a result, the patient expends all of his/her energy arguing against change, which is precisely the opposite of what is desired and may make him/her more resistant to change. MI practitioners therefore avoid arguing and instead use MI methods to "roll with resistance".
4. *Support self-efficacy* or the patient's confidence in his/her ability to make a change. Patients are unlikely to succeed in making a change, even if they are motivated, when they do not know how to change or do not believe they can. MI practitioners therefore make efforts to enhance patient confidence through such means as expressing their belief in the patient's ability to change or pointing out past successes or steps in the right direction.

Giving advice

Although we have highlighted the distinction between advice-oriented health education and MI, it is important to recognize that at times it is appropriate to provide information to address a patient's questions, misapprehensions, or lack of knowledge. The MI skill code (Moyers *et al*. 2003), which is used to assess a practitioner's adherence to the principles of MI, distinguishes between giving advice *without* permission, which is proscribed, and giving advice *with* permission, which is consistent with MI principles. In essence, providing information when the patient is willing and interested in receiving it is consistent with MI. Practitioners commonly err by providing advice too early in an encounter with a patient, resulting in the patient perceiving the practitioner as having an agenda that he/she is trying to "push". In contrast, it is common in MI practice to find that the process of eliciting the patient's perspective reveals gaps in knowledge, questions, concerns, and misapprehensions that the patient would appreciate receiving more information about. The practitioner can then provide particularly relevant information that is much more likely to be well received. Rollnick *et al.* (1999) have outlined a three-step process that serves as a useful framework for providing advice in an MI consistent style:

- Step 1: *elicit* the patient's readiness and interest in hearing the information. For example, a practitioner might say to a patient "I have some information related to that [topic] that you may be interested in. Would you be interested in hearing more about that?"
- Step 2: *provide* the information in as neutral a fashion as possible. For example, a practitioner might say "Research indicates that…" or "Many of my

patients tell me that…" This allows factual information to be presented in a manner that supports the patient's autonomy.

- Step 3: *elicit* the patient's reaction to the information presented. Follow-up will often help the patient integrate the new information in a way that brings about a new perspective and increases motivation to change. Alternatively, follow-up may reveal further gaps in knowledge or misunderstandings that can be addressed. If a patient "rejects" the information, it is important not to enter into a debate about this. It is generally better to simply acknowledge the patient's perspective with statements such as "This information doesn't fit with your experience" or "This information doesn't seem relevant to your situation" and then move on to a more productive area of conversation.

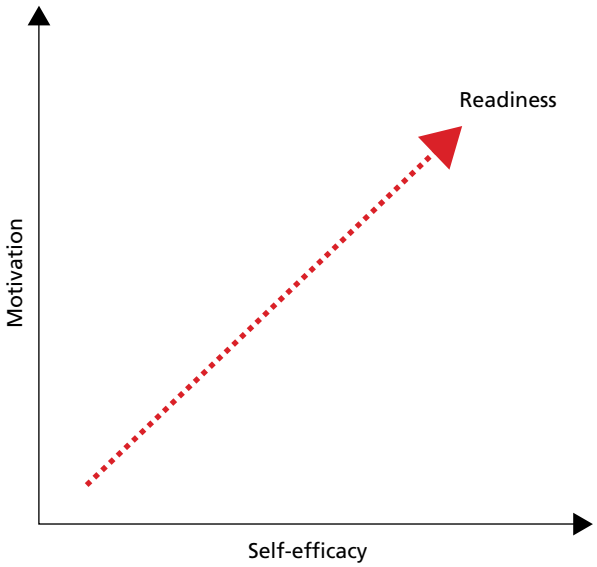

Fig. 35-1 Readiness to change. (Source: Rollnick *et al*. 1999. Adapted with permission from Elsevier.)

Agenda setting

It is often the case that there is more than one health behavior affecting the patient's oral health. Achieving small changes can make a patient feel more able and confident to make other changes (Bandura 1995). In these situations, it is important to start where the patient feels most comfortable, and to encourage him/her to suggest what area he/she would like to talk about, rather than simply selecting what the dental clinician feels is the most pressing issue. One clinical tool that can help with this task is an "agenda setting chart" (Rollnick *et al*. 1999).

The agenda setting chart contains a number of circled picture representations of different issues in oral health, and some blank circles for other factors to be inserted by the patient. The patient then selects the issue that he/she would like to talk about first.

Readiness scale

It may take a number of dental appointments before patients make significant health behavior change. Only relatively small steps towards change are likely to be accomplished following one brief encounter. Dental clinicians who understand how to limit their expectations following each appointment may ultimately feel less inclined to push the patient. By taking a long-term perspective, they may be more aware of what they can accomplish in a relatively short amount of time, and therefore feel less frustration with highly ambivalent patients.

Clinicians usually cannot expect their periodontal patients to be ready to change their oral hygiene habits or tobacco use simply because they would like to have good oral health (Miller & Rollnick 2002). Assessing the patient's readiness to change involves learning about both the patient's motivation and self-efficacy to change (Rollnick *et al*. 1999). Using two questions on motivation and self-efficacy (see below), the clinician can form a rather complete picture of a patient's position regarding readiness to change within a short amount of time.

When assessing both motivation and self-efficacy, the clinician seeks to discover the patient's specific motivators and values, in order to link these to the desired behavior change (Fig. 35-1). As described by Koerber (2010), the readiness scale can be used, particularly in brief interventions in dental settings. It consists of the motivation scale and the self-efficacy scale, as described by Rollnick *et al*. (1999):

- Motivation (importance) scale (Fig. 35-2): consists of three questions. For example:
  - "On a scale from 1 to 10, where 10 is absolutely important and 1 is not at all important, how would you rate the importance of brushing your teeth regularly?"
  - "Why did you rate it as (X) instead of 1?"
  - "Why did you rate it as (X) instead of a 10?"

  Note that the second question reveals the patient's motives, and the third question reveals the patient's ambivalence.
- Self-efficacy (confidence) scale (Fig. 35-2): consists of the following questions:
  - "If you were convinced that brushing your teeth regularly was very important, on a scale from 1 to 10, how confident are you that you could do it? 1 means not at all confident and 10 means completely confident."
  - "Why did you rate it as (X) instead of 1?"
  - "Why did you rate it as (X) instead of 10?"

  Note that the second question reveals a patient's strengths to make the change, and the third question reveals the barriers.

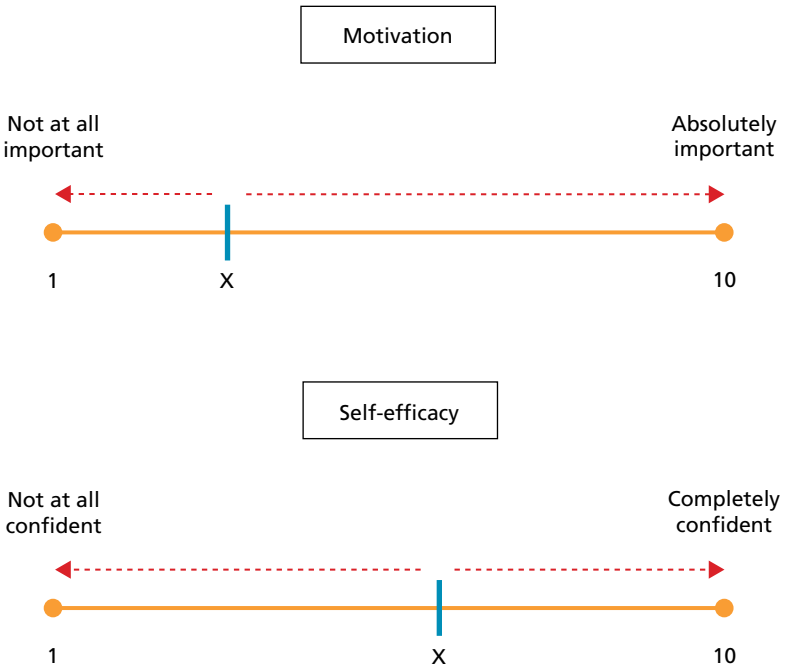

Fig. 35-2 Motivation (importance) and self-efficacy (readiness) scale.

Evidence for motivational interviewing

Evidence in general health care

Because MI was initially developed for the treatment of addictive behavior, particularly alcohol addiction, the bulk of empirical studies has been conducted in this area. Nevertheless, the explosion in the application of MI to other areas of behavior change has generated numerous published meta-analyses (Burke *et al*. 2003, 2004; Hettema *et al*. 2005; Rubak *et al*. 2005; Lundahl *et al*. 2010), the most recent of which include nearly 120 clinical trials. Generally, the meta-analyses indicate that MI-based interventions are at least equivalent to other active treatments and superior to no treatment or placebo controls for problems involving addictive behavior (drugs, alcohol, smoking, and gambling), health behaviors such as diet and exercise, risk behaviors, and treatment engagement, retention, and adherence. Effect sizes are on average in the small-to-medium range (Hettema *et al*. 2005; Lundahl *et al*. 2010). Of particular relevance to dental settings where only brief counseling is feasible is the finding that MI-based interventions are just as efficacious as alternative active interventions despite involving significantly less contact time, suggesting that MI may be a particularly efficient method of counseling in dental settings (Burke *et al*. 2004; Lundahl *et al*. 2010). Rubak *et al*. (2005) reported that of studies evaluating the effectiveness of brief encounters of 15 minutes, 64% showed an effect. In addition, when the intervention was delivered by physicians, an effect was observed in approximately 80% of studies, suggesting that it is feasible for professionals who are not counseling experts to effectively deliver MI in brief encounters.

Studies of MI for tobacco use cessation are also of particular relevance. Recent meta-analyses indicate modest positive effects of MI for smoking cessation (Lai *et al*. 2010; Lundahl *et al*. 2010) and there is evidence that MI leads to significantly more quit attempts (Wakefield *et al*. 2004; Borrelli *et al*. 2005), greater reductions in smoking level, and greater advances in readiness to quit (Butler *et al*. 1999).

Another particularly relevant target behavior for oral health is dietary habits. As already indicated, meta-analyses indicate that MI has significant effects on changing diet: overall dietary intake (Mhurchu *et al*. 1998), fat intake (Mhurchu *et al*. 1998; Bowen *et al*. 2002), carbohydrate consumption (Mhurchu *et al*. 1998), cholesterol intake (Mhurchu *et al*. 1998), body mass index (BMI) (Mhurchu *et al*. 1998), weight (Woollard *et al*. 1995), salt intake (Woollard *et al*. 1995), alcohol consumption (Woollard *et al*. 1995), and consumption of fruit and vegetables (Resnicow *et al*. 2001; Richards *et al*. 2006).

Evidence in dental care

One early study investigating the impact of MI in oral care examined the effect of its use compared to traditional health education on motivating 240 mothers of young children with high risk for developing dental caries to use dietary and non-dietary behaviors for caries prevention (Weinstein *et al*. 2004, 2006). An MI session and six follow-up phone calls over a year in addition to an educational pamphlet and video was more effective than the pamphlet and video alone in preventing new dental caries among the children after 2 years. This result is consistent with the results of meta-analyses that have found MI to be efficacious for dietary change (Burke *et al*. 2003; Hettema *et al*. 2005; Lundahl *et al*. 2010).

Related to clinical periodontology, both short- and long-term studies have demonstrated a positive impact on oral hygiene, as measured by plaque indices, and gingival inflammation, as assessed by gingival indices. Almomani *et al.* (2009) were able to demonstrate a significant positive impact on oral hygiene in a 2-month trial. Jönsson *et al.* (2009b) followed two patients over 2 years to assess the impact of an individually tailored oral hygiene program on periodontal indices (Fig. 35-3). Following MI sessions using

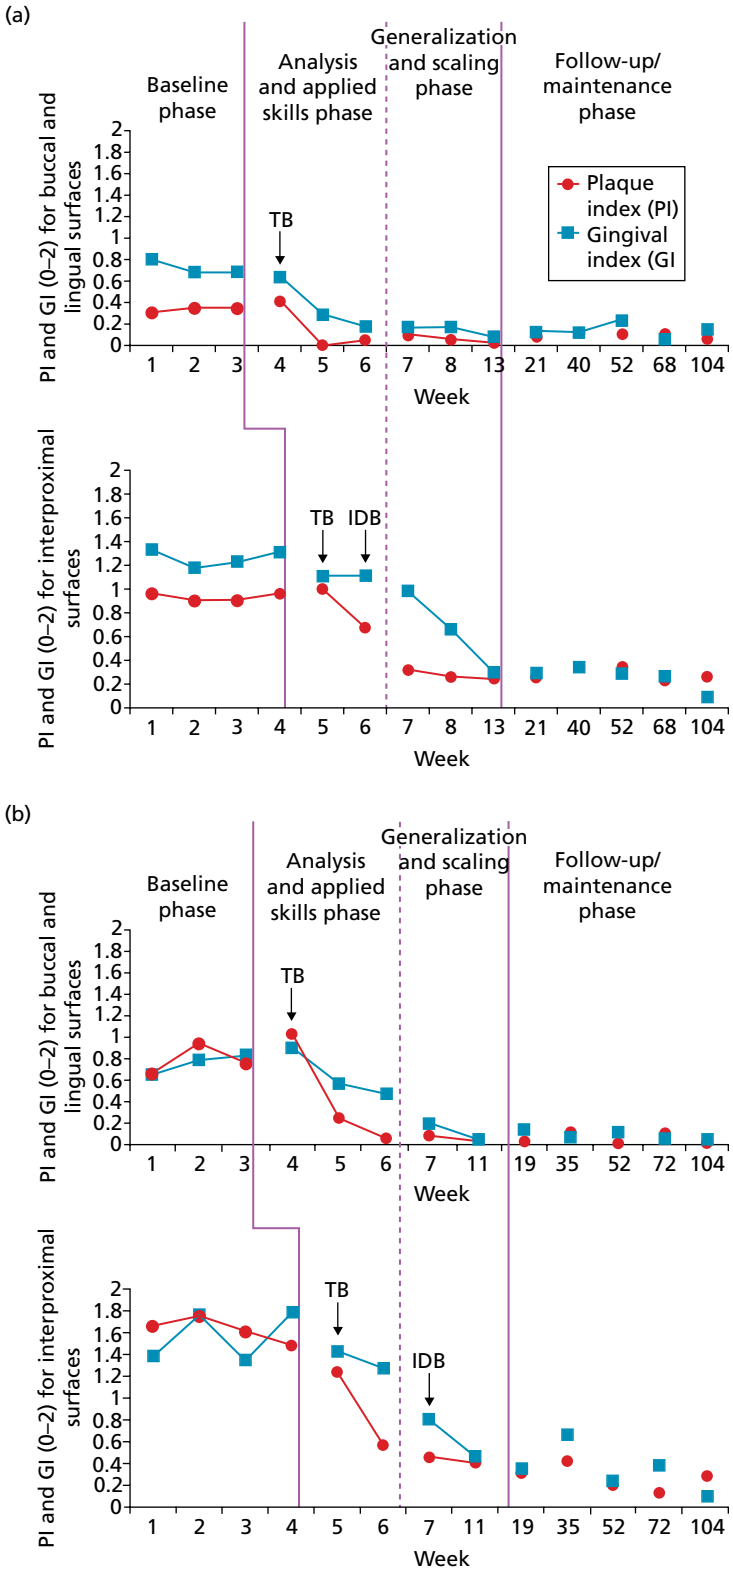

Fig. 35-3 (a) Female patient and (b) male patient. Following an individually tailored treatment program for improved oral hygiene, both full mouth and interproximal Plaque Index and Bleeding Index for both patients dropped significantly over an observation period of 104 weeks. (TB, Toothbrush; TP, toothpick; IDB, interdental brush.) (Source: Jönsson *et al.* 2009b. Reproduced with permission from John Wiley & Sons.)

Table 35-1 Clinical trials evaluating the impact of motivational interviewing (MI) on oral hygiene (as measured by plaque indices specified).

Study	Design	n	Duration (months)	Test method	Primary outcome variables	Plaque scores
Almomani *et al.* (2009)	RCT	27 test, 29 control	2	MI + education	Full-mouth modified Quigley–Hein plaque index	*Test* Baseline 3.6, 8 weeks 1.9 *Control* Baseline 3.3, 8 weeks 2.5
Jönsson *et al.* (2009b)	Case	2	24	MI + education	Interproximal plaque index (Silness and Löe), bleeding index (Löe and Silness)	*Patient A* Baseline 1, 24 months 0.2 *Patient B* Baseline 1.6, 24 months 0.1

Godard *et al.* (2011)	RCT	27 test, 24 control	1	MI only	Plaque index (O'Leary)	*Test* Baseline 35%, 1 month 18% *Control* Baseline 37%, 1 month 27%

RCT, randomized controlled trial.

the techniques described in this chapter, as well as oral hygiene instructions on an individual basis as described in Chapter 36, both patients succeeded in improving their oral hygiene and gingival health over 2 years.

The same authors subsequently demonstrated the positive impact of MI in a lager study of 113 patients over a period of 12 months (Jönsson *et al.* 2009a, 2010). In a recent study by Godard *et al.* (2011), the improvement of oral hygiene was accompanied by greater patient satisfaction in the group of patients receiving MI.

Conclusion: There is a wealth of support for MI as an effective method of counseling for behavior change (Table 35-1). MI has also been shown to be successfully delivered by medical practitioners. In areas of specific relevance to oral health practitioners, MI has either already been shown to be efficacious or offers significant promise.

Patient activation fabric

Implementing MI in a dental setting requires consideration of how to ensure the collaborative and empathetic spirit of the method (Ramseier & Suvan 2010). A specific patient activation fabric was presented by Suvan *et al.* (2010). This model attempts to capture the interdependent elements of the dental visit using the concept of interwoven threads (Suvan *et al.* 2010). Communication and information exchange blend with clinical assessment and treatment (Fig. 35-4).

Band I: Establish rapport

The goal of establishing rapport is to quickly engage the patient and create an environment where both conventional dental treatment and health behavior change counseling can occur. Accomplishing this depends on much more than the amount of time taken. A warm, courteous greeting is a critical start in creating an environment of mutual trust and respect. Furthermore, such basic matters as how the patient and practitioner are seated can contribute to the patient feeling like he/she is truly being invited to engage in a dialog as a partner (Fig. 35-5), rather than feeling he/she is the recipient of expert advice (Fig. 35-6). These simple actions give the perception that the patient and clinician have equal control of the situation, rather than one being dominant. Beginning with an open question that elicits the patient's chief complaint or reason for attending the visit is another simple and valuable step. These opening moments set the scene for the remainder of the

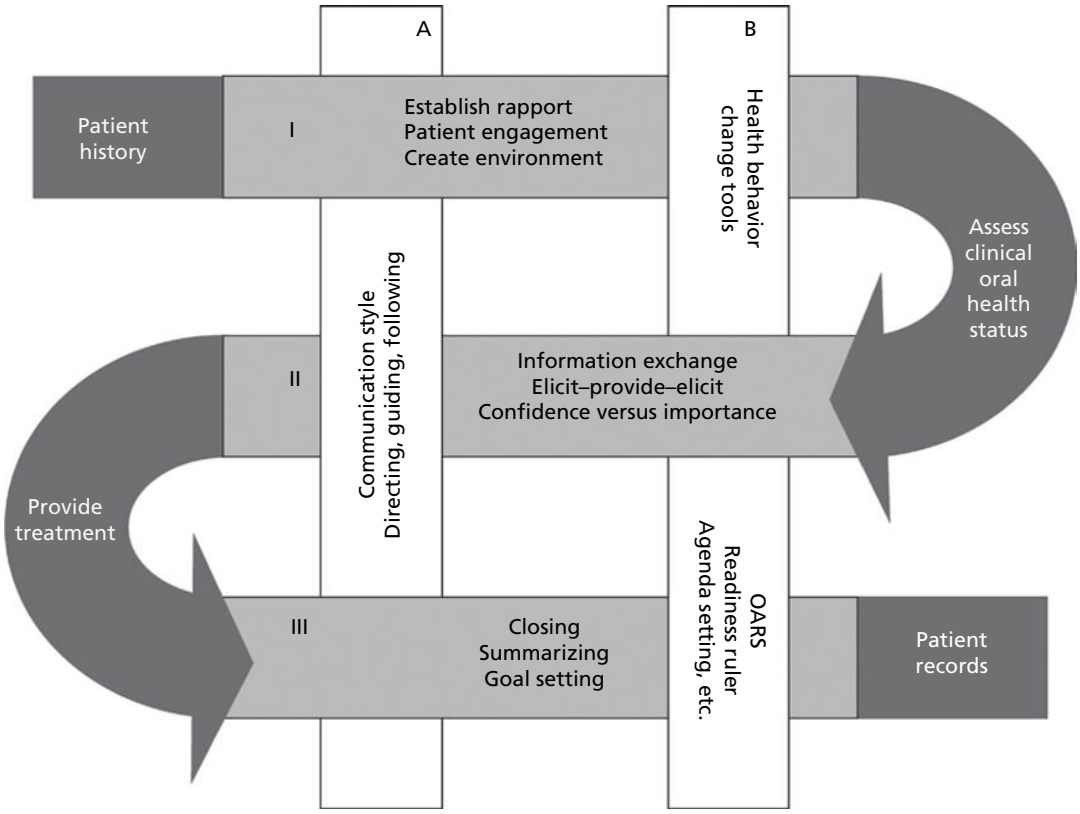

Fig. 35-4 Patient activation fabric for the dental visit (implementation model). The patient history and patient records at the start and the end of a dental visit depict the critical elements of documentation that serve to weave one dental visit into the next. The horizontal bands depict the three core strands of conversations constituting the visit. These bands (I–III) transition directly into the ribbons (A and B) that represent the clinical assessment or treatment that takes place between the conversations as part of the flow of the appointment. The bands are woven together through the vertical ribbons that signify the specific elements of the communication and interaction characterizing the approach. These vertical ribbons represent communication style and health behavior change tools and are consistent, yet flexible, recurring throughout the appointment to provide stability. (OARS, Open-ended questions, Affirm the patient, Reflect, and Summarize.) (Source: Suvan *et al*. 2010. Reproduced with permission from John Wiley & Sons.)

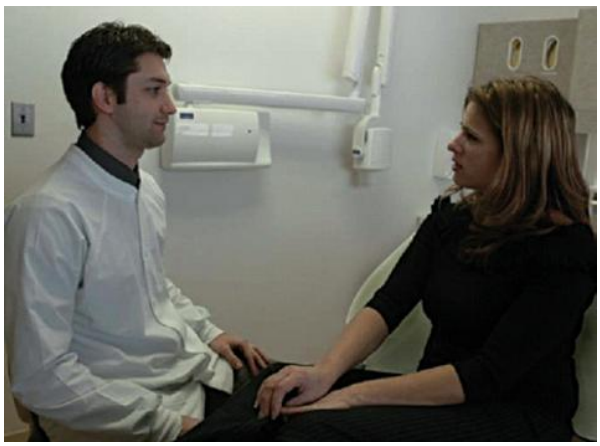

Fig. 35-5 Appropriate position for a conversation: the clinician is facing the patient at the same seating level.

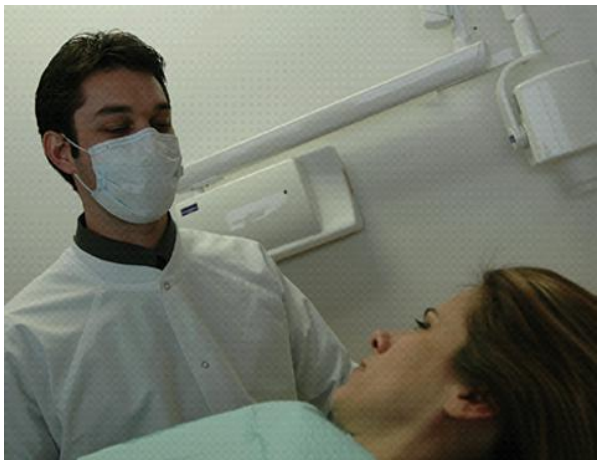

Fig. 35-6 Inappropriate position for a conversation: the clinician is wearing a face mask and is at a level higher than the supine patient.

visit and can save the clinician valuable time later in the session.

Before proceeding with the clinical assessment, it is important to briefly list the elements of the procedure for the patient, and then to ask the patient if he/she is happy for this to be conducted at that time. Asking permission is a simple way to engage the patient while simultaneously encouraging a sense of autonomy. It may be helpful to explain to the patient the relevance of the information that he/she may hear being given to the assistant. These small actions help to keep the patient engaged in the consultation, rather than allowing him/her to shift to a passive role of simply lying on the dental chair throughout the assessment procedure.

Band II: Information exchange

This second part of the interaction most often takes place following initial clinical assessment of the patient's oral health status. This exchange of information allows both clinician and patient to understand the other's perspective and creates a more accurate picture of the clinical problem and approaches to effective management. This discussion can take many different forms.

One approach to providing information is for the practitioner to maintain the focus on patient engagement using the elicit–provide–elicit method. Starting with what the patient already knows (elicit) immediately encourages patients to think, reflect, and acknowledge their own expertise. From that starting point and with permission, the information offered to patients can be tailored (provide). Perhaps the most important step is the question that follows to explore the sense the patient makes of the information provided (elicit). This question can open the door to dialog rich with opportunity for discussions about change.

Leading into and moving on from this middle phase of the visit, a number of clinical tasks can be performed, including assessment and treatment. Conversations about behavior change are most valuable when the clinician and the patient are able to speak freely. These conversations should not be conducted when the patient is unable to be an equal participant, such as when he/she is physically incapable of speaking, or may be feeling pain or discomfort during or after clinical procedures.

Band III: Closing

The third band takes place and functions as a closure to the visit. It may involve a brief summary of the clinical treatment that has been provided and any expected side effects or post-treatment discomfort. An equally important function is to briefly summarize behavior change discussions. This provides the clinician with the opportunity to review the agreed goals or plan of action suggested by the patient in Band II. To ensure this discussion is collaborative, the clinician should ask the patient if there is anything he/she would like to add to the plan and check with the patient that the most important points have been covered. Further treatment options may also be discussed if the patient is not too tired. However, this is not typically the best time for most patients to discuss important facts as they are usually focused on leaving the dental chair as soon as the appointment has concluded.

Ribbon A: Communication style

Earlier in this chapter, styles of communication were presented, highlighting that a spectrum exists with directing and following at its extremes and guiding in the middle as an intermediary style engaging both parties equally. A skillful movement between the three styles constitutes the well-managed interaction with the patient. In the model, communication style is labeled as a vertical ribbon interwoven through the entire visit. This portrays that at certain times during the visit, a particular style will tend to be more advantageous than the others. Maximum patient engagement without compromising the clinician's responsibility and ability to provide important information will be facilitated through use of a guiding style. Fundamental communication techniques such as asking open questions can encourage the two-way communication that characterizes a guiding style. However, this does not infer that it is the only style of communication used during the visit.

Ribbon B: Health behavior change tools

The second vertical ribbon represents the many behavior change tools that can facilitate patient activation or interaction throughout the visit. Like Ribbon A, clinicians may choose the tool they feel will be most beneficial at certain points in the visit or conversation. The choice is driven by the goal to provide a relaxed atmosphere where conversations can be spontaneous and individualized to each patient.

Case examples

Oral hygiene motivation I

Using the following case example, MI for oral hygiene motivation is demonstrated in a dialog between a periodontist (Dr) and a patient (P) diagnosed with chronic periodontitis, at the beginning of periodontal therapy.

Dr "Would you mind if we talk about methods to improve your oral hygiene during and after your gum treatment?" (*raising the topic/asking permission*)
P "No, I don't mind."
Dr "Good. Could you let me know a little bit about how you usually clean your teeth?" (*asking open questions to elicit what the patient already does*)
P "I usually brush once or twice a day."
Dr "So you brush your teeth regularly? What are you using when you clean your teeth?"
P "I use a toothbrush and toothpaste."
Dr "Very good. Could you let me know how you use your toothbrush?"
P "I brush all upper and lower teeth on the outside and the inside as I was shown a long time ago."
Dr "And how do you feel about brushing your teeth that way?"
P "I generally feel quite good about it. But since I have been told I have gum disease, I'm wondering if I haven't been brushing enough?"

Dr "So you have been making efforts to keep your teeth clean but you're worried that maybe you haven't been brushing enough. (*reflective listening*)

It can be difficult to get to all the areas of your teeth and gums to remove the plaque that causes gum disease. (*showing empathy*)

I have some information related to prevention of gum disease that you might be interested in. Would you like to hear about it?" (*asking permission*)

P "Yes."

Dr "The chronic gum or periodontal disease you are diagnosed with was caused by bacterial plaque that has attached to your teeth over time. Plaque has to be entirely removed from all the tooth surfaces on a daily basis in order to prevent and control this disease. (*providing information*)

How confident are you that you were cleaning all the surfaces on a regular basis?" (*assessing confidence*)

P "Not so much, although I thought that I was doing enough."

Dr "Well actually, research indicates that using a toothbrush alone is not sufficient to clean between the teeth. In order to clean these areas, an interdental device is needed such as a dental floss, a toothpick, or an interdental brush. (*providing information*)

Are you using any one of these devices?"

P "Yes, I've tried using dental floss."

Dr "How did you find the use of dental floss?" (*asking open questions*)

P "I had some trouble getting to some of the spaces between my teeth. In other areas, the floss used to rip up too, so I quit using it."

Dr "I am sorry to hear that you had trouble using the dental floss. (*showing empathy*)

The floss can rip up at the edges of dental fillings or crowns. In spaces with extensive tartar build-up, the gap between your teeth may even be blocked with tartar.

Are you using anything else for cleaning?" (*asking open questions*)

P "Yes, I use a toothpick whenever I have something stuck between my teeth."

Dr "So in addition to your regular brushing with toothpaste you are also using a toothpick from time to time to clean your teeth?" (*reflective listening*)

P "That's right."

Dr "Good. During gum treatment, fillings and crowns with rough edges will be smoothed over and tartar can be removed which should make it easier to use things like dental floss or a toothpick between your teeth. (*providing information*)

Thinking of a 10-point scale where 0 is not at all important and 10 is extremely important, how important is it to you to floss or use a toothpick every day to clean the gaps between your teeth? (*using readiness ruler on importance*)

P "Probably a 7."

Dr "That sounds quite important. What makes this so important to you?"

P "I want to do everything necessary to keep my teeth. However, I am not quite sure if I will be able to keep doing it over time."

Dr "So you are quite motivated now because you want to look after your teeth, but you are worried about the long term.

If you were to use the same 10-point scale to rate how confident you are that you can do it over the long term, where would rate yourself?" (*using readiness ruler on importance*)

P "I would be at a 6."

Dr "That sounds fairly confident. What gives you that level of confidence?"

P "Well, taking care of my teeth and gums is part of my routine already so this would just need to be added to it. But it does take extra effort, so it's a matter of realizing that it's really important for my gums."

Dr "So, the fact that it can be part of your existing routine will help. But perhaps I can help you remain motivated in the long run by showing you at your follow-up visits the benefits you are achieving by doing the treatment regularly. How do you think that might help you to stick with it over time?" (*supporting self-efficacy*)

P "Well, yes I think that would probably help a lot to see or learn from you that it really is making a difference to the success of my treatment."

Dr "Great! So let me summarize what we have discussed. You plan to keep brushing on a regular basis with a toothbrush and toothpaste and you will start to use a device for cleaning the gaps between your teeth after the issues with the rough filling and crown margins have been resolved. Then, each time you visit we'll see how you are progressing with your cleaning at home and see if we need to find any other ways to help. Does that sound like it would work for you?" (*summarizing*)

P "Yes, that sounds like it would work."

Oral hygiene motivation II

In this second example dialog, MI is used in a conversation about oral hygiene at a visit for supportive periodontal therapy (SPT).

Dr "From looking at your plaque index, I noticed today that compared to your last visit 3 months ago that there is more plaque around the areas between your teeth. I was wondering if you could tell me a little bit about how you find the cleaning between your teeth." (*raising the topic/asking permission*)

P "Oh… I guess that I don't do it as often as I should. I barely have time now to do it every day, you know."

Dr "I understand. It takes time to clean all the areas between your teeth, you are right. (*showing empathy*)

May I ask you a few questions about your current oral hygiene habits so I can understand your situation better?" (*asking permission*)

P "Sure you can."

Dr "Good. So what do you use to clean your teeth currently?" (*asking open questions to elicit what the patient already does*)

P "I am using an electric toothbrush and the interdental brushes you showed me."

Dr "OK. How often do you use these?"

P "I use the electric toothbrush every day and I use the interdental brushes from time to time."

Dr "So you are using the toothbrush on a regular basis, but only occasionally using the interdental brushes. What is prompting you when you do decide to use the interdental brushes?"

P "Well, sometimes I just feel guilty that I haven't been using them and sometimes I can see the tartar on my teeth and am reminded to use them again."

Dr "So you sometimes worry that you are not using them enough and sometimes you can see from your teeth that you are not using them enough." (*reflecting on ambivalence*)

P "Right, I suppose I should be doing better."

Dr. "Well, let me ask you this. If you had to rate how important it is for you to use the interdental brushes every day on a scale from 0 to 10, 0 being not important at all and 10 being very important, where would you place yourself?" (*using readiness ruler on importance*)

P "I guess the use of these brushes is pretty important. I'd say an 8."

Dr "Well that sounds very motivated. What makes it that important for you?"

P "Well, I don't want to have a lot of problems with my teeth – I hate having fillings and of course I don't want to lose any teeth in the long run."

Dr "So, avoiding pain and discomfort and keeping your teeth is important to you. So how confident are you that you can use the brushes on a daily basis? Where would you rate yourself on that 0–10 scale?" (*using readiness ruler on importance*)

P "As I said, I know that I should use them more often, but finding the time is hard and I even just forget sometimes. I'd give it a 3."

Dr "Using them daily seems quite hard for you. Out of curiosity, though, it seems you do have a little bit of confidence in doing this. May I ask you why gave a score of 3 instead of 0 or 1?"

P "Well, I just think that I would use them more often if they became a part of my routine tooth cleaning, you know? I used to have toothpicks on my dinner table too and so I used them whenever I saw them sitting there. I could think about putting my interdental brushes on my sink next to my toothbrush to remind myself to use them after brushing my teeth with the electric toothbrush."

Dr "That sounds like a really good plan. Can you see any problems with doing that?" (*supporting self-efficacy*)

P "No, not really. Once I have that reminder in place it's just a matter of staying committed to doing it."

Dr "Very good. So if I can summarize, it sounds like you feel quite motivated to use the interdental brushes every day, and that you think that if you put your interdental brushes on your sink next to your electric toothbrush that would help you remember to actually use them." (*summarizing*)

P "Yes, that's right."

Dr "Well does that sound like something you want to do?"

P "Yes, I'll do that tonight."

Tobacco use cessation

In this example, MI is used in a brief intervention for tobacco use cessation at the beginning of periodontal therapy.

Dr "According to your tobacco use history, you are currently smoking cigarettes. May I ask you a few questions about your smoking?" (*raising the topic/asking permission*)

P "Yes."

Dr "Could you tell me how you feel about your smoking?" (*asking open questions to elicit what the patient already knows*)

P "Well I know I should quit. I know it's not good for my health. But I don't want to quit right now."

Dr "So, you don't feel that you want to quit right now, but you do have some concern about the health effects." (*rolling with resistance*)

P "Yes."

Dr "Well, tell me more about what concerns you?"

P "Well, mainly that I would get lung cancer or something."

Dr "So you worry a bit about getting cancer because of smoking. Is there anything else that you don't like about smoking? "

P "Well if I quit my clothes would stop smelling."

Dr "So, the smell of tobacco smoke is something you would like to be rid of?"

P "Yes, but I've smoked for many years, you know and I tried to quit once before."

Dr "So, even though you would like to be a non-smoker for health and other reasons you haven't had much success quitting." (*reflecting on ambivalence*)

P "Yes, and right now I'm enjoying smoking so there's not much motivation to try and quit."

Dr "Well, it sounds like even though you have some important reasons to quit, you're not very confident you could succeed and you don't feel ready to take on this challenge right now.

I wonder if it would be OK for us to talk about this again next time to see where you are with it and whether I could help?" (*summarizing*)

P "Yes, that sounds fine."

Conclusion

Chronic unhealthy behaviors not only affect an individual's general and oral health, but also impact the burden of disease at a community level. Hence, primary and secondary prevention services at an individual level oriented towards the change of inappropriate behavior is a professional responsibility for all oral healthcare providers. MI is a useful method that can be incorporated into the periodontal treatment plan to encourage the modification of all common risk behaviors for periodontal diseases, such as insufficient oral hygiene, tobacco use, unhealthy dietary habits, and alcohol abuse.

Chapter 36

Mechanical Supragingival Plaque Control

Fridus van der Weijden,[1] Dagmar Else Slot,[1] José J. Echeverría,[2] and Jan Lindhe[3]

Importance of supragingival plaque removal

People brush their teeth for a number of reasons: to feel fresh and confident, to have a nice smile, and to avoid bad breath and disease. Oral cleanliness is important for the preservation of oral health because it removes microbial plaque, preventing it from accumulating on the teeth and gingiva (Löe *et al.* 1965). Dental plaque is a bacterial biofilm that is not easily removed from the surface of the teeth. Biofilms consist of complex communities of bacterial species that reside on tooth surfaces or soft tissues. It has been estimated that between 400 and 1000 species can, at various times, colonize oral biofilms. In these microbial communities, there are observable associations between specific bacteria, due in part to synergistic or antagonistic relationships and in part to the nature of the available surfaces for colonization or nutrient availability (see Chapter 10). The products of biofilm bacteria are known to initiate a chain of reactions leading not only to host protection but also to tissue destruction (see Chapter 13). Plaque can be supragingival or subgingival and can be adherent or non-adherent to teeth or tissue. In addition, the microbial composition of plaque varies from person to person and from site to site within the same mouth (Thomas 2004). Maintenance of effective plaque control is the cornerstone of any attempt to prevent and control periodontal disease. In fact, without the continuous collaboration of patients, periodontal treatment has little success and results obtained do not last long.

Supragingival plaque is exposed to saliva and to the natural physiologic forces existing in the oral cavity. Natural self-cleansing mechanisms include tongue movement, by which the tongue makes contact with the lingual aspects of the posterior teeth

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

and, to a lesser extent, also cleans their facial surfaces. The cheek covers the buccal aspects of the posterior maxillary teeth and can thereby help to prevent the copious build-up of dental plaque on these surfaces. Saliva flow has some limited potential for cleaning debris from interproximal spaces and occlusal pits, but it is less effective in removing and/or washing out plaque. Friction through mastication might have a limiting effect on occlusal and incisal extensions of plaque. These defenses can best be classified as superficial actions in controlling or mediating plaque build-up. Natural cleaning of the dentition is virtually non-existent. To be controlled, plaque must be removed frequently by active methods. Hence, the dental community continues to encourage proper oral hygiene and more effective use of mechanical cleaning devices (Cancro & Fischman 1995; Löe 2000).

Therefore, to maintain oral health, regular personal plaque removal measures must be undertaken. The most widespread means of actively removing plaque at home is toothbrushing. There is substantial evidence that demonstrates that toothbrushing and other mechanical cleansing procedures can reliably control plaque, provided that this cleaning is sufficiently thorough and is performed at appropriate intervals. Evidence stemming from large cohort studies has demonstrated that high standards of oral hygiene ensure the stability of periodontal tissue support (Hujoel *et al*. 1998; Axelsson *et al*. 2004). Based on a longitudinal study of the natural history of periodontitis in a dentally well-maintained male population (Schätzle *et al*. 2004), Lang *et al.* (2009) concluded that persistent gingivitis represents a risk factor for periodontal attachment loss and tooth loss.

Given the great importance that has been placed on plaque and personal oral hygiene in the periodontal therapy hierarchy, evidence is needed to support this leading role. In a review, Hujoel *et al.* (2005) systematically searched for evidence from randomized controlled trials regarding whether improved personal oral hygiene was associated with a decreased risk of periodontitis initiation or progression. These reviewers were unable to find randomized controlled trial evidence indicating that improved personal oral hygiene prevented or controlled chronic periodontitis. By itself, this finding is not surprising because, based on common sense, it would be unethical to provide periodontal treatment without oral hygiene instruction. Furthermore, almost 60 years of experimental research and clinical trials in different geographic and social settings have confirmed that effective removal of dental plaque is essential for dental and periodontal health (Löe 2000). The reduction of plaque mass through good oral hygiene will reduce the injurious load on these tissues.

As meaningful as oral hygiene measures are for disease prevention, they are relatively ineffective when used *alone* for the treatment of moderate and severe forms of periodontitis (Loos *et al*. 1988; Lindhe *et al*. 1989). Without an adequate level of oral hygiene in periodontitis-susceptible subjects, periodontal health tends to deteriorate once periodontitis is established, and further loss of attachment can occur (Lindhe & Nyman 1984).

Meticulous, self-performed plaque removal measures can modify both the quantity and composition of subgingival plaque (Dahlén *et al*. 1992). Oral hygiene acts as a non-specific reducer of plaque mass. This therapeutic approach is based on the rationale that any decrease in plaque mass benefits the inflamed tissues adjacent to bacterial deposits. The Socransky group (Haffajee *et al.* 2001) reported that a permanent optimal supragingival plaque control regimen could alter the composition of the pocket microbiota and lower the percentage of periodontopathic bacteria.

Currently, both primary prevention of gingivitis and primary and secondary prevention of periodontitis are based on the achievement of sufficient plaque removal. The concept of primary prevention of gingivitis is derived from the assumption that gingivitis is a precursor of periodontitis and that maintenance of healthy gingiva will prevent periodontitis. Consequently, preventing gingivitis could have a major impact on periodontal care expenditure (Baehni & Takeuchi 2003). Primary prevention of periodontal diseases includes educational interventions for periodontal diseases and related risk factors, and regular, self-performed plaque removal and professional, mechanical removal of plaque and calculus. Optimal oral hygiene requires appropriate motivation of the patient, adequate tools, and professional oral hygiene instruction.

There is a lack of evidence with regard to the most effective self-performed oral hygiene around dental implants. Self-care at present can therefore only be based on the knowledge that is available with regard to home-based care of natural teeth. However, because the anatomic structure of the marginal gingival tissues is different from that around natural teeth, the authors strongly suggest further well-performed clinical trials in the near future to examine various aspects of oral hygiene around dental implants.

Self-performed plaque control

Maintenance of oral health has been an objective of humans since the dawn of civilization. Self-care has been defined by the World Health Organization as all of the activities that the individual undertakes to prevent, diagnose, and treat poor personal health though self-support activities or referral to healthcare professionals for diagnosis and care. Personal oral hygiene refers to the effort of the patient to remove supragingival plaque. The procedures used to remove supragingival plaque are as old as recorded history. The use of mechanical devices for the cleaning of

teeth dates back to the ancient Egyptians 5000 years ago, who made brushes by fraying the ends of twigs. People often chewed on one end of a stick until the fibers of the wood formed a brush, which was then rubbed against the teeth to remove food. These chewing sticks were the ancestors of the *miswak,* which is still used today and is especially popular in Muslim communities. The Chinese are believed to have invented the first toothbrush in approximately 1600 BC. This primitive toothbrush was made of natural hog bristles from pigs' necks with the bristles attached to a bone or bamboo handle (Carranza & Shklar 2003). In his writings, Hippocrates (460–377 BC) included commentaries on the importance of removing deposits from the tooth surfaces. The observation that self-performed plaque removal is one of the foundations of periodontal health was clearly described in 1683 by the well-known Dutch scientist Antonie van Leeuwenhoek, who wrote, "Tis my wont of a morning to rub my teeth with salt and then swill my mouth out with water; and often, after eating, to clean my back teeth with a toothpick, as well as rubbing them hard with a cloth; wherefore my teeth, back and front, remain as clean and white as falleth to the lot of few men of my years, *and my gums never start bleeding*" (Carranza & Shklar 2003). Van Leeuwenhoek examined under the lens of an early microscope the scrapings from his own teeth. He observed tiny moving organisms floating and spinning through the soft mass. This centuries-old discovery seems primitive by today's standards, but this early description of the dental biofilm was the basis for modern-day microbiology.

Currently, toothbrushes of various kinds are important aids for mechanical plaque (dental biofilm) removal, and their use is almost universal. Furthermore, a fluoridated dentifrice is an integral component of daily home oral care. Over the past 50 years, oral hygiene has improved; in industrialized countries, 80–90% of the population brushes its teeth once or twice a day (Saxer & Yankel 1997). The use of interdental cleaning devices, mouth rinses, and other oral hygiene aids is less well documented, but the available evidence tends to suggest that only a small percentage of the population uses such additional measures on a regular basis (Bakdash 1995). The benefits of optimal home-use plaque-control measures include the opportunity to maintain a functional dentition throughout life; reduction of the risk of loss of periodontal attachment; optimization of esthetic values, such as appearance and breath freshness; and a reduced risk of complex, uncomfortable, and expensive dental care (Claydon 2008). There is increasing public awareness in the Western world of the value of good oral health practices. This fact has been demonstrated by the recorded increases in both public spending on oral hygiene products (>$3.2 billion per year in the US) and industry spending on consumer-related advertising (>$272 million per year in the US) (Bakdash 1995).

Brushing

Different cleaning devices have been used in different cultures over the centuries (toothbrushes, chewing sticks, chewing sponges, tree twigs, strips of linen, bird feathers, animal bones, porcupine quills, etc.). Toothbrushing is currently the most commonly implemented measure in oral hygiene practices. The toothbrush, when used properly, has no side effects, is easy to use, and is inexpensive. Used with toothpaste it removes tooth stain and is the vehicle to deliver therapeutic agents in toothpaste. According to the Lemelson-MIT Invention Index (2003), the toothbrush was selected as the number 1 invention that Americans could not live without; when they were asked to select from among five choices — toothbrush, automobile, personal computer, cell phone, and microwave — more than one-third of teens (34%) and almost half of adults (42%) cited the toothbrush. Toothbrushing alone, however, does not provide adequate interdental cleaning because a toothbrush can only reach the facial, oral, and occlusal tooth surfaces. It was suggested (Frandsen 1986) that the outcomes of toothbrushing are dependent on: (1) the design of the brush; (2) the skill of the individual using the brush; (3) the frequency of brushing; and (4) the duration of brushing. Also, the uniformity of the dentition and a person's attitude and commitment towards brushing play a role, and together mean that there is no single toothbrush suitable for all populations. Dental professionals must become familiar with the variety in shapes, sizes, textures, and other characteristics of available toothbrushes to provide their patients with proper advice. From the numerous products currently available on the market, only a few should be selected for any individual patient. It is important that the dental care provider understands the advantages and disadvantages of the various toothbrushes (and other aids) to provide the patient with proper information during oral hygiene instruction sessions. It is quite possible that a given patient will obtain better results with one particular toothbrush than with another. Therefore, the provision of oral hygiene information should be tailored to the individual.

Motivation

Oral hygiene education is essential to the primary prevention of gingivitis. Improvement in a patient's oral hygiene is often accomplished through cooperative interaction between the patient and the dental professional. The role of the patient is to seek education regarding efficient self-performed plaque removal and to undergo regular check-ups to ensure a high level of oral hygiene. The patient must be involved in maintaining the health of the tissues, interested in a proposed treatment plan, and motivated to participate. Without compliance, which has been described as the degree to which a patient

follows a regimen prescribed by a dental professional, a good treatment outcome will not be achieved. In this context, it should be realized that compliance with treatment recommendations is generally poor, particularly in patients with chronic diseases for which the risk of complications is not immediate or life threatening. Also, compliance with oral hygiene recommendations is generally poor (Thomas 2004).

Thus, however effective any toothbrushing method is, it will only be of any real value if the patient is prepared to use the technique on a regular basis (Warren & Chater 1996). The patient's positive attitude toward treatment can have positive long-term effects on her/his tooth cleaning efforts. Thus, well-motivated patients who are compliant with professional advice and instructions are likely to achieve and sustain ideal levels of plaque control. Good oral hygiene should form an integral part of overall health practices, along with regular exercise, stress management, diet and weight control, smoking cessation, and moderation in alcohol consumption. If the clinician can establish the link between oral health and general health for the patient, then the individual might be more willing to establish proper oral hygiene measures as part of her/his lifestyle. The issue of changing a patient's lifestyle is the more difficult part of motivational sessions (see Chapter 35). The principles of brushing and flossing are easy to learn. Integrating them into a person's daily routine is far more difficult. This difficulty can become a source of frustration for the clinician who has provided a patient with information about the necessity of personal oral hygiene measures.

Oral hygiene instruction

Oral hygiene education consists not only of knowledge transfer; it must also consider current habits and personal skills. Patients often present with non-specific brushing techniques and need sufficient support to establish methods that are appropriate for their respective needs. Ganss *et al.* (2009a) assessed toothbrushing habits in uninstructed adults and observed that when using a strict definition of appropriate brushing habits (defined as brushing at least twice daily for 120 seconds with a brushing force not exceeding 3 N and with circling or vertical sweeping movements), only 25.2% of the participants fulfilled all of the criteria.

Twice-daily brushing with fluoridated toothpaste is now an integral part of most people's daily hygiene routines in Western societies. However, it appears that most patients are unable to achieve total plaque control at each cleaning. A systematic review (Van der Weijden & Hioe 2005) was initiated to assess the effect of mechanical plaque control and was then refined to address the effect of manual toothbrushing on plaque and gingivitis parameters. It was concluded that in adults with gingivitis, the quality of self-performed mechanical plaque removal was not sufficiently effective and needed to be improved. Based on studies of 6 months or longer in duration, it appears that a single oral hygiene instruction session, during which the use of a mechanical toothbrush is described, in addition to a single professional session of "oral prophylaxis" at baseline, had a significant, albeit small, positive effect on the reduction of gingival inflammation in adults with gingivitis. A recent study evaluated the effects of yearly oral hygiene instructions during dental check-ups of 284 patients over a 5-year period (Furusawa *et al.* 2011). It was shown that these repeated instructions significantly contributed to improved plaque control compared to control in patients not receiving these instructions. Jönsson *et al.* (2009) reported that an individually tailored oral health educational program, based on an integrated cognitive/behavioral and oral health approach, was more effective than standard treatment in achieving proper long-term oral hygiene behavior resulting in reduced plaque and gingivitis, specifically interproximally.

Toothbrushing

Manual toothbrushes (see Box 36-1)

The exact origins of mechanical devices for cleaning teeth in the Western world are unknown. The Chinese are given credit for developing the first handheld bristle toothbrush, as the earliest record of a toothbrush was found in Chinese writing from approximately 1600 BC. A century later, the nobility were using toothbrushes fashioned from silver. In 1698, Cornelis van Solingen, a doctor from The Hague, published a book in which he presented the first illustration of a toothbrush in Europe (Fig. 36-1). Over the past 350 or so years, toothbrushes have been crafted with bone, wood, or ivory handles that held the stiff bristles of hogs, boars, or other animals.

The first mass-produced toothbrush was made by William Addis of Clerkenwald, England, circa 1780. The idea of the bristle bone toothbrush came

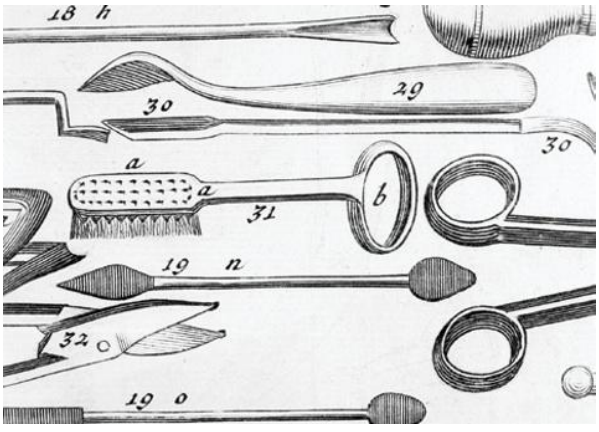

Fig. 36-1 Illustration of a toothbrush and tongue scraper from a book by Cornelis van Solingen. (Courtesy of the University Museum of Dentistry in Utrecht, the Netherlands.)

to William Addis while in prison. Boredom and necessity drove Addis to take a bone left behind from his dinner and to borrow bristles from a guard. The Addis version of the toothbrush had a bone handle and holes for the placement of natural hog bristles, which were held in place by wire. While acceptable at the time and no doubt efficacious in terms of plaque removal, natural products are inherently unhygienic, as the bristle fibers allow the accumulation and proliferation of orally-derived bacteria. The first American to patent a toothbrush was H. N. Wadsworth (in 1857), and many American companies began to produce toothbrushes after 1885. In the early 1900s, celluloid began to replace the bone handle, a change that was hastened by World War I when bone and hog bristles were in short supply. Nylon filaments were introduced in 1938 by Du Pont de Nemours because World War II prevented the exportation of wild boar bristles from China. Nearly all current toothbrushes are made exclusively of synthetic materials (Wilkins 1999). Their nylon filaments and plastic handles are easy to manufacture and are therefore more affordable. This ease of manufacture has made toothbrushing a common practice in most societies. Some unique designs have been developed, including multiple brush heads to allow simultaneous cleaning of tooth surfaces.

During toothbrushing, the removal of dental plaque is achieved primarily through direct contact between the filaments of the toothbrush and the surfaces of teeth and the soft tissues. At the European Workshop on Mechanical Plaque Control, it was agreed that the features of an ideal manual toothbrush are (Egelberg & Claffey 1998):

- Handle size appropriate to user's age and dexterity so that the brush can be easily and efficiently manipulated
- Head size appropriate to the size of the individual patient's requirements
- End-rounded nylon or polyester filaments not larger than 0.23 mm (0.009 inches) in diameter
- Soft filament configurations, as defined by the acceptable international industry standards (ISO)
- Filament patterns that enhance plaque removal in the appropriate spaces and along the gum line.

Additional characteristics could include an inexpensive price, durability, imperviousness to moisture, and easy to clean.

Modern toothbrushes have reached a certain stage of sophistication, and they are designed to be appealing to use. To improve patient comfort, over time the shape of the brush head, the filaments, and the placement of filaments in the handles has changed. Modern toothbrushes have filament patterns designed to enhance plaque removal from hard-to-reach areas of the dentition, particularly from proximal areas. A major shortcoming of the conventional flat-trim toothbrushes has been the "blocking effect" of tight bristle tufts, which prevents individual tufts from reaching interproximal areas. Cross-placed filaments and crimped and tapered filaments are the most recent improvements. The designs are based on the premise that the majority of subjects in any population use a simple horizontal brushing action. Multiple tufts of filaments, sometimes angled in different directions, are also used (Jepsen 1998). These multilevel toothbrushes have alternating rows of taller and shorter bristle tufts acting independently, so they are not influenced by the adjacent bristles during brushing. Once independent motion is achieved, the longer bristles can effectively reach further between the teeth. Multilevel or angled toothbrush designs (Fig. 36-2) yield genuinely improved performance characteristics when compared with flat-headed brushes (Cugini & Warren 2006; Slot *et al.* 2012). Double- and triple-headed toothbrushes have been proposed to reach the lingual surfaces more easily, especially in molar areas, which are normally the tooth surfaces hardest to reach with regular toothbrushes. Although some studies have indicated that the use of such multiheaded toothbrushes might improve plaque control in lingual areas (Agerholm 1991; Yankell *et al.* 1996), their use is not widespread.

Fig. 36-2 Flat-trim, multilevel and angled manual toothbrush bristle tuft design.

Whereas handles used to be straight and flat, round and curved handles are more common today. The modern toothbrush has a handle size that is appropriate to the hand size of the prospective user, and greater emphasis has been placed on new ergonomic designs (Löe 2002). Several studies have investigated differences in plaque removal between brushes with different handle designs. In such studies, brushes with long and contoured handles appear to remove more plaque than brushes with traditional handles (Saxer & Yankell 1997).

Obviously, there can be no single "ideal" toothbrush for all populations. The choice of brush is usually a matter of individual preference, rather than governed by a demonstrated superiority of any one type. In the absence of clear evidence, the best toothbrush is the one that is (properly) used by the patient (Cancro & Fischman 1995; Jepsen 1998).

For a toothbrush company to qualify a toothbrush for the American Dental Association (ADA) Seal of Acceptance, it must be shown that:

- All of the toothbrush components are safe for use in the mouth
- Bristles are free of sharp or jagged edges and end points
- Handle material is manufacturer tested to show durability under normal use
- Bristles will not fall out with normal use
- Toothbrush can be used without supervision by the average adult to provide a significant decrease in mild gum disease and plaque
- Size and shape of the brush should fit in the mouth comfortably, allowing the user to reach all areas easily.

A company earns the ADA seal for its product by producing scientific evidence that the product is safe and effective, claims that are evaluated by an independent body of scientific experts – the ADA Council on Scientific Affairs – according to objective guidelines.

Efficacy

Toothbrush manufacturers have made great efforts to consider many different aspects when designing new models to meet the challenges of enhancing plaque biofilm removal through improved toothbrushing efficacy. Few toothbrush manufacturers have also attempted to evaluate toothbrush efficacy. The enthusiastic use of a toothbrush is not synonymous with a high standard of oral hygiene. Adults, despite their apparent efforts, do not appear to be as effective in their plaque removal as might be expected. The daily experience in dental practice is that patients exhibit plaque even though they reportedly engage in oral hygiene practices. De la Rosa *et al.* (1979) studied the patterns of plaque accumulation and removal with daily toothbrushing over a 28-day period following dental prophylaxis. On average, approximately 60% of the plaque remained after self-performed brushing. Morris *et al*. (2001) reported on the 1998 UK Adult Dental Health Survey and observed that the mean proportions of teeth with plaque deposits were 30% in the 25–34-year-old age group and 44% in those aged 65 years and older. Brushing exercise studies are commonly used for toothbrush evaluations. This study model provides useful indications of the plaque removal capacity of toothbrushes and facilitates the control of confounding variables, such as compliance.

Recently, a systematic review was initiated by Slot *et al.* (2012) to assess the effect of a single brushing exercise using a manual toothbrush. In total, 212 brushing exercises as separate legs of experiments in 10 806 participants, were used to calculate a weighted mean overall percentage plaque reduction score. The sheer magnitude of the number of participants and the heterogeneity observed in the various study designs yielded results of particular value because they reflected what might be generally expected from a routine oral hygiene exercise as encountered among patients in everyday practice. Based on the baseline and end scores, a plaque reduction percentage was calculated for each of the eligible experiments taken from the selected studies. Using these data, a weighted mean difference was calculated as a 42% reduction in plaque index scores from baseline indices.

An interesting aspect of this analysis was that the estimated magnitude of the effect size of toothbrushing appeared to be dependent on the plaque index score used to assess the magnitude of the effect. Compared to the Quigley & Hein plaque index, the estimate with the Navy index resulted in a greater difference between pre- and post-brushing scores: 30% versus 53%, respectively.

The Navy plaque index (Elliott *et al.* 1972) and the Quigley & Hein plaque index (Quigley & Hein 1962) and their modifications are the two indices most commonly used for assessing plaque removal efficacy with toothbrushes. Although these indices score plaque in different ways, there appears to be a strong correlation between them (Cugini *et al.* 2006). The Quigley & Hein plaque index emphasizes the differences in plaque accumulation in the gingival third of the tooth, and it tends to overscore the incisal half of the crown at the expense of the gingival margin. The Navy plaque index gives greater weight to plaque in the immediate gingival area. The scores from both indices are descriptive. They do not represent strictly linear scales; rather, they ascend in severity. A score of 0 is given when no plaque is found. Higher scores are assigned in ascending order, corresponding roughly to increasing areas of tooth surfaces covered by plaque. Because plaque is colorless, it is usually visualized by staining prior to scoring. Plaque is then defined, in an operational sense, as "stainable material" (Fischman 1986). Such practices do not result in precise estimates of the dental biofilm because they fail to evaluate qualitative features.

Methods of toothbrushing

There is no single oral hygiene method that is correct for every patient. The morphology of the dentition (crowding, spacing, gingival phenotype, etc.), the type and severity of periodontal tissue destruction, and the patient's own manual dexterity determine what kind of hygiene aids and cleaning techniques should be recommended. It should also be realized that during the course of periodontitis therapy, the techniques might have to be changed or adapted to the morphologic situation (longer teeth, open interdental spaces, exposed dentin).

The ideal brushing technique is the one that allows for complete plaque removal in the least

possible time, without causing any damage to tissues (Hansen & Gjermo 1971). Different toothbrushing methods have been recommended over time and some have also been abandoned. Such methods can be classified based on the position and motion of the brush.

Horizontal brushing is probably the most commonly used toothbrushing method. It is most frequently used by individuals who have never had instruction in oral hygiene techniques. Despite the efforts of the dental profession to instruct patients to adopt other, more efficient brushing techniques, most individuals use horizontal brushing because it is simple. The head of the brush is positioned perpendicular to the tooth surface, and then a horizontal back-and-forth scrubbing movement is applied (Löe 2000). The occlusal, lingual, and palatal surfaces of the teeth are brushed with an open mouth. To reduce the pressure of the cheek on the brush head, the vestibular surfaces are cleaned with the mouth closed.

Vertical brushing [Leonard (1939) technique] is similar to the horizontal brushing technique, but the movement is applied in the vertical direction, using up-and-down strokes.

Circular brushing [Fones (1934) method] is performed with the teeth closed, the brush placed inside the cheek, and a fast circular motion applied that extends from the maxillary gingiva to the mandibular gingiva, using light pressure. Back-and-forth strokes are used on the lingual and palatal tooth surfaces.

The *scrubbing method* includes a combination of horizontal, vertical, and circular strokes.

Sulcular brushing [Bass (1948) method] (see Box 36-1) emphasizes cleaning of the area directly beneath the gingival margin. The head of the brush is positioned in an oblique direction toward the apex. The filament tips are directed into the sulcus at approximately 45° to the long axis of the tooth. The brush is moved in a back-and-forth direction using short strokes, without disengaging the tips of the filaments from the sulci. On the lingual surfaces in the anterior tooth regions, the brush head is kept in the vertical direction. The Bass method is widely accepted as an effective method for removing plaque, not only at the gingival margin but also subgingivally. A few studies have been conducted on teeth affected with periodontal disease and scheduled for extraction, in which the gingival margin was marked with a groove, and the depth of subgingival cleaning was measured. These studies showed that with the use of this brushing method, plaque removal could reach a depth of approximately 1 mm subgingivally (Waerhaug 1981a).

The *vibratory technique* [Stillman (1932) method], was designed for the massage and stimulation of the gingiva and for cleaning the cervical areas of the teeth. The head of the brush is positioned in an oblique direction toward the apex, with the filaments placed partly in the gingival margin and partly on the tooth surface. Light pressure, together with a vibratory (slight rotary) movement, is then applied to the handle, while the filament tips are maintained in position on the tooth surface.

The *vibratory technique* [Charters (1948) method] was originally developed to increase cleansing effectiveness and gingival stimulation in the interproximal areas. Compared to the Stillman technique, the position of the brush head is reversed. The head of the brush is positioned in an oblique direction, with the filament tips directed toward the occlusal or incisal surfaces. Light pressure is used to flex the filaments and gently force the tips into the interproximal embrasures. A vibratory (slight rotary) movement is then applied to the handle, while the filament tips are maintained in position on the tooth surface. This method is particularly effective in cases with receded interdental papillae because the filament tips can easily penetrate the interdental space and in orthodontic patients (Fig. 36-3).

With the *roll technique*, the head of the brush is positioned in an oblique direction toward the apex of the teeth, with the filaments placed partly in the gingival margin and partly on the tooth surface. The sides of the filaments are pressed lightly against the gingiva. Next, the head of the brush is rolled over the gingiva and teeth in an occlusal direction.

Finally, the *modified Bass/Stillman technique* emerged because the Bass and Stillman methods were both designed to concentrate on the cervical portion of the teeth and the adjacent gingival tissues and could be modified to add a roll stroke. The brush is positioned similarly to in the Bass/Stillman technique. After activation of the brush head in a back-and-forth direction, the head of the brush is rolled over the gingiva and teeth in the occlusal direction, making it possible for some of the filaments to penetrate interdentally.

In the 1970s, several investigators compared various methods of brushing. Because of varying experimental conditions, the outcomes of these studies are difficult to compare. To date, no method of toothbrushing has been shown to be clearly superior to others. As early as 1986, Frandsen commented on this issue, stating, "Researchers have realized that improvement in oral hygiene is not as dependent upon the development of better brushing methods as upon improved performance by the persons using any one of the accepted methods." Therefore, because no particular toothbrushing method has been found to be clearly superior to the others, there is no reason to introduce a specific toothbrushing technique with each new periodontal patient. In most cases, small changes in the patient's own method of toothbrushing will suffice, always bearing in mind that more important than the selection of a certain method of toothbrushing is willingness and thoroughness on the part of the patient to clean his/her teeth effectively. Implementation of the toothbrushing methods described above must be made according to a patient's needs. For example, because the Bass method has been associated with gingival recession

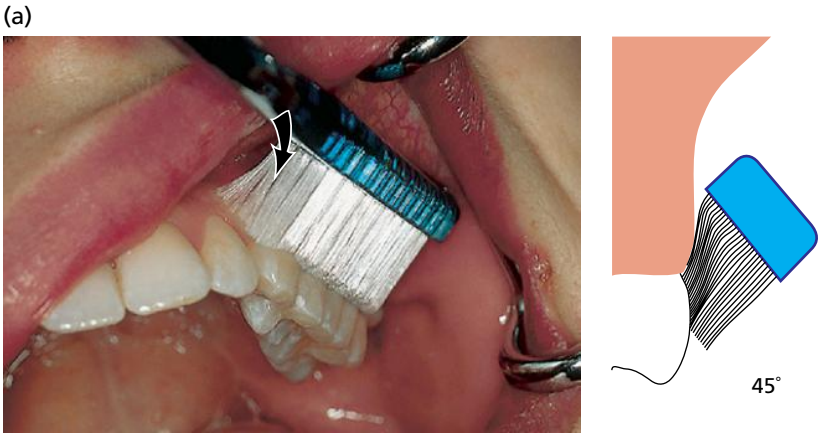

Fig. 36-3 (a) Charters method of toothbrushing. The head of the toothbrush is placed in the left maxilla. Note the angulation of the bristles against the buccal tooth surfaces. The bristles are forced into the interproximal areas. (b) Palatal aspect of the incisor region in the maxilla, illustrating the penetration of the bristles through the interproximal spaces (arrows).

(O'Leary 1980), it is not be indicated in individuals with energetic toothbrushing habits who also have a thin gingival biotype.

Frequency of use

Although the ADA recommends that teeth should be brushed twice per day with a fluoride toothpaste and cleaned in between daily with floss or an interdental cleaner, there is no true consensus as to the optimal frequency of toothbrushing. How often teeth must be brushed and how much plaque must be removed to prevent dental disease from developing are not known. The majority of individuals, including periodontal patients, are usually unable to remove dental plaque completely with daily brushing. However, complete plaque removal does not seem to be necessary. Theoretically, the proper level of oral hygiene is the extent of plaque removal that prevents gingivitis/periodontal disease and tooth decay in the individual patient. The prevention of gingival inflammation is important because inflammatory conditions of soft tissues also favor plaque accumulation (Lang *et al*. 1973; Ramberg *et al*. 1994; Rowshani *et al*. 2004).

Results from cross-sectional studies have been equivocal when the self-reported frequency of tooth cleaning has been related to caries and periodontal disease. A survey, using a questionnaire to assess oral hygiene practices, observed no statistically significant differences in periodontal health measurements (gingival inflammation, probing pocket depth, attachment loss) between subjects performing acceptable (brushing at least once a day) and unacceptable self-reported brushing behavior (Lang *et al.* 1994). However, correlation coefficients have revealed a weakly positive, but significant, relationship between the frequency of tooth brushing and oral hygiene and gingival health (Addy *et al*.1990). Disease appears to be related more to the quality of cleaning than to its frequency (Bjertness 1991). Kressin *et al.* (2003) evaluated the effect of oral hygiene practices on tooth retention in a longitudinal study with 26 years of follow-up. They observed that consistent brushing (at least once per day) resulted in a 49% reduction in the risk of tooth loss, compared to a lack of consistent oral hygiene habits.

If plaque is allowed to accumulate freely in the dentogingival region, subclinical signs of gingival inflammation (gingival fluid) appear within 4 days (Egelberg 1964). The minimum frequency of tooth cleaning needed to reverse experimentally induced gingivitis is once every day or every second day. Bosman and Powell (1977) induced experimental gingivitis in a group of students. Signs of gingival inflammation persisted in those students who removed plaque only every third or fifth day. In the groups who properly cleaned their teeth once per day or every second day, the gingiva healed within 7–10 days.

Based on the observation that the onset of gingivitis appears to be more closely related to the maturation and age of the plaque than to its amount, the minimum frequency of brushing needed to prevent the development of gingivitis was investigated in a prospective study. Dental students and young dental faculty members with healthy periodontal conditions were assigned to study groups with different cleaning frequencies over periods of 4–6 weeks. The results indicated that students who thoroughly removed plaque once daily or even every second day did not develop clinical signs of gingival inflammation over a 6-week period. This tooth cleaning included the use of interproximal aids (dental floss and woodsticks) and toothbrushes (Lang *et al*. 1973). Caution should be exercised in extrapolating the results obtained from studies including dentally aware subjects to the average patient.

As a point of principle, it is reasonable to state that meticulous mechanical removal of plaque by toothbrushing, combined with the removal of interdental plaque once every 24 hours, is adequate to prevent the onset of gingivitis and interdental caries (Axelsson 1994; Kelner *et al*. 1974). From a practical standpoint, it is generally recommended that patients brush their teeth at least twice daily, not only to remove plaque but also to apply fluoride through the use of a dentifrice to prevent caries. This advice also considers feelings of oral freshness. For most patients, it might be desirable to perform all necessary procedures (e.g. brushing and interdental cleaning) at the same time and in the same manner each day. Unfortunately, for subjects who live busy, stressful lives, this level of dedication can be difficult to achieve (Thomas 2004). Despite most individuals claiming to brush their teeth at least twice per day, it is clear from both epidemiologic and clinical studies that mechanical oral hygiene procedures, as performed by most subjects, are insufficient to control supragingival plaque formation and to prevent gingivitis and more severe forms of periodontal disease (Sheiham & Netuveli 2002).

Duration of brushing

Patients usually believe that they spend more time on toothbrushing than they actually do (Saxer *et al*. 1998). The least amount of time spent on brushing was observed in a study performed on English school children; in the 13-year-old group, the children spent approximately 33 seconds on brushing (Macgregor & Rugg-Gunn 1985). Approximately one-third of the studies that were reviewed reported an average brushing time of <56 seconds, whereas two-thirds of the studies reported brushing times of between 56 and 70 seconds. Two investigations reported an average brushing time of ± 90 seconds (Ayer *et al*. 1965; Ganss *et al*. 2009a). MacGregor and Rugg-Gunn (1979) reported that of a mean 50-second brushing time, only 10% of that time was spent on the lingual surfaces.

The best estimates of actual manual brushing time range between 30 and 60 seconds (Van der Weijden *et al*. 1993; Beals *et al.* 2000). Some caution regarding these estimates should be exercised, as the act of measuring brushing time has been shown to affect brushing behavior (MacGregor & Rugg-Gunn 1986).

The toothbrushing in the study by Van der Weijden *et al.* (1993) was performed by a dental professional. This study compared the effect of brushing time on plaque removal using manual and electric toothbrushes, utilizing five different brushing times (30, 60, 120, 180, and 360 seconds). The results indicated that 2 minutes of electric toothbrushing was as effective as 6 minutes of manual toothbrushing. The authors furthermore observed that at 2 minutes, an optimum in plaque-removing efficacy was reached with both manual and electric toothbrushes. Recently, in their systematic review, Slot *et al.* (2012) evaluated in a subanalysis the effect of a single brushing exercise with a manual toothbrush relative to the toothbrushing time. Based on the Quigley & Hein plaque index scores, the estimated weighted mean efficacy as represented in plaque score reduction was 27% after 1 minute and 41% after 2 minutes.

Six studies have been identified in the literature that address the question of whether, in adult patients, the duration of toothbrushing correlates with the efficacy of plaque removal. Three of these studies evaluated the use of electric toothbrushes (Van der Weijden *et al*. 1996a; McCracken *et al*. 2003, 2005). One study compared manual toothbrushes with electric toothbrushes (Preber *et al*. 1991), while two studies evaluated only manual toothbrushes (Hawkins *et al*. 1986; Gallagher *et al.* 2009). The results from all six studies indicated that the duration of brushing was consistently correlated with the amount of plaque that was removed.

Based on the above observations, the duration of toothbrushing is likely to be an important determinant of plaque removal in the general population; therefore, it should be stressed during toothbrushing instruction sessions. As plaque removal is strongly correlated with brushing time for any given toothbrush, brushing for 2 minutes or longer should be encouraged, regardless of the brush used. Brushing time is also likely the most easily controlled parameter of effective everyday brushing.

Brushing filaments

The characteristics of an effective toothbrush correspond to the primary functional properties of the filaments. Most modern toothbrushes have nylon filaments. The end of a toothbrush filament can be cut in either a blunt or a rounded manner (see Filament end-rounding below). Today, many manufacturers vary the length or diameter of the filaments mounted in the head. The degrees of hardness and stiffness of a toothbrush depend on the filament characteristics, such as material, diameter, and length.

Toothbrushes with thinner filaments are softer, while thicker-diameter filaments are stiffer and less flexible. Curved filaments can be more flexible and less stiff than straight filaments of equal length and diameter. Also, the density of the filaments in a tuft influences its stiffness, as each filament provides support to adjacent filaments, and each tuft provides support to adjacent tufts. Consequently, the number of filaments per tuft also determines the hardness of a toothbrush. Increased stiffness will prevent the filament ends from bending back during brushing, avoiding the potential risk of damaging the gums. However, the filament must be sufficiently stiff so that during brushing, sufficient pressure (shear force) is exerted to allow for proper plaque removal.

Concern about toothbrush filaments relates primarily to the potential for hard and soft tissue abrasion. Consider that a rod represents a filament of a toothbrush. While brushing, a vertical upward load is exerted, which, in turn, exerts an effect of the same order of magnitude on the oral mucosa. The force of the brush, acting on the individual filament, is thus always as great as the load exercised by the filament on the mucosa. If the load is increased, then the load on the mucosa increases to the same extent. Consequently, the risk of soft tissue damage increases as the filament's tip can penetrate into the mucosa. However, elastic rods demonstrate a peculiarity in their behavior. They suddenly fold back laterally when a certain load limit is exceeded. When folding back, the rod suddenly gives way elastically (without breaking), and the load on the oral mucosa diminishes abruptly. Thus, a load greater than this fold-back limit cannot be transferred to the mucosa by the rod via its tip.

As late as 1967, most people were buying hard brushes (Fanning & Henning 1967). The shift in preference to soft brushes of a specific design paralleled the change that occurred in oral health care when calculus was identified as the prime etiologic agent in periodontal disease (Mandel 1990). The concentration on plaque, especially in the crevicular area, and attention to intrasulcular brushing strongly influenced the change from hard to soft filaments, primarily because of the concern for trauma to the gingival tissues (Niemi *et al.* 1984). Soft filaments are universally recommended for sulcular brushing, such as with the Bass method. Patients can brush at the cervical areas without fear of discomfort or soft tissue laceration. However, various studies have shown that subjects cleaned significantly better with medium and hard brushes than with soft-bristled brushes (Robertson & Wade 1972; Versteeg *et al.* 2008a). Therefore, it appears that the filaments must have a degree of stiffness to create sufficient abrasion to dislodge plaque deposits. There is no point in using a brush with very thin filaments that merely stroke across the tooth and, as a result of the lack of load, no longer clean the tooth surface. However, to avoid damaging the gums when positioning the toothbrush, they must not be too hard: the harder the toothbrush filaments, the greater the risk of gingival abrasion (Khocht *et al.* 1993). People also tend to prefer medium-to-hard brushes because they feel that their teeth are cleaner after brushing with a stiffer brush. Versteeg *et al.* (2008a) showed that when there is no clinical indication for a soft toothbrush, the professional advice with regard to effectiveness should indeed be for a toothbrush of medium stiffness. Soft-filament brushes are particularly recommended for brushing shortly after periodontal surgery for patients with highly inflamed gingiva and for patients with naturally finely textured atrophic or sensitive mucosa. However, the topic of filament stiffness should not be addressed by itself; brush–toothpaste interaction should also be considered. The capacity of a toothbrush to hold and move polish/abrasive over the tooth surface affects the amount of hard tissue abrasion (see Toothbrush abrasion below).

Filament end-rounding

End-rounding has become increasingly common in the toothbrush-manufacturing process to reduce gingival abrasion (Fig. 36-4). The logic that smooth filament tips would cause less trauma than filament tips with sharp edges or jagged projections has been validated in both animal and clinical studies (Breitenmoser *et al.* 1979). Danser *et al.* (1998) evaluated two types of end-rounding and observed their effects on the incidence of abrasion. However, the form to which the ends were rounded had no effect on the level of plaque removal. Tapered filaments (Fig. 36-5) have endings in the shape of an extreme rotational ellipsoid instead of a hemisphere. This shape has been suggested to give the filaments very soft endings, combined with good stability of the filament corpus. As a result, more flexibility is

Fig. 36-4 Tapered toothbrush filaments.

Fig. 36-5 Filament end-rounding.

introduced into the filaments, which are presumably less harmful. The efficacy of tapered toothbrush filaments has been tested in laboratory studies, and it has been found that they were able to reach into the interproximal areas of the teeth, under the gum line and into the fissures. The outcomes of clinical studies comparing end-rounded filaments with flat-trimmed toothbrush head configurations have been equivocal (Dörfer *et al*. 2003; Versteeg *et al*. 2008b).

Wear and replacement

Common sense dictates that toothbrushes should be replaced because the filaments and tufts do not retain their shape forever. Completely worn brushes lose the capacity to remove plaque effectively. This result most likely occurs because of a loss of shear force, as the tips of the filaments can no longer disrupt the plaque adequately. The exact moment at which a toothbrush should be replaced is difficult to determine. In general, dental associations, professionals, and the oral care industry advocate toothbrush replacement every 3–4 months. While this advice would seem reasonable, there is little actual clinical proof that this recommendation is correct. Patients do not appear to heed this advice; the evidence indicates that the average age at which a toothbrush is replaced ranges from 2.5 to 6 months (Bergström 1973). On average, each person in the US purchases three toothbrushes every 2 years.

Common sense would suggest that a worn toothbrush with splayed or frayed filaments loses its resilience and is less likely to be as effective in removing plaque as a new brush. Because of the variability in subjects' brushing techniques and the force applied to the teeth while brushing, the degree of wear varies significantly from subject to subject. It is also likely that different brushes, made from various materials, would exhibit differences in longevity.

Because many patients use their brushes for periods significantly longer than the recommended time of 3 months, it is important to know whether excessive wear is of clinical relevance. There is inconclusive evidence about the relationship between toothbrush wear and plaque removal. The age of the toothbrush by itself appears not to be the critical parameter that is crucial to plaque removal efficacy. Studies with laboratory-worn toothbrushes have reported that such toothbrushes had inferior plaque removal efficacy compared to new brushes (Kreifeldt *et al*. 1980; Warren *et al*. 2002). However, artificially worn toothbrushes might not properly mimic the characteristics of naturally worn brushes. The wear of laboratory-worn toothbrushes will inevitably be highly uniform and will not reflect the variations in wear seen in normal toothbrush use. Most studies in which naturally worn toothbrushes were studied reported no statistically significant decreases in the reduction of whole-mouth plaque scores after brushing compared to when using new toothbrushes (Daly *et al*. 1996; Sforza *et al*. 2000; Tan & Daly 2002; Conforti *et al*. 2003; Van Palenstein Helderman *et al*. 2006). In a recent study with a parallel design, Rosema *et al.* (2013) evaluated the plaque-removing efficacy of new and used manual toothbrushes and found that wear rate seemed to be the determining factor with regard to loss of efficacy.

Thus, the replacement advice should be related more to wear than to the age of the toothbrush. In this respect, wear, as can be observed by the consumer, is considered to be bending, splaying, or matting of the filaments rather than the tapering effect of the filament ends. Kreifeldt *et al.* (1980) studied tapering of toothbrush filaments with regard to toothbrush wear and reported that new brushes were more efficient in removing dental plaque than old brushes. They also examined worn toothbrushes and observed that, as a result of wear, the filaments exhibited tapering that proceeded from the insertion to the free end. For example, filaments were seen that tapered from 0.28 mm at one end to 0.020–0.015 mm at the free end. They concluded that, among wear factors tapering contributed the most to loss of effectiveness. Their explanation for this observation was that as tapering results in a reduction of filament diameter, the brush will become softer and remove less plaque. Based on this tapering phenomenon, some commercially available brushes have filaments that change color after a certain amount of use. These wear indicator filaments serve to remind patients that it is time to replace the brush.

Electric (power) toothbrushes (see Box 36-2)

In well-motivated and properly instructed individuals who are willing to invest the necessary time and effort, mechanical measures using traditional toothbrushes and adjunctive manual (interdental) devices are effective in removing plaque. Maintaining

a dentition that is close to plaque-free is not easy, however. The high prevalence of gingivitis indicates that toothbrushing is not as effective in practice as it is in supervised studies. The electric toothbrush represents an advance that has the potential to enhance both plaque removal and patient motivation. Electric toothbrushes have been around since the 1940s, starting with devices such as the Motodent (circular brush head) and the Toothmaster (straight brush head). An example of the latter can be found in the National Museum of Dentistry in Baltimore, Maryland. The first successfully marketed electric toothbrushes were introduced more than 50 years ago. In 1954, the Swiss inventor Dr Philippe Guy E. Woog invented an oscillating, motorized electric toothbrush. This toothbrush was further developed by Bemann & Woog and first appeared in 1956 in Switzerland. In 1959, it was introduced in the US as the Broxodent at the centennial celebration of the ADA by E.R. Squibb and Sons. This early electric brush was a plug-in device that featured bristles that moved from side to side. In 1961, a cordless, rechargeable model was introduced by General Electric, the so-called Automatic Toothbrush, which soon took the lead in what was turning out to be a very competitive market.

The first electric toothbrushes were basically mechanized versions of manual toothbrushes, with the bristles moving back and forth in an imitation of the way people brushed by hand. Studies of the use of these early electric toothbrushes showed that there was no difference in plaque removal when compared with manual toothbrushes, although they had mixed effects on gingivitis. In 1966, the consensus from the research reports on toothbrushing of the World Workshop in Periodontics stated, "in non-dentally oriented persons, in persons not highly motivated to oral health care, or in those who have difficulty in mastering suitable hand brushing technique, the use of an electric brush with its standard movements may result in more frequent and better cleansing of the teeth".

Since the 1980s, tremendous advances have been made in the technology of electrically powered toothbrushes. Various electric toothbrushes have been developed with unique motions to improve the efficiency of plaque removal, using increased filament velocity and brush stroke frequency, and various filament patterns and motions. Whereas older electric toothbrushes used a combination of horizontal and vertical movements, mimicking closely the back-and-forth motion of traditional brushing methods, the more recent designs have incorporated a variety of actions, such as vibrating at ultrasonic frequencies, and have heads that rotate, heads that move from side to side, or sets of bristles that move one way and then the other way. The electric toothbrush that in the 1980s successfully steered away from a conventional brushing mode and instead mimicked the small round rotating brush head of dental prophylaxis instruments was the Rotadent (Zila, Fort Collins, CO, USA) (Boyd *et al*. 1989). It was sold with three different brush heads in different shapes to facilitate access to all areas of the oral cavity. However, the consumer found it difficult to control. In the 1980s the Interplak was introduced (Conair, Stamford, CT, USA), with independent tufts of bristles that performed rotary and counter-rotary movements (Van der Weijden *et al*. 1993). Although being effective it lost popularity because of the complicated gearing system which could not cope with the abrasive nature of toothpaste.

The development of an oscillating rotating round brush head by Braun (Kronberg, Germany) made control of the brush easier. Oscillating-rotating brushes are designed with round heads that move back and forth, with alternating one-third turns clockwise and counterclockwise. The original oscillating-rotating toothbrush, the Braun Oral-B Plaque Remover (D5), featured a small, round brush head that made rotating and oscillating movements at a speed of 2800 oscillating rotations/min. A further development of this brush, the Braun Oral-B Ultra Plaque Remover (D9), maintained the oscillating–rotating action but at an increased speed (3600 rotations/min). A clinical study with the D9 demonstrated equivalence in safety and a trend toward greater plaque removal (Van der Weijden *et al*. 1996b). Newer developments in oscillating–rotating brush technology are the addition of high-frequency vibrations in the direction of the bristles, creating three-dimensional movements during brushing. This modification was developed to enhance penetration and the removal of plaque from the proximal spaces of the dentition. Studies have shown that the three-dimensional movements performed by the brush are safe and more efficient regarding plaque removal (Danser *et al*. 1998).

Another advance in this technology has been the development of sonic toothbrushes, which have a high frequency of filament movement in excess of approximately 30 000 strokes/min. For example, the rechargeable Oral-B Sonic Complete® (Oral-B Laboratories, Boston, MA, USA) and the Philips Sonicare® Elite (Philips Oral Healthcare, Snoqualmie, WA, US) both use a side-to-side motion operating at a frequency of 260 Hz, but are based on different technologies. Toothbrushes with bristle motion at a high frequency can generate a turbulent fluid flow in the oral cavity. This flow can cause hydrodynamic forces (wall shear forces) that act parallel to a surface. The vibration of toothbrush bristles could further enable energy transfer in the form of sound pressure waves. *In vitro* studies have indicated that non-contact biofilm reduction can be obtained by these hydrodynamic effects. However, *in vivo*, the additional beneficial effects of higher amounts of non-contact biofilm removal have not yet been shown clinically (Schmidt *et al*. 2013).

The electric toothbrush should not be considered a substitute for a specific interdental cleaning method, such as flossing, but it can offer advantages in terms of an overall approach to improved oral hygiene.

Fig. 36-6 Overview of the development of electric toothbrushes, from brushes mimicking a manual toothbrush to high-frequency brush head movement. Electric brushes versus manual toothbrushes

To some extent, modern design features of electric brushes have overcome the limitations of manual dexterity and skill of the user (Fig. 36-6). These modern toothbrushes remove plaque in a shorter time than a standard manual brush. It takes 6 minutes to remove the same percentage of plaque using a manual toothbrush that is removed in 1 minute using a powered toothbrush in the hands of a professional operator (Van der Weijden *et al*. 1993, 1996a). The new generation of electric brushes has better plaque removal efficacy and gingival inflammation control on the proximal tooth surfaces (Egelberg & Claffey 1998). Of this latter aspect the superiority was clearly demonstrated in a study conducted on extracted teeth (Rapley & Killoy 1994).

The collective evidence, which has been summarized in two independent, systematic reviews, has indicated that oscillating–rotating toothbrushes have superior efficacy over manual toothbrushes in reducing plaque and gingivitis (Sicilia *et al*. 2002; Robinson *et al*. 2005). Electronic toothbrushes with this mode of action reduced plaque by 7% and gingival bleeding upon probing by 17% over the long term, when compared with manual brushes (Robinson *et al*. 2005). The conclusion from a Cochrane Oral Health Group review (Robinson *et al*. 2005) was that there is consistent evidence only for oscillating–rotating brushes to consider them clinically superior to manual brushes and that they offer greater plaque and gingivitis reductions. Any reported side effects were localized and temporary. Sensitivity analyses revealed the results to be robust when selecting trials of high quality, and there was no evidence of publication bias.

Some clinical studies have shown sonic technology to be comparable to or more effective than manual toothbrushes in removing plaque and reducing gingival inflammation (Johnson & McInnes 1994; Tritten & Armitage 1996; Zimmer *et al*. 2000; Moritis *et al*. 2002). Tritten and Armitage (1996) compared the Sonicare Advance to a traditional manual toothbrush in a 12-week parallel group study and concluded that both brushes were equally effective in reducing gingival inflammation.

Modern electric toothbrushes are known to enhance long-term compliance. In a study involving periodontitis patients with persistently poor compliance, Hellstadius *et al.* (1993) found that switching from a manual to an electric toothbrush reduced plaque levels and that the reduced levels were maintained over a period of between 12 and 36 months. The electric brush significantly improved compliance, and patients expressed a positive attitude toward the new brush. Another study reported 62% of people continuing to use their electric toothbrushes on a daily basis 36 months after purchase (Stålnacke *et al.* 1995). In a survey conducted in Germany, most dentists stated that the time their patients spent on toothbrushing was too short (Warren 1998). Approximately half of the dentists stated that they recommended that their patients use an electric toothbrush, and the vast majority of the dentists believed that changing to an electric toothbrush would improve the condition of their patients' teeth and gums. The findings from a US practice-based study, involving a large number of subjects who switched from manual toothbrushes to the Braun Oral-B Ultra Plaque Remover (D9), confirmed those from a German study (Warren *et al*. 2000).

Comparison of different electric toothbrushes

Today's marketplace is crowded with dozens of electric brushes. The choices range from inexpensive, disposable, battery-operated, rotating brushes to sophisticated, rechargeable electric brushes.

Two studies, using the same experimental gingivitis model, compared an earlier Sonicare device and the Oral-B oscillating–rotating toothbrush. In both studies, the oscillating–rotating brush was more effective in improving the level of gingival health (Putt *et al*. 2001; Van der Weijden *et al*. 2002a). These findings confirmed the findings of an earlier 6-week cross-over study (Isaacs *et al*. 1998), in which the improvement in gingival condition was 8.6% greater with the oscillating–rotating brush. Rosema *et al.* (2005) compared the Sonicare Elite to the Oral-B Professional Care 7000 and again found that the oscillating–rotating pulsation brush was more effective.

To establish the superiority of electric brushing over any other mode, the most recent review, performed in collaboration with the Cochrane Oral Health Group, assessed the collective evidence on efficacy of electric brushes and their effects on oral health (Deacon *et al.* 2011). The selection criteria were studies that were randomized, involved at least 4 weeks of unsupervised brushing, enrolled participants who had no impairment of manual dexterity, and compared two or more electric brushes with different

modes of action. Brushes with a rotation–oscillation action reduced plaque and gingivitis more than those with side-to-side action in the short-term. However, the difference was small and its clinical importance unclear. Due to the low numbers of trials using other types of electric brushes, no other definitive conclusions can be drawn regarding the superiority of one type of electric toothbrush over another. However, it must be emphasized that absence of evidence is not evidence of absence, and it might be that future trials show the superiority of specific toothbrush designs. Further research is required before evidence-based advice concerning the relative performances of different electric toothbrushes can be provided by healthcare professionals to the public.

Safety

The safety of electric toothbrushes has been a concern of dental care professionals. One fear was that they would be used excessively and compulsively. For example, enthusiastic electric brush users could apply too much force and compromise their gingival tissues, thereby promoting recession. In a recent systematic review of the effects of oscillating–rotating and manual brushes on hard and soft tissues, the authors determined the safety of this design of electric toothbrush as comprehensively as possible (Van der Weijden *et al.* 2011). They searched the existing literature, using a variety of electronic databases, for any study that compared the safety of rotation–oscillation brushes to that of manual brushes, including all but the weakest levels of evidence. Having extracted the relevant data from the 35 most appropriate original papers, the data were grouped by research design (randomized controlled trials with safety as the primary outcome, trials in which safety was a secondary outcome, studies that used a surrogate marker of safety, and laboratory-based studies). Within these groups, the designs of the original studies were usually so diverse that it was impossible to bring the results together into a single statistical analysis. Nevertheless, the original data consistently failed to indicate problems with the safety of rotation–oscillation brushes. However, the majority of the trials considered safety as a secondary outcome. Therefore, the evidence was usually anecdotal rather than quantitative. The review authors concluded, "This systematic review of a large body of published research in the preceding two decades consistently showed oscillating–rotating toothbrushes to be safe when compared with manual brushes, and collectively indicated that there is no evidence that they do pose a clinically relevant concern to either hard or soft tissues". The outcomes were consistent with the observations of Robinson *et al.* (2005) and Deacon *et al.* (2011) in reviews reporting only minor and transient side effects. Currently, there are no systematic reviews of the safety of any other types of electric brushes.

Electrically active (ionic) toothbrush

Several toothbrushes (ionic, electronic, and electrically active) have been marketed over the years that are designed to send a small, imperceptible electronic current through the brush head onto the tooth surfaces, presumably to disrupt the attachment of dental plaque and to damage the electrostatic bonding of plaque proteins to tooth surfaces. Thus, these currents could enhance the efficacy of brushes in plaque elimination. Electrons should eliminate H^+ ions from the organic acid in the plaque, which could result in decomposition of the bacterial plaque (Hoover *et al.* 1992). The first record of a charged toothbrush, "Dr. Scott's Electric Toothbrush," was found in the February 1886 issue of *Harper's* weekly magazine. The handle of Dr Scott's toothbrush was purportedly "charged with an electromagnetic current which acts without any shock, immediately upon the nerves and tissues of the teeth and gums…arresting decay…and restoring the natural whiteness of the enamel."

Hotta and Aono (1992) studied an electrically active manual toothbrush that was designed with a piezoelectric element in the handle. This brush generated a voltage potential corresponding to the bending motion of the handle as the teeth were brushed. In this study, no difference in the amount of remaining plaque after brushing was observed between the placebo and the electrically active brush. Other toothbrushes that have claimed an "electrochemical" effect on dental plaque have had semiconductors of titanium oxide (TiO_2) incorporated into the brush handle. In the presence of light, saturated low-energy electrons in the wet semiconductor are transformed into high-energy electrons. An electron current of approximately 10 nA was measured to run from the semiconductor to the tooth (Weiger 1988). Some short-term clinical studies of the use of these kinds of brushes have documented beneficial effects in terms of plaque reduction and gingivitis resolution (Hoover *et al.* 1992; Galgut 1996; Weiger 1998; Deshmukh *et al.* 2006), while others have failed to do so (Pucher *et al.* 1999; Moreira *et al.* 2007). One 6-month study reported lower plaque scores and improvement of gingivitis with the ionic brush compared to the control, but these findings were not substantiated in subsequent 6- and 7-month studies (Van der Weijden *et al.* 1995, 2002b).

Interdental cleaning

There is confusion in the literature regarding the definitions of the proximal, interproximal, interdental, and proximal sites. Commonly used indices are not suitable for assessing interdental plaque (directly under the contact area), thereby limiting the interpretation of interdental plaque removal. In 1998, the European Workshop on Mechanical Plaque Control proposed the following definitions. *Proximal* areas are the visible spaces between teeth that are not under

the contact area. These areas are small in healthy dentition, although they can increase after periodontal attachment loss. The terms *interproximal* and *interdental* can be used interchangeably and refer to the area under and related to the contact point.

The rationale for considering interdental cleaning under a separate heading is related to toothbrushing alone being considered optimally capable of thoroughly cleaning the *flat* surfaces of the teeth, that is the buccal, lingual, and occlusal surfaces, with the exceptions of pits and fissures. Toothbrushes do not reach the proximal surfaces of teeth as efficiently, nor do they reach into the interproximal areas between adjacent teeth. Therefore, measures for interdental plaque control should be selected to complement plaque control by toothbrushing (Lang *et al*. 1977; Hugoson & Koch 1979). The interdental gingiva fills the embrasure between two teeth apical to their contact point. This is a "sheltered" area which is difficult to access when the teeth are in their normal position. In populations that use toothbrushes, the interproximal surfaces of the molars and premolars are the predominant sites of residual plaque. The removal of plaque from these surfaces remains a valid objective because in patients susceptible to periodontal diseases, gingivitis and periodontitis are usually more pronounced in these interdental areas than on the oral or facial aspects (Löe 1979). Dental caries also occur more frequently in the interdental region than on the oral or facial smooth surfaces. A fundamental principle of prevention is that the effect is greatest where the risk of disease is greatest. Therefore, interdental plaque removal, which cannot be achieved with a toothbrush, is of critical importance for most patients.

A number of interdental cleaning methods have been developed, ranging from flossing to the more recently introduced electrically powered cleaning aids. Flossing is the most universally applicable method. However, not all interdental cleaning devices suit all patients or all types of dentitions. Factors such as the contour and consistency of the gingival tissues, the size of the interproximal embrasures, tooth position and alignment, and the ability and motivation of the patient should be taken into consideration when recommending an interdental cleaning method. The most appropriate interdental hygiene aids must be selected for each individual patient. The selection made from among the numerous commercially available devices is dependent for the most part on the size and shape of the interdental space and on the morphology of the proximal tooth surfaces. In subjects with normal gingival contours and embrasures, dental floss or tape can be recommended. At sites where soft tissue recession has become pronounced, flossing becomes progressively less effective. Thus, an alternative method (either woodsticks or interdental brushes) should be recommended. In addition, it should be borne in mind that the advice offered might need to change as the effectiveness of treatment and improved oral hygiene change the shapes of the interproximal regions.

Table 36-1 Interdental cleaning methods recommended for particular situations in the mouth.

Situation	Interdental cleaning method
Intact interdental papillae; narrow interdental space	Dental floss or small woodstick
Moderate papillary recession; slightly open interdental space	Dental floss, woodstick or small interdental brush
Complete loss of papillae; wide open interdental space	Interdental brush
Wide embrasure space; diastema, extraction diastema, furcation or posterior surface of most distal molar, root concavities or grooves	Single-tufted/end-tufted brush or gauze strip

A review of interdental cleaning methods (Warren & Chater 1996) concluded that all conventional devices are effective, but each method should be suited to a particular patient and to a particular situation in the mouth (Table 36-1). Furthermore, for maximum effectiveness, the level of oral hygiene advice delivered to the patient must contain enough information to enable the patient to be able to identify each site in turn, to select a device, and to clean all interdental surfaces effectively (Claydon 2008). The starting point is an evaluation of existing products. An ideal interdental cleaning device should be user-friendly, remove plaque effectively, and have no deleterious soft tissue or hard tissue effects. Gingival bleeding during interdental cleaning can be the result of trauma, such as lacerations and gingival erosions, or it can be an indication of inflammation. Patients must be aware that bleeding *per se* is not a sign that interdental cleaning should be avoided, but is more likely an indicator of inflammation that needs to be treated (Gillette & Van House 1980).

Dental floss and tape (see Box 36-3)

Of all the methods used for removing interproximal plaque, dental flossing is the most frequently recommended. Levi Spear Parmly, a dentist based in New Orleans, is credited with being the inventor of modern dental floss. As early as 1815, Parmly recommended tooth flossing with a piece of silk thread. In 1882, the Codman and Shurtleft Company of Randolph, Massachusetts, started to mass-produce unwaxed silk floss for commercial home use. In 1898, the Johnson & Johnson Company of New Brunswick, New Jersey, was the first to patent dental floss. Dr Charles C. Bass developed nylon floss as a replacement for silk floss during World War II. He was also responsible for making teeth flossing an important part of dental hygiene.

Dental floss and tape – the latter a type of broader dental floss – are most useful where the interdental papillae completely fill the embrasure space. When properly used, effective flossing removes up to 80% of proximal plaque. Even subgingival plaque can be removed because dental floss can be introduced 2–3.5 mm beyond the tip of the papilla (Waerhaug 1981b). Several types of floss (waxed, unwaxed) are available. Studies have shown no difference in the effectiveness of unwaxed versus waxed dental floss. Unwaxed dental floss is generally recommended for patients with normal tooth contacts because it slides through the contact area easily. It is the thinnest type of floss available, yet when it separates during use it covers a larger surface area of the teeth than waxed floss. Waxed floss is recommended for patients with tight proximal tooth contacts.

Ease of use is the most important factor that influences whether patients will use floss on a daily basis. Using dental floss is a complicated skill that many people find difficult to master. Unlike toothbrushing, few people have learned how to properly use dental floss. However, like any other skill, flossing can be taught, and those patients who are given appropriate instruction will increase their flossing frequency (Stewart & Wolfe 1989). Patients benefit from step-by-step instructions (see Box 36-3) and frequent re-instruction and reinforcement in the use of floss are necessary. Because many people think that the purpose of flossing is to remove particles of food, they must be advised that the objective is to remove plaque that adheres to the tooth surface.

To facilitate flossing, a special floss holder can be used. These holders can be re-used and are normally made of a plastic that is durable, lightweight, and easy to clean. Research has revealed that reductions in bacterial plaque biofilm and gingivitis are equivalent with either hand flossing or the use of a floss holder. Powered flossing devices have been introduced. In comparison with manual flossing, no differences were found in terms of plaque removal or gingivitis reduction, although patients preferred flossing with the automated device (Gordon *et al*. 1996).

Flossing is also time-consuming. When a patient is unwilling to use dental floss, alternative interdental hygiene aids should be recommended, even if these aids are less efficient. If a patient finds a particular method or device more appealing to use, long-term compliance becomes an achievable goal. Although it is clear that flossing, when properly used, removes plaque in a very efficient manner, there is no evidence that flossing in adult patients with preserved interproximal periodontal tissues should be routinely indicated (Burt & Eklund 1999).

Two systematic reviews are available concerning the efficacy of dental floss. The first, by Berchier *et al.* (2008), evaluated the collective evidence to determine the effectiveness of dental floss, in combination with toothbrushing, on plaque and the clinical parameters of gingivitis in adults. The majority of the included studies showed that there was no benefit from flossing. The meta-analysis of plaque and gingival index scores also showed no significant differences between groups. Advocacy for flossing as an interdental cleaning method hinges, in large part, on common sense. However, common sense arguments are the lowest level of scientific evidence. A more recent Cochrane review included a variety of floss-related products and, based on the combined evidence, concluded that there was some evidence that flossing, in addition to toothbrushing, reduced gingivitis compared to toothbrushing alone (Sambunjak *et al*. 2011). Thus, there is weak, very unreliable evidence that flossing plus toothbrushing could be associated with a small reduction in plaque.

That dental floss has no additional effects on toothbrushing is apparent from more than one review. Hujoel *et al.* (2006) found that flossing was only effective in reducing the risk of interproximal caries when applied professionally. High-quality professional flossing, performed in first-grade children on school days, reduced the risk of caries by 40%. In contrast, self-performed flossing failed to show a beneficial effect. The lack of an effect on caries and the absence of an effect on gingivitis in the systematic review by Berchier *et al.* (2008) were most likely the consequences of plaque not being removed efficiently.

That flossing does not appear to be effective in the hands of the general public does not preclude its use. For instance, in interdental situations that only allow for the penetration of a string of dental floss, floss is the best available tool. Although floss should not be the first tool recommended for cleaning open interdental spaces, if the patient does not like any other tool, flossing could still be part of oral hygiene instruction. The dental professional should realize that proper instruction, sufficient motivation of the patient, and a high level of dexterity are necessary to make the flossing effort worthwhile. Routine instruction in using floss is not supported by scientific evidence.

Woodsticks (see Box 36-4)

While flossing is the most widely advocated interdental cleaning method, picking of teeth may well be one of humanity's oldest habits and the toothpick one of our earliest tools. The toothpick might date back to the days of cave people, who probably used sticks to pick food from between their teeth. The ancient Romans made use of toothpicks fabricated from bone and metal. Saxon women carried ivory toothpicks. The evolution of the primitive toothpick took a second pathway in more acquisitive societies, becoming part of personal care kits, along with depilatory tweezers and earwax scoops (Mandel 1990). In 1872, Silas Noble and J. P. Cooley patented the first toothpick-manufacturing machine.

Originally, dental woodsticks were advocated by dental professionals a "gum massagers" used to massage inflamed gingival tissue in the interdental areas, to reduce inflammation, and to encourage keratinization of the gingival tissue (Galgut 1991).

The key difference between a toothpick and a woodstick (wooden stimulator/cleaner) relates to the triangular (wedge-like) design of the latter. Woodsticks should not be confused with toothpicks, which are simply intended to remove food debris after meals (Warren & Chater 1996). Woodsticks are inserted interdentally, with the base of the triangle resting on the gingival side (see Box 36-4). The tip should point occlusally or incisally, with the triangle against the adjacent tooth surfaces. Triangular, wedge-like woodsticks have been found to be superior in plaque removal compared to round or rectangular woodsticks, because they fit the interdental area more snugly (Bergenholtz *et al*. 1980; Mandel 1990). Woodsticks are usually made of soft wood to prevent injury to the gingiva. Their tapered form makes it possible for the patient to angle the woodstick interdentally and even clean the lingually localized interdental surfaces. Unlike floss, woodsticks can be used on the concave surfaces of the tooth roots. Some are handheld, while others are designed to be mounted in a handle, which facilitates access to the interdental areas in the posterior region of the mouth (Axelsson 2004). The wood can store fluoride crystals, both on the surface and in the porosities. These crystals readily dissolve when woodsticks are moistened with saliva (Axelsson 2004).

Woodsticks have the advantage that they are easy to use and can be used throughout the day, without the need for special facilities, such as a bathroom or a mirror. A national dental survey showed that the Swedish population prefers using woodsticks to dental floss for the removal of interdental plaque: approximately 46% of adults used woodsticks sporadically and 12% used woodsticks daily. In contrast, dental floss was used occasionally by 12% of adults and daily by only 2%. In other words, adults used woodsticks as oral hygiene aids four to six times more frequently than dental floss (Axelsson 1994). Woodsticks can be used in primary prevention, including in posterior areas, even in cases of poor manual dexterity. To use woodsticks, there must be sufficient interdental space available; in these cases, woodsticks are an excellent substitute to dental floss. Woodsticks can clearly be recommended for patients with open interdental spaces for secondary prevention of periodontal diseases.

During use, the soft wood can become splayed. As soon as the first signs of splaying are evident, the woodstick should be discarded.

Although woodsticks have good cleansing capacity in the central part of the interproximal surfaces of teeth in contact, their effect is reduced on the lingual side of these surfaces. Woodsticks are somewhat difficult to use in the far posterior regions of the jaws because of the lack of accessibility and because the triangular cross-section must pass into the embrasure space at a specific angle (Bassiouny & Grant 1981). When used in healthy dentition, woodsticks can depress the gingival margin. Long-term use can cause permanent loss of the papilla and opening of the embrasure, which can have important esthetic implications for the anterior dentition.

Hoenderdos *et al.* (2008) performed a systematic review to evaluate and summarize the available evidence on the effectiveness of using triangular woodsticks in combination with toothbrushing, to reduce both plaque and clinical inflammatory symptoms of gingival inflammation. The heterogeneity of the data prevented quantitative analysis and only allowed for a descriptive analysis. In seven studies, improvement in gingival health represented a significant incremental benefit realized by the use of triangular woodsticks. None of the studies that scored visible interdental plaque demonstrated any significant advantage of using woodsticks, as opposed to alternative methods (toothbrushing only, dental floss or interdental brushes), in patients with gingivitis.

A series of histologic investigations in patients with periodontitis has shown that the papillary area with the greatest inflammation corresponds to the middle of the interdental tissue. It is difficult to assess the mid-interdental area clinically, as it is usually not available for direct visualization (Walsh & Heckman 1985). When used on healthy dentition, woodsticks depress the gingiva by up to 2–3 mm (Morch & Waerhaug 1956) and therefore clean part of the subgingival area. Thus, woodsticks can specifically remove subgingivally located interdental plaque that is not visible and therefore not evaluated by the plaque index. This physical action of woodsticks in the interdental area could produce a clear, beneficial effect on interdental gingival inflammation.

The studies included in the review by Hoenderdos *et al.* (2008) showed that changes in gingival inflammation were as apparent as changes in bleeding tendency as indicators of disease. Numerous studies have shown that sulcular bleeding is a very sensitive indicator of early gingival inflammation. Bleeding following the use of woodsticks can also be used to increase patient motivation and awareness of gingival health. Several studies have illustrated the clinical effectiveness of gingival self-assessment (Walsh *et al.* 1985). The presence of bleeding provides immediate feedback on the level of gingival health. The dental care professional can also easily demonstrate the gingival condition to the patient, using an interdental bleeding index for this obvious clinical manifestation. This monitoring device could encourage patients to include woodsticks as part of their oral hygiene regimens.

Interdental brushes (see Box 36-5)

Interdental brushes were introduced in the 1960s as an alternative to woodsticks. They are effective in the removal of plaque from the proximal tooth surfaces

(Bergenholtz & Olsson 1984). Interdental brushes consist of soft nylon filaments twisted into a fine stainless steel wire. This "metal" wire can prove uncomfortable for patients with sensitive root surfaces. For such patients, the use of plastic-coated metal wires might be recommended. The support wire is continuous or inserted into a metal/plastic handle. Interdental brushes are manufactured in different sizes and forms. The most common forms are cylindrical or conical/tapered (like a Christmas tree).

The length of the bristles in cross-section should be tailored to the interdental space. Interdental brushes are available for the smallest to the largest interdental spaces (Fig. 36-7). Although unconfirmed in the scientific literature, it is believed that the most efficient cleaning is achieved if the brush selected is slightly larger than the embrasure space. Therefore, patients require interdental brushes of various sizes. Schmage *et al*. (1999) assessed the relationship between the interdental space and the position of the teeth. Most of the interproximal spaces in the anterior teeth were small and of an appropriate size for the use of floss. Premolars and molars have larger interproximal spaces and are accessible with interdental brushes. The brush can be inserted obliquely into the interdental space from the apical direction. As the posterior proximal spaces have wider lingual embrasures, conical-shaped interdental cleaners are not the first choice. Approaching then from the lingual side will result in more effective plaque removal, but this technique is not easy. Cleaning is performed with a back-and-forth motion. The interdental brush is the aid of choice when root surfaces with concavities or grooves have been exposed. Interdental brushes are also the most suitable cleaning devices for "through-and-through" furcation defects.

Like woodsticks, interdental brushes are easy to use, although they can have some drawbacks, including different types perhaps being needed to fit differently sized, open interproximal spaces. When not used properly, interdental brushes can elicit dentin hypersensitivity. To minimize the risk of hard tissue abrasion, interdental brushes should be used without dentifrice except in special cases, and then only for the short term. They can also be used as carriers to apply fluoride or antimicrobial agents, for example chlorhexidine gel, into the interdental space to prevent caries or the recolonization of residual pockets. Brushes should be discarded when the filaments become loose or deformed.

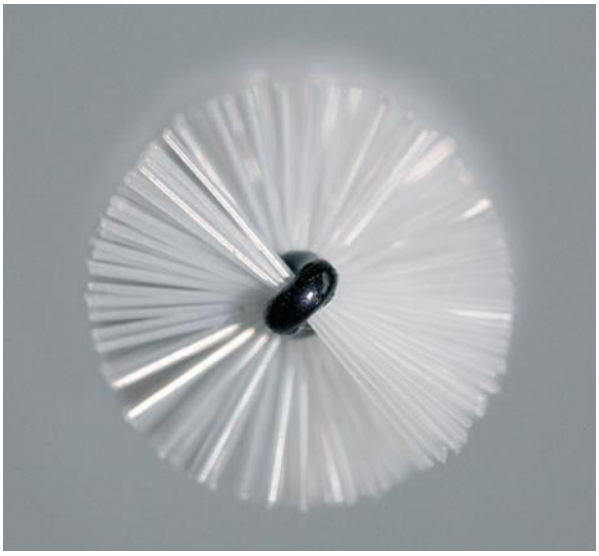

Fig. 36-7 With interdental brushes, the diameter of the metal wire core is a determining factor with regard to access. A close fit of the brushing filaments influences the cleaning capacity.

Interdental brushes represent the ideal interdental cleaning tool, especially for periodontitis patients. Waerhaug (1976) showed that individuals who habitually used interdental brushes were able to maintain supragingival proximal surfaces free of plaque and to remove some subgingival plaque below the gingival margin. In a more recent study in patients with moderate-to-severe periodontitis, Christou *et al.* (1998) demonstrated that interdental brushes were more effective than dental floss in the removal of plaque and in promoting pocket reduction. Patients reported that the use of interdental brushes was easier than using dental floss. This finding is in agreement with those of previous studies (e.g. Wolffe 1976). Additionally, the perception of efficacy was better for interdental brushes. Significantly fewer patients reported problems with using interdental brushes. Even if the efficacy of interdental brushes were not better than that of floss, the long-term use of interdental brushes might be more easily implemented in patients' routines than floss. Patient acceptance is a major issue to be considered when it comes to the long-term use of interdental cleaning devices. Interdental brushes are considered to be less time-consuming and more efficacious than floss for interdental plaque removal.

Slot *et al.* (2008) systematically reviewed the literature to determine the effectiveness in patients with gingivitis or periodontitis of interdental brushes used as adjuncts to toothbrushes in terms of plaque and clinical parameters of periodontal inflammation. The majority of the studies showed a positive significant difference in plaque index when using interdental brushes compared to floss. No differences were identified for gingival or bleeding indices. Meta-analysis revealed a significant effect with the Silness and Löe plaque index in favor of the interdental brush group compared to the floss group. Most of the included studies did not discuss the different interdental brush sizes, nor did they indicate whether interdental brushes were used in all available proximal sites. Two of the included studies showed a significant effect on pocket depth reduction with the use of interdental brushes compared to the use of floss. Jackson *et al.* (2006) proposed that the reduced pocket depth might have been related to the reduction in swelling with concomitant recession. However, the effect on pocket depth cannot readily be explained by a reduction in the level of gingival inflammation (Slot *et al.* 2008). As an alternative explanation for the observed effect,

which seems conceivable, Badersten *et al.* (13) suggested that mechanical depression of the interdental papilla is induced by interdental brushes, which, in turn, causes recession of the marginal gingiva. This result, together with the good plaque removal, could have been the origin of the improved reduction in pocket depth.

A recent development is the Soft-pick, introduced by the GUM Company (Sunstar Europe S.A., Etoy, Switzerland). Its plastic core with soft elastomeric bristles is said to massage the gum and dislodge food. It is presented as an alternative to flossing and should improve patient compliance. It has only been studied in one clinical study to date. Regarding plaque removal or gingival bleeding tendency, no significant differences were observed after 6 weeks of use compared to dental floss; however, a significant difference in favor of interdental brushes was noted (Yost *et al*. 2006).

Single-tufted/end-tufted brushes (see Box 36-6)

Single-tufted brushes have smaller brush heads, which have a small group of tufts or a single tuft. The tuft can be 3–6 mm in diameter and can be flat or tapered. The handle can be straight or contra-angled. Angled handles permit easier access to lingual and palatal aspects. The filaments are directed into the area to be cleaned and are activated with a rotating motion. Single-tufted toothbrushes are designed to improve access to the distal surfaces of the posterior molars and to tipped, rotated or displaced teeth; to clean around and under fixed partial dentures and pontic, orthodontic appliances or precision attachments; and to clean teeth affected by gingival recession and irregular gingival margins or furcation involvement. Little research has been performed with this type of brush. A cross-over study compared the single tuft to a flat-trim toothbrush. The results indicated that the single-tuft brush was effective in removing plaque from relatively hard-to-reach sites. More plaque was removed on the buccal side of the maxillary molars and on the lingual interproximal side of the mandibular molars (Lee & Moon 2001).

Adjunctive aids

Additional oral hygiene aids have been developed in an attempt to augment the effects of toothbrushing on reducing interdental plaque.

Dental water jets/oral irrigators (see Box 36-7)

The dental water jet was developed by a hydraulic engineer, John Mattingly, and a dentist, Gerald Moyer. It was introduced to the dental profession in 1962 and has been studied extensively for the past several decades. Prior to 1964, Mattingly built the units at home, and they were sold exclusively through Dr Moyer's practice. In 1964, a patient who loved the device raised thousands of dollars to help make the units available in stores. A few years later, Water Pik devices could be found in drug stores and department stores. In 2001, the American Academy of Periodontology stated, "Among individuals who do not perform excellent oral hygiene, supragingival irrigation with or without medicaments is capable of reducing gingival inflammation beyond that normally achieved by toothbrushing alone. This effect is likely due to the flushing out of subgingival bacteria". The pulsating, hydrodynamic forces produced by irrigators can rinse away food debris from interdental spaces and plaque-retentive areas. It has been reported that a pulsating stream of water is better than a continuous flow. Irrigation is not, however, a monotherapy but an adjunct designed to supplement or enhance other home oral care methods (brushing and flossing) intended for mechanical plaque removal (Hugoson 1978; Cutler *et al*. 2000) (Fig 36-8).

Husseini *et al.* (2008) performed a systematic review of the existing literature to evaluate the effectiveness of oral water irrigation as an adjunct to toothbrushing on plaque and clinical parameters of periodontal inflammation compared to toothbrushing alone or to regular oral hygiene. The heterogeneity of the data prevented quantitative analysis; therefore, a descriptive approach was undertaken. None of the included studies showed a significant difference between toothbrushing and the use of a dental water jet in combination with toothbrushing. When observing visual signs of gingival inflammation, three of the four studies reported a significant effect with the use of a dental water jet as an adjunct to regular oral hygiene. Two of the four studies showed a significant reduction in probing depth as a result of using a dental water jet as an adjunct to regular oral hygiene. The authors concluded that there is evidence that suggests a positive tendency toward improved gingival health when using a dental water jet as an adjunct to toothbrushing, as opposed to regular oral hygiene (i.e. self-performed oral hygiene without any specific instructions). A recent 4-week evaluation showed (within the limits of this short evaluation period) that when combined with manual toothbrushing, the daily use of an oral irrigator is significantly more

Fig. 36-8 Dental water jet. Fluid flow can be either continuous or pulsated.

effective in reducing gingival bleeding scores than the use of dental floss (Rosema *et al.* 2011).

The selected papers for this systematic review reported no statistically significant reduction in plaque with use of a dental water jet (Husseini *et al.* 2008). Plaque reduction is a prerequisite for an oral hygiene device to be considered valuable. Despite the lack of an effect on the plaque index, these studies did find a significant effect on the bleeding index. The mechanisms underlying these clinical changes in the absence of a clear effect on plaque are not understood. Different hypotheses have been put forward by authors to explain the results. One hypothesis is that when patients with gingivitis perform supragingival irrigation on a daily basis, the populations of key pathogens (and their associated pathogenic effects) are altered, reducing gingival inflammation (Flemmig *et al.* 1990). There is also the possibility that water pulsations alter specific host–microbial interactions in the subgingival environment and that inflammation is reduced independent of plaque removal (Chaves *et al.* 1994). Another possibility is that the beneficial activity of a dental water jet is at least partly due to removal of food deposits and other debris, flushing away of loosely adherent plaque, removal of bacterial cells, interference with plaque maturation, and stimulation of immune responses (Frascella *et al.* 2000). Other explanations include mechanical stimulation of the gingiva or a combination of previously reported factors. Irrigation can reduce plaque thickness, which might not be easily detected using two-dimensional scoring systems. This fact could explain the absence of an effect on plaque but a positive effect on gingival inflammation.

Irrigation devices can increase the delivery of fluid beneath the gingival margin (Flemmig *et al.* 1990). Greater penetration of a solution into periodontal pockets was achieved by patient-applied supragingival irrigation compared to mouth rinsing (Flemmig *et al.* 1995). Studies evaluating the capacity of supragingival irrigation to project an aqueous solution subgingivally have determined that supragingival irrigation with a standard irrigation tip was capable of delivering water or a medicinal fluid 3 mm subgingivally or to approximately half the probing depth of a 6-mm pocket (Larner & Greenstein 1993). Irrigation devices can be used with water or with disinfectant solutions (Lang & Räber 1982). The use of chlorhexidine in suboptimal concentrations (e.g. 0.06%) has resulted in improved plaque inhibition and has had anti-inflammatory effects (Lang & Räber 1982; Flemmig *et al*. 1990).

Success with pulsating oral irrigators with regular tips is limited to the subgingival area and periodontal pockets (Wennström *et al*. 1987). With a specially designed tip (Pik Pocket® subgingival irrigation tip; WaterPik Technologies, Fort Collins, CO, USA), the pulsating stream of fluid can penetrate more deeply into the pocket areas (Cobb *et al*. 1988). These blunt-ended cannulas can also be used to inject antimicrobial agents into shallow-to-moderate periodontal pockets.

Supragingival irrigation applies considerable force to the gingival tissues. Irrigation was shown to have the potential to induce bacteremia. However, given the collective evidence, it appears that irrigation is safe for healthy patients (Husseini *et al.* 2008).

A recent development (2010) is the Sonicare AirFloss (Philips Oral Healthcare, Snoqualmie, WA, USA), which uses a spray of microbubbles and a small dose of fluid to generate the interdental cleaning action, through which it is claimed it disrupts plaque biofilm structures. The nozzle tip is designed to act as a guide to the spaces between teeth. Two studies have reported that the oral irrigator is significantly more effective than the AirFloss in reducing plaque and gingivitis (Sharma *et al.* 2012a, b). There is clearly a need for more published clinical research studies regarding this device to establish its clinical value.

Tongue cleaners (see Box 36-8)

Regular tongue cleaning has been used since ancient times and is still used by the native populations of Africa, the Arab countries, India and South America. Many ancient religions emphasized the cleanliness of the entire mouth, including the tongue. Indian people's daily ritual of oral hygiene was not confined to brushing of the teeth; the tongue was also scraped, and the mouth was rinsed with concoctions of betel leaves, cardamom, camphor or other herbs.

The dorsum of the tongue, with its papillary structure, furrows and crypts, harbors a great number of microorganisms. It forms a unique ecologic oral site with a large surface area (Danser *et al*. 2003). The tongue is said to act as a reservoir, which permits the accumulation and stagnation of bacteria and food residues (Outhouse *et al*. 2006). Tongue bacteria can serve as a source of bacterial dissemination to other parts of the oral cavity, for example the tooth surfaces, and can contribute to dental plaque formation. These bacteria make the greatest contribution to the bacteria found in the saliva. Therefore, tongue brushing has been advocated as part of daily home oral hygiene, together with toothbrushing and flossing (Christen & Swanson 1978). Tongue brushing has also been advocated as a component of the so-called "full-mouth disinfection" approach in the treatment of periodontitis, with the aim of reducing possible reservoirs of pathogenic bacteria (Quirynen *et al*. 2000).

A large variety of tongue cleaners are commercially available. A modern tongue-scraping instrument can consist of a long strip of plastic ribbon. This strip is held in both hands and is bent so that the edge can be pulled down over the dorsal surface of the tongue. Brushing also appears to be an easy method of cleaning the tongue, provided that the gag reflex can be controlled. However, in a systematic review, it was concluded that scrapers or cleaners are more effective than toothbrushes for tongue cleaning

(Outhouse *et al*. 2006) and with them the gag reflex is reduced (Van der Sleen *et al.* 2010). Patients should be informed that it is most important to clean the posterior portion of the tongue dorsum, but in reality, it is likely that many patients do not reach far enough to contact the posterior dorsum during tongue cleaning because extended reaching causes the gag reflex.

Tongue cleaning is a simple and fast procedure that helps to remove microorganisms and debris from the tongue. When tongue cleaning is practiced on a daily basis, the process becomes easier. Eventually, the patient can indeed feel "unclean" when tongue debris is not removed on a regular basis. In a study by Gross *et al.* (1975), the test group was instructed to brush the tongue as an adjunct to normal oral hygiene measures. The control group was not instructed to clean the tongue. A reduction of 40% in the presence of tongue coating was noted in the test group compared to the control group.

Some studies have shown that tongue brushing, in combination with other methods of oral hygiene, is an effective method for reducing the formation of dental plaque. In contrast, Badersten *et al.* (1975) found no difference in *de novo* plaque accumulation between a 4-day period of tongue brushing and a 4-day period of no oral hygiene procedures. The authors suggested that the majority of the important plaque-forming bacteria might not originate from the tongue. Another reason for not finding an effect of tongue brushing on plaque formation might be that brushing the posterior part of the dorsum of the tongue is difficult due to inaccessibility and discomfort.

Yaegaki and Sanada (1992) observed six times more tongue coating in patients with periodontal problems than in those who were periodontally healthy. Consequently, individuals with periodontal diseases will likely present with microbial flora more favorable to exacerbating the formation of volatile sulfur compounds than healthy individuals. Over the years, oral malodor has become a topic of interest to both the scientific community and to people who suffer from it. Regular mechanical tongue cleaning can play a role in controlling bacterial numbers and removing tongue coating. Individuals with coated tongues showed significantly higher malodor scores than individuals with non-coated tongues (Quirynen *et al.* 2004). Van der Sleen *et al.* (2010) demonstrated in their systematic review that mechanical approaches, such as tongue brushing or tongue scraping, to clean the dorsum of the tongue have the potential to reduce tongue coating and oral malodor. This systematic review detected only one study that included patients with chronic oral malodor, with an unknown evaluation period and a high potential risk of bias. This study stood in contrast to the other included studies, which evaluated the effect of tongue cleaning in cases of morning bad breath. Consequently, no firm statement can be made as to whether mechanical tongue cleaning contributed to a reduction in oral halitosis. More research is needed to assess the effect of mechanical tongue cleaning, particularly in true halitosis populations.

Foam brushes, swabs or tooth towelettes

Tooth towelettes are being marketed as a method of plaque removal when toothbrushing is not possible. Their use is not meant to replace a daily toothbrushing regimen.

Finger brushes, such as the I-Brush®, are mounted on the index finger of the brushing hand and use the agility and sensitivity of the finger to clean the teeth. Consequently, the pressure with which they are applied can be well controlled because the finger can actually feel the tooth and gingival surfaces and help position the brush for more effective scrubbing. During a 3-week clinical trial (Graveland *et al*. 2004), no adverse effects were found with the I-Brush®. The results showed that the finger brush removed less plaque than a regular manual toothbrush. In particular, proximal plaque reduction was poor in comparison with manual toothbrushing. Based on these results, it was concluded that there were no beneficial effects of the finger brush in comparison with regular manual toothbrushes.

Foam brushes resemble a disposable soft sponge on a stick, and they have been dispensed to hospital patients for intraoral cleansing and refreshing since the 1970s. They are used in particular for oral care in medically compromised and immunocompromised patients to reduce the risk of oral and systemic infection (Pearson & Hutton 2002). Lefkoff *et al.* (1995) studied the effectiveness of such a disposable foam brush on plaque. In this study, regular manual toothbrushes were found to be significantly more effective in retarding the accumulation of plaque from a plaque-free baseline on both facial and lingual surfaces. However, the foam brush did show some plaque-preventive capabilities by maintaining plaque formation below 2 mm at the cervical margin of the tooth. Nevertheless, according to most authors, foam brushes should not be considered a substitute for regular toothbrushes. In a study by Ransier *et al.* (1995), foam brushes were saturated with a chlorhexidine solution. The authors found foam brushes that had been soaked in chlorhexidine to be as effective as regular toothbrushes in controlling plaque and gingivitis levels. Therefore, if hospitalized patients cannot use a toothbrush, an alternative could be the use of chlorhexidine applied with a foam brush.

Dentifrices

The use of a toothbrush is usually combined with that of a dentifrice, with the intention of facilitating plaque removal and applying agents to the tooth surfaces for therapeutic or preventive reasons, to produce fresh breath, and to make the toothbrushing procedure more pleasant. The term dentifrice is derived from the Latin words *dens* (tooth) and *fricare* (to rub). A simple, contemporary definition of a dentifrice is a mixture

used on the tooth in conjunction with a toothbrush. Dentifrices are marketed as powders, pastes, and gels. Dentifrice was used as early as 500 BC in both China and India; modern toothpastes were developed in the 1800s. In 1824, a dentist named Peabody was the first person to add soap to toothpaste. John Harris first added chalk to toothpaste in the 1850s. Colgate mass-produced the first toothpaste in a jar. In 1892, Dr Washington Sheffield of Connecticut manufactured toothpaste in a collapsible tube (Dr. Sheffield's Creme Dentifrice). Advancements in synthetic detergents made after World War II have allowed the replacement of the soap used in toothpaste with emulsifying agents, such as sodium lauryl sulfate. Later, fluoride was added.

Traditionally, it was believed that dentifrices should contain an abrasive. The addition of abrasives supposedly facilitated plaque and stain removal without producing gingival recession/tooth abrasion or altering the remaining components of the dentifrice. For many decades, abrasive systems, such as calcium carbonate, alumina, and dicalcium phosphate, have been used. Today, most dentifrices contain silica. Although more expensive, silica can be combined with fluoride salts, and it is very versatile. It has also been shown to increase the abrasiveness of dentifrices, resulting in even more plaque removal (Johannsen *et al.* 1993).

Conflicting reports have been published concerning the added value of using dentifrice for plaque removal. Studies by de la Rosa *et al.* (1979) and by Stean and Forward (1980) validated the use of dentifrice because they found that there was a reduction in plaque growth after brushing with a dentifrice as opposed to brushing with water. Similarly, Eid and Talic (1991) reported overall reductions in plaque of 67% for manual toothbrushing with a dentifrice and 59% for toothbrushing with water. In contrast, in a study by Gallagher *et al.* (2009), the use of 1.5 g of dentifrice showed no additional effect after 1 minute of brushing compared to brushing without dentifrice. Paraskevas *et al.* (2006) also studied whether dentifrice had a beneficial effect on plaque removal and whether an abrasive additive was a contributor. Their results showed that among 40 subjects using three different hydrated, silica-based dentifrices in a cross over study, the difference in abrasiveness (RDA 80 and 200) did not play a role in plaque removal. Moreover, significantly more plaque (3%) was removed when the brushing procedure was performed without dentifrice. In another study by Paraskevas *et al.* (2007), the group that used dentifrice removed a significant 6% less plaque compared to the group that did not use dentifrice. Furthermore, in a study by Jayakumar *et al.* (2010), a 9% difference in plaque removal, in favor of the non-dentifrice group, was observed. The results of a recent study by Rosema *et al.* (2013) showed a difference in plaque removal of 2% in favor of the non-dentifrice group. Although this difference in plaque score reduction did not reach the level of significance, it is noteworthy that the use of dentifrice did not seem to increase the amount of "instant" plaque removal (i.e. the immediate effect of brushing, as opposed to prolonged effects beyond the brushing exercise). These results are also supported by a report from the ADA Division of Science (American Dental Association 2001), which accepts that "plaque removal is associated minimally with abrasives." The effectiveness of plaque removal during toothbrushing with dentifrice appears to be essentially a function of the access of brush filaments, rather than dentifrice abrasives (Gallagher *et al.* 2009).

Another factor that might be involved in the process of plaque removal is the detergent (or surfactant) contained in the dentifrice formulation. Detergents are surface-active compounds that are added to the formulation because of their foaming properties. This foaming effect could be beneficial in clearing loosened plaque from the teeth and also in providing the pleasant feeling of cleanness. Today, dentifrice formulations also contain ingredients that could help improve oral health. Fluoride is almost omnipresent in commercially available toothpastes. Problems with dentifrice formulation have involved finding compatible constituents to combine with the active ingredients in dentifrice formulas. Over the years, many dentifrice formulations have been tested and become well established because of their antiplaque and/or antigingivitis properties. For additional information, see Chapter 37.

Some substances in dentifrices can induce local or systemic side effects. Chlorhexidine in dentifrices can foster tooth staining. Pyrophosphates, flavorings, and detergents, especially sodium lauryl sulfate which is present in most commercially available dentifrices, have been implicated as causative factors in certain oral hypersensitive reactions, such as aphthous ulcers, stomatitis, cheilitis, burning sensations, and oral mucosal desquamation. In such cases, the dental professional should identify these conditions and advise the patient to discontinue use of the suspected dentifrice.

Side effects

Brushing force

In a study evaluating toothbrushing habits in unin-structed adults, the mean brushing force was 2.3 ± 0.7 N, with a maximum of 4.1 N (Ganss *et al.* 2009a). Brushing force with electric toothbrushes has consistently been shown to be lower than that with a manual toothbrush (by approximately 1.0 N) (Van der Weijden *et al.* 1996c). McCracken *et al.* (2003) observed, for a range of pressures from 0.75 to 3.0 N, that the improvement in plaque removal when forces in excess of 1.5 N with an electric toothbrush were used was negligible. In a feedback study, a professional brusher was asked to brush with a pressure of 1.0 N, 1.5 N, 2.0 N, 2.5 N, and 3.0 N, during which time the efficacy with regard to brushing force was determined. An increase in efficacy was observed when

the brushing force was raised from 1.0 N to 3.0 N (Van der Weijden *et al*. 1996c). Hasegawa *et al.* (1992) evaluated the effects of different toothbrushing forces on plaque reduction by brushing at 100-g force intervals on a scale from 100 to 500 g. The results of their study corroborated the findings of earlier studies that with increasing force, more plaque is removed. In addition, they observed that 300 g seemed to be the most effective brushing force when using a manual toothbrush for both children and adults. Forces exceeding 300 g caused pain and gingival bleeding in the test patients. As shown in a manual brushing study in which efficacy was plotted against brushing force, the relationship between force and efficacy does not appear to be linear (Van der Weijden *et al*. 1998a). Using a manual toothbrush, a positive correlation was identified between efficacy and force (up to 4.0 N). The greater the force used, the more effective was the plaque removal. However, efficacy decreased when forces of >4.0 N were used. Indeed, there appeared to be a negative correlation. The hypothesis is that this negative correlation was due to the distortion of the brushing filaments. Beyond 4.0 N, brushing was no longer performed with the tip of the filament but, due to bending, with its side, indicating that brushing force is not the sole factor that determines efficacy. Other factors, such as the action of the brush, the size of the brush head, brushing time, and manual dexterity, could be of greater importance.

Excessive brushing force has been mentioned as a factor that is partly responsible for toothbrush trauma (gingival abrasion). For patients who use excessive force, manual and electric toothbrush manufacturers have introduced toothbrush designs that can limit the amount of force used and thus reduce the chance of damage to soft and hard tissues. However, there is no linear correlation between brushing force and gingival abrasion. A recent *in vitro* experiment revealed that under severe erosive conditions, neither total mineral loss nor the spatial loss of mineralized dentin (measured using profilometry) significantly increased after brushing, regardless of the force applied. The demineralized organic dentin matrix was strikingly resistant to mechanical impact, although it was compressed with greater brushing forces (Ganss *et al.* 2009b).

Mierau and Spindler (1989) performed a quantitative assessment of patterns of toothbrushing habits in 28 subjects over nine sessions. The least variations among individuals were observed with regard to brushing force. Brushing force ranged from 1.0 to 7.4 N between individuals. The authors did not observe any (visual) lesions from brushing in those individuals using a brushing force of <2 N. If the brushing force was >2 N, co-factors such as brushing time, brushing method, and frequency of brushing appeared to be associated with acute brushing lesions. Burgett and Ash (1974) argued that the potentially detrimental effect of brushing is related to the force applied at a particular point, that is the pressure. It should be recognized that the head of a manual brush is larger than the head of an electric brush. Because the forces are given as a total of the force over the entire brush, it could be that the unit pressure is less for manual brushes than for electric brushes. Van der Weijden *et al.* (1996c) observed no difference in pressure between soft manual (11.32 g/mm^2) and electric toothbrushes (11.29 g/mm^2), demonstrating that the pressures for the electric and the manual brushes were similar.

Toothbrush abrasion

Because various mechanical products are used in personal control of supragingival plaque, the possibility exists that some deleterious effects can occur as a consequence of these oral hygiene practices (Echeverría 1998). The simple act of removing deposits from teeth requires that the toothbrush–dentifrice combination possess some level of abrasiveness. The filaments must have a sufficient degree of stiffness to create abrasion to dislodge plaque deposits. This stiffness must be balanced against potentially detrimental effects on dental hard and soft tissues. The wear on a tooth consists of a combination of attrition (tooth-to-tooth contact wear), erosion (acid-mediated surface softening), and abrasion (wear because of toothbrushing with toothpastes). Toothbrush abrasion is modified by toothbrush filament stiffness (Wiegand *et al.* 2008).

It has long been known that toothbrushing can have some unwanted effects on the gingiva and hard tooth tissues (Kitchin 1941). Trauma to hard tissues leads to cervical abrasion of the tooth surfaces (Fig. 36-9). These lesions have been associated with toothbrush stiffness, the method of brushing, and brushing frequency. Cervical tooth abrasions have a multifactorial etiology, but in most cases, they are the consequence of toothbrushing with excessive brush pressure and an excessive number of toothbrushing episodes/time. Both situations are likely linked to personality traits (*compulsive brushers*). Tooth wear has also been associated with toothbrush characteristics, especially with the finishing and hardness of the filaments (Fishman 1997). It has been stated that hard tissue damage is mainly caused by the abrasives in dentifrice (Axelsson *et al*. 1997; Meyers *et al*. 2000). The capacity of a toothbrush to hold and move polish/abrasive over the tooth surface particularly affects the amount of hard-tissue abrasion. In a recent study, the influence of the type of toothbrush was negligible when water was used as a substrate, but when toothpaste was added: the abrasion values diverged by more than ten-fold depending on the toothbrush. A softer toothbrush might have caused similar or even more abrasions than a harder brush (Tellefsen *et al.* 2011).

In many instances, *tooth abrasion* is found in combination with *gingival recession*. Whereas gingival recession is associated with different etiologic/risk factors, for example periodontal inflammation, smoking, gingival biotype or repeated periodontal instrumentation, inadequate use of the toothbrush is likely the most significant cause (Björn *et al*. 1981). Clinical

Fig. 36-9 (a) Soft tissue damage as a result of extensive toothbrushing. Note the gingival recession on the buccal gingival surface of tooth 13. (b) Note the multiple ulcerations of the buccal gingival margin in the right maxilla. (c, d) Hard tissue damage (arrows) has resulted after extensive use of interdental brushes.

experience supports the idea that, with improper use, toothbrushing can cause superficial damage to the gingival tissues. Patients with good oral hygiene have been found to have more gingival recession and more dental abrasions than patients with poor oral hygiene. Unfortunately, there have been few studies in the dental literature concerning gingival lesions resulting from toothbrushing. Thus, the extent to which oral hygiene procedures can traumatize the gingival tissues is not clear.

Gingival abrasions as a result of brushing are often reversible, localized, superficial lesions. It is unlikely that gingival abrasion is induced by a single factor. One factor, which has already been mentioned as related to gingival abrasion, is brushing force. In the literature, other factors have been suggested, such as brushing method (e.g. the Bass method), abusive toothbrush use, toothbrushing duration, manual or powered toothbrushing, toothbrush grip, brush head shape, stiffness of the filaments, end-rounding of toothbrush filaments, and toothbrushing frequency (Van der Weijden & Danser 2000).

Toothbrushes with hard bristles remove plaque better but can also cause more soft-tissue trauma compared to brushes with softer bristles. Zimmer *et al.* (2011) investigated the effectiveness and potential harmfulness of manual toothbrushes of the same type but with different bristle stiffnesses. Based on their observations, they suggested that for subjects with poor oral hygiene, a toothbrush with hard bristles should be considered. If a patient already shows soft tissue damage, a soft toothbrush should be recommended. If the patient cannot be classified, a toothbrush with medium stiffness might be the solution (Versteeg *et al.* 2008a). Sharp-edged and unacceptably rounded filament tips represent a greater threat to dental tissues. Breitenmoser *et al.* (1979) evaluated the effects of filament end forms on the gingival surface. It was found that manual toothbrushes with cut filament ends resulted in significantly greater gingival lesions than rounded ends. Further research has shown in several studies that filaments with sharp edges can cause soft tissue injury. The depth of epithelial lesions caused by toothbrushing was influenced by the quality of filament end-rounding (Plagmann *et al.* 1978). Non–end-rounded filaments were approximately twice as abrasive to soft tissues as rounded filament tips (Alexander *et al.* 1977).

The pattern of toothbrushing is that most right-handed people begin on the buccal surfaces of the anterior teeth on the left side. Accordingly, the most severe gingival recession and abrasion defects are localized to the buccal surfaces on the left side (MacGregor & Rugg-Gunn 1979).

Interestingly, there has been little debate regarding the role of dentifrice in the abrasion of soft tissues. This fact is somewhat surprising when abrasion of dental hard tissues is almost entirely a function of dentifrice. Detergents in dentifrice, agitated over a mucosal surface, can enhance the removal of the protective salivary glycoprotein layer and exert cytotoxic action on the overlying epithelial cells (Addy & Hunter 2003). No statistically significant differences in the incidence of gingival abrasions were identified between brushing with dentifrice or without dentifrice (Versteeg *et al*. 2005; Rosema *et al.* 2013). This finding was in agreement with those of Alexander *et al.* (1977), who used hamster cheek pouch tissue that was brushed mechanically for various intervals. The results showed that the dentifrice/polishing agent applied to the tissue with a brush did not increase the abrasive effects of the brush (using protein removed during brushing as an index of tissue abrasion). Meyers *et al.* (2000) investigated the effects of three commercially available dentifrices on tooth and gingival surfaces by means of scanning electron microscopy (SEM) quantification. The results indicated that none of the dentifrices tested was harmful to teeth or soft tissues.

Importance of instruction and motivation in mechanical plaque control

A fundamental principle for all preventive action is that the effect is greatest when the risk of the development of disease is greatest. Needs-related instruction in oral hygiene should therefore aim to intensify mechanical plaque removal on those individual teeth and surfaces that are at risk. A prerequisite for establishing needs-related tooth-cleaning habits is a well-motivated, well-informed, and well-instructed patient (Axelsson 2004). Mechanical plaque control demands active participation of the individual subject; therefore, the establishment of proper home oral care habits is a process that greatly involves and depends on behavioral changes. When implementing behavioral changes, dental professionals should try to ensure that the patient recognizes his/her oral health status and the role of his/her personal oral hygiene procedures in the prevention of caries and periodontal diseases. The patient should be informed about the casual relationship that led to the disease process and should be encouraged to take responsibility for his/her own oral health. The dental team has numerous opportunities to demonstrate to the patient the soft tissue alterations elicited by inflammation and the responsible etiologic factors. Most commonly, as with sports coaching, a one-to-one professional–patient approach should be employed.

Many patients spend too little time brushing, or they brush haphazardly. The importance of thorough plaque removal should be stressed. Toothbrushing instruction for a patient involves teaching what, when, where, and how. A recommended toothbrushing regimen should take into account the characteristics of the toothbrush and dentifrice, and the individual's behavior with regards to brushing frequency, duration, pattern, force, and method. Toothbrushing habits are locally acquired at home and can be supplemented periodically with more formal instruction from the dental professional. In addition, instruction should also involve a description of specific toothbrushing methods, the grasp of the brush, the sequence and amount of brushing, the areas of limited access, and supplementary brushing for occlusal surfaces and the tongue. The possible detrimental effects from improper toothbrushing and variations for special conditions can be described (Wilkins 1999). The design of toothbrushes or a specific toothbrushing method is of secondary importance to the skills of the individual in using the brush (Frandsen 1986). The simplest, least time-consuming procedures that will effectively remove bacterial plaque and maintain oral health should be recommended. If a patient prefers a specific oral hygiene strategy, the clinician can evaluate this and modify the technique to maximize effectiveness rather than changing it. Although it is necessary to give all patients honest feedback on their plaque removal efforts, it is also important to reward positive performance and not entertain unrealistic expectations, so that the patient will not dread each maintenance visit.

Oral hygiene instruction should also include components such as self-assessment, self-examination, self-monitoring, and self-instruction. With this purpose, several devices and chemical agents have been used to make dental plaque more evident to the patient. The interested patient can be informed and motivated, for example, through the use of disclosing agents to visualize plaque at the gingival margin or in the interdental spaces. Disclosing agents are chemical compounds, such as erythrosine, fuchsine or fluorescein-containing dye, that stain dental plaque and thus make it fully evident to the patient using either regular or ultraviolet light. Erythrosine has been used for many years as a means of motivating patients and evaluating the effectiveness of oral hygiene, and it has received Food and Drug Administration (FDA) approval (Arnim 1963) (Fig. 36-10). When applied immediately before toothbrushing, the patient can identify the amount of plaque formed since the last toothbrushing episode, thus receiving immediate feedback about his/her cleaning performance. This procedure is useful during the early phase of plaque control. Later, the disclosing agent should be applied after toothbrushing, which allows the patient to identify those areas needing additional cleaning efforts. Disclosing solution is available in liquid and tablet forms. The liquid form might offer some advantages in that the operator can ensure that all surfaces are adequately covered. Red disclosing solution remains in the mouth for some time and can temporarily stain the lips and gingiva. This may create an esthetic

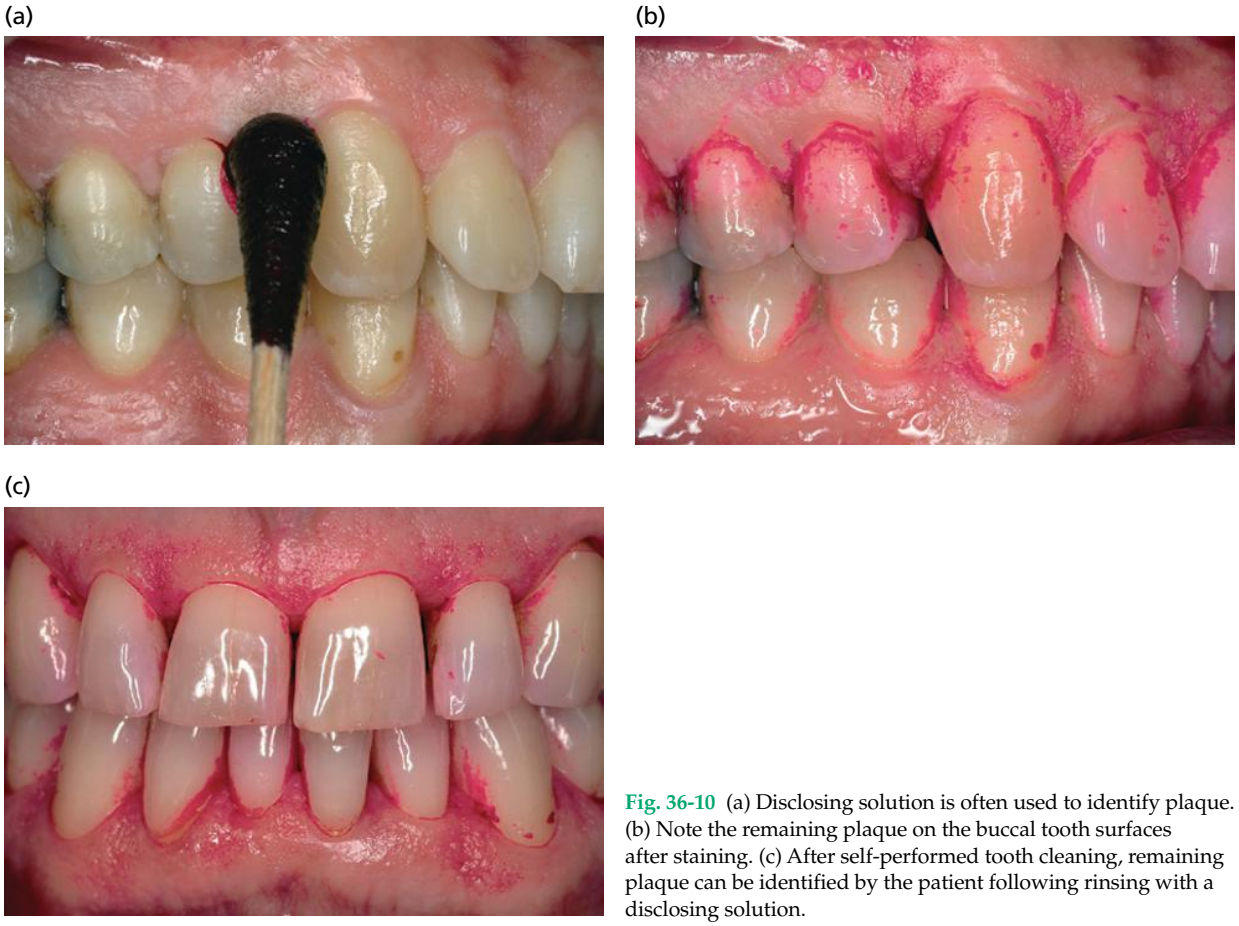

Fig. 36-10 (a) Disclosing solution is often used to identify plaque. (b) Note the remaining plaque on the buccal tooth surfaces after staining. (c) After self-performed tooth cleaning, remaining plaque can be identified by the patient following rinsing with a disclosing solution.

problem for some patients, but can be eliminated by protecting the lips with petroleum jelly. Two-tone agents (containing methylene blue and erythrosine) are also available that distinguish an old plaque accumulation from a more recent one.

Disclosing plaque in the patient's mouth is usually not sufficient to establish good oral hygiene habits. Other factors might influence the individual to modify or determine his/her behavior. These factors could be more or less beyond the control of the dental professional (such as social and personal factors, environmental settings, and past dental experiences), or they may lie within the control of the professional (such as the conditions of treatment and the instruction and education of the patient). All of these factors should be considered in the design of an individualized oral hygiene program.

A variety of methods can be used to deliver advice and instructions. The effects of various oral hygiene instruction programs, administered individually or in groups, have been evaluated in a number of clinical studies. These studies have evaluated whether instruction given during one visit only is similar to step-by-step instruction provided over several visits, and whether the use of pamphlets or videotapes is superior to self-instruction manuals and to personal instruction given by a dental professional. In a study by Renton-Harper *et al.* (1999), an instructional video for an oscillating rotating electric toothbrush was evaluated. The subjects who followed the instructional video benefited significantly and considerably in terms of plaque removal compared to subjects who received only written instructions. Different types and amounts of feedback given to the patients using disclosed plaque scores and phase-contrast demonstrations have also been investigated. These studies have usually reported similar improvements in plaque and gingivitis scores, irrespective of the mode of instruction. However, these results should be interpreted with caution because the subjects participating in these studies were examined at regular intervals; therefore, it is difficult to separate the effects of repeated examinations from the effects of the instructions (Renvert & Glavind 1998).

If oral hygiene motivation, information, and instruction are combined with professional tooth cleaning, the effects in terms of reduction of plaque levels and levels of gingival inflammation can persist even after 6 months. A systematic review concluded, based on ≥6-month–long studies, that a single oral hygiene instruction describing the use of a mechanical toothbrush, in addition to a single professional "oral prophylaxis" provided at baseline, had significant, albeit small, positive effects on the reduction of gingivitis (Van der Weijden & Hioe 2005).

Rylander and Lindhe (1997) recommended that oral hygiene instruction be provided over a series of

visits, allowing for the possibility of giving the patient immediate feedback and reinforcing the patient in his/her home oral care activities. The protocol below is based on the one used in several clinical trials by Lindhe and Nyman (1975), Rosling *et al.* (1976) and Lindhe *et al.* (1982) in which the role of plaque control in preventing and arresting periodontal diseases was clearly demonstrated.

First session

1. Apply a plaque-disclosing solution to the teeth and, with the aid of a hand mirror, demonstrate all sites with plaque to the patient (see Fig. 36-10b). The plaque score should be recorded using a plaque control record (Fig. 36-11).
2. Ask the patient to clean his/her teeth using his/her traditional technique. With the aid of a hand mirror, demonstrate the results of the toothbrushing to the patient, again identifying all sites with plaque (see Fig. 36-10c).
3. Without changing the technique, ask the patient to clean the surfaces with plaque.

Depending on the plaque remaining after this second toothbrushing, the dental professional should either improve the technique or introduce an alternative system of toothbrushing. So as not to overload the patient with too much information during the first session, the use of adjunctive devices for interproximal cleaning can be introduced or improved in the second session.

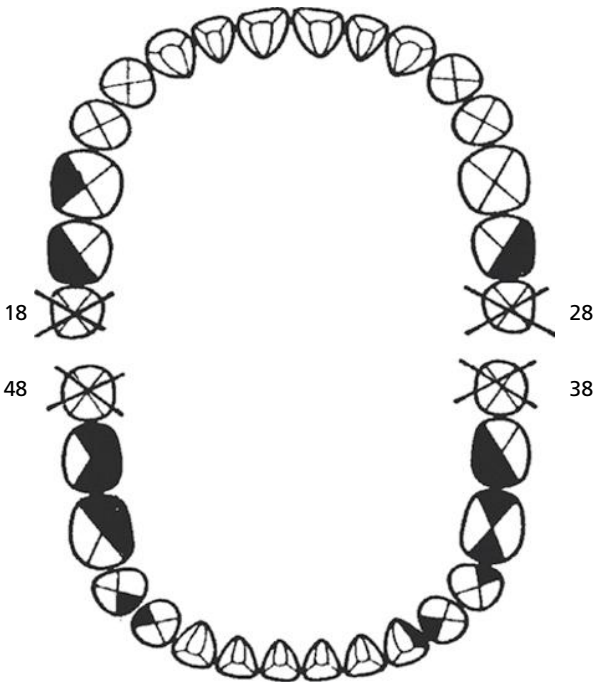

Fig. 36-11 Chart showing the teeth and tooth surfaces in the maxilla and mandible. The distribution of tooth surfaces with dental plaque (shadowed areas) is identified. In this case, the plaque score is 17%.

Second session

1. A few days after the first session, the disclosing solution is again applied. The results, in terms of plaque deposits, are identified in the mouth, recorded in the plaque control record, and discussed with the patient.
2. The patient is then invited to clean his/her teeth, according to the directions previously provided during the first session, until all staining is removed. In many cases, toothbrushing instructions will need to be reinforced. Positive recognition should be given to the patient at the same time.

If necessary, the use of interproximal cleaning aids can now be introduced or improved.

Third and subsequent sessions

1. One or 2 weeks later, the procedure used in the second session is repeated. However, the efficacy of self-performed plaque control should be evaluated and presented to the patient at each appointment. This repeated instruction, supervision, and evaluation aims to reinforce the necessary behavioral changes.

The long-term results of oral hygiene instruction are dependent on behavioral changes. Patients might fail to comply with given instructions for many reasons, ranging from unwillingness to perform oral self-care, poor understanding, lack of motivation, poor dental health beliefs, and unfavorable dental health values due to stressful life events or poor socioeconomic status. Although the use of behavior-modification techniques can offer an advantage over traditional instruction techniques, there is limited research in this area to clarify the relationship between health beliefs and compliance.

Conclusion

- Ultimately, the goal of a patient's self-care program is to prevent, arrest, and control periodontal disease and caries. The patient's ability to remove plaque from all areas, including interproximal areas, is an essential part of this.
- Oral hygiene instruction should be tailored to each individual patient on the basis of his/her personal needs and other factors.
- The patient should be involved in the instructional process.
- An individualized maintenance program should follow basic oral hygiene instruction.

All of the figures illustrating the procedures in Boxes 36–1 to 36–8 are used with permission from the Paro Praktijk Utrecht.

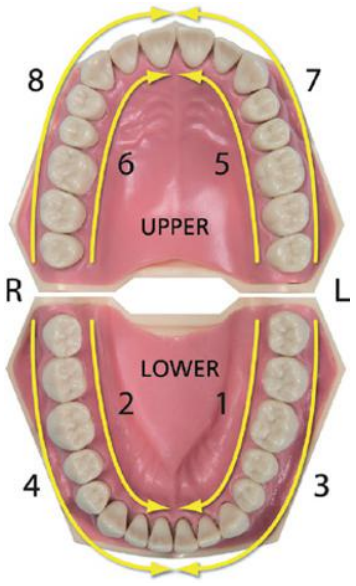
Box 36-1 Instructions for manual toothbrushing.

It is of the utmost importance, in addition to using the correct toothpaste and also brushing for at least 2 minutes, to brush the teeth in a set sequence. This technique prevents certain areas from being missed. Areas untouched by the brush will allow plaque to continue to grow. Try to choose a brush with medium or soft bristles and a small head.

Instructions

- Hold the brush firmly and place the bristles at an angle against the edge of your gums (use a 45° angle). Take care to ensure that the bristles are in contact with a small part of the gum margin.
- Place the brush against the molar or tooth at the back of the mouth and make short back-and-forth scrubbing movements. Brush from the back to the front of the mouth, and try to overlap the strokes. Do not brush more than two teeth simultaneously. Always start at the back and work slowly forward.
- Always hold the brush head horizontally when cleaning the outside surfaces of the teeth. It is easier to hold the head vertically when brushing the inside surfaces of the top and bottom teeth.
- Avoid too much pressure and fast movements, and be aware of feeling contact with the gum margin. Also, avoid brushing too vigorously, thereby preventing damage to the gums.

When cleaning the teeth, keep using the same sequence of brushing. For example, brush the inside of the lower left jaw (15 seconds) and then the inside right (15 seconds). Then, brush the left on the outside (15 seconds), followed by the right on the outside (15 seconds). Repeat the same sequence in the upper jaw. Finally, brush the chewing surfaces with small scrubbing movements. Replace the brush when the bristles start to bend or splay.



Box 36-2 Instructions for electric (power) toothbrushes.

The importance of using a set sequence of brushing movements is applicable when using an electric toothbrush. The question of whether or not an electric brush is better than a manual one has been asked many times. Both brushes allow a high level of oral hygiene to be achieved. However, research has shown that electric toothbrushes are more efficient, and many people report that they are easier to use.

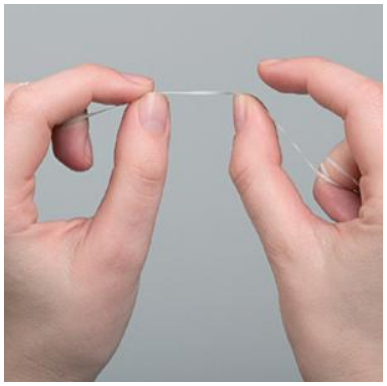
Instructions

- Place the brush firmly on the hand piece. Grip the brush in the palm so that the bristles of the head are somewhat angled toward the gums (at an angle of approximately 70°). Try to allow the longer bristles to penetrate between the teeth, and take care that the bristles contact your gums.
- Switch on the brush, place the head on the last tooth in the mouth (check the angle), and move the head gradually (over approximately 2 seconds) from the back to the front of this tooth.
- Try to follow the contours of both the teeth and the gums. Place the brush head on the next tooth, and repeat this process.
- Allow the electric toothbrush to do the work. It is not necessary to press hard or make brushing movements.
- Use a timer! Many brushes will provide some form of signal after 30 seconds (the apparatus stops for a moment). This is the point at which to move on to a new part of the mouth.

Remember to clean the brush and its head thoroughly when finished.

Box 36-3 Instructions for use of dental floss.

The use of dental floss has become part of oral care, in addition to correct, more frequent, and longer tooth brushing. Floss can be purchased in a variety of thicknesses and types and with or without a layer of wax. If there is sufficient space between the front and back teeth, it is advisable to use the somewhat thicker tape rather than the thinner floss.



Instructions

- Take approximately 40 cm of floss and wind the ends loosely around the middle fingers. Allow for 10 cm between the middle fingers. Then, hold the floss taut between the thumb and first finger so that roughly 3 cm remains between the thumbs. Alternatively a loop or circle of dental floss can be created.
- Using a sawing movement, allow the tightly stretched piece of floss to pass between the contact of the front and back teeth. This action might be difficult where the teeth are so close together that the space between them is limited. Avoid allowing the floss to slip so quickly between the teeth because through this "snapping" the gums may be damaged.
- Stretch the floss in a "U" shape around one of the teeth, press firmly against the side of the tooth surface and carefully allow the floss to pass just under the gum, once again with a sawing movement.
- Draw the floss up to the contact point with a sawing movement, and then repeat the process on the other tooth bordering the space filled with gum tissue.
- Remove the floss from between the teeth, once again with a sawing movement, and repeat this process for all of the other spaces in the mouth.
- Use a clean piece of floss for each separate space by unwinding part of it from around one middle finger while winding it around the other middle finger.

Do not worry if at first your gums bleed slightly. This bleeding will stop after using the floss a number of times. Do not give up!

Box 36-4 Instructions for use of woodsticks.

Most adults have sufficient space available between the incisors and molars to allow woodsticks to be used. These sticks come in differing thicknesses, they are made from wood, and they have a triangular cross-section, mimicking the shape of the space between the teeth. Woodsticks can only be used once and are ideal for use when you have a few spare moments – for example, when sitting in traffic!

Instructions

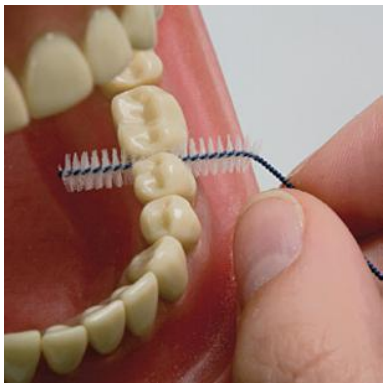
- Hold the woodstick firmly between the thumb and first finger, roughly halfway along its length. When possible, place the other fingers for support on the chin. Moisten the tip of the woodstick by sucking on the point of it, thus making it softer and more flexible.
- Place the flat side of the woodstick (i.e. not the sharp side) against the gum. In the upper jaw, the flat surface will face upward, and in the lower jaw, it will face downward.
- Push the woodstick firmly from the outer side of the space into the space until the stick just becomes wedged. Then, pull it back slightly, and push it back once again, using a light, sawing motion at right angles to the outer surfaces of the teeth. Light pressure can also be applied simultaneously to the gums. Repeat this action a few times, angling the woodstick to contact the surfaces of the teeth enclosing the space.
- When using a woodstick between the premolars and molars, close the mouth slightly to reduce tension in the cheeks, thus making the movements easier.

With this method, all of the spaces between the teeth throughout the mouth can be cleaned. Should the woodstick prick the surface of the gums with the point, angle it a little differently – in the upper jaw, the point will face downward, and in the lower jaw, it will face upward.

Do not be concerned if your gums bleed a little at first – this bleeding will disappear after using the woodsticks repeatedly for a period of time. Do not give up!

Box 36-5 Instructions for use of interproximal brushes.

Interdental brushes can be purchased in a variety of sizes, ranging from small (1.9 mm) to very large (14 mm). It is important to choose the correct diameter of the bristle part of the brush. The size of the space between the teeth determines the size of the diameter of the bristles on the brush. Dental professionals can precisely identify which sizes you need and also demonstrate their proper use. A brush that is too small will not completely clean the interdental spaces, and a brush that is too large can injure the gums. The wire of an interdental brush must be thin and the bristles as fine and as long as possible. With such dimensions, the interdental brush will fill the entire space between the teeth quite softly and gently. Tooth spacing varies, so it is often necessary to use a different size of brush within one mouth for optimal cleansing. To remove dental plaque effectively, there should be a slight degree of resistance when the brush is moved back and forth between the teeth.



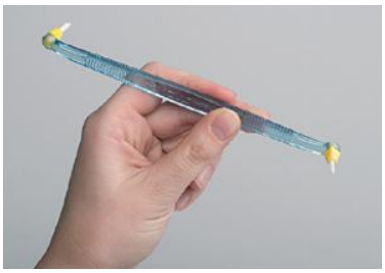
Instructions

- Always use the interdental brush *without* toothpaste.
- Hold the interdental brush just behind the bristles between the thumb and forefinger. Support can be achieved when necessary by placing your other fingers on your chin. From the outer side of the space, push the interdental brush carefully between the teeth, taking care that the brush remains at a right angle to the teeth.
- You may bend the interdental brush slightly to improve accessibility to the posterior interdental spaces.
- Avoid scraping the center (metal spiral part) of the brush against the teeth.
- Slide the brush in and out of the space using the full length of the bristle part of the brush. This action will remove the dental plaque.
- The area of contact between the brush and the teeth can be somewhat increased by using differing angles of insertion.
- Do not push interdental brushes between the teeth with force. Slight pressure of the brush against the gums should be used, as it will allow the bristles to penetrate slightly underneath the gum margin.
- By slightly closing the mouth, it will be easier to manipulate the brush as the tension in the cheeks is lessened. It might also be helpful to bend the brush slightly to ease insertion.
- Cleanse all areas between the teeth where an interdental brush will fit. Rinse interdental brushes thoroughly after use and allow them to dry out. It is often a good idea to combine the use of interdental brushes and woodsticks.

Do not be alarmed if the gums bleed initially. This bleeding does not mean that you have an injury but inflammation, which is caused by concealed, old plaque. This reaction is fairly normal during the first week. Using the interdental brush will soon cure this inflammation, and the bleeding will stop. As the inflammation subsides, the interdental spaces will become slightly larger, and you will most likely need a larger interdental brush. Ask your dental professional.

Box 36-6 Instructions for use of single-tufted/end-tufted brushes.

The single-tufted toothbrush is a small brush with a small, single tuft of short bristles attached to the end. The end-tufted brush has a number of small tufts attached in a similar manner. These brushes are an option for cleansing areas of the dentition that cannot be reached with other oral hygiene aids, for example, a lone-standing tooth, the back surface of the last molar or a tooth in the arches, wires and locks of orthodontic braces, grooves or the entrances to areas where the roots have split apart.



Instructions

- Hold the single-tufted brush as you would hold a pen. This method prevents too much force being applied to the gums.
- Place the single-tufted brush at an angle directed toward the gums (approximately 45°) – this angle allows the bristles to reach just under the gum margin.
- Use small, rotational pencil movements.
- The bristles of the brush will then rotate under and along the gum margin. The brush should then be slowly moved along the tooth surface to cover all areas.

Box 36-7 Instructions for use of oral irrigators.

There are various brands of oral irrigators. Before starting to use a product, it is advisable to read the manufacturer's instructions carefully and to be sure you understand how an oral irrigator works.

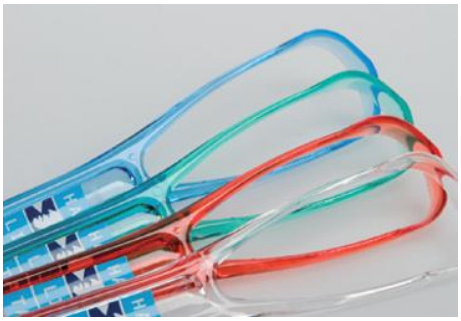
Instructions

- Fill the water reservoir with lukewarm water, and plug the power cord into the wall outlet. You can use a cup to fill the reservoir. If the unit has removable tips, press the appropriate tip firmly into the irrigator handle. The tip should snap into place because it works under pressure and may shoot away otherwise.
- Test the oral irrigator before use.
- Breathe calmly through your nose. Lean over the sink, and close your lips enough to prevent splashing, while still allowing water to fall from the mouth into the sink.
- Aim the tip just above and toward the gum line at a 90° angle, and press the switch that allows the water to flow.
- *Do not* attempt to watch yourself in the mirror. You will make a mess!
- Starting with the back teeth (where your molars are located), follow the gum line. Take your time to get in between teeth. Continue to work slowly forward until all areas around and between teeth have been cleaned.
- Use the same sequence each time you use the irrigator so that you do not miss any teeth.
- At difficult to reach areas you can adjust the angle of the nozzle, for example while cleaning the brackets of an orthodontic appliance or at root furrows
- Spit out excess water as needed.
- Empty any water remaining in the reservoir after use. Dry thoroughly to avoid bacterial growth. Make sure to unplug the unit before cleaning it.

Irrigating is a technique that relies on your sense of touch. At first, it might take a little longer until you develop a routine and become more comfortable with the oral irrigator. Depending on the power level, you might need to refill the water reservoir. Antiseptics can be added if that has been advised by your dental care professional. If so, a mouth rinse or another antiseptic is added to the water in the reservoir.

Box 36-8 Instructions for use of tongue cleaners.

Tongue cleaning is a useful addition to the daily oral hygiene routine. Many bacteria can be found within the grooves on the back of the tongue, which can cause bad breath. By brushing or scraping the tongue, this problem can be markedly helped or prevented entirely. One of the problems associated with tongue cleaning is that it can stimulate a gag reflex, especially when first applying this procedure. This reflex occurs more frequently with brushing than when using a scraper. Some people find it less of a problem if they clean their tongue in the evening.



Instructions

- There are various types of tongue cleaners: the most effective seems to one having the form of a loop.
- Extend the tongue as far as possible out of your mouth.
- Breathe calmly through your nose.
- Place the tongue cleaner as far back as possible on the tongue, and press lightly with it so that the tongue becomes flattened.
- Ensure full contact of the tongue cleaner with the tongue.
- Pull the tongue cleaner slowly forward.
- Clean the middle part of the tongue, first using the raised edge on one side of the instrument.
- Use the smooth surface of the tongue cleaner on the sides of the tongue.
- Repeat these scraping movements a number of times.
- Rinse the mouth several times.

Remember to clean the tongue cleaner thoroughly after each use.

Chapter 37

Chemical Oral and Dental Biofilm Control

David Herrera and Jorge Serrano

ETEP (Etiology and Therapy of Periodontal Diseases) Research Group, Faculty of Odontology, University of Complutense, Madrid, Spain

Rationale for supragingival biofilm control

Bacteria present in oral biofilms are responsible for the most prevalent diseases of mankind: caries and periodontal diseases. Therefore, control of oral biofilms becomes essential for the prevention of those diseases.

Three levels of prevention of periodontal diseases can be distinguished (Baehni & Takeuchi 2003):

- *Primary prevention*: to protect individuals from pathogens by means of barriers between the pathogens and the host; trying to keep the population in health, avoiding the development of the disease.
- *Secondary prevention*: to limit the progression of the disease once the pathogen has contacted the host; trying to recover health, without damage to the host tissues.
- *Tertiary prevention*: to limit the progression of the disease; trying to restore the host tissues, but with some degree of functional damage.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Primary prevention of periodontal diseases is based on supragingival biofilm control by means of mechanical and/or chemical oral hygiene products that are able to limit gingivitis development (Baehni & Takeuchi 2003). Primary prevention of periodontitis assumes that healthy gums (without gingivitis) will not develop periodontitis. Programs for the general population should be implemented to control dental plaque levels and prevent gingivitis with various considerations (Sheiham & Netuveli 2002):

- Toothbrushing must be part of daily personal hygiene habits
- Behavioral factors should be taken into account
- Cleaning methods should be socially acceptable
- Proposed methods should be easy to comply with in daily life
- Hygiene procedures should be simple to perform
- Quality control methods should be part of the program in order to assure its adequate quality.

Secondary and tertiary prevention of periodontal diseases, once disease progression are arrested after proper periodontal therapy of the cause, are achieved by means of supportive periodontal therapy programs that include both individual biofilm control and periodic re-evaluation with professional plaque control (Baehni & Takeuchi 2003).

Oral hygiene products

Thus, supragingival biofilm control is essential in primary, secondary, and tertiary prevention of periodontal diseases. In order to control biofilms in the oral cavity, different oral hygiene products have been developed and marketed. Oral hygiene products refer to "mechanical devices and chemical formulations designed to provide oral health and cosmetic benefits to the user" (Addy & Moran 1997).

Therefore, oral hygiene products include both mechanical devices and chemical formulations.

Mechanical biofilm control

Physical disruption and elimination of dental biofilms can be accomplished by means of manual toothbrushes, different devices for interdental cleaning, powered toothbrushes, etc. (van der Weijden & Slot 2011).

The manual toothbrush is the most widely used method of plaque control (Saxer & Yankell 1997; Hugoson *et al*. 1998), and it has demonstrated efficacy in biofilm control and gingivitis prevention (Hancock 1996; van der Weijden & Hioe 2005). Some powered toothbrushes have also demonstrated efficacy (van der Weijden *et al*. 1998).

Devices for interdental cleaning have also demonstrated efficacy in reducing plaque and gingival indices (Kinane 1998). However, their use is not common due to the lack of proper instruction in their use, difficulties with using them, and limited time and awareness of potential adverse effects. Among the available devices, floss is the most commonly used, but interdental brushes are better accepted.

Mechanical methods of plaque control are covered in detail in Chapter 36.

Limitations

Mechanical devices have demonstrated their efficacy in biofilm and gingivitis control, but different studies (Rugg-Gunn & MacGregor 1978; Lavstedt *et al*. 1982; Addy *et al*. 1986; Albandar & Buischi 1995; Hugoson & Jordan 2004) and systematic reviews (van der Weijden & Hioe 2005) have shown that mechanical control alone may not be enough in a large proportion of the population for the prevention of the onset or the reactivation of periodontal diseases. Different explanations for this can be found:

- Limited time of usage: the normal mean brushing time does not exceed 37 seconds (Beals *et al*. 2000).
- Devices for interdental cleaning are used daily by <10% of the population (Ronis *et al*. 1994); only 2–10% floss daily (Lang *et al*. 1995; Stewart *et al*. 1997; MacGregor *et al*. 1998).
- Even patients instructed in oral hygiene habits tend over time to return to baseline plaque levels (Stewart *et al*. 1997). In most of the studies on mechanical biofilm control, the Hawthorne effect will be present and it may be the case that patients included in a study do not maintain their oral hygiene habits after the end of the study (Johansen *et al*. 1975; Emilson & Fornell 1976; Löe *et al*. 1976; Lindhe *et al*. 1993; Yates *et al*. 1993; Claydon *et al*. 1996; Rosling *et al*. 1997b).
- Lack of control of oral biofilms other than dental plaque, due to lack of adequate instruction on cleaning (tongue dorsum, cheek mucosal surfaces) or access (tonsils) (Quirynen *et al*. 1995; Greenstein 2002, 2004).

In addition, there are circumstances in which adequate mechanical plaque control is not possible, including after oral or periodontal surgery, in patients with intermaxillary fixations, in acute mucosal or gingival infections where pain precludes mechanical hygiene, in mentally or physically handicapped patients, etc. (Storhaug 1977; Nash & Addy 1979; Shaw *et al.* 1984; Zambon *et al*. 1989; Hartnett & Shiloah 1991; Laspisa *et al*. 1994; Eley 1999).

Chemical biofilm control

Chemical plaque control may be necessary in those subjects who are unable to properly control supragingival biofilm with mechanical devices. The use of chemical products should be adjunctive to that of the mechanical devices. The latter reduce the amount of biofilm and disrupt its structure, allowing for a more effective action of the chemical formulations (FDI Commission 2002b). Adjunctive use may be more relevant than sole use, since most chemical agents are only able to act against the most external parts of the

biofilm. However, some agents have demonstrated some capacity for penetration, such as chlorhexidine (CHX) (Netuschil *et al*. 1995) and essential oils (Pan *et al*. 1999, 2000; Fine *et al*. 2001).

The use of chemical formulations (especially antiseptics) to control plaque and gingivitis levels has been widely evaluated, and efficacy for some formulations has been observed in different systematic reviews (Hioe & van der Weijden 2005; Gunsolley 2006; Paraskevas & van der Weijden 2006; Addy *et al*. 2007; Stoeken *et al*. 2007; Gunsolley 2010; Sahrmann *et al*. 2010; Afennich *et al*. 2011; Hossainian *et al*. 2011).

Mechanism of action

Chemical plaque control may be achieved by different mechanisms of action (Fig. 37-1), with a quantitative (reduction of the number of microorganisms)

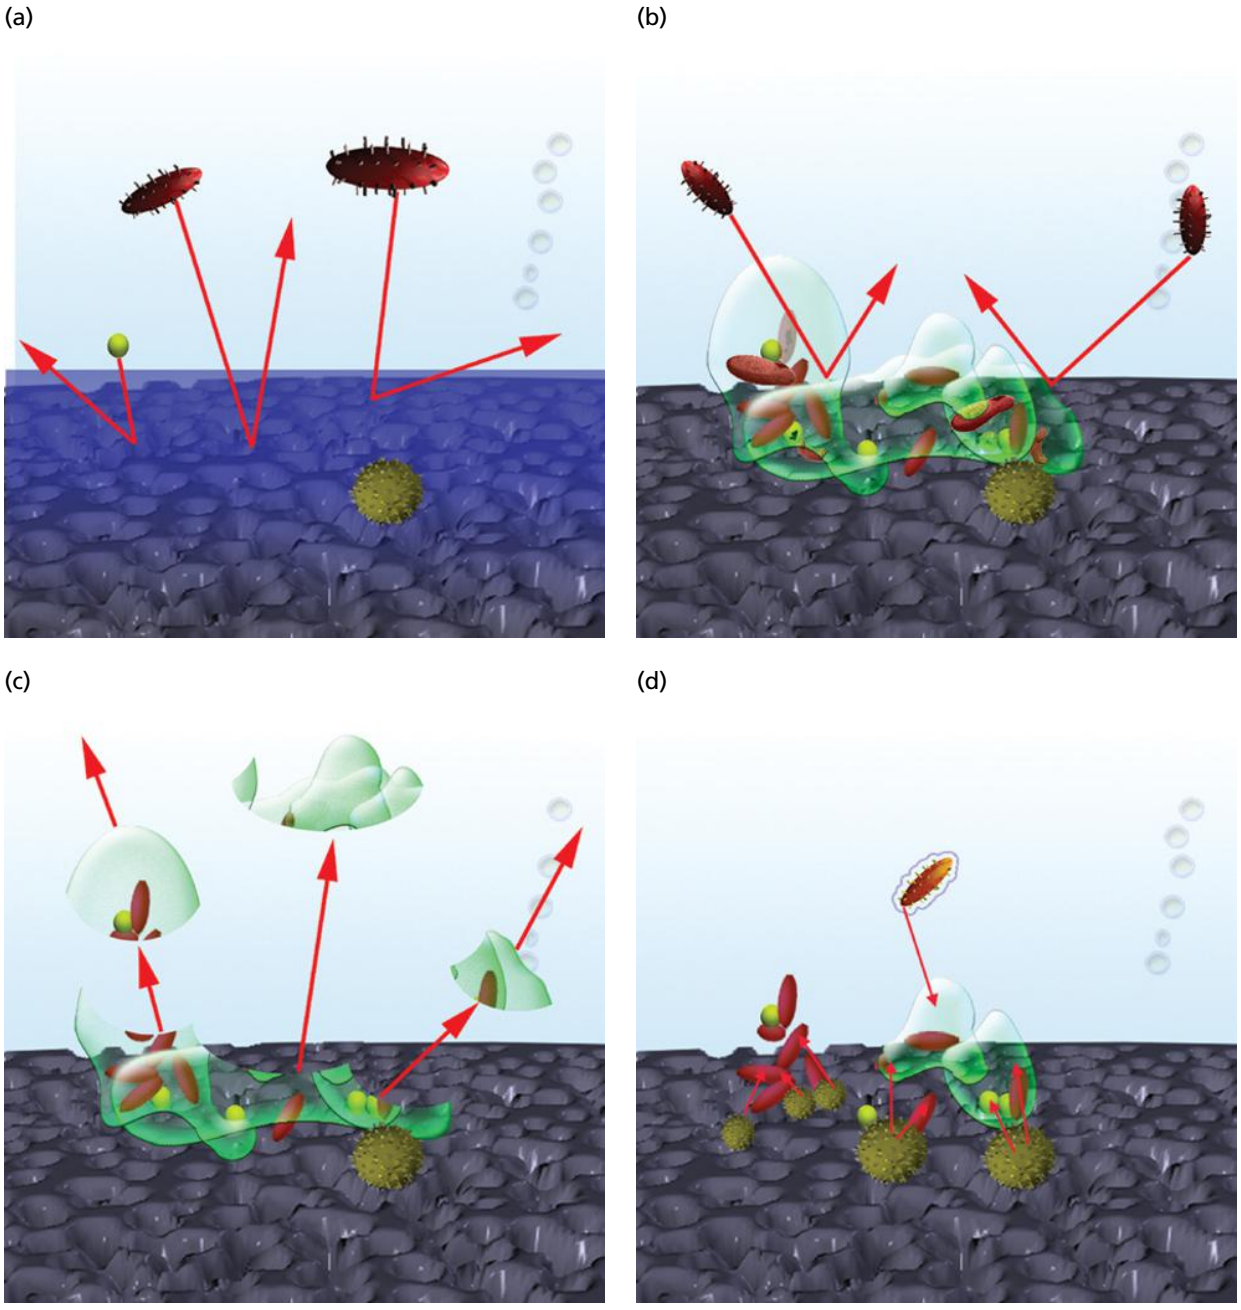

Fig. 37-1 Mechanisms of effect of antiplaque agents on bacterial biofilms (in green). (a) Prevention of bacterial adhesion to tooth surfaces: the active agent forms a pellicle (blue film) over the tooth surface, interfering with bacterial adhesion (red arrows), thus avoiding bacterial colonization. (b) Bactericidal or bacteriostatic effect, avoiding bacterial proliferation and co-aggregation: interference with bacterial division (damaged bacterial cells depicted in red) leads to interference with biofilm formation. In addition, biofilm maturation is also prevented as co-aggregation of new species (red arrows) is impeded, due to the non-favorable environmental conditions. (c) Biofilm disruption from tooth surfaces: "chemical brushing". The agent induces detachment and/or biofilm elimination from the tooth surface by breaking the chemical links between the surface and the biofilms, and by disrupting the biofilm structure (red arrows). (d) Alteration of biofilm pathogenicity or enhancement of host immune systems by different mechanisms: enhanced host defense systems provide more effective biofilm control by the host (short red arrows); or presence of defined bacterial species that may influence biofilm development and maturation, by means of the release of different products, such as bacteriocins, or by competition for nutrients (long red arrow).

and/or qualitative (altering the vitality of the biofilm) effect (FDI Commission 2002b):

- By preventing bacterial adhesion
- By avoiding bacterial growth and/or co-aggregation
- By eliminating an already established biofilm
- By altering the pathogenicity of the biofilm.

Categories of formulations

Formulations for chemical plaque control can be classified according to their effects (Lang & Newman 1997):

- *Antimicrobial agents*: bacteriostatic or bactericidal effects *in vitro*
- *Plaque-reducing/inhibitory agents*: quantitative or qualitative effect on the plaque that may or may not be enough to affect gingivitis and/or caries
- *Antiplaque agents*: affect the plaque sufficiently to show a benefit in terms of gingivitis and/or caries control
- *Antigingivitis agents*: reduce gingival inflammation without necessarily affecting dental plaque, including anti-inflammatory drugs.

These definitions are widely accepted in Europe, but in North America the term "antiplaque" refers more often to agents capable of significantly reducing plaque levels and "antigingivitis" to agents capable of significantly reducing gingivitis levels.

Ideal features

The features of the ideal chemical agent for plaque control have been proposed by different authors (Loesche 1976; van der Ouderaa 1991; Baker 1993; Fischman 1994):

- *Specificity*. Agents and formulations for chemical plaque control should demonstrate a wide spectrum of action, including against bacteria, viruses, and yeasts. More specific products, such as antibiotics, must not be used in the prevention of periodontal diseases, and their use should be limited to the prevention of bacteremia in at-risk patients, and for the treatment of some periodontal conditions (Herrera *et al*. 2008).
- *Efficacy*. Antimicrobial capacity must be demonstrated against microorganisms implicated in gingivitis and periodontitis, in both *in vitro* and *in vivo* studies. Although bactericidal effects may be only achieved at high dosages, antimicrobial effects should also be present at lower dosages (FDI Commission 2002b).
- *Substantivity*. The effects of the chemical formulations do not depend only on the antimicrobial activity *in vitro*. Other factors will influence the *in vivo* activity, among which substantivity may be one of the most relevant. Substantivity has been defined as the duration of the antimicrobial action *in vivo* (FDI Commission 2002b) and as a measurement of the contact time between the agent and the substrate in a defined medium. This time may be longer than expected with simple mechanical deposition (van Abbé 1974) (Fig. 37-2). According to their substantivity, agents have been divided into three distinct generations (Kornman 1986a):
  - First-generation agents show very limited substantivity with limited time of action; examples are phenolic derivatives, plant extracts, fluorides, quaternary ammonium compounds, and oxidizing agents
  - Second-generation agents demonstrate good substantivity; CHX is the best example
  - Third-generation agents include those which interfere or prevent bacterial or biofilm adhesion.

  Since antiseptics are used with the aim of preventing biofilm formation, the longer the duration of their action, the higher their activity. As an example, CHX has demonstrated the highest substantivity and this is associated with its strongest antiplaque effects.
- *Safety*. This must be demonstrated in animal models before use in humans. Due to the chronicity of the conditions to be prevented and the expected long-term use, secondary effects must be minimal.
- *Stability*. Agents must be stable at room temperature for an extended period of time. Care should be taken when mixing different ingredients in a formulation to avoid interference between molecules.

Evaluation of activity of agents for chemical biofilm control

In order to assess the plaque inhibitory and antiplaque activity of chemical compounds, consecutive phases of evaluation have been proposed, with the last being randomized clinical trials of home use with at least 6 months' duration (Addy & Moran 1997).

In vitro studies

Bacterial tests evaluate the antimicrobial activity of a product by measuring the minimum inhibitory concentration (MIC) and the minimum bactericidal concentration (MBC) against different bacterial species. The information provided is limited (antibacterial activity, spectrum of action), because many other factors will influence the effects *in vivo* and because the bacterial species are usually tested as planktonic cells, while in the mouth they are organized as sessile biofilm cells. However, antibacterial tests are useful for initial screening of products or for evaluation of the effects of the addition of new agents to a formulation.

Uptake studies are *in vitro* studies that assess the adsorption of products on different surfaces, such as hydroxyapatite, enamel, and dentin.

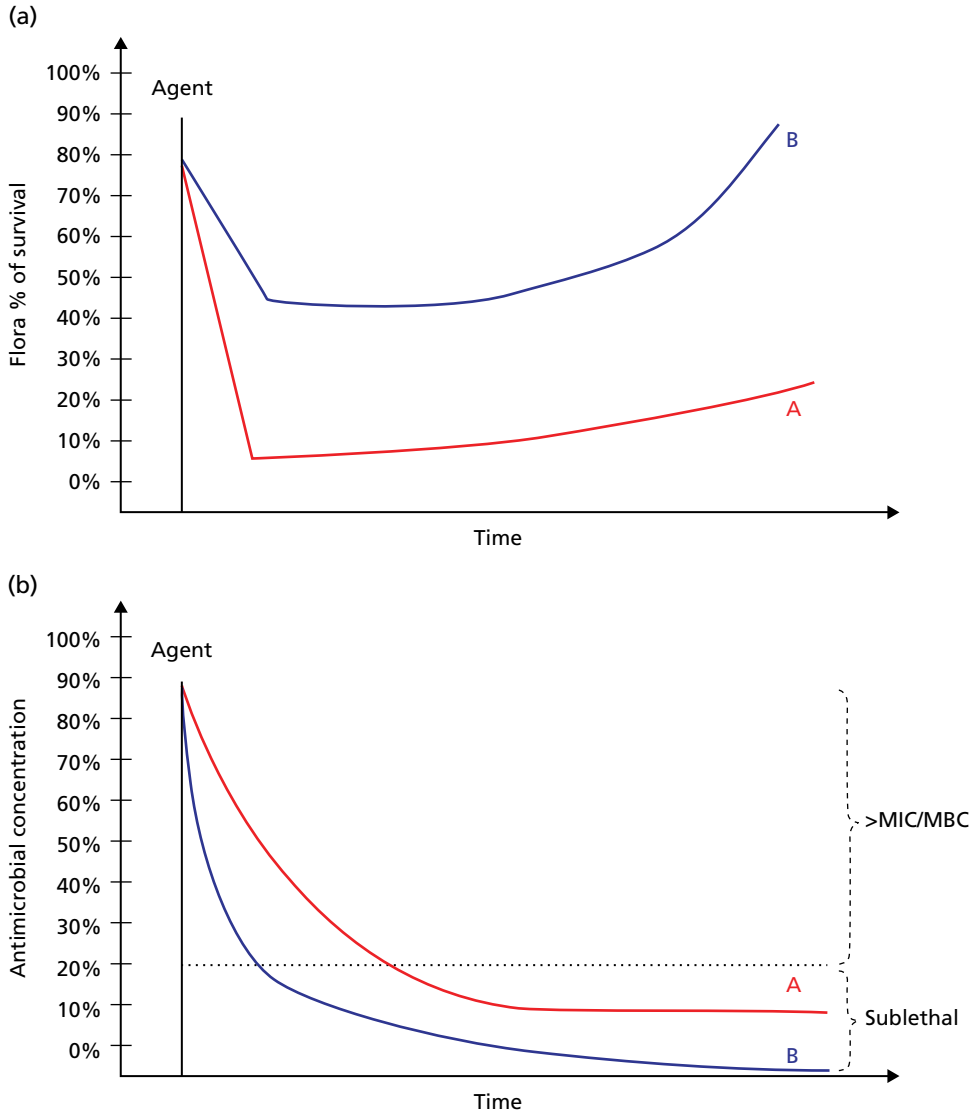

Fig. 37-2 Substantivity. (a, b) Two agents with different substantivity (measurement of the contact time between the agent and the substrate in a defined medium): with time, the concentrations of the products decreases and the bacterial concentration increases. Product A has better substantivity than product B. (a) Time after contact versus percentage bacterial survival. (b) Time after contact versus concentration of the antibacterial agent. (MIC, minimum inhibitory concentration; MBC, minimum bactericidal concentration.)

Bioavailability and activity can be assessed by different chemical methodologies, such as spectrophotometry, or by indirect methods, such as staining.

Biofilm models allow formulations to be tested *in vitro* against sessile biofilm bacterial cells, which may better simulate real-life conditions (Xu *et al*. 2000; Shapiro *et al*. 2002; Socransky & Haffajee 2002). However, no standardized and accepted model is available, but several different *in vitro* biofilm models have been proposed (Sanchez *et al*. 2011). In addition to information on the antimicrobial activity, other relevant information, such as the penetration of the agent in the biofilm, can be obtained with these models. Both CHX and essential oils have demonstrated capacity to penetrate and bactericidal action in biofilms (Arweiler *et al*. 2001; Shapiro *et al*. 2002; Arweiler *et al*. 2003; Ouhayoun 2003; Corbin *et al*. 2011; Guggenheim & Meier 2011; Otten *et al*. 2011) (Fig. 37-3).

In vivo studies

Depot studies assess the retention of an agent in the mouth after a single use by measuring the agent level in saliva or in dental plaque. These studies do not provide information on the activity of the product (Rolla *et al*. 1971; Bonesvoll *et al*. 1974a, b; Gjermo *et al*. 1974, 1975; Bonesvoll 1978).

In vivo biofilm study models assess the effects of different formulations on disks of enamel, dentin or other materials inserted into the mouth of patients (with different prosthetic devices) and retrieved for the evaluation of the biofilms formed in their presence (cross-over designs) (Pan *et al*. 2000; Sreenivasan *et al*. 2004).

Antimicrobial tests *in vivo* are designed as cross-over studies (with a placebo and a positive control), with the amount of bacteria in saliva measured before and after (several hours and at different times) a single

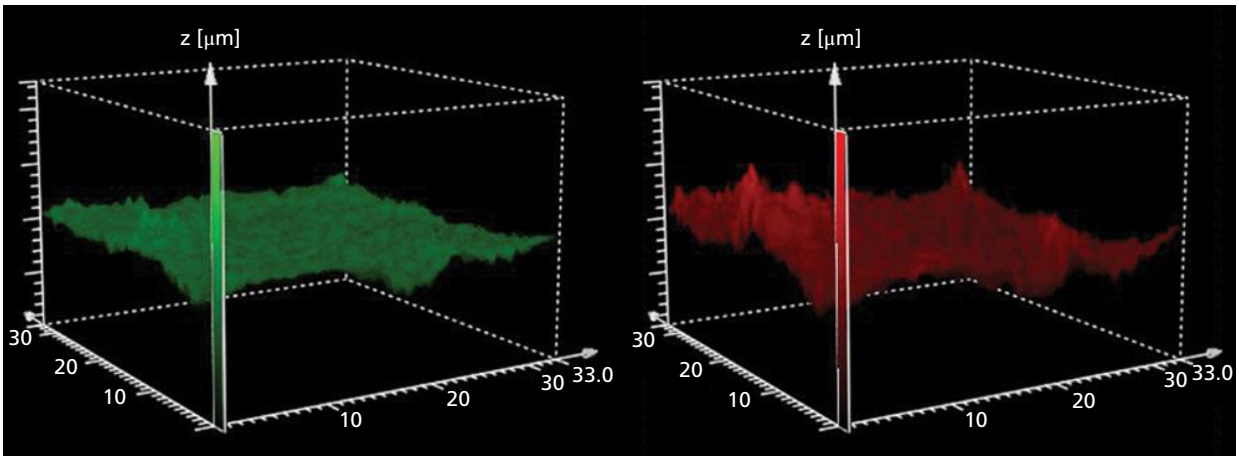

Fig. 37-3 Three-dimensional assessment of cell vitality in a biofilm, with a confocal microscope. Cells in green show vitality and cells with a damaged cytoplasmic membrane appear in red. This tool allows for the assessment of the capacity of biofilm penetration by an antiseptic and its bactericidal activity.

use of a formulation (a mouth rinse, a dentifrice or a dentifrice in an aqueous slurry). This study design has been extensively used since its first use with CHX (Schiøtt *et al*. 1970), and provides information on antimicrobial activity and duration of activity.

Plaque regrowth models are also designed as cross-over studies (with a placebo and a positive control), with the plaque regrowth after professional prophylaxis measured over a period of time (normally 3–4 days) and only the tested formulation allowed for oral hygiene (no mechanical hygiene). Information on the plaque inhibitory capacity of the formulation is obtained (Harrap 1974; Addy *et al*. 1983; Moran *et al*. 1992; Arweiler *et al*. 2002; Pizzo *et al*. 2008).

Experimental gingivitis models have the same design as plaque regrowth models but test the formulation for longer periods of time (typically 12–28 days), allowing for the evaluation of gingivitis indices (Löe 1965; Löe & Schiøtt 1970). No mechanical hygiene is permitted. Parallel studies can be also designed due to the longer duration of the study periods.

Home-use clinical trials

It is a general consensus that plaque inhibitory and antiplaque activities have to be demonstrated in long-term (at least 6 months), home-use, randomized clinical trials, and concomitantly demonstrate safety, based on the lack of relevant side effects. In these studies, the use of the tested formulations is adjunctive to mechanical plaque control. The characteristics of these trials, in order for their conclusion to be valid, have been proposed to be (Council of Dental Therapeutics 1986):

- Double blind (patients and examiner).
- Controlled (negative and/or positive controls). It is not valid to compare the effects of the tested formulation against the baseline values due to the Hawthorne effect (improvement of patients' oral hygiene habits due to their awareness of their presence in the study) and to the performance of a professional prophylaxis at the beginning of these studies (Overholser 1988).
- Minimum of 6 months of duration. This period has a number of advantages: 6 months is the typical period of time between two consecutive supportive periodontal therapy visits; it permits an adequate evaluation of long-term adverse events, including microbiologic effects; and it may compensate for part of the Hawthorne effect, since this effect will slowly disappear as the study progresses (Overholser 1988).
- Microbiologic evaluation to assess the overgrowth of pathogenic, opportunistic or resistant strains.
- Microbiologic sampling and evaluation of plaque and gingival indices should be carried out at the minimum at baseline, the final evaluation, and an intermediate point (e.g. 3 months).

In addition, other factors with regards to the quality of these studies should be considered, such as the selection of a representative population, with study groups homogeneous for different factors (age, smoking, gender, general, oral and periodontal health, etc.). Clinical trials must be clear, comparable, and have internal and external validity (Koch & Paquette 1997).

Based on the availability of at least two independent investigations of 6-month duration demonstrating significant differences, as compared with the negative control, for plaque and gingivitis, different products have received a "seal of approval" for plaque inhibitory and/or antiplaque activity from the American Dental Association (ADA) and the Food and Drug Administration (FDA).

In the following section, the scientific evidence supporting the use of the most common agents is reviewed, with special attention paid to 6-month, home-use, clinical trials and to systematic reviews with meta-analysis of 6-month studies.

Active agents

Antibiotics

Penicillins, tetracyclines, metronidazole, vancomycin, kanamycin, and spiramycin.

- *Characteristics*. When systemically taken, effects are greater due to the maintenance of stable serum levels (also in the gingival crevicular fluid); when topically or locally applied, effects are smaller due to the limited time of action.
- *Evaluation*. Different groups of antibiotics have demonstrated an effect on the dental biofilm.
- *Limitations*. Use against dental plaque is not recommended due to the poor benefit-to-risk ratio, including adverse effects and increase in bacterial resistance (Genco 1981; Kornman 1986b; Slots & Rams 1990; Herrera *et al.* 2000; van Winkelhoff *et al*. 2000).
- *Usefulness, marketed*. Should not be used for chemical plaque control.

Enzymes

Disrupt the biofilm

Dextranase, mutanase, proteases, and lipases.

- *Characteristics*. Very limited substantivity and frequent side effects (Addy 1986).
- *Evaluation*. Use *in vivo* is limited due to side effects. Other enzymes and combinations of enzymes have been evaluated, but only *in vitro* data are available (Johansen *et al*. 1997; Donlan & Costerton 2002).
- *Limitations*. Frequent side effects (Hull 1980; Addy 1986).
- *Usefulness, marketed*. No.

Enhance the host defenses

Glucose oxidase and amyloglucosidase.

- *Characteristics*. Mechanisms of action rely on the catalization of thyocianate into hypothyocianate, through the salivary lactoperoxydase system.
- *Evaluation*. Results for *in vivo* effect on gingivitis have been contradictory and no long-term studies are available (Addy 1986; Moran *et al*. 1989; Kirstila *et al*. 1994; Hatti *et al*. 2007).
- *Limitations*. Limited scientific evidence available.
- *Usefulness, marketed*. Marketed as Zendium® by Opus Health Care AB (Malmö, Sweden) in a mouth rinse with amyloglucosidase, glucosidase and lactoperoxidase, sodium fluoride, xylitol and zinc, and no alcohol; and in toothpaste. Another commercialized toothpaste is Bioxtra® (Bio-X Healthcare, Namur, Belgium), with lactoferrin, lysozyme, and lactoperoxidase.

Amine alcohols

Delmopinol (Fig. 37-4) and octapinol.

- *Characteristics*. Mechanism of action is not fully understood, but they are not antimicrobials and their effect is achieved by the inhibition of biofilm matrix formation or disruption of the biofilm matrix. Delmopinol also inhibits glucane synthesis by *Streptococcus mutans* (Rundegren *et al*. 1992; Elworthy *et al*. 1995) and reduces acid synthesis by bacteria (Simonsson *et al*. 1991).
- *Evaluation*. Delmopinol has been formulated and clinically evaluated as a mouth rinse at 0.1% and 0.2% (Collaert *et al*. 1992; Moran *et al*. 1992; Abbott *et al*. 1994; Claydon *et al*. 1996; Zee *et al*. 1997) and

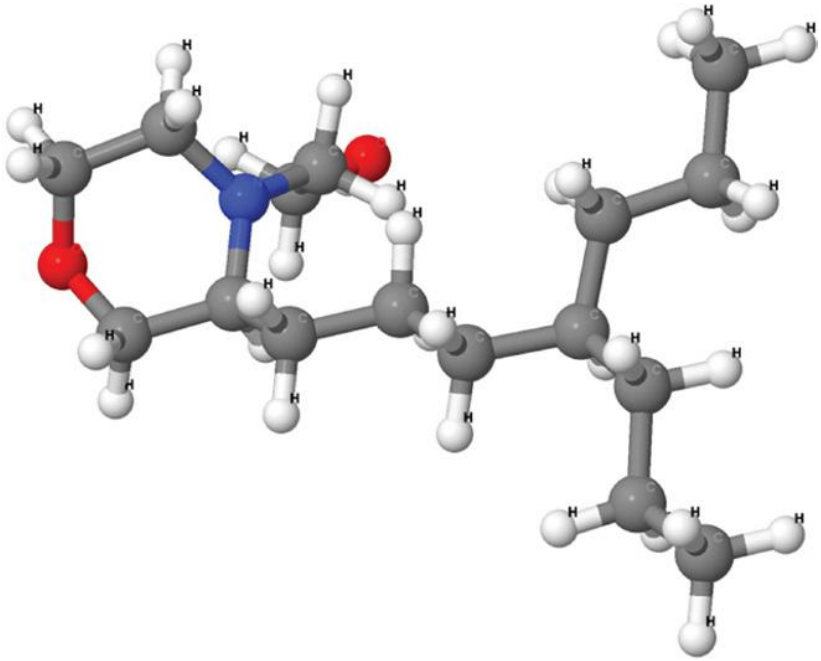

Fig. 37-4 Chemical structure of delmopinol (prepared with Jmol: an open-source Java viewer for chemical structures in 3D. http://www.jmol.org/).

demonstrated efficacy as an antiplaque agent in a systematic review (Addy *et al*. 2007). It was approved by the FDA in 2005 as a 0.2% mouth rinse indicated in the treatment of gingivitis (Imrey *et al*. 1994).
- *Limitations*. Most relevant side effects are dental staining, a temporary feeling of numbness in the mucosa (e.g. tongue), and a burning sensation.
- *Usefulness, marketed*. Delmopinol has been marketed in several countries by Sinclair Pharma (Paris, France) under the name of Decapinol, both as a 0.2% mouth rinse with 1.5% of alcohol, and as a 0.2% toothpaste with 0.11% sodium fluoride.

Detergents

The most important and frequently used detergent or surfactant (active-surface compounds) is sodium lauryl sulfate (SLS).

- *Characteristics*. SLS has demonstrated substantivity of 5–7 hours. The foaming properties of detergents may help in removing plaque, although there is insufficient evidence to support this statement.
- *Evaluation*. SLS has a limited antimicrobial and plaque-inhibitory effect (Addy *et al*. 1983; Moran *et al*. 1988).
- *Limitations*. SLS has been associated with oral hypersensitivity reactions, including cheilitis, stomatitis or aphthous ulcers, burning sensation, and desquamation (Herlofson & Barkvoll 1996; Chahine *et al*. 1997; Plonait & Reichart 1999).
- *Usefulness, marketed*. SLS is present in many dentifrice and mouth rinse formulations, but has not been formulated as a single active agent product.

Oxygenating agents

Sodium peroxyborate and peroxycarbonate, and hydrogen peroxide.

- *Characteristics*. Exert antimicrobial effects through the release of oxygen.
- *Evaluation*. Peroxyborate and peroxycarbonate have demonstrated some antimicrobial and plaque inhibitory activity (Moran *et al*. 1995). Hydrogen peroxide was evaluated in a systematic review (Hossainian *et al*. 2011) of 10 publications, three of which (one with a 6-month follow-up) had a low risk of bias. No effect was observed in the short term, but the 6-month study demonstrated significant benefits in terms of the modified gingival index (Hasturk *et al*. 2004).
- *Limitations*. No long-term data are available for peroxyborate and peroxycarbonate, and only one study for hydrogen peroxide has been published. At low concentrations (i.e. <1.5%) of hydrogen peroxide, adverse events are not common, but at higher concentrations a painful sensation in the mouth and ulcers may be frequent (Rees & Orth 1986).
- *Usefulness, marketed*. Peroxyborate (Bocasan®, Amosan®) and peroxycarbonate (Kavosan®) were widely marketed by Procter and Gamble (Cincinnati, OH, USA), but they are now only available in some countries. Hydrogen peroxide is available in North America as Rembrant® (Dent-Mat Corp., Santa Maria, CA, USA).

Metal salts

Zinc salts

Zinc lactate, zinc citrate, zinc sulfate, and zinc chloride.

- *Characteristics*. At low concentrations, no adverse effects have been reported.
- *Evaluation*. As sole agents they have limited effects on plaque, but if combined with other active agents, there is an improvement in substantivity and action.
- *Limitations*. No data as individual agents are available.
- *Usefulness, marketed*. In combination with CHX, cetylpyridinium chloride (CPC), triclosan, hexetidine, etc. Combination products have been evaluated for plaque control (zinc lactate with CHX; zinc citrate with triclosan), but some combinations have also been evaluated for halitosis control (zinc lactate with CHX and CPC), tartar control (zinc chloride with essential oils), or ulcer healing (zinc sulfate with triclosan).

Stannous fluoride

Stannous fluoride has been included in dentifrices, mouth rinses, and gels since 1940. Several formulations have been tested, but the two most commonly evaluated are the combination of stannous fluoride with amine fluoride (see below), and different formulations of 0.454% stannous fluoride dentifrice [combined with sodium hexametaphosphate (SHMP) in the most recent formulation].

- *Characteristics*. Combination of tin and fluoride (SnF_2); difficult to formulate in oral hygiene products due to limited stability in aqueous solution (Miller *et al*. 1969). It is not frequently formulated in mouth rinses.
- *Evaluation*. Several 6-month studies have been published, evaluating gel or dentifrice products, most frequently (five investigations) with the 0.454% stannous fluoride formulation (Beiswanger *et al*. 1995; Perlich *et al*. 1995; Mankodi *et al*. 1997; McClanahan *et al*. 1997; Williams *et al*. 1997), but also with stannous fluoride plus SHMP (Mankodi *et al*. 2005a; Mallatt *et al*. 2007; Boneta *et al*. 2010) and older formulations (Boyd & Chun 1994; Wolff *et al*. 1989). Less frequently, mouth rinse products

have been assessed (Leverett *et al*. 1984, 1986). In a systematic review, the 0.454% stannous fluoride formulation provided significant benefits in terms of gingivitis [weighted mean difference (WMD) 0.441; P <0.001, with significant heterogeneity P = 0.010] (Gunsolley 2006). In another systematic review (Paraskevas & van der Weijden 2006), the meta-analysis was limited due to the availability of data, and data pooling was performed at the final study visit, assuming that no differences were found at baseline. In addition, the results combined different stannous fluoride formulations, including the combination with amine fluoride. The results demonstrated significant differences at the final visit (and no differences at baseline) for gingival index (WMD −0.15), modified gingival index (WMD −0.21), and plaque index (WMD −0.31), always with significant heterogeneity.

- *Limitations*. Main limiting factor is dental staining (Brecx *et al*. 1993; Paraskevas & van der Weijden 2006).
- *Usefulness, marketed*. Most recently marketed formulation is Crest Pro-Health (Procter & Gamble, Cincinnati, OH, USA), with 0.454% stannous fluoride with SHMP, zinc lactate, and SLS; approved by the ADA. The earlier formulation with 0.454% stabilized stannous fluoride was marketed as Crest Gum Care or Crest Plus Gum Care (Procter & Gamble).

Stannous fluoride with amine fluoride

Amine fluoride was developed in the 1950s at the University of Zurich.

- *Characteristics*. Stannous fluoride and amine fluoride have both demonstrated bactericidal activity against bacteria, and activity is increased if they are combined. Amine fluoride exerts its antimicrobial action by antiglycolytic effects. The activity of stannous/amine fluoride seems to be greater as a dentifrice, with 8 hours of action following use (Weiland *et al*. 2008).
- *Evaluation*. Six-month studies assessing stannous/amine fluoride as dentifrice (Sgan-Cohen *et al*. 1996; Shapira *et al*. 1999), mouth rinse (Zimmermann *et al*. 1993) or both (Mengel *et al*. 1996; Paraskevas *et al*. 2005) reveal no significant benefit of the dentifrice alone, while the mouth rinse achieved significant plaque and gingivitis reductions. If both products were used in combination, either no significant effects (Mengel *et al*. 1996) or significant effects on plaque, but not on gingivitis (Paraskevas *et al*. 2005), were reported.
- *Limitations*. Tooth staining is the most common adverse effect (Paraskevas *et al*. 2005).
- *Usefulness, marketed*. Both the dentifrice and the mouth rinse are marketed as Meridol® (GABA International AG, Therwil, Switzerland).

Other fluorides

Sodium fluoride and sodium monofluorophosphate.

- *Characteristics*. Usefulness has been demonstrated in reducing caries incidence (Petersson 1993).
- *Evaluation*. Fluoride ion has not demonstrated plaque-inhibitory or antiplaque properties.
- *Limitations*. Not evaluated as individual agents.
- *Usefulness, marketed*. Present in most dentifrices.

Natural products

Sanguinarine extract and other herbal ingredients (camomile, echinacea, sage, myrrh, rhatany, peppermint oil).

- *Characteristics*. Sanguinarine is an alkaloid obtained from the plant *Sanguinaria canadensis*.
- *Evaluation*. Sanguinarine extract has demonstrated low bactericidal capacity in an *in vitro* biofilm model (Shapiro *et al*. 2002), while the clinical evaluation reported contradictory results (Moran 1988; Scherer *et al*. 1998; Quirynen *et al*. 1990). At least six home-use, 6-month oral hygiene trials were performed in the 1980s and early 1990s assessing sanguinarine extract with zinc chloride, as dentifrice (Lobene *et al*. 1986; Mauriello & Bader 1988), as mouth rinse (Grossman *et al*. 1989) or the combined use (Hannah *et al*. 1989; Harper *et al*. 1990; Kopczyk *et al*. 1991). Significant reductions in terms of plaque and gingivitis were reported with combined use.
- *Limitations*: Use of formulations of sanguinarine was associated with oral leukoplakia (Mascarenhas *et al*. 2002).
- *Usefulness, marketed*: Viadent (Colgate-Palmolive Co., Piscataway, NJ, USA), with sanguinarine extract is no longer available. Paradontax (GlaxoSmithKline, Middlesex, UK) contains other herbal components.

Essential oils

Mouth rinse with eucalyptol (0.092%), menthol (0.042%), methyl salicylate (0.060%), thymol (0.064%), and alcohol (26.9% in the original formulation) (Fig. 37-5).

- *Characteristics*. Multiple mechanisms of action have been proposed, such as cell wall disruption, inhibition of bacterial enzymes, extraction of endotoxins derived from lipopolysaccharide (LPS) of Gram-negative bacteria (Fine *et al*. 1985), and anti-inflammatory action based on antioxidant activity (Firatli *et al*. 1994; Sekino & Ramberg 2005).
- *Evaluation*. A mouth rinse with essential oils has demonstrated antimicrobial activity in biofilm models *in vitro* (Fine *et al*. 2001; Shapiro *et al*. 2002), and plaque inhibitory and antiplaque effects in different home-use, 6-month oral hygiene studies (Lamster 1983; Gordon *et al*. 1985; Beiswanger *et al*. 1997; DePaola *et al*. 1989; Grossman *et al*. 1989;

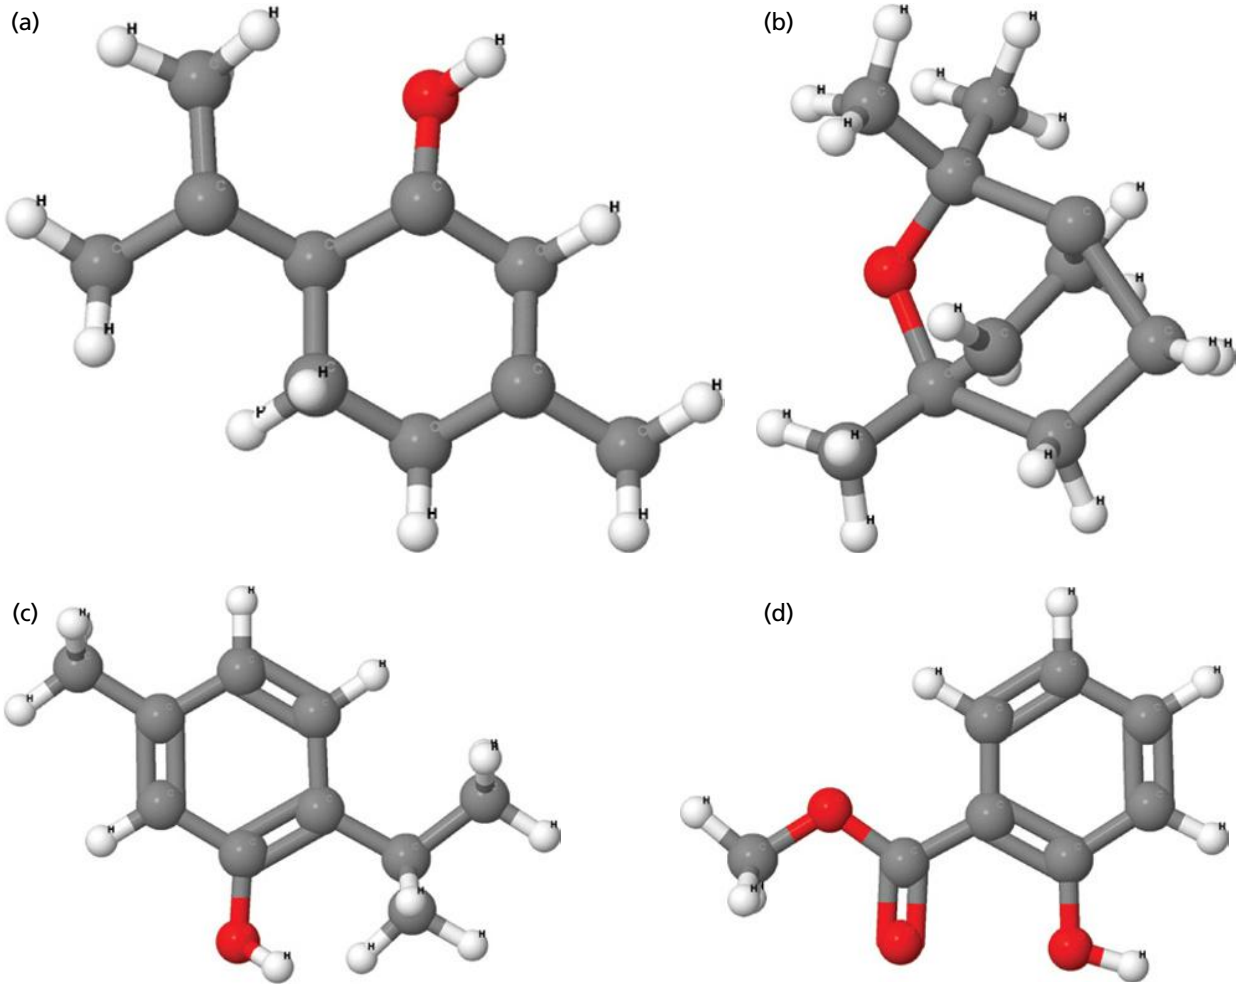

Fig. 37-5 Chemical structure of essential oils. (a) Menthol; (b) eucalyptol; (c) thymol; (d) methyl salicylate (prepared with Jmol: an open-source Java viewer for chemical structures in 3D. http://www.jmol.org/).

Overholser *et al*. 1990; Charles *et al*. 2001; Sharma *et al*. 2002; Bauroth *et al*. 2003; Charles *et al*. 2004; Sharma *et al*. 2004). In a systematic review (Stoeken *et al*. 2007), including investigations of 6 months or more, 11 papers were included and statistically significant differences in the meta-analysis were found for both plaque (WMD −0.83; P <0.00001; with significant heterogeneity, P <0.00001) and gingivitis index (WMD −0.32, P <0.00001; with significant heterogeneity, P <0.00001).

- *Limitations*. Secondary effects include a burning sensation and tooth staining. There is some controversy concerning the association of alcohol-containing mouth rinses (including Listerine®) and oral cancer (Blot *et al*. 1983). However, critical assessment of the literature does not support an association (Ciancio 1993; Claffey 2003).
- *Usefulness, marketed*. There are different formulations of Listerine® as mouth rinse, including one without alcohol (Johnson & Johnson Healthcare Products, Skillman, NJ, USA).

Triclosan

Triclosan [5-chloro-2-(2,4 dichlorophenoxy) phenol] is a non-ionic bisfenolic, broad-spectrum antibacterial agent (Ciancio 2000) (Fig. 37-6).

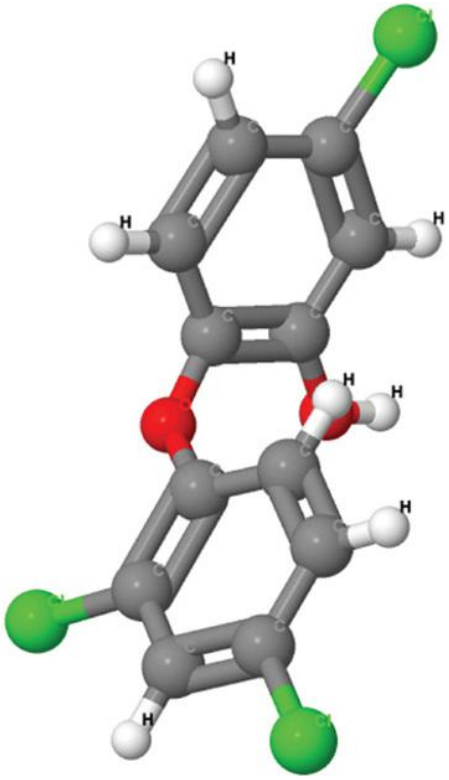

Fig. 37-6 Chemical structure of triclosan (prepared with Jmol: an open-source Java viewer for chemical structures in 3D. http://www.jmol.org/).

- *Characteristics*. Formulated both in mouth rinses and in dentifrices. In mouth rinses, at 0.2%, there is a limited bactericidal activity (Shapiro *et al*. 2002; Arweiler *et al*. 2003) and a substantivity of approximately 5 hours (Jenkins *et al*. 1991a). As a dentifrice, it can be detected for up to 8 hours in dental plaque following application (Gilbert & Williams 1987). It has normally been formulated in combination with polyvinyl-methyl ether maleic acid co-polymer, zinc citrate or pyrophosphate, in order to improve the substantivity and/or the antimicrobial activity. Triclosan may also induce anti-inflammatory effects (Barkvoll & Rolla 1994; Gaffar *et al*. 1995; Kjaerheim *et al*. 1996) through inhibition of the cyclooxygenase and lipoxygenase pathways, which reduces the synthesis of prostaglandins and leukotrienes.
- *Evaluation*. Home-use, 6-month, oral hygiene studies are available for three distinct triclosan dentifrice formulations (triclosan with co-polymer, triclosan with zinc citrate, triclosan with pyrophosphate), and a mouth rinse with triclosan and co-polymer.
  - A *dentifrice with triclosan and zinc citrate* was extensively evaluated in the 1990s (Svatun *et al*. 1989; Stephen *et al*. 1990; Svatun *et al*. 1990, 1993a, b; Palomo *et al*. 1994; Renvert & Birkhed 1995). Conflicting results were reported and a limited meta-analysis conducted (using end of trial values, rather than changes in values), demonstrating a limited but significant effect on plaque (WMD −0.07; P <0.00001) and a more important effect on bleeding (WMD −10.81%; P <0.00001) (Hioe & van der Weijden 2005). Conversely, no significant differences were observed in another systematic review considering differences between baseline and final visit (Gunsolley 2006).
  - A *dentifrice with triclosan and co-polymer* has also been extensively evaluated in 6-month studies (Garcia-Godoy *et al*. 1990; Cubells *et al*. 1991; Deasy *et al*. 1991; Bolden *et al*. 1992, Denepitiya *et al*. 1992; Mankodi *et al*. 1992; Lindhe *et al*. 1993; Svatun *et al*. 1993a; Palomo *et al*. 1994; Kanchanakamol *et al*. 1995; Triratana *et al*. 1995; Hu *et al*. 1997; McClanahan *et al*. 1997; Charles *et al*. 2001; Allen *et al*. 2002; Winston *et al*. 2002). In a limited meta-analysis of final visit values, a significant effect was observed for the Turesky modification of the plaque index (WMD −0.48; P <0.0001) and for the Talbott modification of the gingival index (WMD −0.24; P <0.0001), in both cases with significant heterogeneity (Hioe & van der Weijden 2005). In another meta-analysis evaluating changes between baseline and the final visit, a significant effect on plaque was observed (WMD 0.823), with significant differences in 14 of the 18 included arms; and for gingivitis (WMD 0.858), in both cases with significant heterogeneity (Gunsolley 2006).
  - A *dentifrice with triclosan and pyrophosphate* has been evaluated less frequently (Palomo *et al*. 1994; Renvert & Birkhed 1995; Grossman *et al*. 2002; Winston *et al*. 2002); results have shown significant heterogeneity and conflicting results (Gunsolley 2006).
  - A *mouth rinse with triclosan and co-polymer* was evaluated in the 1990s in at least four 6-month trials (Worthington *et al*. 1993; Ayad *et al*. 1995; Triratana *et al*. 1995; Schaeken *et al*. 1996), demonstrating statistically significant differences both in plaque and gingival indices. The triclosan and co-polymer mouth rinse formulation has also been tested as a prebrushing agent; a meta-analysis of two 6-month studies gave a WMD of 0.269 (P <0.0001) (Angelillo *et al*. 2002).
- *Limitations*. There are no relevant side effects, but risk of formation of the carcinogenic product chloroform was suggested in an *in vitro* study testing the combination of triclosan and free chlorine present in water (Rule *et al*. 2005). Also, environmental problems from the presence of triclosan in the food chain have been suggested.
- *Usefulness, marketed*. Triclosan (0.30%) with co-polymer and sodium fluoride (0.24%) is marketed as Colgate Total® (Colgate-Palmolive Co.). The formulation of triclosan and co-polymer as mouth rinse has been marketed as Plax®, although different products under this name have been marketed, including formulations with sodium benzoate.

Bisbiguanides

CHX digluconate, alexidine dihydrochloride, and octenidine dihydrochloride.

- *Characteristics*. Symmetric molecules with two chlorophenolic rings and two biguanides groups connected by a central bridge of hexametilene (Fig. 37.7).
- *Evaluation*. Excellent antiplaque agent. CHX is the reference, since the other bisbiguanides show similar or inferior activity (Shapiro *et al*. 2002).
- *Limitations*. Similar among all bisbiguanides, but there are more studies for CHX.
- *Usefulness, marketed*. Many CHX formulations are available on the market.

Chlorhexidine

CHX is the most widely evaluated and the most efficacious agent against oral biofilms. Its activity was first investigated >50 years ago (Schroeder 1969).

CHX is most often formulated in mouth rinses with a concentration of 0.1–0.2% (Löe *et al*. 1976; Segreto *et al*. 1986; Grossman *et al*. 1989; Flemmig *et al*. 1990; Lang *et al*. 1998). These concentrations achieve the ideal CHX dosage of 18–20 mg/application. Clinical activity is observed with dosages of 5–6 mg t.i.d. and higher dosages do not increase the effect (but do increase adverse effects) (Cancro *et al*. 1974). To obtain a 20-mg dosage with a 0.2% formulation, rinsing with 10 mL should last for 30 seconds; with a 0.12% formulation, rinsing with 15 mL should last for 60 seconds.

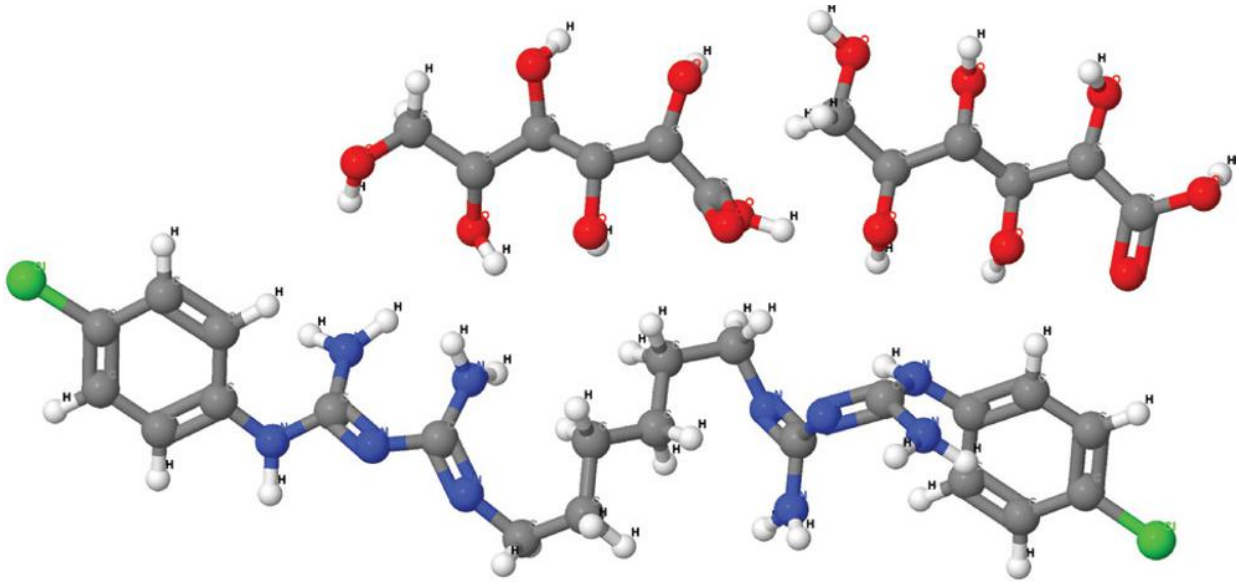

Fig. 37.7 Chemical structure of chlorhexidine digluconate (prepared with Jmol: an open-source Java viewer for chemical structures in 3D. http://www.jmol.org/).

More recently, mouth rinses with lower concentrations (e.g. 0.05%) have been marketed, aiming to decrease adverse effects. The resulting dosages will be approximately 5 mg per application, which is at the lower limit of clinical activity; therefore, the bioavailability of CHX (which depends on the formulation and the presence of other ingredients) is crucial, and combination with other active agents (triclosan, cetylpyridinium chloride, zinc salts) has been proposed (Joyston-Bechal & Hernaman 1993; Marsh & Bradshaw 1995; Claydon *et al*. 2001; Shapiro *et al*. 2002).

- *Characteristics*. CHX is active against Gram-positive and Gram-negative bacteria, yeast, and viruses, including human immunodeficiency virus (HIV) and hepatitis B virus (Wade & Addy 1989).
  - *Antimicobial effect*. This depends on concentration. At low concentrations, CHX increases the permeability of the plasmatic membrane, leading to a bacteriostatic effect (Hugo & Longworth 1964, 1965). At higher concentrations, it induces precipitation of cytoplasmic proteins and cell death, thus having a bactericidal effect (Hugo & Longworth 1966; Fine 1988). CHX has been shown to penetrate biofilms and to actively act inside the biofilm, altering biofilm formation or having a bactericidal effect (Arweiler *et al*. 2001; Shapiro *et al*. 2002).
  - *Plaque inhibitory effect*. In addition to its antimicrobial effect, CHX molecules adhere to the tooth surface and interfere with bacterial adhesion (Rolla & Melsen 1975; Wolff 1985; Fine 1988; Jenkins *et al*. 1988, 1989). CHX also interacts with salivary glycoproteins, thus leading to reduced salivary pellicle formation. In addition, it has been suggested that CHX affects the activity of bacterial enzymes involved in glucan production (glycosiltranferase C) (Vacca-Smith & Bowen 1996).
  - *Substantivity*. CHX molecules bind reversibly to oral tissues, with a slow release (Bonesvoll *et al*. 1974a, b) that allows for sustained antimicrobial effects (up to 12 hours) (Schiøtt *et al*. 1970).
- *Evaluation*: 6-month studies are available both for mouth rinses and for dentifrices.
  - *Dentifrices.* The difficulties in formulating CHX in dentifrices are well known and due to the high risk of inactivation. However, a 1% CHX dentifrice (Yates *et al*. 1993) and a 0.4% CHX dentifrice with zinc (Sanz *et al*. 1994) both demonstrated significant benefits in terms of plaque and, for the 1% CHX dentifrice, also in gingival inflammation.
  - *Mouth rinses*. Different 0.12% and 0.2% mouth rinse formulations have been evaluated in 6-month studies (Sanz *et al*. 1994; Grossman *et al*. 1986, 1989; Flemmig *et al*. 1990; Overholser *et al*. 1990; Hase *et al*. 1998; Lang *et al*. 1998, Charles *et al*. 2004; Stookey 2004), and each independent study revealed statistically significant benefits in terms of both plaque and gingival indices, with one exception. In a systematic review of 0.12% formulations (six studies, one unpublished), the WMD for the plaque index was 1.040 (P <0.001) and for the gingival index was 0.563 (P <0.001; with significant heterogeneity, P = 0.013) (Gunsolley 2006).

    A systematic review *comparing 0.12% and 0.2% formulations* (Berchier *et al*. 2010) included eight papers (with a study duration of 3–14 days, except for one paper reporting 3-month results). For the Quigley & Hein plaque index (Quigley & Hein 1962), meta-analyses of seven papers revealed a significant difference between the two formulations (WMD 0.10; P = 0.008), although this difference was not considered to be clinically relevant and none of the individual studies showed significant differences. For gingival inflammation, no difference was observed in a meta-analysis of three papers.

    CHX and essential oil mouth rinses have been compared. In a systematic review (van Leeuwen *et al*. 2011) of 19 papers, meta-analyses were

carried out on studies with a follow-up of 4 weeks or more. Significant differences (favoring the CHX groups) were found at the final visit for plaque (four studies, WMD 0.19; $P = 0.0009$), but no significant difference for gingival inflammation (three studies, WMD 0.03; $P = 0.58$). Significantly more staining was observed in the CHX groups (WMD 0.42; $P < 0.000001$). It must be highlighted, however, that the meta-analyses considered final visit values, rather than the changes between the baseline and final visit. In addition, different CHX concentrations and formulations were pooled, as well as different follow-up times. Another meta-analysis only included 6-month studies (Gunsolley 2006) and pooled data from four studies (Segreto & Collins 1993; Grossman *et al*. 1989; Overholser *et al*. 1990; Charles *et al*. 2004). A significant difference ($P = 0.02$) in plaque was reported, favoring 0.12% CHX formulations, with two individual studies demonstrating significant differences. For the gingival index, one study reported significant differences, and the pooled results showed a tendency to significant differences ($P = 0.068$). The authors highlighted that the essential oil mouth rinse showed 60% of the effect of CHX mouth rinses for both parameters.

- *Limitations*. CHX safety has been extensively studied. Only heating for long periods of time can induce the formation of 4-chloroanilinine, which has been shown to be cancerogenic and mutagenic. Despite the low risk of formation of 4-chloroanilinine, CHX formulations are marketed in dark bottles, and should be kept at room temperature, out of direct sunlight. No adverse microbiologic changes, including the overgrowth of opportunistic strains, are induced over long-term use (Schiøtt *et al*. 1970, 1976a, b).

  Reported adverse events include:
  - Hypersensitivity reaction (Beaudouin *et al*. 2004)
  - Neurosensory deafness if the product is placed in the middle ear (Aursnes 1982)
  - Taste alterations (Marinone & Savoldi 2000; Breslin & Tharp 2001), particularly affecting salty and bitter taste; these are reversible and disappear soon after discontinuation of product usage
  - Uni- or bi-lateral parotid tumefaction (Fløtra et al. 1971; van der Weijden *et al*. 2010)
  - Mucosal erosion (Almqvist & Luthman 1988)
  - Healing process alterations. *In vitro* studies have suggested some inhibition of fibroblast proliferation in culture. However, *in vivo* studies of CHX mouth rinses after periodontal surgery have found no interference with the healing process; indeed, a better resolution of inflammation was observed (Sanz *et al*. 1989)
  - Increase in calculus formation (Yates *et al*. 1993)
  - *Staining* of teeth, mucosa, tongue dorsum, or restorations (Fløtra *et al*. 1971). Tooth and tongue staining is the most common adverse effect (Fig. 37-8) and different mechanisms have been proposed to explain staining associated with CHX usage (Watts & Addy 2001):
    - Degradation of the CHX molecule to parachloraniline
    - Catalysis through Maillard reactions
    - Protein denaturation with formation of metal sulfide
    - Precipitation of anionic dietary chromogens.

    The intensity of staining seems to correlate with the frequency of intake of chromogenic products, such as coffee, tea, wine, and tobacco, and also with the concentration of CHX in commercial formulations. In addition, a direct correlation has been observed between staining and antimicrobial effect (Addy *et al*. 1989; Claydon *et al*. 2001).

    In recent years, different methods to decrease the staining associated with CHX have been evaluated, including the use of an antidiscoloration system (ADS). Although equivalent antimicrobial efficacy was claimed on the basis of short-term studies (Cortellini *et al*. 2008; Solís *et al*. 2011), other investigations have shown that ADS also diminishes the efficacy of CHX (Arweiler *et al*. 2006; Guggenheim & Meier 2011).

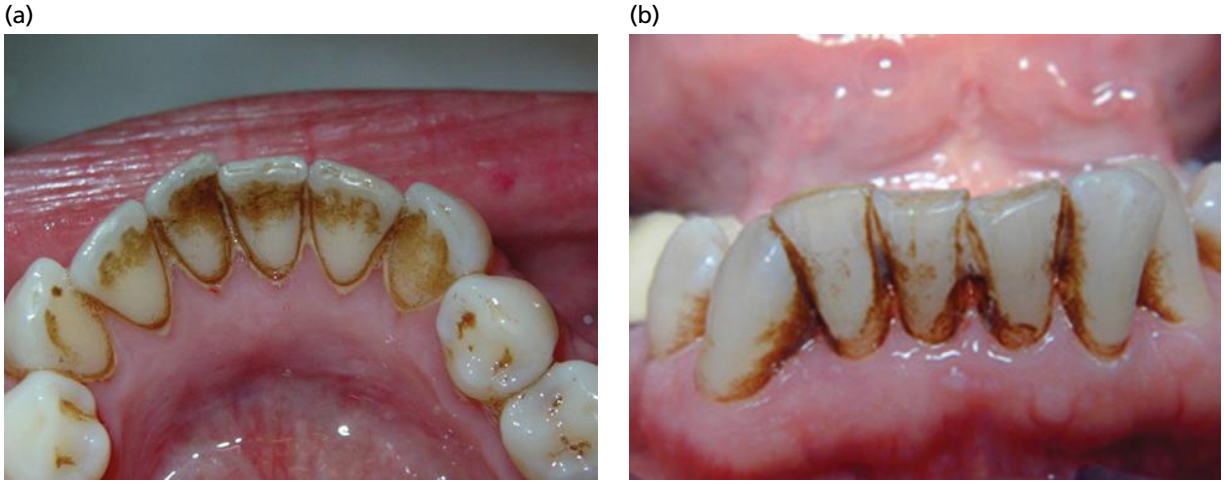

Fig. 37-8 Tooth staining after chlorhexidine use. (a) Lingual aspect; (b) buccal aspect.

- *Usefulness, marketed*. The first CHX formulations in Europe were 0.2% mouth rinses in hydroalcohol vehicle, and the first demonstration of antiseptic activity was in studies of 0.2% products (Löe *et al*. 1976). However, the CHX formulation that obtained the ADA seal was Peridex® (Zila Pharmaceuticals, Phoenix, AZ, USA), which was formulated at 0.12%. Since then, many CHX formulations have been marketed. However, it has been demonstrated that the mere presence of CHX in a product does not assure clinical activity (Harper *et al*. 1995; Herrera *et al*. 2003). Therefore, study models and/or clinical trials are needed to confirm that the activity of a new formulation is similar to that of the reference products. In addition, concerns for adverse effects and the presence of alcohol in mouth rinses, have led to new formulations without alcohol, with lower CHX concentration, and/or combined with other active agents.

Quaternary ammonium compounds

Benzylconium chloride and cetylpyridinium chloride (CPC) (Fig. 37-9).

- *Characteristics*. Monocationic agents that rapidly adsorb to oral surfaces (Bonesvoll & Gjermo 1978). Substantivity approaches 3–5 hours (Roberts & Addy 1981), due to rapid desorption, loss of activity, less retention or neutralization (Bonesvoll & Gjermo 1978). The mechanism of action relies on the hydrophilic part of the CPC molecule interacting with the bacterial cell membrane, leading to the loss of cell components, disruption of cell metabolism, inhibition of cell growth, and finally cell death (Merianos 1991; Smith *et al*. 1991). However, the positive charge of this active hydrophilic part means that it may be inactivated by other products in the formulation, making it crucial that a CPC formulation is evaluated for bioavailability.
- *Evaluation*: Three 6-month trials have been published, one with a 0.05% formulation (Allen *et al*. 1998) and two with 0.07% formulations (Mankodi *et al*. 2005b; Stookey *et al*. 2005). With the addition of four unpublished studies, a meta-analysis demonstrated significant benefits in terms of plaque index (seven studies, two published; P <0.001) and gingivitis index (five studies, two published; P = 0.003), although the studies were highly heterogeneous, and they evaluated different formulations (Gunsolley 2006). In another systematic review, the meta-analysis of the three 6-months studies revealed a WMD of 0.42 (P <0.00001; heterogeneity P = 0.06) for the Quigley & Hein plaque index at the final visit (Haps *et al*. 2008).
- *Limitations*. Safety of CPC formulations, marketed since 1940, has been demonstrated for concentrations of 0.045–0.1% (Nelson & Lyster 1946; Margarone *et al*. 1984; Lin *et al*. 1991; Segreto 2004; Stookey 2004; Federal Register 2004, unpublished studies C.1 and C.2). Adverse effects are less frequent than with CHX formulations, and include tooth and tongue staining, transient gingival irritation, and aphthous ulcers in some individuals (Lobene *et al*. 1979). In addition, no significant changes in the oral microbiota or overgrowth of opportunistic species have been observed (Ciancio *et al*. 1975).
- *Usefulness, marketed*. With 0.05% CPC (Cepacol Combe, White Plains, NY, USA), 0.045% CPC (Scope, Procter & Gamble), and 0.07% CPC (Crest ProHealth, Procter & Gamble; Vitis Xtra Forte, Dentaid;...).

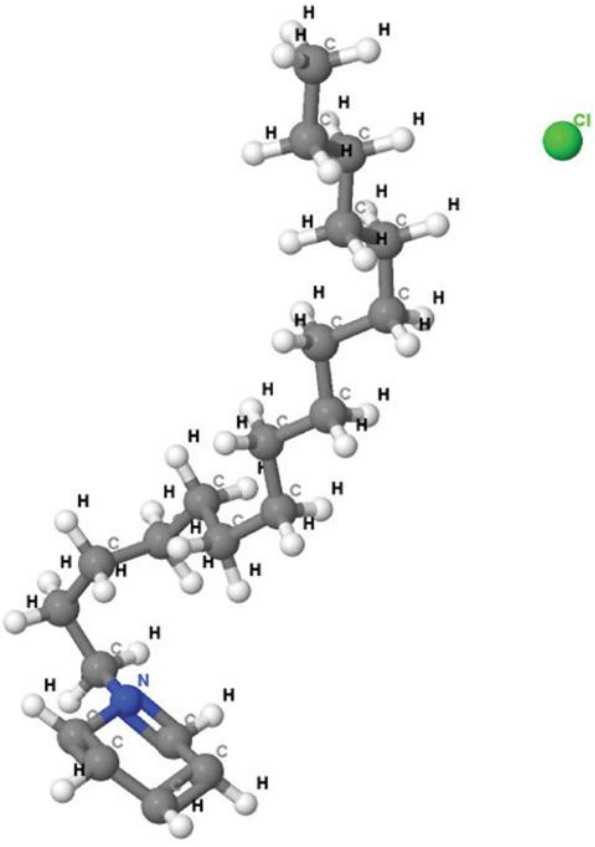

Fig. 37-9 Chemical structure of cetylpyridinium chloride (prepared with Jmol: an open-source Java viewer for chemical structures in 3D. http://www.jmol.org/).

Hexetidine

Hexetidine is a pyrimidine derivative.

- *Characteristics*: Shows antimicrobial properties against Gram-positive and Gram-negative bacteria and yeast (*Candida albicans*) (Menghini & Sapelli 1980; Jones *et al*. 1997). However, oral retention seems to be limited and antimicrobial activity may not last >90 minutes (McCoy *et al*. 2000).
- *Evaluation*. *In vitro* results suggest some bactericidal activity, even in biofilm models (Shapiro *et al*. 2002), but with a wide variability. In a systematic review (Afennich *et al*. 2011), six randomized controlled trials were identified, but the longest follow-up was 6 weeks. The results demonstrated heterogeneity and therefore, *in vivo* results have not demonstrated plaque inhibitory or antiplaque activity for hexetidine products.

- *Limitations*. Tooth staining, mucosal erosion, and parotid gland swelling, but with low frequency (Addy & Moran 1984; Yusof 1990; van der Weijden *et al*. 2010).
- *Usefulness, marketed*. Normally formulated at 0.1%, with many different brand names (Bactidol, Hexalen, Hexoral, Hextril, Oraldene, Oraldine, and Oraseptic).

Povidone iodine

Iodine is a recognized antibacterial agent, which is combined with the synthetic polymer povidone.

- *Characteristics*. At 1% it has demonstrated substantivity of only 1 hour.
- *Evaluation*. Limited substantivity leads to a very limited plaque inhibitory action (Addy *et al*. 1977; Addy & Wrigth 1978). It has been evaluated combined with 1.5% hydrogen peroxide (5% povidone iodine), both short term (Maruniak *et al*. 1992) and for 6 months (Clark *et al*. 1989), combining rinsing and subgingival irrigation, with clear reductions of gingivitis (Greenstein 1999). Povidone iodine has also been used in the treatment of necrotizing gingivitis (Addy & Llewelyn 1978) and as an adjunct to scaling and root planing, and been shown to significantly decrease pocket depth but with only small clinical significance (Sahrmann *et al*. 2010).
- *Limitations*. No relevant side effects, but it may affect thyroid function.
- *Usefulness, marketed*. Betadine (10% povidone iodine; still available), Perimed (1.5% hydrogen peroxide with 5% of povidone iodine; no longer available).

Other evaluated products

- *Acidified sodium chlorite*. Suggested to have similar activity to CHX (Fernandes-Naglik *et al*. 2001), but with the potential to erode enamel (Pontefract *et al*. 2001).
- *Chlorine dioxide*. Frequently used for oral halitosis; its plaque-inhibitory and antiplaque effects have still to be assessed (Paraskevas *et al*. 2008; Shinada *et al*. 2010).
- *Salifluor*. 5n-octanoyl-3′-trifluormethylsalicylanilide was tested in the late 1990s with acceptable results (Furuichi *et al*. 1996; Nabi *et al*. 1996).
- *Polyhexamethylene biguanide hydrochloride*. Evaluated in study models in the early 2000s at concentrations of 0.04-0.2% and demonstrated the capacity to inhibit plaque regrowth (Rosin *et al*. 2002; Welk *et al*. 2005).
- *Herbal products*. Herbal extracts of tea tree oil (*Melaleuca alternifolia*) have shown conflicting results (Arweiler *et al*. 2000). Also, green tea extracts have been formulated in mouth rinses, but there is limited evidence available assessing their activity (Venkateswara *et al*. 2011).

Future approaches

Molecular signaling

Since signaling molecules (such as acyl homoserine lactones) are involved in biofilm architecture and detachment, future treatment approaches may focus on quorum-sensing systems (Donlan & Costerton 2002). In addition, inhibitors of quorum-sensing processes may reduce the virulence of certain pathogens (Rasch *et al*. 2007; Harjai *et al*. 2010).

Inhibition of transcription genes

If the genes that are activated or repressed during initial biofilm formation are identified and selectively targeted, this may inhibit biofilm formation (Donlan & Costerton 2002).

Probiotics

The use of probiotic products (from bacterial species such as *Streptococcus salivarius*, *Lactobacillus reuteri*, *Lactobacillus salivarius*) may have an effect on biofilm composition, either through competition or release of bacteriocins. Some studies have reported a decrease in pathogenic species (Mayanagi *et al*. 2009) and some improvement in the levels of plaque and gingival inflammation with probiotics (Krasse *et al*. 2006; Shimauchi *et al*. 2008; Harini & Anegundi 2010; Teughels *et al*. 2011).

Delivery formats

Different formats are available to deliver agents for chemical plaque control: rinses, gels, dentifrices, chewing gums, aerosols, varnishes, sustained-release devices, lozenges, and irrigators (Addy & Renton-Harper 1996).

Mouth rinses

Mouth rinses are formulated with different ingredients, including colorings, flavorings, preservatives (sodium benzoate), stabilizers, and active agents.

Among the stabilizers, one of the most frequently used is alcohol. However, some controversy exists with regards to the inclusion of alcohol in mouth rinse formulations, due to the suggested association between alcohol and oropharyngeal cancer. However, critical assessment of the literature does not support the statement (Ciancio 1993; Claffey 2003), but alcohol is not recommended in mouth rinses for use by children, former alcoholics, and patients with conditions affecting the oral mucosae (e.g. lichen planus, leukoplakia). Other suggested problems associated with the presence of alcohol in mouth rinses are:

- Systemic toxicity in children: cases arising from swallowing alcohol-containing mouth rinses have infrequently been reported (Eley 1999)
- Intraoral discomfort: which is probably concentration related (Bolanowski *et al*. 1995).

- Softening of composite hardness: this softening effect can be directly related to the percentage of alcohol in the mouth rinse (McKinney & Wu 1985; Penugonda *et al*. 1994).

Most agents for chemical plaque control have been formulated as mouth rinses, since this vehicle has a number of advantages:

- Favorable pharmacokinetics: easier to reach the effective dosage of the active agent
- Can be used independently of the ability of the patient to perform toothbrushing
- Allows access to difficult-to-reach areas; the tonsils can be reached by gargling
- Easy to use and well accepted by patients.

Dentifrices

Dentifrices represent the ideal delivery format, especially from a preventive perspective, since they are used as an adjunct to the most frequently employed oral hygiene measure, toothbrushing. However, a number of disadvantages can be listed:

- Formulation of some active agents may be difficult
- Pharmacokinetics are less predictable
- Not possible to perform toothbrushing in certain clinical situations, thus limiting the use of a dentifrice: disabled patients, after oral surgery, intermaxillary fixations ...
- Do not reach difficult-to-access areas, such as the tonsils or the dorsum of the tongue.

The different ingredients in a dentifrice formulation are:

- *Abrasives*. These determine the consistency of the dentifrice and ease dental plaque and stain removal. However, higher dentifrice abrasivity does not seem to contribute to increased plaque removal with a manual toothbrush. It appears that the mechanical action of the toothbrush is the main factor in the plaque-removing process (Paraskevas *et al*. 2006). The most common abrasives are calcium carbonate, alumina, dicalcium phosphate, and silica.
- *Detergents*. The most widely used is SLS, which provides some antimicrobial action (Jenkins *et al*. 1991a, b), although no evidence is available to support its effectiveness in plaque removal.
- *Thickeners*. These include silica and gums, and they influence the viscosity of the toothpaste.
- *Sweeteners*, such as sodium saccharin.
- *Humectants*. These prevent the toothpaste from drying up; glycerine and sorbitol are the most commonly used.
- *Flavorings*, such as mint and strawberry.
- *Coloring agents*.
- *Active agents*, including fluorides, triclosan, CHX (with some difficulties in the formulation, due to its interference with anionic detergents and with flavorings), CPC, and other active agents (anticalculus agents, whitening products, desensitizing agents).

Gels

Gels do not include abrasives or detergents. Active agents are formulated more easily in gels than in dentifrices, but other disadvantages are similar: less predictable pharmacokinetics, impossible to use in certain clinical situations, and lack of access to some difficult-to-reach areas.

CHX gels are available in different concentrations, including 0.1%, 0.12%, 0.2%, 0.5%, and 1%, to be used with toothbrushing or applied in trays. For toothbrushing, the amount of CHX delivered is not predictable (Saxén *et al*. 1976). Reduction in the levels of plaque and inflammation has been reported with gel application in a dental tray (Francis *et al*. 1987b; Pannuti *et al*. 2003; Slot *et al*. 2010), although the acceptance by disabled patients and therapy providers was not high (Francis *et al*. 1987a).

CHX gel may also be used for other purposes, such as the prevention of alveolitis after tooth extraction (Hita-Iglesias *et al*. 2008; Minguez-Serra *et al*. 2009). Its use has also been suggested as part of the protocol for full-mouth disinfection, including 1% CHX gel for tongue brushing for 1 minute and subgingival irrigation of pockets (Bollen *et al*. 1996, 1998). More recently, it has been evaluated in peri-implant mucositis therapy (Heitz-Mayfield *et al*. 2011), with limited effects.

Gels containing 0.4% stannous fluoride have also been evaluated, with reported reductions in gingival inflammation and bleeding on probing (Tinanoff *et al*. 1989; Boyd & Chun 1994).

Chewing gums

CHX has been formulated in chewing gums for use as an adjunct to or even short-term replacement of mechanical plaque control. A reduction in the levels of plaque and gingival inflammation has been reported with chewing gum use (Ainamo & Etemadzadeh 1987; Smith *et al*. 1996; Simons *et al*. 2001; Kolahi *et al*. 2008).

Varnishes

CHX varnishes have been used in the prevention of root caries (Clavero *et al.* 2006; Baca *et al*. 2009), although no solid evidence is available to support their use (Bader *et al*. 2001; Zhang *et al*. 2006).

Lozenges

Both CPC and CHX have been formulated as lozenges. For CPC lozenges, interactions with other ingredients of the formulation have been observed (Richards *et al*. 1996). Clinical use is associated with a reduction in levels of plaque and gingival inflammation, although these reductions are smaller than those achieved with a CHX mouth rinse (Vandekerckhove *et al*. 1995). Reductions in plaque and gingivitis levels have also been reported for CHX lozenges. Mean plaque score was reduced by 62.8% (from 2.38 to 0.89; $P < 0.0001$), after 1 week of usage (Kaufman *et al*. 1989).

Irrigators

The use of irrigators has been suggested to remove food debris from teeth and dental restorations. They may help to improve oral health in subjects not using interdental devices (Frascella *et al*. 2000). The use of irrigators is not associated with an improvement in plaque levels, but it may have some effect on gingival inflammation (Husseini *et al*. 2008). Different agents can be used with irrigators and good results have been reported for CHX (Lang & Räber 1981).

Sprays

The advantage of aerosols is that the agent can be applied exactly where it is needed. However, the dosage is not predictable. Aerosols with 0.2% CHX have been used in disabled patients to prevent biofilm formation (Francis *et al*. 1987b; Kalaga *et al*. 1989b). Their use on all dental surfaces is associated with a reduction in plaque level similar to that obtained with mouth rinsing, but the adverse effects are also the same (Francis *et al*. 1987b; Kalaga *et al*. 1989a).

Sustained-release devices

CHX is also formulated in sustained-release devices designed with a therapeutic purpose: chips, gels, and xanthan gels (see Chapter 43 for a review of their effects).

Clinical indications for chemical plaque control: Selection of agents

As it has been reviewed, different agents (alone or in combination) in different delivery format and formulations are available for clinical use. In addition, many different indications for their use have been proposed. Therefore, it may be challenging for the clinician to decide whether or not to prescribe a chemical oral hygiene product, and if one is to be prescribed, which one, as well as which formulation, in which delivery format, at which dosage, and for how long. In this section, some guidelines are provided, based on the scientific evidence available. However, due to the limitations of the evidence, all suggestions should be viewed with caution and each clinical case should be considered individually.

Different clinical situations, depending on the duration of product usage and the main objective of the intervention, are considered: single use, short-term use (either with a preventive or a therapeutic aim), and long-term use (either with a preventive or a therapeutic aim).

Single use

Different objectives may be considered for a single use.

To decrease of the bacterial load

CHX has been shown to reduce the aerolized bacterial load during different oral interventions (e.g. debridement with sonic or ultrasonic devices), decreasing the risk of cross-contamination in a dental setting (Stirrups 1987; Worrall *et al*. 1987; Logothetis & Martinez-Welles 1995). Also, a single rinsing with essential oils has been shown to affect aerolized bacterial load (Fine *et al*. 1993).

To decrease the risk of bacteremia

Different studies have assessed the effect of CHX usage on the risk of bacteremia associated with dental interventions (scaling, tooth extraction), both by means of rinsing (Jokinen 1978; Rahn *et al*. 1995; Lockhart 1996; Brown *et al*. 1998; Tomas *et al*. 2007) or subgingival irrigation (MacFarlane *et al*. 1984). Other active agents have also been evaluated for this indication: essentials oils (Fine *et al*. 1993; DePaola *et al*. 1996; Fine *et al*. 2010) and povidone iodine, both as mouth rinse (Jokinen 1978) or subgingival irrigation (Rahn *et al*. 1995). However, following evaluation of the available evidence, a recent consensus report concluded that CHX, used as an oral rinse, does not significantly reduce the level of bacteremia following dental procedures (Centre for Clinical Practice at NICE (UK) 2008). In addition, the American Heart Association concluded: "topical antiseptic rinses do not penetrate beyond 3 mm into the periodontal pocket and, therefore, do not reach areas of ulcerated tissue where bacteria most often gain entrance to the circulation. On the basis of these data, it is unlikely that topical antiseptics are effective in significantly reducing the frequency, magnitude and duration of bacteremia associated with a dental procedure" (Wilson *et al*. 2007).

To decrease the risk of infection of the surgical area

CHX has been evaluated as a preoperative measure before oral surgery, to decrease bacterial load and the risk of postoperative infection (Worrall *et al*. 1987).

Summary: The general aim of single use is to reduce the bacterial load in the oral cavity before an intervention. The highest bactericidal action is desirable and is demonstrated by CHX formulations both *in vitro* and *in vivo*. Due to the single use, side effects are not common and if present, they rapidly disappear. In case of intolerance, other active agents may be considered, such as CPC (Pitten & Kramer 2001), essentials oils (Fine *et al*. 1993; DePaola *et al*. 1996; Fine *et al*. 2010) or povidone iodine (Jokinen 1978; Rahn *et al*. 1995).

Short-term use for the prevention of dental biofilm formation

In clinical situations in which mechanical control may be limited due to discomfort or postoperative instructions to avoid mechanical contact with a treated area (e.g. following regenerative or mucogingival surgery), use of chemical plaque control may have a preventive objective on a short-term basis. The

most widely used agent for preventive indications (aiming to compensate for the limitations of mechanical biofilm control) is CHX, since side effects will be limited due to the short-term usage.

After scaling and root planing or periodontal surgery

Both CHX (Sanz *et al*. 1989; Christie *et al*. 1998; Eley 1999) and essential oil mouth rinses (Zambon *et al*. 1989; Laspisa *et al*. 1994) have demonstrated benefits. Use of the antiseptic products should be maintained until mechanical biofilm control is again adequate.

Prevention of postsurgical infection

When CHX rinses were used during postsurgical care, a lower infection rate (17 infections in 900 procedures, 1.89%) was observed, compared to that following procedures with no CHX as part of the postsurgical care (five infections in 153 procedures, 3.27%) (Powell *et al*. 2005). In addition, a lower incidence of postextraction alveolitis has been reported with the use of a 0.2% CHX gel (Hita-Iglesias *et al.* 2008; Minguez-Serra *et al*. 2009) or a 0.2% CHX rinse (Tjernberg 1979).

Patients with intermaxillary fixations

After bone fractures or after orthognatic or cosmetic maxillary surgeries when no mechanical hygiene is possible, CHX mouth rinses have been shown to be useful in biofilm formation prevention (Nash & Addy 1979).

Patients with mucosal or gingival acute infections

In these patients, pain precludes mechanical hygiene and CHX mouth rinses may be useful in biofilm formation prevention (Eley 1999).

Short-term use for therapy

Other clinical situations may require the short-term use of antiseptic products with a therapeutic aim. The most widely used agent for therapeutic indications (aiming to control the pathogenic microorganisms) is CHX, since the risk of side effects will be limited due to the short-term usage. Also, any side effects are easily reversible.

Necrotizing gingivitis therapy

Chemical agents alone may have limited antimicrobial activity against an organized biofilm because of the difficulties of penetration. Therefore, chemical agents should be used in conjunction with mechanical debridement. The recommended agent is a CHX mouth rinse (Hartnett & Shiloah 1991). Other agents have been evaluated in necrotizing gingivitis, such as oxygenating agents and iodine povidone (Wade *et al*. 1966; Addy & Llewelyn 1978).

Candidiasis therapy

Use of CHX mouth rinses has been proposed in candidiasis treatment (Ellepola & Samaranayake 2001; Torres *et al*. 2007). However, as sole therapy, complete resolution is not achieved, and they are more effective in combination with specific antifungal agents (e.g. itrakonaxole) (Simonetti *et al*. 1988). However, a possible interaction between CHX and nistatine in combined use has been proposed, due to the formation of a less soluble salt (Barkvoll & Attramadal 1989). As part of candidiasis therapy, the immersion of dental prosthesis in 0.2% CHX is effective in eliminating *Candida* spp. from the prosthesis (Olsen 1975; Uludamar *et al*. 2011). In cases of intolerance to CHX, CPC mouth rinses have been proposed as an alternative (Pitten & Kramer 2001).

Peri-implant mucositis therapy

Treatment strategies have been developed based on mechanical or chemical plaque control, alone or in combination, and some of these have been evaluated in randomized controlled trials. No additive effect (over mechanical control) from the application of a CHX gel was observed (Thone-Muhling *et al.* 2010; Heitz-Mayfield *et al*. 2011), as was also true for irrigation of the sulcus (Porras *et al*. 2002). In one study, CHX irrigation provided better results than CHX rinsing (Felo *et al*. 1997). In home-use studies, an essential oil mouth rinse (Ciancio *et al*. 1995) and a triclosan/co-polymer dentifrice (Ramberg *et al*. 2009) demonstrated better clinical results than the control.

Peri-implantitis therapy

Adjunctive CHX application in the treatment of periimplantitis lesions has been shown to have only limited effects on clinical and microbiologic parameters (Renvert *et al.* 2008).

Periodontitis therapy

The adjunctive use of antiseptics (especially CHX mouth rinses) has been evaluated, most frequently in a full-mouth disinfection approach (Quirynen *et al*. 1995, 2000; Greenstein 2002, 2004). Use of different CHX formulations (including mouth rinse, spray, irrigators, gel for the tongue dorsum) in addition to debridement within 24 hours showed additional clinical benefits in some studies (Quirynen *et al*. 2000). However, systematic reviews have not confirmed these results, although modest benefits favoring full-mouth approaches were observed (Eberhard *et al*. 2008a, b; Lang *et al*. 2008). The use of CHX mouth rinses during basic periodontal therapy may help in

controlling the dental biofilm, resulting in additional benefits in terms of clinical and microbiologic parameters (Faveri *et al*. 2006; Feres *et al*. 2009).

Long-term use for the prevention of dental biofilm formation

Patients carrying fixed or removable orthodontic appliances

The presence of these appliances makes mechanical control more difficult, facilitates plaque retention, and thus promotes gingivitis development (Ristic *et al*. 2007; Levin *et al*. 2008). Additionally, many orthodontic patients, especially children and adolescents, fail to floss because they find this procedure time-consuming and tedious in the presence of orthodontic arch wires (Alexander 1993). A common strategy to improve mechanical plaque removal in these patients is the addition, as part of the oral hygiene regimen, of a chemotherapeutic antimicrobial agent (Ainamo 1977). The efficacy of different active ingredients, such as CHX (Brightman *et al*. 1991; Anderson *et al*. 1997; Chin *et al.* 2006; Olympio *et al*. 2006), essential oils (Tufekci *et al*. 2008), amine/stannous fluoride (Ogaard *et al.* 2006) or sanguinarine (Hannah *et al*. 1989), in the form of mouth rinses, toothpastes or gels has been evaluated in clinical studies. Most have reported significant benefits from the adjunctive use of these products, although the magnitude of the reported benefits might not have a clear clinical relevance. In addition, the use of some of the formulations was associated with adverse effects (such as staining with the use of CHX).

Disabled patients

In physically or mentally disabled patients, the use of CHX improves plaque and gingival health (Storhaug 1977). In these patients, a spray (0.2% CHX) is the preferred vehicle (Francis *et al*. 1987a, b; Kalaga *et al*. 1989b; Clavero *et al*. 2003).

Patients with gingival overgrowth or enlargement

In these patients, mechanical control is difficult and a CHX mouth rinse may be helpful (O'Neil & Figures 1982; Saravia *et al*. 1990; Francetti *et al*. 1991).

Periodontitis patients

Together with an adequate professional supportive periodontal therapy program, chemical agents may be recommended to improve biofilm control and to decrease the risk of disease progression. A careful consideration of the risk-to-benefit ratio should be made, since these patients will be in supportive therapy for life. Low-dose CHX mouth rinses have been evaluated and a formulation of 0.05% CHX and 0.05% CPC has been reported to have beneficial effects with limited adverse events (Soers *et al*. 2003; Santos *et al*. 2004; Quirynen *et al*. 2005; Escribano *et al*. 2010). Also, a dentifrice with triclosan and co-polymer, evaluated for 2 years, demonstrated a significant reduction in the detection of deep pockets and sites with clinical attachment loss and bone loss (Rosling *et al*. 1997a, b; Bruhn *et al*. 2002).

Patients with dental implants

The use of different agents (CHX, triclosan, stannous fluoride, essential oils) has been suggested to favor biofilm control and to decrease the risk of peri-implant diseases (Ciancio *et al*. 1995; Di Carlo *et al*. 2008; Sreenivasan *et al*. 2011). In randomized controlled trials, triclosan with co-polymer significantly improved clinical and microbiologic variables, as compared with a fluoride dentifrice, after 6 months (Sreenivasan *et al*. 2011); conversely, no influence on implant survival and clinical variables was observed with the use of 0.12% CHX mouth rinses in a 5-year study (Truhlar *et al*. 2000).

General population

The main aim in the general population is to maintain periodontal health with the presence of a biofilm in equilibrium with the host response. Different agents have demonstrated an antiplaque effect in 6-month trials, including mouth rinses with CHX (Gunsolley 2006), with essential oils (Stoeken *et al*. 2007), with delmopinol (Addy *et al*. 2007), and with CPC (Gunsolley 2006), or with dentifrices with triclosan and co-polymer (Hioe & van der Weijden 2005; Gunsolley 2006), or with stannous fluoride (Gunsolley 2006; Paraskevas & van der Weijden 2006).

The benefit of the daily usage of antiseptic products in a general population is a subject of controversy. However, the results of available studies reflect clinical benefits beyond those obtained with improvement in mechanical oral hygiene due to oral hygiene instructions. As suggested by the systematic review by Gunsolley (2006), reductions in the placebo groups in plaque (15.7 ± 18.7) and gingivitis (18.5 ± 15.6) are associated with the Hawthorne effect and oral hygiene instructions, and should reflect the efficacy of oral hygiene instructions provided in clinical practice. The added benefit of the adjunctive use of CHX or essential oils mouth rinses were evident and significant (for CHX, 40.4 ± 11.5 in plaque reduction and 28.7 ± 6.5 in gingivitis reduction; for essential oils, 27.0 ± 11.0 and 18.2 ± 9.0, respectively).

Long-term use for the prevention of other oral conditions

Predisposed patients, with high risk of suffering oral infections

In patients with blood dyscrasia or who are immunosuppressed, the use of CHX mouth rinses may help to prevent oral or systemic complications, but they may

not be useful once the infection appears (Eley 1999). In patients on mechanical ventilation, reduction of aerobic pathogens in the oropharyngeal tract was observed in patients using a CHX gel (Fourrier *et al*. 2005). Studies with CHX have demonstrated its capacity to prevent oral complications, such as the occurrence of chronic or opportunistic infections, including *Candida* spp., in high-risk patients (irradiated patients, patients on chemotherapy or bone marrow transplant recipients) (Addy & Moran 1997).

Oral mucositis prevention (associated with radiation or chemotherapy in head and neck cancer patients)

CHX rinses have been proposed as part of the treatment to prevent or treat oral mucositis. CHX mouth rinses for the prevention of oral mucositis have been evaluated in numerous randomized controlled trials (Ferretti *et al*. 1990; Spijkervet *et al*. 1990; Epstein *et al*. 1992; Foote *et al*. 1994; Dodd *et al*. 1996; Pitten *et al*. 2003; Lanzos *et al*. 2010, 2011), but the outcomes differed. Seven studies were included in a meta-analysis (Stokman *et al*. 2006) and showed no effect of CHX in the prevention of mucositis in chemotherapy and radiotherapy patients (odds ratio 0.7; 95% CI 0.43–1.12).

Caries prevention

CHX use has been shown to reduce counts of *S. mutans* in at-risk patients (Ullsfoss *et al*. 1994; Quirynen *et al*. 2005). The best vehicle was varnish, followed by gel and mouth rinse (Emilson & Fornell 1976; Emilson 1994). Also, a reduction in caries incidence was reported for CHX in dentifrice with sodium fluoride (Dolles & Gjermo 1980; FDI Commission 2002a), but other studies have reported poorer results for CHX formulations with sodium fluoride as mouth rinses (Shapiro *et al*. 2002; Herrera *et al*. 2003). Essential oil mouth rinses have also been shown to reduce *S. mutans* levels (Fine *et al*. 2000; Agarwal & Nagesh 2011), but no studies on caries incidence are available. Dentifrices with triclosan and co-polymer or a zinc salt have demonstrated superior anticaries activity than fluoride dentifrices (Panagakos *et al*. 2005), even in long-term studies (Mann *et al*. 2001). In high-risk patients, amine and stannous fluoride may also be recommended, based on their proven remineralization and anticaries action (Tinanoff *et al*. 1980; Paraskevas *et al*. 2004).

Candidiasis prevention

CHX has been evaluated with regards to candidiasis prevention in patients with systemic diseases and in patients with dental prosthesis (Ferretti *et al*. 1987, 1988; Toth *et al*. 1990; Barasch *et al*. 2004; Elad *et al*. 2006).

Prevention of recurrent aphthous ulcers

CHX use may reduce the incidence, duration, and severity of ulcers, including in patients with fixed orthodontic appliances (Shaw *et al*. 1984). Triclosan formulations may also decrease the incidence of oral ulcers (Skaare *et al*. 1996).

Halitosis therapy and secondary prevention

Different chemical agents and formulations have been evaluated with respect to two main aims: antibacterial and interference with the volatilization of odoriferous compounds. Among the most evaluated agents, the following may be highlighted: essential oil mouth rinses (Pitts *et al*. 1983; Kozlovsky *et al*. 1996); triclosan with zinc or co-polymer (van Steenberghe 1997; Sharma *et al*. 1999; Niles *et al*. 2003; Hu *et al*. 2005); or CHX, especially if combined with zinc salts and CPC (Roldán *et al*. 2003b; Winkel *et al*. 2003; Roldán *et al*. 2004). In order to be effective, these agents need to be used in conjunction with adequate oral hygiene and tongue scrapping or brushing (Roldán *et al*. 2003a) (see Chapter 36).

Conclusion

The main aim of supragingival biofilm control is to allow for the presence of a biofilm in equilibrium with the host response, in order to maintain a healthy status. Due to the limitations of mechanical biofilm control, chemical control has been extensively evaluated and is widely used.

Although different delivery formats are available to deliver the active agents, two can be highlighted: mouth rinses, due to their favorable pharmacokinetics and ease of use, and dentifrices, due to their concomitant use with toothbrushing, although their pharmacokinetic profiles are less favorable and they are more difficult to formulate.

Most of the agents are antimicrobials, but other mechanisms of action have been proposed and some marketed effective agents are not antimicrobials (e.g. delmopinol). Substantativity is identified as one of their most relevant characteristics associated with their clinical activity.

In the evaluation of the different agents and formulations, 6-month home-use, randomized clinical trials represent the highest level of evidence, especially when their results are pooled in meta-analyses. Based on the available evidence, CHX mouth rinses achieve the highest reductions in plaque levels, with the lowest heterogeneity among studies (Tables 37-1, 37-2). Triclosan with co-polymer in dentifrice has shown the largest reduction in gingival index, but with a high level of heterogeneity.

However, CHX products are not free from adverse effect, especially tooth staining. Therefore, in a clinical situation in which the product is needed for a

prolonged period of time, the risk-to-benefit ratio should be evaluated. In some clinical situations, the benefits will compensate for the adverse effects (staining), such as in disabled patients or those with high systemic risk. In situations in which the benefits do not compensate for the adverse effects, alternatives with lower effect but also with fewer adverse events should be considered.

Chapter 38

Non-surgical Therapy

Jan L. Wennström and Cristiano Tomasi

Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Introduction

Non-surgical therapy involves various means to control the infection causing pathologic lesions in the periodontal tissues. Pocket/root instrumentation (scaling and root planing), combined with effective self-performed supragingival plaque control measures, serves this purpose by altering the subgingival ecology through disruption of the microbial biofilm, reduction of the amount of bacteria, and suppression of the inflammation. A variety of instruments and approaches to treatment may be utilized in non-surgical therapy.

This chapter outlines the various means and methods used in non-surgical periodontal therapy and their respective merits, shortcomings, and clinical efficacy. Addressed also are considerations in relation to the selection of instruments and treatment approach, as well as re-evaluation after initial non-surgical therapy.

Goal of non-surgical pocket/root instrumentation

Periodontitis is strongly associated with the presence of bacterial biofilms and dental calculus on root surfaces. Hence, the ultimate goal of non-surgical pocket/root instrumentation is to render the root free from microbial deposits and calculus. However, several *in vitro* (e.g. Rateitschak-Pluss *et al.* 1992; Breininger *et al.* 2001) and *in vivo* studies (e.g. Waerhaug 1978; Eaton *et al.* 1985; Caffesse *et al.* 1986; Sherman *et al.* 1990; Wylam *et al.* 1993) have shown that complete removal of hard and soft deposits is not a feasible objective of closed pocket/root instrumentation, even with the most meticulous scaling and root planing procedures (SRP). Nevertheless, non-surgically performed SRP is an effective treatment modality for periodontal disease, as demonstrated by the marked reduction in clinical signs and symptoms of the disease following treatment (Cobb 2002; van der Weijden & Timmerman 2002). Taken together, these observations indicate that there may exist an individual threshold level of bacterial load following instrumentation below which the host can cope with the remaining infection, and hence the goal of non-surgical pocket/root debridement is to reach below this threshold level for all pathologic tooth sites. Besides the quantity and quality of the remaining biofilm, host-related and modifiable environmental factors are to be recognized in this respect, for example diabetes, stress, smoking. While it is not feasible by probing the root surface to determine if adequate debridement has been achieved (Sherman *et al.* 1990), clinical signs of resolution of the inflammatory lesion

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

(e.g. lack of bleeding on probing, increased tissue resistance to probing or "pocket closure") are indeed useful assessments to indicate sufficient removal of subgingival biofilms and calculus. Nonetheless, from a practical standpoint, if calculus is detected clinically, the site is more likely to display ongoing inflammation (Sherman *et al*. 1990).

Debridement, scaling, and root planing

Kieser (1994) proposed that, in preference to the traditionally practiced combination of scaling and root planing, pocket/root instrumentation should be performed as three separate stages of treatment – *debridement*, *scaling*, and *root planing* – with objectives pursued in an orderly sequence. According to the author, *debridement* is defined as instrumentation for disruption and removal of microbial biofilms, *scaling* instrumentation for removal of mineralized deposits (calculus), and *root planing* instrumentation to remove "contaminated" cementum and dentin in order to restore the biologic compatibility of periodontally diseased root surfaces. Furthermore, it was advocated that the clinical healing obtained following pocket/root debridement should be assessed before any repeated instrumentation efforts, or proceeding to the next stage of instrumentation. Although the intention of the various stages of instrumentation is different, overlap to some degree is of course inevitable.

Since periodontal diseases are infections caused by bacteria residing in subgingival biofilms, the need to lower the microbial load by disruption/removal of subgingival biofilms is indisputable. Calculus does not in itself induce inflammation, but has a deleterious effect because of its ability to provide an ideal surface for microbial colonization (Waerhaug 1952). In fact, it has been demonstrated that epithelial adherence to subgingival calculus can occur following its disinfection with chlorhexidine (CHX) (Listgarten & Ellegaard 1973). Thus, the rationale for the removal of calculus relates to eliminating, as far as possible, surface irregularities harboring pathogenic bacteria.

The rationale for performing root planing was originally based on the concept that bacterial endotoxins penetrate into the cementum (Hatfield & Baumhammers 1971; Aleo *et al*. 1974), and for this reason it was thought necessary to remove not only biofilms and calculus but also underlying cementum. However, evidence gained from experimental studies demonstrated that endotoxins were only loosely adherent to the surface and did not penetrate into the cementum (Hughes & Smales 1986; Moore *et al*. 1986; Hughes *et al*. 1988; Cadosch *et al*. 2003). Furthermore, animal and human studies revealed similar clinical and histologic healing following treatment of infected root surfaces, previously exposed to the periodontal pocket, in conjunction with flap surgery by polishing only with a low-abrasive paste as following extensive SRP, provided supragingival hygiene was meticulous (Nyman *et al*. 1986, 1988). Hence, aggressive tooth substance removal does not seem warranted and pocket/root instrumentation should preferably be carried out with instruments that cause minimal root substance removal, but are effective in disrupting the biofilm and removing calculus.

Instruments used for non-surgical pocket/root debridement

Non-surgical periodontal treatment may be carried out using various types of instruments, for example hand instruments, sonic and ultrasonic instruments, and ablative laser devices.

Hand instruments

The use of hand instruments allows good tactile sensation, but tends to be more time consuming than other methods, and requires correct and frequent instrument sharpening. A hand instrument is composed of three parts: the working part (the blade), the shank, and the handle (Fig. 38-1). The cutting edges of the blade are centered over the long axis of the handle in order to give the instrument proper balance. The blade is made of carbon steel, stainless steel or tungsten carbide. Instruments with titanium, plastic or carbon fiber blades are also available and used for bacterial biofilm and calculus removal on dental implant surfaces. Depending on the design of the blade, hand instruments are categorized as curettes, sickles, hoes or files.

Curettes are instruments used for debridement and scaling, both supra- and sub-gingivally (Fig. 38-2). The working part of the curette is the spoon-shaped

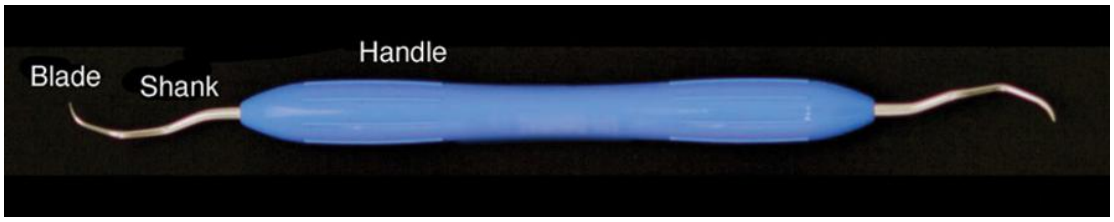

Fig. 38-1 Curette demonstrating the handle, shank, and blade.

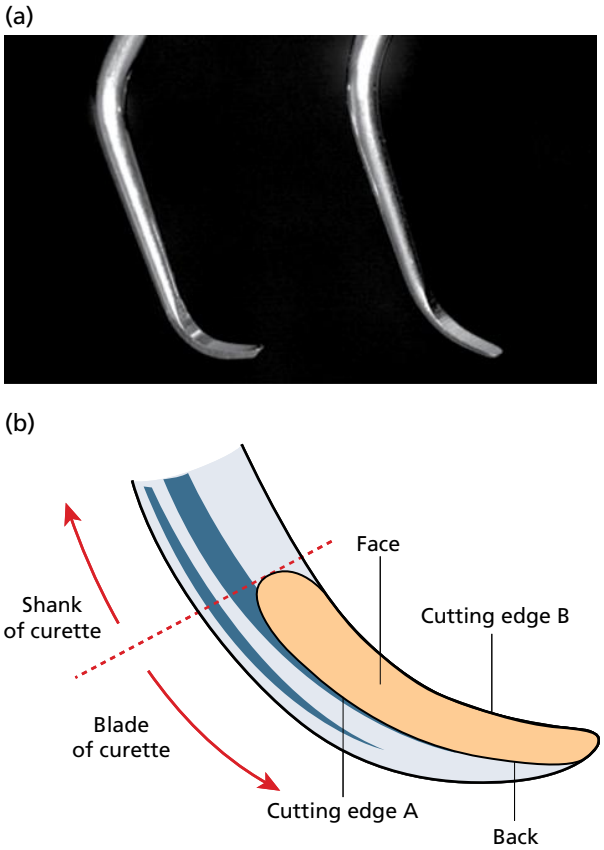

Fig. 38-2 Working end of curettes and schematic illustration of their design with rounded toe, face, and cutting edges.

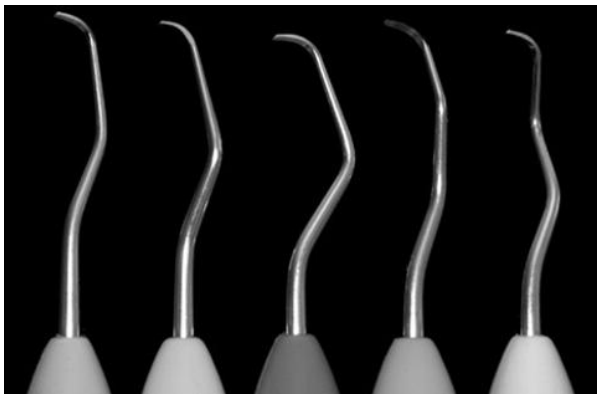

Fig. 38-3 Selection of curettes with varying shank configurations to facilitate debridement of different areas of the dentition.

blade that has two curved cutting edges, united by the rounded toe. The curettes are usually made "double-ended" with mirror-turned blades. The length and angulation of the shank as well as the dimensions of the blade differ between different brands of instruments (Fig. 38-3). Curettes with extended shanks and mini-blades have been designed to improve the efficacy of subgingival instrumentation in deep and narrow pockets.

A *sickle* has either a curved or a straight blade with a triangular cross-section and two cutting edges (Fig. 38-4a). The "facial" surface between the two cutting edges is flat in the lateral direction but may be curved in the direction of its long axis. The "facial" surface converges with the two lateral surfaces of the blade. Sickles are mainly used for debridement/scaling supragingivally or at tooth sites with shallow pockets.

The *hoe* has only one cutting edge. The blade is turned at a 100° angle to the shank with the cutting edge beveled at a 45° angle (Fig. 38-4b). The blade can be positioned at four different inclinations in relation to the shank: facial, lingual, distal, and mesial. The hoe is mainly used for supragingival scaling. Periodontal *files* (Fig. 38-4c) can be useful for smoothing roots in areas of stubborn deposits.

Use of curettes for subgingival debridement/scaling

Subgingival instrumentation should preferably be performed under local anesthesia. The root surface of the diseased site is explored with a probe to identify (1) the probing depth, (2) the anatomy of the root surface (irregularities, root furrows, open furcations, etc.), and (3) the location of the calcified deposits.

The type of hand instrument most suitable for subgingival debridement is the curette. The angulation of the cutting edge of the curette to the tooth surface influences the efficiency of debridement. The optimal angle is approximately 80° (Fig. 38-5a). Too obtuse an angle, as shown in Fig. 38-5b, will result in cratering and consequent roughening of the root surface. Too acute an angle, as shown in Fig. 38-5c, will result in ineffective removal and burnishing of subgingival calculus deposits.

The instrument is held in a modified pen grasp and the blade inserted into the periodontal pocket with the face of the blade parallel to and in light contact with the root. It is important that all root surface instrumentation is performed with a proper finger rest. This implies that one finger – the third or the fourth – must act as a fulcrum for the movement of the blade of the instrument (Fig. 38-6). A proper finger rest serves to (1) provide a stable fulcrum, (2) permit optimal angulation of the blade, and (3) enable the use of wrist–forearm motion. The finger rest must be secured as close as possible to the site of instrumentation to facilitate controlled use of the instrument.

After the base of the periodontal pocket has been identified with the lower edge of the blade, the instrument is turned into a proper working position: that is, the shank is parallel to the long axis of the tooth (Fig. 38-7). The grasp of the instrument is tightened somewhat, the force between the cutting edge and the root surface is increased, and the blade is moved in a coronal direction. Strokes must be made in different directions to cover all aspects of the root surface (cross-wise, back and forth) but, as stated above,

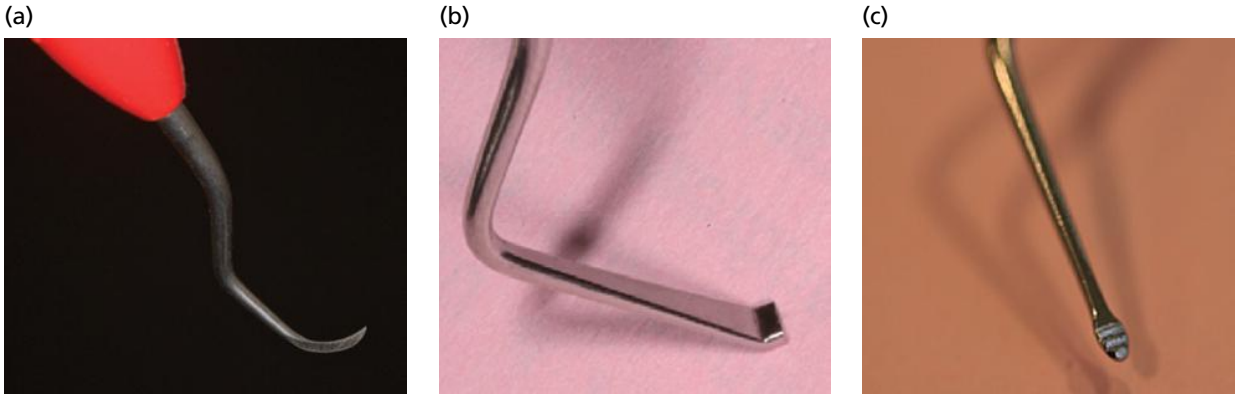

Fig. 38-4 Working end of a (a) sickle, which has a triangular cross-section and two cutting edges, (b) hoe, and (c) file.

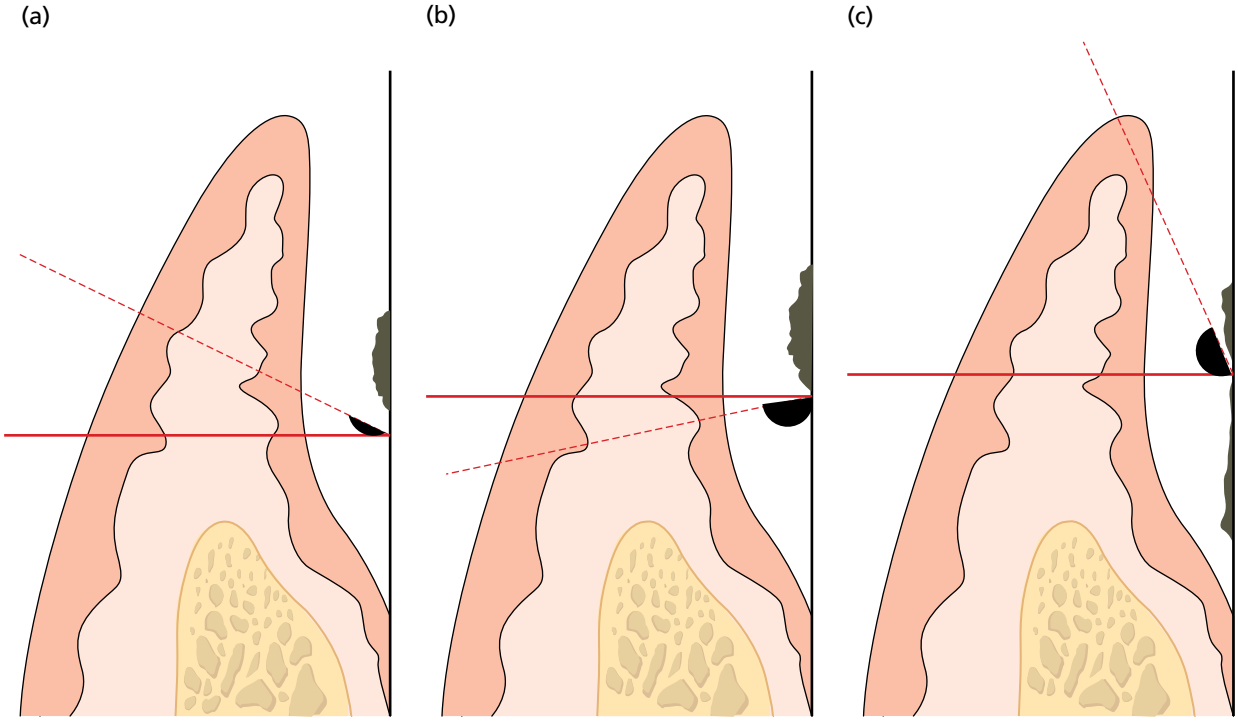

Fig. 38-5 Effect of different angulations of the cutting edge of the curette to the tooth surface. (a) Correct angle of application. (b) Angulation too obtuse resulting in ineffective calculus removal and the possibility of cratering the surface. (c) Angulation too acute resulting in ineffective calculus removal and burnishing of the calculus deposits.

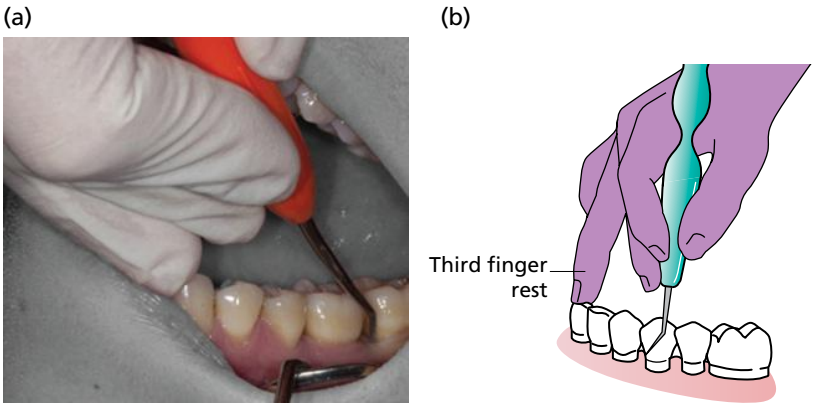

Fig. 38-6 Clinical image and schematic illustration of modified pen grasp and "third finger rest" in the premolar and molar region of the mandible.

strokes should always start from an apical position and be guided in a coronal direction. The probe is inserted into the pocket again and the surface of the root assessed anew for the presence of calculus.

Frequent sharpening of the cutting edge of the instrument is necessary to obtain efficient calculus removal. The angle between the face and the back of curettes must be maintained at approximately 70°

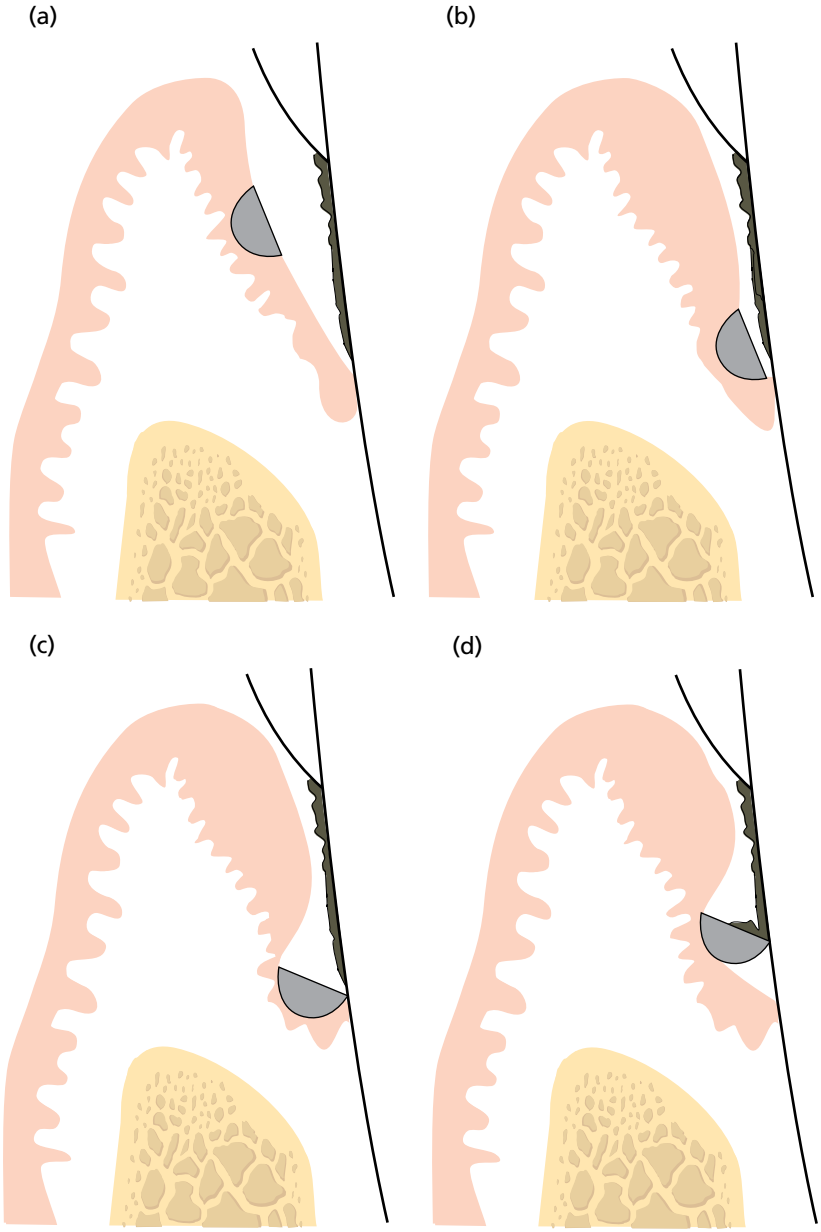

Fig. 38-7 (a) Curette is inserted into the periodontal pocket. Note the near 0° angulation of the face of the curette against the root surface to facilitate access of the pocket. (b) Bottom of the periodontal pocket is identified with the distal edge of the blade of the curette. (c) Curette is turned to a proper cutting position for scaling. (d) Blade is moved along the root surface in a scaling stroke to remove calculus.

during sharpening (Fig. 38-8). A greater angle will result in dulling of the cutting edge. A more acute angle results in a fragile and easily worn cutting edge.

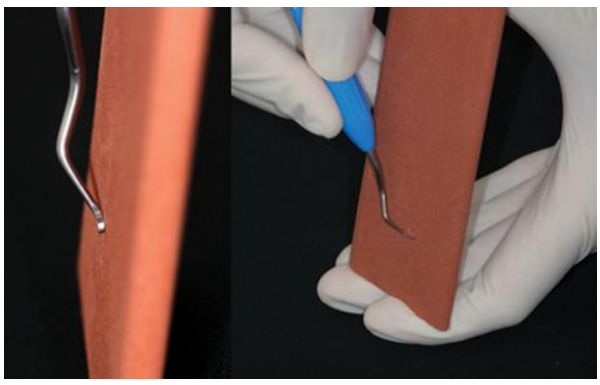

Fig. 38-8 Sharpening of a curette. The original geometry of the cutting edge must be maintained during the sharpening procedure.

Sonic and ultrasonic instruments

A common alternative to hand instrumentation for non-surgical periodontal therapy is the use of sonic and ultrasonic instruments. Sonic devices use air pressure to create mechanical vibration that in turn causes the instrument tip to vibrate; the frequencies of vibration ranging from 2000 to 6000 Hz (Gankerseer & Walmsley 1987; Shah *et al*. 1994). Ultrasonic scalers convert electrical current into mechanical energy in the form of high-frequency vibrations at the instrument

Fig. 38-9 Inserts of different length and curvature for piezoelectric (left) and magnetostrictive (right) ultrasonic devices.

tip; the vibration frequencies ranging from 18 000 to 45 000 Hz and an amplitude range of 10–100 µm.

There are two types of ultrasonic scalers: magnetostrictive and piezoelectric. In *piezoelectric scalers* the alternating electrical current causes a dimensional change in the handpiece that is transmitted to the working tip as vibrations. The pattern of vibration at the tip is primarily linear. In *magnetostrictive scalers* the electrical current produces a magnetic field in the handpiece that causes the insert to expand and contract along its length and in turn causes the insert to vibrate. The pattern of vibration at the tip is elliptical. Modified sonic and ultrasonic scaler tips, for example tiny, thin, periodontal probe type (Fig. 38-9), are available for use in deep pockets. Wear of the ultrasonic tip will affect the working performance of the ultrasonic instrument and therefore the degree of loss of tip dimension should be checked regularly (Fig. 38-10). Water is used as coolant during instrumentation.

Another type of ultrasonic instrument is the Vector system (Sculean *et al*. 2004; Guentsch & Preshaw 2008) which uses a working frequency of 25 000 Hz and a coupling at the head of the handpiece to transfer energy indirectly to the working tip, providing an amplitude of movement of 30–35 µm. These instruments are cooled by a water-based medium containing polishing particles of various sizes dependent on the therapeutic indication. The amount of contaminated aerosol is said to be reduced compared to that produced by other ultrasonic or sonic devices.

Fig. 38-10 Control of wear of the piezoelectric ultrasonic tip. The red line marks the level of wear when the tip should be discarded because of loss of instrument efficacy.

Ablative laser devices

A laser is a device that produces coherent electromagnetic radiation. Laser radiation is characterized by a low divergence of the radiation beam and, with few exceptions, a well-defined wavelength. The term laser is well known as the acronym for "light amplification by stimulated emission of radiation".

Ablative laser therapy has bacteriocidal and detoxification effects, is capable of removing bacterial biofilm and calculus with extremely low mechanical stress and no formation of a smear layer on root surfaces, and can remove the epithelium lining and inflamed tissue within the periodontal pocket (Ishikawa *et al.* 2009). However, with regard to the removal of inflamed tissue, studies have shown that curettage of the soft tissue walls has no added benefit over SRP (Lindhe & Nyman 1985).

Er:YAG lasers are capable of effectively removing calculus from the root surface. To reduce potential damage to the root surface, some Er:YAG laser devices are equipped with a feedback system based on a diode laser that activates the main laser irradiation only if calculus is detected. Er:YAG laser irradiation energy is absorbed by water and organic components of the biologic tissues, which raises the temperature and causes water vapor production, and thus an increase in internal pressure within the calculus deposits. The resulting expansion of the calculus deposits causes their separation from the root surface. Inadvertent irradiation and reflection from shiny metal surfaces may damage a patient's eyes, throat, and oral tissues other than the targeted area. Therefore, care must be taken when using these devices and both patient and operator must use protective eyeglasses (Fig. 38-11). There may also be a risk of excessive tissue destruction from direct ablation and thermal side effects.

Other types of lasers such as carbon dioxide lasers, diode lasers, and Nd:YAG lasers are not effective in removing calculus and hence, their use in periodontal therapy has been primarily as an adjunct therapy to SRP. Carbon dioxide lasers, when used with relatively low energy output in a pulsed and/or defocused mode, have root conditioning, detoxification, and bactericidal effects on contaminated root surfaces. Diode lasers of different wavelength have been introduced as therapy adjunctive to mechanical subgingival debridement to detoxify the root surface or in photodynamic therapy to reduce bacterial load. In photodynamic therapy a photoactive compound such as toluidine blue is placed in the pocket and activated with a laser in order to produce free radical

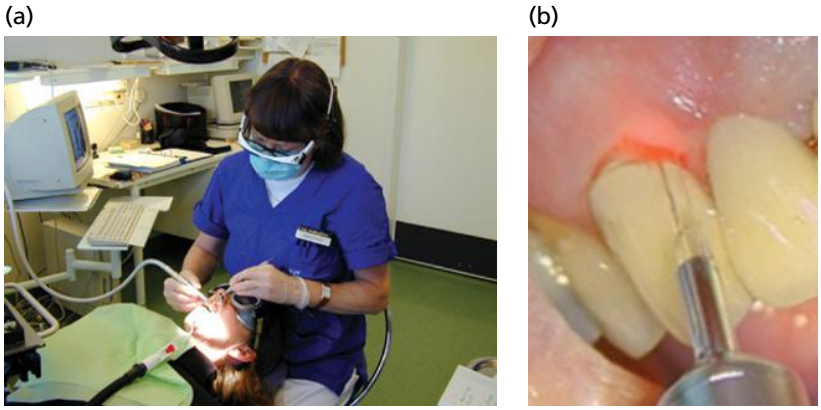

Fig. 38-11 (a) Using laser in periodontal treatment: patient and operator must wear protective eyeglasses. (b) Er:YAG laser tip inserted into the pocket and activated.

ions that have a bactericidal effect (Ishikawa *et al.* 2009). Another potential application for diode lasers is as low-level laser therapy (LLLT), which may stimulate cell proliferation and promote wound healing (Walsh 1997).

Approaches to subgingival debridement

The traditional modality of non-surgical therapy as an initial periodontal treatment phase is pocket/root instrumentation, including root planing, by jaw quadrant or sextant, depending on the extent and severity of the disease, at a series of appointments (Badersten *et al.* 1984). However, various other treatment protocols have also been proposed in the literature as alternatives to this conventional staged approach of SRP for periodontal infection control. In order to prevent re-infection of treated sites from remaining untreated periodontal pockets, Quirynen *et al.* (1995) advocated the benefit of carrying out the pocket/root instrumentation of the entire dentition within a time frame of 24 hours (*full-mouth SRP*). They also considered the risk of re-infection from other intraoral niches such as the tongue and tonsils and therefore also included tongue cleaning and an extensive antimicrobial regimen with CHX (*full-mouth disinfection protocol*). Other proposed treatment protocols that similarly challenge the traditional approach of non-surgical periodontal therapy restrict the number of and the interval between treatment sessions and the time allocated to instrumentation, and may or may not include the adjunctive use of various antimicrobials.

Full-mouth instrumentation protocols

The first full-mouth instrumentation protocol described by Quirynen *et al.* (1995) comprised two sessions of SRP within 24 hours, each covering half of the dentition. However, the total time used for subgingival instrumentation in this approach did not differ from that of the traditional quadrant-wise approach. As already mentioned, the benefit of this treatment protocol was suggested to be a reduced risk of re-infection of treated sites from the otherwise untreated sites, as well as a potential boost to the immunologic response by inoculation of periodontal bacteria into the local vasculature. From the patient's perspective, a tangible benefit of the full-mouth treatment protocol is that fewer appointments, but not necessarily less chair-time for treatment, are required. Apatzidou and Kinane (2004) described a modified protocol in which the SRP of the entire dentition was completed at two sessions on the same day. Another proposed approach consisted of four sessions of SRP on four consecutive days (Eren *et al*. 2002). In all these protocols the time allocated for SRP was 1 hour per jaw quadrant.

Adhering to the concept of differentiation between debridement, scaling, and root planing in non-surgical periodontal therapy (Kieser 1994), modified approaches to the full-mouth instrumentation protocol have been proposed that involve pocket/root debridement by the use of piezoelectric ultrasonic devices in a single-visit, full-mouth procedure, limited to 45–60 minutes to minimize removal of root substance (Wennström *et al*. 2005; Zanatta *et al*. 2006; Del Peloso Ribeiro *et al*. 2008) or without time limit (Koshy *et al*. 2005). Hence, common features of these modified protocols are that the initial subgingival treatment is reduced to one session only and that markedly less time is devoted to instrumentation than that to SRP in the previously described protocols for full-mouth instrumentation.

Full-mouth disinfection protocols

Several intraoral niches, such as the tongue, mucosa, saliva, and tonsils, may act as reservoirs for Gram-negative strains recognized as periodontal pathogens (Beikler *et al*. 2004), and translocation of these bacteria might result in rapid recolonization of a recently instrumented pocket. Hence, as already mentioned, in order to optimize the treatment outcome of the full-mouth SRP approach, Quirynen *et al.* (1995) proposed adjunctive therapy including tongue cleaning and an extensive antimicrobial regimen with CHX (*full-mouth disinfection protocol*). The CHX regimen in conjunction with each treatment session included (1) brushing the dorsum of the tongue for 1 minute with 1% CHX gel, (2) rinsing twice with 0.2% CHX

solution for 1 minute, (3) spraying the tonsils four times with a 0.2% CHX solution, (4) three subgingival irrigations with 1% CHX gel (repeated after 8 days), and (5) instructing the patient to rinse twice daily with a 0.2% CHX solution for 2 weeks. The protocol was later modified by adding the instruction that patients should rinse the mouth and spray the tonsils twice daily with a 0.2% CHX solution for a period of 2 months after the SRP (Mongardini *et al.* 1999).

Other full-mouth instrumentation protocols including adjunctive antimicrobial therapy can be found in the literature, but none is as rigorous as the full-mouth disinfection protocol proposed by the Quirynen group. For example, Koshy *et al.* (2005) included the use of 1% povidone iodine solution as a coolant during the full-mouth ultrasonic debridement session, instruction of patients in careful oral hygiene and brushing of the tongue, as well as mouth rinsing with a 0.05% CHX solution twice daily for 1 month.

Clinical outcomes following various approaches to pocket/root instrumentation

A number of systematic reviews on the efficacy of mechanical non-surgical periodontal therapy have been published (Tunkel *et al*. 2002; van der Weijden & Timmerman 2002; Hallmon & Rees 2003; Suvan 2005; Eberhard *et al.* 2008; Lang *et al.* 2008). There is a consensus among these reviews that pocket/root instrumentation combined with proper supragingival plaque control measures is an effective treatment modality in reducing probing pocket depths (PPDs) and improving clinical attachment levels (CALs) (Figs. 38-12, 38-13), and that there is no major difference in the efficacy of pocket/root instrumentation using hand or power-driven instruments (sonic/ultrasonic). Furthermore, it was deliberated that the data available from published clinical studies are too limited to judge whether the adverse effects of the treatment may vary with the type of instrument used. Table 38-1 shows the mean changes in PPD, CAL, and gingival recession generally observed in clinical studies following an initial treatment phase of *conventional staged quadrant-wise SRP*.

In a Cochrane review (Eberhard *et al.* 2008), a meta-analysis including five studies comparing *full-mouth instrumentation* versus quadrant-wise SRP revealed no statistically significant differences with regard to mean PPD reduction or CAL change. Subgroup analyses of initially moderate (5–6 mm) and deep (>6 mm) pockets at single- and multi-rooted teeth, respectively, disclosed no significant differences for either between the two treatment approaches.

The comparison between *full-mouth disinfection* and quadrant-wise SRP performed in the Cochrane review (Eberhard *et al.* 2008), based on data from three studies, revealed a statistically significant difference in favor of full-mouth disinfection for moderately deep pockets at single-rooted teeth (mean difference 0.53 mm; 95% CI 0.28–0.77), but no difference for deep pockets or for multirooted teeth. With regards to CAL changes for single- and multi-rooted teeth combined (two studies), a significantly greater amount of CAL gain was found for full-mouth disinfection (mean difference 0.33 mm; 95% CI 0.04–0.63), but no significant differences were found in the subgroup analyses. Corresponding analyses in a systematic review by Lang *et al.* (2008) showed outcomes of similar magnitude in favor of the full-mouth disinfection approach. However, none of the systematic reviews found any significant differences for the clinical outcome variables between full-mouth disinfection and full-mouth instrumentation.

Although the analyses performed in the systematic reviews revealed some statistically significant differences favoring the full-mouth disinfection over the quadrant-wise SRP approach, but not in comparison to full-mouth instrumentation, the clinical relevance of the observed improvements with extensive CHX treatment may be questioned.

Conclusion: All three non-surgical treatment approaches to periodontal infection control (conventional staged quadrant-wise SRP, full-mouth instrumentation and full-mouth disinfection) result in marked improvements in clinical conditions, and the decision to select one approach over another has to involve also considerations other than just clinical outcomes.

Microbiologic outcomes following various approaches to pocket/root instrumentation

Removal of subgingival plaque and calculus deposits through subgingival debridement in combination with efficient self-performed supragingival infection control alters the ecology of the pockets through reduction in the quantity of microorganisms, resolution of the inflammation, and a decrease in pocket depth, and species that may have flourished in the subgingival environment of the diseased pocket may find the new habitat less hospitable. A decrease in the total bacterial count for sites of >3 mm depth, from 91×10^5 to 23×10^5, has been observed immediately following subgingival debridement (Teles *et al.* 2006). Furthermore, a decrease in the mean counts and number of sites colonized by *Porphyromonas gingivalis*, *Aggregatibacter actinomycetemcomitans*, *Prevotella intermedia* (Shiloah & Patters 1994), *Tannerella forsythia*, and *Treponema denticola* (Haffajee *et al*. 1997; Darby *et al*. 2005) and an increase in proportion of streptococci (e.g. *Streptococcus gordonni*, *Streptococcus mitis*, *Streptococcus oralis*, and *Streptococcus sanguinis*) and *Actinomyces* spp., *Eikenella corrodens*, and *Gemella morbillarum* were observed several weeks following subgingival debridement. An increase in the proportions of Gram-positive aerobic cocci and rods is

associated with periodontal health (Cobb 2002). Interestingly, microorganisms do not exist in isolation in the subgingival environment, but rather as members of communities. Socransky *et al*. (1998) identified groups of organisms that were commonly found together and subdivided microorganisms into complexes accordingly. Members of the "red" and "orange" complexes are most commonly identified

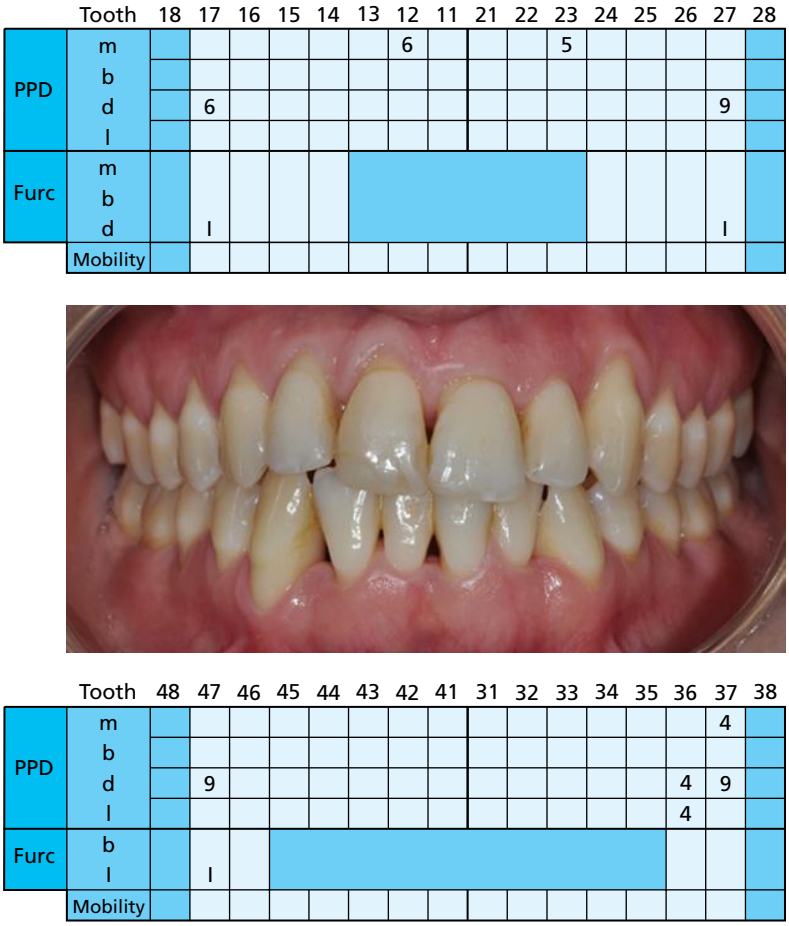

Fig. 38-13 Clinical image and probing pocket assessments of the same patient as in Fig. 39-12, 6 months following initial non-surgical therapy.

Table 38-1 Mean changes (mm) generally observed in studies of bleeding score, probing depth, probing attachment levels, and gingival recession after a single episode of supra- and sub-gingival instrumentation for sites with varying initial probing depths.

	Change (mm)		
Initial probing depth (mm)	**Probing depth**	**Probing attachment level**	**Recession**
≤3	0	–0.5	0.5
4–6	–1–2	0–1	0–1
≥7	–2–3	1–2	1–2

at sites displaying signs of periodontitis. Hence, a re-emergence of species of the red and orange complexes 3–12 months post debridement may indicate lack of resolution of the periodontal lesion (Haffajee *et al*. 2006). It is also important to recognize that in the absence of appropriate home care, the re-establishment of the pretreatment microflora will occur in a matter of weeks (Magnusson *et al*. 1984; Loos *et al*. 1988; Sbordone *et al*. 1990).

In a study comparing the microbiologic outcome of *full-mouth instrumentation* and quadrant-wise SRP (Quirynen *et al.* 2000), it was demonstrated by phase-contrast microscopy and culturing techniques that both treatment approaches reduced the total number of facultative and strict anaerobic species, as well as the number of black-pigmented bacteria, spirochetes, and motile rods in subgingival samples, but also that the reductions were more pronounced following the full-mouth instrumentation. Other studies comparing the microbiologic outcomes following the two treatment approaches using polymerase chain reaction (PCR) techniques (Apatzidou *et al.* 2004; Koshy *et al*. 2005; Jervøe-Storm *et al*. 2007) also reported reductions in presumptive periodontal pathogens, but no detectable differences between the approaches. Hence, these studies failed to support the concept that a full-mouth debridement approach may prevent or delay recolonization of instrumented pockets. Besides the different microbiologic techniques employed in these studies compared to the study by Quirynen *et al.* (2000), the fact that the patients in the former studies showed a high standard of oral hygiene before the initiation of the subgingival instrumentation may explain the contradictory findings. It should be noted that the Quirynen study was primarily designed as a "proof of principle" study, and in order to increase the chance for cross-contamination, interproximal cleaning in the quadrant-wise SRP group was prohibited until the last quadrant had been instrumented.

Studies evaluating microbiologic alterations after *full-mouth ultrasonic instrumentation* with a restricted time protocol (45 minutes of ultrasonic debridement) (Zanatta *et al.* 2006; Del Peloso Ribeiro *et al.* 2008) also showed significant reductions in the frequency and amount of presumptive periodontal pathogens, as evaluated by the use of real-time PCR; reductions were similar to those after conventional quadrant-wise SRP.

More favorable microbiologic changes have been reported following *full-mouth disinfection* as compared to quadrant-wise SRP with respect to decreases in the total amount of motile organisms and spirochetes, total number of facultative or strict anaerobic bacteria, black-pigmented bacteria, as well as frequencies and levels of "red" and "orange" microbial complexes detected using differential phase-contrast microscopy, culturing, and DNA–DNA hybridization technique (Quirynen *et al.* 1999, 2000; De Soete *et al.* 2001). By contrast, Koshy *et al.* (2005) could not detect any added microbiologic benefits as recorded by PCR following their modified full-mouth disinfection approach compared to quadrant-wise instrumentation.

The question of differences in microbiologic outcomes following full-mouth instrumentation, full-mouth disinfection, and conventional staged quadrant-wise SRP has also been addressed in a systematic review (Lang *et al.* 2008). Based on the analysis of seven studies, it was concluded that with the use of modern microbiologic identification methods, no superior reductions in either bacterial load or specific presumptive periodontal pathogens could be identified for any of the three treatment modalities.

Considerations in relation to selection of instruments and treatment approach

Selection of instruments

It has been demonstrated that hand, sonic, and ultrasonic instruments produce similar periodontal healing response with respect to PPD, bleeding on probing, and CAL (Badersten *et al.* 1981, 1984; Lindhe & Nyman 1985; Kalkwarf *et al.* 1989; Loos *et al.* 1987; Copulos *et al.* 1993; Obeid *et al.* 2004; Wennström *et al.* 2005; Christgau *et al.* 2006). With respect to root surface loss, sonic and ultrasonic scalers have been shown to produce less loss than hand instruments (Ritz *et al.* 1991; Busslinger *et al.* 2001; Schmidlin *et al.* 2001; Kawashima *et al.* 2007).

In comparison to hand instrumentation, the use of sonic and ultrasonic instruments may provide better access to deep pockets and furcation areas (Kocher *et al.* 1998; Beuchat *et al.* 2001). In addition, the flushing action of water used as coolant during sonic and ultrasonic instrumentation removes, to a certain extent, debris and bacteria from the pocket area, but the use of antiseptic solutions, for example CHX, iodine and Listerine®, as coolant has shown no greater effects compared to water irrigation (Koshy *et al.* 2005; Del Peloso Ribeiro *et al.* 2006; Leonhardt *et al.* 2006; Del Peloso Ribeiro 2010; Feng *et al.* 2011; Krück *et al.* 2012). However, tactile sensation is reduced, contaminated aerosols are produced (Barnes *et al.* 1998; Harrel *et al.* 1998; Rivera-Hidalgo *et al.* 1999; Timmerman *et al.* 2004), and some patients may find the vibration, sound, and water spray uncomfortable. The use of the Vector ultrasonic system has been shown to result in clinical and microbiologic outcomes comparable to those achieved by manual instrumentation and conventional ultrasonic instruments; however, it may be less efficient in removing large accumulations of calculus (Sculean *et al.* 2004; Christgau *et al.* 2007; Kahl *et al.* 2007; Guentsch & Preshaw 2008).

The use of Er:YAG lasers produces results comparable to those with hand or ultrasonic instrumentation (Schwarz *et al.* 2008; Sgolastra *et al.* 2012). However, no adjunctive benefit of the use of Er:YAG lasers over mechanical debridement alone has been demonstrated (Schwarz *et al.* 2003; Lopes *et al.* 2010; Rotundo *et al.* 2010). The use of other types of lasers has not shown treatment effects comparable to mechanical debridement or any adjunctive effect when used in combination with hand or ultrasonic instrumentation (Ambrosini *et al.* 2005; Schwarz *et al.* 2008; Slot *et al.* 2009). Contradictory findings have been reported with regard to beneficial clinical and microbiologic effects of photodynamic diode laser therapy when used as an adjunct to mechanical debridement (Christodoulides *et al.* 2008; Chondros *et al.* 2009; Lulic *et al.* 2009). There is no evidence of positive healing effects of LLLT when applied following mechanical pocket/root debridement (Lai *et al.* 2009; Makhlouf *et al.* 2012).

Selection of treatment approach

At the VI European Workshop on Periodontology the effects of full-mouth debridement with and without adjunctive use of antiseptics was addressed. Based on evaluation of the systematic reviews by Lang *et al.* (2008) and Eberhard *et al.* (2008), the consensus of the workshop was that *full-mouth debridement* and *full-mouth disinfection* do not provide clinically relevant advantages over the conventional staged quadrant-wise SRP in the treatment of patients with moderate-to-advanced periodontitis (Sanz & Teughels 2008). Furthermore, the clinical recommendations given were that (1) "all three modalities may be recommended for debridement" and (2) "clinicians should choose the modality of debridement according to the needs and preferences of the patient, their personal skills and experience, the logistic setting of the practice and the cost-effectiveness of the therapy rendered. It should be noted that the performance of optimal oral hygiene practices is an inseparable principle to be observed with any protocol of mechanical debridement".

Considering cost-to-benefit issues, it is of interest to note that piezoelectric ultrasonic debridement performed as a single-visit, full-mouth procedure restricted to 45–60 minutes of pocket/root instrumentation has been shown to result in comparable healing outcomes to those of SRP performed in a quadrant-wise manner at weekly intervals (Wennström *et al.* 2005; Zanatta *et al.* 2006; Del Peloso Ribeiro *et al.* 2008). This finding indicates that sufficient removal of subgingival deposits may be attainable using a shorter treatment time than that traditionally allocated to non-surgical pocket/root instrumentation. Calculating the efficiency of the treatment approaches, in this case the time used for instrumentation in relation to the number of pockets reaching the end point of treatment success (PPD ≤4 mm), it was shown that the full-mouth ultrasonic approach was three times more favorable than the quadrant-wise SRP approach (Wennström *et al.* 2005). Hence, tangible benefits of full-mouth ultrasonic debridement as an initial approach to subgingival infection control would be fewer appointments and less chair-time for treatment. Furthermore, available data regarding patients' experience of discomfort/pain related to the treatment do not indicate differences between full-mouth ultrasonic debridement and the quadrant-wise approach. It has to be recognized, however, that it is the quality of the instrumentation, not the time factor, that is the important issue in pocket/root debridement, and that the goal of the instrumentation is to reduce the bacterial load at all tooth sites below the threshold level at which the individual host can cope with the remaining infection. It is important to point out that the studies referred to should not be interpreted to justify a protocol of a defined time for instrumentation in non-surgical periodontal therapy, but merely illustrate that many, but not all, pockets may respond positively to less aggressive instrumentation, which in fact supports the concept proposed by Kieser (1994) that the clinical healing obtained following initial pocket/root debridement should be assessed before more extensive instrumentation efforts, including root planing, are performed.

Re-evaluation following initial non-surgical periodontal treatment

Although recent studies indicate that the conventional quadrant-wise as well as the full-mouth debridement approach, combined with careful instruction in self-performed plaque control methods, are evidence-based and rational initial approaches to the treatment of patients with chronic periodontitis, it is important to be aware that all lesions may not be resolved. Hence, a critical component in the establishment of periodontal infection control is to follow up the initial non-surgical treatment and to perform a re-evaluation examination with regard to sites with remaining clinical signs of pathology.

An increased resistance of the periodontal tissues to probing and absence of bleeding are signs of resolution of the inflammatory lesion related to a sufficient removal of biofilm/calculus. Thus, clinical end points of treatment success may be defined as (1) no bleeding on pocket probing and (2) "pocket closure", that is a probing pocket depth of ≤4 mm. PPD change is a combined result of recession of the gingival margin and decreased probe penetration into the pocket due to resolution of the inflammatory lesion in the bordering soft tissues (Fig. 38-14). Pocket reduction or "pocket closure" as an important outcome variable is validated by data showing that it demonstrates lower risk for disease progression and tooth loss (Westfelt *et al.* 1988; Badersten *et al.* 1990; Claffey & Egelberg 1995; Lang & Tonetti 2003; Matuliene *et al.* 2008). In a retrospective study including 172 subjects followed for a mean of 11 years after active periodontal therapy, Matuliene *et al.* (2008) reported that, compared to a PPD of ≤3 mm, a remaining PPD of 5 mm represented a risk factor for tooth loss with an odds ratio of 7.7. The corresponding odds ratios for a remaining PPD of 6 mm and ≥7 mm were 11.0 and 64.2, respectively. The long-term influence of the variable "bleeding on probing" on tooth loss was addressed in a 26-year longitudinal study of 565 Norwegian males (Schätzle *et al.* 2004), and revealed that teeth that at all examinations were positive for bleeding on probing had a 46 times higher risk of

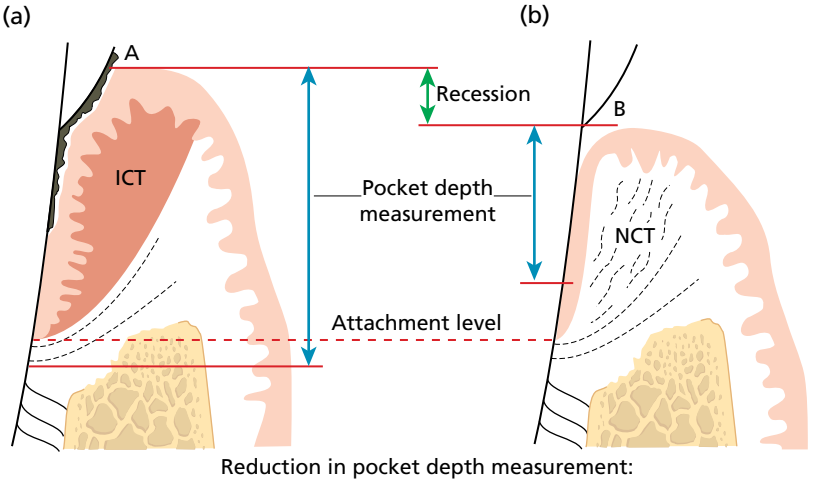

Fig. 38-14 Schematic illustration of a gingival unit (a) before and (b) after periodontal therapy. Probing depth measurements are shown by the blue lines. Dotted line indicates the "histologic" attachment level. Green line shows recession. Location of the gingival margin before therapy (A) and after therapy (B). (ICT, infiltrated connective tissue; NCT, non-infiltrated connective tissue.)

Table 38-2 Predicted probability of pocket closure [probing pocket depth (PPD) ≤4 mm] for sites with different initial PPD.

	Initial PPD		6 mm	7 mm	8 mm
Non-smoker	PL⁻	Single-rooted	84%	63%	36%
		Multi-rooted	70%	43%	19%
	PL⁺	Single-rooted	76%	50%	24%
		Multi-rooted	57%	30%	12%
Smoker	PL⁻	Single-rooted	64%	36%	16%
		Multi-rooted	43%	20%	7%
	Pl⁺	Single-rooted	51%	25%	10%
		Multi-rooted	31%	12%	4%

being lost compared to teeth not showing gingival inflammation. Hence, these data justify the use of "pocket closure" and absence of bleeding on probing as clinical end points of treatment success in the re-evaluation following periodontal treatment.

On average about 35% of initially pathologic pockets may not reach the end point of treatment success at re-evaluation following initial non-surgical periodontal therapy, and this percentage is independent of the type of instruments or approach used for subgingival debridement (Wennström *et al.* 2005; Jervøe-Storm *et al.* 2006). Generally, clinical improvement is less pronounced at molars, particularly at furcation sites, than at single-rooted teeth (Lindhe *et al.* 1982; Loos *et al.* 1989). However, there are certainly many other factors related to the patient, the tooth, and the tooth site that might influence the treatment response. The use of multilevel statistical modeling allows the simultaneous investigation of factors at different levels. As an example, in Table 38-2 the probability of "pocket closure" (final probing pocket depth ≤4 mm) following initial non-surgical therapy could be estimated for pockets of various initial PPD, taking into consideration the factors smoking habit, single- or multi-rooted tooth, as well as presence/absence of supragingival plaque at the level of the tooth site (Tomasi *et al.* 2007). The marked difference in probability of pocket closure noted between smokers and non-smokers (e.g. 36% versus 63% for 7-mm deep pockets) places the focus on smoking as a significant factor influencing treatment outcome following non-surgical periodontal therapy. Smoking is proven to negatively affect the outcome of all modalities of periodontal therapy (Labriola *et al.* 2005; Heasman *et al.* 2006) and hence, if the patient is a smoker, inclusion of a smoking cessation program should be considered as an adjunctive measure.

Efficacy of repeated non-surgical pocket/root instrumentation

If the patient fails to maintain an adequate standard of oral hygiene, efforts have to be devoted to improving the patient's motivation. Persisting pathologic pockets, that is with a PPD of ≥5 mm and bleeding on probing, should be subjected to re-instrumentation efforts which now may include also root planing. The patient is then scheduled for a new re-evaluation and a decision regarding potential need for supplementary active treatment options. Whether it will be worthwhile to once again carry out repeated non-surgical instrumentation of a site/tooth that shows poor response to the performed subgingival debridement, or if other treatment modalities (e.g. adjunctive antimicrobial therapy, open-flap debridement, surgical pocket reduction) to achieve the goal of periodontal infection control should be selected, is a delicate decision in which both subject- and site-specific factors, as well as clinical skills and experience, have to be considered. Largely clinical improvements following pocket retreatment by non-surgical SRP are rather limited compared to those following the initial phase of subgingival instrumentation (Badersten *et al.* 1984; Wennström *et al.* 2005). It has been shown that of all sites that respond poorly to initial mechanical debridement, only 11–16% might be brought to a successful treatment end point following mechanical re-instrumentation, and about 50% of the pockets with an initial probing pocket depth of ≥7 mm will remain as non-successful sites (Wennström *et al.* 2005). Another study evaluating the outcome of re-instrumentation of periodontal sites showed that the overall probability of achieving "pocket closure" 3 months after retreatment was about 45%, while for sites with a PPD of >6 mm, the probability was only 12% (Tomasi *et al.* 2008). The fact that pockets associated with molars, furcation sites, and angular bone defects have been shown to respond less favorably to repeated non-surgical instrumentation (e.g. Axtelius *et al.* 1999; D'Aiuto *et al.* 2005; Tomasi *et al.* 2007) should be considered in the decision-making process regarding selection of retreatment procedure and the potential benefit of repeated non-surgical instrumentation.

Part 12: Additional Therapy

Chapter 39

Periodontal Surgery: Access Therapy

Jan L. Wennström and Jan Lindhe

Department of Periodontology, Institute of Odontology,
The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Introduction

Surgical access therapy must be considered as adjunctive to cause-related therapy (see Chapters 35–38). Therefore, the various surgical methods described in this chapter should be evaluated on the basis of their potential to facilitate removal of subgingival deposits and self-performed infection control, and thereby enhance the long-term preservation of the periodontium.

The decision concerning what type of periodontal surgery should be performed and how many sites should be included is usually made after the effect of initial cause-related measures has been evaluated. The time lapse between termination of the initial cause-related phase of therapy and this evaluation may vary from 1 to several months. This routine has the following advantages:

- Removal of calculus and bacterial plaque will eliminate or markedly reduce the inflammatory cell infiltrate in the gingiva, thereby making assessment of the "true" pocket depths possible.
- Reduction of gingival inflammation makes the soft tissues more fibrous and firmer, which facilitates flap management. The propensity for bleeding is also reduced, making inspection of the surgical field easier.
- The effectiveness of the patient's home care, which is of decisive importance for the long-term prognosis, can be properly evaluated. Lack of effective self-performed infection control is in most cases a contraindication for surgical treatment.

Techniques in periodontal pocket surgery

Over the years, several different surgical techniques have been described and used in periodontal therapy. A superficial review of the literature in this area may give the reader a somewhat confusing picture of the

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

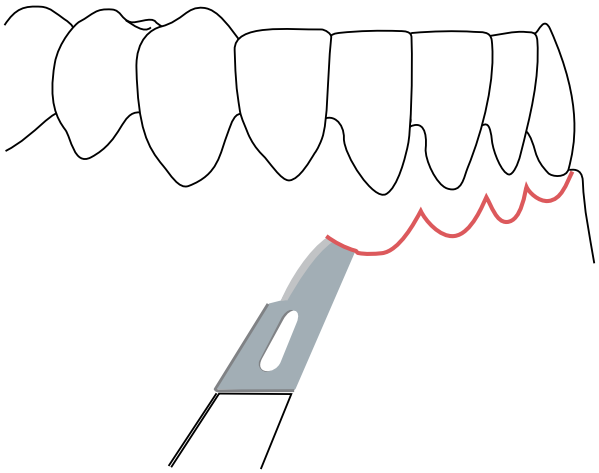

Fig. 39-2 Gingivectomy. Scalloped incision technique. (Source: Zentler 1918. Reproduced with permission of the American Medical Association).

specific objectives and indications relevant to the various surgical techniques. It is a matter of historical interest that the first surgical techniques used in periodontal therapy were described as means of gaining access to diseased root surfaces. Such access could be accomplished without excision of the soft tissue pocket ("open-view operations"). Later, procedures were described by which the "diseased gingiva" was excised (gingivectomy procedures).

The concept that not only inflamed soft tissue but also "infected and necrotic bone" had to be eliminated called for the development of techniques by which the alveolar bone could be exposed and instrumented (flap procedures). Other concepts, such as (1) the importance of maintaining the mucogingival complex (i.e. a wide zone of gingiva) and (2) the possibility for regeneration of periodontal tissues, have also prompted the introduction of "tailor-made" techniques.

This section will describe the surgical procedures which represent important steps in the development of the surgical component of periodontal therapy.

Gingivectomy procedures

The surgical approach as an alternative to "blind" subgingival scaling for pocket therapy was already recognized in the latter part of the 19th century, when Robicsek (1884) pioneered the so-called *gingivectomy* procedure. Gingivectomy was much later defined by Grant *et al*. (1979) as being "the excision of the soft tissue wall of a pathologic periodontal pocket". The procedure, which aimed at "pocket elimination", was usually combined with recontouring of the gingiva to restore its normal architecture.

Robicsek (1884) and later Zentler (1918) described the gingivectomy procedure in the following way. The line to which the gum is to be resected is determined first. Following a straight (Robicsek) (Fig. 39-1) or scalloped (Zentler) (Fig. 39-2) incision, first on the labial and then on the lingual aspect of each tooth, the diseased tissue is loosened and lifted out with a hook-shaped instrument. After elimination of the soft tissue, the exposed alveolar bone is scraped. The area is then covered with some kind of antibacterial gauze or painted with disinfecting solutions. The deepened periodontal pocket is hereby eradicated and a dentition established that can be kept clean more easily.

Technique

The gingivectomy procedure as it is employed today was first described in 1951 by Goldman:

1. When the dentition in the area scheduled for surgery has been properly anesthetized, the depths of the pathologic pockets are identified with a conventional periodontal probe (Fig. 39-3a). At the level of the bottom of the pocket, the gingiva is pierced and a bleeding point is produced on the outer surface of the soft tissue (Fig. 39-3b). The pockets are probed and bleeding points produced at one or more location points around each tooth in the area. The series of bleeding points produced describes the depth of the pockets in the area scheduled for treatment and is used as a guideline for the incision.
2. The primary incision (Fig. 39-4), which may be made with a scalpel (blade No. 12B or 15; Bard–Parker®) in either a Bard–Parker® handle or an angulated handle (e.g. a Blake's handle), or a Kirkland knife No. 15/16, should be planned to give a thin and properly festooned margin of the remaining gingiva. Thus, in areas where the gingiva is bulky, the incision must be placed at a more apical level than in areas with a thin gingiva, where a less accentuated bevel is needed. The beveled incision is directed towards the base of the pocket. In areas where the interdental pockets are deeper than the buccal or lingual pockets, additional amounts of buccal and/or lingual (palatal)

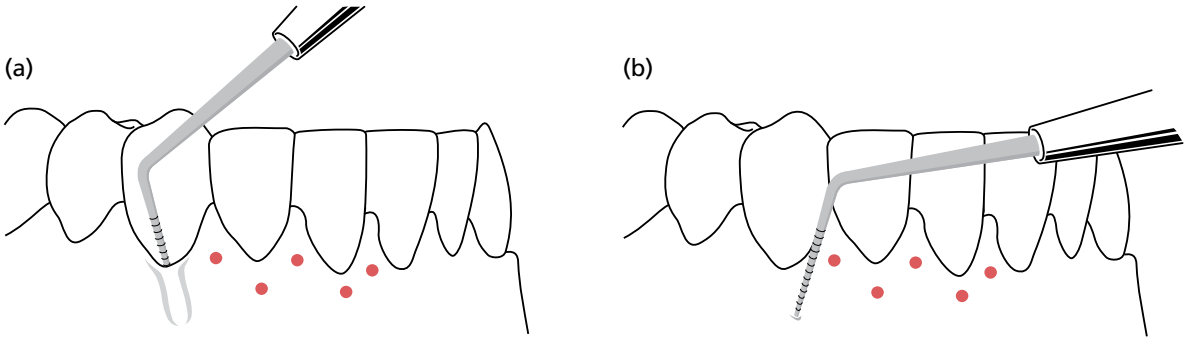

Fig. 39-3 Gingivectomy. Pocket marking. (a) An ordinary periodontal probe is used to identify the bottom of the deepened pocket. (b) When the depth of the pocket has been assessed, an equivalent distance is delineated on the outer aspect of the gingiva. The tip of the probe is then turned horizontally and used to produce a bleeding point at the level of the bottom of the probeable pocket.

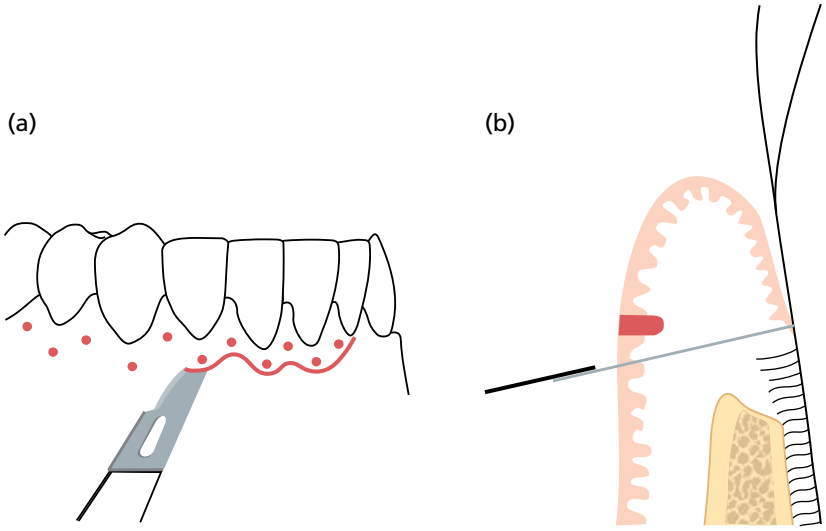

Fig. 39-4 Gingivectomy. (a) Primary incision. (b) The incision is terminated at a level apical to the "bottom" of the pocket and is angulated to give the cut surface a distinct bevel.

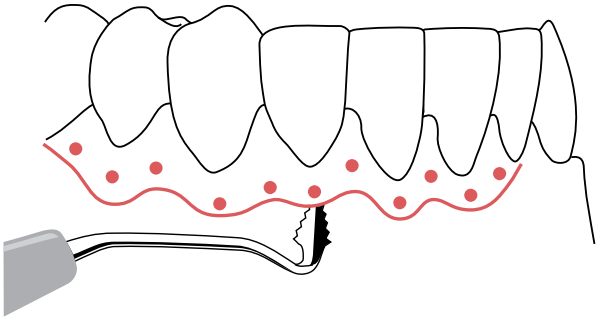

Fig. 39-5 Gingivectomy. The secondary incision through the interdental area is performed with a Waerhaug knife.

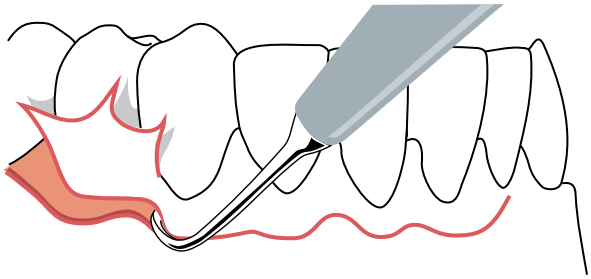

Fig. 39-6 Gingivectomy. The detached gingiva is removed with a scaler.

gingiva must be removed in order to establish a "physiologic" contour of the gingival margin. This is often accomplished by initiating the primary incision at a more apical level.

3. Once the primary incision is completed on the buccal and lingual aspects of the teeth, the interproximal soft tissue is separated from the interdental periodontium by a secondary incision using an Orban knife (No. 1 or 2) or a Waerhaug knife (No. 1 or 2; a saw-toothed modification of the Orban knife) (Fig. 39-5).
4. The incised tissues are carefully removed with a curette or a scaler (Fig. 39-6). Pieces of gauze packs often have to be placed in the interdental areas to control bleeding. When the field of operation is properly prepared, the exposed root surfaces are carefully debrided.
5. Following meticulous debridement, the dentogingival regions are probed again to detect any remaining pockets (Fig. 39-7). The gingival contour is checked and, if necessary, corrected with the use of knives or rotating diamond burs.
6. To protect the incised area during the period of healing, the wound surface must be covered by a periodontal

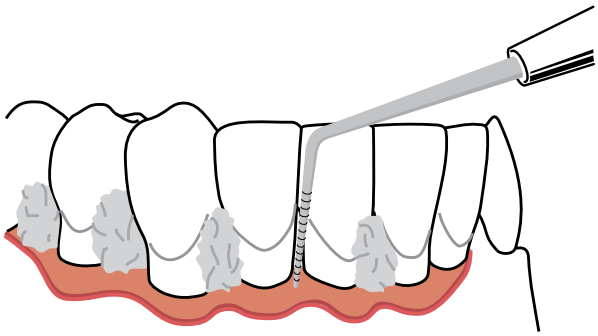

Fig. 39-7 Gingivectomy. Probing for residual pockets. Gauze packs have been placed in the interdental spaces to control bleeding.

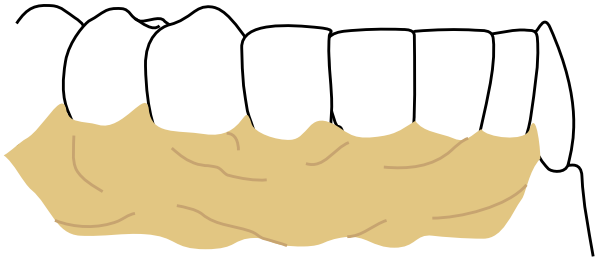

Fig. 39-8 Gingivectomy. The periodontal dressing has been applied and properly secured.

dressing (Fig. 39-8). The dressing should be closely adapted to the buccal and lingual wound surfaces as well as to the interproximal spaces. Care should be taken not to allow the dressing to become too bulky, since this is not only uncomfortable for the patient, but also facilitates its dislodgement.

7. The dressing should remain in position for 10–14 days. After removal of the dressing, the teeth must be cleaned and polished. The root surfaces are carefully checked and remaining calculus removed with a curette. Excessive granulation tissue is eliminated with a curette. The patient is instructed to clean the operated segments of the dentition, which now have a different anatomy compared to the preoperative situation.

Flap procedures

Original Widman flap

In 1918, Leonard Widman published one of the first detailed descriptions of the use of a flap procedure for pocket elimination. In his article "The operative treatment of pyorrhea alveolaris", Widman described a mucoperiosteal flap design that aimed to remove the pocket epithelium and the inflamed connective tissue, thereby facilitating optimal cleaning of the root surfaces.

Technique

1. Sectional releasing incisions are first made to demarcate the area scheduled for surgery (Fig. 39-9). These incisions are made from the mid-buccal gingival margins of the two peripheral teeth of the treatment area and are continued for several millimeters out into the alveolar mucosa. The two releasing incisions are connected by a gingival incision, which follow the outline of the gingival margin and *separate the pocket epithelium and the inflamed connective tissue from the non-inflamed gingiva*. Similar releasing and gingival incisions, if needed, are made on the lingual aspect of the teeth.

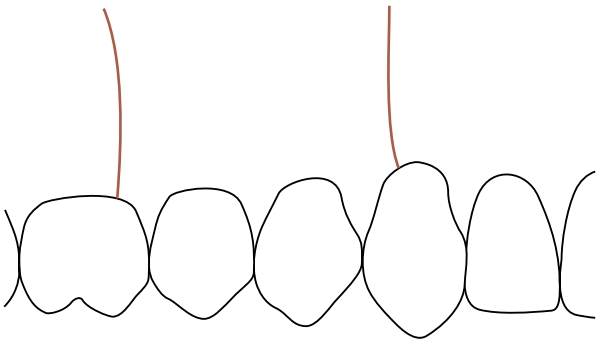

Fig. 39-9 Original Widman flap. Two releasing incisions demarcate the area scheduled for surgical therapy. A scalloped reverse bevel incision is made in the gingival margin to connect the two releasing incisions.

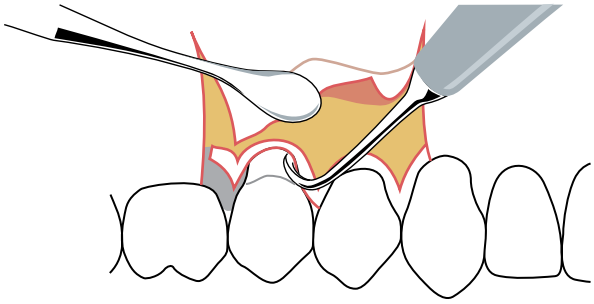

Fig. 39-10 Original Widman flap. The collar of inflamed gingival tissue is removed following the elevation of a mucoperiosteal flap.

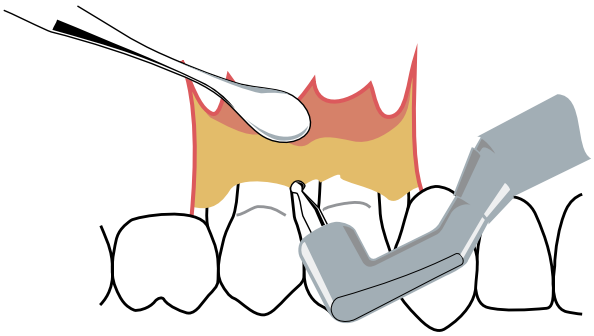

Fig. 39-11 Original Widman flap. By bone recontouring, a "physiologic" contour of the alveolar bone may be re-established.

2. A mucoperiosteal flap is elevated to expose at least 2–3 mm of the marginal alveolar bone. The collar of inflamed tissue around the neck of the teeth is removed with curettes (Fig. 39-10) and the exposed root surfaces are carefully instrumented. Bone recontouring is recommended in order to achieve an ideal anatomic form of the underlying alveolar bone (Fig. 39-11).

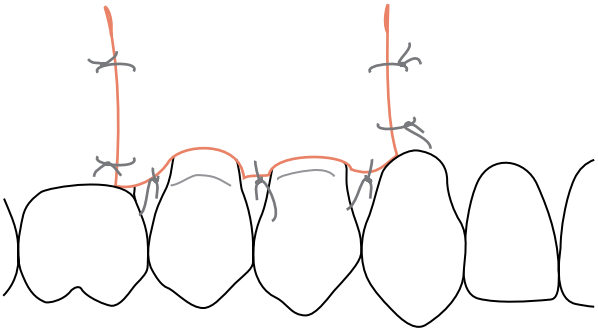

Fig. 39-12 Original Widman flap. The coronal ends of the buccal and lingual flaps are placed at the alveolar bone crest and secured in this position by interdentally placed sutures.

3. Following careful debridement of the teeth in the surgical area, the buccal and lingual flaps are laid back over the alveolar bone and secured in this position with interproximal sutures (Fig. 39-12). Widman pointed out the importance of placing the soft tissue margin at the level of the alveolar bone crest, so that no pockets would remain. Often the interproximal areas are left without soft tissue coverage of the crestal bone.

The main advantages of the "*original Widman flap*" procedure in comparison to the gingivectomy procedure include, according to Widman (1918):

- Less discomfort for the patient, since healing occurred by primary intention
- Possible to re-establish a proper contour of the alveolar bone in sites with angular bony defects.

Neumann flap

Only a few years later, Neumann (1920) suggested the use of a flap procedure, which in some respects was different from that originally described by Widman.

Technique

1. An *intracrevicular incision* is made through the base of the gingival pockets and the entire gingiva (and part of the alveolar mucosa) is elevated in a mucoperiosteal flap. Sectional releasing incisions are made to demarcate the area of surgery.
2. Following flap elevation, the inside of the flap is curetted to remove the pocket epithelium and the granulation tissue. The root surfaces are subsequently carefully debrided. Any irregularities of the alveolar bone crest are corrected.
3. The flaps are then trimmed to allow both an optimal adaptation to the teeth and a proper coverage of the alveolar bone on both the buccal/lingual (palatal) and the interproximal sites. Neumann (1920) pointed out the importance of removing the soft tissue pockets, that is replacing the flap at the crest of the alveolar bone.

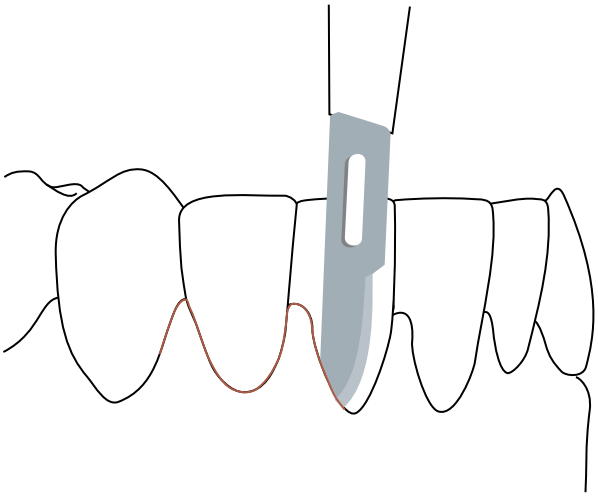

Fig. 39-13 Modified flap operation (the Kirkland flap). Intracrevicular incision.

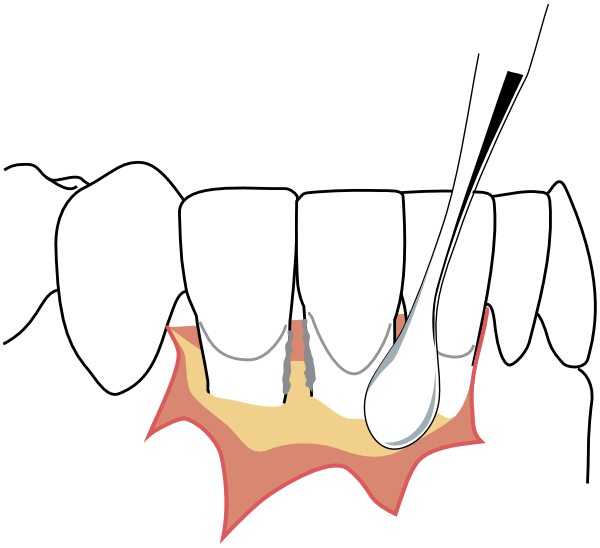

Fig. 39-14 Modified flap operation (the Kirkland flap). The gingiva is retracted to expose the "diseased" root surface.

Modified flap operation

In a publication from 1931, Kirkland described a surgical procedure to be used in the treatment of "periodontal pus pockets". The procedure was called the *modified flap operation*, and is basically an access flap used to allow proper root debridement.

Technique

1. Pocket incisions are made (Fig. 39-13) on both the labial and the lingual aspects of the interdental area. The incisions are extended in a mesial and a distal direction.
2. The gingiva is retracted labially and lingually to expose the diseased root surfaces (Fig. 39-14) which are carefully debrided (Fig. 39-15). Angular bony defects are curetted but no bone is removed.
3. Following the elimination of the pocket epithelium and granulation tissue from the inner surface of the flaps, these are *replaced* at their original position and secured with interproximal sutures (Fig. 39-16).

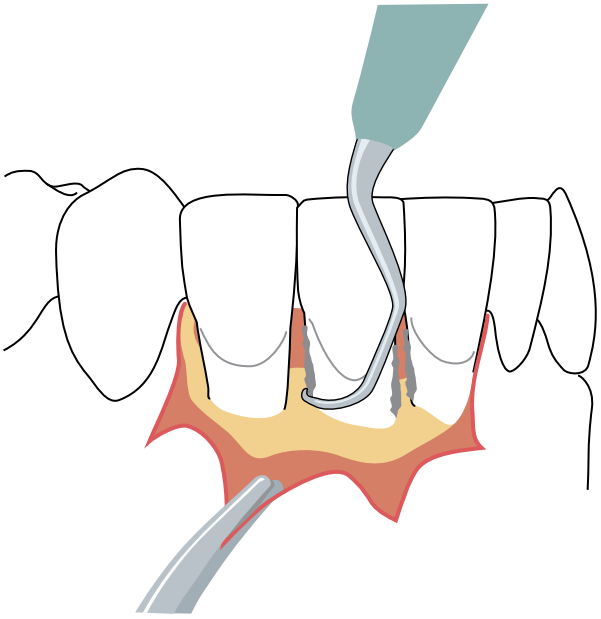

Fig. 39-15 Modified flap operation (the Kirkland flap). The exposed root surfaces are subjected to mechanical debridement.

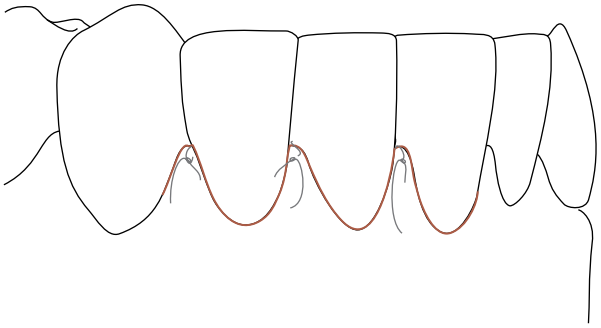

Fig. 39-16 Modified flap operation (the Kirkland flap). The flaps are repositioned at their original position and sutured.

In contrast to the *original Widman flap* as well as the *Neumann flap*, the *modified flap operation* does not include (1) extensive removal of non-inflamed tissues and (2) apical displacement of the gingival margin. The method could be useful in the anterior regions of the dentition for esthetic reasons, since the root surfaces are not markedly exposed. Another advantage of the *modified flap operation* was the potential for bone regeneration in intrabony defects that, according to Kirkland (1931), frequently occurred.

The main objectives of the flap procedures so far described were to:

- Facilitate the debridement of the root surfaces as well as the removal of the pocket epithelium and the inflamed connective tissue
- Eliminate the deepened pockets (the *original Widman flap* and the *Neumann flap*)
- Cause a minimal amount of trauma to the remaining periodontal tissues and a minimum of discomfort to the patient.

Apically repositioned flap

In the 1950s and 1960s new surgical techniques for the removal of soft and, when indicated, hard tissue periodontal pockets were described in the literature. The importance of maintaining *an adequate zone of attached gingiva* after surgery was now emphasized. One of the first authors to describe a technique for the preservation of the gingiva following surgery was Nabers (1954). The surgical technique developed by Nabers was originally denoted "repositioning of attached gingiva" and was later modified by Ariaudo and Tyrrell (1957). In 1962, Friedman proposed the term *apically repositioned flap* to describe more appropriately the surgical technique introduced by Nabers. Friedman emphasized the fact that, at the end of the surgical procedure, the entire complex of the soft tissues (gingiva and alveolar mucosa), rather than the gingiva alone, was displaced in the apical direction. Thus, rather than removing gingiva which would be in excess after osseous surgery (if performed), the whole mucogingival complex was maintained and repositioned apically. This surgical technique was used on buccal surfaces in both upper and lower jaws and on lingual surfaces in the lower jaw, while a bevel flap (see below) technique had to be used on the palatal aspect of maxillary teeth where the lack of alveolar mucosa made it impossible to reposition the flap in an apical direction.

Technique

According to Friedman (1962) the technique should be performed in the following way:

1. A reverse bevel incision is made using a scalpel with a Bard–Parker® blade (No. 12B or No. 15). How far from the buccal/lingual gingival margin the incision should be made is dependent on the pocket depth as well as the thickness and the width of the gingiva (Fig. 39-17). If preoperatively the gingiva is thin and only a narrow zone of keratinized tissue is present, the incision should be made close to the tooth. The beveling incision should be given a scalloped outline, to ensure maximal interproximal coverage of the alveolar bone when the flap subsequently is repositioned. Vertical releasing incisions extending out into the alveolar mucosa (i.e. past the mucogingival junction) are made at each of the end points of the reverse incision, thereby making apical repositioning of the flap possible.
2. A full-thickness mucoperiosteal flap including buccal/lingual gingiva and alveolar mucosa is raised by means of a mucoperiosteal elevator. The flap has to be elevated beyond the mucogingival line in order to be able later to reposition the soft tissue apically. The marginal collar of tissue, including pocket epithelium and granulation tissue, is removed with curettes (Fig. 39-18), and the exposed root surfaces are carefully scaled and planed.

3. The alveolar bone crest is recontoured with the objective of recapturing the normal form of the alveolar crest, but at a more apical level (Fig. 39-19). The osseous surgery is performed using burs and/or bone chisels.
4. Following careful adjustment, the buccal/lingual flap is repositioned to the level of the newly recontoured alveolar bone crest and secured in this position (Fig. 39-20). The incisional and excisional technique used means that it is not always possible to obtain proper soft tissue coverage of the denuded interproximal alveolar bone. A periodontal dressing should therefore be applied to protect the exposed bone and to retain the soft tissue at the level of the bone crest (Fig. 39-21). After healing, an "adequate" zone of gingiva is preserved and no residual pockets should remain.

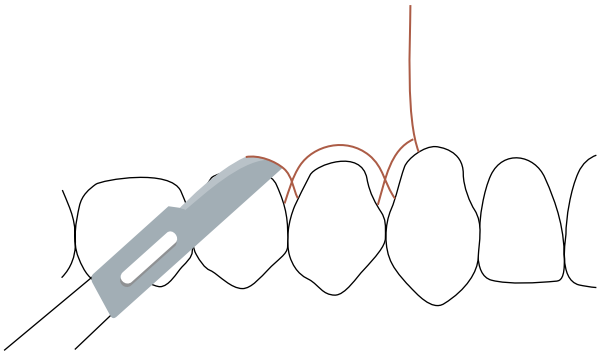

Fig. 39-17 Apically repositioned flap. Following a vertical releasing incision, the reverse bevel incision is made through the gingiva and the periosteum to separate the inflamed tissue adjacent to the tooth from the flap.

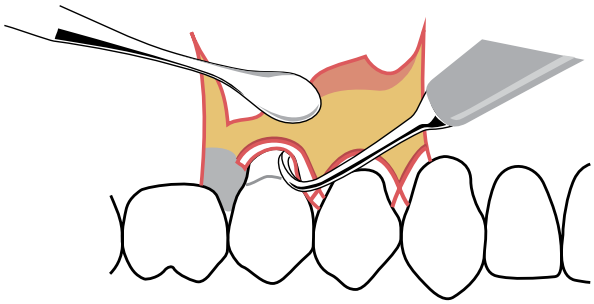

Fig. 39-18 Apically repositioned flap. A mucoperiosteal flap is raised and the tissue collar remaining around the teeth, including the pocket epithelium and the inflamed connective tissue, is removed with a curette.

To handle periodontal pockets on the palatal aspect of the maxillary teeth, Friedman described a modification of the "apically repositioned flap", which he termed the *beveled flap*:

1. In order to allow the tissue at the gingival margin to follow the outline of the alveolar bone crest properly, a conventional mucoperiosteal flap is first elevated (Fig. 39-22).
2. Tooth surfaces are debrided and osseous recontouring is performed (Fig. 39-23).
3. The palatal flap is subsequently replaced and the gingival margin is adjusted to the alveolar bone crest by a secondary scalloped and beveled incision (Fig. 39-24). The flap is secured in this position with interdental sutures (Fig. 39-25).

Among a number of suggested advantages of the *apically repositioned flap* procedure, the following have been emphasized:

- Minimum pocket depth postoperatively
- If optimal soft tissue coverage of the alveolar bone is obtained, the post-surgical bone loss is minimal
- Postoperative position of the gingival margin may be controlled and the entire mucogingival complex may be maintained.

The removal of periodontal tissues by bone resection and the subsequent exposure of root surfaces (which may cause esthetic and root sensitivity problems) are regarded as the main disadvantages of this technique.

Modified Widman flap

Ramfjord and Nissle (1974) described the *modified Widman flap* technique that is also recognized as the *open flap curettage* technique. It should be noted that, while the *original Widman flap* technique included both apical displacement of the flap(s) and osseous recontouring (elimination of bony defects) to obtain proper pocket elimination, the *modified Widman flap* technique is not intended to meet these objectives.

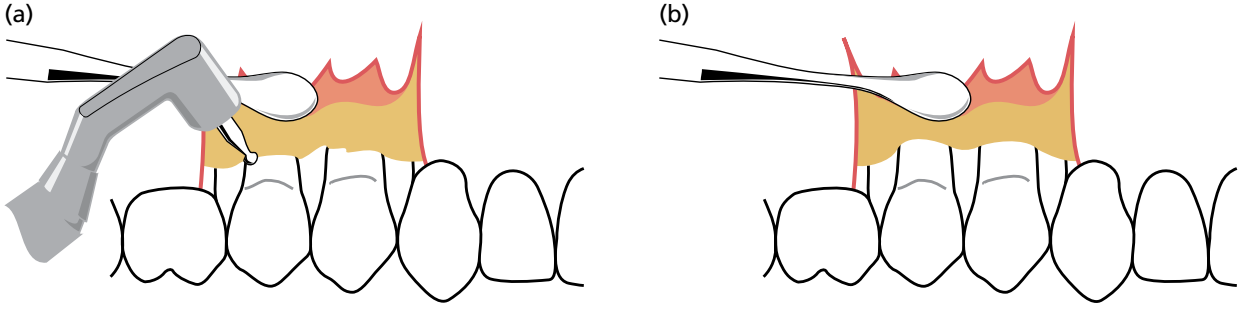

Fig. 39-19 Apically repositioned flap. Osseous surgery is performed with the use of a rotating bur (a) to recapture the physiologic contour of the alveolar bone (b).

Technique

1. According to the description by Ramfjord and Nissle (1974), the *initial incision* (Fig. 39-26), which may be performed with a Bard–Parker® knife (No. 11), should be parallel to the long axis of the tooth and placed approximately 1 mm from the buccal gingival margin in order to properly separate the pocket epithelium from the flap. If the pockets on the buccal aspects of the teeth are <2 mm deep or if esthetic considerations are important, an intracrevicular incision may be made. Furthermore, the scalloped incision should be extended as far as possible in between the teeth, to allow maximum amounts of the interdental gingiva to be included in the flap. A similar incision technique is used on the palatal aspect. Often, however, the scalloped outline of the initial incision may be accentuated by placing the knife at a distance of 1–2 mm from the mid-palatal surface of the teeth. By extending the incision as far as possible in between the teeth, sufficient amounts

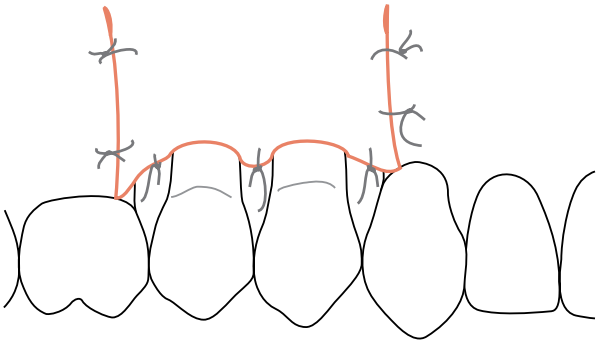

Fig. 39-20 Apically repositioned flap. The flaps are repositioned in an apical direction to the level of the recontoured alveolar bone crest and retained in this position by sutures.

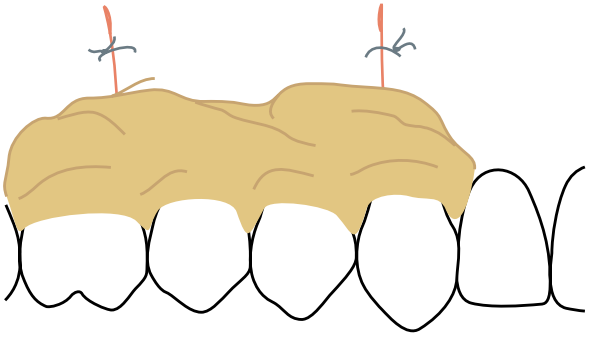

Fig. 39-21 Apically repositioned flap. A periodontal dressing is placed over the surgical area to ensure that the flaps remain in the correct position during healing.

Fig. 39-23 Beveled flap. Scaling, root planing, and osseous recontouring are performed in the surgical area.

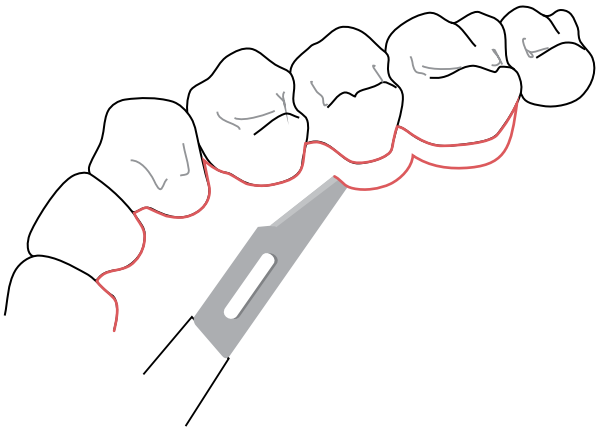

Fig. 39-24 Beveled flap. The palatal flap is replaced and a secondary, scalloped, reverse bevel incision is made to adjust the length of the flap to the height of the remaining alveolar bone.

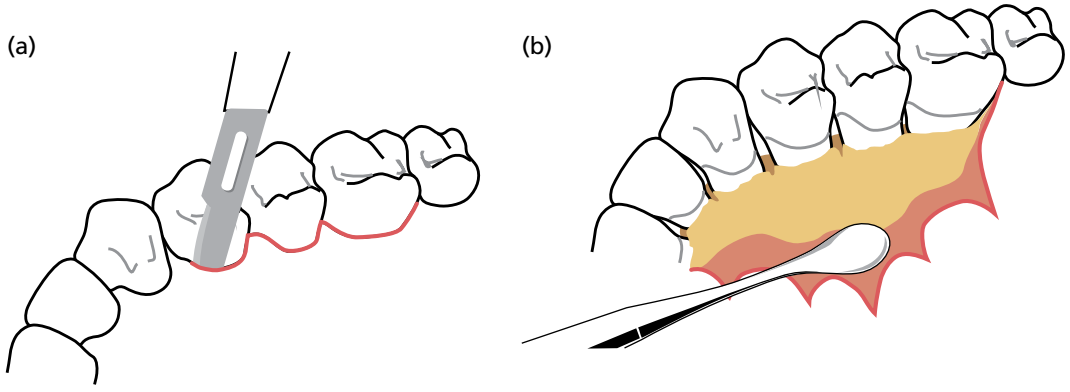

Fig. 39-22 Beveled flap. A primary incision is made intracrevicularly through the bottom of the periodontal pocket (a) and a conventional mucoperiosteal flap is elevated (b).

of tissue can be included in the palatal flap to allow for proper coverage of the interproximal bone when the flap is sutured. Vertical releasing incisions are not usually required.

2. Buccal and palatal full-thickness flaps are carefully elevated with a mucoperiosteal elevator. The flap elevation should be limited and allow only a few millimeters of the alveolar bone crest to become exposed. To facilitate the gentle separation of the collar of pocket epithelium and granulation tissue from the root surfaces, an intracrevicular incision is made around the teeth (*second incision*) to the alveolar crest (Fig. 39-27).
3. A *third incision* (Fig. 39-28) made in a horizontal direction and in a position close to the surface of the alveolar bone crest separates the soft tissue collar of the root surfaces from the bone.
4. The pocket epithelium and the granulation tissues are removed by means of curettes. The exposed roots are carefully scaled and planed, except for a narrow area close to the alveolar bone crest in which remnants of attachment fibers may be preserved. Angular bony defects are carefully curetted.
5. Following the curettage, the flaps are trimmed and adjusted to the alveolar bone to obtain complete coverage of the interproximal bone (Fig. 39-29). If this adaptation cannot be achieved by soft tissue recontouring, some bone may be removed from the outer aspects of the alveolar process in order to

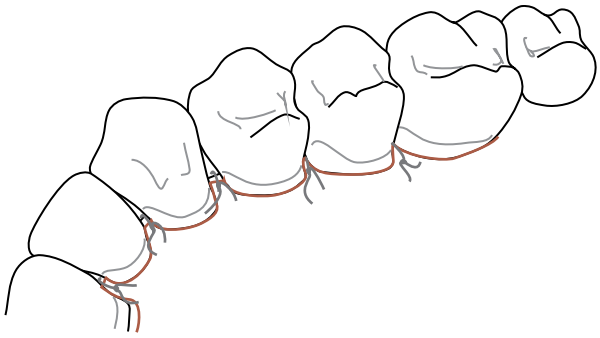

Fig. 39-25 Beveled flap. The shortened and thinned flap is replaced over the alveolar bone and in close contact with the root surfaces.

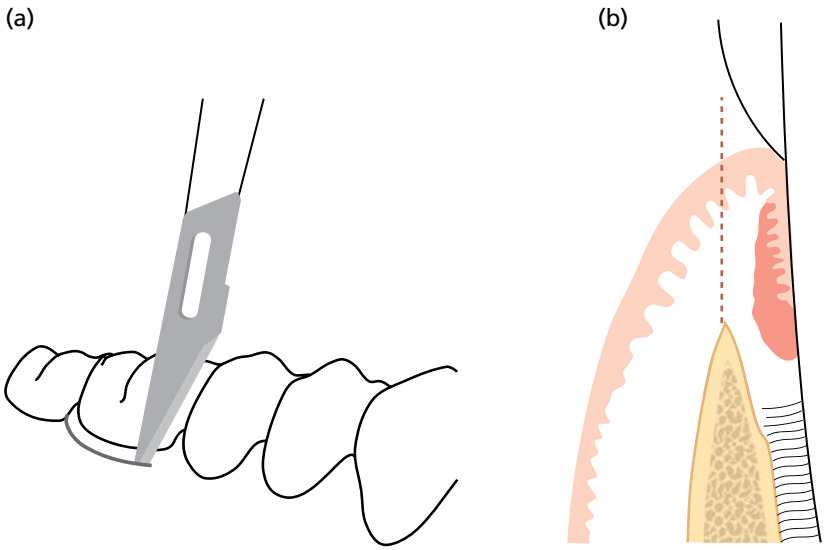

Fig. 39-26 Modified Widman flap. The initial incision is placed 0.5–1 mm from the gingival margin (a) and parallel to the long axis of the tooth (b).

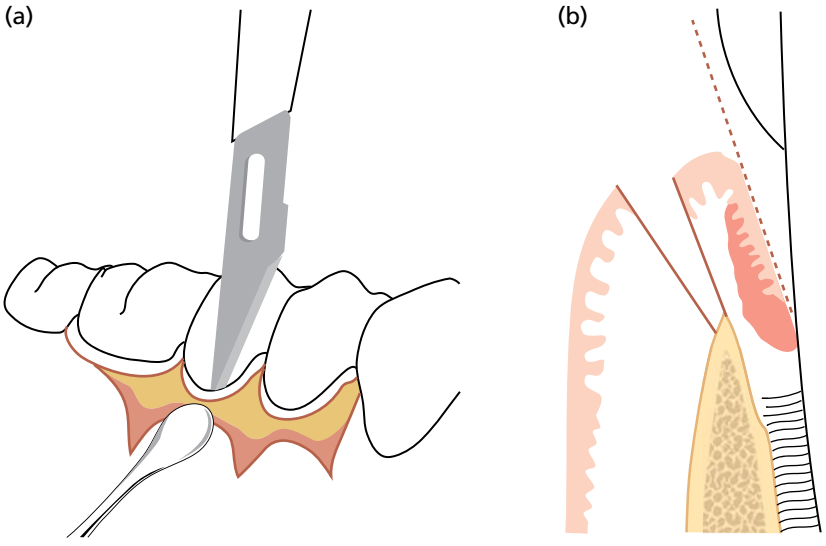

Fig. 39-27 Modified Widman flap. Following careful elevation of the flaps, a second intracrevicular incision (a) is made to the alveolar bone crest (b) to separate the tissue collar from the root surface.

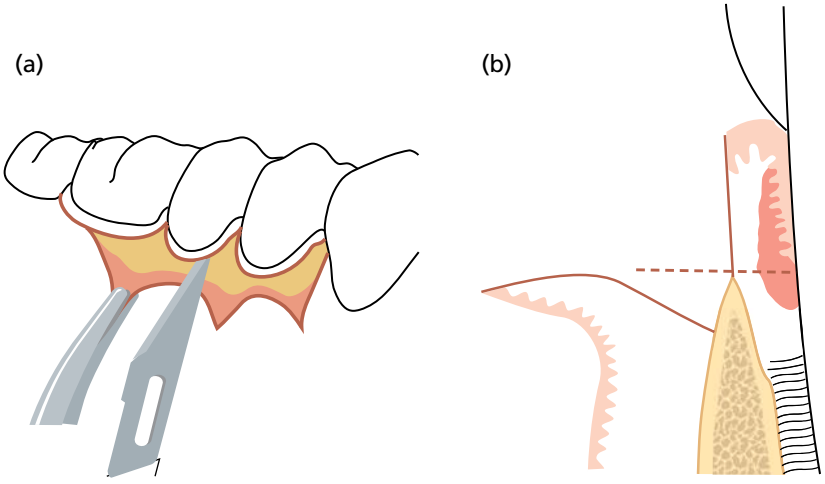

Fig. 39-28 Modified Widman flap. A third incision is made perpendicular to the root surface (a) and as close as possible to the bone crest (b), thereby separating the tissue collar from the alveolar bone.

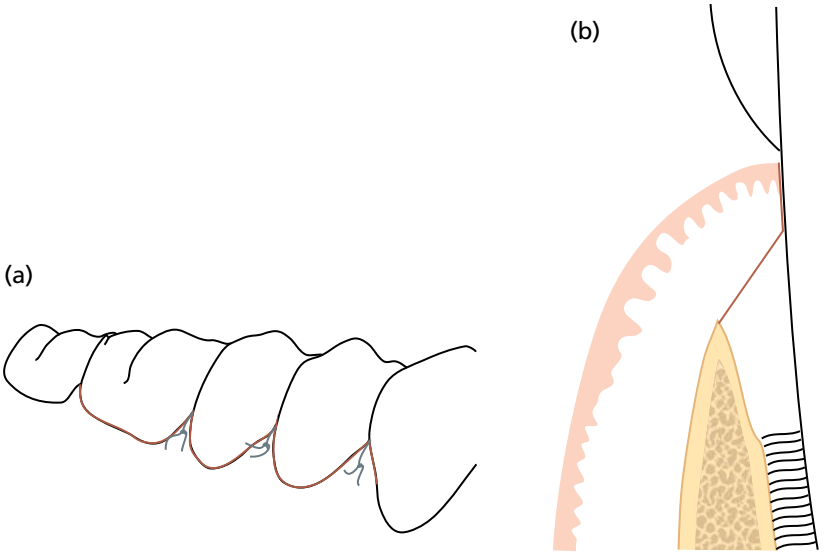

Fig. 39-29 Modified Widman flap. (a) Following proper debridement and curettage of angular bone defects, the flaps are carefully adjusted to cover the alveolar bone and sutured. (b) Complete coverage of the interdental bone as well as close adaptation of the flaps to the tooth surfaces should be accomplished.

facilitate the all-important flap adaptation. The flaps are sutured together with individual interdental sutures. Surgical dressing may be placed over the area to ensure close adaptation of the flaps to the alveolar bone and root surfaces. The dressing, as well as the sutures, is removed after 1 week.

The main advantages of the *modified Widman flap* technique in comparison to the other procedures previously described are, according to Ramfjord and Nissle (1974):

- Possibility of obtaining a close adaptation of the soft tissues to the root surfaces
- Minimum of trauma to which the alveolar bone and the soft connective tissues are exposed
- Less exposure of the root surfaces, which from an esthetic point of view is an advantage in the treatment of anterior segments of the dentition.

Papilla preservation flap

In order to preserve the interdental soft tissues for maximum soft tissue coverage following surgical intervention involving treatment of proximal osseous defects, Takei *et al*. (1985) proposed a surgical approach called *papilla preservation technique*. Later, Cortellini *et al*. (1995b, 1999) and Cortellini and Tonetti (2007) described modifications to the flap design to allow minimally invasive surgical techniques to be used in combination with regenerative procedures. For esthetic reasons, the papilla preservation technique is often utilized in the surgical treatment of anterior tooth regions.

Technique

1. According to the description by Takei *et al*. (1985), the *papilla preservation flap technique* is initiated by an intrasulcular incision at the facial and proximal aspects of the teeth without making incisions through the interdental papillae (Fig. 39-30a). Subsequently, an intrasulcular incision is made along the lingual/palatal aspect of the teeth with a semilunar incision made across each interdental area. The semilunar incision should dip apically by at least 5 mm from the line angles of the teeth, which will allow the interdental tissue to be elevated in the facial flap. In situations where an osseous defect has a wide extension into the lingual/palatal area, the semilunar incision may be placed on the facial aspect of the interdental area to include the papillae in the lingual/palatal flap.

2. A curette or interproximal knife is used to free the interdental papilla carefully from the underlying hard tissue. The detached interdental tissue is pushed through the embrasure with a blunt instrument (Fig. 39-30b).
3. A full-thickness flap is reflected with a periosteal elevator on both facial and lingual/palatal surfaces. The exposed root surfaces are thoroughly debrided and bone defects carefully curetted (Fig. 39-31).
4. While holding the reflected flap, the margins of the flap and the interdental tissue are trimmed to remove pocket epithelium and excessive granulation tissue. In anterior areas, the trimming of granulation tissue should be limited in order to maintain the maximum thickness of tissue.
5. The flaps are repositioned and sutured using cross mattress sutures (Fig. 39-32). Alternatively, a direct suture of the semilunar incisions can be placed as the only means of flap closure. A surgical dressing may be placed to protect the surgical area. The dressing and sutures are removed after 1 week.

Regenerative procedures

In the 1980s, treatment of periodontal pockets was given a new dimension when it was shown that, with specific surgical handling of the periodontal wound, a significant amount of new connective tissue attachment is achievable (Nyman *et al*. 1982; Bowers *et al*. 1989).

Obtaining periodontal regeneration has always been a major challenge to the periodontist and several approaches to periodontal regeneration have been used throughout the years. The earliest attempts involved various bone-grafting procedures, such as the use of autogenous grafts from both extraoral and intraoral

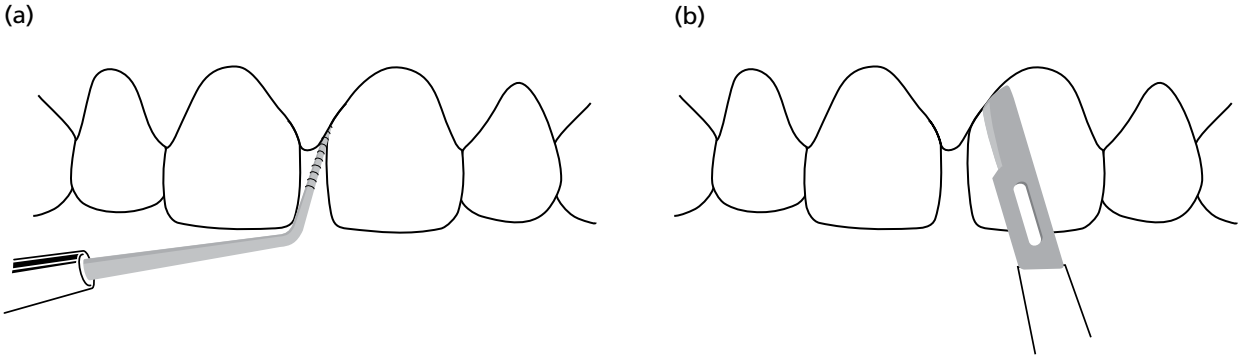

Fig. 39-30 Papilla preservation flap. (a) A deep pocket is present at an approximal tooth site. (b) Intracrevicular incisions are made at the facial and proximal aspects of the teeth.

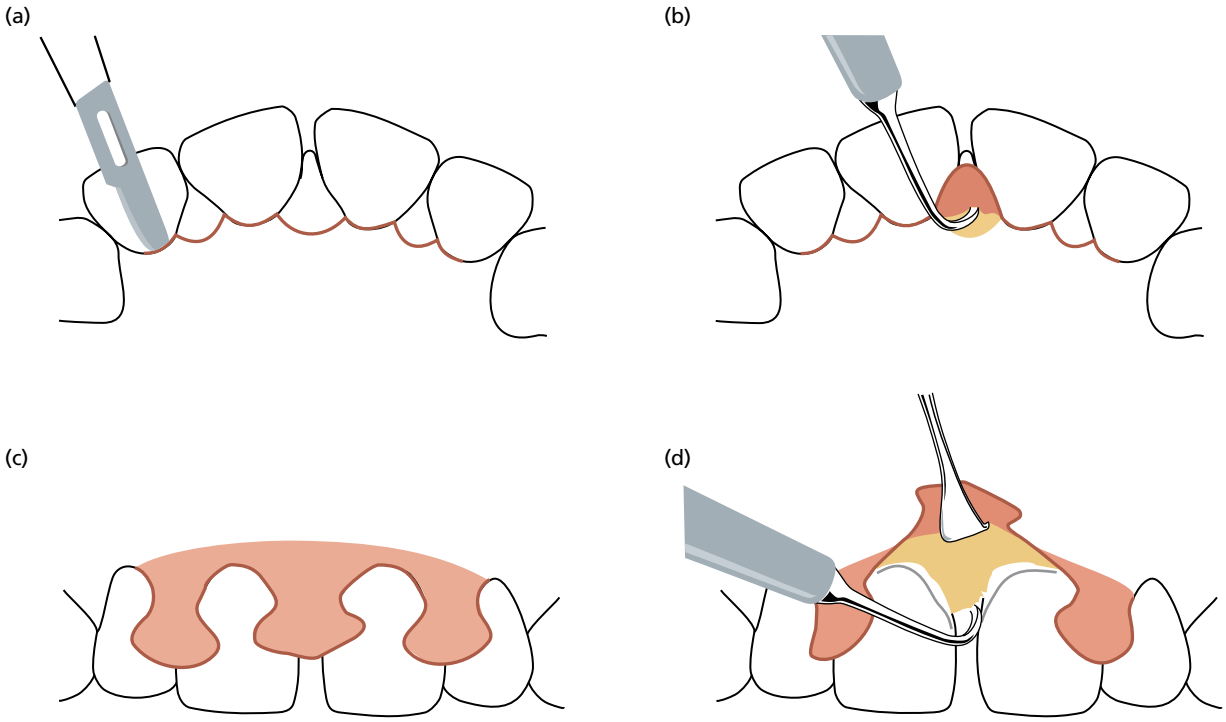

Fig. 39-31 Papilla preservation flap. (a) An intracrevicular incision is made along the lingual/palatal aspect of the teeth with a semilunar incision made across each interdental area. (b) A curette or a papilla elevator is used to carefully free the interdental papilla from the underlying hard tissue. (c, d) Detached interdental tissue is pushed through the embrasure with a blunt instrument to be included in the facial flap.

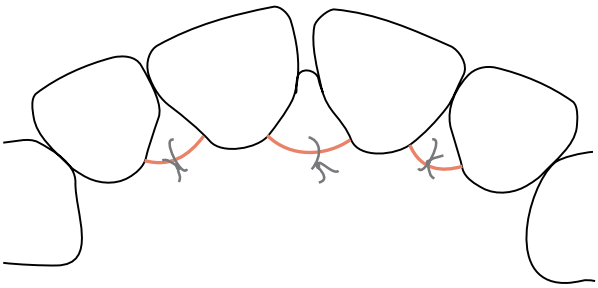

Fig. 39-32 Papilla preservation flap. The flap is replaced and sutures are placed on the palatal aspect of the interdental areas.

donor sites, allogenic grafts, and non-decalcified/decalcified lyophilized bone grafts, or "implant" procedures utilizing slowly resorbable tricalcium phosphate and non-resorbable hydroxyapatite. Other approaches to periodontal regeneration involved the use of citric acid for root surface demineralization or the use of methods for improved root surface biocompatibility or to enhance cellular responses.

The use of physical barriers, such as membranes (non-biodegradable or biodegradable), to retard or prevent apical migration of epithelium as well as exclude gingival connective tissue from the healing wound, formed the basis for the concept known as "guided tissue regeneration" (Gottlow *et al*. 1986). The procedure can be described as a coronally repositioned flap procedure without bone recontouring, with the adjunctive use of a membrane tightened to the tooth to cover the exposed root surface and adjacent intrabony defect before repositioning the soft tissue flaps.

In the late 1990s, a new approach to periodontal regeneration was presented, which involved the use of a derivative of enamel matrix proteins (Hammarström 1997; Heijl *et al*. 1997). These proteins are involved in the embryogenesis of cementum, periodontal ligament, and supporting bone, and when applied to the exposed root surface facing an intrabony periodontal defect, they may mediate regeneration of a new attachment apparatus. The surgical procedure is performed as a coronally repositioned flap procedure without bone recontouring. Before repositioning of the soft tissue flaps, the exposed roots are treated with ethylenediaminetetra-acetic acid (EDTA) for removal of the "smear layer", followed by the application of the derivative of enamel matrix proteins.

Various regenerative procedures for surgical treatment of periodontal lesions, as well as the biologic basis for periodontal regeneration, are discussed in detail in Chapters 28 and 45.

Distal wedge procedures

In many cases the treatment of periodontal pockets on the distal surface of distal molars is complicated by the presence of bulbous tissues over the tuberosity or by a prominent retromolar pad. The most direct approach to pocket elimination in such cases in the maxillary jaw is the gingivectomy procedure. The incision is started on the distal surface of the tuberosity and carried forward to the base of the pocket of the distal surface of the molar (Fig. 39-33).

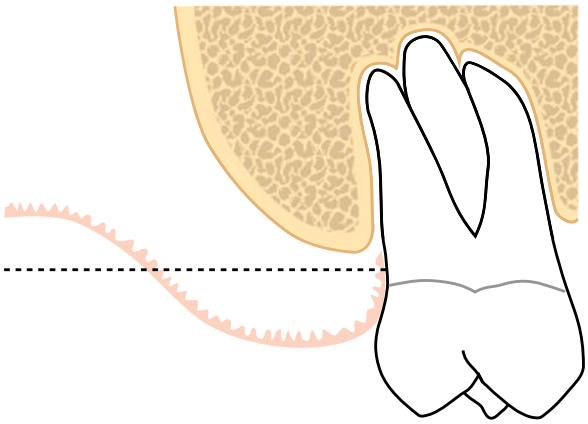

Fig. 39-33 Distal wedge procedure. Simple gingivectomy incision (dashed line) can be used to eliminate a soft tissue pocket and adjacent fibrous tissue pad behind a maxillary molar.

However, when only limited amounts of keratinized gingiva are present, or none at all, or if a distal angular bony defect has been diagnosed, the bulbous tissue should be reduced in size rather than removed *in toto*. This may be accomplished by the *distal wedge procedure* (Robinson 1966). This technique facilitates access to the osseous defect and makes it possible to preserve sufficient amounts of gingiva and mucosa to achieve soft tissue coverage.

Technique

1. Buccal and lingual incisions are made in a vertical direction through the tuberosity or retromolar pad to form a triangular wedge (Fig. 39-34a). The facial and lingual incisions should be extended in a mesial direction along the buccal and lingual surfaces of the distal molar to facilitate flap elevation.
2. The facial and lingual walls of the tuberosity or retromolar pad are deflected and the incised wedge of tissue is dissected and separated from the bone (Fig. 39-34b).
3. The walls of the facial and lingual flaps are then reduced in thickness by undermining incisions (Fig. 39-34c). Loose tags of tissue are removed and the root surfaces are debrided. If necessary, the bone is recontoured.
4. The buccal and lingual flaps are replaced over the exposed alveolar bone, and the edges trimmed to avoid overlapping wound margins. The flaps are secured in this position with interrupted sutures (Fig. 39-34d). The sutures are removed after approximately 1 week.

The original distal wedge procedure may be modified according to individual requirements. Some commonly used modifications of the incision technique are shown in Figs. 39-35, 39-36, 39-37, and 39-38, all having the goals of eliminating the deep pocket and achieving mucosal coverage of the remaining periodontium.

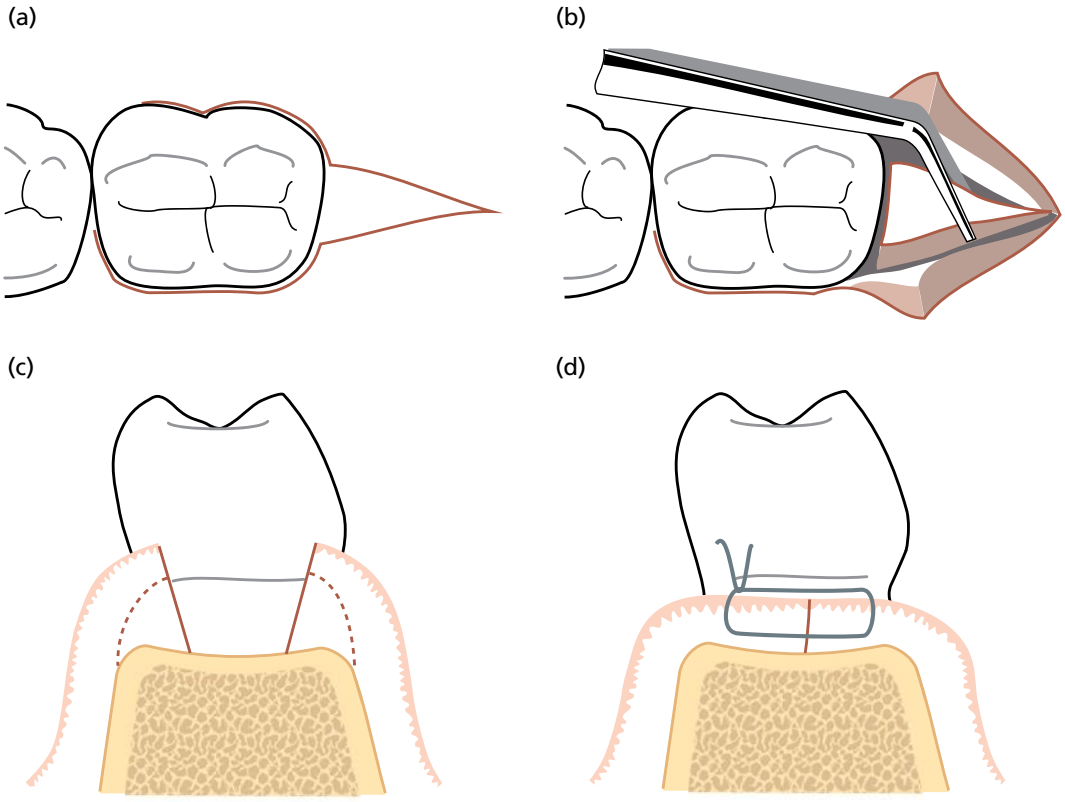

Fig. 39-34 Distal wedge procedure. (a) Buccal and lingual vertical incisions are made through the retromolar pad to form a triangle behind a mandibular molar. (b) Triangular-shaped wedge of tissue is dissected from the underlying bone and removed. (c) Walls of the buccal and lingual flaps are reduced in thickness by undermining incisions (dashed lines). (d) The flaps, which have been trimmed and shortened to avoid overlapping wound margins, are sutured.

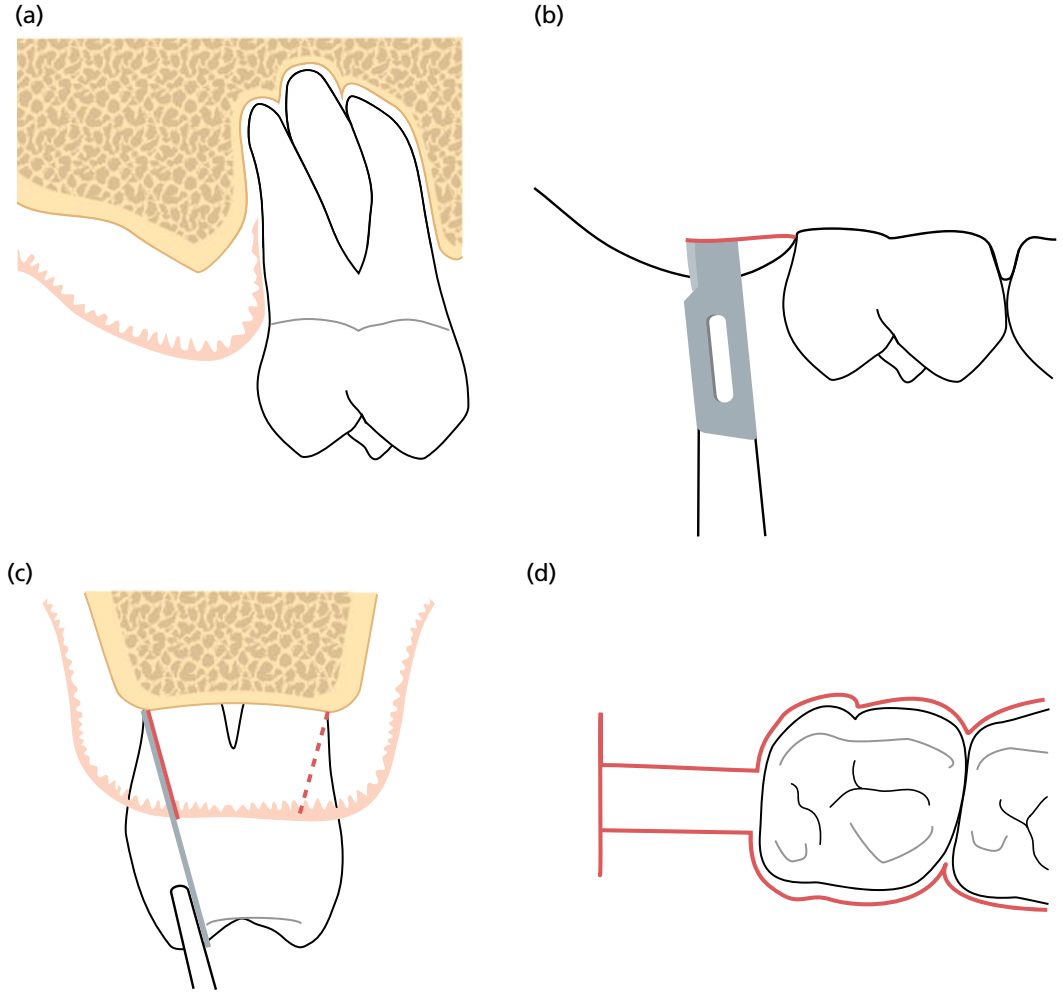

Fig. 39-35 Modified distal wedge procedure. (a) A deep periodontal pocket combined with an angular bone defect at the distal aspect of a maxillary molar. (b–d) Two parallel reverse bevel incisions, one buccal and one palatal, are made from the distal surface of the molar to the posterior part of the tuberosity, where they are connected with a buccolingual incision (d). The buccal and palatal incisions are extended in a mesial direction along the buccal and palatal surfaces of the molar to facilitate flap elevation.

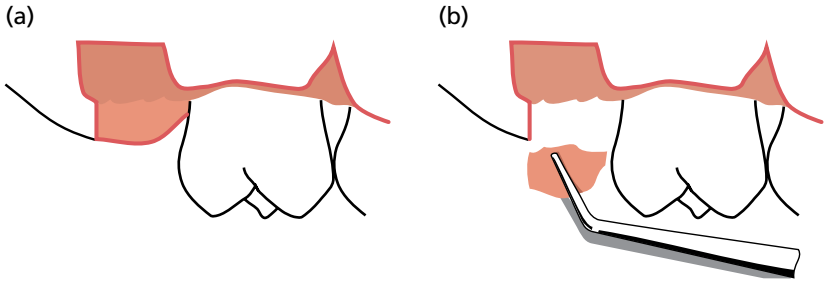

Fig. 39-36 Modified distal wedge procedure. (a) Buccal and palatal flaps are elevated and (b) the rectangular wedge is released from the tooth and underlying bone by sharp dissection and then removed.

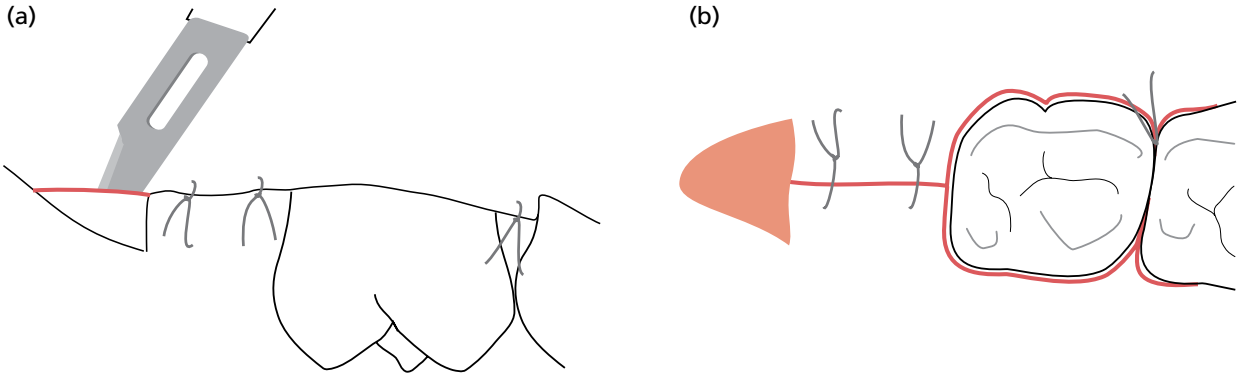

Fig. 39-37 Modified distal wedge procedure. (a, b) Following bone recontouring and root debridement, the flaps are trimmed and shortened to avoid overlapping wound margins and sutured. A close soft tissue adaptation should be accomplished to the distal surface of the molar. The remaining fibrous tissue pad distal to the buccolingual incision line is "leveled" by the use of a gingivectomy incision.

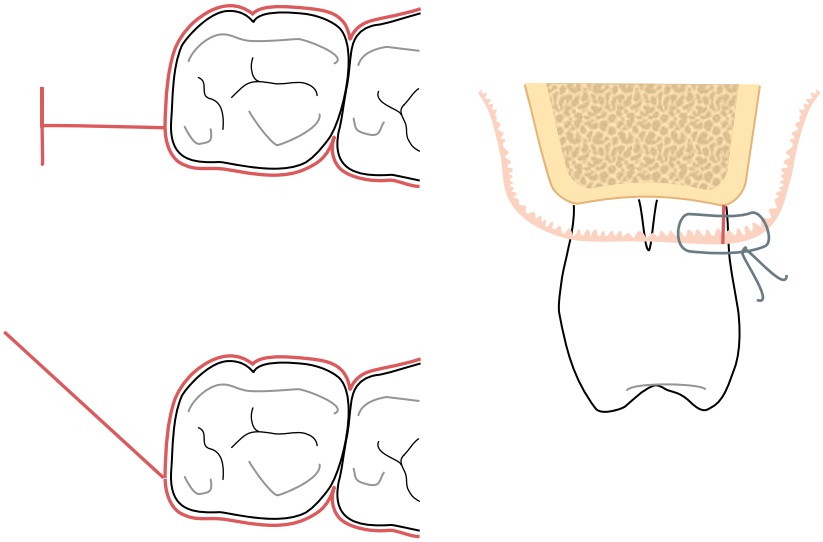

Fig. 39-38 Modified incision techniques in distal wedge procedures. To ensure optimal flap adaptation at the furcation site, the incision technique may be modified. The amount of attached keratinized tissue present as well as the accessibility to the retromolar area has to be considered when placing the incision.

Osseous surgery

The principles of osseous surgery in periodontal therapy were outlined by Schluger (1949) and Goldman (1950). They pointed out that alveolar bone loss caused by inflammatory periodontal disease often results in an uneven outline of the bone crest. Since, according to these authors, the gingival contour is closely dependent on the contour of the underlying bone as well as the proximity and anatomy of adjacent tooth surfaces, the elimination of soft tissue pockets often has to be combined with osseous reshaping and the elimination of osseous craters and angular bony defects to establish and maintain shallow pockets and optimal gingival contour after surgery.

Osteoplasty

The term *osteoplasty* was introduced by Friedman in 1955. The purpose of osteoplasty is to reshape the alveolar bone *without* removing any "supporting" bone. Examples of osteoplasty are the thinning of thick osseous ledges and the establishment of a scalloped contour of the buccal (lingual and palatal) bone crest (Fig. 39-39). In flap surgery without bone recontouring, interdental morphology may sometimes

preclude optimal mucosal coverage of the bone postsurgically, even if pronounced scalloping of soft tissue flaps is performed. In such a situation, removal of non-supporting bone by vertical grooving to reduce the faciolingual dimension of the bone in the interdental areas may facilitate flap adaptation, thereby reducing the risk of bone denudation as well of ischemic necrosis of unsupported mucosal flaps due to flap margin deficiencies.

Removal of non-supporting bone may sometimes also be required to gain access for intrabony root surface debridement. The leveling of interproximal craters and the elimination (or reduction) of bony walls of circumferential osseous defects are often referred to as "osteoplasty" since usually no resection of supporting bone is required (Fig. 39-40).

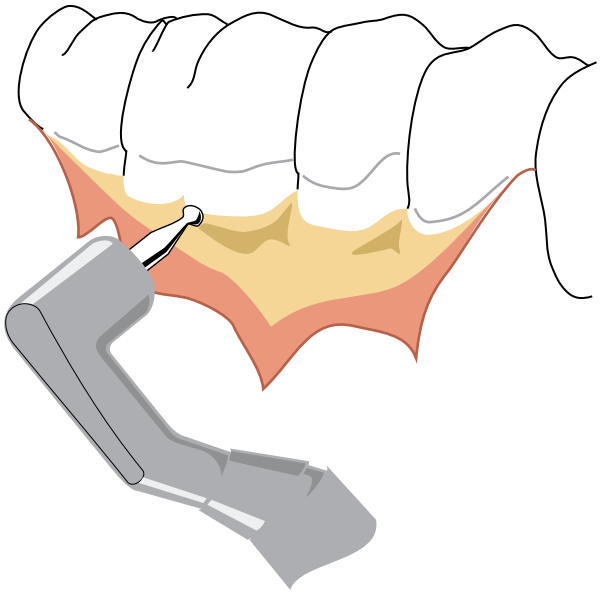

Fig. 39-39 Osteoplasty. Thick osseous ledges in a mandibular molar region area are eliminated with the use of a round bur to facilitate optimal flap adaptation.

Ostectomy

In *ostectomy*, supporting bone, that is bone directly involved in the attachment of the tooth, is removed to reshape hard tissue deformities caused by periodontitis. Ostectomy is considered to be an important part of surgical techniques aimed at pocket elimination. As a general rule, however, care must be exercised when supporting bone is to be removed.

After exposing the alveolar bone by elevation of a flap, buccal and/or lingual crater walls are reduced to the base of the osseous defect using bone chisels and bone rongeurs (Fig. 39-41a). A round bur or a diamond stone under continuous saline irrigation can also be used. If bone resection has been carried out in the interdental area, the buccal and lingual/palatal bone margins may subsequently be recontoured to compensate for discrepancies in bone height resulting from the interdental bone resection (Fig. 39-41b). It is considered important to remove the small ledges of bone, which often remain in the area of the line angles. The objective of bone surgery is thus to establish a "physiologic" anatomy of the alveolar bone, but at a more apical level.

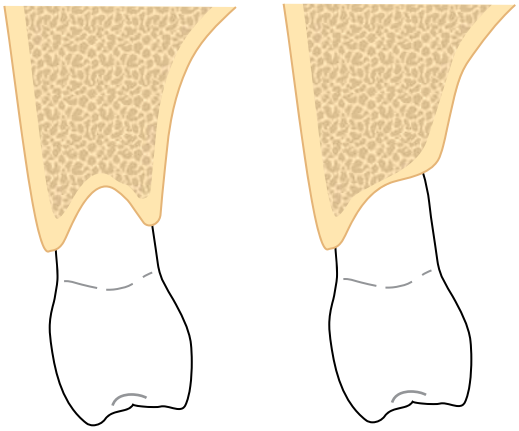

Fig. 39-40 Osteoplasty. Leveling of an interproximal bone crater through the removal of the palatal bone wall. For esthetic reasons, the buccal bone wall is maintained to support the height of the soft tissue.

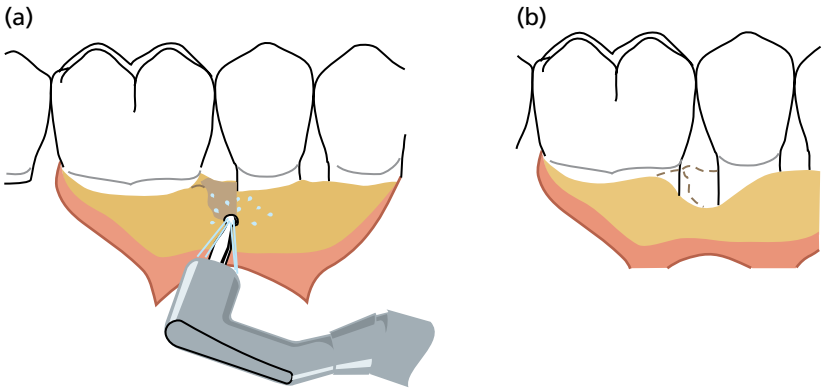

Fig. 39-41 Ostectomy. (a) Combined one- and two-wall osseous defect on the distal aspect of a mandibular bicuspid has been exposed following reflection of mucoperiosteal flaps. Since esthetics is not a critical factor to consider in the posterior tooth region of the mandible, the bone walls are reduced to a level close to the base of the defect using rotating round burs under continuous saline irrigation. (b) Osseous recontouring completed. Note that some supporting bone has to be removed from the buccal and lingual aspect of both the second bicuspid and the first molar in order to provide a hard tissue topography which allows a close adaptation of the covering soft tissue flap.

General guidelines for periodontal surgery

Objectives of surgical treatment

Traditionally, *pocket elimination* has been a main objective of periodontal therapy. The removal of the pocket by surgical means served two purposes: (1) the pocket, which established an environment conducive to progression of periodontal disease, was eliminated and (2) the root surface was made accessible for professional debridement and for self-performed tooth cleaning after healing.

While these objectives cannot be entirely discarded today, the necessity for pocket elimination in periodontal therapy has been challenged. During recent years our understanding of the biology of the periodontium, the pathogenesis of periodontal disease, and the healing capacity of the periodontium has markedly increased. This new information has thus formed the basis for a more differentiated understanding of the role played by periodontal surgery in the preservation of teeth.

In the past, *increased pocket depth* was the main indication for periodontal surgery. However, pocket depth is no longer as unequivocal a concept as it used to be. The *probeable depth*, that is the distance from the gingival margin to the point where tissue resistance stops further periodontal probe penetration, may only rarely correspond to the "true" depth of the pocket (see Chapter 29). Furthermore, regardless of the accuracy with which pockets can be measured, there is no established correlation between probeable pocket depth and the presence or absence of active disease. This means that signs other than increased probing depth should be present to justify surgical therapy. These include clinical signs of inflammation, especially exudation and bleeding on probing (to the bottom of the pockets), as well as aberrations of gingival morphology.

In conclusion, the main objective of periodontal surgery is to contribute to the long-term preservation of the periodontium by facilitating plaque removal and infection control, and periodontal surgery can serve this purpose by:

- Creating accessibility for proper professional scaling and root planing
- Establishing a gingival morphology which facilitates self-performed infection control.

In addition, periodontal surgery may aim to regenerate the periodontal attachment lost due to destructive disease. (New attachment procedures in periodontal therapy are discussed in Chapter 45)

Indications for surgical treatment

Impaired access for scaling and root planing

The difficulties in accomplishing proper root debridement with a non-surgical approach increase with (1) increasing depth of the periodontal pockets, (2) increasing width of the tooth surfaces, and (3) the presence of root fissures, root concavities, furcations, and defective margins of dental restorations in the subgingival area.

Provided a correct technique and suitable instruments are used, it is usually possible properly to debride pockets that are up to 5 mm deep (Waerhaug 1978; Caffesse *et al*. 1986). However, this 5 mm limit cannot be used as a universal rule of thumb. Reduced accessibility and the presence of one or several of the above-mentioned impeding conditions may prevent proper debridement of shallow pockets, whereas at sites with good accessibility and favorable root morphology, proper debridement can be accomplished even in deeper pockets (Badersten *et al*. 1981; Lindhe *et al*. 1982a).

It is often difficult to ascertain by clinical means whether subgingival instrumentation has been properly performed. Following scaling, the root surface should be smooth – roughness will often indicate the presence of remaining subgingival calculus. It is also important to monitor carefully the gingival reaction to subgingival debridement. If inflammation persists and if bleeding is elicited by gentle probing in the subgingival area, the presence of subgingival deposits should be suspected (Fig. 39-42). If such symptoms are not resolved by repeated subgingival instrumentation, surgical treatment should be performed to expose the root surfaces for proper cleaning.

Impaired access for self-performed plaque control

The level of infection control that can be maintained by the patient is determined not only by his/her interest and dexterity, but also, to some extent, by the morphology of the dentogingival area. The patient's responsibilities in an infection-control program must include the cleansing of the supragingival tooth surfaces and the marginal part of the gingival sulcus.

Pronounced gingival hyperplasia and presence of gingival craters (Fig. 39-43) are examples of

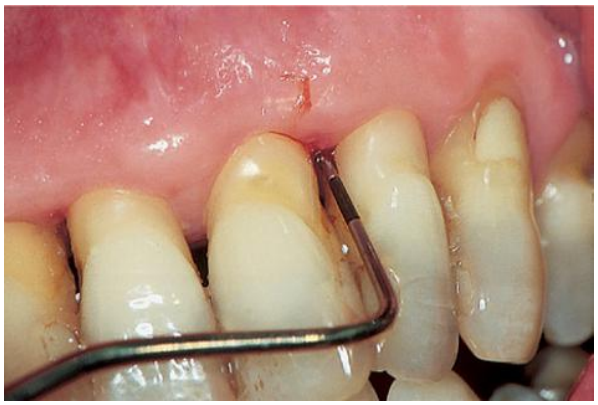

Fig. 39-42 Evaluation following non-surgical instrumentation reveals persistent signs of inflammation, bleeding following pocket probing, and probing depth of ≥6 mm. Flap elevation to expose the root surface for proper cleaning should be considered.

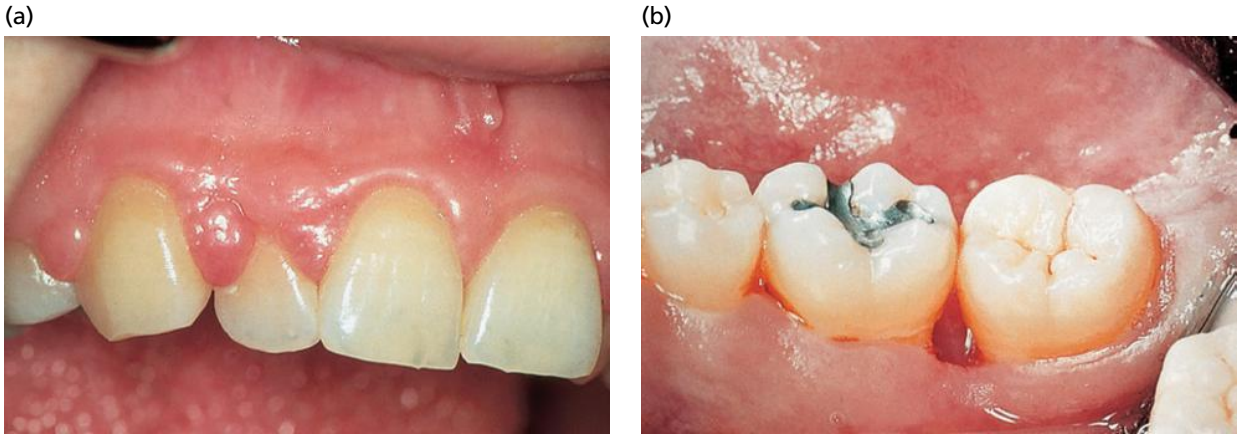

Fig. 39-43 Examples of gingival aberrations, (a) gingival enlargement and (b) proximal soft tissue crater, which favor plaque retention and thereby impede the patient's plaque control.

morphologic aberrations that may impede proper home care. Likewise, the presence of restorations with defective marginal fit or adverse contour and surface characteristics at the gingival margin may seriously compromise plaque removal.

In the professional treatment of periodontal disease, the dentist prepares the dentition in such a way that home care can be effectively managed. At the completion of treatment, the following objectives should have been met:

- No sub- or supra-gingival dental deposits
- No pathologic pockets (no bleeding on probing to the bottom of the pockets)
- No plaque-retaining aberrations of gingival morphology
- No plaque-retaining parts of restorations in relation to the gingival margin.

These requirements lead to the following indications for periodontal surgery:

- Accessibility for proper root debridement
- Establishment of a morphology of the dentogingival area conducive to infection control
- Pocket depth reduction
- Correction of gross gingival aberrations
- Shift of the gingival margin to a position apical to plaque-retaining restorations
- Facilitation of proper restorative therapy.

Contraindications for periodontal surgery

Patient cooperation

Since optimal postoperative infection control is decisive for the success of periodontal treatment (Rosling *et al*. 1976a; Nyman *et al*. 1977; Axelsson & Lindhe 1981), a patient who fails to cooperate during the cause-related phase of therapy should not be exposed to surgical treatment. Even though short-term postoperative infection control entails frequent professional treatments, the long-term responsibility for maintaining good oral hygiene must rest with the patient. Theoretically, even the poorest oral hygiene performance by a patient may be compensated for by frequent recall visits for supportive therapy (e.g. once a week), but it is unrealistic to consider larger groups of patients being maintained in this manner. A typical recall schedule for periodontal patients involves professional consultations for supportive periodontal therapy once every 3–6 months. Patients who cannot maintain satisfactory oral hygiene standards over such a period should normally not be considered to be candidates for periodontal surgery.

Smoking

Although smoking negatively affects wound healing (Siana *et al*. 1989), it may not be considered a contraindication for surgical periodontal treatment. The clinician should be aware, however, that less resolution of probing pocket depth, smaller improvement in clinical attachment, and less bone regeneration might occur in smokers than in non-smokers (Labriola *et al*. 2005; Javed *et al*. 2012; Patel *et al*. 2012).

General health conditions

It is important to re-evaluate the patient's medical history before any surgical intervention to identify whether there is any medical condition that may preclude periodontal surgery or whether certain precautions should be taken, for example prescription of prophylactic antibiotics or the use of local anesthetics without epinephrine. Consultation with the patient's physician should also be considered.

Local anesthesia in periodontal surgery

Pain management is an ethical obligation and will improve patient satisfaction in general (e.g. increased confidence and improved cooperation) as well as recovery and short-term functioning after periodontal surgical procedures. In order to prevent pain during the performance of a periodontal surgical procedure,

the entire area of the dentition scheduled for surgery, the teeth as well as the periodontal tissues, requires proper local anesthesia.

Dental local anesthetics

Anesthetics from the chemical group amino amides, for example lidocaine, mepivacaine, prilocaine, and articaine, are more potent and significantly less allergenic than amino esters (e.g. procaine and tetracaine), and have therefore replaced esters as the "gold standard" for dental local anesthetics.

Due to the specific need for bone penetration, dental local anesthetics contain high concentrations of the active agent. Although most amide local anesthetics may cause local vasoconstriction in low concentrations, the clinically used concentrations in dental solutions will cause an increase in the local blood flow. A significant clinical effect of this induced vasodilatation is an increased rate of absorption, thus decreasing the duration of anesthesia. Major benefits can therefore be obtained by adding relatively high concentrations of vasoconstrictors (e.g. epinephrine >1 : 200 000 or >5 mg/mL) to dental local anesthetic solutions; the duration is considerably prolonged, the depth of anesthesia may be enhanced, and the peak concentrations of the local anesthetic in blood can be reduced. Furthermore, in periodontal surgery, incorporation of adrenergic vasoconstrictors into the local anesthetic is of considerable value to allow for only minimal bleeding during surgery (to better visualize the surgical site and to shorten the procedural time spent maintaining surgical quality). In fact, the use of a dental local anesthetic without a vasoconstrictor during a periodontal surgical procedure is counterproductive because the vasodilating properties of such a local anesthetic will increase bleeding in the area of surgery.

Vasoconstrictors and local hemostasis

Epinephrine is the vasoconstrictor of choice for local hemostasis and is most commonly used in a concentration of 1 : 80 000 (12.5 mg/mL). However, 1 : 100 000 epinephrine also provides excellent hemostasis and most periodontists are unable to detect a clinical difference between the two concentrations. It therefore seems prudent to use the least concentrated form of epinephrine that provides clinically effective hemostasis (i.e. the 1 : 100 000 concentration).

Although the cardiovascular effects of the usually small amounts of epinephrine used during a periodontal surgical procedure are of little practical concern in most individuals, accidental intravascular injections, unusual patient sensitivity, and unanticipated drug interactions (or excessive doses), can result in potentially serious outcomes. It must also be understood that the use of epinephrine for hemostasis during periodontal surgery has some potential drawbacks. Epinephrine will produce a rebound vasodilatation after the vasoconstriction has worn off, leading to increased risk for bleeding in the immediate postoperative period. There is a greater potential for such undesirable delayed hemorrhage following the use of 1 : 80 000 epinephrine than after the use of 1 : 100 000 epinephrine.

Postoperative pain may increase and wound healing may be delayed when adrenergic vasoconstrictors are used because of local ischemia with subsequent tissue acidosis and accumulation of inflammatory mediators. Furthermore, the possibility of an ischemic necrosis of surgical flaps infiltrated with an adrenergic vasoconstrictor (especially if norepinephrine is used instead of epinephrine) cannot be discounted. For these reasons, as well as the possibility of the systemic reactions eluded to above, dental local anesthetics containing adrenergic vasoconstrictors for hemostasis should be infiltrated *only* as needed and *not* according to habit.

Felypressin, another commonly used vasoconstrictor, appears to act preferentially on the venous side of the microcirculation and is not very active in constricting the arteriolar circulation. Felypressin is therefore not nearly as effective as adrenergic vasoconstrictors in limiting hemorrhage during a surgical procedure.

Techniques

Injections of dental local anesthetics prior to a periodontal surgical procedure may be routine for the dentist, but is often a most unpleasant experience for the patient. Reassurance and psychological support are essential and will increase the patient's confidence in his/her dentist. The creation of a relaxed atmosphere to decrease the patient's fear in an unusual situation is of course also a useful way of increasing the patient's own defense mechanisms against pain perception (e.g. release of endogenous endorphins).

Anesthesia for periodontal surgery is obtained by nerve block and/or by local infiltration. In cases of flap surgery, complete anesthesia must be attained before commencing the operation, as it may be difficult to supplement the anesthesia after the bone surface has been exposed. In addition, the pain elicited by needle insertion can be significantly reduced if the mucosa at the puncture site is anesthetized in advance by the use of a suitable topical ointment or spray.

Local infiltration may have a greatly decreased rate of success in areas where inflammation remains in the periodontal tissues, in spite of optimal conservative periodontal therapy and good oral hygiene. The suggested reason for this is that tissue pH tends to be low in inflamed areas and anesthetic solutions are less potent at low pH because there is a greater proportion of charged cation molecules than of the uncharged base molecules. Because of this, diffusion of the local anesthetic into the axoplasm is slower, with subsequent delayed onset and decreased efficacy. Another more recent hypothesis suggests that

nerve growth factor (NGF) released during tissue inflammation will induce sprouting or proliferation of sensory nerve endings expressing a different (sub) type of sodium channel than is expressed in normal tissues. Currently used dental local anesthetics may not be selective enough for proper interaction with these sodium channel subtypes to induce anticipated anesthesia.

Local anesthesia in the mandible

As a rule, analgesia of the teeth and the soft and hard tissues of the mandible should be obtained by a mandibular block and/or a mental block. In the anterior region of the mandible, canines and incisors can often be anesthetized by infiltration, but there are often anastomoses over the midline. These anastomoses must be anesthetized by bilateral infiltration or by bilateral mental blocks. The buccal soft tissues of the mandible are anesthetized by local infiltration or by blocking the buccal nerve. Local infiltration, performed as a series of injections in the buccal fold of the treatment area, has of course the added advantage of providing a local ischemic effect if a suitable anesthetic is used.

The lingual periodontal tissues must also be anesthetized. This is accomplished by blocking the lingual nerve and/or by infiltration into the floor of the mouth close to the site of operation. If necessary to obtain proper ischemia, and only then, supplementary injections may be made in the interdental papillae (intraseptal injections).

Local anesthesia in the maxilla

Local anesthesia of the teeth and buccal periodontal tissues of the maxilla can easily be obtained by injections into the mucogingival fold of the treatment area. If larger areas of the maxillary dentition are scheduled for surgery, repeated injections (into the mucogingival fold) have to be performed, for example at the central incisor, canine, second premolar, and second molar. In the posterior maxillary region, a tuberosity injection can be used to block the superior alveolar branches of the maxillary nerve. However, because of the vicinity to the pterygoid venous plexus, this type of block anesthesia is not recommended due to the risk of intravenous injection and/or hematoma formation.

The palatal nerves are most easily anesthetized by injections made at right angles to the mucosa and placed about 10 mm apical to the gingival margin adjacent to teeth included in the operation. In cases of advanced bone loss, the pain produced by injecting into the non-resilient palatal mucosa can be minimized if the injections are performed from the buccal aspect, that is through the interdental gingiva. Sometimes blocks of the nasopalatine nerves and/or the greater palatine nerves can be applied. Supplementary blocking of the greater palatine nerve should be considered, especially for periodontal surgery involving molars.

Instruments used in periodontal surgery

General considerations

Surgical procedures used in periodontal therapy often involve the following measures (instruments):

- Incision and excision (periodontal knives)
- Deflection and re-adaptation of mucosal flaps (periosteal elevators)
- Removal of adherent fibrous and granulomatous tissue (soft tissue rongeurs and tissue scissors)
- Scaling and root planing (scalers and curettes)
- Removal of bone tissue (bone rongeurs, chisels, and files)
- Root sectioning (burs)
- Suturing (sutures and needle holders, suture scissors)
- Application of wound dressing (plastic instruments).

The set of instruments used for the various periodontal surgical procedures should have a comparatively simple design. As a general rule, the number and varieties of instruments should be kept to a minimum. In addition to particular instruments used for periodontal treatment modalities, equipment and instruments used generally in oral surgery are often needed. Within each category of surgical instruments used for periodontal therapy there are usually several brands available, varying in form and quality, leaving ample room for individual preferences.

The instruments should be stored in sterile "ready-to-use" packs or trays. Handling, storing, and labeling of surgical instruments and equipment must be managed in such a way that interchange of sterile and non-sterile items is prevented.

It is also important that the instruments are kept in good working condition. The maintenance routine should ensure that scalers, curettes, knives with fixed blades, etc., are sharp and the hinges of scissors, rongeurs, and needle holders are properly lubricated. Spare instruments (sterile) should always be available to replace instruments found to be defective or accidentally contaminated.

Instrument tray

Different trays can be used for different procedures or a standard tray can be used for all procedures supplemented with the particular instruments that are needed for a specific procedure.

A commonly used standard tray combines the basic set of instruments used in oral surgery and a few periodontal instruments. The instruments listed below are often found on such a standard tray (Fig. 39-44):

- Mouth mirrors
- Graduated periodontal probe/explorer
- Handles for disposable surgical blades (e.g. Bard–Parker® handle)

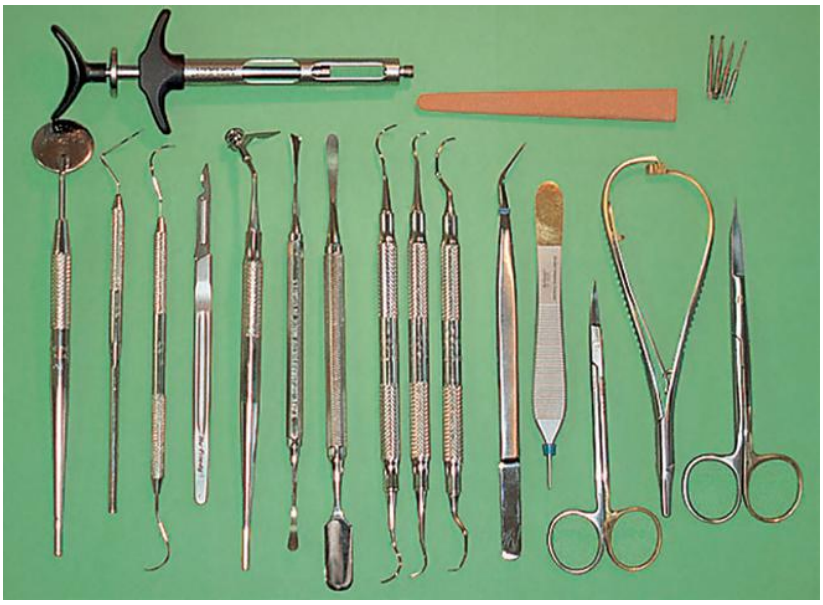

Fig. 39-44 Set of instruments used for periodontal surgery and included in a standard tray.

- Mucoperiosteal elevator and tissue retractor
- Scalers and curettes
- Cotton pliers
- Tissue pliers (*ad modum* Ewald)
- Tissue scissors
- Needle holder
- Suture scissors
- Plastic instrument
- Hemostat
- Burs.

Additional equipment may include:

- Syringe for local anesthesia
- Syringe for irrigation
- Aspirator tip
- Physiologic saline
- Drapings for the patient
- Surgical gloves, surgical mask, surgeon's hood.

Surgical instruments

Knives

Knives are available with fixed or replaceable blades. The advantage of the fixed blade versions is that the blade can be given any desired shape and orientation in relation to the handle. A disadvantage is that such instruments need frequent resharpening. Figure 39-45 shows examples of knives with fixed blades.

New disposable blades are always sharp. They can be rapidly replaced if found to be defective. The cutting edge of the blades normally follows the long axis of the handle, which limits their use. However, knives with disposable blades fitted at an angle to the handle are also available. Disposable blades are manufactured in different shapes (Fig. 39-46). When mounted in ordinary handles (Bard–Parker®), they are used to release incisions in flap operations and mucogingival surgery, and for reverse bevel incisions where access can be obtained. Special handles (Fig. 39-47) make it possible to mount blades in angulated positions, which facilitate the use of such knives for both gingivectomy excisions and reverse bevel incisions.

Fig. 39-45 Examples of gingivectomy knives with fixed blades. From left to right: Kirkland 15/16, Orban 1/2, and Waerhaug 1/2.

Scalers and curettes

Scaling and root planing in conjunction with periodontal surgery take place on exposed root surfaces. Access to the root surfaces for debridement may therefore be obtained with the use of comparatively sturdy

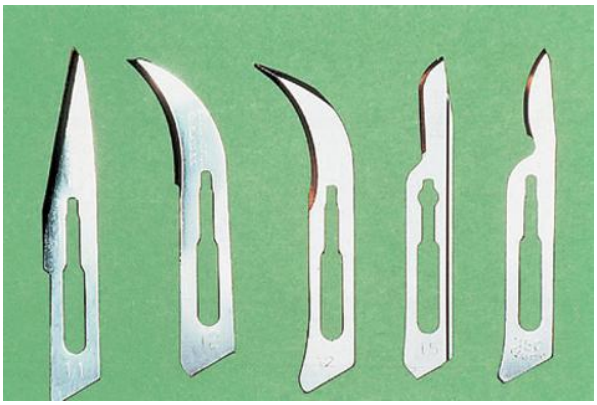

Fig. 39-46 Disposable blades which can be mounted in various types of handles. From left to right, blade shapes are: No. 11, No. 12, No. 12D, No. 15, and No. 15C.

Fig. 39-47 Universal 360° handle for disposable blades, which allows the mounting of the blade in any angulated position of choice.

instruments (Fig. 39-48). Rotating fine-grained diamond stones (Fig. 39-49) may be used within infrabony pockets, root concavities, and entrances to furcations. An ultrasonic device with sterile saline solution as coolant may also be used for root debridement during surgery. With the continuous irrigation of saline during the instrumentation of the roots, blood is rinsed away, offering improved visibility in the surgical field.

Instruments for bone removal

Sharp bone chisels or bone rongeurs (Fig. 39-50) cause the least tissue damage and should be employed whenever access permits. With reduced access,

Fig. 39-48 Examples of double-ended sickle scalers and curettes useful for root debridement in conjunction with periodontal surgery. From left to right: Curette SG 215/16C Syntette, Sickle 215-216 Syntette, and mini-curette SG 215/16MC.

Fig. 39-49 Set of burs useful in periodontal surgery. The rotating fine-grained diamond stones may be used for debridement of infrabony defects. The round burs are used for bone recontouring.

surgical burs or files may be used. The burs should operate at low speed and ample rinsing with sterile physiologic saline should ensure cooling and removal of tissue remnants.

Fig. 39-50 Examples of instruments used for bone recontouring. From left to right: Bone chisels Ochsenbein No. 1 and 2 (Kirkland 13K/13KL), Bone chisel Ochsenbein No. 3, and Schluger curved file No. 9/10.

Instruments for handling flaps

The proper healing of the periodontal wound is critical for the success of the operation. It is therefore important that the manipulations of soft tissue flaps are performed with the minimum of tissue damage. Care should be exercised in the use of periosteal elevators when flaps are deflected and retracted for optimal visibility. Surgical pliers and tissue retractors that pierce the tissues should not be used in the marginal area of the flaps. Needle holders with small beaks and atraumatic sutures should be used.

Additional equipment

Hemorrhage is rarely a problem in periodontal surgery. The characteristic oozing type of bleeding can normally be controlled with a pressure pack (sterile gauze moistened with saline). Bleeding from small vessels can be stopped by clamping and tying using a hemostat and resorbable sutures. If the vessel is surrounded by bone, bleeding may be stopped by crushing the nutrient canal in which the vessel runs with a blunt instrument.

Sterile physiologic saline is used for rinsing and moistening the field of operation and for cooling when burs are employed. The saline solution may be kept in a sterile metal cup on the instrument tray and may be applied to the wound by means of a sterile disposable plastic syringe and a needle with a blunt tip.

Visibility in the field of operation is secured by using effective suction. The lumen of the aspirator tip should have a smaller diameter than the rest of the tube, in order to prevent clogging.

The patient's head may be covered by autoclaved cotton drapings or sterile disposable plastic/paper drapings. The surgeon and all assistants should wear sterile surgical gloves, a surgical mask, and a surgeon's hood.

Selection of surgical technique

Many of the technical problems experienced in periodontal surgery stem from the difficulties in accurately assessing the degree and type of breakdown that has occurred prior to surgery. Furthermore, at the time of surgery, previously undiagnosed defects may be recognized or some defects may have a more complex outline than initially anticipated. Since each of the surgical procedures described above is designed to deal with a specific situation or to meet a certain objective, it must be understood that in most patients no single standardized technique alone can be applied when periodontal surgery is undertaken. Therefore, in each surgical field, different techniques are often used and combined in such a way that the overall objectives of the surgical part of the periodontal therapy are met. As a general rule, surgical modalities of therapy that preserve or induce the formation of periodontal tissue should be preferred over those that resect or eliminate tissue.

General indications for various surgical techniques

Gingivectomy

The obvious indication for gingivectomy is the presence of deep supra-alveolar pockets. In addition, the gingivectomy technique can be used to reshape abnormal gingival contours such as gingival craters and gingival hyperplasias (see Fig. 39-43). In such cases, the technique is often termed *gingivoplasty*.

Gingivectomy is usually not considered suitable in situations where the incision will lead to the removal of the entire zone of gingiva. This is the case when the bottom of the probeable pocket to be excised is located at or below the mucogingival junction. As an alternative in such a situation, an *internal beveled gingivectomy* may be performed (Fig. 39-51). Furthermore, since the gingivectomy procedure is aimed at the complete elimination of the periodontal pocket, the procedure cannot be used in periodontal sites where bony craters are present.

These limitations, combined with the development in recent years of surgical methods which have a broader field of application, have led to less frequent use of gingivectomy.

Flap operation with or without osseous surgery

Flap operations can be used in all cases where surgical treatment of periodontal disease is indicated. Flap procedures are particularly useful at sites where pockets extend beyond the mucogingival border and/or where treatment of bony defects and furcation involvements is required.

The advantages of flap operations include:

- Existing gingiva is preserved
- Marginal alveolar bone is exposed such that the morphology of bony defects can be identified and the proper treatment rendered

- Furcation areas are exposed, and the degree of involvement and the "tooth–bone" relationship can be identified
- Flap can be repositioned at its original level or shifted apically, thereby making it possible to adjust the gingival margin to the local conditions
- Flap procedure preserves the oral epithelium and often makes the use of a surgical dressing superfluous
- Postoperative period is usually less unpleasant to the patient when compared to gingivectomy.

Treatment decisions for soft and hard tissue pockets in flap surgery

Classifications of different flap modalities used in the treatment of periodontal disease often make distinctions between methods involving the marginal tissues and those involving the mucogingival area and, further, between tissue-eliminating/resective and tissue-preserving/reconstructive types (access flaps for debridement). Such classifications appear to be less than precise since several techniques are often combined in the treatment of individual cases, and since there is no clear-cut relationship between disease characteristics and selection of surgical methods. From a didactic point of view, it seems more appropriate to consider surgical therapy with regard to how to deal with (1) the soft tissue component and (2) the hard tissue component of the periodontal pocket at a specific tooth site (Fig. 39-52).

Soft tissue pockets

The description of the various flap procedures reveals that, depending on the surgical technique used, the soft tissue flap should either be apically positioned at the level of the bone crest (original Widman flap, Neumann flap, and apically repositioned flap) or maintained in a coronal position (Kirkland flap, modified Widman flap, and papilla preservation flap) at the completion of the surgical intervention. The maintenance of the presurgical soft tissue height is of importance from an esthetic point of view, particularly in the anterior tooth region. However, long-term results from clinical trials have shown that major differences in the final position of the soft tissue margin are not evident between surgical procedures involving coronal and apical positioning of the flap margin. The reported difference in final positioning of the gingival margin between surgical techniques is attributed to osseous recontouring (Townsend-Olsen *et al*. 1985; Lindhe *et al*. 1987; Kaldahl *et al*. 1996; Becker *et al*. 2001). In many patients it may be of significance to position the flap coronally in the anterior tooth region in order to give the patient a prolonged

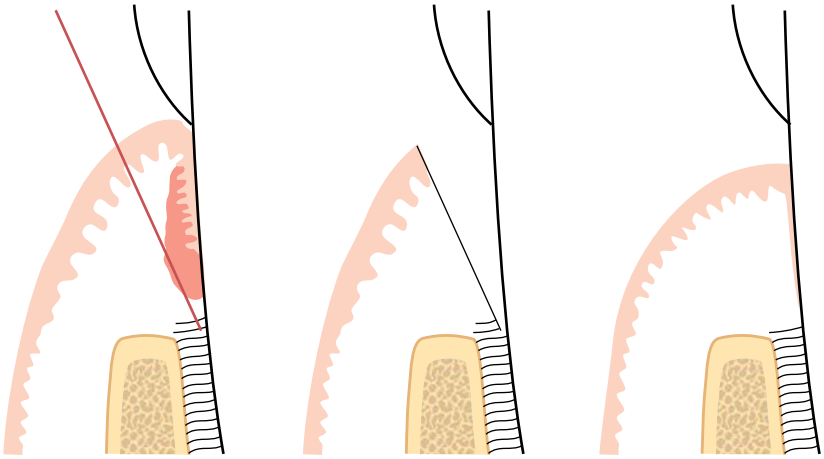

Fig. 39-51 Internal beveled gingivectomy. Schematic illustration of the incision technique in case of the presence of only a minimal zone of gingiva.

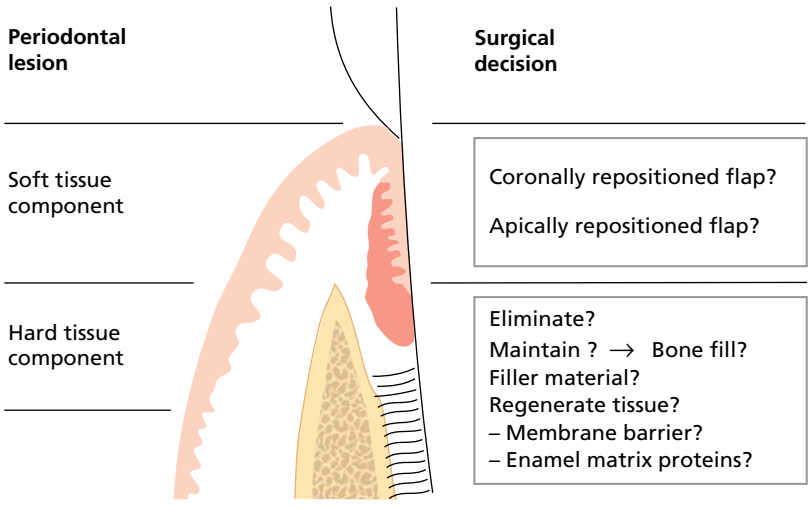

Fig. 39-52 Surgical decisions. Treatment decisions with respect to the soft and the hard tissue component of a periodontal pocket.

time of adaptation to the inevitable soft tissue recession. In the posterior tooth region, however, an apical position should be the standard.

Independent of flap position, the goal should be to achieve complete soft tissue coverage of the alveolar bone, not only at buccal/lingual sites but also at proximal sites. It is therefore of utmost importance to carefully plan the incisions in such a way that this goal is achieved at the termination of the surgical intervention.

Hard tissue pockets

During conventional periodontal surgery, one would usually opt for the conversion of an intrabony defect into a suprabony defect, which then is eliminated by apical repositioning of the soft tissue flap(s). Osseous recontouring of angular bony defects and craters is an excisional technique, which should be used with caution and discrimination. However, the therapist is often faced with the dilemma of deciding whether or not to eliminate an angular bony defect. There are a number of factors that should be considered in the treatment decision, such as:

- Esthetics
- Tooth/tooth site involved
- Defect morphology
- Amount of remaining periodontium.

Since alveolar bone supports the soft tissue, an altered bone level through recontouring will result in recession of the soft tissue margin. For esthetic reasons, one may therefore be restrictive in eliminating proximal bony defects in the anterior tooth region. For example, in the case of an approximal crater, it may often be sufficient to reduce/eliminate the bone wall on the lingual side of the crater, thereby maintaining the bone support for the soft tissue on the facial aspect (see Fig. 39-40). In favor of esthetics, one may even have to compromise the amount of bone removal and accept that a certain pocket depth will remain in certain situations. In addition to esthetics, the presence of furcations may limit the extent to which bone recontouring can be performed.

Defect morphology is a variable of significance for repair/regeneration during healing (Rosling *et al*. 1976a; Cortellini *et al*. 1993, 1995a). While two- and, especially, three-wall defects may show great potential for repair/regeneration, one-wall defects and interproximal craters will rarely result in such resolution. Further, the removal of intrabony connective tissue/granulation tissue during a surgical procedure will always lead to crestal resorption of bone, especially in sites with thin bony walls. This results in reduction of the vertical dimensions of the bone tissue at the site (Fig. 39-53).

The various treatment options available for the hard tissue defect may include:

- Eliminating the osseous defect by resection of bone (osteoplasty and/or ostectomy)
- Maintaining the area without osseous resection (hoping for some type of periodontal repair, e.g. bone fill leading to gain of clinical attachment)

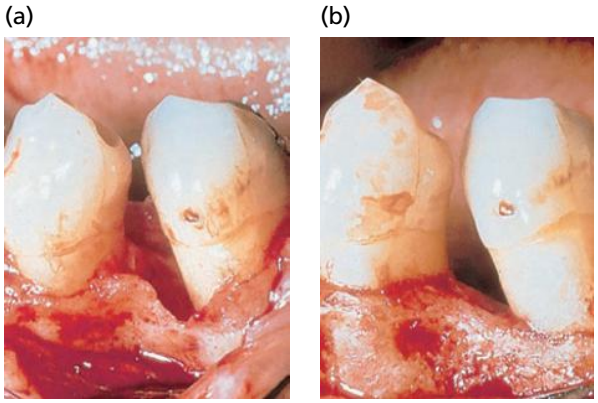

Fig. 39-53 Crestal bone resorption following a modified Widman flap procedure without bone recontouring. (a) View of the area at time of initial surgical treatment. (b) At the re-entry operation performed after 6 months of healing.

- Compromising the amount of bone removal and accepting that a certain pocket depth will remain
- Attempting to improve healing through the use of a regenerative procedure
- Extracting the involved tooth if the bony defect is considered too advanced.

After careful consideration, indications for osseous surgery in conjunction with apical repositioning of flaps may also include subgingival caries, perforations or root fractures in the coronal third of the root, as well as inadequate retention for fixed prosthetic restorations due to a short clinical crown (crown lengthening procedures). The "crown lengthening" needed in such cases is performed by removing often significant amounts of supporting bone and by recontouring. A dimension of approximately 3 mm between the alveolar bone crest and the anticipated restoration margin must be ensured (Brägger *et al*. 1992; Herrero *et al*. 1995; Pontoriero & Carnevale 2001).

Root surface instrumentation

Before incisions are made to excise or elevate the soft tissue, a careful examination should be carried out to identify at which tooth sites periodontal lesions remain. Only tooth sites with signs of pathology (bleeding following pocket probing) should be subjected to root instrumentation following surgical exposure. Before root instrumentation is executed, remaining granulation tissue must be removed and indicated bone recontouring carried out.

The root instrumentation can be performed with hand or ultrasonic instruments according to the operator's preferences. Ultrasonic (sonic) instrumentation offers the additional benefits of improved visibility due to the irrigating effect of the cooling solution (sterile saline). For root instrumentation within intrabony defects, root concavities, and entrances to furcations, the use of rotating fine-grained diamond stones may be used.

Root surface conditioning/biomodification

An important consideration in periodontal surgery is to make the exposed root surface biologically compatible with a healthy periodontium. In addition to mechanical debridement, agents such as citric acid/orthophosphoric acid, tetracycline, and EDTA have been used for root surface conditioning. Root surface conditioning/biomodification by means of an etching procedure may serve several purposes:

- Removal of the smear layer following mechanical debridement
- Demineralization of the root surface (citric acid)
- Selective removal of hydroxyapatite and exposure of the collagenous matrix of the root surface (EDTA)
- Local delivery of antimicrobial compound (tetracycline HCl)
- Inhibition of collagenolytic activity (tetracycline HCl)
- Enhancing cellular responses
- Prevention of epithelial down-growth
- Improving retention of different biomolecules to exposed collagen
- Expression of a cementoblast phenotype for colonizing cells.

It should be noted that etching of a root surface with an agent operating at a low pH (e.g. citric acid or orthophosphoric acid) might exert immediate necrotizing effects on the surrounding periodontal ligament and other periodontal tissues, whereas agents operating at a neutral pH (e.g. EDTA) do not seem to have this negative effect (Blomlöf & Lindskog 1995a, b).

Although *in vitro* results have indicated possible benefits of the use of root surface conditioning/biomodification agents through enhanced cellular responses during wound healing, the usefulness of acids as well as other chemical agents for conditioning of root surfaces in conjunction with conventional periodontal surgery has been questioned (Blomlöf *et al*. 2000). Histologic evidence indicates that healing following root surface conditioning with acids or other chemical agents occurs predominately by a long junctional epithelium or connective tissue attachment without new cementum formation.

Suturing

When a flap procedure has been employed it is important to ensure that, at the end of surgery, the flaps are placed in the intended position and that they are properly adapted to each other and to the tooth surfaces. Preferably, full coverage of the buccal/lingual (palatal) and interdental alveolar bone should be obtained by full (primary) closure of the soft tissue flaps. If this can be achieved, healing is by first intention and postoperative bone resorption is minimal. Therefore, prior to suturing, the flap margins should be trimmed to properly fit the buccal and lingual (palatal) bone margin as well as the interproximal areas; excessive soft tissue must be removed. If the amount of flap tissue present is insufficient to cover the interproximal bone, the flaps at the buccal or lingual aspects of the teeth must be recontoured and, in some cases, even displaced coronally.

Following proper trimming, the flaps are secured in the correct position by sutures. Sutures should not interfere with incision lines and must not pass through the tissues near the flap margins or too close to a papilla, because this may result in tearing of the tissues. The use of non-irritating, mono-filamentous materials is recommended. These materials are non-resorbable and extremely inert, do not adhere to tissues, and are therefore easy to remove. "Wicking", the phenomenon of bacteria moving along or within multistranded suture materials, particularly silk, is also avoided. The dimensions usually preferred are 4/0 or 5/0, but even finer suture material (6/0 or 7/0) may be used. Sutures are removed after 7–14 days.

Since the flap tissue following the final preparation is thin, either curved or straight non-traumatic needles (eyeless), with a small diameter, should be used. Such needles are available as rounded (non-cutting) or with different cutting edges. In the latter case, a reverse-cutting needle should be selected.

Technique

The three most frequently used sutures in periodontal flap surgery are:

- Interrupted interdental sutures
- Suspensory sutures
- Continuous sutures.

The *interrupted interdental suture* (Fig. 39-54) provides a close interdental adaptation between the buccal and lingual flaps with equal tension on both units. This type of suture is therefore not recommended when the buccal and lingual flaps are repositioned at different levels. When this technique of suturing is employed, the needle is passed through the buccal flap from the external surface, across the interdental area, and through the lingual flap from the internal surface, or vice versa. When closing the suture, care must be taken to avoid tearing the flap tissues.

In order to avoid having the suture material between the mucosa and the alveolar bone in the interdental area, an alternative technique with the interrupted interdental suture can be used if the flaps have not been elevated beyond the mucogingival line (Fig. 39-55). With the use of a curved needle, the suture is anchored in the attached tissue on the buccal aspect of the proximal site, brought to the lingual side through the proximal sites, and anchored in the attached tissue on the lingual side. The suture is then brought back to the starting point and tied (Fig. 39-55b). Hence, the suture will lie on the surface of the interdental tissue, keeping the soft tissue flaps in close contact with the underlying bone.

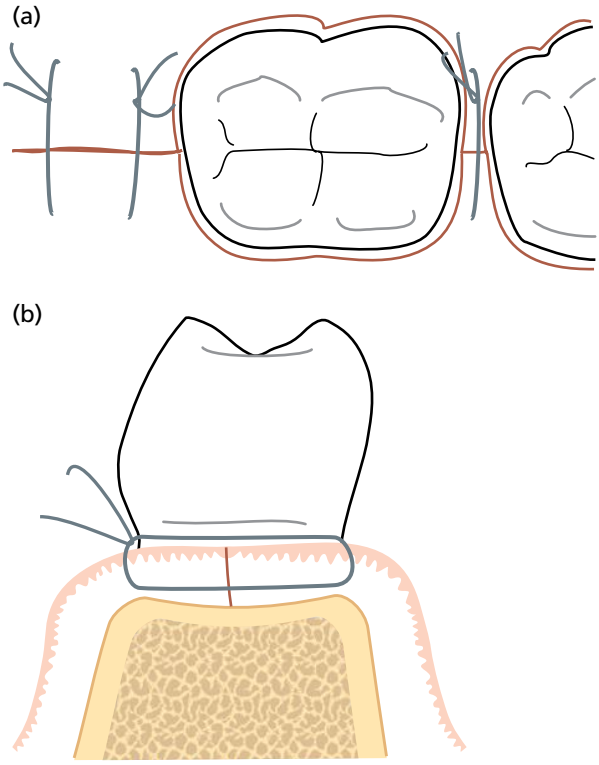

Fig. 39-54 Suturing. (a, b) Interrupted interdental suture.

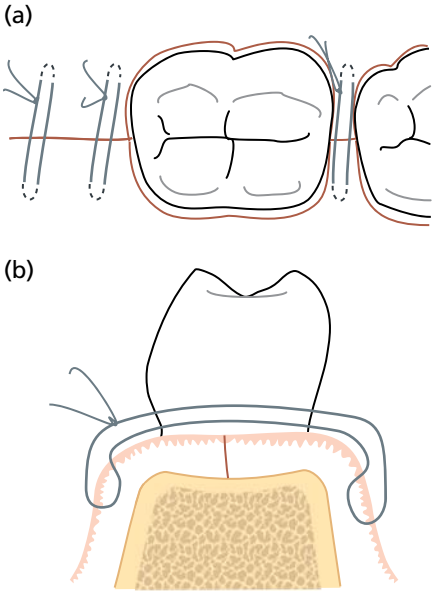

Fig. 39-55 Suturing. (a, b) Modified interrupted interdental suture. Note that with this suturing technique the suture lies on the surface of the interdental tissue keeping the soft tissue flaps in close contact with the underlying bone.

In regenerative procedures, which usually require a coronal advancement of the flap, a *modified mattress suture* may be used as an interdental suture to secure close flap adaptation (Fig. 39-56). As for the interupted suture, the needle is passed through the buccal flap from the external surface, across the interdental area, and through the lingual flap from the internal surface. The suture is then run back to the buccal side by passing the needle through the lingual and buccal flaps. Thereafter, the suture is brought through the approximal site coronally to the tissue, passed through the loop of the suture on the lingual aspect, and then brought back to the starting point on the buccal side and tied.

The *suspensory suture* (Fig. 39-57) is used primarily when the surgical procedure is of limited extent and involves only the tissue of the buccal or lingual aspect of the teeth. It is also the suture of choice when the buccal and lingual flaps are repositioned at different levels. The needle is passed through the buccal flap from its external surface at the mesial side of the tooth, the suture is placed around the lingual surface of the tooth, and the needle is passed through the buccal flap on the distal side of the tooth (Fig. 39-57a). The suture is brought back to the starting point via the lingual surface of the tooth and tied (Fig. 39-57b, c). If a lingual flap has been elevated as well, this is secured in the intended position using the same technique.

The *continuous suture* (Fig. 39-58) is commonly used when flaps involving several teeth are to be repositioned apically. When flaps have been elevated on both sides of the teeth, one flap at a time is secured in its correct position. The suturing procedure is started at the mesial/distal aspect of the buccal flap by passing the needle through the flap and across the interdental area. The suture is laid around the lingual surface of the tooth and returned to the buccal side through the next interdental space. The procedure is repeated tooth by tooth until the distal/mesial end of the flap is reached. Thereafter, the needle is passed through the lingual flap (Fig. 39-58a), with the suture laid around the buccal aspect of each tooth and through each interproximal space. When the suturing of the lingual flap is completed and the needle has been brought back to the first interdental area, the positions of the flaps are adjusted and secured in their proper positions by closing the suture (Fig. 39-58b). Thus, only one knot is needed.

Periodontal dressings

Periodontal dressings are mainly used:

- To protect the wound post-surgically
- To obtain and maintain a close adaptation of the mucosal flaps to the underlying bone (especially when a flap has been repositioned apically)
- For the comfort of the patient.

In addition, periodontal dressings can prevent postoperative bleeding during the initial phase of healing and, if properly placed in the operated segment (especially interproximally), prevent the formation of excessive granulation tissue.

Periodontal dressings should have the following properties:

- Soft, but with enough plasticity and flexibility to facilitate placement in the operated area and to allow proper adaptation

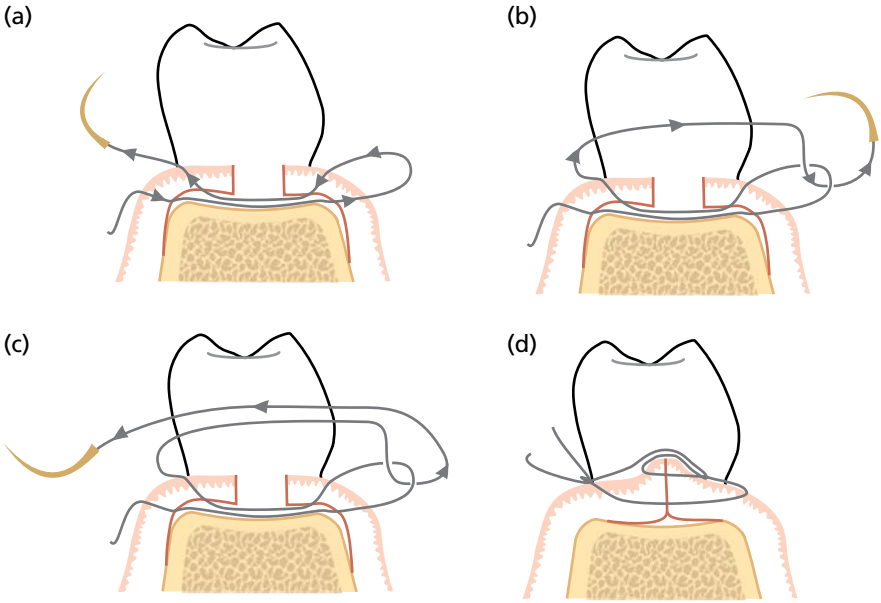

Fig. 39-56 Suturing. (a–d) Modified mattress suture.

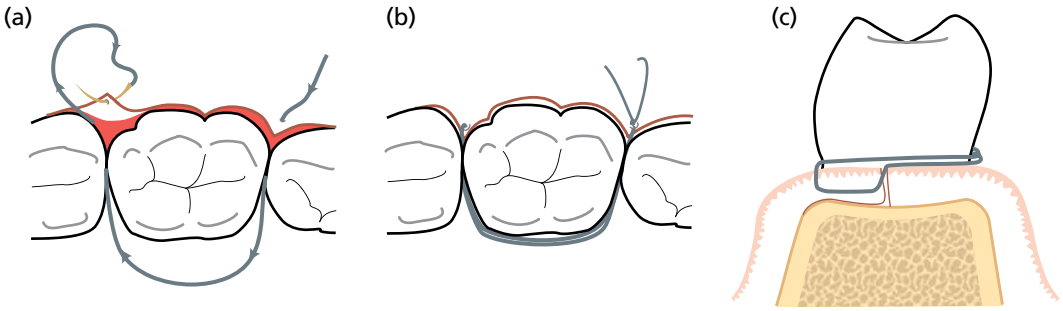

Fig. 39-57 Suturing. (a–c) Suspensory suture.

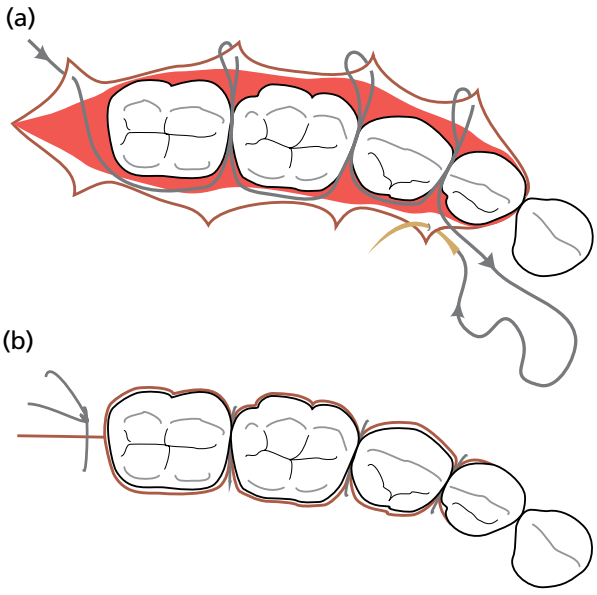

Fig. 39-58 Suturing. (a, b) Continuous suture.

- Hardens within a reasonable time
- After setting, sufficiently rigid to prevent fracture and dislocation
- Smooth surface after setting to prevent irritation of the cheeks and lips
- Preferably, bacteriocidal properties to prevent excessive plaque formation
- Must not detrimentally interfere with healing.

It has been suggested that antibacterial agents should be incorporated into periodontal dressings to prevent bacterial growth in the wound area during healing. Results from clinical studies and *in vitro* evaluation of the antibacterial properties of various periodontal dressings, however, suggest that the antibacterial activity of most commercial dressings probably is exhausted long before the end of the 7–14-day period during which the dressing is frequently maintained in the operated segment (O'Neil 1975; Haugen *et al*. 1977).

Mouth rinsing with antibacterial agents such as chlorhexidine does not prevent the formation of plaque *under* the dressing (Plüss *et al*. 1975) and should therefore not be regarded as a means to improve or shorten the period of wound healing. On the other hand, results from clinical studies as well as clinical experience suggest that a periodontal dressing may often be unnecessary or even undesirable after periodontal flap procedures and may be usefully replaced by rinsing with chlorhexidine only (Sanz *et al*. 1989; Vaughan & Garnick 1989).

A commonly used periodontal dressing is Coe-Pak™ (GC America Inc., Alsip, IL, USA), which is

supplied in two tubes. One tube contains oxides of various metals (mainly zinc oxide) and lorothidol (a fungicide). The second tube contains non-ionizing carboxylic acids and chlorothymol (a bacteriostatic agent). Equal parts from both tubes are mixed together immediately prior to insertion. Adding a retarder can prolong the setting time of the dressing.

A light-cured dressing, for example Barricaid™ (Dentsply Caulk., Milford, DE, USA), is useful in the anterior tooth region and particularly following mucogingival surgery, because it has a favorable esthetic appearance and it can be applied without dislocating the soft tissue. However, the light-cured dressing is not the dressing of choice for situations where the flap has to be retained apically, due to its soft state before curing.

Cyanoacrylates have also been used as periodontal dressings with varying success. These dressings are applied in a liquid directly on to the wound, or sprayed over the wound surface. Although the application of this kind of dressing is simple, its properties often do not meet clinical demands.

Application technique

1. Ensure that bleeding from the operated tissues has ceased before the dressing material is inserted.
2. Carefully dry the teeth and soft tissue before application for optimal adherence of the dressing.
3. Moisten the surgical gloves to avoid the material sticking to the fingertips.
4. When using the Coe-Pak™ dressing material, the interproximal areas are filled first. Thin rolls of the dressing, adjusted in length to cover the entire field of operation, are then placed against the buccal and lingual surfaces of the teeth. The rolls are pressed against the tooth surfaces and the dressing material is forced into the interproximal areas. Coe-Pak™ may also be applied to the wound surfaces by means of a plastic syringe. It is important to ensure that dressing material is never introduced between the flap and the underlying bone or root surface.

   The light-cured dressing (Barricaid™) is preferably applied with the supplied syringe, adjusted, and then cured by light.
5. The surface of the dressing is subsequently smoothened and excess material is removed with a suitable instrument (a knife or finishing burs in a low-speed handpiece). The dressing should not cover more than the apical third of the tooth surfaces. Furthermore, interference of the dressing with mucogingival structures (e.g. vestibular fold, frenula) should be carefully checked to avoid displacement of the dressing during normal function.

Postoperative pain control

In order to minimize postoperative pain and discomfort for the patient, surgical handling of the tissues should be as atraumatic as possible. Care should be taken during surgery to avoid unnecessary tearing of the flaps, to keep the bone moistened, and to secure complete soft tissue coverage of the alveolar bone at suturing. With a carefully performed surgical procedure, most patients will normally experience only minimal postoperative problems. The pain experience is usually limited to the first days following surgery and of a level that in most patients can be adequately controlled with normally used drugs for pain control. However, it is important to recognize that the pain threshold level is subjective and may vary between individuals. It is also important to give the patient information about the post-surgical sequence and that uncomplicated healing is the common event. Further, during the early phase of healing, the patient should be instructed to avoid chewing in the area subjected to surgical treatment.

Post-surgical care

Postoperative plaque control is the most important variable in determining the long-term result of periodontal surgery. Provided proper postoperative infection control levels are established, most surgical treatment techniques will result in conditions that favor the maintenance of a healthy periodontium. Although there are other factors of a more general nature affecting surgical outcome (e.g. the systemic status of the patient at the time of surgery and during healing), disease recurrence is an inevitable complication, regardless of surgical technique used, in patients not given proper post-surgical and maintenance care.

Since self-performed oral hygiene is often associated with pain and discomfort during the immediate post-surgical phase, regularly performed professional tooth cleaning is a more effective means of mechanical infection control following periodontal surgery. In the immediate post-surgical period, self-performed rinsing with a suitable antiplaque agent, for example twice daily rinsing with 0.1–0.2% chlorhexidine solution, is recommended. Although an obvious disadvantage with the use of chlorhexidine is the staining of the teeth and tongue, this is usually not a deterrent for compliance. Nevertheless, it is important to return to and maintain good mechanical oral hygiene measures as soon as possible, particularly since rinsing with chlorhexidine, in contrast to properly performed mechanical oral hygiene, is unlikely to have any influence on subgingival recolonization of plaque.

Maintaining good post-surgical wound stability is another important factor affecting the outcome of some types of periodontal flap surgery. If wound stability is judged an important part of a specific procedure, the procedure itself as well as the post-surgical care must include measures to stabilize the healing wound (e.g. adequate suturing technique, protection from mechanical trauma to the marginal tissues during the initial healing phase). If a mucoperiosteal flap is replaced rather than repositioned apically, early apical migration of gingival epithelial cells will occur as a consequence of a break between root surface and healing connective tissue. Hence, maintenance of a tight adaptation of the flap to the root surface is essential and one may therefore consider keeping the

sutures in place for longer than the 7–10 days usually prescribed following standard flap surgery.

Following suture removal, the surgically treated area is thoroughly irrigated with a dental spray and the teeth are carefully cleaned with a rubber cup and polishing paste. If the healing is satisfactory for starting mechanical tooth cleaning, the patient is instructed in gentle brushing of the operated area using a toothbrush that has been softened in hot water. Toothpicks are prescribed for cleaning the interdental area. In this early phase following surgical treatment, the use of interdental brushes is abandoned due to the risk of traumatizing the interdental tissues. Visits are scheduled for supportive care at 2-week intervals to monitor the patient's plaque control closely. During this postoperative maintenance phase, adjustments to the methods for optimal self-performed mechanical cleaning are made depending on the healing status of the tissues. The time interval between visits for supportive care may gradually be increased, depending on the patient's plaque control standard.

Outcome of surgical periodontal therapy

Healing following surgical pocket therapy

Gingivectomy

Within a few days following excision of the inflamed gingival soft tissues coronal to the base of the periodontal pocket, epithelial cells start to migrate over the wound surface. The epithelialization of the gingivectomy wound is usually complete within 7–14 days following surgery (Engler *et al*. 1966; Stahl *et al*. 1968). During the following weeks, a new dentogingival unit is formed (Fig. 39-59). The fibroblasts in the supraalveolar tissue adjacent to the tooth surface proliferate (Waerhaug 1955) and new connective tissue is laid down. If the wound healing occurs in the vicinity of a plaque-free tooth surface, a free gingival unit will form which has all the characteristics of a normal free gingiva (Hamp *et al*. 1975). The height of the newly formed free gingival unit may vary not only between different parts of the dentition, but also from one tooth surface to another due primarily to anatomic factors.

The re-establishment of a new, free gingival unit by coronal regrowth of tissue from the line of the "gingivectomy" incision implies that sites with so-called "zero pockets" only occasionally occur following gingivectomy. Complete healing of the gingivectomy wound takes 4–5 weeks, although from clinical inspection of the surface of the gingiva, it may appear to be healed after approximately 14 days (Ramfjord *et al*. 1966). Minor remodeling of the alveolar bone crest may also occur postoperatively.

Apically repositioned flap

Following osseous surgery for elimination of bony defects and the establishment of "physiologic contours" and repositioning of the soft tissue flaps to the level of the alveolar bone, healing will occur primarily by first intention, especially in areas where proper soft tissue coverage of the alveolar bone has been obtained. During the initial phase of healing, bone resorption of varying degrees almost always occurs in the crestal area of the alveolar bone (Fig. 39-60) (Ramfjord & Costich 1968). The extent of the reduction of the alveolar bone height resulting from this resorption is related to the thickness of the bone in each specific site (Wood *et al*. 1972; Karring *et al*. 1975).

During the phase of tissue regeneration and maturation, a new dentogingival unit will form by coronal growth of the connective tissue. This regrowth occurs in a manner similar to that which characterizes healing following gingivectomy.

Modified Widman flap

If a "modified Widman flap" procedure is carried out in an area with a deep infrabony lesion, bone repair may occur within the boundaries of the lesion (Rosling *et al*. 1976a; Polson & Heijl 1978). However, crestal bone resorption is also seen. The amount of bone fill

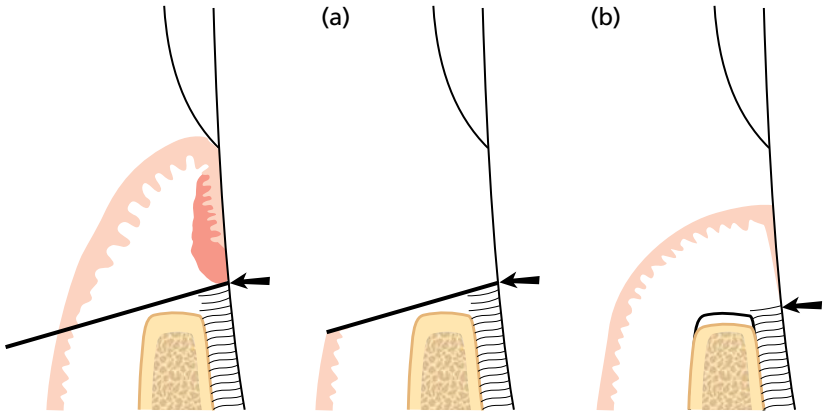

Fig. 39-59 Gingivectomy. Dimensional changes as a result of therapy. (a) Preoperative dimensions and position of the incision line. Black line indicates the location of the primary incision, that is the suprabony pocket is eliminated with the gingivectomy technique; before and after excision of the soft tissue corresponding to the depth of the periodontal pocket. (b) Dimensions following proper healing. Minor resorption of the alveolar bone crest as well as some loss of connective tissue attachment may occur during the healing. The arrows indicate the coronal position of the connective tissue attachment to the root.

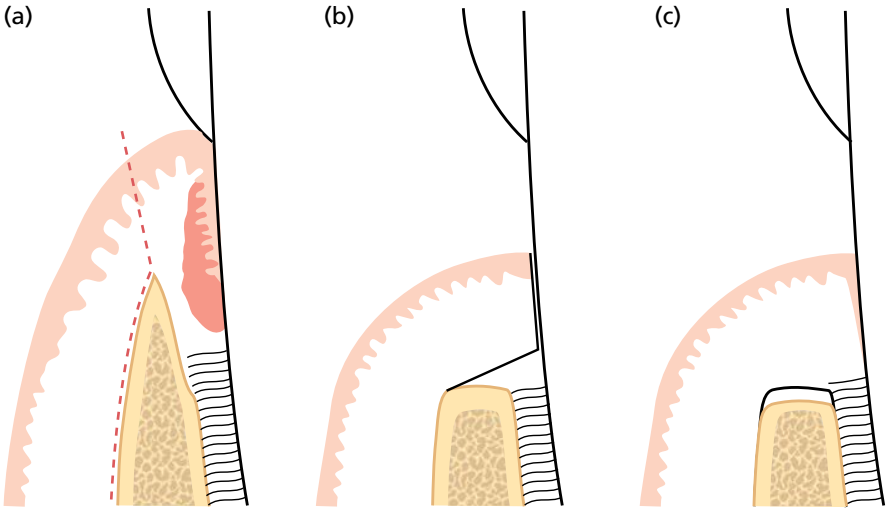

Fig. 39-60 Apically repositioned flap. Dimensional changes. (a) Preoperative dimensions. The dashed line indicates the border of the elevated mucoperiosteal flap. (b) Bone recontouring has been completed and the flap repositioned to cover the alveolar bone. (c) Dimensions following healing. Minor resorption of the marginal alveolar bone has occurred as well as some loss of connective tissue attachment.

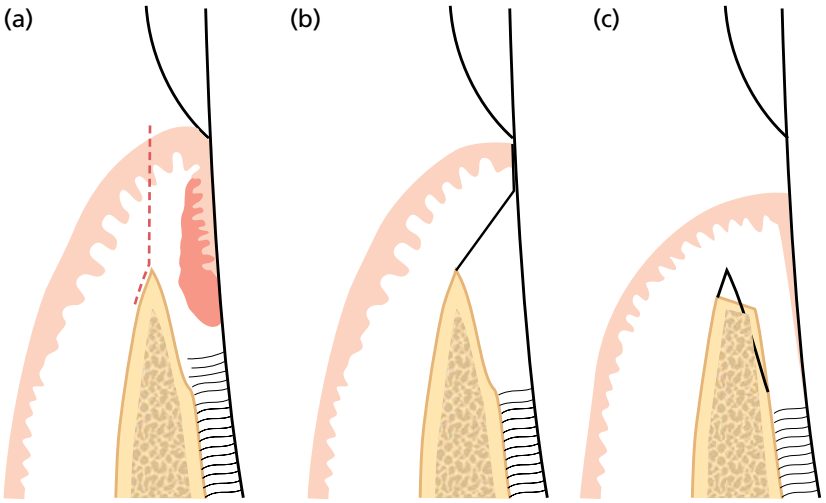

Fig. 39-61 Modified Widman flap. Dimensional changes. (a) Preoperative dimensions. The dashed line indicates the border of the elevated mucoperiosteal flap. (b) Surgery (including curettage of the angular bone defect) is completed with the mucoperiosteal flap repositioned as close as possible to its presurgical position. (c) Dimensions following healing. Osseous repair as well as some crestal bone resorption can be expected during healing with the establishment of a "long" junctional epithelium interposed between the regenerated bone tissue and the root surface. Apical displacement of the soft tissue margin has occurred.

obtained is dependent upon (1) the anatomy of the osseous defect (e.g. a three-walled infrabony defect often provides a better mold for bone repair than two- or one-walled defects), (2) the amount of crestal bone resorption, and (3) the extent of chronic inflammation, which may occupy the area of healing. Interposed between the regenerated bone tissue and the root surface, a long junctional epithelium is always found (Fig. 39-61) (Caton & Zander 1976; Caton *et al*. 1980). The apical cells of the newly formed junctional epithelium are found at a level on the root that closely coincides with the presurgical attachment level.

Soft tissue recession will take place during the healing phase following a modified Widman flap procedure. Although the major apical shift in the position of the soft tissue margin will occur during the first 6 months following the surgical treatment (Lindhe *et al*. 1987), the soft tissue recession may often continue for >1 year. Factors influencing the degree of soft tissue recession as well as the time period for soft tissue remodeling include the initial height and thickness of the supracrestal flap tissue and the amount of crestal bone resorption.

Clinical outcome of surgical access therapy in comparison to non-surgical therapy

Surgical treatment of periodontal lesions mainly serves the purpose of (1) creating accessibility for proper professional debridement of the infected root surfaces and (2) establishing a gingival morphology that facilitates the patient's self-performed infection control, in order to enhance the long-term preservation of the dentition. Hence, the amount of tooth loss is the most relevant

criterion in an evaluation of the relative importance of surgical access therapy in the overall treatment of periodontal disease. However, this requires studies with extremely long follow-up periods and, therefore, other criteria are commonly used to evaluate the efficacy of periodontal therapy, even if these may only be considered as surrogate end points. The most commonly used outcome criteria in clinical research have been resolution of gingivitis (bleeding on probing), probing pocket depth reduction, and clinical attachment level change. An additional variable often of concern is gingival recession, since this outcome variable may affect the patient's overall appreciation of the treatment result. With regard to changes in probing attachment levels, it should be recalled that healing following conventional surgical access therapy consistently results in the formation of a junctional epithelium to a level on the root that closely coincides with the presurgical attachment level. Hence, when evaluating the outcome of various therapeutic approaches, the magnitude of *gain* of clinical attachment may be of less importance since it mainly is a measure of "pocket closure". Instead, maintained probing attachment levels or further loss should be focused on as the pertinent outcome variable.

Pioneering contributions to the understanding of the relative importance of the surgical component of periodontal therapy were generated by the classical longitudinal studies of the Michigan group (Ramfjord and co-workers) and the Gothenburg group (Lindhe and co-workers). Subsequently, several other clinical research centers contributed important data regarding the efficacy of surgical access therapy in comparison to non-surgical periodontal therapy. The topic has been extensively reviewed (e.g. Kaldahl *et al*. 1993; Palcanis 1996; Heitz-Mayfield *et al*. 2002) and some of the general conclusions from these reviews will be highlighted below.

Plaque accumulation

An important factor to consider in the evaluation of the relative effect of the surgical component of periodontal therapy is the standard of postoperative infection control. Nyman *et al*. (1977) reported on a clinical study in which the patients received only a single episode of oral hygiene instruction before the surgical treatment and no specific postoperative supportive care. As a consequence, both plaque and gingival indices remained relatively high during the 2 years of postoperative follow-up. Independent of the surgical technique used, the patients showed a rebound of pocket depths to more or less pretreatment levels and further deterioration of clinical attachment levels at both proximal and lingual tooth sites (Fig. 39-62). In contrast, in a parallel study in which the patients received repeated oral hygiene instructions and professional tooth cleaning once every 2 weeks during the postoperative period (Rosling *et al*. 1976b), the patients maintained the surgically reduced pocket depth throughout the 2-year follow-up period and clinical attachment level gains were observed for most of the surgical procedures evaluated (Fig. 39-63). The fact that the standard of postoperative oral hygiene is decisive for the outcome of surgical pocket therapy is further underlined by data from a 5-year

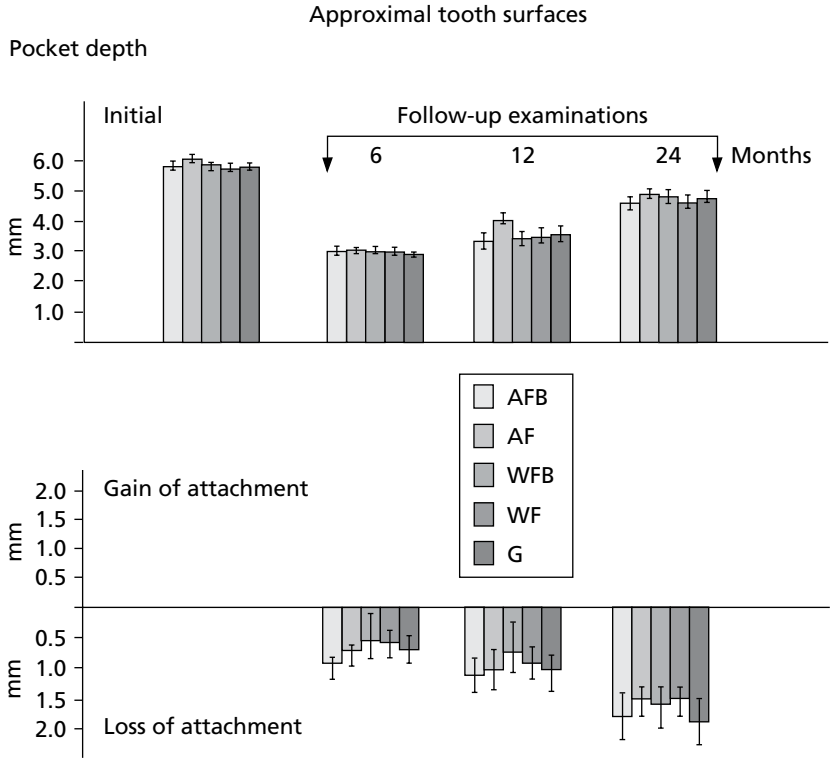

Fig. 39-62 Average approximal pocket depth at the initial examination and 6, 12, and 24 months after surgery (top), and alterations in approximal attachment levels from the initial examination immediately prior to surgery to the re-examinations 6, 12, and 24 months postoperatively (bottom). Note that only areas with pockets that at the initial examination had a depth of 3 mm or more are included in the analysis. (AFB, apically repositioned flap with bone recontouring; AF, apically repositioned flap; WFB, modified Widman flap with bone recontouring; WF, modified Widman flap; G, gingivectomy including curettage of bone defects. Bars show standard error.) (Data from Nyman *et al*. 1977.)

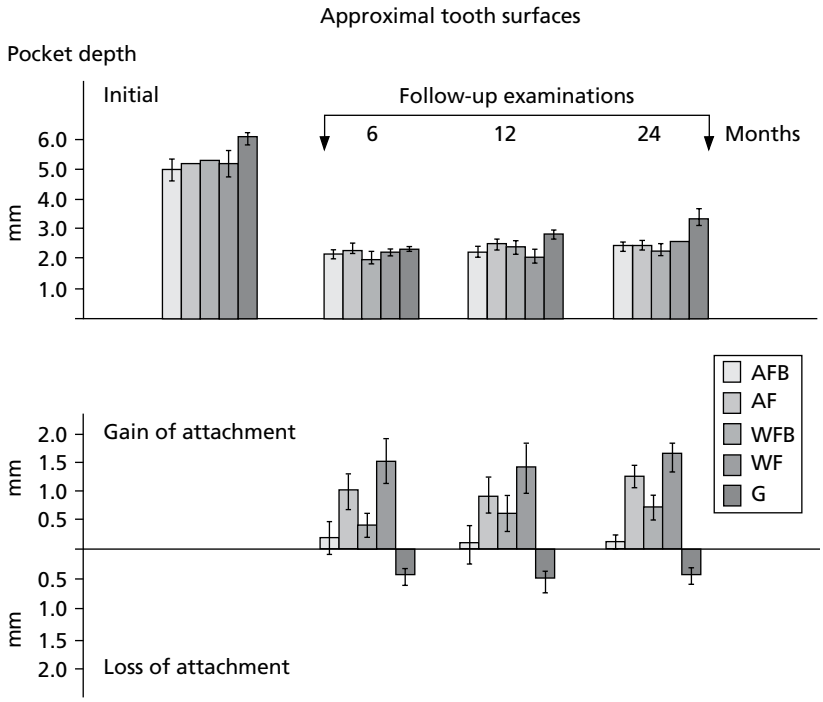

Fig. 39-63 Average approximal pocket depth at the initial examination and 6, 12, and 24 months after surgery (top), and alterations in approximal attachment levels from the initial examination immediately prior to surgery to the re-examinations 6, 12, and 24 months postoperatively (bottom). Note that only areas with pockets that at the initial examination had a depth of 3 mm or more are included in the analysis. longitudinal study by Lindhe *et al*. (1984), which showed that patients with a high standard of infection control maintained clinical attachment levels and probing depth reductions following treatment more consistently than patients with poor plaque control. On the other hand, professional tooth cleaning, including subgingival scaling every 3 months, may partly compensate for the negative effects of variations in self-performed plaque control (Ramfjord *et al*. 1982; Isidor & Karring 1986).

With regard to post-treatment plaque accumulation, there is no evidence to suggest that differences exist between non-surgical or surgical treatment or between various surgical procedures. In addition, most studies have shown that the magnitude of gingivitis resolution is not influenced by the treatment modality.

Probing pocket depth reduction

All surgical procedures result in a decrease in probing pocket depths with greater reduction occurring at the initially deeper sites (Knowles *et al*. 1979; Lindhe *et al*. 1984; Ramfjord *et al*. 1987; Kaldahl *et al*. 1996; Becker *et al*. 2001). Furthermore, surgical therapy generally creates greater short-term reduction of probing depth than non-surgically performed scaling and root planing. Flap surgery with bone recontouring (pocket elimination surgery) usually results in the most pronounced short-term pocket reduction. Long-term (5–8 years) results show various outcomes. Some studies reported greater probing depth reduction following surgery while others reported no differences in relation to non-surgical therapy. Also, the magnitude of the initial probing depth reduction shows a tendency to decrease with time, independent of treatment modality.

Clinical attachment level change

In sites with shallow initial probing depth, both short- and long-term data demonstrate that surgery creates a greater loss of clinical attachment than non-surgical treatment, whereas in sites with initially deep pockets (≥7 mm), a greater gain of clinical attachment is generally obtained (Knowles *et al*. 1979; Lindhe *et al*. 1984; Ramfjord *et al*. 1987; Kaldahl *et al*. 1996; Becker *et al*. 2001) (Fig. 39-64). When clinical attachment levels following surgery with and without osseous resection were compared, either no difference was found between therapies, or flap surgery without osseous resection produced a greater gain. In addition, there was no difference in the longitudinal maintenance of clinical attachment levels between sites treated non-surgically and those treated surgically, with or without osseous resection.

Based on data generated from a clinical trial comparing non-surgical and surgical (modified Widman flap) approaches to root debridement, Lindhe *et al*. (1982b) developed the concept of *critical probing depth* (CPD) in relation to clinical attachment level change. For each treatment approach, the clinical attachment change was plotted against the initial pocket depth and regression lines were calculated (Fig. 39-65). The point where the regression line crossed the horizontal axis (initial probing depth) was defined as the CPD, that is the level of pocket depth below which clinical attachment loss would occur as the result of the treatment procedure performed. The CPD was consistently found to be greater for the surgical approach than for the non-surgical treatment. Furthermore, at incisors and premolars, the surgical therapy showed superior outcome only when the initial probing depth was >6–7 mm, while at molars the corresponding cut-off point was 4.5 mm. The interpretation of the latter

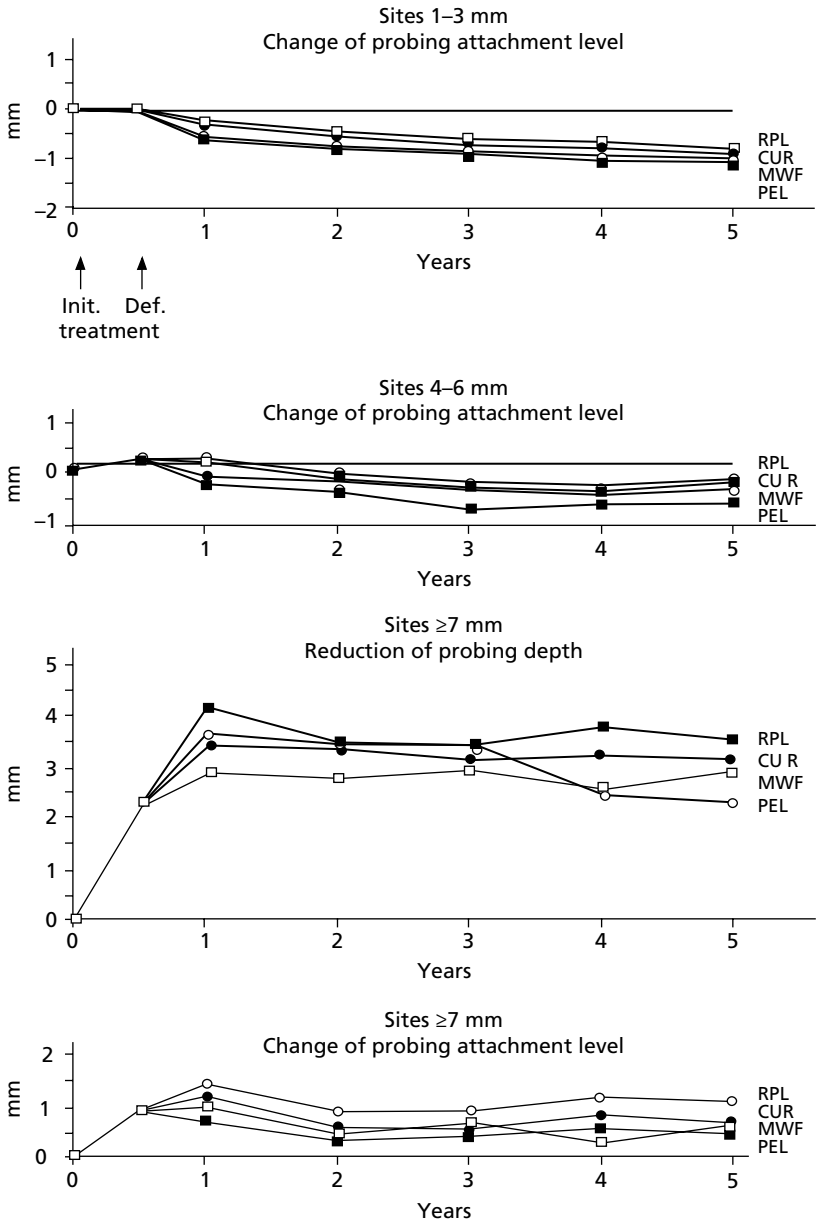

Fig. 39-64 Longitudinal evaluation of four treatment modalities in the three categories of initial probing depth; 1–3 mm, 4–6 mm and ≥7 mm. (RPL, scaling and root planning; CUR, subgingival curettage; MWF, modified Widman flap; PEL, pocket elimination surgery.) (Source: Egelberg 1995. Reproduced from Odonto Science. Data from Ramfjord *et al*. 1987.))

finding is that, in the molar tooth regions, the surgical approach to root debridement offers advantages over the non-surgical approach. This interpretation is supported by the observation that inferior results are obtained by non-surgical therapy in molars compared to single-rooted teeth (Nordland *et al*. 1987; Loos *et al*. 1988). Also, data generated from studies comparing closed and open root debridement in furcation sites favor surgical access therapy in the treatment of molar tooth regions (Matia *et al*. 1986).

The removal of the pocket epithelium and the soft tissue lesion by curettage (Echeverria & Caffesse 1983; Ramfjord *et al*. 1987) or surgical excision (Lindhe & Nyman 1985) is not a prerequisite for proper healing of the treated periodontal site. In the study by Lindhe and Nyman (1985), three treatment modalities were used: excision of the soft tissue lesion during flap surgery (modified Widman flap procedure), surgery without removal of the soft tissue lesion (Kirkland flap), and non-surgical scaling and root planing. The 1-year follow-up examination revealed about 1 mm of gain in clinical attachment level for all three procedures. Thus, deliberate excision of the soft tissue lesion did not improve the healing result.

Gingival recession

Gingival recession is an inevitable consequence of periodontal therapy. Since it occurs primarily as a result of resolution of the inflammation in the periodontal tissues, it is seen both following non-surgical and surgical therapy. Irrespective of treatment modality used, initially deeper pocket sites will experience more pronounced signs of recession of the gingival margin than sites with shallow initial probing depths (Badersten *et al*. 1984; Lindhe *et al*. 1987; Becker *et al*. 2001).

A general finding in short-term follow-up studies of periodontal therapy is that non-surgically performed scaling and root planing causes less gingival

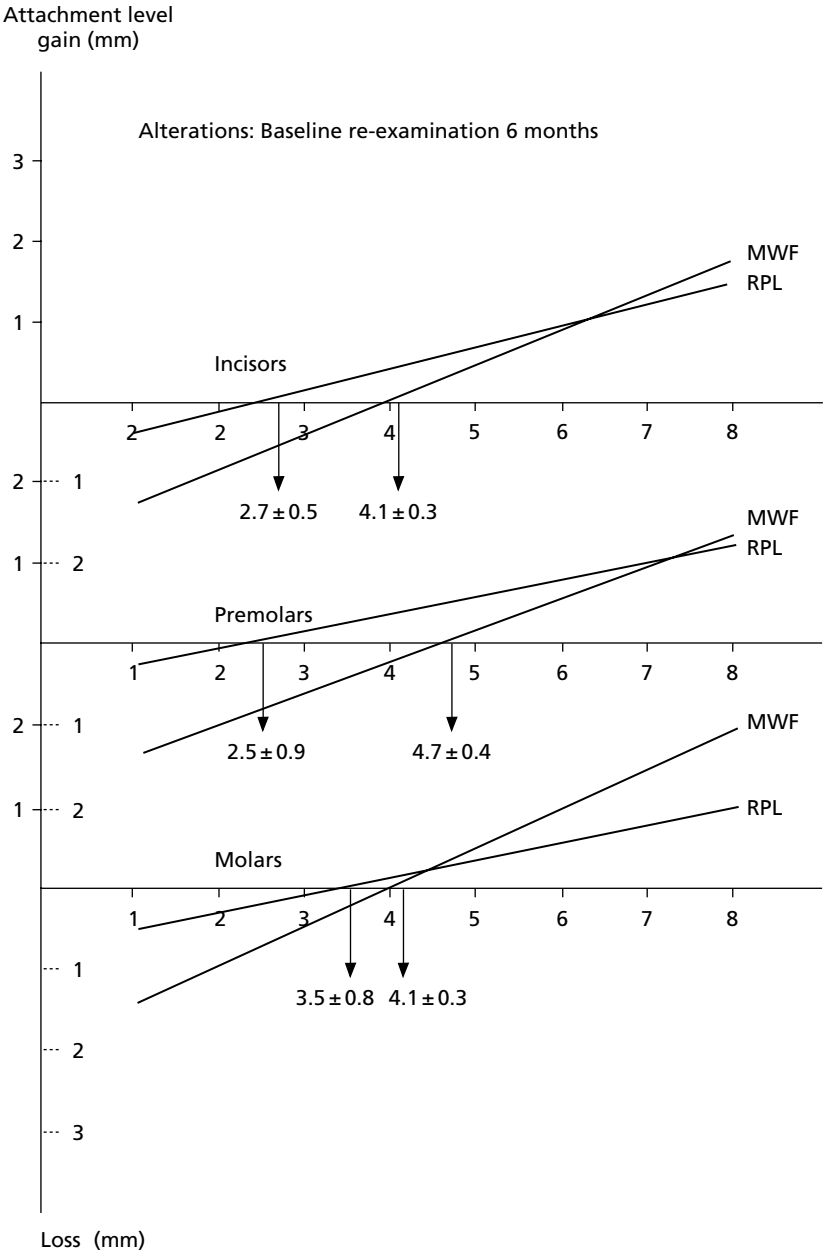

Fig. 39-65 Gain and loss of clinical attachment (y axis) at incisors, premolars, and molars, calculated from measurements taken prior to and 6 months after treatment. The non-surgical approach (RPL) consistently yielded lower critical probing depth (CPD) values than the surgical approach. (RPL, scaling and root planning; MWF, modified Widman flap surgery.) (Data from Lindhe *et al*. 1982b.)

recession than surgical therapy, and that surgical treatment involving osseous resection results in the most pronounced recession. However, data obtained from long-term studies reveal that the initial differences seen in amount of recession between various treatment modalities diminish over time due to a coronal rebound of the soft tissue margin following surgical treatment (Kaldahl *et al*. 1996; Becker *et al*. 2001) (Fig. 39-66). Lindhe and Nyman (1980) found that after an apically repositioned flap procedure, the buccal gingival margin shifted to a more coronal position (by about 1 mm) during 10–11 years of maintenance. In interdental areas denuded following surgery, van der Velden (1982) found an up-growth of around 4 mm of gingival tissue 3 years after surgery, while no significant change in attachment levels was observed. A similar finding was reported by Pontoriero and Carnevale (2001) 1 year after an apically positioned flap procedure for crown lengthening.

Bone fill in angular bone defects

The potential for bone formation in angular defects following surgical access therapy has been demonstrated in a number of studies. Rosling *et al*. (1976a) studied the healing of two- and three-wall angular bone defects following a modified Widman flap procedure, including careful curettage of the bone defect and proper root debridement, in 24 patients with multiple osseous defects. Following active treatment, patients assigned to the test group received supportive periodontal care once every 2 weeks for a 2-year period, while the patients in the control group were only recalled once a year for prophylaxis. Re-examination carried out 2 years after therapy demonstrated that the patients who had been subjected to the intensive professional tooth-cleaning regimen had experienced a mean gain of clinical attachment in the angular bone defects amounting to 3.5 mm.

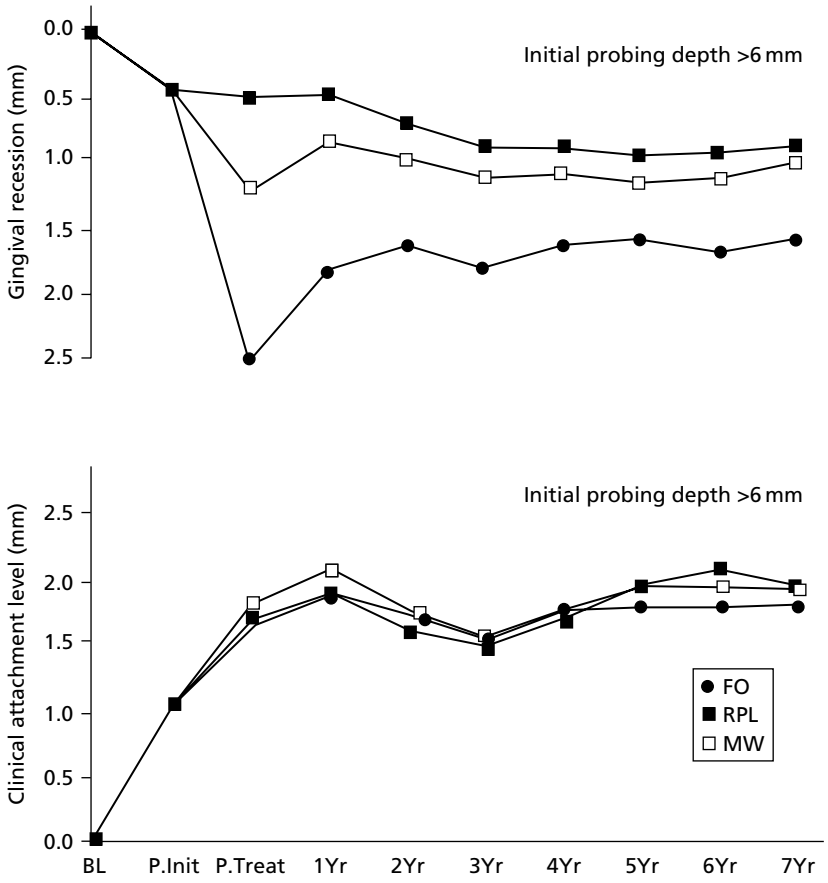

Fig. 39-66 Longitudinal changes over 7 years in recession (top) and clinical attachment levels (bottom) at sites with initial probing pocket depth of >6 mm following three different periodontal treatment modalities. (RPL, scaling and root planning; MWF, modified Widman flap procedure; FO, flap and osseous surgery.) (Data from Kaldahl *et al*. 1996.)

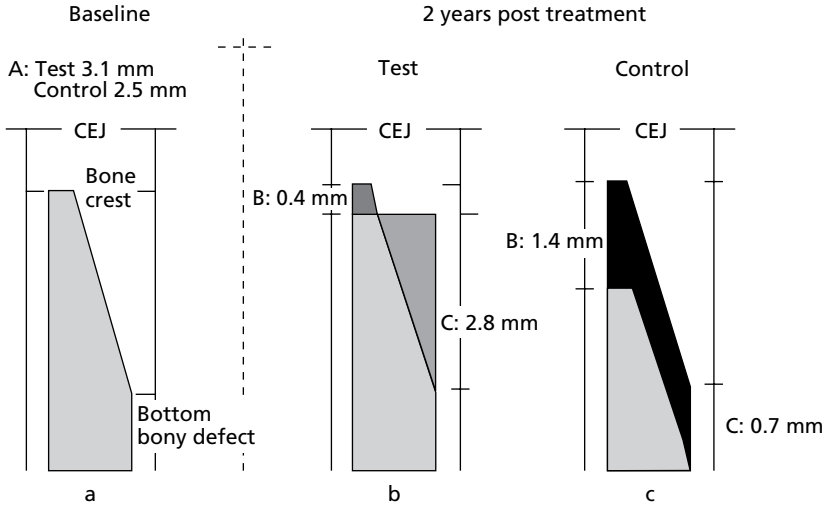

Fig. 39-67 Alterations in the level of the marginal bone crest and the level of the bottom of the bone defects in the test and control groups of the study by Rosling *et al*. (1976a). (a) Distance A denotes the depth of the bone defects at the initial examination; test group 3.1 mm, control 2.5 mm. (b, c) Distance B denotes resorption of the alveolar crest, which amounted to 0.4 mm in the test patients (b) and 1.4 mm in the controls (c). Distance C denotes gain or loss of bone in the apical portion of the defect. There was a refill of bone in the test patients (b) amounting to 2.8 mm, whereas a further 0.7 mm loss of bone occurred in the control patients (c). (CEJ, cementoenamel junction.) (Data from Rosling *et al*. 1976a.)

Measurements performed on radiographs revealed a marginal bone loss of 0.4 mm, but the remaining portion of the original bone defect (2.8 mm) was refilled with bone (Fig. 39-67). All the 124 bone defects treated were completely resolved. In the control group, most of the sites treated showed signs of recurrent periodontitis, including further loss of clinical attachment and alveolar bone. Similar healing results were reported by Polson and Heijl (1978). They treated 15 defects (two- and three-wall) in nine patients using a modified Widman flap procedure. Following curettage of the bone defect and root planing, the flaps were closed to achieve complete soft tissue coverage of the defect area. All patients were enrolled in a professional tooth-cleaning program. The healing was evaluated at a re-entry operation 6–8 months after the initial surgery. Eleven of the 15 defects had resolved completely. The healing was characterized by a combination of coronal bone regeneration (77% of the initial depth of the defects) and marginal bone resorption (18%). The authors concluded that intrabony defects might predictably remodel after surgical debridement and establishment of optimal plaque control.

The results from the studies referred to demonstrate that a significant bone fill may be obtained in two- and three-wall intrabony defects at single-rooted teeth, provided the postoperative supportive

care is of very high quality. Two reviews (Laurell *et al*. 1998; Lang 2000), focusing on the outcome of surgical access therapy in angular bone defects, gave additional information regarding expected bone regeneration in angular defects following open-flap debridement (modified Widman flap). In the review by Laurell *et al*. (1998), 13 studies were included, representing a total of 278 treated defects with a mean depth of 4.1 mm. The weighted mean bone fill in the angular defects amounted to 1.1 mm. Lang (2000) reported an analysis of 15 studies providing data generated from radiographic assessments of the healing of 523 angular bone defects. The analysis yielded a weighted mean of 1.5 mm of bone gain. Since the studies included in these reviews showed great variability in bone fill, one may assume that the standard of post-surgical plaque control varied between the studies. As shown in the study by Rosling *et al*. (1976a), meticulous post-surgical plaque control and close professional supervision of the patients are critical for optimal healing conditions. One also has to consider that the potential for bone fill may differ depending on the morphology of the angular bone defect. Most angular defects appear as combinations of one-, two- and three-wall defects and whereas the two- and three-wall component of an angular bone defect may show great potential for bone fill during healing, the one-wall component will rarely demonstrate this type of healing.

Chapter 40

Treatment of Furcation-Involved Teeth

Gianfranco Carnevale,[1] Roberto Pontoriero,[1] and Jan Lindhe[2]

[1] Private Practice, Milan, Italy
[2] Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Detailed knowledge of the morphology of the multi-rooted teeth and their position in the dental arch is a fundamental prerequisite for a proper understanding of the problems which may occur when such teeth become involved in destructive periodontal disease. The first part of this chapter therefore includes a brief description of some important anatomic features of the root complexes and related structures of premolars and molars.

Terminology

The root complex is the portion of a tooth that is located apical to the cementoenamel junction (CEJ), that is the portion that normally is covered with a root cementum. The root complex may be divided into two parts: the *root trunk* and the *root cone(s)* (Fig. 40-1).

The *root trunk* represents the *undivided region* of the root. The height of the root trunk is defined as the distance between the CEJ and the separation line (furcation) between two root cones (roots). Depending on the position of the separation line, the height of the root trunk may vary from one surface to the next in one given molar or premolar.

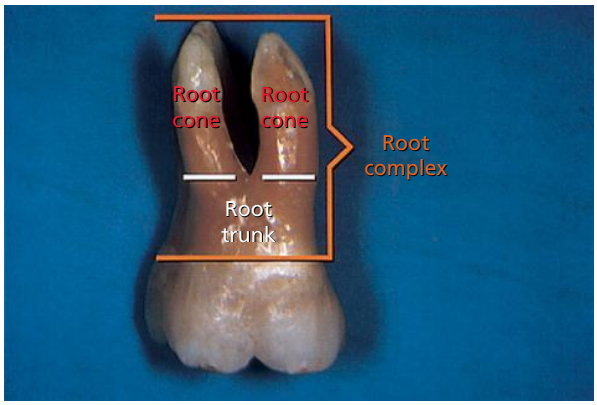

Fig. 40-1 Root complex of a maxillary molar. The root complex is separated into one undivided region – the root trunk, and one divided region – the (three) root cones.

The *root cone* is included in the *divided region* of the root complex. The root cone (root) may vary in size and position, and may at certain levels be connected to or separated from other root cones. Two or more

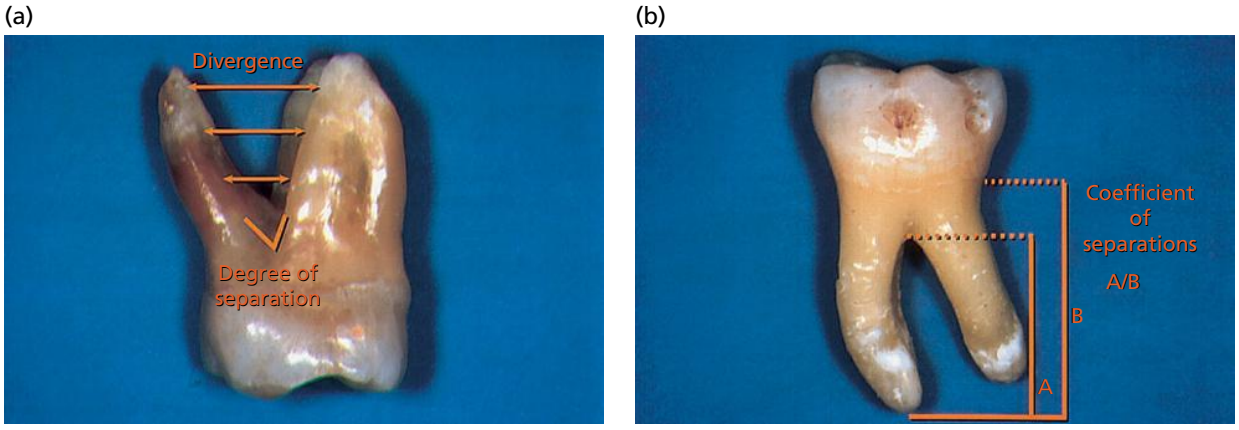

Fig. 40-3 (a) Angle (degree) of separation and the divergence between the mesiobuccal and the palatal roots of a maxillary molar. (b) Coefficient of separation (A/B) of the illustrated mandibular molar is 0.8 (A = 8 mm; B = 10 mm).

root cones make up the *furcated region* of the root complex (Fig. 40-2a). The *furcation* is the area located between individual root cones.

The *furcation entrance* is the transitional area between the undivided and the divided part of the root (Fig. 40-2a, b). The *furcation fornix* is the roof of the furcation (Fig. 40-2b).

The *degree of separation* is the angle of separation between two roots (cones) (Fig. 40-3a). *Divergence* is the distance between two roots; this distance normally increases in the apical direction (Fig. 40-3a). The *coefficient of separation* is the length of the root cones in relation to the length of the root complex (Fig. 40-3b).

Fusion between divergent root cones may occur. The fusion may be complete or incomplete. In the case of an incomplete fusion, the root cones may be fused in the area close to the CEJ, but separated in a more apical region of the root complex.

Anatomy

Maxillary molars

As a general rule, the maxillary first molar in all respects – crown and individual roots – is larger than the second molar, which in turn is larger than the third molar. The first and second molars most often have three roots; one mesiobuccal, one distobuccal, and one palatal. The mesiobuccal root is normally vertically positioned, while the distobuccal and the palatal roots are inclined. The distobuccal root projects distally and the palatal root projects in the palatal direction (Fig. 40-4). The cross-sections of the distobuccal and the palatal roots are generally circular. The palatal root is generally wider in the mesiodistal than in the buccopalatal direction. The distal surface of the mesiobuccal root has a concavity which is about 0.3 mm deep (Bower 1979a, b). This concavity gives the cross section of the mesiobuccal root an "hourglass" configuration (Fig. 40-5).

The three furcation entrances of the maxillary first and second molars vary in width and are positioned at varying distances apical to the CEJ. As a rule, the first molar has a shorter root trunk than the second molar. In the first molar the mesial furcation entrance is located about 3 mm from the CEJ, while the buccal entrance is 3.5 mm and the distal entrance about 5 mm apical to the CEJ (Abrams & Trachtenberg 1974; Rosenberg 1988). This implies that the furcation fornix is inclined; in the mesiodistal plane, the fornix is comparatively

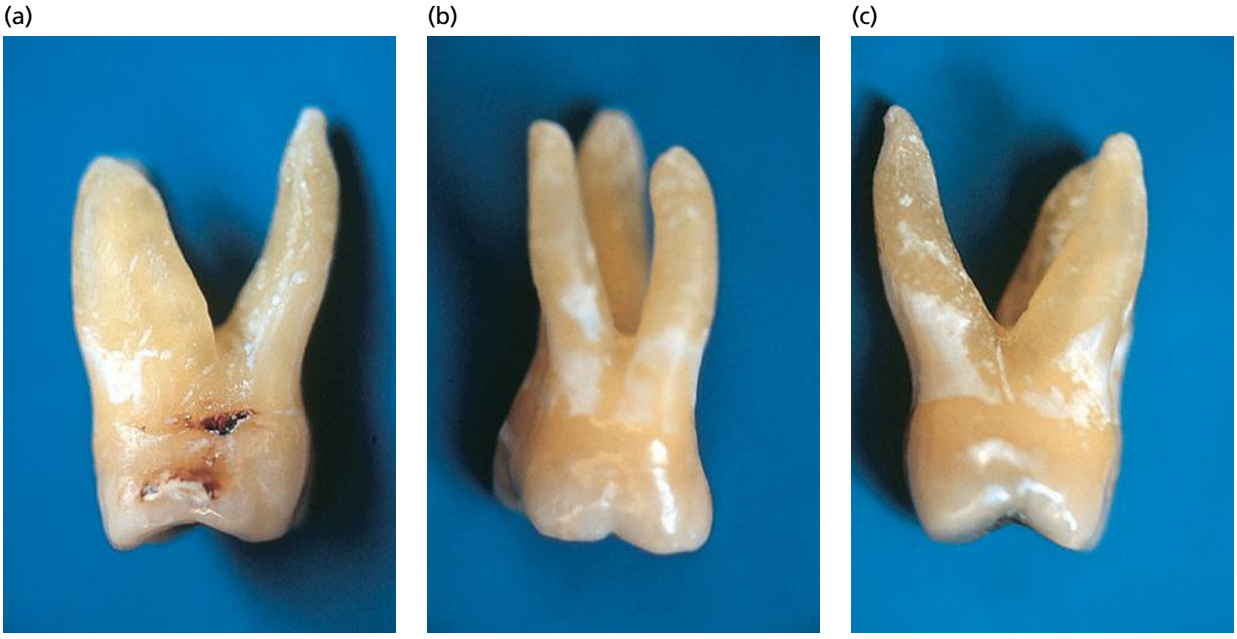

Fig. 40-4 Furcation entrances (a) mesial; (b) buccal; (c) distal), and position of the roots of a maxillary first molar.

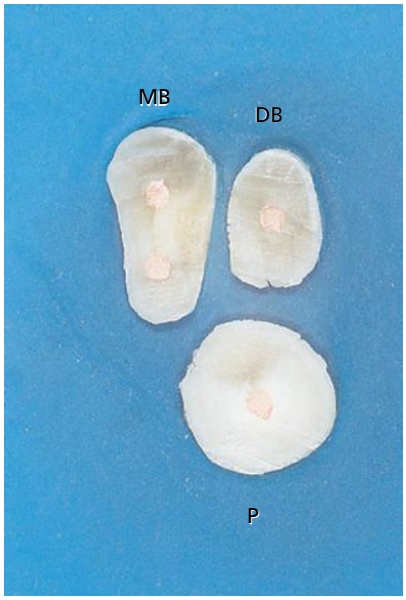

Fig. 40-5 Root shape of a maxillary first molar in a horizontal cut at the level of the coronal third of the cones. Note the circular shape of the palatal root (P) in comparison with the mesiodistally compressed shape of the mesiobuccal root (MB), which also exhibits a concavity in the distal aspect (DB).

close to the CEJ at the mesial surface but closer to the apex at the distal surface. The buccal furcation entrance is narrower than its distal and mesial counterparts.

The degree of separation between the roots and their divergence decreases from the first to the second, and from the second to the third maxillary molar. The mesiobuccal root of the first molar is frequently located more buccally in the arch than the distobuccal root. If the buccal bone plate is thin, the mesiobuccal root frequently projects through the outer surface of the alveolar bone and bone fenestrations and/or dehiscences may occur.

Fig. 40-6 Maxillary first premolar with the furcation located in the apical third of the root complex.

Maxillary premolars

In about 40% of cases, the maxillary first premolars have two root cones, one buccal and one palatal, and hence have a mesiodistal furcation. A concavity (about 0.5 mm deep) is often present in the furcation aspect of the buccal root. In many cases, the furcation is located in the middle or in the apical third of the root complex (Fig. 40-6). The mean distance between CEJ and the furcation entrance is about 8 mm. The width of the furcation entrance is about 0.7 mm.

Mandibular molars

The mandibular first molar is larger than the second molar, which in turn is larger than the third molar. In the first and second molars, the root complex almost always includes two root cones, one mesial and one distal. The mesial root is larger than the distal root. The mesial root has a mainly vertical position, while the distal root projects distally. The mesial root is wider in the buccolingual direction

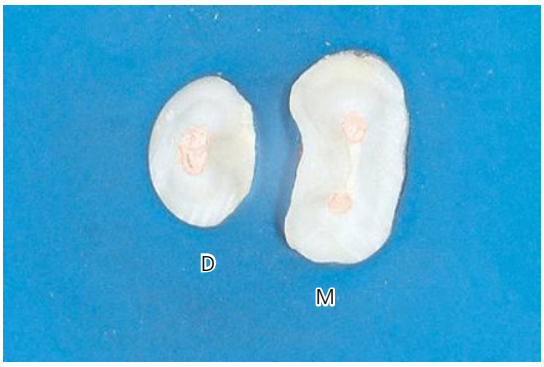

Fig. 40-7 "Hour-glass" shape of the mesial root (M) – with a concavity in the distal aspect, and the circular shape of the distal root (D) (horizontal section at the level of the coronal third of the cones).

Fig. 40-8 From left to right, differences in degree of separation and in divergence between the root cones from the first to the mandibular third molar.

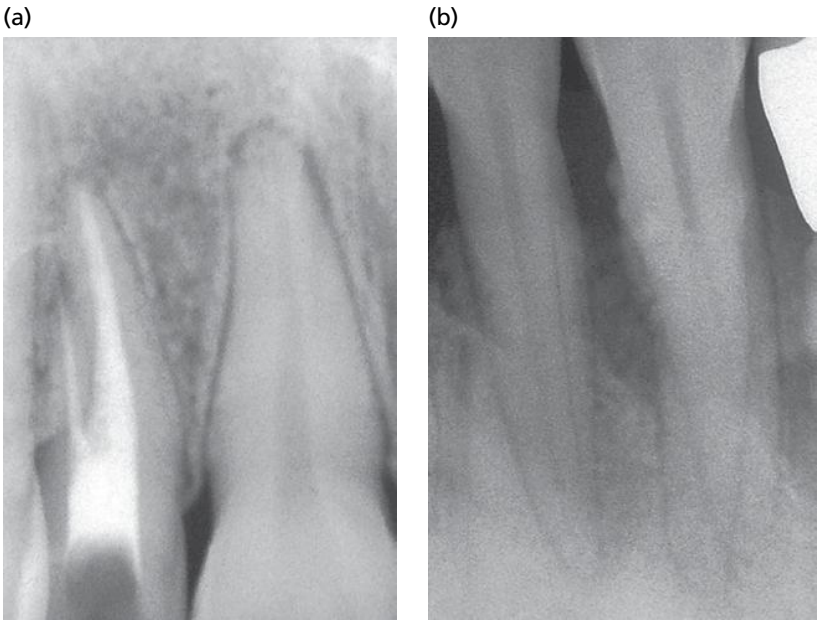

Fig. 40-9 Radiographs showing morphologic variations represented by a two-rooted (a) maxillary lateral incisor and (b) mandibular canine.

and has a larger cross-sectional area than the distal root. The cross-section of the distal root is circular, while the mesial root has an "hour-glass" shape. In addition, furrows and concavities often occur on the distal surface of the mesial root (Fig. 40-7). The distal concavity of the mesial root is more pronounced than that of the distal root (Bower 1979a, b; Svärdström & Wennström 1988).

The root trunk of the first molar is often shorter than the trunk of the second molar. The furcation entrances of the mandibular first molar, similar to those of the maxillary first molar, are located at different distances from the CEJ. Thus, the lingual entrance is frequently found more apical to the CEJ (>4 mm) than the buccal entrance (>3 mm). Thus, the furcation fornix is inclined in the buccolingual direction. The buccal furcation entrance is often <0.75 mm wide, while the lingual entrance is >0.75 mm in most cases (Bower 1979a, b). The degree of separation and divergence between the roots decreases from the first to the third molar (Fig. 40-8).

It should also be observed that the buccal bone plate is thinner outside the roots of the first than of the second molar. Bone fenestrations and dehiscences are, as a consequence, more frequent in the first than in the second molar region.

Other teeth

Furcations may be present also in teeth which normally have only one root. In fact, two-rooted incisors (Fig. 40-9a), canines (Fig. 40-9b), and mandibular premolars may exist. Occasionally three-rooted maxillary premolars (Fig. 40-10a) and three-rooted mandibular molars can be found (Fig. 40-10b).

Diagnosis

The presence of furcation-involved teeth in a periodontal patient will influence the treatment plan (see Chapter 32). The selection of procedures to be used in the treatment of periodontal disease at

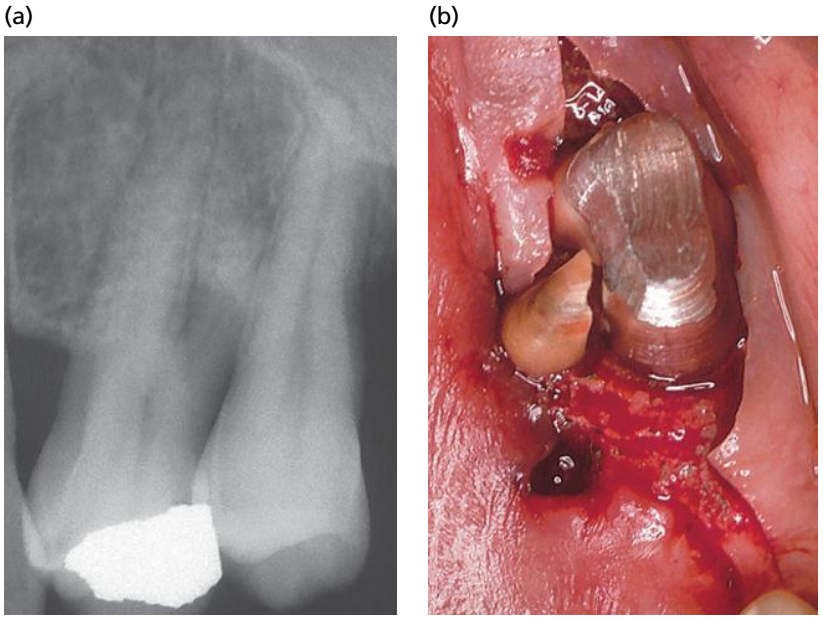

Fig. 40-10 (a) Anatomic variation shown in a radiograph of a three-rooted mandibular first premolar. (b) Clinical surgical photograph showing the separation – before extraction – of an "abnormal" second mesial root of a mandibular molar.

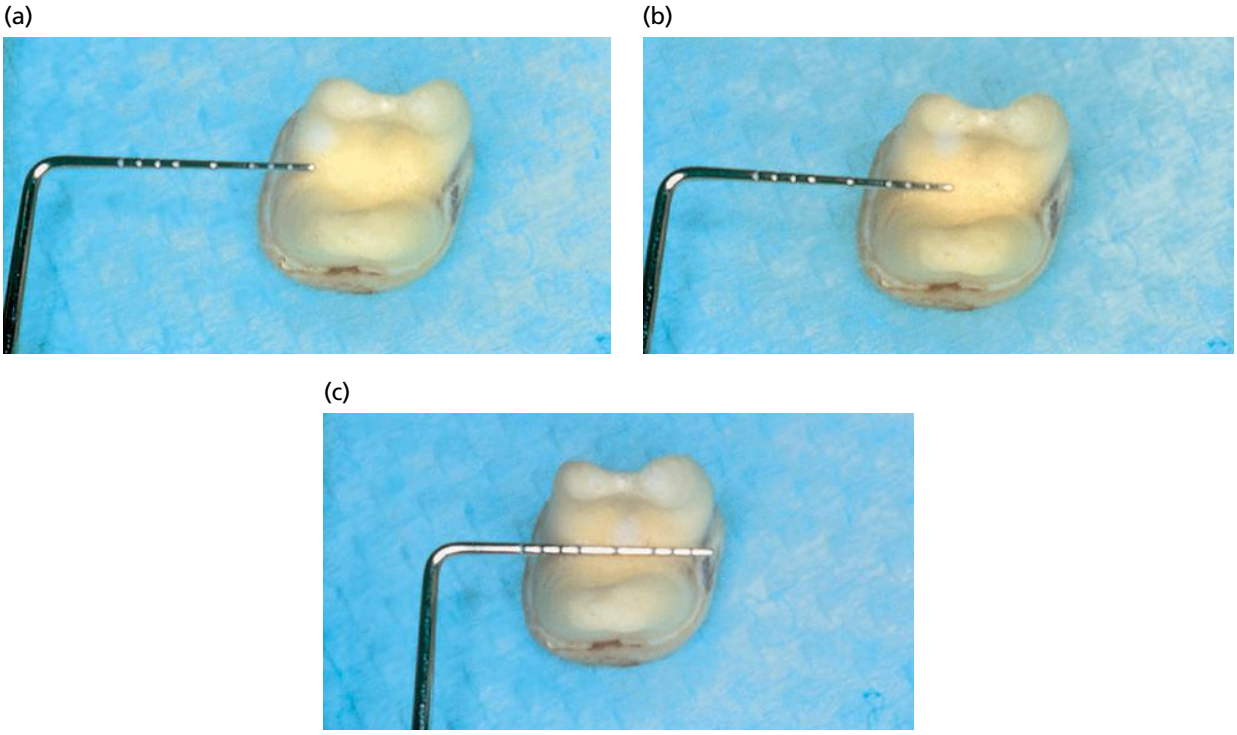

Fig. 40-11 Different degrees of furcation involvement in relation to the probe (penetration/superimposition) in the inter-radicular space of a mandibular molar. (a) Class I; (b) class II; (c) class III.

multirooted teeth can first be made when the presence and depth of furcation lesions have been assessed. In this examination, traditional measures of periodontal disease are used (see Chapter 29), but special attention is paid to findings from clinical probing and analysis of radiographs from the premolar–molar regions.

The classification description of the involved furcation is based on the amount of periodontal tissue destruction that has occurred in the inter-radicular area, that is the degree of "horizontal root exposure" or attachment loss that exists within the root complex. Hamp *et al*. (1975) has suggested the following classification of the involved furcation:

- *Class I:* horizontal loss of periodontal support not exceeding one-third of the width of the tooth (Fig. 40-11a)
- *Class II*: horizontal loss of periodontal support exceeding one-third of the width of the tooth, but not encompassing the total width of the furcation area (Fig. 40-11b)
- *Class III*: horizontal "through-and-through" destruction of the periodontal tissues in the furcation area (Fig. 40-11c).

(a) (b)

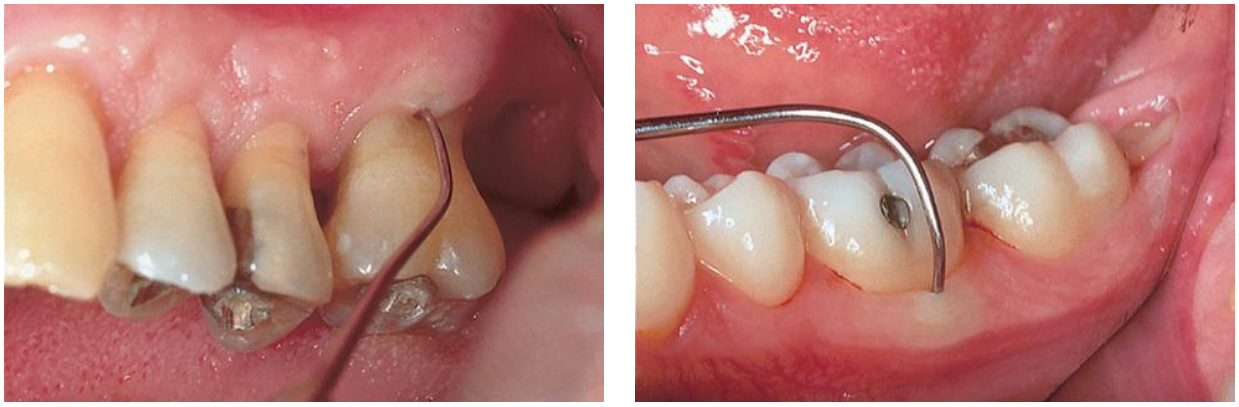

Fig. 40-12 Easily accessible vestibular furcation entrances for probing of a (a) maxillary molar and (b) mandibular molar.

Fig. 40-13 Common access for probing of a mesial furcation entrance of a maxillary molar. The mesial furcation entrance is generally located at the palatal aspect of the tooth, while the distal entrance is located midway between the buccal and the palatal surface.

Fig. 40-14 Radiograph showing the location of the interdental bone level in relation to the furcation entrances of the maxillary first and second molars.

It is important to appreciate that each furcation entrance must be examined and each entrance must be classified according to the above criteria.

Probing

The buccal furcation entrance of the *maxillary molars* and the buccal and lingual furcation entrances of the *mandibular molars* are normally accessible for examination using a curved graduated periodontal probe (Fig. 40-12), an explorer or a small curette. The examination of approximal furcations is more difficult, in particular when neighboring teeth are present. Large contact areas between the teeth further impair access to approximal furcation entrances.

In maxillary molars, the mesial furcation entrance is located much closer to the palatal than to the buccal tooth surface. Thus, the mesial furcation should be probed from the palatal aspect of the tooth (Fig. 40-13). The distal furcation entrance of a maxillary molar is generally located midway between the buccal and palatal surfaces and, as a consequence, this furcation could be probed from either the buccal or the palatal aspect of the tooth.

In *maxillary premolars*, the root anatomy often varies considerably. The roots may also harbor irregularities such as longitudinal furrows, invaginations or true furcations, which may open at varying distances from the CEJ. Due to the above variations and limited access, the clinical assessment of a furcation involvement in maxillary premolars is often difficult. In some patients, a furcation involvement may, in such teeth, first be identified after the elevation of a soft tissue flap.

Radiographs

Radiographs must always be obtained to confirm findings made during probing of a furcation-involved tooth. The radiographic examination should include both paralleling "periapical" and vertical "bitewing" radiographs. In the radiographs, the location of the interdental bone as well as the bone level within the root complex should be examined (Fig. 40-14). Situations may occur when findings from clinical probing and from the radiographs are inconsistent. Thus, the localized but extensive attachment loss which may be detected within the root complex of a maxillary molar with the use of a probe, will not always appear in the radiograph. This may be due to the superimposition in the radiograph of the palatal root and remaining

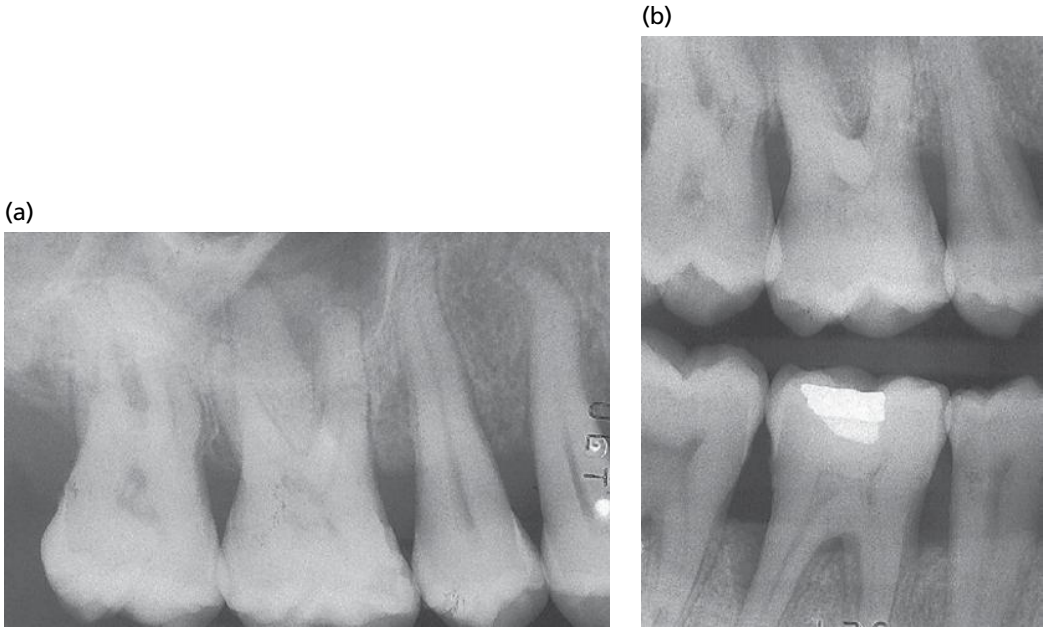

Fig. 40-15 Radiographs of the right maxillary molar region.(a) In a normal bisecting projection, the furcation defect of the first molar is not evident. (b) It is, however, easily identified in a bitewing radiograph.

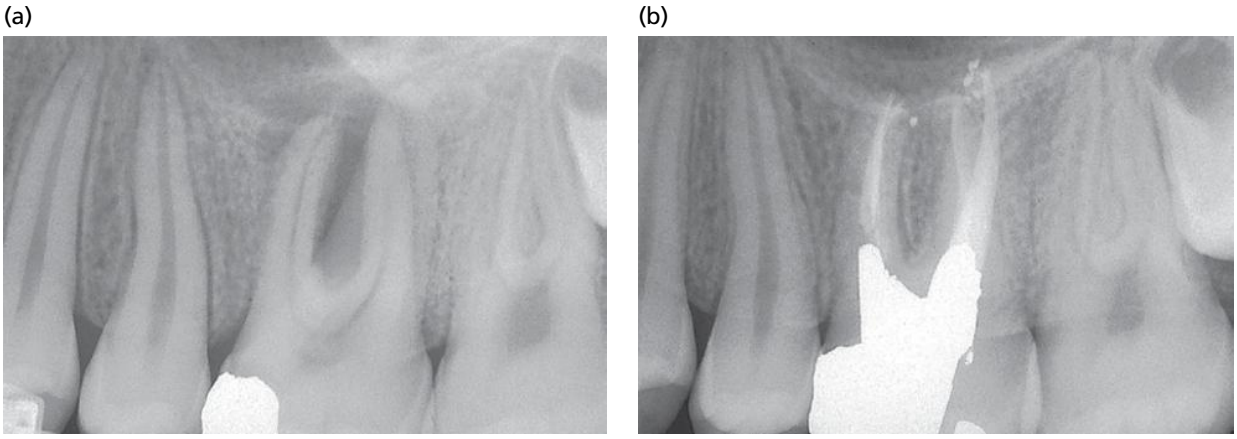

Fig. 40-16 (a) Radiograph demonstrating destruction of inter-radicular bone and the presence of periapical defects at the mesial and distal roots of a maxillary first molar. (b) Radiographic appearance of complete healing of the inter-radicular and periapical lesions after endodontic treatment.

bone structures (Fig. 40-15a). In such a case, additional radiographs with different angles of orientation of the central beam should be used to identify bone loss within the root complex (Fig. 40-15b).

Differential diagnosis

A lesion in the inter-radicular space of a multirooted tooth may be associated with problems originating from the root canal or be the result of occlusal overload. The treatment of a furcation-involved tooth, therefore, should not be initiated until a proper differential diagnosis of the lesion has been made.

Pulpal pathosis may sometimes cause a lesion in the periodontal tissues of the furcation (see Chapter 25). The radiographic appearance of such a defect may have some features in common with a plaque-associated furcation lesion. In order to differentiate between the two lesions, the vitality of the affected tooth must always be tested. If the tooth is vital, a plaque-associated lesion should be suspected. If the tooth is non-vital, the furcation involvement may have an endodontic origin. In such a case, proper endodontic treatment must always precede periodontal therapy. In fact, endodontic therapy may resolve the inflammatory lesion, soft and hard tissue healing may occur, and the furcation defect will disappear (Fig. 40-16). If signs of healing of a furcation defect fail to appear within 2 months of endodontic treatment, the furcation involvement is probably associated with marginal periodontitis.

Trauma from occlusion

Forces elicited by occlusal interferences, for example bruxers and clenchers (see Chapters 16 and 52), may cause inflammation and tissue destruction or

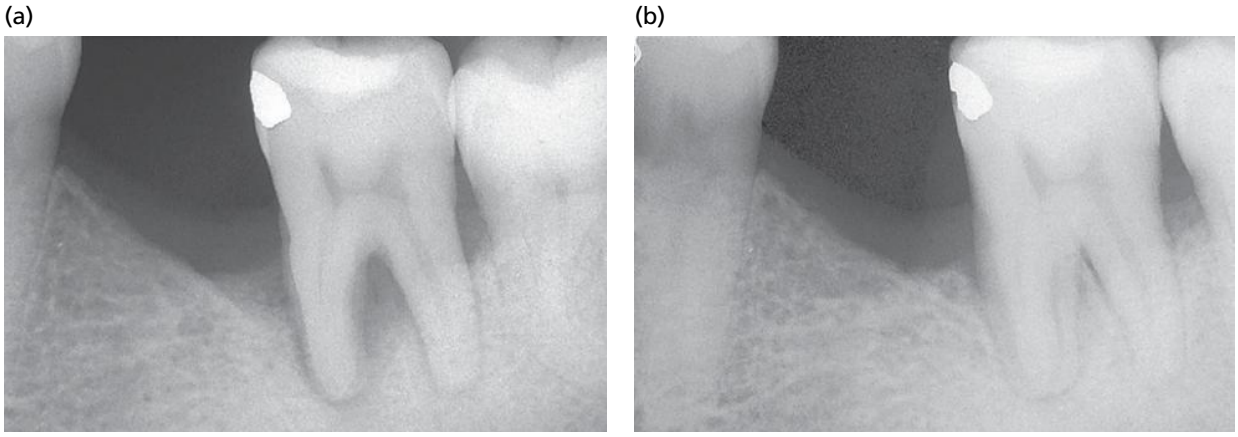

Fig. 40-17 (a) Radiographic appearance of a defect in the furcation area caused by occlusal overload. After occlusal adjustment the inter-radicular defect spontaneously healed, as documented 6 months after therapy in a radiograph (b). (Courtesy of M. Cattabriga.)

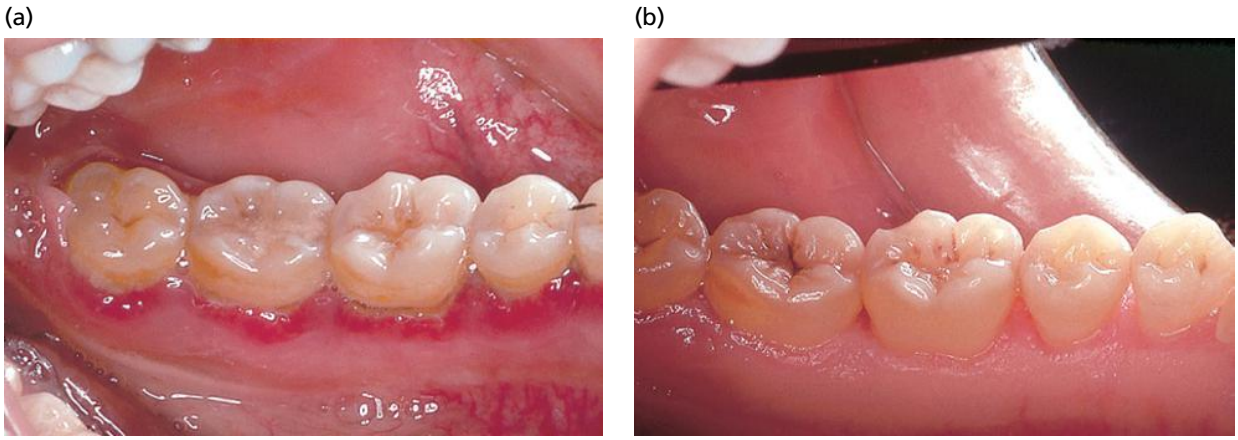

Fig. 40-18 Resolution of inflammatory lesions in the gingiva achieved by scaling and root planing, and the re-establishment of a correct tissue morphology in the inter-radicular area of class I furcation-involved mandibular molars. (a) Before therapy; (b) 6 months after therapy.

adaptation within the inter-radicular area of a multirooted tooth. In such a tooth, a radiolucency may be seen in the radiograph of the root complex. The tooth may exhibit increased mobility. Probing, however, fails to detect an involvement of the furcation. In this particular situation, occlusal adjustment must always precede periodontal therapy. If the defects seen within the root complex are of "occlusal" origin, the tooth will become stabilized and the defects disappear within weeks following correction of the occlusal overload (Fig. 40-17).

Therapy

Treatment of a defect in the furcation region of a multirooted tooth is intended to meet two objectives:

1. Elimination of the microbial plaque from the exposed surfaces of the root complex
2. Establishment of an anatomy of the affected surfaces that facilitates proper self-performed plaque control.

Different methods of therapy are recommended:

- *Class I furcation involvement*: scaling and root planing (SRP); furcation plasty
- *Class II furcation involvement*: furcation plasty; tunnel preparation; root resection; tooth extraction; guided tissue regeneration at mandibular molars
- *Class III furcation involvement*: tunnel preparation; root resection; tooth extraction.

Scaling and root planing

Scaling and planing of the root surfaces in the furcation entrance of a class I involvement in most situations result in the resolution of the inflammatory lesion in the gingiva. Healing will re-establish a normal gingival anatomy with the soft tissue properly adapted to the hard tissue walls of the furcation entrance (Fig. 40-18).

Furcation plasty

Furcation plasty (Fig. 40-19) is a resective treatment modality which should lead to the elimination of the inter-radicular defect. Tooth substance is removed (odontoplasty) and the alveolar bone crest is remodeled (osteoplasty) at the level of the furcation entrance. Furcation plasty is used mainly at buccal and lingual furcations. At approximal surfaces, access is often too limited for this

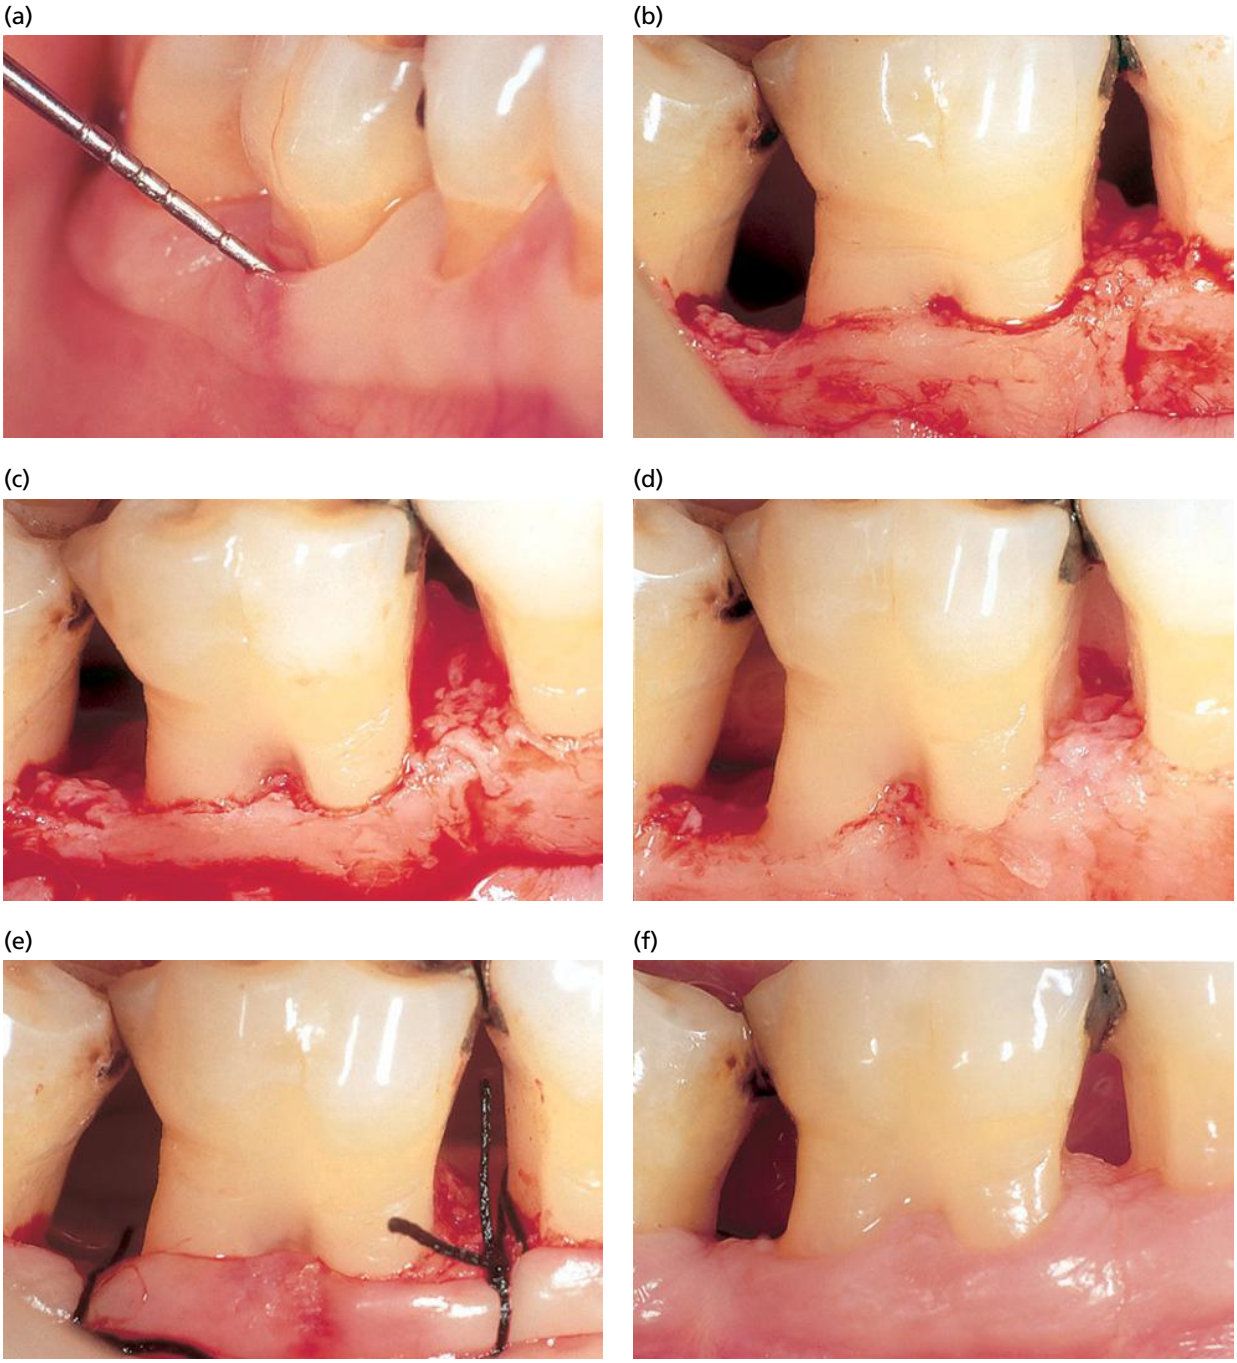

Fig. 40-19 Furcation plasty performed at the buccal aspect of a mandibular molar. (a) Initial class II furcation involvement; (b) after flap elevation, removal of the granulation tissue and scaling of the exposed root surfaces; (c) after odontoplasty; (d) after osteoplasty; (e) apical position of the flap managed by periosteal sutures; (f) healing resulting in the elimination of the furcation defect and in the establishment of a proper soft tissue morphology.

treatment. Furcation plasty involves the following procedures:

- Dissection and reflection of a soft tissue flap to obtain access to the inter-radicular area and the surrounding bone structures
- Removal of the inflammatory soft tissue from the furcation area followed by careful SRP of the exposed root surfaces
- Removal of crown and root substance in the furcation area (odontoplasty) to eliminate or reduce the horizontal component of the defect and to widen the furcation entrance
- Recontouring of the alveolar bone crest in order to reduce the buccal–lingual dimension of a bone defect in the furcation area
- Positioning and suturing of the mucosal flaps at the level of the alveolar crest in order to cover the furcation entrance with soft tissue; following healing a "papilla-like" tissue should close the entrance of the furcation.

Care must be exercised when odontoplasty is performed on vital teeth. Excessive removal of tooth structure will enhance the risk for increased root sensitivity.

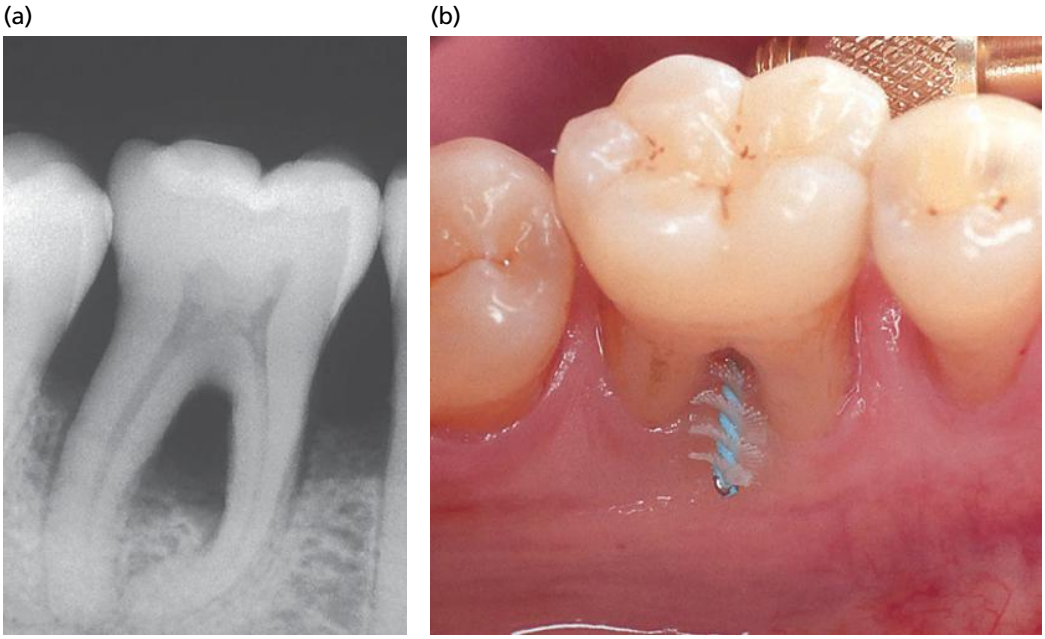

Fig. 40-20 Tunnel preparation of a class III-involved mandibular molar. (a) Radiograph and (b) photograph showing a wide inter-radicular space where self-performed plaque control can be achieved with the use of an interproximal brush.

Tunnel preparation

Tunnel preparation is a technique used to treat deep class II and class III furcation defects in mandibular molars. This type of resective therapy can be offered at mandibular molars which have a short root trunk, a wide separation angle, and long divergence between the mesial and distal root. The procedure includes the surgical exposure and management of the entire furcation area of the affected molar.

Following the reflection of buccal and lingual mucosal flaps, the granulation tissue in the defect is removed and the root surfaces are scaled and planed. The furcation area is widened by the removal of some of the inter-radicular bone. The alveolar bone crest is recontoured; some of the interdental bone, mesial and distal to the tooth in the region, is also removed to obtain a flat outline of the bone. Following hard tissue resection, enough space will have been established in the furcation region to allow access for cleaning devices to be used during self-performed plaque control measures (Fig. 40-20). The flaps are apically positioned to the surgically established inter-radicular and interproximal bone level.

During maintenance the exposed root surfaces should be treated with topical application of chlorhexidine digluconate and fluoride varnish. This surgical procedure should be used with caution, because there is a pronounced risk for root sensitivity and for carious lesions developing on the denuded root surfaces within artificially prepared tunnels (Hamp *et al.* 1975).

Root separation and resection

Root separation involves the sectioning of the root complex and the maintenance of all roots. *Root resection* involves the sectioning and the removal of one or two roots of a multirooted tooth. Root separation and resection (RSR) is frequently used in cases of deep class II and class III furcation-involved molars.

Before RSR is performed, the following factors must be considered:

- *Length of the root trunk*. In a patient with progressive periodontal disease, a tooth with a short root trunk may have an early involvement of the furcation (Larato 1975; Gher & Vernino 1980). A tooth with a short root trunk is a good candidate for RSR; the amount of remaining periodontal tissue support following RSR is often sufficient to ensure the stability of the remaining root cone. If the root trunk is long, the furcation involvement occurs later in the disease process, but, once established, the amount of periodontal tissue support left apical to the furcation may be insufficient to allow RSR.
- *Divergence between the root cones*. The distance between the root cones must be considered. Roots with a short divergence are technically more difficult to separate than roots which are wide apart. In addition, the smaller the divergence is, the smaller also is the inter-radicular (furcation) space. In cases where the divergence between two roots is small, the possibility of increasing the inter-radicular distance with an orthodontic root movement may be considered (Fig. 40-21). The furcation space may also be increased by odontoplasty performed during surgery. Figure 40-22 shows that *odontoplasty* was performed on (1) the distal part of the mesial root and (2) the mesial part of the distal root, with deep finishing lines prepared for the subsequent restoration (Di Febo *et al.* 1985).
- *Length and the shape of the root cones*. Following separation, short and small root cones (Fig. 40-23) tend

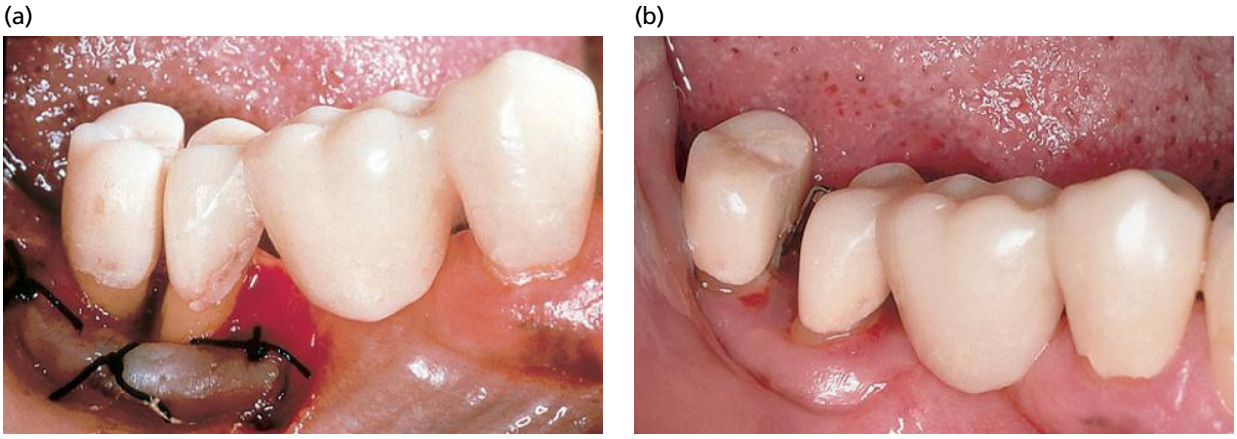

Fig. 40-21 Effect of orthodontic treatment of a separated mandibular molar with a small root divergence. (a) After root separation; (b) 3 months after completion of orthodontic therapy.

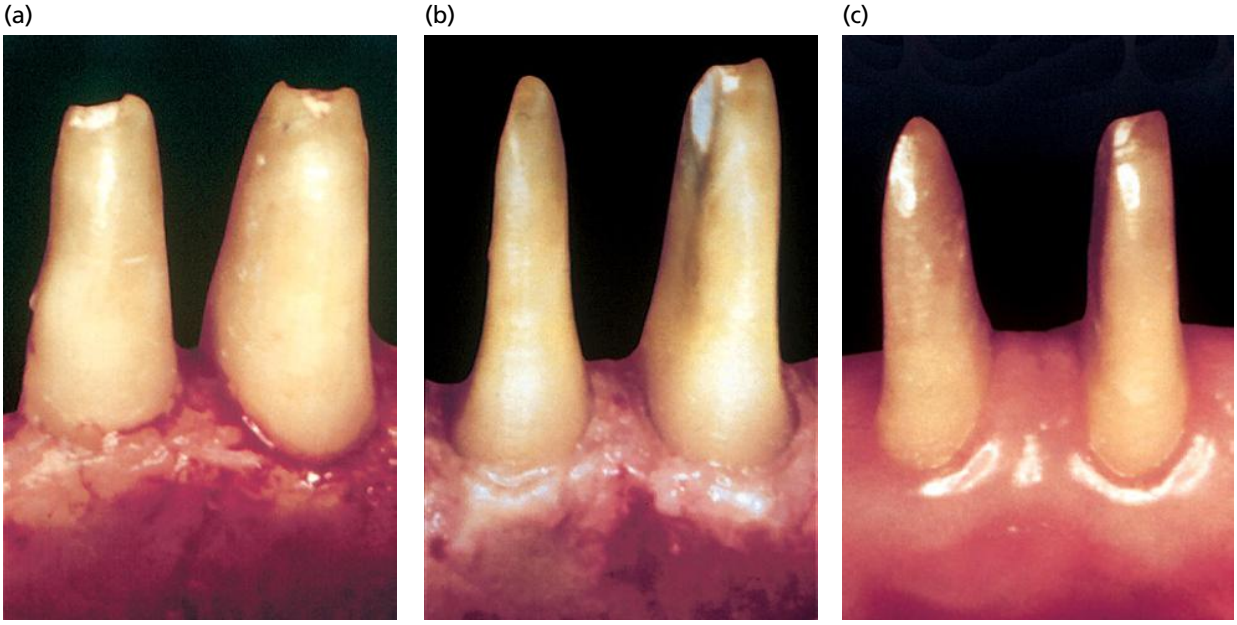

Fig. 40-22 Odontoplasty of a separated mandibular molar performed during surgery to increase the furcation space. (a) After flap elevation and exposure of the alveolar bone, it is evident that the distance between the two roots is small. (b) By preparing the inter-radicular surfaces during surgery, the furcation space is increased and is sufficient for self-performed plaque control measures (c).

Fig. 40-23 Radiograph showing maxillary molars with thin, short, and conical roots.

to exhibit an increased mobility. Such roots, in addition, have narrow root canals which are difficult to ream. Short and small roots consequently should be regarded as poor abutments for prosthetic restorations.

- *Fusion between root cones*. When a decision has been made to perform RSR, it is important that the clinician first determines that the cones within the root complex are not fused. This is generally an uncomplicated diagnostic problem for mandibular molars or for the buccal furcation of maxillary molars (Fig. 40-24). At such teeth, the separation area between the roots can easily be identified both with the probe and on a radiograph. It is more difficult to identify a

separation line between mesiobuccal (or distobuccal) and palatal roots of a maxillary molar or maxillary first premolar with a narrow root complex. In such situations, a soft tissue flap must often be raised to allow the operator to obtain proper access to the approximal tooth surfaces. The mesial (or distal) entrance of the furcation must be probed to a depth of 3–5 mm to ascertain that a fusion does not exist between the roots scheduled for RSR.

- *Amount of remaining support around individual roots*. This should be determined by probing the entire circumference of the separated roots. It should be observed that a localized deep attachment loss at one surface of one particular root (e.g. on the buccal surface of the palatal root or the distal surface of the mesiobuccal root of a maxillary molar) may compromise the long-term prognosis for an otherwise ideal root.
- *Stability of individual roots*. This must be examined following root separation. A rule of thumb is that the more mobile the root cone is, the less periodontal tissue support remains.
- *Access for oral hygiene devices*. After completion of therapy, the site must have an anatomy which facilitates proper self-performed tooth cleaning.

Maxillary molars

Several decisions must be made when RSR is planned for a furcation-involved maxillary molar. Since such teeth have three root cones, one or two cones may be retained after separation. Different treatment alternatives exist (Table 40-1).

Prior to RSR, the morphology of the individual roots as well as the surface area of each root must be carefully analyzed. The *distobuccal root* of a maxillary molar is the shortest of the three roots, but its root trunk is comparatively long. Thus, the distal root has a small quantity of bone support and once separated, the cone may exhibit increased mobility. The distobuccal root is, therefore, often removed as part of RSR (Rosenberg 1978; Ross & Thompson 1980).

The *mesiobuccal root* has a wide buccopalatal dimension and an hour-glass cross-section, and therefore a large root surface area. In fact, the mesiobuccal cone often has a total root surface area that is equal to or greater than that of the palatal root cone. The mesiobuccal root is located centrally in the alveolar process, is properly aligned with the maxillary premolars, and is in an ideal position to function as a separate unit (Fig. 40-25). For these reasons, the mesiobuccal root may be preferred for retention when the clinician is selecting between the mesiobuccal or

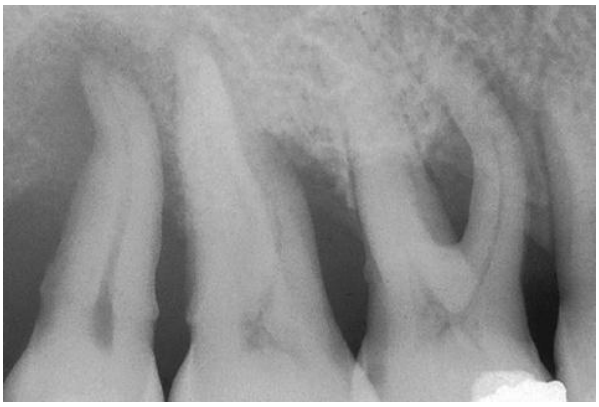

Fig. 40-24 Radiograph indicating the presence of a class III involvement of the buccal furcation of the maxillary first molar. This tooth is a candidate for root resection.

Fig. 40-25 Occlusal view of a restoration using the mesial root of a maxillary first molar as abutment. Note the alignment of the mesial root and the adjacent premolars.

Table 40-1 Root resective treatment possibilities in molars with furcation involvement.

Furcation involvement	Root resection	Root resection plus separation of the remaining roots
Buccal	Mesiobuccal, distobuccal	
Mesial	Mesiobuccal, palatal	
Distal	Distobuccal, palatal	
Buccal and distal	Distobuccal, mesiobuccal, and palatal	Palatal
Buccal and mesial	Mesiobuccal, distobuccal, and palatal	Palatal, distobuccal
Mesial and distal	Palatal, mesial, and distobuccal	Distobuccal
Buccal, distal, and mesial	Distobuccal and palatal, mesiobuccal and palatal, mesiobuccal and distobuccal	Palatal, distobuccal

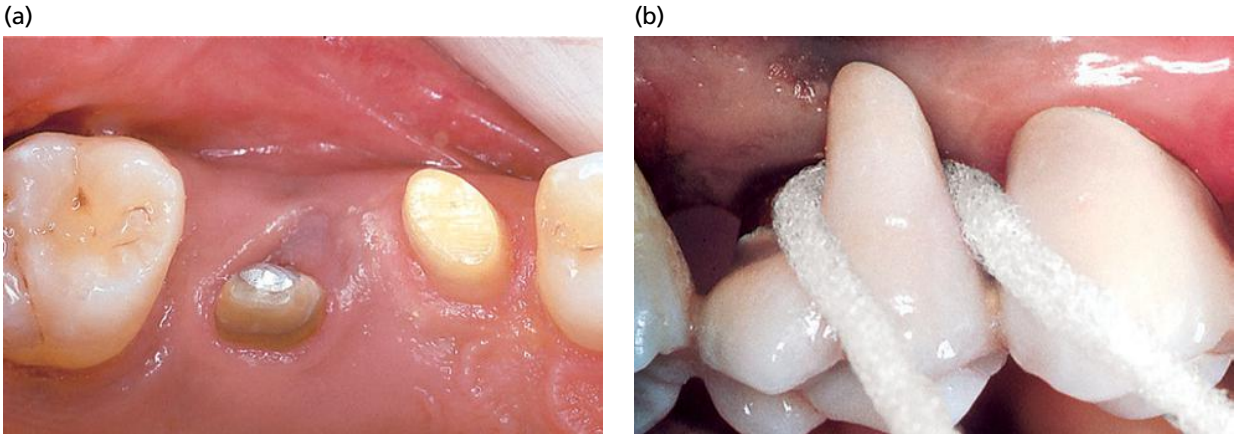

Fig. 40-26 (a) Palatal root of a root-resected maxillary molar serving as a single abutment for a crown restoration. (b) Mesiobuccal root included in the restoration for esthetic reasons.

palatal root. It should be remembered, however, that the root canals of the mesiobuccal root are narrow and more difficult to treat than the single and wide canal of the palatal root.

The tissue destruction in the furcation area often causes deep attachment and bone loss at the distal palatal surface of the mesiobuccal root. In such situations the palatal root remains as the only candidate for retention (Fig. 40-26).

The series of images presented in Fig. 40-27 demonstrates two left maxillary molars (teeth 26 and 27) with class III involvement of all six furcation entrances. Both teeth were, following a detailed examination and diagnosis, scheduled for treatment with RSR. Note that in this case the second premolar was missing. In cases of advanced periodontal disease at maxillary molars, it is often necessary to separate all three roots of the individual tooth to obtain access to the inter-radicular area for assessment of the height of the remaining bone at (1) the buccal surface of the palatal root and (2) the palatal surfaces of the buccal roots. Figure 40-27b shows the two maxillary molars with all six roots separated. Because of anatomic considerations and increased mobility, the distobuccal roots of teeth 26 and 27 were extracted (Fig. 40-27c). The palatal root of the first molar had a deep area of localized attachment loss on its buccal surface, was considered to be a poor candidate for a bridge abutment, and was extracted. The mesiobuccal root of the first molar as well as the mesiobuccal and palatal roots of the second molar (tooth 27) were stable and exhibited moderate probing depth. It was anticipated that at all three roots the anatomy would allow proper plaque control following healing after treatment. The three roots were maintained (Fig. 40-27d). Figure 40-27e shows the area after 3 months of healing and Fig. 40-27f illustrates the segment properly restored. Since in this segment one premolar was missing, the mesiobuccal root of the first molar was used as second premolar in the prosthetic reconstruction and the two roots of the second molar served as abutments for a crown restoration in the position of a molar.

Maxillary premolars

Root resection of maxillary first premolars is possible only in rare instances due to the anatomy of the root complex (Joseph *et al*. 1996) (Fig. 40-28). The furcation of this premolar is often located at such an apical level that the maintenance of one root serves no meaningful purpose. In most cases, therefore, the presence of a deep furcation involvement of class II or class III in a maxillary first premolar calls for tooth extraction.

Mandibular molars

If RSR must be applied in a furcation-involved mandibular molar, three treatment alternatives exist:

1. Separate the two roots, but maintain both roots (premolarization)
2. Separate and extract the mesial root
3. Separate and extract the distal root.

In some situations, both roots may be maintained following separation. If one root is to be removed, the following facts must be considered:

- The *mesial root* has a significantly greater root surface area than the distal root. The mesial root, however, has an hour-glass–shaped cross-section which may be difficult to manage in self-performed plaque control and in the restorative procedure. In addition, the mesial root frequently has two narrow root canals. The root canals are often close to the external root surface. This may complicate root preparation during the subsequent restorative treatment.
- The *distal root* has an oval cross-section and, as a rule, only one, wide root canal. The distal root is comparatively large, providing a greater mass of dentin to resist root fracture (Langer *et al*. 1981); and a good candidate for pin or post placement. Further, when the resected mandibular molar is a terminal abutment for a bridge, the retention of the distal root will result in a longer dental arch than would be the case had the mesial root been retained (Fig. 40-29).

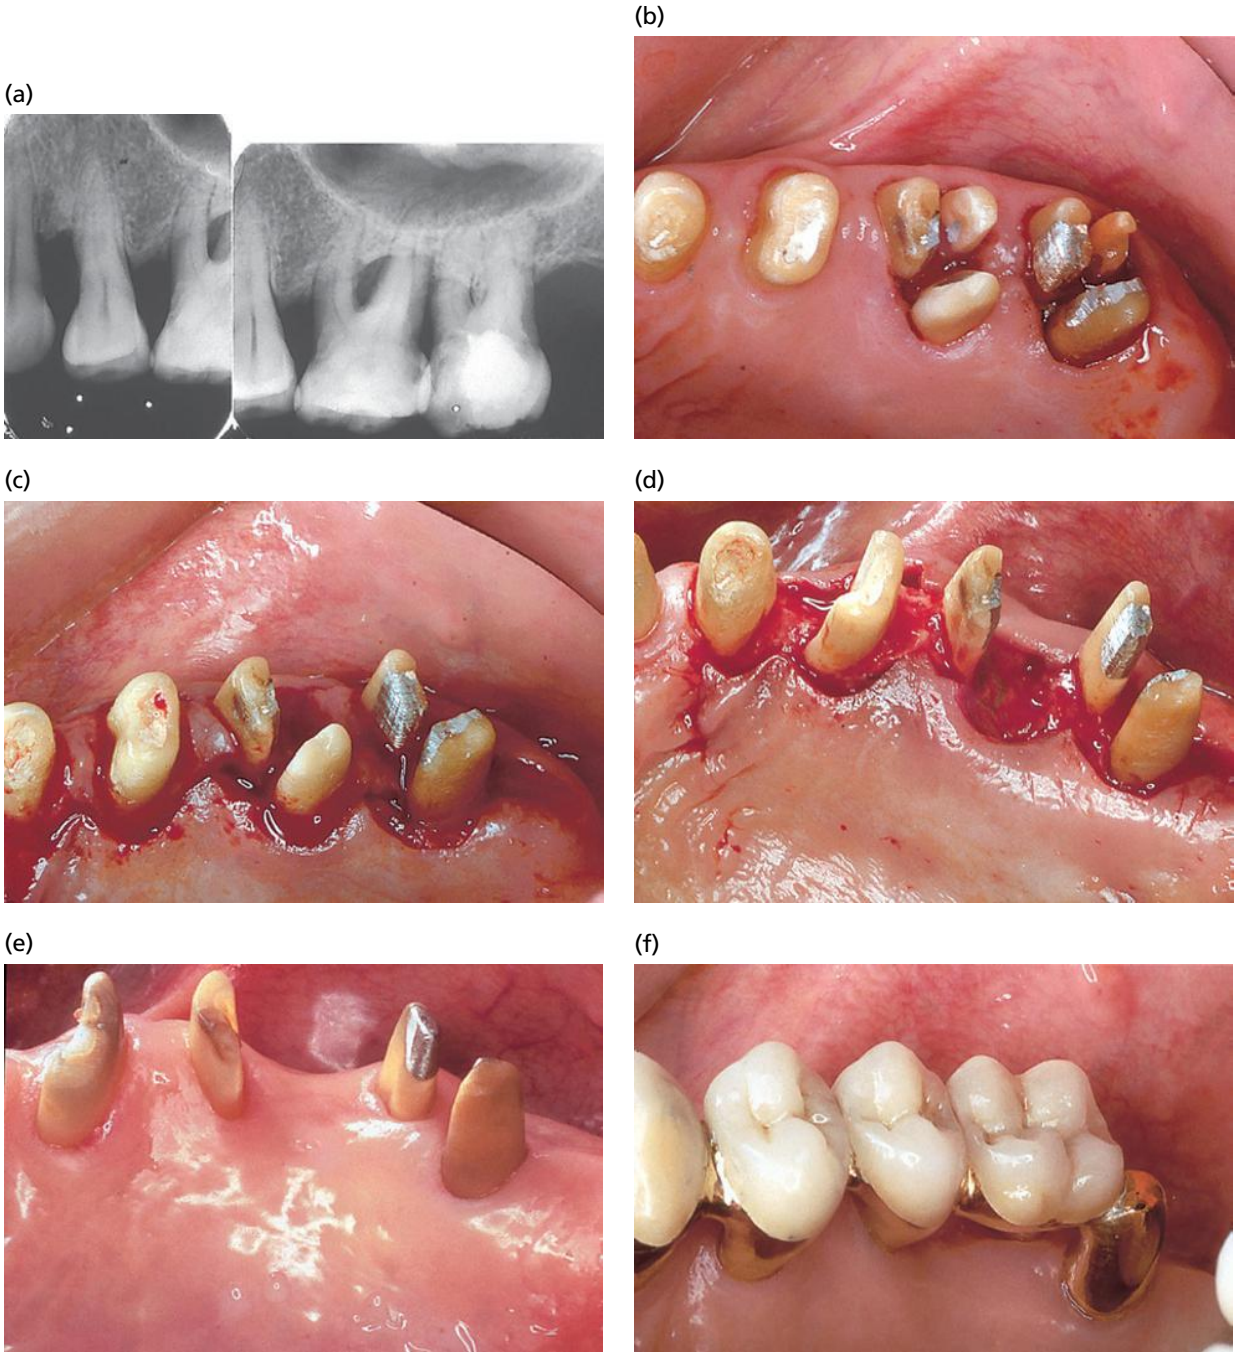

Fig. 40-27 Sequential stages of root separation and resection (RSR) of two maxillary molars with class III involvement. (a) Radiograph showing the pre-RSR situation; (b) roots were separated before flap elevation (c, d) distal roots of both molars and the palatal root of the first molar were extracted and the teeth prepared; (e) after 3 months of healing; (f) final prosthetic restoration of the site.

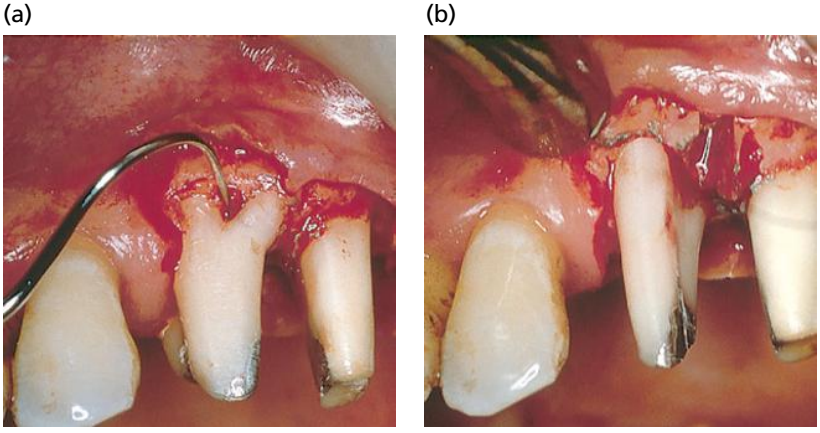

Fig. 40-28 (a, b) Resection of the distobuccal root of a three-rooted maxillary first premolar.

Sequence of treatment

Once anatomic and pathologic characteristics of the root complex(es) of multirooted teeth have been documented, treatment should follow a logical plan (see also Chapter 32).

Endodontic treatment

If the tooth to be resected is vital or if an improper root canal filling was placed in a non-vital tooth, RSR starts with endodontic therapy. A rubber dam can be placed, and optimal conditions thus be established for the important management (cleaning and shaping) of the root canal. The structural integrity of the root must be maintained and minimal amounts of root dentin should be removed (Fig. 40-30a, b). Direct filling with amalgam or chemically-cured composite of the endodontically treated tooth should be performed before RSR (Fig. 40-30c). Each root should have individual retention for a restoration which should not break or detach during RSR, removal and relining of the provisional restorations, impressions, and prosthetic try-in. Endocanal posts or endodontic screws are used only if natural retention needs improvement.

Occasionally, a furcation involvement may first be identified during periodontal surgery. In this emergency situation, RSR may be completed but the root canal entrance(s) of the remaining root(s) must be properly sealed. Definitive root canal therapy must be completed within 2 weeks (Smukler & Tagger 1976).

Fig. 40-29 Results of the root resection of a mandibular first molar of which the distal root was retained.

Provisional restoration

Alginate impressions of the area to be treated are taken and sent to the laboratory together with a wax record of the intercuspal position. A provisional restoration is prepared.

Root separation and resection

RSR may be performed as part of the preparation of the segment for prosthetic rehabilitation ("prosthetic preparation"), that is prior to periodontal surgery (Carnevale *et al*. 1981). During the prosthetic preparation it is important to avoid:

- Exposing the inter-radicular bone to undue mechanical trauma (Fig. 40-31)
- Leaving behind parts of the furcation fornix (Fig. 40-32)
- Perforating the root canals
- Preparing the vertical surfaces of the remaining roots with sharp angles (Fig. 40-33).

Situation 1: Mandibular molar. Following separation, both roots are maintained. The distal surface of the distal root and the mesial surface of the mesial root must be prepared parallel to each other to increase the retention for a subsequent restoration. The mesial surface of the distal root and the distal surface of the mesial root should be prepared with diverging angles to increase the space available between the separated roots (Fig. 40-34).

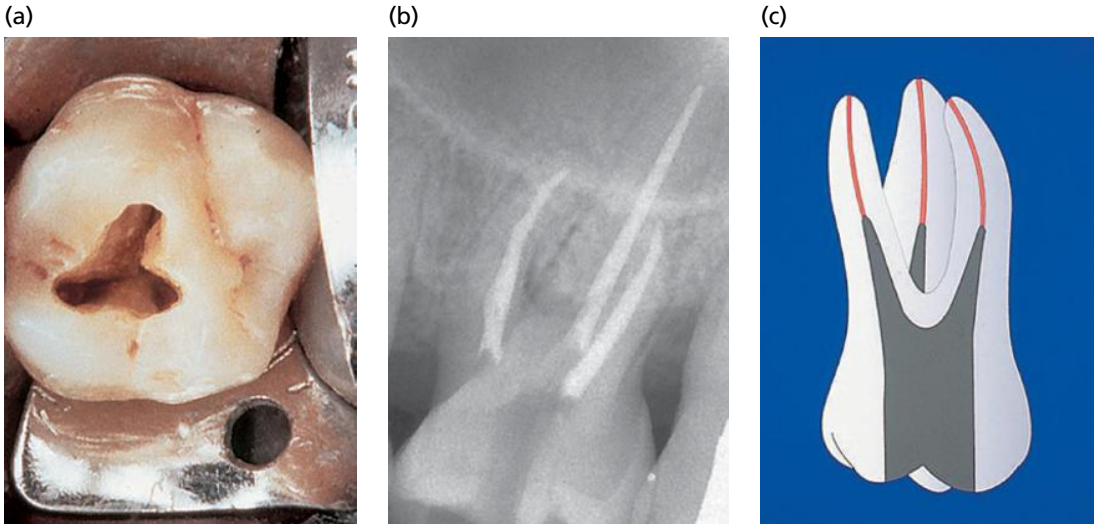

Fig. 40-30 (a) Photograph and (b) radiograph showing the "conservative" approach both regarding the access to the pulp chamber (a) and the shaping and filling of the root canal system (b). (c) Schematic illustration showing the temporary restoration of the endodontically treated tooth.

Situation 2: Maxillary molar. Following separation, the distobuccal root is extracted. The distal surface of the crown is prepared with a bevel cut and in such a way that the concave curvature (in the apicocoronal direction) is eliminated (Fig. 40-35). If the mesiobuccal and the palatal roots of this molar must be separated but maintained, it is important that the buccal surface of the mesiobuccal root and the palatal surface of the palatal root are prepared parallel to each other. This will enhance the retention of the subsequent restoration. The palatal surface of the mesiobuccal root and the buccal surface of the palatal root must be prepared at diverging angles to increase the space available between the separated roots (Fig. 40-36). At this stage the provisional restoration is relined with cold-cured acrylic and cemented after RSR.

Fig. 40-31 Radiograph showing the damage which occurred to the inter-radicular septum during root separation.

Periodontal surgery

Following flap elevation, osseous resective techniques are used to eliminate angular bone defects that may exist around the maintained roots. Bone resection may also be performed to reduce the buccolingual dimension of the alveolar process of the extraction site. The remaining root(s) may be prepared with a bevel cut to the level of the supporting bone (Levine 1972; Ramfjord & Nissle 1974; Carnevale *et al*. 1983). This additional preparation may serve the purposes of eliminating residual soft and hard deposits, and eliminating existing undercuts to facilitate the final impression (Fig. 40-37). The provisional restoration is relined. The margins of the provisional restoration must end ≥3 mm coronal of the bone crest. The soft tissue flaps are secured with sutures at the level of the bone crest. The relined provisional restoration is cemented and a periodontal dressing is applied to cover the surgical area. The dressing and the sutures are removed 1 week later. The roots are debrided and a new dressing applied. After another

(b) During hemisection, an overhang is left behind as a result of an oblique sectioning of the tooth distal to the furcation. (c) In a radiograph obtained 2 years later, the presence of an angular bony defect can be seen adjacent to the "overhang". The lesion was resolved and the angular defect disappeared following removal of the "overhang". (d) Radiograph after 2 years.

Fig. 40-33 Maintenance of the two fused buccal roots of a maxillary first molar. The buccal roots were separated from the palatal root. Note the rounded line angles and the wide space created between the separated roots.

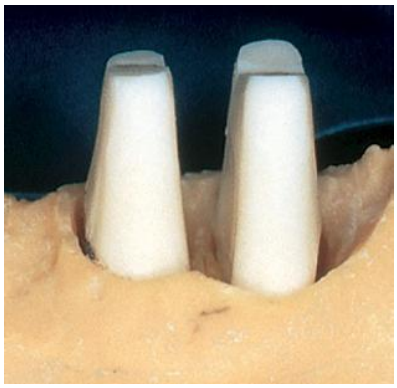

Fig. 40-34 Mandibular molar after root separation. Note the diverging angle of preparation performed to increase the inter-radicular space between the mesial and distal roots and the parallel approximal surfaces.

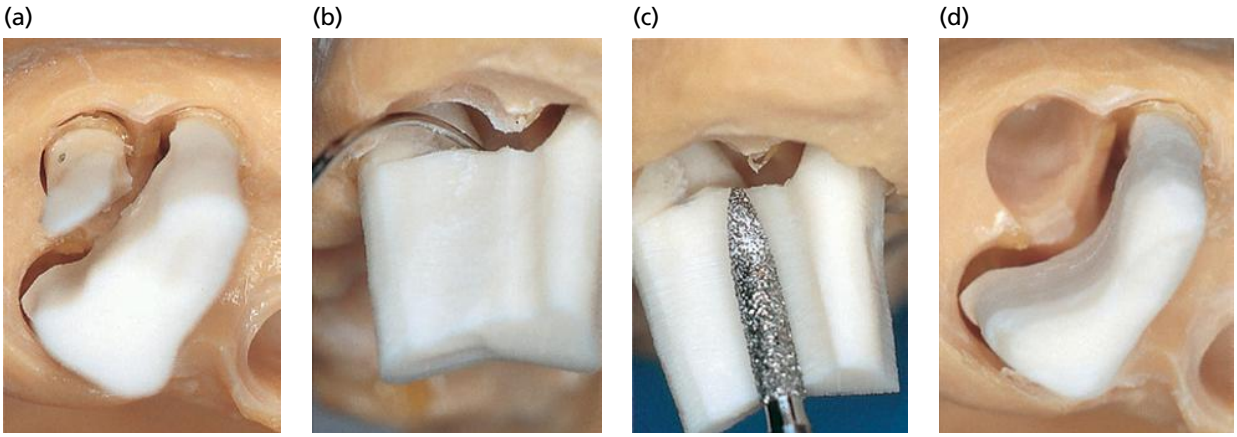

Fig. 40-35 (a, b) Sequential stages of root resection and extraction of the distal root of a maxillary molar. In order to minimize the concave outline of the cut surfaces, the sectioning should be performed with a straight line cut. (c, d) After extraction of the distal root, the furcation area of the remaining roots must be reprepared to eliminate undercuts.

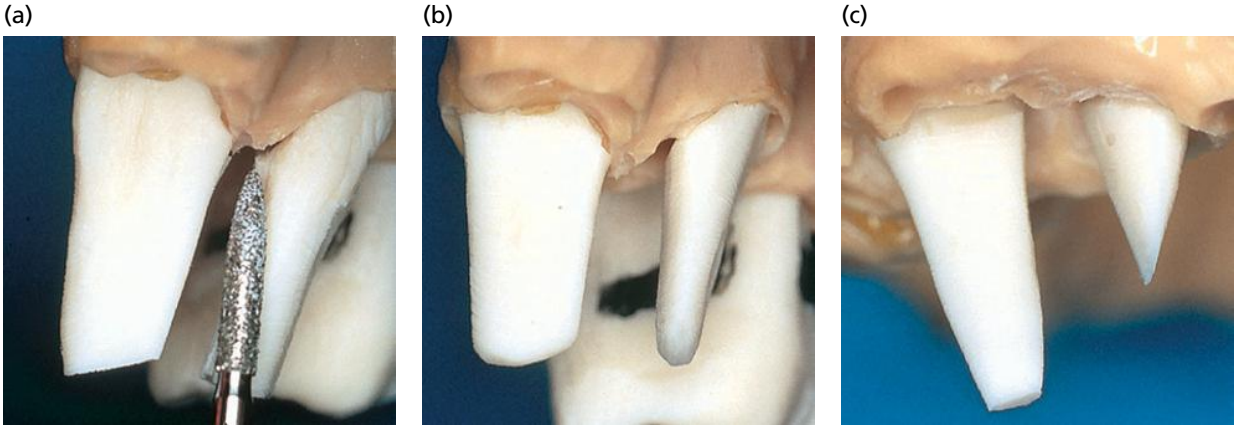

Fig. 40-36 (a, b) Preparation during separation of the mesiobuccal and palatal roots after the distobuccal root of a maxillary molar had been extracted. The internal (furcation) surfaces of the two roots should be prepared with diverging angles to increase the inter-radicular space, while the external surfaces of the two roots should be prepared parallel to each other to increase the subsequent retention of the restoration. (c) When the palatal surface of the palatal root is not prepared parallel to the buccal surface, the palatal abutment will shorten and not be self-retentive.

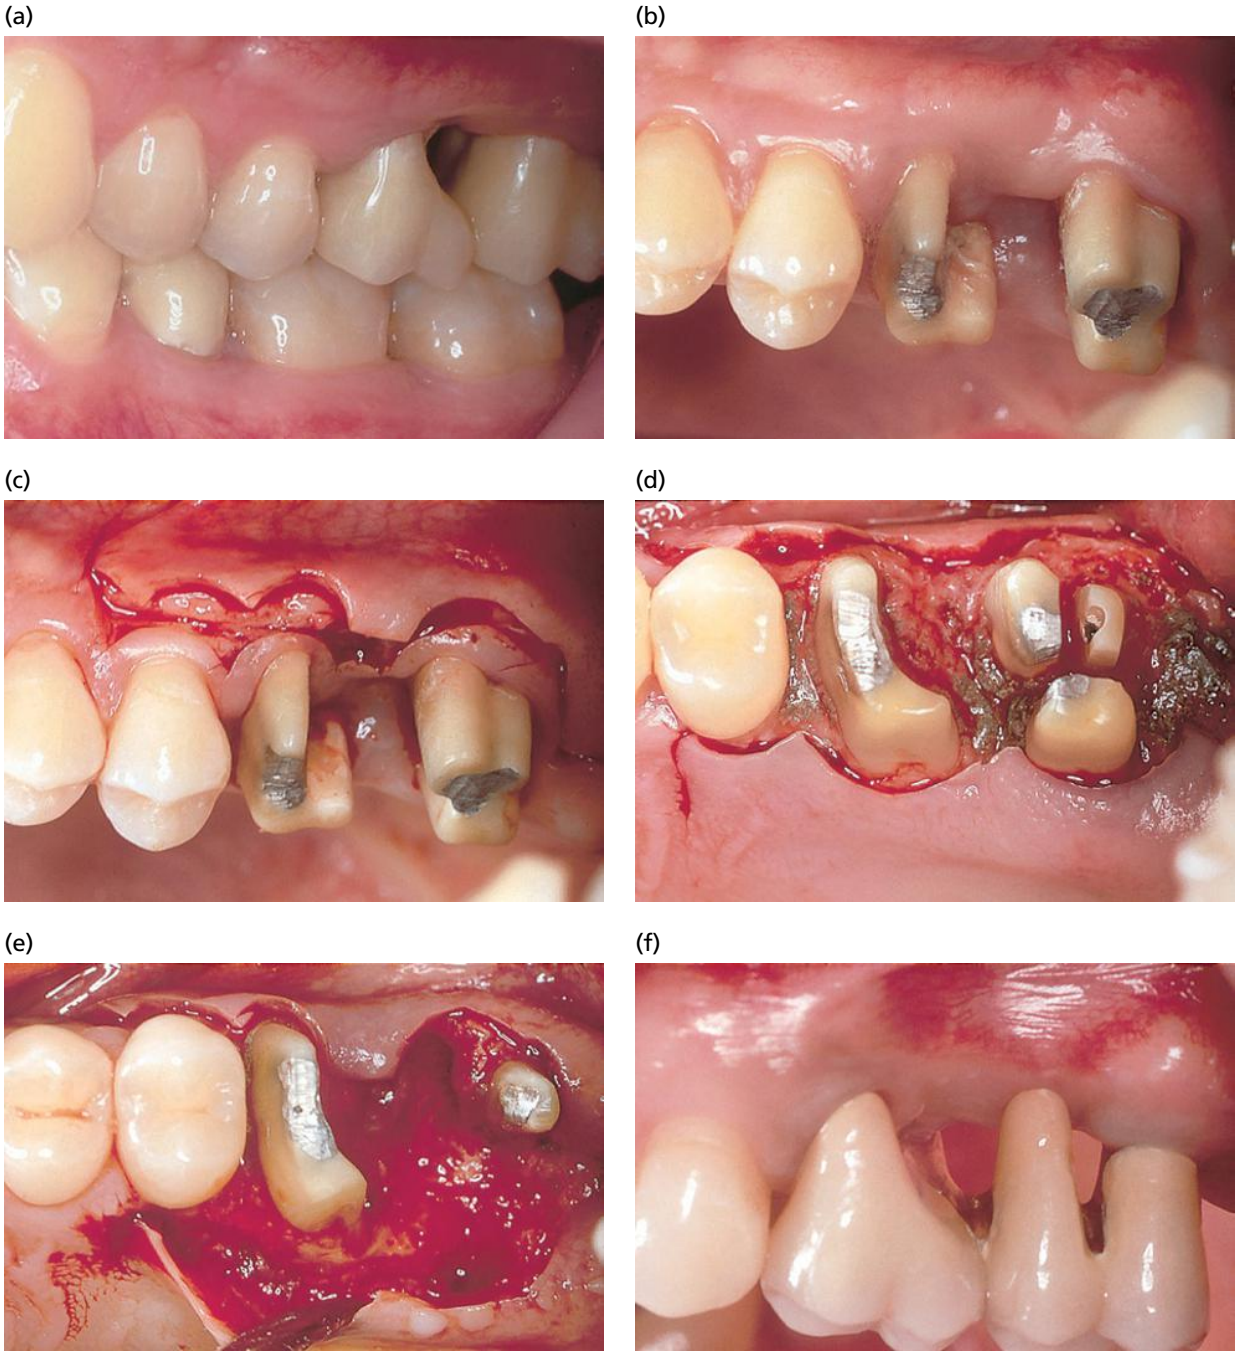

Fig. 40-37 (a, b) Sequential stages of root resection at maxillary first and second molars. The extraction of the distal root of the first molar was performed during tooth preparation and prior to the insertion of the provisional restoration. (c–e) During the surgical procedure, after flap elevation, the furcation-involved second molar was separated, the mesial and palatal roots were extracted, and the osseous defects were eliminated. (f) Healing with the definitive prosthetic restoration in place.

week, the dressing is finally removed and the patient instructed in proper plaque-control techniques.

Final prosthetic restoration

Since the prosthetic preparation of the roots is completed during surgery, the clinician concerns him/herself only with minor adjustments. The preparation margins are located supragingivally, which improves the precision of the definitive crown restoration. The framework of the restoration must be rigid to compensate for the compromised abutments (roots) with a compromised periodontal tissue support. The occlusion should be designed to minimize lateral deflective forces (see Chapter 52) (Fig. 40-38).

Regeneration of furcation defects

The possibility of regenerating and closing a furcation defect has been investigated (see Chapter 45). Following an early case report publication (Gottlow *et al*. 1986), where histologic documentation of new attachment formation in human furcation defects (Fig. 40-39) treated by "guided tissue regeneration" (GTR) therapy was provided, the results of several investigations on this form of

Fig. 40-38 (a) Soft tissue healing at a separated maxillary first molar and at a root-resected second molar. (b) Final prosthetic restoration in place with the occlusion designed to minimize the lateral stresses on the roots left as abutments.

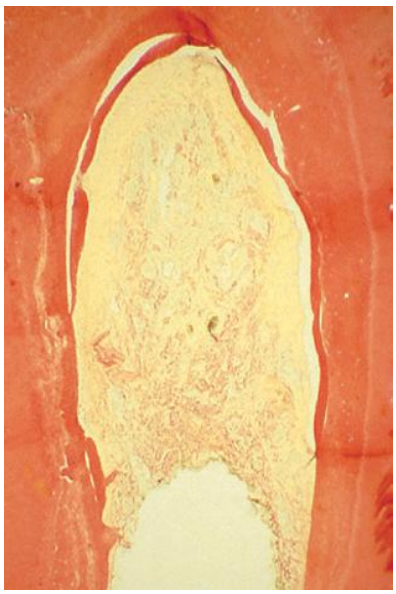

Fig. 40-39 Histologic mesiodistal section of a previous class II furcation involvement of a human mandibular molar, treated with guided tissue regeneration. The section demonstrates that the newly formed cementum covers the entire circumference of the furcation defect.

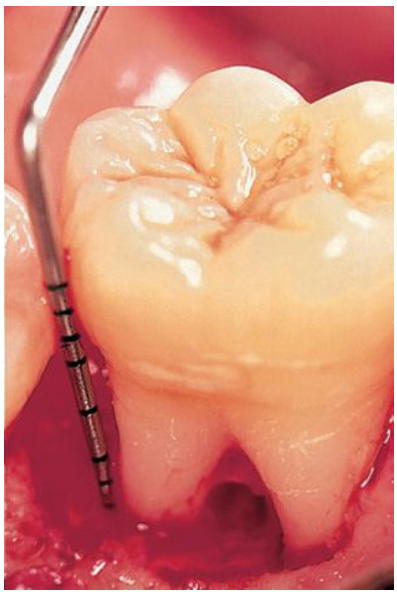

Fig. 40-40 Position of the furcation fornix in relation to the level of the supporting bone and attachment apparatus in a lingual class II furcation-involved mandibular molar.

treatment in furcation-involved teeth have been presented. In these reports, a reasonably predictable outcome of GTR therapy was demonstrated only in class II furcation-involved mandibular molars, where a clinical soft tissue closure or a decreased probing depth of the furcation defect was recorded (Pontoriero *et al.* 1988; Lekovic *et al.* 1989; Caffesse *et al.* 1990). Less favorable results have been reported when GTR therapy was used in other types of furcation defects such as class III furcation-involved mandibular and maxillary molars (Pontoriero *et al.* 1989; Pontoriero & Lindhe 1995a) and class II furcations in maxillary molars (Metzeler *et al.* 1991; Pontoriero & Lindhe 1995b). The reason for the limited predictability of GTR therapy in furcation-involved teeth may be related to several factors:

- Morphology of the periodontal defect, which in the root complex often has the character of a "horizontal lesion". New attachment formation is hence dependent on coronal up-growth of periodontal ligament tissue (Fig. 40-40).
- Anatomy of the furcation, with its complex internal morphology, may prevent proper instrumentation and debridement of the exposed root surface (Fig. 40-41).
- Varying and changing location of the soft tissue margins during the early phase of healing with a possible recession of the flap margin and early exposure of both the membrane material and the fornix of the furcation (Fig. 40-42).

GTR treatment could be considered in dentitions with isolated class II furcation defects in mandibular molars. The predictability of this treatment outcome improves following GTR therapy if:

- The interproximal bone is located at a level which is close to the CEJ of the approximal surface. This "keyhole" type of class II involvement allows for an effective retention of the membrane material and retention also of the position of the coronally placed flap margins (Fig. 40-43).
- The debridement of the exposed root surfaces in the furcation area is comprehensive. Since the width of the furcation entrance and the internal morphology of the inter-radicular area may limit the access of curettes for proper debridement, the removal of hard and soft bacterial deposits from the root surfaces must frequently be done with ultrasonic instruments, rotating, flame-shaped fine diamond burs, and endodontic files (Fig. 40-44).
- The membrane material is properly placed and a "space" between the tooth and the material established. A "primary" wound closure is thereby

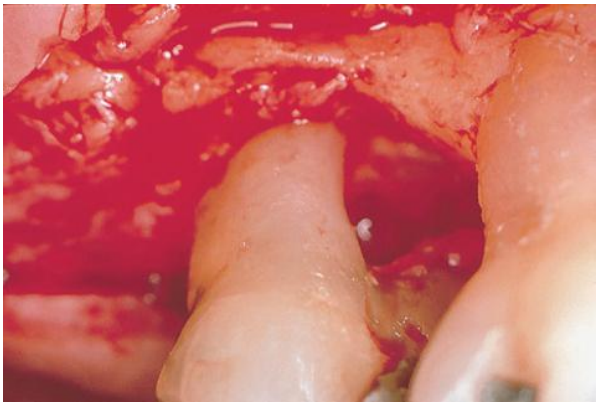

Fig. 40-41 Internal morphology of the furcation of a maxillary molar. Note the invagination of the palatal root.

Fig. 40-42 Exposure of the membrane and of the furcation entrance as a consequence of recession of the flap margin. The photograph is taken at 3 weeks of healing after guided tissue regeneration treatment of a class II buccal furcation of a mandibular molar.

obtained, blood clot protection will occur, and recession of the soft tissue margin during the early phase of healing will be minimized (Fig. 40-45).

- A plaque-control program is put in place. This should include daily rinsing with a chlorhexidine solution and professional tooth cleaning once a week for the first month, and once every 2–3 weeks for at least another 6 months of healing following the surgical procedure.

Enamel matrix proteins included in a commercially available product (Emdogain®; Straumann, Basel, Switzerland) were used in the treatment of furcation defects in experimental studies in animals (Araùjo & Lindhe 1998) and in clinical trials in humans (Jepsen *et al*. 2004; Meyle *et al.* 2004). The ability of Emdogain® (EMD), applied to the root surfaces in the furcation area, to stimulate periodontal regeneration in surgically created class III furcation defects in dogs was documented histologically by Araùjo and Lindhe (1998). In a multicenter randomized controlled clinical trial, including 45 subjects with 45 paired mandibular molars with buccal class II furcation involvements, Jepsen *et al*. (2004) compared EMD with GTR therapy. After 14 months of healing, the subjects were re-examined. The authors reported a mean reduction in the open horizontal furcation depth of 2.8 mm for EMD-treated sites and of 1.8 mm for GTR-treated defects. In addition, the frequency of complete closed furcation defects was higher for EMD sites (8 of 45) than for GTR sites (3 of 45). It was concluded that both treatment modalities resulted in significant clinical improvements although the EMD method provided (1) greater reduction of the furcation depths, (2) a smaller incidence of postoperative pain/swelling, and (3) less gingival recession (Meyle *et al*. 2004) as compared to GTR therapy. The outcome of the regenerative procedures at furcation-involved molars should result in the complete elimination of the defect within the inter-radicular space in order to establish anatomic conditions which facilitate optimal self-performed plaque-control measures. In fact, partial gain of clinical attachment levels within the furcation defect, although statistically significant, will not necessarily improve the site's accessibility for plaque-control measures.

Extraction

The extraction of a furcation-involved tooth must be considered when the attachment loss is so extensive that no root can be maintained or when the treatment will not result in a tooth/gingival anatomy that allows proper self-performed plaque-control measures. Moreover, extraction can be considered as an alternative form of therapy when the maintenance of the affected tooth will not improve the overall treatment plan or when, due to endodontic or caries-related lesions, the preservation of the tooth will represent a risk factor for the long-term prognosis of the overall treatment. The possibility of substituting a furcation-involved tooth with an osseointegrated implant should be considered with extreme caution and only if implant therapy will improve the prognosis of the overall treatment (see Chapter 33). In fact, the implant alternative has obvious anatomic limitations in the maxillary and mandibular molar regions.

Prognosis

Several studies have evaluated the long-term prognosis of multirooted teeth with furcation involvement that were treated in accordance with the principles described in this chapter (Table 40-2). In a 5-year study, Hamp *et al*. (1975) observed the outcome of treatment of 175 teeth with various degrees of furcation involvement in 100 patients. Of the 175 teeth, 32 (18%) were treated by SRP alone, 49 (28%) were subjected, in addition to SRP, to furcation plasty which included odonto- and/or osteo-plasty. In 87 teeth (50%), root resection had been carried out and in seven teeth (4%) a tunnel had been prepared. At the completion of the active phase of therapy, the patients were enrolled in a maintenance program which included a recall visit every 3–6 months. The plaque and gingivitis scores assessed immediately after treatment and once a year during maintenance indicated that the patients' oral hygiene was of high quality. None of the teeth treated was lost during the 5 years of study. Only 16 furcation sites exhibited probing depths exceeding 3 mm. During the observation period, carious lesions were detected in 12 surfaces of the 32 teeth which had been treated by SRP, in three surfaces of the 49 teeth subjected to furcation plasty, in five surfaces of the 78 root-resected teeth, and in four surfaces of the seven teeth where a tunnel was prepared.

The results of this study were basically confirmed in another investigation (Hamp *et al.* 1992). In this 7-year study, the authors followed 100 patients with 182 furcation-involved teeth. Of the 182 furcation-involved teeth, 57 had been treated by SRP alone, 101 were treated by furcation plasty, and 24 were subjected to root resection or hemisection. No tunnel preparation was performed.

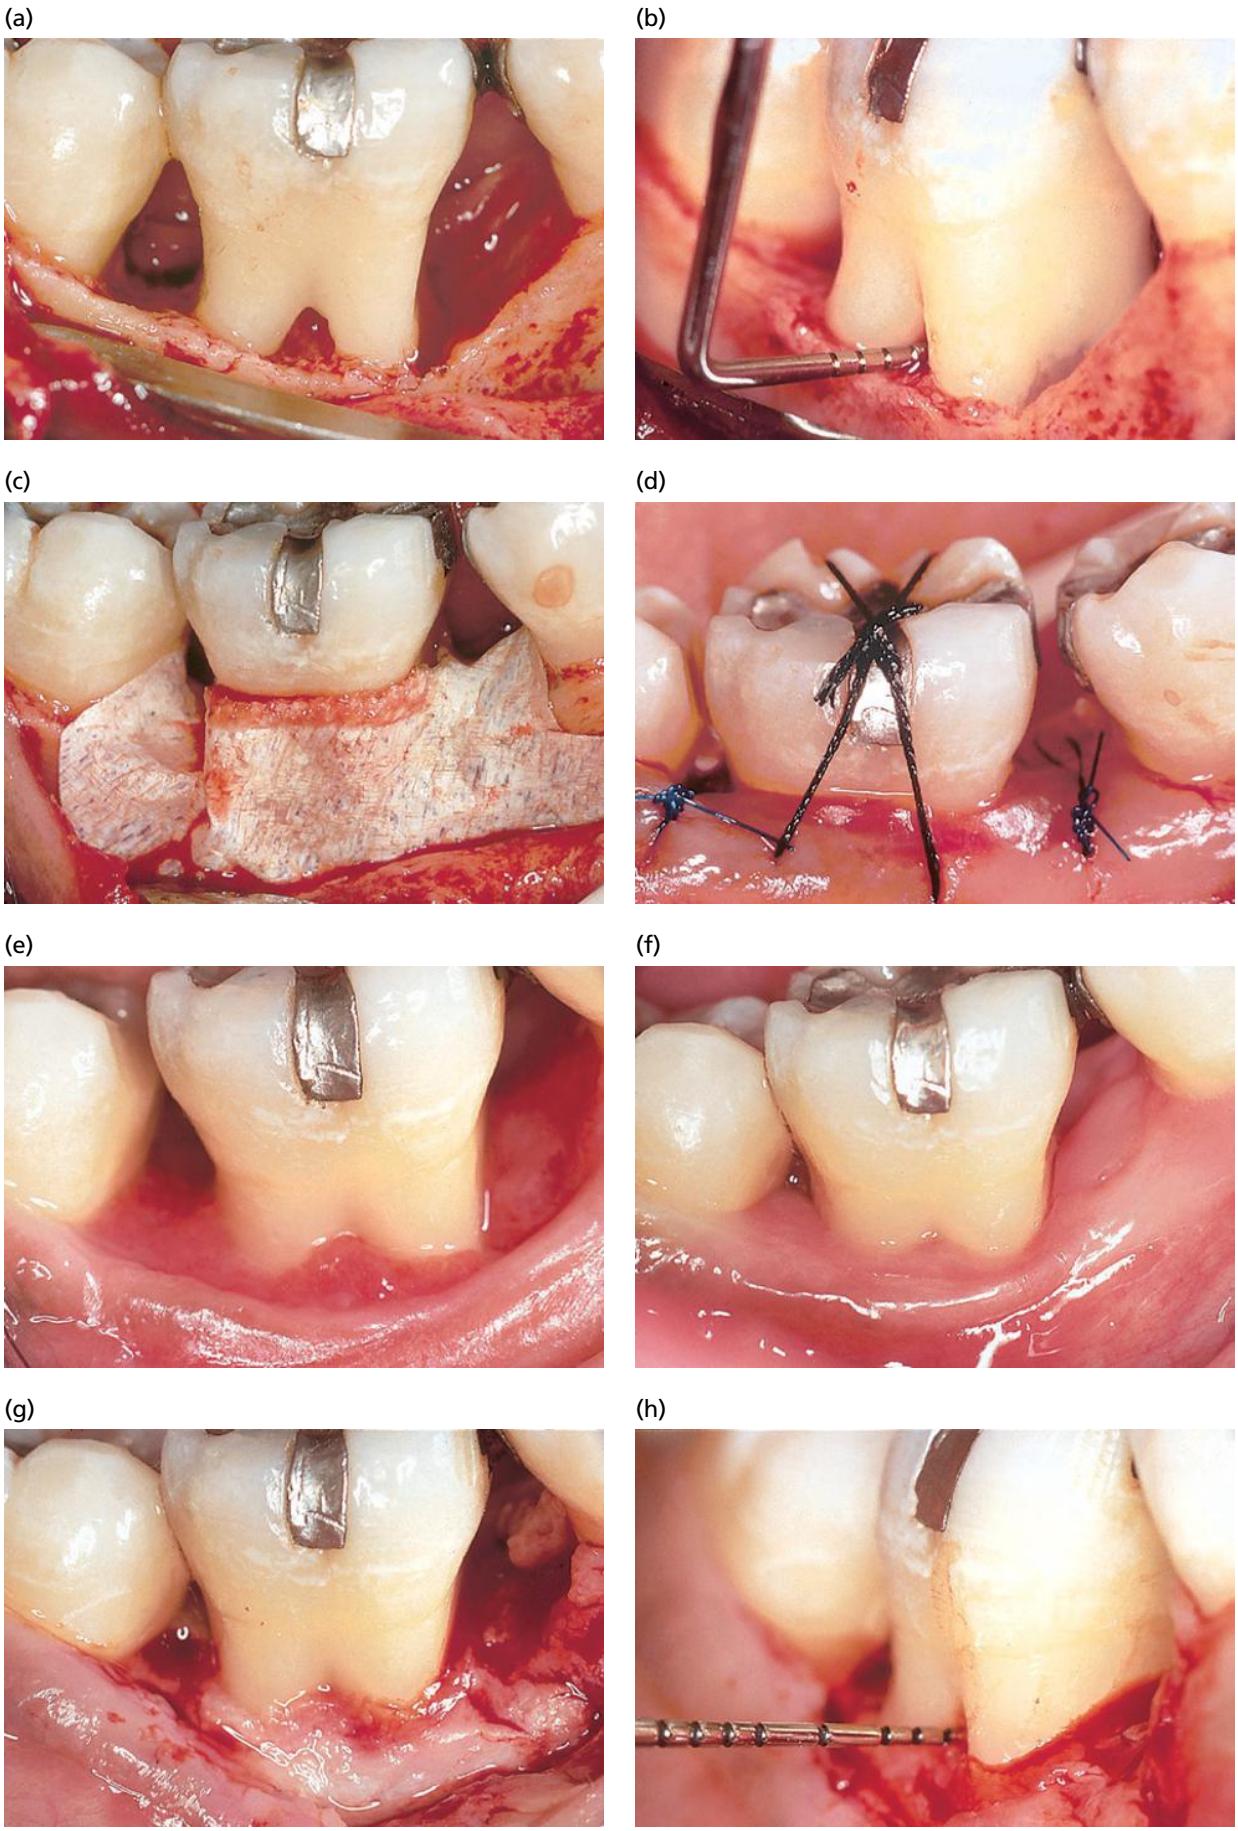

Fig. 40-45 Sequential stages of guided tissue regeneration treatment of a buccal class II furcation-involved mandibular first molar. (a, b) Clinical appearance and horizontal probing of the defect. (c, d) Membrane placement and retention. (e) Clinical aspect of the soft tissue at 4 weeks after membrane removal and (f) after 6 months of healing. During the re-entry procedure the furcation defect appeared completely closed (g) and was not probeable (h).

Table 40-2 Long-term clinical studies on root resection therapy in molars with furcation involvement.

Study	Observation period	No. of teeth examined	Causes of tooth loss					
			% Teeth lost	% Root/ tooth fracture	% Periodontal	% Endodontic	% Caries or decementation	% Strategic
Bergenholtz (1972)	21 teeth/2–5 years 17 teeth/5–10 years	45	6		4	2		
Klavan (1975)	3 years	34	3		3			
Hamp *et al.* (1975)	5 years	87	0

Bühler (1988)	10 years	28	32	3.6	7.1	17.7	3.6	
Carnevale *et al.* (1991)	303 teeth/3–6 years 185 teeth/7–11 years	488	4	1.8	0.4	0.9	0.9	
Basten *et al.* (1996)	2–23 years	49	8			2	4	2
Carnevale *et al.* (1998)	10 years	175	7	1.1	1.8	2.3	1.8	

After the active phase of therapy, the patients were enrolled in a meticulous maintenance care program including recall appointments once every 3–6 months. During the course of the study, >85% of the furcations treated with SRP alone, or in conjunction with furcation plasty, maintained stable conditions or showed signs of improvement. Only one tooth and one mesial root of a mandibular molar were extracted among the root-resected or hemisected teeth.

Carnevale *et al.* (1998), in a 10-year prospective controlled clinical trial, demonstrated a 93% survival rate of root resected furcation-involved teeth and a 99% survival rate of non-furcation-involved teeth.

More recently, Svärdström (2001) presented the results of a retrospective analysis on factors influencing the decision-making process regarding the treatment for 1313 molars with furcation involvement in 222 patients, and the outcome of the treatment decisions after 8–12 years (mean 9.5 years) of regular maintenance care. The treatment options included were: tooth extraction, root separation/resection, and maintenance of the tooth with non-surgically/surgically performed SRP with or without furcation plasty. Of the 1313 furcation-involved molars, 366 (28%) were extracted during the active phase of therapy. The decision for tooth extraction was primarily influenced by factors such as tooth mobility, tooth position, absence of occlusal antagonism, degree of furcation involvement, probing depth, and amount of remaining periodontal support. Of the 685 molars with furcation involvement and the 160 patients who were available for the follow-up examination 8–12 years after treatment, 47 teeth were root separated/resected and 638 teeth were considered to be maintainable after a non-surgical or conservative surgical therapy.

The factor found to have the strongest influence on the decision to perform root separation/resection was the degree of furcation involvement (classes II and III). Tooth position, probing depth, and tooth mobility were also factors of statistical significance. The author indicated that other factors such as endodontic conditions, root anatomy, and overall treatment strategy may also have influenced the choice of treatment. The long-term outcome of the treatment decisions made for furcation-involved molars showed a favorable survival rate for both root resective (89%) and non-resective (96%) therapy options in patients included in a proper maintenance care program. Of the 47 root-separated/resected teeth, only five (11%) were lost during the 9.5 years of follow-up. Of the 638 molars initially considered to be maintainable by a non-resective treatment, 21 (3.5%) were extracted and three were root resected.

Recently, Huynh-Ba *et al.* (2009) published a systematic review of articles reporting the results of different periodontal treatment modalities in multirooted teeth with furcation involvement of various degrees. The authors selected 22 publications where it was possible to determine both the survival rate and the incidence of complications in furcation-involved teeth after a

mean period of at least 5 years of observation following active periodontal therapy. The reported treatment modalities ranged from non-surgical and surgical debridement, furcation tunnel preparation, hemisection, root resection, and regenerative procedures. Reported tooth survival rates by procedure were:

- *Non-surgical furcation therapy*: 90.7–100% at the end of the observation period of 5–12 years. Tooth survival in molars with class I furcation defects (74% of the analyzed teeth at the beginning of the study) was 99– 100%; in molars with class II furcation defects it was 95% and in class III furcation defects it was 25%.
- *Surgical furcation therapy* (i.e. flap with or without osseous resection, gingivectomy/gingivoplasty, but not including furcation odontoplasty): 43.1–96% at the end of an observation period of 5–53 years.
- *Tunnel preparation* of the furcation: 42.9–92.9% after 5–8 years of observation. Carious lesions were a reported complication.
- *Surgical resective therapy* (i.e. root resection or root separation): 62–100% after an observation period of 5–13 years. Reported complications were mainly root fractures and endodontic failures.
- *Surgical regenerative therapy* (i.e. GTR, bone grafts): 62–100% after a period of 5–12 years. However, despite a horizontal furcation depth reduction in most of the cases following treatment, a complete furcation closure was not a consistent finding, especially in severely involved mandibular and maxillary molars.

Table 40-3 Factors to consider in treatment of furcation-involved molars.

Tooth-related factors	Patient-related factors
Degree of furcation involvement	Strategic value of the tooth in relation to the overall plan
Amount of remaining periodontal support	Patient's functional and esthetic demands
Probing depth	Patient's age and health conditions
Tooth mobility	Oral hygiene capacity
Endodontic conditions and root/root–canal anatomy	
Available sound tooth substance	
Tooth position and occlusal antagonisms	

The authors concluded that since no form of treatment performed in the various studies clearly demonstrated superiority over any of the others in terms of tooth survival, guidelines and therapeutic decisions could not be recommended based on this review.

Conclusion

In treatment decisions for furcation-involved molars (Table 40-3), it must be realized that there is no scientific evidence that any given treatment modality is superior to the others.

Introduction

Inflammatory lesions of the attachment apparatus of teeth involve a variety of etiologies other than plaque accumulations in the dentogingival region; these require attention in diagnosis and treatment planning processes. In fact, signs and symptoms seen as typical of periodontitis, such as pocket probing depths, loss of attachment, increased tooth mobility, pain, swellings, and suppurations, may reflect several tooth-associated infections, including infections of endodontic origin (here termed endodontic lesions), infections initiated and maintained by iatrogenic root perforations, vertical root fractures, or root surface resorptions. It should be recognized that microorganisms located in niches other than the gingival sulcus trigger the host reaction in these conditions.

The differential diagnosis of inflammatory conditions of the periodontium is not normally a thorny exercise. This is because symptoms of periodontitis usually affect several teeth in the dentition and are confined to the marginal periodontium. Other tooth-associated infections, by contrast, are usually isolated to a single tooth and display rather typical clinical symptoms and radiographic signs. These conditions can nevertheless produce confusing clinical expressions and lead to misinterpretation of their cause, especially when affecting teeth in dentitions diseased by periodontitis. Diagnostic difficulties arise particularly when lesions appear deep in the lateral aspects of roots in what can be a marginal–apical communication. These lesions present the clinician with exceptional challenges in that the origin and thus the proper course of treatment are not readily revealed. Often the term "endo–perio lesion" is used in this context, as both the pulp and the periodontium may be diseased simultaneously but form what appears to be a single periodontal lesion. Yet, the process may be

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

of periodontal origin in its entirety or the lesion may just be a representation of a root canal infection alone. Hence, determination of causality is crucial in these cases not only to avoid unnecessary and possibly detrimental treatment, but also to assess whether the disease condition stands a reasonable chance of being successfully treated.

To guide clinical decision-making on diagnosis and treatment of inflammatory lesions in the periodontium, the focus of this chapter is on various tooth-associated disorders that display similar signs and symptoms to periodontitis. Specifically addressed are the clinical presentations and the means by which endodontic infections and infections associated with root perforations, root fractures, cemental tears, tooth malformations, and cervical invasive root resorptions can be identified and distinguished from manifestations of periodontitis. Management principles will be addressed where appropriate. Non-infectious processes *viz.* developmental cysts and tumors, which also can interfere with the supporting tissues, will not be discussed in this chapter.

Infectious processes of endodontic origin in the periodontium

General features

Disease conditions of the dental pulp are for the most part infectious in nature and involve inflammatory processes. Caries, restorative procedures, and traumatic injuries are common etiologies (see Chapter 25). In fact, any loss of hard tissue integrity of teeth, exposing dentin or the pulp directly to the oral environment, may allow bacteria and bacterial elements to adversely affect the normally healthy condition of the pulp. The resulting inflammatory lesion will then be directed towards the source of irritation and be confined for as long as the inflammatory defense does not collapse and convert into a major destructive breakdown of the pulpal tissue. Consequently, inflammatory alterations in the vital pulp will not normally produce lesions in the adjoining periodontium that can be detected by clinical means. Yet, disruption of the apical lamina dura or widening of the periodontal ligament space can occasionally be observed radiographically (Fig. 41-1a). Teeth, particularly in young individuals with large pulp chambers, may also display minor radiolucent areas either apically or laterally along the root surface at exits of accessory canals and apical foramina or both, in spite of the fact that vital pulp functions prevail (Langeland 1987; Gesi *et al*. 2006). In such cases, typical clinical signs of pulpitis, including spontaneous pain, thermal sensitivity or tenderness to percussion, may or may not be present.

Overt lesions in the periodontium, on the other hand, are common in teeth where the pulp has lost its vitality. In these cases the process is associated either with a non-treated necrotic pulp or a tooth that has been subjected to endodontic treatment. In both cases, the cause of the lesion is to be found in an existing, in the latter case not successfully managed, root canal infection (Fig. 41-1b). Extrusion of toxic medicaments and root-filling materials into the periodontium in conjunction with endodontic treatments may also cause periodontal lesions. While severe damage to the periodontal tissue support formerly was a rather common complication following the use of arsenic- or formaldehyde-based preparations to devitalize pulps, medicate, and fill root canals (Fig. 41-2), modern day medicaments for canal irrigation and disinfection, as well as materials for root canal filling, are comparatively well tolerated (Geurtsen & Leyhausen 1997). However, severe acute toxic and allergic reactions may be, albeit rarely, encountered from the use of highly

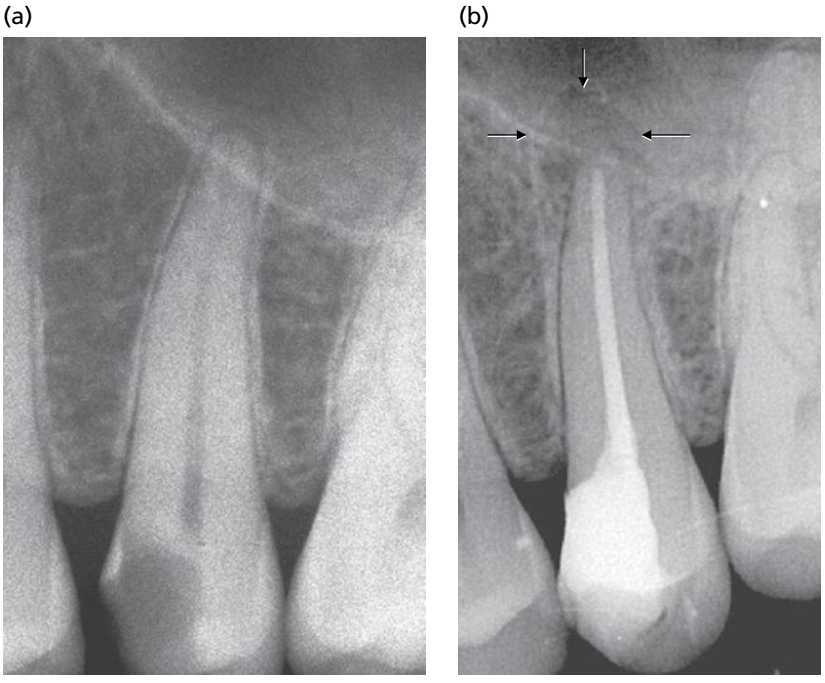

Fig. 41-1 (a) Radiograph of a maxillary second premolar with caries extending to the vicinity of the pulp. There is loss of lamina dura at the root tip. (b) 3-year recall radiograph after pulpectomy of the vital pulp and root filling shows a periapical radiolucency suggesting existence of a persistent root canal infection.

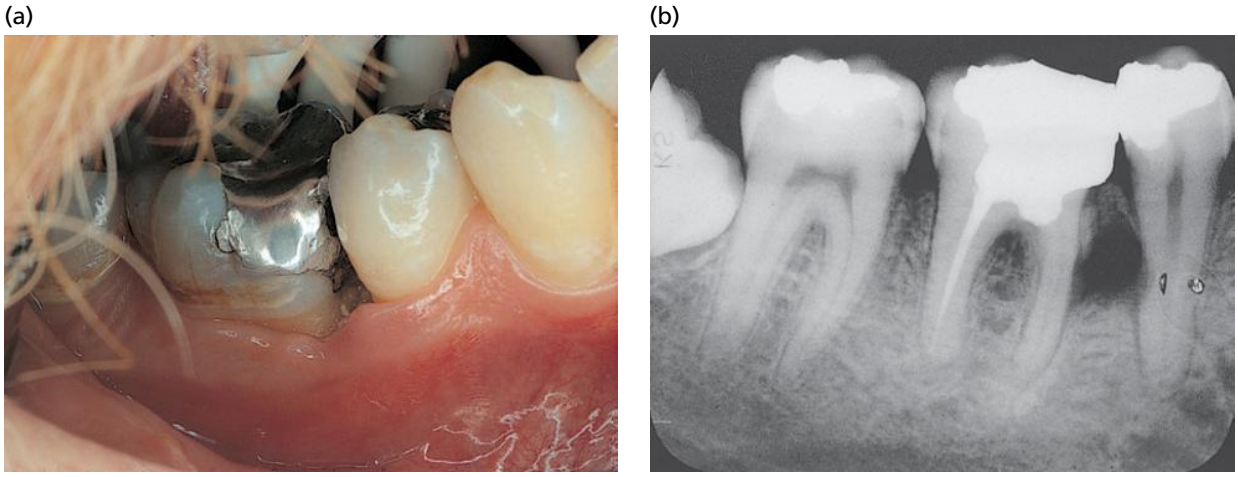

Fig. 41-2 (a) Clinical photograph showing a periodontal defect at the mesial aspect of tooth 46. The pulp had been subjected to devitalization by the use of a paraformaldehyde-containing paste. (b) There is loss of proximal bone and emergence of a bone sequestrum. Leakage of the agent most likely occurred along the margins of the prior temporary filling used between treatment sessions.

concentrated sodium hypochlorite (NaOCl) and adverse components of root-filling material (Swedish Council on Health Technology Assessment 2010).

Conclusion: It is important to realize that as long as the pulp maintains vital functions, even if inflamed or scarred, it is unlikely to produce irritants that cause overt periodontal tissue lesions. For clinically significant periodontal lesions to occur, the pulp must have lost its vitality. Consequently, no benefit will normally be gained from extirpation of vital pulps (pulpectomy) as an adjunct or alternative to the treatment of teeth for periodontal disease.

Clinical presentations

Inflammatory lesions in the periodontal tissues, induced and maintained by root canal infection, typically expand around the apex of teeth, where the root canal space interconnects with the periodontium along apical foramina. Lesions develop more rarely in juxtaposition with the lateral aspects of roots (Fig. 41-3a) and in furcations of multirooted teeth (Fig. 41-4a). An important reason for this is that accessory canals that can mediate the release of bacterial elements from the pulpal chamber to cause discernable lesions clinically are relatively uncommon in cervical and mid-root portions in adult teeth. Many accessory canals are also of a thin diameter (see Chapter 25). Another important factor is that an intact layer of root cementum blocks potential dissemination of bacteria and their products along the dentinal tubules.

The clinical presentation varies. Lesions can either be in a silent, non-symptomatic state or appear with more or less salient signs of acute infection. In the former case, a balanced host–parasite interrelationship has usually been established. The only means to diagnose the condition is then by radiography (see Fig. 41-1b). Unless transformed to a cyst, the extension of such non-symptomatic lesions may remain limited and stable over many years. This applies in particular to lesions associated with root-filled teeth, where the persisting root canal infection has assumed a relatively low grade of metabolic activity (see Chapter 25).

Lesions associated with untreated infections of a necrotic pulp or with inadequately treated root canals by endodontics may, either soon after pulp tissue breakdown or after a period of silence, turn into an exacerbating, acute inflammatory process. Exacerbating lesions may also be induced in conjunction with endodontic treatment from over-instrumentation along with extrusion of bacteria and tissue-irritating medicaments. Exudation and pus production dictate the clinical course. Typical symptoms include throbbing pain, pain on percussion, tenderness to palpation, increased tooth mobility, and apical as well as marginal swellings. The severity of these symptoms may have escalated over a period of time, although a single sign may be the only presenting symptom. It should be noted that the very same symptoms may occasionally occur with some forms of aggressive periodontitis, iatrogenic root perforation, root fracture, malformed teeth, and external root resorption (see below).

The pressure the exudative process exerts results in tissue destruction as a path for drainage is sought. This expansion of the lesion may take a variety of directions. Significant in the context of the differential diagnosis from periodontitis are those lesions that drain off at or near to the gingival margin. The character of the accompanying bone lesion may add to the risk of misdiagnosis, as it may look similar to that of aggressive periodontitis (Figs. 41-5, 41-6).

The following two routes of drainage from a suppurating endodontic lesion should be recognized (Fig. 41-7):

1. Drainage may occur along the periodontal ligament space and exit at the bottom of the sulcus (Fig. 41-7a). This usually results in only a narrow opening of the fistula into the gingival sulcus/pocket and may not be detected unless careful

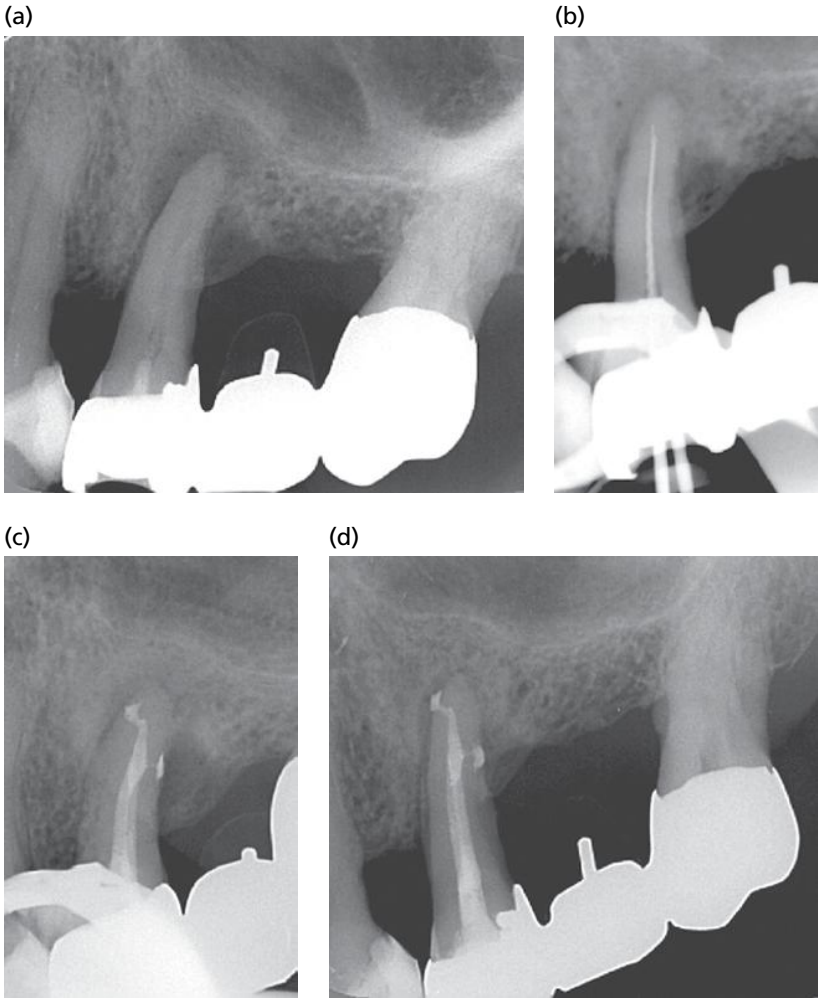

Fig. 41-3 Series of radiographs showing endodontic treatment of a maxillary premolar included as an abutment in a three-unit bridge. The patient, a 78-year-old male, had been treated and maintained for periodontal disease. (a) Bone lesions both at the apical and at the distal aspect of the tooth. Following endodontic treatment of the necrotic pulp (b) and root filling (c), an accessory canal communicating with the lateral lesion became evident. (d) Six-month recall radiograph shows substantial reduction of both bone lesions. (Courtesy of P. Jonasson.)

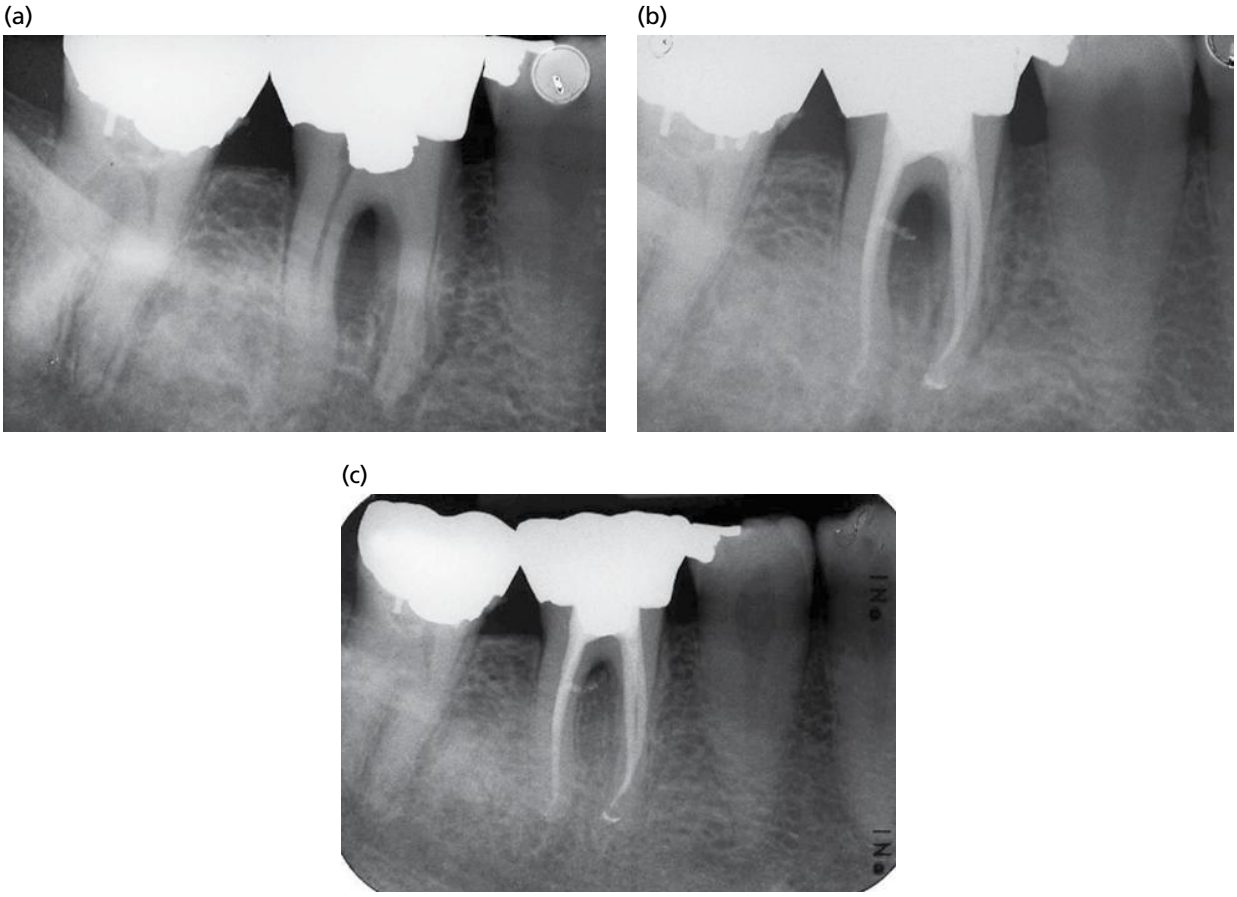

Fig. 41-4 (a) Overt bone loss in the furcal region of a first mandibular left molar with a necrotic pulp. An apical bone lesion can also be seen at the mesial root. (b) Upon root canal filling after endodontic treatment, an accessory canal communicating with the furcal lesion became evident. (c) Eight-month recall radiograph shows a substantially reduced furcal lesion. (Courtesy of A. Gesi.)

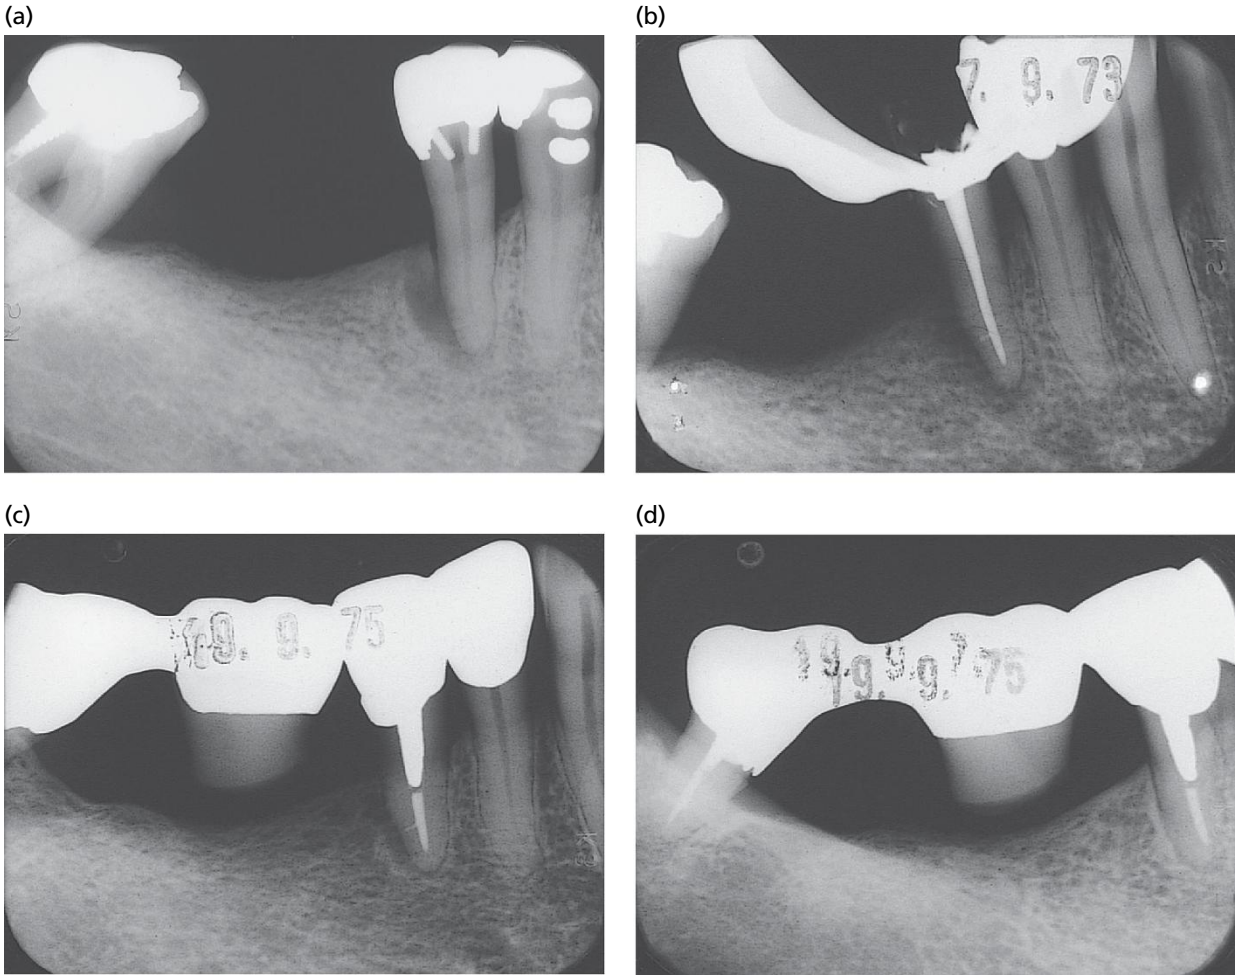

Fig. 41-5 (a) Radiolucent area along the distal root surface of tooth 45 is combined with horizontal loss of marginal bone. (b) Pulp was non-vital and subjected to endodontic treatment. After prosthodontic treatment (c), the 2-year recall radiograph (d) shows bone fill in the previous angular defect. Careful examination of the radiographs in (b) and (c) reveals a filled accessory canal communicating with the lateral bone defect.

probing of the sulcus is carried out at multiple sites. Such a sinus tract may readily be probed down to the apex of the tooth, where no increased probing depth otherwise may exist around the tooth (Fig. 41-8). In multirooted teeth, a sinus tract along the periodontal ligament can drain into the furcation area as it exits along the root surface. The resulting bone lesion may then resemble a "through-and-through" furcation defect from periodontal disease.

2. A periapical abscess can also perforate the cortical bone close to the apex. In this acute stage, the soft tissue, including the periosteum, may be elevated from the bone surface to the extent that a wide opening for drainage of pus is created in the gingival sulcus/pocket area (extraosseous drainage; Fig. 41-7b). Later this route of drainage may develop into a chronic sinus tract that may remain in or near the sulcus, often at the buccal aspect of the involved tooth. Such a fistula may also emerge following a less aggressive process. It is important to note that this type of drainage is not associated with loss of bone tissue at the inner walls of the alveolus, and that a periodontal probe cannot penetrate into the periodontal ligament space.

Conclusion: Endodontic lesions for the most part run without overt clinical signs, but may occasionally present with acute symptoms of root canal infection. The asymptomatic lesions usually assume a limited extension around the apex, while rapid and extensive destruction that may extend marginally along the attachment apparatus may accompany acute exacerbations. Exudation and pus formed in the process may drain off in different directions; pathways along the periodontal ligament space or following penetration of the alveolar bone at the apical region with drainage in or near the gingival sulcus/pocket warrant particular attention from a differential diagnostic point of view. In addition to deep pocket probing depths, the associated bone lesion may mimic that of periodontitis.

Distinguishing lesions of endodontic origin from periodontitis

Pulp vitality testing

Differential diagnosis is important because at times endodontic lesions may produce clinical signs and symptoms similar to those of periodontitis. Tools to

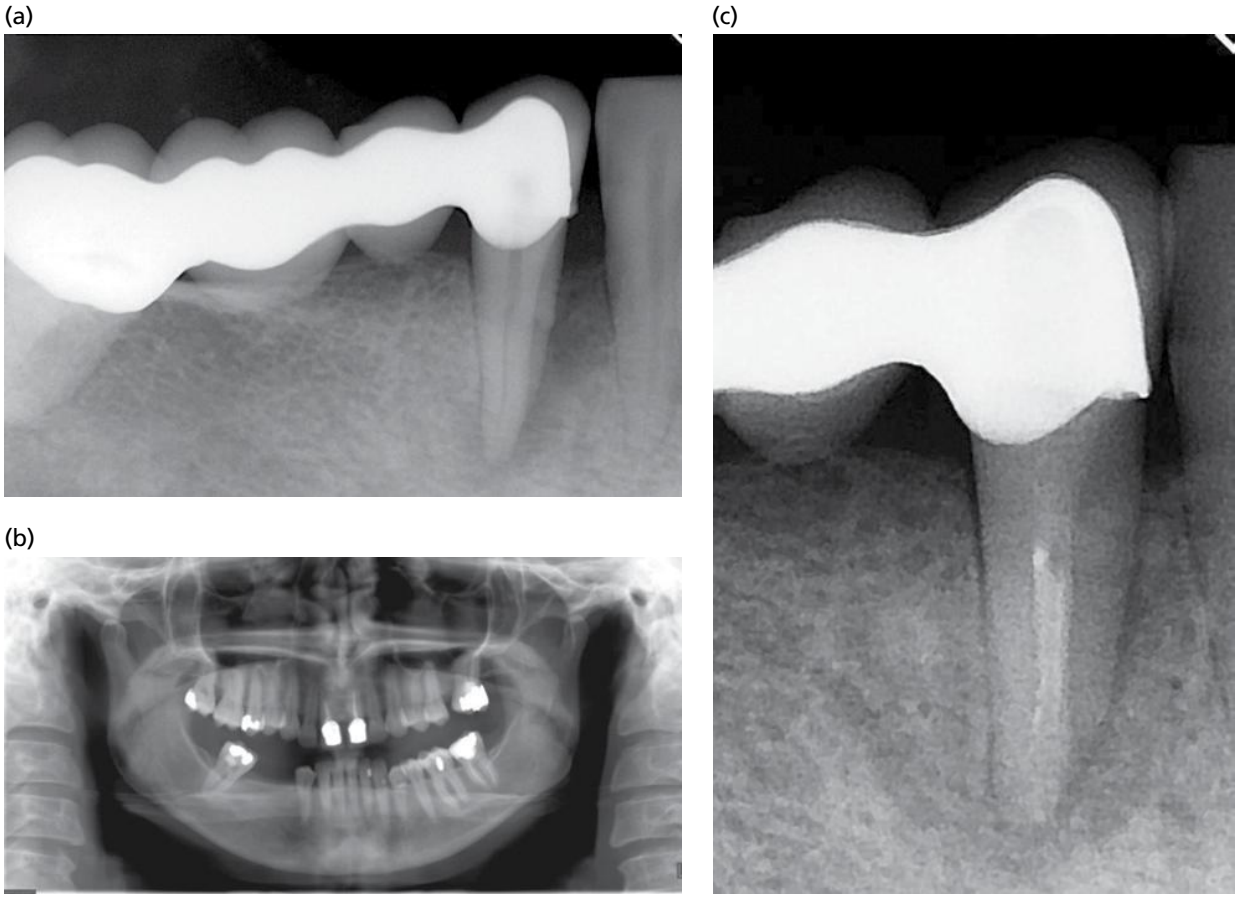

Fig. 41-6 (a) Radiolucency along the mesial aspect of the first mandibular right premolar included in a bridgework 47–44 mimicking an angular bone defect often seen with periodontitis. Prosthetic reconstruction associated with the tooth was severely mobile. (b) Panorex showing normal bone height in the area 8 months prior to prosthodontics. (c) Tooth turned out to have a non-vital pulp. (c) Endodontic treatment followed by calcium hydroxide medication over 5 months resulted in almost complete resolution of the bone defect and substantially reduced tooth mobility.

distinguish the two disease conditions from each other, however, are limited as invariably neither the patient's disease history, nor the clinical presentation, nor the radiographic signs are clear-cut. As an endodontic lesion of clinical significance in this context cannot emerge unless the pulpal tissue has turned necrotic and become infected, determination of pulp vitality is a most important measure in cases where an endodontic etiology is suspected. Endodontic lesions associated with root-filled teeth are discussed separately below.

Pulp vitality implies that the tissue has an intact neurovascular supply to support cell and tissue functions. Although a vital pulp may be inflamed

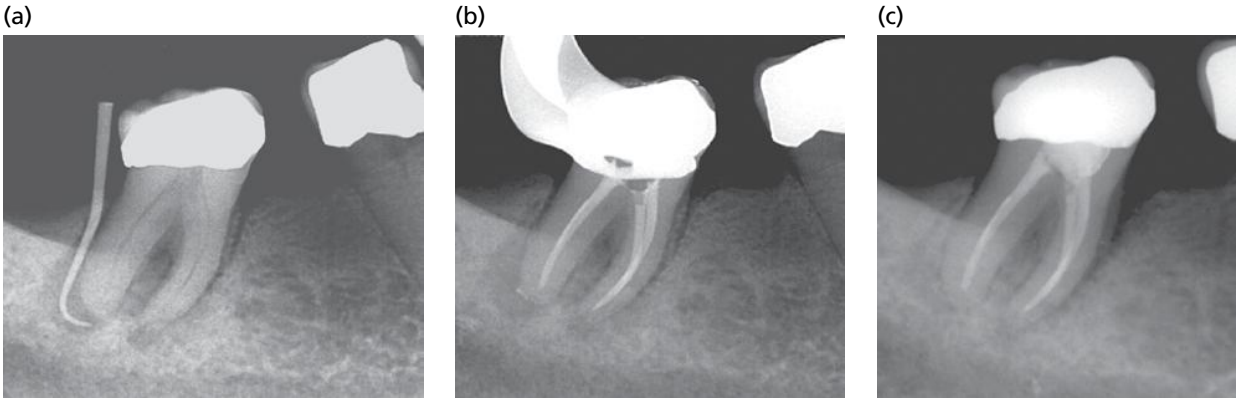

Fig. 41-8 (a) Second mandibular right molar displaying an apical–marginal communication along the distal root surface. The communication was made visible by a gutta-percha point brought into the sulcus. Endodontic treatment (b) resulted in complete resolution of the bone lesions associated with the distal root (c). At an emergency visit 2 years later, the patient complained of pain and tenderness that turned out to be caused by a longitudinal root fracture involving the mesial root. (Courtesy of P. Jonasson.)

or display a variety of degenerative changes, the vasculature is still functioning in a vital pulp. Most methods of determining pulp vitality act by stimulating the pulp's sensory nerve function and presume that the provocation of a sharp pain sensation indicates a vital pulp. This means that in reality the *sensitivity* of the pulp is tested rather than its *vitality*. However, there is ample documentation to support the concept that a tooth that responds to sensory stimuli has vital pulp functions. Conversely, if a tooth does not respond, the pulp may be nonvital (for reviews see Gopikrishna *et al.* 2008; Jafarzadeh & Abbott 2010a, b). Yet, caution should be exercised in interpreting sensitivity tests as findings can reflect both false-positive and false-negative readings (Mumford 1964; Petersson *et al.* 1989; Peters *et al.* 1994; Pitt Ford & Patel 2004; Jafarzadeh & Abbott 2010a, b). A combination of different test methods should therefore be employed to ensure the correct diagnosis, especially in doubtful cases. Also, the equipment and the results should be tested for accuracy by comparing results from tests of neighboring and contralateral teeth. No test that can identify the disease status of the pulp in other terms than vital or nonvital has so far been advanced (Mejàre *et al.* 2012).

Testing non-restored or minimally restored teeth in dentitions affected by periodontitis can usually be successfully conducted by mechanical, thermal, and electric stimulation. Common methods utilize tests to stimulate nociceptive mechanoreceptors at the pulp–dentin border, primarily the fast conducting A-delta fibers. Useful techniques include direction of a jet of compressed air against an exposed root surface, scratching such surfaces, use of a rubber wheel to generate frictional heat, and various cold tests; all are intended to elicit movement of dentinal fluid. Carbon dioxide snow (Fulling & Andreasen 1976) and dichlorodifluoro-methane sprayed on a cotton pellet are highly effective and reliable. The boiling points of these two agents are –72 °C and –50 °C, respectively. For this reason patients should be cautioned prior to application

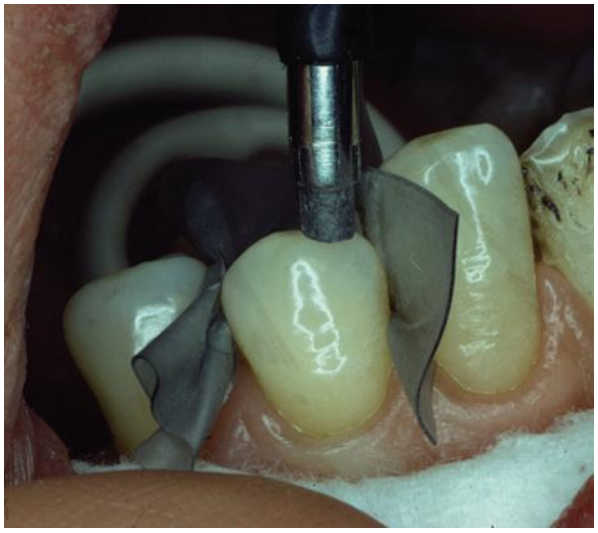

Fig. 41-9 Demonstration of proper tooth isolation to avoid leakage of current during pulp sensitivity testing with an electric pulp tester.

that an intense pain response might be elicited. Clues can also be obtained with less potent means such as ice sticks and ethyl chloride, as well as heated gutta-percha sticks (for review see Pitt-Ford & Patel 2004).

In dubious cases, mechanical and thermal provocation should be supplemented with electric pulp testing. Units are available which provide a read-out value of the voltage or microcurrent being applied to generate the pain response. This function is important so that the test result can be repeated and compared for assessment of patient reliability. Electric pulp testing is technique sensitive and therefore warrants extra precaution to avoid leakage of current to the gingiva and neighboring teeth. To avoid this risk, the test should only be carried out on cleaned and dry teeth isolated from saliva and adjacent teeth with pieces of rubber dam placed in the tooth contacts (Fig. 41-9). The test further requires that the tooth electrode is provided with a good conducting medium and applied directly to the enamel or dentin and not to restoratives.

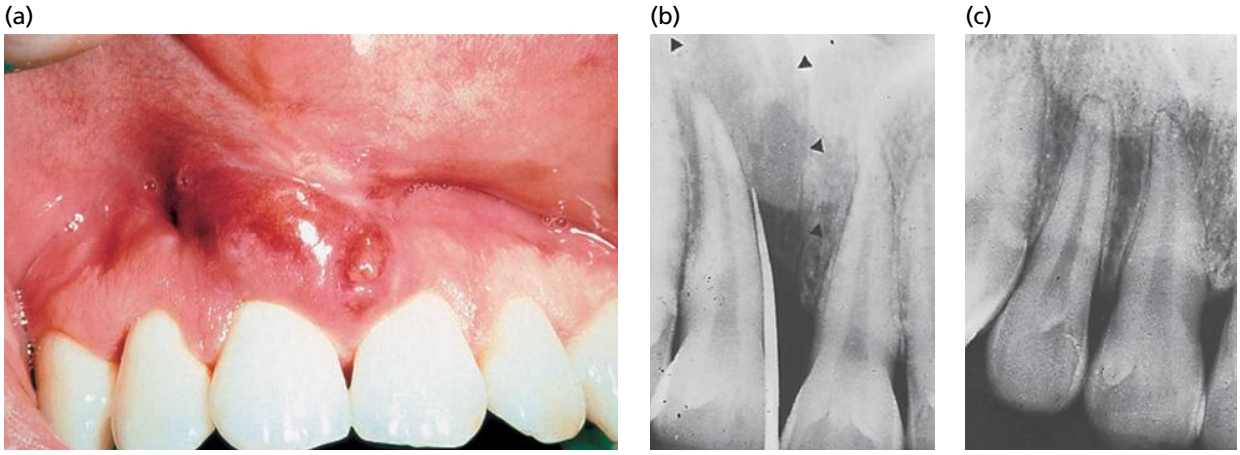

Fig. 41-10 (a) Gingival swelling at the buccal aspect of tooth 11. (b) There is advanced destruction of alveolar bone along the mesial aspect of the root (arrowheads). (c) Following periodontal treatment the bone lesion resolved. (Courtesy of H. Rylander.)

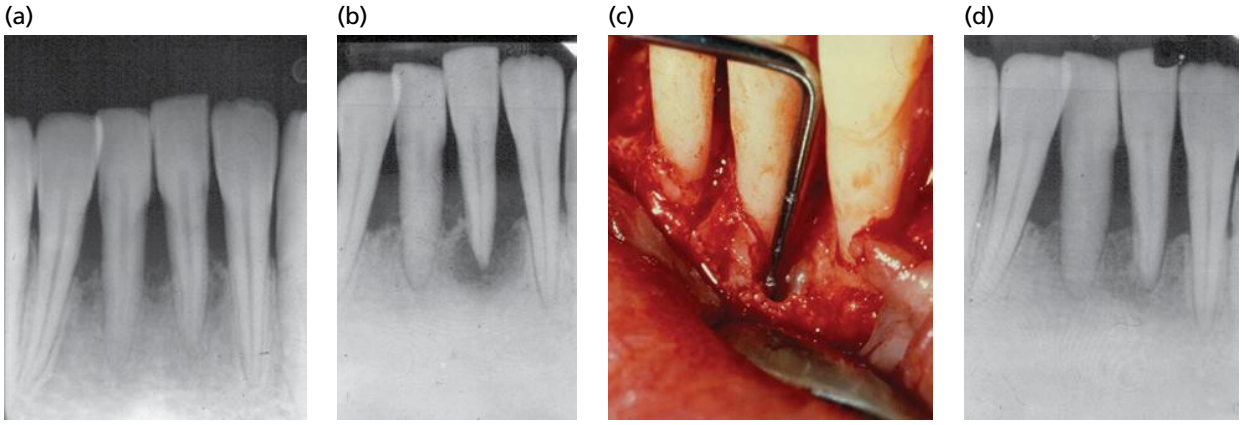

Fig. 41-11 (a) Advanced horizontal loss of alveolar bone in a patient subjected to periodontal therapy. (b, c) In the course of follow-up, a bone defect simulating an endodontic lesion appeared around the root tip of tooth 31. The pulp responded sensitive on testing and the tooth was therefore not subjected to endodontic therapy but to periodontal treatment only (d). For further case history see the text. (Courtesy of I. Magnusson.)

Means to detect blood flow within the pulp by non-invasive methods have been developed and tested. Examples are laser light scattering and pulse oximetry. So far, such methods have gained only limited clinical application.

Cases with extensive restorations and crowned teeth present particular challenges, as none of the normal test procedures is useful. Unless tooth substance can be reached beneath the restoration with a good margin to the gingiva, a test cavity should be prepared to make pulp testing possible. Even then, a false-negative response can be obtained as extensive hard tissue repair may have developed in the pulp from previous disease and cutting traumas, thus attenuating the stimulus.

Three cases are described to illustrate the significance of pulp vitality testing in the process of distinguishing endodontic lesion from periodontitis. The cases demonstrate, in addition, that diagnostic entities such as location, form, and extension of radiolucencies, clinical symptoms of pain or swelling, and increased probing depths may not serve as accurate diagnostic signs.

The clinical photograph in Fig. 41-10a shows swelling of the marginal gingiva on the buccal aspect of tooth 11. Severe throbbing pain had preceded the swelling for a few days. Radiographic examination (Fig. 41-10b) disclosed the presence of an angular bone defect that involved the apical portions of the tooth. In this case the pulp clearly responded on testing, indicating that the pathologic condition was not of endodontic origin. Pocket debridement was combined with irrigation with 0.2% chlorhexidine digluconate solution and systemic administration of an antibiotic. The lesion healed rapidly. Seven months following treatment new bone had formed around the apex and in the defect along the mesial root surface (Fig. 41-10c). Thus, in this case the periodontal lesion was a manifestation of periodontal disease.

In Fig. 41-11a the radiograph of the lower front teeth demonstrates advanced horizontal loss of alveolar bone in a 25-year-old male subjected to periodontal therapy. In the course of the recall program, tooth 31 developed an apical radiolucency (Fig. 41-11b). The form and extension of the lesion suggested an endodontic cause. Clinically, a deep periodontal pocket could be probed along the distobuccal aspect of the root. The gingival conditions after periodontal treatment had been excellent. Sensitivity tests by cold

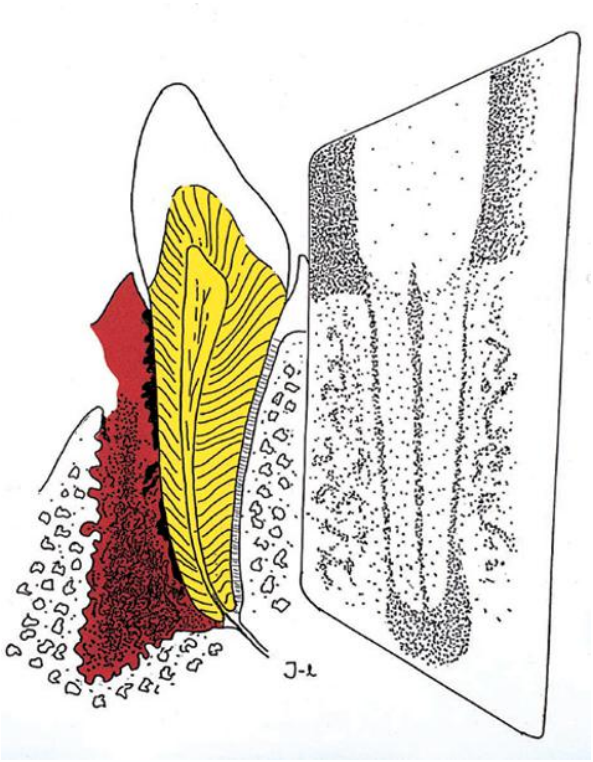

Fig. 41-12 Schematic illustration depicting a potential mechanism for the radiographic lesion in tooth 31 shown in Fig. 41-11. While there was substantial breakdown of alveolar bone, there was no interference of the inflammatory lesion with the neurovascular supply of the pulp. The fact that the bone lesion appeared as an apical radiolucency is explained by the superimposition of the bone loss on the root tip. (Courtesy of M. Jontell.)

and electricity, however, indicated a vital pulp. Therefore, endodontic treatment was not performed. On elevating a mucoperiosteal flap (Fig. 41-11c), an angular bone defect was found at the buccal aspect of the root without involvement of the root tip. The wound area was debrided along with scaling of the root surface. Rapid bone fill followed surgery without undertaking any adjunctive measures to support tissue regeneration (Fig. 41-11d). The pulp maintained its vitality, although later the root canal became obliterated by hard tissue, most likely as a result of ischemic injury in conjunction with the surgical procedure. The apically positioned radiolucency in Fig. 41-11b is explained by superimposition of the loss of alveolar bone buccally to the root tip of tooth 31, which went beyond its most apical level (Fig. 41-12) without interfering with the neurovascular supply of the pulp.

Figure 41-13 shows a clinical case where pulp vitality was difficult to ascertain. A swelling had appeared at the buccal aspect of tooth 46 (Fig. 41-13a) after the patient had experienced pain and tenderness in the area for approximately 1 week. Periodontal probing disclosed a deep facial pocket along the mesial root (Fig. 41-13b). Radiographic examination indicated a lesion that seemed to circumscribe the mesial root with a marginal extension into the furcation (Fig. 41-13c). Frictional heat by drilling, as well as cold and electric tests, failed to give a positive response even in a test cavity preparation. After finding a sensitive and bleeding pulp in the distal root, a necrotic pulp with pus drainage was detected once the mesial root canal orifices were approached, confirming an endodontic cause of the lesion. Endodontic treatment with a temporary intracanal dressing with calcium hydroxide over 3 months resulted in an obvious reduction of the bone lesion (Fig. 41-13d). The gingival lesion resolved with no abnormal pocket probing depth (Fig. 41-13e), although a small bone defect remained in the furcation area (Fig. 41-13d). Treatment was then completed with root canal fillings. The 12-month recall radiograph demonstrates complete resolution of the bone defect (Fig. 41-13f).

Other signs of endodontic lesions

Except for a negative pulp test response, single-tooth lesions in a dentition otherwise free from periodontal disease strongly suggest an endodontic cause, provided other tooth-associated disorders such as external root resorption and root fracture can be excluded. An endodontic etiology should be explored particularly in cases with extensive restoration or a crowned tooth (Figs. 41-4, 41-8, 41-13), bridge abutment (Fig. 41-3, 41-6), caries, a root-filled tooth, and in patients with a history of a previous dental trauma. The character of the pocket probing depth should also be taken into consideration. Endodontic lesions, when extending marginally, usually do not follow more than one root surface and then exit in a rather narrow area of the sulcus. Deep pocket probing depth may also be in an area uncharacteristic of periodontitis, for example at the buccal aspect, when all other sites display normal probing depths.

Conclusion: The clinical presentation and the character of radiographic findings may lead to erroneous diagnosis where an endodontic lesion emerges in a patient with periodontal disease. The recognition of pulp vitality is crucial because clinically significant lesions of endodontic origin rarely develop in teeth with vital but inflamed pulps. The clinician should always be watchful for false leads and consider features normally associated with diseased pulps, such as extensive restoration, previous pulp capping, history of dental trauma, and endodontic treatment.

Endo–perio lesions: Diagnosis and treatment aspects

The potential for an infected, necrotic pulp to cause breakdown of the attachment apparatus with extension into the marginal periodontium has been addressed above, along with the measures to arrive at the diagnosis. Once confirmed, the mode of treatment in this type of case is simple and should involve only conservative root canal therapy.

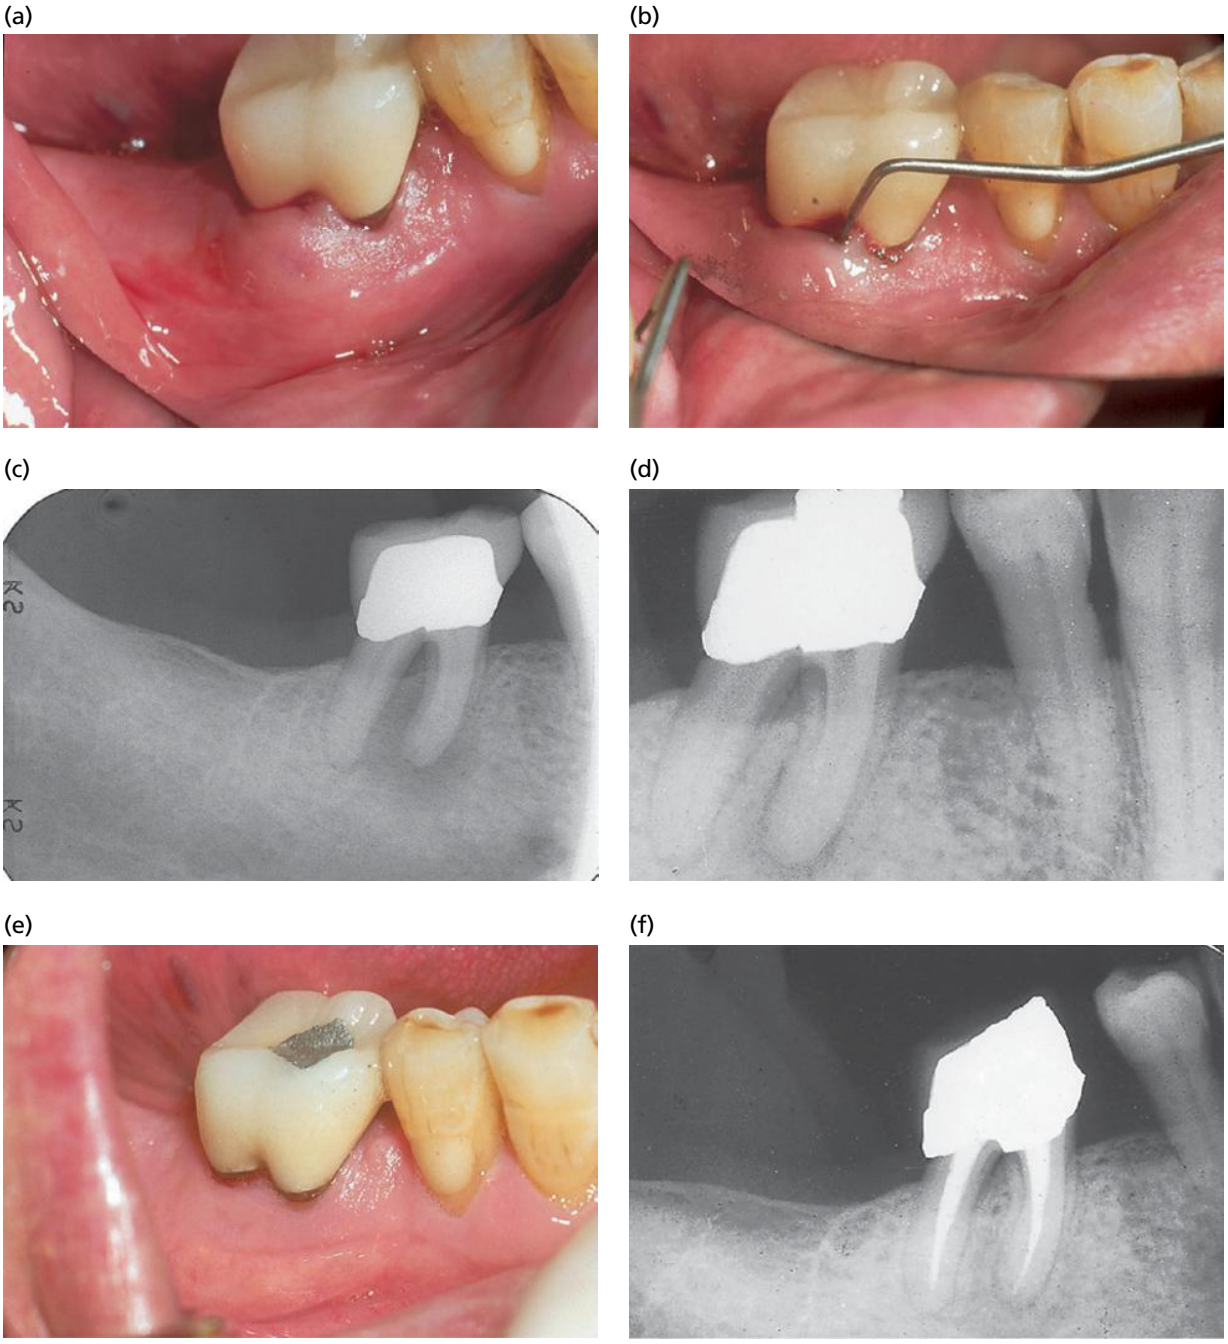

Fig. 41-13 Case with an initially unclear etiology of a facial swelling and deep pocket probing depth that turned out to have an endodontic etiology. The case history is given in the text. Diagnosis and treatment of this case was carried out by one of the authors (G.B.) in collaboration with Dr David Simpson.

Following adequate treatment, directed at elimination of the root canal infection, the lesion should be expected to heal without a persistent periodontal defect (Figs. 41-3, 41-4, 41-5, 41-6, 41-8, 41-13). Adjunctive periodontal therapy will have no treatment effect and would be inappropriate.

A more complex situation arises when a periodontal lesion is sustained by concurrent plaque infection and root canal infection. This kind of lesion is associated with a deep pocket probing depth and a lateral bone defect that extends to the apex (see Fig. 41-8). The problem here is that it is not normally possible to determine how much of the lesion is sustained by which infection. In fact, there are three scenarios: (1) the entire lesion may be a manifestation of a root canal infection alone; (2) the entire lesion may be the result of plaque infection; (3) there are, in fact, two disease processes, one marginal associated with a plaque infection and one apical associated with a root canal infection, but the two soft tissue lesions have merged and there is no longer a clear demarcation zone between the two as a probe easily may penetrate both soft tissue lesions.

Pulp vitality testing only partly settles the diagnostic quandary in this kind of case. Yet, if distinctly positive, one can exclude the contribution of an

Table 41-1 Outline of treatment strategies.

Cause	Condition of the pulp	Treatment
Endodontic	Non-vital	Endodontic
Periodontal	Vital	Periodontal
EndodonticPeriodontal	Non-vital	Endodontic: first observe the result of this therapy and institute periodontal therapy later if necessary

endodontic infection and the process should be subjected to periodontal therapy alone. Taking the pulp out and replacing it with a root filling is then a meaningless and unnecessary treatment effort. In the case of a negative pulp test, death of the pulp may have occurred as a direct result of the periodontal disease process or it may have developed independently as a separate condition. In the former case, prognosis for any other treatment than extraction must be regarded as bleak. A major reason for this is that not only may a substantial portion of the attachment apparatus be lost, but the root surface may be bacterially infected close to the root tip as well. In addition, the infection may have entered the root canal space after the development of pulp necrosis due to severance of the neurovascular supply of the pulp (see Fig. 25-20). Accessing this kind of infection for treatment is therefore a very challenging task with a most questionable outcome.

If a portion of the lesion is sustained by a root canal infection independent of periodontal disease, the potential for periodontal tissue regeneration is much increased. Because it is not possible to know beforehand how far the endodontic lesion has extended along the root, root canal treatment should be attempted first and periodontal treatment postponed until the result of the endodontic treatment can be evaluated. The part of the lesion sustained by root canal infection can usually be expected to heal rapidly (see Fig. 41-3). Periodontal attachment along with bone healing can then be expected within a few months. The part of the lesion caused by plaque infection may also heal following adequate periodontal therapy. Yet, little or no regeneration of the attachment apparatus should be anticipated for this portion of the lesion. Table 41-1 outlines the strategy to be taken for treatment of these so called endo–perio lesions.

Conclusion: Deep pocket probing depths associated with angular bone defects may reflect a combined endodontic and periodontal lesion. Yet, the extent to which an endodontic infection has contributed to the attachment loss cannot normally be determined from a negative sensitivity test, as the entire loss might be caused by plaque infection. Therefore, a treatment strategy should be applied which includes endodontic treatment in the first place, but only in cases where an endodontic etiology is reasonably plausible, that is in teeth with large restorations, full-coverage crowns or history of dental trauma. If the tooth is completely intact without major restoration, caries or history of trauma, the potential of an endodontic etiology of the process is remote (Figs. 41-10, 41-11).

Endodontic treatment and periodontal lesions

Periodontal lesions, as already stated, may be maintained by infectious elements released from endodontically treated teeth. The lesion may have never resolved or may have developed after the completion of treatment. Several routes for dissemination of bacterial elements to the periodontium in such teeth are possible. Except for apical foramina and accessory canals, another possible pathway is inadvertently produced communication by root perforation (see below). The clinical presentation is no different from the one described above and consequently may involve acute exacerbations with extensive breakdown of the attachment apparatus as well as localized, non-symptomatic lesions, only apparent on radiographs.

A persistent infection in root-filled teeth may also impact on the periodontium along the dentinal tubules in areas where cementum has been damaged or lost (Blomlöf *et al*. 1988). The potential significance of such an avenue has been highlighted in clinical studies. Compared with teeth with healthy pulps, endodontically treated teeth with periapical pathology, indicating presence of persistent root canal infection, showed increased pocket probing depths (Jansson *et al*. 1993a), more marginal bone loss (Jansson *et al*. 1993b), and retarded or impaired periodontal tissue healing subsequent to periodontal therapy (Ehnevid *et al*. 1993a, b). Although the differences in probing depths and attachment losses in these studies were rather small, the observations suggest that endodontic retreatment should be considered as an adjunct to periodontal therapy when a root canal filling is defective and/or displays signs of periapical inflammation. Observations in a retrospective analysis of patients affected by periodontitis indicated that the periodontal condition may also affect the periapical status in root-filled teeth (Stassen *et al.* 2006). Significantly fewer teeth with apical periodontitis were seen in patients treated for periodontitis compared with untreated patients. In individuals with no or minor evidence of periodontal disease, the root canal condition, whether root filled or not or infected or not, did not seem to affect the periodontal status in a controlled study (Miyashita *et al*. 1998).

Conclusion: Unfilled spaces in endodontically treated root canals can sustain bacterial growth, and infectious products from these areas may reach the periodontium along the very same pathways as in an untreated tooth

with infected pulp. Endodontic retreatment may be considered as an adjunct to periodontal therapy when a root canal filling is of poor quality and/or the tooth displays signs of periapical inflammation, because of the potential that bacterial elements may become disseminated to the periodontium along dentinal tubules exposed by periodontal instrumentation.

Iatrogenic root perforations

Loss of attachment including pocket formation in a narrow area of a restored, root-filled tooth may be related to an iatrogenic root perforation. The injury may have been induced during the endodontic treatment procedure *per se* or subsequently in conjunction with preparation for a root canal retained post (Sinai 1977; Kvinnsland *et al*. 1989; Eleftheriadis & Lambrianidis 2005; see also review by Tsesis & Fuss 2006). The clinical significance of such a complication depends largely on whether the wound site becomes infected or not (Beavers *et al*. 1986; Holland *et al.* 2007). If promptly and properly treated, a bacterially-induced periodontal lesion can be prevented. Otherwise, and especially if carried out in the crestal bone area, epithelial proliferation and periodontal pocket formation (Lantz & Persson 1967; Petersson *et al*. 1985) will ensue. In more apical areas, a lateral bone lesion may develop, which may or may not be accompanied by clinical symptoms, including acute pain, drainage of pus, loss of fibrous attachment, and deep pocket probing depths (Fig. 41-14).

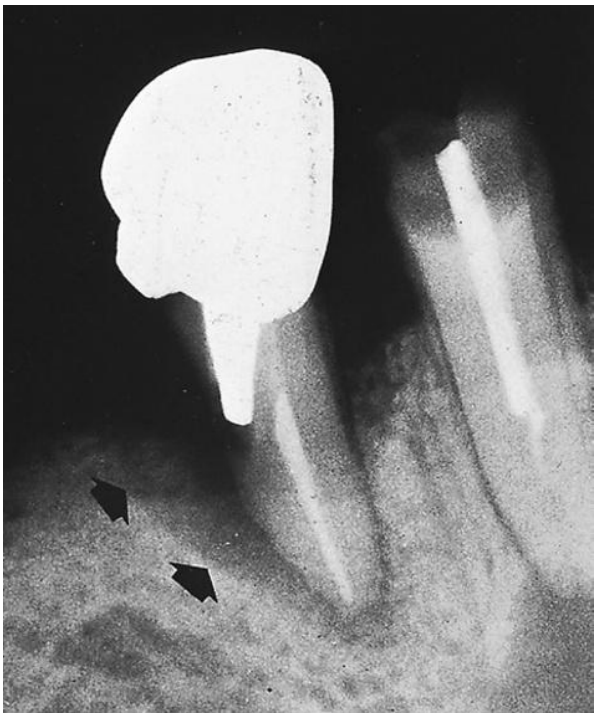

Fig. 41-14 Angular bone defect at the distal root surface of a mandibular molar (arrows). The root is perforated as indicated by the misaligned post. Clinical symptoms included drainage of pus from the pocket and increased tooth mobility. The tooth was extracted.

Occurrence

The occurrence of iatrogenic root perforation in conjunction with endodontic and prosthodontic therapies has been estimated to vary between 2% and 12% (Tsesis & Fuss 2006). In a retrospective analysis of a sample of 2000 patients accepted for treatment in a university clinic, 2.3% of all root-filled teeth (n=5505) showed signs of root perforation on radiography. Pathologic changes in the adjacent periodontal tissues were seen in nearly 70% of these cases (Tsesis *et al.* 2010).

Diagnosis

Diagnosis is based on the occurrence of sudden pain and bleeding during preparation of root canals coronally of the working length. Such signs are likely to be less distinct if the perforation occurs during a procedure conducted under local anesthesia. A perforation may also go undetected as bleeding may not invariably be provoked. For example, when post preparations are carried out by means of a machine-driven instrument, a smear layer is formed that may clog the blood vessels. Thus, in many instances no bleeding will be noticed until the following visit, when granulation tissue will have proliferated into the root canal space along the perforation defect. On attempts to remove the granulation tissue, bleeding is usually profuse, making sealing precarious. Electronic apex locators are helpful to confirm a root perforation, which should be suspected when readings are substantially shorter than the length of the root canal (Fuss *et al*. 1996). New imaging technologies such as cone-beam computed tomography (CBCT) have been reported to aid diagnosis (de Paula Silva *et al.* 2009; Venskutonis *et al*. 2014). Scattering artifacts caused by high density neighboring structures such as metal posts and root-filling material may, however, limit the diagnostic accuracy of CBCT. Further limitations are higher radiation dose and costs than examination by intraoral periapical radiographs (Patel 2009; Shemesh *et al.* 2011).

Treatment approaches

Early detection is critical for a successful outcome of a treatment attempt as the potential for repair of a long-standing perforation with a manifest infection is poor (Holland *et al.* 2007). Successful treatments have, nevertheless, been achieved even in such cases (Tsesis & Fuss 2006; Mente *et al.* 2010).

Over the years many therapeutic agents and methods have been proposed for the management of root perforations (reviewed by Tsesis & Fuss 2006). Materials proposed for sealing from the inside of the root canal space include amalgam, zinc oxide and eugenol cements, both chemically cured and light-cured calcium hydroxide-containing pastes, and plaster of Paris. Alkaline calcium silicate cements such as mineral trioxide aggregate (MTA) based on

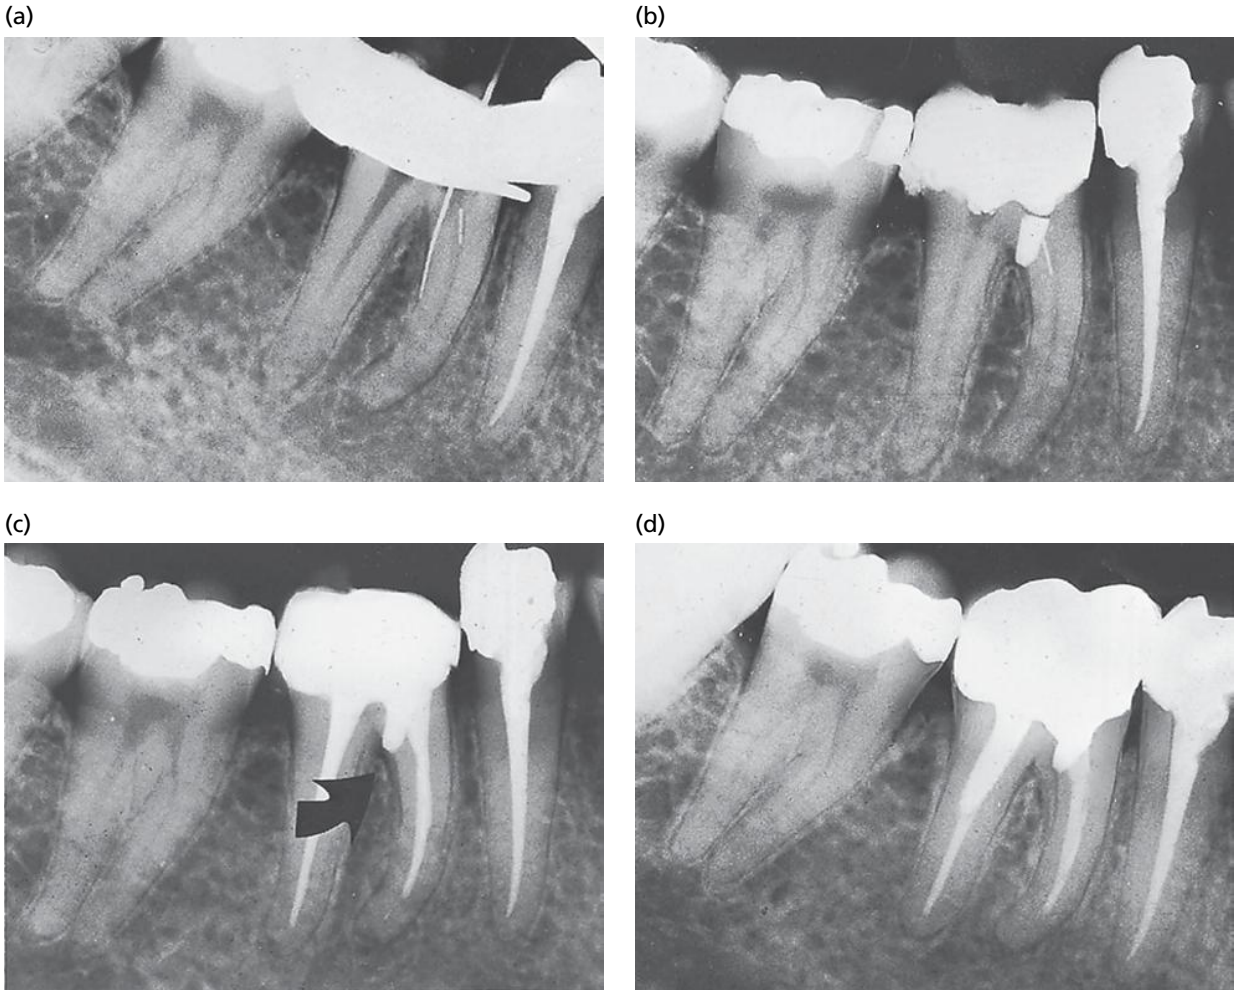

Fig. 41-15 (a) Perforation of the pulpal floor of the mandibular first molar occurred in conjunction with a search for root canal openings. There is also a file fragment in one of the mesial canals. (b) The perforation was immediately sealed with gutta-percha. (c) On a radiograph taken 1 month after treatment, a slight radiolucency is seen at the site of the perforation (arrow). (d) Follow-up after 2 years showed normal periodontal conditions both clinically and radiographically. (Courtesy of G. Heden.)

Portland cement are now considered to be the state-of-the art material to fill root canal perforations. This is because of their antimicrobial properties, superior sealing effect, and biocompatibility in the set stage (for reviews see Parirokh & Torabinejad 2010a, b; Torabinejad & Parirokh 2010). MTA furthermore permits cementum repair (Arens & Torabinejad 1996; Schwartz *et al*. 1999).

The location of the perforation dictates the choice of material to seal the perforation. In supracrestal areas, the dentin can be conditioned, and a dual-curing composite material be applied directly over the perforation. In infracrestal locations, MTA or another biocompatible cement should be applied. Regardless of the material used, healing of the lesion in the periodontium depends on whether bacterial infection can be excluded from the wound site by a tight seal of the perforation (Beavers *et al*. 1986; Holland *et al.* 2007) (Fig. 41-15). This may be difficult to achieve, particularly if the perforation runs deep into the root canal at an oblique angle, giving it an oval-shaped orifice into the periodontium. Nevertheless, for mid-root and cervical perforations, non-surgical approaches, including placement of an internal seal, are preferable to a surgical approach, as the latter often results in persistent pocket formation and furcation involvement. Furthermore, surgical treatment is not always feasible because of the inherent difficulty of accessing many perforation sites. If controlled disinfection and sealing of the perforation site are not possible because of its location or extent, extraction may be the only reasonable therapy. In multirooted teeth, hemisection and extraction of the perforated root may be a treatment of choice.

Conclusion: Inflammatory lesions in the marginal periodontium, as manifested by increased probing depth, suppuration, increased tooth mobility, and loss of fibrous attachment, may result from an undetected or unsuccessfully treated root perforation. If an iatrogenic root perforation occurs during instrumentation of root canals, filling of the artificial canal to the periodontium should be carried out without delay to prevent granulation tissue formation and wound site infection. Outcome of treatment depends on how well the wound site can be disinfected and sealed. The closer the perforation is to the bone margin, the greater the likelihood of proliferation of epithelium at the perforation site with bacterial contamination and a resulting deep, potentially suppurating pocket.

Vertical root fractures

Clinical symptoms that are typical of tooth-associated infections such as endodontic lesions and plaque-induced periodontitis may also appear at teeth with cracks and vertical root fractures. It is important to distinguish between different forms of these complications. The American Association of Endodontists has identified five specific variations of cracked teeth: craze line, fractured cusp, cracked tooth, split tooth, and vertical root fracture. This differentiation appears to be clinically relevant, because cracks are rarely associated with major periodontal breakdown and can be prevented from developing into split teeth by placing a crown (Krell & Rivera 2007). Cracks typically occur in a mesiodistal direction and initiate from the crown (Roh & Lee, 2006) (Fig. 41-16); they may engage the root canal space. Vertical root fractures, on the other hand, usually initiate from somewhere on the root and are typically located in a faciolingual direction. Eventually vertical root fractures extend along the entire length of a root to involve the gingival sulcus/pocket area and will then be associated with periodontal tissue breakdown (Fig. 41-17). It should be noted that vertical root fractures, although often expanding in opposite directions from the root canal space, may extend to one root surface only. Teeth with vertical root fractures have a hopeless prognosis and are reason for extraction or resection of the affected root.

Mechanisms

Endodontically treated teeth appear over-represented among teeth with vertical root fracture in comparison to teeth with vital pulps (Meister *et al*. 1980; Gher *et al*. 1987; Patel & Burke 1995). Generally, the increased fracture propensity of root-filled teeth has been attributed to loss of tooth structure as a result of endodontic instrumentation and subsequent restorative procedures (Reeh *et al*. 1989; Sedgley & Messer 1992). Loss of fracture resistance increases especially after overzealous root canal preparation, leaving thin dentin walls to the periodontium (Tjan & Whang 1985). Notches, ledges, and cracks induced by root canal preparation, root canal filling procedures, and seating of threaded pins and posts also contribute to sites of stress concentration during mastication that eventually may lead to fracture (Kishen 2006). Recently, it has been shown *in vitro* that any type of file inserted into the root canal may cause apical craze lines or cracks, which over time may propagate coronally (Adorno *et al.* 2010). Decrease of moisture content following root canal treatment is another alleged cause of increased fracture susceptibility of root-filled teeth; insignificant moisture differences were found, however, when dentin of teeth with vital pulps and dentin of root-filled teeth were compared (Papa *et al*. 1994). More recent observations have nevertheless demonstrated that effects occur in dehydrated dentin that may render endodontically treated teeth prone to fracture (Kishen 2006). Dehydrated dentin *in vitro* was observed to assume increased stiffness as well as a decrease in toughness (e.g. the total energy a material can absorb before fracturing) in comparison to hydrated dentin (Jameson *et al*. 1994; Kahler *et al*. 2003; Kishen & Asundi 2005). Hence, fluid-filled dentinal tubules as well as a water-rich pulp tissue may give normal teeth better resistance to occlusal loading forces than root-filled teeth. There is evidence that NaOCl as irrigating solution alters the mechanical properties of root canal dentin and may lower its fracture resistance (Pascon *et al.* 2009). Calcium hydroxide, a commonly used medicament for inter-appointment dressing in root canal therapy, may also decrease fracture resistance of root-filled teeth (Andreasen *et al.* 2002). It has also been speculated that, along with loss of vital pulp tissue there is concomitant loss of mechanoreceptive functions, allowing larger loads to be placed during mastication than the patient could normally tolerate (Löwenstein & Rathkamp 1955; Randow & Glantz 1986).

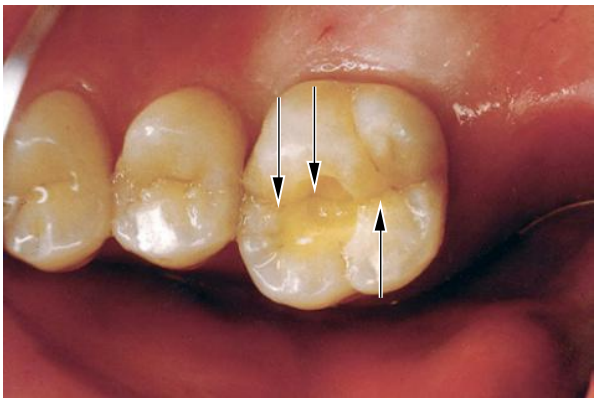

Fig. 41-16 Crack in an unrestored maxillary molar causing symptoms of pulpitis. The patient, a 47-year-old male, had thought the pain problem originated from the temporomandibular joint. Following the preparation of a test cavity, a clear split line was observed at the bottom of the cavity (arrows), confirming the cause of the pain condition. (Courtesy of H. Suda.)

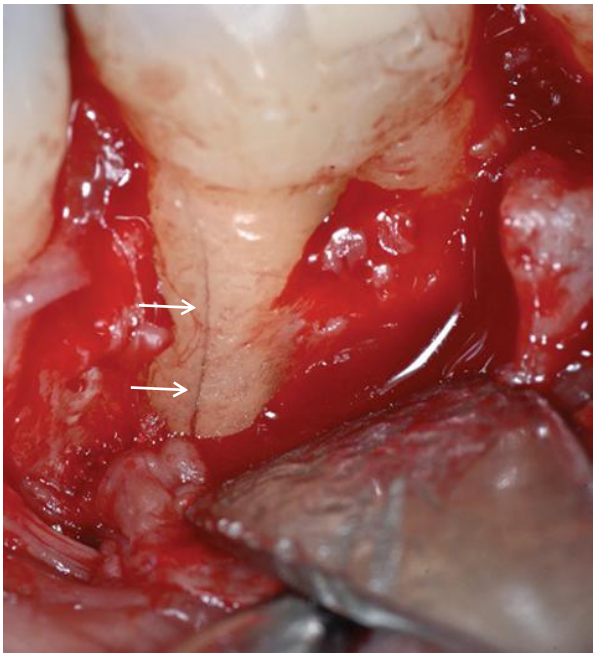

Fig. 41-17 Vertical root fracture of the mesial root of a lower molar (arrows). Note the typical bone dehiscence.

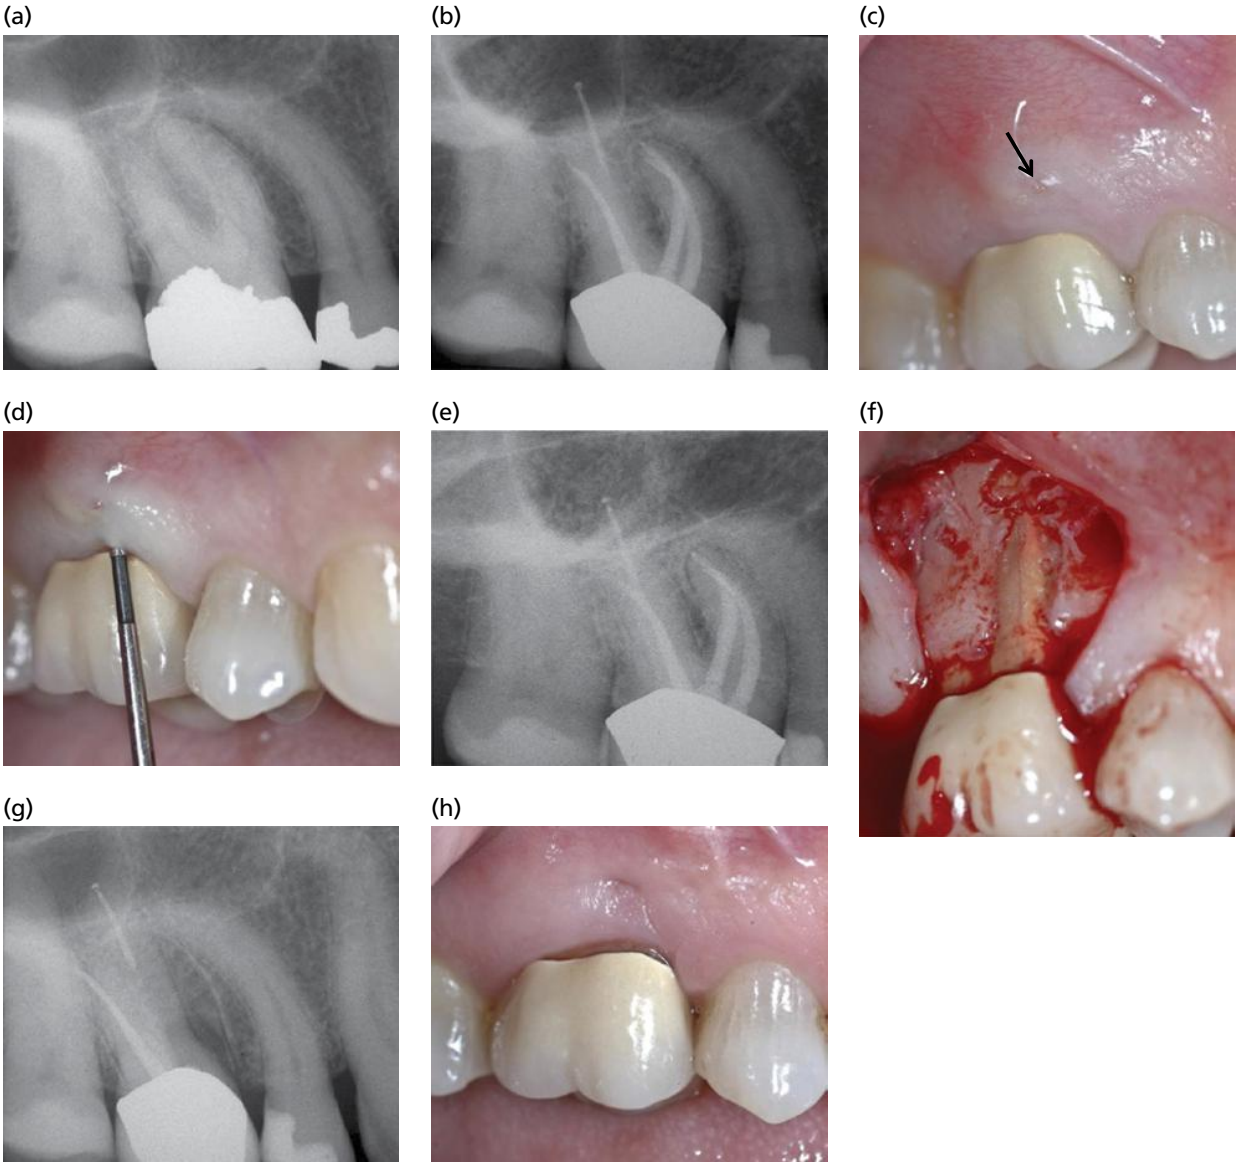

Fig. 41-18 Vertical root fracture in a maxillary right first molar treated endodontically 4 years prior to diagnosis. (a) Root canal treatment initiated because of need for post-retained crown. (b) Cemented crown in place with a composite post in the palatal root canal. (c) At a regular recall appointment 4 years later, the patient complained of a "funny sensation" in the upper right jaw, but reported no other discomfort such as pain or tenderness to biting pressure. Gingiva was slightly inflamed in the area. A closer look revealed a small sinus tract. (d) A pocket probing depth of 8 mm was found over the mesiobuccal root. Remaining probing sites were within normal limits. (e) Radiographic examination was inconclusive. (f) Exploratory surgery revealed a bone dehiscence and a vertical root fracture associated with the mesiobuccal root. (g) Root was extracted. (h) 4 months post surgery, the patient was able to clean the area properly. There was no bleeding on probing or abnormal probing depths.

Vertical root fracture may also occur in clinically intact teeth with no or minor restoration. As posterior teeth are exposed to heavier occlusal forces, mandibular molars appear to be especially at risk for fracture (Yang *et al*. 1995; Chan *et al*. 1999). Subsequent to fracture of teeth with vital pulps, typical pulpitis symptoms may be initiated, together with pain on percussion and mastication.

Occurrence

The rate at which vertical root fractures occur is not well established. While it appears to be a rare condition, the complication is probably more common than clinicians are able to diagnose (Testori *et al*. 1993; Tamse *et al*. 1999b). Endodontically treated teeth appear more prone to vertical root fracture than non–root-filled teeth, with molars and premolars more commonly affected than incisors and canines (Meister *et al*. 1980; Testori *et al*. 1993; Cohen & Louis 2006). In longitudinal clinical follow-up studies of patients treated with fixed prostheses, vertical root fractures were frequent in root-filled teeth with posts and especially so in teeth serving as terminal abutments in cantilever bridges (Randow *et al*. 1986).

It is important to recognize that root fractures of endodontically treated teeth may occur several years after the completion of endodontic therapy and restoration of the tooth (Figs. 41-18, 41-19). In a study comprising 32 vertical root fractures, the average time between the completion of endodontics and

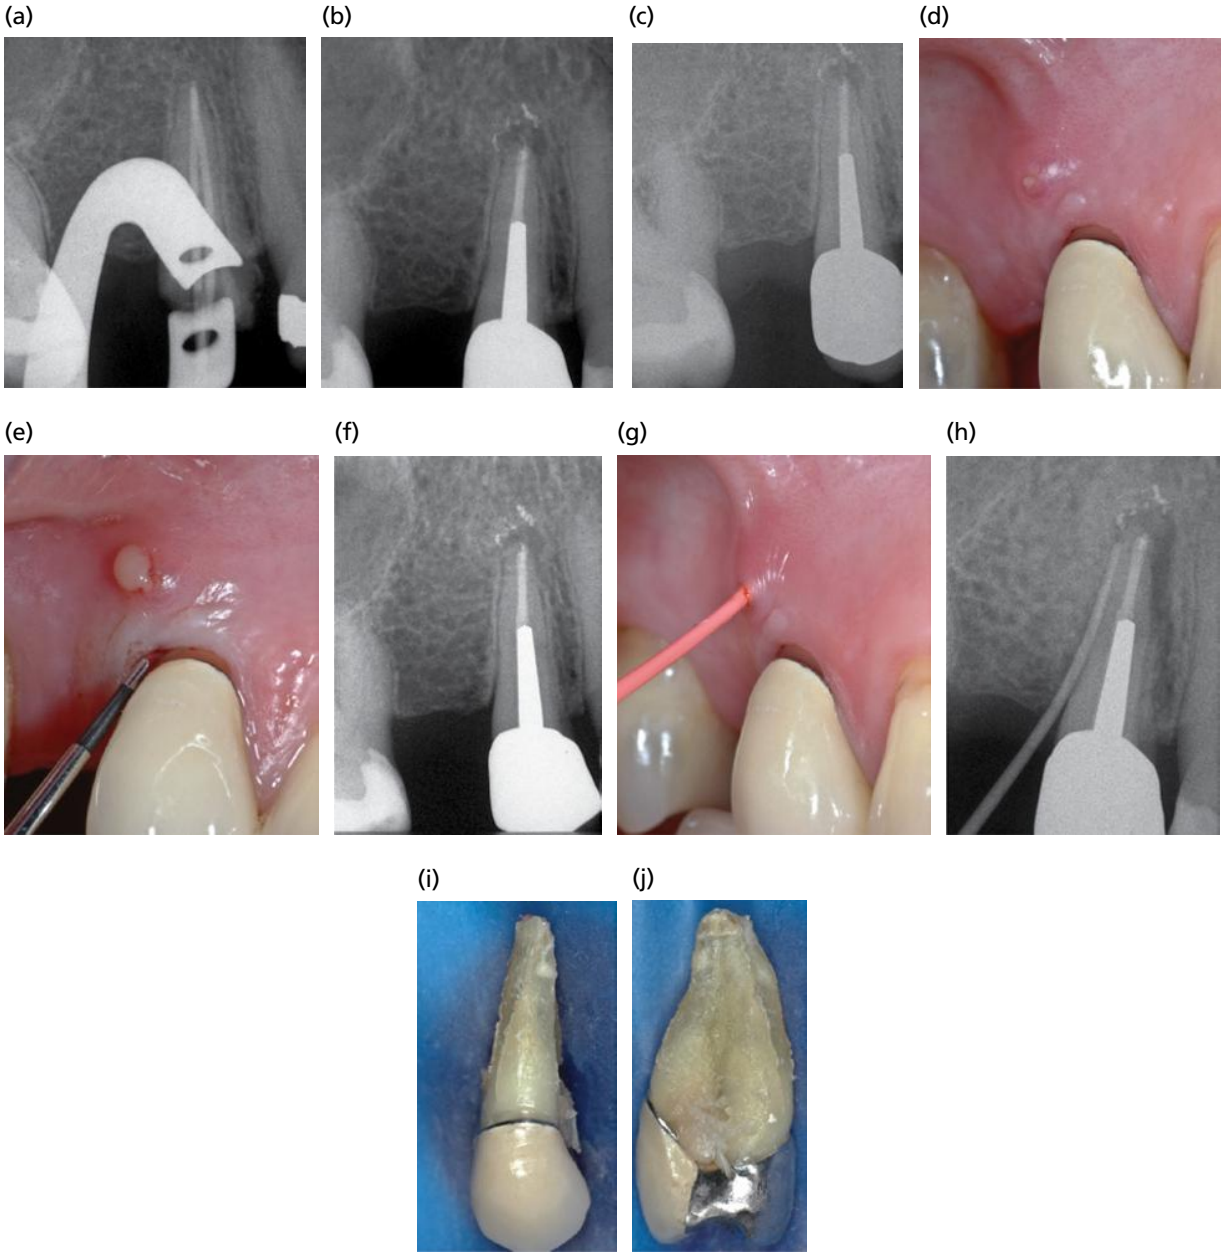

Fig. 41-19 (a) Maxillary right, severely broken down first premolar subjected to root canal therapy. (b) Tooth restored with cast post and core and crown to be included as an abutment in a removable partial denture. Radiograph taken at a recall visit 4 years after initial treatment shows a periapical lesion. Patient had no clinical symptoms and denied further treatment. (c) Over the subsequent 5 years, the size of the lesion did not change. (d) Fourteen years after initial treatment, the patient returned and complained about occasional inflammation at the buccal aspect of the tooth. A slight swelling could be discerned. (e) Periodontal probing to a depth of approximately 6 mm released suppuration of pus of a sinus tract. (f) Ortoradial first radiograph shows the periapical lesion of a similar size as in earlier radiographs. (g) Tracing the fistulous tract with a gutta-percha point with an angulated radiograph (h) shows a periodontal bone lesion extending along the mesial aspect of the root, suggestive of a vertical root fracture. (i, j) Fracture lines can be seen on the buccal as well as on the palatal root surface.

diagnosis of fracture was 3.25 years, with a range of 3 days to 14 years (Meister *et al*. 1980). In another study comprising 36 teeth, symptoms of root fracture developed on average >10 years after completion of treatment (Testori *et al*. 1993). In a further study of 325 endodontically treated and restored teeth, 19 developed a vertical root fracture within a mean observation time of 5.3 years (Salvi *et al*. 2007). In that study, 11 of 13 fractured mandibular molars, restored with a prefabricated titanium post in the distal root, presented with a fracture of the mesial root, which had no post.

Clinical signs and symptoms

Clinical signs and symptoms associated with vertical root fractures vary hugely. Occasionally, there may be pronounced pain and abscess formation because of active bacterial growth in the fracture space (Fig. 41-20). In other instances, clinical symptoms may be limited to tenderness on mastication, mild pain, and dull discomfort. Sinus tracts may emerge near the gingival margin (Figs. 41-18, 41-19). A strong indication of a vertical root fracture is sinus tracts occurring at both buccal and lingual/palatal sites

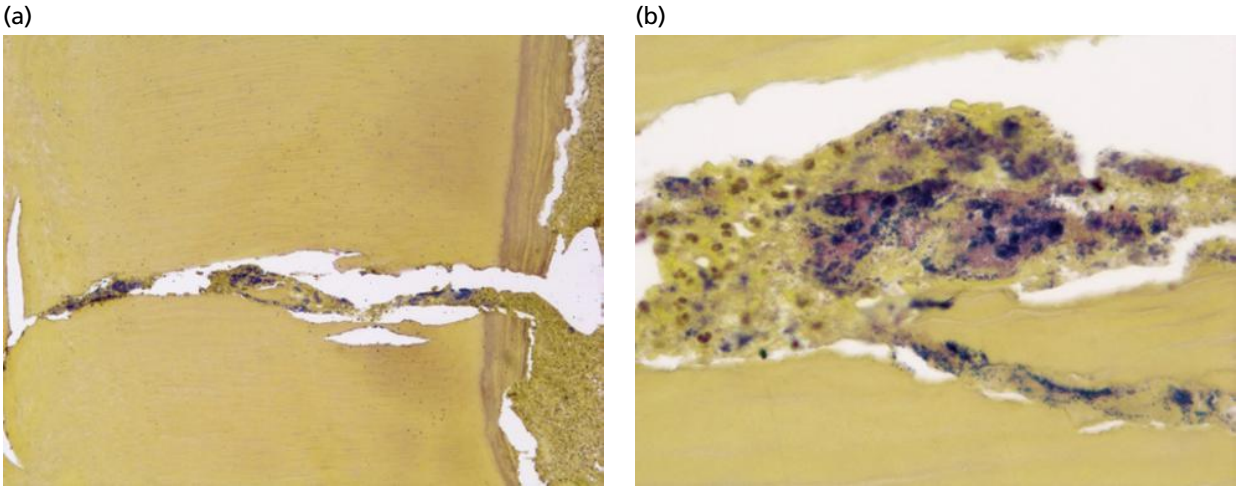

Fig. 41-20 (a) Bacterial masses and polymorphonuclear leukocytes in the fracture space of a maxillary premolar. (b) Magnification of area in the center.

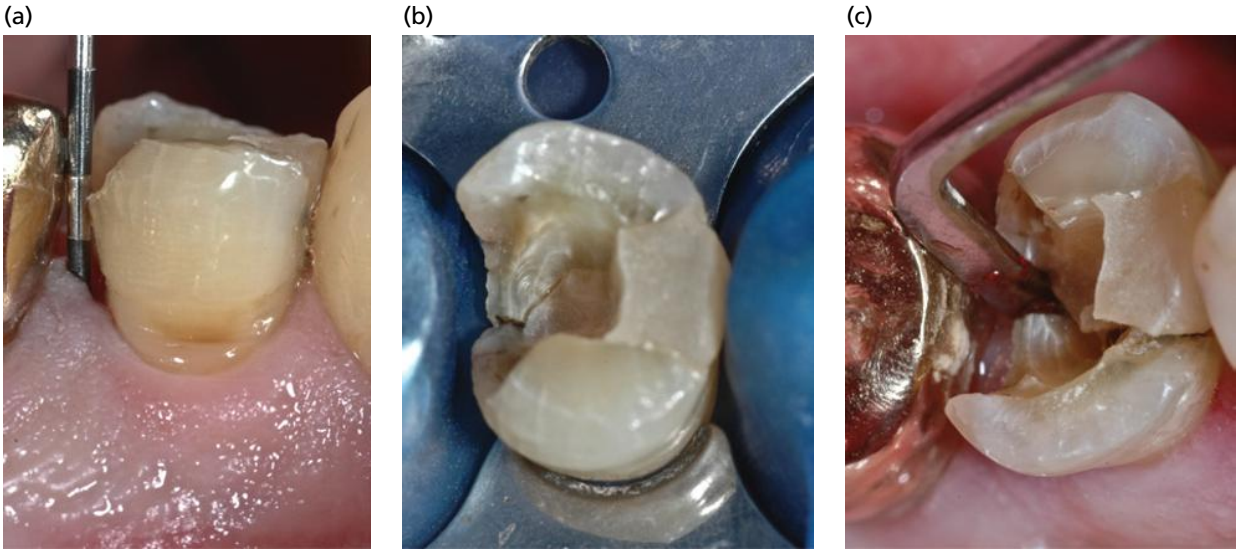

Fig. 41-21 (a) Mandibular second premolar in a periodontally healthy patient with a 5-mm deep pocket probing depth along the distal root surface. Patient had a history of recurring tenderness and abscesses associated with the tooth. Six months earlier it had been subjected to root canal therapy but clinical symptoms prevailed. Radiographs were inconclusive and showed only a minor periapical lesion and slight widening of the periodontal ligament space along the mesial root surface. Except for the pocket probing depth, there were no other clinical signs of acute infection at the time of examination. Mobility was within normal limits. (b) On removing the composite restoration in conjunction with an access opening preparation for endodontic retreatment, a dark line suspicious of a fracture was revealed. (c) Following removal of the clamp and rubber dam, two root fragments could be dislodged with a plastic instrument.

(Tamse 2006). In other instances, a narrow, local deepening of a periodontal pocket may be the only clinical finding (Fig. 41-21).

The osseous defect emanating from the periodontal tissue lesion may take different shapes depending on how the fracture extends. If there is a buccal extension, the thin alveolar bone plate readily resorbs and a typical bone cleft can be seen upon raising a mucoperiosteal flap (Fig. 41-17). At palatal or lingual extensions, the lesion may not resorb the entire bone wall. Therefore, the osseous defect may take a U shape with the height of the bone margin preserved. In fractures that are limited to the apical portion of the root, the bone defect may center on the root apex, similar to that of a periapical lesion associated with an infected root canal.

On conventional intraoral periapical radiographs these bone lesions may not be readily visible, depending on the location, character, and shape of the bone destruction (Fig. 41-22). Absence of a lesion, even when radiographs are taken at different angles, can also be explained by superimposition of roots and bone structures over the bone dehiscence. In yet other cases, radiographic signs may be limited to widening of the periodontal ligament space. Lateral radiolucency along one or both of the lateral root surfaces may be discerned with more pronounced bone lesions. A thin halo-like apical radiolucency is another example of a radiographic lesion suggestive of a vertical root fracture (Pitts & Natkin 1983; Testori *et al*. 1993; Tamse *et al*. 1999a). Developments of tomographic

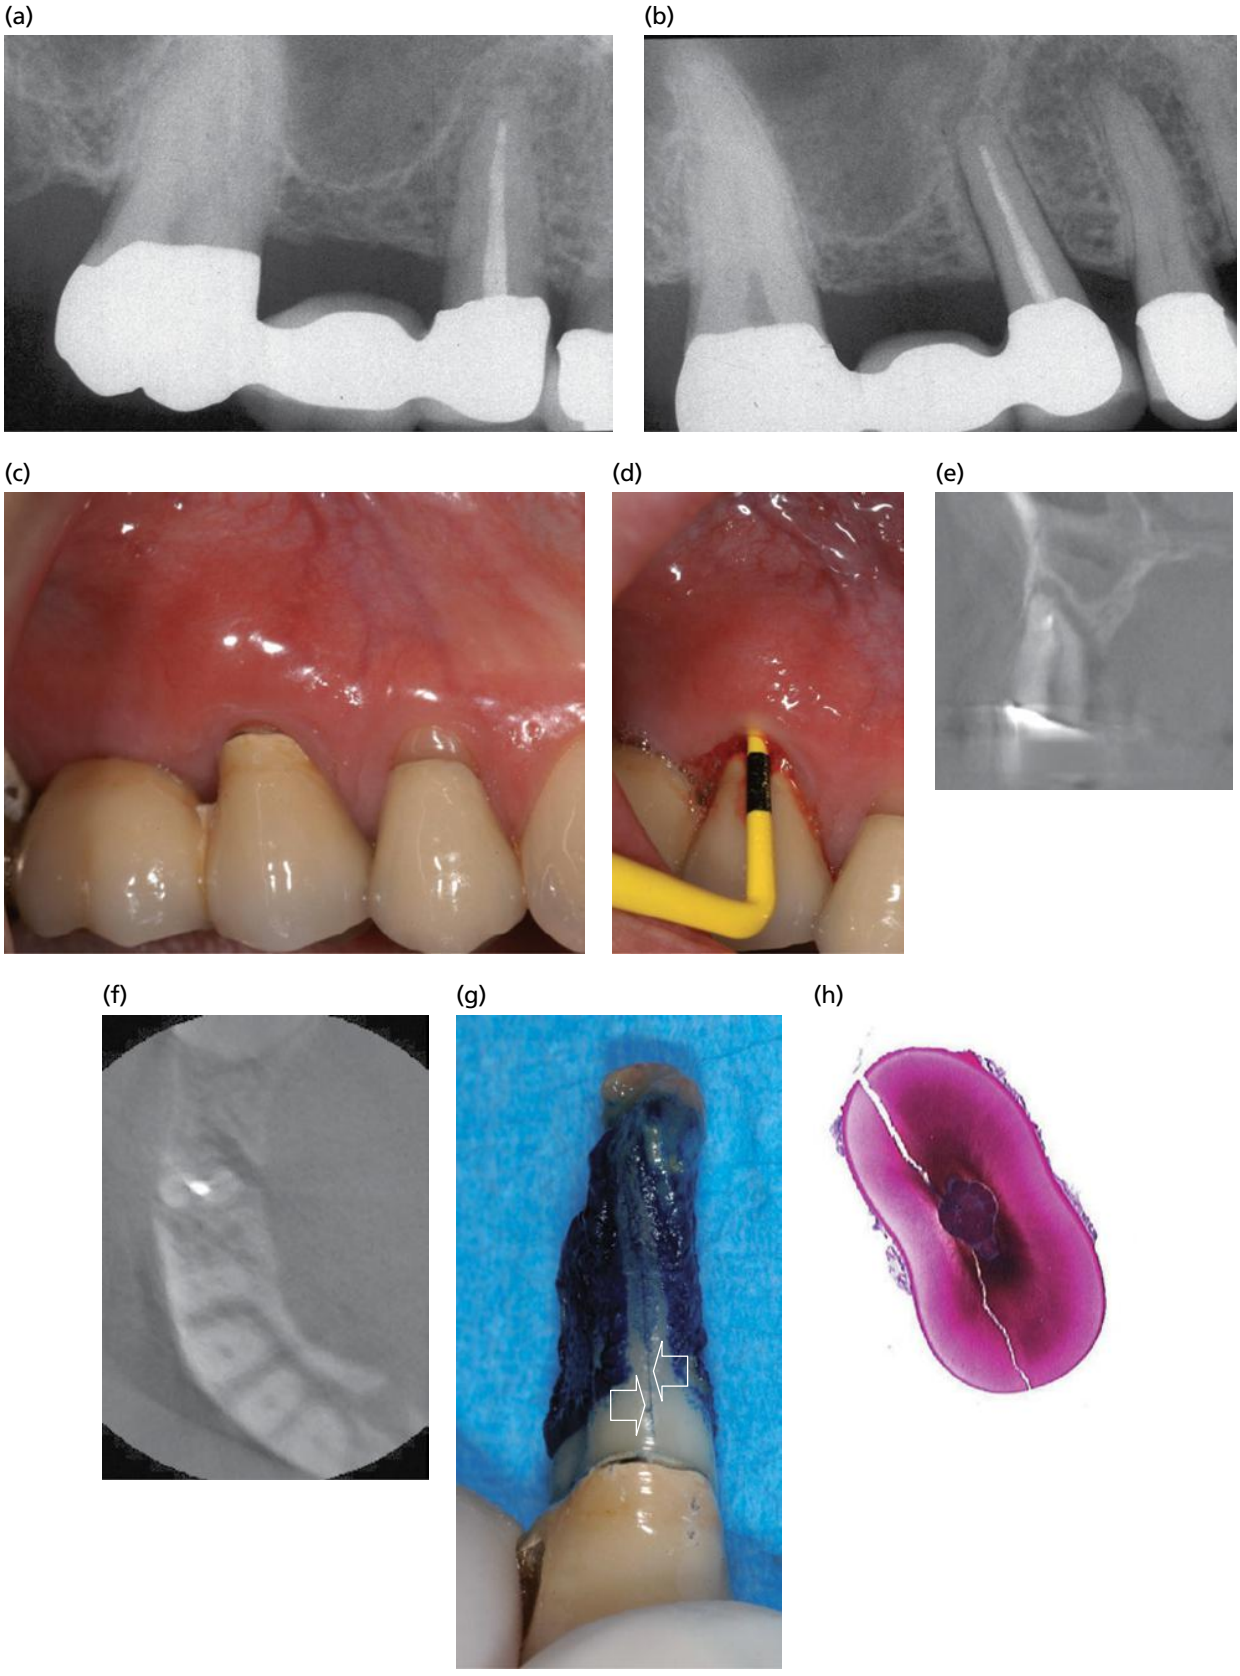

Fig. 41-22 Case of vertical root fracture, where ordinary intraoral radiographs failed to provide evidence of the associated bone lesion. (a) Radiograph shows normal periodontal contours. (b) Second radiograph indicates a widened periodontal ligament space. (c) Patient had complained of recurrent pain on occlusal load for several weeks and presented at the clinic with a slight swelling on the buccal aspect that had appeared several weeks before. (d) Clinically there was an isolated 9-mm pocket probing depth mid-buccally, suggesting root fracture. (e, f) Limited cone beam computed tomography was helpful in revealing a bone lesion along the palatal aspect of the tooth. (g) After extraction, methylene blue staining visualized the fracture line (arrows) that turned out to extend to both the lingual and the buccal root surfaces (h). (Courtesy of T. von Arx.)

techniques have brought valuable new diagnostic tools as they can remove interference from anatomic structures and thereby help to visualize the presence, location, and extension of bone lesions (Gröndahl & Hummonen 2004) (Fig. 41-22e, f).

Diagnosis

The diagnosis of a vertical root fracture is often difficult to ascertain because the fracture is usually not readily detectable by clinical inspection unless there is a clear separation of the root fragments (Testori *et al.* 1993). In fact, diagnosis is often precarious in that the clinical signs often overlap with those of apical and marginal periodontitis. Moreover intraoral radiographs are seldom of diagnostic value unless the central X-ray beam is parallel to the fracture plane, which rarely is achieved (Fig. 41-23). In a sample of 29 patients presenting with clinical signs and symptoms of suspected vertical root fracture in endodontically treated teeth, CBCT provided accurate diagnostic leads (Edlund *et al.* 2011). With surgical exploration as the reference test, sensitivity and specificity were calculated to be 88% and 75%, respectively. To visualize fractures in teeth, it is essential to use CBCT with sufficiently small voxel size. The accuracy of detecting vertical root fracture, however, seems to depend on the CBCT system used (Metska *et al*. 2012).

The suspicion of a vertical root fracture is often inferred from a pocket probing depth in an aberrant position, for example at a buccal or lingual aspect of a tooth, in a dentition otherwise minimally affected by periodontitis (Fig. 41-22d). The sudden appearance of multiple fistulas in a tooth free from restorations may also be indicative. Another strong indicator is the sudden appearance of clinical symptoms and/or a radiographic lesion on a root-filled tooth that has remained asymptomatic and without lesion for many years (Fig. 41-24).

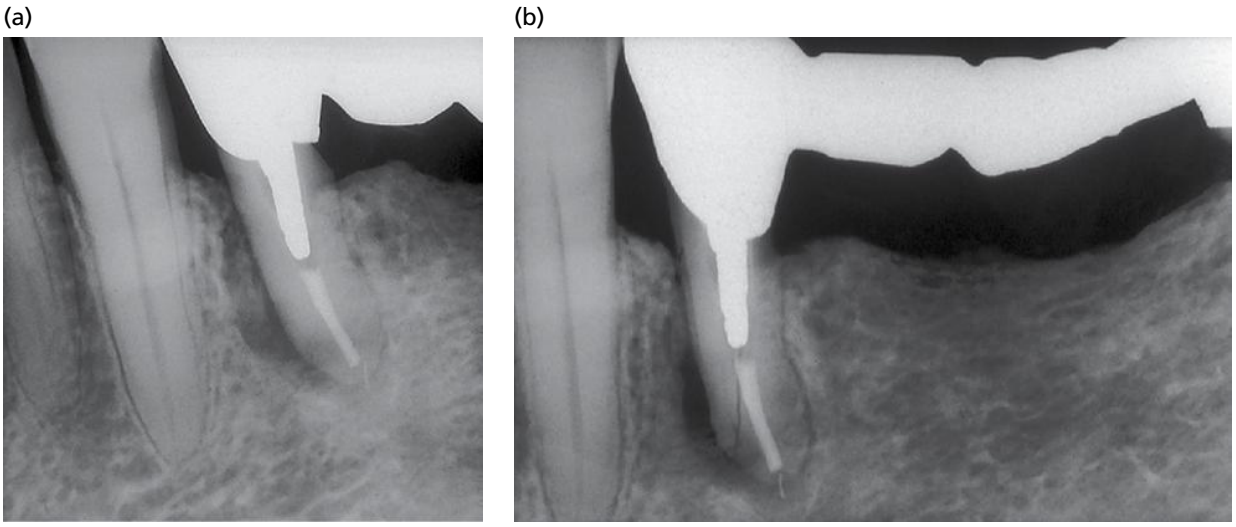

Fig. 41-23 (a) Mandibular premolar included in a four-unit bridge showing a bone lesion at the mesial aspect of the root. In this projection there is no sign of fracture, while in a radiograph (b) taken with a slight shift of angle, a fracture line is clearly visible. (Courtesy of K.-G. Olsson.)

Fig. 41-24 (a) Twelve-year follow-up radiograph of crown-restored, endodontically treated premolar showing excellent periodontal bone tissue structures. (b) Two years later, 14 years after completion of treatment, the tooth became painful and a buccal swelling appeared. (c) Radiograph taken at this time showed severe periodontal tissue breakdown at the mesial aspect of the root. Findings in (b) and (c) are highly suggestive of a vertical root fracture.

Fig. 41-25 Vertical root fracture made visible by a micro-spatulum.

A number of diagnostic procedures can be undertaken to confirm the diagnosis. Application of various dye solutions, e.g. methylene blue or iodine tincture, to the crown and the root surface can sometimes be indicative. As the dye enters the fracture space, it will show up as a distinct line against the surrounding tooth substance. Indirect illumination of the root, using fiber-optic light, can also be of value. The fiber-optic probe should be placed at various positions on the crown or the root to disclose the fracture line. It is often necessary to remove restorations to allow light access to the crown of the tooth. A surgical microscope or an endoscope, providing both enlargement and directed light, are other valuable tools to disclose vertical root fractures. It is also usually helpful to expose the facial or lingual root surface by inserting a micro-spatulum into the sulcus, thus gaining direct sight (Fig. 41-25). This can also be achieved by gently blowing air from a micro-tip into the sulcus. In premolars and molars the diagnosis may be supported from observation of varying pain sensations elicited by loading facial and lingual cusps. The procedure includes asking the patient to bite down on a small object or a specially designed plastic stick (FracFinder). A piece of tooth pick wrapped in tape in such a manner that one can place/steer the piece to different parts of the occlusal surface may also be useful. Separate loading of either buccal or lingual cusps eliciting pain sensation from one, but not the other, loaded cusp suggests the presence of a crack or fracture. Often the diagnosis of a vertical root fracture has to be confirmed by surgical exposure of the root for direct visual examination (Walton *et al*. 1984) at which one may also discover a typical bone dehiscence (see Fig. 41-17).

Treatment considerations

Vertical root fractures that involve the gingival sulcus/pocket area usually have a hopeless prognosis due to continuous microbial invasion of the fracture space from the oral environment. While there are reports of successful management of fractured teeth by reattaching the fragments with bonding resin or laser fusing after extraction followed by re-implantation, fractured teeth are normally candidates for extraction. In multirooted teeth, a treatment alternative is hemisection and extraction of the fractured root.

Conclusion: Symptoms and signs associated with vertical root fractures vary and may be difficult to distinguish from those prevalent with other tooth-associated infections. A variety of diagnostic procedures should therefore be considered. Except for the leads obtained from anamnestic findings and pocket probing depths in buccal or lingual positions or both, clinical examination should include measures to disclose fracture lines *viz.* application of disclosing solutions, use of fiber-optic light, inspection by a surgical microscope or endoscope, or by raising a surgical flap. Pain on selective loading of cusps may indicate root fracture. A vertical root fracture should be anticipated in root-filled teeth, which, after a long history of being asymptomatic and without signs of infection, suddenly present with tenderness, pain, and a radiographic bone lesion. Roots with vertical root fracture usually have a hopeless prognosis and are clear candidates for extraction or, if possible, amputation/hemisection of the fractured root.

Cemental tears

A cemental tear is a special form of root fracture. It is defined as a fracture within the cementum layer or between the cementum layer and the dentin (Leknes *et al.* 1996). These dental hard tissue lesions occur more frequently in men than in women, and in individuals older than 60 years (Lin *et al.* 2011). They seem to be associated with heavy biting and/or grinding. Incisors are the most frequently affected tooth group. In contrast to vertical root fractures, cemental tears do not run perpendicular to the root surface. Consequently, they do not destroy the collagen network of the dentin. This implies that through a cemental tear microbial transgression is not possible between the periodontium and the pulpal space. However, microorganisms can gain access to the marginal periodontium from the oral cavity and thus cause inflammatory lesions. These lesions can be associated with the development of a periodontal pocket adjacent to the torn cementum (Fig. 41-26).

Diagnosis and treatment

Lesions associated with a cemental tear can be hard to differentiate from counterparts induced by vertical root fractures, as it is not always possible to spot the separation in the apparent cementum layer on two-dimensional radiographs (Lin *et al.* 2011). As with suspected vertical root fractures, explorative surgery remains the best option to reach a diagnosis. In contrast to vertical root fractures, however, cemental tears can, depending on their location and extent, be treated conservatively by removing the torn fragment (Fig. 41-26).

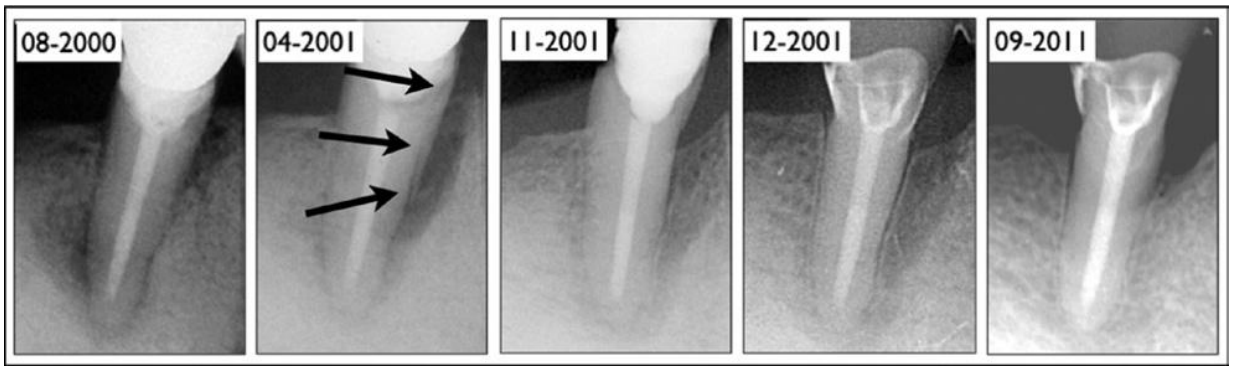

Fig. 41-26 Mandibular right premolar, which had received a root canal treatment through a pre-existing bridge. At the first endodontic recall visit (04-2001), the apical lesion had almost healed. However, a periodontal breakdown mesial to the root of this tooth was noted. Radiographically, the lesion was associated with an apparent abfraction of dental hard tissue in the root opposing the bone defect (arrows). Periodontal surgery was performed, and the diagnosis of cemental tear was verified clinically. The torn fragment was removed and Emdogain® was placed. Seven months later (11-2001), periodontal healing was noted both clinically and radiologically. The tooth was included as an abutment for a new full-ceramic bridge (12-2001). Ten years later (09-2011), the tooth and its surrounding structures were within normal limits. (Courtesy of P. Schmidlin and B. Lehnert.)

Root malformations

Root malformations, which can mediate the development of both localized periodontal tissue breakdown and pulpal infections, are palatoradicular grooves (also known as palatogingival grooves) and invaginations. Both malformations most often affect the lateral maxillary incisor (Lee *et al.* 1968; Alani & Bishop 2008). Their etiology is largely unknown, but genetic predisposition and local factors interfering with normal tooth development have been discussed (Alani & Bishop 2008). Palatoradicular grooves start at the junction of the cingulum with one of the lateral marginal ridges and continue apically, sometimes all the way to the apex (Lara *et al.* 2000). Invaginations can extend into the pulp chamber and/or communicate with the periodontal ligament apically or laterally on the tooth root through a pseudo-foramen (Alani & Bishop 2008). Palatoradicular grooves and invaginations may or may not communicate with the pulpal space (Lara *et al.* 2000; Alani & Bishop 2008).

Diagnosis

Prior to the advent of CBCT, diagnosis of root malformations was hampered by the limitations of intraoral radiographs to depict their anatomic configuration in all dimensions (Patel 2010). Yet, the issue is still complicated, as teeth affected by these malformations often have a vital pulp and thus respond within normal limits to routine sensitivity tests. Consequently, a palatoradicular groove or invagination is often diagnosed only when clinical manifestations are apparent. In the case of a palatoradicular groove, increased probing depth on the palatal aspect of a maxillary front tooth is suggestive. An invagination with a relationship to the pulpal space also reveals itself by symptoms of pulpitis in an otherwise healthy tooth without deep caries or restoration. In other invaginations with an opening to the periodontium, but without a direct communication with the pulpal space, periodontal manifestations of an acute nature mimicking symptomatic apical periodontitis may develop in a tooth with vital pulp (Fig. 41-27). If any of these lesions is suspected, limited-volume CBCT at maximum resolution helps the clinician to render minimally invasive treatment.

Treatment considerations

The type of malformation and the associated clinical features decide the treatment approach. Verifying pulpal vitality of the affected tooth is a first critical step. If clearly vital with no obvious periodontal involvement, treatment aims to prevent oral microorganisms from colonizing these niches to trigger inflammatory periodontal tissue breakdown. The prevention of this colonization by oral hygiene measures is usually not possible (Everett & Kramer 1972). Surgery with removal of granulation tissue combined with scaling and root planing and placement of a polytetrafluoroethylene membrane over the palatogingival groove has been reported to be successful in a limited series of cases with loss of clinical attachment (Anderegg & Metzler 1993). For invaginations with periodontal lesions, cleaning and sealing the defect may be sufficient to attain periodontal healing (Fig. 41-26) (Pitt Ford 1998). Where a groove or invagination corresponds with the pulpal space and has caused a pulpal condition, root canal treatment is necessary. Yet, the outcome is not always predictable and treatment may need to include surgery (Nallapati 2004).

Root surface resorptions

Root surface resorptions usually progress without producing clinical symptoms and may therefore go undetected unless observed radiographically. However, in advanced stages, the surface defect may interfere with the gingival sulcus and thereby initiate an infectious process (Fig. 41-28). Different forms of root surface resorption as sequelae to traumatic incidents have

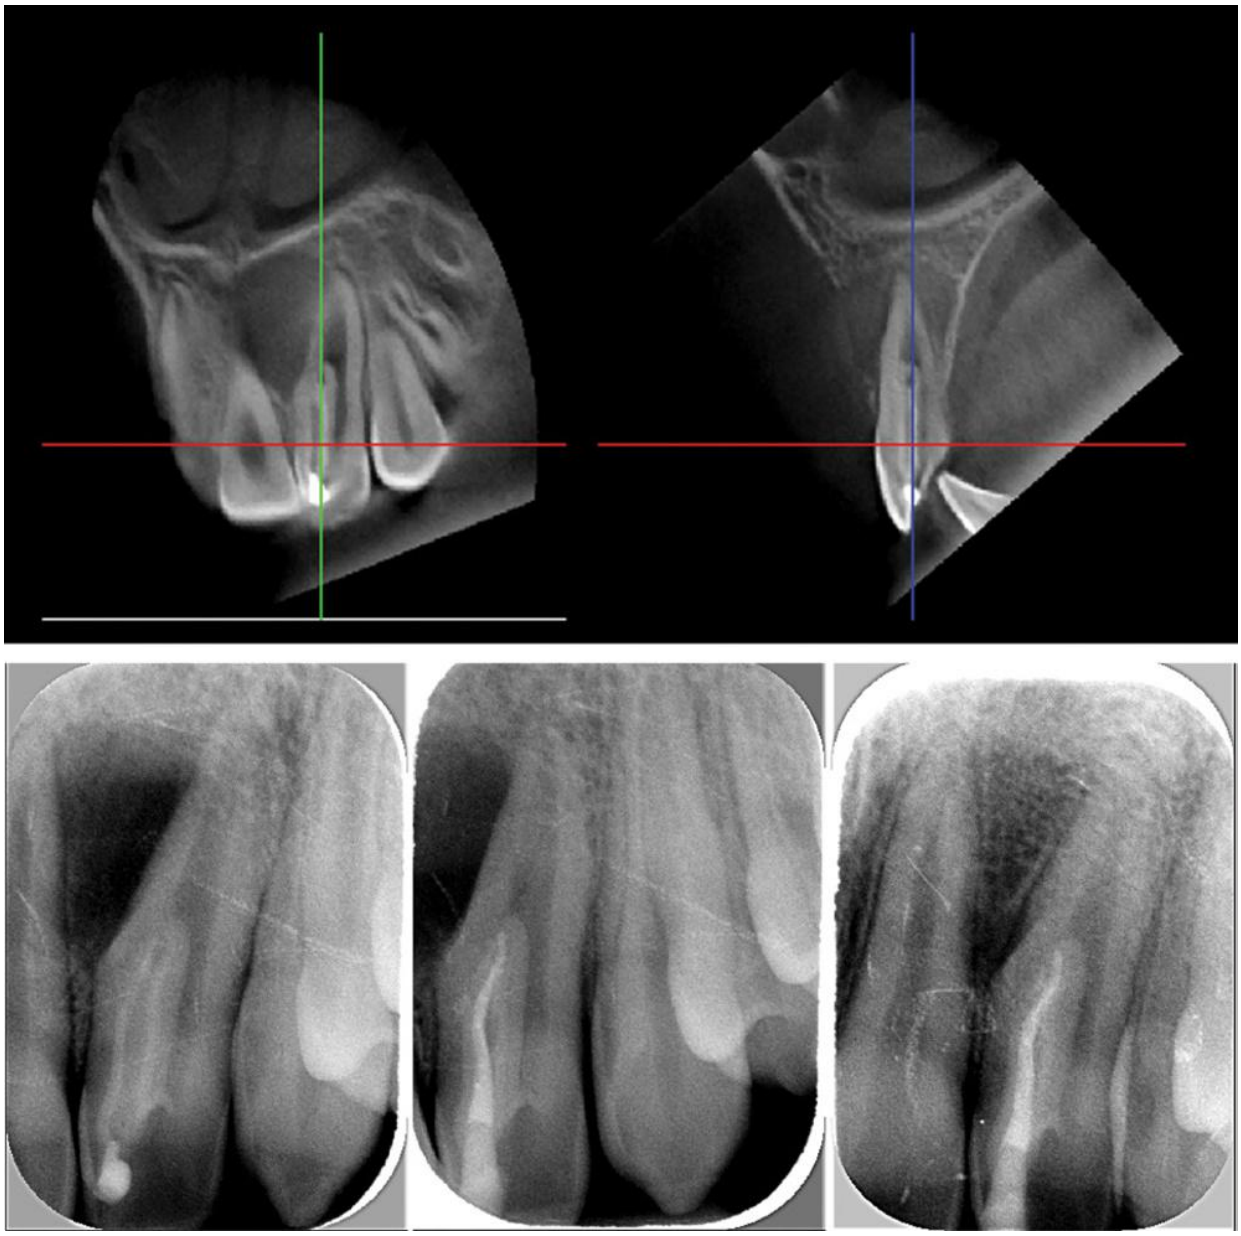

Fig. 41-27 Lateral maxillary incisor of a then 11-year-old boy. The patient presented with an acute abscess related to tooth 22. The tooth had an invagination, which communicated with the marginal periodontium. Note the apparent complete absence of bone on the buccal root aspect as depicted in the cone-beam computed tomogram. There was no communication of the invagination with the pulpal space. Hence, the root canal was not treated. The invagination space was chemomechanically cleaned, filled with gutta-percha and a sealer, and coronally sealed using a bonded composite material. The lesion resolved clinically and radiographically within 1 year (lower right panel). The tooth remained within normal limits to sensitivity tests.

been described (Andreasen & Andreasen 1992). In the discussion of potential interrelationships between endodontics and periodontics, one type is of particular clinical importance. This form of root surface resorption, here termed cervical invasive root resorption, is not, or at least not exclusively, related to injury from trauma (Heithersay 1999b).

Cervical invasive root resorptions

Often misdiagnosed, cervical invasive root resorption has been given various names, including odontoclastoma, asymmetric internal resorption, progressive intradental resorption, idiopathic external resorption, peripheral cervical resorption, cervical external resorption, extracanal invasive resorption, supraosseous extracanal invasive resorption, peripheral inflammatory root resorption, or simply cervical resorption (Frank & Bakland 1987; Gold & Hasselgren 1992; Heithersay 1999a). Geoffrey S. Heithersay, who arguably has studied the disease condition most extensively, coined the term cervical invasive root resorption (CIRR) (Heithersay 1999b). Yet, some dispute regarding the correct nomenclature remains, as these lesions are not always located cervically (Gold & Hasselgren 1992). CIRR can be associated with pulpal breakdown, increased pocket probing depths, as well as drainage of pus upon probing (Fig. 41-28).

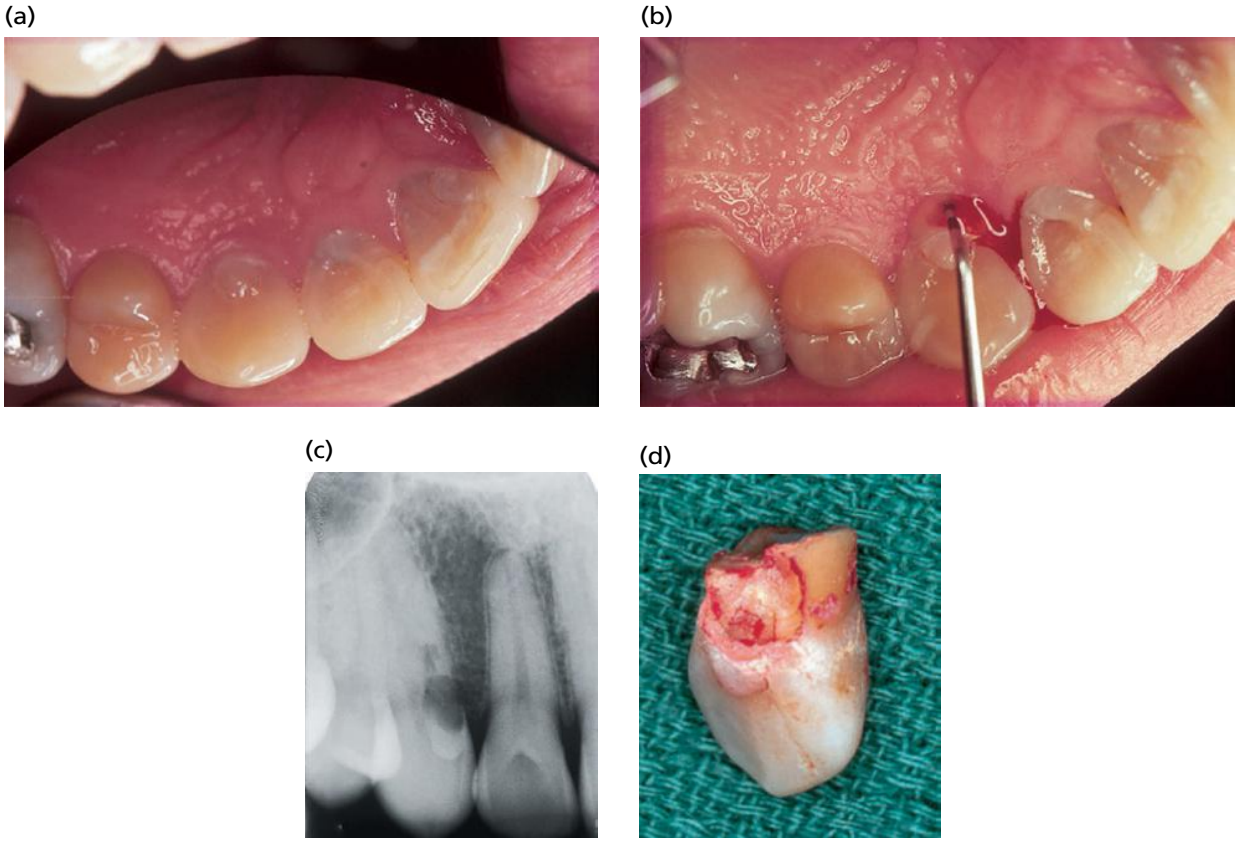

Fig. 41-28 Case of cervical invasive root resorption (CIRR). Pain and tenderness of the right maxilla for several weeks prompted the 30-year-old male patient to seek treatment. (a) Clinical inspection revealed no obvious pathosis. (b) Periodontal probing, however, released pus drainage from the lingual aspect of tooth 13. Pulp sensitivity test of the tooth and its neighboring teeth gave clear positive responses. (c) Angulated radiograph disclosed the presence of a resorptive defect. (d) Tooth was extracted as successful treatment was deemed unlikely. An extensive resorptive defect had undermined the clinical crown.

There are different forms of CIRR. In most cases, small openings penetrate the cementum layer along which the resorptive process continues inside the tooth structure without causing major peripheral breakdown (Fig. 41-29). Other forms of CIRR may be associated with a broad opening to the periodontium (Fig. 41-30).

Etiology

Under normal, physiologic conditions, hard tissues are protected from resorption by their respective surface layers of blast cells; in the case of the cementum, by cementoblasts. As long as these blast cell layers remain intact with the unmineralized layer of osteoid or cementoid at the surface of the mineralized tissue, resorption will not occur (Gottlieb 1942).

While known for several other forms of root surface resorptions, the triggering mechanism for CIRR is far from completely understood. Predisposing factors, which may all interfere with the integrity of the cementoid layer, seem to be orthodontic treatment, trauma, and chemical injury in conjunction with intracoronal bleaching, while few of 222 retrospectively analyzed cases had a history of periodontitis or periodontal treatment (Heithersay 1999b). The reason for the low incidence following periodontal treatment could be that, even upon excessive scaling and root planing, the damaged area of the root surface usually becomes covered by junctional epithelium. A further potential cause of CIRR, especially when it affects multiple teeth in the same dentition, may be viral (von Arx *et al*. 2009). A similar, presumed virus-related, disease known as feline odontoclastic resorptive lesions is common in cats. It has been speculated that virus transmission from cats to humans can occur and is a possible cause of the condition (von Arx *et al*. 2009). Firm evidence of a viral causation of CIRR in multiple teeth is lacking, however.

In the case of CIRR, the predentin is not resorbed unless the lesion becomes infected. Obviously clastic cells avoid non- or less mineralized tissues (Stenvik & Mjör 1970) (Fig. 41-31). This explains why CIRR expands laterally without directly invading the pulp. Yet, this peripheral extension can markedly undermine the tooth structure (Figs. 41-29, 41-32, 41-33). If there is a non-vital pulp and thus no resorption inhibition mechanism in place in the form of odontoblast-supported predentin, CIRR may extend to the pulpal space.

A special form of resorptive process in the cervical region of teeth may develop subsequent to intracoronal bleaching of root-filled teeth (Harrington & Natkin 1979; Montgomery 1984). The use of concentrated, tissue-toxic hydrogen peroxide has been especially implicated as the agent is capable of penetrating dentin and cementum (Fuss *et al*. 1989).

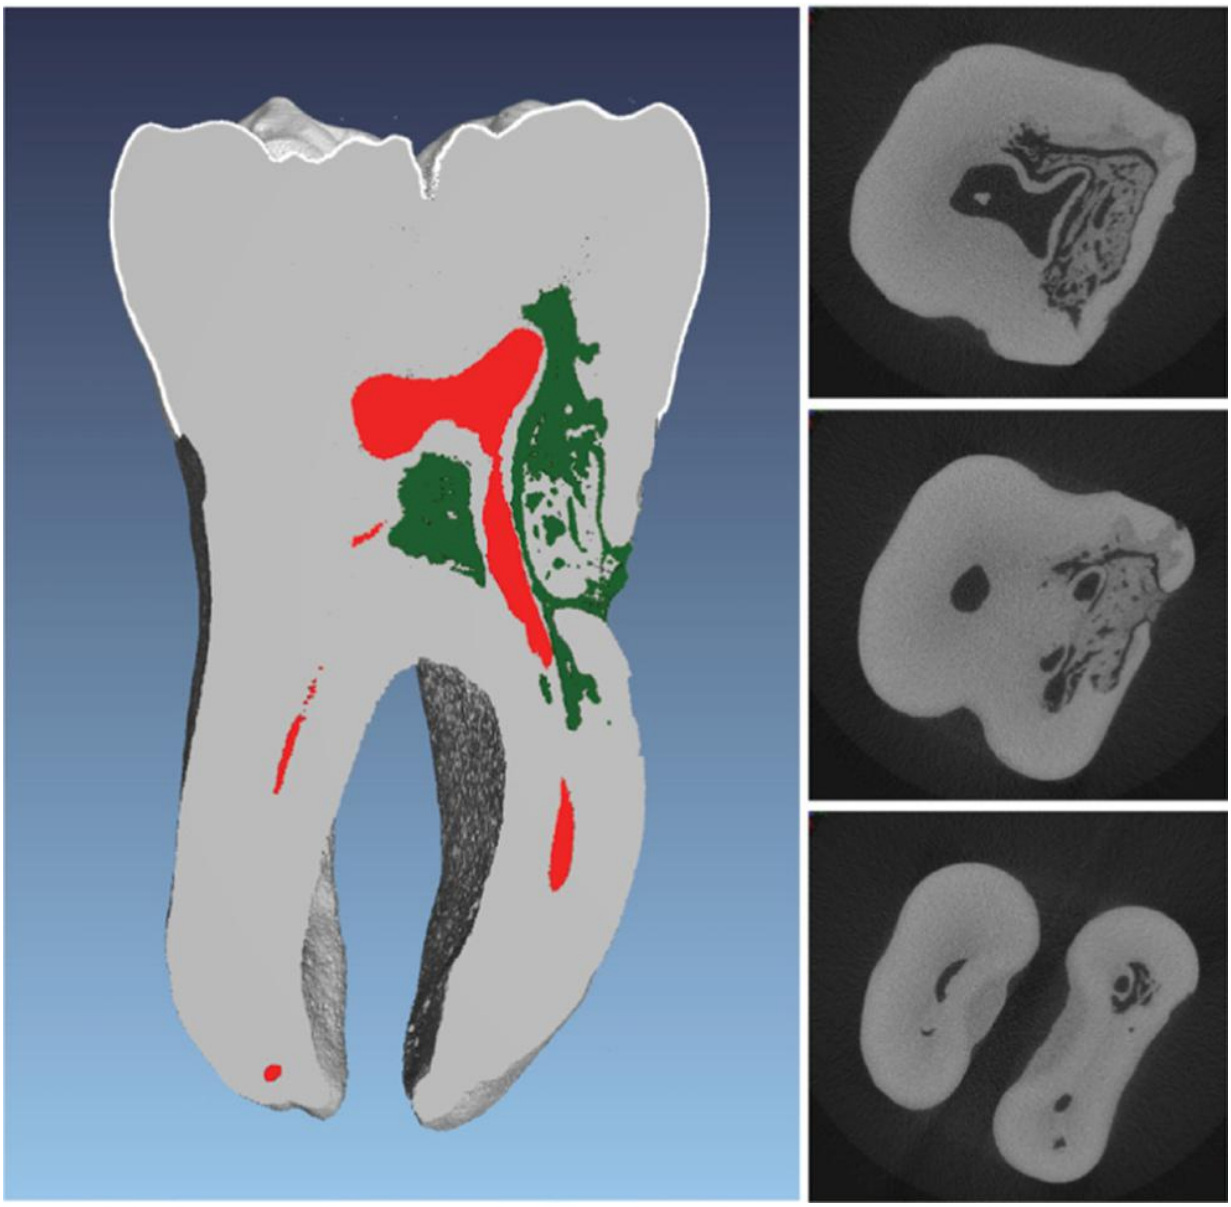

Fig. 41-29 Micro-computed tomography scan depicting a mandibular molar, which was extracted due to advanced cervical invasive root resorption (CIRR). Longitudinal section on left panel: false colors indicate the pulpal space (red) and the invagination (green). Original trans-sections on right panels. Note how the lesion circumvents the pulpal space. The apparent bone structure of the invading tissue is also to be noted. (Courtesy of F. Paqué.)

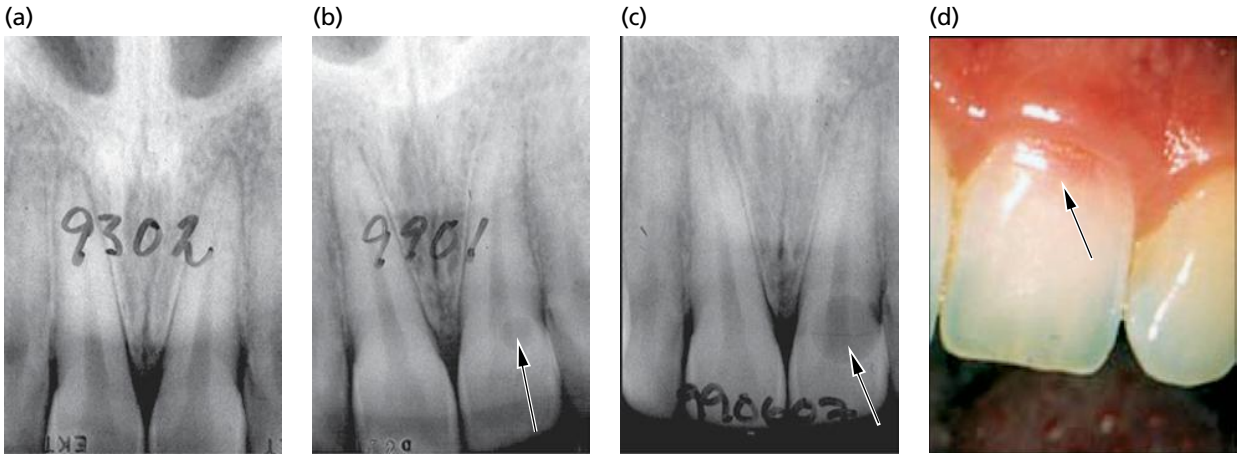

Fig. 41-30 Series of radiographs taken at different time intervals showing the appearance of a cervical invasive root resorption (CIRR) in a young adult patient. (a) At the age of 15 years there was no sign of resorption. (b) Six years later a small radiolucency emerged (arrow). (c) In just 6 months the lesion expanded considerably (arrow). (d) Lesion appeared clinically as a pink spot in the cervical area of the tooth (arrow). (Courtesy of A. Molander.)

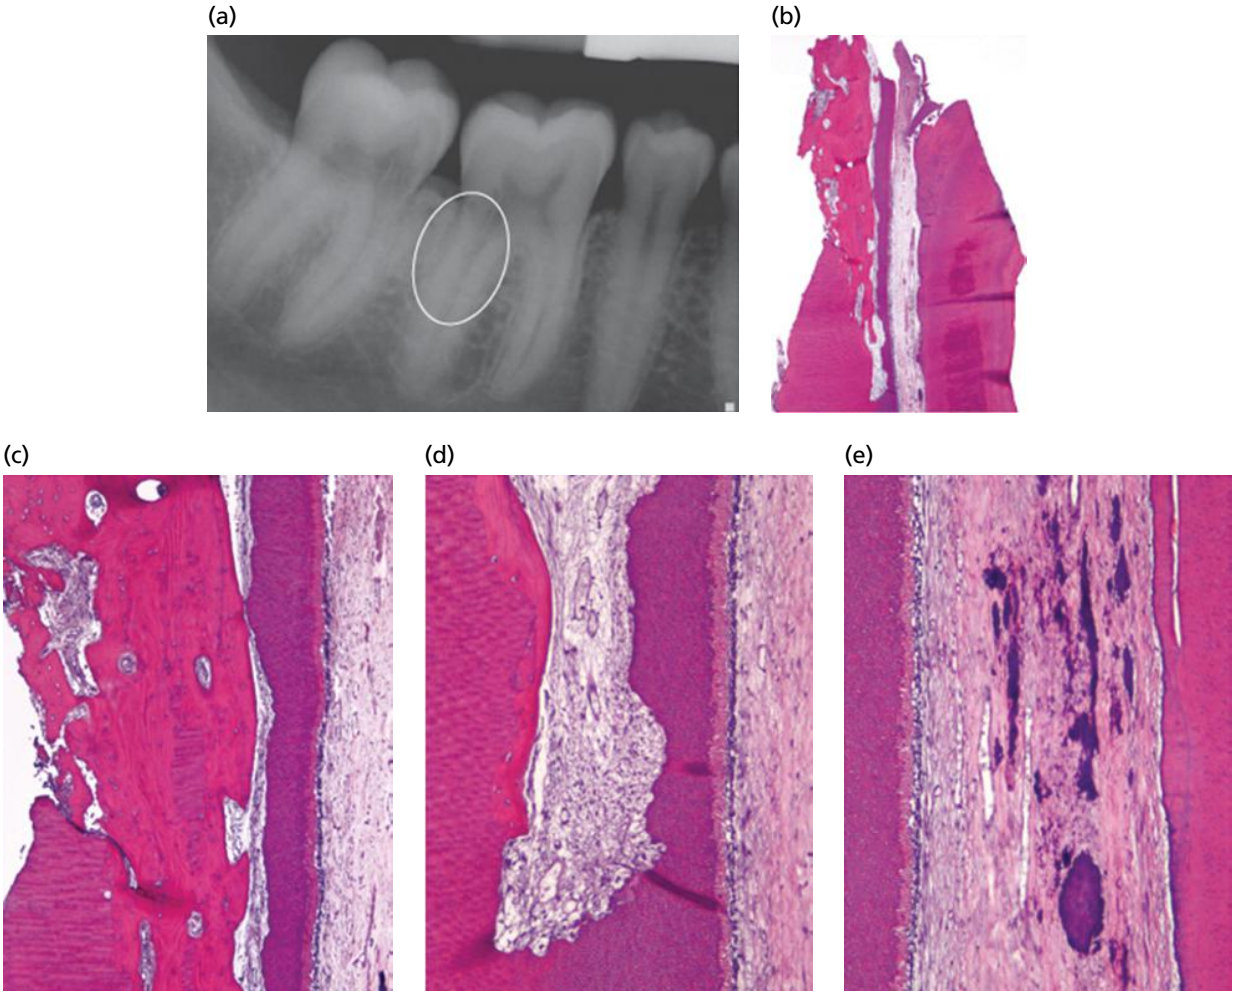

Fig. 41-31 (a) Mandibular first and second molar with the diagnosis of cervical invasive root resorption (CIRR). The teeth were deemed non-treatable and extracted. (b) Histologic section from the distal cervical area of the first molar encircled in (a). Overview shows that distally a large amount of dentin has been resorbed followed by invasion of bone tissue in the defect. The pulp space and the inner dentin layer are unaffected. (c) Detail from (b). The newly formed tissue shows the characteristic of lamellar bone with marrow spaces. (d) Magnification of the most apical portion of the resorptive defect in (b). Resorption of dentin and bone apposition can be observed on the opposite walls of the defect. Note the apparently normal predentin and odontoblast layer. (e) Pulp space immediately apical to the resorption. The pulp is uninflamed with prevalence of fibers and diffuse dystrophic calcifications.

It appears that the resorption is caused by bone remodeling units: clastic cells with hard-tissue forming counterparts in their trail. These cell units gain access to the root dentin by local loss of the cementoid layer. A histologic study by Southam (1967) revealed that CIRR lesions are filled with granulation tissue and bone. Consequently, these types of lesions are not inflammatory in nature, at least not initially. CIRR with a localized entrance to the bone tissue into the tooth are rather *a form of replacement resorption*. Initially, the point of entry of the bone remodeling units is small (Fig. 41-29). However, once the undermining process of the root surface becomes more severe, parts of the root surface layer may be lost, resulting in larger openings. Larger openings in the cervical area may also be related to diffusion of bleaching agents through the dentinal tubules. Oral microorganisms, rendering the case symptomatic, can invade these portals of entry for the resorbing tissue. The portal of entry of the CIRR is usually close to the crest of the alveolar bone. It may also be supraosseous or infraosseous (Frank & Torabinejad 1998).

Diagnosis

Root resorptions *per se* do not cause painful symptoms and may remain clinically quiet for years. While radiography is the only means of detection, a pinkish spot at the facial aspect of a tooth in the cervical region is a warning signal (Fig. 41-30). In very late stages, as the resorptive process engages the gingival sulcus, an infectious process may emerge with typical features of a periodontal abscess (Fig. 41-28).

A single radiograph is usually not sufficient to define a radiolucent area within the confines of a root as an external resorption. In fact, a radiolucency may portray a variety of conditions including a resorptive process inside the root canal (internal root resorption), or a resorptive defect located buccally or lingually as the image of the root is superimposed. It may also be an artifact and reflect a radiolucent bone area superimposed on the root. Therefore, more than one radiograph at different angulations should be

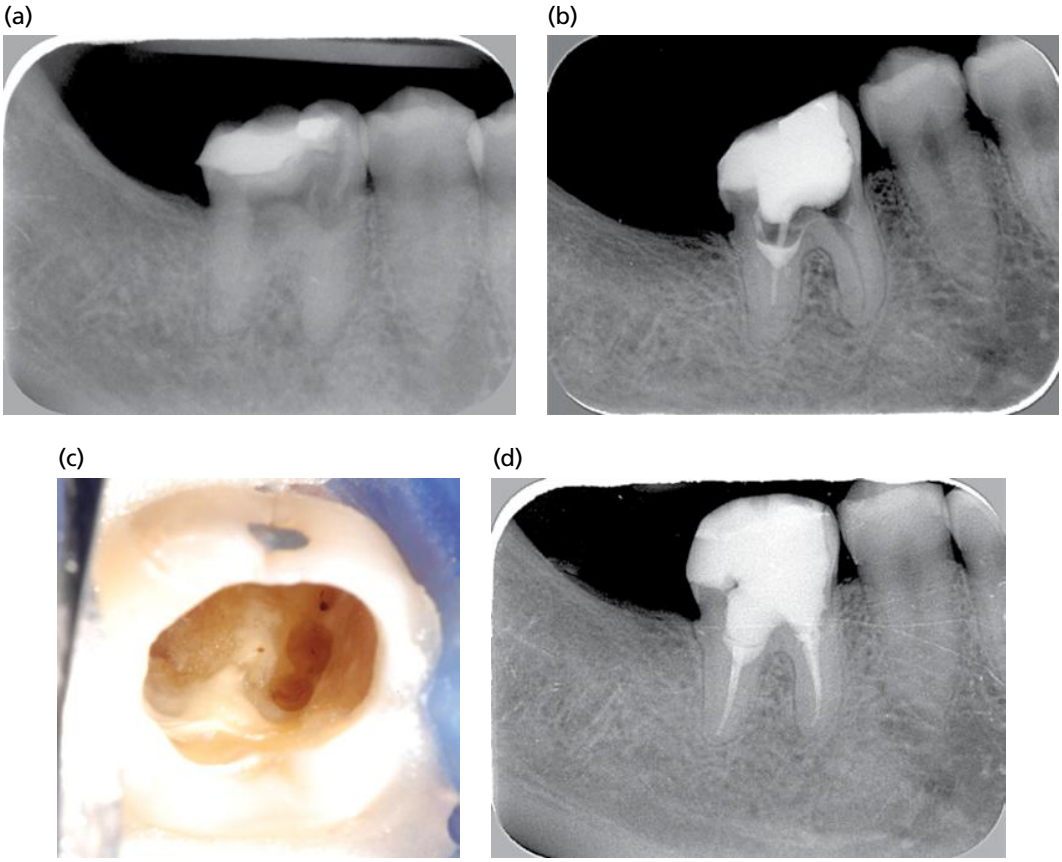

Fig. 41-32 (a) Radiograph of a 40-year-old female patient suffering from multiple cervical invasive root resorptions (CIRR) on her first molars. She had a history of high orthodontic forces applied to these teeth. When she first presented, she complained of severe spontaneous pain in the mandibular right molar region. Tooth 46 was diagnosed with symptomatic pulpitis related to CIRR. (b) Pulp space was accessed, and the resorptive tissue was mechanically removed using a long-shank bur under direct vision with the aid of a dental microscope. Subsequently, the resorption space and the root canal system were dressed with a suspension of calcium hydroxide powder in a 2.5% sodium hypochlorite solution. (c) On the second visit, the patient presented symptom-free. Because the bleeding could now be controlled, the points of entry of the resorptive tissues could be visualized, and the bone-like tissue removed. Mineral trioxide aggregate (MTA) was placed on the communications between the canal space and the periodontium. On the third visit, the root canal system was filled, and the tooth was restored with a bonded composite material. (d) At recall after 2 years, the tooth was free of symptoms and without radiologic signs of rarefaction.

taken to observe whether the radiolucent area affects the external root surface or not. New tomographic techniques can be of great benefit in distinguishing external from internal root resorptions (Patel *et al.* 2009). High-resolution, limited-volume CBCT is now the standard method for diagnosis of these cases. As these lesions are rare (Heithersay 1999a) and CBCT requires relatively high radiation dosages, the method should only be applied when CIRR is suspected.

The location of the lesion is important. A facial or lingual root resorption defect is more difficult to visualize radiographically than a proximal cavity, unless tomography is used. One should be aware that in the cervical region it may be difficult to differentiate radiographically between those cavities caused by caries and those caused by root resorption. To distinguish caries from resorption it is useful to recognize that bacterial acids that demineralize dentin leave a soft cavity surface. By contrast, clastic resorption removes both the mineral and the organic phases of the hard tissues, resulting in a cavity floor that is *hard to probing*.

The clinical features of CIRR include a granulation tissue that bleeds freely on probing. Occasionally, a periodontal abscess may develop due to marginal infection, which may mimic a periodontal or endodontic condition (Fig. 41-29). When the lesion is located more apically or proximally, probing is usually difficult. Radiographically, the lesion may only be seen after it reaches a certain size (Andreasen *et al*. 1987) (Figs. 41-29, 41-31). Sometimes the appearance is mottled due to the proliferation of bone tissue into the resorptive defect (Seward 1963) (Fig. 41-34). The outline of the root canal can often be seen within the radiolucent area (Figs. 41-31, 41-35), which is a diagnostic feature of root surface resorption. The presence of profuse bleeding upon probing and granulation tissue formation, in combination with a hard cavity bottom, confirms the diagnosis of CIRR. Electric pulp test and cold tests are usually positive, but will not distinguish this condition from caries or internal resorption, the two major differential diagnostic options (Frank & Bakland 1987).

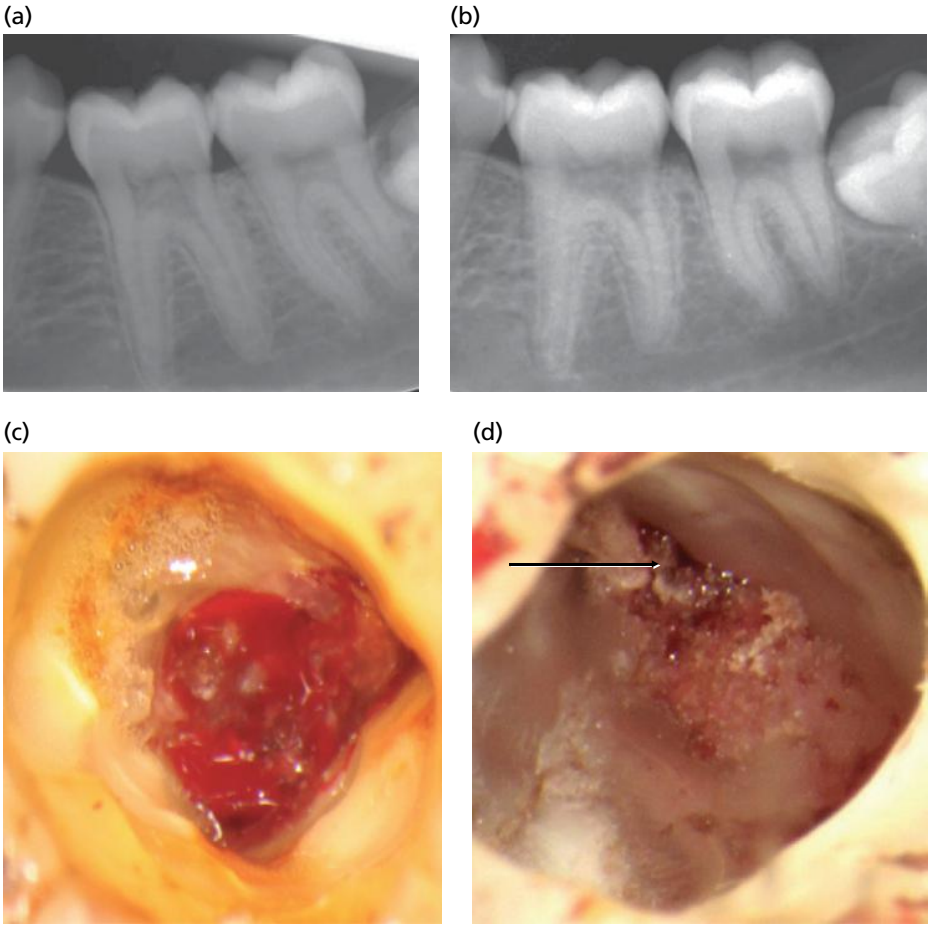

Fig. 41-33 (a, b) CIRR in a first mandibular molar showing a mottled appearance. There are pulp stones within the pulp tissue and bone tissue formation within the resorptive defect superimposed on the pulpal space. Following accessing both the pulp and the resorptive process (c) and removing the bleeding tissue, bone tissue appeared at the lingual wall of the cavity, where the resorptive process had entered the tooth (d). Arrow in (d) indicates the orifice of the root canal in the distal root. (Courtesy of M. Fridjon Ragnarsson.)

Clinical management aspects

The location and size of the portal of entry dictate the choice of treatment attempt. Surgical exposure of the area to allow removal of the granulation tissue is the only reasonable option in cases with accessible, wide openings (Heithersay 1999c). A dental filling, for example a resin composite, is subsequently placed in the defect followed by resuturing of the flap. The mechanical removal of the granulation tissue can be aided by chemically pretreating it with trichloracetic acid (Heithersay 1999c). Other treatment options from the periodontal side include repositioning the flap apical to the resorption or orthodontic extrusion of the tooth (Gold & Hasselgren 1992). Guided tissue regeneration has also been advocated after surgical removal of the granulation tissue, to promote ingrowth of periodontal ligament cells into the resorbed area (Rankow & Krasner 1996). In teeth with root anatomy that allows atraumatic extraction, intentional re-implantation can be performed (Frank & Torabinejad 1998). This approach will require root canal treatment. The costs of root canal treatment and potential resorptive sequelae of intentional re-implantation are reasons why this combined approach is usually not the first treatment choice.

Treating CIRR from the periodontal side has the advantage that the pulp may be kept vital. However, in most cases, the portal of entry is located in areas that are hard to access (Frank & Torabinejad 1998). Maintaining pulpal vitality in these cases is therefore near impossible, and it is often less invasive to sacrifice the pulp and treat the lesion from the pulpal side. This approach has become much easier with the advent of dental microscopes and MTA. To rid the tooth of the resorbing tissue, a two-visit approach is advocated: at the first visit, the defect inside the tooth is located and the bulk of the ossifying granulation tissue is removed using long-shank round burs (Fig. 41-32). A slurry of calcium hydroxide powder in a NaOCl solution can then be placed as an interim medication. This will dissolve soft tissue remnants inside the lesion (Zehnder *et al.* 2003). At the second visit, bleeding can be controlled more easily. The portal of entry of the CIRR can then be identified and closed with a cement such as MTA (Fig. 41-32). As with perforation defects, supracrestal lesions are best sealed directly with a dual-curing composite resin bonded to dentin.

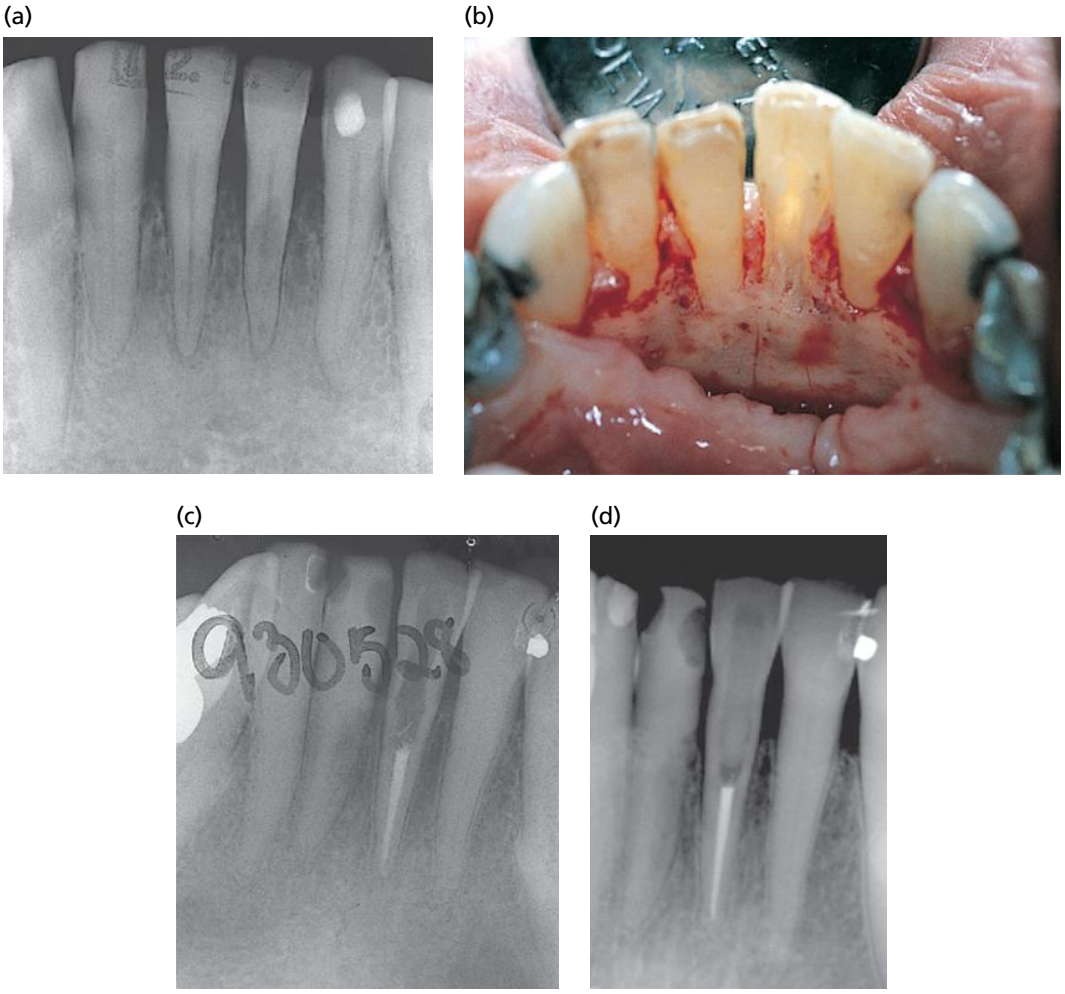

Fig. 41-34 Case with root surface resorption on the lingual aspect of both central incisors. (a) The patient, a 78-year-old woman, presented to the clinic after an episode of severe pain and development of a lingual periodontal abscess. The medical history was unremarkable. The patient was initially managed with antibiotic treatment. (b) Later, upon flap elevation and accessing the resorbing area and removal of the granulation tissue, a necrotic pulp of tooth 31 was noted. (c) Endodontic treatment was carried out during the surgical procedure. Tooth 41 was left without any further treatment and the case was followed clinically and radiographically. No recurrence of resorption occurred on either tooth and the patient remained comfortable. (d) Radiograph of the last follow-up is 8 years after treatment. Note that there is no progression of the resorptive process associated with tooth 41.

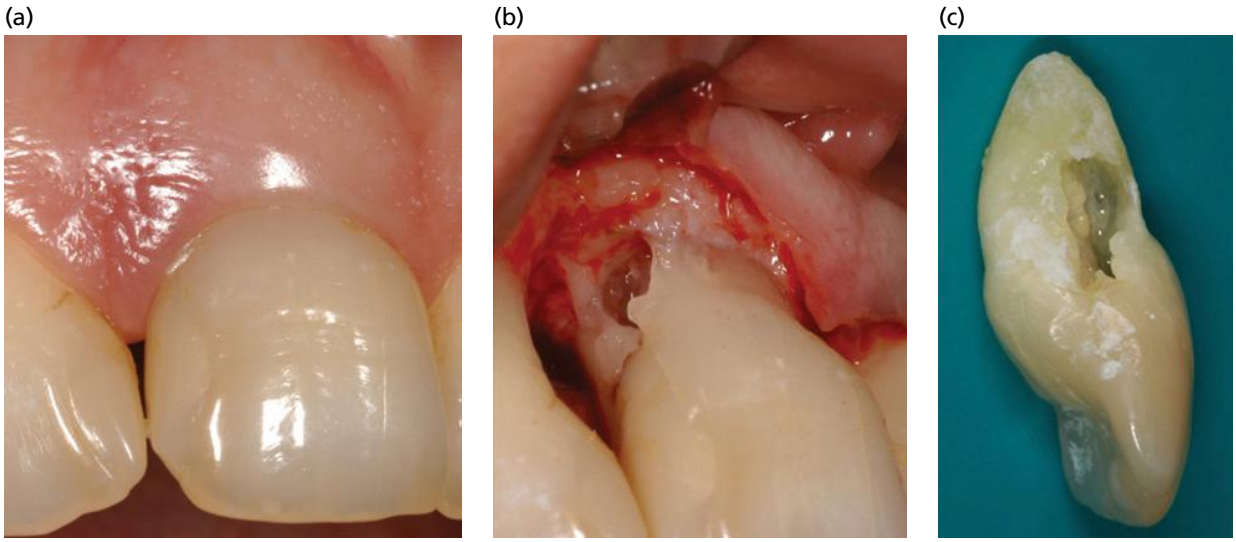

Fig. 41-35 (a) Maxillary left front tooth with a massive CIRR. (b) Periodontal surgery revealed that the lesion was too extensive for the tooth to be saved. (c) In this case, extraction was the only reasonable treatment option. Note the undermining nature of the lesion on the extracted tooth. The predentin is not resorbed, and thus the shell of the pulp space appears like a column in the hollowed space. (Courtesy of C. Schädle.)

Another treatment option is extraction of the affected tooth. This becomes necessary in advanced cases, when it is impossible to restore the structural integrity of the affected tooth (Fig. 41-35). Yet another alternative is to inform the patient about the tooth's lack of viability but to leave it alone for the time being, while recommending regular follow-up checks. Experience has shown that the resorptive process occasionally may slow down and such teeth can therefore last for several years (Fig. 41-34). This option is especially advocated if the CIRR lesion is located in apical portions of the root. Apically positioned subcrestal lesions are hard to reach surgically or endodontically, but have a lower likelihood of becoming infected compared to supracrestal counterparts.

Conclusion: CIRR in advanced stages can be associated with persistent inflammation in the periodontal tissues and pulpal breakdown. The cause for the occurrence of this type of root surface resorption is not well understood. To remedy the condition, it is necessary to remove the resorbing granulation tissue surgically and to fill the resorption cavity. Modern endodontic techniques allow the treatment to be carried out from the pulpal side (Figs. 41-33, 42-34). However, regardless of approach, periodontal tissue complications may ensue, including deep pockets and suppuration from such pockets. Treated cases should therefore be monitored by regular clinical/radiographic follow-ups to observe any signs of recurrence and how the periodontal tissue copes. In advanced cases, extraction is the only reasonable treatment option (Figs. 41-29).

Introduction

Inflammatory lesions occurring in peri-implant tissues were described in Chapter 26. Such processes are the result of opportunistic infections and may, if left untreated, progress deep into the supporting bone and lead to implant loss. It is, therefore, imperative that the tissues around implants be monitored at regular intervals to identify biologic complications and to treat the disease process at an early stage. The appropriate therapy following diagnosis must aim to reduce the submucosal biofilm and alter the ecology of the bacterial habitat.

Treatment strategies

The choice of treatment strategy is based on the diagnosis and the severity of the peri-implant lesion. Peri-implant mucositis and incipient forms of peri-implantitis require less extensive measures than advanced peri-implantitis lesions with severe bone loss. In all situations of peri-implant disease, however, the treatment strategy must include mechanical cleaning (infection control) procedures. Thus, information and instruction on the use of oral hygiene measures must be provided to the patient in combination with professional mechanical cleaning, including removal of plaque and calculus from implant surfaces. In this context it is important that the design of the implant-supported prosthesis allows access for oral hygiene. In cases where access is obstructed, the prosthesis must be modified to promote self-performed and professional mechanical infection control.

Two cases that illustrate the outcome of self-performed and professional mechanical cleaning are shown in Figs. 42-1 and 42-2. While plaque, calculus, and signs of inflammation are evident at implants in the initial examination, the follow-up visit after 3 months of infection control demonstrates improved oral hygiene and soft tissue conditions.

Non-surgical therapy

There are obvious similarities between treatment strategies for periodontal and peri-implant infections. One important difference, however, relates to difficulties with instrumentation of the implant surface below the margin of the mucosa. Thus, subgingival scaling and root planing are well-known procedures in the treatment of periodontitis, while in peri-implantitis the geometry of the implant with threads of different designs may impede the ability of the clinician to detect and remove calculus located below the mucosal margin. During such "blind" instrumentation at implants there is also a risk that deposits may be dislodged and be displaced into the mucosa. It is thus recommended

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

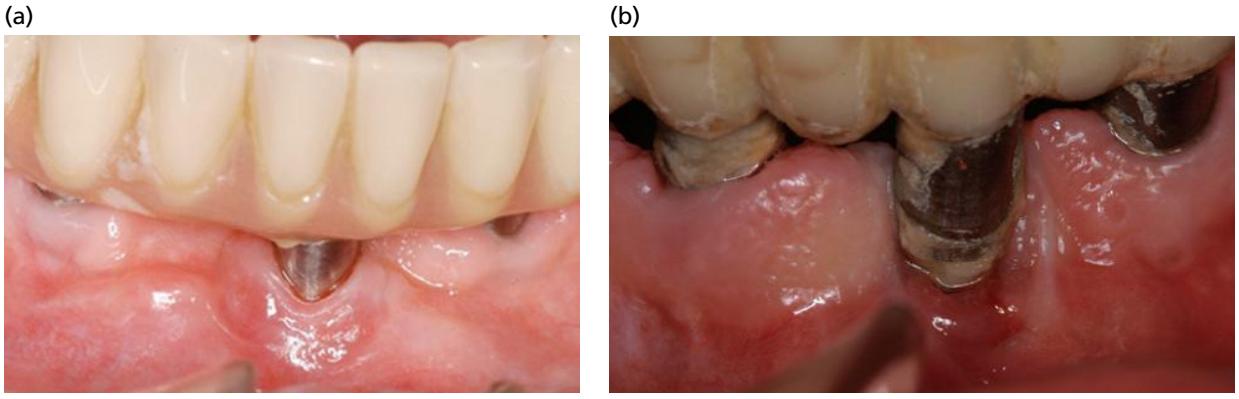

Fig. 42-1 Clinical photographs of implant sites in the mandible of (a) a 70-year-old and (b) a 62-year-old woman. Note the overt signs of inflammation in the peri-implant mucosa (a, b) and the large amounts of plaque and calculus (b).

that non-surgical debridement of implant surfaces, that is procedures that aim to remove calculus and plaque, should be restricted to the portion of the implant located coronal to or at the level of the mucosal margin. While calculus may be chipped off using titanium-coated or carbon-fiber curettes, plaque is removed by polishing the implant surface with rubber cups and a polishing paste. Carbon-fiber curettes do not damage the implant surface. They may be sharpened and are strong enough to remove most accumulations of calculus. Ultrasonic instruments with non-metallic tips may also be used for calculus removal.

Peri-implant mucositis and incipient peri-implantitis lesions may be resolved using the cause-related measures described above. Heitz-Mayfield *et al.* (2011) in a study of treatment of peri-implant mucositis in 29 patients reported that non-surgical debridement and oral hygiene were effective and that the adjunctive use of a chlorhexidine gel did not enhance treatment outcome.

Non-surgical therapy of moderate and severe forms of peri-implantitis, however, is ineffective in resolving inflammation, including the combined use of non-surgical mechanical debridement and topical application of antibiotics and/or the use of lasers.

Surgical therapy

A re-examination of peri-implant tissues following initial therapy that reveals absence of bleeding on probing (BoP) and pocket closure indicates resolution of peri-implant lesions. On the other hand, if signs of pathology, that is BoP and/or suppuration in combination with deep pockets, remain at the re-examination, additional therapy is required. Surgical procedures are one treatment option, which provide access to the implant surfaces harboring biofilms. A prerequisite for surgical therapy in treatment of peri-implantitis is appropriate standards of self-performed infection control.

The goal of surgical treatment of peri-implantitis is to acquire access to the implant surface for debridement and decontamination in order to achieve resolution of the inflammatory lesion (Lindhe & Meyle 2008). Surgical therapy of peri-implantitis lesions is shown in Figs. 42-3, 42-4, and 42-5. Clinical signs of inflammation, probing pocket depth (PPD) of about 10 mm in combination with BoP and suppuration were detected at the initial examination (Fig. 42-3). The radiograph revealed the presence of angular bone defects around the two implants. Flap elevation allowed access to the area and inflamed tissue in the defects was removed

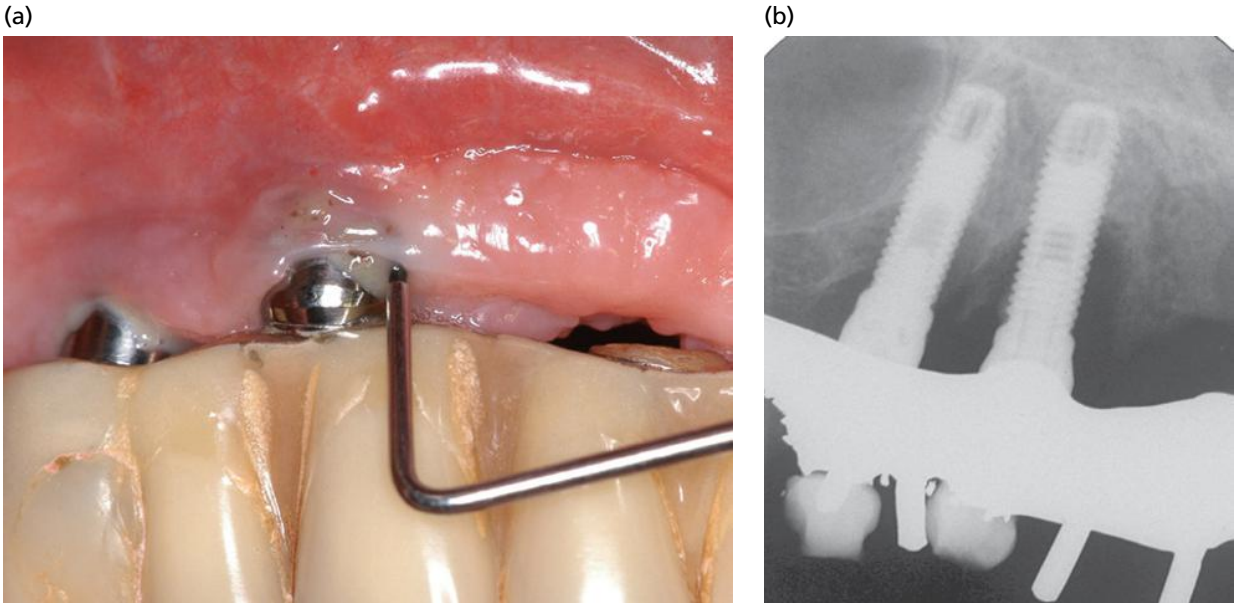

Fig. 42-3 (a) Clinical photograph and (b) radiograph from implant sites with peri-implantitis. Note the probing pocket depth of 10 mm and suppuration (a) and the angular bone defects (b).

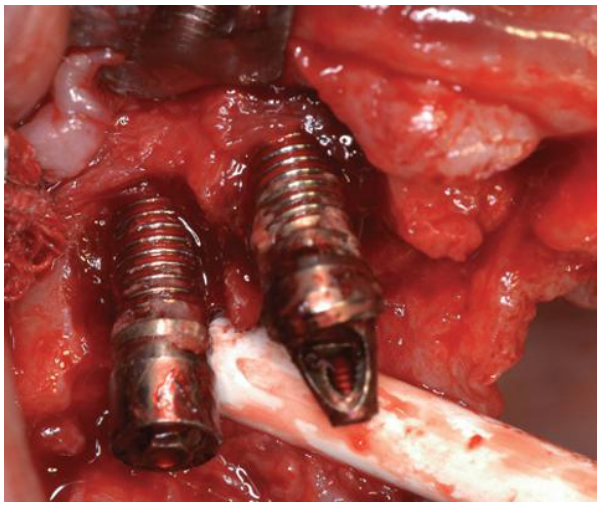

Fig. 42-4 Implant sites shown in Fig. 41-3 after flap elevation and removal of granulation tissue. Note the absence of buccal bone walls of the osseous defects. The implant surfaces are now accessible for mechanical debridement.

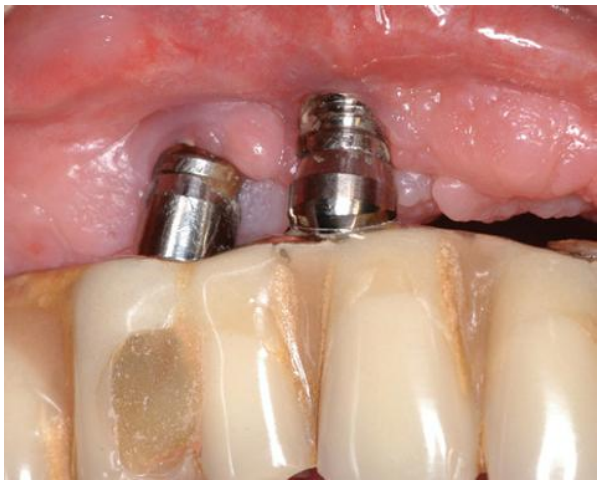

Fig. 42-5 Implant sites shown in Fig. 41-3 at 6 months after surgical therapy. Maintenance therapy with supervised infection control is provided. Note the soft tissue recession following the pocket elimination procedure.

using curettes (Fig. 42-4). Mechanical debridement of the implant surface was performed using carbon-fiber curettes and small pieces of gauze or pellets soaked in saline. The peri-implantitis–associated bone defect may be treated using either resective or reconstructive procedures. In this case, the morphology of the osseous defect was unsuitable for reconstructive techniques and, hence, bone resection was performed to adjust the morphology of the interproximal bone walls. At the 6-month follow-up after surgery, it was observed that PPD was reduced and clinical signs of inflammation were absent (Fig. 42-5).

Most studies on the treatment of peri-implantitis have been carried out using small patient groups and with a considerable variation in case definitions of disease (see Chapter 26). In addition to mechanical debridement, a vast number of different procedures have been proposed, including antiseptic agents and/or systemic antibiotics. Serino and Turri (2011) evaluated results at 2 years after surgical therapy of sites with peri-implantitis in 31 patients. It was reported that pocket elimination combined with bone recontouring was an effective therapy for the majority of patients and implants. The results also indicated that resolution of the disease depended on the amount of bone loss around the implants prior to treatment. In addition, implant sites that resolved following surgical therapy remained healthy during the 2-year period of follow-up, while disease progression occurred at implants that showed lack of disease resolution in the initial phase after treatment. At a 12-month examination following surgical therapy of

peri-implantitis in 24 patients, Heitz-Mayfield *et al.* (2012) reported that a significant reduction of PPD, BoP, and suppuration had occurred. While 47% of the implant sites exhibited complete resolution of disease, 92% of the sites showed stable crestal bone levels or bone gain.

The treatment procedures that were applied in the studies by Serino and Turri (2011) and Heitz-Mayfield *et al.* (2012) included the adjunctive use of systemic antibiotics. Although this approach has been applied in most clinical reports, it is not known if the adjunctive use of systemic antibiotics improves treatment outcome.

Implant surface decontamination

One of the largest challenges in the treatment of peri-implantitis is implant surface decontamination. Figure 42-6 illustrates the complexity of a biofilm residing on implants presenting with peri-implantitis: the high magnification of the micrographs reveals microorganisms of various morphotypes occupying micro-sized compartments of the implant surface. Although complete biofilm removal using a mechanical approach appears to be difficult, results from preclinical and clinical studies demonstrate that resolution of peri-implantitis lesions can indeed occur following implant surface decontamination. In the study by Heitz-Mayfield *et al.* (2012) referred to above, all implants were cleaned during surgery using gauze soaked in saline. Evidence for complete resolution of peri-implantitis lesions following mechanical debridement combined with saline was presented in a preclinical study by Albouy *et al.* (2011). They produced experimental peri-implantitis around different types of implants in dogs according to techniques previously described (Lindhe *et al.* 1992) (see Chapter 26). The surgical therapy was

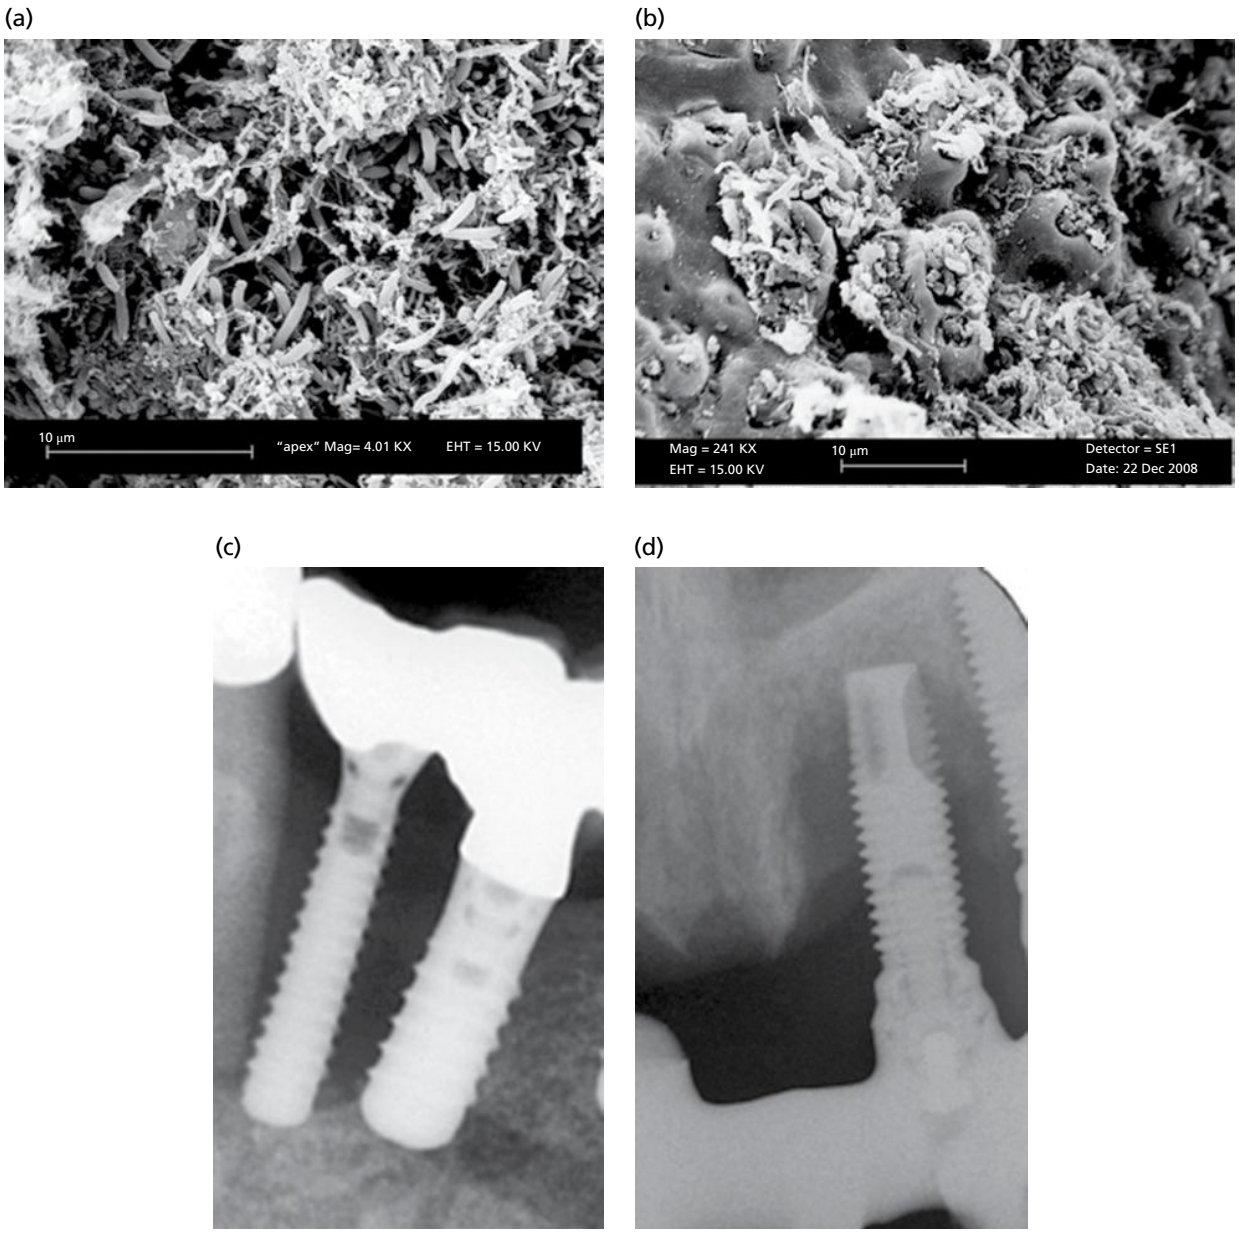

Fig. 42-6 Scanning electron micrographs (a, b) from implants that were surgically removed from sites with severe peri-implantitis (c, d). Note the microorganisms of various morphotypes occupying compartments of the modified implant surfaces (a, b).

carried out without the adjunctive use of systemic antibiotics or local antimicrobial agents. The histologic examination of biopsies obtained at 6 months after surgery revealed complete resolution of the lesions at most implant sites.

Taken together, data from preclinical and clinical research on the treatment of peri-implantitis reveal that the local use of antiseptic agents, air abrasives or lasers for surface decontamination during surgical treatment of peri-implantitis does not enhance treatment outcomes in relation to mechanical debridement combined with topical application of saline.

In the preclinical study by Albouy *et al*. (2011), it was also concluded that the resolution of peri-implantitis lesions was influenced by implant surface characteristics. Thus, the results from the radiologic examination of the experimental sites revealed that, of implants with different types of implant surface modification, those with a turned surface exhibited the largest amount of bone gain following surgery. In addition, the evaluation of the histologic sections disclosed that the peri-implant tissues around the turned implants showed a higher degree of resolution of inflammation than the implants with modified surfaces. Similar observations were made by Roccuzzo *et al*. (2011) in a study of 26 patients with peri-implantitis around implants with either a rough [titanium plasma-sprayed (TPS)] or moderately rough surface [sandblasted large-grit acid-etched (SLA)]. It was reported that reduction of PPD and BoP was more pronounced at the implants with the SLA surface than those with the TPS surface.

Procedures that include more aggressive techniques have also been suggested to achieve implant surface decontamination. Such procedures have included grinding of the implant surface and removing threads from the titanium cylinder together with polishing of rough implant surfaces. Results from one study with a 3-year follow up following surgical therapy indicated some benefit when using such "implant-resective techniques" on TPS surface implants (Romeo *et al*. 2007). In this context, however, the risks involved in implant grinding procedures – potential damage to the peri-implant bone caused by overheating as well as spreading of metal particles – must be considered.

Reconstructive procedures

The bone loss that occurs during progression of peri-implantitis results in osseous defects with varying morphology. As described in Chapter 26, at sites where the width of the ridge exceeds that of the peri-implantitis lesion, a buccal and lingual bone wall may remain and a crater form. Conversely, in sites with a narrow ridge, the buccal and lingual bone walls will be resorbed and lost during progression of peri-implantitis. Thus, sites with peri-implantitis often present with an angular ("one-wall") bone defect on the mesial and distal aspects of the implant only. The potential for a reconstructive approach in such cases is questionable and, hence, hard tissue resection is recommended. On the other hand, at sites with peri-implantitis presenting with circumferential bone craters, a reconstructive approach may be considered. A vast number of procedures have been proposed to promote bone fill of such defects. It is currently not known, however, if the use of bone grafts/substitutes or barrier membranes improves treatment outcome in surgical therapy of peri-implantitis.

Re-osseointegration

Bone fill of osseous defects detected on radiographs following treatment of peri-implantitis indicates that new bone has formed, but this should not be taken to indicate that re-osseointegration has occurred. The term re-osseointegration can be defined as the establishment of *de novo* bone formation and *de novo* osseointegration to a portion of an implant that during the development of peri-implantitis suffered loss of bone–implant contact and became exposed to microbial colonization.

Assessment of bone–implant contact requires histologic examination, which calls for the use of preclinical research models. As described in Chapter 26, experimental peri-implantitis can predictably be produced using well-established techniques and different treatment protocols can be applied accordingly. Persson *et al*. (1999) induced experimental peri-implantitis in dogs according to the model described by Lindhe *et al*. (1992). The subsequent treatment included (1) systemic administration of antibiotics; (2) elevation of full thickness flaps at the experimental sites and curettage of the hard tissue defect; (3) mechanical debridement of the exposed portion of the implants; and (4) flap management and closure of the soft tissue wound. Radiographs and biopsies were obtained after 7 months of submerged healing. The analysis of the radiographs indicated a complete bone fill in the hard tissue defects (Fig. 42-7). Histologic analysis of the biopsy sections revealed that treatment had resulted in a complete resolution of the soft tissue inflammation and the formation of substantial amounts of new bone in the previous hard tissue defects (Fig. 42-8). However, only small amounts of re-osseointegration to the once decontaminated titanium surface could be observed and consistently only at the apical base of the defects. At most sites a thin connective tissue capsule separated the "exposed" implant surface from the newly formed bone (Fig. 42-9). Similar findings were reported by Wetzel *et al*. (1999) from another study in dogs and the use of implants with various surface characteristics (turned, TPS, and SLA surfaces).

Based on the outcome of the above studies, it was concluded that the problem inherent in re-osseointegration appears to be the implant surface rather than the host tissues at the site. The problem regarding the implant surface was addressed in a study in dogs by Persson *et al*. (2001). They evaluated the potential for re-osseointegration to implants designed with either

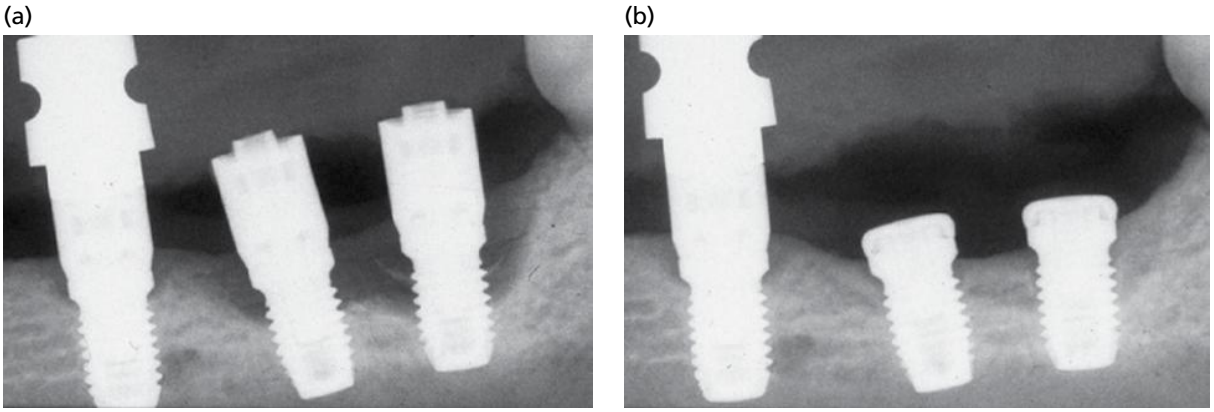

Fig. 42-7 (a) Radiographs obtained from two sites exposed to experimental peri-implantitis. (b) Sites at 7 months of submerged healing after treatment of peri-implantitis. Note the bone fill in the previous osseous defects.

smooth (polished) or roughened (SLA) surfaces. Experimental peri-implantitis was induced and bone loss of about 50% of the peri-implant bone support was produced (Fig. 42-10). Treatment included (1) systemic antibiotics; (2) flap elevation and curettage of the bone defect; and (3) mechanical debridement of the implant surface (gauze soaked in saline). The implants were submerged and biopsies were obtained after 6 months of healing. At all implant sites, most of the crater-like defects had been filled with newly formed bone (Fig. 42-11). However, at sites with smooth surface implants, only small amounts of re-osseointegration had occurred (Fig. 42-12). The examination of the histologic sections from sites with moderately rough surface implants, however, revealed that >80% of the previously exposed rough surface exhibited re-osseointegration (Fig. 42-13).

It may be hypothesized that the surface characteristics (smooth versus rough) of the implant may influence the process of bone healing that eventually may result in re-osseointegration. In this context, it is important to point out that these surface

characteristics do influence the risk for progression of peri-implantitis (see Chapter 26). In addition, from the preclinical study by Albouy *et al*. (2011) it was concluded that resolution of the disease was influenced by implant surface characteristics.

Conclusion

Treatment of peri-implant mucositis and peri-implantitis should include anti-infective measures and the evaluation of treatment outcome must include parameters that describe resolution of inflammation and preservation of the supporting bone. Non-surgical therapy with mechanical infection control procedures is effective in resolving peri-implant mucositis and incipient forms of peri-implantitis. In moderate and severe forms of peri-implantitis, however, non-surgical procedures may be insufficient to resolve disease but should always precede surgical therapy to establish appropriate standards of self-performed infection control. Treatment of peri-implantitis is influenced by the surface characteristics of the implant.

There is no evidence that adjunctive systemic antibiotics or local antiseptics, or reconstructive procedures (bone grafts/substitutes, membranes) have additional beneficial effects on treatment outcome of peri-implantitis.

Chapter 43

Antibiotics in Periodontal Therapy

Andrea Mombelli[1] and David Herrera[2]

[1] Department of Periodontology, School of Dental Medicine, University of Geneva, Geneva, Switzerland
[2] Faculty of Odontology, University of Complutense, Madrid, Spain

Introduction

Antibiotics are drugs that kill or stop the multiplication of bacterial cells at concentrations that are relatively harmless to host tissues, and therefore can be used to treat infections caused by bacteria. The term was originally applied to natural substances produced by certain groups of microorganisms, distinguishing them from other antimicrobial agents that are chemically synthesized. However, some antimicrobial compounds, originally discovered as products of microorganisms, can be synthesized entirely by chemical means. Therefore, in medicine and pharmaceutics, antimicrobial agents used in the treatment of bacterial infections are now generally referred to as antibiotics, interpreting the word literally. Antibiotics are just one group of antimicrobial agents, which also comprise antiviral, antifungal, and antiparasitic chemicals. The capacity of the drug to reach the infected site and the ability of targeted bacteria to resist or deactivate the agent determine the effectiveness of therapy. Based on their effect at concentrations tolerated by the host, antibiotics can be categorized as "bactericidal" or "bacteriostatic", and, depending on the range of susceptible bacteria, "narrow-spectrum" or "wide-spectrum".

In the late 1930s and early 1940s the appearance of powerful agents selectively active against bacteria – sulfonamides, penicillin, and streptomycin – revolutionized the treatment of bacterial infections. The outstanding success of these agents in the treatment of formerly life-threatening diseases led many to believe that bacterial infections would never again be a major medical concern. Seven decades of experience with these and hundreds of additionally developed antimicrobial drugs have shown that, despite their success, this view was too optimistic. Emerging problems resulting from the widespread use of antibiotics have modified the general perception of the capabilities of antimicrobial agents. Many bacteria have developed a significant capacity to resist or repel antibiotic agents. It has been noted that antibiotics may disturb the delicate ecologic equilibrium of

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

the body, allowing the proliferation of non-bacterial microorganisms and resistant strains. Sometimes this may initiate new infections that are worse than the ones originally treated. Antimicrobial agents may have other unwanted properties, such as toxicity, that need to be considered as well.

The purpose of this chapter is to discuss the utility of systemic and locally applied antimicrobials in periodontal therapy. Given the limitations of mechanical treatment, the use antibacterial agents may enhance the effect of therapy. Potential benefits must be balanced against the risks of unwanted effects.

Principles of antibiotic use in periodontics

Is periodontitis an infection and should it be treated as one?

The recognition of periodontitis as an infection caused or sustained by living bacteria that are present at diseased sites is fundamental for any antimicrobial treatment concept. Antibiotics can kill or suppress living bacteria but they cannot remove calculus and bacterial residues, which is traditionally perceived to be an essential part of periodontal therapy.

The continued presence of large masses of bacteria on hard oral surfaces induces inflammation in adjacent soft tissues such as gingiva or mucosa. The importance of removing bacterial deposits for resolution of gingivitis or peri-implant mucositis is therefore undisputed. The propensity of sites to undergo further periodontal destruction is felt to be more specific in nature, since not all sites with gingivitis invariably progress to periodontitis and since increased proportions and detection frequencies of suspected oral pathogens are found in periodontitis lesions. Still, thorough mechanical cleaning of the root surfaces to remove bacterial deposits has proven to be beneficial for all cases of periodontitis, irrespective of type or clinical circumstances. Furthermore, it has been shown that efficient self-performed mechanical oral hygiene to prevent the re-establishment of bacterial deposits is essential for long-term stability (for review see Chapter 60). Nevertheless, this way of treating periodontal disease is time consuming, requires high levels of motivation and manual skills – of both the clinician and the patient – and can induce tissue damage. It would be irrational to believe that mechanical instruments alone are able to completely remove periodontal pathogens from all infected sites (Mombelli *et al*. 2000). Bacteria may be inaccessible to mechanical instruments in concavities, lacunae, and dentin tubules, not to mention invaded soft tissues. Substantial hard tissue trauma can arise from repeated instrumentation attempts in locally unresponsive sites, or sites with recurrent disease. In addition, successfully treated sites may be recolonized by pathogens persisting in non-dental areas.

Specific characteristics of the periodontal infection

Two specific features of periodontal infection are of uppermost importance in relation to the use of antimicrobials.

First, the term infection usually refers to tissue invasion and multiplication of pathogenic microorganisms in tissues. The uniqueness of biofilm-associated dental diseases as infections however relates to the lack of massive bacterial tissues invasion. Although there is confirmation of bacterial penetration in highly active conditions such as periodontal abscesses and necrotizing periodontal diseases (Listgarten 1965; Saglie *et al*. 1982a, b; Allenspach-Petrzilka & Guggenheim 1983; Carranza *et al*. 1983), invasion and multiplication of bacteria within periodontal tissues is not considered to be indispensable for developing disease. Evidently, microorganisms present in subgingival deposits can harm these tissues also without penetrating them. It follows that in order to be effective, antimicrobial agents used in the context of periodontal therapy need to be available at a sufficiently high concentration not only inside but also outside of the affected tissues (Fig. 43-1). In the periodontal pocket environment these agents may be inhibited, inactivated or degraded by the large masses of microorganisms present. Therapeutic concentrations may be difficult to achieve everywhere, and antibiotic resistance is bound to occur first where the penetration of the agent is restricted.

Second, the subgingival microbiota accumulate on the root surface to form an adherent layer of plaque called "biofilm". Comprehensive review papers highlight the importance of biofilm formation in the etiology of many infections and point to the consequences of this for therapy in a broader perspective (Socransky & Haffajee 2002; Costerton 2005; Costerton *et al*. 2005; Marsh 2005; Davey & Costerton 2006,). Dental biofilms have most of the features of other currently known biofilms, with antimicrobial resistance being of special relevance (Marsh 2004; Marsh *et al*. 2011). Periodontal pathogens such as *Aggregatibacter actinomycetemcomitans* (formerly known as *Actinobacillus actinomycetemcomitans*) (Norskov-Lauritsen & Kilian 2006) and *Porphyromonas gingivalis* show higher levels of tolerance to several antimicrobial agents when embedded in biofilms than as planktonic cells (Larsen 2002; Noiri *et al*. 2003; Eick *et al*. 2004; Takahashi *et al*. 2007). Furthermore, within biofilms resistant microorganisms of low intrinsic virulence can protect antibiotic-sensitive pathogens (O'Connell *et al*. 2006).

The mechanisms increasing the antimicrobial resistance of microorganisms in biofilms differ between bacterial species and depend on the composition and the ecologic conditions within a biofilm. These include the protection by extracellular polymeric substances, leading to failure of the antimicrobial agent to penetrate the biofilm, and the adoption

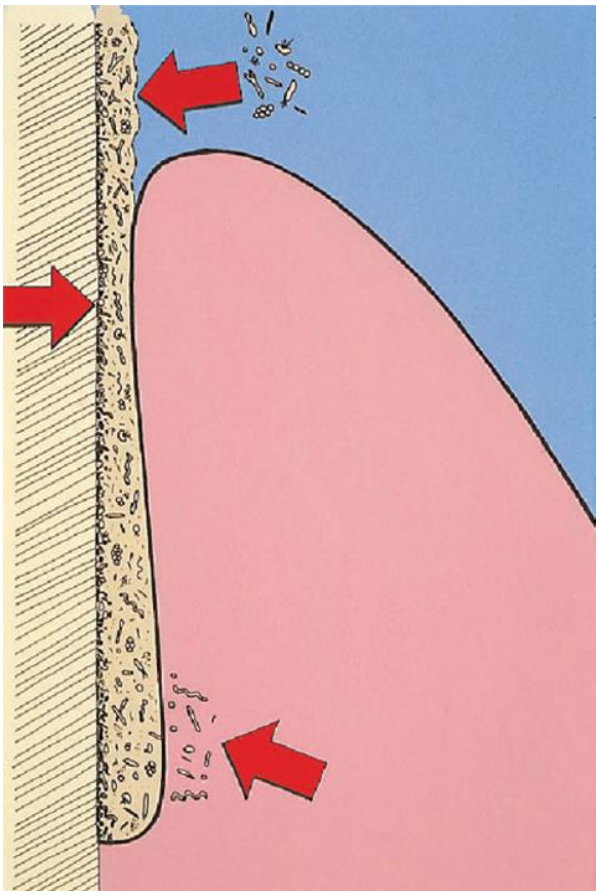

Fig. 43-1 Specific conditions for the use of antimicrobial agents in periodontal therapy: periodontal pocket as an open site is subject to recolonization after therapy (top arrow); subgingival bacteria are protected from antimicrobial agents in a biofilm (middle arrow); agent must be available at a sufficiently high concentration not only within the periodontal tissues, but also in the subgingival environment outside the periodontal tissues (bottom arrow).

of a resistant physiologic state or phenotype related to the multicellular nature of the biofilm community. Biofilms play an important role in the spread of antibiotic resistance. Within the dense bacterial population, efficient horizontal transfer of resistance and virulence genes takes place.

In recognition of these phenomena, there is general consensus that periodontal diseases should not be treated with antimicrobial agents alone (Herrera *et al*. 2008; Sanz & Teughels 2008). Thorough mechanical debridement must always be performed to disrupt the structured aggregates protecting embedded bacteria and to markedly reduce the microbial mass that may inhibit or degrade the antimicrobial agent.

Should antimicrobial therapy be aimed at specific pathogens?

A closer look at the composition of the subgingival microbiota reveals that periodontal treatment is targeted at a variable mixture of different bacteria (Kroes *et al*. 1999; Paster et al. 2001). The number of different species and subspecies occasionally identified in samples from human dental biofilms far exceeds 100, but only relatively few show a distinctive pattern of association with disease. While most of these organisms are thought to significantly harm tissues only if present in high numbers over prolonged periods, certain species may have a negative effect when present in relatively low numbers in susceptible individuals. On the basis of their pathogenicity, demonstrated in animal experiments, and the identification of virulence factors, a limited number of organisms have been suggested as specific periodontal pathogens (for review see Chapter 8). *A. actinomycetemcomitans* and *P. gingivalis* have attracted particular attention because longitudinal and retrospective studies indicated an increased risk for periodontal breakdown in positive sites and because results of treatment were better if these organisms could no longer be detected at follow-up (Haffajee et al. 1991; Grossi *et al*. 1994; Haffajee & Socransky 1994; Dahlén *et al*. 1996; Rams *et al*. 1996; Bragd *et al*. 1987; Wennström *et al*. 1987; Carlos *et al*. 1988; Chaves *et al*. 2000). *A. actinomycetemcomitans* displays a broad genetic and phenotypic diversity and is heterogeneously distributed in various populations and cohorts worldwide (Kilian *et al*. 2006). In one large prospective study (Haubek *et al*. 2008), only one subpopulation of *A. actinomycetemcomitans*, the "JP2 clone" (Tsai *et al*. 1984), showed the properties of a true pathogen. There is an ongoing debate on the utility of microbiologic tests to identify such organisms in order to optimize periodontal therapy. As will be discussed further in the section on Systemic antibiotics, recent studies show clinical benefits of therapies supposedly targeting such organisms even in their absence.

Narrow-spectrum antibiotics, such as metronidazole, have been proposed for periodontal therapy in *A. actinomycetemcomitans*-negative patients based on the hypothesis that beneficial bacteria, which are intrinsically resistant to metronidazole, could suppress the re-emergence of anaerobic pathogens such as *P. gingivalis*. This theory has not been proven by clinical trials. Given the large diversity of the microbiota associated with all forms of periodontitis, and the complex synergistic and antagonistic interactions between the members of this flora, the concept of specifically identifying and eradicating a particular pathogen may be illusionary (Cionca *et al*. 2010), although the results of previous trials may suggest the opposite (Pavicic *et al*. 1994). In most trials showing beneficial effects of antimicrobials, neither the agents nor the subjects have in fact been selected based on microbiologic testing. This does not exclude the possibility that in some cases virulent organisms may be present that are resistant to a tested drug.

Drug delivery routes

By mouth (*per os*, p.o.) is the most common route for delivering antibiotics in the treatment of bacterial infections. Administration by means other than through the alimentary tract (by intramuscular or

Table 43-1 Comparison of local and systemic antimicrobial therapy.

Issue	Systemic administration	Local administration
Drug distribution	Wide	Narrow effective range
Drug concentration	Variable levels in different body compartments	High dose at treated site, low levels elsewhere
Therapeutic potential	May reach widely distributed microorganisms better	May act better locally on biofilm-associated bacteria
Problems	Systemic side effects	Re-infection from non-treated sites
Clinical limitations	Requires good patient compliance	Requires infection to be limited to the treated site
Diagnostic problems	Identification of pathogens, choice of drug	Distribution pattern of lesions and pathogens, identification of sites to be treated

intravenous injection) is usually reserved for serious medical conditions where the oral route has proven ineffective. Some local infections can be treated with topically administered antimicrobials, such as with eye drops or ointments. In the therapy of periodontal diseases, antimicrobials may be delivered via the systemic route or by direct placement into the periodontal pocket. Each method of delivery has specific advantages and disadvantages (Table 43-1).

Local therapy may allow the application of antimicrobial agents at levels that cannot be reached by the systemic route and may be suitable for agents, for example antiseptics, that are too toxic to be delivered by the systemic route. This form of application seems to be particularly promising if the target organisms are confined to the clinically visible lesions.

Systemic administration of antibiotics may be better if the target bacteria are distributed more widely. Studies have shown that periodontal bacteria may in fact be distributed throughout the whole mouth in some patients (Mombelli *et al*. 1991a, 1994), including in non-dental sites such as the dorsum of the tongue or tonsillary crypts (Zambon *et al*. 1981; Müller *et al*. 1993; Pavicic *et al*. 1994; Müller *et al*. 1995; van Winkelhoff *et al*. 1988). Disadvantages of systemic antibiotic therapy relate to the fact that the drug is diluted by dispersal through the whole body, and only a small portion of the total dose actually reaches the subgingival microbiota in the periodontal pocket.

Adverse drug reactions are a greater concern and more likely to occur if drugs are distributed via the systemic route. Even mild forms of unwanted effects may severely decrease patient compliance (Loesche *et al*. 1993). Local delivery is independent of patient compliance.

Methods suggested for local drug application in periodontal pockets range from simple irrigation, or placement of drug-containing ointments and gels, to sophisticated techniques involving devices for sustained release of antibacterial agents. In order to be effective, the drug should reach the entire area affected by the disease, especially the base of the pocket, and should remain there at a sufficiently high concentration for a specific period of time. With mouth rinse or supragingival irrigation, it is not possible to predictably deliver an agent to the deeper parts of a periodontal defect (Pitcher *et al*. 1980; Eakle *et al*. 1986). The gingival crevicular fluid (GCF) rapidly washes out agents brought into periodontal pockets by subgingival irrigation. Based on an assumed pocket volume of 0.5 mL and a GCF flow rate of 20 µL/h, Goodson (1989) estimated that the half-time of a non-binding drug placed into a pocket is about 1 minute. Even a highly concentrated, highly potent agent would thus be diluted below a minimum inhibitory concentration (MIC) for oral microorganisms within minutes. If an agent can bind to surfaces and be released in an active form, a prolonged time of antibacterial activity could be expected. Such an effect has in fact been noted for salivary concentrations of chlorhexidine after use of a chlorhexidine mouth rinse (Bonesvoll & Gjermo 1978). Although there are indications that this may also occur to a certain extent within the periodontal pocket, for instance after prolonged subgingival irrigation with tetracycline (Tonetti *et al*. 1990), the potential to create a drug reservoir of significant size on the small surface area available in a periodontal pocket is limited. To maintain a high concentration over a prolonged period, the flushing action of the GCF flow has to be counteracted by a steady release of the drug from a larger reservoir. Considering the small volume of a periodontal pocket and the pressure exerted by the tonus of the periodontal tissues on anything that is inserted, it appears unlikely that this can be achieved by a carrier that does not maintain its physical stability for some time and that cannot be secured against premature loss. Gels, for instance, rapidly disappear after instillation into periodontal pockets (Fig. 43-2), unless their viscosity changes immediately after placement (Oostervaal *et al*. 1990; Stoltze 1995). Viscous and/or biodegradable devices show an exponential decrease in concentration in gingival fluid. In order to have sustained control over drug release, it is necessary to have a matrix that is stable for longer than the drug load. Controlled delivery of an antimicrobial agent over several days has been shown for tetracycline released from non-degradable monolithic ethylene vinyl acetate fibers (Fig. 43-3).

Systemic antibiotics

Only a limited number of the large range of antimicrobial agents has been tested thoroughly for use in periodontal therapy. The drugs most extensively investigated for systemic use include tetracycline, minocycline and doxycycline, clindamycin, ampicillin, amoxicillin (with or without clavulanic acid), macrolides such as

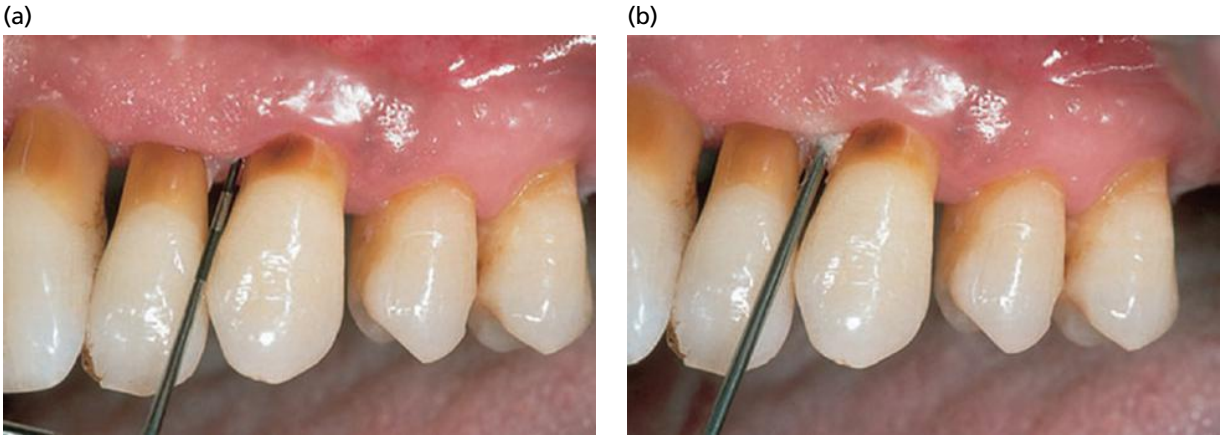

Fig. 43-2 (a) Antimicrobial gel is applied with a syringe inserted into a residual pocket (a). For retention of the agent in the site, the viscosity of the carrier should change immediately. A large portion of the product may otherwise be expelled from the pocket quickly (b).

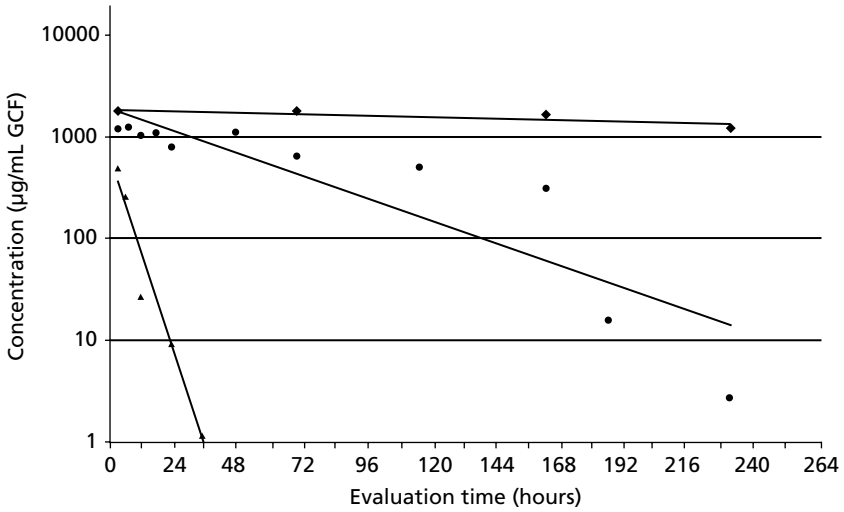

Fig. 43-3 Mean concentration of tetracycline (♦) in gingival crevicular fluid (GCF) during tetracycline fiber treatment (Tonetti *et al*. 1990), of doxycycline hyclate (●) after application in a biodegradable polymer (Stoller *et al*. 1998), and of metronidazole (▲) after application of 25% metronidazole dental gel (Stoltze 1992).

erythromycin, spiramycin, azithromycin and clarithromycin, and the nitro-imidazole compounds metronidazole and ornidazole, and certain combinations thereof.

The first antibiotics used in periodontal therapy were mainly systemically administered *penicillins*. The choice was initially exclusively based on empirical evidence. Penicillins and cephalosporins act by inhibition of cell wall synthesis. They have a narrow spectrum of activity and are bactericidal. Among the penicillins, amoxicillin has been favored for treatment of periodontal disease because of its considerable activity against several periodontal pathogens at levels achievable in gingival fluid. The molecular structure of penicillins includes a β-lactam ring that may be cleaved by bacterial enzymes. Some bacterial β-lactamases have a high affinity for clavulanic acid, a β-lactam molecule without antimicrobial activity. To inhibit bacterial β-lactamase activity, clavulanic acid has been added successfully to amoxicillin. This combination (Augmentin®) has been tested for periodontal therapy in clinical studies.

Tetracycline–HCl became popular in the 1970s due to its broad-spectrum antimicrobial activity and low toxicity. The tetracyclines, clindamycin, and macrolides are inhibitors of protein synthesis. They have a broad spectrum of activity and are bacteriostatic. In addition to their antimicrobial effect, tetracyclines are capable of inhibiting collagenase (Golub *et al*. 1985). This inhibition may interfere with tissue breakdown in periodontal disease. Furthermore, they bind to tooth surfaces, from where they may be released slowly over time (Stabholz *et al*. 1993).

The *nitro-imidazoles* were introduced into the periodontal field in 1962 when *The Lancet* published the report of a female patient, who after a week of treatment for trichomonal vaginitis with metronidazole declared she had undergone "a double cure". The vaginitis was cured and the "acute marginal gingivitis" she was also suffering from was relieved (Shinn 1962). The nitro-imidazoles (metronidazole and ornidazole) and the quinolone antibiotics (e.g. ciprofloxacin) act by inhibiting DNA synthesis. Metronidazole is known to convert into several short-lived intermediates after diffusion into an anaerobic organism. These products react with the DNA and other bacterial macromolecules, resulting in cell

Table 43-2 Characteristics of antimicrobial agents used in the treatment of periodontal disease.

Antibiotic	Dose (mg)	Serum concentration (μg/mL)	Crevicular fluid concentration (μg/mL)	t_{max} serum (h)	Half-life (h)
Penicillin	500	3	ND	1	0.5

Ciprofloxacin	500	1.9–2.9	ND	1–2	3–6

t_{max}, hours to reach peak serum concentration; ND, not determined.
Data from Lorian (1986) and Slots & Rams (1990).

death. The process involves reductive pathways characteristic of strictly anaerobic bacteria and protozoa, but not aerobic or microaerophilic organisms. Thus, metronidazole is active specifically against the obligately anaerobic part of the oral flora, including *P. gingivalis* and other black-pigmenting Gram-negative organisms, but not *A. actinomycetemcomitans*, the latter being a facultative anaerobe.

The concentrations following systemic administration of the most common antimicrobial agents used in the treatment of periodontal disease are listed in Table 43-2. The *in vitro* susceptibility of *A. actinomycetemcomitans* to selected antimicrobial agents is given in Table 43-3 and of *P. gingivalis* in Table 43-4. The data given in these tables may serve as a base for the choice of an appropriate agent. However, it is important to remember that *in vitro* tests do not reflect the true conditions found in periodontal pockets. In particular, they do not account for the biofilm effect. In addition, MIC values depend on technical details that may vary between laboratories. As a consequence, demonstration of *in vitro* susceptibility is no proof that an agent will be effective in the treatment of periodontal disease.

Combination antimicrobial drug therapy

Since the subgingival microbiota in periodontitis often harbors several putative periodontopathic species with different antimicrobial susceptibility, combination antimicrobial drug therapy with a wider spectrum of activity than a single agent may be useful. Overlaps in the antimicrobial spectrums of different agents may reduce the possible development of bacterial resistance. Some combinations of drugs have a synergistic action against target organisms, allowing lower doses of the single agents to be used. A synergistic effect against *A. actinomycetemcomitans* has been noted *in vitro* between metronidazole and its hydroxy metabolite (Jousimies-Somer *et al*. 1988; Pavicic *et al*. 1991) and between these two compounds and amoxicillin (Pavicic *et al*. 1992). Some drugs, however, may interact antagonistically. For instance, bacteriostatic agents such as

tetracyclines, which suppress cell division, may decrease the antimicrobial effect of bactericidal antibiotics such as β-lactam drugs or metronidazole, which act during bacterial cell division. Combination drug therapy may also lead to increased adverse reactions.

Adverse reactions

Table 43-5 lists common adverse reactions to systemic antibiotic therapy (for a detailed overview, see Hersh & Moore 2008). The *penicillins* are among the least toxic antibiotics. Hypersensitivity reactions are by far the most important and most common adverse effects of these drugs. Most reactions are mild and limited to a rash or skin lesion in the head or neck region. More severe reactions may induce swelling and tenderness of joints. In highly sensitized patients, a life-threatening anaphylactic reaction may develop. The systemic use of *tetracyclines* may lead to epigastric pain, vomiting or diarrhea. Tetracyclines can induce changes in the intestinal flora, and superinfections with non-bacterial microorganisms (e.g. *Candida albicans*) may emerge. Tetracyclines are deposited in calcifying areas of teeth and bones where they cause yellow discoloration. Systemic administration of *clindamycin* may be accompanied by gastrointestinal disturbances, leading to diarrhea or cramps, and may cause mild skin rashes. The suppression of the normal intestinal flora increases the risk for colonization of *Clostridium difficile*, which may cause a severe colon infection (antibiotic-associated colitis). Although not related to *C. difficile*, gastrointestinal problems are also the most frequent adverse event of systemic *metronidazole* therapy. Nausea, headache, anorexia, and vomiting may be experienced. Symptoms may be more pronounced with alcohol consumption (disulfiram or antabuse-like effect), because imidazoles inhibit the enzyme acetaldehyde dehydrogenase in the ethanol degradation pathway, resulting in an accumulation of acetaldehyde. Alcohol consumption should therefore be avoided during and immediately after therapy. As cases of permanent peripheral neuropathies (numbness or paresthesia) have been reported, patients should be advised to stop therapy immediately if such symptoms occur. Metronidazole has shown evidence of carcinogenic activity in studies involving chronic oral administration in mice and rats, but not in other tested species. Due to inadequate evidence, metronidazole is not considered a risk factor for cancer in humans (Bendesky *et al*. 2002). Previously unrecognized candidiasis may show more prominent symptoms during antibiotic therapy.

Table 43-5 Adverse effects of antibiotics used in the treatment of periodontal diseases.

Antibiotic	Frequent effects	Infrequent effects
Penicillins	Hypersensitivity (mainly rashes), nausea, diarrhea	Hematologic toxicity, encephalopathy, pseudomembranous colitis (ampicillin)
Tetracyclines	Gastrointestinal intolerance, candidiasis, dental staining and hypoplasia in childhood, nausea, diarrhea, interaction with oral contraceptives	Photosensitivity, nephrotoxicity, intracranial hypertension
Metronidazole	Gastrointestinal intolerance, nausea, antabuse effect, diarrhea, unpleasant metallic taste	Peripheral neuropathy, furred tongue
Clindamycin	Rashes, nausea, diarrhea	Pseudomembranous colitis, hepatitis

Systemic antimicrobial therapy in clinical trials

Although clinical efficacy is not an absolute proof for bacteriologic efficacy (Marchant *et al*. 1992), evidence advocating the use of systemic antibiotics must come from clinical trials in humans with periodontitis. A large number of reports suggesting beneficial effects in various clinical situations have been published. However, many of these have a high risk of bias due to low scores in quality criteria. Studies may be difficult to interpret and compare due to an unclear patient status at baseline (treatment history, disease activity, composition of subgingival microbiota), insufficient or non-standardized maintenance after therapy, short observation periods, or lack of randomization and controls. Studies not only vary with regard to the treatment provided, but also in the selection of subjects, sample size, range of study parameters, outcome variables, duration, and the controls to which the test procedure is compared. In most trials, systemic antibiotics have been used as an adjunct to scaling and root planing (SRP). Typically, the effect of mechanical therapy plus the antimicrobial agent has been compared to mechanical treatment alone or placebo. In studies evaluating the effect of antimicrobial therapy in patients with refractory periodontitis or with recurrent abscess formation, a placebo control is often lacking for ethical reasons.

A decade ago, in the context of consensus conferences issuing recommendations for periodontal care, the benefit of adjunctive systemically administered antibiotics was assessed for the first time in two systematic reviews. Herrera *et al*. (2002) included 25 controlled clinical trials of at least 6 months' duration in which systemically healthy subjects with chronic or aggressive forms of periodontitis were treated with or without adjunctive systemic antibiotics. On the whole, patients treated with antibiotics showed better results than patients not receiving antibiotics. In deep pockets, a specific benefit in terms of change of periodontal clinical attachment level (CAL) was found for the combination of amoxicillin plus metronidazole, as was true for spiramycin with regards to

changes in probing pocket depth (PPD). Results with metronidazole alone showed a tendency to statistical significance. Haffajee *et al*. (2003) included 27 controlled clinical trials with a follow-up of >1 month and using mean CAL change as the primary outcome. Within a broad range of therapeutic protocols, metronidazole, alone or in combination with amoxicillin, was the most frequently used drug. In all studies, the antibiotic groups showed significantly better mean CAL changes than the control groups. Trials allowing a more detailed analysis indicated antibiotics to have the greatest effect in sites with deep pockets (Lindhe *et al*. 1983a, b; Palmer *et al*. 1996, 1998; Winkel *et al*. 1999; Ramberg *et al*. 2001; Winkel *et al*. 2001; Rooney *et al*. 2002). Specifically, useful antibiotic regimens for distinct clinical or microbiologic conditions could, however, not be identified based on the evidence available at that time. Definite conclusions could also not be made concerning the optimal dosage and duration of antibiotic therapy.

Further well-designed trials have been conducted since that substantiate the benefit of adjunctive antibiotics and provide further information. Twenty-three more recent articles, concerning 18 randomized clinical trials, consistently corroborate the specific benefit of supplementing SRP with amoxicillin plus metronidazole (Ehmke *et al*. 2003, 2005; Guerrero *et al*. 2005; Mombelli *et al*. 2005; Giannopoulou *et al*. 2006; Xajigeorgiou *et al*. 2006; Guerrero *et al*. 2007; Kaner *et al*. 2007b; Moeintaghavi *et al*. 2007; Moreira & Feres-Filho 2007; Akincibay *et al*. 2008; Johnson *et al*. 2008; Machtei & Younis 2008; Cionca *et al*. 2009; Ribeiro Edel *et al*. 2009; Valenza *et al*. 2009; Cionca *et al*. 2010; Mestnik *et al*. 2010; Yek *et al*. 2010; Baltacioglu *et al*. 2011; Heller *et al*. 2011; Silva *et al*. 2011; Varela *et al*. 2011). Results of a few studies comparing different antimicrobial regimens are available (Rooney *et al*. 2002; Haffajee *et al*. 2007; Akincibay *et al*. 2008; Machtei & Younis 2008; Baltacioglu *et al*. 2011; Silva *et al*. 2011). No study has demonstrated better results than for systemic amoxicillin plus metronidazole with other protocols in any clinically or microbiologically defined variant of periodontal disease, but the comparison between metronidazole plus amoxicillin and metronidazole alone has not consistently shown significant benefits for the combination (Silva *et al*. 2011).

Timing of systemic antibiotic therapy

The optimal timing of antimicrobial drug administration is a subject of controversy (Table 43-6). In clinical practice, periodontal therapy is usually performed in two stages. An attempt to remove bacterial deposits is made first without flap elevation. After 3–6 months the case is re-evaluated, and, if deemed necessary, further root surface instrumentation follows, this time in the context of a local surgical intervention (Fig. 43-4).

Table 43-6 Potential benefits and risks from early or late adjunctive antimicrobial therapy.

Administration		Effects
Early (initial, non-surgical treatment phase)	Benefits	Shorter anti-infective treatment Reduced need for periodontal surgery
	Risks	Incomplete removal of subgingival biofilm and calculus at time of administration
Late (secondary treatment phase)	Benefits	Constrains prescription of antibiotics to cases that cannot be resolved by scaling and root planing alone
	Risks	No evidence for advantage from specifically designed clinical trials Benefits of antibiotics used as adjunct to surgical procedures unclear

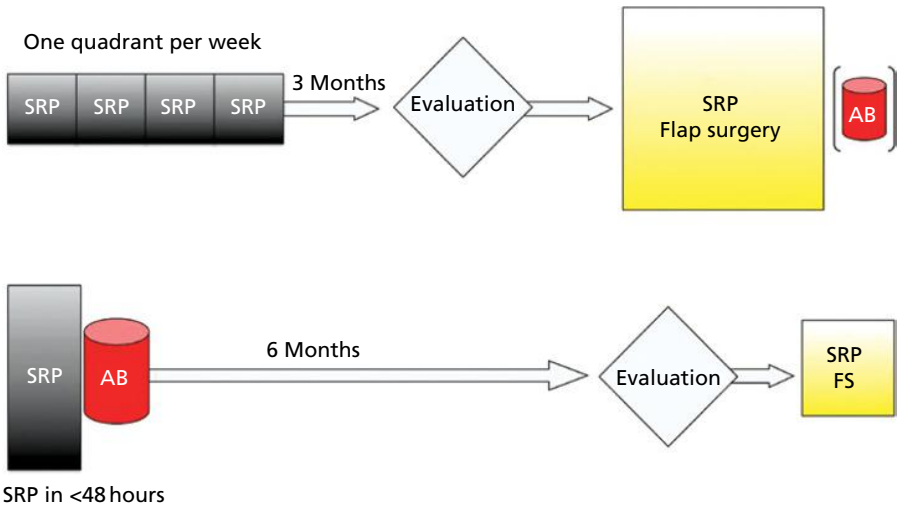

Fig. 43-4 Traditional (top) and alternative approach (bottom) to periodontal therapy. (AB, adjunctive antibiotics; FS, flap surgery, SRP, scaling and root planning.) (Adapted from Mombelli *et al*. 2011, with permission from John Wiley & Sons.)

The first study demonstrating a reduced need for surgical therapy in patients who were treated early with systemic metronidazole as an adjunct to SRP (Loesche *et al*. 1992), as well as a later publication claiming sustained benefits 5 years after initial antimicrobial therapy (Loesche *et al*. 2002), met with disapproval from prominent members of the periodontal community. Postponing antibiotic therapy to the second surgical treatment phase may be defended by two arguments: (1) as it is known that SRP alone is able to resolve a considerable amount of periodontal pathology on its own (Heitz-Mayfield *et al*. 2002; van der Weijden & Timmerman 2002), this strategy may help to restrict the prescription of antibiotics to a minimum; (2) given the restricted effects of antibiotics on intact biofilm (Sedlacek & Walker 2007) and the known limitations of non-surgical mechanical debridement (Rabbani *et al*. 1981; Buchanan & Robertson 1987), surgical intervention may be needed for access to assure complete removal of subgingival biofilm and calculus. As much as this reasoning seems logical, data from specifically designed controlled trials are unavailable to support this recommendation. Contrary to this view, the vast majority of trials have tested antibiotics as adjuncts to non-surgical debridement. A systematic review to assess the relative benefit of prescribing antibiotics either during the non-surgical or the surgical phase of therapy was inconclusive (Herrera *et al*. 2008). However, two studies, not included in this review, showed that for subjects with generalized aggressive periodontitis, better clinical outcomes were achieved if patients were given amoxicillin plus metronidazole immediately after initial SRP rather than after retreatment of persisting pathology (Kaner *et al*. 2007b; Griffiths *et al*. 2011).

Since in most cases mechanical periodontal therapy cannot be accomplished in one session for practical reasons, it is necessary to decide if the adjunctive systemic antimicrobial therapy should start before, during or after debridement. A comparison of outcomes from two studies, one prescribing metronidazole or placebo after the first session of debridement, and the other after the last session of debridement, yielded a significant protocol-effect favoring medication after debridement (Loesche & Giordano 1994). Based on these findings, and on the fact that undisturbed biofilm protects bacteria from the antibiotics, it is recommended that antimicrobial therapy commences immediately after mechanical therapy (i.e. in the evening after the last session of non-surgical treatment). Antibiotics have been administered that way in several studies with good outcomes.

In some cases, mechanical therapy is initially carried out without antimicrobials and evaluated after an appropriate period of time. If it is judged necessary to administer antibiotics at re-evaluation, the subgingival area should be re-instrumented immediately before starting the antimicrobial regimen to reduce the bacterial mass as much as possible and to disrupt newly formed biofilm, even if there is no sign of subgingival persistence of hard deposits. This may be accomplished during a surgical intervention, but is indicated also if no further mechanical therapy seems necessary from a clinical point of view.

Selection of patients who may benefit most from systemic antibiotics

To limit the development of microbial antibiotic resistance in general, and to avoid the risk of unwanted systemic effects of antibiotics for the treated individual, a precautionary, restrictive attitude towards using antibiotics is appropriate. It has been recommended that systemic antibiotics should be considered as adjuncts to SRP for patients with deep pockets, aggressive forms of disease, "active" sites or specific microbiologic profiles (Lindhe & Palmer 2002). However, strictly based on evidence from well-performed randomized clinical trials, and with the exception of patients with known medical contraindications (e.g. confirmed hypersensitivity), it is difficult to define clear-cut exclusion criteria for antibiotic therapy. The following criteria will be addressed in more detail: disease severity, patient compliance, diagnosis as aggressive or chronic periodontitis, microbiologic profile, and risk of adverse events.

Disease severity

It has been pointed out in several of the studies that were cited above that deep pockets benefitted more from antibiotics than shallow ones. Although in some trials treatment with antibiotics reduced PPD in moderately deep pockets by more than if no antibiotics were given, SRP alone is able to predictably resolve a considerable amount of pathology (Heitz-Mayfield *et al*. 2002; van der Weijden & Timmerman 2002). Therefore, it is recommended that in the first place mild and moderate periodontitis are treated non-surgically and without antibiotics. Some studies have shown a certain benefit of antibiotics even when administered without meticulous subgingival debridement (Berglundh *et al*. 1998; Lopez & Gamonal 1998; Lopez *et al*. 2000, 2006). Nevertheless, systemic antibiotics should not be prescribed to counteract incomplete mechanical debridement. Furthermore, for a favorable clinical response and long-term stability, optimal plaque control by the patient is of paramount importance, independent of whether short-term treatment results were obtained with or without antibiotics (Kornman *et al*. 1994).

With regards to diagnosis, it can be stated that not all therapies work equally well in all forms of periodontal disease. It has been noted that after treatment with amoxicillin plus metronidazole patients have an extremely low incidence of suppuration (Rooney *et al*. 2002; Cionca *et al*. 2009), pointing to a potential indication for this regimen particularly in cases with active, suppurating lesions. The problem with recommendations for particular diagnoses is the lack of

Table 43-7 Adjunctive systemic antibiotic regimens currently recommended for the therapy of periodontal diseases.

Antibiotic	Usual dosage	Microbiology
Metronidazole	250–500 mg t.i.d. 7–10 days	*P. gingivalis, T. forsythia, Treponema* spp.
Clindamycin	300 mg q.i.d. 7–8 days	Gram-negative anaerobes Absence of *A. actinomycetemcomitans*
Doxycycline	100–200 mg once a day 7–14 days	Non-specific infection
Metronidazole + amoxicillin	250–500 mg t.i.d. 375–500 mg t.i.d. 7 days	*A. actinomycetemcomitans* or *P. gingivalis* with high numbers of Gram-positive pathogens
Metronidazole + cefuroximaxetil	250–500 mg t.i.d. 250–500 mg b.i.d. 7 days	*A. actinomycetemcomitans*, hypersensitivity towards amoxicillin
Metronidazole + Ciprofloxacin	250–500 mg t.i.d. 500 mg b.i.d. 7 days	*A. actinomycetemcomitans*, hypersensitivity towards β-lactams or presence of susceptible enteric microorganisms

Adapted from van Winkelhoff & Winkel (2005), with permission from John Wiley & Sons.

evidence from specifically designed studies evaluating outcomes of a particular therapy in subjects with different diagnoses. It is however clear from studies with very similar designs (e.g. Guerrero *et al*. 2005; Cionca *et al*. 2009) that the most extensively tested regimen, amoxicillin plus metronidazole, has a beneficial effect in subjects with chronic and aggressive periodontitis.

Table 43-7 lists adjunctive systemic antibiotic regimens currently recommended for the therapy of periodontal diseases. Metronidazole alone has proven to be effective against *P. gingivalis, Tannerella forsythia,* spirochetes, and other strictly anaerobic Gram-negative bacteria. Clindamycin and tetracyclines have also been shown to act on a broad range of periodontal bacteria. Therapy with a single antibiotic as an adjunct to mechanical instrumentation can change the composition of the subgingival microbiota significantly, but certain periodontal organisms cannot be eliminated predictably. The combination of amoxicillin plus metronidazole has a proven capacity to suppress *A. actinomycetemcomitans* from periodontitis lesions and other oral sites (van Winkelhoff *et al*. 1989; Goené *et al*. 1990; Pavicic *et al*. 1992; van Winkelhoff *et al*. 1992; Pavicic *et al*. 1994; Berglundh *et al*. 1998; Flemmig *et al*. 1998b; Mombelli *et al*. 2002; Dannewitz *et al*. 2007) and is therefore the first choice of many clinicians, especially for the treatment of advanced *A. actinomycetemcomitans*-associated periodontitis. For patients intolerant of amoxicillin, metronidazole combined with cefuroximaxetil or ciprofloxacin has been suggested (Rams *et al*. 1992; van Winkelhoff & Winkel 2005).

The problem with issuing a strong recommendation that microbiologic testing should be performed prior to prescribing systemic antibiotics is the lack of unequivocal evidence that patients testing negative for certain bacteria do not benefit from treatment. In four randomized clinical trials (Flemmig *et al*. 1998a; Winkel *et al*. 2001; Rooney *et al*. 2002; Cionca *et al*. 2010), a specific clinical benefit of amoxicillin plus metronidazole in *A. actinomycetemcomitans*-positive subjects only could not be demonstrated. On the contrary, the majority of the participants in these trials were *A. actinomycetemcomitans* negative; hence, the benefit of amoxicillin plus metronidazole resulted to a large part from treatment of *A. actinomycetemcomitans*-negative patients. A recent study determined if microbiologic testing for the presence or absence of *A. actinomycetemcomitans* before therapy identified patients with moderate-to-advanced periodontitis who would specifically benefit from adjunctive amoxicillin plus metronidazole, when given in the context of full-mouth debridement within 48 hours. With respect to the persistence of pockets that are considered to be in need of further therapy according to common practice, that is still deeper than 4 mm and bleeding upon probing at re-evaluation, the answer was no (Mombelli *et al*. 2013). This observation cannot be generalized to all antimicrobial protocols, particularly if agents with a narrow spectrum of activity are used. Findings may have been different if metronidazole alone had been prescribed.

It has been argued that the administration of antibiotics to *P. gingivalis*-negative patients may be overtreatment (van Winkelhoff & Winkel 2009). The authors who raised this issue cited their own study of 49 subjects with chronic periodontitis who were treated with full-mouth SRP and amoxicillin plus metronidazole or placebo (Winkel *et al*. 2001). In this study, *P. gingivalis*-positive patients showed significantly better results when treated with antibiotics than when treated with placebo. However, a closer look at their data shows that the percentage of

pockets of >4 mm decreased to a very similar extent also in *P. gingivalis*-negative subjects treated with antibiotics. At least three other studies (Flemmig *et al*. 1998a; Rooney *et al*. 2002; Cionca *et al*. 2010) clearly demonstrated a benefit of supplementing mechanical therapy with amoxicillin plus metronidazole in *P. gingivalis*-negative cases.

The risk of adverse effects should be considered especially when prescribing more than one antibiotic. Although reported adverse effects tend to be minor, serious problems cannot be discounted. To put things into perspective, the frequency and consequences of adverse effects of antibiotics have to be balanced against the potential health consequences of not rapidly suppressing a periodontal infection, and the inconvenience, discomfort, and financial consequences of further therapy. The traditional approach sometimes expands treatment over several months, while SRP and amoxicillin plus metronidazole may be able to resolve the infection within a few days (Mombelli *et al*. 2011). SRP and amoxicillin plus metronidazole have been shown to decrease clinical signs of inflammation and inflammatory biomarkers in GCF more profoundly than SRP alone (Giannopoulou *et al*. 2006). Although not directly confirmed by a clinical trial, it seems preferable, from a general health point of view, that patients benefit early from the positive systemic effects of successful periodontal therapy (Noack *et al*. 2001; D'Aiuto *et al*. 2004, 2005). If the number of subjects complaining of gastrointestinal problems, notably diarrhea, were indeed higher in the test than the placebo groups of one clinical trial (Cionca *et al*. 2009), it is also worth considering that tooth loss and suppuration despite therapy were exclusively noted in the control group.

Minimizing the risk of the development of antimicrobial antibiotic resistance

Antibiotic therapy carries the risk of promoting the development of bacterial antibiotic resistance. Since periodontal diseases are not life threatening and can be managed largely without antibiotics, this concern needs to be taken seriously. However, the impact of various treatment protocols on the development of bacterial antibiotic resistance has unfortunately not been evaluated thus far in adequately designed clinical trials. Microbiologic evaluations will need to focus not only on their action against microorganisms directly involved in periodontal diseases, that is the predominantly Gram-negative complex of the subgingival microbiota, but also on organisms that are relevant for other reasons, such as staphylococci or enterococci. The resistance developments of greatest concern today are MRSA (*Staphylococcus aureus* strains resistant to methicillin and usually also to multiple other antibiotics), VRE (*Enterococcus* species resistant to vancomycin), PRSP (*Streptococcus pneumoniae* strains highly resistant to penicillin), and ESBL (*Escherichia coli* and other Gram-negative bacteria resistant to antibiotics such as penicillins, cephalosporins, and monobactams).

Table 43-8 Strategies to reduce the risk of bacterial antimicrobial resistance.

Issues	Recommendations
Agents	Consider prescription of a combination therapy (i.e. amoxicillin + metronidazole)
Dosage and timing	Administer a high dose for a short period
Clinical protocol	Use antimicrobials as adjuncts to thorough mechanical debridement
Indication	Use antibiotics for therapy where scaling and root planing alone is insufficient Limit prophylactic use to high-risk patients and to the prevention of severe complications

Source: Mombelli (2012). Reproduced with permission from S Karger AG.

Proposed strategies to reduce the risk of bacterial antimicrobial resistance are listed in Table 43-8. In the mixed subgingival microbiota, some microorganisms can always be expected to be resistant to any single antimicrobial agents (Ardila *et al*. 2010). To overcome single antibiotic resistance, combination therapies may therefore be advantageous. It has been recognized that the dose and duration of antimicrobial therapy are crucial parameters for resistance development. Suboptimal dosage of antibiotics, caused by either inadequate prescribing or poor patient compliance, favors the emergence of antibiotic-resistant bacterial clones. Clinical studies in other fields indicate that it is preferable to deliver antibiotics at a high dose over a short time. As an example, a randomized trial conducted in an outpatient clinic involving 795 children receiving antibiotic prescriptions for upper respiratory tract infections demonstrated the advantage of short-course, high-dose outpatient antibiotic therapy to minimize the impact of antibiotic use on the spread of drug-resistant pneumococci (Schrag *et al*. 2001). The classical oral dosage for metronidazole in many older studies was 250 mg t.i.d. for 10–14 days. This dosage might not be sufficient in subjects with a high body mass. Today, for a person weighing 75–80 kg, 500 mg metronidazole t.i.d for 7 days is recommended. As discussed above, biofilm-associated infections are notoriously resistant to antimicrobial therapy unless the biofilm is disrupted mechanically. It is therefore reiterated here that all antimicrobial therapy should be preceded by mechanical debridement. To limit their overuse, it is furthermore recommended to avoid antibiotics whenever there is ample evidence that thorough non-surgical mechanical debridement alone can resolve the problem, as is the case for mild-to-moderate periodontitis (van der Weijden & Timmerman 2002). Last but not least, the prophylactic use of antibiotics should be limited to high-risk patients and to the prevention of severe complications (Duval *et al*. 2006; Esposito *et al*. 2008; Nishimura *et al*. 2008; Berbari *et al*. 2010).

Local antimicrobial therapy (see also Chapter 44)

Local antimicrobial therapy in clinical trials

Various methods to deliver antimicrobial agents into periodontal pockets have been devised and subjected to numerous types of study. The shortcomings of rinsing, irrigating, and similar forms of drug placement – rapid clearance resulting in inadequate exposure of subgingival bacteria to the drug and lack of significant clinical effects – have already been discussed. This section will deal with clinically tested drug delivery systems that fulfil at least the basic pharmacokinetic requirements of sustained drug release. Much of what has been stated about difficulties in the interpretation of studies dealing with the systemic use of antibiotics applies to the studies conducted with local delivery devices. Again, comparisons are complicated because studies vary with regard to sample size, selection of subjects, range of parameters, controls, duration, and the inclusion of only one form of local drug delivery. Most of the evidence for a therapeutic effect of local delivery devices comes from trials involving patients with previously untreated chronic ("adult") periodontitis. The best available evidence comes from randomized clinical trials where local antimicrobials were administered as an adjunct to SRP, and where the control group was treated with SRP alone or with a placebo. Only a few studies have addressed the use of local drug delivery in recurrent or persistent periodontal lesions, the potentially most valuable area for their application. Some protocols compare local drug delivery to a negative control, such as the application of only the carrier without the drug. These studies may be able to show a net effect of the drug, but they are not able to demonstrate a benefit over the most obvious alternative – SRP – and the question remains as to how much value the procedure has in addition to mechanical treatment. If a study is unable to demonstrate a significant difference between local drug delivery and SRP, this is not automatically proof of equivalence of the two treatments (equivalence testing requires statistical testing of the power of the data, taking into account the size of the study sample).

The drugs investigated for local application include tetracycline, minocycline, doxycycline, metronidazole, azithromycin, and chlorhexidine. The agents were administered using the following devices: varnishes (chlorhexidine), gels (doxycycline, metronidazole, minocycline, azithromycin), nonresorbable polymer fibers (tetracycline), gelatin chips (chlorhexidine; Fig. 43-5), ointments (tetracycline), and resorbable polymer microspheres (minocycline). Unfortunately, several of the commercial formulations that have been adequately tested in clinical trials are currently unavailable in certain regions of the world, or have disappeared completely, while other products without proven clinical efficacy continue to be introduced and are utilized on an empirical basis. Since most studies have been performed in chronic periodontitis patients, the evidence described below will not include studies of early-onset periodontitis (Yilmaz *et al*. 1996) or aggressive periodontitis (Duarte *et al*. 2009).

Minocycline ointment and microspheres

The subgingival delivery of minocycline has been investigated as a 2% ointment (Dentomycin; Cyanamid, Lederle Division, Wayne, NJ, USA) or as a powder consisting of resorbable polymer microspheres (Arestin; OraPharma, Warminster, PA, USA) in at least 13 randomized clinical trials (Nakagawa *et al*. 1991; van Steenberghe *et al*. 1993; Jones *et al*. 1994; Graca *et al*. 1997; Jarrold *et al*. 1997; Kinane & Radvar 1999; Williams *et al*. 2001; Henderson *et al*. 2002; Meinberg *et al*. 2002; Van Dyke *et al*. 2002; Goodson *et al*. 2007; Bland *et al*. 2010).

Differences of changes in mean PPD were statistically significant between test and control groups in five trials. Control groups demonstrated a mean change ranging from 0.4 to 1.9 mm, and the test groups from 0.9 to 2.6 mm. Four trials reported a statistically significant intergroup difference for CAL changes. The magnitude of the differences between groups ranged from 0 to 1.6 mm in the control and

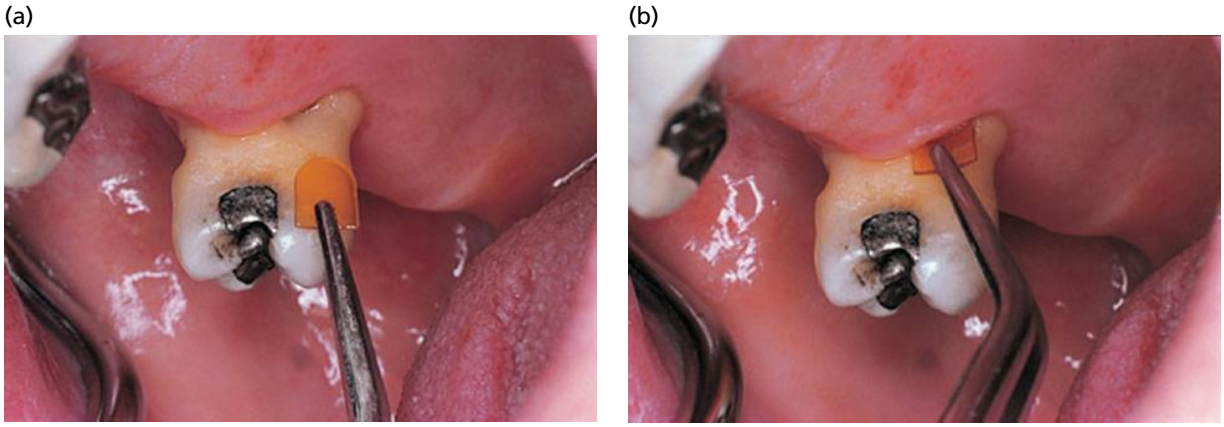

Fig. 43-5 (a, b) Insertion of a chlorhexidine chip into a residual pocket mesial of an upper molar with a furcation involvement.

from 0.8 to 1.9 mm in the test groups. Three trials reported significant differences between groups with regards to bleeding on probing (BoP), with reductions ranging from 5% to 46% in the control and from 4% to 87% in the test groups. Compared to SRP alone, the results from the different studies were consistently in favor of SRP with minocycline with regards to PPD, but not to CAL and BoP.

Doxycycline hyclate in a biodegradable polymer

A two-syringe mixing system for the controlled release of doxycycline (Atridox; Block Drug, Jersey City, NJ, USA) has been available commercially for some years. One syringe contains the delivery vehicle, flowable bioabsorbable poly(DL-lactide) dissolved in *N*-methyl-2-pyrrolidone, and the other a doxycycline hyclate powder. At least seven randomized clinical trials have tested this formulation (Wennström *et al*. 2001; Eickholz *et al*. 2002; Akalin *et al*. 2004; Agan *et al*. 2006; Machion *et al*. 2006; Bogren *et al*. 2008; Gupta *et al*. 2008).

Differences in changes of PPD were statistically significant between test and control groups in three of these seven trials. Control groups demonstrated a mean change ranging from 1.1 to 3.1 mm, and the test groups from 1.2 to 4.0 mm. Three trials reported statistically significant intergroup differences for CAL changes. The magnitude of the differences between groups ranged from 0.5 to 1.6 mm in the control and from 0.7 to 3.2 mm in the test groups. Five papers reported BoP changes, with reductions ranging from 8% to 56% in the control and from 13% to 64% in the test groups, but no significant differences between groups. Short-term data for PPD and CAL consistently favored SRP with doxycycline over SRP alone across the different studies. No clear trends were observed for BoP and plaque levels.

In one study involving 105 patients at three centers (Wennström *et al*. 2001), the effect of Atridox, applied after no more than 45 minutes of debridement without analgesia, was compared to 4 hours of thorough SRP in subjects with moderately advanced chronic periodontitis. Interestingly, clinical parameters indicated a better result for the pharmacomechanical treatment approach after 3 months, although considerably less time had been invested than for conventional mechanical therapy.

Metronidazole gel

Dialysis tubing, acrylic strips, and poly-OH-butyric acid strips have been tested as solid devices for delivery of metronidazole. The most extensively used device for metronidazole application is a gel consisting of a semi-solid suspension of 25% metronidazole benzoate in a mixture of glyceryl mono-oleate and sesame oil (Elyzol Dental Gel; Dumex, Copenhagen, Denmark). The gel is applied with a syringe into the pocket, and its viscosity should increase after placement. Seven randomized clinical trials have evaluated the effects of this formulation as an adjunct to non-surgical mechanical therapy (Noyan *et al*. 1997; Lie *et al*. 1998; Kinane & Radvar 1999; Palmer *et al*. 1999; Riep *et al*. 1999; Griffiths *et al*. 2000; Stelzel & Flores-de-Jacoby 2000).

PPD changes were reported in all seven studies, with the mean differences between groups ranging from 0.7 to 1.7 mm in the control groups and from 0.9 to 2.1 mm in the test groups. However, differences between groups reached significance at the end of the follow-up period in only two trials. For CAL changes, the differences between groups ranged from 0.4 to 0.9 mm in the control and from <0.1 to 0.8 mm in the test groups, and the differences between groups were statistically significant in three studies. BoP was registered in six studies, with changes ranging from 6% to 48% and from 11% to 59% in the control and test groups, respectively, with statistically significant differences between groups in only one trial. The results of the different studies were consistent, favoring SRP with metronidazole over SRP alone in terms of PPD and BoP, but not of CAL.

Tetracycline in a non-resorbable plastic co-polymer

Devices such as dialysis tubing, acrylic strips, collagen, or poly-OH-butyric acid strips have been tested for tetracycline delivery in several studies. Semi-solid viscous media include white petrolatum and poloxamer or carbopol gels. The most extensively tested tetracycline-releasing device is the Actisite periodontal fiber (ALZA, Palo Alto, CA, USA). This currently unavailable product consists of a monolithic thread of a biologically inert, non-resorbable plastic co-polymer (ethylene and vinyl-acetate) containing 25% tetracycline–HCl powder. The fiber is packed into the periodontal pocket, secured with a thin layer of cyanoacrylate adhesive, and left in place for 7–12 days (Goodson *et al*. 1983, 1991). The continuous delivery of tetracycline maintains a local concentration of the active drug in excess of 1000 mg/L throughout that period (see Fig. 43-3). At least nine randomized clinical trials have assessed the effect of tetracycline in this vehicle (Minabe *et al*. 1991; Jeong *et al*. 1994; Newman *et al*. 1994; Drisko *et al*. 1995; Tonetti *et al*. 1998; Wong *et al*. 1998; Kinane & Radvar 1999; Yalcin *et al*. 1999; Aimetti *et al*. 2004).

PPD changes were calculated in all the studies, with reductions amounting to 0.4–1.2 mm and 1.3–2.6 mm in the control and test groups, respectively; three studies found statistically significant differences between the groups. Changes in CAL were also reported in all studies, with differences between groups ranging from 0.1 to 0.7 mm and 0.3 to 2.3 mm in the control and test groups, respectively. The differences between groups were statistically significant in one of these investigations. Changes in BoP ranged

from 5% to 42% in the control groups and from 4% to 79% in the test groups, with significant differences found in five studies. The results of the different studies were quite consistent, favoring SRP with tetracycline fibers over SRP alone in terms of PPD, CAL, and BoP.

Azithromycin gel

Only one study has reported data on the adjunctive effect of local azithromycin on SRP (Pradeep *et al*. 2008). Differences in PPD reduction were statistically significant and CAL gains were significantly greater in the test than in the control group after 3 months. BoP was not assessed.

Chlorhexidine products

Several attempts have been made to develop local delivery devices for the subgingival application of antiseptics, rather than antibiotic agents. Different products containing chlorhexidine have been evaluated, including gelatin chips, varnishes, and a xanthan gel.

PerioChip (Perio Products, Jerusalem, Israel), a degradable gelatin chip containing 2.5 mg of chlorhexidine, has been extensively tested in at least 11 trials (Soskolne *et al*. 1997; Jeffcoat *et al*. 1998, 2000; Heasman *et al*. 2001; Azmak *et al*. 2002; Grisi *et al*. 2002; Mizrak *et al*. 2006; Carvalho *et al*. 2007; Kasaj *et al*. 2007; Paolantonio *et al*. 2008; Sakellari *et al*. 2010). All of them assessed PPD. The improvements ranged from 0.3 to 2.3 mm in the control and from 0.8 to 3.8 mm in the test groups. The differences between groups were statistically significant in only six of the trials. All 11 studies assessed CAL. The changes ranged from −0.4 to 1.6 mm in the control and from −0.9 to +2.8 mm in the test groups and were significantly different between groups in six studies. Changes in BoP ranged from 33% to 64% in the control and from 22% to 63% in the test groups, with differences between groups reaching a level of statistical significance in two trials. The results of the different studies were heterogeneous in terms of PPD and CAL, and only longer-term studies and split-mouth designs provided clear differences between test and control groups.

A chlorhexidine varnish was tested by one research group in four different investigations (Cosyn *et al*. 2005, 2006a, b, 2007). PPD changes ranged from 0.7 to 1.2 mm in the control groups and from 1.1 to 2.0 mm in the test groups, and the differences between groups were statistically significant in two of the trials. For CAL, minor changes were registered, without significant differences between groups. BoP decreased by 27–50% in the control and by 34–47% in the test groups, with no significant differences between groups. The results of these studies performed by the same group consistently favored the test group in terms of PPD, CAL, and BOP.

A xanthan-based gel containing a combination 0.5% chlorhexidine digluconate and 1% chlorhexidine dihydrochloride (ChloSite®; Casalecchio di Reno, BO, Italy) has been proposed for local antimicrobial application. This product has been tested in at least two trials (Gupta *et al*. 2008; Paolantonio *et al*. 2009). PPD changes seen in the test group (range 1.4–2.0 mm) were significantly better than in the control group (range 0.5–0.9 mm). CAL changes ranging from 2.4 to 2.8 mm in the test groups were also significantly better than those in the control groups (range 1.5–1.7 mm). BoP was recorded in one trial and did not show significant differences between the groups.

Comparative evaluation of treatment methods

The results described above indicate that several local antimicrobial treatment protocols have the potential to improve the results of non-surgical periodontal therapy, although primarily relating to PPD changes, but statistically significant benefits were generally ascertained in less than half of the available trials. In addition, most studies tested a single form of local drug delivery instead of comparing various forms of therapy. Understandably, the primary interest of developers and distributors is to register and promote their own product for the broadest possible usage, and not to differentiate specific benefits or shortcomings of various applications. The efficacy of commercially available local delivery systems as adjuncts to SRP was only tested in two trials including patients with persistent periodontal lesions: Actisite, Dentomycin, and Elyzol Dental Gel (Radvar *et al*. 1996; Kinane & Radvar 1999); Atridox, Elyzol Dental Gel, and PerioChip (Salvi *et al*. 2002).

One systematic review has evaluated the combined literature-based evidence to determine the relative effect of local controlled-release anti-infective drug therapy in patients with chronic periodontitis (Hanes & Purvis 2003). A meta-analysis including 19 studies, comparing SRP plus local sustained-release agents with SRP alone, confirmed the clinical advantages of minocycline gel, micro-encapsulated minocycline, doxycycline gel, and chlorhexidine chips over SRP alone. Due to the heterogeneity of the studies, the authors could not make any firm statements regarding the superiority of one system over any other. A further systematic review looked at the relative adjunctive benefits of various locally applied agents (Bonito *et al*. 2005). Unfortunately, data were combined from studies exploring various modes of local treatment, including irrigation, impregnated strips, and pastes. Nonetheless, a statistically significant mean advantage was seen for four agents in terms of additional CAL gain – best for minocycline, followed by tetracycline, chlorhexidine, and metronidazole. One cannot exclude, however, that the differences noted between the drugs primarily reflect

differences in modes of application and study populations, not the potency of the agent.

Few studies have addressed the problem of incorporating local or systemic antimicrobial therapy into an overall treatment strategy. As there has been as yet little direct comparison of the various methods of treatment, well-founded decision algorithms to direct the choice of specific methods of intervention for distinct clinical situations are not yet available. A key issue requiring clarification concerns the selection of a local or a systemic delivery approach whenever the use of an antibiotic seems to be indicated. For patients with chronic periodontitis, two studies reported better results for SRP supplemented with locally applied metronidazole than adjunctive systemic metronidazole (Paquette *et al*. 1994; Noyan *et al*. 1997). Two investigations addressed this question in patients with aggressive periodontitis. No significant differences were noted between systemic administration of either amoxicillin plus clavulanic acid or tetracycline fibers as an adjunct to mechanical therapy (Bernimoulin *et al*. 1995). More recently, the same group reported that SRP plus amoxicillin and metronidazole provided better clinical results after 6 months than chlorhexidine-loaded gelatin chips (Kaner *et al*. 2007a).

As different oral distribution patterns can be recognized in periodontitis patients for microorganisms such as *P. gingivalis* (Mombelli *et al*. 1991a, b), local therapy may be less successful in patients where pathogens are widespread than in patients where their presence is confined to isolated areas. However, no diagnostic tool is available presently that can give the clinician a detailed distribution map of periodontal pathogens at a reasonable cost. However, even if such information were available, a study evaluating the effect of local antibiotic therapy given to every tooth with cultural evidence of *P. gingivalis* or *A. actinomycetemcomitans* demonstrated the limits of this approach (Mombelli *et al*. 2002).

Local antibiotics in clinical practice

To treat periodontal disease successfully, local delivery devices must provide therapeutic levels of antimicrobial agents in the subgingival area over several days. Clinical trials show the efficacy of local antibiotic therapy under these conditions. The current evidence suggests that local delivery may be most beneficial in the control of localized ongoing disease in otherwise stable patients. Maintenance patients with a few non-responding sites may therefore benefit most from local antimicrobial therapy. Potential uses for locally delivered antimicrobials furthermore include the treatment of peri-implant infections (Mombelli *et al*. 2001; Renvert *et al*. 2006). Local antimicrobial therapy adds flexibility and improves the efficacy of periodontal care by providing a non-surgical local treatment alternative with more powerful antibacterial effects than SRP. However, a cost-effectiveness analysis concluded that systemic antimicrobials are more cost-effective than locally delivered antimicrobials (Heasman *et al*. 2011). In recent years, the perceived value of local antibiotic therapy has decreased, as a majority of adequately tested formulations have been withdrawn from the market. So far, no local antimicrobial treatment has proven to be equally efficient or better than systemic amoxicillin plus metronidazole.

Conclusion

Antibiotics delivered either systemically or locally, can enhance the effect of periodontal therapy. To limit the development of microbial antibiotic resistance in general, and to avoid the risk of unwanted systemic effects of antibiotics for the treated individual, a precautionary, restrictive attitude towards using antibiotics is indicated. To limit their overuse, it is recommended not to prescribe antibiotics whenever there is ample evidence that thorough non-surgical mechanical debridement alone can resolve the problem, and this is the case for mild-to-moderate periodontitis. By providing an additional treatment benefit for SRP in deep pockets, systemic antibiotics can reduce the need for further surgical therapy. Systemic antibiotics may be useful also as an adjunct in the retreatment of cases with unsatisfactory response to mechanical therapy. Localized non-responding sites and localized recurrent disease may be treated with locally delivered antibiotics. All antimicrobial therapy should be preceded by thorough mechanical debridement (SRP). After resolution of the periodontal infection, the patient should be placed on an individually tailored maintenance care program to prevent re-infection.

At present, the most thoroughly documented way of using antibiotics in periodontal therapy is SRP with adjunctive oral amoxicillin and metronidazole. Other protocols, including SRP with metronidazole or SRP with azithromycin may be considered, especially in chronic periodontitis patients.

Chapter 44

Local Drug Delivery for the Treatment of Periodontitis

Maurizio S. Tonetti[1] and Pierpaolo Cortellini[2]

[1]European Research Group on Periodontology (ERGOPerio), Genoa, Italy
[2]Private Practice, Florence, Italy

Introduction

Treatment of periodontitis is routinely based on oral hygiene, root debridement, and risk factor modification. Given the bacterial etiology and the inflammatory pathogenesis of periodontitis, the adjunctive use of locally applied or systemic administration of antimicrobials and/or host response-modulating medications has been proposed. Localized therapy has received significant attention because of the site-specific pattern of destruction of periodontal infections and the potential side effects of systemic antimicrobials and anti-inflammatory agents. Another important rationale for the development of effective ways to locally apply medications into the periodontal pockets comes from the realization that systemic administration of many medications (and antibiotics in particular) results in marginally effective local concentrations of free, active drug in the periodontal pocket and surrounding tissues.

There are three basic routes to localized adjunctive pharmacologic periodontal therapy: mouth rinses (toothpaste or varnishes), subgingival irrigation, and periodontal application of local delivery systems.

Rinses are useful for supragingival biofilm control, modulation of gingival inflammation, and potentially for recolonization of the subgingival environment following periodontal treatment. Their major limitation, in the context of pharmacologic therapy of periodontitis, is that they do not gain access to the subgingival environment and therefore do not reach the desired site of action (Pitcher *et al*. 1980).

Irrigation solutions placed directly into periodontal pockets initially reach effective concentrations in the area, but the flow of the gingival crevicular fluid (GCF) – which is replaced about 40 times per hour – leads to rapid clearance of subgingivally placed drugs. Clearance of a medication locally placed in a periodontal pocket follows exponential kinetics and it has been calculated that the concentration of a highly concentrated irrigating solution of a non-substantive (non-binding) drug becomes ineffective about 15 minutes following application. This time can be prolonged by the application of substantive drugs such as tetracyclines or chlorhexidine that bind to the root surface and/or the soft tissue wall of the periodontal pocket and thus establish a drug reservoir that can be slowly released to counteract the clearance by the GCF flow. Limitations on reservoir volume, however, limit the duration of the possible pharmacologic effect. Thus, efficient delivery of pharmacologic agents into the periodontal microenvironment is difficult to achieve using rinses and irrigating solutions.

Goodson – a pharmacologist who in the early 1970s pioneered the field of local delivery to treat

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

periodontitis – pointed out that successful pharmacologic control of the periodontal microflora requires (1) delivery of an intrinsically efficacious drug to the site of action (periodontal pocket and surrounding tissues); (2) a concentration of the drug higher than the minimum efficacious concentration; and (3) maintenance of this concentration long enough for the effect to occur. These three principles – site, concentration, and time – are the key parameters in the optimization of local pharmacologic treatment (Goodson 1989, 1996).

Periodontal pharmacokinetics

The action of an intrinsically efficacious drug in a body site is dependent upon the bioavailability of free active medication at the desired location; here specifically the periodontal pocket and the neighboring soft and hard tissues. From a pharmacologic standpoint, the periodontal pocket is a challenging microenvironment: it is characterized by the rapid flow of GCF, has a small resting volume, and has an uneven topography. Periodontal pockets are uneven in terms of depth, width, presence of furcation involvements, composition and amounts of subgingival biofilm, and calculus deposits. These characteristics translate into specific difficulties for the design of periodontal local delivery devices.

Pocket volume and clearance

Clearance of a drug placed into a periodontal pocket follows the exponential function:

$$C_{(t)} = C_{(0)} e^{-t\frac{F}{V}}$$

where $C_{(t)}$ is the concentration of the drug as a function of time (t), $C_{(0)}$ is the initial concentration obtained in the GCF, F is the GCF flow rate, and V is the resting fluid volume of the pocket.

Using an estimated periodontal pocket volume of 0.5 µL (Binder *et al*. 1987) and a GCF flow rate of 20 µL/h (Goodson 1989), the half-time (the time that it takes to reach half of the initial concentration) for a non-substantive medication placed in the periodontal pocket will be 0.017 hours (or about 1 minute). From these calculations Goodson (1989) concluded that the subgingival irrigation route is theoretically feasible only for very potent (i.e. antimicrobials that can act at very low concentrations) substantive drugs.

In the case of a substantive compound, the exponential function can be rewritten by introducing a multiplicative constant K into the denominator of the exponential term to account for binding of the drug to the root surface (and/or periodontal pocket wall):

$$C_{(t)} = C_{(0)} e^{-t\frac{F}{KV}}$$

where K is the affinity constant, which is experimentally estimated from the determined clearance half-time.

This equation can be conveniently rearranged to estimate the effect of the various parameters on the duration of the desired therapeutic effect:

$$t_{(MIC)} = \frac{KV}{F} \ln \frac{C_{(0)}}{C_{(MIC)}}$$

where $C_{(MIC)}$ is the minimum inhibitory concentration (MIC) and $t_{(MIC)}$ is the time taken to reach the MIC or the expected time of antibacterial action.

From this relation, it is apparent that the time over which a therapeutic effect is observed ($t_{(MIC)}$) will be longer when the:

- Volume of the pocket is large
- GCF flow rate is low
- Affinity constant for the drug is higher, that is a highly substantive drugs is used
- Initial concentration is very high, that is the drug has good solubility in the applied vehicle
- MIC is low, that is a very potent agent is used.

While the first two parameters relate to the specific disease state of each tooth and thus cannot be easily modified without intervention, the remaining three parameters relate to the choice of drug. Preclinical data related to the *in vitro* antimicrobial susceptibility profile and pharmacokinetic data are at the base of the rationale choice of the active agent.

Development of periodontal local delivery devices

To overcome the challenges represented by the pharmacokinetic parameters of the local microenvironment, Goodson designed a first generation of local drug delivery devices for application into periodontal pockets. The concept was to constantly replenish the free drug in the periodontal pocket that is cleared by the GCF flow with the release of drug from a drug reservoir placed into the periodontal pocket (Goodson *et al*. 1979). These devices consisted of permeable hollow cellulose acetate fibers (with an internal thickness of 200 µm) filled with a 20% tetracycline–HCl solution. The fiber was tied around the crevice of the pocket, pressed into the subgingival environment, and removed after 24 hours. In spite of the short duration of application, an important effect on the composition of the subgingival microflora was observed. A subsequent clinical study compared hollow fibers left in place for 2 days with scaling and root planning (SRP). Microbial and clinical parameters improved, but less than in the SRP group (Lindhe *et al.* 1979). These early attempts produced limited clinical outcomes and this was explained by the insufficient duration of drug delivery. Subsequent efforts focused on leaving the delivery device longer

in the periodontal pocket, but it became apparent that these devices were exhausted relatively quickly (Addy *et al*. 1982; Coventry & Newman 1982).

Better release profiles were obtained with a second generation of devices characterized by a monolithic design (drug crystals interspersed within an inert matrix) such as acrylic strips or extruded ethylene vinyl acetate fibers (Addy *et al*. 1982; Goodson *et al*. 1983). In particular, following placement of 0.5-mm diameter 25% tetracycline fibers, GCF concentrations in the order of 500–1500 μg/mL were reported (Tonetti *et al*. 1989). Parallel efforts with bioresorbable matrices focused on chlorhexidine in cellulose acetate (Soskolne *et al*. 1983) and on release platforms made of hydroxypropylcellulose (Noguchi *et al*. 1984) or collagen matrices (Minabe *et al*. 1989a, b).

Studies have estimated that the resting fluid volume of a 5-mm pocket is about 0.5 μL (or 0.5 mm^3). While deeper pockets and pockets at dental implants (that also include a sizeable mucosal tunnel) may have a significantly larger volume, these data indicate that any periodontal local delivery device needs to be able to expand the pocket volume in order to establish a large enough drug reservoir that will be able to release free drug over time to counteract the GCF clearance. Early attempts using dimensionally stable acrylic strips or tetracycline fibers achieved pocket expansion.

Phase I and II studies with these devices reported improvements in the microbial flora and clinical parameters (Addy & Langeroudi 1984; Goodson *et al*. 1985a, b). The pivotal trial required for regulatory clearance by the US Food and Drug Administration (FDA) of 25% tetracycline–HCl ethylene vinyl acetate fibers was the first multicenter trial in the field of periodontology to be conducted under stringent quality control and was a stepping stone towards modern clinical trial design and execution in dentistry (Goodson *et al*. 1991a, b).

Over the following two decades, several local antimicrobial delivery devices have been developed and have undergone clinical testing for safety and effectiveness to satisfy clearance by the local regulatory agencies (Goodson *et al*. 1991a–c; van Steenberghe *et al*. 1993; Soskolne *et al*. 1997, 1998; Stoller et al 1998, Garrett *et al*. 1999; van Steenberghe *et al*. 1999; Garrett *et al*. 2000; Williams *et al*. 2001; Soskolne *et al*. 2003).

Antimicrobial effects of local delivery devices

Early studies mandated by regulatory agencies to provide proof of efficacy of the locally delivered antimicrobial alone showed consistent suppression of total bacterial loads and frequency of detection of target pathogens. A host of later studies, however, showed that better clinical and microbiologic outcomes were obtained by combining mechanical debridement with local delivery of the antimicrobial. This established the key role of mechanical debridement in successful clinical strategies for application of local delivery devices (Johnson *et al*. 1998).

Clinical studies evaluating microbiologic outcomes of local delivery devices – used in combination with mechanical debridement – have shown drastic reductions in both total bacterial load and periodontal pathogens. With the most effective devices (those delivering high concentrations of intrinsically efficacious antimicrobials for >1 week), suppression of 99–99.9% of total microbial load was reported, leading to effective disinfection of the treated periodontal pocket. After exhaustion of the drug reservoir, however, rapid recolonization was observed. Three possible sources for this recolonization were hypothesized: (1) regrowth from the residual microbiota from within the periodontal pocket; (2) recolonization from other intraoral areas of infection; and/or (3) re-infection of the patient from other subjects.

A pilot study conducted at the Forsyth Institute in 1988 by the Goodson group started to address the question of the source of recolonization (Holborow *et al*. 1990; Niederman *et al*. 1990). The study employed tetracycline fibers and SRP with or without chlorhexidine mouth rinsing to complete the treatment of the subjects who had participated in the pivotal study leading to FDA approval of tetracycline fibers (Goodson *et al*. 1991a, b). The hypothesis was that the intraoral antibacterial effect of chlorhexidine would modulate bacterial recolonization of tetracycline fiber-treated pockets. Results showed that chlorhexidine mouth rinsing over a 28-day period led to significant depression of the bacterial recolonization profiles for three target pathogens. The data were interpreted as an indication that the overall oral ecology of the patient was a critical determinant of success with this therapeutic modality. This concept was further assessed by a study conducted at the University of Berne. Subjects with generalized periodontitis who were *Porphyromonas gingivalis* positive were enrolled into a randomized controlled trial testing two extreme forms of therapy: localized treatment of two isolated pockets (with the rest of the dentition being monitored over the study period) and full-mouth disinfection of the whole dentition by tetracycline fiber application, SRP, and chlorhexidine mouth rinsing for 4 weeks. Clinical and radiographic outcomes showed greater improvement in the index teeth of the full-mouth disinfection group compared to the index teeth of the localized treatment group (Mombelli *et al*. 1996, 1997; Fourmousis *et al*. 1998). Most importantly, while similar levels of pocket disinfection were achieved for total bacterial counts at the time of tetracycline fiber removal, the recolonization kinetics showed rapid return towards baseline bacterial levels in the localized treatment group (Fig. 44-1) (Tonetti *et al*. 1995). Persistent, stable suppression of bacterial levels was observed in the full-mouth disinfection group. Interestingly, early recolonization kinetics predicted clinical (reduction of pocket depth and bleeding on probing) and

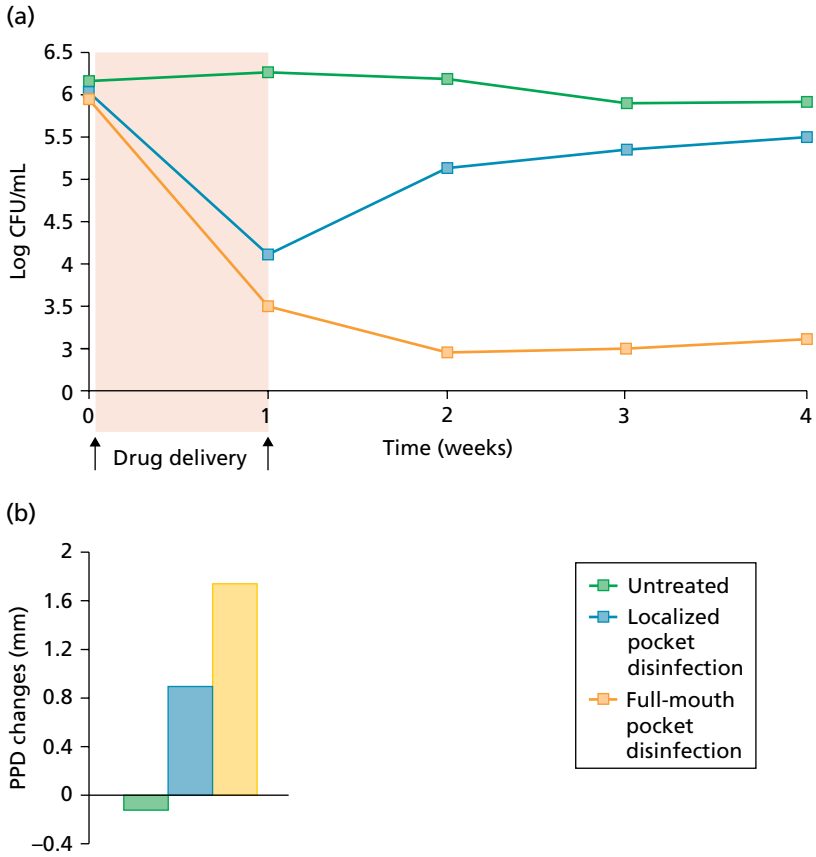

Fig. 44-1 (a) Kinetics of change following local drug delivery with tetracycline fibers in untreated sites; localized treated areas (only two teeth treated in subjects with widespread periodontitis and *P. gingivalis* infection); and full-mouth pocket disinfection (all pockets treated plus chlorhexidine mouth rinse in subjects with widespread periodontitis and *P. gingivalis* infection). Note the different patterns of recolonization. The vertical axis displays total colony forming units (CFU) (Log10)/mL. (b) Changes in probing depths at 6 months for the three groups displayed in (a). Note the greater pocket depth reductions observed in the full-mouth pocket disinfection group.

radiographic (hard and soft tissue subtraction analysis) outcomes 3 and 6 months later (Tonetti *et al*. 1995). Several important conclusions were drawn from these studies and these represent important strategic elements for the rationale use of local delivery devices:

1. Effective local delivery devices have the potential to dramatically change the microbial profile of treated periodontal pockets. Recolonization, however, is a critical phenomenon that may undermine clinical benefit.
2. Bacteria present in other areas of the mouth are the major source of recolonization and need to be addressed by improved oral hygiene measures, treatment of the whole dentition, and – perhaps – antimicrobial mouth rinsing.
3. Local delivery devices are not a promising treatment for subjects who are unable or unwilling to achieve improved (optimal) oral hygiene levels.

Efficacy of local delivery devices

A systematic review and meta-analysis by Hanes and Purvis (2003) along with a more recent one by Matesanz-Pérez *et al*. (2013) represent the major evidence base for the use of local delivery devices.

The 2003 review, conducted for the American Academy of Periodontology workshop, examined the clinical outcomes of 32 studies incorporating 3705 subjects and established that adjunctive local drug delivery resulted in significant reductions in gingival inflammation and probing depths, and improvements in clinical attachment level. Nineteen randomized controlled clinical trials were subjected to meta-analysis and the additional benefit was estimated to be an average 0.34 mm reduction in probing depth (Fig. 44-2). While the estimate seems modest in absolute value, it must be underlined that a systematic review conducted by Haffajee *et al*. (2003) for the same consensus conference and assessing the adjunctive benefit of systemic antibiotics reported exactly the same estimate for systemic antibiotics (see Chapter 43). While the systematic review (Hanes & Purvis 2003) addressed the concept of local delivery as a whole, it also analyzed the single technology platforms and molecules. It observed clinical improvements for the adjunctive application of minocycline gel, microencapsulated minocycline, doxycycline gel, and chlorhexidine chips. Indeed, the efficacy of each of the available local delivery devices needs to be assessed individually, as if any product does not satisfy the pharmacokinetic principles, it cannot be expected to provide significant clinical benefit.

Interestingly, this systematic review found no evidence of an adjunctive benefit from the application of local irrigants during or immediately after mechanical debridement. This finding is consistent with what can be expected based on local pharmacokinetic parameters: irrigating solutions are probably rapidly cleared by GCF flow.

The evidence base for this adjunctive treatment has considered essentially two types of populations: untreated patients and treated patients with recurrent/persistent disease participating in supportive periodontal care programs. Benefits have been established for both populations, although the size of the benefit in treated patients is expected to be smaller.

Few studies have addressed the management of furcation defects with local delivery devices. Short-term (3–6 months) adjunctive benefits in controlling gingival inflammation as well as improvements in probing depths and clinical attachment levels have been reported (Tonetti *et al*. 1995; Dannewitz *et al*. 2009). Interestingly, but perhaps not unexpectedly, the benefits did not persist medium to long term in these difficult anatomic areas.

Another interesting and rapidly emerging area of application of local delivery devices relates to the control of peri-implant infections, particularly peri-implantitis. Two independent systematic reviews on effective interventions for peri-implantitis (Esposito *et al*. 2012; Muthukuru *et al*. 2012) identified some initial evidence that local delivery combined with subgingival debridement may be of greater benefit than subgingival debridement alone. Further studies are necessary in this area.

Clinical indications for treatment of periodontitis with adjunctive local delivery devices

The majority of studies assessing the adjunctive benefit of local delivery devices to mechanical debridement have identified a range of clinical conditions where the addition of these devices leads to improved outcomes (Tonetti *et al*. 1994; Tonetti 1998; Greenstein & Tonetti 2000). These include special local conditions and special patient groups.

Local conditions

As the majority of untreated shallow (4–5 mm) pockets are expected to heal with mechanical debridement alone, local delivery devices are of potential benefit for deeper pockets (6–8 mm range) or furcation involvements (Tonetti *et al*. 1998; Dannewitz *et al*. 2009). Furthermore, incorporation of local delivery devices into the treatment armamentarium requires reconciliation of the localized nature of the treatment target (the periodontal pocket) with the overall ecologic determinants of clinical outcomes in light of available treatment alternatives [adjunctive systemic antimicrobials (see Chapter 43) or adjunctive access flap surgery (see Chapter 39)]. In general, adjunctive treatment with local delivery devices is favored when there are relatively few residual pockets and systemic delivery of the antimicrobial may not be warranted. In this respect, local delivery may be advantageous in the management of local non-responding sites or disease recurrence during supportive periodontal care. This latter application has received considerable attention (Garrett *et al*. 2000; McColl *et al*. 2006; Bogren *et al*. 2009; Tonetti *et al*. 2012).

Another potentially important application is when residual pockets are present in the so-called esthetic zone where a surgical intervention may compromise esthetics or phonetics. Lastly, application of local delivery devices seems to be a rationale choice at sites with deep pockets and persistent bleeding on probing that are associated with intrabony defects after completion of the cause-related phase of therapy. As these sites are likely to be treated with periodontal regeneration (see Chapter 45) and the outcome of periodontal regeneration is negatively affected by the degree of bacterial contamination and spectrum of pathogens persisting into the lesion (Heitz-Mayfield *et al*. 2006), local drug delivery may be an important means of pocket disinfection before regenerative periodontal surgery.

Special patient groups

From a clinical standpoint, important attenuations of the expected benefits of non-surgical and surgical treatment have been observed in high-risk groups. These include smokers and subjects with diabetes, significant co-morbidities or erratic compliance with oral hygiene and/or long-term adherence to the necessary supportive periodontal care program. The effect of adjunctive local drug delivery has been assessed in such subjects.

Studies have reported that the adjunctive effect of local drug delivery may not be adversely affected by cigarette smoking (Ryder *et al.* 1999). In a planned secondary analysis of a multicenter trial assessing the adjunctive benefits of minocycline microspheres, the enhanced response to local delivery device application was greatest among smokers (Paquette *et al*. 2003, 2004).

Older patients as well as those with concomitant self-reported cardiovascular disease have also been reported to respond better to adjunctive local delivery than to mechanical debridement alone. Local drug delivery may contribute to better control of periodontitis in subjects with relative or absolute contraindications to surgical intervention.

Lastly, in patients with diabetes and periodontitis, recent randomized controlled clinical trials have shown benefits in the control of gingival inflammation and better clinical outcomes from the application of adjunctive local drug delivery with respect to subgingival debridement alone (Agarwal *et al*. 2012).

Conclusion

Local drug delivery into the periodontal pocket is an effective treatment adjunct to mechanical debridement. Clinical application requires the use of a well-designed technology platform that is able to counteract GCF clearance of the locally applied antibiotic and maintain effective concentrations for long enough for the desired pharmacologic effect to occur. Pocket disinfection is feasible, but recolonization is a critical phenomenon that needs to be prevented with a specific clinical strategy: optimal supragingival hygiene, full-mouth approach, and/or use of an antiseptic mouth rinse. Clinical applications range from the management of few residual pockets in otherwise healthy subjects to the management of residual lesions in groups at high risk because of age, smoking, frailty, or the presence of important co-morbidities.

Part 13: Reconstructive Therapy

Chapter 45

Regenerative Periodontal Therapy

Pierpaolo Cortellini[1] and Maurizio S. Tonetti[2]

[1]Private Practice, Florence, Italy
[2]European Research Group on Periodontology (ERGOPerio), Genoa, Italy

Introduction

The advances in the understanding of the biology of wound healing and periodontal regenerative technologies are applied to improve long-term clinical outcomes of teeth that are periodontally compromised by intrabony or inter-radicular defects. The treatment objective is to obtain shallow, maintainable pockets by reconstruction of the destroyed attachment apparatus and thereby also limit recession of the gingival margin. In general, periodontal regeneration is selected to obtain: (1) an increase in the periodontal attachment of a severely compromised tooth; (2) a decrease in deep pockets to a more maintainable range; and (3) a reduction of the vertical and horizontal component of furcation defects. Current approaches, however, remain technique sensitive and clinical success requires application of meticulous diagnostic and treatment strategies.

Classification and diagnosis of periodontal osseous defects

Site-specific periodontal breakdown compromises the long-term prognosis of teeth by producing three types of defects: suprabony (or horizontal) defects, infrabony (or vertical) defects, and inter-radicular (or furcation) defects.

According to the classification by Goldman and Cohen (1958), suprabony defects are those where the base of the pocket is located coronal to the alveolar crest. This chapter does not deal with suprabony defects.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

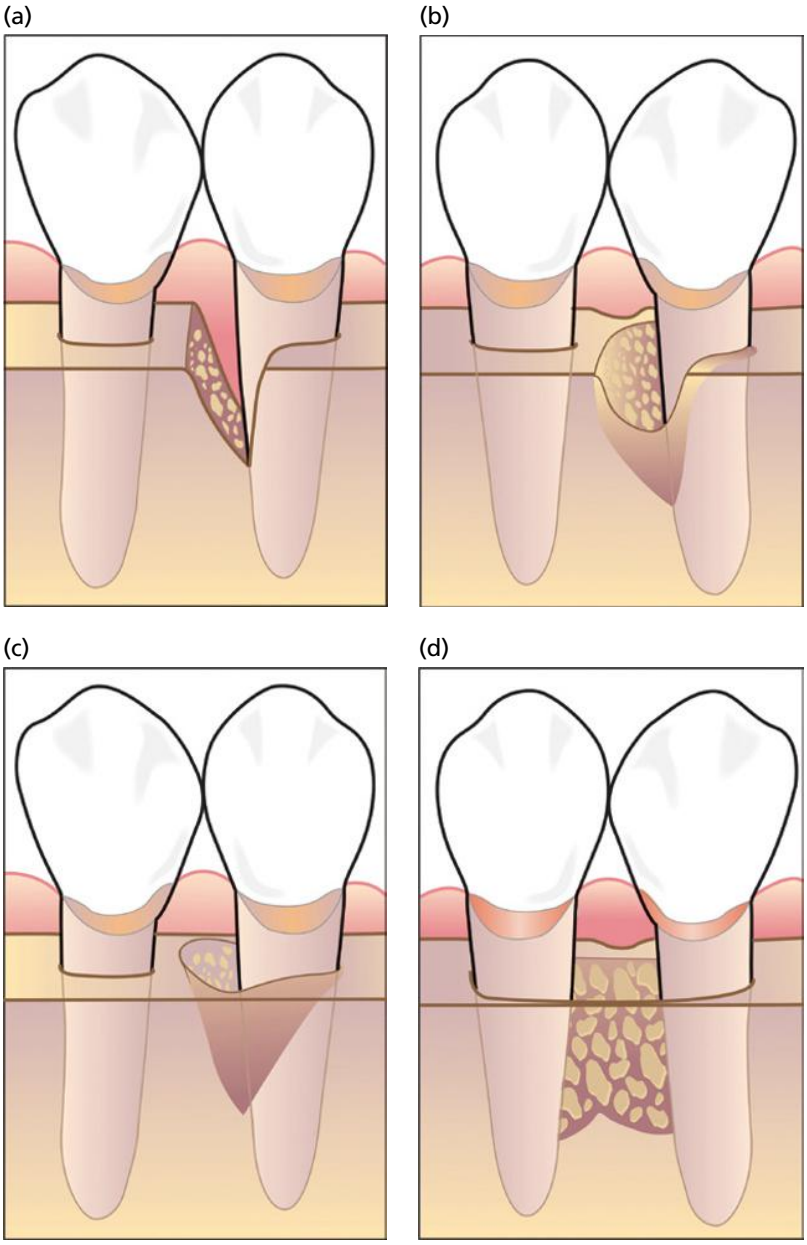

Fig. 45-1 Infrabony defects. (a) One-wall intrabony defect; (b) two-wall intrabony defect; (c) three-wall intrabony defect; (d) interproximal crater. (Source: Papapanou & Tonetti 2000. Reproduced with permission from John Wiley & Sons.)

Infrabony defects, on the other hand, are defined by the apical location of the base of the pocket with respect to the residual alveolar crest. With regard to infrabony defects, two types can be recognized: intrabony defects and craters. Intrabony defects are bony defects whose infrabony component affects primarily one tooth, while in craters the defect affects two adjacent root surfaces to a similar extent. Intrabony defects (Fig. 45-1) have been classified according to their morphology in terms of residual bony walls, width of the defect (or radiographic angle), and topographic extension around the tooth. Three-wall, two-wall, and one-wall defects have been defined on the basis of the number of residual alveolar bone walls. This represents the primary classification system. Frequently, intrabony defects present a complex anatomy consisting of a three-wall component in the most apical portion of the defect, and two- and/or one-wall components in the more superficial portions. Hemiseptal defects, that is vertical defects in the presence of adjacent roots and where half of a septum remains on one tooth, represent a special case of one-wall defects. Several authors have also used descriptive terms to define special morphologic characteristics: funnel-shaped defects, moat-like defects, trenches, etc.

Of particular interest is a special morphology: the crater (Fig. 45-1). It is defined as a cup- or bowl-shaped defect in the interdental alveolar bone with bone loss nearly equal from the roots of two contiguous teeth and a more coronal position of the buccal and lingual alveolar crest; the facial and lingual/palatal walls may be of unequal height. This defect can be considered to be the result of the apical spread of periodontitis along two adjacent roots in a relatively narrow (mesiodistally) interproximal area.

Notably, all the definitions above are not based on radiographic assessments, but on the actual

morphology of the defects after flap elevation. Conditions entailing pathologic resorption of bone within the furcation of a multirooted tooth, defined as furcation invasions, are also classed as periodontal bony defects; the reader is referred to Chapter 40 for a discussion of the anatomy and classification of furcations.

The diagnosis of the presence and the morphology of periodontal osseous lesions represents a major clinical challenge. It is primarily performed by combining clinical information derived from the evaluation of the attachment level with information derived from diagnostic-quality parallel-technique intraoral radiographs. A precise knowledge of root anatomy and its variations is also important for the diagnosis of periodontal osseous defects, and inter-radicular defects in particular. Diagnostic-quality radiographs provide additional information on the morphology of the alveolar bone resorption. In this context, interpretation of the radiographic image of the interdental septum is complicated, since the radiograph provides a two-dimensional image of a three-dimensional anatomy consisting of superimposed structures, including alveolar bone, hard tooth substances, and soft tissue. This complexity of the visualized structures means that a certain amount of tissue destruction must occur before it can be radiographically detected, often rendering incipient bone lesions obscure. Furthermore, even advanced lesions may be masked by the presence of superimposed structures. It is therefore generally stated that radiographic diagnosis has a high positive predictability (i.e. the visualized lesions are indeed there) but a low negative predictability (i.e. the absence of radiographically detectable bone loss does not exclude the presence of an osseous lesion).

Clinical attachment level (CAL), on the other hand, is a highly sensitive diagnostic tool; its combination with radiographs, therefore, confers a higher degree of accuracy to the diagnostic approach (Tonetti *et al.* 1993b). In particular, the site-specific comparison of radiographic bone loss with clinical attachment loss allows the clinician to make a qualified guess of the true osseous architecture, whose exact morphology, however, can only be established after flap elevation. Detection of the defect, its location and extension, along with its major morphologic features, should be performed before flap elevation. A further aid to this end is the use of transgingival probing or bone sounding.

Clinical indications

Periodontal treatment, either surgical or non-surgical, results in recession of the gingival margin after healing (Isidor *et al*. 1984). In advanced cases of periodontitis, this may lead to poor esthetics in the front areas of the dentition, in particular when applying surgical procedures with osseous recountouring for the eradication of bone defects. Treatment of such cases without bone contouring, on the other hand, may result in residual pockets inaccessible to proper cleaning during post-treatment maintenance. These problems can be avoided or reduced by applying regenerative surgical procedures to restore the lost periodontal attachment in the bone defects. Thus, the indication for applying regenerative periodontal therapy is often based on esthetic considerations, besides the fact that the function or long-term prognosis of the treated teeth may be improved.

Other indications for regenerative periodontal therapy include furcation-involved teeth. The furcation area is often inaccessible to adequate instrumentation and frequently the roots present concavities and furrows that make proper cleaning of the area impossible after access or resective surgery. Considering the long-term results and complications reported following treatment of furcation involvements by traditional surgical therapy (Hamp *et al*. 1975; Bühler 1988), the long-term prognosis of furcation-involved teeth can be improved considerably by successful regenerative periodontal therapy.

Case reports also exist demonstrating that "hopeless" teeth with deep vertical defects, increased tooth mobility or through-and-through furcations can be successfully treated with regenerative periodontal therapy (Gottlow *et al*. 1986). Teeth with deep pockets associated with deep intrabony defects are considered a clinical challenge. Most authors have classified such teeth as having either a questionable or a hopeless prognosis. Key elements supporting these opinions are the complex interplay of reduced residual periodontal attachment, deep pocketing, functional demands, and frequently the resulting tooth hypermobility (Lang & Tonetti 1996; McGuire & Nunn 1996a, b; Kwok & Caton 2007). It is therefore clear that the possibility of changing the prognosis of a tooth from "questionable" or "hopeless" to "fair" or "favorable" would greatly help clinicians and patients in the difficult job of maintaining teeth over time, and the possibility of gaining periodontal support would help improve patient comfort and function.

Long-term effects and benefits of regeneration

A pertinent question with respect to regenerative treatment is whether or not the achieved attachment level gains can be maintained over an extended period of time. In a long-term follow-up study, Gottlow *et al*. (1992) assessed the stability of new attachment gained through guided tissue regeneration (GTR) procedures. Eighty sites in 39 patients, which 6 months after surgery exhibited a gain of clinical attachment of ≥2 mm (2–7 mm), were monitored over an additional period of 1–5 years. Of the 80 sites, 65 were monitored for 2 years, 40 for 3 years, 17 for 4 years, and nine for 5 years. The results of this study and those of other trials indicate that attachment gain obtained following GTR treatment can be maintained on a long-term basis (Becker & Becker 1993; McClain & Schallhorn 1993).

An investigation of intrabony defects demonstrated that the stability of sites treated with GTR

was dependent on patient participation in a recall program, and on the absence of bacterial plaque, bleeding on probing (BoP), and re-infection of the treated sites with periodontal pathogens (Cortellini *et al*. 1994). The susceptibility to disease recurrence at sites treated with non-bioresorbable barrier membranes was assessed in a study comparing long-term changes in attachment levels at regenerated and non-regenerated sites in the same patient (Cortellini *et al*. 1996a). Results indicated that there was a high degree of concordance in the clinical outcomes (stability versus recurrence of attachment loss) within the same patient, suggesting that patient factors, rather than site factors, including the specifics of the histologic type of expected wound healing, are associated with disease recurrence. Among patient factors, compliance with oral hygiene, smoking habits, and susceptibility to disease progression were the major determinants of stability of the treated sites, rather than the employed treatment modality.

Support for a limited impact of the histologic type of healing comes from an experimental study. In a study in monkeys (Kostopoulos & Karring 1994), periodontal breakdown was produced by the placement and retention of orthodontic elastics on experimental teeth until 50% bone loss was recorded. The experimental teeth were endodontically treated and subjected to a flap operation, and all granulation tissue was removed. The crowns of the teeth were resected at the level of the cementoenamel junction and a barrier membrane was placed to cover the roots before they were submerged. Following 4 weeks of healing, the membranes were removed. At the same time, the contralateral teeth that served as controls were endodontically treated and subjected to a sham operation during which the crowns were resected at the level of the cementoenamel junction. Artificial composite crowns were then placed on both the experimental and the control roots. The sites were allowed to heal for 3 months during which period careful plaque control was performed. At the end of this period, cotton-floss ligatures were placed on both experimental and control teeth to induce periodontal tissue breakdown. After another 6 months, the animals were sacrificed. With respect to attachment level, bone level, probing pocket depth (PPD), and gingival recession, similar results were recorded in the histologic specimens of experimental (Fig. 45-2) and control (Fig. 45-3) teeth. This indicates that the new connective tissue attachment formed with GTR is no

Fig. 45-2 Microphotograph of test specimen with a reformed connective tissue attachment. After 6 months of ligature-induced periodontitis, loss of attachment has occurred from the coronal cut root surface to the level indicated by the arrow.

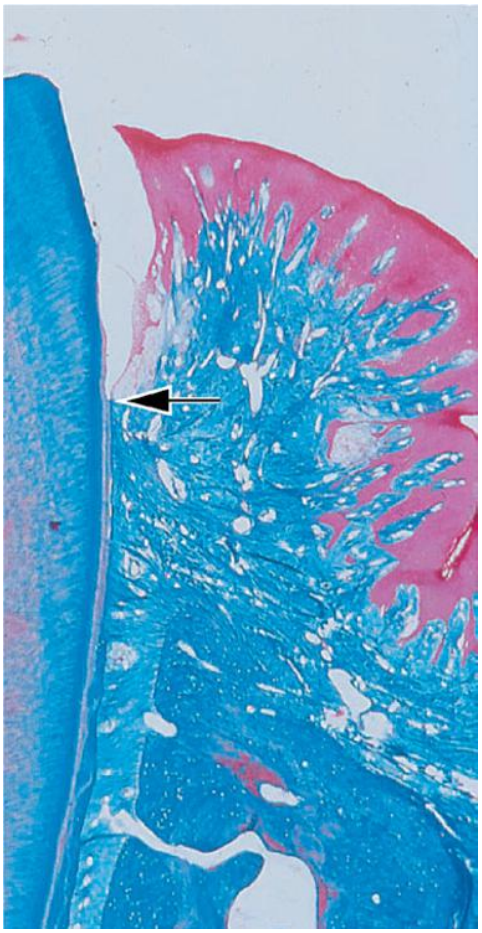

Fig. 45-3 Microphotograph of control specimen with a naturally existing periodontium. After 6 months of ligature-induced periodontitis, loss of attachment has occurred from the coronal cut tooth surface to the level indicated by the arrow.

Table 45-1 Survival analysis of regenerated periodontal attachment over a 16-year follow-up period in 175 subjects treated with periodontal regeneration. In this survival analysis, the event is represented by clinical attachment level (CAL) loss of ≥2 mm from the level of attachment obtained at completion of healing 1 year after regeneration. No substantial recurrence of periodontitis (CAL loss) was observed in 92% of treated cases who participated in a secondary prevention program.

Time at risk (years)	Number of CAL loss ≥2 mm	Censored	Effective sample size	Conditional probability of CAL loss (%)	Survival (%)
0–2	2	0	175	1.1	100
2–4	3	0	166	1.7	98.9
4–6	2	0	155	1.2	97.1
6–8	1	55	119	0.7	96
8–10	0	47	70.5	0	95.3
10–12	2	16	41	3.5	95.3
12–14	0	25	24.5	0	92
14–16	0	21	8	0	92
16	0	1	0.5	0	92

more susceptible to periodontitis than the naturally existing periodontium.

Other long-term studies show that, if the patient participates in a professionally delivered supportive periodontal care program and maintains good oral hygiene, the regenerated attachment can be maintained long term (Sculean *et al*. 2006; Christgau *et al*. 1997; Eickholz *et al*. 2007; Slotte *et al*. 2007; Sculean *et al*. 2008; Nickles *et al*. 2009; Pretzl *et al*. 2009; Nygaard-Østby *et al*. 2010).

Few investigations have looked at the long-term effects of periodontal regeneration on tooth survival. Cortellini and Tonetti (2004) performed a Kaplan–Mayer analysis of tooth survival following periodontal regenerative treatment in a sample of 175 patients followed up for 2–16 years (average 8 ± 3.4 years) in a specialist environment. In this study, 96% of teeth treated with periodontal regeneration survived. Of interest was the observation that tooth loss was observed among only the 32% of the population who smoked (tooth survival was 89% among smokers and 100% among non-smokers). CALs were located at the same level or coronal to the pretreatment levels in 92% of cases up to 15 years after treatment (Table 45-1, Fig. 45-4).

The potential clinical benefits of periodontal regeneration are best illustrated in a consecutive case series of strategic abutments severely compromised by the presence of deep intrabony defects with associated deep pockets, which were followed up for up to 8 years following regenerative treatment (Tonetti *et al*. 1996b; Cortellini *et al*. 1999b). At baseline, the periodontal defect rendered these teeth unsuitable as abutments to be included in a reconstruction. In all cases, periodontal regeneration with barrier membranes was able to change the clinical prognosis by providing both a 30% increase in radiographic bone support and shallow, maintainable PPD. These outcomes remained stable during the follow-up period (Fig. 45-5).

A few studies have evaluated the long-term prognosis for furcation defects treated with regenerative therapy. Sixteen mandibular class II furcation defects, following coronal flap positioning and citric acid root biomodification with and without implantation of demineralized freeze-dried bone allografts (DFDBAs), were determined to be completely resolved with bone fill assessed by re-entry surgery. They were re-evaluated after 4–5 years (Haney *et al*. 1997), when 12 of the 16 sites exhibited recurrent class II furcations and all 16 sites demonstrated probable buccal furcation defects. The investigators concluded that these findings question the long-term stability of bone regeneration in furcations following coronally advanced flap procedures. A similar benefit has been reported following use of combination therapy (barrier membranes and DFDBA) in teeth compromised by class II furcation defects (Bowers *et al*. 2003): 92% of the class II defects were either closed or transformed into class I and thus at lower risk of tooth loss 1 year after therapy (McGuire & Nunn 1996a, b).

The long-term stability of mandibular furcation defects regenerated following GTR alone or in combination with root surface biomodification with citric acid and bone grafting, was also evaluated by McClain and Schallhorn (1993). Of the 57% of the furcation defects that were assessed as completely filled at 6 and 12 months, only 29% were completely filled after 4–6 years. However, 74% of the furcations treated with GTR in combination with the placement of DFDBA were completely filled at both the short- and long-term evaluation, suggesting that the results obtained with the combined procedure were more stable over time. Long-term results of GTR treatment of mandibular class II furcations with expanded polytetrafluoroethylene (ePTFE) membranes were also reported by Machtei *et al*. (1996). The teeth were followed up for 4 years and compared with non-furcated molars. Improvements assessed in vertical (V-CAL) and horizontal CAL (H-CAL) after treatment were also maintained after 4 years, suggesting that changes obtained in class II furcation defects by GTR are stable. Only 9% of the treated defects were unstable, which was similar to the

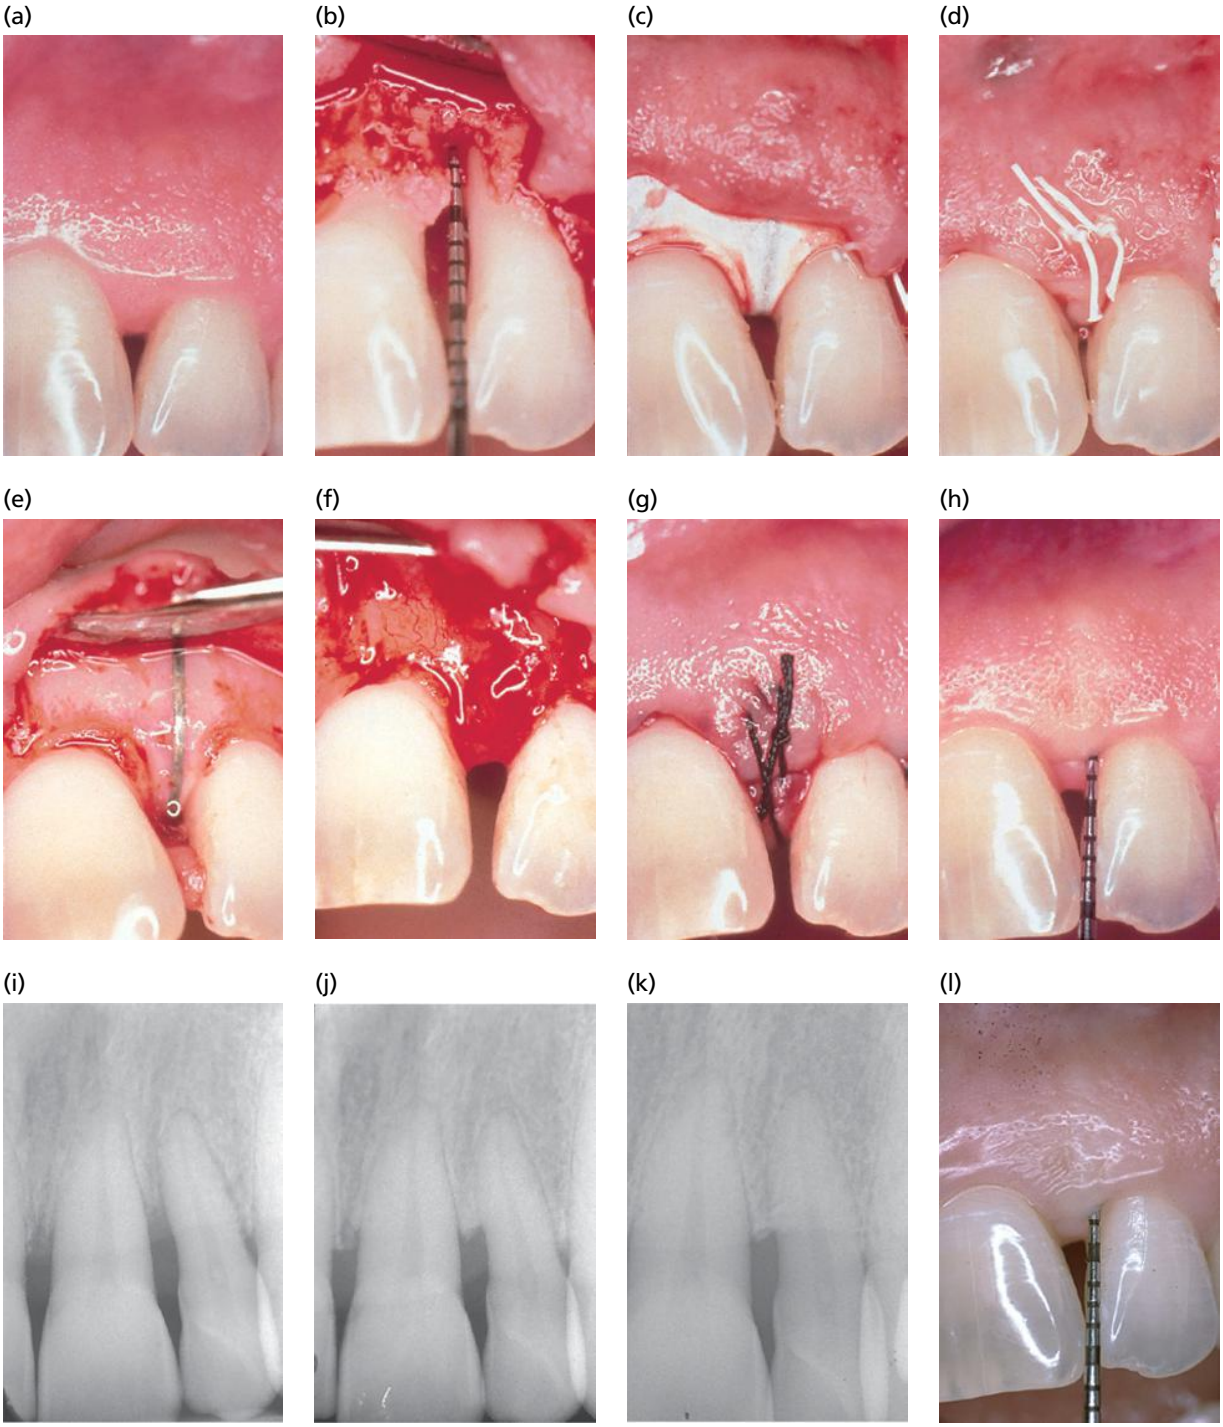

Fig. 45-4 (a, b) Left maxillary lateral incisor with a deep interproximal intrabony defect on the mesial surface. (c) Flaps are raised according to the modified papilla preservation technique, and a titanium-reinforced barrier membrane is placed over the defect. (d) By coronal displacement of the flap and preservation of the interdental papilla, the membrane is completely covered. (e, f) After 6 weeks of uneventful postoperative healing, the membrane was removed and (g) the newly formed tissue was completely covered. (h) At 1 year, residual probing pocket depth was 2 mm and no buccal or interdental recession had occurred. (i) Baseline radiograph showed radiolucency approaching the apex of the tooth, but after 1 year the intrabony defect is resolved and some supracrestal bone apposition seems to have occurred (j). Radiograph taken at 6 years confirms the supracrestal bone regeneration (k) and the clinical image showed the integrity of the interdental papilla with optimal preservation of the esthetic appearance (l).

percentage observed for non-furcated molars. Good oral hygiene, as reflected in low plaque scores and elimination of periodontal pathogens, was closely related to the long-term stability. On the basis of these results, it was concluded that furcation defects treated with membrane barriers can be maintained in health for at least 4 years, provided good oral hygiene and frequent recall visits are established.

The survival rate of furcated teeth treated with regenerative therapy has been investigated in a few studies. Yukna and Yukna (1997) reported a 100% survival rate after an average observation period of

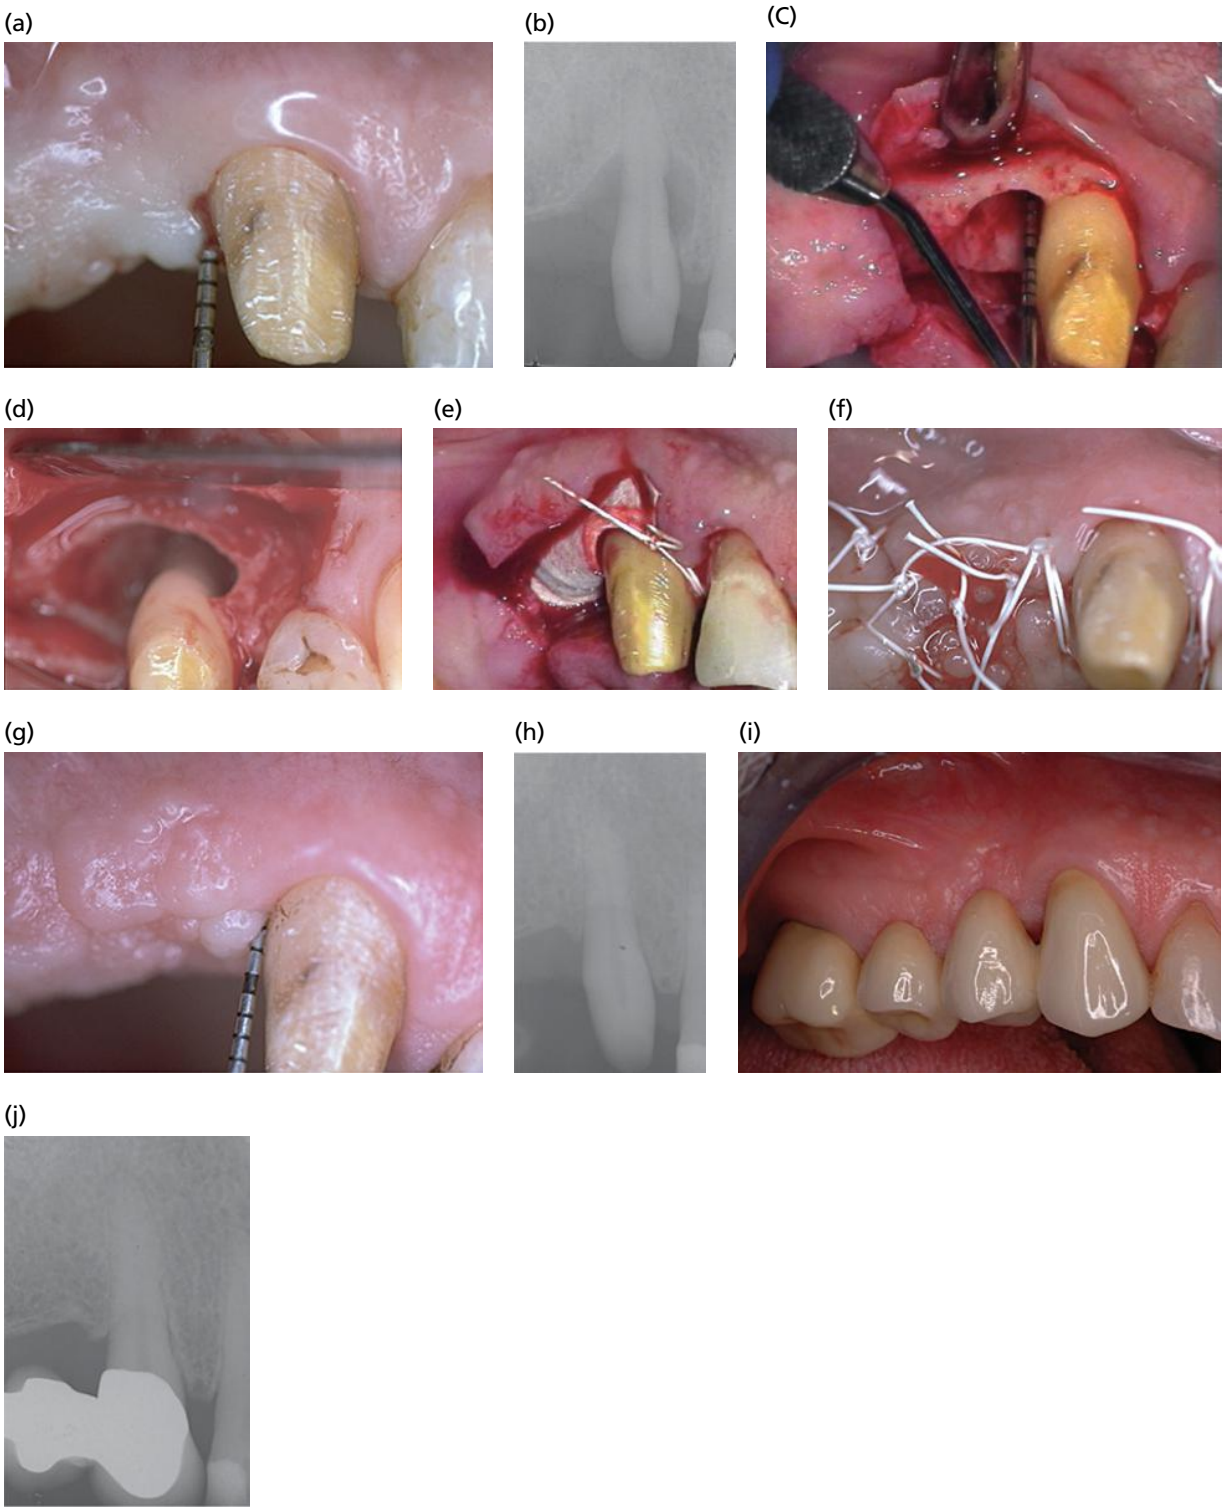

Fig. 45-5 Clinical benefits of periodontal regeneration. Patient presented with periodontally compromised mesial abutment of the bridge: a 10-mm pocket was associated with a 10-mm intrabony defect extending on three of the four surfaces of the tooth (a–d). A barrier membrane was positioned and secured around the root of the tooth (e). Primary closure with internal mattress sutures was achieved (f) and maintained during the healing period. At 1 year, periodontal probing showed a shallow maintainable pocket (3 mm) (g) and the complete resolution of the defect (h). Clinical and radiographic stability of the outcome is shown 10 years following regenerative therapy (i, j): stability of the gingival margin, shallow pockets, good esthetics, and good periodontal support for the abutment are evident.

6.6 years in 26 mandibular and maxillary furcated molars treated with synthetic bone graft and coronally advanced flap. Eickholz and Hausmann (2002) reported a 100% survival rate after 60 months in 10 mandibular and 10 maxillary furcated molars treated with barriers. A survival rate of 98.1% was reported by Dannewitz *et al*. (2006) after a 107-month observation period of 29 maxillary and 24 mandibular furcated molars treated with GTR. Eickholz *et al*. (2006) reported an 83.3% survival rate after 10 years

in 18 mandibular and maxillary molars treated with barriers.

Summary: Several clinical studies addressing the long-term effects of periodontal regeneration show that, if the patient participates in a professionally delivered supportive periodontal care program and maintains good oral hygiene, the regenerated attachment can be maintained long term. Risk factors for attachment loss are those associated with disease recurrence: poor compliance with supportive periodontal care, poor oral hygiene, and cigarette smoking. In addition, most treated teeth affected by intrabony defects or furcation involvement can be maintained over long periods of time provided proper supportive periodontal and home care is undertaken.

Evidence for clinical efficacy and effectiveness

Questions of efficacy relate to the added benefit of a treatment modality under ideal experimental conditions (such as those of a highly controlled research center environment). Effectiveness, on the other hand, relates to the benefit that can be achieved in a regular clinical setting where the procedure is likely to be performed in relation to morbidity and adverse events. Besides efficiency considerations, both evidence for efficacy and effectiveness need to be available in order to provide support for the adoption of a novel approach in clinical practice.

The clinical efficacy of periodontal regenerative procedures has been extensively evaluated in randomized controlled clinical trials that have compared the regenerative procedure with a standard approach. To limit sample size and study duration, these trials have utilized surrogate outcomes – CAL changes, decrease in PPD, furcation closure or radiographic measurements–rather than changes in tooth survival. These surrogate outcomes, however, are considered to be adequate proxies of the true outcome represented by tooth survival: persistence of deep pockets or furcation involvement are associated with a higher risk of periodontal breakdown and tooth extraction.

The majority of clinical trials have been small single-center studies. The evidence from these studies has been summarized in meta-analyses performed on data retrieved by systematic reviews of the published literature. In 2002, 2003, and 2008, the European Workshop on Periodontology and the Workshop on Emerging Technologies in Periodontics provided much of the systematic assessment of the evidence for currently available technologies. These include the use of barrier membranes (GTR), bone replacement grafts (BRGs), and biologically active regenerative materials, as well as the application of combination therapy. The clinical evidence must be interpreted in the context of the biologic mechanisms and evidence for regeneration discussed in Chapter 28.

The evidence for clinical efficacy of barrier membranes has been assessed in the systematic reviews and meta-analyses performed by Needleman *et al*. (2002, 2006), Jepsen *et al*. (2002), Murphy and Gunsolley (2003), and Kinaia (2011).

For intrabony defects, 26 controlled trials with 867 intrabony defects were included (Murphy & Gunsolley 2003). The application of barrier membranes resulted in an additional CAL gain of >1 mm compared to that with an access flap approach control (Fig. 45-6). A more recent meta-analysis (Needleman *et al*. 2006) was performed on 17 randomized controlled trials (16 studies testing GTR alone and two testing GTR + bone substitutes). For CAL change, the mean difference between GTR and open flap debridement (OFD) was 1.22 mm (95% CI random

effects 0.80–1.64) and for GTR + bone substitutes was 1.25 mm (95% CI 0.89–1.61). The authors highlighted that GTR showed a significant benefit when comparing the numbers of sites failing to gain 2 mm of attachment, with a risk ratio of 0.54 (95% CI random effects 0.31–0.96). The number needed to treat (NNT) for GTR to achieve one extra site gaining 2 mm or more of attachment over OPD was therefore eight (95% CI 5–33), based on an incidence of 28% of sites in the control group failing to gain 2 mm or more of attachment. For baseline incidences in the range of the control groups of 3% and 55%, the NNT would be 71 and four, respectively. The authors concluded that GTR has a greater effect on probing measures of periodontal treatment than OPD, including improved attachment gain, reduced PPD, less increase in gingival recession, and more gain in hard tissue probing at re-entry surgery. However, there was marked variability between the studies and the clinical relevance of these changes is unknown.

For class II furcation defects, 15 controlled trials with 376 involved teeth were included (Murphy & Gunsolley 2003). Membrane application resulted in additional vertical and horizontal (depth of the furcation involvement) CAL gains (Fig. 45-7). A meta-analysis of re-entry studies on the treatment of class II molar furcation involvement (Kinaia *et al*. 2011) was performed on 13 controlled clinical trials. There was a significant improvement for bioresorbable versus non-bioresorbable membranes mainly in vertical bone fill (0.77–0.33 mm; 95% CI 0.13, 1.41). Non-bioresorbable membranes showed significant improvement in vertical probing reduction (0.75–0.31 mm; 95% CI 0.14, 1.35), attachment gain (1.41–0.46 mm; 95% CI 0.50, 2.31), horizontal bone fill (1.16–0.29 mm; 95% CI 0.59, 1.73), and vertical bone fill (0.58–0.11 mm; 95% CI 0.35, 0.80) over OFD. Bioresorbable membranes showed significant reduction in vertical probing depth (0.73–0.16 mm; 95% CI 0.42, 1.05), attachment gain (0.88–0.16 mm; 95% CI 0.55, 1.20), horizontal bone fill (0.98–0.12 mm; 95% CI 0.74, 1.21), and vertical bone fill (0.78–0.19 mm; 95% CI 0.42, 1.15) over OFD.

These data alone, however, did not present conclusive evidence of efficacy as the possibility of bias arising from a possible tendency to report studies with positive results could not be ruled out. Multicenter studies were designed to assess efficacy conclusively. These were performed in a private practice environment in order to assess also the generalizability of the benefit to this specific setting (effectiveness). The results of large prospective multicenter studies in private practice settings (Tonetti *et al*. 1998, 2004b; Cortellini *et al*. 2001) conclusively support the additional benefit of membranes in improving CAL in intrabony defects, and thus their efficacy and effectiveness. More limited evidence is also available for combination therapy (BRG + barrier membranes) in furcation defects (Bowers *et al*. 2003).

The efficacy of BRG materials has been assessed in two systematic reviews (Trombelli *et al*. 2002; Reynolds *et al*. 2003). As these two systematic reviews used significantly different criteria for study inclusion, their results do not fully overlap. Trombelli *et al*. (2002), who included only controlled studies that reported changes in CAL as the primary outcome, concluded that there was insufficient evidence to support the clinical use of BRG materials in intrabony defects, since: (1) there was significant heterogeneity among the included studies; (2) the size of the adjunctive effect was small; and (3) there were differences that did not allow pooling of results obtained with different materials. In the other meta-analysis for intrabony defects, 27 controlled trials with 797 intrabony defects were included (Reynolds *et al*. 2003). The application of BRG resulted in an additional CAL gain of 0.5 mm compared to an access flap approach control (Fig. 45-8). Greater additional benefits from the application of BRG were observed whenever hard tissue measurements (bone fill or defect resolution) were utilized as outcome measures.

For furcation defects, the lack of consistent comparisons did not allow a meaningful assessment of the potential benefits of the use of BRGs alone (Reynolds *et al*. 2003). No large multicenter trials

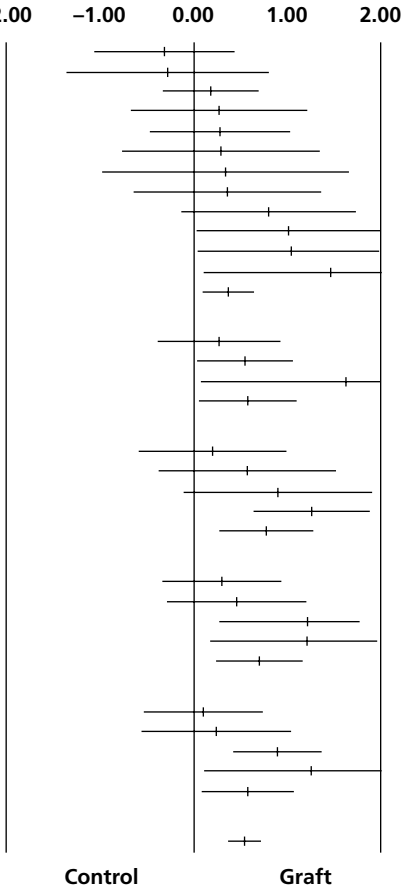

Fig. 45-8 Final meta-analysis of clinical attachment level in randomized controlled clinical studies comparing bone replacement graft (BRG) to open flap debridement (OFD) in the treatment of intrabony defects. (ALL, allograft; AUT, autograft; CER, calcium phosphate (hydroxyapatite) ceramic; COR, coralline calcium carbonate; GLA, bioactive glass.) (Source: Reynolds *et al.* 2003. Reproduced from the American Academy of Periodontology.)

have provided definitive support for efficacy and/or effectiveness of the use of BRGs.

The evidence for clinical efficacy of biologically active regenerative materials has been summarized in meta-analyses for enamel matrix derivatives (EMDs) (Trombelli *et al*. 2002; Giannobile & Somerman 2003; Esposito *et al*. 2009; Koop *et al*. 2012), for growth factors (Darby & Morris 2013), and for platelet concentrate (*et al*. 2011) in the treatment of intrabony defects only.

The outcomes of eight studies including 444 defects have indicated that EMD application provides additional benefits of a magnitude of 0.75 mm in terms of CAL gain (Giannobile & Somerman 2003). These data are in accordance with those of a large practice-based multicenter trial that demonstrated both efficacy and effectiveness of EMDs in intrabony defects (Tonetti *et al*. 2002). The meta-analysis by Esposito *et al*. (2009) included 13 trials. A meta-analysis including nine trials showed that EMD-treated sites displayed statistically significant CAL improvements (mean difference 1.1 mm; 95% CI 0.61–1.55) and PPD reduction (0.9 mm; 95% CI 0.44–1.31) when compared to placebo- or control-treated sites, though a high degree of heterogeneity was found. Approximately nine patients needed to be treated (NNT) for one to gain 2 mm or more probing attachment level (PAL) over the control group, based on a prevalence in the control group of 25%. No differences in tooth loss or esthetic appearance as judged by the patients were observed. When evaluating only trials at a low risk of bias in a sensitivity analysis (four trials), the effect size for PAL was 0.62 mm (95% CI 0.28–0.96), which was <1.1 mm for the overall result.

A more recent meta-analysis (Koop *et al*. 2012) on 20 randomized controlled trials showed a significant additional gain in CAL of 1.30 mm of EMD-treated sites compared with OFD, ethylenediaminetetra-acetic acid (EDTA), or placebo (Fig. 45-9).

The systematic review by Darby and Morris (2013) reported a meta-analysis on two studies on the use of recombinant human platelet-derived growth factor-BB (rhPDGF-BB). Sites treated with rhPDGF-BB had greater CAL gain of around 1 mm, a greater percentage bone fill of around 40%, and an increased rate of bone growth of around 2 mm compared to sites treated with an osseoconductive control, beta-tricalcium phosphate (β-TCP).

Del Fabbro *et al*. (2011) in a meta-analysis on 10 studies reported a significantly greater CAL gain in cases treated with platelet-rich plasma (PRP) compared to control sites (mean adjusted percentage difference 5.50%; 95% CI 1.32–9.67%; $P = 0.01$). The mean weighted CAL gain difference was 0.50 mm (95% CI 0.12–0.88 mm).

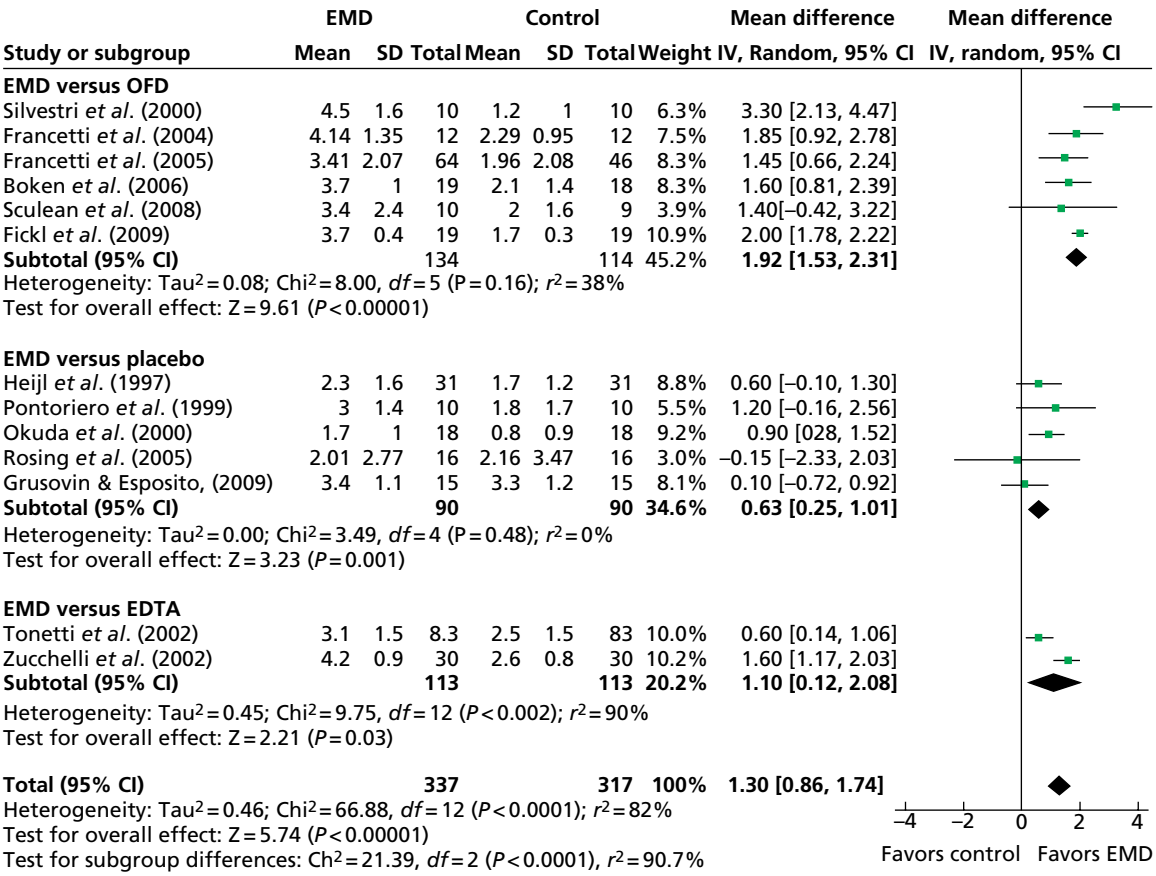

Fig. 45-9 Meta-analysis of intrabony defect studies. Comparison of enamel matrix derivatives (EMDs) versus control: change in clinical attachment level (CAL) after 1 year. (Total, number of patients; IV, inverse variance; CI, confidence interval.) (Source: Koop *et al*. 2012. Reproduced with permission from the American Academy of Periodontology.)

Combination therapy has been explored in two recent meta-analyses. Trombelli *et al*. (2008) evaluated the clinical effects of bioactive agents when used in addition to OFD either alone or in association with grafts and/or barrier membranes. The authors concluded that there was evidence to support the use of EMDs either alone or in combination with grafts to effectively treat intraosseous defects and the additional use of a graft seems to enhance the clinical outcome of EMDs; the combined use of rhPDGF-BB and P-15 with a graft biomaterial has shown beneficial effects in intraosseous defects; contrasting results were reported for PRP and graft combinations. Tu *et al.* (2010) explored the additional treatment effect of barriers or bone grafts to EMDs in 28 studies. EMD plus bone grafts and EMD plus membranes attained 0.24 mm and 0.07 mm more PPD reduction than EMD alone, respectively. EMD plus bone grafts and EMD plus membranes attained 0.46 mm and 0.15 mm more CAL gain, respectively. When different types of bone grafts and barrier membranes were treated separately, EMD with bovine bone grafts showed greater treatment effects. The authors concluded that there was little evidence to support the additional benefits of EMDs in conjunction with other regenerative materials.

Comparative studies between different regenerative approaches have been analyzed in a systematic review by Esposito *et al*. (2009) including six studies. The authors did not find any difference between EMDs and barriers in terms of CAL gain and PPD reduction. These data are supported by two large practice-based multicenter trials (Silvestri *et al*. 2003; Sanz *et al*. 2004). The Sanz *et al*. (2004) study, however, reported a significantly higher prevalence of complications in the barrier-treated group compared to the EMD-treated one. More recently, Tu *et al*. (2012) compared GTR, EMDs, and their use in conjunction with other regenerative materials with a Bayesian network meta-analysis of 53 randomized controlled trials. The authors found small differences between regenerative therapies which were non-significant statistically and clinically. GTR and GTR-related combination therapies achieved greater PPD reduction than EMDs and EMD-related combination therapies. Combination therapies achieved slightly greater CAL gain than the use of EMDs or GTR alone. The authors concluded that combination therapies performed better than single therapies, but the additional benefits were small. The same conclusions were reached by Koop *et al.* (2012).

Patient, defect, and tooth prognostic factors

The results reported in the above-cited meta-analyses indicate that clinical improvements beyond those from flap surgery can be obtained by treating periodontal

Table 45-2 Outcomes of regression analyses performed to explain variability in terms of clinical attachment gain at 1 year.

EMD, enamel matrix derivative.

defects with regenerative therapies, but they also suggest a great variability in clinical outcomes among the different studies. In addition, it is apparent from the results that the complete resolution of the intrabony component of the defect and of the horizontal component of a furcation is observed in only a minority of sites. Regeneration, in fact, is an advanced healing event that occurs when the systemic and local conditions are favorable and when therapy is properly applied. A significant "center effect" was consistently observed in five randomized multicenter studies (Tonetti *et al*. 1998; Cortellini *et al.* 2001; Tonetti *et al.* 2002; Sanz *et al*. 2004; Tonetti *et al.* 2004a). The center variability, defined as the difference in CAL between the best and the worst center, had a highly significant impact on the outcomes, greater than the impact of the tested regenerative materials (Table 45-2).

The observed variability among centers may depend on differences in the enrolled patients in terms of socioeconomic background, form of periodontal disease, response to therapy, and persistence of specific pathogens; or differences in clinical experience, surgical skills, and clinical organization of the clinicians. In addition, a series of prognostic factors associated with the clinical outcomes has been identified using multivariate approaches (Tonetti *et al*. 1993a, Cortellini *et al*. 1994; Machtei *et al*. 1994; Tonetti *et al.* 1995, 1996a; Falk *et al*. 1997; Cortellini & Tonetti 2000b). The main sources of clinical variability are patient-, defect-, and surgery-associated factors (Cortellini & Tonetti 2000a). Attention has focused on some important patient, defect, and tooth factors.

Patient factors

Periodontal infection

Periodontal regeneration does not treat periodontitis, but rather is an approach for regenerating defects that have developed as a result of periodontitis. Therefore, appropriate periodontal treatment should always be completed before periodontal regeneration is initiated. In this context, that is in patients who have undergone a cycle of cause-related periodontal therapy to the satisfaction of the treating clinician, evidence suggests that the level of control of periodontitis achieved before a periodontal regenerative procedure is initiated is associated with outcomes: the persistence of poor plaque control, high levels of bleeding upon probing, as well as the persistence of high loads of total bacteria or of specific microbial pathogens (or complexes of pathogens) have all been associated in a dose-dependent manner with poor clinical outcomes (Tonetti *et al*. 1993a; Cortellini *et al*. 1994; Machtei *et al*. 1994, Cortellini *et al*. 1995a, b; Tonetti *et al.* 1995; Machtei *et al*. 2003; Silvestri *et al.* 2003; Heitz-Mayfield *et al.* 2006).

The level of self-performed plaque control has a great and dose-dependent effect on the outcome of periodontal regeneration. Better CAL gains were observed in patients with optimal levels of plaque control as compared with those in patients with less ideal oral hygiene (Cortellini *et al*. 1994, 1995a, b; Tonetti *et al*. 1995, 1996a). Patients with plaque on <10% of the tooth surfaces [full-mouth plaque score (FMPS)] had a gain of CAL which was 1.89 mm greater than that observed in patients with a FMPS of >20% (Tonetti *et al*. 1995).

Although not formally tested for efficacy in randomized trials, achieving high levels of plaque control and suppression of the pathogenic microflora through behavioral intervention and intensive anti-infective periodontal therapy are generally advocated before proceeding with periodontal regeneration. Furthermore, some proof of principle investigations have assessed the adjunctive effect of using an antibiotic locally delivered within the wound area or in the regenerative material (Yukna & Sepe 1982; Sanders *et al*. 1983; Machtei *et al*. 2003; Stavropoulos *et al*. 2003). Results showed consistently better outcomes in the groups that received the systemic/local antibiotic. At present, however, no regenerative device with enhanced antimicrobial activity is commercially available. Local contamination of the defect-associated pocket should be as low as possible (Heitz-Mayfield *et al*. 2006). Presence of BoP (i.e. bacteria) should be controlled with additional gentle root planing and eventually with the additional use of local antimicrobials (Tunkel *et al*. 2002; Hanes & Purvis 2003).

Smoking

A retrospective study found that cigarette smokers displayed significantly impaired regenerative outcomes compared to non-smokers (Tonetti *et al*. 1995). Data showed that cigarette smoking was associated with reduced CAL gains. The CAL gain in subjects smoking more than ten cigarettes/day was 2.1 ± 1.2 mm versus 5.2 ± 1.9 mm in non-smokers (Tonetti *et al*. 1995). Thereafter a series of investigations has confirmed that cigarette smoking displays a dose-dependent detrimental effect on CAL gains in intrabony defects (Cortellini *et al*. 1995b; Falk *et al*. 1997; Trombelli *et al*. 1997; Tonetti *et al*. 1998; Cortellini *et al*. 2001; Ehmke *et al*. 2003; Stavropoulos *et al*. 2004) and furcations (Luepke *et al*. 1997; Bowers *et al*. 2003; Machtei *et al*. 2003).

Although no formal evidence is available, it is generally suggested that smoking cessation counseling should be initiated in the context of cause-related periodontal therapy, and that patients who are unable to quit the habit should be informed of the possibility of reduced outcomes and of the need to abstain from smoking during the perioperative and early healing period.

Other patient factors

It has been suggested that other patient factors, such as age, genetics, systemic conditions or stress levels, may be associated with suboptimal regenerative outcomes. In the light of lack of evidence, however, no action is required with the exception of considering the patient characteristics that represent a contraindication to surgery (e.g. uncontrolled diabetes or unstable, severe diseases).

Clinical relevance of patient factors

The data discussed above indicate that patient factors play an important role in regenerative periodontal therapy (Fig. 45-10). Some of these factors can be modified by appropriate interventions in some patients. These interventions should be performed before periodontal regenerative therapy. Whenever modification is not possible, reduced outcomes in terms of extent and predictability should be considered.

Defect factors

Type of defect

With the currently available periodontal regenerative technologies, there is no evidence that suprabony (horizontal) defects, supracrestal components of intrabony defects or class III furcation involvements can be predictably treated with regenerative approaches. This limitation is also true for interdental craters, thus limiting the type of defects that can be treated to intrabony defects and class II furcation defects.

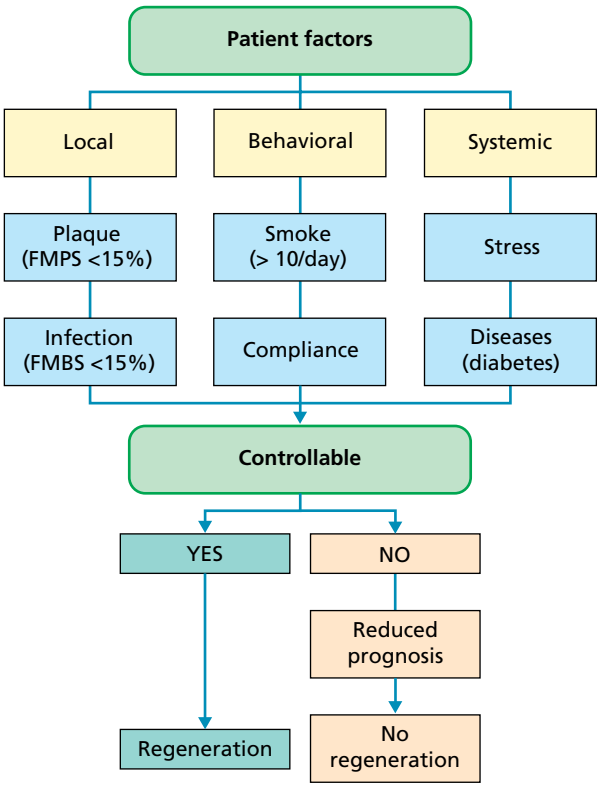

Fig. 45-10 Patient selection criteria. It can be seen that control of local, behavioral, and systemic patient characteristics may improve the treatment outcomes. (FMPS, full mouth plaque score; FMBS, full mouth bleeding score.) (Adapted from Cortellini & Bowers 1995 from Quintessence Pub. Co.)

Morphology of the defect

Defect morphology plays a major role in healing following periodontal regenerative treatment of intrabony defects. This was demonstrated in studies showing that the depth and width of the intrabony component of the defect influenced the amount of CAL and bone gained at 1 year. The deeper the defect, the greater was the amount of clinical improvements (Tonetti *et al*. 1993a, 1996a; Garrett *et al*, 1988; Ehmke *et al*. 2003; Silvestri *et al*. 2003).

In a controlled study, however, it was demonstrated that deep and shallow defects have the "same potential" for regeneration (Cortellini *et al*. 1998). Deep defects (>3 mm) resulted in larger linear CAL gain than shallow defects (3.7 ± 1.7 mm versus 2.2 ± 1.3 mm), but the percentage of CAL gain as related to the baseline defect depth was similar in deep (76.7 ± 27.7%) and in shallow (75.8 ± 45%) defects.

Another important morphologic characteristic of the defect is the *width* of the intrabony component, measured as the angle that the bony wall of the defect forms with the long axis of the tooth (Steffensen & Weber 1989). Wider defects have been associated with reduced CAL and bone gain at 1 year (Tonetti *et al*. 1993, 1996; Garrett *et al*. 1988). In a study on 242 intrabony defects treated with membranes, Cortellini & Tonetti (1999) demonstrated that defects with a radiographic angle of ≤25° gained consistently more attachment (1.6 mm on average) than defects

with an angle of ≥37°. Two follow-up studies addressed the significance of the baseline radiographic angle of the intrabony defect following the use of either EMDs (Tsitoura *et al*. 2004) or a combination of BRG with a barrier membrane (Linares *et al*. 2006). The impact of the width of the baseline radiographic angle was confirmed for the non–space-making biologic mediator, but not for the more stable combination therapy. These data are consistent with the notion that the choice of the regenerative technology may partially overcome negative morphologic characteristics of intrabony defects. An earlier secondary analysis of a controlled clinical trial using titanium-reinforced membranes (Tonetti *et al*. 1996a) indicated that the relevance of defect morphology parameters may be diminished with the use of supported membranes.

It was also shown that the number of residual bony walls was related to the outcomes of various regenerative approaches (Goldman & Cohen 1958; Schallhorn *et al*. 1970). This issue as related to GTR therapy was addressed in three investigations (Selvig *et al*. 1993; Tonetti *et al*. 1993a, 1996a). In one study, the reported 1-year mean CAL gain was 0.8 ± 0.3 mm. This gain corresponded to the depth of the three-wall intrabony component of the defect (Selvig *et al*. 1993). In contrast, in the other two investigations, CAL gain was not related to the defect configuration in terms of one-wall, two-wall, and three-wall subcomponents (Tonetti *et al*. 1993a, 1996a). A total of 70 defects were examined in these two latter studies, utilizing a multivariate approach. The treatment resulted in mean attachment gains of 4.1 ± 2.5 mm and 5.3 ± 2.2 mm, and it was observed that the most coronal portion of the defects, which is the most susceptible to negative influences from the oral environment, was often incompletely filled with bone, irrespective of whether these were one-wall, two-wall or three-wall defects.

Thus, these studies questioned the impact of the number of residual bony walls of the defect on the clinical outcomes of periodontal regeneration with membranes and suggested that location of the one-wall subcomponent (the one most likely to be the most superficial) may have acted as a confounder in other studies and be an important predictor of the outcomes. The number of walls was not significant when titanium barriers (Tonetti *et al*. 1996a) or combination therapy (Tonetti *et al.* 2004a, b) were used, but were significant when bioresorbable barriers (Falk *et al*. 1997; Silvestri *et al*. 2003) and EMDs were used (Tonetti *et al*. 2002; Silvestri *et al*. 2003). In particular, a secondary analysis of a multicenter trial showed that, in intrabony defects, the added benefit of EMDs was greater in three-wall defects compared to one-wall defects (Tonetti *et al*. 2002, 2004a).

These data also questioned the suitability of the gel formulation of EMDs for the treatment of defects with a non-supporting anatomy (wide defects with missing bony walls). More recently, however, two studies demonstrated a reduced impact of the number of residual bony walls and of defect width on the outcomes obtained with EMDs when a minimally invasive surgical technique (MIST) was used (Cortellini *et al.* 2008; Cortellini & Tonetti 2009a). This finding clearly differs from the evidence discussed above of a strong impact of the defect anatomy in terms of residual bony walls and defect width on the clinical outcomes observed in previous studies in which EMDs were used under conventional large and intrinsically less stable papilla preservation flaps (Tonetti *et al.* 2002, 2004a).

Tooth factors

The endodontic status of the tooth has been suggested as a potential relevant factor in periodontal therapy. Emerging evidence (see Chapter 41) indicates that root canal-treated teeth may respond differently to periodontal therapy. A clinical study of 208 consecutive patients with one intrabony defect each demonstrated that properly performed root canal treatment does not negatively affect the healing response and the long-term stability of deep intrabony defects treated with membranes (Cortellini & Tonetti 2000b).

Tooth mobility has long been considered an important factor for periodontal regeneration (Sanders *et al*. 1983). A multivariate analysis of a multicenter controlled clinical trial demonstrated that tooth hypermobility was negatively and dose-dependently associated with the clinical outcomes of regeneration (Cortellini *et al*. 2001). Though significant, the size of the effect was small, within the range of physiologic mobility. Another secondary analysis of three previously reported trials assessed the regenerative outcomes for hypermobile teeth (Trejo & Weltman 2004). This report indicated that teeth with baseline mobility amounting to <1 mm horizontally could be successfully treated with periodontal regeneration. Although no intervention trial has been performed to date, these results are generally considered supportive of an approach that does not base the prognosis of the tooth or the regenerative procedure on tooth mobility, but rather considers splinting hypermobile teeth before periodontal regenerative surgery.

Conclusion: Based on these results, it can be concluded that deep and narrow intrabony defects at either vital or endodontically-treated teeth are the ones in which the most significant and predictable outcomes can be achieved with GTR treatment. Number of walls and width of the defect are influential when non-supportive biomaterials are used. The influence of defect anatomy appears to be reduced to some extent when a more stable flap design is applied. Severe, uncontrolled dental hypermobility (Miller class II or higher; Miller 1943) may impair the regenerative outcomes. Significant clinical improvements can be expected only in patients with optimal plaque control, with reduced levels of periodontal contamination, and who are non-smokers.

Factors affecting the clinical outcomes in furcations

Significant evidence has demonstrated that treatment of maxillary class II furcations and maxillary and mandibular class III furcation involvements with regeneration is unpredictable, while clinical improvements can be expected for mandibular class II furcations. The great variability in clinical outcomes following treatment of mandibular class II furcations with regeneration is probably related to the factors discussed relative to intrabony defects.

Regarding tooth/defect factors, it was shown that first and second mandibular molars and buccal and lingual furcations respond equally well to GTR treatment (Pontoriero *et al*. 1988; Machtei *et al*. 1994). It was also demonstrated that the preoperative horizontal pocket depth directly correlates with the magnitude of attachment gain and bone formation in the furcation area (Machtei *et al*. 1993, 1994; Horwitz *et al*. 2004). The deeper the baseline horizontal pocket, the greater the H-CAL and bone gain. The anatomy of the furcations in terms of height, width, depth, and volume, however, did not correlate with the clinical outcome (Machtei *et al*. 1994). Horwitz *et al*. (2004) demonstrated that a long root trunk, a wide furcation entrance, and a furcation fornix coronal to the alveolar crest have negative influences on the success of therapy. Anderegg *et al*. (1995) demonstrated that sites with a gingival thickness of >1 mm exhibited less gingival recession post surgery than sites with a gingival thickness of <1 mm. Bowers *et al*. (2003) reported that increases in presurgical PAL-H were associated with monotonic decreases in the percentage of sites demonstrating complete clinical closure, with only 53% of lesions of ≥5 mm responding with complete closure. Similarly, significant reductions in the frequency of clinical closure were associated with increases in the distance between the roof of the furcation and the crest of the bone, roof of the furcation and base of the defect, and depth of the horizontal defect and the divergence of the roots. The authors concluded that the highest frequency of clinical furcation closure was observed in early class II defects. Tsao *et al*. (2006a) treated class II furcations in lower molars with either OFD alone or with additional use of bone graft or bone graft plus a collagen barrier. Among the anatomic factors, only the baseline vertical depth was found to affect the clinical outcomes in terms of vertical CAL gain. The most influential factor was the type of surgical treatment: the regenerative procedures performed better than the flap alone.

Relevance of the surgical approach

At the beginning of the 1980s, the need to modify standard periodontal surgical procedures to favor periodontal regeneration became apparent. In particular, the need to preserve soft tissues in order to attempt primary closure of the interdental space to contain grafts or coronally advanced flaps to cover furcation entrances led to the development of specific flap designs for periodontal regeneration (Takei *et al*. 1985; Gantes & Garret 1991).

In fact, graft exfoliation and membrane exposure with consequent bacterial contamination during healing represented the major complications of periodontal regenerative procedures at the time. Membrane exposure was reported to be a major complication with a prevalence of 50–100% (Becker *et al*. 1988; Cortellini *et al*. 1990; Selvig *et al*. 1992; Cortellini *et al*. 1993a; Selvig *et al*.1993; Murphy 1995a; De Sanctis *et al*. 1996a, b; Falk *et al*. 1997; Trombelli *et al*. 1997; Mayfield *et al*. 1998). Cortellini *et al*. (1995c, d) reported that the prevalence of membrane exposure could be greatly reduced with the use of access flaps specifically designed to preserve the interdental tissues (modified papilla preservation technique) (Fig. 45-11).

Many studies have shown that the exposed membranes are contaminated with bacteria (Selvig *et al*. 1990; Grevstad & Leknes 1992; Selvig *et al*. 1992; Machtei *et al*. 1993; Mombelli *et al*. 1993; Tempro & Nalbandian 1993; Nowzari & Slots 1994; Novaes *et al*. 1995; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a, b). Contamination of exposed non-bioresorbable as well as bioresorbable membranes was associated with lower PAL gains in intrabony defects (Selvig *et al*. 1992; Nowzari & Slots 1994; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a, b). The impaired clinical results in some studies were associated with high counts of bacteria and with the presence of *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans* (Machtei *et al*. 1994; Nowzari & Slots 1994; Nowzari *et al*. 1995).

Bacterial contamination of the regenerative biomaterials may occur during surgery, but also during the postoperative healing phase. Bacteria from the oral cavity may colonize the implanted biomaterials. Frequently, this results in recession of the gingival tissues, which allows colonization of the material further apically. The significance of bacterial contamination was addressed in an investigation in monkeys (Sander & Karring 1995). The findings of this study showed that new attachment and bone formation occurred consistently when bacteria were prevented from invading the membrane and the wound during healing.

In order to prevent wound infection, some investigators have administered systemic antibiotics to patients before and during the first weeks after membrane application (Demolon *et al*. 1993; Nowzari & Slots 1994). However, despite the application of systemic antibiotics, postoperative wound infection related to implanted barrier membranes was noted. This indicates that either the drug administered is not directed against the microorganisms responsible for the wound infection, or that the drug does not reach the infected site at a concentration sufficiently high enough to inhibit the target microorganisms. An

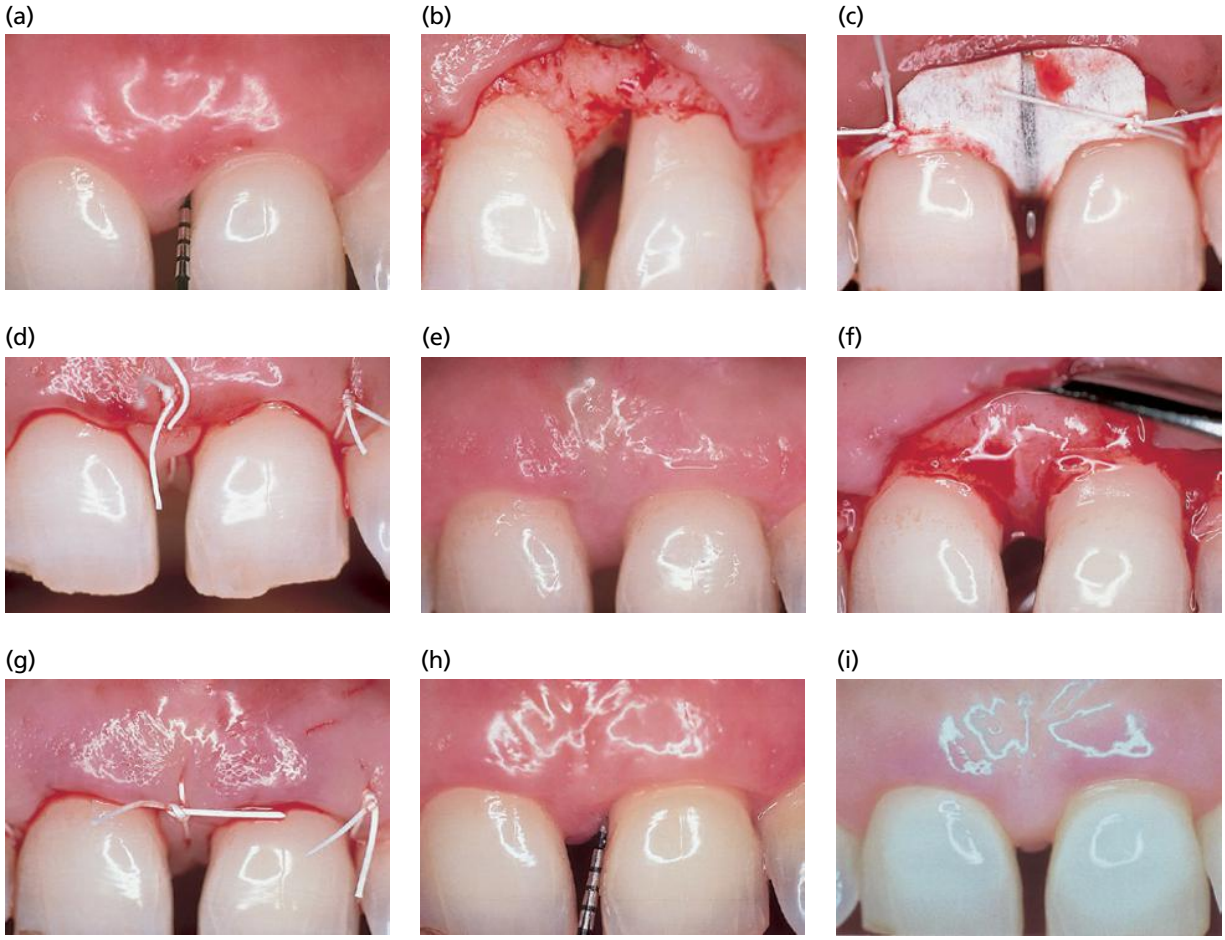

Fig. 45-11 (a) Left maxillary central incisor with a 10-mm pocket depth and 11 mm of clinical attachment loss on the mesial surface. A diastema is present between the two central incisors. (b) Full thickness buccal and palatal flaps have been raised and an intrabony defect can be seen. The interdental papilla has been incised on the buccal aspect and elevated with the palatal flap (modified papilla preservation technique). (c) Titanium-reinforced e-PTFE barrier membrane has been placed and fixed close to the level of the cemento-enamel junction. (d) Membrane is completely covered. This primary closure has been obtained by preserving the interdental papilla and by coronal displacement of the buccal tissue flap. (e) At 6 weeks, the membrane is completely covered with healthy tissue. (f) After membrane removal at 6 weeks, dense newly formed tissue is evident in the defect and in the supracrestal space maintained by the titanium-reinforced membrane. (g) Newly formed tissue is completely covered by the raised and well-preserved tissue flaps. (h) Clinical photograph after 1 year showed a 4-mm residual pocket depth. A gain of clinical attachment of 6 mm was recorded, and no recession had occurred compared to baseline. (i) Ten-year clinical photograph showing the optimal preservation of the interdental tissues.

improved effect on periodontal healing after GTR in association with local application of metronidazole was reported by Sander *et al*. (1994). Twelve patients each with two similar intrabony defects participated in this intraindividual study. Metronidazole in a gel form was placed in the test defects and on the membrane prior to wound closure, while the control defects were treated with a membrane alone. Six months following membrane removal the medium gain in PAL, presented as a percentage of the initial defect depth, was 92% for the test defects versus 50% for the control defects. Other clinical parameters, like plaque index, BoP, PPD reduction, and recession of the gingival margin, were similar in the test and control sites. Although local or systemic antibiotics may reduce the bacterial load on exposed membranes, they seem ineffective in preventing the formation of a microbial biofilm (Frandsen *et al*. 1994; Nowzari *et al*. 1995). In addition to the erythema and swelling related to such infection of the wound, more severe postoperative complications such as suppuration, sloughing or perforation of the flap, membrane exfoliation, and postoperative pain have been reported (Murphy 1995a, b).

Another important issue associated with the clinical results is the coverage of the regenerated tissue after removal of a non-bioresorbable membrane. Many authors have reported that the frequent occurrence of a gingival dehiscence over the membrane is likely to result in insufficient protection of the interdental regenerated tissue (Becker *et al*. 1988; Selvig *et al*. 1992; Cortellini *et al*. 1993a; Tonetti *et al*. 1993a). Exposure of the regenerated tissue to the oral environment introduces the risk of mechanical and infectious insults that in turn may prevent complete maturation of the regenerated tissue into a new connective tissue attachment. In fact, incomplete coverage of the regenerated tissue was associated

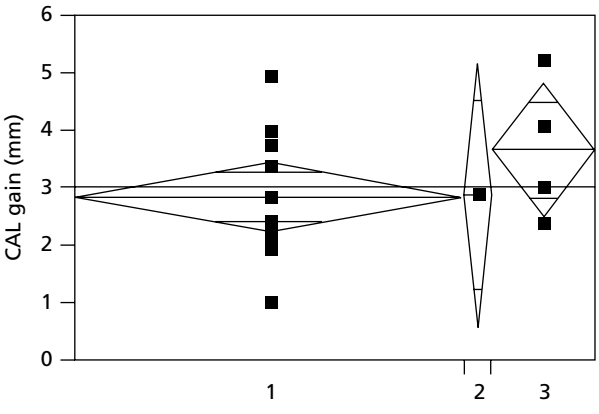
Fig. 45-12 Clinical case illustrating the management of the most common complication following application of a non-bioresorbable barrier membrane: membrane exposure and consequent loss of interdental soft tissue. Upon completion of cause-related periodontal therapy, regenerative periodontal surgery was performed to resolve a deep pocket associated with a deep intrabony defect (a, b). The 7-mm intrabony defect was accessed with a modified papilla preservation flap (c) and a non-bioresorbable barrier membrane was placed (d). Primary closure with multilayered sutures was obtained, but 5 weeks after surgery, the membrane became exposed to the oral cavity (e). Upon membrane removal (f), a newly regenerated tissue completely filled the space below the membrane, but inadequate soft tissue was available to completely cover the regenerated tissue in the interdental space. In order to protect the maturation of this tissue, a saddle-shaped interdental free gingival graft was harvested from the palate and shaped to precisely fit the interdental area (g). The graft healed well on the highly vascularized recipient bed and allowed good healing of the interdental tissues. Nine years after completion of therapy, the clinical and radiographic outcomes show healing with shallow probing depths and elimination of the defect (h, i).

with reduced attachment and bone gain at 1 year (Tonetti *et al*. 1993a). The positioning of a saddle-shaped free gingival graft over the regenerated interdental tissue (Fig. 45-12) was suggested to offer better coverage and protection than a dehiscent gingival flap (Cortellini *et al*. 1995a). In this randomized controlled study (Cortellini *et al*. 1995a) more gain of attachment was observed in the 14 sites where a free gingival graft was positioned after membrane removal (5.0 ± 2.1 mm), than in the 14 sites where conventional protection of the regenerated tissue was accomplished (3.7 ± 2.1 mm).

The systematic assessment of the relevant factors associated with variability of periodontal regenerative outcomes performed at the beginning of the 1990s (Tonetti *et al*. 1993a; Machtei *et al*. 1994; Tonetti *et al*. 1995, 1996a; Falk *et al*. 1997) provided further evidence that surgical factors had a great impact on regeneration and led the way to the development of procedures specifically designed for periodontal regeneration. In general, the development of new procedures was aimed at complete tissue preservation in order to achieve and maintain primary closure on top of the applied regenerative material during the critical stages of healing and to save space for blood clot formation and maturation. Specifically, flap designs attempted to achieve passive primary closure of the flap combined with optimal wound stability. In fact, basic and clinical research indicate that, among many, absolute requirements for

regeneration include the presence of space for the formation of the blood clot at the interface between the flap and root surface (Haney *et al*. 1993; Sigurdsson *et al*. 1994, Cortellini *et al*. 1995b, c; Tonetti *et al*. 1996a; Wikesjo *et al*. 2003; Kim *et al*. 2004), the stability of the blood clot to maintain a continuity with the root surface and thereby prevent the formation of a long junctional epithelium (Linghorne & O'Connel 1950; Hiatt *et al*. 1968; Wikesjo & Nilveus 1990; Haney *et al*. 1993), and protection of the soft tissue of the treated area to avoid bacterial contamination (Selvig *et al*. 1992; Nowzari & Slots 1994; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a, b; Sanz *et al*. 2004).

Development of periodontal regenerative medicine in the last 25 years has followed two distinct, though totally interlaced, paths. The interest of researchers has so far focused on regenerative materials and products on the one hand and on novel surgical approaches on the other hand.



Ranks	Number of studies	Mean (mm)
1	15	2.84
2	1	2.90

Surgical approach to intrabony defects

Papilla preservation flaps

The modified papilla preservation technique (MPPT) was developed in order to increase the space for regeneration and to achieve and maintain primary closure of the flap in the interdental area (Cortellini *et al*. 1995c, d). This approach combines special soft tissue management with the use of a self-supporting titanium-reinforced membrane capable of maintaining a supra-alveolar space for regeneration. The MPPT allows primary closure of the interdental space, resulting in better protection of the membrane from the oral environment (Cortellini *et al*. 1995d). The technique involves the elevation of a full-thickness palatal flap which includes the entire interdental papilla. The buccal flap is mobilized with vertical and periosteal incisions, coronally positioned to cover the membrane, and sutured to the palatal flap through a horizontal internal crossed mattress suture over the membrane. Primary closure between the flap and the interdental papilla is obtained with a second internal mattress suture. Representative cases are shown in Figs. 45-4 and 45-11.

In a randomized controlled clinical study of 45 patients (Cortellini *et al*. 1995c), significantly greater attachment gain were obtained with the MPPT (5.3 ± 2.2 mm) in comparison with either conventional GTR (4.1 ± 1.9 mm) or flap surgery (2.5 ± 0.8 mm), demonstrating that a modified surgical approach can result in improved clinical outcomes. In this study, 100% of the sites were closed on top of a titanium-reinforced membrane and 73% remained closed for up to 6 weeks, when the barrier membrane was removed. This study provided proof of principle of the benefit of specific flap designs for periodontal regeneration. The MPPT has been successfully applied in multicenter randomized clinical trials designed to test the generalizability of the added benefits of regenerative approaches in deep intrabony defects (Tonetti *et al*. 1998; Cortellini *et al*. 2001; Tonetti *et al*. 2002, 2004b).

A meta-analysis (Murphy & Gunsolley 2003) showed the existence of a trend associating better clinical outcomes with flap designs and closing techniques considered conducive to the achievement and maintenance of primary closure of the flap (Figs. 45-13, 45-14). A similar trend was observed by Graziani *et al*. (2011) in their meta-analysis of flap surgery studies, where papilla preservation flaps performed better than conventional flap surgery.

The reported MPPT can be successfully applied in sites where the interdental space width is at least 2 mm at the most coronal portion of the papilla. When interdental sites are narrower, the reported technique is difficult to apply. In order to overcome this problem, a different papilla preservation procedure [the simplified papilla preservation flap (SPPF)] has been proposed for narrow interdental spaces (Cortellini *et al*. 1999a). This approach includes an oblique incision across the defect-associated papilla, starting from the buccal angle of the defect-associated tooth and continuing to the mid-interdental part of the papilla at the adjacent tooth under the contact point. In this way, the papilla is cut into two equal parts of which the buccal part is elevated with the buccal flap and the lingual part with the lingual flap. In the cited study, 100% of the narrow interdental papillae could be closed on top of bioresorbable barriers, and 67% maintained primary closure over time, resulting in 4.9 ± 1.8 mm of CAL gain. This approach has been successfully applied in different multicenter randomized clinical trials designed to test the generalizability of the added benefits of using barrier

membranes on deep intrabony defects (Tonetti *et al*. 1998, 2002, 2004b; Cortellini *et al*. 2001).

In the cited studies, GTR therapy of deep intrabony defects performed by different clinicians on various patient populations resulted in both greater amounts and improved predictability of CAL gain than access flap alone. The issue of soft tissue manipulation to obtain stable protection of the regeneration site has been further explored by applying a microsurgical approach in the regenerative therapy of deep intrabony defects (Fig. 45-15). In a patient cohort study of 26 patients with 26 intrabony defects treated with papilla preservation techniques, primary closure on the barrier was obtained in 100% of the cases and maintained over time in 92.3% of the sites (Cortellini & Tonetti 2001). Treatment resulted in large CAL gain (5.4 ± 1.2 mm) and minimal gingival recession (0.4 ± 0.7 mm). Thus, the improved vision and better soft tissue handling improved the predictability of periodontal regeneration.

Today, the use of papilla preservation flap designs and closure techniques has become the standard approach for regenerative periodontal surgery.

Modified papilla preservation technique

The rationale for developing this technique was to achieve and maintain primary closure of the flap in the interdental space over the membrane (Cortellini *et al*. 1995d) (Figs. 45-16, 45-17, 45-18). Access to the interdental defect is achieved with a horizontal incision traced in the buccal keratinized gingiva at the base of the papilla and connected to mesiodistal buccal intrasulcular incisions. After elevation of a full-thickness buccal flap, the residual interdental tissues are dissected from the neighboring teeth and the underlying bone, and elevated towards the palatal aspect. A full-thickness palatal flap, including the interdental papilla, is elevated and the interdental defect exposed. Following debridement of the defect, the buccal flap is mobilized with vertical and periosteal incisions, when needed.

This technique was originally designed for use in combination with self-supporting barrier membranes. In fact, the suturing technique requires a supportive (or supported) membrane to be effective (Figs. 45-16, 45-17). To obtain primary closure of the interdental space over the membrane, a first suture (horizontal internal crossed mattress suture) is placed beneath the mucoperiosteal flaps between the base of the palatal papilla and the buccal flap. The interdental portion of this suture hangs on top of the membrane, allowing the coronal displacement of the buccal flap. This suture relieves all the tension in the flaps. To ensure primary passive closure of the interdental tissues over the membrane, a second suture (vertical internal mattress suture) is placed between the buccal aspect of the interdental papilla (i.e. the most coronal portion of the palatal flap, which includes the interdental papilla) and the most coronal portion of the buccal flap. This suture is free of tension.

An alternative type of suture to close the interdental tissues has been proposed by Dr Lars Laurell. This modified internal mattress suture starts from the external surface of the buccal flap, crosses the interdental area, and runs through the lingual flap at the base of the papilla. The suture runs back through the external surface of the lingual flap and the internal surface of the buccal flap, about 3 mm distant from the first two bites. Finally, the suture is passed through the interdental area above the papillary tissues, passed through the loop of the suture on the lingual side, and brought back to the buccal side, where it is tied. This suture is very effective in ensuring stability and primary closure of the interdental tissues.

In a randomized controlled clinical study of 45 patients (Cortellini *et al*. 1995c), significantly greater

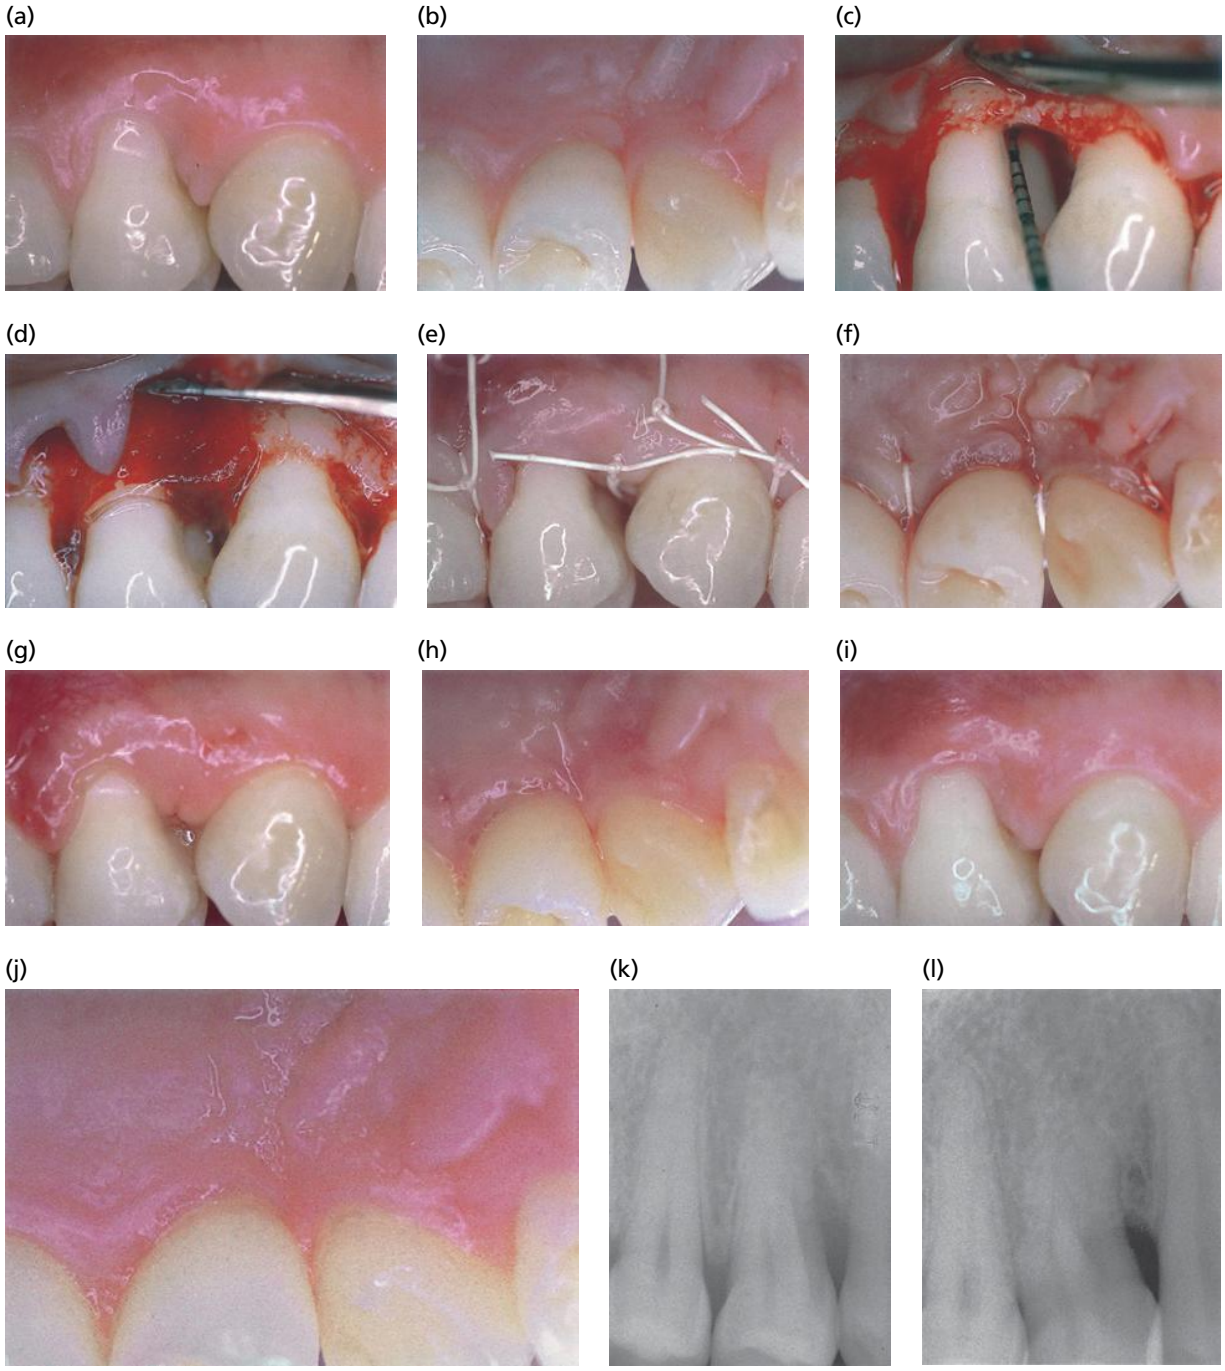

Fig. 45-15 (a) Right first maxillary premolar with a 7-mm pocket on the mesial surface. The interdental space (b) is very narrow (>2 mm), and is accessed with a simplified papilla preservation flap using a microsurgical approach (operative microscope and microsurgical instruments). The 5-mm deep intrabony defect (c) is covered with a bioresorbable barrier membrane (d). Primary closure of the flap over the membrane (e, f) is maintained over time (g, h). After 1 year, the interdental papilla is completely preserved and the residual pocket depth is 3 mm (i, j). The radiograph taken at baseline (k) compared with that taken 1 year after treatment (l) shows that the intrabony defect has healed completely.

PAL was gained with the MPPT (5.3 ± 2.2 mm) in comparison with either conventional GTR (4.1 ± 1.9 mm) or access flap surgery (2.5 ± 0.8 mm), demonstrating that a modified surgical approach can result in improved clinical outcomes. The sites accessed with the MPPT showed primary closure of the flap in all but one case, and no gingival dehiscence until membrane removal in 73% of the cases.

This surgical approach has also been used in combination with non-supported bioresorbable barrier membranes (Cortellini *et al*. 1996c), with positive results. Clinical attachment level gains at 1 year were 4.5 ± 1.2 mm. In all the cases, primary closure of the flap was achieved and about 80% of the sites maintained primary closure over time (Fig. 45-19). It should be underlined, however, that the horizontal internal crossed mattress suture most probably caused an apical displacement of the interdental portion of the membrane, thereby reducing the space for regeneration.

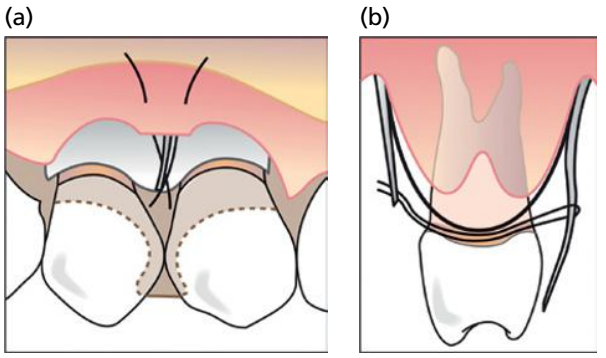

Fig. 45-16 Suture to obtain coronal positioning of the buccal flap: schematic illustration of the crossed horizontal internal mattress suture between the base of the palatal papilla and the buccal flap immediately coronal to the mucogingival junction. Note that the suture crosses above the titanium reinforcement of the membrane. (a) Buccal view; (b) mesiodistal view. (Source: Cortellini *et al*. 1995d. Fig. 45-18 Clinical case illustrating the modified papilla preservation technique (MPPT) used to completely close the interdental space above a barrier membrane. Following completion of initial cause-related therapy, an 8-mm pocket associated with 2 mm of recession of the gingival margin was present on the distal aspect of the central incisor (a). A wide intrabony defect was detectable on the radiograph (b). Defect was accessed with the MPPT, keeping the whole interdental tissue connected with the palatal flap. A 7-mm intrabony defect was uncovered (c). Following root debridement, a titanium-reinforced barrier membrane was positioned (d). Primary closure of the interdental space was obtained by suturing back the papilla preservation flap using a multilayered suturing technique aimed at coronal advancement of the flap, complete relief of wound tension, and good flap stability (e). Six weeks thereafter, the same flap was elevated in order to remove the membrane that had remained completely submerged for the whole time. New tissue filled the space maintained beneath the membrane (f). Following completion of healing (1 year), a 3-mm probing depth and fill of the intrabony defect were observed. The results were maintained over time as indicated by the clinical and radiographic appearance 6 years after regeneration (g, h).

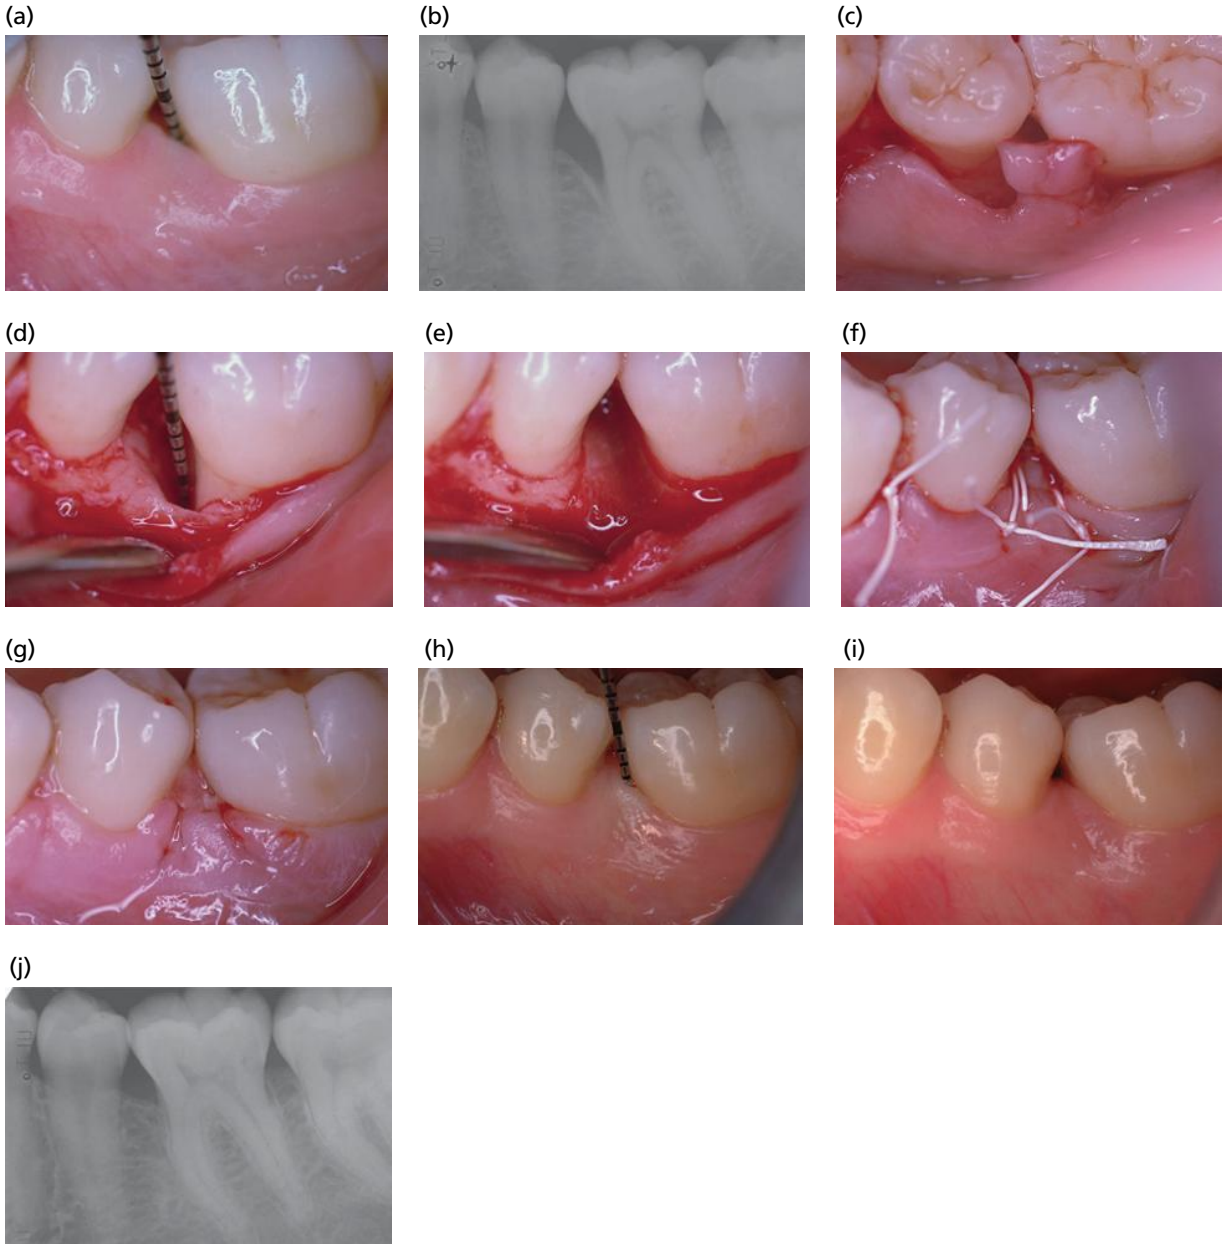

Fig. 45-19 Clinical case illustrating the application of the modified papilla preservation technique (MPPT) to a case treated with a bioresorbable barrier membrane. An 8-mm pocket associated with an intrabony defect persisted on the mesial aspect of the lower first molar following completion of initial cause-related therapy (a, b). The defect was accessed with the MMPT. Note the papilla preserved attached to the lingual flap (c) as well as the presence of a 7-mm intrabony defect (d). Following root debridement, a bioresorbable barrier membrane was positioned and secured around the root of the tooth with bioresorbable sutures (e). Primary closure of the interdental space was obtained with multilayered sutures (f) and was fully maintained at the 1-week suture removal appointment (g). At 6 years, probing depths were 2–3 mm, the soft tissue profile was conducive to optimal self-performed oral hygiene measures, and the radiograph showed elimination of the defect (h–j).

The MPPT can be successfully applied in conjunction with a variety of regenerative materials, including biologically active materials such as EMDs (Tonetti *et al*. 2002) (Fig. 45-20) or growth factors and BRGs (Fig. 45-21) (Tonetti *et al*. 2004b; Cortellini & Tonetti 2005).

The surgical access of the interdental space with the MPPT is technically very demanding, but it has been reported to be very effective and applicable to wide interdental spaces (>2 mm at the interdental tissue level), especially in the anterior dentition. In properly selected cases, large attachment gain and consistent reduction of PPD associated with no or minimal recession of the interdental papilla can be consistently expected. It is, therefore, indicated in cases in whom esthetics are particularly important.

Simplified papilla preservation flap

To overcome some of the technical problems encountered with the MPPT (difficult application in narrow interdental spaces and in posterior areas, suturing technique not appropriate for use with

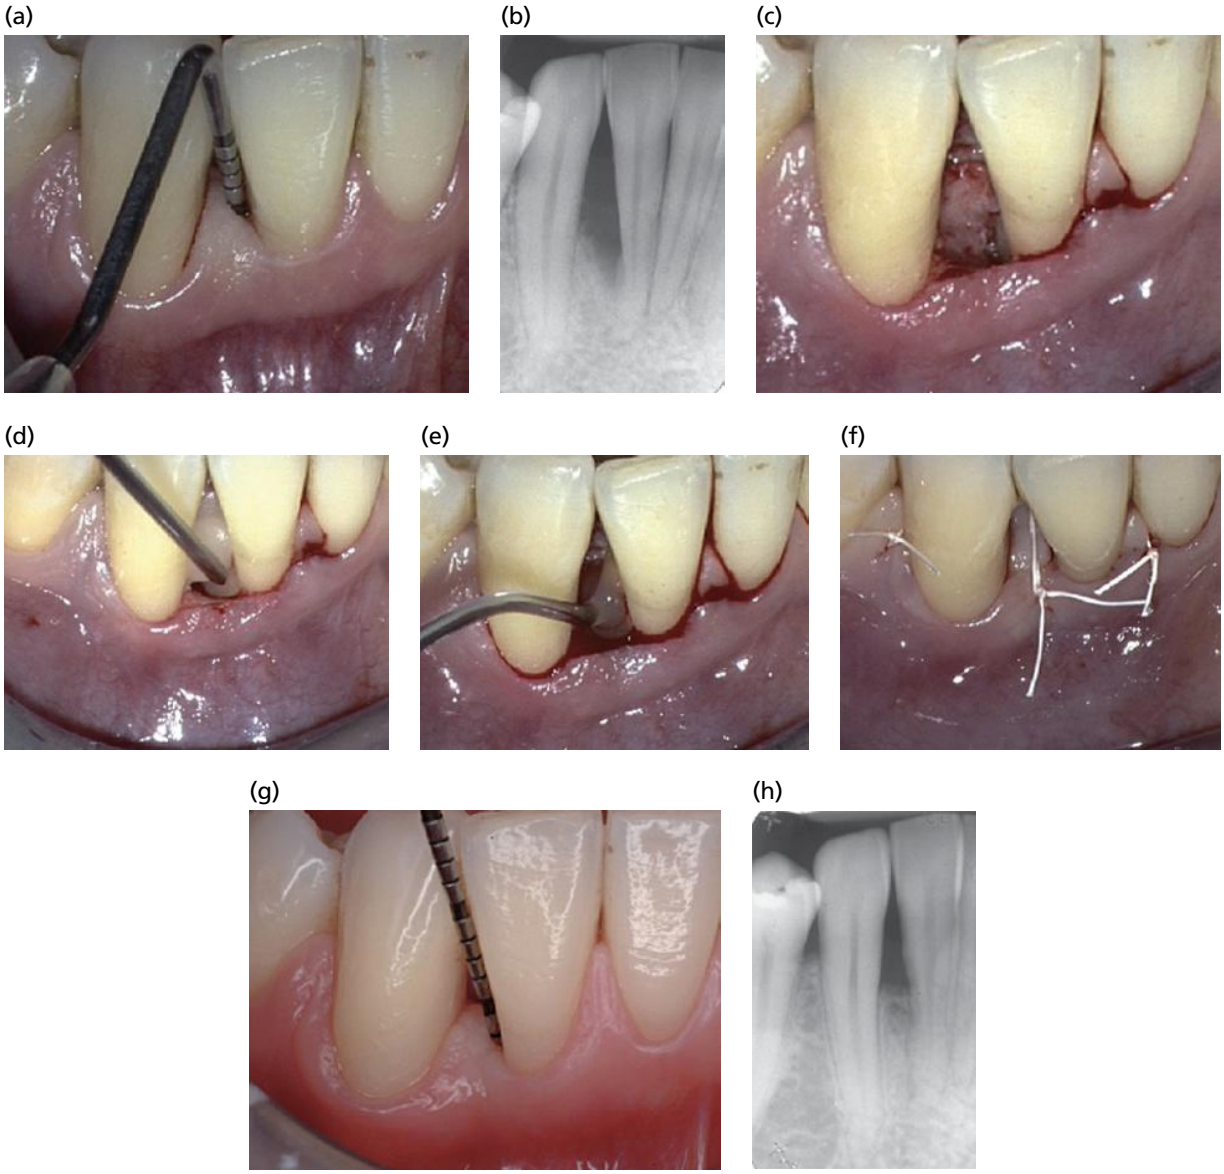

Fig. 45-20 Clinical case illustrating the application of the modified papilla preservation technique (MPPT) in conjunction with the application of enamel matrix derivatives (EMDs). A 10-mm pocket was detectable on the distal aspect of the lower lateral incisor following successful completion of initial cause-related therapy (a). The radiograph showed the presence of a deep intrabony defect extending to the apical third of the root (b). The defect was accessed with the MPPT (c) with limited mesial and distal extension of the flap. Following careful debridement, the root was conditioned with an EDTA gel according to the manufacturer's instructions for the application of EMDs (d). After rinsing and drying of the defect and root surface, the EMD gel was applied to the root surface and to fill the defect (e), and flaps were sutured with a multilayer technique to achieve primary closure in the absence of tension (f). One year following regenerative surgery, shallow pockets and radiographic resolution of the defect were apparent (g, h).

non-supportive barriers), a different approach, the simplified papilla preservation flap (SPPF) (Figs. 45-15, 45-22) was subsequently developed (Cortellini *et al*. 1999a).

This simplified approach to the interdental papilla includes a first incision across the defect-associated papilla, starting from the gingival margin at the buccal-line angle of the involved tooth and extending to the mid-interdental portion of the papilla under the contact point of the adjacent tooth. This oblique incision is carried out by keeping the blade parallel to the long axis of the teeth in order to avoid excessive thinning of the remaining interdental tissues. The first oblique interdental incision is continued intrasulcularly in the buccal aspect of the teeth neighboring the defect. After elevation of a full-thickness buccal flap, the remaining tissues of the papilla are carefully dissected from the neighboring teeth and the underlying bone crest. The interdental papillary tissues at the defect site are gently elevated along with the lingual/palatal flap to fully expose the interdental defect. Following defect debridement and root planing, vertical releasing incisions and/or periosteal incisions are performed, when needed, to improve the mobility of the buccal flap. After application of a barrier membrane, primary closure of the interdental

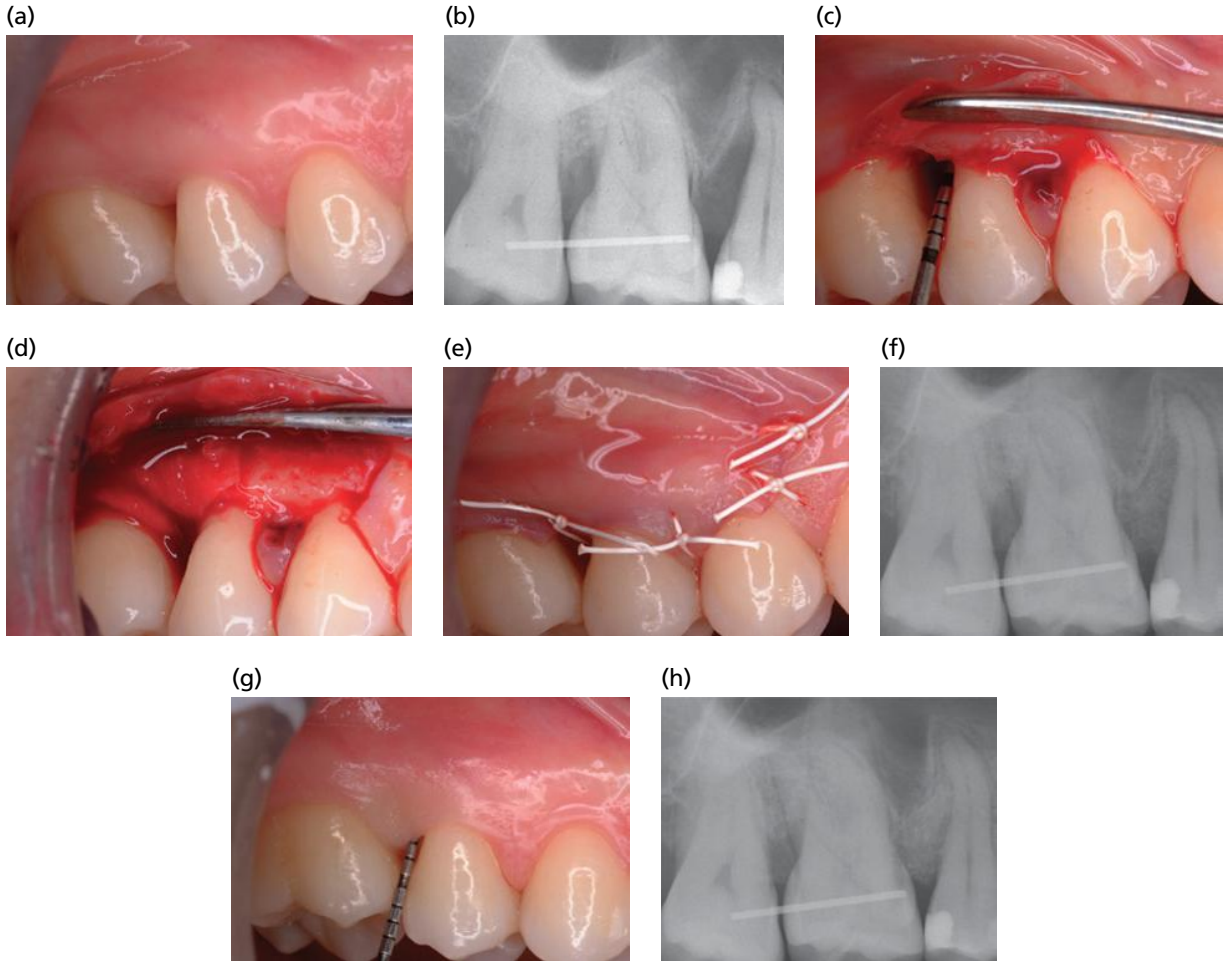

Fig. 45-21 Clinical case illustrating the application of the modified papilla preservation technique (MPPT) in conjunction with a bone replacement graft (BRG) in combination with a bioresorbable membrane. After completion of initial cause-related therapy, a 9-mm pocket associated with an intrabony defect was present on the distal aspect of the upper second premolar (a, b). The defect reached the apical portion of the root and had a 9-mm intrabony component (c). Following careful root debridement, a bioresorbable membrane was adapted to the local anatomy and was positioned to contain the defect. A BRG was subsequently inserted under the membrane to provide additional support for the membrane and for the soft tissues (d). Primary closure was achieved with a single internal mattress suture (e). The control radiograph taken upon completion of the surgery showed the presence of the radio-opaque BRG in the defect (f). At 1-year follow-up, a 3-mm probing depth associated with resolution of the intrabony component of the defect was apparent (g, h). Note that the radio-opaque BRG particles are still detectable but appear embedded in newly formed mineralized tissue.

tissues above the membrane is attempted in the absence of tension, with the following sutures:

1. A first horizontal internal mattress suture (offset mattress suture) is positioned in the defect-associated interdental space running from the base (near to the mucogingival junction) of the keratinized tissue at the mid-buccal aspect of the tooth not involved with the defect to a symmetrical location at the base of the lingual/palatal flap. This suture rubs against the interdental root surface, hangs on the residual interdental bone crest, and is anchored to the lingual/palatal flap. When tied, it allows the coronal positioning of the buccal flap. Importantly, this suture, lying on the interdental bone crest, does not cause any compression at the mid-portion of the membrane, therefore preventing its collapse into the defect.
2. The interdental tissues above the membrane are then sutured to obtain primary closure with one of the following approaches: one interrupted suture whenever the interdental space is narrow and the interdental tissues thin; two interrupted sutures when the interdental space is wider and the interdental tissues thicker; an internal vertical/oblique mattress suture when the interdental space is wide and the interdental tissues are thick.

Special care has to be paid to ensure that the first horizontal mattress suture relieves all the tension in the flaps, and to obtain primary passive closure of the interdental tissues over the membrane with the second suture. When tension is observed, the sutures should be removed and the primary passive closure attempted again.

This approach has been preliminarily tested in combination with bioresorbable barrier membranes in a case series of 18 deep intrabony defects (Cortellini *et al*. 1999a). The average CAL gain observed at 1 year was 4.9 ± 1.8 mm. In all the cases it was possible to

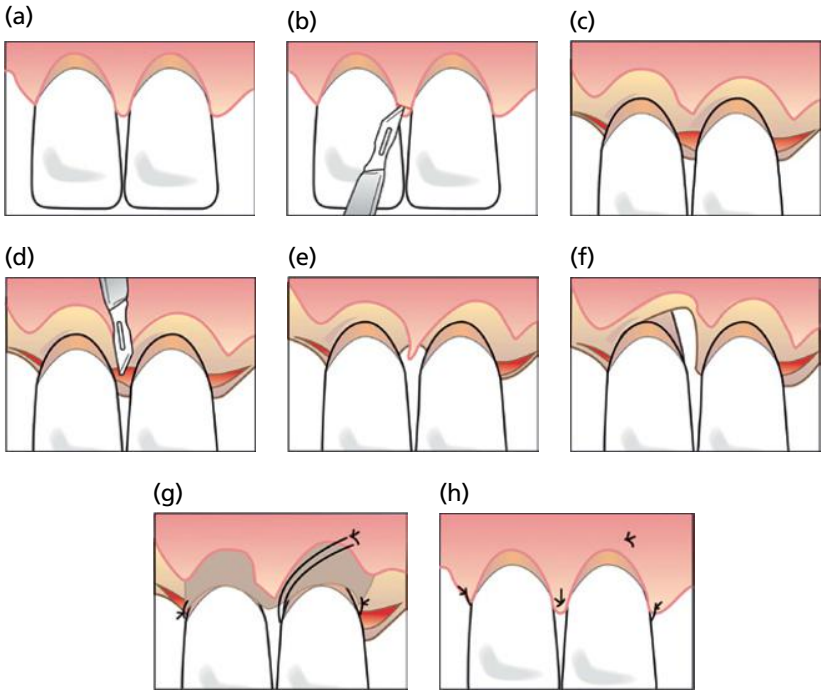

Fig. 45-22 (a) Presurgical appearance of the area to be accessed with a simplified papilla preservation flap (SPPF). The defect is located on the mesial aspect of the maxillary right lateral incisor. (b) First oblique incision in the defect-associated papilla begins at the gingival margin of the mesiobuccal line angle of the lateral incisor. The blade is kept parallel to the long axis of the tooth and reaches the mid-point of the distal surface of the central incisor just below the contact point. (c) First oblique incision continues intrasulcularly in the buccal aspect of the lateral and central incisors, extending to the adjacent papillae, and a buccal full-thickness flap is elevated to expose 2–3 mm of bone. Note the defect-associated papilla is still in place. (d) Buccolingual horizontal incision at the base of the papilla is as close as possible to the interproximal bone crest. Care is taken to avoid a lingual/palatal perforation. (e) Intrasulcular interdental incisions continue in the palatal aspect of the incisors to the adjacent partially dissected papillae. A full-thickness palatal flap including the interdental papilla is elevated. (f) Intrabony defect following debridement. Note the position of the bone crest on the distal aspect of the central incisor. (g) Membrane is positioned to cover the defect and 2–3 mm of remaining bone and secured to neighboring teeth. A horizontal internal mattress suture runs from the base of the keratinized tissue at the mid-buccal side of the central incisor to a symmetric location at the base of the palatal flap. This suture causes no direct compression of the mid-portion of the membrane, preventing its collapse into the defect. (h) Primary closure and complete coverage of the membrane are obtained. (Source: Cortellini *et al*. 1999a. Reproduced with permission from Quintessence Pub. Co.)

obtain primary closure of the flap over the membrane, and 67% of the sites maintained primary closure over time. This approach was tested in a multicenter controlled randomized clinical trial involving 11 clinicians from seven different countries and a total of 136 defects (Tonetti *et al*. 1998). The average CAL gain observed at 1 year in the 69 defects treated with the SPPF and a bioresorbable barrier membrane was 3 ± 1.6 mm. More than 60% of the treated sites maintained primary closure over time. It is important to underline that these results were obtained by different clinicians treating different populations of patients and defects, including those with narrow spaces and involving the posterior areas of the mouth. The SPPF was successfully applied in conjunction with a variety of regenerative materials, including biologically active materials such as EMDs (Tonetti *et al*. 2002) (Fig. 45-23) and BRG (Fig. 45-24) (Cortellini & Tonetti 2004; Tonetti *et al*. 2004b).

Minimally invasive surgical technique

More recently there has been a growing interest in a friendlier, patient-oriented surgery and clinical investigators have focused their interest on the development of less invasive approaches. Harrel and Rees (1995) proposed the minimally invasive surgery (MIS) approach with the aim of producing minimal wounds, minimal flap reflection, and gentle handling of the soft and hard tissues (Harrel & Nunn 2001; Harrel *et al*. 2005). In order to provide even greater wound stability and to further limit patient morbidity, a papilla preservation flap can be used in the context of a minimally invasive, high-power magnification-assisted surgical technique (Cortellini & Tonetti 2007a). Such a minimally invasive approach is particularly suited for treatment in conjunction with biologically active agents such as EMDs or growth factors and/or grafting materials.

The defect-associated interdental papilla is accessed either with the SPPF (Cortellini *et al*. 1999a) or the MPPT (Cortellini *et al*. 1995d). The SPPF is performed whenever the width of the interdental space is 2 mm or narrower, while the MPPT is applied at interdental sites wider than 2 mm. The interdental incision (SPPF or MPPT) is extended to the buccal and lingual aspects of the two teeth adjacent to the defect. These incisions are strictly intrasulcular to preserve all the height and width of the gingiva, and their mesiodistal extension is kept to a

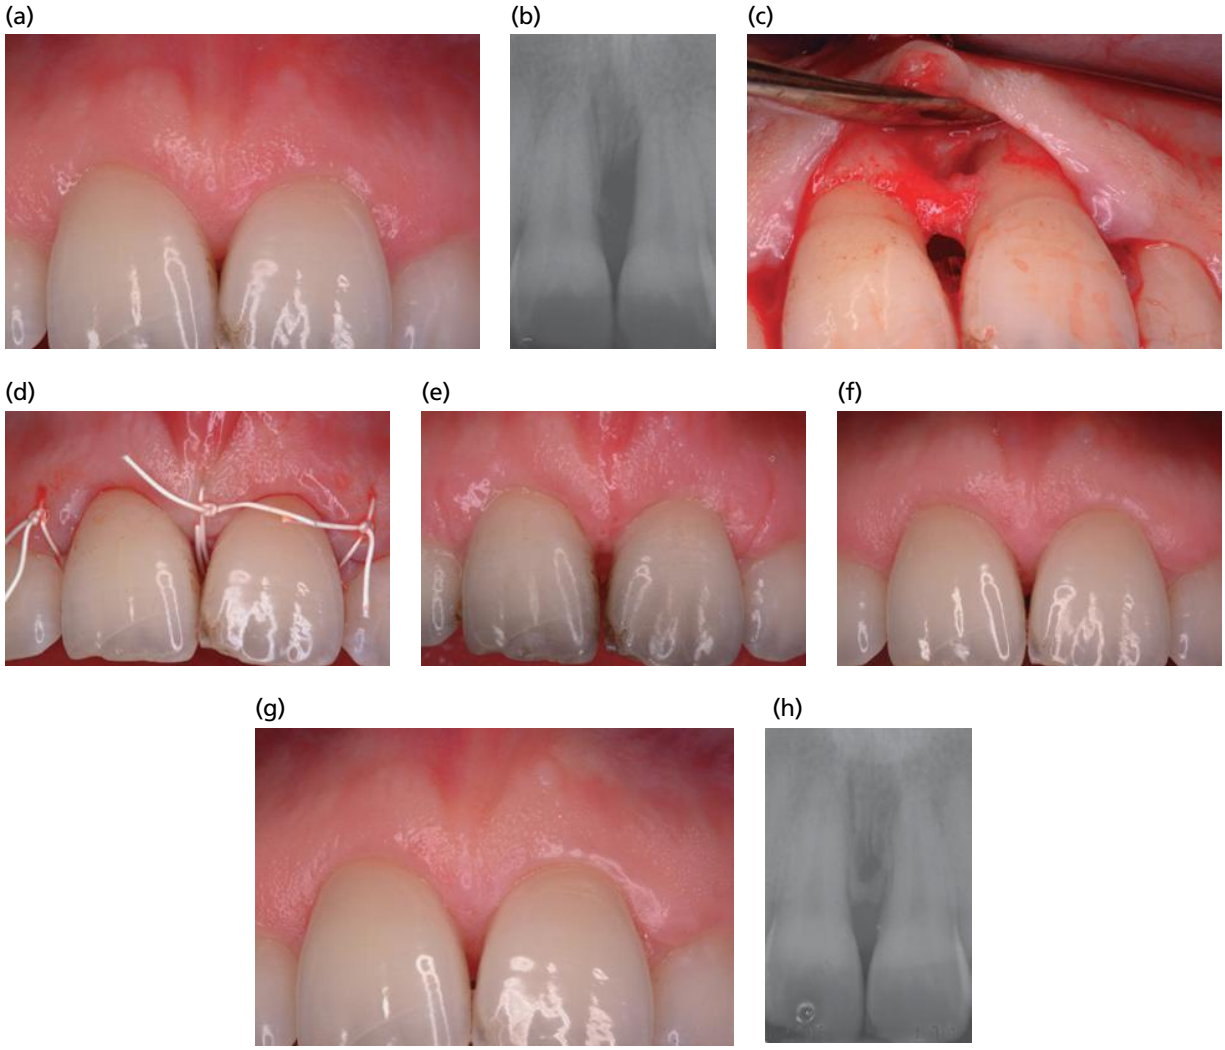

Fig. 45-23 Clinical case illustrating the clinical application of the simplified papilla preservation flap (SFFP) in conjunction with the application of a biologically active regenerative material [enamel matrix derivatives (EMDs) in gel form]. At re-evaluation following completion of successful initial cause-related therapy, an 8-mm pocket was detected on the mesial palatal aspect of the left central incisor (a). An angular defect was evidenced on a periapical radiograph (b). The complex anatomy of the defect was apparent following access to the defect with the modified papilla preservation technique (MPPT): a buccal fenestration was apparent with the majority of the defect extending palatally to the apical third of the root (c). Following application of the EMDs, primary closure of the flap was achieved with a multilayered suture (d). At the 1-week suture removal appointment, excellent maturation of the soft tissue healing was apparent (e). At 6 months, a well-represented interdental papilla was present thanks to both the papilla preservation approach and the presence of a bony bridge that assisted in soft tissue support, in spite of the gel formulation of the EMDs (f). Clinical and radiographic outcomes at 1 year showed preservation of excellent esthetics and elimination of the defect (g, h). Probing depths were in the 2–3-mm range.

minimum to allow the coronoapical elevation of a very small full-thickness flap with the objective of exposing just 1–2 mm of the defect-associated residual bone crest. When possible, only the defect-associated papilla is accessed and vertical releasing incisions are avoided. With these general rules in mind, different clinical pictures can be encountered in different defects.

The shortest mesiodistal extension of the incision and the minimal flap reflection occurs when the intrabony defect is a pure three-wall, or has shallow two- and/or one-wall subcomponents allocated entirely in the interdental area. In these instances, the mesiodistal incision involves only the defect-associated papilla and part of the buccal and lingual aspects of the two teeth neighboring the defect. The full-thickness flap is elevated minimally, just enough to expose the buccal and lingual bone crest delineating the defect in the interdental area (Fig. 45-25).

A larger coronoapical elevation of the full-thickness flap is necessary when the coronal portion of the intrabony defect has a deep two-wall component. The coronoapical extension of the flap is kept to a minimum at the aspect where the bony wall is preserved (either buccally or lingually), and extends more apically at the site where the bony wall is missing (lingually or buccally), the objective being to reach and expose 1–2 mm of the residual bone crest (Fig. 45-26).

When a deep one-wall defect is approached, the full-thickness flap is elevated to the same extent on both the buccal and the lingual aspects.

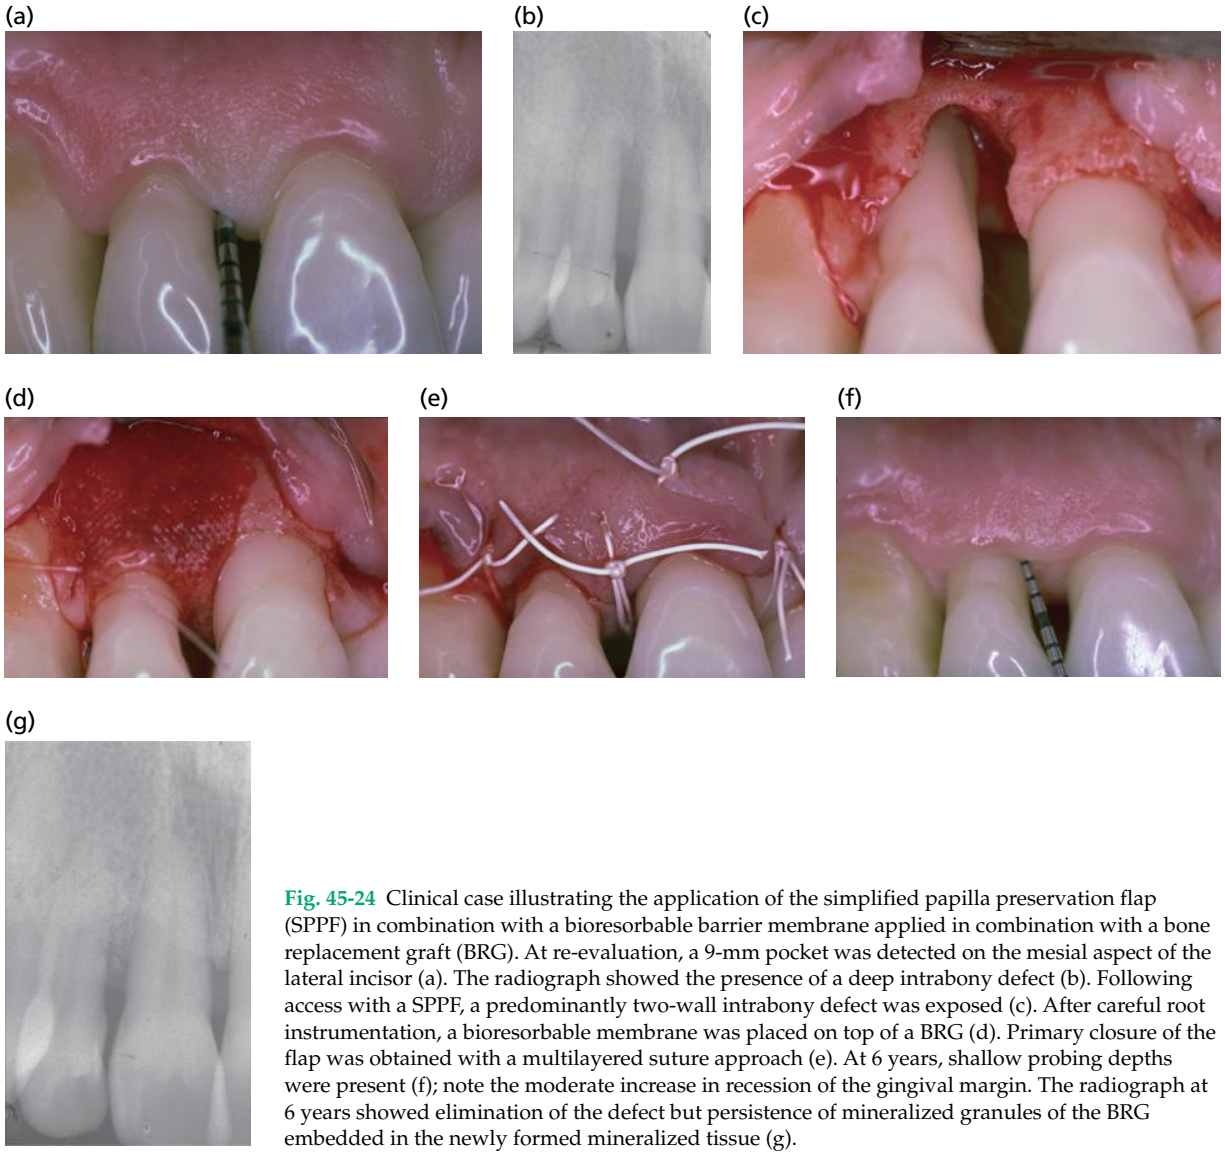

Fig. 45-24 Clinical case illustrating the application of the simplified papilla preservation flap (SPPF) in combination with a bioresorbable barrier membrane applied in combination with a bone replacement graft (BRG). At re-evaluation, a 9-mm pocket was detected on the mesial aspect of the lateral incisor (a). The radiograph showed the presence of a deep intrabony defect (b). Following access with a SPPF, a predominantly two-wall intrabony defect was exposed (c). After careful root instrumentation, a bioresorbable membrane was placed on top of a BRG (d). Primary closure of the flap was obtained with a multilayered suture approach (e). At 6 years, shallow probing depths were present (f); note the moderate increase in recession of the gingival margin. The radiograph at 6 years showed elimination of the defect but persistence of mineralized granules of the BRG embedded in the newly formed mineralized tissue (g).

When the position of the residual buccal/lingual bony wall(s) is very deep and difficult or impossible to reach with the above-described minimal incision of the defect-associated interdental space, the flap(s) is(are) further extended mesially or distally and one extra interdental space is involved to obtain a larger flap reflection. The same approach is used when the bony defect also extends to the buccal or the palatal side of the involved tooth, or when it involves the two interdental spaces of the same tooth (Fig. 45-27) or two approximal teeth (Fig. 45-28). In the latter instance, a second interdental papilla is accessed, either with an SPPF or an MPPT, according to the indication. Vertical releasing incisions are performed when flap reflection causes tension at the extremities of the flap(s). The vertical releasing incisions are always kept very short and within the attached gingiva (never involving the mucogingival junction). The overall aim of this approach is to avoid using vertical incisions whenever possible or to reduce their number and extent to a minimum when there is a clear indication for them. Periosteal incisions are never performed.

The defects are debrided with the combined use of mini-curettes and power-driven instruments, and the roots carefully planed. During the instrumentation, the flaps are slightly reflected and carefully protected with periosteal elevators and frequent saline irrigations. At the end of instrumentation, the biologically active agent is applied. Then the flaps are repositioned.

The suturing approach in most instances consists of a single modified internal mattress suture at the defect-associated interdental area to achieve primary closure of the papilla in the absence of any tension (Cortellini & Tonetti 2001, 2005). When a second interdental space has been accessed, the same suturing technique is used to obtain primary closure in this area. Vertical releasing incisions are sutured with simple passing sutures. The buccal and lingual flaps are repositioned at their original level, without any coronal displacement to avoid any additional tension in the healing area.

All the surgical procedures can be performed with the aid of an operating microscope or magnifying loupes at a magnification of ×4 to ×16 (Cortellini &

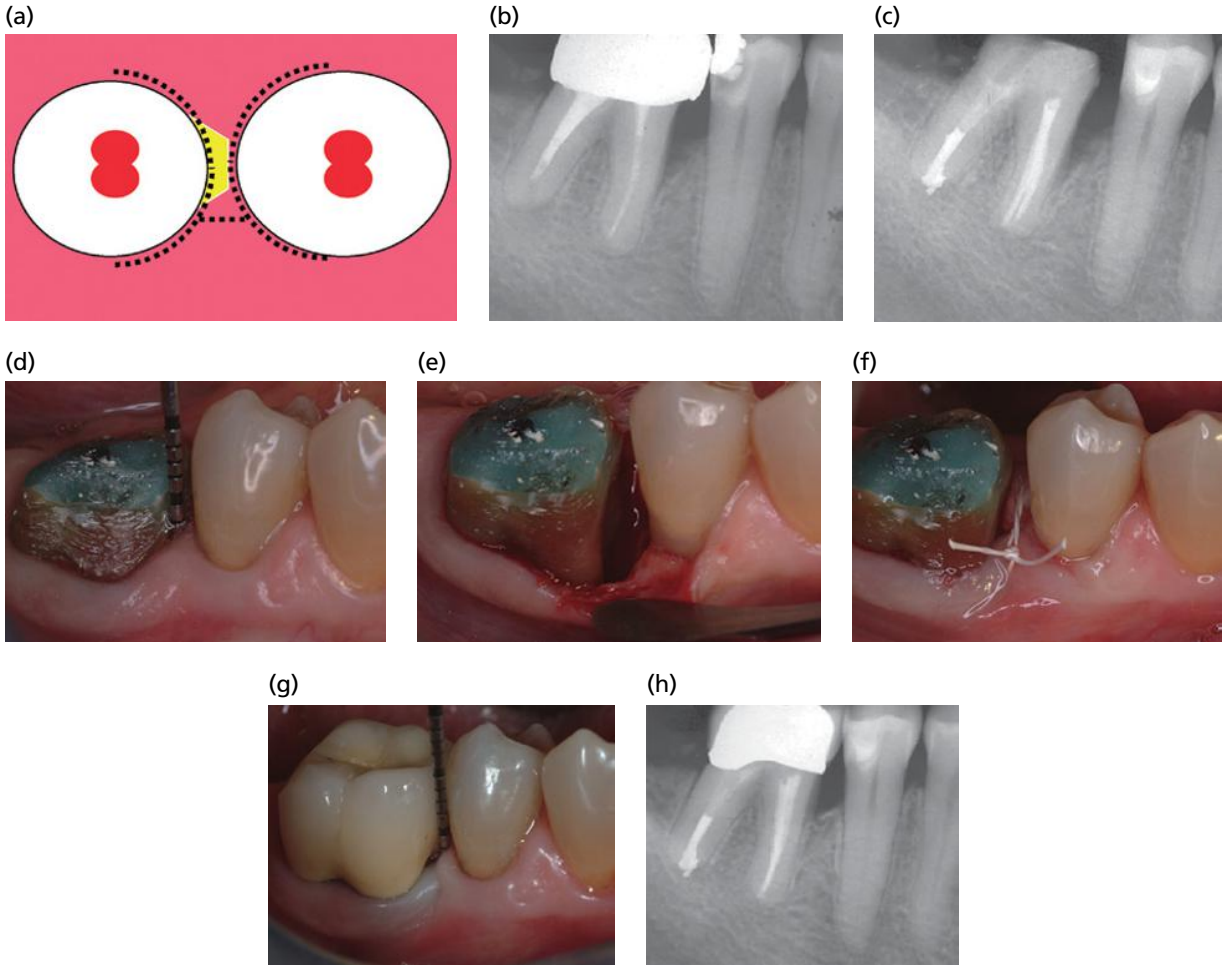

Fig. 45-25 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in an isolated interdental three-wall defect. The schematic diagram shows the extent of the incision performed according to the principles of the modified papilla preservation technique (MPPT) in the interdental space associated with the defect. Mesiodistal extension of the flap was limited to the buccal aspect of the teeth adjacent to the defect in order to optimize wound stability (a). The baseline radiograph showed the presence of dental diseases (periapical infection and caries) that needed to be controlled during the initial cause-related phase of therapy (b). At re-evaluation, an 8-mm pocket associated with the presence of a deep intrabony defect was detected on the mesial aspect of the first molar (c, d). The defect was accessed in a minimally invasive fashion using the MPPT. The three-wall intrabony defect was exposed and carefully debrided (e). After application of enamel matrix derivatives, primary closure was obtained with a single modified internal mattress suture (f). One-year outcomes showed shallow probing depths and almost complete resolution of the defect (g, h).

Tonetti 2001, 2005). Microsurgical instruments are utilized, whenever needed as a complement to the normal set of periodontal instruments.

This approach has been preliminary tested in two case series with a total of 53 deep intrabony defects (Cortellini & Tonetti 2007a, b). One-year results showed clinically significant improvements (CAL gain of 4.8 ± 1.9 mm with 88.7 ± 20.7% clinical resolution of the defect) and greatly reduced patient morbidity. The same approach was successfully applied to multiple intrabony defects in 20 patients (Cortellini *et al.* 2008). The 44 treated defects gained on average 4.4 ± 1.4 mm of clinical attachment and 73% of defects showed CAL improvements of ≥4 mm. This corresponded to an 83 ± 20% resolution of the defect (15 defects were completely filled). Residual PPDs were 2.5 ± 0.6 mm. A minimal increase of 0.2 ± 0.6 mm in gingival recession between baseline and 1 year was recorded.

A recent controlled clinical study of 30 patients compared MIST plus EMD to MIST alone (Ribeiro *et al.* 2011a). The authors reported significant PPD reduction, CAL gain, and radiographic bone gain at 3 and 6 months in both groups. No differences were detected between therapies at any time point. It was concluded that the use of EMDs did not improve the outcome of the MIST for the treatment of intrabony defects.

An enhancement of this technique, the modified minimally invasive surgical technique (M-MIST) (Cortellini & Tonetti 2009b) has been tested (Fig. 45-29). The M-MIST was designed especially to improve flap stability and to provide self-ability to maintain space for regeneration. The surgical approach consists of a tiny interdental access through which only a buccal triangular flap is elevated, while the papilla is left in place, connected to the root of the crest-associated tooth with its supracrestal fibers

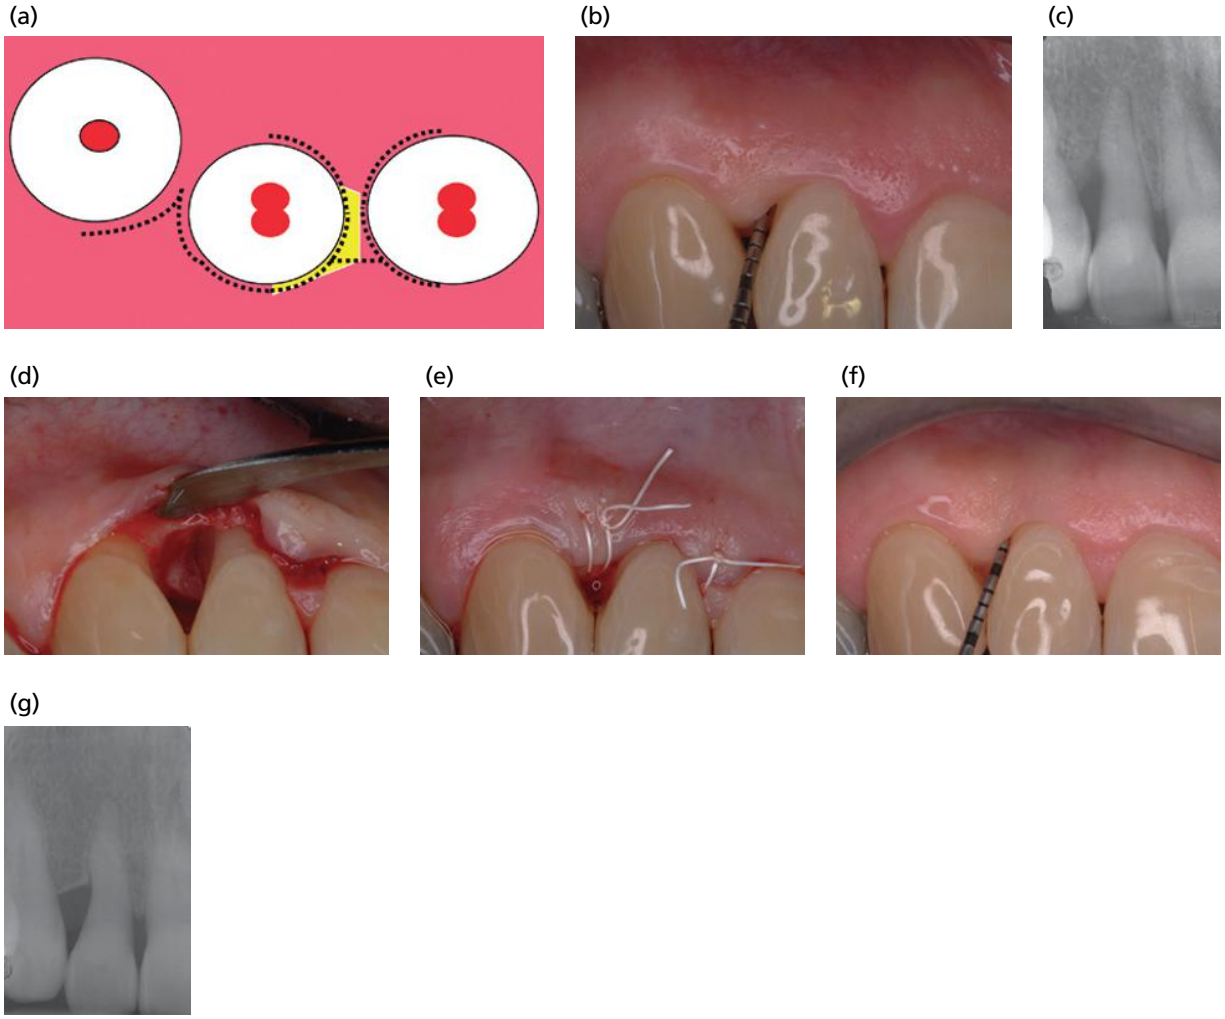

Fig. 45-26 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in an isolated interdental defect extending towards the buccal aspect of the tooth. The schematic diagram shows the extent of the incision performed according to the principles of the modified papilla preservation technique (MPPT) in the interdental space associated with the defect. Mesiodistal extension of the flap was limited to the buccal aspect of the teeth adjacent to the defect and to the interdental aspect adjacent to the buccal extension of the defect in order to optimize wound stability (a). Following completion of successful initial cause-related therapy, a 6-mm pocket associated with an intrabony defect was detected on the distal aspect of the lateral incisor (b, c). The attachment loss extended to the buccal aspect of the lateral incisor, suggesting the need to obtain access to the buccal aspect of this tooth. The defect was therefore accessed with a minimally invasive approach using the MPPT to access the interdental area and extending the incision to the papilla between the lateral and central incisors to ensure adequate access to the defect (d). Primary closure was obtained with a modified internal mattress suture and a simple passing suture (e). One-year outcomes showed shallow probing depths, good preservation of the soft tissue heights, and resolution of the defect (f, g).

(see Fig. 45-5). Access to the defect is gained through the tiny buccal triangular flap: from the buccal "window", the soft tissue filling the defect (i.e. the so-called granulation tissues) is sharply dissected from the papillary supracrestal connective tissue and from the bony walls with a microblade, and removed with a mini-curette. Then, the root surface is carefully debrided with hand and mechanical instruments. The supracrestal fibers of the defect-associated papilla and the palatal tissues are left untouched. The minimal wound and the minimal flap elevation allows for preservation of most of the vessels providing the blood supply to the interdental tissues, with obvious advantages for the healing process of the interdental wound. This surgical approach with its novel design ensures self-support to the interdentally soft tissues through the "hanging" papilla, thereby enhancing space provision. The flap is extremely stable since most of the soft tissue around the bony defect is not incised or elevated, thereby enhancing blood clot stability. Minimal flap trauma, integrity of the blood supply, and absolute passivity in the suturing technique ensures primary closure of the interdental wound in the majority of the cases, thereby preventing bacterial contamination. The suturing approach is based on the use of a single internal modified mattress suture. Additional sutures can be applied to further increase primary closure, when needed. The reduced buccal access, however, means this approach is not applicable to very deep defects that involve the lingual side of a tooth for which the diseased root surface is not easily accessible for instrumentation from the small buccal window (Cortellini & Tonetti 2009b).

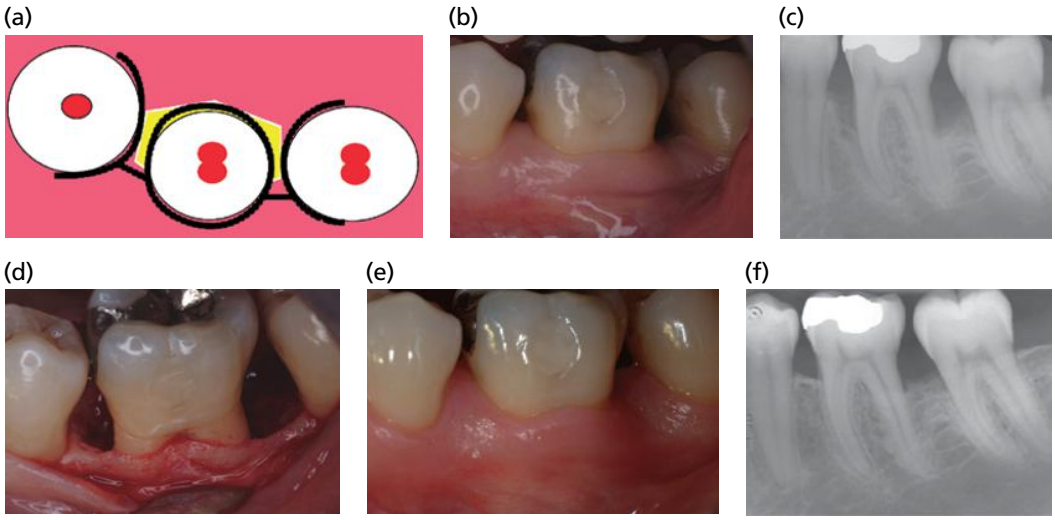

Fig. 45-27 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in intrabony defects involving both interdental spaces of the same tooth. The schematic diagram shows the extent of the incision performed according to the principles of the modified papilla preservation technique (MPPT) in the two interdental spaces associated with the defects. Mesiodistal extension of the flap was limited to the two interdental papillae associated with the defects (a) and reached the line angle of the two adjacent teeth in order to limit the loss of wound stability, while allowing adequate access to the defects. The clinical and radiographic appearance at baseline highlighted the good control of inflammation obtained following completion of initial cause-related therapy and the presence of deep mesial and distal pockets with associated intrabony defects (b, c). Both the mesial and distal defects were accessed with papilla preservation flaps, the defects were debrided, and the root surfaces were carefully instrumented (d). Following application of enamel matrix derivatives in the well-contained defects, primary closure of the flap was achieved by modified internal mattress sutures. At 1-year follow-up, shallow pockets, preservation of soft tissues, and elimination of the defects were apparent (e, f).

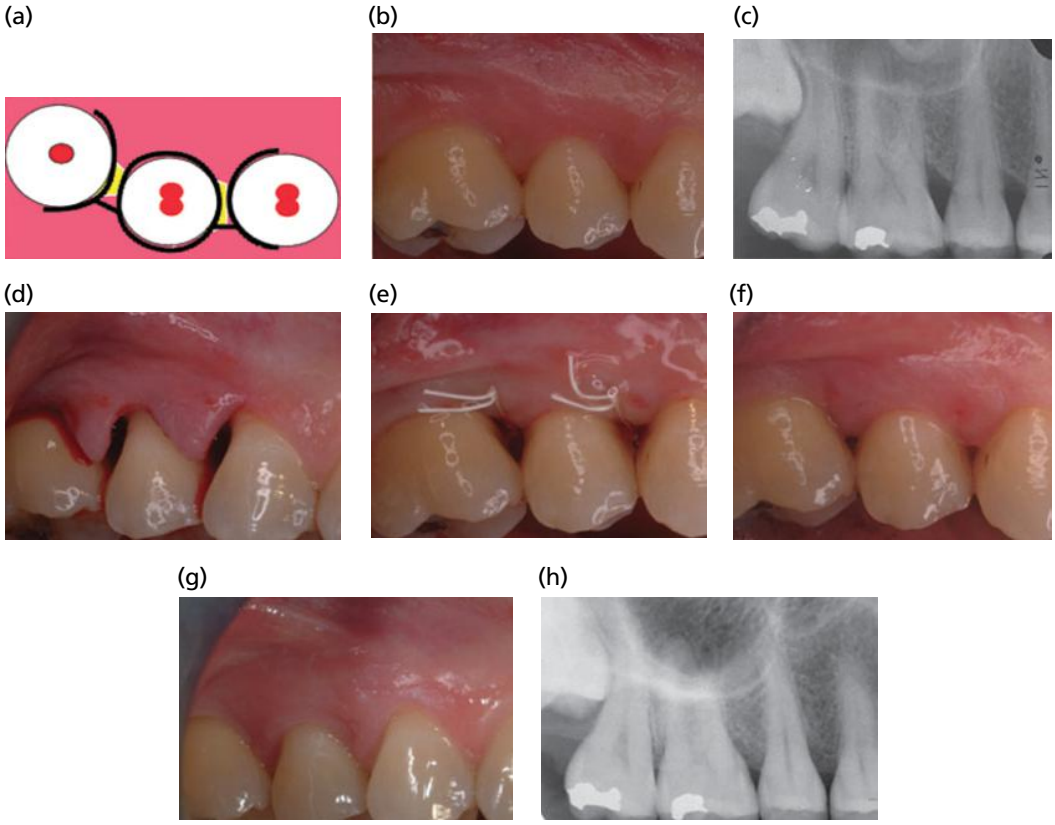

Fig. 45-28 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in intrabony defects involving two adjacent teeth. The schematic diagram shows the extent of the incision performed according to the principles of the papilla preservation flaps in the two interdental spaces associated with the defects. Mesiodistal extension of the flap was limited to the two interdental papillae associated with the defects (a) and reached the line angle of the two adjacent teeth in order to limit the loss of wound stability and to limit flap extension. After successful initial cause-related therapy, two defects were present on the mesial aspect of the first molar and second premolar (b, c). Simplified papilla preservation flaps (SPPF) were used to access the defects (d). Incisions were stopped at the distal line angle of the first premolar and on the buccal aspect of the first molar. Root debridement and application of enamel matrix proteins in gel form were performed before primary closure of the flap with two modified internal vertical mattress sutures (e). Excellent early healing in the absence of pain or discomfort was evident at the 1-week suture removal (f). At 1-year follow-up, absence of inflammation, shallow probing depths, and resolution of the defects were evident (g, h).

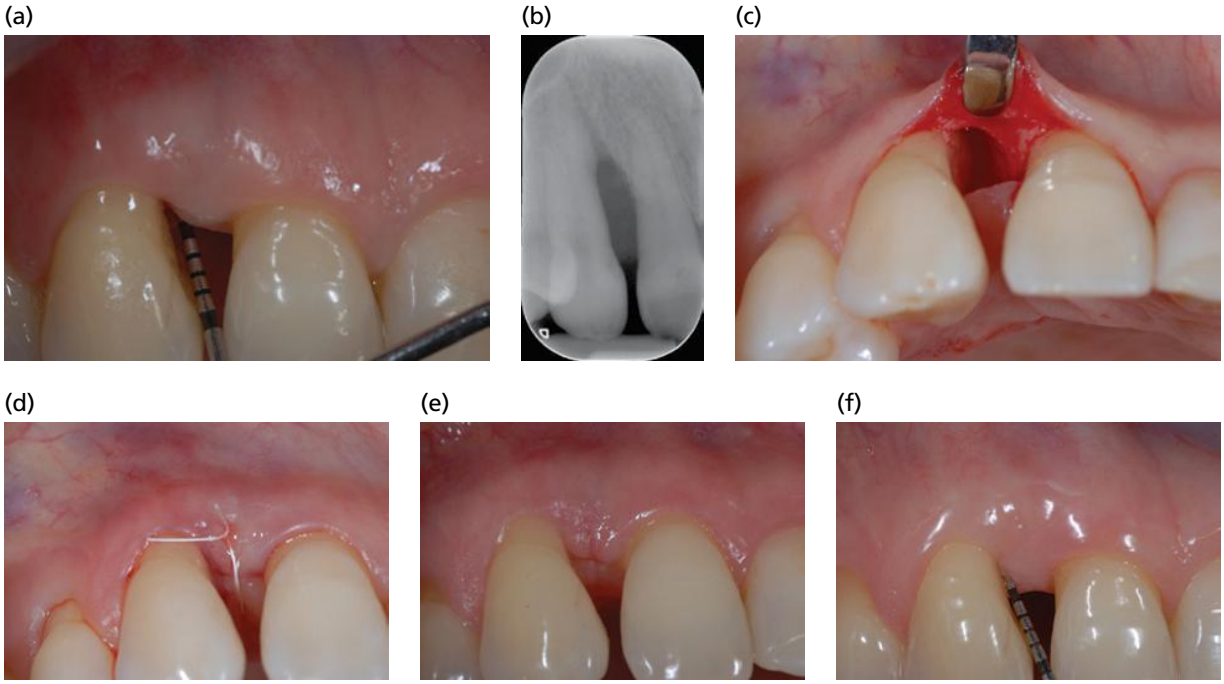

Fig. 45-29 Clinical case treated with the modified minimally invasive procedure (M-MIST). A 10-mm pocket mesial to the upper right cuspid (a) was associated with a deep intrabony defect reaching the mid third of the root (b). Area was accessed with the M-MIST procedure (c). Buccal flap was minimally elevated to the mid-buccal contour of the cuspid and the lateral incisor. The defect-associated interdental papilla was left untouched and the lingual flap was not elevated. The intrabony defect and the exposed root surface were instrumented through the small buccal surgical "window". A single modified internal mattress suture was positioned to close the area (d). No regenerative material was placed into the defect, leaving the natural blood clot alone to fill the intrabony component. Integrity of the primary closure of the wound was maintained after 1 week (e). One-year clinical photograph showed a 3-mm normal sulcus, associated with a 7-mm clinical attachment gain and no increase in gingival recession (f). One-year radiograph showed the complete resolution of the intrabony component of the defect (g).

Recently, a three-arm randomized controlled clinical trial was designed to compare the clinical efficacy of the M-MIST alone versus M-MIST combined with EMD and EMD plus bone mineral derived xenograph (BMDX), in the treatment of isolated, interdental intrabony defects (Cortellini & Tonetti 2011). The study was performed on 45 deep isolated intrabony defects accessed with the M-MIST and randomly assigned to three experimental groups: 15 to M-MIST alone, 15 to M-MIST + EMD, and 15 to M-MIST + EMD–BMDX (Fig. 45-30). The differences between baseline and 1 year were statistically significant in the three groups for PPD reduction (P >0.0001, student t-test) as well as CAL gain (P >0.0001). Comparisons between the three groups showed no statistically significant difference in any of the measured clinical outcomes. In particular, CAL gain of 4.1 ± 1.4 mm was observed in the M-MIST control group, 4.1 ± 1.2 mm in the EMD group, and 3.7 ± 1.3 mm in the EMD + BMDX one. The percentage radiographic bone fills of the intrabony component were 77 ± 19%, 71 ± 18%, and 78 ± 27%, respectively. This initial controlled study could detect a true difference in CAL of 0.96 mm between the treatment groups. However, the fact that the outcomes among the three groups could not be discriminated raises a series of hypotheses that focus on the intrinsic healing potential of a wound when ideal conditions are provided with the surgical approach. In other words, the outcomes of this study lay down the challenge to clinicians of possibly achieving substantial clinical improvements without the use of products or materials. An independent study (Trombelli *et al*. 2010) reported similar outcomes with no difference between a single flap approach (SLA) alone and SLA plus a bioresorbable barrier and hydroxyapatite.

Technical implications

The above cited studies propose two different minimally invasive approaches to intrabony defects. The MIS (Harrel 1995) and the MIST (Cortellini & Tonetti 2007a, b) include the elevation of the interdental papillary tissues to uncover the interdental space, gaining complete access to the intrabony defect, while in the M-MIST (Cortellini & Tonetti 2009a) access to the defect is gained through the reflection of a small buccal flap, without elevation of the interdental papilla (Figs. 45-27, 45-28, 45-29, 45-30). The major problem to be overcome when applying minimally invasive surgery is the visibility and manipulation of

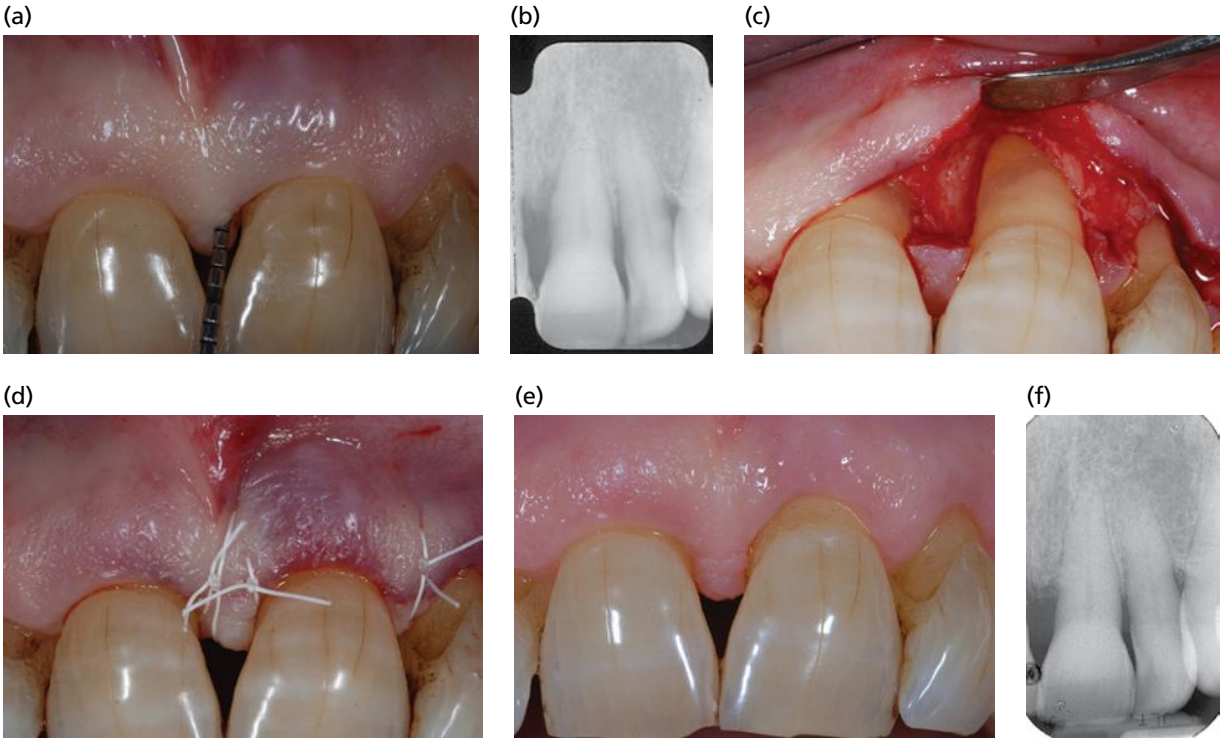

Fig. 45-30 Clinical case treated with the modified minimally invasive procedure (M-MIST) + enamel matrix derivatives (EMDs) + Bio-Oss. A 7-mm attachment loss was associated with a 6-mm pocket depth at the mesial side of the left upper central incisor (a). The intrabony defect was evident on the baseline radiograph (b). Area was accessed with the M-MIST approach. The flap was extended to the distal interdental space to uncover the buccal bone dehiscence (c). Flap was sutured after positioning of EMDs and grafting material (d). Clinical photograph (e) and radiograph (f) at 1 year showed the resolution of the periodontal lesion.

the surgical field. This issue is clearly enhanced in the M-MIST approach with its high magnification and direct optimal illumination. Traditionally, dental surgeons are taught to raise large flaps to completely expose the area of interest. In reality, visibility of the defect is restricted by the residual bony walls that surround the defect. The elevation of a flap to the edge of the residual bony walls should therefore be sufficient to visualize the defect: over-reflection of the flaps does not increase defect visibility. However, the minimal flap reflection narrows the angle of vision and especially the light penetration into the surgical field. In addition, the soft tissue manipulation during instrumentation requires more care since the flaps, which are not fully reflected, lie very close to the working field. Use of small instruments, like small periosteal elevators and tiny tissue players, is mandatory for soft and hard tissue manipulation. Microblades, mini-curettes, and mini-scissors allow for full control over the incision, debridement, and refinement of the surgical area, and sutures from 6-0 to 8-0 are mandatory for wound closure.

Flap design for furcation involvement

Flap design for buccal and lingual mandibular and buccal maxillary class II furcations were described >20 years ago and have not been substantially modified since (Pontoriero *et al*. 1988; Andersson *et al*. 1994; Jepsen *et al*. 2004). Following intrasulcular incisions, a mucoperiosteal flap is raised at the buccal or lingual aspect of the alveolar process (Fig. 45-31). The root surfaces are carefully scaled and planed using hand and power-driven instruments and rotating, flame-shaped diamond burs. Remaining granulation tissue in the furcation area is carefully removed to expose the surface of the alveolar bone.

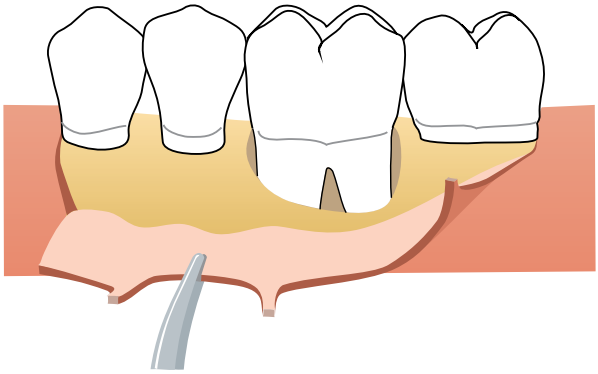

Fig. 45-31 Furcation involvement: step-by-step approach. Following marginal incisions and vertical releasing incisions on the buccal aspect of the jaw, buccal and lingual full-thickness flaps are elevated.

The regenerative material of choice (a non-bioresorbable or a bioresorbable barrier, a bone graft, a biologically active agent, or a combination approach) is positioned at the furcation area (Fig. 45-32). When a barrier is used, it is adjusted to cover the entrance (buccal or lingual) of the furcation area, the adjacent root surfaces (from the distobuccal/lingual line angle of the distal root to the mesiobuccal/lingual line angle

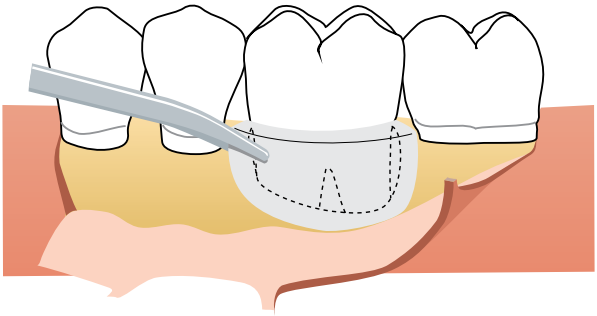

Fig. 45-32 Furcation involvement: step-by-step approach. The barrier material is placed in such a way that it completely covers the defect and extends over at least 3 mm of bone beyond the defect margin.

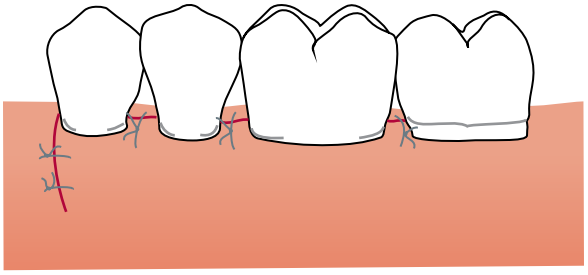

Fig. 45-33 Furcation involvement: step-by-step approach. The elevated tissue flaps are coronally displaced and sutured in such a way that the border of the barrier material is at least 2 mm below the flap margin.

of the mesial root), and a 4–5-mm wide surface of the alveolar bone apical to the bone crest. The membrane can be retained in position by sutures placed around the crown of the molar using a sling technique. When a graft is preferred, it is positioned to completely fill the furcation area and slightly overfill the entrance. Biologically active agents are delivered into the furcation area. A combination approach requires the positioning of different biomaterials according to the properties of each material.

Following placement of the regenerative material, the mucoperiosteal flap is repositioned to completely cover the furcation and the biomaterials (Fig. 45-33). A periosteal incision can be made, when needed, to coronally advance the flap. The flap is secured with interdental or sling sutures. The sutures are removed 7–15 days after surgery. When a non-bioresorbable barrier is positioned, a second surgical procedure to remove the barrier is performed after a healing period of about 6 weeks (Fig. 45-34).

The surgical technique has been carefully refined and revised by McClain and Schallhorn (2000). Their surgical technique is especially designed for combination therapy (barrier plus grafting material) and is based on a common core, modified as necessary for specific situations. This common core employs a sulcular incision full-thickness envelope flap with maximum retention of gingival and papillary tissues and sufficient exposure of the defect for adequate visualization and access for debridement. If recession

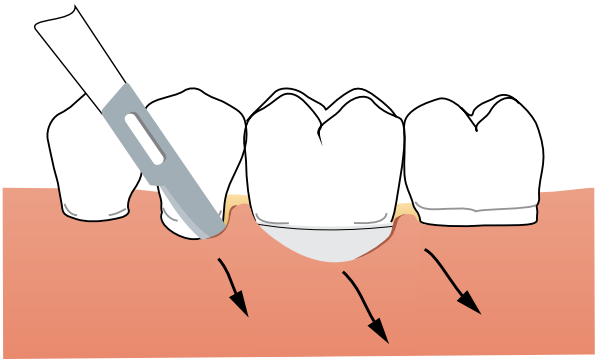

Fig. 45-34 Furcation involvement: step-by-step approach. In order to remove the barrier material, an incision is made extending one tooth mesially and distally to the border of the barrier. After reflecting the covering tissue flaps, the barrier can be removed without compromising the newly regenerated tissue.

has occurred and/or coronal flap positioning is required for membrane coverage, periosteal separation is also performed.

The defect is debrided and the root surface planed to remove plaque, accretions, enamel projections, and other root surface alterations (grooves, notches, caries, etc.) employing ultrasonic or sonic, hand and rotary (fine diamond and/or finishing burs) instrumentation. Odontoplasty and/or osteoplasty are performed if required for adequate access to the defect, including intraradicular or furcation fundus concavities, and/or for reduction of enamel projections. Adequate root preparation is considered critical to a successful outcome.

The bone graft is prepared (typically by DFDBA) in a dappen dish with hydration with sterile saline or local anesthetic solution and, if there is no contraindication, combined with tetracycline (125 mg/0.25 g of DFDBA). After mixing, the dappen dish is covered with a sterile, moistened gauze to prevent drying of the graft. The appropriate membrane is selected and trimmed to fit into the desired position, and then placed on sterile gauze. Care is taken to prevent membrane contamination via contact with the lips, tongue, mucosa or saliva.

The area is thoroughly cleansed and isolated, and the root surface at the regenerative site is treated with citric acid (pH1) for 3 minutes using cotton pellets, with care taken to contain the solution to the root and bone surface. The pellets are removed and the site inspected for any residual cotton fibers prior to flushing it with sterile water or saline. Intramarrow penetration is then performed with a 1/4 round bur if a sclerotic bone surface exists in the graft site. The ligament surface is "scraped" with a periodontal probe to remove any eschar and to stimulate bleeding, and the DFDBA is packed firmly into the defect using an overfill approach, along with covering the root trunk and combination or confluent intrabony, dehiscence or horizontal/crestal osseous defects. The custom-made membrane is placed over the graft and secured as appropriate. After rechecking

to be sure adequate graft material remains in the desired area, the flap is positioned to cover the membrane and secured with non-bioresorbable sutures (typically Gore sutures). Throughout the root conditioning and subsequent treatment to closure, the site remains isolated to avoid saliva contamination.

If a non-bioresorbable membrane is used, it is removed at 6–8 weeks postoperatively by employing minor flap reflection, de-epithelialization of the internal aspect of the flap adjacent to the membrane, gentle removal (peeling) of the membrane outward from the site, and flap positioning to cover the regenerated tissues as feasible. Closure with sutures is then accomplished with non-bioresorbable sutures.

Postoperative regimen

The postoperative regimen prescribed to the patients is aimed at controlling wound infection or contamination as well as mechanical trauma to the treated sites. A meta-analysis indicated that differences in regenerative outcomes can be expected based on the postoperative care protocol: more frequent, intensive regimens were associated with better CAL gain in intrabony defects (Murphy & Gunsolley 2003) (Fig. 45-35). It generally includes the prescription of systemic antibiotics (doxycycline or amoxicillin) in the immediate postoperative period (1 week), 0.2 or 0.12% chlorhexidine mouth rinsing b.i.d. or t.i.d., and weekly professional tooth cleaning until the membrane is in place. Professional tooth cleaning consists of supragingival prophylaxis with a rubber cup and chlorhexidine gel. Patients are generally advised not to perform mechanical oral hygiene and not to chew in the treated area.

Non-bioresorbable membranes are removed 4–6 weeks after placement, following elevation of partial-thickness flaps. Patients are re-instructed to rinse b.i.d. or t.i.d. with chlorhexidine, not to perform mechanical oral hygiene, and not to chew in the treated area for 3–4 weeks. In this period, weekly professional control and prophylaxis are recommended. When bioresorbable membrane, BRG or biologically active regenerative materials are used, the period of tight infection control is extended for 6–8 weeks. After this period, patients are re-instructed to resume mechanical oral hygiene gradually, including interdental cleaning, and to discontinue chlorhexidine. Patients are then enrolled in a monthly periodontal care program for 1 year. Probing or deep scaling in the treated area is generally avoided before the 1-year follow-up visit.

Postoperative period and local side effects

From the very beginning of the "guided tissue regeneration era", the frequent occurrence of complications, in particular barrier exposure, was apparent. Complications occurred in almost 100% of the cases in the prepapilla preservation techniques period (Becker *et al*. 1988; Cortellini *et al*. 1990; Selvig *et al*. 1992; Cortellini *et al*. 1993a, b; Falk *et al*. 1997; Trombelli *et al*. 1997; Murphy 1995a, b; Mayfield *et al*. 1998) but negative occurrences reportedly reduced to amounts ranging from 50% to 6% when papilla preservation flaps were adopted (Cortellini *et al*. 1995a, 1996; Tonetti *et al*. 1998; Cortellini *et al*. 1999a; Cortellini & Tonetti 2000; Cortellini *et al*. 2001; Machtei 2001; Tonetti *et al*. 2002; Murphy & Gunsolley 2003; Tonetti *et al*. 2004a; Cortellini & Tonetti 2005). A consistent decrease of complications was observed when barriers were not incorporated into the surgical procedure. In particular, the adoption of EMDs largely reduced the prevalence of complications (Tonetti *et al*. 2002; Esposito *et al*. 2009; Sanz *et al*. 2004). Sanz

et al. (2004) showed that all sites treated with membranes showed at least one surgical complication during healing, while a complication was observed in only 6% of sites treated with EMDs. This study indicates that some regenerative materials/procedures may be less technique sensitive than others.

The development of minimally invasive surgery has greatly reduced the amount of complications and side effects in the postoperative period. Primary closure of the flap was reported in 100% of cases treated with MIST and was maintained in single sites in 95% of cases at 1 week (Cortellini & Tonetti 2007a, b) and in multiple sites in 100% of cases (Cortellini *et al.* 2008). Edema was noted in few cases (Cortellini and Tonetti 2007a, b; Cortellini *et al*. 2008). No postsurgical hematoma, suppuration, flap dehiscence, presence of granulation tissue, or other complications were reported in any of the treated sites (Cortellini & Tonetti 2007a, b; Cortellini *et al*. 2008). Root sensitivity was not a frequent occurrence: reported at 1 week by about 20% of the patients but this percentage rapidly decreased in the following weeks, with only one patient still reporting some root sensitivity a 6 weeks (Cortellini & Tonetti 2007b). Ribeiro *et al*. (2011a) reported that the extent of root hypersensitivity and edema was very discreet and no patients developed hematoma.

When applying the M-MIST, Cortellini and Tonetti (2009b) reported primary closure obtained and maintained in 100% of the cases. In a second controlled study (Cortellini & Tonetti 2011), one M-MIST/EMD/BMDX-treated site presented at suture removal (week 1) with a slight discontinuity of the interdental wound. At week 2, the gap appeared to have closed. No edema, hematoma or suppuration was noted in any of the treated sites in these studies (Cortellini & Tonetti 2009a, 2011).

Surgical and post-surgical morbidity

To date, little consideration has been given to critical elements that could contribute to the patient's assessment of the cost–benefit ratio of GTR procedures. These include postoperative pain, discomfort, complications, and the perceived benefits from the treatment. A parallel group, randomized, multicenter and controlled clinical trial designed to test the efficacy of GTR versus flap surgery alone assessed these patient issues (Cortellini *et al*. 2001). During the procedure, 30.4% of the test group and 28.6% of the controls reported moderate pain, and subjects in the test group estimated the hardship of the procedure as 24 ± 25 units on a visual analog scale (VAS from 0 to 100, with 0 = no hardship and 100 = unbearable hardship) and subjects in the control group 22 ± 23 VAS. Surgery with membranes required longer chair time than flap surgery alone (on average 20 minutes longer). Among the postoperative complications, edema was most prevalent at week 1 and most frequently associated with the GTR treatment, while postoperative pain was reported by fewer than 50% of both the test and control patients. Pain intensity was described as mild and lasted on average 14.1 ± 15.6 hours in the test patients and 24.7 ± 39.1 hours in the controls. Postoperative morbidity was limited to a minority of subjects: 35.7% of the test patients and 32.1% of the controls reported that the procedures interfered with daily activities for an average of 2.7 ± 2.3 days in the test group and 2.4 ± 1.3 days in the control group. These data indicate that GTR adds almost 30 minutes to a flap procedure and is followed by a greater prevalence of post-surgical edema, while no difference was observed between GTR and flap surgery alone in terms of postoperative pain, discomfort, and interference with daily activities.

No comparative study has reported the morbidity associated with the various regenerative approaches. Reports of multicenter trials on the application of EMDs or barrier membranes using the same methodology, however, show similar results for the two regenerative materials (Tonetti *et al*. 1998, 2004a; Cortellini *et al*. 2001).

Morbidity of the regenerative procedure was tested on a population treated with MIST and EMDs. Patients were questioned at the end of surgery and at week 1 about the intraoperative and postoperative period, respectively, and reported no pain (Cortellini & Tonetti 2007a). Three of the 13 patients reported very limited discomfort in the first 2 days of the first postoperative week. Seventy-seven percent of the patients described the first postoperative week as uneventful, reporting no feeling of having been surgically treated after the second postoperative day.

In a large case cohort of 40 patients treated with MIST and EMDs (Cortellini & Tonetti 2007b), none of the patients reported intraoperative pain or discomfort and 70% did not experience any postoperative pain. The subjects reporting pain described it as being very moderate (VAS 19 ± 10, with 0 = no pain and 100 = unbearable pain). In these patients, pain lasted for 26 ± 17 hours on average. Home consumption of analgesic tablets was 1 ± 2 on average. Twenty-three patients did not use any pain killer in addition to the first two compulsory tablets that were administered in the practice immediately after the surgery and 6 hours later. Seven of the 12 patients (17.5%) reporting pain also experienced some discomfort (VAS 28 ± 11, with 0 = no discomfort and 100 = unbearable discomfort) that lasted for 36 ± 17 hours on average. Only three patients reported some interference with daily activities (work and sport) for 1–3 days.

In a second case cohort study of MIST and EMDs on multiple adjacent intrabony defects (Cortellini *et al*. 2008), 14 of the 20 patients did not experience any postoperative pain. The six subjects reporting pain described it as being very mild (VAS 19 ± 9) and lasting for 21 ± 5 hours on average. Home consumption of painkillers was 0.9 ± 1.0. Nine patients did not use any analgesic in addition to the first two

Table 45-3 Comparison between clinical studies of conventional versus those of minimally invasive surgery.

	Cortellini *et al.* (2001)	Tonetti *et al.* (2004b)	Cortellini *et al.* (2007b)	Cortellini & Tonetti (2011)
Regenerative approach	SPPF/MPPT + bioresorbable barrier	SPPF/MPPT+ EMD	MIST + EMD	M-MIST + EMD

compulsory tablets. Ten patients experienced mild discomfort (VAS 21 ± 10) that lasted for 20 ± 9 hours on average. Only four patients reported some interference with daily activities (work and sport) for 1–3 days.

Ribeiro *et al*. (2011b) reported that the extent of discomfort/pain experienced during therapy with MIST and EMDs was very limited. In addition, the extent of discomfort during the first postoperative week was very discreet, and no patients developed high fever or reported any interference with daily activities. The quantity of analgesic medication taken by patients was minimal (fewer than one analgesic medication per patient).

In a case cohort study where 15 patients were treated with M-MIST and EMDs (Cortellini & Tonetti 2009b), none of the patients reported intraoperative or significant postoperative pain. Three of the patients reported very limited discomfort in the first 2 days after surgery. Fourteen described the first postoperative week as uneventful, reporting no feeling of having been surgically treated after the second postoperative day.

In a controlled study of the additional benefit from EMDs or EMD/BMDX with M-MIST compared to M-MIST alone (Cortellini & Tonetti 2011), none of the 45 patients reported having experienced intra- and post-operative pain. Slight discomfort was reported by three patients in the M-MIST group (average VAS 10.7 ± 2.1), by two patients in the M-MIST/EMD group (VAS 11.5 ± 0.7), and by four patients in the M-MIST/EMD/BMDX group (VAS 12.3 ± 3.1). Few patients needed pain control medications: three patients from the M-MIST group (average number of tablets 0.4 ± 0.7; maximum 2), four patients from the M-MIST/EMD group (average 0.3 ± 0.6; maximum 2), and four patients from the M-MIST/EMD/BMDX group (average 0.5 ± 1; maximum 3).

Table 45-3 gives some of surgical and postsurgical parameters used in four studies. Two studies concerned the application of traditional large papilla preservation flaps (MPPT and SPPF) with bioresorbable barriers (Cortellini *et al*. 2001) or EMDs (Tonetti *et al*. 2004b). The other two studies concerned the MIST in combination with EMDs (Cortellini *et al*. 2007; Cortellini & Tonetti 2011). This historical comparison clearly shows differences in most of the parameters between the four studies. Surgical chair time was the longest when large papilla preservation flaps and barriers were applied, shorter when large papilla preservation flaps were combined with EMDs, and by far the shortest when M-MIST and EMDs were used. The number of subjects reporting postoperative interference with daily activities, discomfort, and pain was similar in the two papilla preservation flap studies, much reduced in the MIST study, and very limited or none in the M-MIST study; similarly pain intensity and consumption of pain killers was very low in both studies. The reported outcomes indicate that postoperative discomfort and pain apparently are not influenced by the type of regenerative material, but are by the type of surgical approach: a more friendly, shorter chair time, minimally invasive surgery is associated with fewer postoperative problems. These considerations may prompt clinicians to adopt more patient-friendly approaches whenever possible.

Barrier materials for regenerative surgery

In the first GTR attempts, a bacterial filter produced from cellulose acetate (Millipore®) was used as an occlusive membrane (Nyman *et al*. 1982; Gottlow *et al*. 1984; Magnusson *et al*. 1985). Although this type of membrane served its purpose, it was not ideal for clinical application.

Non-bioresorbable materials

Later studies have utilized membranes of e-PTFE specially designed for periodontal regeneration (Gore Tex Periodontal Material®). The basic molecule of this material consists of a carbon–carbon bond with four attached fluorine atoms to form a polymer. It is inert and does not result in any tissue reaction when implanted in the body. This type of membrane persists after healing and must be removed in a second operation. Membranes of e-PTFE have been used successfully in animal experiments and in several clinical studies. From such studies it was found that for a barrier material to function optimally, it has to meet certain essential design criteria:

- Biocompatibility to assure good tissue acceptance. The material should not elicit an immune response, sensitization or chronic inflammation that may interfere with healing and present a hazard to the patient. Biocompatibility, however, is a relative term since practically no materials are completely inert.
- Acts as a barrier to exclude undesirable cell types from entering the secluded space adjacent to the root surface. It is also considered to be an advantage that the material allows the passage of nutrients and gases.
- Tissue integration that allows the tissue to grow into the material without completely penetrating it. The goal of tissue integration is to prevent rapid epithelial down-growth on the outer surface of the material or encapsulation of the material, and to provide stability to the overlying flap. The importance of tissue integration was demonstrated in a study in monkeys (Warrer *et al*. 1992) in which bioresorbable membranes of polylactic acid, a synthetic polymer, were used to treat circumferential periodontal defects. Due to the lack of tissue integration, the membranes in this study became surrounded by an epithelial layer and were often encapsulated and exfoliated.
- Capable of creating and maintaining a space adjacent to the root surface. This allows the blood clot to form at the interface between the flap and root surface (Haney *et al*. 1993; Sigurdsson *et al*. 1994; Cortellini *et al*. 1995c, d; Tonetti *et al*. 1996a; Wikesjo *et al*. 2003; Kim *et al*. 2004). Some materials may be so soft and flexible that they collapse into the defect. Other materials are too stiff and may perforate the overlying tissue.
- Provide stability to the blood clot to maintain continuity with the root surface, thereby preventing the formation of a long junctional epithelium (Linghorne & O'Connel 1950; Hiatt *et al*. 1968; Wikesjo & Nilveus 1990; Haney *et al*. 1993).

Bioresorbable materials

In recent years, natural or synthetic bioresorbable barrier materials for GTR have been introduced in order to avoid the second surgery necessary for removal of non-bioresorbable materials. Barrier materials of collagen from different species and from different anatomic sites have been tested in animals and in humans (Blumenthal 1988; Pitaru *et al*. 1988; Tanner *et al*. 1988; Paul *et al*. 1992; Blumenthal 1993; Wang *et al*. 1994; Camelo *et al*. 1998; Mellonig 2000). Often the collagen used is a cross-linked variety of porcine or bovine origin. When a collagen membrane is implanted in the human body, it is resorbed by the enzymatic activity of macrophages and polymorphonuclear leukocytes (Tatakis *et al*. 1999). Successful treatment with these barrier materials has been demonstrated, but the results of studies vary. Several complications, such as early degradation, epithelial down-growth along the material, and premature loss of the material, have been reported. The varying results are probably due to differences in the properties of the material and the handling of the material at the time of implantation. Although probably very minimal, there is a risk that infectious agents from animal products can be transmitted to humans, and autoimmunization has also been mentioned as a risk.

Barrier materials of polylactic acid or co-polymers of polylactic acid and polyglycolic acid were evaluated in animal and human studies and are now commonly used (Magnusson *et al*. 1988; Caffesse *et al*. 1994; Caton *et al*. 1994; Gottlow *et al*. 1994; Laurell *et al*. 1994; Hugoson *et al*. 1995; Polson *et al*. 1995a; Cortellini *et al*. 1996c; Hürzeler *et al*. 1997; Sculean *et al*. 1999a; Tonetti et al 1998; Cortellini *et al*. 2001). These materials are biocompatible, but by definition they are not inert since some tissue reaction may be expected during degradation. The materials are degraded by hydrolysis and eliminated from the organism through the Krebs cycle as carbon dioxide and water (Tatakis *et al*. 1999).

The types of barrier materials that have been tested differ both in configuration and design. It appears that a number of bioresorbable materials meet to a varying extent the requirements of a good barrier listed above. Indeed, there are several studies (Hugoson *et al*. 1995; Cortellini *et al*. 1996b; Smith MacDonald *et al*. 1998; Tonetti *et al*. 1998; Cortellini & Tonetti 2000a, 2005) indicating that similar satisfactory results can be obtained with bioresorbable barrier materials of polylactic and polyglycolic acid as with non-bioresorbable materials.

Membranes for intrabony defects

Early evidence that GTR treatment of deep intrabony defects may produce clinical improvements in terms of CAL was presented in several case reports (Nyman *et al*. 1982; Gottlow *et al*. 1986; Becker *et al*. 1988; Schallhorn & McClain 1988; Cortellini *et al*. 1990). In recent years, a considerable number of clinical investigations have reported on intrabony defects treated with GTR (see Table 43-2). In these studies, the issue of evaluating the predictability of the clinical outcomes following application of GTR procedures was addressed. Table 43-4 gives the results for a total of 1283 intrabony defects treated with GTR. The weighted mean of the reported results indicates a mean CAL gain of 3.8 ± 1.7 mm, with a 95% CI of 3.7–4.0 mm (Cortellini & Tonetti 2000a). The reported CAL gains following GTR treatment were significantly larger than those obtained with conventional flap surgery. A review 40 studies on flap surgery with a weighted mean of 1172 defects reported CAL gains of 1.8 ± 1.4 mm (95% CI of 1.6–1.9 mm) (Lang 2000). A more recent review and meta-analysis of 27 trials on access flap surgery included 647 subjects and 734 defects (Graziani *et al*. 2011). Twelve months after flap surgery, tooth survival was 98% (IQ 96.77–100%), CAL gain was 1.65 mm (95% CI 1.37–1.94; P <0.0001), PPD reduction was 2.80 mm (CI 2.43–3.18; P <0.0001), and recession (REC) increase 1.26 mm (CI 0.94–1.49; P <0.0001).

Different types of non-bioresorbable (Fig. 45-36) and bioresorbable (Fig. 45-37) barrier materials were used in the clinical studies summarized in Table 45-4. Analysis of the results reported in some of the published studies (Proestakis *et al*. 1992; Cortellini *et al*. 1993a; Cortellini & Pini-Prato 1994; Laurell *et al*. 1994; Cortellini *et al*. 1995b, c; Mattson *et al*. 1995; Mellado *et al*. 1995; Cortellini *et al*. 1996b; Tonetti *et al*. 1996b) provides important information regarding the predictability of GTR in intrabony defects. CAL gains of 2–3 mm were observed in 29.2% of the defects, of 4–5 mm in 35.4% of the defects, and of ≥6 mm in 24.9% of the defects. Only in 10.5% of the treated defects was the gain <2 mm, while no change or attachment loss was observed in two cases.

In some of the investigations, changes in bone levels were also reported (Becker *et al*. 1988; Handelsman *et al*. 1991; Kersten *et al*. 1992; Cortellini *et al*. 1993a, b; Selvig *et al*. 1993). Bone gains ranged between 1.1 and 4.3 mm and correlated with the reported CAL gains. In a study by Tonetti *et al*. (1993b), 1 year after GTR the bone was found to be located 1.5 mm apically to the position of the attained CAL.

Another important parameter related to the outcome of regenerative procedures is the residual pocket depth. In the studies in Table 45-4, shallow pockets were consistently found at 1 year. The weighted mean residual pocket depth was 3.4 ± 1.2 mm (95% CI 2.3–3.5 mm).

The reported outcomes indicate that GTR procedures predictably result in clinical improvements in intrabony defects beyond those of flap surgery (see Fig. 45-6). This was further confirmed in 11 controlled randomized clinical trials in which GTR was compared with conventional flap surgery (Table 45-5). A total of 267 defects were treated with flap surgery and 317 with GTR. In nine of the 11 investigations, GTR resulted in a statistically significantly greater PAL gain when compared to flap surgery. Similar results were also observed for residual pocket depth.

Membranes for furcation involvement

The invasion of the furcation area of multirooted teeth by periodontitis represents a serious complication in periodontal therapy. The furcation area is often inaccessible to adequate instrumentation, and the roots frequently present concavities and furrows which make proper cleaning of the area impossible (see Chapter 40). As long as the pathologic process only extends a small distance (<5 mm; class I and II involvements) into the furcation area, further progress of the disease can usually be prevented by scaling and root planing, provided a proper oral hygiene program is established after treatment. In more advanced cases (5–6 mm; class II involvements), the initial cause-related treatment is frequently supplemented with surgery involving contouring of the inter-radicular bone (osteoplasty) or reduction of the tooth prominence at the furcation entrance by grinding (odontoplasty), in order to reduce the horizontal extension of the furcation involvement. In cases where the involvement extends even deeper into the furcation area (>5mm; class II involvements), or a through-and-through defect (class III involvements) has developed, tunnel preparation or root resection has been advocated as the treatment of choice. However, both of these treatments run a risk of complications on a long-term basis. Following tunnel preparation, caries frequently develops in the furcation area and root-resected teeth often present complications of a non-periodontal nature, although controversial reports exist regarding the long-term results of these treatment modalities (Hamp *et al*. 1975; Langer *et al*. 1981; Erpenstein 1983; Bühler 1988; Little *et al*. 1995; Carnevale *et al*. 1998).

Considering the complexity of current techniques for the treatment of furcation problems, and in view of the long-term results and complications reported following treatment of advanced furcation involvements by traditional resective therapy, predictable regeneration of the periodontium at furcation-involved sites would represent considerable progress in periodontics.

Mandibular class II furcations

Pontoriero *et al*. (1988) reported a controlled randomized clinical trial in which significantly greater H-CAL gain (3.8 ± 1.2 mm) were obtained in 21 mandibular class II furcations treated with e-PTFE

membranes compared to those in a control group treated with OFD alone (H-CAL gain of 2.0 ± 1.2 mm). Complete closure of the furcation was observed at 67% of the test sites and at only 10% of the control sites. Results from later studies, however, have not been as promising (Becker *et al*. 1988; Lekovic *et al*. 1989; Caffesse *et al*. 1990). Analysis of a series of studies published between 1988 and 1996 demonstrates a great variability in the clinical outcomes (Figs. 45-38, 45-39). Table 45-6 summarizes the outcomes of 21 clinical trials in which a total of 423 mandibular class II furcations were treated with different types of non-bioresorbable and bioresorbable barrier membranes. The weighted mean of the reported results showed an H-CAL gain of 2.3 ± 1.4 mm (95% CI 2.0–2.5 mm) in defects with a baseline horizontal PPD of 5.4 ± 1.3 mm. The reported number of complete furcation closures after GTR ranged from 0% to 67%. In three studies none of the treated furcations was closed (Becker *et al*. 1988; Yukna 1992; Polson *et al*. 1995b), in seven studies <50% were closed (Schallhorn & McClain 1988; Blumenthal 1993; Bouchard *et al*. 1993; Parashis & Mitsis 1993; Laurell *et al*. 1994; Mellonig *et al*. 1994; Hugoson *et al*. 1995), and in only one study were >50% of the treated furcations completely resolved (Pontoriero *et al*. 1988).

A subset analysis of the studies reported in Table 45-6 indicated that furcations treated with non-bioresorbable barrier membranes (287) showed a gain in H-CAL of 1.8 ± 1.4 mm (95% CI 1.5–2.1 mm) as compared with 2.3 ± 1.2 mm (95% CI 2–2.6 mm) in 174 defects treated with bioresorbable barrier membranes. Five controlled clinical trials compared treatment with non-bioresorbable e-PTFE membranes and treatment with different types of bioresorbable membranes (Table 45-7). In particular, one investigation reported significantly greater H-CAL gain in the non-bioresorbable group (Bouchard *et al*. 1993), while another trial (Hugoson *et al*. 1995) showed a significantly greater H-CAL gain in the bioresorbable group. The remaining three investigations failed to detect any significant differences between the outcomes of treatment with bioresorbable or non-bioresorbable membranes. Generally, the results indicate that the predictability of GTR in the treatment of mandibular class II furcations is questionable if the treatment objective is the complete resolution of the furcation involvement.

Significant gain in V-CAL and reduction in PPD was also reported by several investigators following treatment of mandibular class II furcation defects (Pontoriero *et al*. 1988; Lekovic *et al*. 1989, 1990; Blumenthal 1993; Machtei *et al*. 1993; Black *et al*. 1994; Laurell *et al*. 1994; Machtei *et al*. 1994; Mellonig *et al*. 1994; Wang *et al*. 1994; Hugoson *et al*. 1995; Polson *et al*. 1995b). The reported mean values ranged from

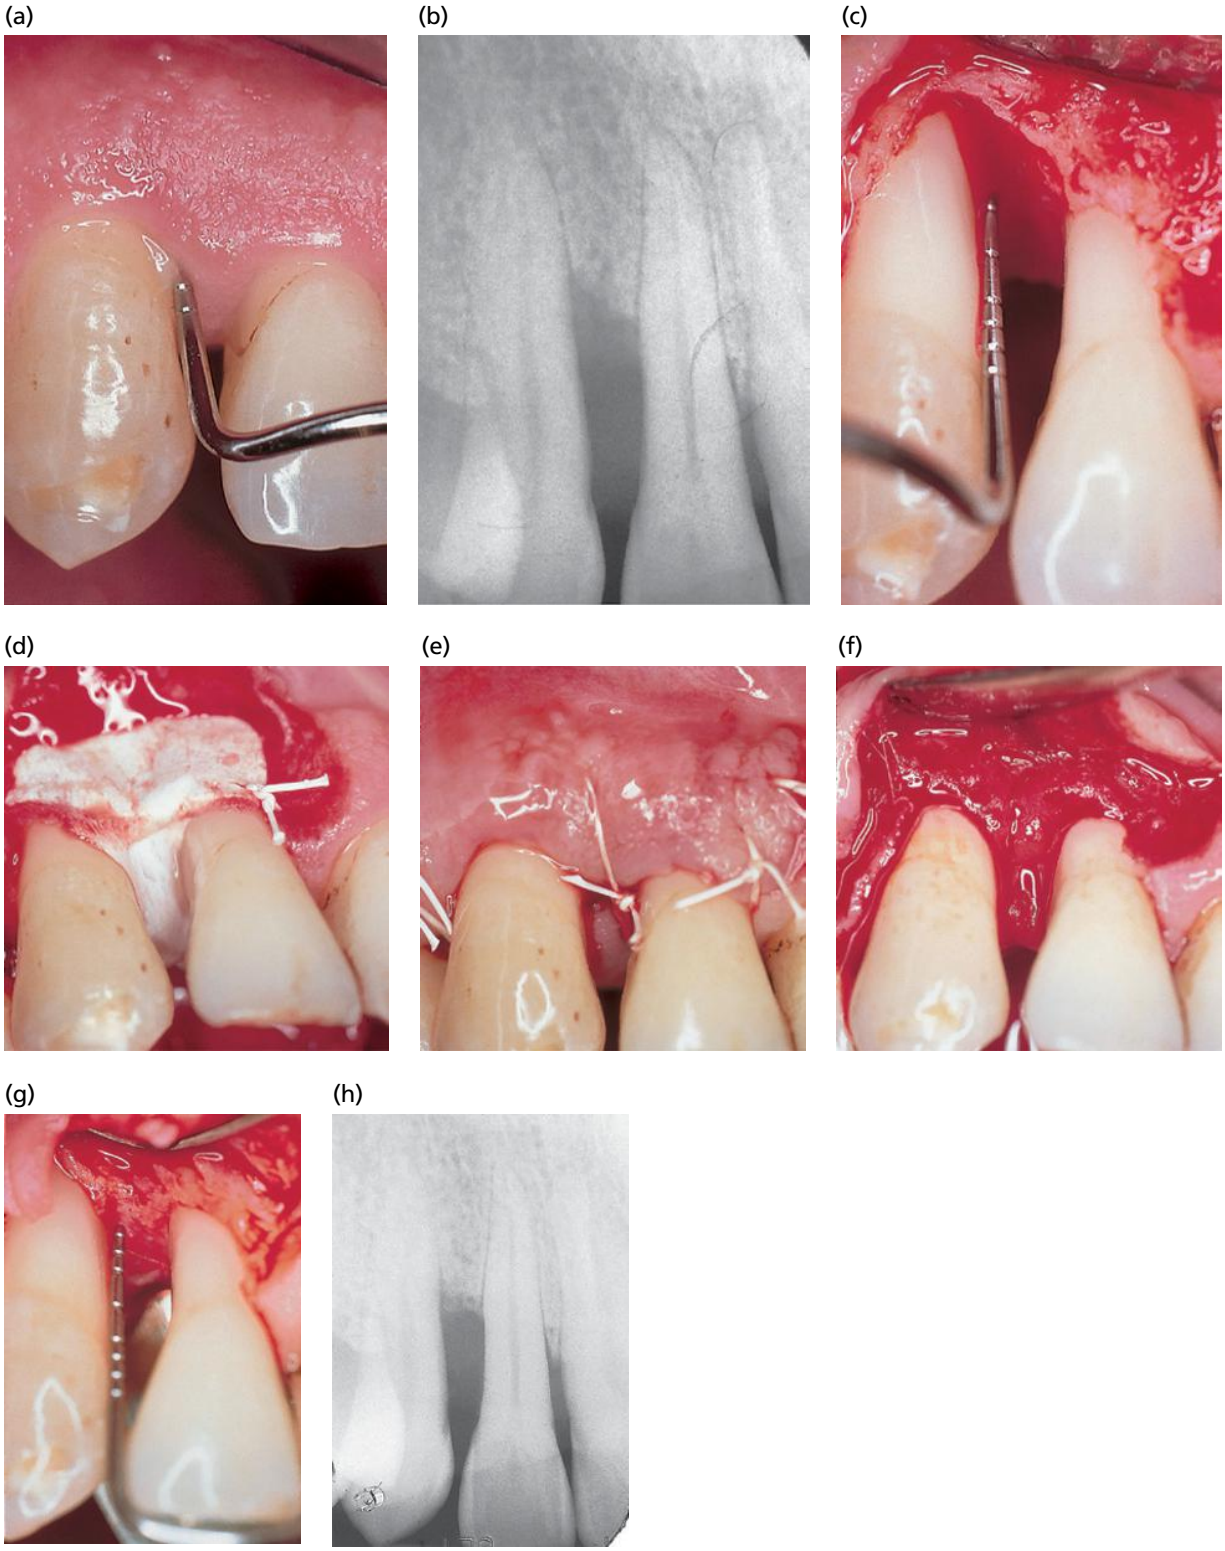

Fig. 45-36 Intrabony defect on the mesial aspect of a right maxillary canine treated with a non-bioresorbable barrier membrane. (a) Pocket depth was 9 mm and loss of clinical attachment was 10 mm. (b) Radiograph showing the presence of an interproximal intrabony defect. (c) After full-thickness flap elevation, defect debridement, and root planing, a 4-mm intrabony defect was evident. (d) An e-PTFE non-bioresorbable barrier membrane was tailored, positioned, and tightly sutured around the teeth adjacent to the defect. (e) Flap was repositioned and sutured to cover the membrane. Optimal preservation of the soft tissues was accomplished with an intrasulcular incision. (f) After removal of the membrane at 5 weeks, the defect appeared to be completely filled with newly formed tissue. (g) Treated site was surgically re-entered after 1 year. The intrabony defect was completely filled with bone. (h) One-year radiograph confirmed the complete resolution of the intrabony defect.

0.1 mm to 3.5 mm for V-CAL gain and from 1 mm to 4 mm for PPD reduction.

The effect of using barrier membranes for the treatment of mandibular class II furcations was investigated in six controlled randomized clinical trials in which GTR procedures were directly compared to flap surgery (Table 45-8). Sixty-six furcations treated with flap surgery and 87 treated with GTR

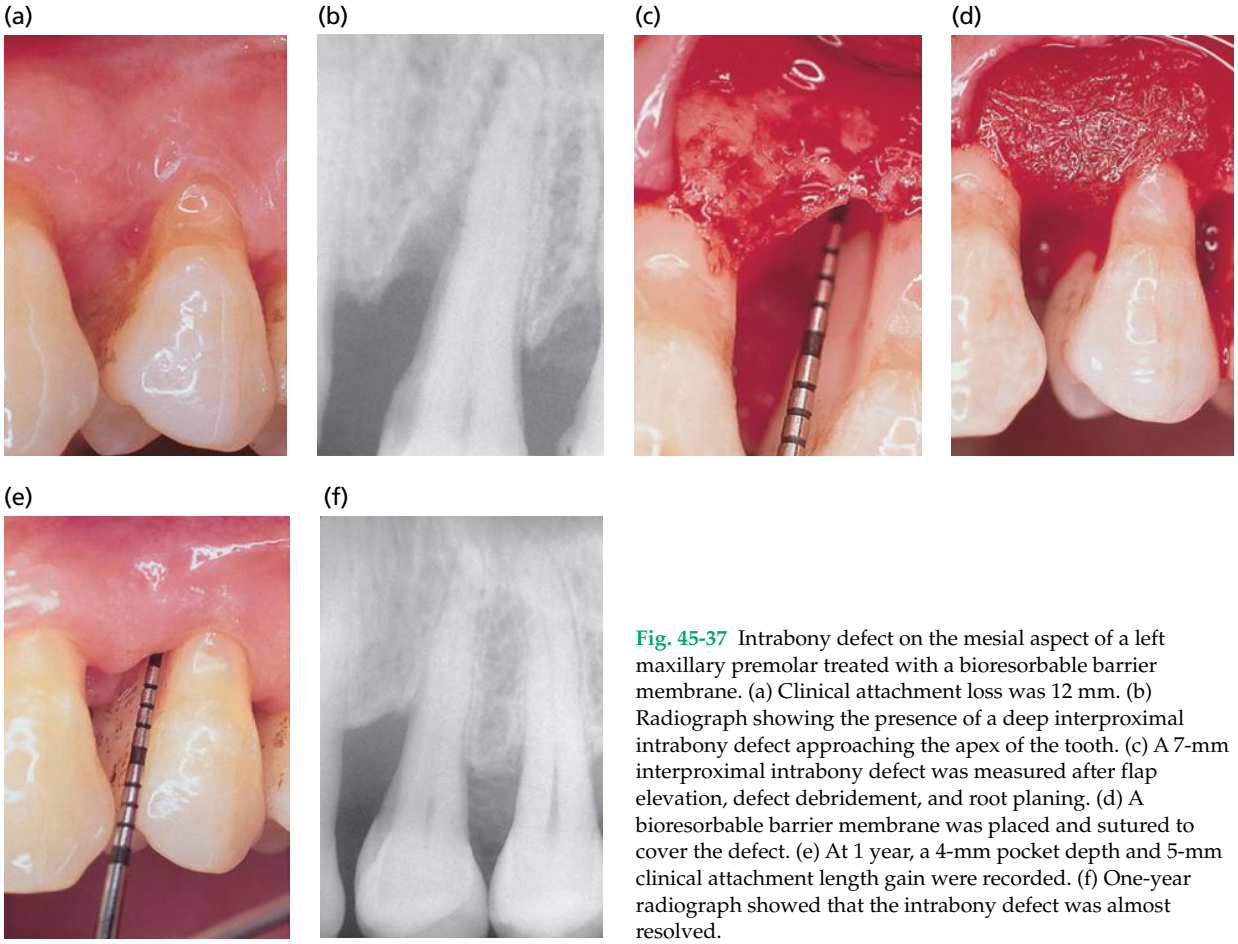

Fig. 45-37 Intrabony defect on the mesial aspect of a left maxillary premolar treated with a bioresorbable barrier membrane. (a) Clinical attachment loss was 12 mm. (b) Radiograph showing the presence of a deep interproximal intrabony defect approaching the apex of the tooth. (c) A 7-mm interproximal intrabony defect was measured after flap elevation, defect debridement, and root planing. (d) A bioresorbable barrier membrane was placed and sutured to cover the defect. (e) At 1 year, a 4-mm pocket depth and 5-mm clinical attachment length gain were recorded. (f) One-year radiograph showed that the intrabony defect was almost resolved.

were included. Three of the four studies reporting H-CAL gains concluded that GTR resulted in statistically significantly greater H-CAL gains than flap surgery (Pontoriero *et al*. 1988; Van Swol *et al*. 1993; Wang *et al*. 1994). The weighted mean of the results of these studies for H-CAL gain in furcations treated with GTR was 2.5 ± 1 mm (95% CI 2.1–2.9 mm), and 1.3 ± 1 mm (95% CI 0.8–1.8 mm) for furcations treated with flap surgery. These results indicate an added benefit from GTR in the treatment of mandibular class II furcations.

Maxillary class II furcations

Results reported in three controlled studies (Metzeler *et al*. 1991; Mellonig *et al*. 1994; Pontoriero & Lindhe 1995a) comparing GTR treatment of maxillary class II furcations with non-bioresorbable e-PTFE membranes and with OFD indicated that GTR treatment of such defects is generally unpredictable. In a study including 17 pairs of class II furcations, Metzeler *et al*. (1991) measured CAL gains of 1.0 ± 0.9 mm in the GTR-treated sites versus 0.2 ± 0.6 mm in the control sites. Following re-entry, horizontal PAL gains (H-OPAL) of 0.9 ± 0.4 mm and 0.3 ± 0.6 mm were detected in the GTR- and flap-treated furcations, respectively. None of the furcations of the two groups was completely resolved. Similarly, Mellonig *et al*. (1994) treated eight pairs of maxillary class II furcations and reported H-OPAL gains of 1.0 mm (GTR sites) and 0.3 mm (flap-treated sites). Again, none of the treated furcations in the two groups was completely closed. On the other hand, in a study of 28 maxillary class II furcations, Pontoriero and Lindhe (1995a) found a significant gain in CAL (1.5 mm) and horizontal bone (1.1 mm) in buccal class II furcations. Although these three investigations show a slight clinical improvement following treatment of class II maxillary furcations with GTR, the results are generally inconsistent.

Class III furcations

Four investigations of the treatment of mandibular class III furcations (Becker *et al*. 1988; Pontoriero *et al*. 1989; Cortellini *et al*. 1990; Pontoriero & Lindhe 1995b) indicate that the treatment of such defects with GTR is unpredictable. A controlled study by Pontoriero *et al*. (1989) showed that only eight of 21 "through-and-through" mandibular furcations treated with non-bioresorbable barrier membranes healed with complete closure of the defect. Another ten defects were partially filled and three remained open. In the OFD-treated control group, 10 were partially filled and 11 remained open. Similar results were reported by Cortellini *et al*. (1990) who, in a case cohort of 15 class III mandibular furcations, found that 33% of the defects had healed completely, 33% were partially

CAL, clinical attachment level; e-PTFE, expanded polytetrafluoroethylene; PPD, probing pocket depth; SD, standard deviation.

closed, and 33% were still through-and-through following treatment. Becker *et al*. (1988) did not observe complete closure of any of 11 treated class III mandibular furcations. Similarly, in a controlled clinical trial by Pontoriero and Lindhe (1995b) of 11 pairs of maxillary class III furcations randomly assigned to GTR or flap surgery, none of the furcation defects was closed.

Conclusion: Based on current evidence, it seems that mandibular class II furcations in the first or second molars, either buccal or lingual, with deep pockets at baseline and a gingival thickness of >1 mm, may benefit from GTR treatment.

Bone replacement grafts

Grafts for intrabony defects

BRGs comprise a heterogeneous group of materials of human (autologous or allogeneic), animal or synthetic origin. Some consist of bone or exoskeletal minerals; others contain mainly bone matrix. There is evidence for periodontal regeneration for only a few of these materials. A randomized controlled clinical trial provided histologic support that the healing outcome following application of DFDBA in intrabony defects has a regenerative component in the apical to middle portion of the depth of the defect (Bowers *et al*. 1989a–c). Isolated evidence also supports the fact that allograft and bovine bone mineral may yield a regenerative outcome when used alone [i.e. without other regenerative materials such as barrier membranes or biologically active regenerative materials (BARGs); see also Chapter 28] (Nevins *et al*. 2000).

BRGs were the first periodontal regenerative materials to be applied clinically. Today they are widely used in North America as DFDBAs and are frequently used in combination with other regenerative materials (GTR and/or BARG). Biologic principles supporting the use of *autologous and heterologous grafts* include osteoconductivity and osteoinductivity, but also their capacity for space provision and blood clot stabilization (Rosen *et al*. 2000; Trombelli & Farina 2008).

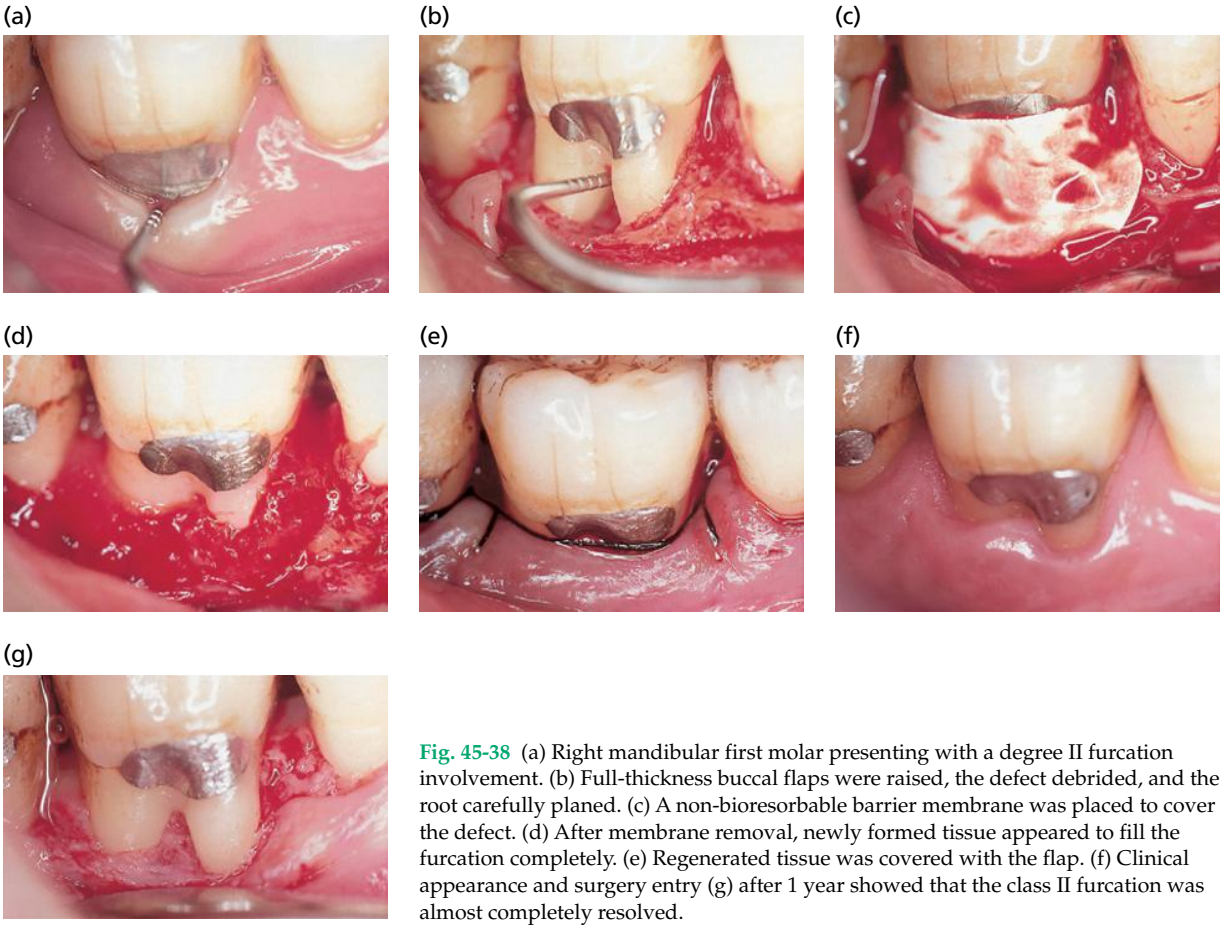

Fig. 45-38 (a) Right mandibular first molar presenting with a degree II furcation involvement. (b) Full-thickness buccal flaps were raised, the defect debrided, and the root carefully planed. (c) A non-bioresorbable barrier membrane was placed to cover the defect. (d) After membrane removal, newly formed tissue appeared to fill the furcation completely. (e) Regenerated tissue was covered with the flap. (f) Clinical appearance and surgery entry (g) after 1 year showed that the class II furcation was almost completely resolved.

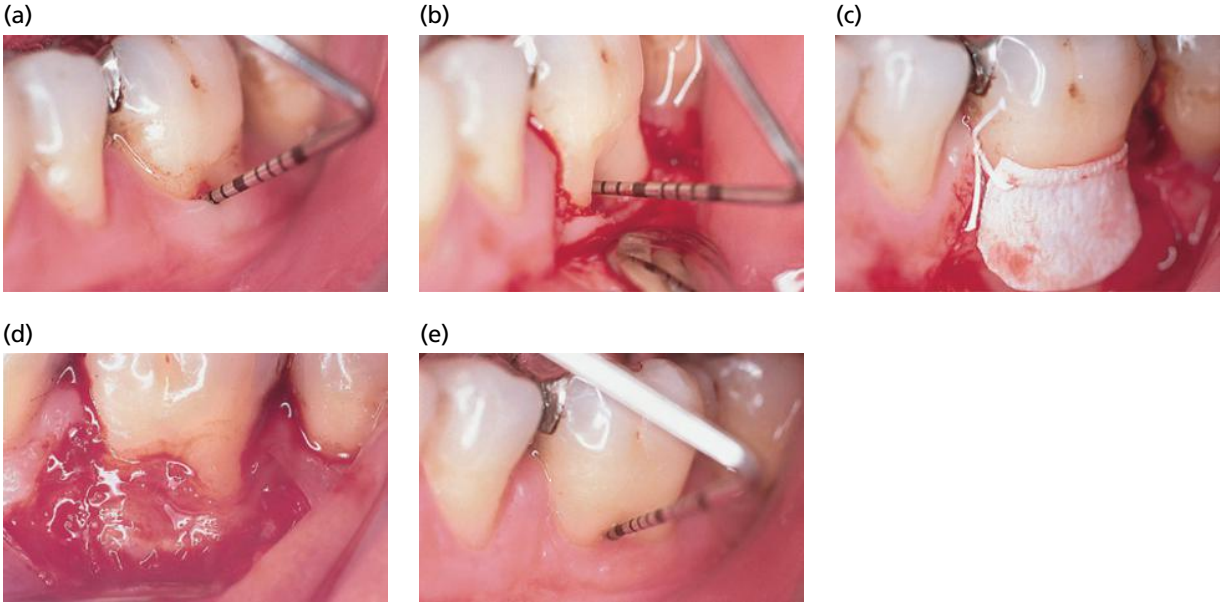

Fig. 45-39 (a) Left mandibular first molar presenting with a deep class II furcation involvement. (b) Horizontal loss of tooth support of 7 mm was probed. (c) An e-PTFE barrier membrane was trimmed and sutured to cover the furcation. (d) At membrane removal after 5 weeks, newly formed tissue filled the furcation completely. (e) At 1 year, a 3-mm gain of tooth support was measured, but a residual 4-mm class II furcation involvement was still present.

The clinical efficacy of allografts in terms of bone fill and CAL gain is supported by a meta-analysis of 27 controlled studies indicating that additional bone fill of 1 mm and additional CAL gain of 0.4 mm were observed (see Fig 45-8) (Reynolds *et al*. 2003). The total number of defects contributing to this meta-analysis however was relatively small (136 for CAL gain and 154 for bone fill). Furthermore, no large-scale multicenter trial has ever been performed and hence the

applicability of these results to clinical practice settings remains to be established.

BRGs can be applied alone following elevation of a papilla preservation flap for the treatment of intrabony defects. The graft is applied to overfill the defect to compensate for an expected degree of shedding of the graft in cases of imperfect containment of the graft by the closed flap. A study has suggested using BRGs in combination with an antibiotic powder to enhance control of the bacterial contamination of the surgical wound (Yukna & Sepe 1982). This study reported improved outcomes from mixing the graft with tetracycline powder. DFDBAs have been successfully used along with minimally invasive surgery (Harrel 1999).

Grafts for furcation involvement

A series of controlled clinical trials has evaluated the clinical performances of BRGs in the flap approach to the treatment of furcation defects. Reynolds *et al*. (2003) in their review found an overall PPD reduction ranging from 1.9 mm to 2.31 mm in class II furcations treated with BRGs, compared to 0–1.8 mm for those

treated with OFD alone. For class III defects, BRGs produced a PPD change of 0.7–2.6 mm, as compared –1–2.6 mm in the controls. CAL changes were similar for mandibular class II and III furcations, ranging from 1.5 to 2.5 mm for grafted sites compared to 0–1.5 mm for the flap controls. The authors concluded that the results of these studies suggest that BRGs alone add relatively modest clinical benefit in the treatment of class II and III furcations, especially if complete closure of the furcation is the desired end point of treatment. More recently, Tsao *et al*. (2006b) tested a solvent-preserved, mineralized human cancellous bone allograft (MBA) with or without a collagen membrane in the treatment of 27 mandibular class II furcations. Their results indicated that solvent-preserved MBA, with or without a collagen membrane, can significantly improve bone fill in mandibular class II furcation defects.

Biologically active regenerative materials

Preclinical and clinical evidence for the use of BARGs has been reviewed (see also Chapter 28). The adoption of *biologic products/compounds* is based on their ability to induce or accelerate the processes of matrix formation and cell differentiation (Bosshardt 2008). These products promote the healing process, but lack mechanical properties to aid space provision and blood clot stabilization. Some of these, therefore, are

loaded on solid, bioresorbable carriers to add some mechanical properties (Palmer & Cortellini 2008; Trombelli & Farina 2008). Currently, preparations based on growth factors or amelogenins are available for use in periodontal regeneration. Significant preclinical evidence supports the positive effect of both on periodontal wound healing and regeneration (Howell *et al*. 1997; Bosshardt 2008).

Growth factors for intrabony defects

Support for the clinical use of growth factors comes from two multicenter studies on recombinant human-derived growth factor (Nevins *et al*. 2005; Jayakumar *et al*. 2011) and two on fibroblast growth factor-2 (FGF-2) (Kitamura *et al*. 2008, 2011). Nevins *et al*. (2005) treated 180 defects comprising both intrabony and furcation defects with one of two concentrations of PDGF (0.3 mg/mL and 1.0 mg/mL) combined with the β-TCPdelivery device or TCP alone. Results were assessed at 3 and 6 months and included both clinical and radiographic assessments. CAL gains at 6 months failed to demonstrate a significant benefit for either concentration of PDGF compared to the BRG alone. With regards to radiographic assessments, however, the lower tested concentration of PDGF resulted in significantly higher percentages of bone fill of the defect (57% versus 18%) and linear bone growth (2.6 mm versus 0.9 mm). The results of this study led to the approval of this material by the US Food and Drug Administration. The authors interpreted the dichotomy between the reported added benefit in terms of radiographic parameters and the lack of significant changes in CAL as the result of the biologic action of the growth factor formulation in shortening the healing time of the hard tissues.

In the Jayakumar *et al.* study (2011), 54 patients were treated with rhPDGF-BB1b combined with the β-TCP delivery device or tricalcium phosphate alone. CAL gain, bone growth, and percent bone fill at 6 months were significantly greater in the test group as compared to the TCP control group.

The study of 74 patients by Kitamura *et al*. (2008) compared three different concentrations of a FGF-2 vehicle with 3% hydroxypropylcellulose (HPC) to HCP alone. No difference was reported in terms of CAL gain between the test and control groups. However, a significant difference in terms of bone gain was reported in favor of the 0.3% concentration of FGF-2 as compared to HCP alone. The other two concentrations (0.03% and 0.1%) did not show any advantage in terms of bone gain. A second randomized, double-blind, placebo-controlled clinical trial on 253 adult patients compared 0.2%, 0.3%, or 0.4% FGF-2 to vehicle alone in two- or three-walled vertical bone defects (Kitamura *et al*. 2011). Each dose of FGF-2 showed significant superiority over vehicle alone (P <0.01) for the percentage of bone fill at 36 weeks after administration. No significant differences were observed between the groups in CAL gain.

No clinical safety problems were reported in any of the four cited studies.

Drawing conclusions from the four studies, it is apparent that both the tested growth factors resulted into a measurable added benefit compared to controls in terms of bone gain, while three of the four studies did not reach a significant difference in terms of CAL gain. Both efficacy and effectiveness of rhPDGF-BB1b and FGF-2 have to be further explored for use in private settings.

A recent controlled study evaluated clinical and histologic wound healing/regeneration following surgical implantation of recombinant human growth/differentiation factor-5 (rhGDF-5) adsorbed onto a particulate β-TCP carrier (rhGDF-5/b-TCP) into periodontal defects in 28 patients (Stavropoulos *et al*. 2011). Control defects were treated with OFD alone. The authors reported greater PPD reduction, CAL gain, alveolar bone regeneration, and periodontal regeneration at sites that received rhGDF-5/β-TCP compared to control sites. However, these differences were not statistically significant. Block biopsies of the defect sites were collected at 6 months post surgery. Histologically, bone regeneration height was almost three-fold greater for the rhGDF-5/β-TCP treatment compared with OFD alone (2.19 ± 1.59 mm versus 0.81 ± 1.02 mm; $P = 0.08$). Similarly, an almost two-fold increase was observed for periodontal ligament (2.16 ± 1.43 mm versus 1.23 ± 1.07 mm; $P = 0.26$), cementum (2.16 ± 1.43 mm versus 1.23 ± 1.07 mm; $P = 0.26$), and bone regeneration area (0.74 ± 0.69 mm^2 versus 0.32 ± 0.47 mm^2; $P = 0.14$). Root resorption/ankylosis was not observed. Future studies with larger sample sizes need to be conducted to verify these findings.

Growth factors for furcation involvement

A human clinical trial (Camelo *et al*. 2003) was designed to evaluate the clinical and histologic response to rhPDGF-BB delivered in bone allograft for the treatment of advanced class II furcation defects. Three mandibular and one maxillary molar furcation defects were treated: two received 0.5 mg/mL and two 1.0 mg/mL of rhPDGF-BB, in all cases mixed with DFDBA. Both concentrations of rhPDGF-BB resulted in substantially improved horizontal (mean 3.5 mm) and vertical (mean 4.25 mm) probing depths and attachment levels (mean 3.75 mm). Histologic evaluation revealed periodontal regeneration, including new bone, cementum, and periodontal ligament coronal to the reference notch. This study documented the favorable tissue response to rhPDGF-BB treatment at both the clinical and microscopic levels, and demonstrated that periodontal regeneration can be achieved in advanced class II furcation defects using a combination of purified recombinant growth factor and bone allograft. These outcomes were confirmed by a second study of 15 sites presenting with class II furcations in which the PDGF was

loaded on DFDBA (Nevins *et al*. 2003), and in another study of four class III furcations in which the growth factor was loaded on TCP (Mellonig *et al*. 2009).

Promising histologic and clinical outcomes can be envisioned from these pilot studies. However, larger controlled clinical trials are needed to assess the real potential of growth factors in the treatment of teeth with furcation involvement.

Enamel matrix derivatives for intrabony defects

EMDs have been in clinical use for >10 years and its clinical efficacy is very well established. The benefit of use of EMD gel in the treatment of intrabony defects is supported by human histologic evidence, case report studies, meta-analysis of randomized controlled clinical trials, and a large multicenter trial (Heijl *et al*. 1997; Heden *et al*. 1999; Sculean *et al*. 1999b; Silvestri *et al*. 2000; Heden 2000; Tonetti *et al*. 2002; Giannobile & Somerman 2003; Heden & Wennström 2006) (Figs. 45-26, 45-27, 45-40). The prospective multicenter randomized controlled clinical trial (Tonetti *et al*. 2002) was designed to compare the clinical outcomes of papilla preservation flap surgery with or without the application of EMDs in 172 patients with advanced chronic periodontitis in 12 centers in seven countries. All patients had at least one intrabony defect of 3 mm or deeper. Heavy smokers (>20 cigarettes/day) were excluded. The surgical procedures included access for root instrumentation using either the SPPF or the MPPT in order to obtain optimal tissue adaptation and primary closure. After debridement, roots were conditioned for 2 minutes with a gel containing 24% EDTA. EMDs were applied to the test subjects and omitted in the controls. A total of 166 patients were available for the 1-year follow-up. On average, the test defects gained 3.1 ± 1.5 mm of CAL, while the control defects yielded a significantly lower CAL gain of 2.5 ± 1.5 mm. Pocket reduction was also significantly higher in the test group (3.9 ± 1.7 mm) compared to the controls (3.3 ± 1.7 mm). A multivariate analysis indicated that the treatment, the clinical centers, cigarette smoking, baseline PPD, and defect corticalization significantly influenced CAL gain. A frequency distribution analysis of the studied outcomes indicated that EMDs increased the predictability of clinically significant results (CAL gain >4 mm) and decreased the probability of obtaining negligible or no gain in CAL (CAL gain <2 mm). The results of this trial indicated that regenerative periodontal surgery with EMDs offers an additional benefit in terms of CAL gain, PPD reduction, and predictability of outcomes over papilla preservation flaps alone.

A secondary analysis of the multicenter trial has shown that, in intrabony defects, the added benefit of EMDs was greater in three-wall defects than in one-wall defects (Tonetti *et al*. 2002). Furthermore, another secondary analysis of the trial, but this time assessing the effect of the radiographic angle of the defect angle on the outcome (Tsitoura *et al*. 2004), uncovered a negative association between this angle and the CAL gain observed at 1 year. These data have questioned the suitability of the gel formulation of EMDs for the treatment of defects with a non-supporting anatomy (wide defects with missing bony walls) and spurred considerable research interest in the incorporation of EMDs into a variety of BRGs in order to enhance

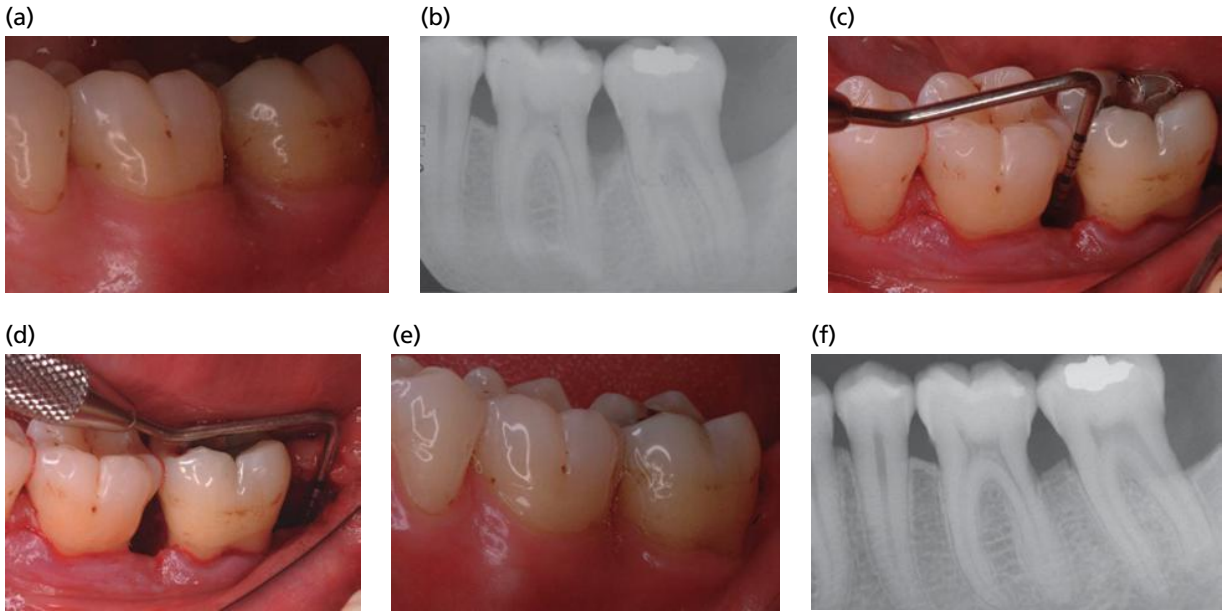

Fig. 45-40 Clinical case illustrating the use of enamel matrix derivatives (EMDs) to regenerate defects located on two adjacent teeth. At re-evaluation, deep pockets associated with deep intrabony defects were evident on the distal aspect of the first and second molars (a, b). Defects were accessed with the modified papilla preservation technique (MPPT) on the distal aspect of the first molar and with the use of a crestal incision in the retromolar area (c, d). Deep defects were exposed following debridement and root instrumentation (c, d). Following application of EMDs in gel form, primary closure was obtained with multilayered sutures. At 1-year follow-up, shallow probing depths associated with the elimination of the defects were observed (e, f).

wound stability and space maintenance. At this stage, however, no systematic evidence is available to support the use of such combinations.

More recently, EMDs have been successfully used in combination with minimally invasive techniques from MIS (Harrel et al 2005), to MIST (Cortellini & Tonetti 2007a, b, Cortellini *et al*. 2008; Ribeiro *et al*. 2011a), and to M-MIST (Cortellini & Tonetti 2009a, 2011). This product is very well suited to sites where flap reflection is minimal since its positioning does not require any flap extension and the improved stability provided by minimally invasive surgery to the wound seems to favor the expression of its activity (Cortellini *et al*. 2008; Cortellini & Tonetti 2009a).

Clinically, the rate of wound healing following application of EMDs seems to be enhanced. A study looking at soft tissue density in the surgical site by using underexposed radiographs (Tonetti *et al*. 2004b) found that the rate of increase in density following application of EMDs may be faster than in the access flap control. Such modulation has been interpreted as the outcome of the local release of growth and differentiation factors by the cells involved in local wound healing. Given their hydrophobic nature, enamel matrix proteins for clinical use are mixed in a gel carrier at low pH. Following an increase in pH in the periodontal wound and rapid elimination of the gel, enamel matrix proteins (consisting mainly of EMDs) are deposited in the wound environment and the root surface. While the mechanism(s) of action of EMDs are not fully understood, significant evidence suggests that periodontal ligament cells exposed to EMDs switch their phenotype by increasing expression of a host of growth and differentiation factor-related genes (Brett *et al*. 2002; Parkar & Tonetti 2004), including transforming growth factor-beta (Lyngstadaas *et al*. 2001). A recent review (Bosshardt 2008) concluded that (1) EMDs increase the cell proliferation of periodontal ligament and gingival fibroblasts and cells of osteoblast and chondrocyte lineage; (2) EMDs have biologic effects on cells of the osteoblast lineage, including up-regulation of markers of bone formation; (3) specific small amelogenin polypeptides (5 kDa) have osteoinductive properties when tested in an ectopic bone-forming model; (4) the evidence does not demonstrate an inductive role for EMDs on cementogenesis.

Enamel matrix derivatives for furcation involvement

Treatment of mandibular class II furcations with EMDs was attempted by Jepsen *et al*. (2004). A randomized intraindividual study of 45 patients was designed to compare EMDs and bioresorbable barriers. Both treatment modalities led to a significant clinical improvement. The authors reported a median reduction of open furcation depth of 2.8 mm in the EMD-treated sites compared to a reduction of 1.8 mm in the barrier-treated sites. Complete furcation closure was recorded in eight of 45 EMD-treated sites and three of 45 barrier-treated sites. Differences between test and control sites were not statistically significant. Chitsazi *et al*. (2007) reported an H-CAL gain that was significantly greater in EMD-treated mandibular class II furcations than in OFD controls ($P = 0.002$).

Another randomized study (Casarin *et al*. 2008) compared the use of EMDs to open flap alone in 15 patients with contralateral proximal maxillary class II furcations. At 6 months, the V-CAL gains in the control and test groups were 0.39 ± 1.00 mm and 0.54 ± 0.95 mm, respectively, while the H-CAL gains were 1.21 ± 2.28 mm and 1.36 ±1.26 mm, respectively ($P = 0.05$). The vertical bone level and horizontal bone level gains of the control group were 1.04 ± 1.12 mm and 1.00 ± 1.79 mm, respectively, and of the test group were 0.82 ± 1.82 mm and 1.17 ± 1.38 mm, respectively ($P = 0.05$). However, a statistically significantly greater number of reduced/closed furcations was observed in the test group ($P = 0.05$). The authors concluded that the use of EMDs in proximal furcations does not promote a superior reduction in PPD or a gain in clinical and osseous attachment levels, but can result in a higher rate of conversion of class II to class I furcations.

Controversial outcomes have been so far observed in the treatment of class II either maxillary or mandibular furcations with EMDs. Their use seems however to provide an added benefit compared to flap treatment alone.

Combination therapy

Combination therapy for intrabony defects

Biologic principles supporting *combination therapy* relate to the possibility of obtaining an additive effect from combining different regenerative principles, including osteoconductivity and osteoinductivity, capacity for space provision and blood clot stabilization, and ability to induce or accelerate the processes of matrix formation and cell differentiation that are inherent in barriers, grafts, and bioactive substances.

Compromised results after GTR may be observed in cases where the gingival flap, eventually supported by a membrane, collapses/falls (partially or totally) into the defect and/or towards the root surface, thereby reducing the space available for blood clot formation and growth of new tissues capable of forming periodontal ligament and bone in particular. Reduced amounts of regenerated bone due to membrane collapse were noted in early studies of GTR. In the study of Gottlow *et al*. (1984), it was observed that collapse of the membrane towards the root surface resulted in new cementum formation on the entire exposed root surface, whereas bone regeneration was minimal. Although the authors reported that the degree of coronal regrowth of bone was unrelated to the amount of new cementum formation, they did

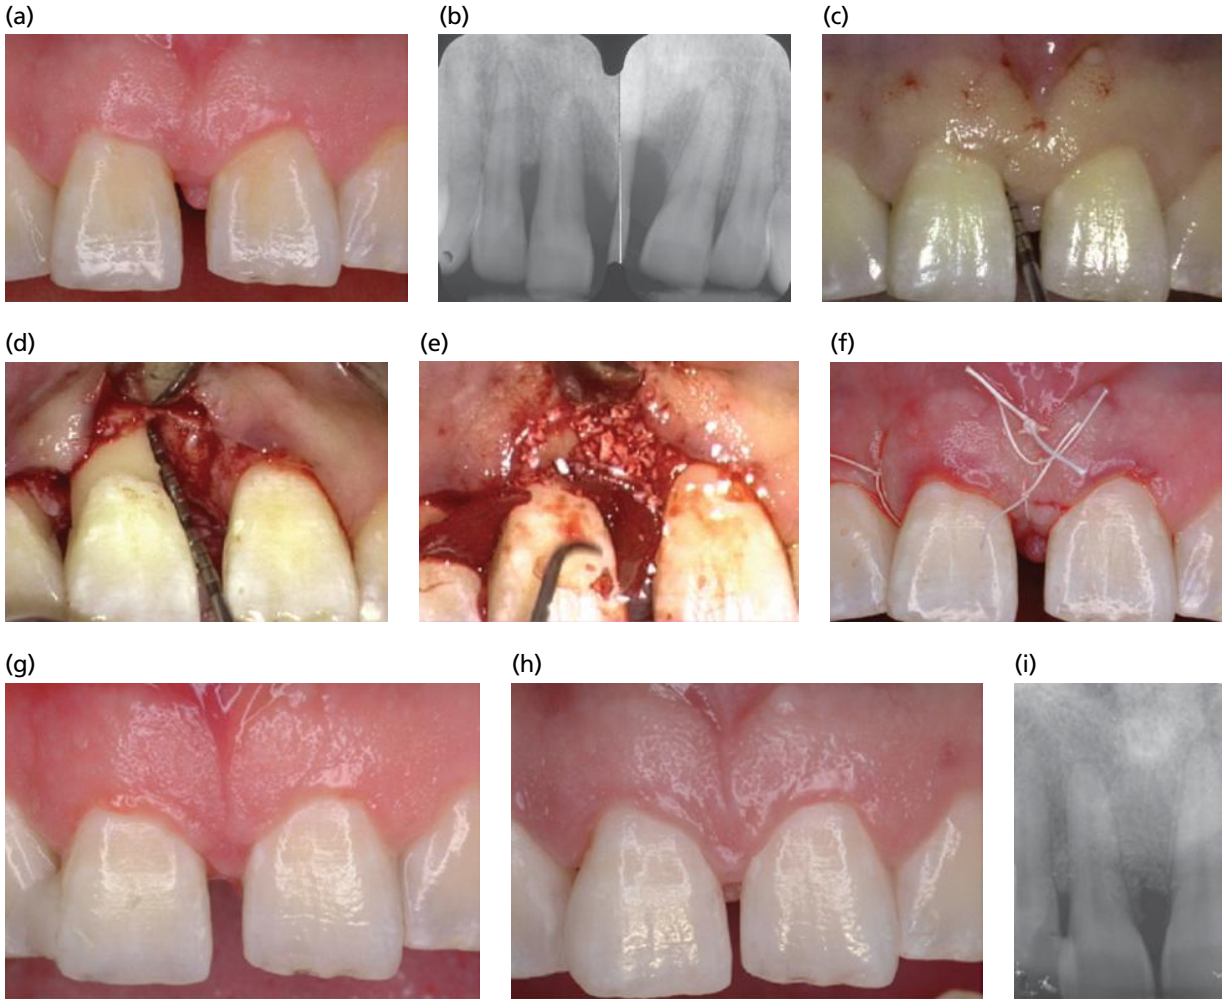

Fig. 45-41 Clinical case illustrating the application of a bone replacement graft (BRG) to support a bioresorbable membrane in a defect with poor space maintaining anatomy. Following control of periodontitis and risk factors, the upper right central incisor presented with a 12-mm deep pocket associated with a defect extending close to the apex of the tooth (a–c). The defect was accessed with the modified papilla preservation flap to reveal an 8-mm intrabony component (d). A BRG was placed under a bioresorbable collagen membrane (e). Primary closure was achieved with a multilayered suture technique (f). Excellent early healing was observed already at the 2-week follow-up (g). At 1 year, periodontal regeneration resulted in shallow probing depths and good resolution of the intrabony defect (h, i). Radio-opaque BRG particles were visible within the newly formed mineralized tissue.

not comment on what effect membrane collapse might have had. Experimental studies, however, recognized the negative effect of membrane collapse on periodontal regeneration generally and on bone formation in particular (Caton *et al*. 1992; Haney *et al*. 1993; Sigurdsson *et al*. 1994; Sallum *et al*. 1998). Haney *et al*. (1993) observed a highly significant correlation between the space provided by the membrane and the amount of regenerated alveolar bone in a supra-alveolar defect model in dogs. This finding corroborates that of Cortellini *et al*. (1995c) who reported that clinical application of self-supporting (reinforced with titanium) e-PTFE membranes, which could be positioned more coronally than ordinary e-PTFE membranes, yielded a statistically significant increase in PAL gain in intrabony defects. A particular risk for gingival flap/membrane collapse exists in cases where the configuration of the defect is incapable of supporting/preserving the membrane at the position where it was originally placed.

As already discussed, membrane materials must possess certain characteristics in order to be efficient. Among these, the membrane needs to be capable of keeping its shape and integral features, thereby maintaining the space created adjacent to the root surface. The e-PTFE membranes reinforced with titanium are the closest to meeting these requirements, but they have the disadvantage that they are non-bioresorbable. At present there are no bioresorbable membranes available that fulfil this requirement sufficiently, which means that the placement of a bioresorbable membrane on, for instance, a wide one-wall defect involves the risk of membrane collapse. The collapse may be prevented by implantation of a biomaterial into the defect to support the membrane so that it maintains its original position (Figs. 45-24, 45-41). While biologic products can enforce the healing process, they also lack mechanical properties to aid space provision and blood clot stabilization. A potential solution, therefore, could be to load the biologic

Table 45-9 Controlled clinical trials evaluating the combined effects of decalcified freeze-dried bone allografts (DFDBAs) and barrier membranes in deep intrabony defects.

products onto solid, bioresorbable carriers to provide the necessary mechanical properties (Palmer & Cortellini 2008; Trombelli & Farina 2008). However, the biomaterial to be used for this purpose must not interfere with the process of periodontal regeneration and ideally it should also promote bone regeneration.

As previously described, periodontal regeneration has been attempted with a variety of grafting materials, among which DFDBAs apparently facilitate regeneration in humans (Ouhayoun 1996). In three controlled clinical trials, the treatment of a total of 45 pairs of intrabony defects with DFDBA grafting and GTR was compared to GTR treatment alone (Table 45-9). The weighted mean of the results of the reported investigations showed similar gain in CAL in the GTR group (2.1 ± 1.1 mm; 95% CI 1.6–2.6 mm) and in the GTR + DFDBA group (2.3 ± 1.4 mm; 95% CI 1.7–2.9 mm). The differences between the two treatments did not reach statistical significance, thus indicating no added effect of combining DFDBAs with barrier materials in the treatment of intrabony defects. Guillemin *et al*. (1993) compared the effect of DFDBAs alone with a combination of barrier materials plus DFDBAs in 15 pairs of intrabony defects. Both treatments resulted in significant CAL gain and bone fill at 6 months, but no difference was found between the treatments. Reynolds *et al*. (2003), in their systematic review, highlighted that clinical improvements from graft/barrier combinations were often obtained in large non-space maintaining defects. They concluded that the combination of graft and barriers can provide a significant gain in CAL and PPD reduction and a non-significant increase in bone fill when compared to graft alone.

Promising clinical results with a PAL gain of 1.0–5.5 mm were obtained in human case reports in which the GTR technique was combined with grafting of Bio-Oss®, an anorganic bovine bone xenograft, for the treatment of intrabony periodontal defects (Lundgren & Slotte 1999; Mellonig 2000; Paolantonio *et al*. 2001). The combined use of Bio-Oss® and GTR treatment resulted in greater PPD reduction, PAL gain, and defect fill compared to implantation of Bio-Oss® alone in case series (Camelo *et al*. 1998) and to flap surgery alone in a split-mouth study (Camargo *et al*. 2000).

In a randomized controlled clinical study including 60 patients (Stavropoulos *et al*. 2003), Bio-Oss® alone or impregnated with gentamicin was used as an adjunct to GTR in the treatment of one-wall or two-wall intrabony defects, and the outcomes were compared to those obtained following GTR or flap surgery alone. Treatment with a membrane alone (Fig. 45-42) resulted in a mean PAL gain of 2.9 mm, while it was 3.8 mm and 2.5 mm, respectively, when Bio-Oss® grafts with or without gentamicin were placed in the defects prior to membrane coverage (Fig. 45-43). The control defects treated with flap surgery demonstrated a PAL gain of only 1.5 mm. The clinical improvements in defects treated with GTR alone or in combination with Bio-Oss® grafting were significantly better than those obtained with flap surgery, whereas the differences between the groups treated with membranes were not statistically significant. A prospective multicenter randomized controlled clinical trial (Tonetti *et al*. 2004b) was designed to compare the clinical outcomes of papilla preservation flap surgery with or without the application of a GTR/bone replacement material. One hundred and twenty-four patients with advanced chronic periodontitis were treated in 10 centers in seven countries. All patients had at least one intrabony defect of at least 3 mm. One year after treatment, the test defects gained 3.3 ± 1.7 mm of CAL, while the control defects yielded a significantly lower CAL gain of 2.5 ± 1.5 mm. Pocket reduction was also significantly higher in the test group (3.7 ± 1.8 mm) when compared with the controls (3.2 ± 1.5 mm). A multivariate analysis indicated that the treatment, the clinical centers, baseline PPD and baseline full-mouth bleeding score (FMBS) significantly influenced CAL gains. The odds ratios (OR) for achieving above-median CAL gains were significantly improved by the test procedure (OR 2.6, 95% CI 1.2–5.4) and by starting with deeper PPD (OR 1.7, 1.3–2.2), but were decreased by receiving treatment at the worst-performing clinical center (OR 0.9, 0.76–0.99). The results of this trial indicated that regenerative periodontal surgery with a GTR/bone replacement material offers an additional

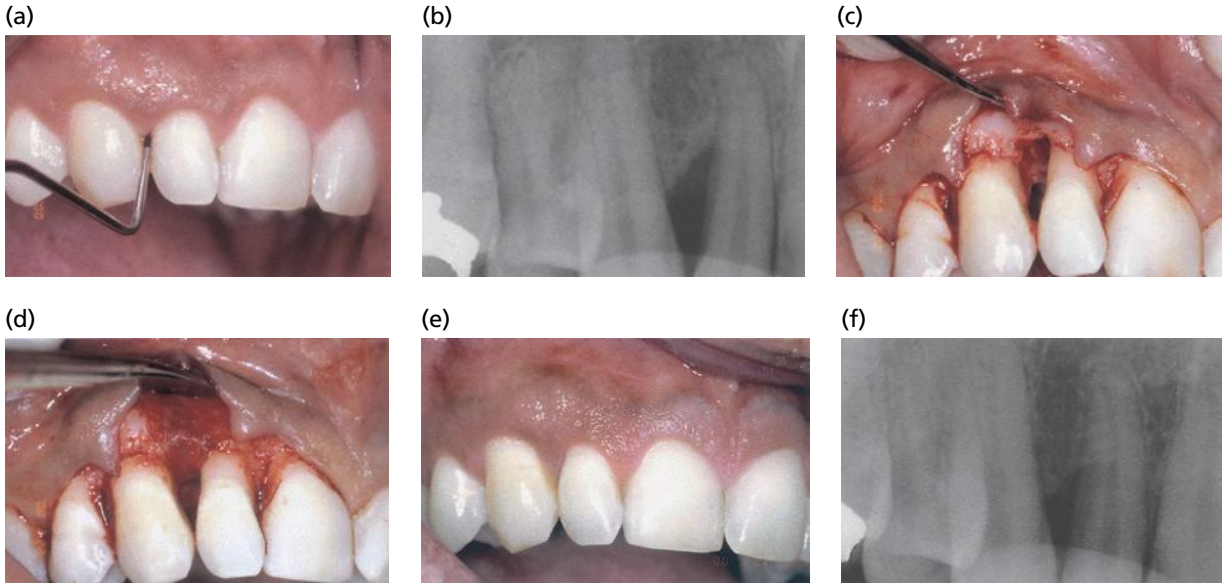

Fig. 45-42 Right lateral maxillary incisor with an 8-mm deep pocket associated with an intrabony defect on the distal aspect (a), as seen on the radiograph (b). Full-thickness buccal and palatal flaps were raised and the defect was debrided (c). A bioresorbable membrane was placed over the defect (d). The level of the interdental gingiva was maintained after 1 year (e) and the intrabony defect (f) had resolved.

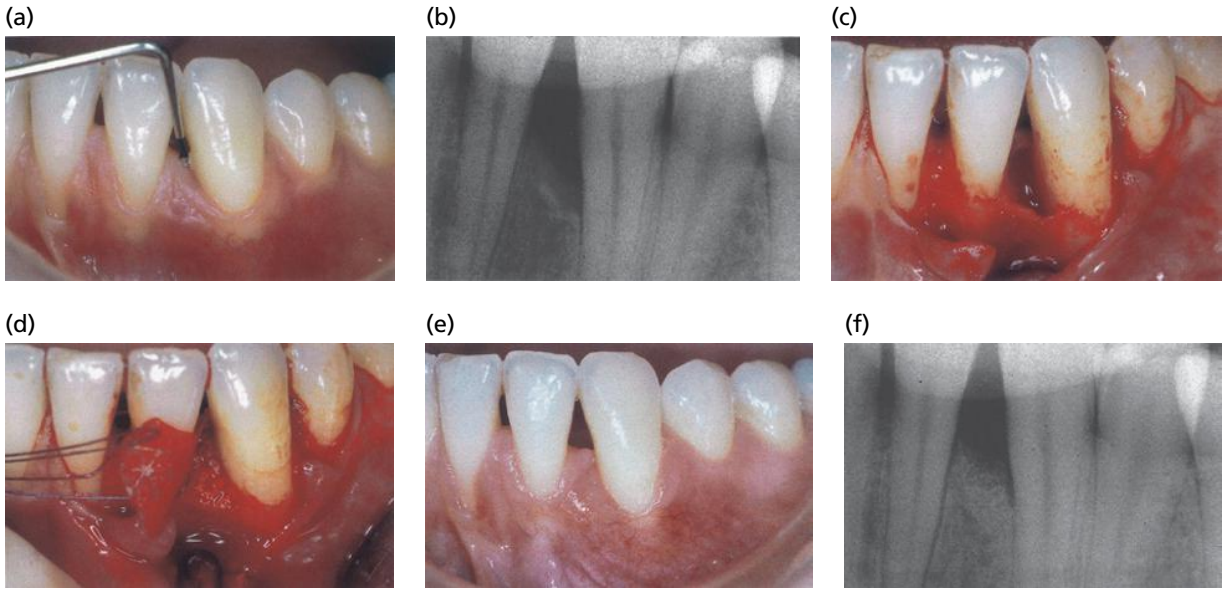

Fig. 45-43 Left mandibular canine with an 8-mm deep pocket (a) associated with an intrabony defect on its mesial aspect (b). The defect was debrided after flap elevation (c) and Bio-Oss® particles were placed in the defect (d) prior to placement of a bioresorbable membrane. After 1 year (e), no gingival recession had occurred and the intrabony defect had almost resolved (f).

benefit in terms of CAL gain, PPD reduction, and predictability of outcomes with respect to papilla preservation flaps alone.

In a controlled study (Pietruska 2001), similar clinical improvements were obtained when Bio-Oss® combined with GTR was compared with to the use of enamel matrix protein (Emdogain®).

Camelo *et al*. (1998) and Mellonig (2000) presented histologic data indicating that the use of Bio-Oss® under a membrane may result in partial regeneration of the periodontal apparatus, but in all the cases most of the defect was still occupied by deproteinized bone particles. Bone was not observed near the root, and the connective tissue fibers of the "new" periodontal ligament were mostly oriented parallel to the root surface. These results corroborate findings reported by Paolantonio *et al*. (2001), who observed only limited bone formation in the vicinity of the pre-existing bone in a biopsy, taken from a site treated 8 months earlier with Bio-Oss® and a collagen membrane. Most of the space in the defect was occupied by Bio-Oss® particles embedded in connective tissue. However, in a case report where intrabony defects were treated with Bio-Oss® combined with intraoral autogenous bone and GTR, new attachment formation had occurred consistently, but a major portion of the regenerated osseous tissue consisted of deproteinized bone particles (Camelo *et al*. 2001).

Combination therapy including use of EMDs plus barrier membranes and/or grafting materials have been tested. A systematic review (Trombelli & Farina 2008) concluded that there is evidence to support the use of EMDs either alone or in combination with grafts to effectively treat intraosseous defects and the additional use of a graft seems to enhance the clinical outcome with EMDs alone; the combined use of rhP-DGF-BB and P-15 with a graft biomaterial has shown beneficial effects in intraosseous defects; contrasting results were reported for PRP and graft combinations. A systematic review by Tu *et al*. (2010) concluded that there was little evidence to support the additional benefits of EMDs in conjunction with other regenerative materials when compared to EMDs alone. When different types of bone grafts and barrier membranes were used, EMDs with bovine bone grafts showed greatest treatment effects.

More recently, combination therapy has been successfully used in sites treated with minimally invasive surgeries. Cortellini and Tonetti (2011) proposed a combination of EMDs and Bio-Oss® with the M-MIST, and Trombelli *et al*. (2010) a combination of a bioresorbable barrier and a graft with the single flap approach.

Combination therapy for furcation involvement

Schallhorn and McClain (1988) reported on improved clinical results in intrabony defects and class II furcations, following a combination therapy including barrier membranes plus DFDBA and citric acid root conditioning. The authors reported a complete furcation closure in 75% of the treated sites (McClain & Schallhorn 1993).

In one study, barrier membranes alone were compared to combination therapy with hydroxyapatite. The difference in clinical outcomes between the two treatments was not statistically significant, but the combination therapy resulted in a greater extent of furcation fill (Lekovic *et al*. 1990).

In three studies on mandibular class II furcations, GTR treatment alone was compared with GTR treatment combined with DFDBA. In one of these investigations, a statistically significant improvement was found in terms of H-OPAL in the group of furcations treated with the combination therapy (Anderegg *et al*. 1991). In a second investigation, a non-bioresorbable barrier with and without DFDBA was tested in six patients with 17 mandibular class II buccal molar furcal invasions (Wallace *et al*. 1994). Ten teeth were randomly selected as test sites (ePTFE + DFDBA) and seven as controls (ePTFE alone). After 6 months, all sites were re-entered and both soft tissue and open surgical measurements were recorded. The addition of DFDBA to the GTR procedure did not significantly improve any of the mean soft tissue and open surgical measurements between the control and test groups. Both treatment procedures resulted in significant decreases in PPD, distance from the cementoenamel junction to the bottom of the defect (CEJ–BD), and horizontal bone fill (HBF) and a significant increase in REC. In a third study, a bioresorbable barrier with and without DFDBA was tested in 14 subjects with paired class II mandibular molar furcation defects (Luepke *et al*. 1997). When the bioresorbable barrier alone was compared to the bioresorbable barrier in combination with DFDBA, PPD reduction was significantly (P <0.01) in favor of the combination therapy. Vertical bone gain was significant greater with the combination treatment (P <0.02). The authors concluded that the combination therapy of bioresorbable barrier plus DFDBA is superior to the control therapy of bioresorbable barrier alone.

Lekovic *et al*. (2003) tested a combination of PRP, bovine porous bone mineral (BPBM), and GTR in 52 class II furcations (26 treated with the test material and 26 with OFD, which served as controls). The experimental group presented with significantly greater pocket reduction (4.07 ± 0.33 mm for experimental and 2.49 ± 0.38 mm for control sites), CAL gain (3.29 ± 0.42 mm for experimental and 1.68 ± 0.31 mm for control sites), vertical defect fill (2.56 ± 0.36 mm for experimental and −0.19 ± 0.02 for control sites), and horizontal defect fill (2.28 ± 0.33 mm for experimental and 0.08 ± 0.02 mm for control sites) than the control group. The authors concluded that the PRP/BPBM/GTR combined technique is an effective modality of regenerative treatment for mandibular grade II furcation defects. However, further studies are necessary to elucidate the role played by each component of the combined therapy in achieving these results.

Houser *et al*. (2001) compared the use of Bio-Oss® in combination with a bioresorbable collagen barrier (BioGide®) to OFD surgery in human mandibular class II furcation defects. A total of 31 furcations (18 test, 13 control) in 21 patients were treated. There was a statistically significant improvement in most clinical parameters for the experimental group, with minimal improvement noted for the flap control group. Vertical PPD reduction of 2.0 mm and horizontal PPD reduction of 2.2 mm were reported for the experimental group, while 0.3 mm and 0.2 mm reductions, respectively, were reported for the control group. Hard tissue measurements showed 2.0 mm of vertical furcation bone fill for the test group and 0.5 mm for control group. The test group had 3.0 mm of horizontal furcation bone fill and the control group had 0.9 mm. The test group had a defect resolution of 82.7% compared with 42.5% in the flap control group. There was a statistically significant difference between the two groups in all soft and hard tissue measurements with the exception of attachment level, recession, and alveolar crest resorption. The authors concluded that the combination of Bio-Oss® and Bio-Gide® is effective in the treatment of mandibular class II furcations.

Belal *et al*. (2005) treated 50 furcations in 20 patients with five different approaches (bioresorbable membrane or a connective tissue graft with or without bioresorbable hydroxylapatite, and flap alone as a control therapy). All experimental groups showed statistically significant improvement in the clinical parameters and bone density as compared to the control group. However, no statistically significant differences were observed between any of the experimental groups. Percentages of complete furcation closure ranged from 20% to 40% in the experimental groups, but was 0% in the flap control group.

Root surface biomodification

The effect of combining citric acid root biomodification with GTR treatment was evaluated in two randomized controlled clinical trials in intrabony defects. The first investigation (Handelsman *et al*. 1991) demonstrated significant CAL gain in both the test (e-PTFE membranes + citric acid; 3.5 ± 1.6 mm) and control sites (e-PTFE membranes alone; 4.0 ± 1.4 mm). Less favorable results following these two treatment modalities were reported by Kersten *et al*. (1992) who found CAL gains of 1.0 ± 1.1 mm in the test group and of 0.7 ± 1.5 mm in the control group. Both studies, however, failed to demonstrate any added effect of the use of citric acid in combination with non-bioresorbable barrier membranes.

Root surface biomodification with tetracycline alone and in combination with GTR was evaluated in two controlled studies on class II furcations (Machtei *et al*. 1993; Parashis & Mitsis 1993). Both investigations failed to show significant differences between sites treated with non-bioresorbable barrier membranes alone or in combination with tetracycline root surface biomodification. Similarly, the use of other surface-active chemicals like EDTA also failed to provide a significant added effect to GTR treatment in humans (Lindhe & Cortellini 1996).

The suggested role of root surface biomodification for improving periodontal regeneration has been assessed in a systematic review (Mariotti *et al*. 2003). The results of that exhaustive review of the evidence indicated that there was no evidence for a measurable improvement following root conditioning with agents like citric acid, tetracycline–HCl, phosphoric acid, fibronectin or EDTA.

Clinical potential and limits for regeneration

From the very beginning of modern periodontal regeneration it was apparent that periodontal tissues could express a surprising regenerative potential under favorable circumstances. Sparse case reports demonstrated that very deep defects reaching the apical third of the root could be filled with new bone and new clinical attachment (Pini Prato *et al*. 1988; Becker *et al*. 1988; Cortellini *et al*. 1990). Larger studies suggested that in deeper defects, greater clinical improvement is generally obtained (Tonetti *et al*. 1993a, 1996a; Garrett *et al*. 1998; Slotte *et al*. 2007). These observations raised a question about the "potential" for regeneration: is the potential greater in deeper defects? Cortellini *et al*. (1998) addressed this question in a controlled study and reported similar attachment gain in defects presenting with an intrabony component of ≤3 mm (76% defect resolution) and defects of ≥4 mm (77% defect resolution), indicating that the potential for regeneration is similar in both shallow and deep intrabony components. The conclusions of this study are indirectly supported by the results of large controlled clinical trials performed with the application of different successful regenerative approaches (Cortellini *et al*. 1995c, 1996b; Tonetti *et al*. 1998; Cortellini *et al*. 2001; Tonetti *et al*. 2002, 2004b). Unpublished subanalyses of these experimental populations, in which the treated defects were clustered according to defect depth, showed that CAL gain is obtained in all defects from shallow to deep, but deeper defects gain more attachment in millimeters than shallow ones. In other words, regeneration seems to express its potential as much as the "container" allows it, independent of the "regenerative approach" chosen, within the panel of the well tested, sound regenerative approaches. A recent controlled study has challenged the limits of the periodontium to repair or regenerate (Cortellini *et al*. 2011). The aim of this randomized, long-term clinical trial was to compare clinical and patient-based outcomes following periodontal regeneration or extraction and replacement of hopeless teeth with attachment loss to or beyond the apex. Twenty-five hopeless teeth were treated with a regenerative strategy. Most of the treated teeth had a periodontal lesion exceeding the apex of the tooth and involving three to four sides of the root (Fig. 45-44). Twenty-three of the 25 regenerated teeth obtained extensive clinical improvements. The average CAL gain was 7.7 ± 2.8 mm, the radiographic bone gain 8.5 ± 3.1 mm, and the PPD reduction 8.8 ± 3 mm. Most of the regenerated teeth showed a decrease in tooth mobility. Only two teeth showing unsatisfactory outcomes were extracted at 1 year. The 23 successfully regenerated teeth (92%) were in good health and function at the 5-year follow-up visit and 84% did not develop biologic complications during the recall period. The authors concluded that regenerative therapy can be successfully applied even to hopeless teeth and has the potential to change their prognosis. However, it should be underlined that the reported outcomes were obtained in a carefully selected patient population, and by applying "state of the art" regenerative therapy by very experienced clinicians, within a high quality program of periodontal and dental therapy and a strict periodontal supportive care program. In other words, it is apparent from the cited studies that to succeed in extreme conditions, a sound strategy has to be adopted.

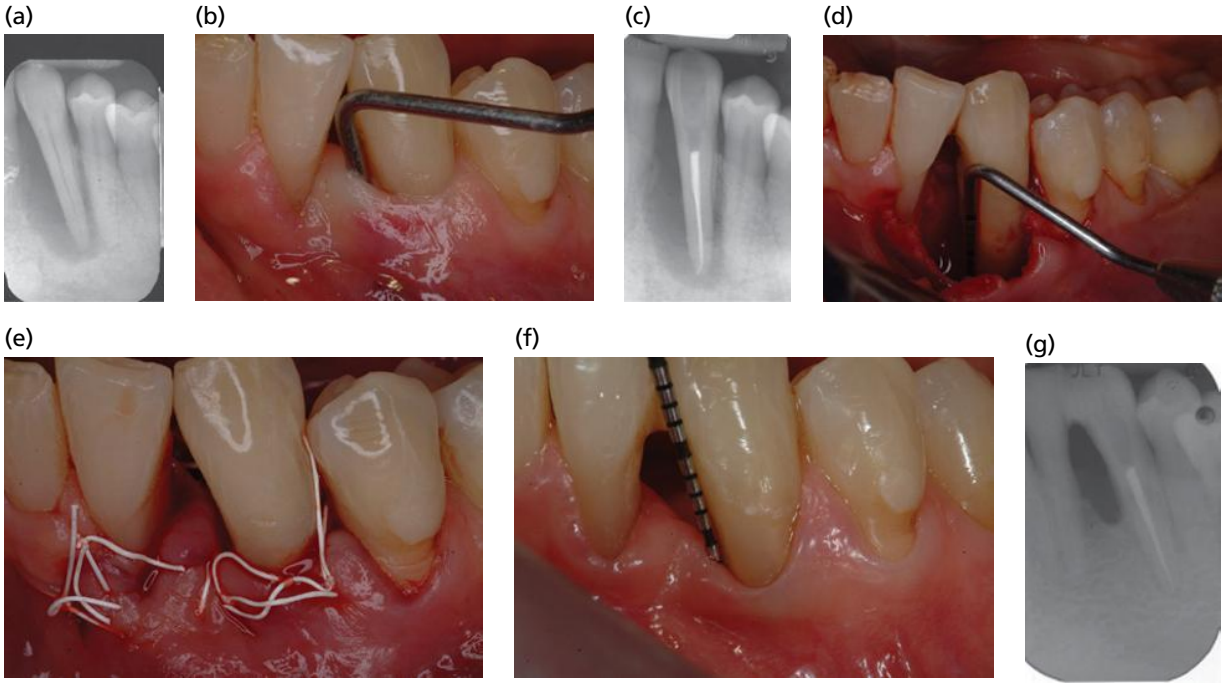

Fig. 45-44 Treatment of a very severe periodontal defect with periodontal regeneration. Baseline radiograph showed a very severe defect extending far beyond the apex of the tooth (a). A pocket deeper than 15 mm was evident at the mesial aspect of the lower left cuspid (b). The tooth was root canal treated (c). The area was accessed with a large flap: bone destruction almost all around is evident (d). The gingival flap was repositioned and sutured with a multilayer technique (e). At 1 year, a 4-mm pocket was probed (f). The radiograph showed the resolution of the periodontal defect (g).

Clinical strategies

Periodontal regeneration in intrabony defects has been successfully attempted with a variety of different approaches. As discussed, meta-analyses of randomized controlled clinical trials as well as human and animal histologic findings support the potential of barrier membranes (Nyman *et al*. 1982; Gottlow *et al*. 1986), DFDBAs (Bowers *et al*. 1989a–c), combinations of barrier membranes and grafts (Camelo *et al*. 1998; Mellonig 2000), and the use of EMDs (Mellonig 1999; Yukna & Mellonig 2000) or growth factors (Howell *et al*. 1997) to induce periodontal regeneration. Controlled clinical trials report that these approaches provide added benefits in terms of CAL gain as compared to OFD alone (Needleman *et al*. 2002; Trombelli *et al*. 2002; Giannobile & Somerman 2003; Murphy & Gunsolley 2003; Esposito *et al*. 2009; Needleman *et al*. 2006; Darby & Morris 2013). Comparisons between some of the regenerative approaches failed to demonstrate a clear superiority of any of the tested materials (Giannobile & Somerman 2003; Murphy *et al*. 2003; Reynolds *et al*. 2003).

The existing evidence, therefore, does not support any particular single regenerative approach. In addition, all the cited studies have shown a substantial degree of variability in terms of CAL gain, reporting failures or unsatisfactory outcomes in part of the treated population.

Research conducted mostly in the past decade has clearly established that the variability observed in outcomes of periodontal regenerative procedures is dependent on a variety of patient-, defect-, and surgical-associated factors. This is not unexpected since each individual patient presents with unique characteristics as well as each defect presenting with very different and unique anatomies. The outcomes of the randomized studies indicates clearly that none of the regenerative approaches can solve all the different patient/defect presentations. It is therefore mandatory to build up a clinical decision tree that allows clinicians to apply the regenerative strategy most appropriate to each individual case.

While relevant patient factors include cigarette smoking, residual periodontal infection, and oral hygiene, factors associated with the morphology of the defect are consistently found to be of relevance to the final outcome (Tonetti *et al*. 1998; Cortellini *et al*. 2001). Interestingly, however, the number of residual bony walls defining the defect seems to impact the outcomes of different periodontal regenerative materials in a divergent way. Non-bioresorbable (e-PTFE and titanium-reinforced e-PTFE) barrier membranes and bioresorbable barriers supported by a graft do not seem to be affected by the number of residual bony walls of the defect (Tonetti *et al*. 1993a, 1996a, 2004b), while EMDs result in better outcomes in three-wall defects (Tonetti *et al*. 2002). Furthermore, healing following application of bioresorbable barriers and non-bioresorbable e-PTFE barriers as well as EMDs is associated with the radiographic width of the intrabony defect (Tonetti *et al*. 1993a; Falk *et al*. 1997; Tsitoura *et al*. 2004). No such association has been found for the use of a xenogenic BRGs and bioresorbable barrier combination (Tonetti *et al*. 2004b).

Among the technical/surgical factors, membrane exposure and contamination have been associated with poorer outcomes (Selvig *et al*. 1992; Nowzari & Slots 1994; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a, b). Similar problems were also encountered with bone grafting (Sanders *et al*. 1983). Poorer outcomes were also observed when the regenerated tissue was not properly protected with the flap on removal of non-bioresorbable barrier membranes (Tonetti *et al*. 1993a; Cortellini *et al*. 1995c).

A controlled clinical trial demonstrated that the combination of a papilla preservation flap and titanium-reinforced e-PTFE membrane resulted in greater CAL gain as compared to a conventional flap approach with an e-PTFE membrane (Cortellini *et al*. 1995c). This evidence, also partly supported by a systematic review (Murphy & Gunsolley 2003), strongly suggests that optimization of the surgical approach and control of surgical variables, particularly in relation to flap design and management and selection of the regenerative material, could improve outcomes. In the context of periodontal regeneration, several flap designs aimed specifically at the full preservation of the soft tissues during access to the defect have been described (Cortellini *et al*. 1995c, d, 1996c; Murphy 1996; Cortellini *et al*. 1999a; Cortellini & Tonetti 2007a, 2009b). Experimental testing of these regenerative flaps showed great improvements in achieving primary closure during the surgical session, with optimal interdental closure being obtained in virtually all cases (Cortellini *et al*. 1995c, d, 1999, 2001; Tonetti *et al*. 2004b). During the subsequent healing, however, dehiscence of the interdental tissue and membrane exposure was observed in up to a third of the cases. The ability to accomplish and maintain primary closure of the tissues over a GTR membrane was further improved by the use of a microsurgical approach that resulted in maintenance of primary wound closure in 92.3% of the treated sites for the whole healing period (Cortellini & Tonetti 2001, 2005, 2007a, b, 2009b, 2011).

This body of evidence has been utilized together with a degree of clinical experience to develop an "evidence-based regenerative strategy" to guide clinicians through a decision-making process aimed at the optimization of the clinical outcomes of periodontal regeneration in intrabony defects (Cortellini & Tonetti 2000a, 2005). Key steps of this process are the careful evaluation of the patient and of the defect, access to the defect with a papilla preservation flap, choice of the most appropriate regenerative technology/material, and ability to seal the regenerating wound from the contaminated oral environment with optimal suturing techniques.

The performance of this clinical strategy has been assessed in a 40-patient consecutive case series (Cortellini & Tonetti 2005). Following completion of initial, cause-related periodontal therapy, subjects presented full-mouth plaque scores of 10.2 ± 2.7% and full-mouth bleeding scores at baseline of 7.9 ± 2.8%. At the intrabony defects, CAL was 10.2 ± 2.4 mm and PPD 8.9 ± 1.8 mm. The radiographic defect angle was 29 ± 5.9°. CEJ–BD was 11.2 ± 2.7 mm and the intrabony component of the defects (INFRA) was 6.6 ± 1.7 mm. In this population, the SPPF could be used in 37.5% of sites, while the MPPT was selected in 45% of cases. The remaining sites, presenting with defects adjacent to edentulous areas, were accessed with a crestal incision.

Based on defect anatomy, non-bioresorbable titanium-reinforced e-PTFE barrier membranes were used in 30% of cases. In these cases, defect angles ranged from 27° to 42° (average 32.4 ± 4.3°), and eight of the 11 selected defects had a one-wall intrabony subcomponent of 1–3 mm (the average one-wall component of the 12 sites was 1.4 ± 1.2 mm). Ten of the 11 defects treated with bioresorbable membranes supported with a BRG presented a one-wall subcomponent of 1–5 mm (the average one-wall component of the 11 sites was 1.8 ± 1.3 mm); defect angles in this group ranged from 21° to 45° (average 31.4 ± 7°). Bioresorbable barriers alone were used in seven sites presenting with a prevalent two- and three-wall morphology and narrow defect angles, ranging from 20° to 28° (average 24.1 ± 3.7°). EMDs were applied to ten defects with a prevalent three-wall component. The defect angle in this group ranged from 19° to 31° (average 26.5 ± 4.3°).

Primary closure was obtained at completion of the surgical procedure for all treated sites. At the 1-week follow-up, when sutures were removed, two sites, both accessed with a SPPF, presented with a small interdental wound dehiscence: one had been treated with a bioresorbable membrane and BRG, the other with EMDs. At week 2, two additional small wound dehiscences were detected: one accessed with MPPT and treated with a bioresorbable membrane and BRG, the other accessed with SPPF and treated with a bioresorbable barrier alone. All the other sites (90%) remained closed during the entire early healing phase.

The 40 patients presented at the 1-year follow-up visit with excellent levels of plaque control and low levels of BoP. The 1-year CAL gain was 6 ± 1.8 mm (range 4–11 mm). No sites gained <4 mm of CAL; 77.5% gained ≥5 mm and 40% >6 mm. Residual PPDs were 2.7 ± 0.6 mm, with an average reduction of 6.1 ± 1.9 mm. Only four sites showed a residual PPD of 4 mm; all the other sites had a 1-year PPD of ≤3 mm. A minimal increase of 0.1 ± 0.7 mm in gingival recession between baseline and 1 year was recorded.

This study indicated that, whenever the treatment choice was made according to the protocol (i.e. based on: width of the interdental space to select the papilla preservation surgery; morphology of the defect to select the regenerative material; and choice of the material and local anatomy to select the suturing approach), all four approaches gave excellent results with CAL gains equal to 88–95% resolution of the original depth of the intrabony component of the defect (Cortellini & Tonetti 2005).

The CAL gain of 6 ± 1.8 mm at 1 year was obtained in defects with an intrabony component of 6.6 ± 1.7 mm. The percentage CAL gain therefore was 92.1 ± 12%. This indicates that a large part of the intrabony component of the defects was resolved. Using the Ellegaard criteria (Ellegaard *et al*. 1971), resolution of the intrabony component of the defect was either satisfactory or complete in all treated cases. In particular, 40.5% of defects had CAL gains equal to or greater than the baseline depth of the intrabony component, while the defect with the worst response showed a 71.4% CAL gain. Historical comparison with clinical experiments using bone grafting or GTR clearly indicates that the results of this trial approach were in the top percentiles in terms of CAL gains and defect resolution (Cortellini & Tonetti 2000a; Rosen *et al*. 2000).

A novel, more comprehensive clinical strategy has been developed to further improve the clinical capacity to ensure appropriate therapy for each patient/defect. This approach takes into proper account the relevance of the patient characteristics, as described earlier in this chapter, and is based on the need to satisfy the three major contributors to periodontal regeneration: (1) space for the formation of the blood clot at the interface between the flap and root surface (Haney *et al.* 1993, Sigurdsson *et al.* 1994, Cortellini *et al*. 1995b, c, Tonetti *et al*. 1996a; Wikesjo *et al*. 2003; Kim *et al.* 2004); (2) stability of the blood clot to maintain a continuity with the root surface and thereby avoid the formation of a long junctional epithelium (Linghorne & O'Connel 1950; Hiatt *et al*. 1968; Wikesjo & Nilveus 1990; Haney *et al*. 1993); (3) and soft tissue protection of the treated area to avoid bacterial contamination (Selvig *et al*. 1992; Nowzari *et al.* 1995; De Sanctis *et al*. 1996a, b; Sanz *et al*. 2004; Polimeni *et al*. 2006). *Space* and *blood clot stability* are self-provided in the so-called "containing defects", particularly the narrow three-wall defects (Goldman & Cohen 1958; Schallhorn *et al*. 1970; Selvig *et al*. 1993; Cortellini & Tonetti 1999; Tsitoura *et al*. 2004; Linares *et al*. 2006). The "non-containing defects", the large one- or two-wall defects, require an intervention to supplement the deficient anatomy (Tonetti *et al*. 1993, 1996; Falk *et al*. 1997; Tonetti *et al*. 2002, 2004a, b). The intervention can be based on the use of biomaterials such as "exoskeleton"-like barriers or "endoskeleton"-like grafts that are able to support the soft tissues and to stabilize the blood clot, or a combination of the two approaches. In other words, the anatomic deficiencies of the defects have to be supplemented by the additional use of biomaterials. The same goal could be obtained by adopting different surgical strategies in which tissues are minimally elevated to increase their stability (the MIST and the M-MIST approaches) (Cortellini & Tonetti 2007, 2009). Blood clot stability is also clearly influenced by tooth hypermobility: splinting teeth with class II or III mobility is mandatory to avoid the disruption of the blood clot in the early healing phase (Cortellini *et al*. 2001; Trejo & Weltman 2004).

Protection of the regenerating area has to be provided with the adoption of specifically designed surgical approaches. The different surgical approaches differ in terms of flap design and suturing technique. In addition to their ability to provide protection to the regenerating area, they could differently contribute to improving one or more of the many aspects potentially relevant to the wound healing process. The traditional papilla preservation flaps (Cortellini *et al*. 1995a, 1999) were designed as wide and very mobile flaps in order to allow for perfect visibility of the defect area, for easy placement of biomaterials, and for the coronal positioning of the buccal flap to cover barriers and biomaterials. In other words, papilla preservation flaps do not have the mechanical characteristics to improve wound stability or the capacity to independently create space for regeneration. The MIST (Cortellini & Tonetti 2007a, b), in contrast, was designed to reduce flap extension and mobility as much as possible to increase the capacity for primary wound closure and blood clot stability. This potential was illustrated in two studies that demonstrated the reduced impact of the number of residual bony walls and of the defect width on the outcomes obtained with EMDs under a MIST (Cortellini *et al*. 2008; Cortellini & Tonetti 2009a), and recently confirmed in a comparative study demonstrating similar outcomes between MIST alone and MIST plus EMDs (Ribeiro *et al*. 2011a).

A further development of the surgical approach was the M-MIST (Cortellini & Tonetti 2009b, 2011). This advanced flap design further enhanced the potential of the flap to provide space and stability for regeneration by leaving the interdental papillary soft tissues attached to the root surface of the crest-associated tooth and by avoiding any palatal flap elevation. The interdental soft tissues are the stable "ceiling" of a "room" into which blood flows and forms a clot. In addition, the hanging papilla prevents the collapse of the soft tissues, thereby maintaining space for regeneration: the anatomic bone deficiencies are potentially supplemented by the peculiar novel flap design that provides additional "soft tissue walls" in place of the missing bony walls and thus improves stability. The walls of the "room" are the residual bony walls, the root surface, and the buccal/lingual soft tissues. The minimal flap extension and elevation also reduces greatly the damage to the vascular system. It is clear that such a flap is not designed to allow the positioning of a barrier, but biologicals or grafts can easily be used with it.

Clinical flowcharts

Clinical flowcharts have been developed that take into account also the scientific contributions on surgical and post-surgical events, like chair time, side effects, and postoperative pain.

The step-by-step clinical approach to the treatment of intrabony defects includes two presurgical flow

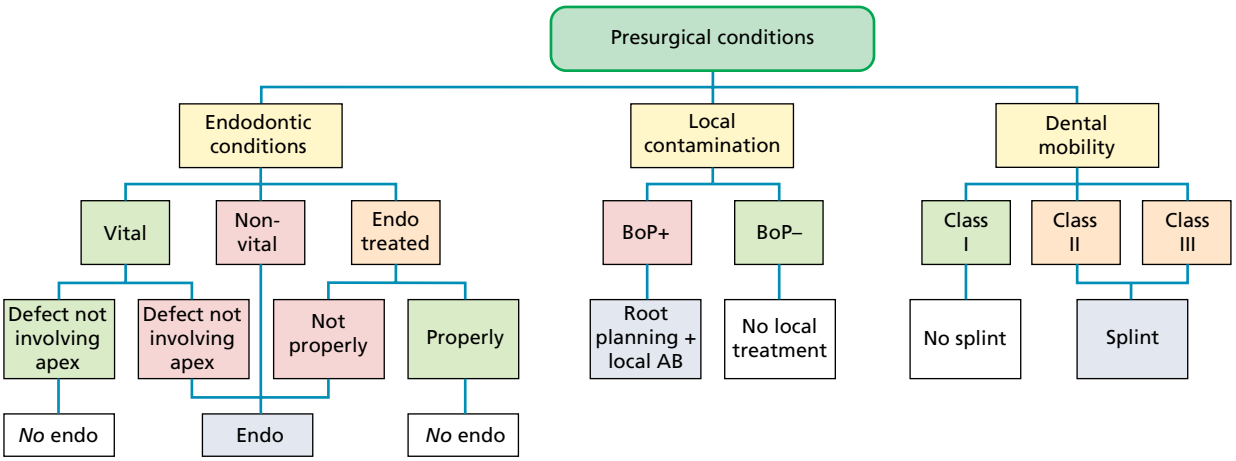

Fig. 45-45 Decision-making algorithm highlighting the clinical conditions to be checked before periodontal regeneration. These relate mainly to the endodontic status, presence of local contamination, and dental hypermobility of the tooth to be treated with periodontal regeneration. (BoP, bleeding on probing; AB, antibiotic.)

charts dealing with patient and local factors and four surgical flow charts (surgical nodes). The development of the surgical nodes was driven by the wish to treat any given defect with the procedure judged fastest, easiest, least burdened by side effects, and best tolerated by the patients. Lastly, postoperative care is suggested.

The step-by-step approach starts with control of patient-associated characteristics (see Fig. 45-10): low levels of plaque and residual infection, high levels of compliance, and absence of adverse conditions like smoking, stress, and uncontrolled diabetes or other systemic diseases have to be well established.

A few conditions, like endodontic condition, local contamination, and mobility of the involved tooth, must be controlled before surgery (Fig. 45-45). Endodontic diagnosis and eventual treatment should be performed well in advance of the regenerative approach (Cortellini & Tonetti 2001). Vital teeth should preferably be kept vital, with the only exception being a tooth whose apex is involved with the periodontal lesion (Cortellini *et al*. 2011). Non-vital teeth must be properly treated with root canal therapy. Existing root canal therapies should be carefully evaluated: improper treatments should be corrected. Local contamination of the defect-associated pocket should be as low as possible (Heitz-Mayfield *et al.* 2006). The presence of BoP (i.e. bacteria) should be controlled with additional gentle root planing and then the additional use of local antimicrobials (Tunkel *et al*. 2002; Hanes & Purvis 2003) a few weeks before regeneration (Cortellini *et al*. 2011). Teeth with mobility of class II or III should be splinted before or immediately after the surgical procedure (Cortellini *et al.* 2001; Trejo & Weltman 2004). Tooth hypermobility should be re-evaluated during the early healing phase: any detected increase in mobility should be taken care of.

The surgical access to the intrabony defects is selected from three different approaches: the SPPF

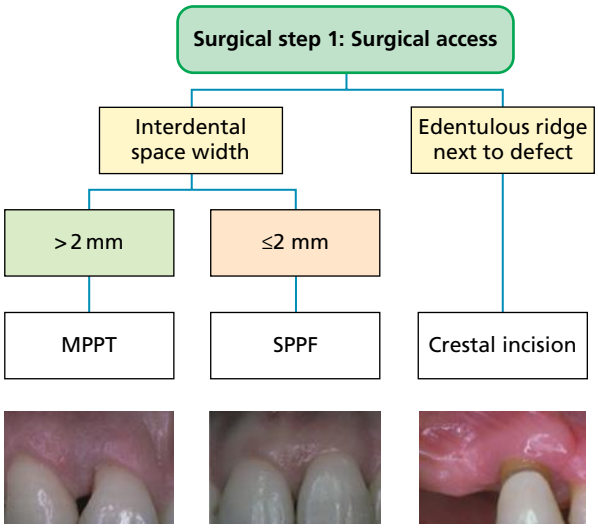

Fig. 45-46 Decision-making algorithm for obtaining access to an intrabony defect: the simplified papilla preservation flap (SPPF) is used for narrow interdental spaces (2 mm or narrower), while the modified papilla preservation technique (MPPT) is used to access defects associated with wider interdental spaces (3 mm or wider). Crestal incision is applied at a tooth neighboring an edentulous ridge.

(Cortellini *et al.* 1999a), the MPPT (Cortellini *et al.* 1995d), and the crestal incision (Cortellini & Tonetti 2000a) (Fig. 45-46). The SPPF is chosen whenever the width of the interdental space is 2 mm or less, as measured at the level of the supracrestal portion of the papilla. The MPPT is used at sites with an interdental width of >2 mm; the crestal incision is applied next to an edentulous area.

The next surgical step (Fig. 45-47) concerns the selection of the flap design. Whenever a defect involves one or two sides of a root and can be cleaned through a tiny buccal window, an M-MIST is applied (Cortellini & Tonetti 2009b, 2011). In some instances, the M-MIST can be applied to both the interdental spaces neighboring the defect-associated

tooth, allowing for instrumentation of a defect involving up to three sides of a root. If the defect cannot be cleaned through the buccal window, the interdental papilla is elevated by applying a MIST approach (Cortellini & Tonetti 2007a; Cortellini *et al*. 2008). A large flap, extended to the neighboring teeth and including also an eventual periosteal incision and/or vertical releasing incisions, is chosen in the presence of a very severe and deep defect, involving three or four sides of the root, which requires ample visibility for instrumentation and the use of either endo- or exo-skeletons (Cortellini *et al*. 1995d, 1999a).

Selection of the regenerative material is based on the defect anatomy and on the flap design chosen to expose the defect (Fig. 45-48). If an M-MIST approach is applied, EMDs or no regenerative materials are the elective choices (Cortellini & Tonetti 2009b, 2011). If a MIST is applied, EMDs can be used alone in containing defects or in combination with a filler in non-containing defects (Cortellini & Tonetti 2007a; Cortellini *et al*. 2008; Ribeiro *et al*. 2011a). If a large flap is elevated, the area should be stabilized by applying barriers or fillers, or a combination of barriers and fillers, or a combination of EMDs/growth factors and fillers. EMDs alone are preferred in defects with a prevalent three-wall morphology or in well-supported two-wall defects.

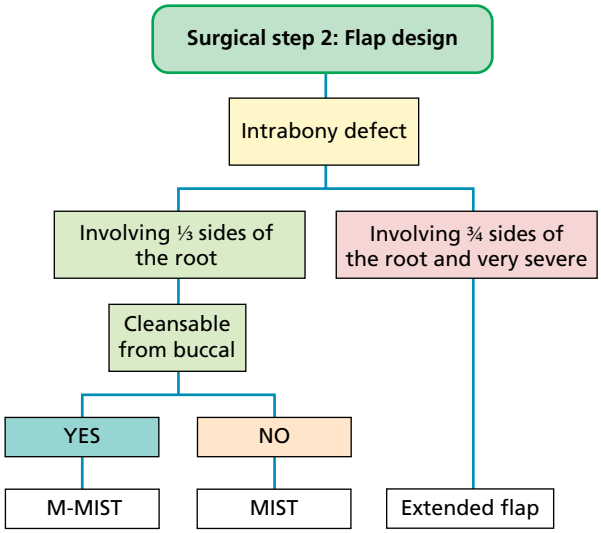

Fig. 45-47 Decision-making algorithm for choice of flap design. The type of surgical access from very small to very ample is chosen according to the severity and extension of the periodontal defect.

The suturing approach is selected according to the type of regenerative strategy applied (Fig. 45-49). It will consist of a single internal modified mattress suture when an M-MIST or an MIST approach is chosen and EMDs alone are applied (Cortellini & Tonetti 2007a; Cortellini et al 2008; Cortellini & Tonetti 2009a, 2011). When a large flap with a periosteal incision is used in association with a barrier or a graft or a combination of these, the suturing approach will consist of two internal mattress sutures applied at the defect-associated interdental area to achieve primary closure of the papilla in the absence of any tension (Cortellini *et al*. 1995b, c, 1999; Cortellini & Tonetti 2000a, 2005).

The surgical procedure is preferably performed with the aid of magnification such as loupes or an operating microscope (Cortellini & Tonetti 2001; Wachtel *et al*. 2003; Cortellini & Tonetti 2005). Microsurgical instruments and materials should be utilized to complement the normal periodontal set.

Post-surgical and early home-care protocols are derived from the experiences gained from running many controlled clinical trials (Cortellini *et al*. 1995c, 1996b; Tonetti *et al*. 1998; Cortellini *et al*. 2001; Tonetti *et al*. 2002, 2004b). An empirical protocol for the control of bacterial contamination consisting of doxycycline (100 mg b.i.d. for 1 week), 0.12%

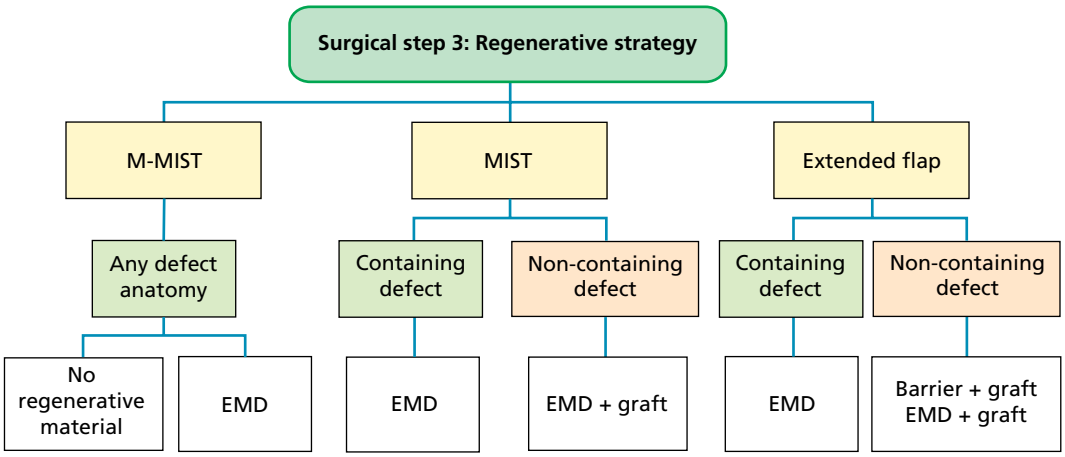

Fig. 45-48 Decision-making algorithm for choice of currently available technologies for application of regeneration in the treatment of intrabony defects. The clinical decision is based on two main parameters: (1) type of surgical access performed; (2) morphology of the periodontal defect. (MIST, minimally invasive surgical technique; M-MIST, modified minimally invasive surgical technique; EMD, enamel matrix derivative.)

chlorhexidine mouth rinsing t.i.d., and weekly prophylaxis is prescribed. Sutures are removed after 1 week. Patients are requested to avoid normal brushing, flossing, and chewing in the treated area for periods of 6–10 weeks. A post-surgical soft toothbrush soaked in chlorhexidine is adopted from week 1 to gently wipe the treated area. Non-bioresorbable membranes are removed after 6 weeks. Patients can resume full oral hygiene and chewing function in the treated area 2–4 weeks after membrane removal or when bioresorbable membranes are fully resorbed. Patients treated with EMDs can resume full oral hygiene after a period of 4–5 weeks. At the end of the "early healing phase", patients are placed in a 3-month recall system. A general suggestion to avoid any invasive clinical maneuver, like hard subgingival instrumentation, restorative dentistry, orthodontics, and additional surgery, for a period of about 9 months is also part of the strategy to optimize the clinical outcomes of periodontal regeneration.

Conclusion
